Using a controlled-stress rheometer, measurement of the yield stress using the vaned rotor is straightforward. The torque is ramped slowly and the stress at which a finite displacement is detected is reported as the yield stress.

Practical Aspects of Yield Behavior

Some of the practical consequences of yield behavior occur in the processing of pigment dispersions, for example. Dispersions with high yield stresses may be difficult to dispense accurately or reproducibly via automatic metering systems. Pumps may actually refuse to move or such materials may cavitate while being pumped; solenoid valves may "freeze." Coatings with significant yield stresses may exhibit poor leveling [1] since, as the shear stress decreases during the course of the leveling process, the material effectively becomes immobile when the dynamic yield stress is reached.

On the other hand, a small yield stress can be of great value in inhibiting settling of particulate suspensions. The shear stress exerted on the surrounding medium by a spherical particle falling under the influence of gravity may be calculated using the following relationships:

$$\sigma = \frac{F_g}{A} = \frac{\text{Force of gravity on particle}}{\text{Surface area of particle}}$$

$$F_g = \frac{4}{3}\pi R^3(\rho_p - \rho_l)g; \quad A = 4\pi R^2$$

$$\sigma_g = \frac{R}{3}(\rho_p - \rho_l)g$$

where R is the particle radius, ρ_p is the particle density, ρ_l is the liquid density, and g is gravitational acceleration. For a titanium dioxide particle of radius 0.2 mm and density 4 g·cm^{-3}, the shear stress acting on the particle due to gravity is about 0.2 dyne/cm^2. To prevent settling of such a particle, the surrounding medium need only resist with an opposing stress of greater than 0.2 dyne/cm^2. Even this, alas, is impossible for a Newtonian liquid, be it water or honey since it will flow under all stresses no matter how small (it is only a question of how slowly). A pigment particle will inevitably settle out of such a fluid, especially for viscosities of practical magnitudes. However, if the suspending medium possesses a yield stress equal to or greater than the particle shear stress, the particle "thinks" it is suspended in a solid and will remain suspended indefinitely. This argument assumes more or less ideal yield behavior, which, as described above, may rarely be encountered. A medium with a measured yield stress of apparently sufficient magnitude may or may not permit the particle to settle over long periods of time due to the possibility of viscous flow below the apparent yield point. In addition, ambient vibration can break the structure locally around a particle, leading to settling even where the measured yield stress appears adequate. Therefore, to ensure practical stability, one should build in a higher yield value than that calculated from the above.

Elastic Liquids (Viscoelasticity)

In ideal viscous flow, all input energy is converted either to heat or energy of motion. None is stored (i.e., none is converted into potential energy). Therefore, viscous flow results in irreversible deformation. Newtonian liquids show essentially ideal viscous (also called "inelastic") behavior over a wide range of deformation rate. For ideal elastic ("Hookean") substances, all the energy of deformation is stored, similar to a stretched rubber band. Consequently, elastic deformation is not permanent, but is in fact completely reversible. Real materials can display a mixture of elastic and viscous character, in varying degrees. Hence, the term *viscoelastic* is applied to such materials. Not all non-Newtonian fluids have significant elastic properties, but many do. Significant elasticity in fluids generally indicates the presence of some association network or microstructure. That is, elementary flow units are linked together in some fashion such that the structural relaxation time (see below) is measurably long. This structure, and particularly the destruction and rebuilding process that occurs during and after coating application, can have great consequences for application and film formation processes. An example of this is the influence of elasticity on leveling of an applied coating [41] (see also Massouda [42], Glass [43], and Cohu and Magnin [44]).

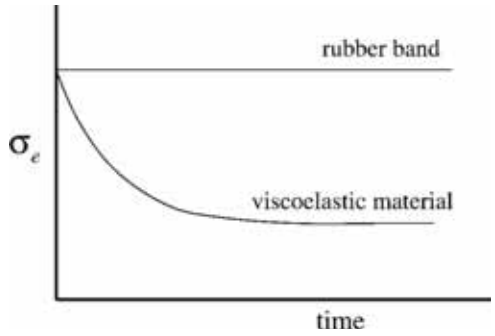

Fig. 13—Viscoelastic stress-memory loss: stretch-force experiment. Rubber band is cross-linked polymer, does not relax stress (σ_E) when stretched. Viscoelastic material can accommodate to strain by molecular motion (viscous flow), allowing elastic stress to decay.

As the term implies, viscoelasticity refers to a material response, which is a combination of viscous and elastic behavior. Viscous flow superimposed on elastic strain results in the "relaxation," or gradual disappearance, of stress within the strained object. This is manifested as an imperfect, or fading, stress memory. Fig. 13 illustrates the material response to an applied elongational stress for a material with permanent stress memory (e.g., rubber band) and one with fading stress memory (e.g., "bouncing putty").

The Viscoelastic Parameters and Their Measurement

A convenient way of experimental characterization of viscoelastic materials is by alternating the direction of strain (or stress). Most often, a sinusoidal deformation is employed (Fig. 14). The strain amplitude must be kept small so that the material response remains in the linear viscoelastic regime, where stress and strain are linearly related.[8] For perfectly elastic behavior (Hookean spring), the stress and strain are "in phase" with each other. That is, upon

[8] This is a requirement because the equations used are valid only for linear viscoelasticity.

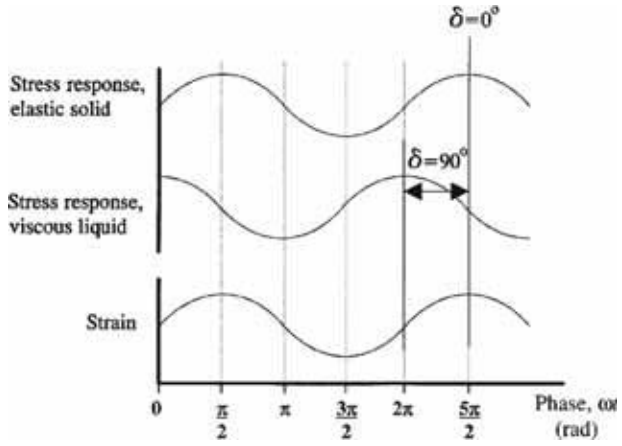

Fig. 14—Stress response to oscillatory strain for ideal viscous and elastic bodies. Stress is in phase with the strain for an elastic solid; the stress leads the strain by phase shift δ =90° for an ideal viscous liquid.

deformation, the maximum stress and maximum strain occur at the same instant in time. However, if there is any viscous (energy-loss) component in the material response, the stress and strain maxima will not be coincident but will be "out of phase." This happens because viscous flow continually relieves the stress within the material, causing the stress to reach a maximum and die away before the strain maximum. That is, as the rate of strain decreases near the maximum (or minimum) of the strain sine wave, stress relaxation "catches up" and overtakes the stress-building effect of the strain. Thus, the maximum in the stress must occur before the maximum in strain, and will do so earlier in the deformation cycle the more rapid is the viscous relaxation. The separation of the stress and strain maxima is called the *phase shift* (or *phase angle,* the angular part of a complete cycle in degrees or radians represented by the phase shift). The phase shift is often given the symbol δ. The faster the viscous stress-relaxation process, the earlier in the cycle the stress maximum will occur, i.e., the larger the phase shift will be. The limiting value of the phase angle for purely viscous liquids is 90° (see Fig. 14). This is because for sinusoidal deformation the maximum strain rate (maximum slope of the strain sine wave) occurs 90° ahead of the maximum strain, and for Newtonian liquids the stress is proportional to strain rate. Therefore, the maximum stress must occur at the maximum strain rate, which corresponds to a phase shift of 90°.

The derivation of viscoelastic parameters from a sinusoidal shear experiment begins with the calculation of the complex shear modulus G^*. This is simply the ratio of the maximum stress, σ_0, to the maximum strain, γ_0 ($G^* = \sigma_0/\gamma_0$). From G^* may be separated G' the modulus of elasticity (storage modulus) and G'', the viscous modulus (loss modulus). Fig. 15 demonstrates the geometric relationship of G^* to its in-phase and out-of-phase components G' and G'', governed by the phase angle δ. It is obvious from geometry that when δ is zero, $G^* = G'$, and when δ =90°, $G^* = G''$. The physical meaning is that when δ = 0, the measured modulus is comprised solely of an elastic response, and when δ = 90°, the modulus is due entirely to a viscous response. This follows from the discussion of the phase shift, above. By trigonometry, $G' = G^*\cos\delta$ and $G'' = G^*\sin\delta$. Alternately

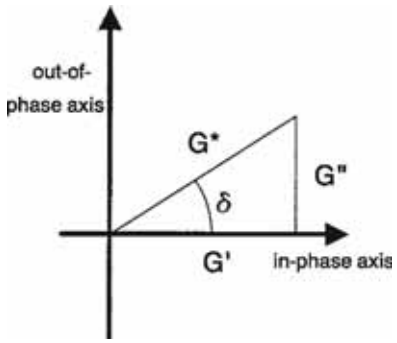

Fig. 15—Viscoelastic relationships in the complex plane.

stated, G' is the component of the complex shear modulus, which is in phase with the strain. G' therefore represents the elastic part of viscoelastic behavior. The viscous component (G''), on the other hand, is derived from the part of the modulus which is out of phase with the strain but in phase with the strain rate.

Consider a dynamic test in which a sinusoidally varying strain is applied to a viscoelastic material. The angular frequency of the deformation is given by $\omega = 2\pi f$, where f is the frequency of oscillation (s^{-1}) and ω is in rad/s. Now, the amplitude of the strain with time is given by

$$\gamma = \gamma_0 \cos \omega t \tag{21}$$

which describes a cosine wave of maximum amplitude γ_0 and period $1/\omega$. The strain rate experienced by the material is then

$$\dot{\gamma} = -\omega\gamma_0 \sin \omega t \tag{22}$$

The oscillating strain produces a stress response

$$\sigma = \sigma_0 \cos(\omega t + \delta) \tag{23}$$

where δ is the phase shift, advancing the phase of the stress relative to the strain. Eq (23) may be equivalently written [45]

$$\sigma^* = \sigma_0 \cos\delta \cos\omega t - \sigma_0 \sin\delta \sin\omega t \tag{24}$$

which describes a complex stress where, by complex plane relationships analogous to Fig. 15, $\sigma_0 \cos\delta$ is the stress component in-phase with strain and $\sigma_0 \sin\delta$ the stress component that is out-of-phase with the strain (but in-phase with the strain rate). We therefore can define a dynamic viscosity η' as the quotient of the stress in-phase with the strain rate, divided by the strain rate

$$\eta' = \frac{\sigma_0 \sin\delta}{\dot{\gamma}_0} = \frac{\sigma_0 \sin\delta}{\gamma_0\omega} = \frac{G^* \sin\delta}{\omega} = \frac{G''}{\omega} \tag{25}$$

The above expression is obtained using the relationships γ_0 (strain-rate amplitude) = $\gamma_0\omega$ and $G^* = \sigma_0/\gamma_0$.

The magnitudes of G'' and G' reveal the relative importance of viscous and elastic behavior in the mechanical response of a material. In Fig. 15, again by trigonometry, the tangent of the phase angle equals the ratio G''/G'. Thus, tan δ quantifies the balance of energy storage and loss measured under particular conditions of temperature, pressure, and frequency or rate of deformation. For solids, tan δ *as*

a function of frequency can be useful to predict the likelihood of brittle or ductile failure of a polymer or the sound absorption or vibration damping properties. For liquids, tan δ can monitor the progress of fluid restructuring in thixotropic recovery. The latter may be useful in computing sag resistance, for when tan S becomes less than unity the system has essentially become immobilized (i.e., reached a "dynamic yield point"). When tan $\delta > 1$, viscous flow (i.e., a steady-state viscosity) is possible. When tan $\delta < 1$, however, the material is more elastic than viscous (i.e., a percolating network extends throughout the bulk, and it is essentially an elastic solid).

Viscoelastic Models

It turns out that viscoelasticity can be rather realistically modeled by simple mechanical analogues. These are useful not only as an aid to conceptualization of viscoelastic behavior, but also in helping to understand the elementary mathematics of viscoelasticity. As we have said, viscoelasticity is a combination of two idealized behaviors: Hookean elasticity and Newtonian viscosity. The mechanical analogue of Hookean behavior is a spring of force constant G, and that of Newtonian flow is a "dashpot" (a piston-in-cylinder filled with a fluid of viscosity η). These elements are combined in various ways to model viscoelastic mechanical response.

To build our first model we will connect a spring and dashpot in series (Fig. 16), an arrangement known as the Maxwell model. To imagine what response the model has, let us apply a constant stress σ_0 to one end, the other being fixed. By the way, our dashpot is considered to be infinitely long so that the piston never runs out of travel. This being the case, one can see that an equilibrium strain would never be reached but rather the dashpot would continually move as long as the stress is applied. Since the model can "flow" without limit, this is obviously a model for viscoelastic liquids (sometimes called "elasticoviscous"). We have just described what is known as a creep experiment, in which a sudden stress σ_0 is applied, and the evolution of the strain, or deformation, is followed with time. The creep of a Maxwell liquid is not very interesting, however. The strain-time curve consists merely of a straight line with intercept equal to σ_0/G and slope of σ_0/η [Eq (28)].

We will use the Maxwell model to illustrate how equations describing viscoelastic behavior may be derived. Just as the stress is the same in every part of a stretched string, so is the stress the same on both elements for the Maxwell model, and also, therefore, the rate of change of stress is identical as well

$$\sigma_{\text{total}} = \sigma_{\text{clastic}} = \sigma_{\text{viscous}} (= \sigma_0) \tag{26}$$

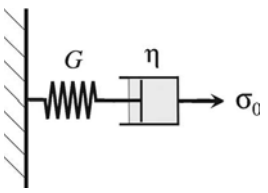

Fig. 16—Maxwell model for viscoelastic liquid behavior. G is force constant (modulus) of spring, η is the viscosity of the dashpot fluid, and σ_0 is the applied stress.

and

$$\dot{\sigma}_T = \dot{\sigma}_E = \dot{\sigma}_V \tag{27}$$

Furthermore, the total strain is clearly the sum of the strains undergone by the two elements

$$\gamma_T = \gamma_E = \gamma_V = \frac{\sigma_E}{G} + \frac{\sigma_V t}{\eta} \tag{28}$$

The expression on the right follows from the definition of the modulus ($G = \sigma/\eta$), Eq (4), and the fact that $\gamma = \dot{\gamma}_t$. It is also true that

$$\dot{\gamma}_T = \dot{\gamma}_E = \dot{\gamma}_V = \frac{\dot{\sigma}_E}{G} + \frac{\sigma_V}{\eta} \tag{29}$$

An alternative to the creep method that is particularly useful for viscoelastic solids is to apply a sudden deformation and follow the decay of stress with time. This is similar to the experiment depicted in Fig. 13 and is known as *stress relaxation*. Sudden imposition of a strain γ_0 results in instantaneous lengthening of the spring. The dashpot experiences, in turn, an initial stress σ_0 from the extended spring, causing a gradual movement of the dashpot's piston, resulting in relaxation of the stress. By manipulation of the above equations, we can arrive at a quantitative way of describing this relaxation process.

Since the strain γ_0 in a stress-relaxation experiment is constant, the total strain rate $\dot{\gamma}_T = 0$. Therefore, from Eq (29)

$$\frac{\sigma_V}{\eta} = -\frac{\dot{\sigma}_E}{G} = -\frac{d\sigma/dt}{G} \tag{30}$$

rearranging

$$\frac{d\sigma}{\sigma_V} = -\frac{G}{\eta} dt \tag{31}$$

Integrating Eq (31) from time 0 to time t results in the Maxwell stress relaxation expression

$$\sigma = \sigma_0 e^{-Gt/\eta} \tag{32}$$

Fig. 17 illustrates the decay of stress in a constant strain or stress relaxation experiment for the Maxwell model, described by Eq (32). Note that the quantity η/G has the

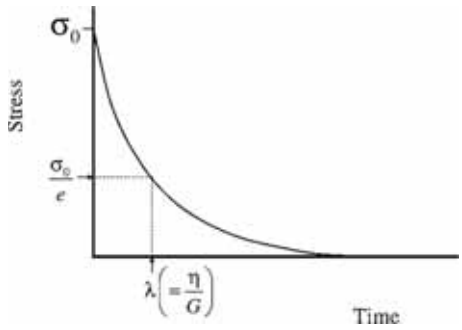

Fig. 17—Stress relaxation experiment. A fixed strain is imposed, creating an initial elastic stress σ_0, which relaxes viscously with time constant λ (=η/G). λ is the time at which the stress has decayed to σ_0/e.

dimension of time. We will assign to this quantity the symbol λ and refer to λ as the stress-relaxation time constant. It can be seen from Eq (32) that when $t = \eta/G$, $\sigma = \sigma_0/e$. Therefore, λ represents the time required for the stress to fall to 1 /*e* of its initial value (Fig. 17) and gives a convenient way of quantifying the rate of decay of stress in viscoelastic materials.

The time constant, λ, could also be called the stress memory time constant since it is related to the time it takes for a viscoelastic material to "forget" its initial elastic stress level when subjected to a constant strain. As such, λ determines the role that viscoelasticity plays in an industrial process. That is, elastic materials generate an "elastic extra stress" when deformed, which can result, among other things, in the stabilization of fluid structures that would ordinarily collapse too quickly to be of consequence. These include, for example, liquid fibers and webs, which result in roller spatter [46], and the formation of ribs on rollcoating [47]. The latter effects are particularly sensitive to extensional viscoelasticity [48] (see "Extensional Rheology.") The magnitude of the undesirable effect will depend on the rate at which the elastic extra stress decays or "relaxes," as we will see below.

In modern rheometers, sinusoidal oscillation is a common method of viscoelastic characterization. (Creep is also available as a viscoelastic test mode for controlled-stress instruments and stress relaxation for controlled-rate instruments—see below.) Equations derived for the Maxwell model [49,50] show how the viscoelastic time constant λ may be obtained from the oscillatory data

$$\eta'\omega = G'' = \frac{G_\infty \omega\lambda}{1+\omega^2\lambda^2} \tag{33}$$

and

$$G' = \frac{G_\infty \omega^2\lambda^2}{1+\omega^2\lambda^2} \tag{34}$$

from which

$$\tan\delta = \frac{G''}{G'} = \frac{1}{\omega\lambda} \tag{35}$$

where G_∞ is the plateau modulus (limiting value of G' reached at high frequency = Maxwell spring constant). Eq (35) says that when G' and G'' cross over (tan δ=1), $\lambda = 1/\omega_c$ (ω_c is the crossover frequency). The plateau modulus can be obtained from Eq (34), as well, since at the crossover point $G_\infty = 2G'c$. Similarly, at crossover, the zero-frequency plateau viscosity, $\eta_0 = 2\eta'_c$ [from Eq (33)].

If the mechanical elements are connected in parallel rather than in series, they each experience identical strain, but the stresses are now additive. This arrangement is called the Kelvin–Voigt model (Fig. 18). Because the elements are now in parallel, the Kelvin–Voigt model can only undergo finite strain, limited by the extensibility of the spring. Therefore, this is a model for a viscoelastic solid below its yield point. Equations for creep, stress relaxation, and tan δ for the Kelvin–Voigt model are:

Kelvin–Voigt creep

$$\gamma = \frac{\sigma_0}{G}(1-e^{-t/\lambda}) \tag{36}$$

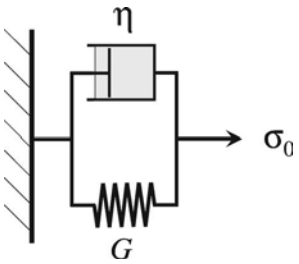

Fig. 18—Kelvin-Voigt model. Symbol definitions same as Fig. 16.

Kelvin–Voigt stress relaxation

$$\sigma = \gamma_0 G \tag{37}$$

and

$$\tan\delta = \omega\lambda \tag{38}$$

These equations describe an exponentially increasing strain at constant stress [see Fig. 19 and Eq (36)] and a nonrelaxing stress at constant strain [Eq (37)], respectively.

The Maxwell and Voigt models, by themselves, are too simple to accurately describe most real viscoelastic materials. However, a Maxwell element connected in series with a Kelvin–Voigt element turns out to model the linear viscoelasticity of many real systems rather well. Fig. 20 shows such an arrangement, known as the Burgers model. For completeness (and also because an error in the Burgers stress-relaxation expression has crept into the literature), equations describing creep and stress relaxation behavior for the Burgers model are given:

Burgers creep

$$\gamma = \frac{\sigma_0}{G_2} + \frac{\sigma_0 t}{\eta_2} + \frac{\sigma_0}{G_1}(1-e^{-t/\lambda_1}) \tag{39}$$

Burgers stress relaxation

$$\sigma = \gamma_0 G_2 e^{-t/\lambda_2} + \gamma_0 G_1 \tag{40}$$

where $\lambda_1 = \eta_1/G_1$ and $\lambda_2 = \eta_2/G_2$. The creep and stress relaxation behavior for the Burgers model are shown in Figs. 21 and 22. Modern rheometers of the type known as "controlled stress" (see "Rotational Instruments") are capable of performing creep measurements. Viscoelastic constants

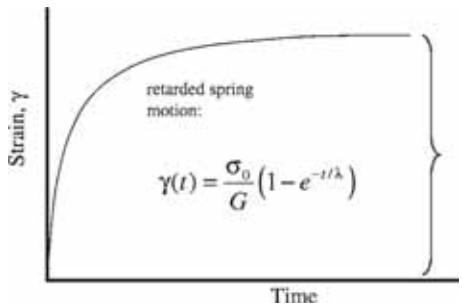

Fig. 19—Kelvin-Voigt creep experiment. At constant applied stress σ_0 the strain γ increases exponentially with time constant λ ($=\eta/G$).

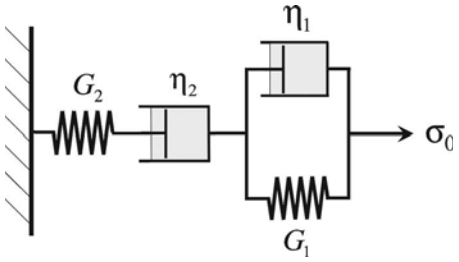

Fig. 20—Burgers model. Symbol definitions same as Fig. 16. Subscript 1 refers to the Voigt element; subscript 2 to the Maxwell element.

can then be extracted from the data by analysis according to one or more of the above models.

Viscoelasticity and Industrial Processes

The role of viscoelasticity in an industrial process depends on the rate (or frequency) of deformation. Put another way, the response of a viscoelastic material depends on how long a stress is applied ($1/\omega$), relative to the time required for any elastic "extra" stress to decay. This suggests taking a ratio of the stress relaxation time λ to the time (duration) of the process stress, t

$$De = \frac{\lambda}{t} \tag{41}$$

This ratio is a defined rheological term known as the Deborah number, *De*. It is named for the Biblical prophetess Deborah, who prophesied that the "mountains flow before the Lord" [51]. This is a perfectly accurate statement (long before being verified by the science of geology) of the fact that, on God's time scale, rock formations can be observed to undergo permanent deformation, or flow. In other words, if the stress time scale, t, greatly exceeds the relaxation time, λ ($De \ll 1$), the material will respond as a viscous fluid (because elastic stress has time to decay). Conversely, if $De \gg 1$, the stress duration is too brief to provide an opportunity for viscous relaxation, and the material behaves as if an elastic solid. Thus, the Deborah number quantifies the proportion of elastic to viscous control of a process. This is one reason why a determination of the viscoelastic properties of paints and coatings is important. Keunings and Bousfield [41] give the following expression for the effect on leveling rate a of elastic extra stress, through the relaxation time constant λ

$$\alpha = \frac{\alpha_{Newt}}{1 = \lambda\alpha_{Newt}} \tag{42}$$

where α_{Newt} is the leveling rate in the absence of viscoelastic relaxation. Since the Newtonian leveling rate is always positive, elasticity ($\lambda > 0$) always retards leveling, in the above expression. Eq (42) can be adapted to the situation of a typical paint, and the influence of elastic-stress relaxation is seen in Table 4.

To be sure, real materials may not exhibit simple exponential stress decay (i.e., a single relaxation time), but rather may possess a spectrum of relaxation times. However, the mechanical response will be dominated by a "mean" relaxation time (or sometimes the longest relaxation time [41]), obtained from experiments such as described in foregoing sections. Simple viscoelastic dispersions can show Maxwellian behavior with a single relaxation time [52,53].

One of the reasons that associative thickeners (ATs) have been so successful in being able to thicken paints without at the same time adversely affecting flow and leveling is no doubt due in part to their low elasticity. Even though ATs generate a three-dimensional network structure within the fluid,[9] they often have negligible G' values, in contrast to typical cellulosic thickeners, for example. This is believed to be due to the extreme lability of the micellar junctions of the associative network, resulting in very short network relaxation times [52,54]. Thus, the decay of elastic stress in ATs is so rapid that such stresses are virtually unobserved ($De \ll 1$).

As stated before, the process consequences of viscoelasticity are due in part to the stabilization of otherwise unstable liquid structures by the elastic "extra stress." Thus, liquid fibers and "webs," which would ordinarily collapse by surface tension, are stabilized, producing, for example, excessive rollcoat spatter (or "misting") and ribbing, and inhibiting atomization of sprayed materials. The importance of viscoelasticity for a particular process

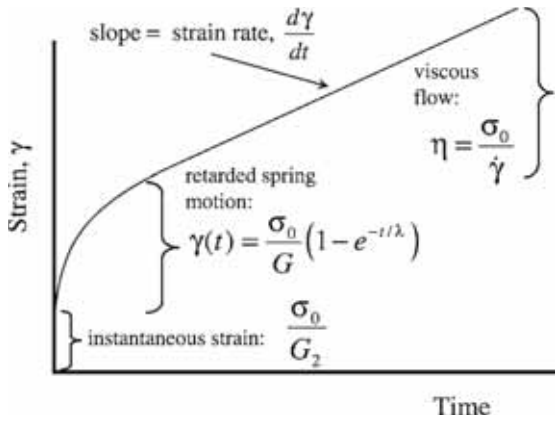

Fig. 21—Burgers creep experiment. Under constant applied stress σ_0, the Burgers model undergoes instantaneous deformation of magnitude σ_0/G_2. The next segment of the curve is retarded spring motion where strain increases exponentially with time. Finally, the spring is fully extended and viscous flow occurs with a constant strain rate $d\gamma/dt$.

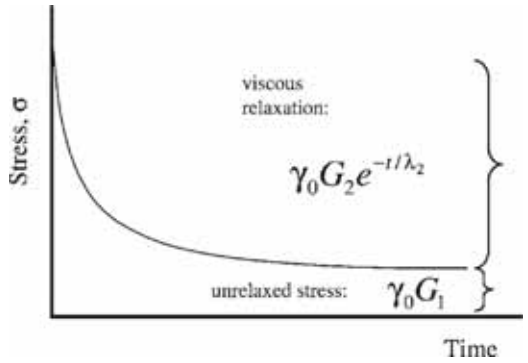

Fig. 22—Burgers model stress relaxation. Imposition of constant strain γ_0 causes stress which decays exponentially, governed by the relaxation time λ_2 ($=\eta_2/G_2$). Voigt element contributes unrelaxed stress $\sigma_\infty = \gamma_0 G_1$.

[9] See Chapter 33—Thickeners and Rheology Modifiers.

TABLE 4—Leveling rate dependence on Maxwell relaxation time, λ. α = *da*/*dt*, where a = roughness amplitude, and $t_{1/2}$ = time for a→0.5a_0 (initial amplitude).

λ, s	0.0	0.1	1	10	50	100
α, s^{-1}	34.5	7.75	0.972	0.0997	0.02	0.01
$t_{1/2}$	0.02	0.09	0.67	6.95	34.7	69.3

is gauged using the Deborah number, by the ratio of the stress-relaxation time constant to the time duration of the process stress. Of course, both the magnitude and lifetime of the elastic stress will be important, for together they will govern the degree of stabilization.

The analysis of the industrial problem of viscoelastic effects is complicated by the fact that many processes, particularly of coatings application, involve strain magnitudes beyond the range of linear viscoelasticity. Approaches to nonlinear viscoelasticity exist, but are beyond the scope of this chapter. Quantitative prediction of viscoelastic effects would require the use of a model for the fluid behavior, or viscoelastic constitutive equation, also outside the scope of this presentation. However, it is often possible to build experimental correlations between coating elasticity and performance problems, so that guidance may be provided for formulation efforts to solve them.

For most modern coatings, in particular, the origin of elasticity is likely to be an associated structure built up from a dispersed phase rather than polymeric entanglement. Such particulate flocs are generally shear-sensitive and are reduced or destroyed by high-shear application processes. The elastic modulus G' will be seen to decrease with increasing strain and strain rate outside the linear regime. Thus, in most cases, G' is a measure of structure that has its greatest effect at low strain and strain rate (unless the elastic character is due to polymeric entanglement). Therefore, under most conditions of application, structure (and elasticity) is destroyed and must rebuild in the applied film. Herein, it is seen that thixotropy and viscoelasticity are kindred phenomena for disperse systems.

EXTENSIONAL RHEOLOGY

In addition to simple shear, the other important mode of deformation that is important for coatings is extensional (or elongational) deformation. Extensional or "stretching" deformation causes an increase in length and decrease in cross section of an object. In a simple shear field, particles or polymer coils (i.e., the flow units) rotate with a velocity $\dot{\gamma}/2$. The rotational motion lessens the friction between the solvent and solute particles. In an extensional flow, this rotational accommodation to the flow field is not possible because there is no velocity gradient normal to the flow direction. The separation of flow units is thus more costly in terms of energy dissipation due to friction. Thus, the viscosity of a Newtonian fluid in extension turns out to be three times greater than its viscosity measured in shear (Trouton rule).

The extensional viscosity (η_e) is calculated as the ratio of tensile stress to extensional deformation rate

$$\eta_e = \frac{\alpha_e}{\dot{\varepsilon}} \tag{43}$$

The strain in extension is usually defined as a Hencky strain, $\varepsilon = \Delta l/l_0$, where l_0 is the original length and Δl the increase in length under tensile stress σ_e. The Hencky strain rate is then the time derivative of the strain or

$$\dot{\varepsilon} = \frac{1}{l}\frac{dl}{dt} = \frac{d(\mathrm{In}\, l)}{dt} \tag{44}$$

Extensional Viscosity in Coatings Processes

Many coatings processes involve stretching (elongational) flows (Table 1) and when coatings can support large extensional stresses (i.e., possess high extensional viscosity) performance can be dominated by such flows. As mentioned, the viscosity of a Newtonian liquid in extension is three times that measured in shear. For non-Newtonian fluids, the Trouton ratio $[\eta(\dot{\varepsilon})/\eta(\dot{\gamma})]$ can be as much as 10^4. Furthermore, whereas the shear viscosity is usually a decreasing function of shear rate, extensional viscosity frequently displays strong extensional strain rate thickening. For example, Lu [55] observed that polyacrylamide thickeners in latex paint systems showed extensional thickening behavior, whereas hydroxyethyl cellulose-type thickeners did not. Coatings application processes are generally high strain rate, so it is clear that η_e can possibly dominate the mechanical response, generally leading to detrimental consequences. Extensional stresses can stabilize liquid "webs" and fibers, such as form in direct rollcoating, allowing them to grow large instead of dissipating. This can result in heavy ribbing and "misting" (roll spatter) [56]. On the other hand, the breakup of a liquid jet to form atomized droplets in spray application is suppressed by a high extensional viscosity because the liquid fibers formed intermediary to droplet formation are inhibited from disintegration. J. E. Glass has been the chief proponent of the study of extensional viscosity in relation to paint performance, correlating it to roller spatter [46] and the performance of sprayed coatings [57]. Massouda did a clever and, unfortunately, largely overlooked study of the relationship of extensional stress measurements to viscoelastic relaxation kinetics and thence to spattering of paints [42].

Extensional Viscosity Measurement

There have been, unfortunately, few commercial instruments suitable for extensional measurement on coatings. The Spin-Line Rheometer (SLR) formerly offered by TA Instruments, utilizing the fiber-spinning geometry, and the Rheometrics (now part of TA Instruments) RFX rheometer, using opposed-nozzle flow to measure extensional forces, are no longer commercially available. However, the recent introduction by Thermo Electron Corporation of the CaBER Rheometer (Capillary Breakup Extensional Rheometer) provides a promising method of extensional rheometry that is appropriate for paints, adhesives, inks, gels, and polymer solutions. With the necessary electromechanical design and fabrication resources, one might attempt to build a simple extensional rheometer, perhaps patterned after that of Gupta [58]. The relatively simple technique of convergent flow analysis was used by Lu for measuring extensional properties of latex paints [55]. An overview of extensional rheometry has been published by James and Walters [59].

POLYMER MELT AND SOLUTION RHEOLOGY

High-polymer solution rheology is a subject of relatively little interest with respect to coatings due to the shift from solvent-borne to environmentally compliant technologies, such as waterborne, higher solids, and powder coatings. The polymers used for high solids and powder coatings are little more than oligomers in order to achieve necessary flow for satisfactory processing and film formation. Even the polymers used in solvent-borne varnishes and paints are below the entanglement molecular weight M_c, hence both their neat and solution rheology are Newtonian. Similarly, powder coating melts are Newtonian until near gelation [60]. The viscosity of polymer solutions below M_c is proportional to the weight-average molecular weight, M_w

$$\eta_0 = KM_w (M_w < M_c) \tag{45}$$

where K is a constant dependent on chain flexibility (T_g), polymer-solvent interaction, temperature, etc. If $M_w > M_c$, the motion of entangling polymers becomes much more complex, and the viscosity now depends on M_w raised to the power of approximately 3.4 [61]

$$\eta_0 = KM_w^{3.4} (M_w > M_c) \tag{46}$$

The viscosity of polymermelts follows a similar relationship. It should be noted that polymers having highly polar or hydrogen-bonding functionalities (such as commonly used in high-solids formulations) can show nonlinear dependence of viscosity on molecular weight even below M_c due to transient intermolecular associations [62].

The sole use of high-polymer binders in coatings today is where they exist as a separate phase dispersed in a liquid carrier medium[10]. Such materials are known as polymer latexes, or latex dispersions Because the latex polymer is segregated from, and therefore non-interacting with, the solvent, the rheology of latexes is much simpler than for the same high polymer in the solution state. The rheology of polymer dispersions will be discussed below.

DISPERSION RHEOLOGY

Dispersions of solids in liquids, for example, titanium dioxide particles dispersed in a liquid medium, play a central role in the manufacture and performance of coatings. Fully dispersed, stable dispersions favor the attainment of optimum intrinsic properties, improved process ability and workability, improved storage stability (shelf-life), and can provide higher solids at application viscosity. Rheology is particularly useful for dispersion characterization because of its sensitivity to the microstructure. Both stability and quality of dispersions can be evaluated. Dispersion rheology has two broad aspects: (1) The dependence of viscosity on the concentration of the dispersed phase, and (2) the dependence of viscosity on shear stress and shear rate (discussed in "Classes Of Non-Newtonian Behavior"). A third important aspect is the viscoelastic properties of dispersions, that will not be discussed here. Factors that determine the foregoing properties include particle shape, rigidity, particle size and size distribution, and interparticle forces, both attractive and repulsive. All these elements combine to determine the microstructure of the dispersion, its response to stresses, and hence its rheology.

A dispersion (or suspension) consists of a suspended or dispersed discontinuous phase contained within a continuous phase. As an example, this might be a system in which a fine particle size solid is wetted by and thoroughly mixed in a liquid. However, the dispersed phase may be a liquid (an emulsion), a solid (suspension), or gaseous (a foam) as well. The dividing line of terminology between "dispersions" and "suspensions" is essentially one of particle size. Dispersions are generally of colloidal dimension, about 10 nm to 1 μm. Due to their small size and mass, colloidal particles are very slow settling or nonsettling because Brownian motion effectively keeps them randomly suspended. Suspensions above 1 μm generally exhibit rapid settling because Brownian forces are ineffective with such massive particles, and also because Van der Waals attractive forces increase in proportion to particle size.

Addition of a particulate phase to a liquid increases its viscosity in proportion to the *volume fraction* ϕ of the dispersed phase. ϕ is the fraction of the total volume of the dispersion occupied by the dispersed material (a dimensionless number),

$$\phi = \frac{\text{volume of particles}}{\text{volume of dispersion}} \tag{47}$$

A convenient way of expressing the effect of a dispersed phase on the viscosity of a liquid is by normalizing the dispersion viscosity to the pure-liquid viscosity. This ratio is termed the *relative viscosity* η_r and is also dimensionless

$$\eta_r = \frac{\eta_d}{\eta_l} \tag{48}$$

The contribution of a single particle to the viscosity of a dispersion is characterized by its *intrinsic viscosity* (or *limiting viscosity number)* $[\eta]$, a function of particle shape and deformability. $[\eta]$ is obtained as the slope of a plot of $\eta_r - 1$ (formerly known as the *specific viscosity*) versus ϕ

$$[\eta] = \lim_{\phi \to 0} \frac{\eta_r - 1}{\phi} \tag{49}$$

It is reasonable that the viscosity of a liquid will be augmented by a factor equal to the product of the particle intrinsic viscosity and the concentration of particles

$$\eta_r = 1 + [\eta]\phi \tag{50}$$

Einstein [56] was the first to calculate the intrinsic viscosity for noninteracting rigid spheres in a Newtonian liquid, obtaining the number 2.5

$$\eta_r = 1 + 2.5\phi \tag{51}$$

The intrinsic viscosities of other particle shapes (e.g., prolate and oblate spheroids—discs and rods) have been calculated [63] and are always greater than 2.5. This means that any deviation from spherical particle shape will increase the viscosity of a dispersion. Equation (51) is valid only in the very dilute regime ($\phi < 0.05$), where the flow around a

[10] Some high-molecular-weight, water-soluble polymers are used as thickeners. However, they are used at low levels, and their effects on rheology are mainly colloidal/osmotic rather than as solution polymers.

single particle is not affected by the presence of other particles. At higher concentrations, the motion of particles is perturbed by interactions with other particles. These interactions are accounted for by higher-order terms in ϕ, as, for example, by Batchelor [64], who extended the rigorous treatment to somewhat higher volume fractions by using a second-order expression in ϕ

$$\eta_r = 1 + 2.5\phi + k\phi^2 \tag{52}$$

The value of k is of the order of 5. Fig. 23 illustrates the typical dependence of η_r on ϕ for actual dispersions (using data of Eilers [65]) and shows curves corresponding to the predictions of Einstein's and Batchelor's equations. It can be seen that Batchelor's equation predicts a finite viscosity at $\phi = 1$, which is not realistic. Also in Fig. 23, it is seen that η_r rises toward infinity at a volume fraction considerably less than unity. The volume fraction ϕ_m corresponding to $\eta_r \rightarrow \infty$ is called the maximum volume fraction, or maximum packing fraction. At $\phi = \phi_m$, the density of particle packing is such that the dispersion can no longer flow. The value of ϕ_m will be system-dependent (also shear dependent) and will be determined by particle shape, particle-size distribution, the ionic strength of the medium, the degree of particle flocculation, and the manner in which the particles arrange themselves (pack) in three-dimensional space.

Numerous models have been proposed containing ϕ_m [15,66,67]. Probably the most successful in fitting a variety of data is the Krieger–Dougherty equation [68]

$$\eta_r = \left(1 - \frac{\phi}{\phi_m}\right)^{-[\eta]\phi_m} \tag{53}$$

Fig. 23 shows the fit of the Krieger–Dougherty model to data of Eilers [65] using a value of $[\eta]$ close to the Einstein value. The maximum packing fraction will have different, unique values at low and high shear rates because the strength of the shear field determines how efficiently

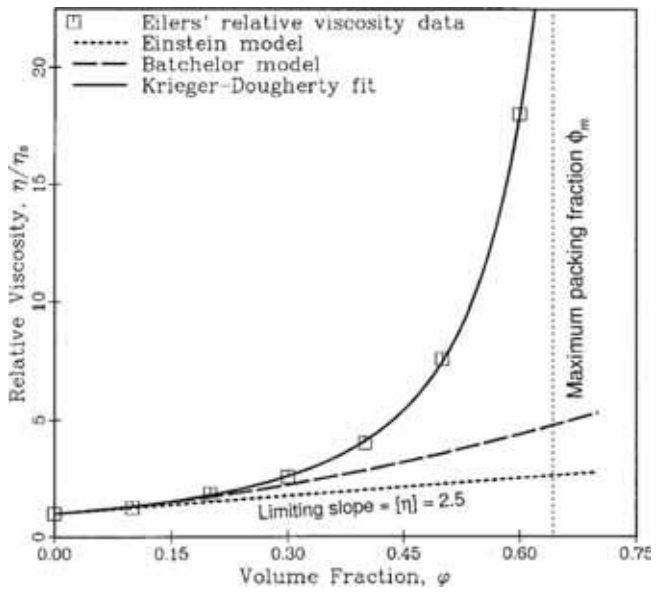

Fig. 23—Dispersion relative viscosity data of Eilers, together with best-fit curves for the Einstein model, Batchelor model, and the Krieger-Dougherty model.

particles are able to pack together. Reviews of the rheology of polymer colloids are recommended for further reading [6,14,69].

It should be noted here that although the dispersion rheology is controlled by the disperse-phase volume fraction ϕ, the effect of the particle phase on the rheology may be greater than expected solely on the basis of the volume of material added to make up the dispersion. This is because the disperse-phase volume may be augmented by various effects tending to increase the effective particle radius. It is the "hydrodynamically effective" particle volume that determines the rheology. Thus, the rheological behavior will be found to scale with the effective volume fraction ϕ_{eff}, rather than with the formulated volume fraction ϕ.

There are two mechanisms that can cause ϕ_{eff} to be greater than ϕ. In the first, the effective particle radius increases as a consequence of various methods of dispersion stabilization. For example, adsorption of a polymeric stabilizer onto the surface of a particle adds the thickness of the stabilizer layer to the particle radius. By steric-osmotic interactions between stabilizer layers, the close approach and flocculation of particles is prevented, resulting in *steric stabilization*. If the thickness of the steric stabilizing layer on the particle is δ, the effective volume fraction is [69]

$$\phi_{\text{eff}} = \phi\left[1 + \left(\frac{\delta}{R}\right)^3\right] \tag{54}$$

where R is the original particle radius. Quantitative viscometric methods have been developed for inferring the adsorbed-layer thickness [69,70].

The effective particle radius and hence the effective volume fraction ϕ_{eff} can also be increased by the effects of particle electrical charge. Aqueous dispersions are often stabilized by association of repulsive electrical charge with the particle, known as electrostatic stabilization. The charge may be due to adsorption of ions, anionic or cationic surfactants or polyelectrolytes, or, in the case of polymer colloids, to the presence of ionizable groups which are part of the polymer molecules. (In the case of functionalized polymer latexes, such groups tend to migrate to the particle surface.) The surface ionic charge surrounds the particle with an electrical field, which propagates into the aqueous phase a distance inversely proportional to the ionic strength of the medium. In the presence of dissolved counterions, an ionic atmosphere envelops the charged particle. These phenomena are the origin of the so-called electroviscous effects, which have to do with the way the electrical field surrounding the particle affects the effective volume fraction or collision cross section, and also the nature of the hydrodynamic interaction between particle and surrounding liquid [63,71]. The rheology of a dispersion can be greatly altered as a consequence of these effects, as the solution ionic strength or pH are varied. In a study by Krieger and Eguiluz, in a dispersion of uniform polystyrene latex spheres (ϕ = 0.4) the η_r decreased from 10^6 to 10 as the result of increasing the concentration of electrolyte by two orders of magnitude [72]. In that study, the low-electrolyte latexes exhibited apparent yield stress behavior, a consequence of the increase of the effective volume fraction of the latex particles due to the expansion of the repulsive electrostatic field. The effect is so great that the particles

become "locked" into crystalline arrays that can diffract light, producing striking iridescent colors. As the electrolyte concentration is increased, the counterion "cloud" both shrinks the electrostatic field and shields particle fields from each other. Consequently, the viscosity drops dramatically (remember that the volume change depends on the cube of the radius change).

A second mechanism by which ϕ_{eff} can exceed ϕ is flocculation. When particles form flocs, the liquid phase contained within the interstices of the floc is not free-draining, but effectively becomes part of the floc. Thus the volume of a flocculated phase is augmented by the volume of trapped interstitial liquid. Consequently, the disperse-phase volume fraction is higher than for the deflocculated system.

Dispersions can exhibit the full range of rheological behavior mentioned previously, including Newtonian, shear-dependent, time-dependent, plastic, and elastic behavior. A dispersion of noninteracting spherical particles will be Newtonian up to about ϕ = 0.2 [15]. Above this concentration, onset of non-Newtonian character begins due to particle interactions and hydrodynamic factors. Mechanisms for these effects are discussed in the section "Shear-Thinning Fluids."

RHEOLOGY AND FILM FORMATION

In the next two sections two coating flows, *sagging* and *leveling,* are discussed. These two flows occur early in the "film formation" phase in an applied coating layer. In sagging flow, gravity acts on the wet coating layer on a vertical substrate, causing drainage downward, which can lead to unsightly dripmarks. In leveling flow, surface tension attempts to level out any nonuniformities in surface height. Oftentimes good leveling and acceptable sagging are in opposition. Acceptable appearance of a paint layer will be dependent on proper rheological control of these flows.

In discussing how coating rheology influences these flows, there is an important point to be made: Both sagging and leveling are driven by specific shear stresses, which can be calculated from the forces acting (gravity and surface tension, respectively) and the geometry of the film. However, the shear rates over which these processes occur can vary widely depending on the coating's viscosity at the acting shear stress. The shear rate is a *dependent* variable, for real processes. The appropriate *independent* variable to best differentiate the performance of paints according to their rheology is the shear stress. For this reason (and others), it is preferable to plot flow curves as viscosity versus *shear stress*, as opposed to viscosity versus *shear rate,* which is the more common practice. To do otherwise is wrong in principle and will result in incorrect relative ranking of paints by their rheology with respect to their rates of sagging, leveling, pigment settling, or to their ease of application. This issue is key to using rheological data correctly in the interpretation of flow curves.

Viscosity versus shear rate plots are in fact an incorrect representation of the flow properties of paints with respect to specific coating processes, which are governed not by shear rate but by shear stress. Plotting with shear stress as the independent variable, as in Fig. 24, permits a direct comparison of paints *at the shear stress specific to a particular process*. Viscosity is a nonlinear function of

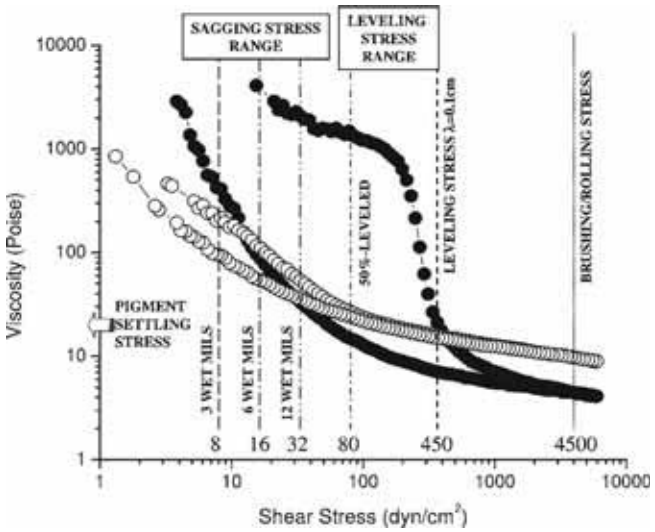

Fig. 24—Log-log plot of viscosity versus shear stress for two paints: ○ = Paint 05; ● = Paint 07. "Stress-Map" plot showing shear stresses calculated for specific coating processes, indicated as dashed vertical lines, with calculated stresses, in dyne- cm^{-2}, attached. Process stresses indicated are for brush/roller application; initial leveling of sinusoidal striations of wavelength 0.1 cm and same when 50 % leveled; sagging stresses at 3, 6, and 12 wet-mils film thickness. (From Eley, R. R., *Rheology Reviews 2005,* 173-240, K. Walters and D. M. Binding, Eds., British Society of Rheology (2005). Used by permission of British Society of Rheology.)

the shear stress, and each part of the sometimes complex curve has a role to play in various coating processes. Furthermore, because of geometrical and process variables, the shear stress for a given process may not be constant for the duration of the process. The process stresses illustrated by dashed lines in Fig. 24 are for (a) application by brush or roller, (b) surface tension-driven leveling of surface roughness, and (c) gravity-driven sagging of 3-, 6-, and 12-mil wet films. Gravitational settling of pigment particles occurs at even lower stresses. The point is that, for a given process, the shear stress acting on a coating layer is independent of the rheology (for a given geometry, density, surface tension). The shear rate for the process, however, is dependent on the rheology, and will vary with the viscosity of a particular coating at the process shear stress. Fig. 25 shows the same two paints as in Fig. 24, but this time with the viscosity plotted as a function of shear rate. Note that the constant-shear-stress dashed lines now slant to the left, and shear rates for the processes identified in Fig. 24 are shifted to the left for the higher viscosities. The constant-shear-stress lines cut the flow curves at the shear rate of the process for that paint. It can be seen for the two paints that shear rates for some process stresses are shifted nearly two decades (100-fold). Clearly, the assumption that processes such as leveling and sagging occur at a constant shear rate (say, 1 s^{-1}) can be wrong by orders of magnitude.

Fig. 25 also shows that if one were to predict comparative paint performance from viscosities at constant shear rate, the viscosity ratios would be several times smaller than the correct ratios measured at the true process shear stress. Table 5 shows viscosities at selected shear stresses and at approximately corresponding shear rate values from

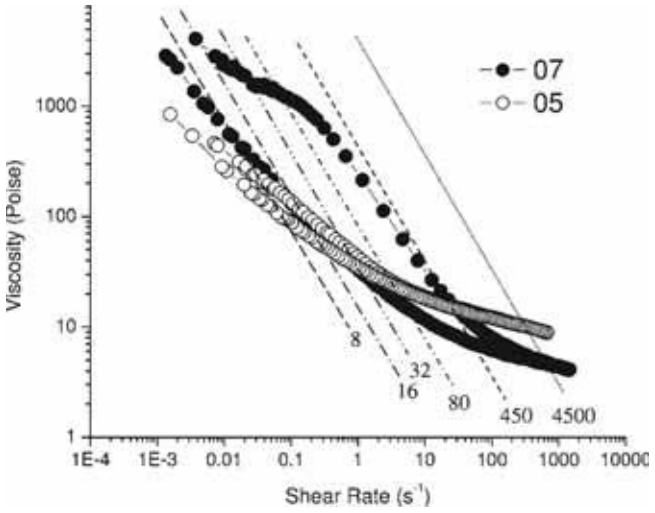

Fig. 25—Log-log plot of viscosity versus shear rate for two paints: ○ =Paint 05; ● = Paint 07. Shown also are the same dashed lines representing constant process shear stresses as in Fig. 24, now leaning leftward. As consequence of the leftward slant, ratios of the viscosities of the two paints at an arbitrary shear rate are much smaller than those at roughly similar shear stress in Fig. 24. See Table 4. (From Eley, R. R., *Rheology Reviews 2005,* 173–240, K. Walters and D. M. Binding, Eds., British Society of Rheology (2005). Used by permission of British Society of Rheology.)

Fig. 25. "Crossover" rheological behavior, as in Figs. 24 and 25, is very common among paints and can often lead to a failure of "lab-bench" measures of rheology to correlate to paint performance.

SAGGING

A coating layer on a nonhorizontal surface will experience a tangential shear stress due to gravity, given by

$$\sigma_g = \rho g h \cos\theta \tag{55}$$

where ρ is the liquid density, g is the gravitational acceleration, and h is the uniform layer depth. θ is the angle of inclination of the substrate to the vertical. For a vertical substrate, $\sigma_g = \rho g h$ (Fig. 26).

TABLE 5—Viscosity ratios at constant shear stress versus constant shear rate for Paints 05 and 07. (From Eley, R. R., *Rheology Reviews DCMP48 2005*, 173–240, K. Walters and D. M. Binding, Eds., British Society of Rheology (2005). Used by permission of British Society of Rheology.)

	Viscosity, Poise			
	Shear stress =8 dyn·cm^{-2}	Shear rate =0.01 s^{-1}	Shear stress =80 dyn·cm^{-2}	Shear rate =1.0 s^{-1}

Paint 07	8000	2526	1445	259
Viscosity ratio	38	6.2	54	6.1

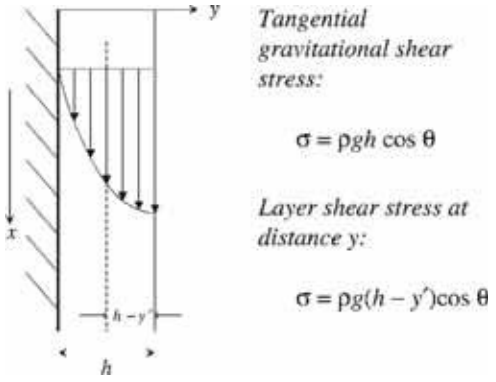

Fig. 26—Sagging driven by gravitational shear stress. Gravity acts in the *x*-direction, film thickness coordinate is *y*, wet film thickness is *h*. Shear stress is maximum at the substrate surface, due to the "weight" of outer layers of coating.

The shear stress on any layer within a coating will be equal to the load from the outer layers. For a vertical surface

$$\sigma_g = \rho g(h - y') \tag{56}$$

is the shear stress acting on a layer a distance y' from the substrate, due to the weight of the outer layer of thickness $h - y'$ (Fig. 26).

Coating layers having a yield stress σ_0 (see "Plastic (Yield) Behavior") will not sag unless the gravitational shear stress exceeds the yield value. The shear plane where yield occurs will therefore be at y' (for ideal yield behavior) when the following expression is satisfied

$$\sigma_0 \le \rho g(h - y') \tag{57}$$

Since only layers deeper than y' experience sufficient stress to flow, it follows that the layer $h - y'$ (from y' to the free surface) is solid and slides as a solid sheet over the fluid inner layers. For a coating with a large yield stress, the load necessary to cause yield and flow is correspondingly greater. Therefore, the yield plane moves deeper into the coating layer, leading to a phenomenon known as slumping. Slumping, therefore, is diagnostic of the presence of a significant yield stress. Fig. 27 illustrates the effect of a yield stress on sagging, leading to plug flow (slumping). Croll [73] showed direct evidence of plug flow in a sagging coating possessing a yield stress.

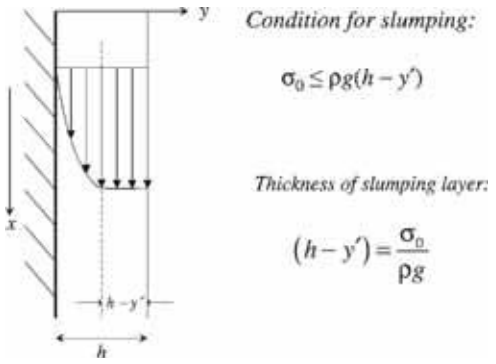

Fig. 27—Slumping (plug flow), caused by the presence of a yield stress, σ_0. Coating layer of thickness h-y' will "slump" or slide downward as a solid sheet over liquid sublayer if $\sigma_0 \le \rho g(h\text{-}y')$.

Wu [74] gives sagging velocity expressions for various types of non-Newtonian behavior. The surface velocity of a sagging Newtonian liquid is

$$v = \frac{\rho g h^2}{2\eta} \tag{58}$$

Sagging transmits substrate imperfections to the coating surface and amplifies them [75]. This is because any surface irregularity necessarily results in fluctuations in the local coating thickness normal to gravity and therefore in the local sagging shear stress. Furthermore, any local variations in film thickness due to application or to substrate features (e.g., a hole or a corner) can produce local accelerations of sagging in which thicker elements overtake thinner elements. This is a self-accelerating process, leading to drips, "tears," "runs," or "curtaining" [76]. Such undesired flows can be minimized by proper characterization and control of rheology [77].

The sagging of a coating is similar to the problem of drainage of a liquid layer from an inclined surface. The difference between the two is that, in sagging, the coating layer is assumed infinite in extent; hence, sagging causes no change in the local coating thickness, on a flat substrate. If this assumption is not correct, then gravitational flow will result in thinning of the coating layer at the top and thickening at the bottom of a finite substrate. The distinction between the two processes may be useful for those desiring to calculate, for example, the degree of "wedging" on a dip-coated part as against simply calculating a sag length or sagging velocity. Again, in the case of sagging, h is assumed constant and a sagging distance x may be calculated, whereas for drainage the thickness h varies with distance x down the substrate. The equations describing the flow are otherwise identical and interchangeable. By a derivation similar to that of Wu [74,78] for sagging, the expressions below, describing drainage, can be obtained.

For a Newtonian liquid, the thickness at time t at a distance x down from the upper edge of the liquid layer is given by

$$h = \sqrt{\frac{\eta x}{pt\cos\theta}} \tag{59}$$

The angle θ is as defined above. Most coatings are non-Newtonian, however, which will have great impact on the drainage behavior. For example, shear-thinning fluids will drain to a much more uniform film thickness than Newtonian fluids. The gravity drainage of a power law fluid (see "Shear-Dependent Viscosity") is given by

$$h = \left[\left(\frac{n+1}{n}\right)\left(\frac{x}{t}\right)\right]^{n/(n+1)}\left(\frac{K}{\rho g\cos\theta}\right)^{1/(n+1)} \tag{60}$$

In the above, K is the "consistency" term and n the exponent in the power law expression (see "Shear-Dependent Viscosity"). Here we see a practical application of mathematical flow models. The parameters obtained from fitting the power law to an experimental flow curve can be inserted into the above equation and the sagging behavior of a coating formula can be calculated and graphed. For shear-thinning fluids with yield stress, the drainage equation is

$$h = \left[\left(\frac{n+1}{n}\right)\left(\frac{x}{t}\right)\right]^{n/(n+1)}\left(\frac{K}{\rho g\cos\theta}\right)^{1/(n+1)} + \frac{\sigma_0}{\rho g} \tag{61}$$

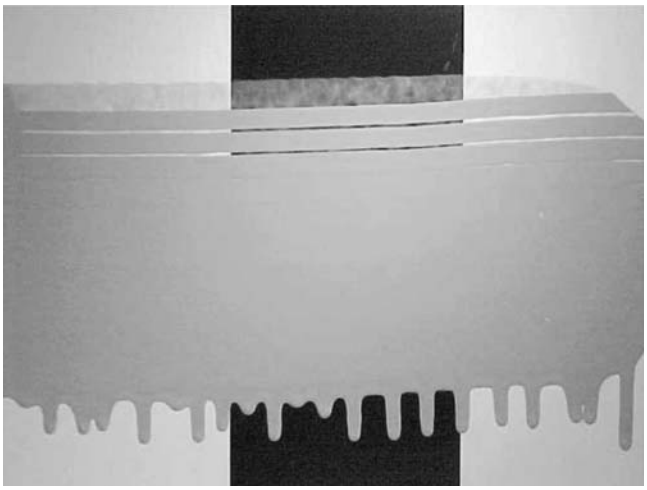

Fig. 28—Sagging evaluated by Leneta drawdown blade. Sagging is rated by the thickest paint stripe that does not show sag.

The constants n, K, and σ_0 are obtained by fitting the Herschel–Bulkley flow model to the experimental flow curve (see "Shear-Dependent Viscosity").

As with leveling, a realistic description of sagging must include not only non-Newtonian effects, but also effects of drying, geometry of the applied film, and the instantaneous rheological state of the applied film. Croll has published a review, analysis, and experimental study of sagging which examines these effects [73]. Eley and Schwartz [79] have used numerical simulation to analyze in detail the effect of rheology and substrate shape on the variation of film thickness in a drainage flow.

Measures of Sagging

A number of laboratory methods for evaluating sagging have been used, some of which measure some rheological property related to sagging behavior [80] and some of which measure sagging directly. Among the latter is ASTM D4400, in which a drawdown blade with multiple slots of graduated depths spreads paint stripes of graduated thicknesses over a nonabsorbent substrate (Leneta drawdown bar and sag chart). The chart is suspended vertically and the paint stripes allowed to flow under gravity. Sag is rated according to the thickest stripe that does not show sag (Fig. 28). A similar but somewhat simpler test involves the use of a wire device that scribes two lines, of 1/8 and 1/4 in. (0.32 and 0.64 cm) width across a 3-wet-mil paint stripe, which is then hung vertically, and sagging is visually evaluated on the dry paint film.[11] The method is illustrated in Patton [81]. Another device that has apparently met with some success is the so-called "sagging balance" [82], which uses an electronic balance to measure the shift in mass accompanying drainage of a coating applied to an inclined plate.

Sagging is, of course, driven by gravitational shear stress. The magnitude of the sagging shear stress depends solely on the wet film thickness and density [Eq (55)]. The resulting shear rate of sagging is determined by the rheology profile of the paint in question. It is imprecise to attempt to predict sagging from viscosity measure-

[11] Federal Test Method 4493, September 1965.

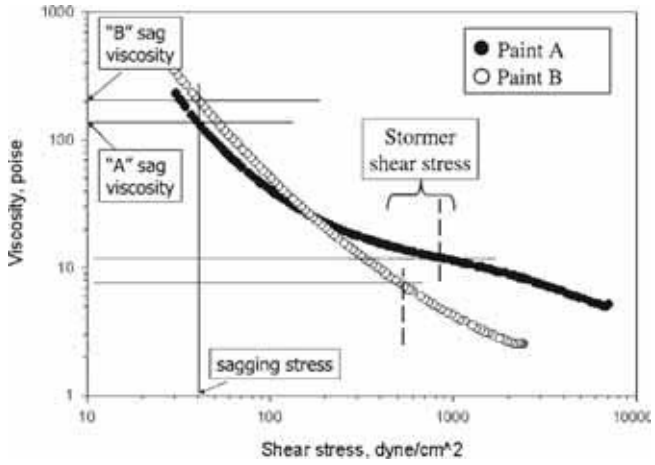

Fig. 29—Illustration of how to obtain the viscosity governing sagging from flow curve data. The gravitational shear stress driving sagging is indicated for a 6-mil wet film thickness. This stress intercepts the flow curves for paints A and B at the viscosities resisting drainage flow. "B" is higher than "A" at sagging stress and so would sag less. Stormer® viscometer shear stresses and corresponding viscosities are also indicated, and show the reverse order.

ments at an arbitrary "sagging shear rate" and may lead to incorrect estimates of relative sagging. The proper way to predict relative sagging tendency is to plot viscosity as a function of shear stress rather than shear rate as in Fig. 24. Shear stress levels corresponding to the pertinent wet film thickness can be calculated, and the magnitude of the viscosity controlling sagging, determined from the graph. Fig. 29 compares two paints in this manner, with indicated gravitational shear stress levels corresponding to a wet film thickness of 12 mils. The dashed lines in Fig. 29 indicate the approximate shear stress of the Stormer® paddle viscometer for the two paints. At the Stormer shear stress (approximately like hand stirring), the viscosity of A is higher than B (12 vs. 7.5 P). This difference is easily felt when hand stirring the two paints. However, at the sagging shear stress of about 40 dyn·cm^{-2} paint B is over 60 % higher in viscosity, and should therefore sag less than A, which is observed experimentally.

LEVELING

The mechanics of coating application generally cause the applied coating layer to be initially rough and consequently of varying thickness. Uniform film thickness is desired both for reasons of appearance (color and hiding uniformity) and for substrate protection (necessary minimum film thickness). The process of smoothing of the initial rough surface is called *leveling*. Adequate leveling is of obvious critical importance to the success of a protective or decorative coating. Hence, a large number of studies of the subject have been published (e.g., Refs. [1,41,83–91]), but the role of rheology and other factors in the leveling of paint films is not fully understood. One might expect leveling to correlate reasonably well to low-shear viscosity. However, factors such as viscoelasticity, time dependence, volatilization, wicking, and surface tension gradient flows make leveling a complex process. The leveling and film formation of a paint layer is so complex that, in the opinion of this author, only computer modeling has the potential to provide a wholly

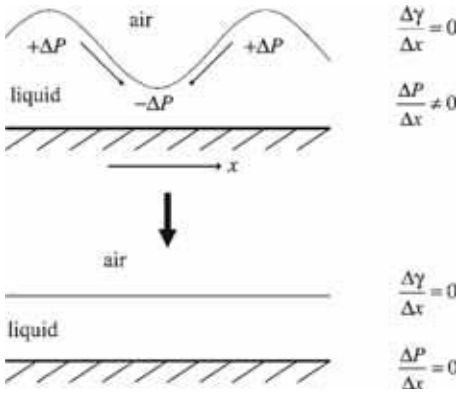

Fig. 30—Surface tension-driven leveling. Curvature of liquid surface creates capillary overpressures and underpressures ΔP. There is no surface tension gradient along the film coordinate ($\Delta\gamma/\Delta x = 0$). Pressure is not uniform, however ($\Delta P/\Delta x \neq 0$), and drives fluid flow toward leveling of surface height variations.

satisfactory method of analysis and prediction (see, for example, Eley and Schwartz [79,87]). However, such modeling capability is not readily available to most practitioners, so we will review some of the analytical models of leveling. These can provide at least a qualitative understanding of the role of rheology and other factors in leveling.

The mechanism of leveling is illustrated in Fig. 30 for a liquid without surface tension gradient ($\Delta\gamma/\Delta x = 0$), having a sinusoidal surface profile. The sum of all surface tension vectors in the curved surface produces a net force downward at the "peaks" and upward in the "valleys," the liquid-air interface acting as if it were a stretched elastic membrane. Forces due to liquid surface curvature are called *capillary forces* and result in capillary pressure variations within the liquid layer ($\Delta P/\Delta x \neq 0$). Thus, leveling is driven primarily by capillary pressure gradients due to local surface curvature, under conditions of uniform surface tension. Liquid is "pumped" from the peaks into the valleys, ultimately producing a level surface. For thin films, gravity is of negligible effect on leveling unless a critical roughness wavelength is exceeded. For a typical paint, the critical wavelength is of the order of 1 cm [93].

The quantitative prediction of leveling from physical properties requires the use of some mathematical model of the process. Smith et al. [1] derived such a model by a linear lubrication approximation-type analysis, assuming a uniform sinusoidal surface profile. (The Los Angeles Paint Club obtained a similar equation in 1953 [94] for surface roughness approximated by semicircular arcs.) Orchard later [95] developed a complicated expression for the leveling of a more realistic, arbitrarily rough surface profile in terms of a Fourier series. However, the expression simplifies considerably when the coating thickness is assumed to be small relative to the roughness wavelength. Assuming a single sinusoidal wavelength (which is a reasonable approximation since the leveling behavior will be dominated by the longest wavelength), the Orchard equation is

$$\ln \frac{a_t}{a_0} = -\frac{16\pi^4 h^3 \gamma t}{3\lambda^4 \eta} \tag{62}$$

for constant surface tension γ and viscosity η. The equation says that the ratio of the surface wave amplitude a at time

t to its initial amplitude a_0 decays exponentially with time, and the rate of decay depends on the coating layer thickness h to the third power and inversely on the wavelength of the surface roughness λ to the fourth power. For roughness geometry other than sinusoidal, the constant term $(16\pi^4/3)$ will take other values.

The Orchard equation is only an approximation to the leveling behavior of most real paints because it assumes Newtonian fluid behavior and neglects time-dependent effects (and other effects such as surface tension gradients [85]). Time-dependent effects include thixotropy and changes in rheology from loss of solvent due to drying or to "wicking" (absorption) of the liquid phase into a porous substrate. Nevertheless, the Orchard model conveys the important influence of film geometry and physical properties on leveling rates, and allows estimation of the order of magnitude of effects of changes in these variables. For example, it should generally hold, despite complicating factors, that doubling the wet film thickness will increase the leveling rate eight-fold. However, a more realistic description is warranted, taking into account other film properties and processes that affect leveling significantly. A step was taken by Murphy [96] (see also Refs. [85,84]), who rederived the Orchard equation for pseudoplastic paints assuming power law behavior (see "Shear-Thinning Fluids"), obtaining

$$a^{(n-1)/n} = a_0^{(n-1)/n} - \frac{n-1}{2n+1}\left(\frac{\gamma}{K}\right)^{1/n}\left(\frac{2\pi}{\lambda}\right)^{(3+n)/n} h^{(2n+1)/n_t} \qquad (63)$$

This expression contains the power law coefficients, K and n, all other terms retaining the same definitions as above. Note that the leveling rate increases as the power law exponent, n, decreases (i.e., as the paint becomes more shear thinning). As expected, the leveling rate decreases with increasing K (consistency). Lu [55] found the Murphy equation valid for correlating the change of brushmark amplitude with time for systems where the leveling was clearly dominated by the viscosity. However, the Murphy equation still assumes that viscosity depends only on shear rate and that surface tension does not change during the leveling process. In reality, viscosity and surface tension will both change due to evaporation of the volatile phase of the coating or to wicking. The Murphy equation may be modified to take account of time-dependent viscosity increase by including a time-integral expression for the viscosity

$$a^{(n-1)/n} = a_0^{(n-1)/n} - \frac{n-1}{2n+1}\gamma^{1/n}\left(\frac{2\pi}{\lambda}\right)^{(3+n)/n} h^{(2n+1)/n}\int_0^t\left(\frac{1}{\eta(t)}\right)dt \qquad (64)$$

where $\eta\ (t)$ is some time function of viscosity relating effects of thixotropy, drying, wicking, etc. The effect of time-dependent viscosity on leveling is dramatic, as shown in Fig. 31. Here, for two different paints, the decay of surface amplitude is calculated using Eq (63) and (64), together with an experimentally determined expression for the increase of viscosity with time due to drying. Camina [84] reported that the viscosity of a drying paint increases exponentially in the initial stages. Therefore, an expression such as the following would fit drying-viscosity data

$$\eta(t) = \eta(0)e^{kt} \qquad (65)$$

where $\eta(0)$ is the viscosity before drying has begun, k a drying rate constant, and t the time. Such an expression can be inserted into Eq (64) in place of $\eta(t)$ and integrated[12] to calculate the leveling curve for a paint whose viscosity is increasing with time due to solvent loss.

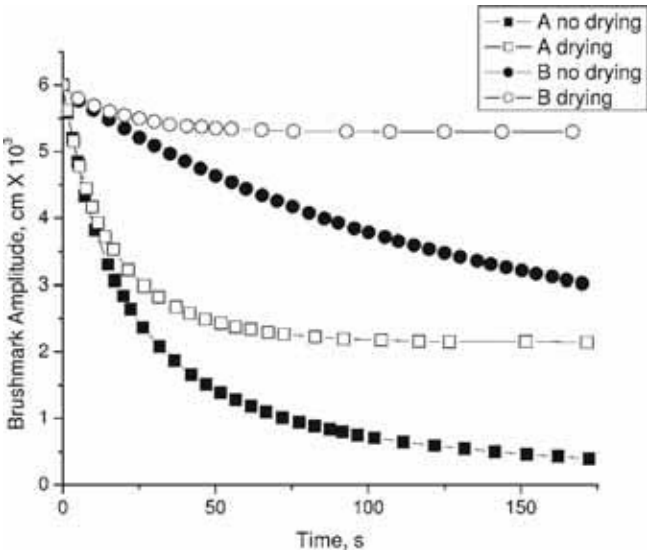

Fig. 31—Calculated brushmark leveling for two paints, with and without effects of drying. Curves calculated using Eqs (64) and (65): ○—Paint A, with drying; ●—Paint A, without drying; □—Paint B, with drying; ■—Paint B, without drying.

Quach [93] has discussed and summarized the shortcomings of various laboratory methods of leveling evaluation. As noted by Quach, much work on leveling has been done without adequately taking into account the numerous interacting subprocesses whose final result is the dried film profile. An additional important factor dealt with experimentally and theoretically is the influence of surface tension gradient-driven flows (Marangoni flows) [86,97,98]. Surface tension gradients may arise due to a number of causes during film formation and can have consequences for the course of film leveling, among other things. Figure 32 illustrates the mechanism of surface tension gradient-driven flow, which can result in the deleveling of an initially level liquid layer. Local surface tension gradients can develop due to differential solvent evaporation or to temperature gradients (or other causes). This results in a surface flow from regions of low surface tension toward regions of high, in an attempt to reach surface equilibrium. The moving surface "drags" subsurface liquid along, creating a bulk flow. This is the Marangoni effect. In the case of differential evaporation, the driving force for Marangoni flow is a shear stress σ_s tangent to the film surface, given by

$$\sigma_s = \frac{\partial\gamma}{\partial[S]}\frac{\partial[S]}{\partial x} = \frac{\partial\gamma}{\partial x} \qquad (66)$$

where $\partial y/\partial\,[S]$ is the dependence of surface tension on solvent concentration and $\partial[S]/\partial x$ is the solvent concentration gradient (x is the coordinate along the substrate). Hence, the surface tension gradient $\partial\gamma/\partial x$ drives the flow. For the case where Marangoni flow is driven by thermal surface tension gradients, replace $\partial[S]$ by ∂T in the above. If sur-

[12] Provided that the viscosity during drying is measured at unit shear rate, K in Eq (63) becomes η in Eq (64).

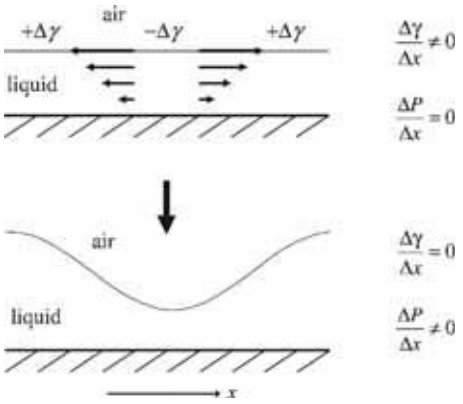

Fig. 32—Deleveling by Marangoni (surface tension gradient-driven) flow. Surface tension gradient ($\Delta\gamma/\Delta x \neq 0$) drives surface flow, resulting in bulk flow and de-leveling of initially level surface.

face tension gradients persist until the film is incapable of reflow, an appearance defect will result. Overdiep [86] demonstrated (for solvent-based paints) that Marangoni flows initially enhance the leveling rate, but can produce a "rebound" effect that ultimately worsens film roughness. Wilson [98] recently modeled this behavior by a linear perturbation analysis. Other authors have discussed the importance of Marangoni flows for waterborne, cosolvent-containing coatings [87,99].

The role of viscoelasticity in leveling has been a subject of some debate, with some authors concluding that elasticity enhances leveling [100] and some that it retards leveling [41,101]. The evident link between elasticity and the underlying structural rheology for coatings (see "Viscoelasticity and Industrial *Processes*") suggests the presence of a gel-like structure of some sort in systems possessing significant elasticity. Such a structure would be expected to inhibit flow at low stress levels so that coatings that exhibit elasticity should also show poorer leveling. The leveling behavior of viscoelastic systems has been modeled by Keunings and Bousfield [41], where the presence of viscoelastic relaxation shown to retard leveling. The leveling rate α as a function of the Newtonian leveling rate α_{Newt} was shown to be

$$\alpha = \frac{\alpha_{Newt}}{1 + \lambda\alpha_{Newt}} \tag{67}$$

where α = rate of change of roughness amplitude (s^{-1}), and λ is the elastic stress-memory time constant (or relaxation time) (see *Viscoelastic Models*). In Eq (67), the Newtonian leveling rate is always positive, hence elastic "extra stress" ($\lambda > 0$) always retards leveling. Interestingly, if surface tension gradients are present, α_{Newt} may actually become negative (i.e., deleveling). In such cases, late-developing elasticity will be of benefit by retarding the de-leveling. Table 4 shows the results of a calculation similar to that of Keunings adapted for the case of a typical paint. It is seen that, for λ =100 s, the leveling rate dramatically decreases and the leveling half-time increases (by a factor of 3,500), relative to the Newtonian ($\lambda = 0$) values.

Measures of Leveling

Visual evaluation of leveling is common practice. However, it is generally agreed that visual rating is subjective, and leveling rankings are often found to be operator-dependent. Numerous objective methods and standards have been published. Quach [93] discussed aspects of both scientific and laboratory practical studies of leveling. For the latter, special drawdown blades have been used such as the NYPC leveling test blade (ASTM D2801: now withdrawn—no longer an ASTM method), which has five pairs of notches over a range of depths. Leveling is judged by the flowing together of adjacent paint stripes. This method has been criticized by Quach and others [29] because the paint passing through the notches experiences a varying shear rate with notch depth, resulting in a different shear history for each stripe, and because the shear rate achieved is unrealistically low. The latter test has been superseded by ASTM D4062, based on a grooved drawdown rod. In this method, the paint is presheared, simulating brushing shear rates, by ejection from a syringe and 15-gauge needle prior to drawdown. The leveling quality is then estimated by visual comparison of the dried film with plastic leveling standards viewed against oblique lighting.

Kornum [102] gives a good discussion of issues of measurement under test conditions approximating real paint processes, including leveling. Dodge [29] also emphasizes that the best rheological test for leveling should most closely simulate the application experience of the paint. This means (1) the paint should experience shear rates/stresses of similar magnitude and duration to those of the application process, (2) the shear rate/stress should then be step-changed to values representative of the leveling process, and (3) the change of viscosity with time should then be followed under the latter conditions. This protocol is essentially identical to the "step-shear" method of characterizing thixotropic recovery described in "Thixotropy Test Methods." This kind of procedure is most easily accomplished by employing a rheometer capable of "job streaming" or "linked methods." However, the foregoing method still suffers from the limitation that the effect of drying on viscosity during the leveling period is neglected. Fig. 31 demonstrates that this can be a very significant effect. Paints "A" and "B" were commercial formulas which differed markedly in leveling performance. The increase of viscosity with time during drying of a film of typical applied thickness was measured for both and found to obey Eq (65). The latter expression was then inserted into Eq (64) as the time-integral function for viscosity (as described in the previous section) and the leveling curves in Fig. 31 were calculated. There are two curves for each paint, one showing how the paint levels without the effect of drying, and one calculated taking the increase of viscosity due to drying into account. The effect of drying is most dramatic on Paint B, where the reduction of surface roughness achieved after 3 min decreases from 50 % to 10 %.

It is established that leveling shear stress decays exponentially as leveling progresses [80]. A controlled-stress rheometer with programmable logarithmic stress ramps offers the ability to simulate the variation of viscosity with realistic shear-stress decay using variable ramp times. Leveling efficiency might then be judged by numerically integrating the fluidity over the "leveling" period

$$\Phi = \int_0^t \frac{1}{\eta} dt \tag{68}$$

The leveling might be expected to be logarithmically related to the fluidity integral Φ [103].

A very promising method for direct observation of paint leveling has been described by Klarskov [88]. It is an optical interferometric method that is simple but quite precise for real-time surface profile measurement, having a vertical resolution of a fraction of a micron. At present, unfortunately, there is no commercial instrument based on Klarskov's method.

RHEOLOGY INSTRUMENTATION

A great number of instruments have been devised to measure viscosity or "consistency" in the industrial laboratory. However, a number of them have serious design limitations that make them generally poorly suited for measurements of non-Newtonian fluids. The importance of this issue becomes apparent when it is realized that the majority of coatings and coatings components are non-Newtonian, yet many laboratories continue to use methods that are not suited for such materials. The problem with many familiar laboratory viscometers is that the flow field (trajectories of fluid elements or "streamlines") is complex and not subject to mathematical analysis. The result is that an accurate stress or strain rate cannot be calculated. Therefore, the true (absolute) viscosity cannot be known. Furthermore, the nonuniformity of the shear field causes the viscosity to vary within the test specimen for non-Newtonian materials. For complex flow fields, such an error cannot be corrected. The measurement error will be in proportion to the degree of deviation from Newtonian character. A second important deficiency of most simple viscometers is a lack of temperature, which can contribute a very significant measurement error. Nevertheless, such instruments have been in use throughout the industry for decades and no doubt will continue to be used for the foreseeable future. The approximate measurement given is somehow related by the practitioner to something believed relevant to the performance. One suspects that when the result is contradictory, as is probably often the case, it is either ignored or "worked around." We shall refer to this type of device as a "Q/C (quality control) instrument" or a "qualitative viscometer." It should be emphasized that these instruments are accurate for Newtonian or near-Newtonian materials and are generally useful as Q/C test devices even when the measurement is approximate. However, the practitioner should be alert to situations where their deficiencies can be of significance.

In years past, many coating fluids were nearly Newtonian, which accounts in part for the success of Q/C-type instruments. As alluded to before, it is very easy to characterize a Newtonian fluid. Virtually any type of flow measurement device may be used to obtain accurate information on the viscosity of such a material provided the device used is calibrated with known standard fluids and the temperature is controlled. It is not even necessary to know the shear rate of the measurement since Newtonian fluid viscosity is independent of the shear rate. Consequently, Newtonian viscosity measured by any test is valid for all process conditions (except turbulent flow). Even instruments which measure viscosity according to some arbitrary scale may be used since they may be calibrated in absolute units using Newtonian standard fluids.

A requirement for an instrument to measure non-Newtonian fluids properly is that the flow field within the test fluid be viscometric, defined as "everywhere indistinguishable from steady simple shear" [104]. Instruments which measure under such well-controlled conditions we will call "research instruments." Nonviscometric flows such as tube flow can be used for non-Newtonian fluids when necessary corrections are applied.

Q/C INSTRUMENTS

These are of three types of Q/C instruments, which are as follows: (1) efflux devices, (2) rotational devices, and (3) obstructed-flow devices (following Barnes et al. [105]).

Efflux Devices (Orifice Flow)

Efflux devices, or orifice cups, come in a variety of types, but share one principle: measuring viscosity by flow from a reservoir or cup through a restriction of some type. In most cases, the restriction is simply a hole in the bottom of the reservoir, but in some it is a short tube. These devices have the advantages of low cost, ease of cleaning, durability, and simplicity in the measurement, which is simply the time to empty (in whatever manner "empty" is defined). However, they also have a number of limitations. The first is that the flow is never viscometric. Even when the fluid exits via a short capillary tube, the length-to-diameter ratio is too small for proper tube flow to develop, so that the flow is dominated by entrance effects. In fact, the orifice cups have been described as "poor capillary viscometers." Since substantial shear stress is not developed in the exit hole, orifice cups are not suitable for very thin liquids because a significant fraction of energy is dissipated not in viscous flow, but rather to accelerate the fluid. In other words, measurements on low viscosity fluids are subject to significant fluid inertia errors. Thus, for the Ford No. 4 Cup (ASTM Method D1200), liquids with an efflux time of less than 20 s should not be used. The flow in efflux cups is stress-driven, controlled by the hydrostatic head, i.e., the fluid height in the cup. The pressure varies as the liquid drains; consequently, the shear stress and flow rate vary during the test. The viscosity of shear-thinning liquids, therefore, will increase in the course of the test, and in extreme cases such materials may not fully drain from the cup. Because the flow field is complex, the shear rate cannot be calculated, and from the previous argument will depend on the viscosity-shear stress relationship for non-Newtonian materials. For the above reasons, it must be concluded that orifice cups are really only suitable for viscosity measurements of Newtonian liquids of moderate viscosity. Non-Newtonian liquids should not be tested unless they are nearly Newtonian within the shear rate range of the test. Materials with possible yield stress (meaning any thixotropic materials) should not be tested with efflux devices. A final caution for these devices is that, unless the temperature of the cup is controlled by means of a water jacket, large errors are likely to result. Even if the test liquid is thermostatted in a water bath prior to test, it can rapidly change in temperature and viscosity when placed in a cup that is at the temperature of the room. Fig. 33 shows data for replicate measurements on a Ford #4 cup with and without temperature control. Obviously, the errors in the data taken with the standard cup would hide the real batch-to-batch differences of the

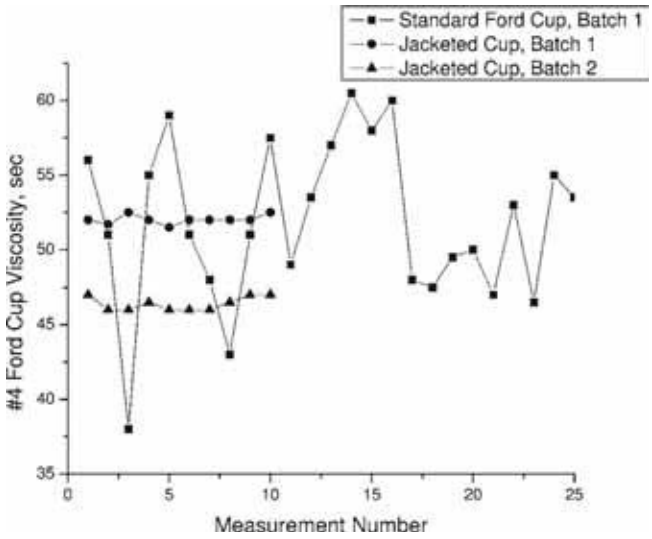

Fig. 33—Ford cup viscosity data taken with and without temperature control of the cup. Test temperature was 130°F (54°C).

product. A good Q/C test should reveal, not obscure, product variability.

Rotational Devices

STORMER® VISCOMETER

The widely-used Stormer Viscometer[13] was one of the earliest controlled-stress rotational viscometers [106]. Rotors of various geometries are available, but the "paddle" rotors, in which two small vanes are attached in offset fashion to a rotating shaft, are used exclusively for the measurement of the consistency of paints. During a measurement (in the original device), the rotation is driven by a free-falling weight attached to a string and pulley arrangement, the string being wound around a drum. The shear stress is varied by use of different weights. A counter tallies up the number of revolutions as the weight falls. After the first ten revolutions, the time required for the next 100 is measured. (Stroboscopic timers are available.) The apparent viscosity is calculated from a plot of applied torque versus rotor rpm. The measurement can also be made in terms of the weight, W, required to achieve a rotational speed of 200 rpm. The viscosity is obtained according to an arbitrary scale called "Krebs units" (KU). A conversion table of *W* versus KU is supplied. Electronic versions of the device are available (see below), which operate at constant speed rather than at constant stress. This difference may produce slightly different results as compared to the nonelectronic versions of the instrument, unless care is taken to reproduce the same conditions of measurement. As with any viscometer whose flow field is complex, an absolute viscosity (i.e., in engineering units of Poise or Pascal seconds) cannot be calculated with the Stormer for non-Newtonian fluids. The Stormer viscometer is specified in a number of standard test methods.[14]

[13] The name "Stormer" is a trademark of the Thomas Scientific Company.

[14] Test methods include ASTM D115, D562, D816, D856, D1084, D1131, D1337, and D1338 and Federal Test Methods 3011.1, 3012, 3018, 3019, 3022, and 4281.

For its purpose, i.e., to measure the in-can "feel" of paint, the Stormer is a very good viscometer—that is, the Stormer measures by stirring the paint, as the consumer would. Thus, the instrument satisfies the criterion of measuring under conditions closely approximating those of a relevant process. This justifies the use of an arbitrary measurement scale, in this case, and makes the Stormer a useful component of the paint laboratory. The only *caveat* would be not to violate the above-mentioned principle by attempting to use Stormer data to predict paint performance for a process that is far removed from the flow kinematics of the instrument.

THOMAS-STORMER® VISCOMETER MODEL ETS-1000

This instrument is an electronic implementation of the Stormer paddle viscometer by the Thomas Scientific Company.[15] Weights are done away with, as the instrument is motor-driven. A selector switch allows a digital readout to display the measured viscosity in centipoise, KU, or in grams (for comparison to the standard Stormer instrument).

BROOKFIELD DIGITAL VISCOMETER MODEL KU-1

The Brookfield Model KU-1 is likewise an electronic paddle viscometer, similar to the Stormer, by Brookfield Engineering Laboratories. A digital panel readout displays either the weight in grams corresponding to the applied motor torque or the viscosity in KU.

ICI ROTOTHINNER

The Rotothinner, originally developed by ICI Paints, is driven by a constant-speed motor and utilizes a large, disk-shaped rotor that is immersed in the sample under test. A standard steel sample container is used, which is held magnetically to a turntable. The torque transmitted through the sample rotates the turntable until a steady position is reached. (The rotary motion is resisted by a spring.) The turntable is graduated in poise units, and a pointer attached to the instrument base indicates the viscosity. The viscosity range of a given model is somewhat narrow, and measurement over a wide viscosity range necessitates purchase of separate instruments. The instrument is calibrated for use only with standard containers. There is no provision for temperature control of the specimen. For "rheologically structured" materials, the manufacturer recommends to allow up to 4 min under shear for the reading to become steady, thus providing for a more or less constant shear history. However, temperature may vary during this period due to the input of energy resulting from the 575 rpm rotor speed.

Although the instrument has a scale graduated in poise units, the shear rate of test is unknown since the flow field is not viscometric. Flow near a rotating disk can be quite complex, especially for non-Newtonian and viscoelastic materials. As a further complication the Rotothinner disk has diagonal holes bored through it, presumably to increase shear. Consequently, the apparent Rotothinner viscosity must be considered only approximate and the scale graduations arbitrary for such materials. The Rotothinner is manufactured by Sheen Instruments, Ltd. and is widely used in Europe.

[15] The Thomas-Stormer ETS-1000 is available from the Cannon Instrument Company.

Obstructed-Flow Devices

These are gravity-driven instruments in which flow is due to density differences between the test fluid and a falling object (falling ball viscometer, falling needle viscometer) or a rising bubble (bubble tube viscometer). In each case, the fluid has to flow around the moving object; hence, they are classed as obstructed-flow devices. In the falling ball and rising bubble instruments, the flow field is complex with the consequence that these devices are generally not useful for non-Newtonian fluids. The falling needle viscometer, however, possesses a well-defined flow field [105], is therefore suitable for non-Newtonian materials, and will be discussed in the section on "Research Rheometers."

FALLING BALL VISCOMETER

A ball falling in a viscous fluid will reach a constant velocity U_∞ which is dependent on the density difference of the sphere and the liquid, the diameter of the ball d and the fluid viscosity η. The viscosity of an unknown fluid may be calculated from the Stokes equation

$$\eta = \frac{(\rho_s - \rho_l) g d^2}{18 U_\infty} \tag{69}$$

where g is gravitational acceleration. This deceptively simple method has several drawbacks, however. For one, the Stokes solution is only valid for low Reynolds numbers (viscous forces controlling, rather than fluid inertia, i.e., slow flow), and for low-viscosity fluids the ball density must be small enough to produce appropriately slow rates of fall. For another, a wall correction may be needed to account for the interference of the container wall with the flow field of the ball and hence its falling rate. Perhaps the greatest difficulty, however, is the fact that the flow field around a moving sphere is complex, and when the fluid is non-Newtonian the complexity becomes mathematically intractable. Therefore, for non-Newtonian fluids, the falling-ball apparatus will not yield absolute viscosity, and the results would not be expected to correspond with those from an instrument having viscometric flow geometry. A solution to the above problems is provided by a relatively new instrument called the falling needle viscometer (see below).

Rising-Bubble Viscometers

If certain flow field assumptions are made for a rising air bubble in a liquid, the viscosity of the liquid can be calculated from [49]

$$\eta = \frac{1}{3} \frac{\rho g R^2}{\nu} \tag{70}$$

where ρ is the liquid density, R is the radius of the air bubble, and v is the rising velocity. However, the calculation is only approximate because the air bubble shape often deviates from the assumed sphericity due to buoyancy. Furthermore, if the liquid phase were non-Newtonian, significant errors would result for which there is no correction available.

The Gardner-Holdt bubble tubes provide a rapid means of estimating the kinematic viscosity (see "Capillary Viscometers") of transparent liquids such as varnishes and resins using the rising bubble principle. These consist of a series of sealed glass tubes containing mineral oils comprising a range of standard viscosities. The test liquid is placed into a similar tube (ensuring the contained air bubble is the same volume) and thermostatted in a water bath. The test material and a rack containing the standard tubes are inverted, and the viscosity of the test specimen is identified according to the letter (or sometimes number) designation of the standard tube whose rate of bubble rise is nearest the same. Interpolation between the standards is sometimes done. Bubble tubes are disposable, easy to use, and the results can be converted to kinematic viscosity by means of tables. Bubble tubes can also be used to measure resin color. For process resins nearing the gelation point, the bubble can display a pointed "tail," or pronounced "inverted teardrop" shape, an indication of the onset of viscoelasticity. As a reference for the use of the Gardner-Holdt method, see ASTM D1545.[16]

RESEARCH RHEOMETERS/VISCOMETERS

Research-quality rheometers are mainly of two types: rotational rheometers and efflux rheometers. Rotational rheometers employ steady (uniform) shear, oscillatory shear, and transient (time-dependent) shear experiments of various types. Efflux rheometers extrude the fluid through a small-gap orifice, which can be a capillary tube, a slit, or an annulus (concentric cylindrical-walled tube). The flow in these devices is well-defined and data can be obtained in absolute or engineering units for non-Newtonian fluids. Summaries of instrumentation and methods are found in Refs. [107–109]. Although dated, Van Wazer's book is still a useful source [49]. Appendix A lists vendors of research rheometers and viscometers.

Rotational Instruments

CONTROLLED STRESS AND CONTROLLED RATE

There are two basic types of rotational viscometers, which work in the following ways: (1) apply a controlled rotation rate and measure the opposing viscous torque or (2) apply a controlled torque and measure the resulting rate of rotation. In the first case, which may be termed "controlled-strain" or "controlled strain rate," the applied angular velocity is the independent variable and the viscous drag torque the dependent or measured variable. In the second case, termed "controlled-stress," the applied torque is the independent variable and the measured angular velocity the dependent variable. Examples of controlled strain rate instruments include the Wells-Brookfield Cone and Plate Viscometer, the Haake RotoVisco 1, and the TA Instruments ARES. Instruments of the controlled-stress type include the TA Instruments ARG2, the Reologica Stresstech HR, the Thermo Haake Rheostress 600, and the Physica MCR-series rheom-eters. See "Appendix" for a list of instrumentation vendors.

The choice between the two types of instruments depends on the material under test and the intended experiments. In terms of performance, controlled-stress (CS) instruments can measure much lower angular velocities than can controlled-strain-rate (CR) instruments, but CS instruments tend to be more limited at the high angular velocity and oscillation frequency end. Both CS and CR

[16] Additional standard test methods using bubble tubes are ASTM D803, D1131, and D1725 and Federal Test Method 4271 (141-a).

instruments have inertia issues affecting the accuracy at high frequencies or for rapid accelerations. In the case of CS, the issue is measurement system inertia and is correctable; for CR the problem is torque measurement system resonance and is not correctable. CS is well suited to measuring long relaxation times because of the stability of the applied torque [110].

CR instruments impose a shear-rate sweep while measuring the drag-torque response of materials. Structured fluids tend to be shear-sensitive (more precisely, strain-sensitive). Consequently, as strain increases exponentially under a linear strain-rate sweep protocol, fluid structure tends to collapse rapidly, with the result that relatively few data points are obtained to provide information on structure. In contrast, CS devices use linear (and logarithmic) rates of stress increase, an intrinsically "gentler" mode of deforming materials, which allows materials to "obey their own rules" of stress-strain response, thus resolving the maximum amount of information. CS instruments are especially useful for characterizing structured fluids, such as paint, printing ink, adhesives, ceramic slips, coal slurries, cement, pigment and colorant dispersions, drilling muds, medicines, foodstuffs, cleaners, personal care products and cosmetics, solder pastes, etc. This is particularly true where materials exhibit yield behavior. CS instruments can, in principle, directly measure the stress at the onset of yield (see "Plastic (Yield) Behavior"), avoiding errors associated with extrapolation or curve-fitting methods (see *Yield Stress Test Methods*).

CS and CR instruments each do their own version of a transient experiment: creep for CS and stress relaxation for CR. The stable torque and high strain resolution capabilities of CS mean creep experiments can be used to probe very slow relaxation processes. A modified creep method—a programmed series of small torque increments—can be used for determining the first Newtonian plateau down to very low shear rates, e.g., region I of the equilibrium flow curve (see "Shear-Thinning Fluids"). A limiting factor in the accuracy of such methods, however, is the ability to minimize or correct for spurious air bearing torque.

INERTIA CORRECTION

It can be particularly important for rotational rheometers of the controlled-stress type to correct the data for inertia error. If the test fluid is low in viscosity, and/or the test rotor has a large moment of inertia, and/or the acceleration is too high (short ramp time), a significant portion of the applied torque is dissipated not viscously, but in the acceleration of the rotor. A correction for this error has been published by Krieger [111]. Some commercial controlled-stress instruments now feature on-line inertia correction.

Brookfield Viscometers

BROOKFIELD SYNCHRO-LECTRIC

The Brookfield Synchro-Lectric viscometer utilizes a set of spindles or disks as the rotor/sensor, which are rotated in the test fluid at selected rpm, so that the apparent viscosity may be measured at several shear rates to obtain a flow curve. Its advantages include low cost, simplicity of use, ease of cleaning, and durability. The instrument is in wide use throughout the industry and is the basis for ASTM D2196 and a number of other ASTM test methods.[17] It is included here in the list of "research quality" viscometers because the viscosity can be reported in absolute units over a range of shear rate, although often it is not (see below). Its limitations include the latter fact, plus that temperature control is not integral to the instrument. The Synchro-Lectric is available with digital output, automatic viscosity calculation, and computer-interfaced versions with analysis and graphing software.

Brookfield spindle viscometer measurements suffer from the use of arbitrary or nonfundamental units in reporting the result. Even though the viscosity is reported in absolute units (cP or mPa·s), the shear rate is not. Thus, both the spindle speed (rpm) and the spindle identity must be reported along with the measured viscosity. The measured viscosity can be different at the same rpm if a different size spindle is used. Without knowing the actual shear rate of measurement, an absolute flow curve cannot be constructed from the results. The true flow curve is desirable for several reasons, among them the possibility of comparison with results from other instruments, the quantitative description of the sample rheology by use of mathematical flow models and the subsequent application of such models to predict paint performance (see "Leveling" and "Sagging" for example). Methods for calculation of the corrected shear rate for Brookfield RVT spindles were given by Williams [112] and also Pierce [113]. Smith [85] has given a simplified method. (See also Ref. [22], pp. 28–31.) Some of the foregoing issues are at least partially resolved with certain accessories available from Brookfield. These include options that have small-gap bob-in-cup geometry and temperature control, e.g., the small-sample adapter.

WELLS-BROOKFIELD CONE AND PLATE VISCOMETER

Brookfield also offers an instrument possessing a well-defined geometry and good temperature control—the Wells-Brookfield cone and plate viscometer. Its operation and appearance are very similar to the Synchro-Lectric, except the lower end has been modified to mount a cone and plate geometry with integral temperature control via a water jacket. Because the true shear rate can be calculated from the cone geometry and rpm, the viscosity of non-Newtonian materials can be measured in absolute units and an equilibrium flow curve determined. This instrument, therefore, is recommended over the standard Synchro-Lectric for routine viscosity measurement.

BROOKFIELD DV SERIES RHEOMETERS

The DV series of viscometers is basically an enhanced spindle-disk system offering programmability, a range of rotation speeds and computer interface and control capability.

BROOKFIELD CAP 2000 VISCOMETER

The Brookfield CAP 2000 multispeed digital cone-plate viscometer is similar to the ICI cone and plate viscometer, but represents an improvement in that it is capable of variable shear rate measurement (10 to 12,000 s^{-1}). It also provides a digital display of viscosity and temperature as well as a

[17] These include ASTM D115, D816, D1076, D1084, D1286, D1337, D1338, D1417, D1439, D1638, D1824, D2364, D2393, D2556, and D2669 and Federal Test Method 4287.

data interface to a personal computer or data logger with applications software.

ICI CONE AND PLATE VISCOMETER

The ICI cone and plate viscometer is a relatively high shear rate instrument capable of absolute viscosity measurement. It is normally sold in a room-temperature, single-speed configuration. Temperature control is integral to the instrument, but there is no provision for control of solvent loss from the sample. This can be improvised, if desired. A high-temperature version is available, which is useful for resin melt viscosity measurement. The chief use of the instrument has been the measurement of viscosity at a shear rate of 10,000 s^{-1} (at 50 Hz alternating current) or 12,000 s^{-1} (at 60 Hz ac) for the prediction of brushability. (See ASTM method D4287, titled "High-shear viscosity using a cone and plate viscometer.")

FALLING-NEEDLE VISCOMETER

This is an "obstructed-flow" device that utilizes a long, slender rod or "needle" as the falling object. In so doing, it overcomes the objections to the falling ball viscometer while retaining the latter's simplicity of operation and relatively low cost [114]. The needle is hollow (allowing a wide range of needle densities) with hemispherically capped ends. End effects due to the finite needle length are mathematically correctable. This geometry produces a well-behaved flow field known as "annular-ducted flow," with the central tube (needle) moving at a constant (terminal) velocity. Because of the well-defined flow field the true velocity gradient between the needle and container wall can be obtained, and the instrument therefore is suitable for measurements of non-Newtonian fluids [115]. The falling-needle viscometer may be useful for determination of very low shear stress or shear rate behavior of non-Newtonian fluids, for example the zero-shear viscosity (region I of Fig. 3) and measurement of yield stresses [116].[18] Fig. 34 compares first- and second-run flow curves of a semigloss paint, obtained on a rotational rheometer, with data points obtained from the Irvine-Park Falling Needle Viscometer (FNV). The agreement is quite good with the "up" curve of the second run, indicating that the FNV experiment imposes enough shear on the sample during the measurement that the results correspond to a pre-sheared system rather than to a previously unsheared system. This was found to be a consistent result for several paints. For highly thixotropic paints, the result was in between the first- and second-run flow curves.

CAPILLARY VISCOMETERS

Capillary tube flow is a classical viscometric method that is useful for coatings in two main ways. Capillary viscometry is the method of choice for measurement of intrinsic viscosity (ASTM Method D446 and D2162) (see also "Dispersion Rheology") and also for the measurement of very high shear rate rheological properties (see below).

For fluid flowing through a tube, the shear stress at the tube wall is

$$\sigma_w = \frac{\Delta PR}{2L} \tag{71}$$

[18] A new ASTM method for falling-needle viscometry is D5478.

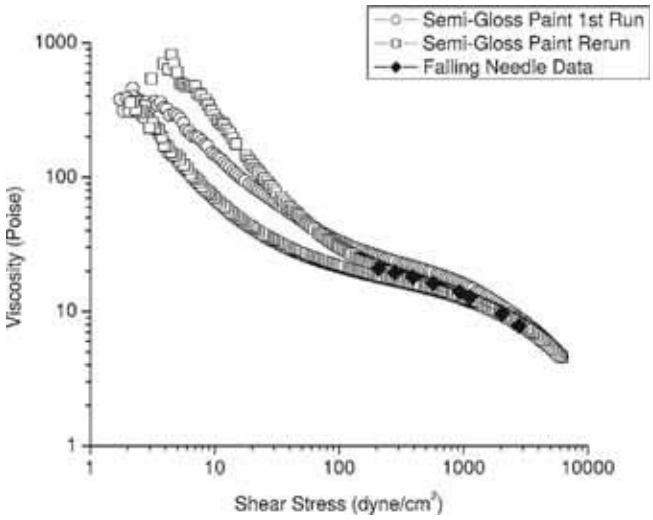

Fig. 34—Comparison of Falling Needle Viscometer® data with that from a rotational controlled-stress rheometer

where ΔP is the decrease in pressure occurring over tube length L of radius R. The shear rate at the tube wall for a Newtonian fluid is given by

$$\dot{\gamma}_w = \frac{4Q}{\pi R^3} \tag{72}$$

where Q is the volumetric flow rate ($cm^3 \cdot s^{-1}$). The viscosity is then

$$\eta = \frac{\sigma_w}{\dot{\gamma}_w} = \frac{\pi R^3 \Delta P}{8LQ} \tag{73}$$

which is the well-known Hagen-Poiseuille equation. For pressure-driven capillary flow, particularly for high-shear measurements, a correction to Eq (73) is required because the fluid undergoes a large acceleration as it enters the capillary. Therefore, the acceleration of the fluid accounts for part of the energy loss represented by the pressure drop ΔP. As a result, the calculated viscosity will be too high and a subtractive term or kinetic energy correction is necessary

$$\eta = \frac{\pi R^4 \Delta P}{8LQ} - \frac{m\rho Q}{8\pi L} \tag{74}$$

where ρ = fluid density and m is a constant equal to unity for Newtonian fluids. For non-Newtonian fluids obeying the power law (see "Shear-Thinning Fluids"), m is calculated from

$$m = \frac{3(3n+1)^2}{(4n+2)(5n+3)} \tag{75}$$

where n is the power law exponent. Various additional corrections for capillary flow are described in van Wazer [49].

The pressure head ΔP can be created two ways: By pressurizing the delivery vessel or by relying on a gravitational hydrostatic head to drive the flow through the capillary. In the latter case, the density of the fluid becomes an important part of the measurement because the rate of flow will depend both on the fluid's viscosity and on the magnitude of ΔP, which now depends on the fluid density ρ and on the height of the fluid above the capillary, h ($\Delta P = \rho g h$).

The fluid density is taken into account by the kinematic viscosity, defined as

$$\nu = \frac{\eta}{\rho} \tag{76}$$

That is, the kinematic viscosity is equal to the shear viscosity divided by the density. The viscosity obtained from gravity-driven capillary flow is in units of stokes (stoke = $P \cdot g \cdot cm^{-3}$). The absolute shear viscosity can then be calculated from $\eta = \nu\rho$.

The velocity profile in tube flow is parabolic in shape for Newtonian liquids [as can be proven by integration of Eq (72)], with the maximum shear rate at the walls and zero shear rate in the tube center. For non-Newtonian fluids the velocity profile is nonparabolic and of complex shape. Because the shear rate in tube flow is nonuniform, the viscosity of non-Newtonian materials will vary across the diameter of the tube. Non-Newtonian fluid measurements may be made accurately only if the Weissenberg-Rabinowitsch correction is applied [117], which corrects for the variations in viscosity across the capillary arising from the nonuniform shear field

$$\eta = \eta_a \left[1 - \frac{1}{4} \frac{d(\log \eta_a)}{d(\log \sigma_w)} \right]^{-1} \tag{77}$$

where η_a is the uncorrected apparent viscosity.[19] The second term inside the brackets is obtained by calculating the slope of a log-log plot of the measured viscosity versus wall shear stress.

Tube flow is inappropriate for materials with yield behavior. Reviews by Schoff [108,109] describe the application of capillary viscometry to coatings.

HIGH-SHEAR CAPILLARY RHEOMETRY

It has been claimed by some that the measurement of very high shear rate viscosity is not necessary because it may be estimated from moderate-shear data. This is true to an extent, especially if one can obtain an adequate description of the general flow curve by use of one of the flow models containing the high-shear limiting Newtonian viscosity η_∞ (e.g., the Sisko, Cross, or Carreau models). If a good enough fit to experimental data is obtained, the latter models can be extrapolated to predict viscosity beyond the experimental range of shear rate, with caution. The simple power-law models should not be used for estimation of high-shear viscosity since they predict unrealistic high-shear behavior (see "Shear-Dependent Viscosity"). However, under the best of circumstances, data should be extrapolated no further than about a decade of shear rate. This means that, in general, shear rates of only about 10^5 s^{-1} can be reached, even by extrapolation methods. It should be pointed out here that the onset of shear thickening (region IV, Fig. 3) cannot be predicted by extrapolation, yet it can cause disastrous consequences in high-shear application processes. In any case, for precise comparisons of materials, extrapolation will be unsatisfactory. There are several industrial processes which involve shear rates of 10^5 to 10^6 s^{-1}. These include airless spray and reverse rollcoating, for example. It will be difficult to resolve performance problems of coatings exposed to such high shear without direct experimental measurement under the appropriate deformation conditions. Such severe conditions of shear can cause a fundamental change in a material, such as gross coagulation of an emulsion, with a possible deleterious effect on rheology and hence on postapplication film formation behavior. It is recommended, therefore, to characterize by high-shear rheometry materials that must be exposed to high-shear processing.

There are some commercial high-shear viscometers which use small-gap bob-in-cup geometry. Problems with this geometry include poor temperature control due to viscous heating and a tendency toward flow-field instabilities. Capillary viscometry has some advantages in both regards. The very short residence time in the capillary at high flow rates minimizes temperature rise, and, for length-to-diameter (L/D) ratios of 50 or greater, entrance effects are negligible and the flow field will be essentially uniform.

By use of short, small-diameter capillaries and high pressures, shear rates of approximately 10^6 s^{-1} are achievable for fluids in the range of viscosities typical of paints [118]. At this writing, however, we are unaware of any commercial capillary rheometers suitable for high-shear rate measurement of coatings fluids other than the Paar-Physica HVA-6.

Rank Pulse Shearometer

This instrument is a relatively inexpensive and simple viscoelastometer. A fixed-frequency acoustic wave pulse is passed through a test sample and the signal detected by a receiving transducer. The propagation velocity v is measured from the signal transit time and used to calculate the shear elastic modulus according to

$$G' = \rho v^2 \tag{78}$$

The signal wave is of high frequency but very small amplitude (10^{-4} rad), so that weak gels are not disturbed (the induced strain will likely be within the linear viscoelastic regime). Because of the high frequency used, the measured shear modulus corresponds to the plateau modulus G_∞ (see "Viscoelastic Models"). This gives a useful measure of the gel strength of even weak gels and has an advantage in this regard over instruments which subject the sample to uncontrolled shear upon closure.

RHEOMETRY

Rheometry is the experimental aspect of rheology. A rheometer is an instrument that measures some rheological property, or material function, such as the viscosity as a function of shear rate or shear stress. Normally, a curve will be produced representing the functional dependence of the measured property. A viscometer, in contrast, will generally measure viscosity at a single (sometimes even unknown) value of the shear rate (or shear stress), or perhaps over a limited range of values. These types of devices are typically found in the industrial quality control or formulation laboratory, and have been discussed in earlier sections. This

[19] The "apparent viscosity" is simply the quotient of the apparent (or experimentally measured) shear stress and the apparent shear rate. The true values of the foregoing, however, may be different from the apparent, as for example for flow fields where the shear rate varies across the field and must be corrected for non-Newtonian effects, or where inertia errors are involved.

section will focus on techniques for the use of rotational rheometers to characterize fluids with complex rheological properties.

Rotational Rheometry

Simple shear deformation was defined previously for a fluid confined between a stationary surface and a moving surface that are in parallel, rectilinear motion (i.e., a "sliding plate" rheometer). There are, however, very few rheometric instruments that utilize this test geometry. This is due to the fact that it is not a practical geometry, because either the experiment must be rather short in duration or one of the shear faces must be very long. This predicament is solved by using rotational motion to shear a material between, say, a fixed plate and a rotating disk. The majority of commercial rheometers operate in this way, using a variety of rotating fixtures or geometries, mainly:[20]

1. cone and plate
2. parallel plate
3. concentric cylinder (bob and cup).

Detailed descriptions of these standard geometries can be found in the referenced monographs [22,45,107,119].

There are three principal rheometric techniques typically used for *rotational rheometers,* discussed below.

1. Steady shear (large strain)
   a. Equilibrium viscosity measurement
   b. Non-equilibrium viscosity measurement
   c. Normal stress measurement.
2. Creep (medium strain)
3. Oscillation (small strain).

Steady Simple Shear (Equilibrium Flow)

Steady simple shear involves a uniform flow field in which the shear rates and stresses are independent of position. Not all rheometer test geometries meet this criterion exactly, but they do generally satisfy the requirements of *viscometric flow,* defined by Dealy [120] as a flow field that is "everywhere indistinguishable from steady simple shear." Viscometric flow is a necessary requirement in order to properly measure the viscoelastic material functions.

Some rotational rheometers utilize steady-shear equilibrium viscosity measurements to characterize flow behavior by means of a series of shear rate steps. If, for example, a constant torque is applied to a specimen until a constant shear rate is observed (after inertial and structural relaxation effects have equilibrated with time), the system is undergoing *steady simple shear* and the *steady-state viscosity* or *equilibrium viscosity* can be measured. (Even with thixotropic materials, one should generally be able to observe a steady-state viscosity value eventually.) An equilibrium flow curve (as in Fig. 3) can be generated in this way.

Time-Dependent Materials: Nonequilibrium Flow Curve

As mentioned, one can construct a curve of equilibrium viscosity versus shear rate or shear stress by a series of step-equilibrium experiments. However, the *nonequilibrium flow curve* is less time-consuming experimentally and perhaps more informative with regard to the processability of time-dependent materials. The nonequilibrium flow curve is obtained by recording the viscosity while either the angular velocity or the torque is "ramped"—i.e., increased with time (usually followed by a decreasing torque or velocity ramp) [Fig. 9A]. Time-dependent effects such as *hysteresis* can be seen in this way [Figs. 9B and 24]. The collapse of structure can be seen, but which is lost in an equilibrium measurement. Fig. 24 (solid circles) shows a flow curve for a structured fluid, measured by a stress-ramp procedure, with the upper curve corresponding to the increasing-stress ramp and the lower curve the decreasing-stress ramp.

SHEAR HISTORY EFFECTS: SAMPLE MOUNTING AND CONDITIONING

A great many industrial and commercial fluids possess time-dependent rheology, usually thixotropy, but occasionally anti-thixotropy (see "Time-Dependent Fluids"). Time-dependent materials pose a special set of challenges to the experimentalist, and it is easy to make mistakes in characterizing them. For time-independent systems, the pre-experiment shear history is of no consequence. In contrast, the shear history of time-dependent materials prior to the experiment can greatly influence the results.

Both the degree of deformation in mounting a sample and the time lapse since mounting will determine the rheological state of a time-dependent material, and hence the experimental result. Failure to take account of this issue often leads to poor repeatability of data on such systems. Some approaches to the control of the shear history problem are:

1. Controlling the rate of closure of the platens in a parallel plate or cone-plate experiment (e.g., exponentially decreasing closure rate)
2. Allowing a rest time for the sample after mounting (limited by evaporation and productivity issues)
3. Giving a controlled shear history to the sample, e.g., preshearing the specimen for a set period, then initiating the experiment immediately on cessation of shear. (An up-down ramp cannot be applied in this case, since the sample would begin to recover in an uncontrolled way concurrent with the initial low-shear ramp onset. Instead, a series of step reductions from high shear can be applied, with the time delay between steps being varied, in order to simulate the effects of varying degrees of structural recovery [121].

Method (1) reduces the strain rate (but not the strain) that the sample experiences as the instrument gap closes, but will be limited in its effectiveness because practical rates of closure (and the coupled deformation) are likely to be significant in terms of their effect on the specimen's structural integrity. Furthermore, depending on the geometry (e.g., cone and plate) the strain may not be uniform. Method (2) is limited by the time one can afford to wait for structure recovery. It is not uncommon for a material to require hours in order to regain its "rest-state" condition. The use of an arbitrary rest time is a compromise that provides a practical (if not ideal) method of characterizing thixotropic materials. Method (3) is somewhat arbitrary, too, in that it is not known *a priori* at what shear stress or shear rate or for how long a material must be preconditioned in order to achieve adequate or consistent structural breakdown. Whatever the method chosen, it is important to

[20] Another principal test geometry used in steady shear flow is tube flow or capillary rheometry. Its use is somewhat limited outside of the characterization of polymer melts, and will not be further discussed here.

adhere strictly to a constant protocol if results are wanted on a comparable basis.

RAMP METHODS

Many rotational rheometers are able to apply a time-based ramp of torque or angular velocity for purposes of flow curve measurement. Some allow a choice of a linear time-based ramp or one that is logarithmic with time. The latter method spaces the data points very close together in the beginning of the ramp, which increases the amount of information obtained at low shear rates and stresses. For time-dependent systems, it is important to keep both the pre-experiment shear history and the experimental protocol constant, in order to assure valid comparison of materials. This means keeping the following experimental settings the same for a given series of experiments:

1. Sample preconditioning
2. Choice of linear or log time-based ramp
3. Ramp duration
4. Initial and maximum shear stress (or shear rate)
5. Duration of any "hold-time" at ramp maximum.

TRANSIENT METHODS

Transient methods are non-steady state, i.e., the stresses, strains and material properties are not at equilibrium, and it is their behavior as a function of time that is being studied, as they move toward equilibrium. Transient methods include:

1. Step shear stress (creep and recovery)
2. Step shear strain (stress relaxation)
3. Step shear rate (thixotropic recovery)
4. Startup of flow. The first two methods have been briefly discussed in the section on "Elastic Liquids." The third method was described in the "Time-Dependent Fluids" section. The last method will not be discussed here. For more detail on creep methods see Ref. [122].

Oscillatory Shear

If, instead of applying a stress (or, interchangeably, strain)[21] in a constant direction, the direction of the strain undergoes cyclic reversal, then the specimen is subjected to oscillatory deformation, sometimes also referred to as a dynamic test. Most commercial rheometers are capable of oscillatory shear using a variety of test geometries. Oscillatory testing is normally done in the linear viscoelastic regime (LVER), where the stress and strain are related by a linear differential equation. The usual practice is to employ sinusoidal variation of strain or stress. Testing modes in oscillation include:

1. Torque sweep or strain sweep at constant frequency
2. Frequency sweep at constant strain
3. Time or temperature sweep at constant frequency and strain.

Oscillation is a convenient way of characterizing medium to short time-scale response of viscoelastic materials. The employment of small strains (below the critical strain limit of the LVER) at low frequencies is a reasonable simulation of the physical state of a newly applied coating layer in the process of film formation. Hence, the low-frequency linear viscoelastic properties of coatings are of interest in understanding this phase of coating performance, especially if measured subsequent to a high-shear, high-strain experience.

[21] Note that it is immaterial whether the independent variable is the stress or the strain, for oscillatory linear viscoelastic measurements. Wherever the discussion mentions "stress," one may equally well read "strain."

TORQUE SWEEP/STRAIN SWEEP

Torque sweep on a controlled-stress rheometer or strain sweep on a controlled-strain-rate rheometer are used to determine the strain-sensitivity of the viscoelastic parameters, and thus determine the *critical strain* γ_{cr}, which is the strain limit of linear viscoelastic response. Above the critical strain, the fluid microstructure responsible for elastic response begins to break down. The elastic modulus G' is a sensitive indicator (more so than the dynamic viscosity) of the breakdown of structure, and is often used to determine the critical strain. The experiment is done by applying a constant frequency (e.g., 1 Hz) while increasing the torque gradually, so that the strain amplitude steadily increases. G' will be constant within the linear viscoelastic regime. The critical strain is sometimes arbitrarily chosen as the point where G' has fallen by 10 % (Fig. 35). The strain is then held constant at the critical value for subsequent frequency sweep experiments, ensuring that the deformation remains within the linear regime. It should be noted, however, that the critical strain is not a single value for a given material but will decrease as the oscillation frequency decreases, a consequence of the superposition of viscous and elastic deformation responses in a viscoelastic material.

Polymeric systems can have quite large critical strains (>10 %), while γ_{cr} for colloidal systems can be quite small (<10 %). The critical strain value is a measure of the "brittleness" or "ductility" of the microstructure, and an indicator of the relative length scale of the forces responsible for the elastic behavior. Difficulty is often encountered in finding the linear regime for thixotropic materials composed of flocculated or associated particles, because the structure is rather "brittle," attractive forces are short-range, and the critical strain is consequently small.

FREQUENCY SWEEP

In a frequency sweep experiment, the oscillation frequency is steadily increased, while the strain is held constant below the critical value. Typically, the frequency is swept logarithmically with time, so that the discrete frequency points are linear on a log axis. A typical plot of viscoelastic

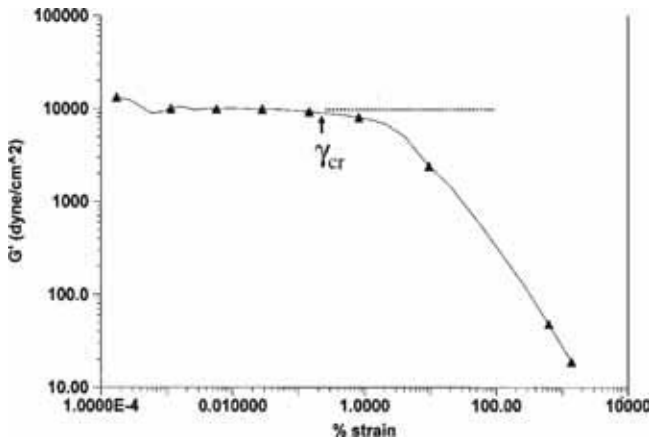

Fig. 35—Illustration of torque-sweep (strain-sweep) data and the location of the critical strain γ_{cr} for oscillatory shear testing.

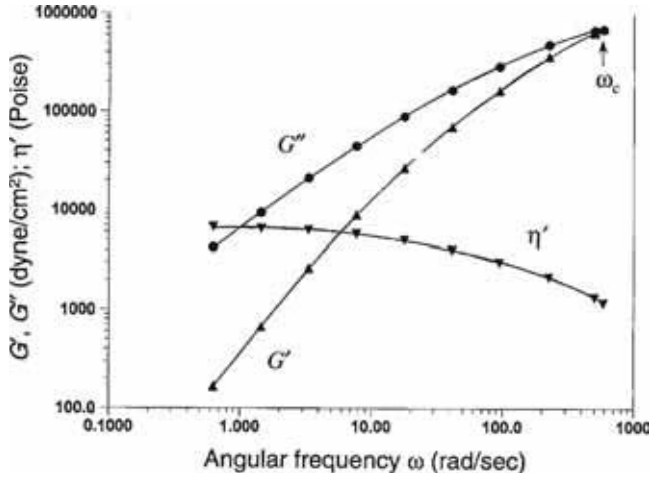

Fig. 36—Typical dependence of the viscoelastic parameters on frequency in a frequency-sweep experiment. Crossover frequency ω_c is indicated.

functions for a frequency sweep experiment is shown in Fig. 36. G' and G'' normally increase with frequency while η' decreases with frequency, trends which can be understood by examination of the mechanical models' response. As pointed out in "Elastic Liquids," values for the viscoelastic functions can be obtained from frequency-sweep data, e.g., the frequency ω_c where G' and G'' cross equals the inverse of the relaxation time (Maxwell model). A gel is distinguished by having a nearly constant value of G' with frequency.

TIME OR TEMPERATURE SWEEP

A time sweep at constant frequency is used to characterize recovery of structure after shear, e.g., for a thixotropic material (see "Time-Dependent Fluids"). Emulsion stability can be indicated by temperature sweep experiments at constant frequency [123]. An oscillatory temperature sweep is an excellent way to characterize the chemical advancement of thermosetting polymers, a technique used in a subdiscipline known as chemorheology (study of the rheology of chemically reacting systems) [60,124].

EXPERIMENTAL PROTOCOL

Similar to the discussion of shear-history effects above, the rheological state of a specimen is of concern, with an eye to obtaining repeatable results. Consequently, the following series of experimental steps is recommended:

1. Specimen should be prior-sheared in steady shear at an arbitrary high shear rate or stress value, to put the specimen in a low-structure state;
2. A constant-frequency small-strain oscillatory time-sweep step should be immediately begun, following the structural recovery to a constant-property state, if possible;
3. Once the specimen has recovered to equilibrium properties, either of two experiments can be done:
   a. Oscillatory frequency-sweep experiment, or
   b. Steady-shear flow curve ramp experiment.

The above protocol is a logical sequence that permits tests to be done on a specimen that is in a repeatable rheological state.

Surface Energetics

Gordon P. Bierwagen,[1] Andrew Huovinen,[1] and Bobbi Jo Merten[1]

Nomenclature

a	=	**Integration limit, distance from surface into bulk of material, Eqs (3) and (6)**
a	=	Subscript for advancing contact angle
A	=	Surface area
A	=	Subscript indicating adhesion, Eqs (12), (13), (31), and (32)
b	=	Variable in Eq (25), the difference in maximum and minimum diameters in elliptical orifice
c	=	Constant in Eq (33)
c	=	Surfactant concentration
c_i	=	Concentration of species i
c_{i0}	=	Concentration of species i in the bulk
C	=	Subscript indicating cohesion, Eqs (11) and (13)
D	=	Diffusion coefficient
E	=	Surface elasticity
f	=	Correction factor, Eq (22)
f	=	Fractional surface area, Eq (15)
F	=	Pull-off force, Eq (31)
g	=	Acceleration of gravity
G	=	Gibbs free energy
h	=	Variable defined in Eq (9)
h	=	Height in capillary rise measurements
h	=	Width of falling film in curtain coating, Eqs (36)–(38)
i	=	Index identifying species i
j	=	flux of adsorbing and desorbing species
k	=	Wave number = $2\pi/\lambda$ (λ = wavelength, see below), Eq (27)
l	=	Subscript indicating liquid phase
l	=	Length of capillary pore path in Eq (23)
$\mathbf{n}$	=	Normal vector to surface, Eq (3)
n	=	Exponent in Eq (4)
n	=	Most probable number of drops from breakup of charged drop, Eq (31)
n_i	=	Number of moles of component i, Eq (2)
p	=	Pressure
$\mathbf{p}$	=	Pressure tensor in the bulk phase, Eq (3)
$\mathbf{p}^T$	=	Tangential pressure tensor, Eq (3)
$\mathcal{P}$	=	Perimeter length
$\mathcal{Q}$	=	Liquid flux, volume/second
q	=	Charge on drop
r	=	Variable in Eq (25), sum of maximum and minimum radii in elliptical orifice
r	=	Radius
r	=	Roughness ratio, Eq (14)
r	=	Subscript for receding contact angle
r	=	Average pore size in rate of penetration into powder measurements, Eq (34)
R	=	Ring radius in Du Nouy ring surface tension measurement
R	=	Diameter of probing tip in direct force AFM measurements, Eqs (31) and (32)
R_1, R_2	=	Principal radii of curvature
s	=	Subscript indicating solid phase
S	=	Entropy
S	=	Subscript indicating spreading, Eq (13)
T	=	Temperature
T_c	=	Critical temperature
u	=	Velocity, Eqs (26) and (26*a*)
x	=	Distance from surface in Eq (6)
v	=	Index indicating vapor phase
v	=	Velocity, Eq (25)
V	=	Volume
W	=	Weight
W	=	Work, Eqs (11)–(13)
Y	=	Subscript for Young's contact angle
γ^0	=	Liquid surface tension at $T = 0$
γ	=	Liquid surface tension

[1] *Department of Coatings and Polymeric Materials, North Dakota State University, Fargo, ND 58105.*

Copyright © 2012 by ASTM International

Γ, Γ_i	=	Surface excess concentration, of *i*th species
δ_f	=	Final film thickness in dip coating
Δ	=	Difference
ε	=	Dielectric constant
η	=	Viscosity
θ	=	Contact angle
λ	=	Wavelength
μ_i	=	Chemical potential of species *i*
π	=	3.141 59
ρ	=	Density
ω	=	Frequency
0	=	Subscript indicating zeroth or bulk phase, or reference value

INTRODUCTION

SURFACES ACT AND PERFORM DIFFERENTLY FROM the bulk material because they have two distinct properties that do not exist in the bulk. First, the unbalanced forces on molecules or atoms at the surface cause it to have excess free energy when compared to the bulk [1] (i.e., they are in a higher state of potential energy). This excess energy per unit area is the thermodynamic cost of forming a new surface; it has the units of energy/area or force/length. The latter units are those of tension, and the surface excess free energy is often known as surface tension and can be measured for liquids as such. (A more detailed discussion of this excess free energy identified with a surface, including the thermodynamic definition of surface tension, is given below.) Second, there is a preferred direction normal to the surface that can be defined in the mechanical definition [2] of surface tension. This directional effect of surfaces can be observed in molecular directionality in adsorption phenomena, surface area minimization by surface tension effects, and molecular ordering in Langmuir-Blodgett films deposited from ordered mono-molecular layers (monolayers).

Since the first version of this chapter was published in 1995, there has been a significant increase in the attention given to surface and interfacial effects, including those in organic coating systems [3]. Much of this interest has been due to the increasing importance of science at the nanoscale. When one approaches nanometer dimensions, surface effects begin to predominate, and careful consideration must be given to surface energetics [4]. For this reason, we have revised and updated this chapter into its present form. Much of what was stated in the first version remains true, but more recent research has yielded additional knowledge regarding the science of surfaces. Scanning tunneling microscopy, atomic force microscopy [5], and a broad range of new characterization tools that greatly enhance our capabilities to characterize and visualize surfaces at nm dimensions have become everyday tools for scientists and engineers working in many fields.

Surfaces occur only when the energetic cost of creating an interface between two dissimilar materials or phases is satisfied. Thus, there are no stable interfaces between gases, nor among phases in a material above its critical point. However, surfaces can occur between gas and liquid (g/l), liquid and liquid (l/l), gas and solid (g/s), liquid and solid (l/s), and solid and solid (s/s) phases. An example of a g/l interface is the surface of an open, unfrozen body of water. Because a liquid surface cannot support a stress, its surface energy phenomena can be analyzed directly by equilibrium thermodynamics. For a solid, object history will affect the properties of the surface. As a result, surface energy and surface stress must both be considered in analyzing the properties of an interface [6]. Even though this is well known, there has not been as much concern given to the surface history of solids when determining their surface properties as is necessary [7].

Surface effects relative to bulk properties become more important as the surface area to volume ratio for materials becomes larger. In the simplest case, a sphere, this ratio is given by

$$\frac{A}{V} = \left[\frac{4\pi r^2}{\frac{4}{3}\pi r^3}\right] = \frac{3}{r} \tag{1}$$

In the most general case, one can estimate that the surface to volume ratio for any object shape always scales as the reciprocal of some characteristic linear dimension of the object. Surface effects thus increase in importance as the size of the object being considered becomes smaller. Statistical thermodynamics and molecular dynamics considerations indicate that the range of surface effects as two to five molecular diameters [8]. Simple arguments concerning the dimensions of a [solid polymer 1/polymer 2] interface give similar estimates [9]. An interesting feature of this type of analysis of surface effects and their ranges is that the distance of propagation of surface effects into the bulk from a polymer adsorbed at an interface can be quite large in atomic dimensions. In effect, the interface pins one end of the polymer, removing one of its degrees of freedom, and thus making it a location of different thermo-mechanical properties than the bulk of the polymer. This is of exceptional importance when analyzing the adhesion of polymeric films to bulk substrates. The strength of the adhesive bond can be influenced by these directionality effects and can be even more important if the substrate is a plastic (polymer), since the ordering effects propagate on both sides of the interface [10]. The directionality and ordering of surrounding polymeric bulk media near an interface can extend unexpectedly large distances. Many of the properties of self-ordering systems have these effects as their origin. This will be commented upon further in the discussion of surface effects in pigment dispersion and emulsions.

Anyone dealing with coatings must realize that surface effects are very important in all stages of coating preparation, application, and utilization. Coatings are thin films with high surface-to-volume ratios. Pigments also have large surface-to-volume ratios, and their surfaces are often chemically reactive or catalyze reactions [11]. Latex polymers also occur in fine particulate form, and their use and stability depends on surface-dominated effects. Foaming, cratering, and other coating defects develop through surface-mediated events [12,13]. The wetting, coverage and adhesion of a coating to a substrate is strongly affected by

surface effects. Adsorption at surfaces of particulate materials in a coating, be they pigments or polymer particles, is controlled by the energetics of the interface between the particles and the suspending liquid.

SURFACE THERMODYNAMICS—BASICS

Liquid Surfaces

To understand surface energetics in coatings, one must first understand the basic thermodynamics of surfaces and interfaces. However, when the system under consideration contains a surface, the definition of the Gibbs free energy is modified. The defining equation for liquids is

$$dG = -SdT + Vdp + \sum_i \mu_i dn_i + \gamma dA \tag{2}$$

where G, T, S, V, p, μ_i, and n_i are the thermodynamic quantities Gibbs free energy, temperature, entropy, volume, pressure, chemical potential of component i, and the number of moles of component i, respectively, and γ and A are the surface tension and surface area. The other equations of thermodynamics can be similarly modified. As can be seen, the energetic cost of expanding a liquid surface is the γdA term. Again, the use of γ is valid only for liquid interfaces; it cannot be considered a thermodynamic quantity for solid surfaces because they store energy as surface stress and are thus not in true equilibrium [7]. Many references discuss this equation in detail (see Ref. [4], for example) Another equation for γ is the mechanical definition given in Ref. [2], also discussed by Adamson [1] and reviewed by Burshtein [14] and Navascues [15] as

$$\gamma = \int_{-a}^{+a} \left(\mathbf{p} - \mathbf{p}^T\right) d\mathbf{n} \tag{3}$$

where $+a$ and $-a$ are distances in either direction from the surface such that molecules at these positions are in the bulk phases, $\mathbf{p}$ and $\mathbf{p}^T$ are the bulk and tangential pressure tensors, respectively, and $\mathbf{n}$ is the normal vector to the surface; this is shown schematically in Fig. 1. The direction of $\mathbf{n}$ is the preferred direction of a surface referred to above. Even if it is not commonly included in introductory discussions of surface phenomena, it is important to consider Eq (3) when considering the thermodynamics of surfaces because it is the relationship between the bulk mechanical properties of the system and the almost "discontinuous" behavior of the system properties at an interface. A more recent discussion of this manner of expressing surface tension is given by Davis [16]. This expression also describes the *directionality* that an interface possesses and is very crucial to modern theories of capillarity [17].

In general, the surface tension, γ, of pure liquids decreases with increasing temperature. An approximate form of this temperature dependence is [16,18]

$$\gamma = \gamma^0 \left(1 - \frac{T}{T_c}\right)^n \tag{4}$$

where γ^0 is the surface tension at $T = 0$, T_c is the critical temperature of the material, and n is an empirical exponent, ~11/9 for organic liquids.

The other important thermodynamic relation for surfaces is the Gibbs equation. In multi-component systems, one must consider the effects of materials absorbing at the interface. When these are properly taken into account, the Gibbs equation (at constant T and p) gives

$$d\gamma = -\sum_i \Gamma_i d\mu_i \tag{5}$$

where Γi is the surface excess concentration for component i [4,19]. This equation gives the relationship between the surface tension of a fluid interface and the amounts of surface active materials (hereafter referred to as surfactants) in the solution (component i). The surface excess concentration Γi is the difference between the actual and bulk concentrations, c_i and c_{i0}, of component i and can be calculated in a manner analogous to Eq (3) as

$$\Gamma_i = \int_{-a}^{+a} \left(c_i - c_{i0}\right) dx \tag{6}$$

where x is again the direction normal to the interface and $+a$ and $-a$ are locations equidistant from the interface in the bulk of the material. Fig. 2 expresses this schematically for a single surfactant. In adsorption of materials to an interface, the local concentration in the neighborhood of the interface can be much higher (by factors of up to 10^8 or greater—see Ref. [1], Chapter 3 for further details or for a more recent version, see Ref. [20]) than that in the bulk.

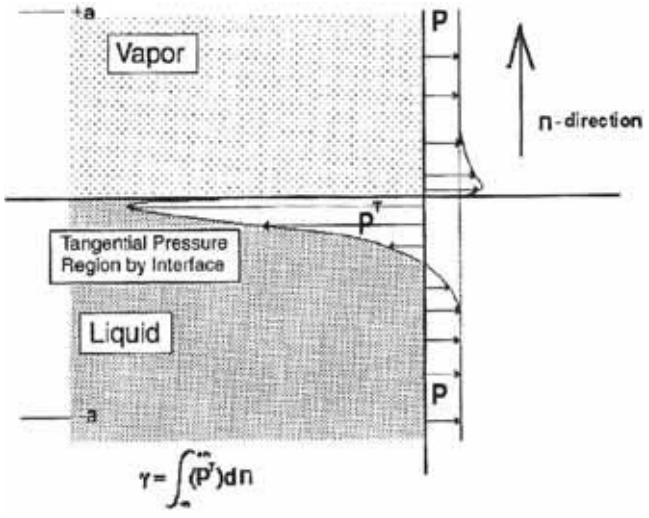

Fig. 1—Schematic of local pressure changes at surface giving surface tension.

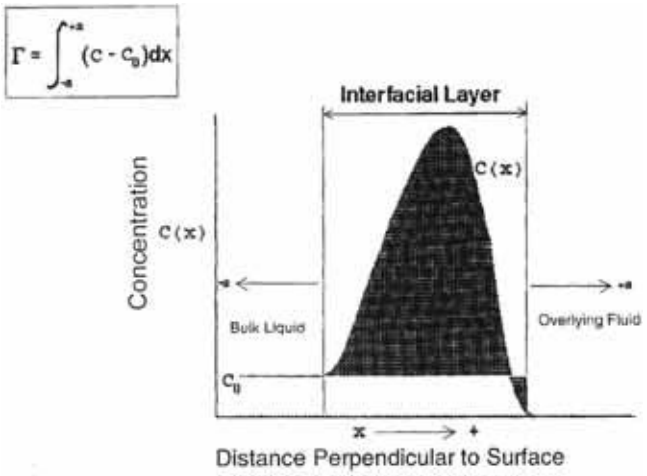

Fig. 2—Schematic of surface excess concentration as calculated as difference for bulk concentration.

The net energy of the system is minimized by the surfactant molecules adsorbing and orienting at the interface to reduce interactions between unlike molecular components. The terms often used to describe the compositional differences in surfactants are polar/nonpolar or hydrophobic/hydrophilic. Materials that act as surfactants are those that have a distinct separation of properties between different sections of their molecules, the classic example being soaps, with an alkyl nonpolar group and a [carboxylat+metal ion] polar group.

In concentrated systems of surface-active materials, especially those of low inherent solubility in the liquid phase, there exists a certain concentration where the addition of further surfactant no longer depresses the surface tension, as the surface is saturated, and the molecules of the surfactant begin to form self-ordered structures, or micelles, in the bulk liquid [21]. Micelles are aggregates of surfactant molecules that form in solution to minimize the total system energy. In water, they orient with the hydrophobic portion of the molecule directed toward the interior of the micelle, and in non-aqueous systems they have the hydrophilic end in the interior. At the surfactant concentration where micelles just begin to form, many of the solution properties also undergo rapid change; this breakpoint in surfactant solution properties is known as the critical micelle concentration (CMC) (Fig. 3). The CMC is a unique concentration for a surfactant/solvent combination at a specified temperature. The book by Rosen [22] gives an expanded discussion of surfactant behavior, and Tanford's book [23] provides further description of micellar behavior in aqueous systems. These texts also describe the complex aggregates that form in surfactant/solvent mixtures, including membrane-like structures and liquid crystals.

Micellar effects and the more general case of self organization in materials has become a very important part of recent studies in materials science. Much of what is considered under what is termed "Soft Matter" concerns itself with colloidal and surfactant behavior involving self-organized matter [3,4,9,24,25]. This still-evolving area of materials science appears to be very pertinent to the science of organic coatings [3].

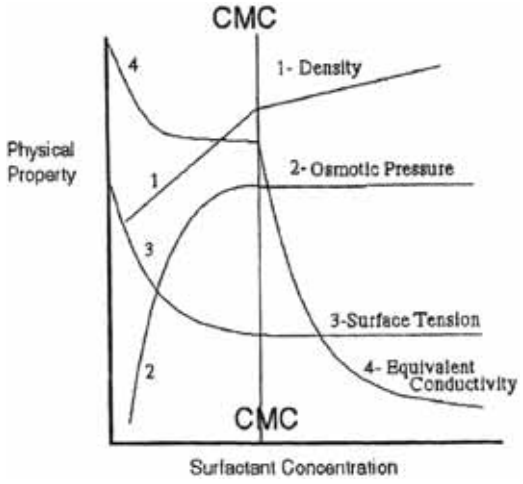

Fig. 3—Schematic of physical property changes in surfactant solution at critical micelle concentration (CMC).

As Gibbs first noted, the presence of a material adsorbing preferentially at an interface imparts elasticity to the surface, as it will tend to resist expansion and contraction. This surface elasticity is given by

$$E = \frac{d\gamma}{d\ln A} = -\frac{d\gamma}{d\ln \Gamma} \tag{7}$$

where A is the surface area. This elasticity is the resistance to disturbance of a film by the presence of a surfactant. The effects of this surface elasticity have been reviewed with respect to liquid films and liquid threads [26]. Recent reviews of surface elasticity discuss this effect in surfactant solutions [25,27], furthermore, an examination in coating application processes emphasizes the importance of dynamic effects in such processes [28]. Surface elasticity measurements have been used to characterize the properties of monomolecular layers at surfaces [29]. If a soluble surfactant diffuses to the surface (see below, "Dynamic Properties of Liquid Surfaces"), it will reduce the surface elasticity, effectively short circuiting the surface tension changes by surface replenishment [30–32]. In these cases, Eq (7) should be modified to read

$$E = \frac{-(d\gamma / d\ln \Gamma)}{\left[1 + (h/2)(dc/d\Gamma)\right]} \tag{8}$$

where c is the surfactant concentration and h is given by the relationship

$$h = 2\sqrt{\frac{D}{\omega}} \tag{9}$$

where D is the surfactant diffusion coefficient, and ω is the frequency of the surface motion [31]. Surface elasticity effects are a major consideration in foam stability [33] and where there are rapid surface area changes and creation of new surfaces [34].

Liquid/Solid Interfaces: Wetting and Contact Angles

When a liquid comes into contact with a solid, a three-phase contact, or wetting, line develops between the liquid, solid, and vapor. Three interfaces are generated; thermodynamic equilibrium exists when the total interfacial energy, the excess energy attributed to the solid-liquid, solid-vapor, and liquid-solid interfaces, is minimized. The liquid-vapor interface forms a characteristic angle tangent to the solid surface as a result [35]. This contact angle is often used to determine the surface excess energy, or surface tension, of the solid-vapor interface through Young's equilibrium equation [4,36]:

$$\gamma_{sv} = \gamma_{sl} + \gamma_{lv}\cos\theta \tag{10}$$

Here, γ_{sl}, γ_{sv}, and γ_{lv} represent the solid-liquid, solid-vapor, and liquid-vapor surface tensions, respectively, and the contact angle is measured between the solid-liquid and liquid-vapor interfaces. The equation is applicable to any solid surface when γ_{sl} and γ_{lv} are known and θ is measurable; issues such as roughness and chemical heterogeneity will be revisited later [24,37]. Often γ_{sl} is unknown; here, two measurements using different liquids of known γ_{lv} gives two equations with two unknowns and γ_{sv} is

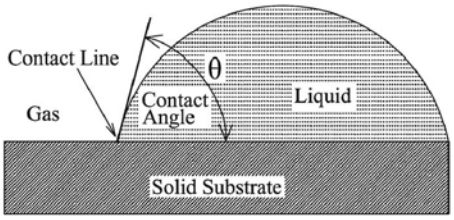

Fig. 4—Schematic of contact angle in G/L/S system.

solved algebraically. Fig. 4 shows the measured contact angle between the three phases. Further derivations and applications of Young's equation are discussed in the review by Churaev and Sobolev [38]. The case where the "substrate" is an immiscible liquid is discussed in Chapter 13 of Ref. [4].

A contact angle describes the wetting behavior of a liquid for a given solid. Complete wetting, or a contact angle of zero, occurs when the liquid spreads spontaneously over the substrate. In this case γ_{lv} is lower, or more favorable, than γ_{sv} and the liquid displaces the air in contact with the solid surface. Any contact angle greater than zero causes the liquid to not wet the solid, or to bead up and form a sessile drop. From Young's equation the relation between γ_{sv} and γ_{sl} determines the shape of the drop such that the contact angle is less than 90° when $\gamma_{sv} > \gamma_{sl}$ and 90° when $\gamma_{sv} < \gamma_{sl}$. Fig. 5 lists the possible scenarios for wetting. The work of spreading, W_S, is a measure with which a liquid favors spontaneously wetting a solid. This value is the difference between the work of adhesion, W_A, and work of cohesion, W_C, for the solid-liquid interface [39].

$$W_C = 2\gamma_{sl} \tag{11}$$

$$W_A = \gamma_{sv} + \gamma_{sl} - \gamma_{lv} \tag{12}$$

$$W_S = W_A - W_C = \gamma_{sv} - (\gamma_{sl} + \gamma_{lv}) \tag{13}$$

A positive spreading coefficient indicates the liquid possesses sufficient excess energy in the liquid to spread

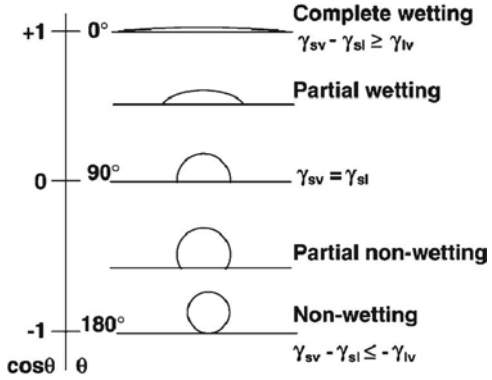

Fig. 5—Schematic of the possible scenarios for wetting. (*Image duplicated from Fig. 4 of Ref. 37*). Reprinted from *Advances in Colloid and Interface Science*, Vol. 133, Kumar, G. K., Prabhu, N., "Review of Non-Reactive and Reactive Wetting of Liquids on Surfaces," pp. 61-89, 2007, with permission from Elsevier.

spontaneously under equilibrium conditions, whereas a finite contact angle is formed for W_S less than zero [40,41].

The surface energy of a substrate is the determining factor in the degree of wetting that occurs. Polarity, which often describes affinity to water, has also been discussed as a basis for predicting extent of wetting and is dependent on the nature of the substrate [42]. Low surface energy, hydrophobic solids such as hydrocarbons or fluorocarbons are not easily wet and form high contact angles with most pure solvents or solutions; poly(tetrafluoroethylene), or Teflon®, is an extreme example of this. Superhydrophobicity and supero-leophobicity describe solid materials whose contact angle with water and organic liquids, respectively, is larger than 150° [43]. Also unique to these surfaces is that they have near-zero contact angle hysteresis, or the difference between the advancing, θ_a, and receding, θ_r, contact angles [44]. Materials of this nature have been the subject of extensive research within the last decade, especially in areas including stimulus-response chemistry, biologically inspired synthesis, and hierarchical structuring [45]. Substrates with these properties are of great interest and are considered for a variety of possible uses such as self-cleaning and self-healing applications. Additional publications concerning these topics and the chemical and topographical sources of their extreme contact angles are found in Refs. [42–54].

High surface energy materials include metals and metal oxides that form low contact angles and are easily wet. When coating these materials, caution should be taken during surface preparation; oils and low surface energy impurities readily adsorb and have the effect of lowered surface energy and reduced wetting. Wettability is essential in the application of coatings to polymeric or metallic substrates; the liquid must wet the surface completely to obtain good adhesion [40]. This is commonly achieved by cleaning the substrate well, or adding surfactants to the wetting liquid to depress its surface tension and reduce the contact angle to zero. Cationic surfactants are most commonly used because the surfaces to be wet generally have a negative charge [38]. Methods for measuring the extent of cleanliness, such as contact angle, have been discussed by Durkee and Kuhn [55]. Surface preparation is the single most important step in coating application to ensure substrate/coating adhesion and guarantee its protection. In addition to cleaning with detergents, physical and chemical surface pre-treatment options for altering the substrate surface energy are available; a section at the end of this chapter is dedicated to their discussion. Pre-treatments such as flame and corona are especially necessary for low surface energy polyolefin substrates such as polyethylene or polypropylene.

Adjusting the surface roughness of a substrate also affects a coating's ability to wet a substrate [40]. Substrate pre-treatments may often include sanding or other roughening techniques. Increased surface roughness promotes wetting when the contact angle is below 90° but decreases wetting for those above 90°. Roughened surfaces generally have the adverse effect of creating a hysteresis in the contact angle measurements, with the advancing drop being the larger than the receding [39]. In order to maintain the applicability of Young's equation, Wenzel developed a relation to account for surface roughness. Here, cos θ_{rough} is the measured contact angle, cos θ_{smooth} is the thermodynamic

contact angle for an atomically smooth surface, and r is the roughness ratio [37]:

$$\cos\theta_{rough} = r\cos\theta_{smooth} \quad (14)$$

$\cos\theta_{smooth}$ is also the theoretical Young's equilibrium contact angle, θ_Y. Aside from wettability, contact angle measurements are also valuable for studying the weathering and degradation of organic coatings. Wenzel's equation has been applied to polymer photodegradation; chemical bonds are broken at the surface, polymer segments are liberated, and the contact angle is decreased [56,57]. This roughening is not unlike surface pre-treatments.

Hysteresis effects also arise from compositional variations or impurities at the surface [37]. Heterogeneity in a polymer surface is almost inevitable when considering the phase separation that occurs between crystalline and amorphous regions. The Cassie-Baxter equation can be applied to chemically heterogeneous surfaces if an estimate of the partial surface area of each material is known [58]:

$$\cos\theta = f_1\cos\theta_1 + f_2\cos\theta_2 \quad (15)$$

Here, θ is the contact angle and f is the fractional surface area for the chemically homogeneous materials of respective indices. The combination of these and other variables result in contact angle measurements that are slightly ambiguous and irreproducible within small standard deviations. However, with great care, techniques such as the low-rate dynamic automated axisymmetric drop shape analysis-profile (ADSA-P) have yielded contact angle accuracy greater than 0.3° [59].

It may be of interest to determine the surface tension required of a coating to wet a given substrate. Zisman and co-workers derived a method using contact angle measurements for determining the "critical surface tension," or the energy needed for a liquid to spontaneously wet the solid surface of interest. This is the γ_{lv} value for a contact angle of zero. Experimentally it is determined by plotting the cos θ versus γ_{lv} for various liquids of known surface tension. A linear extrapolation of the data to zero contact angle, or cos θ = 1, gives the critical surface tension. Pure liquids eliminate the preferential absorption issues associated with surfactant solutions although both have been used in practice [60,61]. Caution is advised by van Oss [42] in regards to polar liquids, especially water and aqueous solutions, as they introduce interactions and error in the measurement of thermodynamic properties. Therefore, Zisman's technique should be used in situations where van der Waals forces dominate [62].

The study of deriving surface tensions from contact angles has evolved into two approaches: surface tension components and equations of state [43]. Surface tension components include the previously mentioned method by Zisman as well as major contributions by van Oss and Good, Fowkes, Owens and Wendt, and Wu and the acid–base approach; discussion and supplemental references can be found within Refs. [58,62]. The equation of state approach obtains the relation between the three interfacial tensions theoretically. As mentioned before, Zisman's technique revealed a linear trend for cos θ versus γ_{lv}; Neumann and co-workers went on to show that γ_{lv} cos θ versus γ_{lv} yielded a smooth curve representative of the solid surface

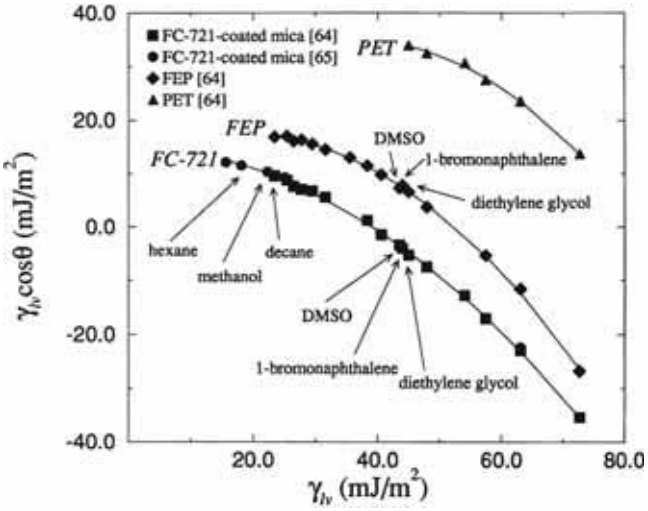

Fig. 6—Schematic of the parallel curve that suggests an equation of state, found by changing the substrate. (*Image duplicated from Fig. 2 of Ref. 61*). Reprinted with permission of John Wiley & Sons, Inc.

tension [61,63]. Changing the substrate produced a parallel, smooth curve as shown in Fig. 6; this indicated that an equation of state exists for surface tension, which is independent of inter-molecular interactions. The equation of state was developed using contact angle measurements on polymeric substrates and does not work well for polar substrates; other criticisms also persist as indicated in the publications by Morrison [64] and Janczuk et al. [65]. One main advantage of this approach is that it alleviates the deviations seen in the Fowkes equation for large liquid and solid surface tension differences.

DYNAMIC PROPERTIES OF LIQUID SURFACES

Fresh surfaces in liquid solutions have an initial surface tension unlike their equilibrium value. Considerations of this are necessary in manufacturing processes, such as coating application, where fresh surfaces are formed. The instantaneous γ_{lv} is characteristic of the bulk solution and approaches an equilibrium surface tension, γ_{eq}, as a function of time, $\gamma(t)$. The time-dependent behavior associated with fresh liquid interfaces is referred to as dynamic surface tension (DST) in the literature; this is represented by Eq (16):

$$\gamma_{eq} = \lim \gamma(t) \quad \text{for} \quad t \to \infty \quad (16)$$

A minimized free energy conformation is approached as a result of adsorption of surface active agents, or surfactants, at the liquid/vapor interface. Aside from fresh surfaces, changes in the surface area of an existing interface or bulk surfactant concentration also tend toward a new γ_{eq} and are applicable to DST models [66]. For additional details on the state-of-art, refer to the reviews by Miller et al. [67] and Eastoe and Dalton [68] for air-water interfaces and Ravera et al. [66] for liquid-liquid interfaces.

By the end of the 19th century, researchers recognized that instantaneous γ_{lv} differed from γ_{eq}; however, it was not until 1946 that a quantitative model was published [69]. Utilizing Fick's equations, Ward and Todai [69] proposed the first analysis to support the theory that surfactant

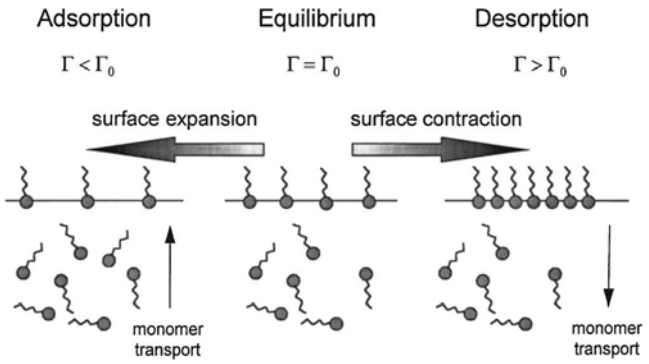

Fig. 7—Schematic of surfactant flux and surface excess concentration with regard to liquid surface area. (*Image duplicated from Fig. 1 of Ref. 68*). Reprinted from *Advances in Colloid and Interface Science*, Vol. 85, Eastoe, J., Dalton, J.S., "Dynamic Surface Tension and Adsorption Mechanisms of Surfactants at the Air-Water Interface," pp. 103–144, 2000 with permission from Elsevier.

molecules were driven to the interface by diffusion processes. The work also includes definition of the subsurface, the region a few molecular diameters below the interface, which regulates adsorption to the interface. Initially the surface excess is zero and each molecule in or reaching the subsurface subsequently diffuses to the interface, represented as the adsorbing flux, j_{ads}. Over time, the number of occupied surface sites increases and adsorption is no longer automatic. The desorbing flux, j_{des}, or back diffusion to the subsurface becomes significant as the system continues towards equilibrium. The surface excess concentration, Γ, over time is the result of balancing the flux of surfactants to and from the interface, respectively.

$$d\Gamma/dt = j_{ads} - j_{des} \tag{17}$$

Fig. 7 shows how the surfactant flux and F adjust to changes in the liquid surface area where Γ_{eq} is the equilibrium surface excess concentration. Significant contributions to the DST models were later made by Sutherland [70], Hansen [71], and Miller and co-workers [67,72]. References [28,29] discuss the importance of dynamic effects in relation to micellar solutions.

Two models persist for DST; they are the diffusion-controlled model and the mixed kinetic-diffusion model. In the diffusion-controlled model, diffusion to the subsurface is the rate-limiting step followed by a fast adsorption to the interface as theorized for short-time scenarios. On the contrary, the mixed kinetic-diffusion model assumes the transfer of surfactant molecules from the subsurface to the interface to be the rate-limiting step. Also, there is an energy barrier for adsorption which is possibly related to the number of available sites for adsorption or increased surface pressure [68]. Comparatively, the diffusion-controlled model contains one kinetic parameter, that is diffusion, D, whereas the mixed kinetic-diffusion model contains an additional parameter for the adsorption energy barrier denoted by β [73]. Once a surfactant molecule has adsorbed at the interface, additional reorientation and relaxation further minimizes the surface excess energy, or surface tension.

Both models are used experimentally in association with a chosen adsorption isotherm to measure γ_{eq} and Γ_{eq} for surfaces of interest. Experimental techniques for measuring DST are explained in the following section along with those for static surface tension. It must be understood that DST is interested in solution, particularly surfactant solutions, and the appropriate measurement should reflect this. For example, the Wilhelmy Plate method is appropriate for solutions whereas Du Nuoy ring is reserved for pure liquids. DST is especially important in coating application and all other processes that generate fresh surfaces [35,74]. Wetting in thin film spreading [75] and the dynamics effects of contact angles on moving substrates [76] are also pertinent. Schunk and Scriven [28] review the dynamic effects of surfactants in continuous application processes and give an extensive bibliography. More recent studies of dynamic wetting effects include wetting phenomena at structured surfaces, and surfaces of variable composition [77,78].

MEASUREMENT OF THE SURFACE TENSION OF LIQUIDS

Introduction

There are many ways of measuring surface tension, but in essence, they are all related to two effects of capillarity. The first effect is the excess pressure due to surface tension at a curved interface. The Young–Laplace equation describes this as

$$\Delta p = \gamma\left(1/R_1 + 1/R_2\right) \tag{18}$$

where Δp is the excess pressure due to the curved interface, and R_1 and R_2 are the two principal radii of curvature of the interface. In the case of a sphere of radius r, where the radii of curvature are both equal to r, this equation reduces to

$$\Delta p = 2\gamma/r \tag{19}$$

The other capillary effect is that the surface tension of a liquid exerts a force upon a solid body immersed in it equal to the surface tension times the perimeter of that body times the contact angle the liquid makes with the solid. If one is using a balance, one can write

$$\Delta W = \mathcal{P}\gamma\cos\theta \tag{20}$$

where $\mathcal{P}$ is the perimeter of the solid, θ is the contact angle of the solid-liquid interface, and ΔW is the extra force on the solid body due to surface tension. These two effects yield—together with various modifications of geometry, etc.—many methods to measure static and dynamic surface tension. The most widely used methods are described in the following sections.

It should be noted that all surface tension measurements require the cleanliness of all apparatus and the purity of all materials. Organic impurities in aqueous systems will have drastic effects in reducing the surface tension values measured. The concentration levels necessary to alter surface tension measurements can be as little as 10^{-8} *M*. Trace amounts of impurities on solid apparatus surfaces can alter contact angles and, as will be shown, the measured surface tension values. All water used in surface tension measurements should be at least double distilled, and often the presence of a strong oxidizing agent in one step of the distillation ensures that trace surfactants are removed. The water should be used fresh, as surface active

impurities can be leached from glass and plastic containers. The same holds true for all solvents used in surface characterization studies.

Static Surface Tension Measurements

Certain surface tension measurement methods work well only in a static system. These methods must thus be used on systems where there is no formation of fresh surfaces, or with pure liquids.

Capillary Rise

Within a small capillary tube, there exists a pressure on a liquid relative to the pressure on a large vessel of the liquid. Using Eq (19) and allowing for the contact angle between the liquid and the capillary, we have at equilibrium between the force of gravity and the capillary pressure

$$\Delta\rho g h = \frac{2\gamma\cos\theta}{r} \tag{21}$$

where Δp is the density difference between the liquid and air, g is the acceleration of gravity, h is the height of the capillary rise, and the rest of the terms are defined above. This equation allows one to measure the surface tension from a simple measurement of the height of the rise of the liquid in a capillary of known radius and contact angle with the test liquid. This method is shown schematically in Fig. 8. As a measurement technique, it has remained largely unchanged since its inception, with only the addition of computer-aided analysis of the instrument.

Drop Weight

The weight of a drop when it is formed slowly is the weight just to exceed the force of surface tension times the radius of the capillary tip from which it is formed, with a correction factor required for the formation of small satellite drops. Thus, one has

$$W = 2\pi\gamma r f \tag{22}$$

where W is the weight of the drop and f is the correction factor, which is discussed in Adamson [1]. This method is simple to use and accurate if precautions are taken for cleanliness and very slow flow rates of the liquid in the formation of drops. The method is shown schematically in Fig. 9. The simplicity of this measurement, and easy availability of the equipment, results in it being a popular technique. Reference [79] provides a review of this technique.

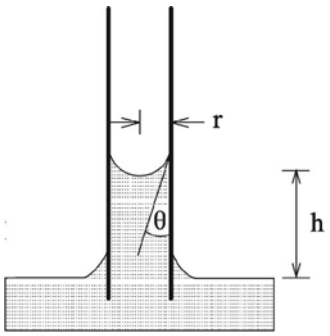

Fig. 8—Schematic of capillary rise method of measuring surface tension.

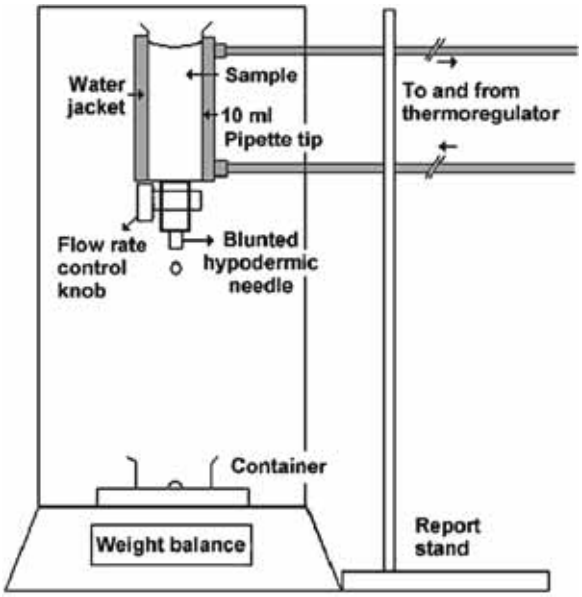

Fig. 9—Schematic of drop weight method of measuring surface tension. (*Image duplicated from Fig. 1 of Ref. 79*). "A Critical Review: Surface and Interfacial Tension Measurement by the Drop Weight Method," Boon-Beng, L., Ravindra, P., Chan, E.-S., *Chem. Eng. Comm,* Vol. 195, 2008, pp. 889–924, reprinted by permission of the publication (Taylor & Francis Group, http://www.informaworld.com).

Du Nouy Ring

Applying Eq (13) to the case where the object is a ring being pulled from the surface of a liquid, one has

$$W = W_{\text{ring}} + 4\pi\gamma R \tag{23}$$

where W is the total weight sensed by a balance, W_{ring} is the ring weight, and R is the ring radius as shown in Fig. 10. However, this formula requires a correction to be accurate and holds only for a zero contact angle between the ring and test liquid. Again, see Adamson [1] for further details. The force measured by the balance is that force just at detachment of the ring and so involves motion of the sensor; the method is thus not an appropriate technique to use in studying solutions. In general, this method is infrequently used, compared to the other options available.

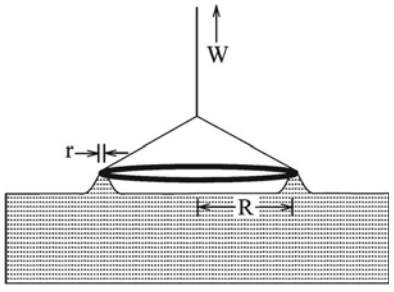

Fig. 10—Schematic of Du Nouy ring method of measuring surface tension.

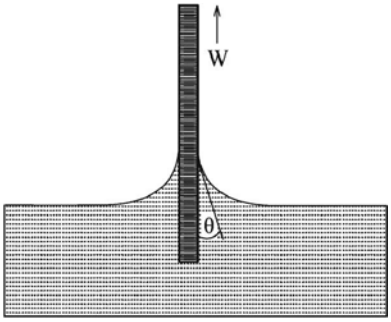

Fig. 11—Schematic of Wilhelmy plate method of measuring surface tension.

Wilhelmy Plate

If one uses a thin plate instead of a ring and measures the force exerted on the plate just touching the surface of a liquid, one has

$$W = W_{\text{plate}} + \gamma \mathcal{P} \tag{24a}$$

where $\mathcal{P}$ is the perimeter of the plate. If the liquid does not perfectly wet the plate, the expression

$$W = W_{\text{plate}} + \gamma \mathcal{P} \cos\theta \tag{24b}$$

must be used as illustrated in Fig. 11. The perimeter of the plate may be determined in practice as an experimental constant from γ measurements with liquids of known surface tension. Again cleanliness is most crucial, and a roughened platinum plate cleaned in a Bunsen burner flame is often used to create a clean plate that is wet by most liquids. Because there is no motion of the plate in the measurement, this method can be used to measure dynamic as well as static values of γ. This technique may be used as well with a rod [80] or cone [81] instead of a plate and may also be used to measure the contact angle of a liquid of known surface tension against a specific plate, fiber, or cone-shaped substrate (see later in this chapter under "Contact Angle Measurements"). Also, the method does not require corrections as with the drop weight or the Du Nouy ring methods.

Sessile or Pendant Drop Shape Methods

If the shape of a sessile or pendant drop is measured photographically or by a digital camera, a solution of Eq (18) for the specific shape of the drop in the presence of a gravitational field can be used with the measurements of the drop profile to back calculate the surface tension of the drop. Fig. 12 gives a schematic of the method. This method works well at liquid–air or liquid–liquid interfaces and can also be used to make dynamic measurements if the camera response is continuous and rapid [82]. A variation of the drop-shape method of measurement is used wherein the drop is deformed by a centrifugal field or an electrical field. The spinning drop shape method allows very small interfacial tensions to be measured between two liquids [83].

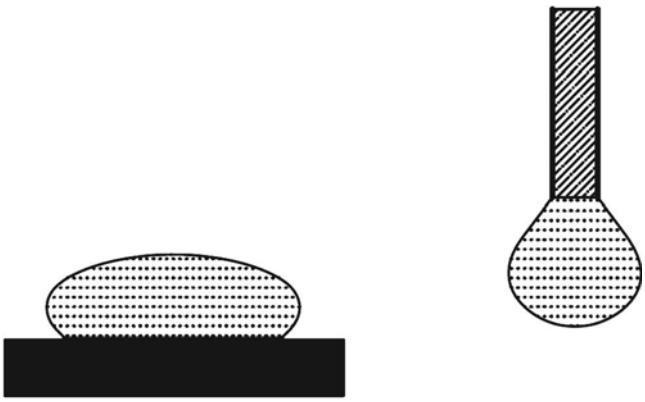

Fig. 12—Schematic of sessile and pendant drop methods of measuring surface tension.

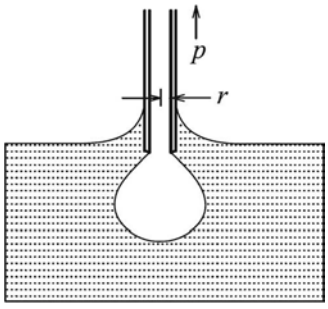

Fig. 13—Schematic of maximum bubble pressure method of measuring surface tension.

Maximum Bubble Pressure Methods

A bubble created by forcing a gas through the end of a capillary in a liquid and the maximum pressure on the resultant bubble can be used to measure surface tension by Eq (19). This measurement procedure is illustrated in Fig. 13. However, this is another measurement that requires correction, in this case for the nonspherical shape of the bubble. With rapid formation of the bubbles and accurate differential pressure measurements, the technique may be used to make dynamic measurements [84]. If capillaries of two different radii are used simultaneously and the pressure difference between the bubbles formed and the two capillaries is measured, a rapid, accurate measurement of surface tension can be made and has been used as a process monitor in emulsion polymerization [85]. This is known as the differential bubble pressure method and is illustrated in Fig. 14. This technique has been improved by the use of computers with the ADSA/ ABSA technique [86,87].

Dynamic Surface Tension Methods

When confronted with situations where fresh surfaces are formed, flow is occurring, or there are polymer solutions with long equilibrium times, it becomes necessary

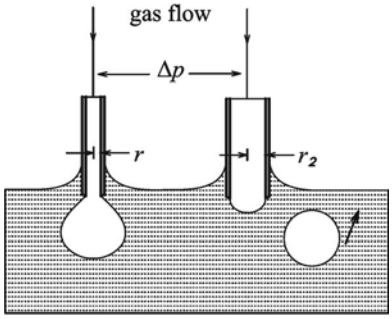

Fig. 14—Schematic of differential bubble pressure method of measuring surface tension.

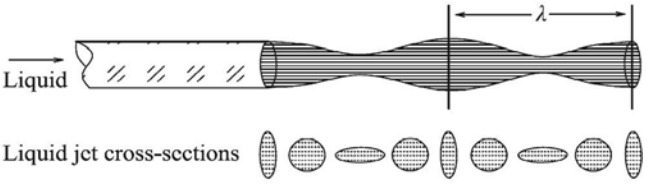

Fig. 15—Schematic of oscillating jet method of measuring surface tension.

to consider dynamic surface tension. As previously mentioned, bubble pressure, drop-shape methods, and the Wilhelmy plate method can be used for static as well as dynamic γ measurements. These methods are appropriate only for relatively slow changes in γ, and they will be discussed briefly below with literature references that discuss their use in characterizing $\gamma(t)$ effects. In addition to the already mentioned methods, other techniques have been developed to measure γ for short-time scales and fresh, rapidly changing surfaces.

Oscillating Jet

The mechanical instability of a liquid jet leaving an elliptical orifice causes the stream to oscillate about a circular shape and eventually break up into droplets, as illustrated in Fig. 15. The oscillations are periodic, and measurement of their wavelength can be used to determine γ as given by

$$\gamma_{app} = \frac{4\rho v^2\left(1+\frac{37b^2}{24r^2}\right)}{6r\lambda^2\left(1+\frac{5\pi^2 r^2}{3\lambda^2}\right)} \tag{25}$$

where ρ is the liquid density, v is the velocity of the jet, λ is the wavelength of the oscillation, r is the sum of the minimum and maximum radii, and b is their difference [1]. This dynamic measurement of γ has been considered by Vijian and Ponter [88], who give references to the earlier work of Ray-leigh, Bohr, Sutherland, Hansen, and others.

Falling Curtain

In an analysis of curtain coating, Brown [89] observed that the angle θ in the falling curtain formed by the break around a small, non-wettable obstacle could be used to measure surface tension as

$$\sin\theta = \frac{2\gamma}{Qu} \tag{26a}$$

where Q is the mass flow rate per unit orifice slit length in the curtain and u is the velocity of the liquid. This can enable one to calculate the dynamic surface tension in the falling film at the point where the obstacle intersects the falling curtain if the velocity u is greater than the "bursting velocity" of the falling sheet. A schematic of this method is given in Fig. 16. This has been considered further by Van Havenburgh and Joos [90]. Antoniades et al. [91] reconsidered the work of Brown and suggested that Eq (26), when derived correctly, should be written as

$$\sin^2\theta = \frac{2\gamma}{Qu} \tag{26b}$$

and give experimental evidence for this corrected equation.

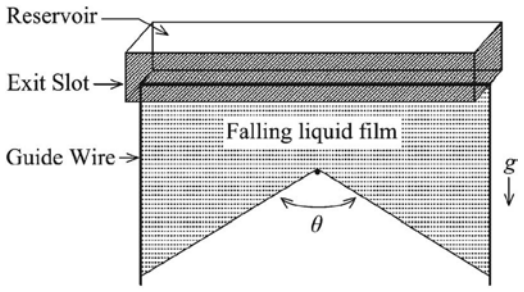

Fig. 16—Schematic of falling film method of measuring surface tension.

Capillary Waves

The properties of capillary waves, small wavelength waves on the surface of a liquid with the dominant restoring force being surface tension, can be studied to provide a measurement of surface tension, surface elasticity, and other dynamic surface properties. For clean surfaces of an inviscid liquid, Kelvin [92] determined that on a liquid of density, ρ, waves of frequency, ω, and wave number k, the surface tension is given for small wavelengths.

$$\gamma = \frac{\rho\omega^2}{k^3} \tag{27}$$

The situation for interfaces in real systems, viscous liquids with surfactants present, has been studied in detail [15,17], and the use of mechanically generated capillary waves for studying interfaces has been reviewed by Hansen and Ahmad [93]. The capillary waves generated by temperature fluctuations at a surface can be measured by laser-light scattering techniques, and these data can be used to generate very accurate values of surface and interfacial tensions [94]. Capillary wave studies can be used to study the time dependence of γ in some detail and are probably the most accurate and complete of the methods for measuring all dynamic surface properties.

The Falling Meniscus Method

The measurement of the height of a column of liquid in a tube with a small opening on top can be used to measure the dynamic surface tension of aqueous systems. The height measurement versus time may be analyzed to calculate the surface tension as a function of time. This is discussed in further detail, together with a full description of the experimental apparatus and analytical equations, by Defay and Hommeln [95].

Modified Static Surface Tension Measurements

Maximum Bubble Pressure

If one can monitor the time response of pressure to the time-dependent surface tension, one can use the maximum bubble pressure technique described above to measure dynamic surface tension [84]. The equipment required for such measurements is the same as the static maximum bubble technique plus instrumentation for time-dependent measurement of the bubble pressure. Various authors have examined the theoretical and experimental aspects of these methods [96,97].

Wilhelmy Plate

If a time-recording balance is used to monitor the force of surface tension pulling on the immersed plate, the Wilhelmy plate technique can be used for characterizing dynamic surface tension. As discussed above, the method is not useful for short times, but for slowly varying $\gamma(t)$ values. The method is used considerably with Langmuir film balances and has been applied to various other problems [98].

Other Methods

If a sensing technique that can be time resolved is coupled to a specific static surface tension measurement, $\gamma(t)$ data can be acquired. Reference [82] discusses this for drop-shape methods, and Jho and Burke [99] present a modification of the drop weight technique for $\gamma(t)$ characterization. Reference [29] discusses the general issue of characterizing surfactant effects in dynamic systems.

CONTACT ANGLE MEASUREMENTS

Introduction

Contact angle measurement remains the most common method for determining γ_{sv} or wettability. Arguments suggest, however, that θ_Y is difficult to obtain for a variety of reasons. Surface roughness results in contact angle hysteresis, as mentioned earlier, in which θ_a gives the closer fit to θ_Y. A rigid, physically smooth, and chemically homogeneous surface should be used in order to get the best approximation. Other assumptions include: the use of pure liquids to eliminate preferential adsorption effects, physical and chemical reactions do not occur between phases, γ_{lv} is higher than γ_{sv} such that a drop forms on the surface, and that γ_{sv} is constant and independent of the liquid used. The review by Kwok and Neumann [61] includes further details on contact angle measurement techniques and their interpretations.

In addition to the common contact angle measurements, a partial list of practiced solid surface tension measurement techniques not discussed here includes: solidification front techniques, sedimentation techniques, gradient theory, film flotation, Lifshitz theory of van der Waals forces, and theory of molecular interactions. All approaches share in common the assumed validity of Young's equilibrium equation. References relevant to these solid surface tension determining techniques are given in the review by Tavana and Neumann [63]. Recent work has also been done to determine contact angles at high temperatures [100] and under flow conditions [101]. This chapter includes information on direct/indirect sessile drop methods, Wilhelmy plate, capillary rise, rate of penetration, ADSA-P, and atomic force microscopy (AFM).

Direct Measurement of Contact Angle by Sessile Drop

The common contact angle measurement is also known as the sessile drop measurement and refers to optical techniques for determining contact angles [102]. These include contact angle goniometry of the drop profile using a photograph or digital video image, see Fig. 17. The drop must be small enough that gravitational forces have insignificant effects on the drop shape; therefore, magnification is necessary either using a digital image or goniometer-fitted microscope. Once the contact angle is known, Eq (10) can be used to calculate the surface tension of the solid if desired. Often

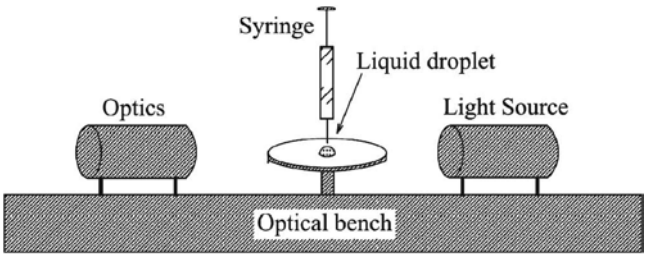

Fig. 17—Schematic of contact angle goniometer.

experimentation with two different liquids is necessary to obtain two equations with two unknowns and solve for γ_{sv} algebraically.

The contact angle measured by this method is referred to as the equilibrium angle, θ_e, which lies between θ_a and θ_r but nearer to the former and is not necessarily equal to θ_Y. It may be desirable to know the values for θ_a and θ_r; this is accomplished by slowly adding or removing liquid from the sessile drop until the maximum and minimum contact angles are recorded, respectively [63]. Differences of 5° to 20° are common between the two angles. The method was first performed by Zisman and co-workers using a thin platinum wire to add liquid and a fine glass capillary to remove liquid [63]. Later, Good and co-workers [103] applied the technique using micrometer syringes.

Two similar techniques for measuring the contact angle are the captive bubble method and the tilting plate method [104]. The captive bubble method places a drop of air on the solid surface in a liquid environment instead of vice versa. The same contact angle is measured as before, however, it is now nearer to θ_r. Although this method deviates from the simplicity of a liquid drop on a surface, it assures one that the saturated vapor pressure of the liquid and the solid-vapor interface are in equilibrium [63]. The tilting plate method suspends a plate or cylinder of the solid material in a bath of liquid with known γ_{lv}. The solid is then tilted until the capillary rise on the plate is zero, such that the liquid-vapor interface is flat at the contact line. A simple goniometer scale gives the contact angle to be the plate's displacement from the position normal to the liquid. Placing a sessile drop on the tilted plate at this position gives a good approximation of θ_a and θ_r. Considerations must be taken when choosing the liquid used in this method as it requires appreciable quantities.

Contact angle measurements are considered to be dynamic when there is a time dependency. For example, θ_a and θ_r are found through dynamic techniques in which the drop volume is steadily increased or decreased, respectively. The key factor is that the contact line is not static; the review by Blake [105] contains theoretical information on dynamic contact angles, velocity of the wetting line, and the models that describe them.

Measurement of Sessile Drop Dimensions

Using the same drop preparation as the direct measurement, the contact angle may be calculated through trigonometric equations by measuring drop diameter and height, volume, or mass (only if the liquid is of known density to obtain drop volume). Reference [62] further explains the methods and derives the necessary equations. The technique assumes that the drop is a section of a sphere of

radius, r, such that the surface tension is satisfied by the Laplace equation

$$\Delta p = 2\gamma/r \tag{28}$$

where Δp is the difference in pressure across the liquid-vapor interface. Error is commonly associated surface heterogeneities, leading to variations in the diameter and contact angle along the drop perimeter.

Wilhelmy Plate

The equation for Wilhelmy plate method is adjusted to give the contact angle of a solid if the liquid surface tension is known. Eqs (29a) and (29b) both satisfy the solution of this method.

$$\cos\theta = \Delta W/\gamma\mathcal{P} \tag{29a}$$

$$\sin\theta = 1 - \left(\rho g h^2/2\gamma_{sl}\right) \tag{29b}$$

As before, the surface tension of the solid is determined from the Young equation using this contact angle. This is the static Wilhelmy plate method; information on the dynamic method is given above and by Erbil [62].

Capillary Rise Method

The capillary rise method is also used to determine contact angles:

$$\cos\theta = \Delta\rho r g h/2\gamma_{sl} \tag{30}$$

Automated Curve-Fitting Approaches

In an effort to enhance the reliability of contact angle measurements, curve-fitting programs have been developed to analyze the profile of a sessile drop by transferring the image to a computer for digitizatiion and analysis [58]. The first such approach ADSA-P by Neumann and co-workers [106,107]; adjustments have consistently been made to improve its applicability as a high-accuracy technique. Assuming that the profile is both Laplacian and axisymmetric, an integration of the Laplace equation gives the contact angle [104]. The method is used as a low-rate dynamic technique to measure the advancing and receding contact angles [61]. A similar approach, the automated polynomial fitting, was proposed using a polynomial fitting of the drop profile. This technique has similar accuracy to ADSA-P but is applicable to non-axisymmetric systems also [108].

Direct Force Measurement by AFM

Drelich et al. [109] have reviewed the use of AFM in determining the surface tension of a solid. Although this technique is very sensitive to experimental conditions and requires extensive setup and calibration, it is applicable to microscopic surfaces that are too small for regular sessile drop techniques [104]. Corrections must also be made for the elastic deformation of the materials. The theory for this technique is based on the work of adhesion between two materials, being the solid surface of interest and the instrument probe. The pull-off (adhesion) force, F, is measured directly in this experiment as a function of W_A

$$F = 2\pi R W_A \tag{31}$$

where R is the diameter of the probing tip. The coefficient 2π assumes the particles in contact are perfectly rigid. Once W_A is known, the Young equation can be combined with Eq (12) to obtain the Young-Dupre equation [37]:

$$\cos\theta = W_A/\gamma_{lv} - 1 \tag{32}$$

Similarly the surface tension can be solved using a constant, c, generally 1.5 or 2 depending on the model chosen; more details can be found in Ref. [109].

$$\gamma_{sv} = F/2c\pi R \tag{33}$$

Rate of Penetration into Powder

The rate of penetration relation is utilized when it is desirable to know the amount of time it will take for a liquid to wet a porous medium; examples include enhanced oil recovery operations, the movement of water through geological systems, or absorption in the clean-up of spilled liquids [110]. In this dynamic contact angle measurement, the liquid enters the powder at a given velocity, v, and subsequently wets the surfaces by capillary forces as a function of γ_{lv} and θ as shown in the Washburn equation [111]:

$$\cos\theta = 4v\eta l/\gamma_{lv} r \tag{34}$$

Here, η is the viscosity of the penetrating liquid, l is the length of the capillary path in the powder, and r is the average pore size; the equation assumes inertial and gravitational effects to be negligible. Often the technique is used to find the γ_{lv} of the wetting liquid that minimizes the rate of penetration. Refer to Lavi and Marmur [110] or Subrahman-yam et al. [112] for more information on this method.

SOME SPECIFIC APPLICATIONS OF SURFACE ENERGETICS TO ORGANIC COATINGS

Coatings Application and Defects

Flow phenomena, and their control, at surfaces are very important to coatings film application technology [12,113]. It is such an important consideration that there have been several books written on this topic since the first version of this chapter [12,114,115]. The creation of uniform thin films at high speeds involves many problems that are determined by a combination of the application geometry, the velocity of the substrate relative to the liquid coating, the physical properties of the liquid coating, especially the energetics of the surface of the liquid coating, the surface of the substrate, and the new liquid/solid and gas/liquid interfaces created in the application processes. Analysis of several application techniques is given below to illustrate the importance of the use of concepts discussed in the prior portion of this chapter.

Dip Coating

Dip coating is a coating method in which a sheet of material is constantly withdrawn vertically from a coating liquid bath at constant velocity, producing a constant film thickness coating adhering to the sheet, which is usually then dried or cured to produce the final coating on the sheet (see Fig. 18). This problem was originally analyzed by Landau and Levich [116], and its solution has been given in the most commonly used form by Probstein [117]. Only the solution of the problem will be given here, but it is representative of the problems identified by chemical engineers as coating flows. In these cases, the geometry of the coating device, the relative velocity, v, of the object to be coated, and

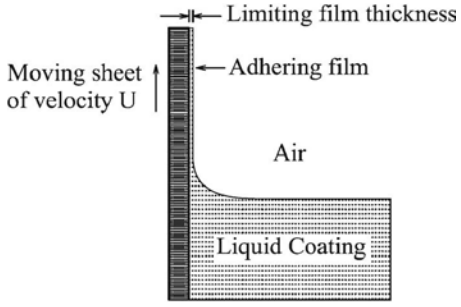

Fig. 18—Schematic of dip coating process.

the physical properties of the coating fluid (surface tension, γ; viscosity, η; density, ρ; and acceleration of gravity, g) fix the solution to the coating flow problem. In this case, the limiting film thickness, δ_f, at large distances from the coating bath surface, is given by

$$\delta_f = 0.946 \frac{(\eta\nu)^{2/3}}{\gamma^{1/6}\sqrt{\rho g}} \tag{35}$$

This solution is derived from the physical effects of surface tension, as described above, plus the Navier-Stokes equation fluid mechanics. These authors assume Newtonian viscosity behavior of the liquid, i.e., the viscosity, η, is independent of shear rate, time-independent surface tension, and an absence of surface tension gradient-driven flows (Marangoni flows), with the appropriate boundary conditions determined by the coating process. This solution can be used by the coating designer and user to establish a first order estimate of the film thickness of the liquid film by the properties of the coating and the velocity of sheet withdrawal. Further analyses of the dip coating processes are given in more recent monographs [3,12,118].

Curtain Coating

As described above in the section on measurement of dynamic surface tension, analysis of the curtain coating process has yielded a measurement method for dynamic surface tension. In the analyses of this problem, Brown [89] and Ha-venburgh and Joos [96] both modeled curtain coating by a falling liquid film held in place by two vertical wires (see Fig. 19). The flux Q of falling liquid is

$$Q = v_0 h_0 \tag{36}$$

where v_0 is the velocity of the falling film and h_0 is the width of the falling film at time zero at the slot through which the liquid exits. The velocity of the falling film at a position x from the slot is given by

$$v^2 = v_0^2 + 2gx \tag{37}$$

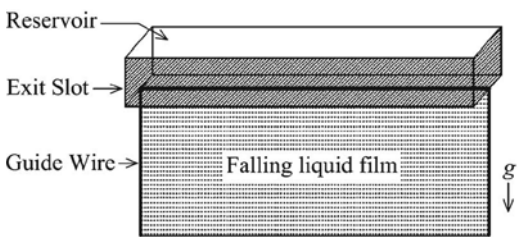

Fig. 19—Schematic of curtain coater.

where g is the acceleration of gravity. Since the flux of material is constant through the slot, we know that

$$Q = v_0 h_0 = hv \tag{38}$$

and therefore

$$h(x) = \frac{Q}{\sqrt{v_0^2 + 2gx}} \tag{39}$$

This equation gives the user a description of the thickness of liquid film as a function of distance from the slot of the curtain coater. This can also be used to estimate the surface tension at a given position x by the following relation [96]:

$$\gamma(x) = \frac{\rho h(x) v_0^2}{2} \tag{40}$$

These equations give the application engineer a reasonably complete description of the curtain coating process. Stokes and Evans [3] and Guthoff [119] give more recent descriptions with a discussion of multilayered curtain coating processes. Fig. 20 illustrates the system discussed in these references. Miamoto and Katagari [120] give an extensive discussion of curtain coating stability with respect to the falling film and and give the following criteria for stability

$$\rho Q v > 2\gamma \tag{41}$$

Electrostatic Spray

The application of surface energetics to the problem of charged liquid droplets was first done by Rayleigh [121]. In this study, the electrical repulsion forces between charges on a drop are equated to the surface tension forces holding a drop together to give the following equation as an estimate of the upper limit on the charge that can be held on a drop

$$q = \sqrt{16\pi\varepsilon r^2 \gamma} \tag{42}$$

where ε is the dielectric constant of the drop and r is the drop radius. This can be used to gain an estimate of the drop size in electrostatic spray of liquid paints. Further stability analysis of this problem indicates that if a drop at this charge limit breaks up, the total energy of the system will be minimized if it does so into n droplets, where n is given by

$$n = \frac{q^2}{4\pi\varepsilon r_0^2} \tag{43}$$

where r_0 is the radius of the original drop [122]. This charge limit has been studied and verified experimentally by several workers [123,124] and also applied to problems of spray painting [125]. All of this work further illustrates the importance and extensive applications of surface energetics to coatings use. A computer simulation of electrostatic spray processes has been used to predict spray patterns on planar substrates [126].

Powder Coating

An environmentally friendly process that often yields high-performance coating films is the powder coating process. This process is one of the fastest growing in terms of market for recently introduced application methods for organic coatings [127]. The process can be described by many of the variables that describe liquid electrostatic painting for both

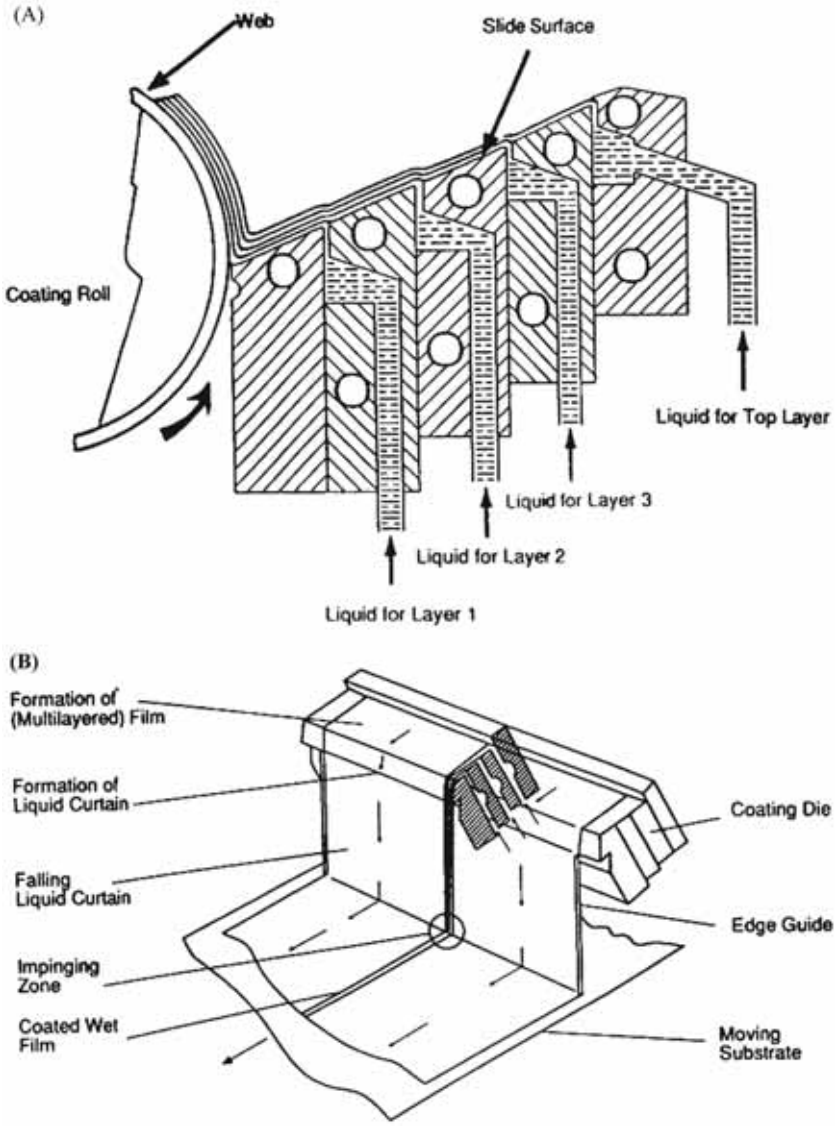

Fig. 20—Schematic of multiple layer (A) curtain coater and (B) slide coater. (*Image duplicated from Figs. 4.2 and 4.3 of Ref. 119*). Reprinted with permission of John Wiley & Sons, Inc.

electrostatic spray powder coating and electrostatic fluidized bed coating [128,129].

Coating Defects

There are many ways in which surface energetics are involved in coating defects, and these are discussed in many references (for example, see Ref. [12]). There is indeed, a whole book devoted to this topic [12]. Surface defects occur by either imperfect coating applications or distortions of the film during the film formation process [130]. The control and prevention of defects in organic coating films requires a knowledge of surface energetics and film formation processes. Cratering occurs, for example, when a suface active impurity with a lower surface tension than the bulk coating spreads over the surface of a wet film displacing or thinning the coating film. The leveling process occurs because of the Laplace pressure at sites of curvature, such as brushmarks, in coatings. Bubbles stabilized by surfactant adsorption can be carried into films during application and cause subsequent imperfections. Any thinning or non-uniformity in film is a potential site for corrosion attack on the underlying substrate, especially in purely barrier coatings [131].

Cleaning and Pretreatment of Substrates for Coating

A very important step in the total process of creating a high-performance organic coating/substrate system is the cleaning and pretreatment of the substrate prior to the coating application step. The processing time and costs of the cleaning step often exceed that of the coating and curing steps, indicating the importance often assigned to this part of the coating process by many users. The specific purpose of cleaning and pretreating substrate surfaces is to control and/or modify the surface energy of the substrate so that a coating may be successfully applied to the substrate and that the coating will subsequently adhere properly to the substrate and provide the performance desired. Cleaning, as a general rule, involves the removal of substances foreign to the substrate by a surfactant/detergent

solution, followed with rinsing by a solvent that leaves the substrate surface clean of contaminants. This may have to be preceded by a mechanical sandblasting, grinding, sanding, scrubbing, etc., to remove thick layers of mil scale, rust, scum, and other built-up material on what is the real substrate. Vapor or organic solvent degreasing/cleaning is also often used to yield a clean surface for coating. These mechanical cleaning steps, along with the cleaning and rinsing of the surface with low surface tension solutions that leave no residue, are best done just before the coating step lest recontamination occur while waiting for the coating step. The goal of all these cleaning procedures is to insure a uniform surface that has a uniform contact angle, usually and desirably zero, for wetting by the coating, and to insure the interface created is the coating liquid/substrate interface only. The mechanical sanding, polishing, etc., will also contribute to a lower contact angle by the surface roughness effect discussed above. Oil, dirt, rust, or other contaminants will give poor and incomplete wetting and poor adhesion of the coating at the contaminated sites. Complete wetting is further assisted by insuring the surface tension of the coating liquid is low so that all air is displaced by the coating and the contact angle between the liquid coating and the substrate is zero, or near to it. The surface tension of the liquid coating is best lowered by the polymer of the system or by surfactant additives to the liquid system. Attempts to control the surface tension by the solvent can cause problems in having the surface tension increase as the solvent evaporates. As mentioned above, control of surface defects in coating processes is often achieved by proper cleaning and handling of the objects/substrates coated in the process [12].

Substrate pretreatment is usually performed just after the cleaning discussed above and is done to further insure complete wetting and adhesion of the coating, as well as, in the case of metallic substrates, to deposit a corrosion inhibitive layer [132]. In the case of plastic substrates, the pretreatment may be corona or flame modification to oxidize the surface layer and lower the contact angle to near zero. Metal pretreatments often involve the deposition or creation of a rough-surfaced crystalline layer of metallic phosphates, which give an easily wetted surface.

Standard Surface Phenomena Testing Methods

ASTM International is a source of testing methods and procedure documents (www.ASTM.org). Table 1 contains a listing of several ASTM documents that are related to surface technology and may be useful to those investigating in this area of science. In addition to this listing, other ASTM methods exist that may be pertinent and can be found at the above indicated web site.

TABLE 1—ASTM standards used in testing surface phenomena (partial listing)

Designation	ASTM Title
C813	Hydrophobic Contamination on Glass by Contact Angle Measurements
D971	Interfacial Tension of Oil Against Water by the Ring Method
D2578	Wetting Tension of Polyethylene and Polypropylene Films
D3825	Dynamic Surface Tension by the Fast-Bubble Technique
D5725	Surface Wettability and Absorbency of Sheeted Materials Using an Automated Contact Angle Tester
D5946	Corona-Treated Polymer Films Using Water Contact Angle Measurement
D7334	Surface Wettability of Coatings, Substrates and Pigments by Advancing Contact Angle Measurement
D7490	Measurement of the Surface Tension of Solid Coatings, Substrates and Pigments Using Contact Angle Measurements
D7541	Standard Practice for Estimating Critical Surface Tensions

SUMMARY

The concepts of surface energy, surface tension, and wetting and contact angle phenomena are of exceptional importance to the science and technology of organic coating; these are topics that are ongoing. Their understanding is vital for the proper formulation and application of coating. Many of the features of the final organic coating/substrate system are controlled by proper understanding of the surfaces of the liquid coating and the substrate, as well as creation of a proper coating/substrate interface. Both the static and dynamic aspects of liquid surface properties should be considered and the dynamic aspects properly accounted for in coating production and application. These concepts have been reviewed, and references to further reading in this important area of organic coatings science have been given.

Solubility Parameters

Charles M. Hansen[1]

NOMENCLATURE

c	=	Dispersion cohesion energy from Figs. 2 and 3
D	=	Dispersion cohesion (solubility) parameter—in tables and computer printouts
DM	=	Dipole moment—Debyes
ΔE_d	=	Dispersion cohesion energy
ΔE_p	=	Polar cohesion energy
ΔE_h	=	Hydrogen bonding cohesion energy
ΔE_V	=	Energy of vaporization (=) cohesion energy
ΔG^M	=	Molar free energy of mixing
H	=	Hydrogen bonding cohesion (solubility) parameter—in tables and computer printouts
ΔH_v	=	Molar heat of vaporization
ΔH^M	=	Molar heat of mixing
P	=	Polar cohesion (solubility) parameter—in tables and computer printouts
R	=	Gas constant (1.987 cal/mole K)
R_s	=	Distance in Hansen space
R_O	=	Radius of interaction sphere in Hansen space
RED	=	Relative energy difference, R_S/R_0
ΔS^M	=	Molar entropy of mixing
T	=	Absolute temperature
T_b	=	(Normal) boiling point
T_c	=	Critical temperature
V_M	=	Molar volume
ΔT	=	Lydersen critical temperature group contribution
α	=	Thermal expansion coefficient
δ_d	=	Dispersion cohesion (solubility) parameter
δ_h	=	Hydrogen bonding cohesion (solubility) parameter
δ_p	=	Polar cohesion (solubility) parameter
δ_T	=	Total cohesion (solubility) parameter
φ_i	=	Volume fraction of component "i"
X	=	Polymer-liquid interaction parameter (Flory-Huggins)

INTRODUCTION

SOLUBILITY PARAMETERS ARE USED IN THE COAT-ings industry to select solvents. Liquids with similar solubility parameters will be miscible, and polymers will dissolve in solvents whose solubility parameters are not too different from their own. The basic principle is "like dissolves like." Solubility parameters help put numbers into this simple qualitative idea.

The solubility parameter approach has been used for many years to select solvents for coating materials. The lack of total success has stimulated research. The skill with which solvents can be optimally selected with respect to cost, solvency, workplace environment, external environment, evaporation rate, flash point, etc., has improved over the years as a result of a series of improvements in the solubility parameter concept and widespread use of computer techniques. Most, if not all, commercial suppliers of solvents have computer programs to help with solvent selection. One can now easily predict how to dissolve a given polymer in a mixture of two solvents, neither of which can dissolve the polymer by itself.

This contribution to the paint testing manual unfortunately cannot include discussion of all of the significant efforts leading to our present state of knowledge of the solubility parameter. An attempt is made to outline developments, provide some background for a basic understanding, and give examples of uses in practice. The key is to determine which affinities the important components in a system have for each other. For coatings, this means affinities of solvents, polymers, pigment surfaces, additives, and substrates.

It is noteworthy that the concepts presented here have developed toward not just predicting solubility, which requires high affinity between solvent and solute, but to predict affinities between different polymers leading to compatibility, and affinities to surfaces to improve pigment dispersion and adhesion. Attempts are also being made to extend these developments, largely attributable to the coatings industry, to understand affinities and phenomena for a large number of other materials not specifically related to coatings. In these applications, the solubility parameter has become a tool, using well-defined liquids as energy probes, to measure the similarity, or lack of same, of key components. Materials with widely different chemical structures may be very close in affinities. Only those materials that interact differently with different solvents can be characterized in this manner. Many inorganic materials, such as fillers, do not interact differently with these energy probes since their energies are (presumed to be) very much higher. Changing their surface energies by various treatments can lead to a surface that can be characterized. It is also known that the surfaces of such materials are covered with water. The extent to which this is bound will influence practical performance, i.e., how easily can it be replaced?

Solubility parameters are cohesion energy parameters since they derive from the energy required to convert a liquid to a gas. The energy of vaporization is a direct measure of the total (cohesive) energy holding the liquid's molecules

[1] *Jens Bornoes Vej 16, 2970 Hoersholm, Denmark.*

Copyright © 2012 by ASTM International

together. All types of bonds holding the liquid together are broken by evaporation, which has led to the concepts described in more detail below. The term cohesion energy parameter is more appropriately used when referring to surface phenomena.

HILDEBRAND PARAMETERS

The term solubility parameter was first used by Hildebrand and Scott [1,2]. The solubility parameter is the square root of the cohesive energy density

$$\delta = (c \cdot e \cdot d)^{1/2} = \left(\frac{\Delta E_v}{V_M} \right)^{1/2} (\text{cal/cm}^3)^{1/2} \text{or MPA}^{1/2} \qquad (1)$$

where V_M is the molar volume and ΔE_V is the (measurable) energy of vaporization [see Eq (14)]. The solubility parameter is an important quantity in predicting solubility relations, as can be seen from the following brief introduction.

Thermodynamics requires that the free energy of mixing must be zero or negative for the solution process to occur spontaneously. The free energy change for the solution process is given by the relation

$$\Delta G^M = \Delta H^M - T\Delta S^M \qquad (2)$$

where ΔG^M is the free energy of mixing, ΔH^M is the heat of mixing, T is the absolute temperature, and ΔS^M is the entropy change in the mixing process.

The heat of mixing, ΔH^M, is given by Hildebrand and Scott as

$$\Delta H^M \approx \Delta E^M = \phi_1 \phi_2 V_M (\delta_1 - \delta_2)^2 \qquad (3)$$

where the ϕ's are volume fractions and V_M is the average molar volume of the solvent. It is important to note that the solubility parameter, or rather the difference in solubility parameters for the solvent-solute combination, is important in determining the solubility. It is clear that a match in solubility parameters leads to a zero heat of mixing, and the entropy change should ensure solution. The maximum difference in solubility parameters that can be tolerated where solution still occurs is found by setting the free energy change equal to zero in Eq (2). It is, in fact, the entropy change that dictates how closely the solubility parameters must match each other. It can also be seen that solvents with smaller molecular volumes promote lower heats of mixing, which, in turn, means that smaller solvent molecules will be thermodynamically better than larger ones when their solubility parameters are equal. A practical aspect of this effect is that solvents with relatively low molecular volumes, such as methanol and acetone, can dissolve a polymer at larger solubility parameter differences than expected from comparisons with other solvents with larger molecular volumes. The converse is also true. Larger molecular species may not dissolve even though solubility parameter considerations might predict this. This can be a difficulty with plasticizers.

A first impression ADD of the Hildebrand approach is that negative heats of mixing are not possible. Likewise, the approach is limited to regular solutions as defined by Hildebrand and Scott [2] and does not account for association between molecules, such as polar and hydrogen bonding interactions would require. The latter problem seems to have been largely solved with the use of multicomponent solubility parameters. Patterson and co-workers have cleared up many questions in polymer solution thermodynamics [3-8]. One of the more important matters was to clearly show that negative heats of mixing are allowed by the solubility parameter theory, thus eliminating one of the major mental stumbling blocks for further use of this concept.

A more detailed description of the theory presented by Hildebrand and the succession of research reports which have attempted to improve on it can be found in Barton's extensive handbook [9]. The slightly older excellent contribution of Gardon and Teas [10] is also a good source, particularly for coatings and adhesion phenomena. The approach of Burrell [11], who divided solvents into hydrogen bonding classes, has found numerous practical applications, and the approach of Blanks and Prausnitz [12], who divided the solubility parameter into two components, nonpolar and "polar," are worthy of mention, however, in that these have found wide use and greatly influenced the author's earlier activities, respectively.

It can be seen from Eq (2) that the entropy change can be considered beneficial to mixing. When multiplied by the temperature, this will work in the direction of promoting a more negative free energy of mixing. Higher temperatures will also promote this more negative free energy change. The entropy changes associated with polymer solutions will be smaller than those associated with liquid-liquid miscibility, for example, since the "monomers" are already bound into the configuration dictated by the polymer they make up. They are no longer free in the sense of a liquid solvent and cannot mix freely to contribute to a larger entropy change. This is one reason polymer-polymer miscibility is difficult to achieve. The free energy criterion dictates that the polymer solubility parameters match extremely well since there is little help from the entropy contribution when progressively larger molecules are involved. However, polymer-polymer miscibility can be promoted by introduction of suitable co-polymers or co-monomers that interact specifically within the system.

HANSEN SOLUBILITY PARAMETERS

A widely used solubility parameter approach to predicting polymer solubility is that proposed by the author. The basis of these so-called Hansen solubility parameters is that the total energy of vaporization of a liquid consists of several individual parts [13–17]. Needless to say, without the work of Hildebrand and Scott [1,2] and others not specifically referenced here such as Scatchard, this postulate could never have been made. The total cohesive energy, ΔE_t, can be measured by evaporating the liquid, i.e., breaking all the cohesive bonds. It should also be noted that these cohesive energies arise from interactions of a given solvent molecule with another of its own kind. The basis of the approach is, therefore, very simple, and it is surprising that so many different applications have been possible over the past 40 years. A number of applications are discussed below. A lucid discussion by Barton [18] enumerates typical situations where problems occur when using solubility parameters. These are most often where the environment causes the solvent molecules to interact with or within themselves differently than when they make up their own environment, i.e., as pure liquids.

Materials having similar (Hansen) solubility parameters have high affinity for each other. The extent of the similarity in a given situation determines the extent of the interaction. The same cannot be said of the total or Hildebrand solubility parameter [1,2]. Ethanol and nitromethane, for example, have similar total solubility parameters (26.1 versus 25.1 $MPa^{1/2}$, respectively), but their affinities are quite different. Ethanol is water soluble, while nitromethane is not. Indeed, mixtures of nitroparaffins and alcohols were demonstrated in many cases to provide synergistic mixtures of two nonsolvents that dissolved polymers [13].

There are three major types of interaction in common organic materials. The most general are the "nonpolar" interactions, which derive from atomic forces. These have also been called dispersion interactions in the literature. Since molecules are built up from atoms, all molecules will contain this type of attractive force. For the saturated aliphatic hydrocarbons, for example, these are essentially the only cohesive interactions, and the energy of vaporization is assumed to be the same as the dispersion cohesive energy, ΔE_d. Finding the dispersion cohesive energy as the cohesion energy of the homomorph, or hydrocarbon counterpart, is the starting point for the calculation of the three Hansen parameters for a given liquid.

The permanent dipole-permanent dipole interactions cause a second type of cohesion energy, the polar cohesive energy, ΔE_p. These are inherently molecular interactions and are found in most molecules to one extent or another. The dipole moment is the primary parameter in calculating these interactions. A molecule can be primarily polar in character without being water soluble, so there is misuse of the term "polar" in the general literature. The polar solubility parameters referred to here are well-defined, experimentally verified, and can be estimated from molecular parameters as described below. As noted above, the polar solvents include those with relatively high total solubility parameters, which are not particularly water soluble such as nitroparaffins, propylene carbonate, tri-*n*-butyl phosphate, and the like. Induced dipoles have not specifically been treated by Hansen, but are recognized as a potentially important factor, particularly for solvents with zero dipole moments.

The third major cohesive energy source is hydrogen bonding, ΔE_h. Hydrogen bonding is a molecular interaction and resembles the polar interactions in this respect. The basis of this type of cohesive energy is attraction among molecules because of the hydrogen bonds. In this perhaps oversimplified approach, the hydrogen bonding parameter has been used to more or less collect the energies from interactions not included in the other two parameters. Alcohols, glycols, carboxylic acids, and other hydrophilic materials have high hydrogen bonding parameters. Other researchers have divided this parameter into separate parts, for example, acid and base cohesion parameters, to allow both positive and negative heats of mixing. These approaches will not be dealt with here, but can be found described in Barton's Handbook [9] and elsewhere [19–21]. The most extensive division of the cohesive energy has been done by Karger et al. [22], who developed a system with five parameters: dispersion, orientation, induction, proton donor, and proton acceptor. The Hansen hydrogen-bonding parameter may be termed an electron interchange parameter as well. As a single parameter, it has remarkably accounted well for the experience of the author and keeps the number of parameters to a level, which allows ready practical usage.

It is clear that there are other sources of cohesion energy in various types of molecules arising, for example, from induced dipoles, metallic bonds, electrostatic interactions, or whatever type of separate energy can be defined. Hansen stopped with the three major types found in organic molecules. It was and is recognized that additional parameters could be assigned to separate energy types. The description of organometallic compounds could be an intriguing study, for example. This would presumably parallel similar characterizations of surface-active materials, where each separate part of the molecule requires separate characterization for completeness. The Hansen parameters have mainly been used in connection with solubility relations, mostly, but not exclusively, in the coatings industry, but their use is now spreading to other industries.

Solubility and swelling have been used to confirm the solubility parameter assignments of many of the liquids. These have then been used to derive group contribution methods and suitable equations based on molecular properties to arrive at estimates of the three parameters for additional liquids. The goal of a prediction is to determine similarity or not of the cohesion energy density parameters. The strength of a particular type of hydrogen bond or other bond, for example, is important only to the extent that it influences the cohesive energy density.

Hansen parameters do have direct application in other scientific disciplines of interest to the coatings industry, such as surface science, where they have been used to characterize the wettability of various surfaces and adsorption properties of pigment surfaces [10,14,16,23–25]. Many other applications of widely different character have been discussed by Barton [9] and Gardon [26]. Surface characterizations have not been given the attention deserved in terms of a unified similarity-of-energy approach. The author can certify that thinking in terms of similarity of energy, whether surface energy or cohesive energy, can lead to rapid decisions and plans of action in critical situations where data are lacking. In other words, the everyday industrial crisis situation can often be reduced in scope by appropriate systematic approaches based on similarity of energy.

The basic equation that governs the assignment of Hansen parameters is that the total cohesion energy, ΔE_t, must be the sum of the individual energies that make it up

$$\Delta E_t = \Delta E_d + \Delta E_p + \Delta E_h \tag{4}$$

Dividing this by the molar volume gives the square of the total (or Hildebrand) solubility parameter as sum of the squares of the Hansen *D, P,* and *H* components.

$$\frac{\Delta E_t}{V_M} = \frac{\Delta E_d}{V_M} + \frac{\Delta E_p}{V_M} + \frac{\Delta E_h}{V_M} \tag{5}$$

$$\delta_t = \delta_d^2 + \delta_p^2 + \delta_h^2 = D^2 + P^2 + H^2 \text{ (computer printouts)} \tag{6}$$

METHODS AND PROBLEMS IN THE DETERMINATION OF PARTIAL SOLUBILITY PARAMETERS

The best method to calculate Hansen solubility parameters depends to a great extent on what data are available.

Hansen originally adopted an essentially experimental procedure and established numbers for 90 liquids based on solubility data for 32 polymers [13]. This procedure involved calculation of the nonpolar parameter according to the procedure outlined by Blanks and Prausnitz [12]. This calculational procedure is still in use and is considered to be the most reliable and consistent for this parameter. It is outlined below. The division of the remaining cohesive energy between the polar and hydrogen bonding interactions was done by trial and error to fit experimental polymer solubility data. A key to parameter assignments in this initial trial and error approach was that mixtures of two nonsolvents could be systematically found to synergistically (but predictably) dissolve given polymers. This meant that these had parameters placing them on opposite sides of the solubility region, a spheroid, from each other. Having a large number of such predictably synergistic systems as a basis, reasonably accurate divisions into the three energy types were possible.

Using the experimentally established, approximate, δ_p and δ_h parameters, Skaarup [15] found that the Böttcher equation could be used to calculate the polar parameter quite well, and this led to a revision of the earlier values to those now in wide use for these same liquids. These values were also consistent with the experimental solubility data for 32 polymers available at that time and Eq (6). Furthermore, Skaarup developed the equation for the solubility parameter "distance," R_s, between two materials based on their respective partial solubility parameter components

$$R_s = 4(\delta_{d1} - \delta_{d2})^2 + (\delta_{p1} - \delta_{p2})^2 + (\delta_{h1} - \delta_{h2})^2 \qquad (7)$$

This equation was developed from plots of experimental data where the constant 4 was found convenient and correctly represented the solubility data as a sphere encompassing the good solvents. When the scale for the dispersion parameter is doubled compared with the other two parameters, essentially spherical rather than spheroidal regions of solubility are found. This greatly aids two-dimensional plotting and visualization. There are, of course, boundary regions where deviations can occur. These are most frequently found to involve the larger molecular species being less-effective solvents compared with the smaller counterparts that define the solubility sphere. Likewise, smaller molecular species, such as acetone and methanol, often appear as outliers in that they dissolve a polymer even though they have solubility parameters placing them at a distance greater than the solubility sphere radius, R_0. This dependence on molar volume is inherent in the theory developed by Hildebrand and Scatchard as discussed above. Smaller molar volume favors lower heats of mixing, which in turn promotes solubility. Such smaller molecular volume species, which dissolve "better" than predicted by comparisons based on solubility parameters alone, should not necessarily be considered outliers. This statement is justified by Eq (3), where it can be seen that the molar volume and the square of the solubility parameter difference are weighted equally in estimating the heat of mixing in the Hildebrand theory.

The molar volume is frequently used as a fourth parameter to describe molecular size effects. These are especially important in correlating diffusion phenomena with the solubility parameter, for example. The author has preferred to retain the three well-defined, partial solubility parameters with a separate, fourth, molar volume parameter, rather than to multiply the solubility parameters by the molar volume raised to some power to redefine them. In response to a reviewer request stating that molar volumes calculated by software that is generally available do not agree with those found by the author, it can be said that the approach of dividing the molecular weight by the density was the way the molar volume was found when the ideas for this chapter emerged over 40 years ago. The author has seen no reason to diverge from this practice. When densities are not known or cannot be found in standard reference works, recourse can be taken to comparison with related compounds or other suitable procedure for determining the density. There are various types of free volume, which can be a cause of some difference in estimations depending on the assumptions made, but a deeper discussion at this point appears to be beyond the scope of this chapter.

The exact reason for the constant 4 in Eq (7) is discussed below. It is currently considered both as an experimental result related to the entropy changes in the systems described and as a theoretically well-defined constant. The author has also found in unpublished studies that values close to 5 could represent solubility data equally well for a few cases studied. The differences in solubility parameters between the solvent and solute in the polar and hydrogen bonding parameters are larger by a factor of two than is tolerated when nonpolar solvents dissolve the same polymer. This factor of 2 is squared to give 4 in Eq (7). The term "specific interactions" is often applied to the molecular polar and molecular hydrogen bonding (electron interchange) interactions implying that these are especially beneficial to achieving a solution since larger differences in the characteristic parameters are allowed with a successful result.

Another way to view this is as follows. It is assumed that the (center-of-the-sphere) partial solubility parameters assigned by computer optimization techniques to polymers using Eq (7) are the theoretically correct ones. A solvent with parameters corresponding to the center is to be changed in quality. If the nonpolar parameter difference only is changed by one unit, the effect on R_s is four units. If the polar or hydrogen bonding parameter difference is changed by one unit, the effect on R_s is also one unit. The entropy changes associated with the polar and hydrogen interactions have reduced the total (free energy change) effect by a factor of 4 and are thus four times larger than those associated with the nonpolar interactions.

The discussion above follows from the fact that the boundaries of the regions of solubility are characterized by a free energy change of zero for the solution process. The Flory-Huggins limiting chi parameter, χ, of about 0.5 is also characteristic for the boundary of the solubility region. Patterson [6,27], in particular, has been instrumental in showing the relations between the chi parameter and solubility parameters. Patterson's work led to the developments reported in the next section. This is strictly valid only for the interactions described by this theory. So-called theta solvents will also be located in boundary regions on solubility parameter plots with these same restrictions. Much polymer research has focused on these boundary

regions only, for the above reasons and because relatively small changes in temperature, molecular weight, solvent quality, etc., give large easily measurable changes in other quantities.

The approach of computer optimizing solubility data to spheres, which is currently in use, still seems most favorable, at least until an improvement is offered by an improved theory. Plotting experimental solubility data defines boundaries of solubility, which in fact are fixed by the free energy of mixing being experimentally equal to zero.

Equation (7) is readily used on a computer (or on a hand calculator), and supplementary relations allow easier scanning of large sets of data. It is obvious that solubility, or high affinity, requires that R_s be less than R_0. The ratio R_s/R_0 has been called the RED number, reflecting the relative energy difference. A RED number of 0 is found for no energy difference. RED numbers less than 1.0 indicate high affinity, RED equal to or close to 1.0 is a boundary condition, and progressively higher RED numbers indicate progressively lower affinities. Scanning a sizeable computer output for RED numbers less than 1.0, for example, rapidly allows location of the most interesting liquids for a given application.

The revised set of parameters for the 90 solvents was the basis for group contribution procedures developed by (most notably) Van Krevelen [28] and Beerbower [17,29], who also used Fedors, work [30]. These various developments have been summarized by Barton [9], although Beerbower's latest values have only appeared in the NASA document [29]. Table 1 is an expanded table of Beerbower group contributions, which was distributed among those who were in contact with Beerbower in the late 1970s. Beerbower also developed a simple equation for the polar parameter [17], which involved only the dipole moment and the square root of the molar volume. This is also given below and has been found quite reliable by Koehnen and Smolders [31]. This equation has also been found reliable by the author as well, giving results generally consistent with Eq (6), which, again, is the basis of the whole approach. Koehnen and Smolders also give correlation coefficients for other calculation procedures to arrive at the individual Hansen parameters.

A sizeable number of liquids have now been assigned Hansen parameters using the procedures described here. Many of these have not been published. Exxon Chemical Corporation [32,33] has indicated a computer program with data for over 500 solvents and plasticizers, 450 resins and polymers, and 500 pesticides. The author's files contain the three parameters for about 1200 liquids, although several of them appear with two or three sets of possible values awaiting experimental confirmation. In some cases, this is due to questionable physical data, for example, for latent heats of vaporization or wide variations in reported dipole moments. Another reason for this is that some liquids are chameleonic [34] as defined by Hoy in that they adopt configurations depending on their environment. Hoy [34] cites the formation of cyclic structures for glycol ethers with (nominally) linear structure. The formation of hydrogen bonded tetramers of alcohols in a fluoropolymer has also been cited [35]. The term "compound formation" can be found in the older literature, particularly where mixtures with water were involved, and structured species were postulated to explain phenomena based on specific interactions among the components of the mixtures. Barton has recently discussed some of these situations and points out that Hildebrand or Hansen parameters must be used with particular caution where the extent of donor-acceptor interactions, and in particular hydrogen bonding within a compound, is very different from that between compounds [18]. Amines and water, for example, are known to associate. Pure component data cannot be expected to predict the behavior in such cases.

Still another reason for difficulties is the large variation of dipole moments reported for the same liquid. The dipole moment for some liquids depends on their environment, as discussed below. A given solvent can be listed with different values in files to keep these phenomena in mind.

Large data sources greatly enhance searching for similar materials and locating new solvents for a polymer based on limited data, for example. Unfortunately, different authors have used different group contribution techniques, and there is a proliferation of different "Hansen" parameters for the same chemicals in the literature. This would seem to be an unfortunate situation, but may ultimately provide benefits. In particular, partial solubility parameter values found in Hoy's extensive tables [9,36] are not compatible with the customary Hansen parameters reported here. Hoy has provided an excellent source of total solubility parameters. He independently arrived at the same type division of cohesion energies as Hansen, although the methods of calculation are quite different.

Many solvent suppliers have also presented tables of solvent properties and/or use computer techniques to get these in their technical service. Partial solubility parameters not taken directly from earlier well-documented sources should be used with caution. In particular it can be noted that the Hoy dispersion parameter is consistently lower than that found by Hansen. Hoy subtracts estimated values of the polar and hydrogen bonding energies from the total energy to find the dispersion energy. This allows for more calculation error and underestimates the dispersion energy since the Hoy procedure does not appear to fully separate the polar and hydrogen bonding energies. The Van Krevelen dispersion parameters appear too low. The author has not attempted these calculations, being completely dedicated to the full procedure described here, but values estimated independently based on the Van Krevelen dispersion parameters are clearly low. A comparison with related compounds, or similarity principle, gives better results than those found from the Van Krevelen dispersion group contributions.

In the following, calculation procedures and experience are presented according to the procedures found most reliable for the experimental and/or physical data available for a given liquid.

RECENT DEVELOPMENTS—THEORY

A new understanding of the Hansen solubility parameter approach has developed since the publishing of the 14th edition of the Gardner-Sward Handbook [37,38]. Chapter 2 in Ref. [38] and also Chapter 2 in Ref. [39] include a comparison of the HSP approach with different theories of polymer solution behavior. These include those developed or modified by Huggins, Flory, Hildebrand, Prigogine, and Patterson [6,27,38–42].

[a]Based on very limited data. Limits shown are roughly 95 % confidence; in many cases, values are for information only and not to be used for computation.
[b]Includes unpublished infrared data.
[c]Use formula in $\Delta V\delta_p^2$ column in calculation, with *V* for total compound.
[d]Twin and triplet values apply to halogens on the same C atom, except that $\Delta V\delta_p^2$ also includes those on adjacent C atoms.
[e]These values apply to halogens attached directly to the ring and also to halogen attached to aliphatic double-bonded C atoms.
[f]From R. F. Fedors[25].

For those familiar with the widely used Flory interaction coefficient, χ_{12} it can be shown [38,39] that there is a relation between this and the RED number given by Eq (8).

$$\chi_{12} \text{ corresponds to } \chi_c\,(\text{RED})^2 \qquad (8)$$

χ_c is usually taken as being near 1/2 for the interaction of typical solvents with polymers of very large molecular weight. Unfortunately, χ_{12} does not explicitly take account of hydrogen bonding. Equation (8) is therefore only indicative of a relation had the Flory approach included polar and hydrogen bonding interactions explicitly.

It is instructive to arrange Eq (8) in the form given in Eq (9):

$$(\text{RED})^2 = (R_s/R_o)^2 \text{ corresponds to } \chi_{12}/\chi_c \qquad (9)$$

$(R_s)^2$ corresponds to χ_{12}, both being interaction parameters. These are respectively divided by the corresponding limiting or critical values that allow solubility to find $(\text{RED})^2$. These limiting values are $(R_o)^2$ in the Hansen system and χ_c in the Huggins-Flory approach. Thus R_s greater than R_o indicates nonsolubility just as values of χ_{12} greater than χc have the same function. Values of R_s and χ_{12} that are less than zero are not allowed (even though one finds many measured values of the latter in the literature which are negative).

The coefficient 4 in Eq (7) has been found correct for all practical purposes in over 1,000 correlations using Hansen solubility parameters. The coefficient 4 in front of the difference in the nonpolar interactions shows that the specific interactions described by the differences in the polar and hydrogen bonding parameters are only 0.25 times as significant as the differences in the nonpolar term. This factor (0.25) is predicted theoretically by the Prigogine corresponding states theory of polymer solutions for the importance of specific interactions relative to the atomic/nonpolar interactions [38–42]. This same factor can also be traced back to still earlier approaches (Lorentz-Berthelot mixtures) studying affinities among gases, for example [42]. The Hansen approach and the (first term in the) Prigogine approach are in agreement with each other. The so-called geometric mean to estimate the interaction between two unlike species is used in both of these, and the coefficient 4 experimentally confirms that this type of mean is also valid for hydrogen bonding interactions. The coefficient 4 must be used to differentiate the behavior of the atomic (nonpolar, dispersion, or London) type forces from that of the molecular dipolar and molecular hydrogen bonding forces. The Hansen approach cannot be considered empirical. The Huggins-Flory and subsequent "new Flory" approaches seem inadequate for other than strictly nonpolar systems since hydrogen bonding is not included. The pioneering Hildebrand solubility parameter approach did not treat specific interactions either, although it led the author to develop the Hansen approach that does. The Prigogine approach is too difficult to use and lacks specific consideration of hydrogen bonding as well. This leaves the Hansen approach as the only proven, reliable, and generally useful means to systematically study the common types of interactions involved in systems with hydrogen bonding and with permanent dipoles. It is not in conflict with the other theories. It extends them in a general way to applications with polar and hydrogen bonding.

Panayiotou has recently used a statistical thermodynamica approach to calculate the HSP that is reported in Chapter 3 in Ref. [39]. Expanding on earlier work, he first calculates the hydrogen bonding solubility parameter. After this the other HSP and the total solubility parameter are calculated. There is also a new large set of group contributions to help those not fully competent in statistical thermodynamics. The values for all the parameters for about 50 liquids calculated by Panayiotou are in amazingly good agreement with those reported by Hansen over 40 years ago [13–16]. There is also exceptionally good agreement for a number of the common polymers. These results, coupled with the agreement, or perhaps better, lack of disagreement, with the other theories of polymer solutions, appear to confirm that the three-parameter approach based on a division of the cohesion energy is fundamentally sound.

CALCULATION OF THE DISPERSION SOLUBILITY PARAMETER, δ_d

The δ_d parameter is calculated according to the procedures outlined by Blanks and Prausnitz [12]. Figs. 1 and 2, or 3, can be used to find this parameter depending on whether the molecule of interest is aliphatic, cycloaliphatic, or aromatic. These figures have been inspired by Barton [9], who converted earlier data to SI units. All three of these figures have been straight line extrapolated into a higher range of molar volumes than that reported by Barton. Energies found with these extrapolations have also provided consistent results. The solubility parameters in SI units, $\text{MPa}^{1/2}$, are 2.0455 times larger than those in the older centimeter, gram, second system, $(\text{cal/cc})^{1/2}$, which still finds extensive use in the United States, for example.

The figure for the aliphatic liquids gives the dispersion cohesive energy, ΔE_d, whereas the other two figures directly report the dispersion cohesive energy density, c. The latter is much simpler to use since one needs only take the square root of the value found from the figure to find the respective partial solubility parameter. Barton also presented a similar figure for the aliphatic solvents, but it is inconsistent with the energy figure and in error. Its use is not recommended. When substituted cycloaliphatics or substituted aromatics are considered, simultaneous consideration of the two separate parts of the molecules is required. The dispersion energies are evaluated for each of the types of molecules involved, and a weighted average for the molecule of interest based on numbers of significant atoms is taken. For example, hexyl benzene would be the arithmetic average of the dispersion energies for an aliphatic and an aromatic liquid, each with the given molar volume of hexyl benzene. Liquids such as chlorobenzene, toluene, and ring compounds with alkyl substitutions with only two or three carbon atoms have been considered as cyclic compounds only. Such weighting has been found necessary to satisfy Eq (6).

The author has directly used these figures to find the cohesion energy for nonpolar molecules. This introduces a small but unaccountable error since, for example, ΔE_D, for an aromatic compound such as toluene, is not equal to the total cohesion energy ΔE_t. In practice (so far) this has not led to any apparent problems. The error becomes less significant as the polar and hydrogen bonding effects increase.

The critical temperature, T_c, is required to use the dispersion energy figures. If the critical temperature cannot be found, it must be estimated. A table of the Lydersen group contributions, ΔT, [43] as given by Hoy [36] for calculation of the critical temperature, is included here as Table 2. In some cases, the desired groups may not be in the table, which means some educated guessing is required. The end result does not appear too sensitive to these situations. The normal boiling temperature, T_b, is also required in this calculation. This is not always available, either, and must be estimated by similarity, group contribution, or

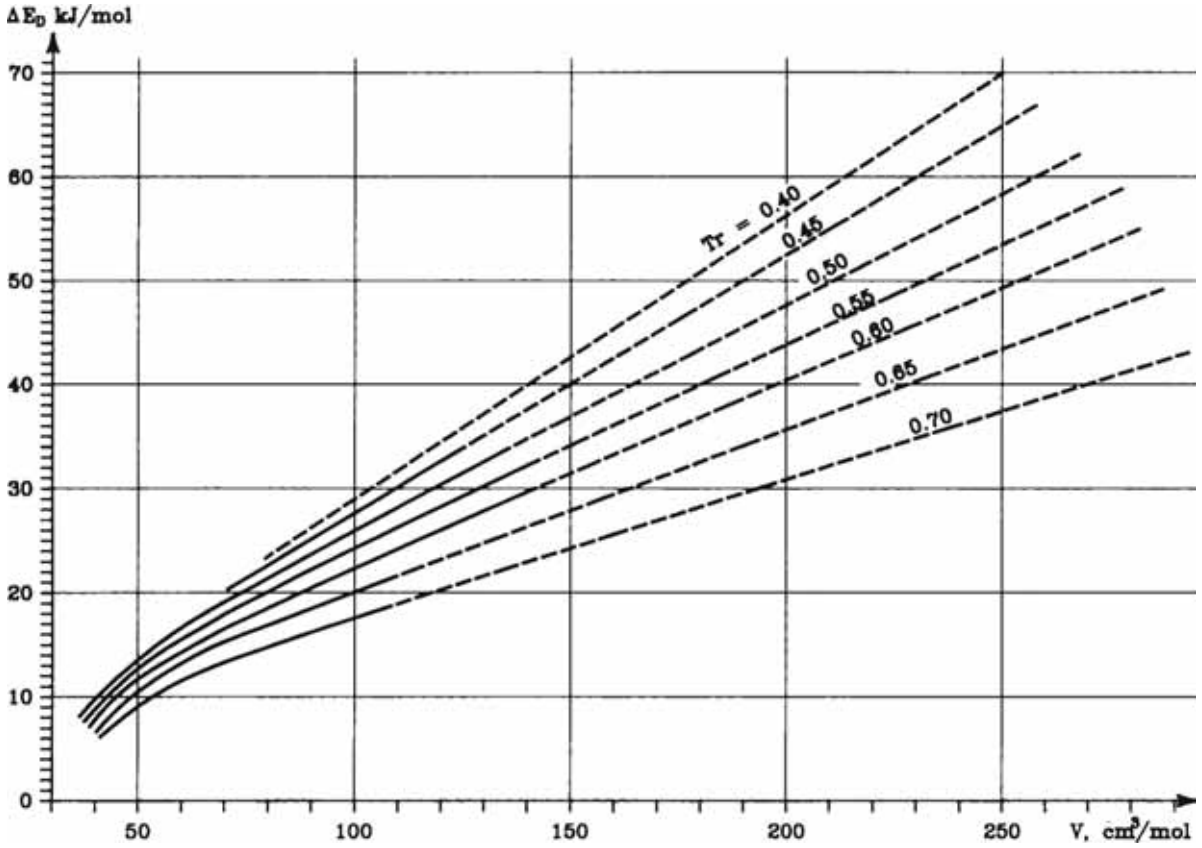

Fig. 1—Energy of vaporization for straight chain hydrocarbons as a function of molar volume and reduced temperature.

other technique. The Lydersen group contribution method involves the use of Eqs (10) and (11),

$$T_b / T_c = 0.567 + \sum \Delta_T - \left(\sum \Delta_T\right)^2 \quad (10)$$

$$T_r = T / T_c \quad (11)$$

where T has been taken as 298.15 K.

The dispersion parameter is an atomic force parameter. The size of the atom is important. It has been found that corrections are required for atoms significantly larger than carbon, such as chlorine, sulfur, bromine, etc., but not for oxygen or nitrogen, which have a similar size. The carbon atom in hydrocarbons is the basis of the dispersion parameter in its present form. These corrections are applied by first finding the dispersion cohesive energy from the appropriate figure. This requires multiplication by the molar volume for the cyclic compounds using data from the figures here since these figures give the cohesive energy densities. The dispersion cohesive energy is then increased by adding on the correction factor. This correction factor for chlorine, bromine, and sulfur has been taken as 1,650 J/mol for each of these atoms in the molecule. Dividing by the molar volume and then taking the square root gives the (large atom corrected) dispersion solubility parameter.

The need for these corrections has been confirmed many times, both for interpretation of experimental data

and to allow Eq (6) to balance. Research is definitely needed in this area. The impact of these corrections is, of course, larger for the smaller molecular species. The taking of square roots of the larger numbers involved with the larger molecular species reduces the errors involved in these cases since the corrections themselves are relatively small.

It can be seen from the dispersion parameters of the cyclic compounds that the ring also has an effect similar to increasing the effective size of the interacting species. The dispersion energies are larger for cycloaliphatic compounds than for their aliphatic counterparts, and they are higher for aromatic compounds than for the corresponding cycloaliphatics. Similar effects also appear with the ester group. This group appears to act as if it were, in effect, an entity that is larger than the corresponding compound containing only carbon (i.e., its homomorph), and it has a higher dispersion solubility parameter without any special need for corrections.

The careful evaluation of the dispersion cohesive energy may not have major impact on the value of the dispersion solubility parameter itself because of the taking of square roots. Larger problems arise because of Eq (4). Energy assigned to the dispersion portion cannot be reused when finding the other partial parameters using Eq (4) [or Eq (6)]. This is one reason why group contributions are recommended for the polar and hydrogen bonding components in some cases below. The author has not used older tables of group contributions for the dispersion parameter. These were found to be not as reliable as the longer procedure discussed above when data are available. Frequent use has been made of simple comparisons of similarity to molecules whose dispersion parameters have already been established. The group contributions for the dispersion solubility parameter presented by Panayiotou in Chapter 3 in Ref. [39] appear to be a good third alternative, however.

CALCULATION OF THE POLAR SOLUBILITY PARAMETER, δ_p

The earliest assignments of a polar solubility parameter were given by Blanks and Prausnitz [12]. These parameters were in fact the combined polar and hydrogen bonding parameters as used by Hansen and cannot be considered polar in the current context. The first Hansen polar parameters [13] were reassigned new values by Skaarup according to the Böttcher equation [15]. This equation requires the molar volume, the dipole moment (DM), the refractive index, and the dielectric constant. These are not available for many compounds, and the calculation is somewhat more difficult than using the much simpler equation developed by Beerbower [17]

$$\delta_p = \frac{37.4}{(V_M)^{1/2}}(\mathrm{DM}) \qquad (12)$$

The constant 37.4 gives this parameter in SI units.

Equation (12) has been consistently used by the author over the past few years, particularly in view of its reported reliability [31]. This reported reliability appears to be correct. The molar volume must be known or estimated in one way or another. This leaves only the dipole moment to be found or estimated. Standard reference works have tables of dipole moments, with the most extensive listing still being McClellan [44]. Other data sources also have this parameter as well as other relevant parameters and data such as latent heats and critical temperatures. The so-called DIPPR database has been found useful for many compounds of reasonably common usage, but many interesting compounds are not included in DIPPR. This abbreviation is for Design Institute for Physical Property Research,[2] Project 801 of the American Institute of Chemical Engineers at the Pennsylvania State University [45]. When no dipole moment is available, similarity with other compounds, group contributions, or experimental data can be used to estimate the polar solubility parameter.

It must be noted that the fact of zero dipole moment in symmetrical molecules is not basis enough to assign a zero polar solubility parameter. An outstanding example of variations of this kind can be found with carbon disulfide. The reported dipole moments are mostly 0 for gas phase measurements, supplemented by 0.08 in hexane, 0.4 in carbon tetrachloride, 0.49 in chlorobenzene, and 1.21 in nitrobenzene.

There is a clear increase with increasing solubility parameter of the media. The latter and highest value has been found experimentally most fitting for correlating permeation through a fluoropolymer film used for chemical protective clothing [46]. Many fluoropolymers have considerable polarity. The lower dipole moments seem to fit in other instances. Diethylether has also presented problems as an outlier in terms of dissolving or not, or rapid permeation or not. Here the reported dipole moments [44] vary from 0.74 to 2.0 with a preferred value of 1.17, and with 1.79 in chloroform. Choosing a given value seems rather arbitrary. The chameleonic cyclic forms of the linear glycol ethers would also seem to provide for a basis of altered dipole moments in various media [34].

When Eq (12) cannot be used, the polar solubility parameter has been found using the Beerbower table of group contributions, by similarity to related compounds, and/or by subtraction of the dispersion and hydrogen bonding cohesive energies from the total cohesive energy. The question in each case is: "Which data are available and judged most reliable?" New group contributions have also been developed from related compounds where their dipole moments are available. These new polar group contributions then become supplementary to the Beerbower table.

For large molecules, especially those with long hydrocarbon chains, the accurate calculation of the relatively small polar (and hydrogen bonding) contributions present special difficulties. The latent heats are not generally available with sufficient accuracy to allow subtraction of two large numbers from each other to find a very small one. In such cases the similarity and group contribution methods are thought best. Unfortunately, latent heats found in a widely used handbook [47] are not clearly reported as to the reference temperature. There is an indication that these are 25°C data, but checking indicated many of the data were identical with boiling point data reported elsewhere in the literature. A more recent edition of this handbook has a completely different and less voluminous section for the latent heat of evaporation [48]. Again, even moderate variations in reported heats of vaporization can cause severe

[2]Design Institute for Physical Property Research, Department of Chemical Engineering, 167 Fenske Laboratory, The Pennsylvania State University, University Park, PA 16802.

problems in calculating the polar (or hydrogen bonding) parameter when Eqs (4) or (6) are strictly adhered to.

CALCULATION OF THE HYDROGEN BONDING SOLUBILITY PARAMETER, δ_h

In the earliest work, the hydrogen bonding parameter was almost always found from the subtraction of the polar and dispersion energies of vaporization from the total energy of vaporization. This is still widely used where the required data are available and reliable. At this stage, however, the group contribution techniques are considered reasonably reliable for most of the required calculations and, in fact, more reliable than estimating several of the other parameters to ultimately arrive at the subtraction step just mentioned. Therefore, in the absence of reliable latent heat and dipole moment data, group contributions are judged to be the best alternative. Similarity to related compounds can also be used, of course, and the result of such a procedure should be essentially the same as for using group contributions. The work of Panayiotou in Chapter 3 of Ref. [39], discussed above, also provides an alternative method to arrive at the hydrogen bonding parameter.

SUPPLEMENTARY CALCULATIONS AND PROCEDURES

The procedures listed above are those most frequently used by the author in calculating the three partial solubility parameters for liquids where some data are available. There are a number of other calculations and procedures that are also helpful. Latent heat data at 25°C have consistently been found from latent heats at another temperature using the relation given by Fishtine [49].

$$\frac{\Delta H_v(T_1)}{\Delta H_v(T_2)} = \left[\frac{T_c - T_1}{T_c - T_2}\right]^{0.38} = \left[\frac{1 - T_{r1}}{1 - T_{r2}}\right]^{0.38} = \left[\frac{1 - T_{r1}}{1 - T_{r2}}\right]^{0.38} \quad (13)$$

This is done even if the melting point of the compounding being considered is higher than 25°C. The result is consistent with all the other parameters, and to date no problems with particularly faulty predictions have been noted in this respect, i.e., it appears as if the predictions are not significantly in error. When the latent heat is given in cal/mole, the above equation is used to estimate the latent heat at 25°C. RT equal to 592 cal/mole is then subtracted from this according to Eq (14) to find the total cohesion energy, ΔE_V, in cgs units at this temperature:

$$\Delta E_v = \Delta E_t = \Delta H_v - RT \quad (14)$$

Only limited attempts have been made to calculate solubility parameters at a higher temperature. Solubility parameter correlations of phenomena at higher temperatures have generally been found satisfactory when the established 25°C parameters have been used. Recalculation to higher temperatures is possible, but has not been found necessary. In this direct but approximate approach, it is assumed that the parameters all demonstrate the same temperature dependence, which, of course, is not the case. It might be noted in this connection that the hydrogen bonding parameter, in particular, is the most sensitive to temperature. As the temperature is increased, more and more hydrogen bonds are progressively broken, and this parameter will decrease more rapidly than the others.

The gas phase dipole moment is not temperature dependent, although the volume of the fluid does change with temperature, which will change its cohesive energy density. Beerbower has suggested relations to predict the changes of the partial solubility parameters with temperature [17]. The coefficient of thermal expansion, α, appears in all of these relations. These are

$$\frac{d(\delta_d)}{dT} = -1.25\alpha\delta_d \quad (15)$$

$$\frac{d(\delta p)}{dT} = -0.5\alpha\delta_p \quad (16)$$

$$\frac{d(\delta p)}{dT} = -\delta_H(1.22\times10^{-3} + 0.5\alpha) \quad (17)$$

A computer program has been developed by the author to assign the three Hansen parameters for solvents based on experimental data alone. This has been used in several cases where the parameters for the given liquids were desired with a high degree of accuracy. The procedure is to enter solvent quality, good or bad, into the program for a reasonably large number of polymers where the solubility parameters and appropriate radius of interaction for the polymers are known. The program then locates that set of δ_d, δ_p, and δ_h parameters for the solvent that best satisfies the requirements of a location within the spheres of the appropriate polymers where solvent quality is good and outside of the appropriate spheres where it is bad.

An additional aid in estimating the Hansen parameters for many compounds is that these parameters can be found by interpolation or extrapolation, especially for homologous series. The first member may not necessarily be a straight line extrapolation, but comparisons with related compounds should always be made where possible to confirm assignments. Plotting the parameters reported in Table 3 for homologous series among the esters, nitroparaffins, ketones, alcohols, and glycol ethers will aid in finding the parameters for related compounds.

Table 3 contains Hansen solubility parameters for a large number of liquids and plasticizers. These are given in SI units. Over 800 HSP values can be found in Refs. [38,39].

SOLUBILITY PARAMETERS FOR POLYMERS

The solubility parameters for numerous polymers and film formers are given in Table 4. Suppliers and trademarks are given in Table 5. These data are based on solubility determinations unless otherwise noted. There are four parameters, the three describing the nonpolar, polar, and hydrogen bonding interactions as for the liquids, and the fourth, R_0, a radius of interaction for the type of interaction described. Most of these are taken from a report [50] from the Scandinavian Paint and Printing Ink Research Institute. (This institute unfortunately no longer exists.) Additional values have been contributed according to the notes in the table to indicate the types of data, which have been correlated with these techniques. Barton [51] has also provided solubility parameters for many polymers in a handbook. Additional values are also found in Refs. [38,39].

Experimental determination of polymer solubility parameters involves trying to dissolve the polymer at a

[a] Indicates use in author's standard set of test solvents.

given concentration, usually 10 % by weight, in a selection of solvents intended to maximize information regarding all types of interaction. Whenever possible, the author uses a set of parameters indicated with an "[a]" in Table 3. The "yes" or "no" solubility data can be plotted by hand or processed by computer to yield a "spherical" characterization as described above. Teas [52] has developed a triangular plotting technique, which helps visualization of three parameters on a plain sheet of paper. Examples are found in Refs. [9,10] as well.

Swelling, weight gain, solvent resistance, and surface attack have also been used as a primary data to characterize polymers. The weighted-averaging of the respective Hansen solubility parameters for the test liquids should be done with caution. Many polymers have polar and hydrogen bonding parameters higher than any liquids, for which

TABLE 5—List of suppliers and trademarks for paint binders and polymers

Suppliers	Trademarks
Bayer (D)	Cellit, Desmophen, Desmolac, Pergut, Cellidora, Desmodur, Baysilon Alkydal
Hercules (USA)	Piccolyte, Cellolyn, Pentalyn, Ester Gum, Parlon
Ciba-Geigy	Araldite
Shell (D)	Epikote, Cariflex
Union Carbide (USA)	Vinylite, Phenoxy
Hoechst (D)	Macrynal, Phenodur, Alpex, Mowithal, Alftalat, Mowilith
Reichhold (CH)	Super Beckasite, Uformite
Polymer Corp. (CAN)	Polysar
Goodrich (USA)	Hycar
Huls (D)	Vilit, Vesturit, Buna Huls
BASF (D)	Lutonal, Laroflex, Plastopal, Polystyren
Monsanto (USA)	Modaflow, Multiflow, Butvar
Montecatini Edison (I)	Vipla
ICI (GB)	Cereclor, Allopren, Suprasec
Du Pont (USA)	Lucite
Hagedorn (D)	1/2-sec. nitrocellulose H 23
Röhm (D)	Plexigum
Rohm and Haas (USA)	Paraloid
Dynamit Nobel (D)	Dynapol
SOAB (S)	Soamin
BIP Chemicals (GB)	Beetle
Dyno Cyanamid (N)	Dynomin
DSM Resins (S)	Uracron
Reichhold Chemie (CH)	Super Beckasite, Uformite
Wacker (D)	Wacker
Dow Chemical (CH)	Ethocel
Cray Valley Prod. (GB)	Versamid
W. Biesterfeld (D)	Chlorparaffin
Synres (NL)	Synresen
American Cyanamide (USA)	Cymel
Polyplex (DK)	Plexal
Pennsylvania Industrial Chemical Corp. (USA)	Piccopal, Piccoumarone

reason any average will be too low. This is discussed in more detail in Refs. [38,39].

APPLICATIONS

There are many applications documented in the literature where solubility parameters have aided in selection of solvents, understanding and controlling processes, and, in general, offered guidance where affinities among materials are of prime importance. In all of the examples below the technical aspects only are discussed. It is clear that worker safety and environmental impact must also be considered in any solvent usage. Discussion of these aspects is beyond the scope of this report.

To find the optimum solvent for a polymer using solubility parameters, it is most desirable to have the solubility parameters for the polymer. Matching the parameters of an already existing solvent or combination of solvents can be done, but does not necessarily optimize the new situation. The optimum depends on what is desired of the system. A solvent with highest possible affinity for the polymer is both expensive and probably not necessary.

Most coatings applications involve solvents safely within the solubility limit with a maximum of cheaper hydrocarbon solvent. Some safety is advised because temperature changes, potential variations in production, etc., can lead to a situation where solvent quality changes in an adverse manner. Balance of solvent quality on evaporation of mixed solvents is also necessary. Here again computer approaches are possible.

An oxygenated solvent frequently added to hydrocarbon solvent and that has been cost effective in increasing the very important hydrogen bonding solubility parameters has been *n*-butanol. The mixture of equal parts xylene and *n*-butanol can be used in conjunction with many polymers, but a third solvent, such as a ketone or ester, is often included in small amounts to increase the polar parameter/solvency of the mixture. Glycol ethers can also be added to hydrocarbon solvents with advantage, and the polar and hydrogen bonding parameters are higher than had *n*-butanol been added to the same concentration. There are many possibilities, and a solubility parameter approach is particularly valuable in quickly limiting the number of candidates.

Coalescing solvents in water-reducible coatings are often those with somewhat higher hydrogen bonding parameters than the polymer, which also means they are water soluble or have considerable water solubility. The distribution between the water phase and the dispersed polymer phase depends on the relative affinities for water and the polymer. Solvents that are not particularly water soluble will preferentially be found in the polymer phase. Such coalescing solvents may be preferred for applications to porous substrates, making certain they are where they are needed. Otherwise a water-soluble coalescing solvent would tend to follow the aqueous phase penetrating the substrate and not be available to do its job in the film itself.

When water evaporates, the solvent must dissolve to some extent in the polymer to promote coalescence. This can be determined and adjusted by either increasing or decreasing the affinity for the polymer.

Amines are frequently added in water-reducible coatings to neutralize acid groups in polymers, thus providing a water-solubilizing amine salt. Amine in excess of that required

for total neutralization acts like a solvent. Such amine salts have been characterized separately to demonstrate that they have higher solubility parameters than either (acetic) acid or organic bases [53]. These salts are hydrophilic and have very little affinity for coatings polymers, which means they are to be found in a stabilizing role in interfaces in the aqueous phase, still being attached to the polymer. Electrostatic repulsion contributes to stability as well.

Surface active agents, whether nonionic or ionic, are also to be found where the affinities of the respective parts of their molecules dictate their placement. The hydrophilic end with a high hydrogen bonding parameter will be in the aqueous phase, and the hydrophobic end will seek out an environment where energy differences are lowest.

Increases in temperature lead to lower hydrogen bonding parameters, especially. For this reason, solvents with high hydrogen bonding parameters, such as glycols, glycol ethers, and alcohols, become better solvents for most polymers at higher temperatures. This can markedly affect hot-room stability in water-reducible coatings, for example, since more of the solvent will partition to the polymer phase, which swells, becomes more fluid, and has altered affinities for stabilizing surface active agents, for example. They may dissolve too readily in the dispersed polymer. Carefully controlled, these temperature effects are an advantage in water-reducible, oven-cured coatings, leading to higher film integrity.

A simple approach to many practical problems is to make a two-dimensional plot of polar versus hydrogen bonding parameters with a circle (or estimated circle) for the polymer in question. One can plot the points for potential solvents and quickly arrive at a starting composition for an experiment. This can subsequently be adjusted if necessary. It should also be kept in mind that cyclic solvents generally have higher nonpolar parameters than aliphatic solvents.

A long list of applications, in coatings and elsewhere, was provided as early as 1975 in a review article by Barton [54]. Many applications are given in Table 6 and in the present discussion to give an idea of what can be studied systematically using this concept. More recent references and varied applications can be found in Refs. [9,10,38,39].

Beerbower [55] has given many of the more theoretical applications for solubility parameters including correlations of the Rehbinder effect of crushing strength of aluminum oxide under various liquids, the work of adhesion for liquids on mercury, the Joffe effect of the consequences of immersion in various liquids on the fracture strength of soda-lime glass, and correlations of friction on polyethylene treated with fuming sulfuric acid $H_2SO_4 + SO_3$ [55].

Direct and practical applications of solubility parameters in coatings have included their use as an aid in the selection of solvents and solvent blends for many years. Most solvent suppliers and frequent solvent users have computer programs for this purpose, although as noted above, such programs are not an absolute necessity. Reformulation to meet environmental requirements is especially important in this respect since one can quickly evaluate which of the alternatives is most likely to meet the given requirements. This includes reducing amounts of volatile organic solvent, worker safety, or other environmental concern. Optimum formulation in such cases often involves mixtures.

The main thing to remember in solvent selection using solubility parameters is that the resultant values for mixtures can be estimated from volume fraction averages for each solubility parameter component. Solvent quality can be adjusted by the RED number concept or graphically as described above.

A computer search for nearest neighbors for a given single solvent has been used many times to locate alternates. A similar application is to predict which other solvents will probably be aggressive to a chemically resistant coating where very limited data have indicated a single solvent or two are somewhat aggressive. A nearest neighbor search involves calculation of the quantity R_s for a whole

database, for example, and then arranging the printout in RED number order with the potentially most aggressive at the top of the list. Solvents with RED less than 1.0 are "good" and easily recognized.

In many cases a marginal solvent is desired, in which case RED numbers just under 1.0 will be sought. Marginal solvent quality will ensure that polymer adsorbed onto pigment surfaces has little reason to dissolve away from that surface where it is desired as a stabilizing factor in the product. The solvent in this case should have a RED number for the pigment surface greater than 1.0 to aid in the planned affinity approach to pigment dispersion stability. A sketch of the optimum relations is given in Fig. 4, where the marginal solvent is Number 1. Solvent 2 would probably be too expensive and, in addition, will probably dissolve the polymer too well. In special applications this extended polymer chain configuration is desirable, but a solid anchor to the pigment surface is required. A good anchor has high affinity for the pigment surface and marginal or no affinity for the solvent. Solvent 3 would adsorb onto the pigment surface preferentially, and pigment dispersion stability will be poor. Pigments have been characterized by long-time suspension studies where some solvents will suspend the fines for days, months, or years, while others of similar viscosity yield rapid settling. The suspending solvents are the good ones and can be used to define a sphere for surface wetting/adsorption. Details of such characterizations are given in Refs. [38,39].

In other cases, better matches between solvent and polymer solubility parameters are required. This is true when two polymers are mixed and one of them precipitates. This is most likely the polymer with larger molecular weight, and it must be dissolved better. Lower RED numbers with respect to this polymer are desired, while still maintaining affinity for the other polymer. Miscible blends of two polymers have been found using a solvent mixture composed exclusively of nonsolvents. This is demonstrated schematically in Fig. 5, where it can be seen that different percentage blends of solvents 1 and 2 will have different relative affinities for the polymers. No other alternative theory of polymer solution thermodynamics can duplicate this predictive ability. Polymer miscibility is enhanced by larger overlapping solubility regions for the polymers as sketched in Fig. 6. Polymers A and B should be compatible, while C will not be. Such a systematic analysis allows modification of a given polymer to provide more overlap and enhanced compatibility. The advantages of a copolymer containing

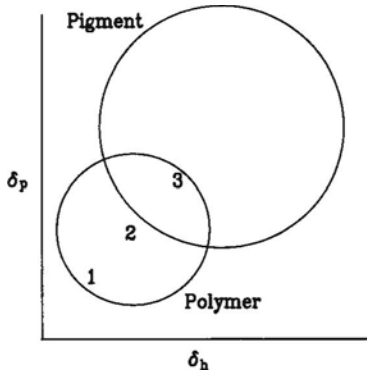

Fig. 4—Solubility parameter relations for optimum pigment dispersion stability.

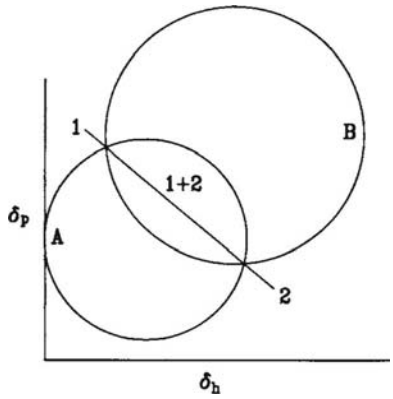

Fig. 5—Solubility relations for polymer mixtures can be quickly evaluated to ensure solution stability. Even mixtures of nonsolvents can be systematically used to regulate solution behavior.

the monomers of A or B and C should also be evident. Such a copolymer will essentially couple the system together.

Van Dyk et al. [56] have correlated the inherent viscosity of polymer solutions with the solubility parameter. This is interesting in that the solubility parameter is a thermodynamic consideration, while the viscosity is a kinetic phenomenon. Solvents with higher affinities give greater polymer chain extension in solution, and the inherent viscosity—the solution viscosity divided by the solvent viscosity at polymer concentrations approaching zero—is an expression reflecting polymer chain extension in solution. Higher intrinsic viscosities were found for solvents with solubility parameters nearest the polymer solubility parameters. As stated above, this approach may not always be advisable since many polymers have polar and hydrogen bonding parameters higher than the test liquids that have been used.

The use of supercritical gases as solvents has become more common in recent years. Space limitations prevent going into the details of these developments. It should be noted, however, that when a gas is compressed, its cohesive energy density increases. This means that nonpolar gases with their low nonpolar solubility parameters can begin to dissolve given organic materials, which otherwise have solubility parameters that are too high. Increasing

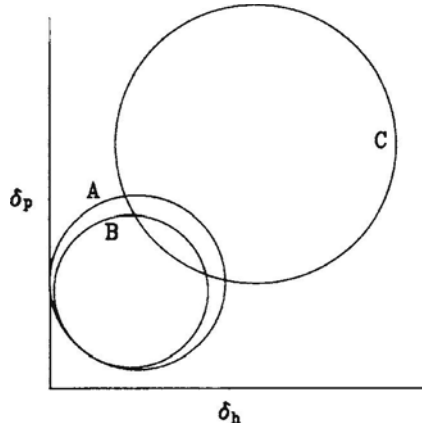

Fig. 6—Schematic representation showing expected miscibility of polymers A and B with each other but not with polymer C.

the nonpolar solubility parameter of the gas by increasing the pressure causes a closer match with the corresponding parameter for potential solutes. Similar behavior is found for polar gases such as carbon dioxide. The prevailing pressure and temperature conditions determine its cohesive energy density and changes in pressure or temperature change solubility relations for this reason. Whereas nonpolar gases are most suitably used for relatively nonpolar solutes, carbon dioxide—and in principle other polar gases—are most suitably used in connection with more polar solutes. The solubility parameters for carbon dioxide have been reported [57] based on the room temperature solubility of the gas in different liquids (δ_d, δ_p, δ_h equal to 15.3, 6.9, 4.1). These parameters resemble those of a higher ketone, but are subject to revision when larger data sets are processed. The δ_d, δ_p, δ_h parameters for carbon dioxide have been revised to 15.7, 6.3, and 5.7 based on a correlation with a perfect data fit and R_0 equal to only 3.3, using a much larger data set collected by Williams and reported in Chapter 10 of Ref. [39]. The HSP are also reported in this reference at higher temperatures and pressures. The δ_p parameter experimentally confirms the presence of sizeable values for compounds with zero dipole moments, and the δ_h parameter emphasizes the need to use terminology electron exchange for this parameter, traditionally called the hydrogen bonding parameter, since there is no hydrogen atom. Chapter 3 in Ref. [39] has a plot of the HSP for water at temperatures above the normal boiling point.

Pigment wetting/suspension characteristics have been presented earlier [10,14,16]. Mixtures of nonsuspending solvents could also be found which, when admixed, provided predictably higher affinity and suspension of pigment particles for prolonged periods of time. An exceptionally clear demonstration of pigment adsorption properties is given in Ref. [10] where a triangular plot of the three partial parameters shows the clearly different adsorption properties of untreated zinc oxide powder and organic phosphate surface-treated zinc oxide powder. This triangular approach to plotting was developed by Teas [52].

Other surface characterizations have also been given for surfaces such as coatings and metal substrates [23,24]. These characterizations have been of the type sketched in Fig. 7. Such cohesive energy plots can lead to systematic modifications of systems to improve adhesion. It might be added parenthetically that equal information can be obtained from plots of the cosine of the contact angle versus the solubility parameter as for plots of these same data versus liquid surface tension [23]. The energy information obtained in these types of studies, the critical surface tension, corresponds to the condition of RED equal to 1.0, with a solubility parameter approach, that is, marginal affinity.

The list of applications has recently been expanded to include correlations of the breakthrough times for common types of chemical protective clothing such as butyl rubber, nitrile rubber, plasticized polyvinyl chloride, neoprene, Viton rubber, polyvinyl alcohol, etc. [58]. Fig. 8 shows the importance of combined use of the RED number and molecular volume in correlating 3 h breakthrough times for a fluoropolymer chemical protective product [59]. Monomers with terminal double bonds diffuse more rapidly than comparisons with non-double-bonded molecules of similar size and solubility parameter would have predicted. The smaller cross section at the end of the molecule reminds

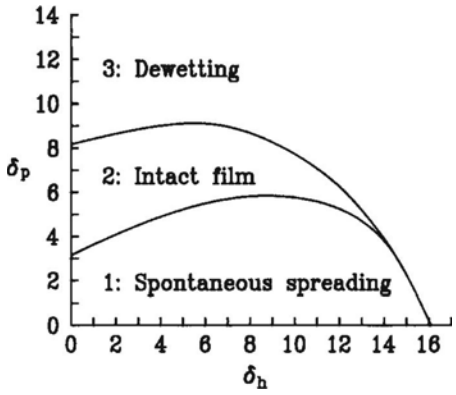

Fig. 7—Schematic diagrams showing surface energy/contact angle characterizations using the Hansen solubility parameters (cohesion energy parameters).

one of a nail, and the preferred direction and relative rapidity of transport become easily understandable.

In addition it should be noted that even biological materials, some of which have interest for coatings applications and use, have been assigned Hansen solubility parameters [60]. These include keratin (which relates to skin permeation), fat, sucrose, blood serum and zein (which are proteins), urea, lignin (wood penetration), and chlorophyll (which closely resembles lignin) [57,60]. The characterization of other biological materials is also possible, of course, with the assignment of HSP to DNA being one of the most recent results [39].

Even inorganic salts have been characterized by solubility parameters [61]. The practice of dissolving polymers in solutions of organic liquids and inorganic salts can thus be explained by the solubility parameter. A solubility parameter correlation of the chemical resistance of an inorganic zinc silicate coating is reported in Table 4. Finally, it might be noted that Hildebrand presented a chapter on the solubility parameters of metals [1]. Unfortunately, we do not often coat metal, but rather metal oxides, for which no solubility parameter work has been reported.

Examples in addition to the above are discussed in a larger context in Refs. [38,39]. The material in the following section has not been discussed in Ref. [38], but rather in Refs. [39,62]. Inclusion here is justified by the presence of solvents and additives in coatings, which may produce these catastrophic effects in rigid polymeric systems.

HANSEN SOLUBILITY PARAMETERS AND ENVIRONMENTAL STRESS CRACKING (ESC)

The Hansen solubility parameter approach allows systematic analysis of environmental stress cracking situations [62]. One can locate those liquids that are most likely to cause the problem based on limited experimental data for a reasonable number of different solvents. The state of the stress in a polymer is clearly important. Tensile stress is required for the phenomena to occur. Higher stress levels lead more easily to cracking. Test solvents to evaluate the stress level present in given polymers can be systematically located. However, it is clearly not just solubility relations that control the phenomena. The size and shape of the environmental challenge chemical are also important. These relate to the rate of uptake (diffusion coefficient). These factors collectively control how rapidly a challenge

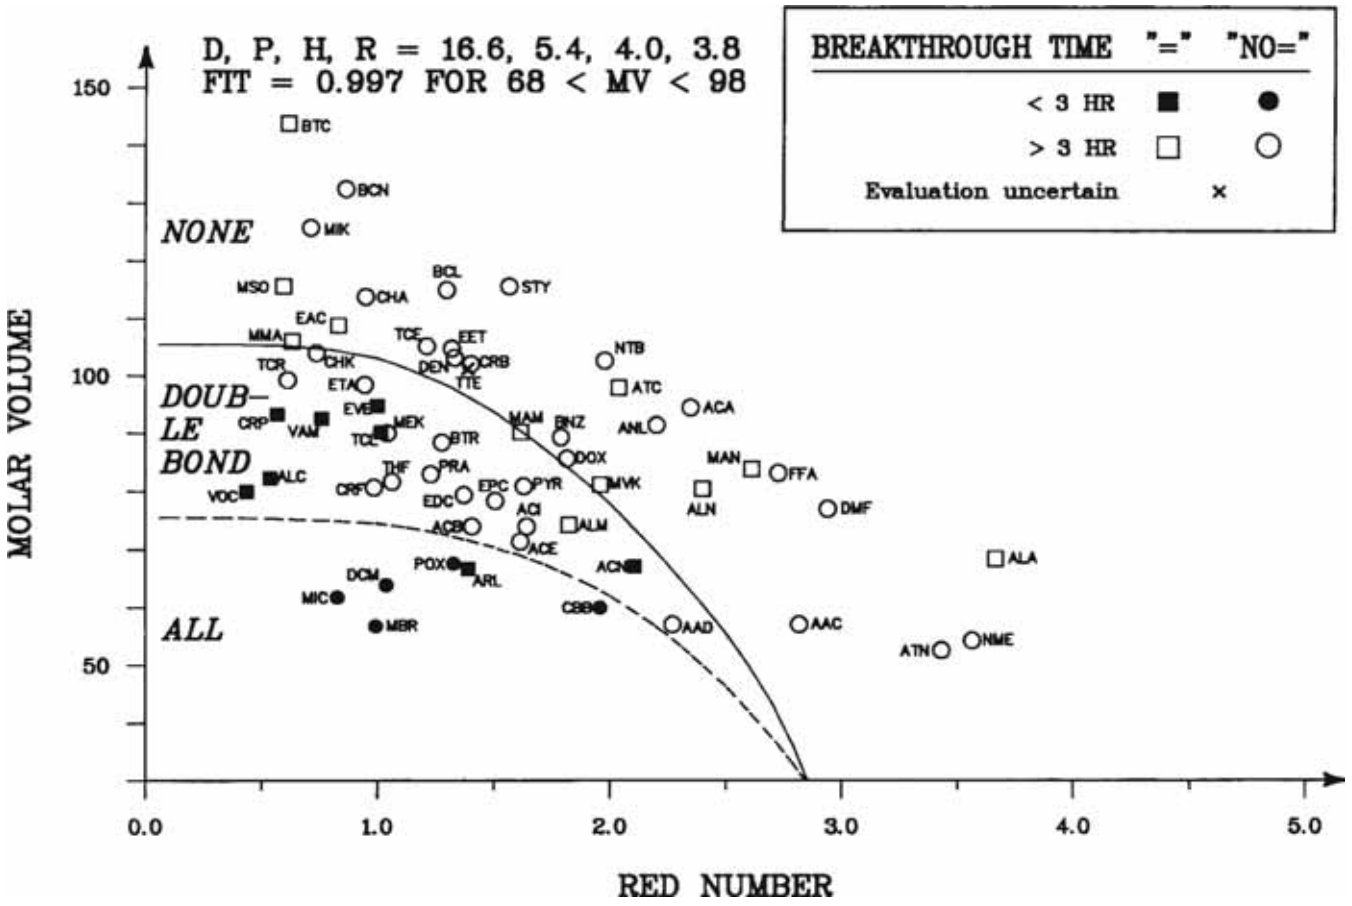

Fig. 8—Effects of molecular size (molar volume) and affinity (RED number) on the breakthrough time of Challenge 5100 [59].

chemical can absorb into the surface of a polymeric material, this being a requirement for the cracking to occur. The absorbed chemical changes the local stress-bearing properties, and cracking can occur in unfavorable situations. The times required may vary from seconds to years, depending on the situation. Stress relaxation caused by the plasticizing effect of absorbed liquid can reduce the risk of ESC, but can cause other problems, such as excessive softening of the polymer. ESC phenomena in polymers are not fully understood, but progress toward this goal is being made as discussed in the following.

In general, those solvents causing cracking of a given polymer will be taken up in lesser amounts at equilibrium absorption than those amounts which will fully dissolve the polymer. In terms of the Hansen approach, this means that there will be the usual spherical characterization for polymer solubility. Essentially concentric to this, but with a larger radius, is another spherical characterization encompassing both the true solvents at RED numbers less than about 0.8, and the cracking solvents at RED numbers typically between about 0.8 and 1.0. Fig. 9 shows these relations for a COC type (Cyclo-olefinic Copolymer) polymer. The basis for this correlation was to consider as aggressive (RED < 1) both those solvents that truly dissolve the polymer as well as those that cause cracking. This type of plot can be made for other polymers.

The above discussion is for exposure to a pure liquid. It is also known that aqueous solutions can leave smaller amounts of aggressive chemicals when the water has evaporated. In this case almost any solvent, either good or swelling only, will be a potential problem in this respect. The small amount acts like a concentrated solvent, but only at the surface. Solution can not occur, other than at the

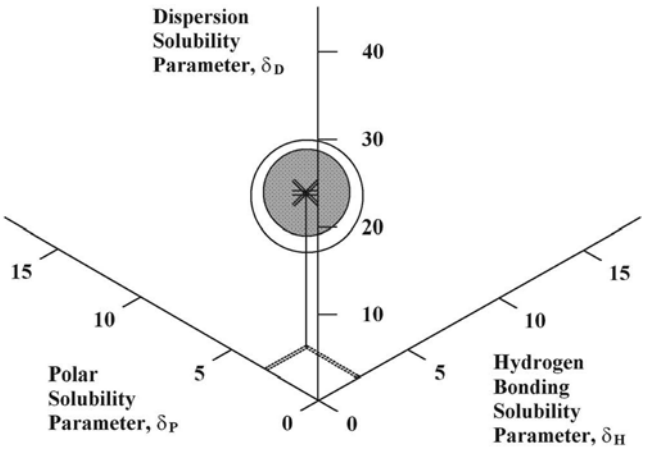

Fig. 9—Hansen solubility parameters correlate both solubility (inner sphere) and solubility plus environmental stress cracking (outer sphere). The liquids that crack the polymer without application of external stress have Hansen solubility parameters placing them in the clear shell in the figure. From Ref. [62]. surface, because of the limited amount of solvent, but the stress situation at the surface is altered unfavorably, thus allowing cracks to form. There are also examples of ESC where there was no measurable weight gain of the liquids causing the failure. Crack initiation by the rotation of segments of polymers at the surface exposed to these liquids is thought to be the reason. The rotation is driven by the HSP of the liquid resembling the HSP of a buried or partially buried polymer segment, thus reducing the free energy of the system by rotation to surroundings of similar (cohesion) energy. Higher energy segments of polymers are most often buried just beneath the surface, if this is possible. The polymer segments in contact with air are most often those of lower energy, again, to keep the free energy at a minimum [39].

CONCLUSIONS

The background and many uses of the solubility parameter concept have been described in detail. Tables of solubility parameters for many liquids and polymers have been presented. Systematic use of solubility, swelling, or permeation data for polymers allows their characterization by these same cohesive energy parameters. Surfaces can also be characterized using these same parameters. This provides data for optimizing solvent selection, improving compatibility, and enhancing pigment dispersion and adhesion. When all of the materials involved in a given product and application can be characterized with the same energy parameters, the possibility exists to predict interactions among them, even in complicated situations. Methods for estimating the three Hansen solubility parameters have been given with as much detail as has been possible to ensure their more uniform use in the future. It has not been possible to deal with all the primarily theoretical problems with the solubility parameter concept. Some of these are dealt with in the literature cited, most notably in Refs. [6,9,10,18,26,38,39].

A simple approach is described to understand affinities in such varied materials as gases, liquids, polymers, biological materials, surfaces, organic and inorganic coatings, inorganic salts, and metals. An appeal made to the scientific community earlier [37] to expand research on this seemingly universal approach appears to have been responded to by Panayiotou in Chapter 3 of Ref. [39]. Statistical thermodynamics calculations of the δ_d, δ_p, and δ_h parameters, starting with the hydrogen bonding parameter, and extending to the other parameters, have shown amazing agreement with the values reported by the author 40 years ago [13–16]. Information related to the Hansen solubility parameters is continually being updated on the website www.hansen-solubility. com.

Cure: The Process and Its Measurement

Thomas J. Miranda[1]

INTRODUCTION

AMONG THE MOST CRITICAL AND OFTEN MIS-understood properties of a coating are cure and the measurement of cure. If ASTM standard technology [1] is examined, one will find no listing for the word "cure." Cure is something that can have different meanings for different people. In the coating and paint field of study, cure is usually thought of as the chemical reaction between functional groups that results in cross-linking of a system by one or more of a variety of schemes including polymerization of monomers, rearrangement, condensation or elimination, reaction with adventitious moisture or oxygen, as well as others. However, the word can be taken to mean much more and should include the drying of a lacquer as when thermoplastic coatings are applied, the solidification and/or crystallization of polyolefins or other hot-melt applied coatings, the drying of latexes or emulsions that can form films through the high-pressure compacting forces of surface tension, as well as of other ways of forming a coherent, useful thin film with good mechanical, electrical, or other properties. This chapter will mainly be concerned with cross-linked systems and cure will be taken to mean reactions that result in a thermoset or network-formed coating [2], unless otherwise indicated.

The desired and often optimum chemical and physical properties of a coating are dependent on proper curing conditions—time, temperature, and humidity. For example, if a thermosetable, acrylic polymer-based lacquer is applied to a substrate and solvent is allowed to evaporate under ambient conditions, the resulting film might have cracks, low gloss, and be hard and brittle. Yet, the same system could result in a coherent, useful film if the solvent were evaporated under controlled temperatures for specific times. The film might still be brittle and have poor chemical resistance, but such factors may not be important in certain instances. However, strength properties will be markedly improved as a cross-linking agent is added, and the system is allowed to react under proper temperature conditions for an appropriate length of time. The resulting coating will be glossy, hard, tough, and chemical resistant. The time and temperature relationship and the interaction of these parameters has been reported by Neag and Prime [3] in the case of powder coating cure.

Concept of Cure

Polymer is a word meaning many (poly) units (mers) wherein the units are monomers or single-unit mers. Thus, polymers are high molecular weight molecules that are comprised of monomers that may be the same or different, though if the monomers comprising the polymer are different, the polymer is referred to as a "copolymer." Polymers are formed by a variety of polymerization mechanisms including addition (such as the polyacrylates, polyvinyls, etc.), cationic (as polyepoxides), condensation (as polyesters), coordination (as polyolefins), ring opening (as Nylon 6 and polylactones), and rearrangement (as polyurethanes).

These compounds known as polymers range from high to low molecular weight in nature. High molecular weight polymers can form coating films with high gloss and good mechanical properties; however, to achieve such useful properties, the applied solids must be low due to the high viscosities involved when such large-size molecules are used. In the coatings arena, usually low molecular weight polymers or oligomers comprising a relatively small number of chain units that either have one or more functional groups or a co-unit that has functional or polyfunctional groups on as many of the oligomer molecules as possible. If used alone, the oligomers would have poor mechanical and chemical properties and would either be sticky masses (glass transition temperature, Tg, below room temperature) or "rock hard" chunks (Tg above room temperature). To transform these oligomers into useful materials with good mechanical and other properties, it is necessary to build or increase molecular weight. This transformation is accomplished by the addition of a cross-linking agent to the coating formulation wherein said compound will react with the functional groups on the oligomers and then *cure* the liquid system into a film comprised of extremely high molecular weight molecules.[2]

It should be clear from the above that thermoplastic coatings are soluble in particular compounds we term "solvents" and, in addition, if heated will liquefy with the viscosity dependent on the molecular weight. In contrast, thermoset coatings are insoluble but will often swell in particular compounds and if heated may soften but will thermally degrade rather than liquefy.

Of course, additives [4] that will markedly improve the path to achieving a coating with designed gloss, good

[1] *Senior Consultant, Consolidated Research Inc., 16731 Brick Road, Granger, IN 46530.*

[2] The concept of molecular weight becomes lost when one discussed cross-linked systems. Dr. Herman Mark described the "rubber" in an automobile tire after vulcanizing or cross-linking as one gigantic molecule. Although the definition may be a bit ambitious, since defects and the laws of probability exist, it is a good model to keep in mind when thinking about cross-linked chemicals. Thus, a chemical coating can be thought of as a huge molecule with an extremely high molecular weight that is incapable of being dissolved.

mechanical and chemical properties, as well as rapid cure are very important to the cure process. Accelerators, catalysts, or other additives insure that cure or cross-linking will be effected in an acceptable time. For example, in radiation cure [5], monomeric and/or oligomeric molecules are combined into a very fluid formulation and ultraviolet radiation-activated cationic or free-radical initiator additives known as photoinitiators cause the molecules to react in an extremely rapid manner at coating line speeds of even several hundred feet per minute. When an electron beam is used to effect cure of such systems, photoinitiators are not required, though flow-control additives would be used. With radiation activation, cure is achieved in the "snap of a finger."

When less-energetic reactions than those used in radiation curing are involved, the cure process will be relatively slow, say on the order of minutes at an elevated temperature. Examples of such a cure system might be the acid-catalyzed, aminoplast cross-linking of hydroxyl-functional oligomers to form thermoset films or the controlled evaporation of solvent or other diluent from lacquers or latexes to form thermoplastic films. In the case of powder coatings, the coating material is in a dry form and thermal energy is used to melt the powder particles and time at a temperature is required to allow the particles to flow into a continuous coating. If a cross-linking agent is present in the powder coating, the cure system must be orchestrated in such a manner that liquefaction and flow take place before significant network formation occurs. Very slow reactions occur in thermoset systems that cure by reaction of adventitious oxygen with unsaturation in the oligomeric molecules.

Many details regarding coating film formation [6] and the preparation of films for coating tests [7] can be found elsewhere.

CURING MECHANISMS

Lacquers

Lacquers consist of thermoplastic polymers that are dissolved in a solvent. When the coating is applied, the solvent evaporates under controlled conditions and a thermoplastic film is formed. This is the type coating used in certain high quality furniture finishes. A number of years ago, many automobiles were coated in this manner, but today such coatings are thermoset in nature.

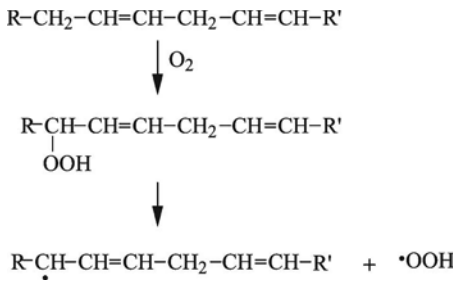
Emulsions and Latexes

Another means of forming a thermoplastic film is film formation from an aqueous-based emulsion or latex. In this instance, a polymer such as a vinyl acetate-acrylic copolymer latex is formulated with colorants and additives, cast, and the water carrier is evaporated with a coherent film resulting. In such systems, the water is not a solvent but a dispersing medium. Microscopically, the polymer appears as tiny ball bearings suspended in water with surface active agents present to keep the polymer particles dispersed and free from settling. As the water evaporates, hydrodynamic pressure causes the small spheres to crowd closer and closer until capillary action forces the particles to fuse and form a continuous film. If the polymer is too hard in nature, a poorly adherent, brittle film is formed. Often, this is the reason paint manufacturers recommend that water-based latex paints not be applied at low temperatures. To facilitate fusion and continuity, small amounts of a coalescing solvent such as diethylene glycol monobutyl ether are added to decrease the glass transition temperature. As described, the curing results in a thermoplastic coating. If desired, these systems can be made into thermoset films by incorporating a functional group into the latex molecules and employing a cross-linking agent.

Oxidative Cross-linking

Oxidative cross-linking takes place in systems that contain reactive, unsaturated double bonds as are found in unsaturated fatty acids, drying oils such as linseed, soy, tung, and tall oil (see Chapters 4 and 5 for a discussion of drying oils and driers), as well as certain alkyds and oleoresinous varnishes. This vehicle is formulated with a suitable solvent, a drier (often termed a "siccative") such as cobalt, manganese, or zirconium salts in the form of naphthenates, octanoates, or the like, and other ingredients. Curing takes place through adventitious oxygen interacting with the molecular unsaturation.

The coating film is applied by brushing, spraying, or other means and solvent is removed by evaporation. The resultant liquid or tacky film then undergoes an induction period in which natural antioxidants inherent in the starting materials are overcome as oxygen is absorbed from the atmosphere. This is followed by hydroperoxide formation on carbon atoms alpha to double bonds. This is followed by peroxide decomposition and formation of free radicals that initiate cross-link formation at the unsaturated sites with the result formation of a cross-linked thermoset film [8,9]. A simplified reaction scheme in which R and R′ are alkyl groups is shown below [10].



The starting materials are converted into polymer according to the following scheme:

$$\text{Initiation} \quad RH + O_2 \rightarrow R\cdot + \cdot OOH$$

$$\text{Propagation} \quad R\cdot + O_2 \rightarrow ROO\cdot$$

$$ROO\cdot + RH \rightarrow ROOH + R\cdot$$

$$\text{Termination} \quad ROO\cdot + R\cdot \rightarrow ROOR$$

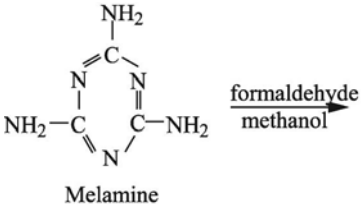
$$ROO\cdot + ROO\cdot \rightarrow ROOR + O_2$$

$$R\cdot + R\cdot \rightarrow R-R$$

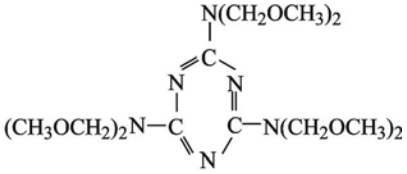
Termination by coupling increases the molecular size—say, doubling if the joined chains are the same in size—and eventually a network or cross-linked system is formed. If properly formulated, the final product has the desired chemical and physical characteristics.

Reactive Cross-linking

In this type of cure system, a reactive intermediate is added to a functionalized polymer or oligomer and a further chemical reaction is initiated by heating alone or in the presence of a catalyst or by some other means. The functionality on the polymer molecules often is hydroxy in nature. The reactive intermediate is often an amino compound such as hexa(methoxymethyl)melamine.



Melamine



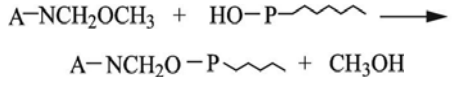
Hexa(methoxymethyl)melamine

MELAMINE

Melamine-formaldehyde condensates are often used to cure a reactive polymer. Melamine is 2,4,6-triamino-1,3,5-triazine, a compound prepared by condensing three molecules of dicyandiamide. Melamine, in turn, can be condensed with up to six molecules of formaldehyde and 6 molecules of methanol to form hexa(methoxymethyl) melamine (HMMA) (see Chapter 8) or an oligomeric phenolic compound (see Chapter 11).

Alcohols other than methanol can be used as the hydroxyl-capping groups. Examples of commonly used alcohols are isobutanol and butanol.

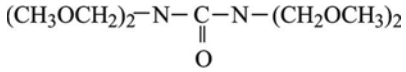
In practice, these compounds can be reacted with a functionalized polymer such as an acrylic or an alkyd that contain either acid or hydroxyl groups, which will react with the melamine compound to liberate an alcohol by-product with the multifunctional nature of the melamine compound leading to a cross-linked coating film. This cure system is briefly indicated by the following reaction scheme:



wherein A is the residue from HMMA and P represents the hydroxyl functionalized polymer that is being cross-linked. Note that after the above reaction, the residue A still has five functional groups that can react with other hydroxyl groups on the same polymer molecule or on other polymer molecules to set up the network. In addition to the by-product methanol, it is possible for formaldehyde to be a by-product. Narayan and coworkers [11] have addressed various aspects of the cure and properties of polyesters cured with HMMA. Numerous other articles can be found in the literature.

UREA COMPOUNDS

A scheme similar to that described above for HMMA and other melamine compounds is also applicable to ureaformaldehyde (UF) compounds. To form the UF compounds, urea is reacted with formaldehyde and the product is end capped with alkyl alcohols—usually methyl, isopropyl, or butyl alcohols. A full reacted urea intermediate in which methanol has been used as the capping agent has the following structure:



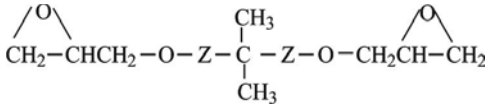
N,N'-bishydroxymethylurea

This multifunctional compound is capable of reacting with hydroxyl groups to produce cross-links with by-products such as alcohol, water, and formaldehyde.

Note that in the above examples, neither the melamines, ureas, or most polymers would form a good coating if used alone. The polymers act as flexibilizers and/or toughers for the hard, brittle cross-linking agents.

EPOXIDES

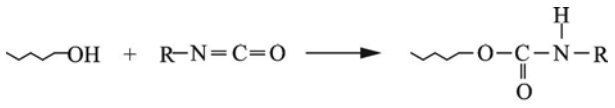
Epoxides represent a ring-opening-mechanism form of curing coatings. Aromatic epoxides are produced by the reaction of epichlorohydrin and bisphenol A, with the latter compound a condensation product of acetone and phenol. Aliphatic epoxides are prepared by the peroxidation of unsaturated linear or cyclic olefins. A typical epoxide used in coatings, is the diglycidylether of bisphenol A, which is described below and wherein Z is a phenylene group.



The epoxide groups can react with active hydrogen atoms such as those found on amine, hydroxyl, and carboxylic acid groups. Aromatic epoxides react very rapidly with amines and hydroxyl groups and cycloaliphatic epoxides react very rapidly with cations derived from acid functionality or hydroxyl groups. Opening an epoxide ring results in linkage to the donating compound an formation of a secondary hydroxyl group that may undergo further reaction. Thus, the above described epoxide may be considered as tetrafunctional when it is in the presence of active hydrogen atoms and as a result will rapidly lead to a highly cross-linked, cured coating. Under the proper conditions, the formed hydroxyl group can react with another epoxide group or with a melamine-formaldehyde compound to produce coatings with improved properties such as hardness, toughness, chemical resistance, and/or solvent resistance in the cured film.

URETHANES

Urethane linkages represent a rearrangement mechanism for the formation of cross-links and cure in polymeric systems. Urethanes are the reaction product of a hydroxyl group and an isocyanate group that undergo a rearrangement with the formation of a urethane linkage as described in the following.



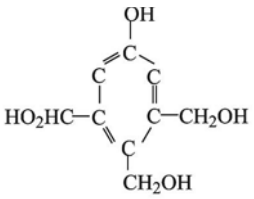
Isocyanate Urethane

This reaction is used in the manufacture of a broad range of products from insulation and seating foams, reaction injection moldings, in high-performance coatings, and other end uses. The isocyanate used in coatings and many other end uses is usually a di- or tri-functional compound that will lead to cross-linked systems. Monofunctional isocyanates are used to end-cap hydroxyl compound in the preparation of intermediates or to impart particular, desirable characteristics for certain end uses. Included are isocyanates such as iso-phorone diisocyanate, 4,4′-diphenylmethane diisocyanate, 4,4′-dicyclohexylmethane diisocyanate, trimers of hexam-ethylene diisocyanate, and others. The higher molecular weight isocyanates are preferred when practical, since they have a lower vapor pressure than their lower molecular weight counterparts and thus provide for improved working conditions. As would be expected, saturated epoxides have better weathering characteristics than aromatic epoxide coatings.

Isocyanates are used to cross-link a variety of polymers containing hydroxyl or amine functionality. In the case of amine functionality, the reactions are very rapid and result in the formation of urea cross-links. The reactions with hydroxyl functionality are usually catalyzed and proceed at easily controllable rates. Among the coating systems cured isocyanates or that contain urethane linkages are a variety of acrylic polymers and copolymers; polyesters; poly ether, polyester, and polylactone polyols; polyols capped with isocyanates and cured with adventitious moisture, urethane acrylates cured with ultraviolet or electron beam radiation, as well as others.

PHENOLICS

Phenolic compounds used in coatings are the condensation reaction products of phenol or substituted phenols and formaldehyde. Two main types of phenolics are made with the type depending on the catalyst used and the reaction conditions. When an acid is used as the catalyst, a thermoplastic, soluble novolac phenolic is obtained. Under basic conditions, the product obtained is a resole phenolic that is thermoset in character and is cross-linked in the final stages of the reaction. A phenol-formaldehyde condensate (P-F) may have the following structure:



Phenol-formaldehyde Condensate

Hydroxyl-containing oligomers such as the alkyds can be cross-linked through reaction of the hydroxy-methyl function of the P-F with an hydroxyl group on the alkyd with the elimination of water.

CURE MEASUREMENT

Complete or essentially complete cure development is a very important factor in meeting coating specifications and/or in determining the ultimate performance characteristics of any particular coating. Therefore, it is very important for the developer and the user of coatings to know how the curing process takes place and whether or not the final coating is adequately cured. As cross-links develop and molecular weight increases in a coating, performance characteristics such as adhesion, solvent resistance, toughness, hardness, gloss, and the like approach an optimum value, which is near a set, desired, or specification value. Coatings that are undercured will tend to be soft (lack hardness), have poor solvent resistance, and probably have poor adhesion. Overcured coatings may be hard and brittle, take on a dark, undesirable color, have low gloss, or not meet other criteria.

Cure measurement can be determined by simple, qualitative testing or through analytical techniques that require sophisticated instrumentation. Often simple testing can be used to give an investigator a quick benchmark and tell if they are on the correct developmental track. Then sophisticated techniques can be used to completely understand the coating system and the coating's ultimate properties. Finally, investigators attempt to correlate simple and sophisticated tests so performance features may be confidently determined during production, which is often taking place at high line speeds, with relatively simple testing. Also important is being aware that coating properties may change after leaving a thermal curing oven, a radiation source, or other curing device and properties after a length of aging time should be considered. Methods for measuring degree of cross-linking and the distance between cross-links can be found in Chapter 46.

Rapid test methods are desirable because of time constraints and cost, but sometimes they do not tell the true story. Yet, they do provide much useful information. It should be kept in mind that one is attempting to ascertain a molecular process, cross-linking (unless thermoplastics are involved), and its relationship to coating performance.

Most thermoplastic coatings cure or "dry" by simple evaporation of solvent. This is true for nitrocellulose, cellulose acetate, and solvent soluble acrylic lacquers wherein no cross-linking takes place. To measure cure of such systems, the time for either a print-free or tack-free condition is determined. As the evaporation process takes place, the nature of the coating goes from tacky to set-to-touch to tack free. On further drying, the coating becomes print free wherein a thumb print will not be visible on the coating surface. At times the effect of a twisted thumb print under moderate hand pressure will be observed. Another testing method involves dropping cotton linters or cotton balls onto the surface and noting the time after which they do not adhere to the coating. Thermoplastic or thermoset coatings on metal substrates can be quickly tested with a hand-held, fairly new nickel (U.S.A. five-cent piece) by applying a quick, rapid, gouging scratch with the edge of the coin to the coating and observing the results. One quickly finds out if the coating is tough and adherent, since

the hard, sharp coin edge will have a marked effect on the coating.

Solvent Rubs

A convenient, often-used method for determining cross-linking involves solvent rubs. A cloth soaked with a solvent such as methyl ethyl ketone (MEK) or acetone is rubbed vigorously back and forth on the film, and then the film is examined after a specific number of rubs. If the film is removed, softened, or loses gloss, it is considered inadequately cross-linked or it is considered nonresistant to solvent. Often, the number of back-and-forth double rubs that the film does pass is reported. Thermoplastic coating are not expected to pass the test. The tests involved include ASTM D5402, Practice for Assessing the Solvent Resistance of Organic Coatings Using Solvent Rubs, and ASTM D4752, Test Method for Measuring MEK Resistance of Ethyl Silicate (Inorganic) Zinc-Rich Primers by Solvent Rubs. Related tests include ASTM D5109, Test Methods for Copper-Clad Thermosetting Laminates for Printed Wiring Boards; ASTM D1676, Test Methods for Film-Insulated Magnet Wire; and ASTM D2671, Test Methods for Heat-Shrinkable Tubing for Electrical Use.

One difficulty associated with this test is that the individual testing the coating is not standardized. One person may exert more pressure than another and this can have a bearing on the final result. However, even with this deficiency, the test does provide useful information when the number of double rubs passed is reported.

Hardness

Hardness and scratch resistance provide another method for obtaining information about the degree of cross-linking and cure. There are a variety of tests that provide information about this characteristic. The topic is discussed in detail in another chapter in this manual.

PENCIL HARDNESS

A very simple, but complex, test for measuring the hardness of coatings is pencil hardness, which is carried out according to ASTM D3363, Test Method for Film Hardness by Pencil Hardness. The test originated with manufacturers of pencils who tried to develop a consistent means for checking the quality of pencils. Along the development way, someone suggested scratching a paint film, and it was noticed that the different hardness of pencils were able to penetrate the coating down to the substrate or to scratch the coating to different degrees.

The test was later used by coating technologists and currently is widely used in the industry to determine coating hardness. In this technique, a number of pencils of known hardness, usually from a specified manufacturer, are used. The pencil is trimmed so that 5 mm of "lead" is exposed. The lead diameter is 1.8 mm and is sharpened by rubbing it perpendicular to the surface of No. 400 carbide abrasive paper. The sharpened pencil is held at a 45° angle to the coating and pushed along the surface with hand pressure to attempt peeling away the coating. The pencil that fails to scratch or cut through the coating is considered the "Pencil Hardness Value." The method is simple, the equipment is low in cost, and results are quickly obtained. However, values obtained can be operator dependent as well as dependent on the method of sharpening the lead point, variances of lead hardness from different pencil lots, and different manufacturers. Yet, as mentioned above, the test is widely used and does provide useful information.

KNOOP AND PFUND HARDNESS

The Knoop hardness test, described in ASTM D1474 Test Methods for Indentation Hardness of Organic Coatings, is a useful test in which a spherical, pyramidal, or conical indentor is pressed into the film to cause indentation with the depth of penetration a measure of hardness. In the test, a 25 g load is applied for 18 s and the length of the indention line is measured with a microscope. The Knoop hardness number (KHN) is calculated from the expression [12]

$$KHN = L/A_p = L/l^2/C_p$$

where L is the applied load in kilograms, A_p is the projected indentation area in square millimeters, l is the length in millimeters of the long diagonal of the indentation mark, and C_p is an instrument constant. Because of the thinness of most coating films, this method is more useful for plastics, since it required almost a 75 % indentation into the film and can be influenced by substrate considerations. A more generalized formula than the above can be found in the referenced ASTM Test Method.

The Pfund Hardness Number (PFN) is obtained in an analogous manner by using a hemispherical quartz or sapphire indenter that is pressed into the film. PFN is calculated from the expression

$$PFN = L/A = 4L/\pi d^2 = 1.27L/d^2$$

where L is the applied load in kilograms, A is the area of the projected indentation in square millimeters, and d is the diameter of the projected indentation in millimeters.

SWARD HARDNESS

Sward hardness depends on the change in surface properties and the viscoelastic nature of a film. This method, which was discontinued in 1990, is used for automotive finishes and consists of a rocker containing two spirit-bubble indicators. The method is described in ASTM D2134, Test Method for Determining the Hardness of Organic Coatings with a Sward-Type Rocker and in ASTM D4366, Test Methods for Hardness of Organic Coatings by Pendulum Damping Tests. The pendulum is rocked and the number of swings are recorded and a reading is taken at the point where the swing distance is equal to half the original value. As cure increases, the Sward number increases. The value of a Sward test is that a number that can be compared to that of other coatings is obtained. This test must be conducted under very clean conditions as lint and surface imperfection can interfere with the results. Temperature control is another important factor. The difficulty with this test is that it only measures cross-link density or cure to a point. Then, it cannot detect further cure or over cure, since a plot of Sward numbers as a function of time or cure tends to reach a limiting value. A comparison [13] of hardness values obtained by different test methods is shown in Table 1.

TABLE 1—Hardness test comparisons [13]

Sample	KHN	Sward[a]	Pencil (Brands)				
			A	B	C	D	E
1	3.09	24	5B	6B	5B	6B	4B
2	4.33	28	4B	6B	6B	6B	4B
3	2.77	24	5B	6B	5B	4B	3B
4	2.61	22	3B	4B	5B	4B	3B
5	5.81	38	2B	2B	2B	2B	HB
10	25.7	54	H	H	H	H	2H
12	39.1	40	3H	2H	2H	4H	3H
14	—	40	8H	9H	7H	7H	9H

[a]Note how the values differ in this investigation—especially between the different brands of pencils and the limiting values of Sward Hardness.

IMPACT RESISTANCE

Tests that measure the impact resistance of a coating can be used to correlate with cure. An undercured coating may exhibit a low impact value, but as cross-link density increases, impact values improve. Of course, overcured coating may be brittle and have a low impact value. ASTM D2794, Test Method for Resistance of Organic Coatings to the Effects of Rapid Deformation (Impact), is a widely used test. It consists of placing a flat coated panel under a weighted spherical ball assembly and then dropping the weighted ball onto the panel from different heights. The cylinder in which the ball assembly is mounted is calibrated such that an operator can directly read the impact resistance in inch-pounds. The measurements are carried out by dropping the ball directly on the coated surface or on the reverse side with the results being reported as direct or reverse impact, respectively. The impact causes a dimple to form in the test panel, and it is examined visually or with a ten-power lens to determine the extent of cracking or other failure. This is a simple test that is widely recognized in the coatings industry, and it gives useful information about the performance characteristics of the coating.

Related tests include ASTM D5420, Test Method for Impact Resistance of Flat, Rigid Plastic Specimen by Means of a Striker Impacted by a Falling Weight (Gardner Impact); ASTM D950, Test Method for Impact Strength of Adhesive Bonds; and ASTM D2137, Test Methods for Brittleness Point of Flexible Polymers and Coated Fabrics. In addition to these methods, certain industries, such as the automotive industry, often develop their own in-house test methods and these will vary from manufacturer to manufacturer.

Thermal Analysis

Thermal analysis is an important analytical tool for determining the response of materials to changes in temperature and is useful in determining cure of coatings. The technique can be used to monitor the glass transition temperature, Tg, of a coating and this property can be related to cross-link density. For example, if a number of paint films that are cured at various times and/or temperatures are evaluated, thermal analysis can be used to determine the change in Tg as a function of a bake schedule or, for that matter, of formulation composition. From such studies, optimum cure cycles can be determined to ensure quality finishes are produced.

Thermal analysis devices have several modes for determining Tg and these include Differential Scanning Calorimetry (DSC), Thermomechanical Analysis (TMA), and Dynamic Mechanical Analysis (DMA). The glass transition temperature is a second-order transition, and it represents a temperature where segmental motion occurs in a polymer chain. This motion also causes a volume change in the polymer. Comparative changes of cross-linking measured by Sward hardness, evaporative rate analysis, and DSC indicated that the changes can be followed to high levels of cross-linking, but Sward measurements reached a limiting value while Tg continued to increase [14]. The importance of using the correct window of time and temperature when curing powder coatings has been described in the literature [15].

When DSC is used, a plot of endotherm/exotherm as a function of temperature is obtained at a set rate of temperature increase. As Tg is reached, there is an abrupt change in the endotherm that appears on the plot. Similarly, Tg can be measured using a plot of change in expansion as a function of temperature with the TMA method. In this method, a specimen is placed under a quartz probe and then heated. As the film expands, a plot is obtained in which a change in slope occurs. The intersection of the tangents of the expansion cure yields the Tg value. In the penetration mode, a depression occurs at Tg. Further details about thermal analysis can be found in the literature [16–19].

DYNAMIC MECHANICAL ANALYSIS

Another method for obtaining Tg is to use dynamic mechanical analysis in which a coating film is fixed to the ends of a tuning fork and the fork is driven over a frequency range and at different temperatures to provide a plot of damping as a function of temperature. Tg, being a second order transition, is a function of both temperature and of frequency. Information from both variables can be used to obtain information about the film [20].

TORSION PENDULUM

The torsion pendulum provides another way to obtain Tg as well as other dynamic properties such as the real and the imaginary shear modulus. A coating film is either imbibed into an inert substrate or used in a neat form (often difficult for this technique) and suspended between jaws and a counterbalanced disk that is used to apply a twisting torque to the specimen. The applied shear force then freely decays. A difficulty is that many coating films do not have the strength to support even the light stress of the counterbalanced disk, especially when the glass transition region is approached. This is why the coating is usually imbibed into an inert substrate such as fiberglass. If the sample is held at a constant temperature for a period of time, changes in cross-link density are reflected in modulus and damping changes. Details of the method and ways to construct a torsion pendulum can be found in the literature [21,22].

Impedance Measurements

Meyers [23] investigated the drying behavior of latex systems using ultrasonic impedance measurements. In his

studies, a latex coating was cast onto a quartz crystal and ultrasonic energy was beamed at an eleven degree angle at the underside of the coating, reflected to a detector that measured the attenuation of the initial beam as absorbed by the drying coatings. As water evaporated, there were changes in impedance that could be correlated to curing in the sense of drying.

EVAPORATIVE RATE ANALYSIS

A novel method for studying cure is Evaporative Rate Analysis (ERA), which was developed by Anderson and coworkers [24]. This methodology was applied to determine the cleanliness of the surface of spacecraft. It was reasoned that if a radioactive C^{14} liquid were placed on a clean surface, the evaporation would be retarded due to cleanliness. In fact, the opposite was true. Nevertheless, this technique was developed to measure the degree of cleanliness. If a small amount of diethyl succinate-C^{14} is deposited on a surface and a controlled sweep of nitrogen is applied over the surface, the rate of evaporation can be monitored using a Geiger counter. The principle is that on a clean surface, there is no interaction between the solvent and a clean substrate and as a result normal evaporation takes place. If, however, the surface contains a contaminant, then the radioactive liquid will interact with the surface contaminant and retard the rate of evaporation of the radioactive component. Plots that relate cleanliness to evaporation rate can be prepared.

The investigators applied this technique to the cure of organic coatings. They demonstrated that in an undercured surface, solvent retention increased and this led to longer residence times for the radioactive substance on the under-cured surface. By preparing coated panels having different cure times or temperatures, and then measuring the ERA of each panel, a plot of retention as a function of bake schedule was obtained. The method was applied to the cure of a variety of coatings by many coating technologists [14,24].

Other instruments are useful for determining the cross-linking of coatings including the Vibrating Needle Curometer that is used for liquid systems such as adhesive and sealants. The instrument drives a vibrating needle at a fixed frequency into the sealant or adhesive, and the damping amplitude is measured as a function of gel and cure time [25]. Products that can be monitored for cure with this technique include coatings, adhesive, foams, and sealants.

Recent Information

Readers are referred to other chapters in this manual for related cure-measuring techniques. The information provided in this chapter is also applicable to radiation-cured and powder coatings, since the performance of these coatings depends on proper extent of cross-linking consistent with the design of the polymers used [5,15].

In addition there have been recent advances in analytical techniques that provide coating chemists with better tools to understand the process of cross-linking [26]. Analytical techniques for measuring key polymer properties are reviewed in polymer chemistry texts [27–29]. A recent application of space technology in which a technique known as Near Infrared Thermal Processing is being used to cure a wide range of coatings, printing inks, and adhesives [30]. The technique involves high energy sources that radiate near the infrared spectrum (more than 90 % of the energy emitted is below 2 μm) and allow markedly higher rates of cure than infrared or hot air systems. The systems have high process efficiencies and reliability. The importance of cure and its characterization is apparent from the recent April 2006 two-part, virtual-learning course offered about this topic by the Federation of Societies for Coating Technology and presented by Dr. T. Provder.

Film Preparation for Coating Tests

Robert D. Athey, Jr.[1]

THE PERFORMANCE OF A COATING FILM IN A TEST is likely to be dependent on the physical form of the film. For instance, film thickness is an important factor in physical and appearance measurements (until the coating gets too thick), so there must be some control of the film thickness. Appearance is also related to how smooth the film surface is, and care to make the film appropriately will ensure that the appearance measurements are germane to the end use. The substrate used as the carrier for the test film, even temporarily, may affect the property measurements, as well.

The primary concern in making films for tests is that the film prepared be homogeneous and consistent with previous or future films for the same test. The jargon of the trade calls the art of making films "casting," but many film formation methods are used to form the film, and each method has its own set of advantages and drawbacks.

TEST REQUIREMENTS OF FILMS

Test requirements come in two classes, appearance (aesthetics) and physical properties. Choice of application method for the film may affect the appearance in some cases. For instance, the "multicolor" paints must be applied by dip or spray techniques for laboratory testing or the appearance does not give the desired mottle of nearly circular spots. Roller, brush, or even drawdown bar will cause these spots to become streaks. Choice of application method for appearance includes drying technique, as some films require special drying conditions to attain their desired special appearance. Examples include leafing aluminum flake "metallic"-look paints, hammer tones, and wrinkle finishes.

Choice of application method driven by physical property testing is also necessary. Think carefully of the three kinds of stresses (tensile, compression, shear) and recognize that all are blended in a hardness or adhesion evaluation by indenter, pencil, mandrel bend, or dart impact test on a coating. Recognizing these stress combinations can make one aware of film preparation needs. In cases where adhesion is stronger than cohesion of the film, one should be able to distinguish between adhesive failure and cohesive failure. Film preparation should not conflict with these objectives.

The physical properties to be tested in specific ASTM methods have a "significance and use" section in the method to ascribe the relation of the test value to some "in use" performance criterion. The preparation of the test film should thus correspond to the standard field application of the material, as well.

Another portion of film influence on the test is film thickness. The presentation by the Technical Committee from Toronto in the 1990 National FSCT Meeting and Paint Show [1] dealt with hardness measurements in films of varying thickness. However, the control of film thickness was not as straightforward as might have been thought. Hardness values turned out to be dependent on film thickness along with other equally important variables [2].

Fluid rheology, concentration, and other factors govern the amount of coating left after the application process. Knowing the process variables associated with a film-casting technique are essential to getting what is needed for the ultimate test and results therefrom. Certain other properties of the film (opacity, permeability, erosion rate by some attacking mode, etc.) will depend on the thickness of the film. So, understanding thickness control in the casting process is crucial to obtaining meaningful results in terms of meeting specifications in reproducibility.

In instances where fluid or gas permeation resistance or corrosion barrier properties are to be tested, a "pinhole," "holiday," or "mud-crack" in the film is a fatal flaw. The film preparation technique must eliminate (as much as possible) any such fatal flaw, or the test method should prescribe what is to be done (for example, replications) in cases where an unseen fatal flaw is detected by the test.

FILM CASTING TECHNIQUES

Free Films

Free films, that is, films not applied permanently to a substrate, are used for a wide variety of tests and accordingly vary in thickness and size. The most common castings of free films are used for permeation or strength and elongation testing. They can also be used for cold flex tests or moisture/ solvent absorption studies related to permeation. Free film thickness can be measured as described in ASTM D1005, "Test Method for Measurement of Dry-Film Thickness of Organic Coatings Using Micrometers."

Probably the most common free film castings are laid down on a "nonstick" surface, such as the silicone-coated papers (available through Leneta and other suppliers), Teflon™, or polyethylene sheets. Release substrates are described in ASTM D823, Standard Practices for Producing Films of Uniform Thickness of Paint, Varnish, and Related Products on Test Panels. Lack of release-substrate wetting is the most common problem encountered when trying to obtain a continuous film. Water-borne coatings are especially difficult to formulate for good wetting of these substrates. One trick to use with such formulations

[1] *Athey Technologies, P.O. Drawer 7, El Cerrito, CA 94530-0007.*

is to prepare the sample at higher than normal solids content, which results in increased viscosity and resistance to beading is improved. An alternative is to apply several coats until the dried "beaded-up" portions merge to form a continuous film.

A vacuum plate makes it easier to hold down the paper or polymer film for film casting and is an aid to good results. Fig. 1 is a diagram of the vacuum plate formed from aluminum. Older versions had eyes at the bottom surface through which screws could affix the plate to a tabletop. If this system is to be vacuum supplied from a sink faucet aspirator, a liquid trap (vacuum side-fitted Erlenmeyer flask) should be placed in line between the vacuum plate and the aspirator. This will ensure that any liquid coming from the aspirator will not get to the vacuum plate or coating substrate.

Grenko [3] suggested several coated paper techniques for obtaining free films, such as decal paper coated on the face side or outdated matte or semimatte photopaper. The decal paper could be floated on water and the paper peeled off. Grenkodid not describe the removal of photopapers from the film. He also cited Sager [4] for a technique using an embroidery hoop for holding nonmoisture proof cellophane. After the coating film had been applied, one simply poured water on the inverted cellophane and the coating film dropped off. These techniques are likely to be most appropriate for solvent-borne or 100 % reactive formulations. Water-borne coatings may be inappropriately leached or weakened by the water used to loosen and isolate the films.

Grenko [3] also mentioned the use of metal substrates for free film isolation. Brightwell [5] used glass onto which a thin silver film had been vacuum deposited. Bayor and Kempf [6] used thin aluminum foil that was later dissolved from most of the back by using hydrochloric acid doped with a minute amount of platinum chloride. The latter dissolved off only enough aluminum foil to leave a foil "frame" at the edges of the film to support it and to facilitate handling. This technique with aluminum foil dissolution in an acidic, aqueous medium presumes no sensitivity of the coating components to acid or water.

For thicker films (1 cm or more), a Pyrex™ TV or Teflon™ coated baking pan can be used with some success. For instance, about 300 mL of a latex formulation in a 9 by 12 in. (23 to 30 cm) Pyrex™ baking dish will yield a sufficient quantity of thick film for testing. Occasionally, there is a "mud cracking" problem, but it can be reduced periodically by releasing the edges of the film from the vertical sides of the dish with a spatula to allow uninhibited shrinkage. This way usually results in pieces of increased size, and 1 in.^{2} (6.25 cm^2) is all that is required for the moisture absorption or solvent-swell test. Using this technique, it is possible to obtain large enough pieces of test coating for moisture vapor transmission tests at an application thickness that is common for roof coatings.

The "mud cracking" problem is serious for any coating. The cause is the lack of "wet gel strength" to resist the tensile stresses within the shrinking membrane. Strictly speaking, unless the coating cross-links, it is not a gel, but simply a high-viscosity fluid or "pseudogel." Assuring that the upper surface does not "skin over" by controlling the humidity or solvent-vapor environment over the drying surface may alleviate the problem.

The literature describes mercury pool casting [7,8] or tin foil casting [9] with mercury amalgamation used to remove the tin without stressing the coating film. ASTM D4708, "Standard Practice for Preparation of Uniform Free Films of Organic Coatings," also describes the tin foil amalgamation technique. These techniques are no longer in common use, as the mercury vapor is deemed a health hazard and caution is advised if the technique is attempted.

Rarely, but occasionally, for instance, a free film of a polymer or binder material is needed for testing water vapor permeation or absorption. Some of these tend to be tacky, and powder applied to the surface will make them easier to handle. Although pearl cornstarch is preferred over the powdered talc for this purpose, baby powders and similar talcum powders are often used.

Rotational casting is a means of obtaining nonporous, non-mud cracked-free films. The standard jar-mill roller (see Fig. 2) may be used with a variety of open containers (quart or gallon jars, earless paint cans) with a 4-in. (10-cm) circle cut out of the bottom, to centrifugally cast the film with good thickness control. An alternative device, the Caframo REAX2 rotating mixer [10] may be used to hold the paint can with its main axis along the rotation axis of the clamp (see Fig. 3).

The Los Angeles Society for Coating Technology Technical Committee successfully used this rotational casting technique in a study to obtain tensile and moisture vapor permeation film samples from acrylic latex compounded with silane-modified talcs [11]. It is derived from an older

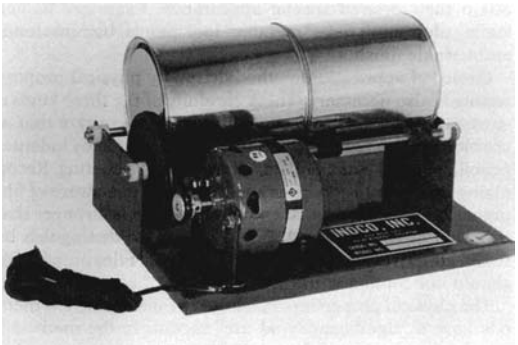

Fig. 2—Lab roller mill—Although this device is most often used for pebble milling, an empty "earless" paint can on the rollers may be used to cast films. (Courtesy of Indco Inc.)

Fig. 3—Heidolph "REAX 2"—This device was designed as a rotational mixer for fluids, but a gallon paint can will fit in it for rotational film casting, as well. (Courtesy of Heidolph USA.)

practice at the Thiokol Rubber Co. that was used to obtain films of castable elastomers in a rolling pipe [12].

Equipment for this technique is easy to set up and use. Introduce 100 mL of coating into a 1-gal can and let it roll overnight. This will result in a film approximately 6 by 18 in. (15 by 46 cm). That is a sufficient quantity for 6-in. (15-cm) tensile bars and 2-in. (5-cm) permeation circles. Close control of film thickness is achieved by knowing the area of the cylinder and concentration. From these, the weight of coating needed can be calculated. Films of tacky coatings or pressure-sensitive adhesive formulations can be made by this technique. After the film is formed, the can is placed in a refrigerator or freezer to facilitate film removal.

To obtain a centrifugally cast powder coating film, a sample of the powder is introduced into the can. Then, a hot air gun is held at the outside of the rolling can, and the powder coating will melt to coat the inside. Care is needed to eliminate scorching, and practice is needed to determine how close the flame should be to the can to get a good film. Other techniques to obtain a film include melting on a Teflon™ sheet on a hot plate or in between Teflon sheets in a heated press.

Spraying one to a silicone-coated paper is occasionally used to make free films. There is no problem with this technique when a skilled practitioner does it. However, films made with this technique may not give as good permeation test results as from one made by a film from a fluid-flow technique.

A note of caution should be added about handling free films made for physical testing. Any undue stresses may chip, stress, or crack the film. This is especially important for permeation or physical property tests. In the case of the latter, some materials are "notch sensitive," that is, the results of a tensile or other physical test may be markedly reduced by the presence of a notch, scratch, or crack in the film [13].

Dry Coatings on Substrates

Test coatings on a substrate are generally applied for a wide variety of appearance and physical property tests. Color and opacity are commonly evaluated on coated paper charts, though unsealed paper charts with a porous surface are available, as well. Coating on substrates to simulate actual use is common so the paint laboratory has many kinds of steel, aluminum, wood, or other substrates in stock as needed by the customer or the paint company.

Plastic panels are rarer, but they can be made available when needed. Several companies now offer such products. Plastic panels may need special surface preparation techniques to assure wetting and adhesion (solvent washes, chemical etches with alkali or acid, low-temperature plasma, or corona discharge or chemical oxidation, etc.). As painting plastics become more and more important for automotive, computer, sign, and other industries, the manufacturers are making panels available to potential paint suppliers.

Panels of metal are a special case for the preparation of test films for paint. It may be necessary to do a precoating surface preparation on the metal, and consultation with appropriate specifying agencies may be necessary. The Society for Protective Coatings (SSPC) has many grades of hot-rolled steel preparation techniques that vary from wire brushing through sand blasting to expose "white metal" [14]. Other preparations such as phosphatizing, galvanizing, anodizing, etc., are unique to specific industries or industry segments and will require lab preparation of panels or freshly treated panels from the customer or a commercial source. An annual handbook contains descriptions of some of these techniques for laboratory usage [15]. Preordered steel panels that are subsequently stored in special corrosion-inhibitor-treated packaging may skew exposure tests if they are not rigorously cleaned of corrosion inhibitor just prior to the coating steps. Cleaning procedures may require rinsing with hydrocarbon solvent or acetone and hot air drying just before paints are applied. Exposure panels made of metal must also have special edge protection to ensure that only the coated face has the exposure test applied.

The casting technique on a paper or paperboard substrate is a skill that is learned through apprenticeship. First, the panel needs to be clean and dust free. For horizontal castings, which is a way to obtain good flat films, it is necessary to ensure that the surface is level during casting and drying. Tape the chart or panel to the level surface so it does not curl as the film loses solvent or dispersing media and starts to shrink. Unsealed paper charts will curl in a convex manner since any water in the coating swells the paper fibers, and the substrate may try to curl the sheet in a concave manner when the film tries to shrink across the top surface from which evaporation is taking place. Vacuum plates are available, as noted earlier, to hold down the paper, foil, or cardboard chart during the film-casting process. The paperboard chart should be stored in the same humidity environment that will be used in drying/curing the coating as the wood-pulp fibers are hygroscopic.

Concrete, plaster, and asphalt/gravel test blocks or panels may be prepared in the laboratory or they may be purchased. However, whenever possible such blocks should be obtained from the customer since paint-laboratory results may not compare well with the customer's results if details such as porosity, surface salinity, surface pH, soluble calcium or sodium ion content, etc., are not equivalent. These materials may be hygroscopic and will need equilibration in the drying/curing environment prior to coating. In addition, some concrete castings, that is, tilt-up wall constructions, often have surface residues of form coatings that had been used to aid release from the forms. Surface

characterization for such release aids or rigorous cleaning may be needed. There is an ASTM standard practice for preparation of mortar panels for testing paints: ASTM D1734, "Standard Practice for Making Cementitious Panels for Testing Coatings."

Grenko [3] has described press coating of bitumens on aluminum or felts, with shims placed in the press to attain appropriate thickness. His work was based on earlier studies by Greenfield [16].

Wet Films for Testing

There are a variety of reasons one may want to have a close look at a wet coating film. Simply watching the drying process may make any problems with moisture condensation on the film, pigment float, etc., apparent. There are test films made to assess wet hiding or sag resistance (ASTM D4400, "Standard Test Method for Sag Resistance of Paints Using a Multinotch Applicator"). Good film casting practice, for example, a level surface for casting, consistent technique, etc., is a requirement for reproducibility of results. Equipment required for special tests will be included in the following section.

EQUIPMENT FOR FILM PREPARATION

Drawdown Bars

The drawdown bars are the simplest of the film casting devices to use. One simply makes a puddle of coating on the desired substrate and moves the drawdown bar over the puddle to make the desired wet film thickness. Application of the film with a drawdown bar nominally gives a good continuous film, but the spacing between the bar and the substrate may have little to do with the film thickness obtained. Speed of pulling the drawdown bar over the fluid will affect the film thickness since fluid rheology influences film thickness. High molecular-weight polymers may cause the edges of the film to draw in and increase the wet-film thickness. The formulation may not wet the drawdown bar, and, if this happens, it adds another factor to the control of film thickness. Wetz and coworkers [17] showed almost 100 % deposition of the wet film and found a relationship between wet-film and dry-film thickness.

$$T_{df} = 0.057 + 0.588GS(\rho_l/\rho_f)$$

or

$$T_{df} = 0.057 + 0.955T_{wf}(\rho_l/\rho_f)$$

where:

T_{df} = dry film thickness, mils,
T_{wf} = wet film thickness, mils,
ρ_l = density of liquid,
ρ_f = density of dry film,
G = clearance of drawdown barmils, and
S = weight fraction of solids in liquid.

Grenko [3] makes the point that these relationships are only true for drawdown blades having substantial flat surface between the leading edge of the bar and the trailing edge. The Byk-Gardner information [18] suggests the following expectations for cast films of varying thickness:

15 to 100 μm	50 %
100 to 300 μm	60 %
300 to 500 μm	80 %
over 500 μm	90 %

The hand-held drawdown bars are covered in an ASTM specification, Method E in ASTM D832, "Standard Practice for Rubber Conditioning for Low Temperature Testing."

A wide variety of drawdown bars are commercially available, and your local machine shop can make special orders of any design, if needed. Table 1 lists a few of the available types of drawdown bars, with commercial sources of some suppliers. Some rectangular design devices have differing gap depths on the sides so one may choose the film thickness needed for casting (see Figs. 4 and 5).

Stainless steel or aluminum are the preferred materials of construction, as corrosion can damage the region of the drawbar controlling thickness of applied film. Good laboratory practice dictates immediate cleaning of the paint contact surfaces after every usage to minimize the threat of corrosion or other damage. A caution on marking the draw down bars, as some manufacturers label them not with the gap spacing, but a number half the gap spacing since that is the expected wet film thickness to be obtained.

TABLE 1—Drawdown bars for film casting

Type	Design Details	Supplier[a]	Reference
"Bird" knife	Permanent fixed gap	Byk-Gardner	3
Two-path applicator	Bar has two cuts of different depth machined into top and bottom	P. N. Gardner	20
Eight-path applicator	Stainless-steel square tube with eight different depth cuts in each of top and bottom edges	P. N. Gardner	20
Gardner "Microm" applicator (also Hercules-Gardner adjustable [3])	Micrometers on each side lower or raise blade of "U" shaped device	P. N. Gardner	20
"Universal" blade applicator	Blade forms "U" shape with sides having slots and thumb screws to raise or lower	P. N. Gardner	20
Dow latex film applicator	"U"-shaped blade with wider cut for larger gap so second cast film	Byk-Gardner	3

[a] There may be many other suppliers, but only one is cited herein as a space-savings technique.

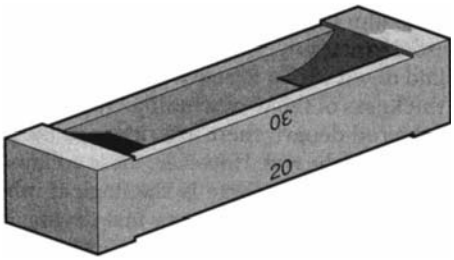

Fig. 4—Applicator frame/step gap applicator—Two film thickness choices are available with this device. (Courtesy of Byk-Gardner Inc.)

Some drawdown bars have film thickness adjustment choices by micrometers or other techniques (see Table 1 and Fig. 6). When these are used, the settings should be checked with feeler gages to make certain user wear has not made them inaccurate. These also require dismantling and cleaning after every use. If oil is used to inhibit corrosion and make the mechanics move smoothly, make sure they are rigorously cleaned of oil prior to usage.

Several drawdown bars have gradations of cuts into the wet-film thickness controlling surfaces. For instance, the Erichsen suppliers offer the Kruse Multi Clearance applicator, having six to ten adjacent film strips of 10 to 200 μm in thickness for assessment of color yield, opacity, etc. (see Fig. 7) [19]. A similar device, the Leneta TG19 Logicator, is intended for hiding power and spreading rate measurements. It is available from Gardner [20] and has eight "gates" ranging from 2.65 to 10.4 mil in depth.

There are motorized film application devices specified in Method C of ASTM D823, "Standard Practices for Producing Films of Uniform Thickness of Paint, Varnish, and Related Products on Test Panels." The Model 509/1 Film Applicator from Erichsen [19] may be fitted with any sort of drawdown bar or blade (see Fig. 8). Speed of the motion of the applicator may be preset, so the variation among several samples may be minimized.

Two devices Grenko [3] included with drawdown bars are more like bulk coating devices, as they do not require putting down a puddle of coating before applying the blade. Indeed, these devices contain the coating and apply it to a stack of sheets, one sheet at a time as the sheets are pulled out from underneath the device. One such device is the Parks Film-O-Graph cylinder. One puts the cylinder on a stack of Leneta charts or metal panels, fills the cylinder with the coating, and pulls each sheet from underneath the cylinder. A portion of the rim edge of the cylinder is milled

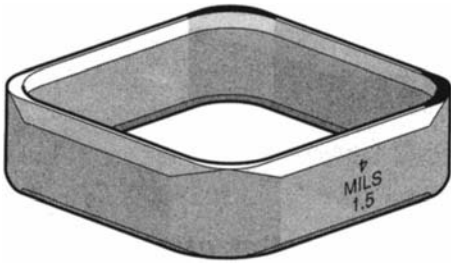

Fig. 5—Multiple clearance applicator—Eight film thickness choices are available on one device. (Courtesy of Byk-Gardner Inc.)

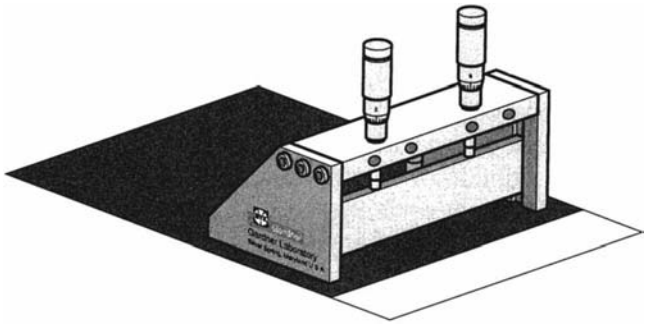

Fig. 6—Fllm casting knife—Micrometers adjust the blade clearance. (Courtesy of Byk-Gardner Inc.)

out to act as the gate to allow coating at a desired thickness. One may even use it for very viscous coatings (even putty) by forcing the fluid through the tube with a loose-fitting plug from the top and wiping the bottom of the tube over the substrate to be coated.

The second of the devices discussed was the Parks Rapid coater. Paper sheets were stacked in the bottom of a box with their ends out of a side slot at the bottom. The box was then filled with coating fluid, and each sheet was withdrawn individually. Grenko [3] noted that this was not a precision device, but it was adequate for some purposes.

Grenko [3] also described the flat Parks Film-O-Graph, which used a flat plate with spring clips to hold shims along the sides of the sheet of substrate. One poured the coating onto the substrate between the shims and used a bar such as a ruler or other straight edge to doctor off the excess and make the coating as thick as the shims. Bending of the scraper bar by the very slightest amount would make very thin films almost impossible, but for thick films (for example, roof coatings), this technique worked well.

Some applicators are meant only for the wet film tests. Two especially useful applicators for these are the sag test devices and the wet hiding test devices. The latter, most frequently the Pfund Cryptometers (available from Erichsen [19] and Byk-Gardner [20]), have black or white glass (ceramic) beds over which a transparent wedged cover levels the coating film (see Fig. 9). Although these devices are quite hard, care in cleaning will assure they do not get scratched. They must be stored carefully, wrapped, and covered.

The sag test film casters in effect drawdown several narrow films in gradations of film thickness. Many are simply slotted U-shaped drawdown bars with variations in slot depth from 1 to 6 mil, 3 to 12 mil, and 14 to 60 mil.

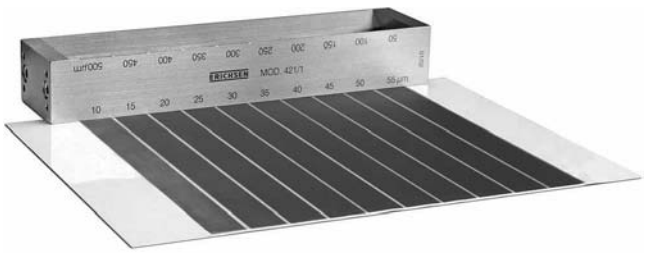

Fig. 7—Multiple gap drawdown bar—Six or eight gaps are machined along the same edge for casting side-by-side films for comparison. (Courtesy of Erichsen GMBH & Co.)

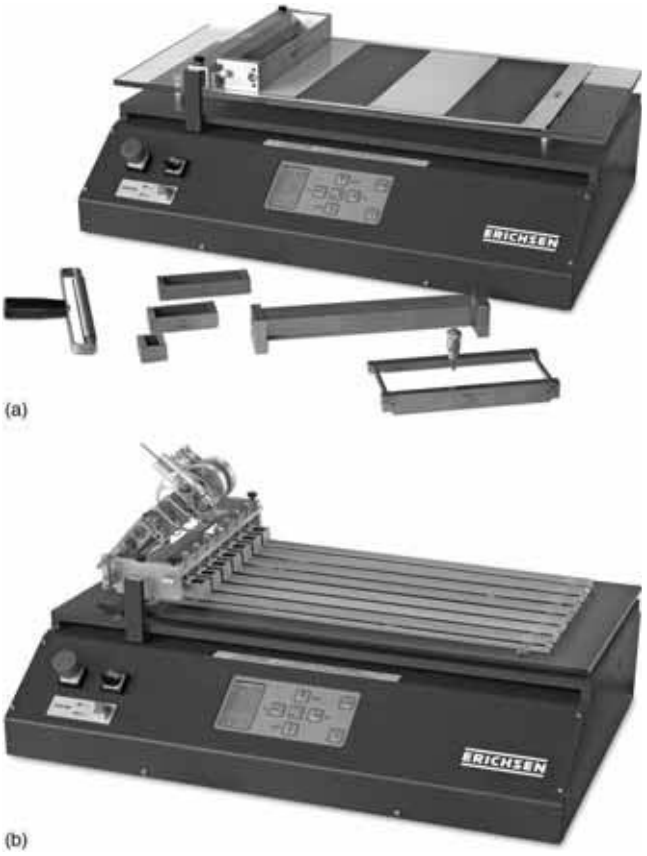

Fig. 8—Electrically driven drawdown device—Four speeds may be chosen to control drawdown rate. (Courtesy of Erichsen GMBH & Co.)

However, the New York Paint Club Technical Committee designed a special "leveling test blade" that had double slots for each depth with a wide space between each set of double slots [21]. Their slots are 1, 2, 4, 8 and 16 mil in depth (see Fig. 10).

How a paint film drips or sags depends on the rheological characteristics, and the thickness of the coating that first sags may be related to the gravity-applied shear stress by the outer elements furthest away from the substrate on that film. Other rheological factors (high shear viscosity, ca. 10 000 s^{-1}, for instance) are also important in sag and leveling. Sag test devices complying with ASTM D3730, "Standard Guide for Testing High-Performance Interior Architectural Wall Coatings," and several federal specifications as well as the New York leveling test blades are available from Gardner [20] and Byk-Gardner [18].

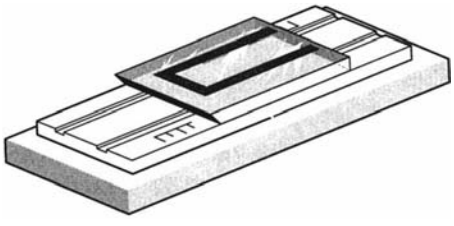

Fig. 9—Pfund crytometer—The white style shown is for black/dark paints, while a similar black style is used for white/light paints. (Courtesy of Byk-Gardner Inc.)

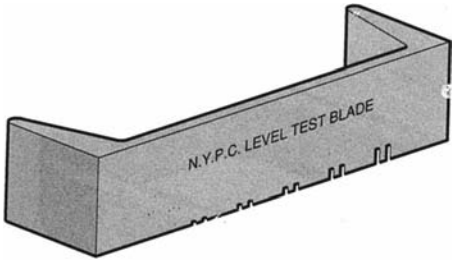

Fig. 10—New York paint club leveling test blade—The slotted blades are for assessment of sag and leveling. (Courtesy of Byk-Gardner Inc.)

Wire-Wound Rods

For very thin films, the wire-wound rods are quite useful for quickly and easily applying films. The wire-wound rods are simple rods of 12- or 16-in. (30- to 40-cm) length, of 1/4, 3/8, or 1/2 in. (0.63, 0.45, or 1.27 cm) diameter, with a spiral wind of wire tight about 75 % to 80 % of the rod. Table 2 shows a selection of the wet film thickness that is obtained from the rods with different wire diameter.

The film laid down with a wire-wound rod is almost exactly a tenth the thickness of the wire winding. Strictly speaking, as the film has the rod depart, there are ridges in the film in the direction of travel of the rod. However, these collapse to make a quite smooth film unless there is rheological inhibition in the formulation or the coating is very fast drying. This technique is quite effective to simulate paper or can coating end products. There are industrial production systems that employ wire-wound rods to meter coatings onto roll substrates, as well.

TABLE 2—Selected coating thickness obtained from various wire-wound rods

Wire		Wet Film Thickness	
Size	Diameter (in.)	Mils	Micrometers
2.5	0.0025	0.25	6.4
3	0.003	0.3	7.6
3.5	0.0035	0.35	8.9
4	0.004	0.4	10.2
4.5	0.0045	0.45	11.4
5	0.005	0.5	12.7
5.5	0.0055	0.55	14.0
6	0.006	0.6	15.2
10	0.01	1.0	25.4

30	0.03	3.0	76.2
40	0.04	4.0	101.6
50	0.05	5.0	127.0
60	0.06	6.0	152.4
70	0.07	7.0	177.8
80	0.08	8.0	203.2
90	0.09	9.0	228.6

Fig. 11—Spiral wire drawdown applicator—The handle shown grips the end of the wire-wound rod for application with one hand. (Courtesy of Erichsen GMBH & Co.)

A similar device called the "spiral-film applicator" is available from Erichsen [19]. It is a wire-wound rod with a perpendicular handle (see Fig. 11). It is available to apply a film thickness of from 10 to 200 μm in widths of 80, 150, or 220 mm. Byk-Gardner offers a handle that attaches to the ends of the wire-wound rod for lab film preparation as well [18]. The Accu-Lab™ Lab Drawdown Machine has a rod holder and substrate holder to assure precision in laboratory manual film preparation [22].

There are also two-wire rods in which a second, smaller wire is wound in the grooves made by the first winding wire. These yield higher application rates than do the single-wound wire rods. There is potentially an advantage to the two-wire rods since they leave a different pattern in the coating. The ridges left are larger and may level faster and more uniformly.

Spray Outs

Spray application, including by weight on a panel hanging on a balance in a spray booth, can be done with good precision. Good spray-out application on panels can be done by those skilled in the art. To control the weight applied in a spray booth, a triple beam balance may be attached to a beam 5 or 6 ft (1.5 or 1.8 m) above the floor, and a hanger-wire panel holder is hung from it as the spray target. A cardboard shield over the balance will keep off overspray off the positioned balance. Take off a few tenths of a gram to give a pointer indicator warning when the spray has almost reached the desired weight. Spray quickly to minimize evaporation.

There are automated spray devices. Grenko [3] related the automated spray device design from Bell Labs [23] to Method A of ASTM D823. The Bell Labs design has the gun travel over stationary panels, while an alternative design has the panels on a moving belt under a stationary spray gun, similar to a design reported from Battelle [24]. In either case, the amount of coating applied to the panel is controlled by the speed of the moving belt and by nonvolatile content of the sprayed fluid. Grenko [3] notes the sample panels on the moving belt may be held to the belt with magnets or suction cups. Erichsen [19], Gardner [20],

Fig. 12—Single setting lab spray applicator. (Courtesy of Erichsen GMBH & Co.)

and others offer automated spray applicators for laboratory sample preparation (see Figs. 12 and 13).

The spray technique is particularly important, but precautions are necessary to assure evenness of coating on the substrate. The spray pattern should extend beyond

Fig. 13—Programmable lab spray applicator. (Courtesy of Erichsen GMBH & Co.)

the edges of the substrate when the nozzle is aimed at the center of the target. The spray pattern—be it flat, fan, or circular—has less paint at the edges than at the center. Moving the spray nozzle across the target or the target under the center of the nozzle makes the deposition more likely to be consistent in thickness.

Dip Coating

Dip coating is particularly important in some special cases. For instance, the edge protection of corrodible panels in preparation for the application of a test coating is a common practice. Printed circuit board coatings, including conformal coatings and baseball bats, are other areas that employ this technology. A red lead vinyl 1/2-in. (1.27-cm) dip was successfully used for edge protection of exposure panels, since attack corroded only the desired exposure surfaces [25]. The point is that dipping assures film thickness without holidays and other techniques do not provide such assurance. This is particularly true for odd-shaped test specimens such as fragments of a pressurized gas cylinder and items as mentioned above.

Grenko [3] briefly reviewed two-dip coaters. Bruins [26] first designed a dip coater using a tire pump and needle valve to control the rate of panel withdrawal from the coating, while Payne designed an electric motor-driven device adopted for Method B of ASTM D823. A commercial laboratory device is available from Gardner [20], with variable withdrawal speeds of 2 to 20 in. (~5to ~50 cm) per minute. It can dip a panel of up to 2 lb (0.9 kg) and 1 ft^2 (0.3 m^2) in area—12 by 12 in. (30.5 by 30.5 cm).

Again, care must taken when dip coating. Film thickness control is a battle between wetting surface forces and the shear forces of drainage through the thickness of the film. Drip edges on the bottom edge may be avoided to some degree by having the panel holder inverted to hold the bottom edge upward for a portion (or intermittent portions) of the drying period.

Spin Coating

Grenko [3] described the work of Walker and Thompson [27] attaching a panel to a turntable and rotating for 1 min at 300 rpm to obtain a 25-μm varnish film thickness. He also described the Sward-Gardner [28] relation of film thickness (F) to viscosity (V in poise) and nonvolatiles, % N, as

$$F = 0.4N + V^4 + 3$$

where the spin rate was 290 rpm for 60 s. Their work had a precision of 5% to 10%, and corrections for time or rpm variations were offered. Parker and Siddle [29] suggested modifying the method by adjusting viscosity to equivalence for all fluids to be compared and using volume solids rather than weight percent nonvolatiles. Plots of film thickness versus volume percent nonvolatile were straight lines for nonhixotropic fluids, but curvature existed for thixotropic fluids.

A commercial lab spin coating device is currently available from Erichsen [19]. There are two versions, one with 600-rpm speed set, and another that is adjustable from 50 to 2000 rpm (see Fig. 14).

Fig. 14—Lab spin coating device. (Courtesy of Erichsen GMBH & Co.)

OTHER TIPS ON PRACTICE OF THE ART

Dust is always a problem, especially in formulation laboratories that have pigment dusting in the lab and plant. Cover cast films immediately to keep the dust off. The easiest cover is the top of a box or similar device. Simply cut out 1/2 in. (or ~1 cm) strip from two, three, or four sides for free flow of air. Of course, a similar cover can be made from thin plywood. Keep the cover on top of the lab refrigerator or bookshelf so it is always at hand.

Make sure the film is drying under appropriate temperature and humidity conditions. Something in the formulation may respond in an adverse manner to condensing moisture that can form droplets on the surface as evaporating solvent rapidly cools the system. In moisture-cure and reactive two-package urethanes, the condensing moisture may react with the isocyanates to modify degree of cure, which can reduce strength, solvent resistance, or other properties. In systems that do not react with the condensing water, one may still get pits, pinholes, or haziness from the condensing water droplets on the surface. Paint applicators are learning to pay attention to humidity variation and its effects on the end product surface.

CONCLUSION

How the film is prepared for testing can have a dramatic effect on the test results. The thought put into film preparation prior to preparation and the care used in film formation can be crucial factors in obtaining meaningful and reproducible results.

Measurement of Film Thickness

John Fletcher[1] and Joseph Walker[2]

PREFACE

IN PREPARATION OF THIS CHAPTER, THE CONTENTS of the 14th edition were drawn upon. The current edition will review and update the topics, introduce new technology that has been developed, and include up-to-date references.

INTRODUCTION

One of the major requirements of paint and coating testing is the measurement and control of film thickness. Ensuring that a thickness specification is achieved is important in laboratory tests, manual paint application, automatic spraying, and other coating application methods, be they solvent based or powder coatings.

A number of test methods are available, and the choice is dependent on: (1) the location—laboratory or site; (2) the material coated—metal (ferrous or nonferrous), wood, plaster, brick, and plastic; (3) the condition of the coating—wet or dry, cured or uncured; and (4) the condition of the surface—rough or smooth, flat or shaped, thick or thin, etc.

WET FILM THICKNESS

The measurement of wet film thickness provides the first opportunity in the coating application process to check the coating thickness. It also offers an assessment of the spreading rate of paints. It is very important that wet film measurements are made as soon as the coating is applied to avoid error due to solvent loss during the curing process.

Reference to the technical data for volume solids in the coating is required to establish the wet and dry ratio so that wet film thickness values can be converted to dry film equivalents. Wet film gages are manufactured from a range of materials, aluminum, stainless steel, etc., and in most cases, wet film thickness gages can be cleaned with solvents and reused. The main exception to this are the notched gages (wet film combs) molded from plastic. Although the materials used, such as loaded ABS, are resistant to many solvents, it is recommended that plastic wet film combs be used only once.

Wet film measurement can be carried out on most substrate materials, both metal and nonmetal. However, the substrate must be rigid and not prone to distortion when the measurement device is applied.

ASTM D1212, Standard Test Methods for Measurement of Wet Film Thickness of Organic Coatings, describes the Inmont wet film gage (formally known as Interchemical gage and commonly known as the Wet Film Wheel) and the Pfund wet film gage. These two gages are detailed in the following sections, as Inmont Wet Film Gage (ASTM D1212 method A) and Pfund Wet Film Gage (ASTM D1212 method B).

ASTM D4414, Practice for Measurement of Wet Film Thickness by Notched Gages, describes a third wet film measurement method using notch gages, which are also known as wet film combs. This method is described in the section called Notch Gage.

Inmont Wet Film Gage (Wet Film Wheel)

The Inmont wet film gage consists of two concentric outer disks with an inner eccentric disk and a smaller diameter positioned between them as shown in Fig. 1. The outer disks are scaled, with the clearance between the inner disk and the outer disk from zero to a maximum value as shown.

The gage is used by placing the disks with the maximum clearance on the specimen of wet coating and rolled toward the minimum clearance on the gage in either direction. The paint will coat the inner disk until the clearance is greater than the wet film thickness. The point at which the coating stops on the inner wheel is referenced to the scale on the outer wheel and the value noted.

Starting from maximum value avoids the possibility of pushing paint ahead of the inner disk, creating an error condition when the gage indicates a value higher than the true wet film thickness. A number of range options are available for the wet film wheel and wheels with notched outer rims are particularly useful for measuring wet films in coil coating, as the notches help to ensure even rotation on the fast-moving substrate.

Pfund Wet Film Gage

As shown in Fig. 2, this gage consists of a convex lens, L, whose radius of curvature is 250 mm, at the lower end of tube T1 that slides in the outer tube T2. Compression springs, S, keep the lens out of contact with the paint film until pressure is applied on tube T1. In making a measurement, the gage is placed on the painted surface and the lens is pushed slowly through the film until stopped by the substrate. The pressure is released, and the diameter of the spot of paint transferred to the lens is measured. A 1-to-1 ratio for the thickness added by the paint displaced by the lens to the actual thickness has been assumed and is accounted for in the equation

$$t = D^2/16R \quad (1)$$

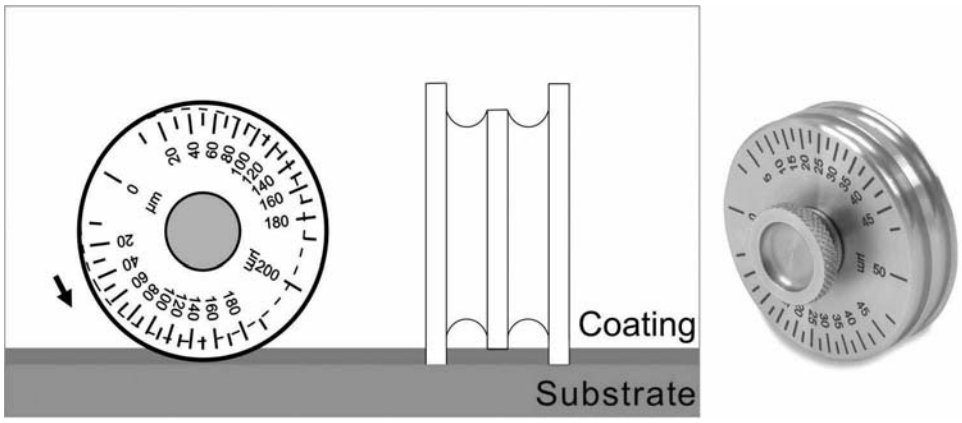

Fig. 1—Inmont gage (Interchemical) wet film wheel schematic diagram (left) and photograph (right).

where D = diameter, mm of spot and R = radius of curvature mm of the lens.

Table 1 gives film thickness and the corresponding spreading rate in square feet per gallon for spots from 3 to 38 mm in diameter.

It has been observed that a substantial proportion of paints do not obey the 1-to-1 relationship. The actual thickness, obtained by independent methods, may be several times, or only a fraction of, the thickness calculated by the equation. A small amount of thinner added to a paint may increase the diameter of the spot on the lens and give a corresponding increase in the calculated thickness. This phenomenon has been ascribed to the effects of surface tension. Hence, for best results, a correction factor should be established for each type of paint based on the known thickness of a freshly prepared film measured by the Inmont gage.

Reproducibility is within about 2 % for films 2 mils (50 μm) thick, decreasing to about 10 % for films 5 mils (125 μm) thick, and then becoming better as thickness increases.

Notch Gage (Wet Film Comb)

Notch gages (wet film combs) are formed on the edge of a strip of material so that each notch has a different clearance from the reference shoulders to that of its neighbors (Fig. 3). Many different materials are used to make these gages, such as stainless steel, aluminum, and plastic, in a variety of shapes: square, rectangle, triangle, hexagon, etc.

The Notch gage is a simple low-cost device, which is useful when approximate values of wet film thickness are satisfactory, as the notches have discrete values and are not continuous across the range of thickness. The gage is dipped vertically into the film until the reference shoulders are resting firmly on the substrate. The thickness of the film is between the highest coated notch or tooth face and the next highest, uncoated, value.

Several different methods of manufacture of these gages exist from spark-eroded stainless steel precision combs, through punched aluminum sheet, to plastic flow molded combs. The stainless steel combs can be certified with measurements of the tooth displacements, which are

38	0.36100	2.77	113	129

traceable to national standards. As the stainless steel is hard wearing, this certificate can be valid over a period of up to one year. On the other hand, plastic combs, although manufactured from solvent-resistant ABS plastic, should only be used once as the solvent in the coating may soften the plastic. Plastic combs can be tagged and kept as a permanent record of wet film measurement.

Aluminum combs are prone to wear, and the condition of an aluminum wet film comb should be carefully checked before use.

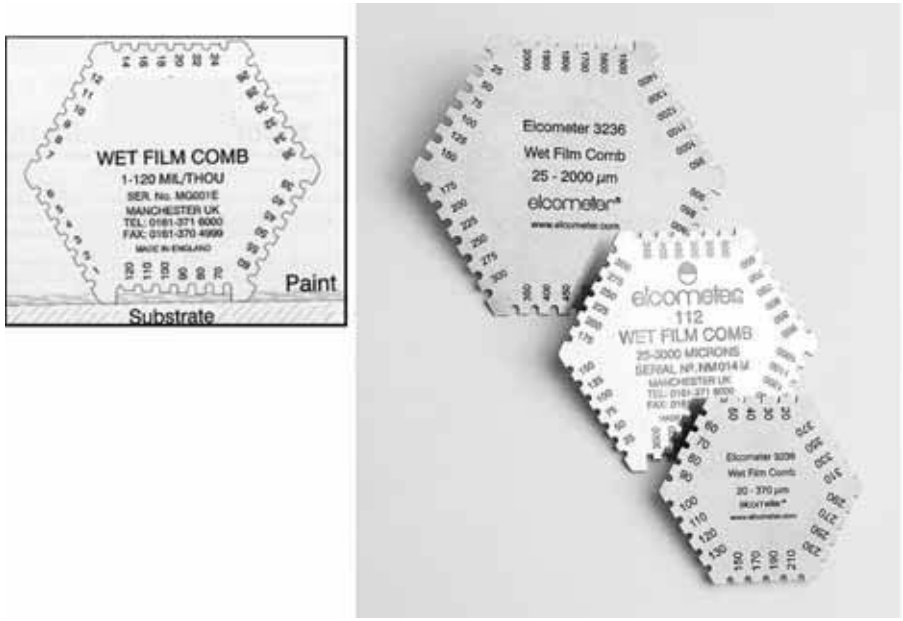

Fig. 3—Wet film comb schematic (left) and photograph (right).

Wet film gages are available covering many ranges, from 0.5 mil (2.5 μm) to 160 mils (4 mm/4000 μm). The teeth are normally square ended, but for thicker coatings pointed teeth are sometimes used.

Notch gages are supplied by various coating equipment suppliers, e.g., Elcometer Inc., Paul N Gardner, etc. and are fully described in ASTM D4414, Practice for Measurement of Wet Film Thickness of Organic Coatings by Notched Gages.

ASTM D4414 describes methods; Method A uses a square or rectangular notch gage made from a thin rigid material, and Method B uses a circular notch gage made from a thin rigid material.

Needle Micrometer

This method was used to study the relationship between the clearance of a doctor blade and the thickness of the wet film left by the blade [1]. A needle is attached vertically to the objective holder of a microscope. The barrel is lowered until the needle just touches the film that has been spread on a plain metal panel. The contact is observed through a horizontal microscope. When contact is made, the needle and its image reflected by the film just meet. The needle is then lowered into the film until it just touches the metal panel. This contact is noted by the deflection of a galvanometer in series with the panel, a dry cell, and the needle. The thickness of the film is calculated from the number of turns made by the focusing screw of the vertical microscope between the two points of contact.

It should be noted that this technique is only applicable to measurements made in a laboratory, as it is impractical for work on site. The equipment is no longer available but may still be in use in certain laboratories.

DRY FILM THICKNESS (DESTRUCTIVE METHODS)

As there are many circumstances under which coatings and paints are used with many different materials as the substrate, no single method of dry film thickness measurement is universal. Some methods are destructive, and these are most often used when nondestructive methods cannot be applied. The following sections describe the use of the Micrometers and Dial Gages, the Gardner Needle Thickness Gage, the Gardner Carboloy Drill Thickness Gage, and the Gardner Gage Stand and the Gardner Micro-Depth Gage.

Micrometers and Dial Gages

When a chip or flake of coating is freed from the surface of the coated object, its thickness can be measured directly using a micrometer. Alternatively, the total thickness of the substrate and coating can be measured; the substrate can then be re-measured after removing the coating with a scraper or solvent. The coating thickness is then the difference between the two measurements. This "before and after" coating measurement is also the basis of the method for manufacturing coated thickness standards.

ASTM D1005, Test Method for Measurement of Dry-Film Thickness of Organic Coatings using Micrometers, describes four methods as follows:

Procedure A—Stationary micrometer for measuring coatings applied to plane rigid surfaces.

Procedure B—Stationary micrometer for measuring free films.

Procedure C—Hand-held micrometer for measuring coatings applied to plane rigid surfaces.

Procedure D—Hand-held micrometer for measuring free films.

Procedures A and C require the thickness of the test panel and film to be measured and then the film is removed to allow just the thickness of the test panel to be measured. The difference between the two thickness values is then calculated and reported as the film thickness. It is also possible to measure the uncoated test panel in selected and identified locations before the coating is applied and the combined test panel and dry film measured together at the locations used for the initial measurements.

Procedures B and C require the preparation of free films as outlined in ASTM D2370 and detailed in ASTM D823.

Fig. 4—Dial micrometer.

Procedure D, using a hand-held micrometer mounted on a support with a clamp to hold the specimen (see Fig. 4), is recommended only for thicknesses over 0.5 mil and is accurate to ±0.1 mil.

A hand-held dial coating thickness gage (Fig. 5), may be used to measure coated samples. In this case the dial records the difference in position between the foot that sits on the surface of the coating and the stylus with its ball end, which passes through a hole prepared in the coating to the surface of the substrate. This is particularly useful for site work. However, for best accuracy and precision, the mounted dial gage specified in ASTM Method D1005 is preferred.

Gardner Needle Thickness Gage

This instrument is designed to measure the thickness of electrically nonconducting films on metal (conducting) substrates. It is small enough to be used in the field where the substrate can be made part of the electric circuit. The needle makes only a minute puncture in the film. In many instances, particularly in a go-no-go determination, the damage is so slight that the method may be considered nondestructive for many end users.

The aluminum housing case contains the needle screws for forcing the needle through the film and a lamp to signal when the needle contacts the substrate. For use in the field and for occasional use in the laboratory, the electric circuit comprises the needle, the substrate, a dry cell, the lamp, and a cord that connects with the substrate. In the laboratory, if many measurements are to be made, it is advisable to use a step-down transformer and to connect to a 110 V source.

The thickness is read on a dial attached to the screw. One turn of the dial raises or lowers the needle by 2 mils. The dial is graduated in steps of 0.05 mil. Range is 0 to 15 mils.

Fig. 5—Dial type coating thickness gage.

The zero setting of the needle is obtained by retracting the needle within the housing, placing the gage on a plane metal block, and lowering the needle until the lamp signals contact. The specimen replaces the block and the needle is lowered until the lamp again signals contact. The difference between the two readings is the thickness of the film.

Gardner Carboloy Drill Thickness Gage

In many instances films are so hard that they successfully resist penetration by the needle penetrometer described above. This difficulty has been overcome by substituting a Carboloy drill for the needle. The drill is a needle terminating in a pyramid having three faces. The drill is secured in a chuck that can be rotated and advanced independently. The rotation is controlled by finger action on a knob at the upper end of the chuck shaft. In all other respects, the operation is the same as that of the needle gage. This method is not now widely used.

Gardner Gage Stand

Although the Gardner needle gage and the Carboloy drill gage may be operated by manually holding the gage against the specimen, using the Gardner gage stand is less tiring and more accurate, especially when many measurements are to be made. The stand provides constant known pressure [up to 10 lb (5kg)] on the specimen and ensures that the needle or drill is always perpendicular to the specimen.

Gardner Micro-Depth Gage

Although in outward appearance this gage resembles the gages described in the last two subsections, only the

establishing of the zero setting is the same. Measurement is not restricted to nonmetallic films on metal—any type of film on any type of substrate may be measured, and the film is always damaged.

In this gage, a chisel replaces the needle of the gage. The zero setting having been established, the chisel is advanced by an amount estimated to be less than the thickness of the film. The gage is placed on the specimen and drawn toward the operator through a distance of a few millimeters. If the scratch made by the chisel does not penetrate the film, the chisel is advanced by a small increment, and another scratch is made. The procedure is repeated until the substrate is reached and exposed. Inspection is best made with the aid of a low-power magnifier. The range is 0 to 40 mils (1000 μm). Repeatability depends on the magnitudes of the increments and the compressibility of the film and substrate. For example, specimens with poor adhesion may be torn off, exposing the base, even if the chisel does not penetrate the film.

Microscope for Film Thickness

CLASSICAL METHOD

To use a microscope to assess film thickness, a section is prepared and the width of the coating is measured using a graticule in the eyepiece of the microscope. For an approximate assessment, a flake of the coating can be used, but for best results from this method the specimen should be prepared as follows.

The specimen is mounted in a block of wax. The face of the mount is cut or ground to a smooth surface. The prepared specimen is then inspected under the microscope.

BRIGHTWELL METHOD

This method does not require removal of a chip and elaborate mounting and preparation [2]. A tiny furrow is made in the film or a small chip is removed. A prism or ribbon of light is projected on the selected area at an angle of 45°. The distortion of the beam is examined with a microscope equipped with a micrometer eyepiece. Apparatus for this is available in the Schmaltz optical surface analyzer (Carl Zeiss).

The apparatus is calibrated by measuring known depths milled in a smooth metal block. The ribbon of light is focused on line A, and the filar micrometer reading is recorded. The procedure is repeated on line BC. The difference multiplied by the calibration factor equals the thickness of the film.

STOPPED METHOD

A cut is made in the film with a sharp knife. The microscope is focused, in turn, on the upper and lower edges of the cut. The thickness of the film is computed from the vertical adjustments of the microscope [3]. If the value is not known, it may be found as follows: Put a piece of plate glass on the stage. Lower the tube until it just touches the plate. Record the reading of the fine adjustment. Now raise the tube as far as possible and again record the fine adjustment. Now raise the tube as far as possible and again record the fine adjustment.

The distance of the tube from the plate divided by the number of turns of the adjusting screw gives the value for each turn.

TOOKE INSPECTION GAGE (PAINT INSPECTION GAGE)

ASTM D4138, Standard Test Methods for Measurement of Dry Film Thickness of Protective Coating Systems by Destructive Means, describes three methods as follows:

Test method A: Using grove cutting instruments
Test method B: Using grinding instruments
Test method C: Using drill bit instruments

The Tooke Inspection gage [4], also known as the Paint Inspection Gage (Fig. 6), provides for estimating the thickness of a film from the geometry of a V-groove cut in the film by a special tool. With the aid of a ×50 illuminated magnifier equipped with a reticle in the eyepiece, the operator measures the lateral distance from the top edge of the cut and the projection of the intersection of the cut and the substrate. To make a measurement, a "bench mark" of ink applied to the surface of the film serves to make the top edge of the cut readily visible. A short cut is then made at a right angle to the benchmark with the selected cutting tip. Film thickness is then obtained by counting the scale divisions as described previously.

SÄBERG DRILL

ASTM D4138 Test method C is similar to the method described in the previous subsection; however, a circular drill is used to penetrate the film. The hole can then be

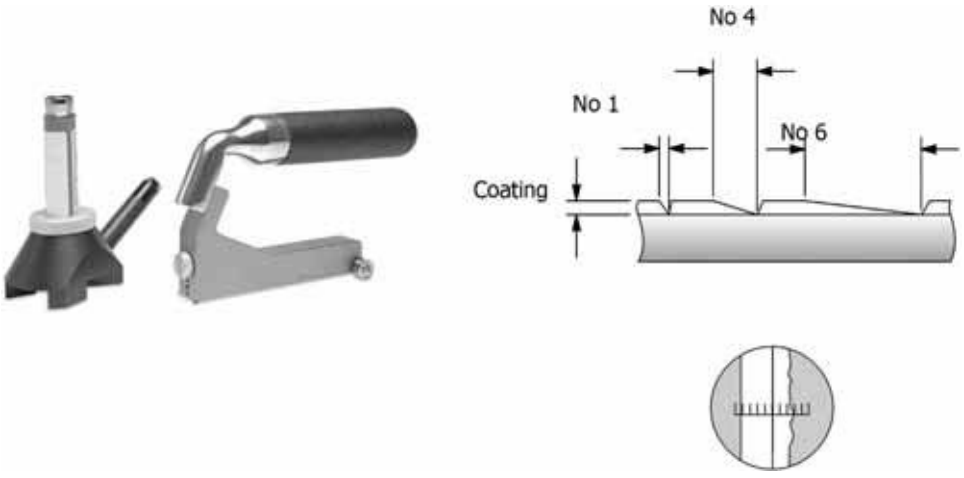

Fig. 6—Paint Inspection Gage (Tooke gage) with section through coating and view through the microscope.

Fig. 7—Säberg Drill.

inspected using the ×50 magnifier with graticule, and the width of the cut from the outer edge to the print where the drill penetrates to the substrate is a measure of the coating thickness. For the Säberg Drill illustrated in Fig. 7, the calculation of coating thickness is as follows:

1. For measurement in micrometers, multiply graduations by 20.0.
2. For measurement in mils, multiply graduations by 0.79.

DRY FILM THICKNESS (NONDESTRUCTIVE METHODS)

There are two main groups of gages for the nondestructive measurement of dry films on metal substrates and these are the permanent magnet gages, which can be used for coatings on magnetic metal substrates and electronic gages, which can be used for coatings on ferro-magnetic substrates, such as steel, nonferrous metals and where ultrasonic measurement methods are used on some nonmetal substrates. The following sections describe the Permanent Magnet Thickness Gages, the Electronic Thickness Gages with some of their features and limitations, and Ultrasonic Gages.

Permanent Magnet Thickness Gages

Permanent magnet coating thickness gages can be used to determine the thickness of films applied to magnetic substrates such as steel, iron, magnetic stainless steel, etc., providing that the coating is nonmagnetic. Materials such as nickel and cobalt, which are naturally magnetic, have to be treated with care, while paints containing magnetic particles, such as some ferrous micaceous iron oxide, can cause errors when using magnetic gages, both mechanical and electronic.

Simple magnetic coating thickness gages, also known as pull-off gages, use the principle that the attractive force between a permanent magnet and the magnetic metal substrate is inversely proportional to the distance between them.

The principal limitations are (1) the film must be sufficiently hard to prevent indentation, and (2) the film must not be tacky, causing the magnet to be held by the surface of the coating.

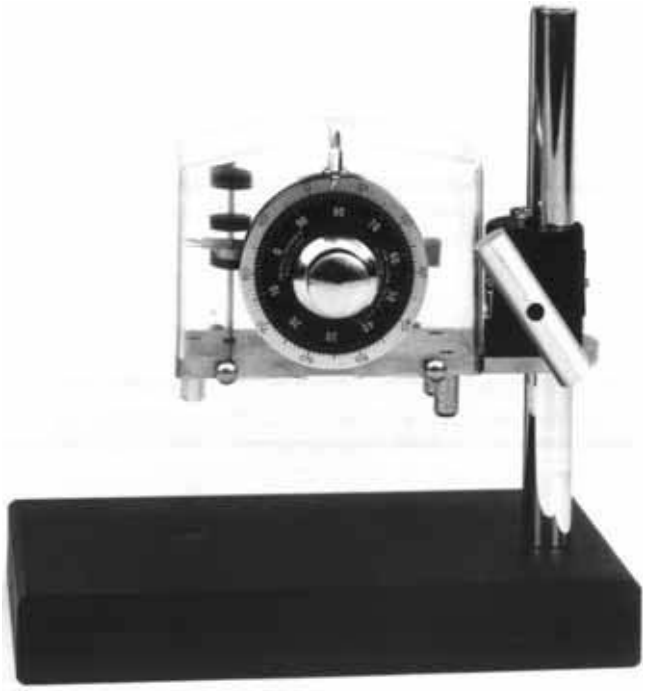

Fig. 8—Magne-Gage. (Courtesy of Magne-Gage Sales & Service Co., Inc.)

Electronic magnetic coating thickness gages are also available, but these will be described in a separate section entitled Electromagnetic Thickness Gages; this section includes the electronic gage based on the magneto-resistor (Hall-effect) probe.

MAGNE-GAGE

This instrument (Fig. 8) consists of a small permanent bar magnet, 2 mm in diameter, suspended from a horizontal lever arm [5]. The arm is actuated through a spiral spring by turning a dial. The tip of the magnet is brought into contact with the paint film (on iron or steel), and the dial is then turned until the magnet is detached. The attractive force between the magnet and the film support is indicated on the dial, and the thickness of the nonmagnetic paint film is obtained from a calibration curve relating thickness to dial reading.

The Magne-gage can be used to measure coatings on convex and concave surfaces as well as on flat ones provided the radius of the curvature is not too small. Unless special calibrations are made, cylinders should not be less than 1/2 in. (1.27 cm), in diameter spheres not less than 3/4 in. (1.9 cm), and flat pieces should be at least 3/4 in. (1.9 cm) square.

Magnets for thicknesses in the following ranges are available: 0.0 to 0.002, 0.002 to 0.007, and 0.007 to 0.025 in.

Within ASTM D7091 (Standard Practice for Nondestructive Measurement of Dry Film Thickness of Nonmagnetic Coatings Applied to Ferrous Metals and Nonmagnetic, Non-conductive Coatings Applied to Non-Ferrous Metals) the Magne-gage is described as a Type 1 or magnetic pull-off gage. It should be noted that the Magne-gage is not now in common use but the apparatus is still available in the USA.

Fig. 9—Magnetic coating pull-off thickness gage.

HAND-HELD MAGNETIC PULL-OFF GAGES

Electronic gages are superseding the mechanical gages, and some—such as the Tinsley gage and the chemigage—are no longer manufactured. However, many thousands of these Type 1 gages are still in use, so it is appropriate to describe them.

The simplest form of these gages contains a magnet suspended from a coil spring housed in a pen-style body manufactured from aluminum or plastic. A scale is drawn on the body and a marker is used to indicate the extension of the spring on the scale. The reading on the scale when the magnet lifts off the surface corresponds to the thickness of the coating.

The scale on these instruments is nonlinear, leading to low reading resolution at the maximum range, usually 20 mils (500 μm), and great care must be taken to ensure that they are used vertically to avoid the influence of gravity on the spring-magnet combination. Some of these types of gages have design features to overcome the gravity effect when the gage is used horizontally.

The accuracy of this type of gage is typically ±15 % of the readings and therefore these gages do not satisfy the accuracy requirement of ASTM D7091.

A common form of the hand-held magnetic pull-off gage is shown in Fig. 9. A balanced beam with a magnet fitted to one end and counterbalanced by a brass weight at the other is attached at the pivot to a helical spring. The other end of the spring is attached to a ring holding the scale. Rotation of the ring raises or lowers the magnet. This type of gage is described in ASTM D7091 as a Type 1 gage.

The gage is placed on the surface to be tested in any orientation as the balance weight ensures that gravity effects are neutralized. The ring or scale wheel is pushed forward (anticlockwise rotation) to bring the magnet in contact with the coating and to set the scale to a maximum reading. The ring or scale wheel is then rotated clockwise until the magnet breaks free, the thickness of the coating being indicated by a pointer.

This type of gage is calibrated against plated standards available from NIST, and accuracy against these standards of ±5 % of reading is achieved. It should be noted that the steel used to make NIST standards is not always representative of engineering steels, and therefore a practical operating accuracy of ±10 % is obtained in the field unless coated standards using steel that is typical of the substrate on which the coating is applied can be used to verify the accuracy of the gage for the specific application.

THE MAGNETIC RELUCTANCE GAGE

The coating thickness gage based on the magnetic permeability principle (Fig. 10) is one of the first magnetic thickness gages to be commercially available, having been patented in 1948. The magnetic flux from a permanent magnet acts on an armature suspended in between two magnetic arms of the unit, forming north and south poles. The turning moment of the magnetic flux is countered by a helical spring, and the magnitude of the magnetic flux changes with the distance between the tips of the magnetic arms (ball feet) and the substrate beneath the coating, i.e., the coating thickness. A pointer attached to the armature indicates the thickness of the coating. Gages covering thickness ranges from 0 to 3 mil (0 to 80 μm) to 0 to 0.75 in. (0 to 18 mm) are still available. The accuracy of this type of gage is typically ±10 % of the reading and these gages do not, therefore, meet the requirements of ASTM D7091. However, this type of gage is useful where electronic gages cannot be used, for example in places where flammable vapors are present or underwater.

Electronic Coating Thickness Gages

Electronic coating thickness gages use the electromagnetic induction principle or the Hall effect to measure nonmagnetic coatings on magnetic substrates or the eddy current principle to measure nonconductive coatings on non-ferrous metals. Gages can also make use of the Hall effect to measure coatings on magnetic substrates.

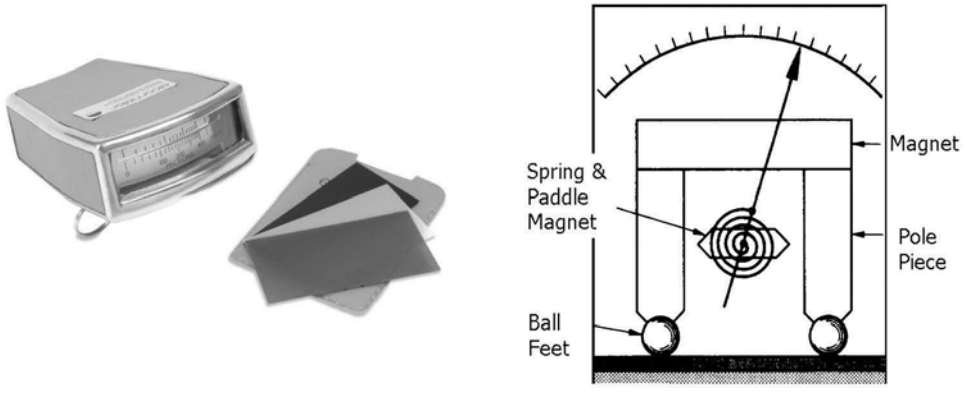

Fig. 10—Magnetic reluctance coating thickness gage.

ELECTROMAGNETIC INDUCTION PROBES

The electromagnetic induction method for measuring film thickness is based on the effect of a magnetic metal substrate on the balance of the alternating magnetic field in the probe tip, generated in the probe by a signal applied to the central coil that has two neighboring search coils.

When the probe is away from the influence of the substrate (free-air condition), the net voltage output from the two search coils tends to zero. As the substrate is brought toward the tip, the field is increasingly out of balance between the two search coils until, with the uncoated substrate in contact with the tip, the net voltage output from the coils tends toward V max.

The voltage output from the probe can be amplified and calibrated and then used to display a thickness value. Three types of electronic coating thickness gages have been developed on the basis of this probe technology using analogue, digital, and microprocessor electronics. ASTM D7091 describes these gages as Type 2 gages.

EDDY CURRENT PROBES

The eddy current method for measuring film thickness is used to measure coatings on nonferrous metals. It is based on the effect that a high-frequency alternating field (~3 000 000 Hz or 3 MHz) has an electrically conductive surface causing highly localized current (eddy currents) to flow. These currents generate their own magnetic fields, which influence the impedance of the coil, generating the high-frequency field. The magnitude of these changes is proportional to the distance from the probe coil to the substrate, that is, to the thickness of the coating.

This type of gage is also described as a Type 2 gage in ASTM D7091.

Calibration adjustment by adjustment to zero and to a known thickness on a piece of metal of the same type, shape, and thickness as the samples to be measured is vital to ensure accuracy. Modern eddy current instruments are available using microprocessor designs and some of these designs offer the facility for a dual-purpose ferrous (F) electromagnetic induction and nonferrous (N) eddy current principle combined in a single probe. Using the dual FNF probe, the gage can be made to measure automatically on either type of substrate, with the gage displaying the substrate type, F or N, when the measurement is complete and the reading displayed.

This type of gage can be used to measure paint galvanizing on a steel substrate. The F probe is used to measure the total thickness of the zinc and the paint on the steel and, if the zinc layer is 2 mil (50 μm) or greater, the N probe can be calibrated to measure the paint thickness only. By subtracting the paint thickness from the total thickness, the thickness of the zinc (galvanizing) can be estimated.

HALL EFFECT PROBES

This type of gage makes use of a probe that combines a permanent magnet with a Hall-effect semiconductor sensor a signal, which varies with the intensity of the magnetic field. The strength of the magnetic field is influenced by the distance of the magnetic substrate from the tip of the probe, i.e., the thickness of the coating.

The scale of these gages is nonlinear and they use either an analogue meter movement or digital electronics to indicate the thickness. In operation it is necessary to set zero on the uncoated metal and calibrate to a thickness of known value to obtain the best accuracy, as with other electronic gages.

These gages meet the requirements of ASTM D7091 and are also described as Type 2 gages.

ANALOGUE COATING THICKNESS GAGES

The simplest form of electronic coating thickness gage uses a nonlinear scale on a meter movement to display the voltage output from the probe against a thickness scale. These gages are now relatively expensive to manufacture and have almost completely been replaced by digital gages, although some of these gages may still be in use in the field.

In common with most electronic coating thickness gages, calibration adjustment to the substrate to be tested is required. Setting the needle to zero with the probe on the uncoated magnetic metal substrate and then setting the upper scale point, using the calibration control, with the probe on a known thickness of coating, will adjust the gage for use on surfaces typical of the uncoated metal substrate used.

Two forms of thickness standard are in common use: (1) the pre-coated type, which can be the plated type, as illustrated by the standards available from NIST, or the hard-wearing epoxy coating applied to metal substrates of known thickness type, and (2) the measured and unmeasured plastic shims available commercially from gage manufacturers. In many applications the plastic shims are preferred as the thickness standards for calibration adjustment because they can be used as a sample of the uncoated substrate to be measured, reducing the errors of calibration adjustment due to surface finish, curvature, substrate composition, and thickness of the substrate. More details of these sources of error are given later in this chapter under the heading "EFFECTS OF SURFACE FINISH, CURVATURE AND SUBSTRATE COMPOSITION ON ELECTROMAGNETIC AND EDDY CURRENT MEASUREMENTS."

DIGITAL COATING THICKNESS GAGES

Advances in electronic components and instrument design techniques over the last 30 to 40 years have made it possible to significantly reduce the size of coating thickness gages while retaining and enhancing the features users find necessary in their applications. The use of digital electronics means that the voltage output from the probe can be converted to a numerical value early in the processing of the signal, thus reducing the effects of temperature changes and component drift on the accuracy of the result. It is also possible to use a linear scaling, making it possible to have a fixed resolution over the full range of the instrument scale although resolutions are often enhanced in the 0 to 125 or 0 to 250 μm (0 to 5 mil or 0 to 10 mil) ranges.

It should be noted that this type of product has been superseded by microprocessor-based designs, although some digital gages are still being used. The same principles of calibration adjustment apply to digital electromagnetic coating thickness gages as they apply to the analogue types, and accuracy capabilities of ±5 % of readings are readily achieved using digital gages in the field.

MICROPROCESSOR ELECTROMAGNETIC THICKNESS GAGES

The application of microprocessor electronics to the design of portable coating thickness gages has made it possible to improve the accuracy and reproducibility of these

Fig. 11—Microprocessor electromagnetic thickness gage.

instruments as well as allowing developments in range, special calibration techniques for rough surfaces, memory of readings, statistical calculation, printouts and data transfer.

In a microprocessor design, the characteristic of the probe voltage output against coating thickness value is stored in the memory of the instrument for many values over the range of the probe. The actual voltage output from the probe is digitized and then compared with the stored values. A thickness value is then calculated from these data and displayed. This is typically achieved in 0.3 s. Using this technique, accuracies of ±3 % of reading are possible. A simple form of this gage is shown as Fig. 10. Note that this gage has no user adjustments and this simple operation is made possible by a factory calibration to the specific requirements of the automotive industry for which it was designed.

As a microprocessor instrument is in effect a dedicated computer, many calculations can be performed on the data, and features such as correction for temperature changes, storage of calibration conditions and corrections to these calibrations, averages, and other statistical values can be included in the instrument's firmware.

Fig. 11 illustrates one of these microprocessor-based electromagnetic thickness gages that have memory-operated features such as a large reading memory, statistics, printout and data transfer.

Fig. 12—Dual microprocessor electromagnetic coating thickness gage.

Fig. 13—Coating Thickness Gage with Hall Effect probe. (Courtesy of DeFelsko Corporation)

Fig. 12 illustrates the current trend in microprocessor design with a dual microprocessor coating thickness gage. This unit has a microprocessor to control the gage, display the readings, perform the calculations, and provide data transfer with a second microprocessor, contained in the separate probe electronics, so that the probe can be individually characterized to thickness standards for optimum accuracy, ±1 % or ±1 μm, whichever is the greater, across the full thickness range of the probe.

Fig. 13 illustrates a coating thickness gage with the Hall effect type probe.

The use of microprocessor electronics also makes it possible for a single gage to make use of a wide variety of probes with different ranges, different formats, and different access capabilities. In general, the greater the thickness range of a probe the larger the physical size of the probe.

EFFECTS OF SURFACE FINISH, CURVATURE, AND SUBSTRATE COMPOSITION ON ELECTROMAGNETIC, EDDY CURRENT, AND HALL EFFECT MEASUREMENTS

The accuracy of coating thickness measurements carried out using the methods described above depends on the technique used in adjusting the gages for the conditions of the measurement. The major influences on the adjustment of these gages are surface finish, curvature, thickness, and material composition of the substrate. In the case of magnetic substrates the substrate material composition will influence the magnetic properties and hence the calibration of the gage. In the case of nonferrous metals the effect is that different materials will have different electrical conductivity, which will influence the generation of eddy currents and the resulting calibration adjustment.

Surface Finish

A variety of surface finishes are to be found on metal to which a protective or decorative coating is to be applied. In some cases the coatings used require an anchor pattern

of profile depth, which forms a part of the specification. Comparators such as the Keane-Tator Surface Profile Comparator or the International Standards Organization ISO 8503 are used to determine the surface finish after shot or grit blasting. Also Testex Tape and the Elcometer Surface Profile Gage can be used to measure peak-to-valley heights of profiles. These instruments are shown in Fig. 14.

Surface finish also influences the calibration adjustment of a coating thickness gage, as the mass of the metal directly beneath the probe is reduced by the effects of shot and grit blasting and the probe tip sits on the highest peaks of the profile. This has the effect of increasing the value of thickness indicated using a gage calibrated on a smooth surface by as much as 1.5 mils (35 μm) at 4 mils (100 μm) coating thickness for the highest values of profile.

It is possible to use a rough surface calibration technique to eliminate this error and make the instrument read the correct value of coating thickness over the peaks by using the statistical power of the microprocessor type gages to calibrate on the profile. This is achieved by using a thin foil 1.0 mil (25 μm) over the profile to set the lower calibration point and a thicker foil 5.0 mils (125 μm) or 10.0 mils (250 μm) to set the upper value over the profile. The instrument will then indicate the thickness over the peaks for the coating between the values of foil chosen.

This method is most accurate and reproducible when 15 to 20 readings are taken on each calibration foil to establish a mean value and the mean value is then reset to the correct value of the foil. Trials have shown that the mean of 15 to 20 readings taken over an area of coating give a mean value within a few percent of the actual value over peaks determined by sectioning.

The method does not, however, take into account situations where access to the substrate is not possible for calibration purposes. In this case, the method described in SSPC PA2 where a correction value is applied to readings taken using a smooth surface calibration in the instrument is more appropriate. This method is also described in EN ISO 19840. For either case it is important to agree with the method before measurements start to avoid discrepancies in reporting.

Curvature

The shape and metal wall thickness can also influence the accuracy of the calibration. The degree to which a particular gage is affected depends on the design of the probe. Most modern instruments exceed the limits identified in SSPC PA2.

The effect of shape is most evident when taking readings on an uncoated sample. With an instrument calibrated on a smooth piece of metal 0.125 in. (3.175 mm) thick, changes of more than 0.2 mil (5 μm) in the reading at zero will be seen on curves with a radius below 0.12 in. (3 mm) convex or 0.96 in. (25 mm) concave on a typical

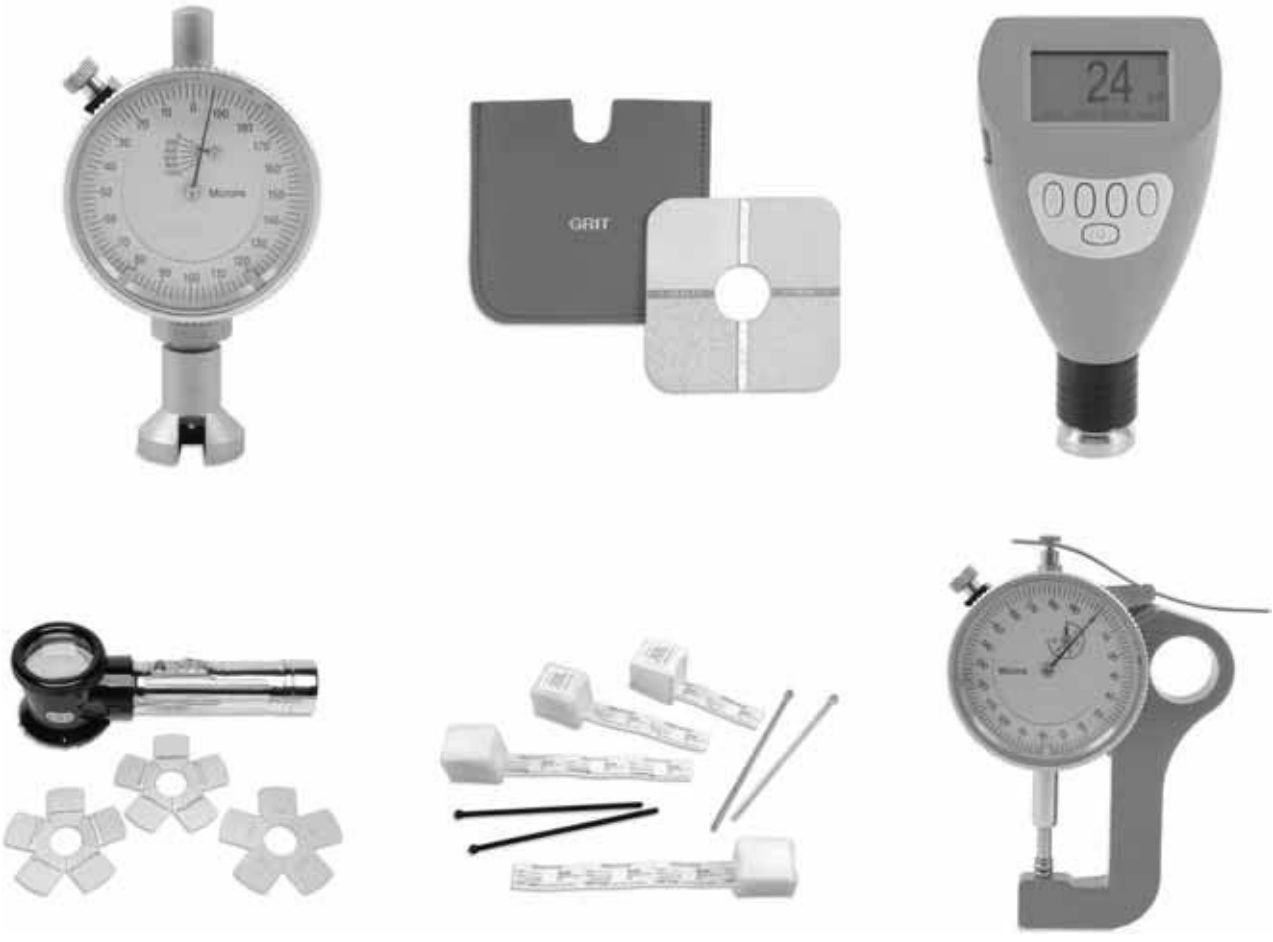

Fig. 14—Surface profile gages.

electromagnetic induction probe. Values will vary between manufacturers and from different probe types.

This error can also be eliminated by calibration on a shape closely representing the specimen to be tested. However, it should be noted that once below the values of curvature indicated in the manufacturer's literature, changes in curvature have a significant effect on calibration, i.e., the calibration on a shape will not be applicable to another shape.

Substrate Thickness

The minimum thickness of substrate required to provide stable readings will vary with the type and design of probe. Typically both F and N probes can be used on substrates down to 6 mil (300 μm). Special gage adjustment techniques can be used to measure on substrates thinner than this value but it should be noted that flexing of these thin substrates also changes the measurement condition and support from a solid nonmetallic base may be required.

Measurement close to the edge of a substrate can also lead to errors. A good rule of thumb for electronic gages is that the area to be measured should be at least the same as the total area of the probe face. The performance of the gage and probe close to an edge can be determined by noting the change in the zero value on an uncoated sample as the probe is brought closer to the edge of the sample. The zero reading will start to increase as the edge effect comes into play.

Substrate Composition

In the case of electromagnetic induction probes, most are insensitive to the differences between the majority of steel specifications in general engineering use. However, when high-carbon steels are coated, the carbon content sufficiently alters the magnetic properties of the steel to cause the normal calibration curve applied within the instruments to be in error with respect to linearity. Thus, an instrument calibrated at zero and say 5 mils (125 μm) may have an error at 2 mils (50 μm) of more than 0.2 mil (50 μm), or 10 %. A similar effect can be seen with some cast irons.

This error can be overcome by calibrating as for the rough surface described in the section earlier in this chapter entitled "Surface Finish." For best accuracy, choose a foil just below the expected coating thickness value for the lower calibration points and a value well above the expected coating thickness value for the upper calibration point.

When coatings applied to nonferrous metals are being measured using eddy current techniques, the composition of the substrate and its effect on electrical conductivity are the important factors with respect to calibration. Materials such as aluminum and copper have very similar characteristics and similar calibration values. However, zinc, brass, and other nonferrous metals and alloys have different characteristics, and calibration on an uncoated sample is essential. Differences of up to 2 mils (50 μm) can be seen between "zero" with an aluminum calibration and zero on a brass component.

D7091 explains calibration, adjustment, and verification for dry film thickness gages. Calibration of a coating thickness gage is normally carried out by the manufacturer of the gage or an authorized laboratory using a documented procedure and thickness standards that are traceable to a National Metrology Institute. The frequency of such calibration is determined by the quality assurance procedure of the user, particularly when operating to a quality management system that is independently audited such as ISO 9001. The re-calibration period for gages within such a system will be specified and is typically 12 months.

The adjustment of a dry film thickness gage is a procedure to minimize the errors caused by the conditions under which the measurements are to be made. These include the topics covered in the paragraphs above, surface finish, curvature, substrate thickness, and substrate composition but may also include issues such as the temperature of the substrate or the prevailing climatic conditions.

The verification of a coating thickness gage should be carried out by the user before the gage is used to measure the work in hand by checking the accuracy of measurements on known thicknesses standards, preferably on a sample of the substrate that is typical for the work that is being coated. The gage must be verified for the range of thickness for which it is to be used and if the gage readings are outside the combined accuracy of the coating thickness standards and the manufacturer's accuracy specification for the gage, then the gage should be sent for re-calibration and repair should that be required to restore the correct calibration.

STATISTICS IN FILM THICKNESS MEASUREMENT

As many random variations can be expected in a coating process, it is appropriate to classify the thickness of the coating using a statistical analysis. In fact, many national specifications utilize a statistical approach in recognition of these variations, e.g., SSPC PA2.

The sources of these variations are many, and only a few examples can be cited here—operator error in taking the measurement, recording error, variation due to surface or curvature or composition, local variation in substrate due to local heat treatment or due to forming or working the metal, inclusions in the metal or in the coating, etc.

The influence of these factors can be greatly reduced by taking a statistically significant number of readings for each area of the coating to be tested. This group of readings can then be summarized using mean and either standard deviation or range to show the average and the spread of readings about the average.

A statistically significant number of readings would be 20 to 50; however, if the process is under statistical control as defined, five readings in each group or subgroup are sufficient.

Many of the microprocessor-based coating thickness instruments are capable of calculating and recording mean values (X), standard deviation (σ), and highest and lowest values (range) within a batch of readings.

It is important to establish the method of evaluating the information before embarking on an evaluation of a coating system so that the correct disciplines are applied to collecting the data and evaluating it for further decisions.

DATA MANAGEMENT

Some gages have memory and data transfer features such as RS 232 serial data transfer by cable or wireless communication via Bluetooth. These features used together allow readings for a project to be collected in a batch or batches in the gage and then this data can be transferred to a

computer running Data Management software for analysis, reporting, and archiving and fulfilling the requirements of Paperless Quality Assurance systems.

One of the major benefits of this approach is the removal of any potential transcription errors that can arise when manual records of coating thickness readings are kept in an inspector's notebook and are then transcribed into a report or a spreadsheet for further analysis.

It is possible to transfer data directly from the memory of the coating thickness gage into a spreadsheet if a suitable function is included either in the gage or in the supporting software. The spreadsheet can then be used in the normal way to provide statistical values and charts. There are Data Management systems that also allow supporting data such as paint datasheets, inspection procedures, photographs and other project-related information to be associated with the specific gage data from an inspection. This then allows detailed reports to be prepared for clients in a semiautomatic fashion.

FILM THICKNESS MEASUREMENT USING ULTRASONICS

Thickness measurements of certain dry films can be made using ultrasonic energy, measuring the time of flight of a pulse through the coating and back from the coating/substrate interface. ASTM D6132, Nondestructive Measurement of Dry Film Thickness of Applied Organic Coatings Using an Ultrasonic Gage, describes this method.

The pulse echo layer thickness measurement technique using an ultrasonic transducer with a scan display is capable of measuring individual layer thickness in a multiple layer system but calibration is sensitive to the differences in these layers and a change of pigment may be sufficient to change the calibration conditions.

A rigid substrate is required to obtain a good reflection of the ultrasonic energy and the coating must be able to transmit the sound energy without attenuation or dispersion. Coatings that include bubbles of air or that have certain types of fillers or pigments cannot be measured using this technique as they absorb the ultrasonic energy. Some substrates exhibit characteristics that tend to disperse the ultrasonic energy, as they are rough or are not sufficiently different to the material of the coating to adequately reflect the energy, e.g., certain coating on plastic substrates.

UNCURED POWDER COATING THICKNESS TO PREDICT FINAL FILM THICKNESS

ASTM D7378, Standard Practice for Measurement of Thickness of Applied Coating Powders to Predict Cured Thickness, describes three procedures. Procedure A uses a rigid metal notched (comb) gage (see Fig. 15).

Procedure B uses a special magnetic or eddy current probe, depending on the substrate material. The probe is designed to minimize the damage to the uncured coating and measures the actual coating thickness of the uncured powder film.

For both Procedure A and Procedure B a correction value has to be applied to the uncured powder thickness readings to predict the cured coating thickness.

Procedure C describes noncontact ultrasonic powder gages (see Fig. 16). These gages use a characterization of the reflected sound energy from the uncured coating to predict the final thickness of the coating after cure. Calibration can be checked by measuring the powder before the cure using the ultrasonic gage and after the cure using a dry film coating thickness gage as described earlier in this chapter. This procedure is awaiting a round robin test to be carried out.

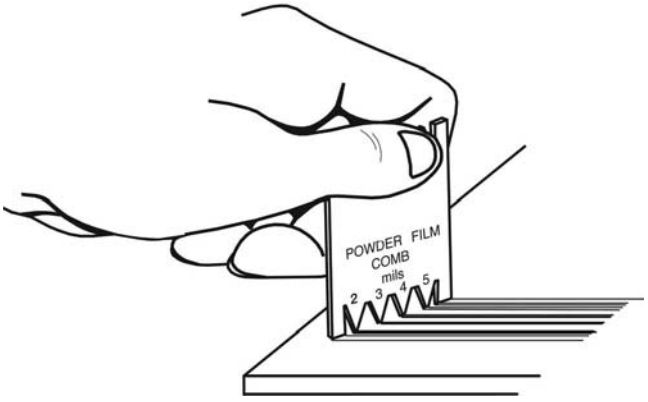

Fig. 15—Notch Gage for uncured powder thickness measurement—schematic diagram.

X-RAY FLUORESCENCE (XRF)

Recent developments in performance and reductions in cost have pushed X-ray fluorescence to center stage, particularly for metal coatings on metal substrate applications and smaller parts, such as fasteners. Beta-ray backscatter (BBS) techniques had been widely used to measure plated coatings; however, limitations in performance—e.g., a minimum of 20 % difference in atomic number between the coating and the substrate is required—mean that while gold over nickel, copper, or Kovar can be measured, nickel

Fig. 16—Noncontact ultrasonic coating thickness gage for uncured powder coatings.

TABLE 2—Thickness ranges for some common coating materials using X-ray fluorescence [7]

Coating	Substrate	Approximate thickness range (μm)
Aluminium	Copper	0–100.0
Copper	Aluminium	0–30.0
Copper	Iron	0–30.0
Copper	Plastic	0–30.0
Gold	Ceramics	0–8.0
Gold	Copper or nickel	0–8.0
Lead	Copper or nickel	0–15.0
Nickel	Aluminium	0–20.0
Nickel	Ceramics	0–20.0
Nickel	Copper	0–20.0
Nickel	Iron	0–20.0
Palladium	Nickel	0–40.0
Palladium-nickel	Nickel	0–20.0
Platinum	Titanium	0–8.0
Rhodium	Copper or nickel	0–50.0
Silver	Copper or nickel	0–50.0
Tin	Aluminium	0–60.0
Tin	Copper or nickel	0–60.0
Tin-lead	Copper or nickel	0–25.0
Zinc	Iron	0–40.0

over copper or Kovar cannot be measured using BBS techniques. Other disadvantages exist, such as limits in the aperture/component geometry, and measurement times have led to the further development of XRF techniques and technology.

Principle of XRF Measurement

If sufficient light energy collides with an electron, it is possible for the electron to be driven out of its atomic orbit, a process known as the photoelectric effect [6]. An atom with an electron removed from its orbit is unstable, so to restore equilibrium, an electron from a higher shell must drop into the vacant orbit. This transition causes an emission of energy in the form of a light wave or photon.

When the inner shell electrons are ejected from an atom, the emitted photon has high energy, and they fall into the region of the electromagnetic spectrum called X rays. X rays have characteristic energy levels determined by the element, which is emitting and can therefore be used to identify the elements in a sample.

In XRF instruments an X ray source or tube is used to produce photon emissions as they have an energy distribution capable of fluorescing all elements commonly used in plating. The X ray beam can be accurately illuminated to provide a small focal spot and high-intensity energy suitable for noncontact measurement of complex layers on small components. The characteristic X rays emitted by the target materials are detected using a gas-filled "proportional counter" in which the passage of the X ray ionizes the gas and produces a pulse of electrical charge proportional to the energy of the X ray.

The XRF instruments' electronics convert the charge pulse into a digital signal that can be interpreted as thickness or analyzed for composition and produce the measurement information by comparison with standards of known thickness. XRF instruments have developed with optical alignment systems and motor-driven sample stages to position the sample and computerized analytical equipment to store calibration data to calculate and present data to the user in a suitable format. Table 2 shows some of the applications, which can be successfully measured using XRF.

Drying Time

Thomas J. Sliva[1]

THE PROCESS OF DRYING INVOLVES SEVERAL physical and/or chemical changes, such as solvent evaporation, oxidation, and polymerization, all of which are time dependent. The various stages of drying that occur in organic films may be subjective, difficult to measure reproducibly, and are influenced by many factors such as film thickness, substrate, temperature, humidity, light, and air circulation. Therefore, it is essential that most of these variables must be minimized in order to make drying time determinations more quantitative.

PREPARATIONS OF SPECIMENS

Substrate Preparation

It is essential that the substrate to be used and the applied wet film thickness be agreed upon in advance, preferably to conform to the intended use of the coating. Flat glass panels are typically the substrate of choice. Ground and polished glass plates are more suitable for low-viscosity coatings that may tend to crawl. All panels must be thoroughly cleaned, dried, and placed in a horizontal position on a level surface.

Application

The test coating should be filtered to remove any dirt or contamination. Test films are typically prepared, in duplicate, using a drawdown bar or doctor blade adjusted to obtain a uniform film thickness. Films should be drawn down at a uniform rate of application to avoid drag on the coating. It is recommended that all test films should be prepared and tested by one operator properly skilled in the method to be used and that a control (known) coating be run alongside the test coating. All testing should be done within an area, any point of which is not less than 1/2 in. (~ 15 mm) from the edge of the test film.

Table 1 can be used as a general guide for film application when nothing more specific is agreed upon between the purchaser and the seller. The dry film thicknesses shown in Table 1 are suggested. Other methods of application, such as spraying, dipping, or flood coat, may be used provided the film thickness obtained is consistent with that recommended under actual usage. Other substrates, such as metal, may be used provided they are smooth and flat.

ENVIRONMENT

When determining drying time, a controlled environment is essential. Variations in temperature, relative humidity, circulation of air, and light will have an effect on the drying time of a coating. The typical standard environment used for determining the drying time of air dry coatings is a temperature of 73.4° ± 3.6°F (23° ± 2°C) and a relative humidity of 50 % ± 5 % under diffuse daylight (about 25 fc).

Relative humidity should be strictly controlled for moisture-cure and two-package urethane coatings since their cure is greatly affected by the existing relative humidity. The effect of variation in temperature was discussed by Algeo and Jones [1], who observed a difference of 4 h for a particular paint dried at 73 and 77°F (22.7 and 25°C), both at 50 % relative humidity.

All testing should be conducted in a well-ventilated room free from direct drafts and dust. Airflow is important in determining drying time. For films that dry by oxidation, the rate of drying is a function of the concentration of oxygen at the interface. Since oxygen can reach the surface only by diffusion, the rate of drying is a function of the thickness of the stationary air layer. For films that dry by solvent evaporation, the continuous removal of solvent-laden air hastens drying [2].

TEST METHODS

ASTM D1640, Test Methods for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature

Method D1640 is the most commonly used method to determine the various stages and rates of film formation in the drying of organic coatings normally used under conditions of ambient room temperature. The method describes eight stages of the drying process:

1. *Set-To-Touch Time*
   The test film is lightly touched with the tip of a clean finger, and the finger tip is immediately placed against a piece of clean, clear glass to determine when the film does not adhere to the finger or transfer to the glass.
2. *Dust-Free Time*
   This test is generally performed to determine when dust or cotton fibers lightly dropped on the test film can be removed by blowing over the test film. Individual absorbent cotton fibers are dropped from a height of 1 in. (25 mm). The film is considered to be dust free when the cotton fibers can be lightly blown off the test film.
3. *Tack-Free Time*
   The test film is considered to be tack free when no stickiness is observed under moderate pressure. This can be measured by either of two methods:
   a. *Paper Test Method*
   A special paper (K-4 Power Cable Paper) [3] is placed on the test film under a weight of 2 psi (13.8 kPa). After 5 s, the weight is removed and the test film inverted. If

[1] *Deceased, formerly of DL Laboratories, 116 East 16th St., New York, NY 10003.*

TABLE 1—Recommended film thickness of material to be tested

Material	Dry Film Thickness, mils
Oil paints	1.8±0.2
Enamels	1.0±0.1
Drying oils	1.0±0.1
Water-based paints	1.0±0.1
Varnishes	0.85±0.1
Lacquers, polymer solutions	0.5±0.1

the paper drops off within 10 s, the film is considered tack-free.

A variation of the above method is used to test the tack-free time of insulating varnishes. The varnish is considered tack free when the paper is placed on the test film under a weight of 1 lb (450 g) for 1 min and tested as above.

b. *Tack Tester*

This is a mechanical device that consists of a strip of metal 1 in. (25 mm) wide, 3 in. (75 mm) long, and 0.016 to 0.018 in. (0.41 to 0.46 mm) in thickness. It is bent to form a base 1 in. (25 mm) square and a vertical length 1 in. by 2 in. (25 mm by 50 mm) angled at 135°. The bottom of the base of the tester is covered with aluminum foil [4] (Fig. 1). A 300 g weight is placed on the center of the base and allowed to set for 5 s. The test film is tack free when the tester tips over immediately after the weight is removed. Occasionally, tack-free time may be longer than dry-hard or dry-through time due to the inclusion of external plasticizers in the coating.

4. *Dry-To-Touch Time*

The test film is considered dry-to-touch when no mark is left when the film is touched by a finger. The following variations are used:

a. *Drying Oils*—The film is considered dry-to-touch when it does not rub up appreciably when a finger is rubbed lightly across the surface.

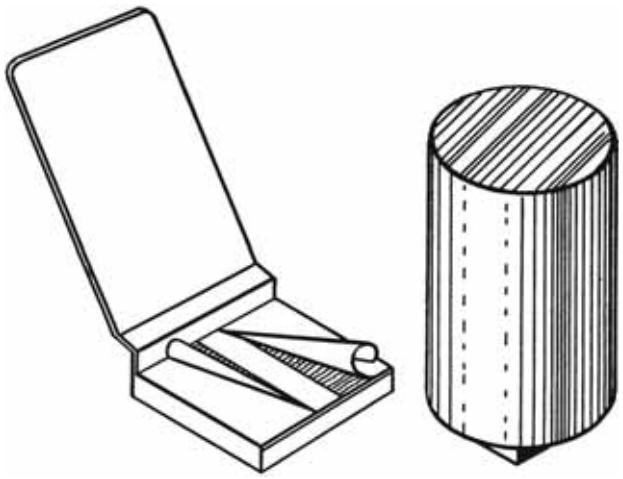

Fig. 1—Zapon Tack Tester. The base of the tester is padded and wrapped with aluminum foil. The weight, at right, is set on the base for a definite interval. After the weight is removed, the time required for the tester to tip over is the measure of tack.

b. *Lacquers* (*and Sealers*)—The film is considered dry-to-touch when no pronounced marks are left by a finger touching the film. Sealers are generally tested on wood or other porous substrates.

5. *Dry-Hard Time*

The test film is considered dry-hard after maximum downward thumb pressure (without twisting) applied to the test film leaves no mark when the contacted area is lightly polished with a soft cloth.

6. *Dry-Through* (*Dry-To-Handle*) *Time*

The test panel is placed in a horizontal position at such a height that when a thumb is placed on the film, the arm of the operator is in a vertical line from the wrist to the shoulder. The operator bears down on the film with the thumb, exerting moderate pressure and at the same time twisting the thumb through an angle of 90°. The test film is considered dry through when the film is not distorted by bearing down with moderate thumb pressure and twisting 90°.

7. *Dry-To-Recoat Time*

The test film meets this requirement when a second coat can be applied without causing any film irregularities, e.g., lifting, wrinkling.

8. *Print-Free Time*

The test film meets this requirement when imprinting fabric under a pressure of 1/2 or 1 lb/in.^{2} (3.5 or 7.0 kPa) shows the coating to be print free. This procedure is similar to ASTM D2091, Test Method for Print Resistance of Lacquers.

An indication of the accuracy of these methods is the precision statement developed in ASTM D1640 in which duplicate determinations within a laboratory should agree within ± 10 % [5].

Federal Test Method Standard 141C, Method 4061.2: Drying Time

This method is similar to ASTM D1640. It includes essentially the above stages of drying with the exception of dry-to-touch. However, it includes a test for free-from-after-tack. This test is applicable to coatings where tackiness persists beyond, or reappears at, the through-dry stage. It is similar to the Paper Test Method, discussed earlier in this chapter, except that a 2.8 kg (6.2 lb) weight is used.

ISO Standard 9117, Paints and Varnishes—Determination of Through-Dry State and Through-Dry Time—Method of Test

This standard describes a method for determining under standard conditions whether a single coat or a multi-coat system of paint or related material has, after a specified drying period, reached the through-dry state, i.e., a pass/fail test. The test procedure may also be used to determine the time taken to achieve that state.

1. *Through-Dry State*

This state defines the condition of a film in which it is dry throughout its thickness as opposed to that condition in which the surface of the film is dry but the bulk of the coating is still mobile. A single coating or a multi-coat system of paint or varnish is considered to be through-dry when a specified gauze attached to a plunger is placed on the test film under specified pressure (1,500 g) for 10 s, after which time the plunger head is turned through an angle of 90° over a period of

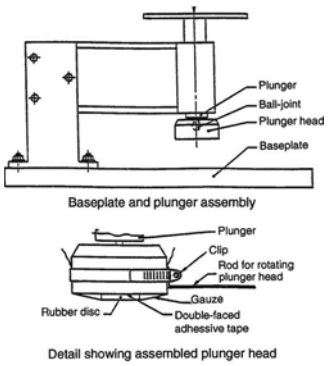

Fig. 2—Through-dry tester.

2 s and removed (Fig. 2). If no damage or markings are noted on the test panel, the film is said to have achieved "through-dry state."

2. *Through-Dry Time*
   This is the period of time between application of a coating to a prepared test panel and the time to achieve the "through-dry state" as outlined above.

British Standard B.S. 3900, Methods of Test for Paints

Parts C-1 thru C-4 of British Standard B.S. 3900 describe drying tests for determining the wet edge time, surface drying, hard-drying, and freedom from residual tack tests. Part C-8 describes a test for determining print-free state or time.

1. *Wet Edge Time* (*BS3900, C1*)
   This procedure is used for determining whether the edge of a film of paint remains "alive" after a specified period of drying. Following a touch-up coat over the film after the specified drying period, the area is evaluated for lack of film continuity, absence of leveling, or variation in color or sheen.
2. *Surface Drying* (*BS3900, C2*)
   This procedure is used to determine the time after which a coating is applied and when approximately 0.5 g of the ballotini (small transparent solid glass spheres) can be poured onto the surface of the film from a height of between 50 and 150 mm and lightly brushed away without damaging the surface.
3. *Hard-Drying Time* (*BS3900, C3*)
   A rubber-faced plunger is covered with cotton twill, rough side outwards, and then loaded to a total weight of 1.8 kg (4lb). The rotating plunger drops into the panel and makes a three-quarter turn while in contact. The paint film is dry-hard when no damage is observed (Fig. 3).

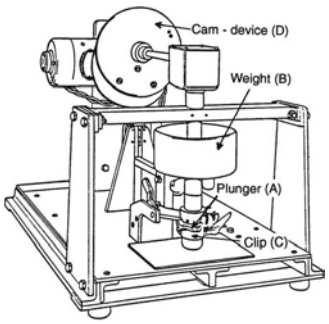

Fig. 3—Hard-drying time apparatus: Assembly.

4. *Freedom from Residual Tack* (*BS3900, C4*)
   After a specified drying period, a paper-backed gold leaf is placed on the test panel and covered with a microscope slide and an 800 g weight. After 10 s, the weight and slide are removed and the panel is held vertically and lightly tapped to detach the gold leaf. The surface of the paint film is examined for adhesion of gold leaf.
5. *Print-Free* (*BS3900, C8*)
   The state of a coating or varnish when gauze of a specified grade, under specified force and after a specified time, does not leave an imprint on the surface of a coating.

DIN 53 150, Determination of Drying Time of Paints

Drying time is determined in this method by the adherence or non-adherence of sand or paper to the film under various loadings. Stage 1 is determined with sand (0.16 to 0.315 mm) or glass beads (ballotini). The sand is allowed to remain on the film for 10 s. The remaining stages are determined using disks of typewriter paper (22 mm in diameter and weighing about 60 g/m^2) and various loads ranging from 5 to 5,000 g/cm^2. Interposed between the load and the test disk is a soft rubber cushion. The load remains on the disks for 60 s. The criteria for the seven stages are as follows:

1. Sand easily removed with a soft brush.
2. Disk under load of 5 g/cm^2 does not adhere.
3. Disk under load of 50 g/cm^2 does not adhere.
4. Disk under load of 500 g/cm^2 does not adhere, but film is temporarily marred.
5. Disk under load of 500 g/cm^2 does not adhere, but film is not marred.
6. Disk under load of 5,000 g/cm^2 does not adhere, but film is temporarily marred.
7. Disk under load of 5,000 g/cm^2 does not adhere, but film is not marred.

MECHANICAL DEVICES

In an attempt to improve the accuracy and reproducibility of the drying time test procedure, various mechanical devices have been developed. The following sections outline these devices and the procedures used in determining drying characteristics.

ASTM D5895, Test Methods for Evaluation Drying or Curing During the Film Formation of Organic Coatings Using Mechanical Recorders

1. *Circular Drying-Time Recorder*
   The device consists of a synchronous motor in a metal case resting on a rubber-tipped tripod and rotating

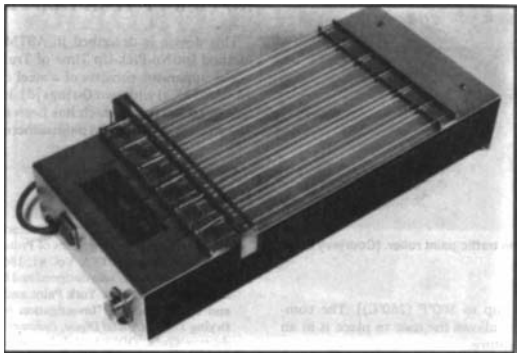

Fig. 4—Straight line recorder. (Courtesy of Byk-Gardner.)

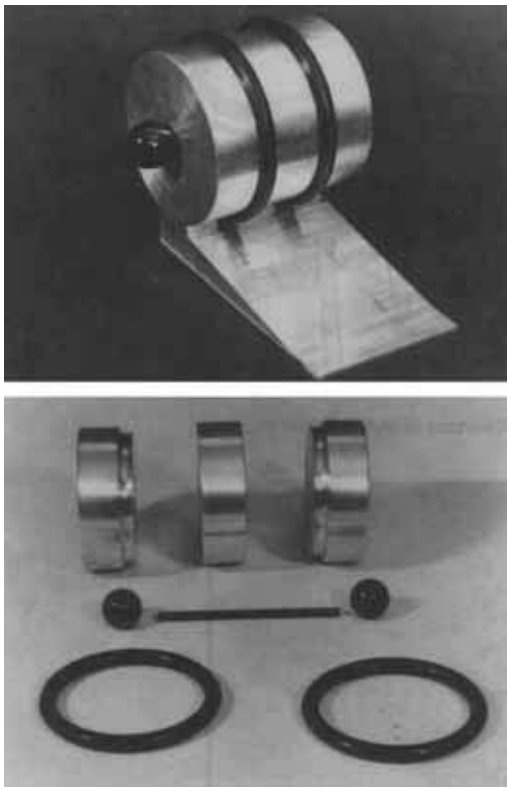

Fig. 5—No pick-up time traffic paint roller. (Courtesy of Byk-Gardner.)

a vertical shaft. A pivotal arm assembly is attached to the shaft, operating a vertical stylus with a Teflon sphere that does not stick to the drying film [6]. Under a 12 g load, the Teflon stylus scribes an arc in the drying film. Programmable units that are designed to control motor speeds and cover drying times of 1 min to 96 h—i.e., one 360° rotation of the stylus.

A transparent, plastic template with time increments can be placed over the dried coating at the end of the test. The appropriate scale number of circular degrees required for the film to cure hard dry is then used to determine the dry time. During the early stages of drying, the coating tends to flow back into the wake of the stylus. When the tendency of the flow has ceased, the film may be considered set. As the drying process continues, a skin will form. Visually, this part of the film formation is seen when the stylus begins to tear the surface of the film. The film may be considered surface dry or dust free when the skin is no longer ruptured by the stylus. It is considered through-dry when the stylus rides above the film.

Circular drying time devices have been developed for use when determining the drying time of bake finishes that cure at elevated temperatures [up to 500°F (260°C)]. The compactness of the instrument allows the user to place it in an oven at a specified temperature.

2. *Straight Line Drying Time Recorder*

This device consists of multiple needles being drawn over multiple (up to six) parallel coated glass strips [7]. Its speed can be varied to cover drying periods of 6, 12, and 24 h (Fig. 4). It defines the following stages in the drying process:

1. The first stage is a pear-shaped depression corresponding to the time it takes for the solvent to evaporate.
2. The second stage is the cutting of a continuous track corresponding to a sol-gel transition.
3. The third stage is an interrupted track corresponding to the surface dry time.
4. In the fourth stage, the needle no longer penetrates the film, indicating the final drying time.

Five-gram brass weights may be added to apply greater pressure on the needles and thus record through drying. The instrument has also been found useful in evaluating gel time of many two-component surface coatings.

NO PICK-UP TIME TRAFFIC PAINT ROLLER

This device is described in ASTM Standard D711, Test Method for No-Pick-Up Time of Traffic Paint. The apparatus consists of a steel cylinder weighing 11 lb, 14 oz (5385 g) with two O-rings [6]. It is rolled along a drying film of traffic paint which has been applied on a glass plate. The paint is dry when no paint adheres to the O-rings (Fig. 5).

Color and Light

Robert T. Marcus[1]

PREFACE

IN PREPARATION OF THIS CHAPTER, THE CONTENTS of the fourteenth edition were drawn upon. The author acknowledges the authors of the fourteenth edition, Fred W. Billmeyer Jr. and Harry K. Hammond III. The current edition will review and update the topics as addressed by the previous authors, introduce new technology that has been developed, and include up-to-date references.

TERMINOLOGY

To understand this chapter and to make the best use of it, the reader should be familiar with the terminology of appearance. The precise definition of terms is becoming increasingly important in today's world community. The paint terminology standard, Definitions of Terms Relating to Paint, Varnish, Lacquer, and Related Products (D16), is the primary source of terms and definitions relating to paint, but it contains very few appearance terms. The reader should refer to Terminology of Appearance (E284) for terms and definitions relating to color and other appearance attributes. All significant terms used in this section are defined in Terminology E284.

An important international source of appearance terms is the *International Lighting Vocabulary* [7], published jointly by the International Commission on Illumination (CIE) and the International Electrotechnical Commission (IEC). However, this is structured from the viewpoint of illuminating engineering. It is less readily available and a much more costly document than Terminology E284.

Because color is a significant factor in the appearance of an object, it is an important characteristic of any paint. Appearance, of which color is a part, is one quality of a product that every customer can judge for himself. No matter how good the physical properties of a paint, if its color does not meet the expectation of the customer, the finished product will be rated as unsatisfactory.

Color, often thought to be a property of the paint itself, depends on three objective aspects: (1) the spectral composition of the light in which the paint is viewed, (2) the spectral reflectance of the paint, and (3) the spectral response of the eye of the observer. The subjective interpretation of the response to these aspects by the brain is also an essential part of color. Describing the color of a paint or other material requires consideration of all of these and not merely the spectral character of the material. The three objective aspects of color are considered in sections entitled "Light Sources," "Reflection and Transmission," and "The Eye." The sciences involved include chemistry, physics, physiology, and psychology. These are broad subjects, and only enough discussion is included to provide a background for understanding the development of test methods. Readers desiring to pursue these subjects in detail should consult an appropriate text [1–6].

LIGHT SOURCES

Light is electromagnetic radiation weighted by the response of the normal human eye. It occupies a small portion of the electromagnetic spectrum between ultraviolet and infrared radiation. Its wavelength range is approximately 380 to 780 nm (Fig. 1).

Natural and Artificial Daylight

Despite modern dependence on interior illumination, daylight is still an important light source since most objects are at some time viewed in it. The spectral composition of daylight, however, is quite variable, depending upon the hour of the day, the season of the year, and the amount of cloud cover. One way of dealing with this variability is to use standard light sources and their spectral power distributions when making visual or instrumental color measurements and calculations (see CIE Standard Sources and Illuminants).

Incandescent Sources

Other light sources must replace daylight when appropriate. For use in homes, incandescent lamplight is generally preferred because it imparts a soft, mellow effect similar to that of candlelight.

Fluorescent Sources

In stores and offices, fluorescent lamps can provide high levels of illumination with low power consumption and heat generation. The most commonly used fluorescent lamp, known as cool white, has a spectral distribution consisting of a relatively smooth curve throughout the visible spectrum. This arises from the fluorescent emission from a phosphor coated on the inside of the lamp tube. The fluorescence is excited by ultraviolet radiation from mercury vapor inside the tube. This lamp is, however, deficient in power in the red end of the visible spectrum. Modifications of it, known as deluxe and super-deluxe versions, have been designed to overcome this deficiency. Fluorescent lamps have also been designed with phosphors emitting only in three rather narrow regions of the spectrum. When these three bands are selected to peak near 450, 530, and 610 nm, light is provided that is especially pleasing to the eye and is energy efficient.

[1] *Senior Color Scientist, Sun Chemical Corporation, 1701 Westinghouse Blvd., Charlotte, NC 28273.*

Copyright © 2012 by ASTM International

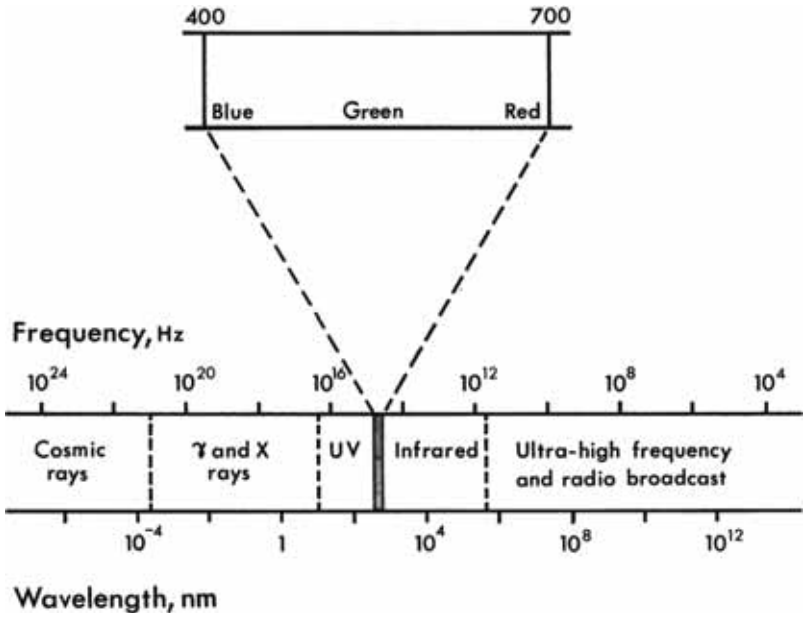

Fig. 1—Electromagnetic spectrum showing the relatively small portion that the visible spectrum occupies.

The color-balance and color-rendering properties among the various types of commercial fluorescent lamps can be vastly different one from another.

Other Sources

Other light sources have been developed for special purposes. They include arc lamps (sodium, mercury, neon, xenon), metal halide lamps, and high-intensity discharge lamps. None of these lamps has been adopted as a standard for use in color measurement.

Color-Matching Booths

Because of the variation in spectral composition of different natural and artificial sources, it is essential that visual color evaluation and matching be done under standardized illumination, such as that provided by a color-matching booth. This device allows the colorist to compare the colors of specimens under controlled and standardized illumination. Carefully manufactured and maintained light booths permit a colorist to make a visual match with confidence that the illumination duplicates that used at another time or place. However, the spectral power distribution of daylight illumination in color-matching booths is not the same as that of natural daylight.

REFLECTION AND TRANSMISSION

Opaque, Transparent, and Translucent Films

When light strikes an object, some of it may be reflected, some may be absorbed, and if the object is not opaque, some may be transmitted. The reflected light may be concentrated in a glossy, mirror-like, specular reflection, scattered uniformly in all directions (diffuse reflection), or distributed between these two extremes. A highly polished metal can reflect as much as 99 % of the incident light in the specular direction. A white powder, such as barium sulfate, scatters light uniformly in all directions, and it, too, can reflect as much as 99 % of the incident light. Specular reflection is related to the visual perception of gloss; diffuse reflection is related to the visual perception of lightness and, when it is wavelength dependent, to that of color.

Transmission can also be diffuse or regular, depending on whether or not light is scattered in passing through a material. Specimens that both transmit and reflect light are called translucent.

A spectrophotometer is used to provide information on the spectrally selective character of a material. Fig. 2 shows typical spectral reflectance curves of some paints. A trained colorist can obtain valuable information from such curves, but spectral data alone are unsatisfactory as a means for color identification.

Among the ASTM standards on reflectance and transmittance measurement [8], the most useful are shown in Table 1[2].

Retroreflection

Retroreflection is defined in Terminology E284 as "reflection in which the reflected rays are preferentially returned in directions close to the opposite of the direction of the incident rays." It is important in paints and coatings used for signs viewed at night, pavement and pedestrian markings, and other safety devices. The measurement of retroreflection requires special instrumentation and special test methods for the determination of daytime and nighttime colors of retroreflecting materials. Table 2 lists the ASTM standards dealing with this subject. The last two items in the table are standards in preparation and may never become official ASTM standards.

[2]As noted in Terminology E284, in the Discussion under *reflectance,* "The term *reflectance* is often used in a general sense or as an abbreviation for *reflectance* factor...." This simplifying convention is used in this chapter, as it is in many textbooks. The reader should refer to Terminology E284 for the definitions of *reflectance, transmittance,* and *radiance,* and the corresponding factors. Note that commercial instruments measure *reflectance factor,* not *reflectance*.

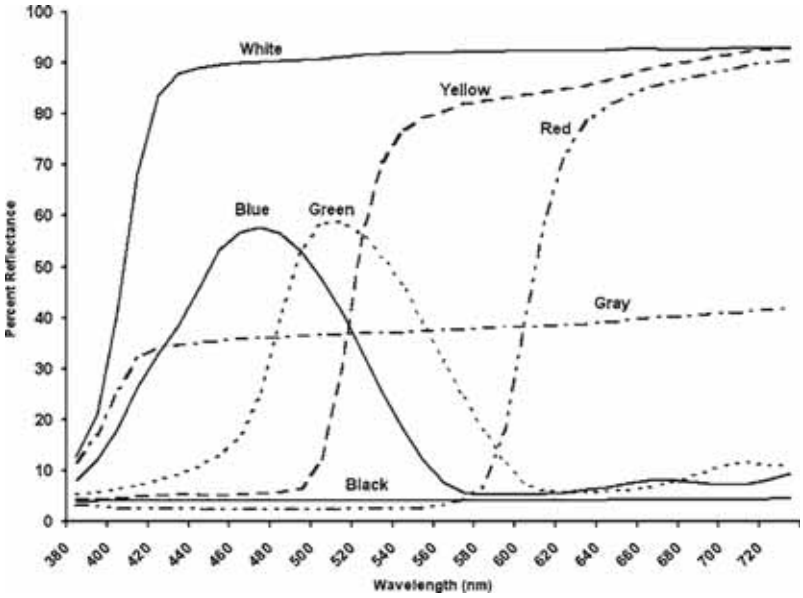

Fig. 2—Spectrophotometric curves typical of those measured on paint films. Note the sharp drop in the curve for rutile titanium dioxide (white) as the violet end of the spectrum is approached. The drop continues in the ultraviolet, where this pigment absorbs light strongly.

Gonioappearance

Gonioapparent coatings change one or more attributes of color with a change in the illuminating or viewing angle. Coatings containing metallic flakes exhibit a change in lightness, while coatings containing mica-based interference pigments or other effect pigments change their hue and chroma. Often metallic flakes are combined with other effect pigments so that the coating will change hue, lightness, and chroma with a change in the illuminating and viewing angles. Multiangle spectrophotometers, sometimes called goniospectrophotometers, are used to measure gonioapparent coatings. These are bidirectional instruments that have the capability of measuring with a variety of illuminating and/or viewing angles. More than one illuminating angle is required to characterize interference pigments, whereas only one illuminating angle can be used to satisfactorily characterize materials containing only metallic flakes. Practice for Multiangle Color Measurement of Metal Flake Pigmented Materials (E2194) describes how to measure gonioapparent materials containing only metallic flake pigments; Practice for Multiangle Color Measurement of Interference Pigments (E2539) describes how to measure gonioapparent materials containing thin film interference pigments; and Practice for Specifying the Geometry of Multiangle Spectrophotometers (E2175) provides a way of specifying geometric properties that are peculiar to multiangle spectrophotometry.

Ultraviolet and Infrared Spectral Regions

Ultraviolet and infrared radiation can have important effects on paint. Ultraviolet radiation, with wavelengths shorter than 380 nm, is the principal stimulus of fluorescence of certain pigments, is an aid to identification and analytical determination of certain ingredients of paint, and may promote decomposition of pigments or binders. Colorless pigments absorbing in the ultraviolet region can impart protection against such decomposition. Rutile titanium dioxide absorbs in the ultraviolet, as its spectral curve shows (see Fig. 2).

Infrared radiation, with wavelengths longer than 780 nm, is associated with heat transfer. It is widely used for the identification and analysis of chemical compounds. The near-infrared region, with wavelengths from 780 to about 1100 nm, is important for camouflage detection. Most paint pigments do not absorb radiation in this region, but some inorganic pigments reflect visible light and absorb radiation in the near-infrared.

Fluorescence

Some materials have the property of fluorescing when irradiated by ultraviolet or visible radiation. They typically emit radiation at longer wavelengths in the visible range or even in the near-infrared. The effect of fluorescence is to increase the apparent reflectance since the eye responds to the sum of the fluoresced and the reflected energy. This sum may even exceed the amount of light reflected by an ideal white material at the wavelengths of maximum fluorescent emission. Fluorescent pigments had a reputation for poor lightfastness in outdoor applications, but improved technology is changing this. Some fluorescent pigments can now survive at significant levels for several years.

Most modern colorimeters and spectrophotometers are designed to properly evaluate the colors of fluorescent materials. However, many of these instruments do not have light sources adequately simulating the ultraviolet content of natural daylight. In such a case, the instrument will not produce the same amount of fluorescence as would daylight. While many instruments will measure the color of fluorescent materials, generally it is necessary to use an instrument that both illuminates the specimen monochromatically and also views monochromatically to separate the fluorescence component from the reflection or the total radiance of a material. These instruments are called either spectrofluorimeters or bispectrometers.

Five ASTM standards apply to the measurement of fluorescence. Practice for Color Measurement of Fluorescent Specimens Using the One-Monochromator Method (E991) specifies the instrument geometry required for the measurement and shows how to assess the performance of daylight-simulating instrument light sources. Practice for Detecting Fluorescence in Object-Color Specimens by Spectrophotometry (E1247) provides instrumental methods to supplement simple visual examination of the specimen under ultraviolet light to detect the presence of fluorescence. Practice for Computing the Colors of Fluorescent Objects from Bispectral Photometric Data (E2152) and Practice for Obtaining Bispectral Photometric Data for Evaluation of Fluorescent Color (E2153) specify how to collect and interpret fluorescence data using bispectral, fluorescence-measuring instruments. Test Method for Daytime Colorimetric Properties of Fluorescent Retroreflective Sheeting and Marking Materials for High Visibility Traffic Control and Personal Safety Applications Using 45°:Normal Geometry (E2301) specifies how to collect and interpret fluorescent-retro-reflective materials by bispectral colorimetry using a 45:0 or 0:45 optical measuring system.

Recently, fluorescence has been used for the detection of defects in industrial coatings including fluorescing primer coatings, as well as non-fluorescent top coatings. A Specification for Light Source Products for Inspection of Fluorescent Coatings (E2501) was developed to provide the requirements for light source products intended for the excitation of fluorescent materials used for the detection of defects in industrial coatings. Test Method for Luminance Ratio of a Fluorescent Specimen using a Narrow Band Source (E2630) was developed as a companion to Specification E2501 to support the development and specification of industrial coatings that are used in a system for the detection of coating defects when inspected with a Specification E2501 light source. Specification E2501 establishes

a quantitative measure of the optical property of a coating that correlates to its ability to enhance defect contrast under the specified inspection light source.

Phosphorescence

Phosphorescence is similar to fluorescence. However, while fluorescing materials will stop emitting radiation once the irradiation stops, phosphorescing materials continue to emit. This makes phosphorescing materials ideal for safety markings. Two ASTM standards and one specification apply to phosphorescing materials—Guide for Recommended Uses of Photoluminescent Phosphorescent Safety Markings (E2030), Test Method for Photopic Luminance of Photoluminescent (Phosphorescent) Markings (E2073), and Specification for Photoluminescent (Phosphorescent) Safety Markings (E2072).

THE EYE

The Visual System

The human eye functions in a manner similar to a camera. It has a lens to focus images of objects and an iris to control the amount of light that enters. A complex light-sensitive layer, called the retina, plays a role analogous to that of the film in a camera. Neither the structure of the retina nor its function are fully understood. It contains two different types of light receptors that send information along neural pathways to the visual cortex of the brain. They are called rods and cones because of their shapes. The rods are responsible for black-and-white vision at low light levels, and they are not considered further in this section. At usual daylight levels, the rods are overwhelmed and do not contribute to vision. The cones are responsible for color vision. There are three types of cones, each with a different spectral sensitivity. The exact spectral response of each type of cone is not known, although it is assumed that each cone response function is related to the absorption curve of its pigment. The absorption curves are broad and overlapping (Fig. 3). They peak in the short, middle, and long wavelength regions of the visible spectrum; thus the designations blue, green, and red (sensitive) cones are sometimes used [9-12].

Detailed models of color vision have been proposed [13,14], but they are presently based on incomplete information. What happens to the neural signals from the retina on the way to and in the brain is not well understood, but for most work related to color and appearance, it does not need to be.

Perception

Perception is defined as the translation of retinal images by the observer into meaningful information about the environment. The perception of objects and their colors thus represents the overall response of the visual system, including both the eye and the brain. Vision is called a psychophysical phenomenon—physical in the way light reaches the eye, psychological in how the brain interprets the neural signals. The psychological factor determines, for example, whether a given color combination is interpreted as pleasing or displeasing. The mechanism of seeing is physical; the interpretation of what is seen is psychological.

Objective color measurement is, however, confined to physical aspects. For example, the perceived color of a specimen may be changed by changing the color of the area surrounding it. This phenomenon, called simultaneous contrast, cannot yet be evaluated instrumentally.

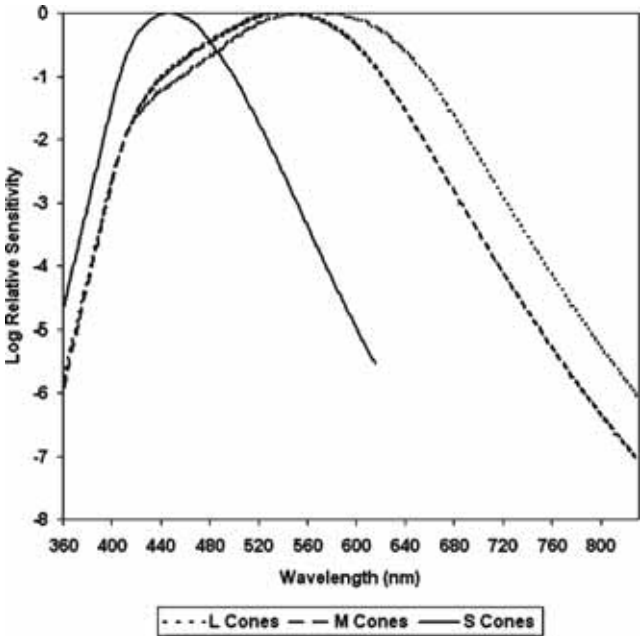

Fig. 3—Spectral curves showing the relative sensitivities of the three types of cones in the eye, peaking in the short (S), medium (M), and long (L) wavelength regions.

Another example of a perceptual phenomenon is chromatic adaptation, defined as the changes in the visual system's sensitivities due to changes in the spectral quality of the illuminating and viewing conditions. These changes tend to compensate, for example, for the effect of the change in illumination from distinctly bluish daylight to distinctly yellowish incandescent lamplight. The perceived colors of familiar objects tend to appear the same (known as color constancy) when the observer goes between environments illuminated by the two kinds of light, while the actual colors have all been shifted because of the change in spectral composition of the incident light.

The Variables of Perceived Color

The fact that the eye perceives color because it has three types of cones with differing spectral sensitivities implies, and experience confirms, that perceived color should have three variables. Several sets of these variables are of interest because of their wide use.

Object Colors: L, C, and H Cylindrical Systems

Of great interest to the paint colorist are the variables applying to the perception of object colors. Hue is always one of the variables. Hue is defined as the attribute of color described by common names such as red, yellow, green, blue, etc. The hues are commonly arranged in a circle in the order of their appearance in the spectrum, with the circle closed by the purples, mixtures of the red and blue at the ends of the visible spectrum (Fig. 4).

A second important variable of object colors is lightness, the attribute by which an object is judged to reflect more or less light. It is often represented graphically by a line through the center of the hue circle and perpendicular to its plane (also shown in Fig. 4). The upper and lower

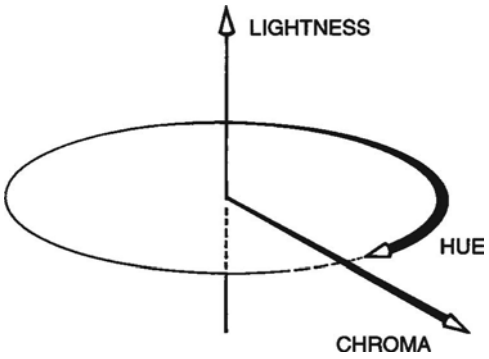

Fig. 4—Arrangement of the hue, lightness, and chroma axes in the usual cylindrical representation of color space.

ends of this line, often called the neutral or achromatic axis, are white and black, respectively.

The third variable in this set has several different names, referring to variations among what we can perceive: Chroma, saturation, and colorfulness are examples. The common factor among these names is a sense of the amount, in contrast to the kind, of hue in the color. In this section we use chroma as the name for this third variable and show it in Fig. 4. This quantity is exemplified by the distance between the point representing the color and the neutral axis. The Munsell system (see Munsell System) is an example of a cylindrical system.

Colored Lights

When we deal with colored lights instead of objects, two changes need to be made in the above system: Lightness is replaced by brightness and chroma by saturation. Brightness in this sense is defined as the attribute by which an area appears to emit more or less light.

Object Colors: L, a, and b Opponent Systems

A widely used alternative to the hue-lightness-chroma system described above is an opponent-color system that mimics the behavior of the neural signals transmitted from the retina to the brain. The lightness axis, often labeled *L,* is retained, but the hue circle is replaced by two opponent-type axes at right angles and perpendicular to the lightness axis (Fig. 5). Commonly they are a redness-greenness and a yellowness-blueness axis labeled *a* and *b,* respectively, as in the figure. Scales of this type are displayed in many color-measuring systems; examples are given later in Color Order Systems.

Color Constancy and Metamerism

Color Constancy

As previously noted under Perception, color constancy is the general tendency of colors to remain constant in appearance when the color of the illumination is changed. Note that this term refers to what happens to the color of a single specimen when the illumination is changed.

Metamerism

Of greater concern to the colorist is what happens to the relationship of two colors when the illumination is changed. This phenomenon is of industrial importance and largely under the control of the colorist. Suppose that two

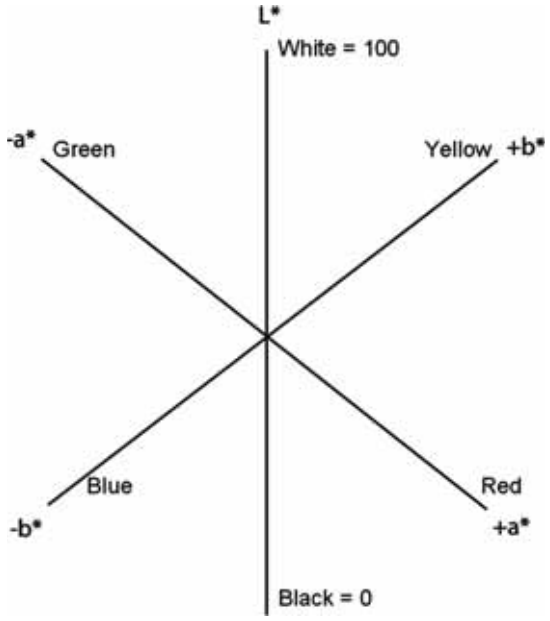

Fig. 5—Arrangement of the lightness, redness-greenness, and yellowness-blueness axes in the usual opponent-color representation of color space.

colors, which match in daylight, are formulated by using different sets of pigments. The two colors may not match under another type of illumination, such as incandescent lamplight, since the two specimens may exhibit different types and degrees of color constancy. This phenomenon is known as illuminant metamerism, and the colors are said to be metameric. Illuminant metamerism is defined as the property of two specimens having different spectral characteristics and having the same color when viewed by a normal observer under a given illuminant, but different colors when viewed under a different illuminant when other conditions remain the same. The metameric samples whose spectral curves are shown in Fig. 6 were created by using different pigments in each specimen. Observer metamerism is the phenomenon in which two specimens having different spectral characteristics match to some observers but not to others under the same illuminating and viewing conditions.

Only when colors have identical spectral curves can they be expected to match under all types of light and to all observers. To avoid metamerism, the same pigment formulation should be used when remaking the color. Correcting a batch by adding pigments that were not in the original formulation can result in metamerism. Whenever pigments used for the match have different spectral characteristics from those used in the target, the resultant color match should be tested for the metamerism by several observers and under several different types of illumination. Daylight, incandescent lamplight, and fluorescent lamplight are commonly used sources for evaluating metamerism. A color-matching booth should be used for making the evaluation. If the match is not satisfactory, spectrophotometric analysis of the two formulations should be carried out to determine their spectral differences, and the formulation should be adjusted to minimize metamerism. Practice for Visual Evaluation of Metamerism (D4086) specifies procedures

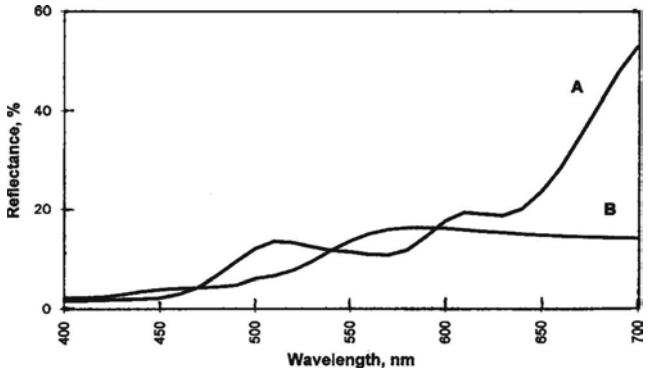

Fig. 6—Spectrophotometric curves of two highly metameric paint films. To most observers, the films match visually and are a dull green color in daylight, but sample A shifts color to a strong reddish brown in incandescent lamp light while sample B exhibits color constancy for this change of illumination.

for identifying the presence of metamerism and evaluating it semiquantitatively. Means of minimizing metamerism in both visual and instrumentally aided color matching are described later in "Color Matching."

COLORIMETRY AND THE CIE SYSTEM

Colorimetry is defined as the science of color measurement. Its modern development began in 1931, when, in the interest of standardization and to focus attention on the properties of material objects such as paint films, international standards and recommendations were established by the International Commission on Illumination (Commission Internationale de l'Éclairage, CIE). These recommendations [15] define standard lights and observers and a methodology for combining their properties with those of the objects to describe color and related appearance parameters.

CIE Standard Sources and Illuminants

Here, it is necessary to note two conventions of CIE terminology [7] reflected in Terminology E284. A source is defined as a real emitter of light, whereas an illuminant is defined as a spectral power distribution.

Incandescent Source and Illuminant

In 1931 the CIE defined a tungsten-filament incandescent lamp of 2856 K color temperature (see "Other Features of the CIE System") as Source A. Later, when measurement of spectral power distributions became easier, the fundamental definition was changed to the lamp's spectral power distribution, known as Illuminant A. The spectral power distribution of Illuminant A is given in Ref. [15], in a CIE/ISO standard [16], and in abbreviated form in Practice for Computing the Colors of Objects by Using the CIE System (E308).

Daylight Source and Illuminants

The CIE also recommended standard Source C in 1931, consisting of liquid filters used in combination with Source A, representing north-sky daylight. Later, the fundamental definition was changed to that of Illuminant C [15].

Source and Illuminant C do not duplicate the ultraviolet content of natural daylight and thus do not provide correct daylight color rendition of fluorescent materials. In 1968 the CIE adopted the D series of illuminants, which duplicate the spectral power distributions of various phases of natural daylight. They are designated by their correlated color temperatures (see "Other Features of the CIE System"). The most important of these daylight illuminants [15,16] is D65, with a correlated color temperature of 6500 K. The spectral power distributions of Illuminant C and several of the D series are tabulated in Practice E308. Unfortunately, very few real sources, whether for visual or instrumental use, simulated any of the D illuminants satisfactorily. The CIE has recommended procedures for assessing the quality of daylight simulators [17]. The relative spectral power distributions of CIE Standard Illuminants A, C, and D65 are shown in Fig. 7.

Fluorescent Illuminants

In 1986, the CIE defined [15], but did not recommend as standard illuminants, a series of 12 spectral power distributions representative of various types of fluorescent lamps, including cool white lamps simulating daylight well, and three-band lamps. These data should be used when calculations involving fluorescent lamps are required.

CIE Standard Observers

1931 CIE Standard Observer

In order to evaluate colors consistently, a standard observer was defined by the CIE in 1931 [15,18] by evaluating the spectral responses of a small group of well-trained individuals. The spectral responses of the CIE 1931 Standard Observer were determined by means of experiments, like those described later in Additive Mixing of Lights, in which the observer determined the amounts of three primary colors (red, green, and blue) required to match the colors of all wavelengths of the visible spectrum. These sets of three values are called tristimulus values. For convenience, the data were transformed mathematically to correspond to the use of imaginary primary lights designated *X, Y,* and *Z*. The Standard Observer is defined by the amounts, $\bar{x}(\lambda)$, $\bar{y}(\lambda)$ and $\bar{z}(\lambda)$, of these primaries required to match the spectrum colors; these are plotted in Fig. 8. The symbol (λ) indicates that the quantity depends on the wavelength, λ. The quantities $\bar{x}(\lambda)$, $\bar{y}(\lambda)$ and $\bar{z}(\lambda)$, are known as the color-matching functions of the 1931 CIE Standard Observer.

The transformation from real primaries to *X, Y,* and *Z* was made so that the color-matching function $\bar{y}(\lambda)$ is equal to the spectral luminous efficiency function $V(\lambda)$, that is, the effectiveness of radiation to stimulate the perception of light. This choice means that the tristimulus value *Y* of a given color, called its luminance, contains all the information about the lightness of the color.

1964 Supplementary Standard Observer

The data for the CIE 1931 Standard Observer were obtained with a visual colorimeter in which the field of view subtended an angle of only 2° at the eye of the observer. This was selected to correspond to the size of the fovea, which is that part of the retina containing only cones used in color vision. Later, the CIE studied color vision in a 10° field, with the central 2° portion disregarded. This corresponds to sample sizes more like those used in commerce, but for which the spectral sensitivity of the eye is somewhat differ-

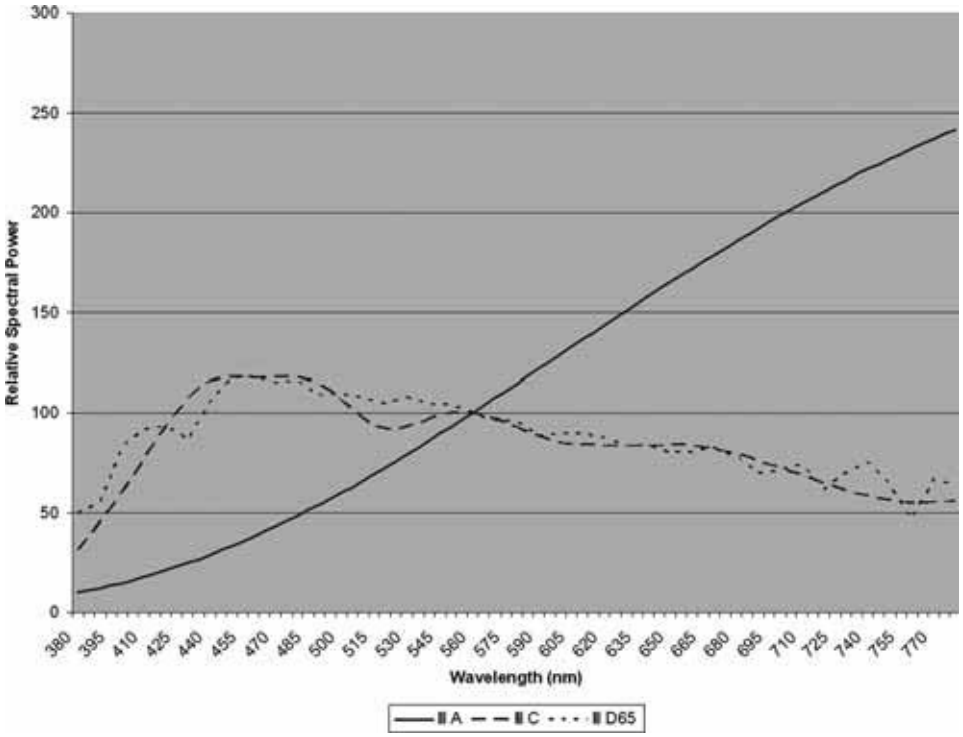

Fig. 7—Relative spectral power distributions of CIE standard illuminants A (incandescent lamp light), C (north-sky daylight), and D65 (actual daylight).

ent from that for the 2° field. With the newer data, the CIE established the 1964 Supplementary Standard Observer [15,18]; see also Practice E308. Where confusion might result, quantities referring to the 1964 Supplementary Standard Observer are given the subscript 10; for example, its color-matching functions are $\bar{x}_{10}(\lambda), \bar{y}_{10}$ and $\bar{z}_{10}(\lambda)$.

Calculation of Tristimulus Values

The tristimulus values *X, Y,* and *Z* of a color can, in principle, be obtained by direct matching, as were the tristimulus values of the spectrum colors defining the standard observers. But this is impractical, and one of two other methods is always used. One of these involves the design and use

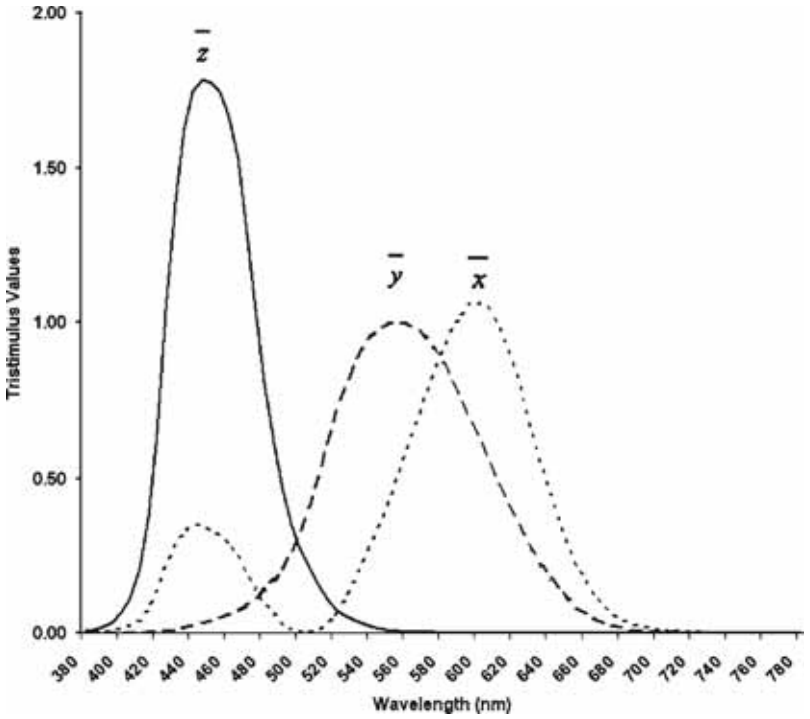

Fig. 8—The color-matching functions of the CIE 1931 standard observer; they are the tristimulus values of the colors of the spectrum.

of tristimulus (filter) colorimeters and is discussed later in "Tristimulus (Filter) Colorimeters." The other requires knowledge of the spectral reflectance curve of the specimen, obtained by spectrophotometry, and the following procedure.

At any wavelength, the contribution to a tristimulus value is given by the product of the relative spectral power of the illuminant, $S(\lambda)$, the reflectance of the specimen, $R(\lambda)$, and one of the color-matching functions of the observer, for example, $\bar{x}(\lambda)$. These products are summed over the visible wavelengths, then normalized by multiplication by a normalization factor k; for example

$$X = k\sum S(\lambda)R(\lambda)\bar{x}(\lambda)$$

(and similar equations for Y and Z), where Σ indicates the summation over the visible wavelength region. The quantity k is chosen to make Y for perfect white equal to 100

$$k = \frac{100}{\sum S(\lambda)\bar{y}(\lambda)}$$

The CIE had defined perfect white as the perfect reflecting diffuser, the ideal reflecting surface that neither absorbs nor transmits light, but reflects all of it. Most textbooks, Practice E308, and Ref. [15] provide examples of the use of these equations. Because the fundamental process is integration, for which summation is an approximation, the process is usually referred to as tristimulus integration.

If a large number of sets of reflectance data are to be integrated for the same illuminant and observer, it is convenient to combine quantities such as $S(\lambda)\bar{x}(\lambda)$ by multiplying them together and normalizing the products so that $k = 1$. The resulting tristimulus weighting factors can then be stored and used by multiplying them by whatever function $R(\lambda)$ is desired. The CIE has not tabulated or recommended specific sets of tristimulus weighting functions, but a substantial number can be found in Practice E308. They may be used for wavelength intervals of 10 or 20 nm. For closer intervals, such as 5 or 1 nm, the tables in Practice E308, Ref. [15], or Refs. [16,18] should be used. For the wavelength intervals of 10 or 20 nm, the raw spectral data acquired by the instrument are affected by the spectral bandpass error. This error is introduced because the spectral bandpass must be of significant bandwidth to allow sufficient energy to reach the detector. However, the spectral data being reported has a theoretical zero bandwidth. ASTM developed a Practice for Rectification of Spectrophotometric Bandpass Differences (E2729). This Practice outlines the methods that can be used to deconvolve, at least in part, the spectral bandpass error of raw spectral data acquired by abridged spectrophotometry.

Chromaticity Coordinates and Diagram

An important use of the CIE tristimulus values *X, Y,* and *Z* is the calculation of coordinates describing the chromaticity of a color, that is, its hue and chroma, ignoring its luminance or lightness. The CIE chromaticity coordinates *x, y,* and *z* are computed from the tristimulus values *X, Y,* and *Z* by dividing each of these by the sum *X*+*Y*+*Z*. Thus

$$x = \frac{X}{X+Y+Z}$$

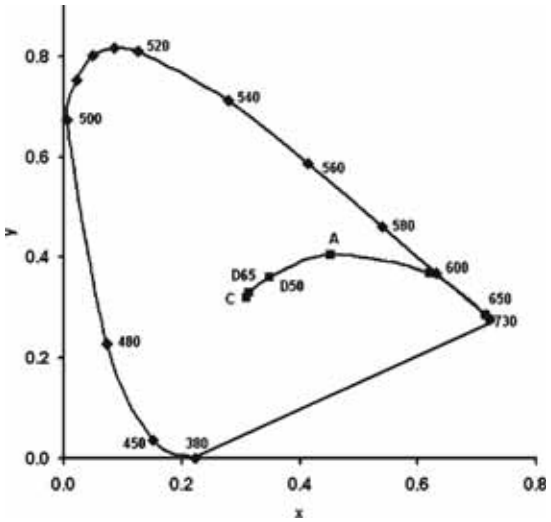

Fig. 9—The CIE 1931 *x, y* chromaticity diagram showing the various features described in the text.

$$y = \frac{Y}{X+Y+Z}$$

$$z = \frac{Z}{X+Y+Z}$$

Since $x + y + z = 1$, only two chromaticity coordinates need be given; usually they are *x* and *y*. These chromaticity coordinates can be plotted to yield the 1931 CIE *x, y* chromaticity diagram, shown in Fig. 9, or the 1964 CIEx_{10},y_{10} diagram for the Supplementary Standard Observer; the two are quite similar.

Features of the chromaticity diagrams include: (1) the locations of the spectrum colors around the horseshoe-shaped spectrum locus, from 400 nm (violet) at the lower left to 700 nm (red) at the right; (2) the straight line along which purples lie joining these two ends of the spectrum locus; and (3) the location of whites (illuminant points) near the middle of the diagram. As an alternative to the three tristimulus values, colors can be specified by the chromaticity coordinates *x* and *y* together with the luminance *Y* (or their equivalents in the 1964 system). These can be arranged in a three-dimensional color space.

Other Features of the CIE System

Dominant Wavelength, Complementary Wavelength, and Purity

Dominant wavelength is defined as the wavelength along the spectrum locus at the end of a line drawn from the white point (usually Illuminant C**)** through the sample point to the spectrum locus. For purple colors where the line would end at the purple locus, it is extended back through the white point to the spectrum locus, and the wavelength at that point is designated as the complementary wavelength of the sample. The fractional distance from the white point to the sample point relative to the distance to the spectrum or purple locus is called the (excitation) purity of the sample. Dominant wavelength correlates well with the hue of the sample, but purity does not correlate well with any perceived quantity and is rarely used today.

Blackbody Locus, Color Temperature, and Correlated Color Temperature

When a metal, such as a lamp filament, is heated, it first radiates heat in the infrared region, then light with a chromaticity at the red corner of the diagram. As it gets hotter, the chromaticity shifts through the oranges and yellows. The line along which these chromaticities lie for perfect absorbers and emitters of radiation is called the blackbody locus and is shown in Fig. 9. If the metal did not melt, its color would continue along this locus through white to light blue at infinitely high temperature. The temperature of a perfect blackbody can be correlated with its chromaticity and is called the color temperature of the body. It is measured in kelvins, K; the color temperature of Illuminant A is, for example, 2856 K. Many light sources, including the phases of daylight and fluorescent lamps, have chromaticities that are close to, but not on, the blackbody locus. In that case, the color temperature closest to the chromaticity of the source is used and called its correlated color temperature. An example is Standard Illuminant D65, with a correlated color temperature of 6500 K.

Uniform Color Spaces

From almost the beginning of the CIE system, it was recognized that distances in the CIE space did not correlate well with visual estimates of the magnitudes of color differences. Many proposals have been made for deriving quantities that are more uniformly visually spaced. In 1976, the CIE recommended two more nearly uniform color spaces that, although not perfect, have been widely used. Here we describe the one that is most widely used in the paint and related industries and mention briefly the second, more useful, when colored lights are considered. The equations for these two spaces, known by official acronyms CIELAB and CIELUV, are found in Refs. [1,6,15] and in the Practice E308.

CIE 1976 L* ,a*, b* (CIELAB) Space

CIELAB is an opponent-type color space, with a lightness axis L^*, a redness (positive values)-greenness (negative) axis a^*, and a yellowness (positive)-blueness (negative) axis b^*, all mutually perpendicular, as illustrated in Fig. 5. The transformations from Y to L^*, from X and Y to a^*, and from Z and Y to b^* are all nonlinear, using cube-root functions.

The equations for these transformations are

$$L^* = 116(Y/Y_n)^{1/3} - 16$$

$$a^* = 500[(X/X_n)^{1/3} - (Y/Y_n)^{1/3}]$$

$$b^* = 200[(Y/Y_n)^{1/3} - (Z/Z_n)^{1/3}]$$

$$\frac{X}{X_n}, \frac{Y}{Y_n}, \frac{Z}{Z_n} \geq 0.008856$$

where X_n, Y_n, and Z_n are the tristimulus values of the illuminant or white point. See Practice for Calculation of Color Tolerances and Color Differences from Instrumentally Measured Color Coordinates (D2244) for alternate equations *when* $X/X_n, Y/Y_n, \cdot Z/Z_n < 0.008856$.

Because CIELAB does not have tristimulus values or chromaticity coordinates as defined for the 1931 and 1964 CIE systems in Chromaticity Coordinates and Diagram, it does not have a chromaticity diagram.

An alternative set of CIELAB coordinates results in an LCH cylindrical color space. L remains the same but a^* and b^* are combined to give a chroma C^* and a hue angle h (measured in degrees)

$$C^* = (a^{*2} + b^{*2}); \quad h = \tan^{-1}(b^* / a^*)$$

These correlate well with visual judgments of lightness, chroma, and hue, respectively. Perhaps the widest use of CIELAB is in the calculation of color differences (see "Color Difference Calculations").

CIE 1976 L*,u*,v* (CIELUV) Space

The CIELUV space has a chromaticity diagram with coordinates u' and v', which are linear transformations of x and y, respectively. The linearity is important for the additive mixing of colored lights (see Additive Mixing of Lights). For the three-dimensional CIELUV space, these are combined with the (nonlinear) L^* transformation to give opponent-type axes u^* and v^*, whose meanings are the same as those of CIELAB a^* and b^*, respectively. An alternative set of hue angle and chroma coordinates, like those in CIELAB, and a color-difference equation, much less widely used than the CIELAB equation, are also part of this system.

COLOR ORDER SYSTEMS

A color order system is a rational method or plan of ordering and specifying all producible object or display colors, or all within a limited domain, by means of a set of physical standards selected and displayed so as to represent adequately the whole set of such colors under consideration. In this section the major color order systems, which have physical exemplifications or atlases illustrating underlying systems, are briefly discussed. References [19, 20] provide useful general coverage.

Munsell System

Dating from the early 1900s, the Munsell system is accepted by most users as the standard for equal visual spacing. It is described in the Practice for Specifying Color by the Munsell System (D1535). Its color solid is like that of Fig. 4 with the sole exception that lightness is called *value* in the Munsell system. Munsell Hue is designated by position around the hue circle in a notation combining letters designating five major hues (red, yellow, green, blue, purple) and their pairs (R, YR, Y, GY, G, BG, B, PB, P, RP) with numbers from 1 to 10. Munsell Value, to which CIE lightness L^* is a good approximation, runs from zero for black to 10 for white. Munsell Chroma, which expresses the degree of departure of the color from the gray of the same lightness, starts at zero and is open-ended. To describe a color in the Munsell system, the hue, value, and chroma are noted in a prescribed sequence, as for example, 8R 4/10. This designation indicates that the hue is red (toward yellow-red, i.e., an orange color), the value is 4, and the chroma is 10.

In 1943, the underlying Munsell system was defined in colorimetric terms [21], and since 1968 the chips in the glossy editions of the *Munsell Book of Color* have been produced to match these specifications. Fig. 10 shows contours of equal Munsell Hue and Chroma at value 5 on the 1931 CIEx,y chromaticity diagram.

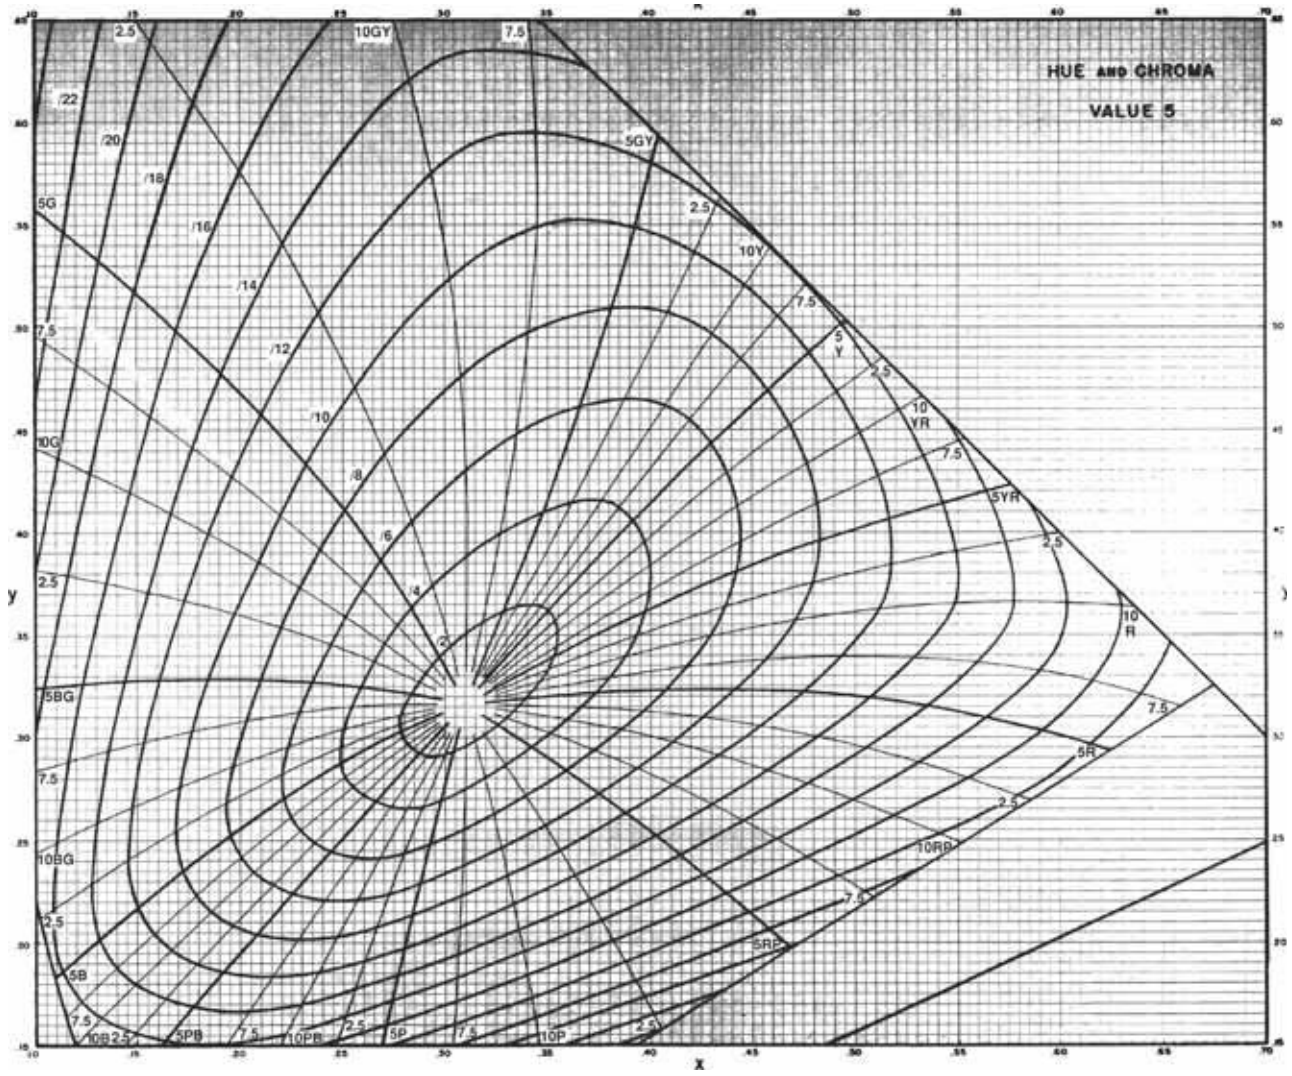

Fig. 10—Lines of constant Munsell Hue and closed curves of constant Munsell Chroma, at Munsell Value 5 plotted on the CIE 1931 chromaticity diagram.

The *Munsell Book of Color* [22], which is available in the United States, exemplifies the Munsell system.

ISCC-NBS System

In the 1950s the Inter-Society Color Council (ISCC) and the National Bureau of Standards (NBS) developed the ISCC-NBS Method of Designating Colors [23] based on the Munsell system but grouping similar colors to produce a smaller number (267) of categories. These are designated by descriptive color names, for example, dark reddish orange for the group containing 8R 4 /10.

Universal Color Language

The Munsell system and the ISCC-NBS system are both parts of a Universal Color Language [23], a six-level system for describing color to any desired degree of accuracy. Level 1 consists of the use of 13 hue and neutral names. At this level, the color with Munsell notation 8R 4/10 would be described as orange. In Level 2, which has 29 categories, intermediate hue names are added. Here the color would be described as reddish orange. Level 3 is the ISCC-NBS system, and Level 4 is the Munsell system as used in the *Munsell Book of Color;* designations at these levels are given above. Level 5 uses interpolated Munsell notations based on visual comparison of the color with *Munsell Book* chips. With practice it is possible to interpolate accurately to 1/10 value step, 1/4 chroma step, and from 1 hue step at chroma /2 to 1/4 hue step at chroma near /10 and above. Thus, at this level the color might be designated very accurately as 8.25 R 4.1/9.75. The final stage, Level 6, of the Universal Color Language is based on the results of color measurement, expressed as CIE chromaticity coordinates x,y, and Luminance Y. Now the color might be specified with greatest accuracy as $x = 0.527, y = 0.343, Y = 12.5$.

DIN System

The DIN Color System is the official German Standard Color System [24]. Its coordinates are hue (for which dominant wavelength is used), saturation (like chroma except representing difference from black instead of from gray of the same lightness), and relative darkness. From time to time, atlases of DIN samples have been available in glossy and matte finish and in transparent films. In the former

two, chips are arranged on pages of constant hue, similar to the Munsell arrangement.

NCS

Developed in the late 1960s and 1970s, the Natural Color System (NCS) [25] is the national standard color order system in Sweden and several other European countries. It is based on an entirely different principle from that of the other systems discussed, namely the resemblances of colors to six imaginary elementary colors, unique red, yellow, green, and blue, and black and white. The four hues are placed 90° apart on the hue circle. This does not lead to visually equal hue spacing. Two opponent-type axes result, perpendicular to the black-white lightness axis. The third variable of the system is chromaticness.

In terms of resemblances, hue is defined as the resemblance of a color to the two nearest chromatic elementary colors. For example, orange might be said to have 80 % resemblance to red and 20 % to yellow; its hue notation would be Y80R. Chromaticness is the resemblance of the color to the (imaginary) color of the same hue having the maximum possible chromatic content. Lightness is not an explicit variable in the system; the third resemblance can be to either white or black. Scales of resemblances to white, black, and the aforementioned maximally chromatic color are chosen so that these three add to 100 %, so only one of the resemblances to white or black need be specified. For the notation, resemblance to black has been selected, so that the three variables of the system are blackness, chromaticness, and hue. The complete NCS notation for the orange sample considered above in the Munsell system is approximately 3070 Y80R.

In the NCS atlas, pages of constant hue notation contain chips arranged on a grid in the form of an equilateral triangle. The corner points of the NCS triangles are imaginary elementary colors.

OSA-UCS System

The Optical Society of American Uniform Color Scales (OSA-USC) system [26,27] was developed by a committee of the OSA between 1947 and 1976. Although the committee concluded that no perfectly equally visually spaced system can exist because color space itself is not Euclidean, it attempted to achieve the best possible compromise and is generally thought to have succeeded. The axes of the color solid are lightness, L (with both positive and negative values around zero at middle gray) and two opponent axes, j (from the French *jaune* for yellow), with positive values toward yellow and negative values toward purple-blue, and g (for greenness), with blue-greens at the positive end and pinks at the negative end.

The OSA-UCS system in described in Practice for Specifying Color by Using the Optical Society of America Uniform Color Scales System (E1360). The 558 samples of the OSA atlas are arranged in a rhombohedral lattice in which each sample, except those at the edges, has 12 nearest neighbors.

COLORCURVE SYSTEM [28]

This new color order system was introduced in the United States in 1989. It is based on a color space similar to CIE 1964 tristimulus space [29]. Aim points are laid out according to additive mixing (see "Additive Mixing of Lights") of CIE 1964 tristimulus values X_{10}, Y_{10}, Z_{10} for Illuminant D65, starting from eight specified CIELAB points. The CIELAB lightness axis L (designated only as L) is retained, but coordinates along the CIELAB-type opponent axes are replaced by a simple numbering system, giving the sample location in terms of the number of lattice steps between it and the neutral axis in the directions of two adjacent major axes directed toward reds, yellows, greens, and blues. A typical Colorcurve notation would be L40 R1Y3 representing at lightness level 40 the lattice point one step away from neutral toward the reds and three steps toward the yellows. This is an orange, only slightly different from the sample discussed above.

Another feature of the Colorcurve system is that spectral reflectances are furnished for the aim points. These can be additively mixed like tristimulus values to obtain the spectral curve corresponding to any Colorcurve notation; this can be the basis for computer colorant formulation (see "Instrumental and Computer-Aided Color Matching") to provide a match with minimum metamerism to the surrounding Colorcurve samples. Practice for Specifying and Matching Color Using the Colorcurve System (E1541) describes the system in more detail, including a tabulation of spectral reflectances, tristimulus values, and CIELAB coordinates for the sample aim points.[3] The Colorcurve atlas [30] contains about 2,200 painted samples.

Color Collections

For each of the color order systems described above, atlas samples consist of painted chips individually matched to the specified aim points with a mean accuracy of about one CIELAB unit. A number of color collections have been produced by coating paint on paper, printing, molding plastic chips, and dying textiles. A colorist may be required to match these collections. Painted samples are probably the easiest to match because of the similarity of pigments and resins. Plastic samples can present problems because they are often translucent. However, many of the pigments used in plastics are similar to paints and may be fairly easy to match. Printed samples are often very difficult to match. Most are at incomplete hiding and have high chromas because they are printed over white (possibly fluorescent) paper. It may be impossible to achieve the high chromas in a conventional paint system at complete (or nearly so) hiding. The color reproducibility achieved by printing is usually significantly lower than can be achieved with a paint system. Textile samples are made by dying fabric. It may not be possible to match the spectral curve of a dyed fabric with the pigments used in a paint system.

Single-Number Color Scales

Occasions arise in which the colors of samples vary along a single direction in color space. In such a case the color can be described adequately by a single scale value. Three cases are of interest: whiteness, yellowness, and series ranging from colorless to highly colored as the concentration of a colored component increases.

[3]E1541 was withdrawn in 2007 after production of the Colorcurve atlas and related materials ceased. This section is included for historical purposes.

TABLE 3—Coefficients for the Equations for CIE Whiteness Index and Tint						
	CIE Standard Illuminant and Observer					
Value	C, 1931	D_{50}, 1931	D_{65}, 1931	C, 1964	D_{50}, 1964	D_{64}, 1964
x	0.3101	0.3457	0.3127	0.3104	0.3477	0.3138
y_n	0.3161	0.3585	0.3290	0.3191	0.3595	0.3310
WI,x	800	800	800	800	800	800
WI,y	1700	1700	1700	1700	1700	1700
T,x	1000	1000	1000	900	900	900
T,y	650	650	650	650	650	650

Whiteness and Tint Indices

Whiteness scales start at the point corresponding to an ideal white, which may be the perfect reflecting diffuser (see "Calculation of Tristimulus Values") or some other industry standard, often assigned a whiteness of 100.

Practice for Calculating Yellowness and Whiteness Indices from Instrumentally Measured Color Coordinates (E313) extends the equations recommended by the CIE [15] to Illuminants C and D50. The equation for the whiteness index is

$$WI = Y + (WI,x)(x_n - x) + (WI,y)(y_n - y)$$

where:

Y,x,y = the luminance factor and the chromaticity coordinates of the specimen,

x_n and y_n = the chromaticity coordinates for the CIE standard illuminant and source used, and *WI,x* and *WI,y* = numerical coefficients.

The whiteness index is valid only for specimens with $40 < WI < (5Y–280)$.

E313 also includes a tint index

$$T = (T,x)(x_n - x) - (T,y)(y_n - y)$$

where the symbols have meanings analogous to those for the whiteness index.

The tint index is valid only for specimens with $-3 < T < +3$.

Values for all the coefficients, except those measured for the specimen, are given in Table 3.

Yellowness Indices

Yellowness indices show the departure of a specimen from achromatic toward yellow. The yellowness index described in Practice E313 is calculated using the equation

$$YI = \frac{100(C_X X - C_Z Z)}{Y}$$

Values for all the coefficients, except those measured for the specimen, are given in Table 4.

This equation supercedes the one given in the ASTM Test Method for Yellowness Index of Plastics (D1925), which has been withdrawn.

Scales for Liquids

When only a limited range of color is involved, for example, in the testing of the color of oil, clear varnish, lacquer, or solvents used in the paint industry, simple methods are used consisting of comparison of the specimen with standard colored solutions or glasses ranging from colorless to highly colored. A standardized series of these colors is used to provide a specialized color scale. The color is often a measure of concentration of an ingredient. One difficulty in the use of these special color scales is that the color of the specimen may not match that of the standard; this can make rating on a single-number scale difficult. Nevertheless, their simplicity, low cost, and adaptability to special situations has resulted in wide use of single-number scales for certain applications. Scales useful to the paint industry are shown in Table 5.

Test Method D6045 is an instrumental version of Test Methods D1500 and D156. Practice E313 can be used to determine the whiteness and yellowness indices of transparent liquids. A number of single-number color scales were compared by Johnston [31].

INDUSTRIAL COLOR MEASUREMENT

Instruments Using the Eye as Detector

The eye is the ultimate arbiter in color evaluation because, of course, it is the means for making the final judgment on the acceptability of a color. The first color-measuring instruments used the eye as a detector. This practice is still followed when use of a simple color comparator suffices, as in many of the test methods for single-number color scales described in the preceding paragraph. But there are many factors, such as fatigue, poor color memory, and subjectivity, as well as the perceptual phenomena described earlier under

TABLE 4—Coefficients of the Equation for Yellowness Index				
	CIE Standard Illuminant and Observer

"Perception," that make the eye at least suspect for close color evaluation work. Therefore, the use of the eye as a detector has been almost entirely replaced by the use of two types of photoelectric instruments developed since the 1940s for color measurement.

Spectrophotometers

Spectrophotometers provide the spectral reflectances (or transmittances) required for the calculation of CIE tristimulus values and derived color coordinates, which were described earlier under "Colorimetry and the CIE System" and in Practice E308.

When radiation strikes a sample, it may be reflected, absorbed, or transmitted. Each of these can be measured by most spectrophotometers. All spectrophotometers consist of a light source, a monochromator, arrangements for illuminating and viewing the sample, a photodetector, and an output device. In modern instruments, the latter consists of a computer that processes the signals from the detector and provides for the calculation of tristimulus values and a wide variety of other color-related quantities. Each of these components is described briefly.

The Illuminator

The illuminator is that part of a spectrophotometer that provides the illuminating beam on the specimen, including the source, occasionally a monochromator or spectral filters, a diffuser such as an integrating sphere, if used, and associated optics. In most cases the exact nature of the light source in a spectrophotometer is of little importance as long as it has adequate power and stability at all wavelengths in the visible spectrum. Incandescent lamps or xenon flash tubes are widely used. When fluorescent samples are measured (see "Fluorescence"), the source must illuminate the sample directly and may be filtered to simulate a standard source, such as CIE daylight D65. Most color measuring spectrophotometers are designed with these features. Practice E991 provides more information on the measurement of fluorescent samples.

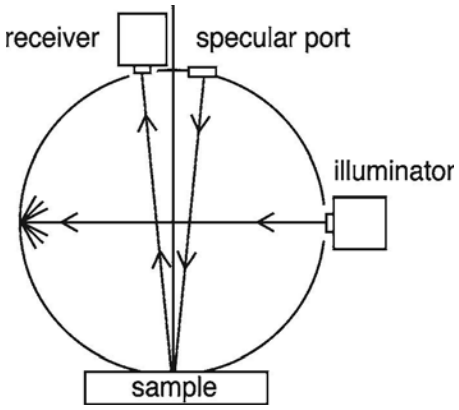

Fig. 11—A representation of the CIE hemispherical geometry. Light illuminates the integrating sphere to diffusely illuminate the sample. The receiver is placed slightly off of the normal so that the specular reflection can be either included or excluded during the measurement.

Illuminating and Viewing Geometry

In most spectrophotometers, the geometry of sample illumination and viewing follows CIE recommendations [15]. Two standard geometries are widely used. In hemispherical geometry, light from the source usually illuminates the white interior of a hollow, approximately spherical cavity called an integrating sphere, and the diffused light from the sphere illuminates the sample from all angles in the hemisphere bounded by its surface. The sample is viewed at an angle near the normal or perpendicular to its surface. If the sample is glossy, the specular or mirror reflection from its surface will result in a portion of the wall of the integrating sphere also being viewed. The user is given the option of making this part of the sphere white, thus including the specular component, or black, excluding it (Fig. 11).

In bidirectional geometry, illuminating and viewing are at angles along the normal to the sample surface (designated 0°) and 45° from the normal, or the reverse (Fig. 12). The use of bidirectional geometry with the specimen illuminated by white light is recommended when fluorescent samples are measured. Hemispherical and bidirectional geometries are described in the Guide for Selection of Geometric Conditions for Measurement of Reflection and Transmission Properties of Materials (E179) and in Practice E1164, as well as by the CIE [15].

In typical 45/0 or 0/45 geometry, several illuminating or viewing beams, distributed around the azimuth at 45° to the normal, may be used. When a specimen exhibits directionality, that is, its reflectance changes when it is rotated in its own plane, the use of an instrument with multiple beams provides data that average over the directionality, giving a single number characteristic of the average properties of the specimen. If it is desired to measure the directionality, an instrument with one illuminating (or viewing) beam, or two 180° apart in azimuth, should be used and measurements made at several different specimen orientations.

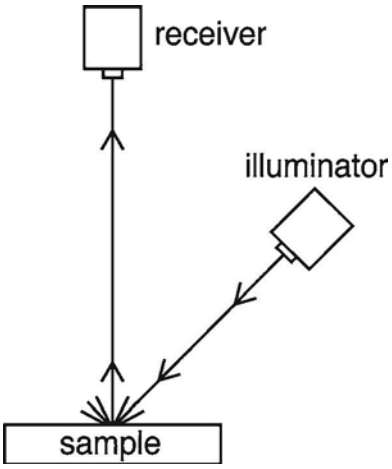

Fig. 12—A representation of the CIE 45/0 bidirectional viewing. Light illuminates the sample from an angle of 45° and the receiver views the light reflected from the sample along its normal. The positions of the illuminator and receiver can be reversed to obtain the 0/45 illuminating/viewing geometry. For non-directional specimens, the two measurements will be equivalent.

For the measurement of specimens exhibiting gonioappearance, in which the reflectance changes when the illuminating or viewing angles are changed, the use of special instruments capable of measuring at different combinations of these angles is required. Several such multiangle instruments, known as goniospectrophotometers, are commercially available (Fig. 13). See the earlier section on "Gonioappearance."

The Receiver

The receiver converts the light reflected or transmitted by the specimen into an electrical signal and includes all the optics necessary to focus the light onto a photodetector. The optics in the receiver direct the light to the spectral analyzer in which a narrow (typically 10 to 20 nm) band of wavelengths is selected from the full spectrum of the incident light. The spectral analyzers in modern instruments usually use holographic diffraction gratings or interference filters to isolate the narrow wavelength range. Spectral light is received by the photodetector, usually a silicon photodiode. The photo-detector may consist of an array of diodes, each positioned permanently to receive light of a given wavelength, thus eliminating the need for a spectrum scanning device. The electrical signal from the detector is usually amplified, digitized, and entered in an interfaced computer. In addition to Practice E1164, the following ASTM test methods cover the operation of modern spectrophotometers: Test Method E1331, Test Method E1348, and Test Method E1349.

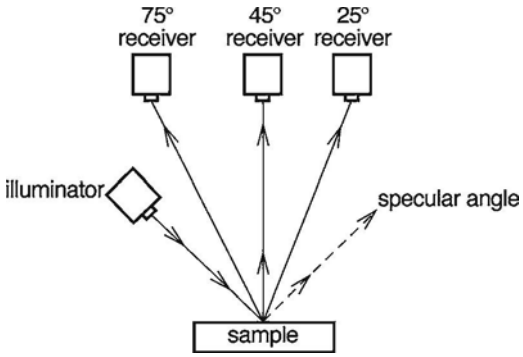

Fig. 13—A representation of a multiangle instrument (goniospectrophotometer) for measuring materials containing metallic flake pigments. One illuminating angle and three viewing angles are sufficient for these materials. To characterize interference pigments, at least two illuminating angles are required.

Spectroradiometers

Instruments closely related to spectrophotometers but made to measure light incident from external sources are known as spectroradiometers. They could be used in the paint industry when, for example, the specimen must be sensed remotely after being illuminated externally to the instrument. Methods for making such measurements are described in Test Method for Obtaining Colorimetric Data From a Visual Display Unit by Spectroradiometry (E1336), Practice for Obtaining Spectroradiometric Data from Radiant Sources for Colorimetry (E1341), and Practice for Obtaining Colorimetric Data from a Visual Display Unit Using Colorimeters (E1455).

Obtaining Tristimulus Values from Spectral Data

The first step in utilizing spectral data is the calculation of CIE tristimulus values, as described earlier under Calculation of Tristimulus Values. This step is performed automatically as part of the measurement sequence in all modern spectrophotometers designed for color measurement. It is usual that the spectral bandpass of the monochromator and the measurement interval are selected to be the same. For highest accuracy, the correct set of tristimulus weighting factors, corresponding to the instrument bandpass, selected from among those added to the Practice E308 in 1994 (Table 6), must be used in calculating tristimulus values. In addition, the user must select the standard illuminant and the standard observer used.

Spectrocolorimeters

Some spectrophotometers are designed so that the measured spectral reflectances or transmittances cannot be accessed for examination; only the resulting tristimulus values and other color coordinates can be printed out. Such instruments are designated spectrocolorimeters.

Tristimulus (Filter) Colorimeters

Among the earliest photoelectric color-measuring instruments were those in which the source-filter-photodetector combinations duplicate the tristimulus functions of the Standard Observer and a CIE Standard Illuminant, usually Illuminant C [32]. How well their filters are designed and matched to the spectral characteristics of the source and of the detector determines how accurately the instrument performs. Today a high degree of accuracy is attained in the resulting tristimulus values.

Because of their ease of operation, good precision, and relatively low cost, tristimulus (filter) colorimeters had found wide application for industrial control. They are used primarily as color-difference meters to evaluate the difference in color between a production specimen and a standard of similar spectral character. This last limitation is important for most colorimeters. Because of their design,

TABLE 6—Standards pertinent to calibration and maintenance of color-measuring instruments

E2214	Practice for Specifying and Verifying the Performance of Color-Measuring Instruments

most colorimeters provide colorimetric data for only one combination of illuminant and observer and therefore cannot detect metamerism. When specimens are metameric, a colorimeter can give incorrect data on the differences among them. Filter colorimeters should not be used to evaluate pairs of specimens that may be metameric. This limitation should be clearly understood. As a result of improved technology and lower costs, most tristimulus colorimeters have been replaced by spectrophotometers.

The use of colorimeters is described in Test Method E1347.

Selection and Calibration of Instruments

The potential user of color-measuring instrumentation must carefully consider the selection of the proper instrument(s), depending on his samples and measurement needs. Guide E179 and Practice E805 address this topic. They should be consulted, if possible, before the purchase of a new instrument.

The user of any color-measuring instrument must give regular attention to its calibration. Appropriate calibration standards, available from instrument manufacturers and, in some cases, national standardizing laboratories, should be obtained, maintained in good condition, and used at frequent intervals in an established routine [33]. A collaborative reference program [34] is available by means of which a user's instrument performance can be compared to that obtained for the same samples by the color community as a whole and by national standardizing laboratories.

With proper calibration and maintenance, modern color-measuring instruments are capable of a repeatability and reproducibility far greater than the repeatability with which the samples themselves can normally be prepared for industrial measurement. Thus, special care must be taken to establish a highly reproducible method of paint sample preparation and to establish by careful measurement and periodic verification the uncertainties associated with this step in the measurement process. ASTM standards pertinent to this topic are shown in Table 6.

The following two subsections apply mainly to spectrophotometers.

Precision

The modern age of computer-interfaced color measuring spectrophotometers began in the mid-1970s. By then it had been clearly demonstrated that such instruments could surpass the eye in the precision of color measurement. In 1981 the short-term repeatability of instrumental color measurement was reported to be about 0.1 CIELAB unit of color difference [35] (see "Color Difference Calculations"). By 2002 instrument manufacturers were specifying the short-term repeatability for top-of-the-line benchtop instruments to be in the neighborhood of 0.01 CIELAB units. In 1979 the average reproducibility within a group of similar instruments was reported to be about 0.2 CIELAB units [36]. By 2002 instrument manufacturers were specifying the inter-instrument agreement for top-of-the-line benchtop instruments as less than 0.10. It should be noted that the very low repeatability and reproducibility numbers can only be achieved with stable standards at a tightly controlled temperature. Note that 0.5 CIELAB unit is approximately the smallest difference that can be detected visually. Repeatability and reproducibility values are published in the Precision and Bias section of Practice E1164 and Practice for Calculation of Color Tolerances and Color Differences from Instrumentally Measured Color Coordinates (D2244).

Bias

This quantity, the difference between a measured result for a standard sample and the result when it is measured in a reference laboratory, is difficult to quantify for color measurement where there are no absolute values. It is usual to accept the results obtained in a national standardizing laboratory as the reference. On this basis, when instruments are selected to minimize differences in measuring geometry and are properly calibrated and used, the average bias for a group of standard samples can be as low as 0.5 CIELAB unit [37]. In addition, the differences between the two sets of measurements can be utilized effectively to model and correct the systematic spectrophotometric errors leading to the bias [38].

Commercial Instruments

Specific information about instruments published in a manual such as this would almost certainly become obsolete by the time the manuscript is printed. For this reason, detailed information on suppliers and their instrumentation is not included. Such information, including types of instruments manufactured, their design features and performance characteristics, can best be found by first consulting buyers' guides [39,40] that are revised annually. Another useful source of information is the lists of exhibitors at paint shows, such as the descriptions published annually in the *JCT Coating Tech.* An additional source of information on commercial instruments is the internet.

Most color instrument suppliers maintain internet sites with current information on their products and services. Registered users can also obtain product updates and support. In contacting suppliers of instrumentation, the user might request that they send literature, measure samples sent them, or have a representative visit the user to demonstrate the instrument. Another procedure is to negotiate a rental-purchase contract. While some suppliers are reluctant to negotiate such contracts, the procedure provides users the opportunity to evaluate the instrument with their own operators at their own facilities.

1. *Portable instruments*. In earlier times, production samples had to be taken to a quality-control laboratory for evaluation. This procedure is still desirable in some instances to permit control of such variables as ambient light, temperature and humidity, and atmospheric contamination. However, time can be saved by making measurements on the production floor using portable instruments. Many manufacturers now supply portable spectrophotometers and colorimeters that provide small size and light weight. Some portable instruments perform nearly as well as benchtop instruments. In many, the precision is good, but limitations related to measurement geometry may increase bias. If very small illuminated and viewed areas are used, there may be an advantage in that smaller portions of samples can be measured, but averaging of multiple measurements (see Practice E1345) may be required to obtain representative values for nonuniform samples.
2. *Multiangle Evaluation*. Several manufacturers now supply instruments with multiangle geometry for the measurement of gonioapparent samples, such as those containing metal flake or pearlescent pigments. For research in this field, a goniospectrophotometer is required. For quality control, however, use of one angle of illumination with several angles of view, or several angles of illumination with one angle of view, may suffice.
3. *Location and Type of Use*. For continuous processes, online instrumentation is finding greater use. In addition, color measurement and computer-aided color matching (see Instrumental and Computer-Aided Color Matching) are used extensively at point-of-purchase locations such as retail paint stores.

COLOR DIFFERENCE EVALUATION FOR COLOR CONTROL

The color control of industrial paint products is generally aided by color measurement, as described in the last section. The instruments provide color coordinates of sample and standard from which accurate measures of color difference may be derived. These data can also be used to establish color tolerances. Of course, color differences may also be judged visually, and several ASTM standards address this topic: Practice for Visual Appraisal of Colors and Color Differences of Diffusely-Illuminated Opaque Materials (D1729), Test Method for Evaluation of Visual Color Difference With a Gray Scale (D2616), and Guide for Selection, Evaluation, and Training of Observers (E1499). This guide also describes materials and methods for the testing and evaluation of the observer's color vision.

Color-Difference Calculations

In the 1931 and 1964 CIE systems, equal distances in different parts of color space do not represent equally perceived color differences. Although many proposals for more uniform color spaces have been made, an ideal uniform space has not been and may not ever be devised. Sets of color coordinates can be derived from tristimulus values that correlate better with perceived color differences than do the original CIE tristimulus values.

Modifications of CIE tristimulus values have been proposed for more uniform color spaces. Those proposed by Hunter [32], MacAdam [41-43], and the CIE [15] had been widely use in the paint industry. The color-difference equation based on the CIE 1976 $L^*a^*b^*$ (CIELAB) space discussed earlier in Uniform Color Spaces and color-difference equations based on that equation perform significantly better than the Hunter and MacAdam equations when compared to experienced visual color judgments. As a result, the Hunter and MacAdam equations can no longer be recommended.

The total CIELAB color difference, ΔE^*_{ab}, is given by

$$\Delta E^*_{ab} = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}$$

where

$$\Delta L^* = L^*_{\text{TRIAL}} - L^*_{\text{STANDARD}}$$

$$\Delta a^* = a^*_{\text{TRIAL}} - a^*_{\text{STANDARD}}$$

$$\Delta b^* = b^*_{\text{TRIAL}} - b^*_{\text{STANDARD}}$$

It is convenient to express ΔE^*_{ab} in terms of differences in the Munsell-type coordinates hue, chroma, and lightness, but the hue angle h defined earlier in Uniform Color Spaces does not have the same dimensions and scaling as chroma C^* and lightness L^*. Instead of using h, it is necessary to define CIELAB hue difference ΔH^* to combine with ΔC^* and ΔL^*

$$\Delta H^*_{ab} = \left[\left(\Delta E^*_{ab}\right)^2 - \left(\Delta C^*_{ab}\right)^2 - \left(\Delta L^*\right)^2 \right]^{1/2}$$

Then

$$\Delta E^*_{ab} = \left[\left(\Delta H^*_{ab}\right)^2 - \left(\Delta C^*_{ab}\right)^2 - \left(\Delta L^*\right)^2 \right]^{1/2}$$

This method of computing ΔH^*_{ab} loses the information about the sign of the hue difference (positive or negative) and can be unstable for pairs of colors near the neutral axis. Alternative equations for determining ΔH^*_{ab} and its sign have been proposed [44] that corrects both problems

$$\Delta H^*_{ab} = s\left[2\left(C^*_{ab,B} C^*_{ab,S} - a^*_B a^*_S - b^*_B b^*_S \right) \right]^{1/2}$$

where

$$s = 1 \text{ if } a^*_S b^*_B > a^*_B b^*_S, \qquad \text{else } S = -1$$

in which the subscript B indicates the trial and the subscript S indicates the standard. The unit of CIELAB color difference is two to three times the just perceptible color difference.

In the use of color differences, it is important to examine the components of the color difference, such as ΔL^*, Δa^* and Δb^*, or ΔL^*, ΔC^*_{ab}, and ΔH^*_{ab}, as well as ΔE^*_{ab} itself. The magnitudes and signs of these components can provide valuable information on remedial action needed to bring a production batch on shade. For near-neutral and pastel colors, there are advantages to using the ΔL^*, $\Delta^* a$, and $\Delta^* b$ forms of the color-difference equation.

The interpretation of measured color differences becomes more complex when the specimens are gonioapparent and measurements are made at several combinations of illuminating and viewing angles. The quantitative meaning of color differences as the angles change has not yet been thoroughly studied.

Since the adoption of the CIELAB equations, a number of new color-difference equations have been developed. One of these, known as the CMC (l:*c*) equation [45,46], is a modification of CIELAB that has improved uniformity of visual perception of its color differences. The CMC (l:c) equation has found widespread use in the coatings industry. The CMC (l:c) equation modifies the ΔL^*, ΔC^*, and ΔH^* components of the CIELAB color difference

$$\Delta E_{\mathrm{CMC}}(l:c) = cf * \sqrt{\left(\frac{\Delta L^*}{l * S_L}\right)^2 + \left(\frac{\Delta C^*}{c * S_C}\right)^2 + \left(\frac{\Delta H^*}{S_H}\right)^2}$$

$$S_L = \frac{0.040975 * L^*}{1 + (0.01765 * L^*)} \quad \text{for} \quad L^* \geq 16$$

$$S_L = 0.511 \quad \text{for} \quad L^* < 16$$

$$S_C = \frac{0.0638 * C^*}{1 + (0.0131 * C^*)} + 0.638$$

$$S_H = S_C\{(T * f) + 1 - f\}$$

where

$$f = \left\{\frac{(C^*)^4}{(C^*)^4 + 1900}\right\}^{1/2}$$

$$T = 0.56 + \mathrm{abs}\left|0.2\ \cos(h + 168\ ^\circ)\right| \quad \text{if } 164\ ^\circ < h < 345^\circ$$

else

$$T = 0.36 + \mathrm{abs}|0.4 * \cos(h + 35^\circ)|$$

in which "abs" indicates the absolute, i.e., positive value, of the term inside the brackets.

The parameters *l* and *c* are to compensate for systematic bias or parameteric effects such as texture and sample separation. The most common values for *l:c* are 2:1. The parameter *cf* is a commercial factor [47] used to adjust the total volume of the tolerance region so that accept/reject decisions can be made on the basis of a unit value of the tolerance.

In 2001 the CIE recommended an improved color-difference equation, CIEDE2000, based on the CIELAB color space [48]. This equation has been shown to outperform the CMC (l:c) equation [49]. CIEDE2000 is calculated from

$$L' = L^*$$

$$a' = (1 + \mathrm{G}) \cdot a^*$$

$$b' = b^*$$

$$C' = \sqrt{(a')^2 + (b')^2}$$

If $b' \neq 0$, then $h' = 180 - (180/\pi)\ \arctan(a'/b') - 90\ \mathrm{sign}(b')$

If $b' = 0$, then $h' = 90\ \mathrm{sign}((a')^2) - 90\ \mathrm{sign}(a')$

where *sign* is a function that returns the sign of the argument and *arctan* is the inverse tangent function returning angles in units of radians

$$G = 0.5 * \left(1 - \sqrt{\frac{(\bar{C}^*)^7}{(\bar{C}^*)^7 + 25^7}}\right)$$

where $\bar{C}^*$ is the arithmetic mean of the CIELAB C^* values for the pair of specimens (standard and batch).

$$\Delta L' = L'_B - L'_S$$

$$\Delta C' = C'_B - C'_S$$

$$\Delta H' = s * \sqrt{2\left[\left(C'_{\mathrm{B}} * C'_{\mathrm{S}}\right) - \left(a'_{\mathrm{B}} * a'_{\mathrm{S}}\right) - \left(b'_{\mathrm{B}} * b'_{\mathrm{S}}\right)\right]}$$

where

$$s = 1 \text{ if } a'_S\, b'_B > a'_{B^*} b'_S, \quad \text{else s} = -1$$

$$\Delta E_{00}^{\ 2} = \left(\frac{\Delta L'}{K_L \cdot S_L}\right)^2 + \left(\frac{\Delta C'}{K_C \cdot S_C}\right)^2 + \left(\frac{\Delta H'}{K_H \cdot S_H}\right)^2 + R_r \cdot \left(\frac{\Delta C' \cdot \Delta H'}{K_C \cdot S_C \cdot K_H \cdot S_H}\right)$$

$$\Delta E_{00} = \sqrt{\Delta E_{00}^2}$$

The factors K_L, K_C and K_H are correction terms for variation in perceived color-difference due to the viewing conditions. To obtain color-differences similar to CMC (2:1), set $K_L = 2$ and $K_C = K_H = 1$.

$$S_L = 1 + \frac{0.015\ *\ \left(\bar{L}'\ -\ 50\right)^2}{\sqrt{20 + \left(\bar{L}'\ -\ 50\right)^2}}$$

where $\bar{L}'$ is the arithmetic mean of the CIELAB L' values for the pair of specimens (standard and batch).

$$S_C = 1 + (0.045\ *\ \bar{C}')$$

where $\bar{C}'$ is the arithmetic mean of the CIELAB C' values for the pair of specimens (standard and batch).

$$S_H = 1 + (0.015\ *\ \bar{C}' * T)$$

$$R_T = -R_C * \sin(2 * \Delta\theta)$$

$$R_C = 2 * \sqrt{\frac{(\bar{C}')^7}{(\bar{C}')^7 + 25^7}}$$

$$\Delta\theta = 30 * \exp - \left\{\left[\frac{\bar{h}' - 275^\circ}{25}\right]^2\right\}$$

$$T = 1 - [0.17 * \cos(\bar{h}' - 30°)] + [0.24 * \cos(2\bar{h}')] + [0.32 * \cos(3\bar{h}' + 6°)] - [0.20 * \cos(4\bar{h}' - 63°)]$$

where $\bar{h}'$ is the arithmetic mean of the CIELAB L' values for the pair of specimens (standard and batch). All angles are in degrees. Take care calculating the mean hue-angle if the color-difference pair has samples in different quadrants. For example, a color-difference pair has hue angles of 30° and 300°. The mean hue-angle for this example is 345°. To determine the mean correctly, calculate the absolute difference of the hue angles. If the absolute difference is larger than 180° then add 360 to the smaller hue angle and divide that sum by 2.

Color Tolerance

A valuable means of recording the experience gained in the production of a given color is through the use of color tolerances, expressed as numerical limits to ΔE^* and its components or as color-tolerance charts. Because no color space is entirely uniform, industrial color tolerances are often based on acceptability, not perceptibility, considerations between buyer and seller. General color differences should be used only as a guide until enough experience has been accumulated for each color to allow specification of a firm tolerance limit.

Tolerance Charts

Color-tolerance charts are usually enlarged sections of a nearly visually equally spaced diagram, such as the CIELAB a^*,b^* diagram. A color-tolerance chart is set up with the coordinates of the standard at the center, and the differences Δa^* and Δb^* of production batches are entered as they are made (Fig. 14(*a*)). The process is described in Practice for Establishing Color and Gloss Tolerance (D3134). As experience is gained, it should be possible to draw a tolerance-limit curve enclosing most, if not all, of the acceptable batches and excluding most, if not all, of the unacceptable batches. Because no known diagram is perfectly visually uniform or if there is a preferred direction for the batches relative to a standard, then the tolerance limit figure may not be a circle or an ellipse and may not be centered on the location of the standard.

Lightness differences between the standard and batch must also be taken into account. This can be done by use of a separate tolerance for ΔL^*, but better practice is to use a second chart (Fig. 14*(b)*), in which ΔL^* is plotted against either Δa^* or Δb^*, depending on the data. The batch readings should fall within the tolerance figure on both charts.

It must be emphasized that the final criterion for acceptance of a color is always its visual appearance, to which instrumental measurements, color differences, and tolerance charts provide only clues. Instrument malfunctions, miscalibrations, miscalculations, and operator errors can be revealed only by use of confirming visual observations.

Indices of Metamerism

Another important use of color-difference equations is to quantify indices of metamerism as an aid in reducing this defect between standard and batch. The CIE [15,50] has recommended that indices of metamerism be calculated as the color differences between two samples that match under a standard illuminant or to a standard observer when measured for a test illuminant or a test observer. For illuminant metamerism, the standard illuminant is usually daylight. The second observer is selected by the user and is usually incandescent light. Often a third illuminant is specified, which is usually a fluorescent lamp. For observer metamerism, the standard observer is either the CIE 1931 or 1964 observer. To determine the index of metamerism, a corresponding second standard deviate observer is provided [50] based on the range of normal color vision found in the human population.

COLOR MIXING

Additive Mixing of Lights

When a white card is illuminated, its apparent color is the color of the incident light; a red light, for example, makes it appear red. Three colored lights (red, green, and blue), if carefully chosen, would, when placed to overlap on the same area of the card, produce white again (Fig. 15). In this area, the reflected lights from the three sources add together. These three lights are called the additive primaries. By adjusting the intensities of each of the three lights, a wide range of colors can be produced.

The procedure just described can provide an analytical tool for color measurement. If an adjacent spot on the white card is illuminated by light of an unknown color, it could be matched visually, in principle, with the three-light combination by adjusting their intensities. This is the basis for color matching by addition of lights. The additive principle is used to produce the colors in television and computer monitors [51].

The analytical device described above is also a simple version of the visual colorimeter used to generate the tristimulus values of the spectrum colors that form the basis for the CIE Standard Observers (see CIE Standard Observers). At each wavelength, the total light reflected is the sum of the power reflected from each of the three primary lights. Since tristimulus values are obtained by adding such sums across the spectrum, they too are produced by additive mixing. It is not necessary to know the spectral nature of the additive primaries to predict the resulting colors.

Subtractive Mixing in Transparent Films

Now consider the light falling on a white card after passing through a film that contains three transparent colorants, yellow, cyan (blue-green), and magenta (red-purple). This might be the situation with a free-standing transparent plastic film, for example. If the three colorants are ideally chosen, all the light would be absorbed when all three colorants are present, and the result would be black (Fig. 16). These three colorants are called the subtractive primaries. If varying quantities of them were combined in subtractive mixing, a wide variety of colors could be produced. However, these mixture colors cannot be predicted from the colors of the primaries alone, as in the additive mixing described above. One must also know their spectral character and compute, wavelength by wavelength, how much light is removed by each primary through absorption, using the well-known Beer's law relationship. From what is not absorbed, tristimulus values can be calculated in the usual way.

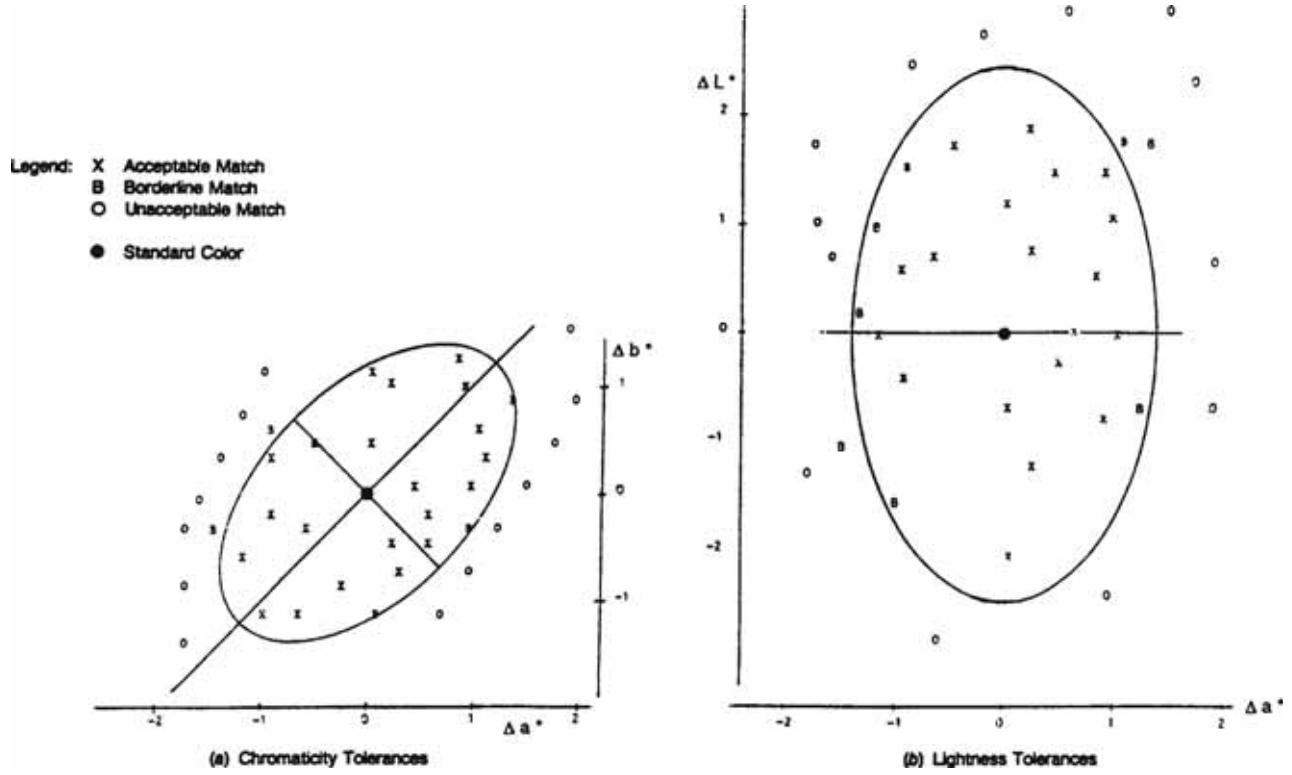

Fig. 14—Color tolerance charts plotted in the CIELAB system: (a) chromaticity tolerance figure on a Δ*a**, Δ*b** diagram; (b) lightness tolerance figure on a Δ*L**, Δ*a** diagram. In this case, a plot of Δ*L** versus Δ*b** would have served as well. (Based on ASTM D3134.)

Pigment Mixing

Pigments are added to paints to produce a wide variety of colors. The pigmentation is chosen to control the three components of color—hue, lightness, and chroma. Four pigments are needed to control the components. Generally two pigments are used to control the hue, one (a black or umber) to control the chroma and usually a white to control the lightness. The white pigment is also used as an opacifier. Mixing of colors using pigments is more complex than simple subtractive mixing in transparent films because of the scattering of light caused by the pigments. Again, it is necessary to know the spectral character of all the colorants present. The Beer's law calculation of the transparent case is replaced by the Kubelka-Munk relation: For opaque films, as is often the case in the paint industry, there are simple equations relating the reflectance $R(\lambda)$ of the film at each wavelength to the ratio of two constants describing what happens to the light in the film

$$K(\lambda)/S(\lambda) = [1 - R(\lambda)]^2 / 2R(\lambda)$$

$$R(\lambda) = 1 + K(\lambda)/S(\lambda) - \left\{[K(\lambda)/S(\lambda)]^2 + [2K(\lambda)/S(\lambda)]\right\}^{1/2}$$

in which $K(\lambda)$ is the Kubelka-Munk absorption coefficient, and $S(\lambda)$ is the Kubelka-Munk scattering coefficient. Here, $R(\lambda)$ must be expressed as a decimal instead of the usual percentage. The quantities $K(\lambda)$ and $S(\lambda)$ refer to the mixture of pigments in the paint film. These are calculated by adding the separate contributions of each pigment, using its $K(\lambda)$ and $S(\lambda)$ weighted by its concentration C in the mixture

$$\frac{K(\lambda)_{\text{MIXTURE}}}{S(\lambda)_{\text{MIXTURE}}} = \frac{[C_1 * K_1(\lambda)] + [C_2 * K_2(\lambda)] + \ldots}{[C_1 * S_1(\lambda)] + [C_2 * S_2(\lambda)] + \ldots}$$

in which there are as many terms as there are pigments used. These equations form the basis for computer color

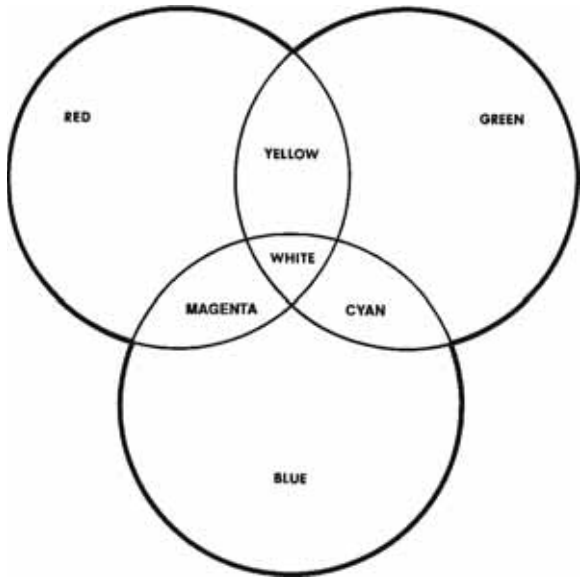

Fig. 15—Representation of the additive mixing of colored lights showing the additive primaries red, green, and blue forming the mixture colors yellow, cyan, and magenta where the primaries overlap in pairs and white where all three overlap.

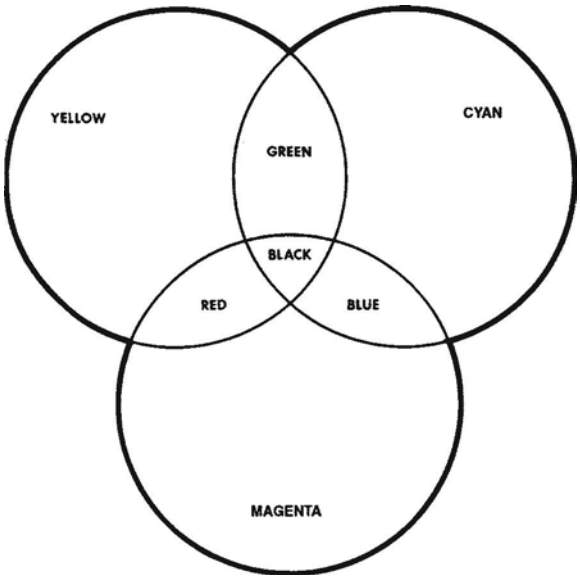

Fig. 16—Representation of the subtractive color mixing of transparent colorants showing the subtractive primaries yellow, cyan, and magenta forming the mixture colors green, blue, and red where the primaries are mixed in pairs and black where all three are mixed together.

matching described in the next section. The equations for dealing with translucent films are more complex [52].

COLOR MATCHING

One of the major objectives of industrial coloring is to match the color a customer wants. Whether this is done visually or with the aid of instruments and computers is often a matter of work load and economics. Therefore, we address both visual and instrumental matching. In either case, a major objective of color matching in paint systems is the formulation of a nonmetameric match to a given paint sample. The difference in spectral character of the samples of a metameric pair is the property determining their metamerism, and achieving a nonmetameric match places several requirements on the formulation.

First, the same pigments must be used. This requires identification of the pigments in the sample to be matched. Second, the pigments must be used in the same resin system since the spectral properties of pigments can depend upon the choice of binder. Finally, the same degree of dispersion must be achieved since the absorption and scattering properties of pigments that determine their spectral character change with degree of dispersion. This usually means that the same method of dispersion must be used.

Visual Color Matching

The selection of visual color matchers should be made with great care, and reference should be made to Guide E1499 for details of how to make the selection, test the color vision of the candidates, and train them in making visual judgments.

Beyond this there is no substitute for the experience of the visual color matcher. He or she must learn the skill by practice. This should include becoming familiar with one of the better color order systems and atlases and learning how to use it, coupled with knowledge of the behavior of the paint system and pigments available, to predict the colors that result from mixing them under carefully controlled conditions. Careful record keeping to document the results is essential. Visual methods of recognizing and controlling metamerism have been described [53,54]. These require no more than knowledge of the behavior in mixtures of the pigments used and a good color matching booth (see "Color Matching Booths").

Instrumental and Computer-Aided Color Matching

The importance of eliminating metamerism dictates that the instrument of choice is clearly a spectrophotometer. Display of the spectral curves of samples, and the computer-aided color-matching operations that lead to spectral curve shapes minimizing metamerism, cannot be achieved by the use of other types of instruments. The spectrophotometer can also be used in a simple but powerful method of organic pigment identification [55] based on extraction of the pigments into solution followed by spectrophotometry. This can be an important aid to selecting the same pigmentation for the match as was used in the standard.

Many modern color-measuring spectrophotometers can be obtained with computer software for color matching. Most of these systems work very well, but it must be emphasized that the investment in building up the database that is essential for their use, and in taking all the steps necessary to bring the coloring process under precise control, is not a small one.

The details of how computer color matching works are beyond the scope of this chapter. In summary, most systems call for measurement of the sample to put its spectral data into the computer. These data are usually matched at each of 16 or 31 wavelengths across the spectrum by Kubelka-Munk-type calculations [56] using stored values of $K(\lambda)$ and $S(\lambda)$ for the useful pigments in the product line. The results are the pigment concentrations in the formulation. Several formulations arising from mixing different pigments are usually produced. Additional calculations of metamerism indices and pigment costs allow the selection of the most suitable results.

Computer color matching has been discussed in a book [57], and some textbooks [1,2,5,58,59] provide useful summaries. The underlying Kubelka-Munk theory, applied to paint systems, has been the subject of a number of articles [56,60-65] directed to paint colorists. More complex theory appears to be needed only in special cases, such as matching automotive paints containing metal flake or pearlescent pigments. The development of such theories is still in its early stages.

Gloss

Gabriele Kigle-Böckler[1] and Harry K. Hammond III[2]

THE APPEARANCE OF THE SURFACE OF AN OBJECT or material can be described by its color and gloss characteristics. Like color, gloss can be subdivided into several aspects depending on viewing conditions. In 1937, Hunter identified five aspects of gloss [1] and the functions of reflectance by which they could be evaluated. Later studies by Lex [2] expanded Hunter's gloss terms and divided them into two groups. One group is based on visual observation with the eye focused on the surface of the material (Fig. 1). For the other group, the eye is focused on the image of the object reflected by the material (Fig. 2). However, investigations have shown that no single objective measurement of gloss will provide perfect correlation with the integrated subjective appraisal of glossiness that the eye so quickly renders. For this reason, the gloss evaluation requirement of an object or material should first be examined and the most useful gloss measurement aspects then selected.

ASPECTS OF GLOSS AND THEIR DEFINITION

The simple term "gloss" is defined in ASTM E284, Terminology of Appearance [3] as "angular selectivity of reflectance, involving surface-reflected light, responsible for the degree to which reflected highlights or images of objects may be seen as superimposed on a surface." To indicate specific types of "angular selectivity," such as those involving specular gloss (see below), sheen, or haze, and to illustrate the difference between an evaluation where the focus is on the surface and one where the focus is on the reflected image, the complexity of the phenomenon "gloss" is illustrated in Fig. 3.

By focusing on the reflected image of an object, an observer obtains information on the image forming capabilities of the surface. A reflected light source may appear brilliant or diffuse depending on the specular gloss of the surface. The outline of a reflected object may appear distinct or blurred depending on the distinctness-of-image. A halo surrounding the image of the reflected object is an indication of haze. Focusing on the surface of an object provides information on the size, depth, and shape of surface structures contributing to such things as waviness or directionality of brush marks.

Specular Gloss

Specular gloss is defined in ASTM E284 [3] as the "ratio of flux reflected in specular direction to incident flux for a specified angle of incidence and source and receptor angular apertures" (Fig. 4). This aspect of gloss has been measured most frequently because it is the one for which an instrument is most easily constructed. In practice the divergence angles of source and receptor are precisely specified in ASTM Test Method for Specular Gloss [4], D523, as are the directional angles of incidence and reflection. Tolerances are specified for all angles. For simplicity, glossmeter geometries are identified by reference to the incidence angles, most frequently 20°, 60°, and 85°. However, the associated source and receptor aperture angles and their tolerances play a vital role in determining the reproducibility of instrument readings. The measurement result is dependent on the amount of light reflected in the specular direction and the refractive index of the surface. ASTM D523 Test Method for Specular Gloss [4] lists the gloss values in dependence of the refractive index. A polished glass with a refractive index of n = 1.550 has a maximum 20° gloss value of 95.4. If the refractive index changes to n = 1.510, the 20° gloss value will decrease to 84.7. Therefore, gloss readings of materials with different refractive indices, such as 1 and 2 K clear coat systems, will not correlate with the visual perception (Fig. 5). As long as the refractive index of the material does not change, a glossmeter will give objective measurement results.

Sheen

Sheen is defined in ASTM E284 [3] as "the specular gloss at a large angle of incidence for an otherwise matte specimen." The usual angle for sheen measurement is 85°; from the perpendicular to the specimen. This is about the maximum angle that can be used without encountering difficulty in positioning the optics to illuminate and view the specimen at near-grazing angles.

Haze

Haze of opaque products is called reflection haze, while haze of transparent products is encountered as near-forward scattering in transmission that is designated transmission haze. ASTM E284 [3] defines haze in reflection as "percent of reflected light scattered by a specimen having a glossy surface so that its direction deviates more than a specified angle from the direction of specular reflection."

Distinctness-of-Image

This aspect of gloss is also referred to as "image clarity." ASTM E284 [3] defines distinctness-of-image gloss as "the

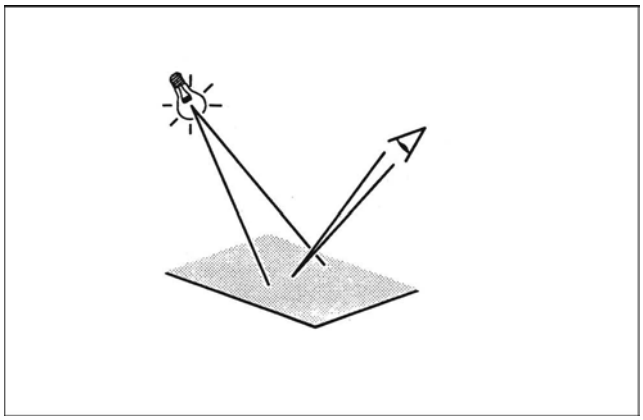

Fig. 1—Observer focuses on the image of reflected object.

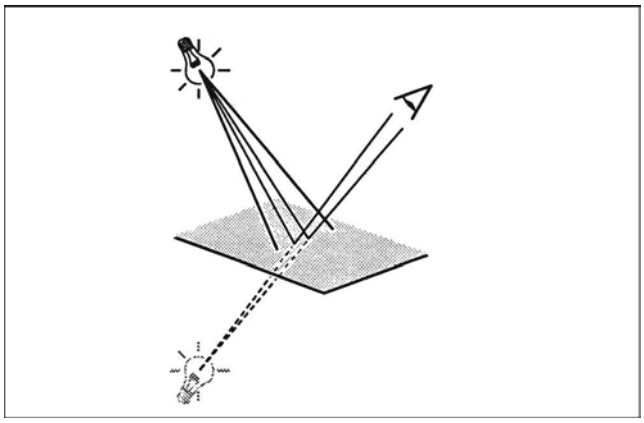

Fig. 2—Observer focuses on the illuminated surface of object.

aspect of gloss characterized by the sharpness of images of objects produced by reflection at a surface." During visual observation, the sharpness of the light-dark edge of a reflected object can be observed.

Waviness

One obvious type of waviness is designated "orange peel." ASTM E284 [3] defines orange peel as "the appearance of irregularity of a surface resembling the skin of an orange." A surface may be described as exhibiting orange peel when it has many small imperfections that are perceived as a pattern of both highlighted and non-highlighted areas. This pattern is interpreted by an observer as a three-dimensional structure of peaks and troughs.

Directionality

ASTM E284 [3] defines directionality, perceived as "the degree to which the appearance of a surface changes as the surface is rotated in its own plane, under fixed conditions of illumination and viewing." A surface exhibits directionality when specular gloss measurements are a function of the direction for which measurements are made. When paint is applied by brushing in one direction, the brush marks can cause the surface to have a directional characteristic. Metallic materials frequently exhibit directionality when the surface is polished in one direction.

VISUAL GLOSS EVALUATION

Early investigations of gloss were carried out by observing differences in the characteristics of images reflected in the surfaces of specimens. In 1932, the Detroit Paint and Varnish Production Club [5] reported on investigations carried out with their distinctness-of-image gloss comparator. In 1936, Hunter [6] reported an investigation where reflected images of a target pattern were observed.

Only in comparatively recent times has there been a major effort to investigate visual scaling of gloss and to endeavor to develop correlation between visual and instrumental measurements. O'Donnell did a doctoral thesis on visual gloss scaling at Rensselear Polytechnic Institute, Troy, New York. Results were first presented, in part, at an ASTM Symposium in 1984 [7] and more fully in a journal article in 1987 [8]. In 1997, the DFO (Deutsche Forschungsgesellschaft für Oberflachenbehandlung) started a research project to investigate which of the physically measurable parameters influence the visual assessment of gloss. The conclusion of this study was that the visual perception is influenced by scattered light reducing the contrast and microstructures distorting an object's outlines, which results in a lower sharpness. Specular gloss measurement is dependent on the refractive index of the material and the curvature of the sample. Therefore, the visual assessment of gloss requires

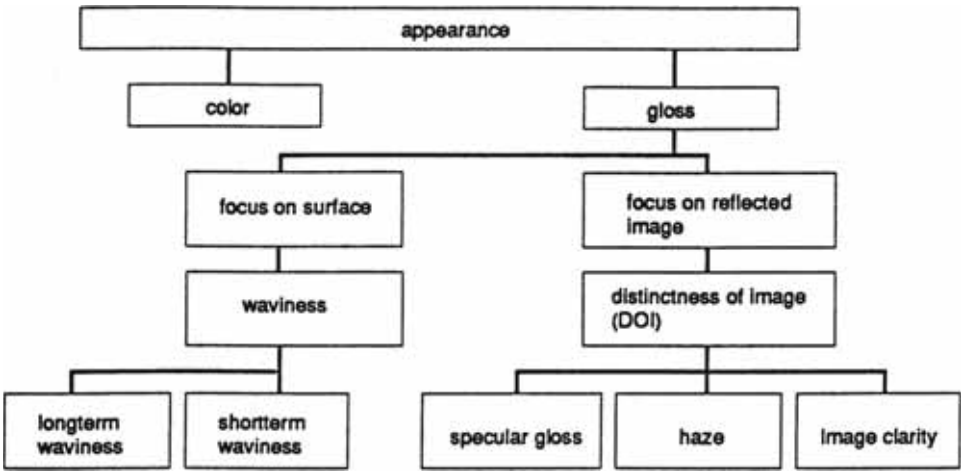

Fig. 3—Block diagram depicting relationships of various appearance characteristics.

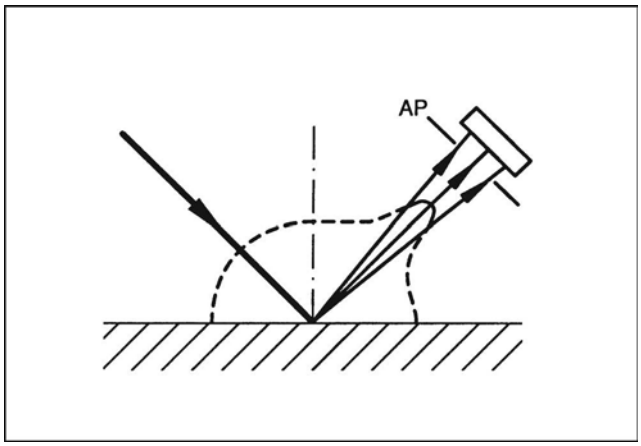

Fig. 4—Reflected light flux distribution from a semigloss surface is depicted by a broken curve. Three lines are shown proceeding from the specimen surface. The center one depicts the specular direction, the image of a ray reflected from a mirror-like surface. The two other rays represent the range of angles passing through the aperture (AP) to the detector (shown as a rectangle).

a multi-dimensional description [9]. At about the same time the ASTM committee E12 on Color and Appearance started a new subcommittee, E12.14, on Multidimensional Characterization of Appearance. The scope of this subcommittee is to develop standards for visual and instrumental assessment of appearance that address the multiple dimensions of appearance. In the first step the committee has conducted several round robin experiments to judge distinctness of image both visually and instrumentally [10].

Development of a Documentary Standard

In 1990, ASTM Committee D-1 on Paint and Related Coatings and Materials published ASTM D4449, Method for Visual Evaluation of Gloss Differences Between Surfaces of Similar Appearance [11], for making visual evaluations of gloss between surfaces of similar appearance. It uses two types of light sources. One source consists of a tubular fluorescent desk lamp modified by placing a matte-black reflecting material behind the tubes and a coarse wire-mesh screen in front. The directions of illumination and view can be adjusted to be 20°, 60°, or 85° as desired for comparing specimens having high gloss, intermediate gloss, or sheen. The other light source is a clear-bulb incandescent lamp. Light from the selected source illuminates the specimens at the chosen angle. The sharpness of reflected images permits a subjective comparison of the relative gloss of similar surfaces.

Use of Landolt Rings to Visually Analyze Distinctness of Image

Landolt rings have been used by ophthamologists to evaluate visual acuity for nearly a hundred years [12]. The test consists of locating the gaps in a graduated series of sizes of incomplete rings whose radial thickness and gap are equal to one fifth the diameter of the ring. For gloss evaluation of trans-illuminated rings, reflections are viewed on a Mylar polyester film. Rings have different sizes and different gap orientations. An image-gloss scale is associated

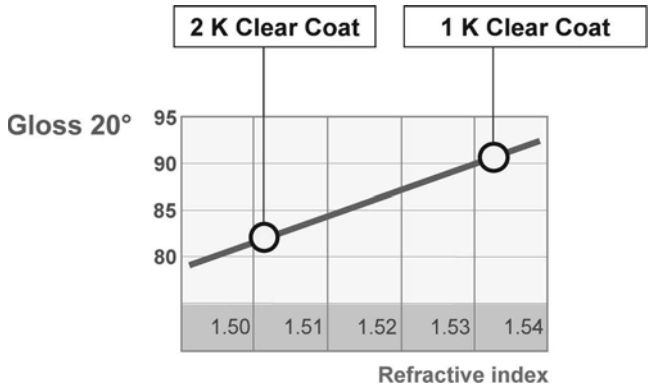

Fig. 5—Specular gloss is dependent on the refractive index of the material: The 1 K and 2 K clear coat system look the same. Due to the difference in refractive index the 2 K clear coat system has a lower specular gloss value than the 1 K clear coat system.

with the different sizes of rings. An image-gloss scale ranging from 10 to 100 in steps of 10 was established for 11 sizes of rings from the largest to the smallest. The development of the scale is not documented, but it ostensibility took place in the General Motors Automotive Division about January 1977. Visual observers select the smallest size of ring for which they can call the gap orientation correctly. The visual judgment is influenced by the loss of contrast and sharpness of the outlines. The numerical size of the rings is used as an inverse index of distinctness-of-image gloss (Fig. 6). ASTM has not published a method for visually evaluating distinctness-of-image gloss by using Landolt rings, but equipment for this purpose is available.[3]

Visual Evaluation of Orange Peel

The automotive industry established a physical standard for orange peel consisting of ten high-gloss panels with various degrees of orange peel structure.[4] The panels are visually ranked from 1 to 10 with Panel Number 1 depicting very pronounced orange peel and Panel Number 10 illustrating no orange peel. The visual observer can use these panels as a supportive tool to evaluate degree of orange peel.

In order to understand this visual ranking it is important to realize that our visual impression is influenced by the structure size and the observing distance (Figs. 7–9)

INSTRUMENTAL MEASUREMENT TECHNIQUES

Specular Gloss Measurement

The design of many gloss meters is based on the precise measurement of the specular component of reflected light [13]. A light source, simulating CIE illuminant C, is placed at the focal point of a collimating lens. The axis of the collimated beam is set to the desired angle of illumination. A receptor lens with an aperture in the focal plane followed by an illumination detector completes the basic optical design (Figs. 10 and 11). The size of the receptor aperture and the size of the source image in that aperture are the elements that complete the optics and that

[4] Set of orange-peel panels can be obtained from Advanced Coatings Technology, 273 Industrial Dr., Hillsdale, MI 49242.

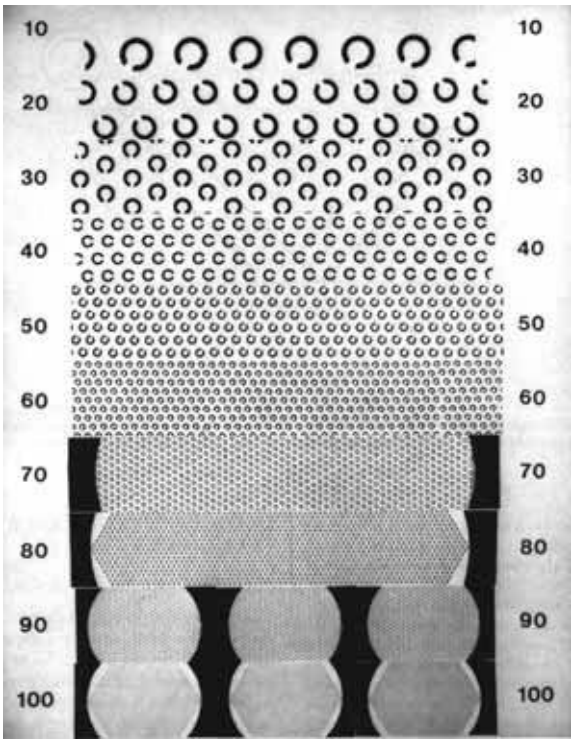

Fig. 6—"Landolt Rings." Broken rings of various sizes are used to provide a scale for visual evaluation of the distinctness of surface-reflected images.[3]

determine the high, low, and intermediate gloss scale readings. The specular angle largely determines the magnitude of the reflected light. However, the tolerances assigned to the source and receptor apertures are what determine the accuracy and reproducibility of measurements made with instruments having the same angles of illumination and view.

Periodic calibration or verification of instrument performance requires the use of calibrated gloss standards. For permanence they should be made of glass or ceramic material. ASTM D523 recommends the use of a primary standard of polished black glass of known refractive index for which the Fresnel (specular) reflectance [14] has been computed for the angle of incidence of the geometry for which the instrument is designed. Since about 1990, national standardizing laboratories have preferred a primary reference standard made of a wedge of clear quartz. Polished black glass working standards can be calibrated by direct comparison of their reflectances with that of a quartz wedge.

A single measurement geometry, such as 60°, may not provide instrument readings of gloss that correlate well with visual observations when comparing different gloss levels. This is why ASTM D523 [4] provides for measurement at three different angles of incidence, namely 20°, 60°, and 85° (Fig. 12). Each of the three geometries uses the same source aperture, but a different receptor aperture. The choice of geometry depends on whether one is: (1) making a general evaluation of gloss, (2) comparing high-gloss finishes, or (3) evaluating low-gloss specimens for sheen. ASTM D523 [4] states that the 60° geometry is used for intercomparing most specimens and for determining when

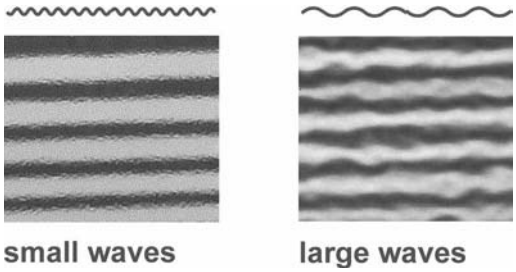

Fig. 7—Appearance changes with structure size.

the 20° or 85° geometry may be more applicable. The 20° geometry is advantageous for comparing specimens having 60° gloss values higher than 70. The 85° geometry is used for comparing specimens for sheen or near-grazing shininess. It is most frequently applied when specimens have 60° gloss values lower than 10.

The ASTM documentary gloss standard originally published in 1939 contained only the 60° geometry [15]. The desirability of using an auxiliary geometry of 85° for sheen evaluation was recognized shortly afterward. However, the use of another geometry with smaller angles of incidence and view, such as 20°, and a smaller receptor aperture to provide improved differentiation of high-gloss finishes was not published until 1947 [16]. The three geometries, 20°, 60°, and 85°, were originally published as separate ASTM standards. In 1953, ASTM D523 was revised to incorporate all three geometries, and it still does.

Meanwhile, the Paint Committee of the International Organization for Standardization, ISO TC-35, was investigating gloss measurements with various commercial instruments prior to drafting an international standard. A paper documenting what the committee had been doing was published in 1976 by the Chairman of the Gloss Task Group, Dr. Ulrich Zorll [17]. In 1978, the ISO Paint Committee published ISO 2813, essentially an international version of ASTM D523 [18]. In keeping with the usual ISO procedure, the standard was made available in English, French, and German.

Instrument manufacturers report that measurement precision, reproducibility, and data handling capabilities of gloss meters have been improved markedly in recent years. New instruments have been designed that are smaller, more portable, and more convenient to use. Data storage and analysis are frequently included as well as the capability of electronically transferring data to a personal computer [19,20].

Goniophotometry

"Gonio" means angle, and a photometer measures radiance; so a goniophotometer is an instrument for measuring the angular distribution of reflected or transmitted light intensity. This type of instrument is often used in the research laboratory to investigate the distribution of light flux (Fig. 13). A goniophotometer with appropriate apertures can also be used to provide gloss data for a wide variety of angles and apertures. When goniophotometric measurements are desired, reference should be made to ASTM E167, Practice for Goniophotometry of Objects and Materials [21]. Analysis of goniophotometric curves was treated by Nimeroff [22].

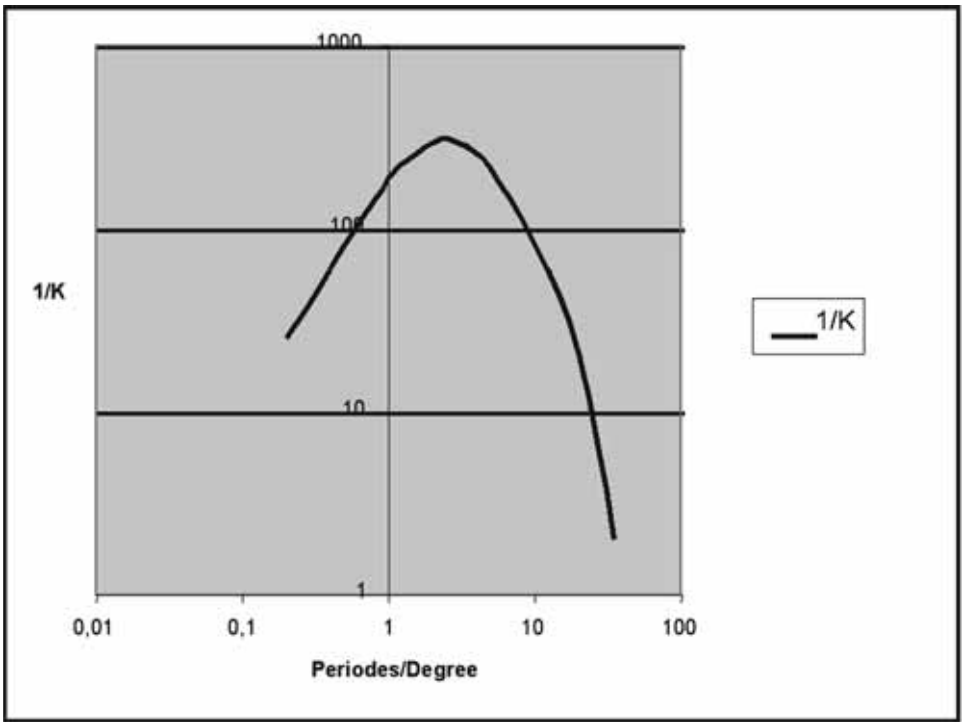

Fig. 8—Contrast sensitivity of our eyes is highest at three periods per cycle. Therefore, our visual assessment is dependent on the observing distance.

Measurement of Reflection Haze

Haze is a gloss parameter that causes a high-gloss surface to appear milky and lighter, thereby losing contrast. When visually evaluating the reflected image of a hazy object, one observes halos around distinct reflection outlines caused by scattered light. Haze can result from various material or process parameters such as degree of dispersion, flocculation, incompatibility of raw materials (pigment-additive-resin), or from poor application procedures.

Haze is most often associated with high-gloss surfaces when small amounts of reflected light are scattered in a region 1° to 4° from the direction of specular reflection. Therefore, it is useful to place apertures several degrees wide on each side of the specular receptor aperture (Fig. 14). ASTM E430, Test Methods for Measurement of Gloss of High Gloss Surfaces by Goniophotometry [23], describes two methods for evaluating reflection haze, one at 20° and another at 30°. The instrument using a 30° angle is no longer commercially available.[5] Since about 1992, a 20° laboratory gloss meter[6] was equipped with auxiliary apertures for haze evaluation, thus permitting measurement of 20° specular gloss and haze with the same instrument (Fig. 15).

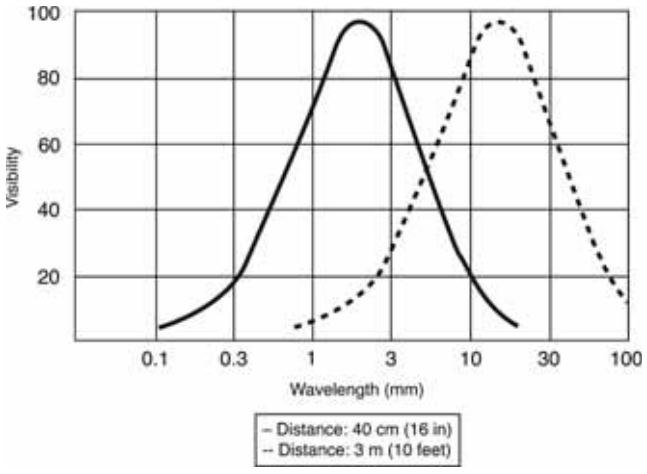

Fig. 9—At a 40 cm observing distance structures with a wave length size of 3–5 mm can be best seen. While at a 3 m observing distance structures with a wave length size of 10–15 mm can be best seen: Typical orange peel.

Fig. 11—Photograph of a modern miniature glossmeter[5] (courtesy of BYK-Gardner).

Measurement of Distinctness-of-Image

A variety of different technologies is commercially available to measure Distinctness of Image (DOI) [24–28]. The two most-often used principles are: (1) evaluation of the steepness of the reflection indicatrix or (2) measurement of contrast in dependence of the structure elements.

ASTM E430 [23] describes the design of an instrument based on the evaluation of the reflection indicatrix (Fig. 16). The instrument illuminates the specimen at a 30° angle and measures the light reflected at 0.3° from the specular angle with an aperture of 0.3° width. This instrument[7] is no longer commercially available.

Based on the DFO research project the visual perception of DOI is influenced by loss of contrast and microstructures distorting outlines. Therefore, in 1999 a new measurement technology[8] [29] was developed to measure light scattering caused by structure sizes smaller than 0.1 mm. This new measurement parameter was named "Dullness." A light emitting diode light source and a CCD detector are used to detect the reflected image of the source aperture (Fig. 17).

In Fig. 18 two different surfaces are compared. Surface A is a polished black glass standard without dullness. In this case the camera will detect a perfectly sharp image—no light scattering outside the aperture. Surface B shows some light scattering, which results in a lighter image outside the aperture. The dullness measurement determines the amount of light scattering within and outside the aperture in a defined range. The dullness value is a ratio of these two values. Therefore, this measurement parameter is independent of the refractive index. In addition, an adaptive filter is used to separate between the inner and outer image, which minimizes the influence of curvature.

[8] Apparatus designated "wave-scan" available from BYK-Gardner USA, Columbia, MD.

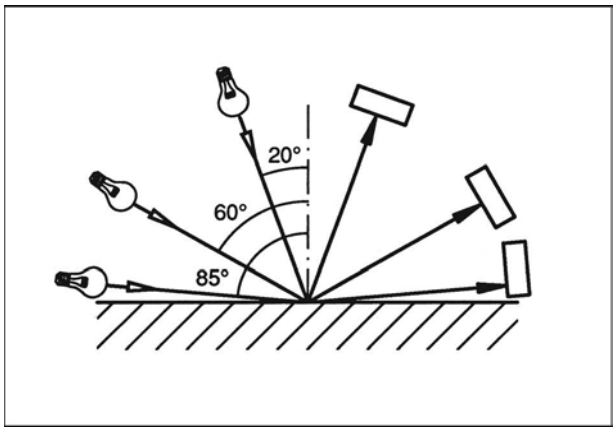

Fig. 12—Diagram depicting the positions of source and receptor for the three geometries of ASTM D523.

Microstructures larger than 0.1 mm also influence our impression of DOI. They are in the wavelength range of 0.1–1 mm and can be objectively detected with the same measurement principle as used for orange peel measurement.

Measurement of Waviness (Orange Peel)

The phenomenon of waviness is most observable on a glossy surface, a critical appearance phenomenon in the automotive industry. Waviness has been evaluated by visual means and by use of a profilometer. The correlation between pro-filometry measurements and visual perception is satisfactory for surfaces with similar optical properties. The operation of a profilometer, however, is very time consuming and limited to laboratory use. When the eye of an observer is focused on a painted surface, various types of waviness can be identified that involve size, structure, and shape. Variations in process or material parameters can cause differences in surface structure. For example, poor flow or leveling properties of a coating will usually cause a long wave structure often called orange peel. Changes in substrate roughness, on the other hand, will exhibit a short wave structure of higher frequency. Because waviness is often caused on the production line, it is important to control it there.

After considerable research, an instrument was introduced in 1992 to provide an objective evaluation of waviness with structure sizes between 0.3 and 12 mm [30]. In 1999 the measurement principle of this instrument was further developed to increase the resolution and expand the measurement range from 0.1 to 30 mm (Fig. 19).

A diode laser source is used to illuminate the specimen at 60°. The reflected light intensity is evaluated at the specular angle. During the measurement the instrument is moved along the surface for a distance of about 10 cm. The intensity of the reflected light is a maximum when coming from a concave structure element. The detector receives less light from a convex structure element. The human eye cannot resolve the actual heights of the structural elements of a painted surface, but the contrast between light and dark areas provides an impression of depth. The contrast of a surface structure can be expressed by use of the statistical parameter "variance." The final measurement results

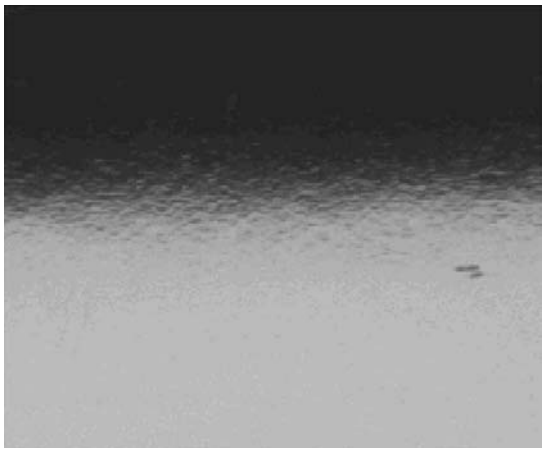

Fig. 23—Surface appearance is dominated by short waves after longer waves were reduced: Surface appears "dull."

are divided into five wave length ranges (Wa–We) using electronic filtering procedures. As a final result a structure spectrum is obtained for structure sizes between 0.1 and 30 mm (Fig. 20).

In order to get a complete picture of the surface appearance, this new instrument also includes the measurement principle for dullness. The combination of two measurement principles in one instrument simulates the visual perception at different distances and permits categorizing structure sizes with their causes.

Changes in Structure Spectrum Compared to Changes in Color Measurement

For better understanding of how various structure sizes influence the visual perception, changes in the structure spectrum can be compared to color measurement. The visible spectrum of color measurement is between 400 and 700 nm (blue → red). For simplicity three colors can be allocated to three structure sizes: Long waves correspond to the color red, short waves correspond to the color green, and micro-structures (DOI) correspond to the color blue.

The ideal surface would be perfectly smooth, i.e., no waves. In colorimetric terms we would be dealing with

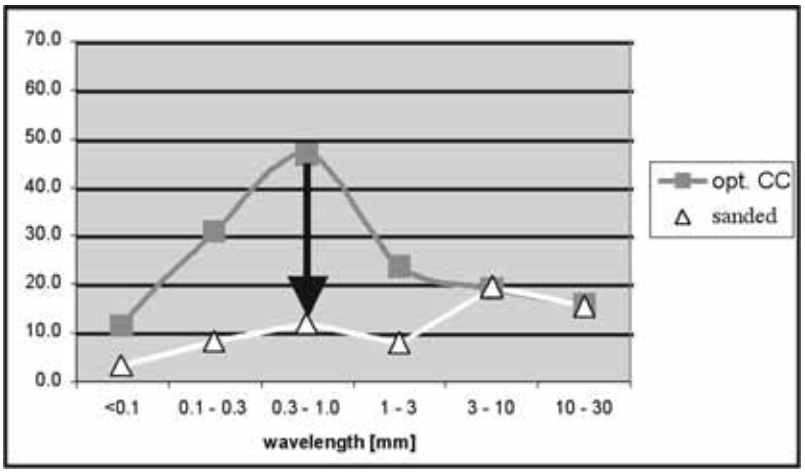

Fig. 24—Structure spectrum with reduced short waves by, e.g., sanding primer surfacer.

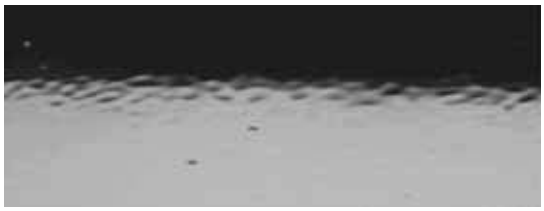

Fig. 25—Very brilliant surface with a low amount of short waves makes long waves very apparent.

the color black (no waves = no color). In the following example a coating with severe waviness is to be improved whereas the main target is to reduce the longer waves. The original surface has a high amount of long, short, and microstructures corresponding to the color gray (Fig. 21).

The structure spectrum of the original surface is shown in Fig. 22. A reduction of the longer waves can be achieved by optimizing the basecoat/clearcoat application (e.g., higher clear coat film thickness).

As a result the new look will be dominated by the shorter waves, which would be equivalent to a blue/green color (Fig. 23). In practice dominance in shorter waves can be caused by, e.g., a poor-quality primer.

This high amount of shorter waves can be reduced by, e.g., sanding the primer. In our example the shortened microstructures were reduced below the amount of longer waves (Fig. 24).

In color measurement the color red would be dominating the look. And the same is true in appearance measurement: The very low levels of shorter waves will make the surface very brilliant with a high DOI and consequently the small amounts of long waves will be very obvious (Fig. 25).

It is important to realize that the impression of gloss is a multi-dimensional phenomenon. By changing the ratio of different structure sizes, the visual appearance can be dramatically changed. The structure spectrum is like the fingerprint of a surface and can be compared to the spectral curve of colorimetry. Currently the correlation of the different wavelength ranges to the visual perception is under investigation. The goal is to obtain a measurement system for appearance similar to the L*, a*, b* system of color measurement [31].

Hiding Power

Leonard Schaeffer

CONCEPTS, RELATIONSHIPS, TERMINOLOGY

Opacity

WHEN LIGHT ENTERS A PAINT FILM, SOME OR ALL of it is absorbed or reflected by the film before reaching the substrate, thereby hiding the substrate to a lesser or greater degree. The light that reaches the substrate is partly absorbed by it and partly reflected back in conformance with the substrate's visual pattern. Reflection from the substrate eventually emerges from the film carrying the substrate reflectivity information perceived as visibility or lack thereof, and referred to as *hiding*. Opacity may be qualitatively defined as the property of a paint film that enables it to prevent the passage of light and thereby to hide the substrate on which it has been applied. Note that *opacity* is a film property, whereas *hiding power* is a property of the whole paint. *Hiding* is a more general term used frequently to refer to either opacity or hiding power (HP).

Light Absorption

If most of the light is absorbed by the film before reaching the substrate, the film is dark in color and hides the substrate well, in which case hiding has been produced by light absorption.

Light Scattering

If most of the light entering the film is reflected back and reemerges without having reached the substrate, the film is white or light in color and hides the substrate well. The reflection mechanism of the film involves multiple internal refractions and reflections that scatter the light to produce a net reversal in its direction. Hiding in this case is produced by light scattering.

Incomplete Hiding

In all cases, the light-absorbing and light-scattering properties of the film act together to produce its opacity. If the film is low in both light-absorption and light-scattering ability, much of the light reaches the substrate. Such a film, therefore, hides poorly and is characterized as being low in opacity.

Test Substrates

An opacity test substrate generally has an ordered pattern of contrasting colors or shades, usually black and white, although black and gray and gray and white are also used. Juxtaposition of contrasting areas permits both visual observation and photometric measurement of film opacity. Sealed paperboard charts are the most commonly used substrates of this description. For photometric measurements only, individual black glass and white glass panels are sometimes employed to take advantage of their excellent planarity. Clear plastic can also be used as an opacity test substrate by placing it over black-and-white backgrounds. Black and white painted metal panels are commercially available for use with powder coatings. Standard black-and-white opacity test substrates are defined in paint technology as having CIE-Y reflectances of 0.01 (1 %) maximum and 0.80 (80 %), respectively.[2] White test areas are seldom exactly 80 %, but equations are available for correction of photometric values to that and any other standard (see "Kubelka–Munk Equations for Correcting Reflectance and CR_n Measurements to a Standard White Substrate Reflectance").

CR

The extent to which a paint film obscures or hides the contrasting features of the test substrate on which it is uniformly applied is the measure of its opacity. This is expressed photometrically as the ratio of the luminous (CIE-Y) reflectance over the darker, to that over the lighter, area of the substrate, which is referred to as the CR (CR). The *Y*-reflectance is employed because this CIE parameter is designed to match the sensitivity of the human eye. The CR and the reflectance are expressed as a percentage or as a decimal fraction, the latter to be assumed unless otherwise indicated. A CR value of unity indicates that too little light has reached the substrate for the substrate reflectance characteristics to have a measurable effect on the emergent light flux; thus, there is complete absence of contrast, or complete hiding. Lesser CR values define intermediate levels of contrast, or incomplete hiding. The CR of a given paint film varies with substrate reflectances, and therefore has significance only with respect to a known substrate and primarily to a standard black-and-white substrate as defined in Test Subtrates. In practice, the white area of a commercially available black-and-white substrate normally deviates somewhat from the ideal reflectance of 80 %, whereas the black area is normally 1 % or less, which has no measurable effect on test results, and is therefore treated mathematically as having zero reflectance. Conventional symbols used in this connection are as follows:

W = the reflectance of the white area of the test substrate,

[1] *The Leneta Company, 15 Whitney Road, Mahwah, NJ 07430. (Author deceased 2002.)*
[2] CIE = Commission Internationale d'Eclairage. Reflectances are measured with specular (mirror) reflection excluded.

Copyright © 2012 by ASTM International

R_w = the reflectance of the paint film over a white area of reflectance W,
R_0 = the reflectance of the paint film over the black area,
$C_w = R_0/R_w$, the CR of the applied paint film,
$C_{0.80} = R_0/R_{0.80}$, the CR when $W = 0.80$, and
$C = C_{0.80}$, the abbreviation sometimes used in equations.

In careful HP measurements, if the white substrate reflectance deviates more than 0.01 from the standard value of 0.80, one of the following correction equations[3] is employed. Correction equations[3] for normalizing CR values to a standard white substrate reflectance are given in "Calculation of Hiding Power from Tinting Data."

$$C_{0.80} = f(R_0, R_w, W) = \frac{WR_0(1-0.80R_0)}{R_0(W-0.80)+0.80R_w(1-WR_0)} \quad (1)$$

$$C_{0.80} = f(C_w, R_0, W) = \frac{WC_w(1-0.80R_0)}{C_w(W-0.80)+0.80(1-WR_0)} \quad (2)$$

Visual Observations of Contrast

Although intermediate levels of contrast cannot be directly quantified by visual means, the eye is qualitatively very sensitive to contrast variations. It can identify equalities or nearly complete absence of contrast with considerable precision, which is the basis for the original, as well as several current, HP methods to be described. Indeed, such visual observations are the basic criteria of what constitutes hiding and HP, to which all instrumental hiding measurements trace their validity.

Film Thickness

This is usually expressed in thousandths of an inch (mils) or in micrometres (μm). A liquid paint usually contains a substantial quantity of volatiles, so that its dry film thickness (DFT) is substantially less than the original wet film thickness (WFT). The WFT of architectural paints applied in the field are typically in the neighborhood of 3 to 4 mils (75 to 100 μm). With other coating types, it might be as low as 1 mil (25 μm) or as high as 60 mils (1500 μm). With volatile-free liquid coatings, the WFT and DFT are the same except for a possible small increase in density during curing. With powder coatings, for which film formation and curing are concurrent, the term WFT is inapplicable and DFT redundant, so that it is appropriate to refer simply to *film thickness*.

SR

When paint is applied, whether for test purposes or in actual usage, the area covered per unit quantity of paint is called the spreading rate (SR) for that particular application. When the quantity of coating is expressed volumetrically, as is usual with liquid paints, the SR is usually expressed in square feet per gallon (ft²/gal) or square metres per litre (m²/L). When the quantity is expressed gravimetrically, the SR is usually expressed in square feet per pound (ft²/lb) or square metres per kilogram (m²/kg). SR is inversely related to the film thickness; thus, for a given paint, the lower the SR, the higher the film thickness and film opacity.

[3] Derived from Eq (41) by equating to $W = 0.80$.

SR and Film Thickness Relationships

Let

H = SR of the coating (equivalent to SR),[4]
T = wet film thickness (equivalent to WFT),[4]
D = coating density (prior to loss of volatiles),
t = DFT (exclusive of air)[5] (equivalent to DFT),
d = dry film density (displacement density),[5]
N = Nonvolatile fraction by weight (equivalent to nonvolatile fraction by weight (NVW)), and
N_v = nonvolatile fraction by volume (equivalent to nonvolatile fraction by volume (NVV)).

U.S. UNITS

$$H(\text{ft}^2/\text{gal}) \times T(\text{mil}) = 1604.2 \quad (3)$$

$$H(\text{ft}^2/\text{gal}) \times t(\text{mil}) = 1604.2ND \div d \quad (4)$$

$$H(\text{ft}^2/\text{lb}) \times T(\text{mil}) = 1604.2 \div D(\text{lb/gal}) \quad (5)$$

$$H(\text{ft}^2/\text{lb}) \times t(\text{mil}) = 1604.2N \div d(\text{lb/gal}) \quad (6)$$

METRIC UNITS[6]

$$H(\text{m}^2/L) \times T(\mu\text{m}) = 1000 \quad (7)$$

$$H(\text{m}^2/L) \times T(\mu\text{m}) = 1000 \quad (8)$$

$$H(\text{m}^2/\text{kg}) \times T(\mu\text{m}) = 1000 \div D(\text{kg/L}) \quad (9)$$

$$H(\text{m}^2/\text{kg}) \times t(\mu\text{m}) = 1000N \div d(\text{kg/L}) \quad (10)$$

U.S.—METRIC UNIT CONVERSIONS

$$H(\text{ft}^2/\text{gal}) = H(\text{m}^2/\text{L}) \times 40.746 \quad (11)$$

$$H(\text{ft}^2/\text{lb}) = H(\text{m}^2/\text{kg}) \times 4.8882 \quad (12)$$

$$T(\text{mil}) = T(\mu\text{m}) \div 25.4 \quad (13)$$

$$D(\text{lb/gal}) = D(\text{kg/gal}) \times 8.3454 \quad (14)$$

DRY VERSUS WET FILM RELATIONSHIPS[7]

$$ND = N_v d \quad (15)$$

$$t = N_v T \quad (16)$$

$$T = td \div ND \quad (17)$$

DEFINITION OF HP

Qualitatively, HP is the property of a paint that is manifested as opacity in its films. Quantitatively, it is the SR at

[4] Note that WFT and SR, when the latter is expressed by volume, are inverse ways of stating the same information.
[5] Refers to films containing no air or hypothetically compressed to exclude air.
[6] The following metric notations are identities: kg/L = g/mL = g/cm³ = g/cc.
[7] These are applicable to both common and metric units since the units all cancel.

which the film opacity is just sufficient to give complete hiding over the specified standard black-and-white substrate (see "Test Substrates"). The "complete hiding" point is determined visually in some test procedures and photometrically in others.

Visual HP End-Point

In the visual determination of HP, the operator increases the film thickness gradually and records the amount of paint applied at the supposedly exact point of complete hiding. In practice, instead of perceiving such a point, a range of uncertainty is reached beyond which, when hiding seems unquestionably complete, it also seems that the true end-point has been exceeded. To resolve this dilemma and to obtain repeatable results, the operator chooses an end-point at which it seems that only a negligible increase in film thickness is required to completely obscure the contrasting features of the substrate. This so-called *complete hiding* end-point is therefore more accurately described as just short of complete hiding.[8]

Photometric HP End-Point

Uncertainty as to the end-point also exists when measuring HP photometrically. A curve of film thickness versus CR approaches CR = 1 asymptotically, so in theory there is no point at which the contrast is completely obscured. Thus in practice the CR end-point for HP measurements must be less than unity. A CR value of 0.98 is generally accepted in paint technology as representing the point of photometric *complete hiding* because it is in fact very close to being visually complete, and a higher CR end-point could not be identified with as much precision. The concept of 98 % as the CR for complete hiding was originally based on the Weber–Fechner law, from which it can be deduced that differences of 2 % in reflectance (with moderate illumination) are imperceptible to the human eye [1]. Actually, this level of contrast, though slight, is definitely visible.

THE ROLE OF PIGMENTS IN HP

Binders and Pigments

A typical paint binder, by itself, forms a transparent and virtually colorless film that neither absorbs nor scatters light to any appreciable degree and therefore makes no contribution to the HP of the coating of which it is a part. This task resides entirely in the pigment constituent of the paint. Pigments are fine-particle-size, insoluble, and usually crystalline solids that when dispersed in paint vehicles contribute to the various properties of the mixture, among which are the optical properties of color and HP. Pigments that absorb light strongly over the entire visible spectrum are black; those that are optically selective, absorbing strongly in parts of the visible spectrum and poorly in other parts, are colored, viz. blue, red, yellow, etc., corresponding to the spectral region of nonabsorption. Those that absorb poorly over the entire visible spectrum are white.

White Pigments

When dispersed in a paint binder, some white pigments scatter light strongly and thereby contribute to hiding, while others scatter very poorly and make little, if any, contribution. On that basis, white pigments are classified as *hiding pigments* or as *extenders*. White hiding pigments in a paint formulation are sometimes called "prime pigments" as distinguished from the nonhiding "extender" types. The latter are also referred to as "inerts" in view of their apparent passivity with regard to both light absorption and scattering. The difference in scattering behavior between hiding and extender pigments is a function of their refractive indices.

Refractive Index

Most pigments are crystalline in nature. If a single crystal of white pigment were grown sufficiently large, it would be perceived as shiny and transparent like glass, and objects observed through it would look bent and distorted as when observed through a glass prism. This is due to the change in direction, referred to as refraction, that occurs when light passes between media in which it has different velocities, as illustrated in Fig. 1. The relationship between the angles in this figure is expressed by Snell's law of refraction

$$n = \sin i / \sin r \tag{18}$$

in which i and r are the angles of incidence and refraction, respectively, and n is a constant referred to as the refractive index, which is the ratio of the velocity of light in the incident to that in the refraction medium. If the large pigment crystal postulated previously is pulverized and dispersed in a paint film, each small particle will refract incident light in the same way as described for the large one. Light will also be partially reflected at the surface, and both refractions and reflections will occur within the pigment particle itself. This activity, endlessly repeated with a multitude of pigment particles as illustrated in Fig. 2 (Ref. [2], p. 1), results in the scattering of the original incident light with concomitant film opacity and paint HP. The greater the difference between the refractive indices of the pigment and the surrounding medium, the greater the amount of light scattering that will occur. Refractive indices are reported in Tables 1 and 2 with respect to a vacuum as the medium of incidence. Values with respect to air are practically the

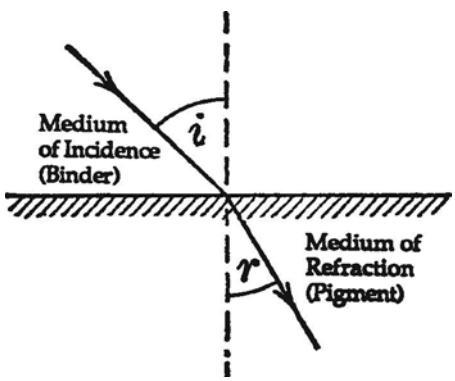

Fig. 1—Bending of a light ray by refraction toward the normal as it enters a medium of lower light velocity (higher refractive index).

[8] It has been proposed to use ΔE of a uniform color space as the HP endpoint instead of CR. This is a valid and feasible concept, although to the writer's knowledge it has not yet been employed in a published test method.

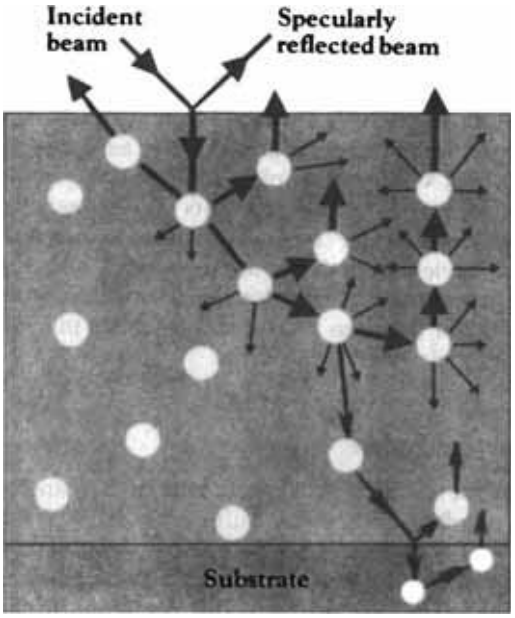

Fig. 2—Light-scattering behavior of a pigmented film.

same. Since white pigments are crystalline in nature, they usually possess different refractive indices along the different crystal axes. Their indices also vary somewhat with the wavelength of the light, generally being higher at the blue (short wavelength) end of the spectrum than at the red (long wavelength) end. Tables 1 and 2 give average values [1,3].

White Hiding Pigments

A rough indication of the relative HP of a white pigment can be calculated from its refractive index using the Fresnell equation of reflectivity (Ref. [2], p. 1)

$$F\ \% = \frac{(n - n_m)^2}{(n + n_m)^2} \times 100 \qquad (19)$$

where F is the Fresnell reflectivity, n is the refractive index of the pigment, and n_m is the refractive index of the medium

TABLE 1—Refractive index and relative HP of some white hiding pigments

Pigment	Refractive Index	Relative HP F %[a]
Titanium dioxide (rutile)	2.76	8.8
Titanium dioxide (anatase)	2.55	6.7
Zirconium oxide	2.40	5.3
Zinc sulfide	2.37	5.0
Antimony oxide	2.19	3.5
Zinc oxide	2.02	2.2
White lead carbonate	2.01	2.1
White lead sulfate	1.93	1.6
Lithopone	1.84	1.0

[a] Calculated from Eq (20).

TABLE 2—Refractive index and relative HP of some extender pigments

Pigment	Refractive Index	Relative HP F %[a]
Barium sulfate	1.64	0.20
Calcium sulfate	1.59	0.08
Calcium carbonate	1.57	0.05
Magnesium silicate	1.57	0.05
Aluminum silicate	1.55	0.03
Silica	1.55	0.03

[a] Calculated from Eq (20).

in which it is dispersed. Since the refractive index of a paint binder is, in general, very close to 1.5, Eq (19) can be rewritten as

$$F\ \% = \frac{(n - 1.5)^2}{(n + 1.5)^2} \times 100 \qquad (20)$$

Tables 1 and 2 illustrate the use of this equation and the general principle that the higher the refractive index of a pigment the greater its HP. The relative HP values shown therein indicate the magnitude of variation related to index of refraction. Other factors can also affect HP substantially, as discussed in "Factors Affecting White HP."

Extender Pigments

Pigments in this category have low refractive indices in the neighborhood of 1.5. In the form of a powder, with the surrounding medium being air with a refractive index of 1.0, the difference in the two indices produces substantial light scattering, so that extender pigments look white. But dispersed in paint binders, which like themselves typically have a value of about 1.5, they scatter light very poorly and are virtually transparent. This is indicated by the low HP values listed for them in Table 2 as compared with the white hiding pigments in Table 1. Although extender pigments are also referred to as inerts, the latter term is somewhat of a misnomer. They have an indirect but strong influence on light scattering and HP through phenomena referred to as "crowding" and "dry hiding." They also have important effects on other physical properties of paints such as consistency and gloss.

Colored Pigments

If a pigment absorbs some wavelengths of light more strongly than others, it reflects back a higher proportion of the weakly absorbed wavelengths and is perceived as having the color of the latter (e.g., red, blue, yellow, etc.). Light absorption of this nature is referred to as selective. Colored pigments can vary greatly in HP depending on their light absorption and light-scattering abilities. With regard to light scattering, as with white pigments this is a function of the refractive index or, more specifically, the difference in refractive index between the pigment and surrounding medium. Refractive indices of colored pigments vary widely with wavelength, ranging from 1.3 to 2.7. These variations cause such phenomena as bronzing, dichroism, color

change with film thickness, and differences in undertone upon dilution with white pigments (Ref. [4], p. 22).

EARLY VISUAL HP METHODS

Brushouts

The earliest methods for determining HP employed the practical procedure of brushing the paint uniformly onto combination black-and-white test substrates, increasing the amount of paint in small increments until reaching the point of essentially complete hiding at which the amount of visual contrast was considered negligible. The quantity of paint was determined by weighing the container and brush in grams before and after painting. The corresponding SR is the HP by definition and was calculated from the equation

$$\mathrm{SR}(\mathrm{ft}^2/\mathrm{gal}) = \frac{\text{test area}(\mathrm{ft}^2) \times \text{paint density}(\mathrm{lb/gal}) \times 454}{\text{weight of paint (g)}} \tag{21}$$

For single-pigment paints, the value calculated from Eq-(21) can be converted to pigment HP using the equation

$$\mathrm{SR}_{\text{pigment}}(\mathrm{ft}^2/\mathrm{lb}) = \frac{\mathrm{SR}_{\text{pigment}}(\mathrm{ft}^2/\mathrm{gal})}{\text{pigment concentration}(\mathrm{lb/gal})} \tag{22}$$

Variants of these equations provide for the use of metric instead of U.S., units.

Early Test Substrates

Originally in the study of HP, test surfaces were prepared in individual laboratories by painting black stripes on white-painted panels. In response to the need for standardized test surfaces, studies were made on oil cloth and linoleum having printed checkerboard-type designs [5]. The Gardner Contrast HP Board was a two-square-foot area glass checkerboard with black and white squares painted on the underside of a thin piece of glass (Fig. 3). The first formalized ASTM method used a linoleum checkerboard surface in the brushout test procedure described in "Brushouts." The Gardner glass board was used in the same way. Since the "complete hiding" end point in those early methods was determined when the paint was freshly applied and still wet, the resultant HP value pertained only to the wet HP of the paint, not to the dry. This was not a problem in the earliest days of HP measurement, when typical paints contained relatively little volatile constituent and the opacity of the film therefore did not change markedly while drying. But, with the advent of modern paint formulations containing substantial amounts of volatiles, the composition and with it the opacity of the dry paint film could be substantially different than that of the initially applied film. The need to measure dry HP therefore became of paramount importance. As a practical problem in this connection, expensive linoleum and glass test surfaces had to be cleaned for reuse after each test, which made it very difficult to use them for the study of *dry* HP. This problem was partly overcome with the introduction of paper test charts circa 1931 that were printed in various designs such as checkerboard, concentric diamond-shaped bands, spirals, crescents, etc., and with various degrees of contrast such as black-white, black-gray, gray-white, and a graded series of stripes from black to white. After printing, a coat of nitrocellulose lacquer or other suitable clear sealer was applied. Many of those chart types became and continue to be commercially available.

Contrast Design and Visual Sensitivity

Kraemer and Schupp [6] evaluated contrast surfaces in a variety of designs prepared on glossy photographic paper. These included the customary checkerboard design, a design of narrow 15-mm-wide bands, another with much broader bands, and one with dark half circles on a light background. The results seemed to favor a narrow band design subsequently employed by the Krebs Pigment Co. in preparing the diamond stripe gray-and-white contrast charts illustrated in Fig. 4. The test area of that chart was 1 ft^2 (0.0929 m^2). The use of a gray-and-white contrast

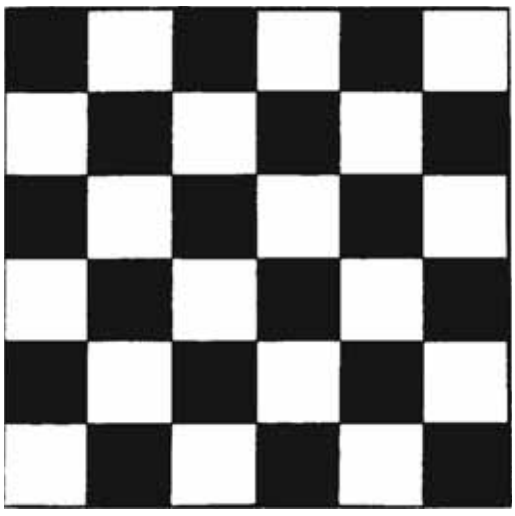

Fig. 3—Gardner contrast HP board.

Fig. 4—Krebs diamond-stripe HP chart.

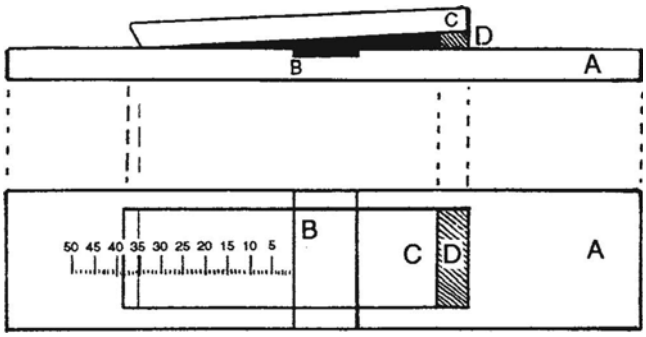

Fig. 5—Diagram of early model of Pfund cryptometer.

combination was based on the idea that this is more representative than black and white of the degree of contrast encountered by paints in actual use.

Relative Dry HP—Krebs Method

Although the introduction of paper test charts as replacements for linoleum or glass made dry HP measurements easier, they were still not easy enough. The problem was that it required the preparation of a considerable number of paint-outs at various SRs to obtain one that after drying could be identified with confidence as representing the "complete hiding" end-point. One solution to this problem was to determine comparative or relative dry HP. In the Krebs Pigment Co. method, their square-foot gray-and-white diamond stripe chart was used for that purpose in the following manner: A partial hiding ladder of six to eight brushout standards is made by applying a standard paint at SRs ranging from 400 to 800 ft²/gal (10 to 20 m²/L) and allowing the brushouts to dry. The SRs are precontrolled approximately by syringing specified volumes of paint onto each chart and then determined accurately by weight measurements and calculation as described in "Brushouts." A single test paint panel is likewise prepared at an intermediate SR. After drying, that panel is compared with the standard panels to determine the two that bracket it in contrast. Then, by visual interpolation, a fairly precise estimate is made of the SR of the standard paint required to match the contrast of the test paint panel. The relative dry HP of the test paint is the percent ratio of its SR to that of the standard paint at equal visual contrast, thus

$$\% \text{ Relative Hiding Power} = \frac{SR_{\text{Test Paint}}}{SR_{\text{Std. Paint}}} \times 100 \quad (23)$$

[a] Multiply by 4.9 to obtain HP in ft²/lb.

Pfund Cryptometers

ALL BLACK

Introduced in 1919, this was one of the first laboratory instruments made for determining HP [7]. Referring to Fig. 5, A is a plate of black glass whose upper surface is optically flat; B is a transverse groove 10 mm wide and about 2 mm deep. Beginning at the left edge of the groove is a millimeter scale etched in the upper surface of Plate A. C is a plate of clear glass whose lower surface is optically flat. D is a steel shim cemented to C so that a wedge of paint may be formed between the plates. This wedge abruptly becomes infinitely thick at B, and so long as hiding is not complete, the line of demarcation is visible. Sliding the wedge to the left eventually causes the line to disappear. The WFT at the point of complete hiding is determined from the scale reading at the toe of the wedge and the thickness of the shim at the heel, from which the HP in ft²/gal or m²/L can be calculated using Eq (3) or Eq (7). Dark-colored paints cannot be measured using this instrument because of the lack of contrast with the black glass background. Nelson and Norris of the New Jersey Zinc Co. used this cryptometer to determine HP of colored pigments with results as shown in Table 3. The pastes were prepared by rubbing the colors in No. 0000 lithograph varnish. The rubbing was regulated to represent the maximum development usually obtained in practice. In addition to the regular black glass instrument,

they used one specially made with white glass for several measurements.

BLACK AND WHITE

Pfund [8] introduced the black-and-white cryptometer in 1930. It eliminated the well, making cleaning easier, and worked for use with paints of any color because of the black-and-white instead of all-black background. Referring to 6, the black glass B and the white glass W are fused along line LM. Longitudinal grooves catch the overflow of paint. The wedge is moved to the right to make the line disappear, then to the left to make it reappear. The position of the plate is reversed and the observations repeated. From the mean of all readings, the hiding is calculated as with the all-black cryptometer (see "All Black"). Comparison of results for white paints shows that the two cryptometer types (all-black and black-and-white) yield the same values within experimental error (Ref. [4], p. 22).

ROTARY TYPE

The rotary cryptometer was a short-lived device designed to overcome the jerky movement of the top plate of the regular cryptometer [9]. The wedge of the cryptometers of Fig. 5 and 6 was replaced with a circular glass plate mounted in a metal frame (Fig. 7). The thickness of the film was read on a scale located on the bottom plate. While the movement of the plate was much smoother with this instrument, it was found that bubbles often obscured the end-point.

ASSESSMENT OF CRYPTOMETERS (REF. [4], P. 25)

The cryptometer is a simple instrument requiring only small quantities of paint, and determinations are quickly made. However, reading the end-point is difficult, and the mean of a number of determinations is therefore advisable.

Most users can repeat their own results, but agreement among different users is not satisfactory although it is improved by the use of a standard paint [10]. Another major disadvantage of cryptometers is that they measure only wet HP. One study [11] reported that cryptometers were satisfactory with low-opacity but not high-opacity paints. Consideration of its advantages and disadvantages suggests that the cryptometer is better suited for control work than for specification requirements. The cryptometers shown in Fig. 5 and 6 continue to be commercially available.

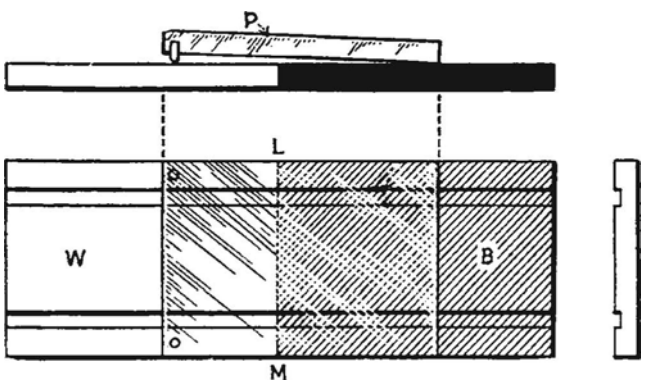

Fig. 6—Pfund black-and-white cryptometer.

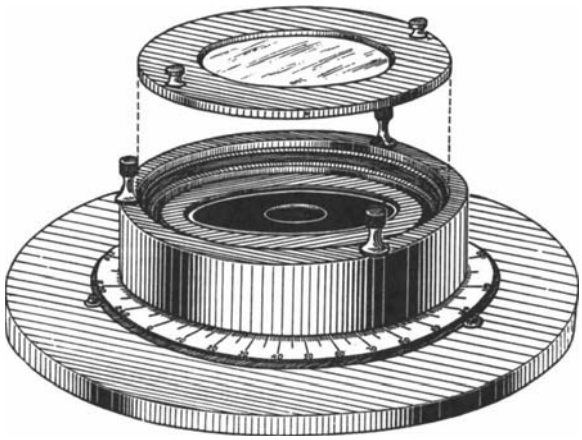

Fig. 7—Rotary cryptometer.

Hallet Hidimeter

Along with the Pfund cryptometer, the Hallet hidimeter [12] was one of the very early devices for evaluating HP. The objective of a regular microscope is replaced by a long tube fitted with a plain ground glass objective; the eyepiece is replaced with a small hole. The principle of the device is the light-diffusing property of ground glass. If a contrast substrate is viewed through a plate of ground glass, the contrast boundaries become more blurred as the distance between plate and substrate increases. If a liquid paint sample is sandwiched between them, it blurs the boundary further, and the distance required to make the boundary disappear decreases. Since that distance is the thickness of the intervening paint film, it is a measure of the HP of the paint. This measurement is essentially comparative because it cannot be translated into regular HP units.

EARLY PHOTOMETRIC HP METHODS

Pfund Precision Cryptometer

In this device (Fig. 8) a photoelectric cell is used to measure the reflectance of paint contained in a wedge-shaped layer [13]. The base plate consists of black-and-white areas B and W, whose boundary is parallel to the length of the plate instead of perpendicular as with the visual cryptometer. The photoelectric device is shifted until a position is found where the reflectance of the paint over the black area is 98 % of that over the white area. The film thickness and HP

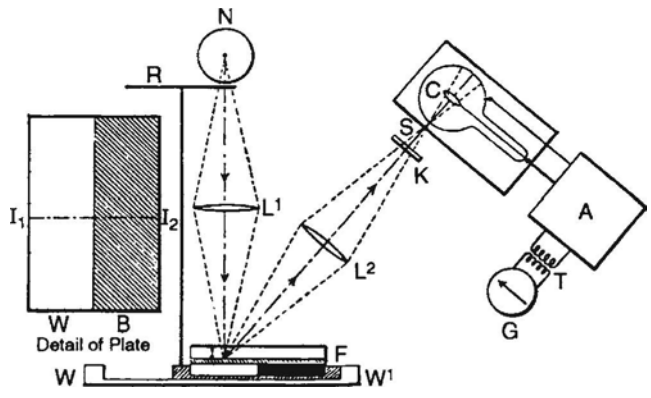

Fig. 8—Pfund precision cryptometer. Uses a photoelectric cell instead of the eye to measure reflectance.

calculations are the same as with the visual cryptometers described in "Pfund Cryptometers."

This cryptometer eliminates the uncertainties of the visual type, as there is no sliding of the top plate over the base plate and no need to estimate visually the appearance and disappearance of an indistinct line. However, it retains the disadvantage of permitting only wet hiding measurements and has therefore been superseded by other photometric devices and methods that permit the measurement of dry HP.

Hanstock Method

Hanstock [14] studied the relationship of light transmission through free paint films to opacity and HP on a black-and-white substrate. For his transmission work, he employed a flicker photometer and found that paint films were perfectly diffusing and that films having the same degree of light transmission had approximately equal opacity. He further showed the correspondence between refractive index, the Fresnel relationship, and HP.

The problem with the transmission concept is that modern paints have so much opacity it is difficult to accurately measure the transmission of films of commercial thickness. Moreover, HP is concerned in practice with paint in intimate contact with opaque surfaces and not as a free film. Consequently, measurement of light transmission through paint films is done today only for very specialized research.

Use of the Fell Equation

An empirical relationship between SR and CR was found by Fell and reported by Sawyer [15] in the following form

$$\log(\text{CR} \times 10) = m \times \text{SR} + b \tag{24}$$

where m and b are experimental constants.

Since the graph for this equation is a straight line, it is a simple matter after determining m and b from measurements at two CR levels to find the SR required for any desired CR. This procedure was adapted by Marchese and Zimmerman to determine the HP of paints at a CR of 0.98, and the method was used for many years by the Titanium Pigment Co. (Ref. [4], p. 24). Experience has shown that reasonably satisfactory results can be obtained if the equation is used for interpolation between points close to the desired CR. But, as pointed out by Switzer [16], extrapolation of results can lead to serious errors. He further pointed out that the Fell equation method allows only a single estimate of HP from at least two test applications, thus requiring a considerable effort to obtain an estimate of intralaboratory precision.

New York Paint Club (NYPC) Method

This method employed doctor blades to apply films at several thicknesses on black-and-white cardboard HP charts. After the films had dried, reflectance, weight, and area measurements were made from which CRs and corresponding WFT were calculated. CR values (rather than log 10 CR as in the Fell equation) were plotted against reciprocal film thickness and the HP calculated from the WFT at 0.98 CR. If the white area of the chart deviated appreciably from the standard reflectance of 0.80, the CR was corrected using Eq (1) or Eq (2). The Club reported that most of the effort in this method was to determine film thicknesses. To minimize that effort they modified the method by casting films on black and white glass plates and determined thicknesses with an interchemical WFT gage in accordance with ASTM Test Methods for Measurement of Wet Film Thickness of Organic Coatings (D1212). Any error in film thickness, of course, carries over to the HP value. According to Mitton, the revised method sacrifices accuracy and precision for speed [17]. In addition, graphical averaging makes it burdensome to estimate the precision with which the HP has been determined for the same reason pointed out in "Use of the Fell Equation" in connection with the Fell equation method.

Van Eyken–Anderson Method

The method proposed by Van Eyken and Anderson [18] uses CRs and film thicknesses in the same way as the NYPC method described in New York Paint Club (NYPC) Method Section, except that films of different thicknesses are applied in a single operation by using a doctor blade having seven clearances. A die is used to prepare uniform area punch-outs of the paper charts to determine SR by the basic weight-area-density-NVW calculation (see Eq (26)). The defects of this method are that the small areas used for reflectance and weighing make the achievement of good precision difficult (Ref. [4], p. 31), and there is no provision for correcting CR if the white substrate reflectance differs from 0.80.

Federal Test Method for Dry Opacity

This is Method 4121 of U.S. Federal Test Method Standard No. 141. It is a pass–fail test calling for a minimum dry film CR at a specified WFT. Black-and-white HP charts are used as the test substrate. For routine testing, the paint may be applied either by brush or doctor blade. For referee tests, application is by doctor blade only. The density and the nonvolatile content of the paint are also required. Several drawdowns are made to bracket the specified WFT. The weight of dry paint film is determined for a measured area on each drawdown and the WFT is then calculated from the equation

$$\text{WFT(mils)} = \frac{61M(\text{g})}{A(\text{in.})^2 \times N \times D(\text{g/mL})} \tag{25}$$

where

M = the dry film weight,
N = the fractional nonvolatile content of paint by weight,
A = the film area, and
D = the density of the paint.

The CR of each chart is measured and plotted against the corresponding WFT. From a smooth curve drawn through the points, the CR at the specified WFT is obtained. If this is equal to or greater than the specified CR, then the requirement for dry opacity has been met.

GENERAL HP METHODOLOGY

Film Application

The objective is to determine the SR at a specified level of dry film opacity, which is usually full hiding as perceived visually or corresponding to the CR: $C = R_0/R_{0.80} = 0.98$. The basic experimental procedure is to apply a uniform film on

a suitable test substrate, to observe its opacity either visually or photometrically, and to determine its SR. Since it is not possible to apply a film with precision at a predetermined dry opacity, several such applications need to be made over a range of SRs and their results plotted graphically or otherwise interpolated to the desired HP end-point. This laborious procedure is exemplified in the visual methods discussed in "Brushouts" and "Relative Dry HP–Krebs Method" and in the CR (CR) methods discussed in "Van Eyken–Anderson Method" and "Federal Test Method for Dry Opacity." The Fell equation and NYPC methods ("Use of the Fell Equation" and "New York Paint Club (NYPC) Method") attempt to reduce the workload to only two SR determinations by plotting SR against CR or log CR and finding the hiding end-point graphically on the basis of perceived empirical straight-line relationships. Kubelka-Munk (K-M) theory (see "K-M Two-Constant Theory") shows how the end-point can be calculated with just one SR determination.

SR (or Film Thickness) Determination

In both visual and photometric HP methods, the procedures for observing film opacity are well-defined and can be performed with dispatch. The experimental task most demanding on the operator's time and ingenuity is to determine the SR or film thickness of the applied coating with good precision. Although gages are available to measure WFT and DFT directly and quickly, the most accurate procedure, by far, is to determine the weight of applied paint film on a measured test area and then to calculate the SR or film thickness as described in "Brushouts" and "Federal Test Method for Dry Opacity." The equations in both of those methods contain mixed metric and common units. When the units are all metric, the equations are simpler. Letting M = dry film weight and A = the film area and using the symbolism in SR and Film Thickness Relationships:

$$H(\mathrm{m}^2/\mathrm{L}) = \frac{A(\mathrm{cm})^2 \cdot N \cdot D(\mathrm{kg/L})}{10M(\mathrm{g})} \tag{26}$$

$$T(\mu\mathrm{m}) = \frac{10^4 M(\mathrm{g})}{A(\mathrm{cm})^2 \cdot N \cdot D(\mathrm{kg/L})} \tag{27}$$

See "Metric Units" for equations interrelating SR, WFT, and DFT. See "U.S.—Metric Unit Conversion" for conversions between metric and U.S. units.

If the volatiles have a relatively low evaporation rate as with most architectural coatings, the film might be weighed rapidly before appreciable loss of volatiles, in which case Eqs (26) and (27) would still apply but with M as the wet film weight and N as unity. The disadvantage of this procedure is that it demands very skillful and speedy manipulation to minimize loss of volatiles before weighing. For that same reason, it is not applicable at all to coatings containing fast-evaporating solvents.

With powder coatings, for which the SR is normally expressed on a weight basis, Eq (26) becomes

$$H(\mathrm{m}^2/\mathrm{kg}) = \frac{A(\mathrm{cm})^2 \cdot N}{10M(\mathrm{g})} \tag{28}$$

Assuming negligible volatile content, the value of N in this equation can be taken as unity.

Photometric Measurements

The CIE-Y reflectance is measured because this function defines the human eye's quantitative response to the luminous character of light across the visual spectrum. This is valid for chromatic, as well as achromatic colors, as reported by Tough [19], who found good correlation in a large series of colored paints between visual HP measurements and CR values based on CIE-Y measurements with a spectrophotometer. The end-point of 0.98 CR is effective with colors, although it appears that other end-points, for example CIELAB color difference: ΔE = 1.5, would make some difference in the relative HP of various colored paints [20]. However, the simplicity of the 0.98 end-point and its history of validity and general agreement among various workers make it the best choice regardless of color (Ref. [4], p. 31). CIE-Y measurements can be made with the green filter of a tristimulus colorimeter or with a spectrophotometer. When properly standardized, results with the two instrument types should be the same. As a precaution, there should be coordination between correspondent laboratories with regard to instrumentation. In all cases, reflectance measurements must be made excluding surface reflection, which is implicit for instruments designed with 0°/45° geometry and optional with most other instrument types.

CURRENTLY USED TEST SUBSTRATES

The substrate is generally the major factor affecting the specific experimental details of a test procedure. It is selected or specified on the basis of its adaptability to the type of coating being tested and for its perceived advantages in the required or preferred test procedure.

Paperboard Charts

Substrates of this type are described in "Relative Dry HP—Krebs Method." Their employment with baking finishes is limited because of distortion and discoloration at high temperatures, but they are used widely with air-dried coatings for general HP observations. Black-and-white charts can be used for precision photometric HP measurements by taking appropriate steps to allow for weight variations in the substrate due to humidity and inherent random variations in the area weight of paper. These steps include the use of unpainted control charts and the averaging of multiple test results. Charts with combinations of gray and black, gray and white, and gradations of gray on a white background are used in visual HP tests to obtain what are considered to be more practical HP measurements.

Clear Plastic Film

Polyester is the preferred chemical type. Because of heat distortion, its use is generally confined to air-dried coatings. After the film has dried, a square of convenient size is cut and the area measured. Values of R_0 and R_w are read by placing the painted plastic film alternately on a black and a white background with the underside moistened with a suitable liquid (e.g., mineral spirits or dibutyl phthalate) to remove the air interface and establish good optical contact. The dry film weight is determined as the difference in the weight of the painted and unpainted substrate by stripping off the paint film with a strong solvent.

Glass Panels

Individual black and white glass panels are used to take advantage of the superior levelness of glass for casting of uniform films and because the hard, smooth surface permits rapid WFT measurements with an ASTM-type of WFT gage (New York Paint Club (NYPC) Method). The same information is obtained less rapidly, but with much better precision by scraping off and weighing a defined area of dry film and calculating as described in SR (or Film Thickness) Determination. In some tests, CRs are calculated on the questionable assumption that separate film applications on black and white glass panels are identical in film thickness.

Painted Metal Panels

Panels of this type are generally used with coatings that are applied by spraying and cured by baking. The weight of the applied film is determined by weighing the panel before the coating is applied and again after drying. The SR or film thickness is then calculated as described in SR (or Film Thickness) Determination. If desired, the DFT can be determined without weighing, though with considerably less precision, by direct measurement with a magnetic or an eddy current thickness gage. Black-and-white panels are used for CR measurements or for visual observation of opacity. Mitton has described the use of all-black panels for measuring the HP of baking enamels [21].

K-M TWO-CONSTANT THEORY

Introduction

The light that enters a paint film is subjected to scattering and absorption as described in "The Role of Pigments in HP," and whatever is not absorbed by the film or substrate eventually re-emerges as reflected light. In 1931 Kubelka and Munk [22] published equations defining the optical behavior of a translucent material in terms of two constants referred to as coefficients of scattering and absorption. Steele [23] in 1935 showed how these equations were adaptable to the measuring of paper opacity, and Judd et al. [24] in 1937 did the same in connection with coatings. Kubelka [25] in 1948 rearranged the original equations into new and simplified forms from which Switzer [26] in 1952 developed equations designed specifically for the study of HP by expressing the film thickness (or SR) as a function of the CR. Using these equations and their derivatives, the CR of a coating can be calculated for any SR (or vice versa) from measurements made at only one and its photometric HP thereby determined by a single test application. This is in contrast with the more laborious procedure of obtaining CR values at two or more SRs for interpolation or extrapolation to the HP end-point. The calculations appear formidable, but are readily accomplished with a suitably programmed computer. Graphs and tables are also available for this purpose, although not as convenient and accurate as a computer. The experimental steps are straightforward, and, as with most HP methods, the most difficult and time-consuming operation is to determine the experimental SR (or film thickness) with sufficient precision. How that is accomplished is the essential difference between various K-M-based methods.

Equation Symbols

The symbols used here are based on ASTM Test Method for HP of Paints by Reflectometry (D2805-2003) as follows:

G = the substrate luminous reflectance (CIE-Y)
For a white substrate $G = W$.
For a standard white substrate $G = W = 0.80$.
For a black substrate $G = B$.
For a standard black substrate $G = B \leq 1 \approx 0$.

R_G = the luminous reflectance of a film applied over a substrate of reflectance G.

R = *reflectivity*—a property of the paint—the limiting reflectance of the paint film as it is increased in thickness. Also defined as the reflectance at complete hiding as evidenced by $R_0 = R_w$ over a black-and-white substrate of uniform film thickness.

C_w = the CR of a film applied at uniform thickness over a black-and-white substrate; thus, $C_w = R_0/R_w$,

$C_{0.80}$ = the CR over a standard black-and-white substrate, thus $C_{0.80} = R_0/R_{0.80}$.

C = abbreviation for $C_{0.80}$; the two are used interchangeably, thus $C = C_{0.80} = R_0/R_{0.80}$.

T = the film thickness in any stated unit, e.g., μm, mils.

H = the SR in any stated unit, e.g., m^2/L, ft^2/gal, m^2/kg, ft^2/lb, cm^2/g.

S = the scattering coefficient, a measure of the ability of the paint to scatter light, expressed in units reciprocal to T or the same as H.

K = the absorption coefficient—a measure of the ability of the paint to absorb light, expressed in the same unit(s) as S.

e = 2.718 28… the exponential base for natural logarithms.

P = scattering power—a measure of the ability of a film to scatter light. A unitless film constant defined mathematically by the relationships: $P = ST$ or $P = S/H$.

Subscripts

x = an experimentally determined value, e.g., T_x, H_x, P_x.

c = a value calculated for a specified CR C, e.g., P_c, H_c.

0.98 = a value calculated for $C = 0.98$, e.g., $H_{0.98}$, $T_{0.98}$.

H = indicates a value pertaining to a SR e.g., C_H, P_H, S_H.

T = indicates a value pertaining to a film thickness, e.g., C_T, S_T.

a and b = simplifying functions of R, defined by

$$a = 1/2\ (1/R_\infty + R_\infty) \tag{29}$$

$$b = 1/2\ (1/R_\infty - R_\infty) \tag{30}$$

From these definitions are derived the additional relationships

$$b = (a^2 - 1)^{1/2} \tag{31}$$

$$R_\infty = a - b = a - (a^2 - 1)^{1/2} \tag{32}$$

Note that R_∞, a, and b are three forms of the same constant, so that the determination of any one of them is

equivalent to determining all three. Sometimes they are used together in the same equation.

Additional simplifying functions which can be expressed in exponential-logarithmic form, or using hyperbolic co-tangents are

$$U = f(P, R_\infty) = b\left(\frac{e^{2bp}+1}{e^{2bp}-1}\right) = b \coth bP \qquad (33)$$

and the converse of Eq (31)

$$P = f(U, R_\infty) = \frac{1}{2b}\ln\left(\frac{U+b}{U-b}\right) = \frac{1}{b}\coth^{-1}\left(\frac{U}{b}\right) \qquad (34)$$

in which

ln = designation for natural logarithms, viz., $\log_e x = \ln x$,

coth = designation for hyperbolic co-tangents, defined by coth x

$$= \frac{e^{2x}+1}{e^{2x}-1}$$

and

$\coth^{-1}$ = designation for inverse hyperbolic cotangents, defined by

$$\coth^{-1} x = \frac{1}{2}\ln\frac{x+1}{x-1}$$

Values of natural logarithms and hyperbolic functions are available in published tables and in calculators. Since the tangent function is frequently provided without the cotangent, the relationships between the two are stated here as follows

$$\coth x = 1/\tanh x, \quad \coth^{-1} x = \tanh^{-1} 1/x$$

Original K-M Equations

The original equations are as follows:

For nonopaque films

$$R_G = f(ST, R_\infty, G) = \frac{G/R_\infty - 1 + (1 - GR_\infty)e^{(1/R_\infty - R_\infty)ST}}{G - R_\infty + (1/R_\infty - G)e^{(1/R_\infty - R_\infty)ST}} \qquad (35)$$

For opaque films

$$R_\infty = f(K/S) = 1 + K/S - (K^2/S^2 + 2K/S)^{1/2} \qquad (36)$$

whose converse and more useful form is

$$K/S = f(R_\infty) = (1 - R_\infty)^2/2R_\infty \qquad (37)$$

Functional forms are shown in this discussion along with the corresponding explicit forms for a clearer perception of the variables. Sometimes the functional form will be used by itself for both brevity and clarity.

Eq (35) shows the reflectance of a paint film in terms of two basic optical characteristics of the paint: the scattering coefficient S, and reflectivity R_∞, and two values that are characteristic of the particular application: the reflectance G of the substrate and the thickness T of the film.

Scattering Coefficient and Scattering Power

The product ST in Eq (35) is a unitless film constant referred to by Kubelka [23] and Judd [22] as the scattering power of the film and symbolized here by the letter P. Thus, given that $P = ST$ and employing simplifying forms of R_∞ and the function U of Eq (33), Eq (35) can be rewritten in the much abbreviated form

$$R_G = f(U, R_\infty, G) = f(P, R_\infty, G) = \frac{1 - G(a - U)}{a + U - G} \qquad (38)$$

Since film thickness T and SR H are reciprocally interdependent (see Eqs (6) and (7)), it follows that $P = S_T T = S_H/H$, with the scattering coefficient (S_T or S_H) being expressed in a unit reciprocal to that of T (e.g., mil^{-1}, μm^{-1}) or in the same SR units as H (e.g., ft^2/gal, m^2/L, ft^2/lb, m^2/kg, cm^2/g). A clarifying concept in which SR units are mandatory is to consider scattering as an entity quantifiable in area units, with the scattering coefficient as the amount of scattering per unit quantity of coating or coating ingredient, and scattering power as the amount of scattering per unit area of film. SR units have the further advantage over film thickness and reciprocal film thickness of being directly relatable to gravimetric, as well as volumetric quantities. Thus, for understandability, convenience, and standardization, it is preferable to use SR units for scattering coefficients and HP and more specifically the metric SR units m^2/L and m^2/kg. These are translatable into film thicknesses and U.S. units using the conversion equations in "U.S.—Metric Unit Conversions." Equations for the numerical conversion of scattering coefficients expressed in various units to standardized metric SR units are given in Table 4.

General K-M HP Method

The experimental procedure, in brief, is to determine the reflectivity R_∞ of the paint and R_0 and H_x of a nonopaque paint film, from which the scattering coefficient S of the paint is calculated. From R_∞ and S is then calculated the SR H_c at any specified CR C or vice versa, or more specifically the SR $H_{0.98}$ when $C = 0.98$, which by definition is the HP of the paint. The K-M equations used in these calculations are derived from Eq (38) (the simplified form of Eq (35)) and can be programmed for quick computer solutions.

DETERMINATION OF REFLECTIVITY R_∞

A paint film is applied uniformly over a black-and-white substrate at normal SR (or film thickness) and dried in the manner usual for the particular coating. After drying, the

TABLE 4—Unit conversion equations for scattering coefficients.

$S(m^2/L) = S(ft^2/gal) \div 40.746$
$S(m^2/L) = S(mil^{-1}) \times 39.37$
$S(m^2/L) = S(\mu m^{-1}) \times 1000$
$S(m^2/L) = S(mm^{-1}) \times 1$
$S(m^2/kg) = S(ft^2/lb) \div 4.888$
$S(m^2/kg) = S(cm^2/g) \div 10$
$S(m^2/L) = S(m^2/kg) \times D(kg/L)$

reflectance values R_0, R_w, and W are measured. If the CR C_w=R_0/R_w is less than 0.96, the application is repeated as a second coat or at a somewhat higher film thickness. A porous film should not be recoated, nor an impractically high film thickness applied in a single coat, due to the possible effect on R_∞. If the original or recoated film hides completely, then $R_0 = R_w = R_\infty$. If not, calculate

$$a = f(R_0, R_w, W) = \frac{1}{2}\left(Rw + \frac{R_0 + W - R_w}{WR_0}\right) \quad (39)$$

and from Eq (32)

$$R_\infty = a - \left(a^2 - 1\right)^{1/2}$$

The preceding two equations may be programmed sequentially to give

$$R = f\left(R_0, R_w, W\right) \quad (40)$$

DETERMINATION OF R_0 AND H_x

This requires the application of a uniform film at a SR (or film thickness) such that the CR C_w is within the range of 0.96 to 0.985. These limits are established because too low a CR requires excessive extrapolation to the C = 0.98 endpoint, and higher CR values become increasingly insensitive to SR (or film thickness) variations. If the initial application is outside that range, the application is repeated at a higher or lower film thickness, as required.

The film may be applied on a black-and-white or an all-black substrate. If black-and-white, then the test application can be the same one used for determining R_∞ in Determination of Reflectivity R_∞. If an all-black test surface is employed, the indicated CR range is still required, but since it cannot be measured directly, it is calculated from

$$C_{0.80} = f(R_0, R_\infty) = \frac{R_0(1 - 0.80R_0)}{R_0 + 0.80(1 - 2_a R_0)} \quad (41)$$

Having obtained a film within the specified CR range, R_0 is recorded and H_x is determined by a suitable method. Various techniques for determining the SR are available, but the most precise is a weight-area-density-NVW method as discussed in "SR (or Film Thickness) Determination," using applicable Eqs (26) and (27). The dry film weight M in those equations is usually obtained as the difference in the weight of the test area before and after application of the paint. Sometimes, as with black glass, it is obtained by removing a known area of film and weighing it directly. Such weighings can be performed on an analytical balance with great accuracy. The density D and nonvolatile N of the paint must, of course, also be determined if not already known.

With considerably less precision, the thickness of the dry film can be measured using a caliper or electronic gage on a metal panel, from which the SR can be calculated using one of the following relationships

$$H(\mathrm{m}^2/\mathrm{L}) = \frac{1000ND}{t(\mu\mathrm{m}) \cdot d} \quad (42)$$

or

$$H(\mathrm{m}^2/\mathrm{kg}) = \frac{1000N}{t(\mu\mathrm{m}) \cdot d(\mathrm{kg/L})} \quad (43)$$

where

N = the nonvolatile fraction by weight NVW of the test paint,
D = the density of a liquid paint,
d = the density of the dry or cured film, and
t = the thickness of the dry or cured film.

CALCULATION OF $H_{0.98}$

Having determined R_∞ of the paint and R_0 and H_x of the testfilm, $H_{0.98}$ is obtained by the following sequence of calculations:

(a) The scattering power, P_x of the test film is calculated from

$$P_x = f(R_0, R) = \frac{1}{b}\coth^{-1}\left(\frac{1 - aR_0}{bR_0}\right) = \frac{1}{2b}\ln\left(\frac{1 - R_0R_\infty}{1 - R_0/R_\infty}\right) \quad (44)$$

(b) The scattering coefficient S of the paint is calculated from $S = P_xH_x$.

(c) The scattering power P_c of a paint film at the CR C = 0.98 is calculated from

$$U_0 = f(C, R_\infty) = \left[\left(a + \frac{1 - C}{1.60C}\right)^2 - \frac{1}{C}\right]^{1/2} + \frac{1 - C}{1.60C} \quad (45)$$

and Eq (34)

$$P = f(U, R_\infty)$$

which are solved sequentially to give

$$P_c = f(C, R_\infty) \quad (45)$$

(d) The HP $H_{0.98}$ is then calculated from $H_c = S/P_c$ where C = 0.98.

CR AT A SPECIFIED SR

Although this is not HP as such, it is frequently used as an alternative HP criterion. After Step (b) of Calculation of $H_{0.98}$, calculate the scattering power P at the specified SR H from: $P_H = S/H$, then calculate the CR C_H from Eq (33)

$$U_H = f(P_H, R_\infty) \quad (46)$$

and

$$C_H = f(U_H, R_\infty) = \frac{a + U - 0.80}{(a + U)[1 - 0.80(a - U)]} \quad (47)$$

which together give

$$C_H = f(PH, R_\infty) \quad (48)$$

Judd Graph (Information Included for Historical Purposes)

Prior to the availability of modern computers, K-M equations were much too complex for a practicable HP test method. Judd [24], therefore, laboriously worked out a general solution to Eq (35) in the form of a graph repro-

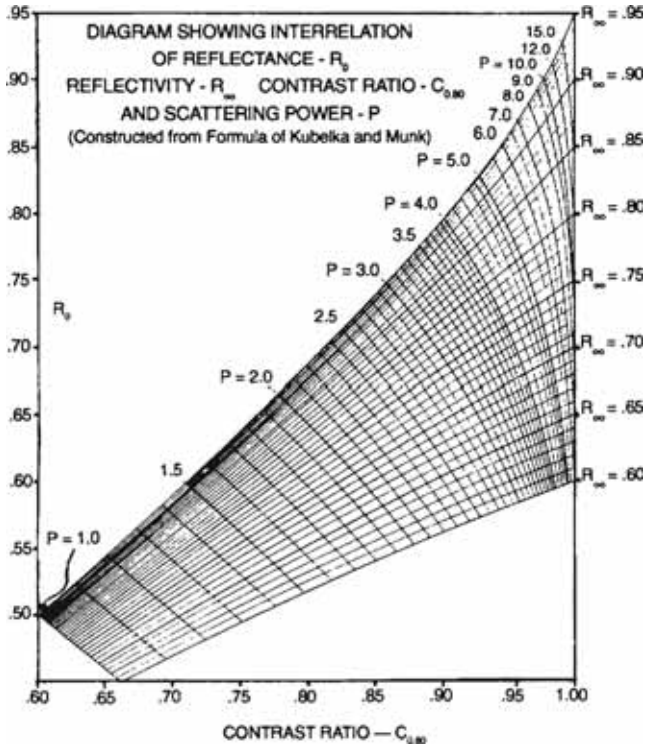

Fig. 9—Judd graph derived from Kubelka–Munk Eq (35).

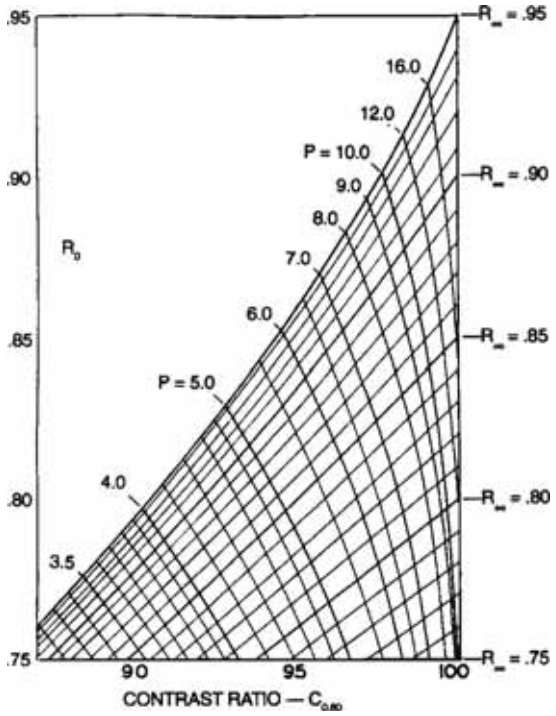

Fig. 10—Judd graph derived from Kubelka–Munk Eq (35)—a portion of Fig. 9 enlarged.

duced in Fig. 9. The graph relates the four variables R_0, $C_{0.80}$, R_∞, and P so that from any two of them the other two can be determined. It consists of two families of curves for constant values of R_∞ and P, plotted on the coordinates R_0 and $C_{0.80}$. The P curves were referred to in the original Judd graph as curves of SX (or ST). The portion pertinent to white paints ($R_\infty \geq 0.75$) has been enlarged and is shown in Fig. 10. Experimentally, R_0, R_W, and H_x are determined as in Determination of R_0 and Determination of Reflectivity R_∞ for a film applied uniformly on a black-and-white test substrate. If W deviates from 0.80 by more than 0.01, $C_{0.80}$ is calculated using correction Eqs (1) and (2). P_x and R_∞ are determined at the graph point corresponding to $C_{0.80}$ and R_0, and the scattering coefficient of the paint calculated from $S = P_x H_x$. The value of $P_{0.98}$ is located at the intersection of the R_∞ curve with the vertical line for $C = 0.98$. The HP is then calculated from $H_{0.98} = S/P_{0.98}$. If desired, the SR can be determined for CRs other than 0.98 in the same way. Conversely, C_H may be determined for any specified value of H by first calculating: $P_H = S/H$, then finding the desired value of C_H at the intersection of the curves for the determined P_H and R_∞.

The Judd graph is also useful for depicting the basic optical properties of paints. It shows that paints with high S values are lighter over black backgrounds than paints of the same reflectivity with low S values. Also, if their S values and film thicknesses are the same, paints with high reflectivity are poorer in hiding than paints of low reflectivity. The latter fact may be demonstrated as follows: Suppose a portion of paint for which $R_\infty = 0.85$ is tinted with a black colorant to an R_∞ value of 0.78 and the untinted and tinted paints are applied at the same thickness such that $P = 5.0$. From Fig. 9, or more accurately from Fig. 10, it can be determined that the colorant addition has increased the CR to 0.965 from its original value of 0.945, representing a considerable increase in visual film opacity. To determine what this amounts to in terms of photometric HP, the P values of the untinted and tinted paints at the intersection of their R_∞ curves with the vertical line $C = 0.98$ are found to be 7.5 and 6.0, respectively. Since S is unaffected by tinting, the SR change at $C = 0.98$ is calculated as

$$\frac{H_{\text{tinted}}}{H_{\text{untinted}}} = \frac{P_{\text{untinted}}}{P_{\text{tinted}}} = \frac{7.5}{6.0} = 1.25$$

representing an increase of 25 % in HP by tinting to a lower R_∞ value. This hiding increase was obtained at negligible monetary cost but at a sacrifice in paint quality in regard to brightness of appearance. For that reason, in evaluating a series of paints experimentally, a fair comparison requires that all R_∞ values be adjusted by tinting to that of its lowest reflectivity member. Examination of the Judd graph shows that, after adjustment to the same R_∞ value, films of the different paints applied at the CR $C = 0.98$ all have the same $P_{0.98}$ value and, since $H_{0.98} = S/P_{0.98}$, their HPs will be directly proportional to their scattering coefficients. Thus the scattering coefficient alone can be an adequate HP comparator, without actually tinting the individual paints.

Mitton Graph and Table [27] (Information Included for Historical Purposes)

As with the Judd graph, these provide precalculated solutions to K-M equations, but with much greater precision. They were designed for the experimental procedure described in "General K-M HP Method," in which R_0 and H_x are determined for a film applied on an all-black test surface, and R_∞ is determined in a separate test application. The test surface of choice is black float glass because the

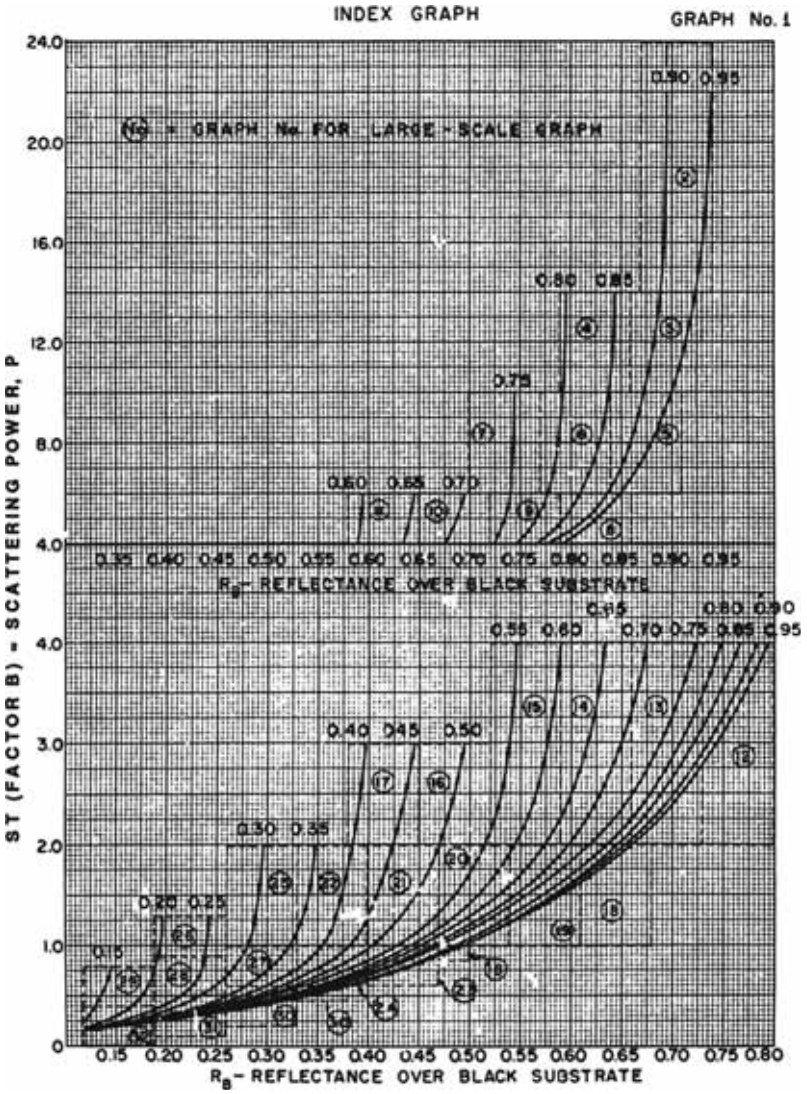

Fig. 11—Mitton graph of Kubelka–Munk Eq (44).

extremely level nature of the surface permits the application of very uniform films with a doctor blade. Mitton also describes the use of all-black metal panels to test spraying/baking-type finishes [21]. The graph is derived from Eq (44): $P = f(R_0, R_\infty)$ and is plotted as a family of curves at constant R_∞ on coordinates of scattering power P and reflectance R_0. The ordinate is indicated as ST (Factor B), which is the same as P, and the abscissa as R_B, which is usually, and in this case necessarily, the same as R_0. It consists of a small-scale index graph (Fig. 11) divided into 31 sections, each then expanded to a much larger scale on a separate sheet. Fig. 12 shows one of the expanded sections.

Associated with the Mitton graph is a table of factor A values derived from Eq (46): $P_c = f(C, R_\infty)$, in which factor $A_c = 1604.2/P_c$. Values of factor A_c are given in this table for C = 0.98, 0.95, and 0.93, for all values of R_∞ from 0.08 to 0.98 (8 to 98 %). The C value of most interest for HP calculations is 0.98, representing full photometric hiding as defined in Section Photometric HP End-Point. If desired, P_c is easily calculated from factor A_c.

The graph and table are typically used as follows: After determining R_∞ and R_0 experimentally, the index graph is consulted in order to select the appropriate expanded graph on which the scattering power P_x of the experimental paint film is to be found. Factor $A_{0.98}$ is determined from the table for the measured value of R_∞. At this point either the film thickness T_x, or SR H_x of the test film associated with R_0 is determined. If, as Mitton intended, T_x is determined in mils, then the scattering coefficient S is calculated in reciprocal mils from $S = P_x/T_x$, and the HP is calculated from the equation

$$H_{0.98}\left(\text{ft}^2/\text{gal}\right) = \text{S}\left(\text{mil}^{-1}\right) \cdot A_{0.98}$$

The preceding simple relationship holds when S is expressed in reciprocal mils and HP is expressed in ft²/gal. If the SR in m²/L is determined instead of the film thickness, then after determining P_x and R_∞, the scattering coefficient is calculated as: S (m²/L) $= P_x \cdot H_x$(m²/L) and the HP calculated from

$$H_{0.98}(\text{m}^2/\text{L}) = \frac{S(\text{m}^2/\text{L}) \cdot A_{0.98}}{1604.2} = \frac{S(\text{m}^2/\text{L})}{P_{0.98}}$$

At a later date, Mitton commented that graphical and tabular aids for K-M calculations had become unnecessary

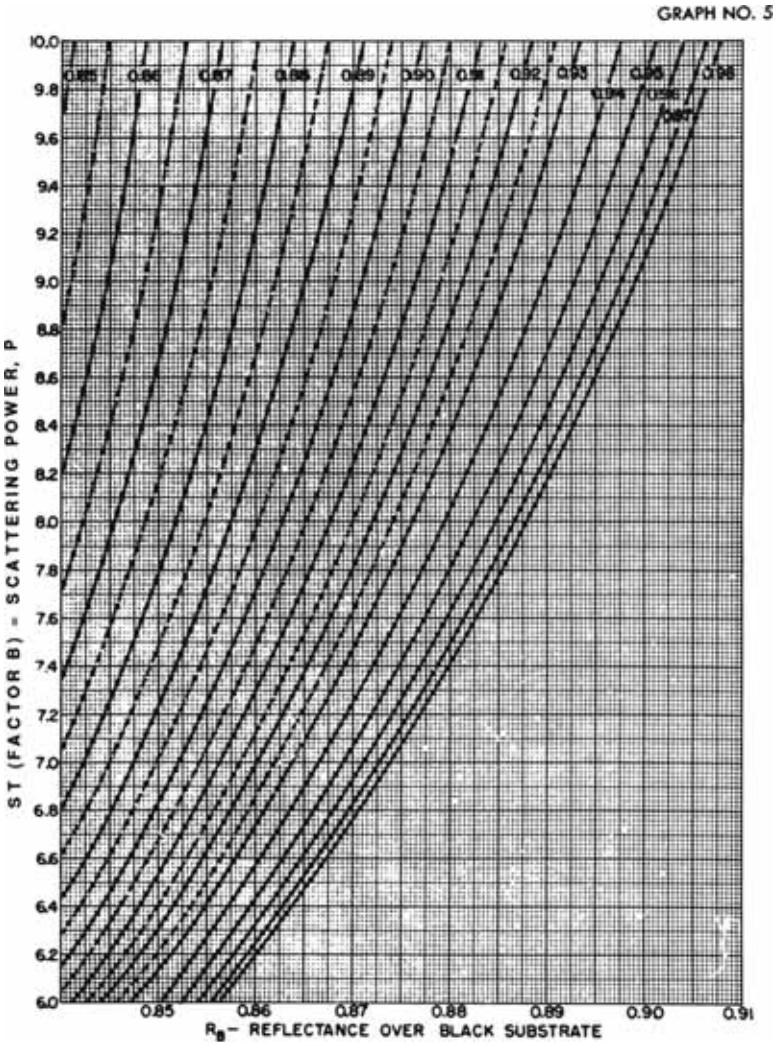

Fig. 12—Mitton graph—expansion of Sector 5 in Fig. 11.

with the advent of inexpensive programmable calculators [28]. Nevertheless, the Mitton graph and table continue to be used in a number of important test methods, and both the Judd and Mitton graphs are useful for instructional purposes. Currently, software is available with color-measuring instruments, and it can be used to carry out these calculations. For this reason, the graphical techniques are seldom used today.

Typical K-M HP Results

Tables 5 and 6 are based on the testing of various commercial paints and pigments. They are intended to illustrate magnitudes of HP and scattering coefficient values encountered in K-M HP measurements. The scattering coefficient values are intended to supplement and clarify, by specific examples, the relationships shown in Table 4. With regard to pigments are (Table 6), it is of course dispersions that are actually measured and the values for the pigments then calculated from their concentrations in the dispersions. For example

$$\frac{H_{\text{pigment}}(\text{m}^2/\text{kg})}{H_{\text{coating}}(\text{m}^2/\text{L})} = \frac{\text{S}_{\text{pigment}}(\text{m}^2/\text{kg})}{\text{S}_{\text{coating}}(\text{m}^2/\text{L})} = \frac{1}{\text{Pigment Conc.(kg/L)}}$$

The values in Table 6 should be considered as comparative because the scattering coefficient of a pigment can vary widely depending on the conditions of measurement (Ref. [4],

p. 34), being affected by pigment volume concentration (PVC), effectiveness of dispersion, the presence of other pigments in the same dispersion, and the nature of the vehicle. Even within a specific chemical class it can vary considerably depending upon the particular method of manufacture employed. Nevertheless, it is frequently useful to determine pigment HP values for a comparison of their efficiency under specified conditions.

Theoretical Problems and Practical Considerations

The validity and usefulness of the K-M equations in HP calculations are predicted on the constancy of the scattering coefficient *S* over a suitably wide film thickness range. Judd [24] studied this question in connection with water-borne paints and vitreous white enamels and concluded that at practical film thicknesses *S* is constant within experimental error. The author has experimentally obtained essentially constant *S* values within a WFT range of 50 to 100 μm (2 to 4 mils), equivalent to a SR of 10 to 20 m^2/L (400–800 ft^2, /gal), with white alkyd gloss, latex gloss, and latex flat paints. Moreover, the effect of any variation of S with film thickness that might occur is minimized in experimental practice by casting films with CRs fairly close to the 0.98 CR hiding endpoint, as called for in Determination of R_0 and H_x. This is not difficult to do.

Refractive indices and resultant scattering coefficients vary with the wavelength of light. Thus, the effective scattering coefficient of a paint is actually an average for all of the encountered wavelengths. With achromatic paint films, the wavelength composition of the light flux remains constant and, therefore, so does the scattering coefficient upon which constancy the validity of K-M equations is predicated. Chromatic paint films, however, absorb light selectively and therefore change the composition of broadband illuminants with a resultant change in the effective scattering coefficient as the light passes through the film. This would, in theory, appear to disqualify chromatic paints from K-M HP calculations. In practice, however, the equations are used successfully for that purpose (Ref. [29]; Ref [4], p. 31), which is undoubtedly related to the previously noted fact that the experimental measurements are made fairly close to the HP end-point (C = 0.98), so that the K-M extrapolation and thus any associated error is relatively small.

As discussed by Mitton (Ref. [4], p. 27), the use of K-M theory for HP calculations has been questioned because it is phenomenological rather than based on fundamental theoretical considerations, and the measurements and equations omit needed corrections for surface reflection that are theoretically substantial. However, in experimental practice the errors are generally small despite the theoretical defects. Simpson took note of this in his comment that when uncorrected values of *S* and *K* are inserted back into the uncorrected K-M equations, "it would appear that an approximately correct answer is obtained" (Ref. [2], p. 111).

Calculation of HP from Tinting Data

Initially, the *S* and R_∞ values of a standard white paint are determined in accordance with the procedure described in "General K-M HP Method." The *K* value of the paint can then be calculated from Eq (37): $K/S = (1 - R_\infty)^2/2R_\infty$.

From Scattering Coefficient and Scattering Power, *S* and *K* can be considered as concentrations of "scattering" and "absorption" per unit weight or volume. The *K* value of a black tinter is determined by adding a measured ratio to the standard paint sufficient to reduce the reflectivity to about 0.40. The *K* value of the tinted paint is its initial *K* value plus the tinter contribution, thus

$$K_2 = K_1 + XK_t \tag{49a}$$

from which

$$XK_t = K_2 - K_1 \tag{49b}$$

and dividing through (b) by the common value of *S*

$$XK_t/S = K_2/S - K_1/S \tag{49c}$$

in which

K_t = the absorption coefficient of the tinter,
X = the ratio of tinter to paint,
K_1 = the initial K value of the paint,
K_2 = the K value of the paint after tinting, and
S = the scattering coefficinet of the paint.

The ratios K_2/S and K_1/S are calculated from measured values of R_∞ for the tinted and untinted paints using Eq (37): $K/S = (1 - R_\infty)^2/2R$). If the standard paint is an untinted white with a reflectivity no lower than 0.93, then its absorp-

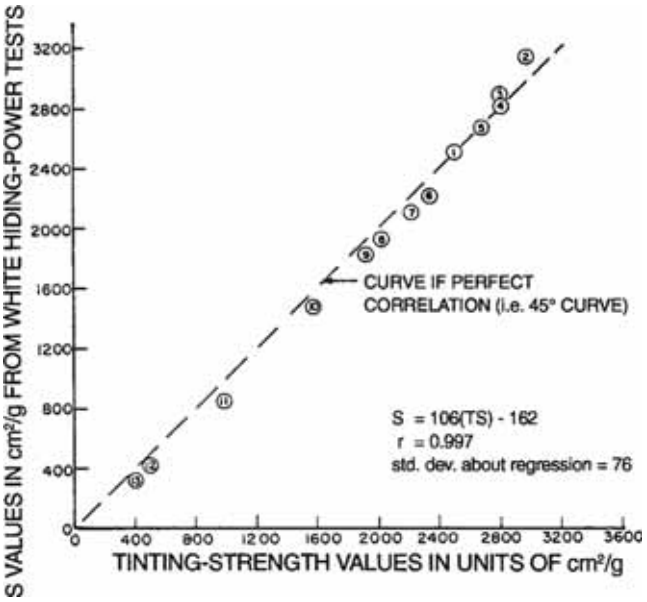

Fig. 13—Scattering coefficients determined by tinting and by HP tests.

tion contribution K1 is considered negligible compared with that of the tinter, in which case K_1/S is dropped from Eq (49c) to give

$$XK_t/S = K_2/S \tag{49d}$$

The absorption coefficient K_t of the tinter can be calculated from Eqs (49c) or (49d) since all other terms in these equations are known [30,31].

Having determined K_t, the *S*-value of a test paint can be determined using the same tinting procedure and equations as before, but this time calculating unknown *S* from known K_t, instead of vice versa. With the values *S* and R_∞ of the test paint having thus been determined, its HP $H_{0.98}$ can be calculated as in Calculation of $H_{0.98}$ (c) and (d) without the tedious requirement of measuring the SR.

Experimental evidence for the validity of this procedure is given by Mitton and Jacobsen [32], who, equating the tinting strength of a white pigment with its scattering coefficient, measured *S* (cm²/g) for a number of white pigments by direct HP measurement and by the tinting procedure. As shown in Fig. 13, the correlation between the two methods is very close. If this simplified method is to work, the *K* value of the black tinter must be the same in any paint being tested. Also, the tinter must not change the degree of dispersion of the white pigment so as to cause a change in its *S* value. These conditions are not always met, so that it is safest to apply the method only under favorable circumstances, when interaction of tinter and paint are known to be negligible.

Determination of Relative HP of Untinted White Paints from Tinting Data

For this purpose there is no need to determine the *K* value of the tinter as in "Calculation of HP from Tinting Data." An equal ratio of black tinter is added to comparison paints A and B, sufficient to reduce their R_∞ values to about 0.40. The R_∞ values of paints A and B are measured before and after tinting and the four corresponding *K*/*S* values calculated from Eq (30). Then, as in Eq. (49c) of "Calculation of HP from Tinting Data," for paint A:

$$XK_t/S_A = K_{A2}/S_A - K_{A1}/S_A \tag{50a}$$

for paint B

$$XK_t/S_B = K_{B2}/S_B - K_{B1}/S_B \tag{50b}$$

Next, dividing Eq (49b) into Eq (49a), *X* and K_t cancel to give

$$S_B/S_A = (K_{A2}/S_A - K_{A1}/S_A) \div (K_{B2}/S_B - K_{B1}/S_B) \tag{50c}$$

If the comparison paints are both untinted high reflectance whites then, as pointed out in "Calculation of HP from Tinting Data," the untinted *K*-values can be considered negligible and Eq (49c) becomes

$$S_B/S_A = K_{A2}/S_A \div K_{B2}/S_B \tag{50d}$$

As stated at the end of Judd Graph, at the same reflectivity R_∞, the HP values of paints A and B will be in the same ratio as their scattering coefficients.

K-M EQUATIONS FOR CORRECTING REFLECTANCE AND CR MEASUREMENTS TO A STANDARD WHITE SUBSTRATE REFLECTANCE

The reflectances of applied paint films, and hence their CRs, vary with the substrate reflectance. In practice, black substrates are effectively zero and constant, but white substrates can vary appreciably. Normalization equations that correct for this variation, derived from Eq (39) of "Original K-M Equations," are as follows:

$$R_G = f(R_w, R_0, W, G) = R_w - \frac{(W-G)(R_w - R\ )}{W(1-GR_\infty} \tag{51a}$$

$$C_G = f(R_w, R_0, W, G) = \frac{WR_0(1-GR_0)}{R_0(W-G)+GR_w(1-WR_0)} \tag{51b}$$

$$C_G = f(C_w, R_0, W, G) = \frac{WC_w(1-GR_0)}{C_w(W-G\ )+G(1-WR_0)} \tag{51c}$$

TABLE 7—Scattering coefficient of a 20 % PVC TiO_2-alkyd paint film versus crystal size of pigment.

FACTORS AFFECTING WHITE HP

As shown in Table 1 and Table 6, rutile titanium dioxide is by far the most effective of the white hiding pigments in producing light scattering and HP, which is true on a cost as well as a weight basis. This fact has effectively eliminated the use of other white hiding pigments except for special properties or considerations. The important variables that determine the scattering and hiding efficiency of a titanium dioxide pigment in a paint are: (1) its mean crystal and particle size, (2) the state of pigment dispersion, (3) its concentration in the paint film, and (4) film porosity.

Crystal and Particle Size

By decreasing the particle size of the pigment, the number of particles and surfaces for light reflection and refraction increase, and the light-scattering ability of a given quantity of pigment will, therefore, tend to be enhanced. However, if the particle size is too small in relation to the wavelength of light, the wave front passes around rather than through it, so there is no light scattering, and the dispersion is transparent. Obviously, there is some intermediate optimum size related to the wavelength of light at which maximum scattering efficiency is obtained. The wavelength of the visible spectrum ranges from approximately 0.4 to 0.7 μm, peaking in luminosity at 0.55 μm. The mean crystal size for maximum opacity ranges from approximately 0.20 to 0.30 μm depending on both the PVC and the fraction of the pigment consisting of single crystals. Commercial grades of titanium dioxide developed for high-gloss finishes exhibit a single-crystal content of about 20 % and have a mean crystal size between 0.22 and 0.24 μm. The adverse effect of a lesser crystal size in such formulations is shown in Table 7 [33].

Pigment Dispersion

The process of obtaining a satisfactory dispersion involves the wetting of the pigment by the dispersion medium to displace air, breakdown of larger particles by milling, and stabilization after the dispersion has been obtained. With alkyd media, standard grades of titanium dioxide disperse easily and develop full hiding with very little milling. Thus, the main reason for milling alkyd dispersions is to reduce or eliminate oversize particles that affect the appearance of the film. With latex paints, milling can have an important effect on opacity depending on the grade of pigment employed [33], but the appearance factor is also an important consideration, particularly with semigloss and gloss finishes.

A major factor affecting the efficiency of TiO_2 in the completed formulation is the phenomenon referred to as flocculation, which is the formation of large particle groups or floccules due to weak forces of cohesion. Floccules are easily broken down but can spontaneously and quickly recur in the wet paint or drying paint film. Despite their weak bonding, floccules have the optical effect of increasing the mean particle size, thereby decreasing the scattering efficiency of the pigment. An auxiliary phenomenon related to increased particle size is the preferential scattering of longer wavelengths. Balfour and Hird took advantage of this phenomenon to quantify pigment flocculation by measuring backscattered infrared radiation (wavelength 25 μm) from a dried paint film to obtain what they refer to as a "flocculation gradient" [34,35].

Pigment Concentration

In "Refractive Index," it was pointed out that a very large single crystal of a white hiding pigment is actually transparent. Without undertaking a theoretical analysis, it is to be expected that as the concentration of pigment increases and its particles become more crowded, they approach the optical condition of a very large particle with resultant loss of scattering efficiency and HP. The crowding effect was studied by Stieg [36–38], whose results were used by Mitton (Ref. [4], pp. 34–35) to draw curves of HP $H_{0.98}$ versus PVC for pure rutile and anatase titanium dioxide in alkyd enamels. These are shown in Fig. 14, in which HP is expressed in ft²/lb of nonvolatile matter. If the paint is formulated at 50 % nonvolatile by volume, the HP results would be half that shown in Fig. 14, but the shape of the curves would be unchanged. Note the maximums in the curves at 25 to 30 % PVC, above which HP actually begins to decrease with increasing concentration of pigment. When calculated in terms of ft²/lb of pigment, the results appear as shown in Fig. 15, clearly indicating the drastic decrease in TiO_2 efficiency due to crowding.

Stieg [36] found empirically that the relationship between TiO_2 HP and PVC, as shown in Fig. 15, could be expressed by the equations

$$\text{rutile:} H_{0.98}(\text{ft}^2/\text{lb}) = 370 - 410(\text{PVC})^{1/3} \quad (52)$$

$$\text{anatase:} H_{0.98}(\text{ft}^2/\text{lb}) = 290 - 330(\text{PVC})^{1/3} \quad (53)$$

The PVC values in these equations are decimal fractions. Expressed in metric units, the equations become:

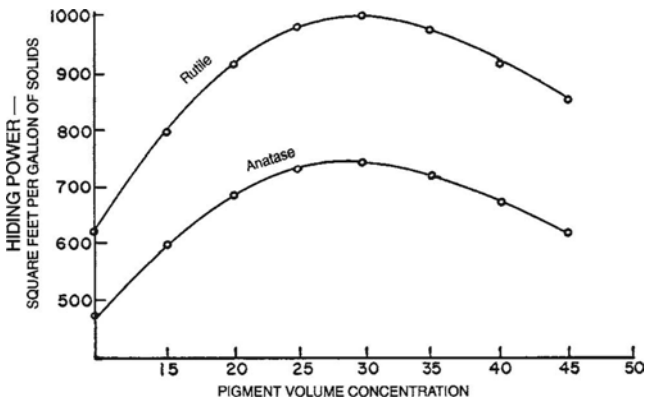

Fig. 14—HP $H_{0.98}$ (ft² /gal) of solids at various PVC levels.

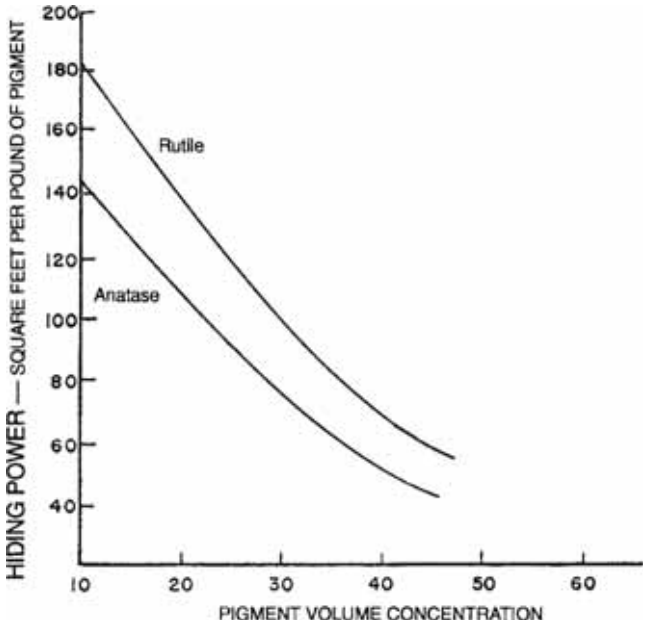

Fig. 15—HP $H_{0.98}$ (ft²/lb) of pigment at various PVC levels.

$$\text{rutile: } H_{0.98}(\text{m}^2/\text{kg}) = 75.7 - 839(\text{PVC})^{1/3} \quad (54)$$

$$\text{anatase: } H_{0.98}(\text{m}^2/\text{kg}) = 59.3 - 67.5(\text{PVC})^{1/3} \quad (55)$$

The question has been studied [36,39] of whether extenders added to a gloss or semigloss paint film might tend to increase the spacing of the TiO_2 pigment and thereby its scattering efficiency. The physical picture that emerges is of large particle-size extenders acting as massive intrusions having no effect on the original TiO_2 spacing, and of fine particle-size extenders dispersing uniformly so as to increase TiO_2 spacing, but no differently in this respect than an equal volume of binder. Consequently, when binder is replaced by an equal volume of large particle-size extender, TiO_2 efficiency decreases, whereas with small particle-size extenders, TiO_2 efficiency has been found to remain essentially the same and in no case improved.

Film Porosity

The preceding relationships pertain to pigment concentrations at which there is sufficient binder to wet the pigment completely and form a continuous phase, which means below the critical pigment volume concentration (CPVC). Above the CPVC, the dried film becomes porous, containing entrapped air that increases pigment-scattering efficiency by effectively lowering the refractive index of the surrounding medium. The air itself, as particulate matter in contact with the higher refractive index binder, contributes to light scattering. Thus, if the curves of Fig. 14 were extended to a sufficiently high PVC, the HP of the film would begin to rise again due to the opacification effect of film porosity. Obviously this is an extremely impractical use of expensive titanium dioxide with no relation to actual formulation practice. However, porosity does in practice make a major contribution to HP in the important interior flat wall paint sector. In paints of that type, inexpensive inert white pigments are included in the formulation, along with titanium dioxide for the esthetic purpose of producing a flat finish and to contribute HP by means of porosity. Stieg and Ensminger [38] showed that with paints over the CPVC that contain both TiO_2 and extender, HP is in a straight-line relationship with the Porosity Index (P.I.), with the slope of the line depending on the percentage of prime pigment and the nature of the extender. The P.I. is calculated from the equation

$$\text{P.I.} = 1\frac{\text{CPVC}(1 - \text{PVC})}{\text{PVC}(1 - \text{CPVC})} \quad (56)$$

The low-cost HP obtained from porosity is unfortunately accompanied by a deterioration in the quality of the film as manifested by poor scrub, soil, and stain resistance. This is due to an insufficiency of binder, resulting in an air phase continuum that gives ready capillary access to staining materials.

MICROVOIDS FOR WHITE HP

Through the use of encapsulated preformed microvoids, it has been found possible to obtain some of the HP benefit of entrapped air while avoiding or minimizing the deleterious effect of film porosity. The microvoids are supplied as a water dispersion of hollow beads having a plastic outer shell and water-filled core. Incorporated into a latex paint, the water in the core evaporates during the drying of the film and is replaced by air that functions as light-scattering particulates shielded from staining penetrants by the surrounding plastic shell. Because the microvoids alone are not able to produce the desired level of opacity in a film of normal thickness, the inclusion of titanium dioxide pigments in the paint formulation along with microvoids is essential. One widely used microvoid bead product is referred to as "opaque polymer" and employs a shell of thermoplastic polystyrene. Another type is a vesiculated bead in which titanium dioxide and water-filled "vesicles" are associated in a cross-linked polyester/styrene matrix. By using such products to partially replace titanium dioxide pigment, raw-material cost savings have been demonstrated with no loss in film integrity or HP [35,40].

FORMAL HP METHODS

ASTM Methods

ASTM D344: TEST METHOD FOR RELATIVE HIDING POWER OF PAINTS BY THE VISUAL EVALUATION OF BRUSHOUTS

This is essentially the same as the Krebs Method described in "Relative Dry HP—Krebs Method," differing only in requiring black-and-white instead of gray-and-white charts and in permitting checkerboard or other suitable contrast designs as well as the diamond-stripe pattern. Modern charts are 0.1 m² in area (1.076 ft²) instead of 1 ft² as specified originally. Provision is made for reporting results in m²/L as well as ft²/gal.

ASTM D2805: TEST METHOD FOR HIDING POWER OF PAINTS BY REFLECTOMETRY

This was adopted in 1969 and is actually a combination of two earlier methods, ASTM D1738 and ASTM D2614, that differed only in technique. It conforms with the general K-M method described in "General K-M HP Method" but is

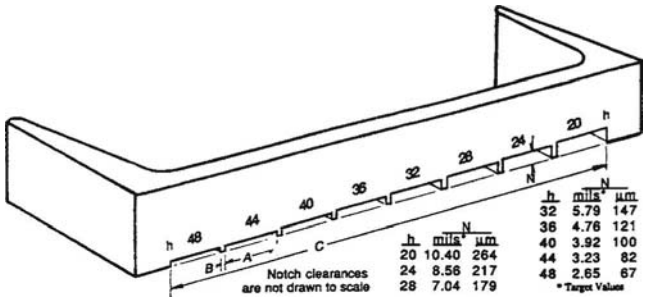

Fig. 16—Multi-notch applicator for ASTM D5007.

designed specifically for air-dried coatings. Originally it provided for the use of either black glass or charts for determining H_x and R_0. In later versions, black glass is mandatory. R_∞ is determined by a separate application as described in "Determination of R_0 and H_x." The need for two test applications does not represent a significant extra effort since only the application on black glass requires the time-consuming SR determination. The latter is accomplished by placing a template of predetermined area on the dry film, scraping off and discarding the film outside the confines of the template, then carefully scraping off the remaining film in the defined test area and weighing it on an analytical balance. The SR is then calculated from the density and nonvolatile content of the paint using Eq (26). Having obtained the experimental values R_0, H_x, and R_∞, the scattering coefficients and HP $H_{0.98}$ of the paint are calculated from these values using the K-M sequence shown in Calculation of $H_{0.98}$, thus: $P_x = f(R_0,R_\infty)$, $S = P_x H_x$, $P_c = f(C;R_\infty)$, $H_c = P_c/S$ for $C = 0.98$.

Earlier versions of ASTM D2805 and its predecessor standards included or referenced the Mitton tables and graphs described in Mitton Graph and Table [27], for solving the K-M equations. The method can be adjusted by appropriate experimental modifications to the measurement of baked enamels on black-painted metal panels as discussed in "Painted Metal Panels," or to other types of coatings and test substrates.

ASTM D5007: TEST METHOD FOR WET-TO-DRY HIDING CHANGE

This test method is concerned with determination of the change in hading power of an architectural coating during drying by visual evaluation of the wet and dry coating films. It is a rapid visual test designed to measure percent change in HP during drying. The paint is drawn down on a black-and-white test chart using a special multinotch applicator (Fig. 16) having eight notches with clearances in geometric progression ranging from 67 to 264 μm (2.65 to 10.4 mils). The clearance corresponding to an agreed visual endpoint (Visual HP End-Point) is estimated immediately after application and again after drying. The ratio of the two clearances multiplied by 100 gives the percentage change in HP:

$$\frac{\text{CLEARANCE}_{\text{WET ENDPOINT}}}{\text{CLEARANCE}_{\text{DRY ENDPOINT}}} = \frac{\text{WFT}_{\text{WET ENDPOINT}}}{\text{WFT}_{\text{DRY ENDPOINT}}}$$

$$= \frac{\text{SPREADING RATE}_{\text{DRY ENDPOINT}}}{\text{SPREADING RATE}_{\text{WET ENDPOINT}}} \qquad (57)$$

The equation assumes that, for any one drawdown, the ratio of clearance to WFT for the several notches does not deviate appreciably. On that basis, WFT variations due to application technique or paint rheology would not affect the final test result. This is not a precision test, but provides significant information of a practical nature with minimal effort.

ASTM D5150: TEST METHOD FOR HIDING POWER OF ARCHITECTURAL PAINTS APPLIED BY ROLLER

This is a visual comparison method designed for use with interior wall finishes and intended to provide practical information from tests performed on a convenient laboratory scale. The test substrate is a large, sealed paper test chart (Fig. 17), with a series of stripes numbered 1 through 6 on a white background. The stripes range in shade from very light gray to black and were selected so that the color difference ΔE^*_{ab} between each successive stripe and the white surround is in a geometric progression from 2 to 64 CIELAB units. The dimensions of the test area are 24 by 36 in. = 6 ft^2 (610 by 914 mm = 5575 cm^2), sufficiently large to simulate practical application of paints with a roller. The paint is applied at a specified, controlled SR, and the HP is reported as the stripe number of the darkest stripe perceived as being completely obscured. The concept of this test is that in practical applications the levelness of the paint film and, hence, its effective opacity are affected by the rheological properties of the paint. Thus, in practice paints tend to have lower HP than indicated by more customary test methods in which films are applied with maximum uniformity using a blade-type applicator. Relative practical HP among paints can be influenced for that same reason.

ASTM D6441: TEST METHOD FOR MEASURING THE HIDING POWER OF POWDER COATINGS

This standard conforms with the power coating industry practice of reporting HP in terms of film thickness rather than SR. A "wedge" shape film providing a range of film thicknesses is applied by electrostatic spraying on black and white painted metal panels. After curing, film thicknesses are measured with an electronic film thickness gage and reluctances measured with a small aperture (e.g. 4 mm)

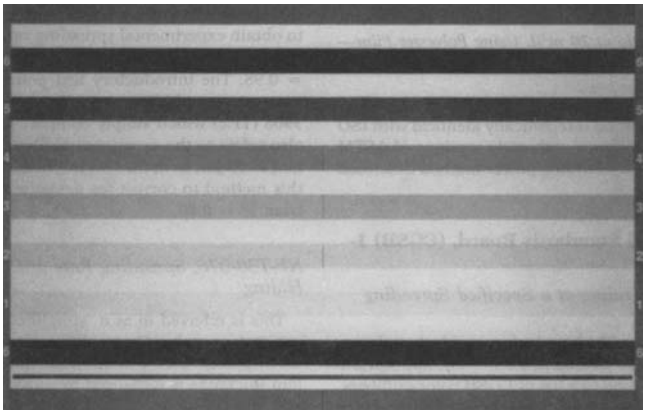

Fig. 17—Large gray scale chart (6 ft^2, 5575 cm^2) for roller application tests per ASTM D5150.

spectrophotometer. Method A reports the CR at a specified film thickness, and Method B the film thickness at a specified CR.

Federal Test Method Std. 141

METHOD 4121, CR AT A SPECIFIED SR

This pass–fail test was previously described in some detail in "Federal Test Method for Dry Opacity." Paint films are applied on black-and-white charts by brush or drawdown, and SRs are determined by a typical weight-area-density procedure, discussed in "SR (or Film Thickness) Determination." CR values are plotted at several SRs to obtain graphically the CR at a specified SR. For the test paint to pass, the CR at the specified SR must have a specified minimum value.

ISO (International Standardization Organization) Methods

ISO 2814, CR (CR) AT A NOMINAL SR (SR) OF 20 m^2/L ON BLACK-AND-WHITE CHARTS OR POLYESTER FILM

A paint film is applied with a 100-μm clearance applicator to give a nominal WFT of 50 μm, corresponding to a SR of 20 m^2/L. Black and white substrate reflectance are measured and the CR calculated without a determination of actual SR. Films cast on clear polyester film are measured, as described in Clear Plastic Film, by placing the film alternately on black and white glass. Because different paints and application techniques with the same applicator give films differing significantly in thickness, the method is satisfactory only as a rough guide for paints of the same type and color evaluated by one operator.

ISO 6504-1, KUBELKA-MUNK METHOD FOR WHITE AND LIGHT-COLORED PAINTS

This is in accordance with the general K-M HP method described in "General K-M HP Method" section. It calls for an all-black substrate, which can be glass or polyester film over black glass. The Mitton graph and table described in Mitton Graph and Table [27] are included, which makes it very similar to early versions of ASTM D2805.

ISO 6504-3, DETERMINATION OF CR (OPACITY) OF LIGHT-COLORED PAINTS AT A FIXED SR

This method is analogous to ISO 2814, but the SR is determined precisely by a weight-area-density procedure at several film thicknesses. Substrates are clear polyester film in Method A and black and white charts in Method B. The CRs and SRs are plotted graphically and the CR at 210 m^2/L is reported. The CIE-Y reflectance of the white substrate is specified to be 80 ± 2 %.

British Standards Institute, BSI 3900

Part D4. Comparison of CR of Paints of the Same Type and Color—This method is technically identical with ISO 2814 (11.c).

Part D6. CR at 20 m^2/L *Using Polyester Film*—This method is technically identical with ISO 3906-1980 (11.c).

Part D7. True HP (*SR at C* = 0.98) *by the Kubelka-Munk Method*—This method is technically identical with ISO 6504-1 (11.c) and in accordance with early versions of ASTM D2805 and the general K-M HP method described in "General K-M-HP Method" section.

Canadian General Standards Board, (CGSB) 1-GP-71

METHOD 14.1, VISUAL HIDING AT A SPECIFIED SR

The test substrates are black-and-white or black-and-gray checkerboard charts with an area of 0.1 m^2. The appropriate chart is specified according to a list of CGSB color numbers, with black-and-gray being used for lighter colors. The paint is applied by brush or drawdown. In brush application the SR is controlled accurately by weighing container and brush before and after application, with a specified volume being delivered to the chart surface by syringe. With drawdowns, presumably identical applications are made on glass and charts and the WFT determined on glass by means of an Interchemical (ASTM D1212) WFT gage. For the test paint to pass, the dry paint film is required to completely obscure the contrast pattern of the chart.

METHOD 14.2, SR DETERMINED AT FULL VISUAL HIDING (FOR QUICK-DRYING COATINGS)

Successive thin coats are applied by spraying onto black-and-gray or black-and-white charts until visual hiding of the dry film is complete. The SR is calculated from the difference in weight of the coated and uncoated chart. This can be expressed in m^2/kg of dry film or m^2/L of the original liquid coating.

METHOD 14.7, CR ON BLACK AND WHITE GLASS PANELS AT A GIVEN SR OR DRY FILM THICKNESS

This is modeled after the NYPC method described in "New York Paint Club (NYPC) Method." WFT is determined with an interchemical gage or DFT with a micrometer. The target film thickness is bracketed experimentally to obtain two points on a CR versus reciprocal film thickness graph and the CR at the target thickness determined by interpolation. The experimental CR values are corrected for $W = 0.80$ before plotting the graph.

French Standards Association (AFNOR)

NF-T30-075, SR AT A CR (CR) OF 0.98

Paint films are cast on clear polyester at several thicknesses and CR values are determined after drying by measuring reflectance over a black-and-white substrate. Dry films just below and above 0.98 in CR are measured by weight or micrometer to obtain experimental SRs in m^2/kg or m^2/L and results interpolated to obtain the SR at exactly CR = 0.98. The introductory text points out that this method measures true HP in preference to ISO methods that simply compare CR values at 20 m^2/L. It also refers to the experimental film thickness not being limited to 50 μm as in ISO methods. No provision is made in this method to correct for deviations of the white substrate from $W = 0.80$.

NF-T30-076, SR AT COMPLETE VISUAL HIDING

This is referred to as a "simplified" method. Several films are cast on polyester to obtain one that shows full hiding when placed over a black-and-white background. The DFT is measured by difference with a micrometer and the HP calculated in m^2/L. Potential users should consider whether this method, though simple in concept, might be excessively burdensome in execution.

German Standards Institute (DIN)

DIN 53162, HP OF AIR DRYING NONCHROMATIC PAINTS

This is a K-M method that is essentially the same as ISO 6504-1, but includes auxiliary test procedures for measuring paint density and nonvolatile content. The Mitton nomograph and table Mitton Graph and Table [27] are employed.

DIN 53164, RELATIVE SCATTERING POWER OF WHITE *(TiO_2)* PIGMENTS

This method measures the K-M scattering coefficient S of a TiO_2 pigment and reports its value as a percentage of the scattering coefficient of a reference pigment measured in the same way. The determination of S is based on the solution of Eq 44: $P = f(R_0, R_x)$ using the Mitton monograph. The method calls for the test pigment to be dispersed in an alkyd or a plasticized polyvinyl chloride vehicle. R_∞ is measured from a thick, full hiding film of the dispersion and R_0 from a nonopaque film applied on a black plastic substrate. The SR H_x of the pigment is determined in a unique way, by igniting a known area of film on plastic and weighing the residue. This method is basically the same as DIN 53162 and other K-M methods (General K-M HP Method), with the difference that only relative values are reported. There is no attempt to report actual scattering coefficients or to calculate HP in physical units, although this could easily be done on the basis of the accumulated data.

Mass Color and Tinting Strength of Pigments

Joseph V. Koleske[1]

PREFACE

IN PREPARATION OF THIS CHAPTER, THE CON-tents of the Fourteenth Edition of this manual were drawn upon. The author acknowledges the author of the chapter in the Fourteenth Edition, Julio I. Aviles. The current edition will review and update the topics as addressed by the previous author, introduce new technology, and include up-to-date references.

INTRODUCTION

Color is a common but complex subject that can be described by perspective and in mathematical terms. As early as 1666, when he was 23, Isaac Newton developed his famous and useful "Newton color circle" that provided an understanding about additive color mixing and complementary colors. His experiments with prisms demonstrated that ordinary sunlight is made up of all wavelengths in the visible spectrum and thus all colors. Thomas Young,[2] an English physicist, in the early 1800s suggested that color perception is three-fold in nature, and he speculated that there were three kinds of nerve fibers or receptors in the eye's retina—something that was experimentally proven in 1959. These eye receptors are for long, middle, and short wavelengths that correspond to the primary colors of red, green, and blue (the RGB primaries) that had been useful in matching many visual colors by additive mixing. Later Hermann von Helmholtz put the qualitative analysis on a quantitative basis wherein three parameters are used to describe a color sensation—the well-known tristimulus values.

While James Maxwell was examining usage of the three primary colors in the 1860s, he found that no additive combination would cover the entire range of hues perceivable to the eye. It was found that the set of primary colors was not unique and that more widely wavelength-separated spectral primaries would produce a more complete range of perceived hues. In addition, with some subtractive combinations, the entire range of perceived colors could be included. Maxwell also demonstrated that the hue and saturation or chromaticity of a colored surface is in effect insensitive to brightness. His studies are considered the basis of modern colorimetry.

In the 1920s and early 1930s, experimental efforts by W. David Wright and John Guild pointed out that all colors within a particular range could be matched with the additive RGB primaries but not all spectral colors could be matched. The lack of matching was particularly true in the green portion of the range. However, if an amount of red wavelength light were added to the color being matched, all colors were possible. These quantitative studies were expressed in the modern terms of tristimulus values for the RGB primaries, but negative values had to be imposed for the red values so that all colors could be matched.

In 1931 the International Commission on Illuminations (CIE)[3] defined a color system in which all tristimulus values were positive and all visible colors could be represented by two color coordinates, x and y, that specify the color point on a chromaticity diagram. The third or Y parameter used in the CIE system for defining colors is a luminance parameter. This CIE system has some difficulties associated with it, and a new system was introduced in 1976. While the 1976 CIE standard removes the difficulties, it has not gained acceptance, and currently the 1931 CIE standard is the basis for almost all quantitative color measurements.

Basic tristimulus color measurement is usually carried out with either a colorimeter or a spectrophotometer. Tristimulus colorimeters are a combination of an illumination source, an array of filters, and a photoelectric output instrument. Measurements are comparative with the device standardized by using ceramic or glass standards that have colors similar to those of the materials to be measured. If precise measurements are needed, spectrophotometers that measure reflectance at each wavelength are used to determine the tristimulus values.

This brief passage into the history of color merely scratches the surface of color technology. Color and its management in paint and coatings are important from both an aesthetic and a practical or economic standpoint. It plays a role in our everyday lives and it affects our emotions and moods as we react to the colors around us. From an economic standpoint, it was well pointed out by Rich [1], who stated, "Getting the customer's color right the first time, whether it involves paint, coatings, or ink, is often the first and most crucial test of quality."

The tinting strength of pigments is often used as a guide for estimating relative hiding power of a pigment or paint to completely obliterate the background to which it has been applied. It may seem as if one is stating the

[1] *1513 Brentwood Road, Charleston, WV 25314.*

[2] Young is also the investigator who devised the concept of a modulus of elasticity that is known in mechanical properties as Young's modulus.

[3] The abbreviation CIE is taken from the French title for the commission, *Commission Internationale de l'Eclairage*. The address for the commission, which is an independent organization that was conceived in 1913, is International Commission on Illuminations, CIE Central Bureau, Kegelgasse 27, A-1030 Wien, Austria.

obvious, but when light falls on a painted substrate, some of the light is reflected from the surface and the remainder enters the paint or coating film. The light that enters the film either emerges from the various faces, including the top face, or is absorbed. If all or most of the light is absorbed, the film appears dark in color or black, the coating effectively hides the substrate, and the pigment involved is said to have good tinting strength. The factors that have an effect on tinting strength and mass color include pigment refractive index, particle size, concentration, degree of dispersion, and inherent light-absorbing characteristics. Applied coating thickness also has an effect on this characteristic. It has been suggested to the author that most industrial colorists consider tinting strength as a "quality control measurement comparing a batch to a standard of the identical materials." The ASTM definitions of tinting strength are given in a following section dealing with definitions.

For both mass color and tinting strength, it is the final appearance or reflectivity (R_∞-value) of the opaque film that is of importance. In turn, reflectivity depends on pigment light-scattering and light-absorption characteristics and particularly with variation of these properties with wavelength(s) of the impinging light. In the case of mass color, the R_∞-value depends primarily on the relative quantity of each characteristic and secondarily on the absorption property of the vehicle. For tinting strength, reflectivity depends on the amount of each characteristic as related to the amount found in a standard paint or pigment.

Historical information about these parameters and early studies related to their development can be found in the literature, and they have been summarized by Mitton [2] and in a follow-up publication by Aviles [3]. A fairly recent publication by Völz [4] deals with color testing and includes chapters that deal with determination of tinting strength and related hiding power. An easy-to-read handbook concerned with color can be found on the Internet [5].

DEFINITIONS

Mass color is the color, when viewed by reflected light, of a pigment-vehicle mixture of such thickness as to obscure completely the background. Sometimes mass color is referred to as over-tone or mass-tone [6]. In a different ASTM publication [7], mass color is not listed, but mass-tone (note, no hyphen) is defined as "in paint technology, a pigment-vehicle mixture containing a single colorant only," but the discussion points out that "at times colorants are developed that contain more than one pigment, but are tested and used as if they contained only a single pigment. This definition is meant to include such colorants."

Mass color is produced by the reflected light, R_∞, of an opaque coating, and it depends on the pigment concentration, degree of dispersion, coating thickness, and the light absorption, K, and scattering, S, of pigments and binders. Mass color is applicable to both chromatic and achromatic pigments.

Tinting strength is a "measure of the effectiveness with which a unit quantity of a colorant alters the color of a material. For scattering and absorbing colorants, both scattering and absorption tinting strength must be specified" [7]. ASTM D16 [6] defines tinting strength as "the power of coloring a standard paint or pigment." ASTM E284 defines tinting strength as a "measure of the effectiveness with which unit quantity of a colorant alters the color of a material."

Other definitions that are of interest include the following [7]. The listing is by no means complete and it is given to help guide a reader/user to the terms used in the technology. In certain cases, designation symbols are listed to again provide guidance.

- Absorption is the transformation of radiant energy to a different form of energy by interaction with matter.
- Absorption tinting strength is the relative change in the absorption properties of a standard white material when a specified amount of an absorbing colorant, black or chromatic, is added to it.
- Achromatic (1) *for primary color sources,* the computed chromaticity of the equal-energy spectrum; (2) *for surface colors,* the color of a whitish light, serving as the illuminant, to which adaptation has taken place in the visual system of the observer; (3) the perception of having no hue, that is, as white, gray, or black.
- Brightness (1) is an aspect of visual perception whereby an area appears to emit more or less light or (2) brightness of an object is the combination of lightness and saturation. Different definitions of brightness are used in the textile industry, the paper industry, and by dyers.
- Chroma is an attribute of color used to indicate the degree of departure of the color from a neutral color of the same lightness. Munsell chroma is an attribute of color used in the Munsell color-order system to indicate the degree of departure of a color from a gray to the same Munsell value, in steps that are visually approximately equal in magnitude.
- Chromatic describes the perception of something having a hue; not white, gray, or black.
- Chromaticity Diagram is a plane diagram in which points specified by chromaticity coordinates represent the chromaticities of lights (color stimuli).
- CIE is an abbreviation for the French title of the International Commission on Illumination, *Commissione Internationale de l'Eclairage.*
- CIE 1931 standard colorimetric system is a system for determining the tristimulus values of any spectral power distribution using the set of reference color stimuli X, Y, Z and the three CIE color-matching functions $x(\lambda)$, $y(\lambda)$, and $z(\lambda)$ adopted by the CIE in 1931.
- Colour Index International is a listing of colors by name and number by the Society of Dyers and Colourists and American Association of Textile Chemists and Colorists [8].
- Hue is the attribute of color perception by means of which a color is judged to be red, orange, yellow, green, blue, purple, or intermediate between adjacent pairs of these, considered in a closed ring (red and purple being an adjacent pair). Neutral colors are judged to have no "hue." Munsell hue is an attribute of color used in the Munsell color-order system to indicate the hue of a specimen viewed in daylight.
- Lightness is (1) the attribute of color perception by which a non-self-luminous body is judged to reflect more or less light; (2) the attribute by which a perceived color is judged to be equivalent to one of a series of grays ranging from black to white.
- Luminance is the luminous flux in a beam, emanating from a surface, or falling on a surface, in a given

direction, per unit of projected area of the surface as viewed from that direction, per unit solid angle.

- Munsell Color System was developed just before the end of the nineteenth century by A. Munsell, an American artist. The system is depicted as a globe with a band of colors running equatorially and an axis of gray values wherein white is the North Pole and black is the South Pole. At each gray value, there is a change in color that gradually ranges from full saturation to neutral gray, and in this manner a myriad of colors could be described by their hue, chroma, and value.
- Saturation is the attribute of a visual sensation that permits a judgment to be made of the proportion of pure chromatic color in the total sensation.
- Scattering is the process by which light or other electromagnetic radiant flux passing through matter is redirected over a range of angles.
- Scattering tinting strength is the relative change in the scattering properties of a standard black material (with no scattering colorant present) when a specified amount of a white or chromatic scattering colorant is added to it.
- Shade is (1) a color produced by a dye or pigment mixture including black dye or pigment; (2) an expression of color difference from a reference dyeing such that another dye must be added to produce a match; and (3) a color slightly different from a reference color. Shade is related to "tint."
- Tint is a color produced by the mixture of white pigment or paint with a chromatic pigment or paint. When used as a verb, "tint" means to adjust the color of a test specimen to be a closer color match to the standard. Also see "Shade" above.
- Tristimulus values are the amount of three specified stimuli required to match a color. In the CIE system, these three stimuli are assigned the symbols X, Y, and Z.

TINTING STRENGTH

As mentioned above, tinting strength is a measure of the effectiveness with which a unit quantity of a colorant changes the color of a material. One may think of it as a pigment's "coloring power." For colorants that both absorb and scatter light, scattering and absorption tinting strengths must be specified. Scattering tinting strength is the relative change in scattering properties of a standard black material that has no scattering colorant present when a specified amount of white or chromatic scattering colorant is added to it. Absorption tinting strength is the relative change in absorption properties of a standard white material when a specified amount of an absorbing colorant, black or chromatic, is added to it.

Since pigment concentration is important to coating strength and cost, tinting strength is an important economic factor when selecting one paint over another. There is no particular value of tinting strength that can be stated as desirable unless an end use is stated. In certain cases, a high value is desirable and in other cases a low value is required to achieve a desired color/strength effect. Pigments each have a different ability to vary the color of a mixture. When economy is a factor in paint formulation, stronger tinting strength is desirable. Some colors, such as phthalocyanine blue, are very strong in their tinting strength whereas other colorants can be relatively weak. Tinting strength increases as pigment particle size decreases with synthetic organic pigments generally having greater tinting strength than mineral pigments.

In a general sense, tinting strength is determined by dilution of a test paint and a reference paint with a standard "mixing white paint" in the case of chromatic paints or a standard "tinting color" in the case of white paints. These diluted pastes are then drawn down on a suitable substrate, and then either instrumentally measuring tristimulus values or visually comparing the specimens. As would be expected, the visual comparison technique has lower precision than the instrumental method. Details for preparation of standard white paints are described [9] or a commercial titanium dioxide-white artists' paint may be used as the standard. It should be understood that the mixing white paint must be made with the same vehicle chemical type—acrylic, alkyd, or oil—as the paint to be tested.

When color tints are considered, differences in gloss and haze can be mistaken for a lighter tint or lower tinting strength than really exists. In grays, these factors may be interpreted as higher white pigment strength than exists. Instruments cannot compensate for specular gloss or haze differences between a sample and a standard, and this can result in erroneous tint strengths. It is possible to equalize gloss differences between specimens by top coating them with a clear coating. Evaluation through the clear coating reveals the true tinting strength differences between sample and standard.

Tinting strength results can also be affected if the lightness, chroma, and saturation of the sample differ significantly from those of the standard, since the measurements involve matching two color variables—either lightness and chroma or lightness and saturation—by adjusting only the amount of pigment used [10,11].

Chromatic Paints

ASTM D4838 [12] is a method used for determining the absorption tinting strength of a chromatic test paint relative to that of a standard or reference paint of the same chemical type. The procedures in this method are based on dilution of paints with a standard mixing white paint followed by instrumental measurement and calculation. Provision is made for correcting the results for small differences in hue or chroma (or both) between the test and reference chromatic paints. The method is meant for comparison of paints that contain the same chemical type vehicle (acrylic, alkyd, or oil) and single-pigment colorants of the same Colour Index name and number. It is unnecessary to have information about the amounts of pigments or other components in the paint.

The color-measuring instrument can be either a spectrophotometer that provides 1931 CIE tristimulus values, X, Y, and Z for CIE standard illuminant C or a tristimulus colorimeter providing either such tristimulus values or colorimeter readings R, G, and B. Other test methods or practices useful in following the results of this test method can be found in the literature [13–15]. ASTM E1347 [16] deals with a test method for the use of a tristimulus colorimeter to evaluate specimens and provide color coordinate and color difference values. The device is also known as a tristimulus filter colorimeter or a color-difference meter.

ASTM D387 is used to compare the color and strength of a pigment that is being tested with a reference standard of the same type and grade [17]. The method specifically points out that it does not apply to white pigments. The pigments are dispersed in a suitable vehicle with a mechanical muller. Opaque drawdowns are made on white paper charts that have a black band and a surface that is impervious to paint liquids. These drawdowns are compared either visually or instrumentally for color and strength differences. ASTM D3022 is similar to this method, but it utilizes a miniature sandmill rather than a mechanical muller to disperse the color pigment [18].

ASTM D2066 is a related test method that is applicable to the relative tinting strength of paste-type printing ink dispersions [19] and is similar in nature to other referenced ASTM test methods [12, 17]. The strength may be determined by instrumental or visual observation of manually or automated mixed tints. The methods are applicable to paste-type printing inks, flushed pigments, and other pigment dispersions that are essentially nonvolatile under ordinary room conditions and for which there is a wet reference standard of the same pigmentation and consistency. If the proper choice of tinting base is used, the methods are applicable to dispersions of any color, including black and white.

White Paints

ASTM D2745 is a standard method for determination of the relative tinting strength of white pigments by reflectance measurements made on black tints [20]. It is only applicable for comparing the test pigment with a reference standard of the same type and grade. The method is carried out by dispersing the pigment in an agreed-on, solvent-free vehicle and then letting it down with additional vehicle that has been tinted with a lampblack that has been predispersed in a vehicle similar in nature to the test vehicle. Refined or low-bodied linseed oil should not be used with this procedure. Both dispersion and let-down are done with an automatic, mechanical muller. Tristimulus values are determined with a colorimeter.

ASTM D332 is a test method for determination of the relative tinting strength of white pigments by visual assessment of blue tints [21]. It is only applicable for comparing a test pigment with a reference standard of the same type and grade. The test is conducted by dispersing specified amounts of a white pigment and a blue tinting pigment that conforms to specifications [22] in a refined linseed oil with an acid number of about 4 using a glass, hand muller, or an automatic muller. The pastes are drawn down on a specified panel and visually evaluated for tinting strength. A numerical rating of tinting strength is obtained by preparing dispersions with the standard white pigment and more or less of the tinting pigment. These are compared until the lightness of the test paste is matched. The weight of the tinting pigment is used to calculate the relative tinting strength.

PIGMENT DISPERSION

Tinting strength and mass color require that pigments be well dispersed in the binder to achieve maximum tinting strength. Ideally, it would be desirable to break down pigment agglomerates into the smallest possible individual particles, i.e., to an ultimate dispersion state. The smaller the particle size the greater the surface area of a given weight or mass of pigment. This then results in more intense color production in the same volume of liquid. However, an ultimate dispersion state is impractical and effectively impossible to achieve. Therefore, pigments under investigation for these properties must be processed in the same manner and receive the same level of mechanical work. Mechanical mullers, which are instruments that have two circular, usually ground-glass grinding surfaces that contain the pigment and vehicle, are used to disperse the two components. A variety of these devices are commercially available. Development of tinting strength is dependent on the force applied to the glass plates, the number of revolutions used, and the mass of pigment and vehicle used. If muller conditions, pigment, and vehicle have not been agreed on by purchaser and seller, the mandatory dispersing conditions given in the Annex of ASTM 387 should be used to attain a consistent level of tinting strength [17]. These conditions include:

- Determination of the appropriate ratio of color pigment to dispersing vehicle for the standard and test pigments.
- Determination of appropriate masses of pigment and vehicle to use.
- Preparation of a standard tint by application of 100 lbf (N) to the muller plates, introducing the appropriate mass of pigment/vehicle, and mulling the paste for 100 revolutions in two stages of 50 revolutions each. This is then repeated on three more specimens of the standard mixture except the mulling is carried out for 200, 300, and 400 revolutions in stages of 50 revolutions.
- Each of the four specimens is compared one to the other for tinting strength and the minimum number of revolutions needed to develop maximum or full tinting strength is ascertained.

The parameters and dispersing conditions used for three pigments that were investigated in an interlaboratory test to determine the precision of this standard method are given in Table 1.

TABLE 1—Interlaboratory pigment dispersing parameters and specific conditions obtained for maximum tinting strength [17]

	Pigment Type		
Parameter	**Yellow Iron Oxide**	**BON Red**	**Phthalocyanine Green**
Force applied, lbf (N)	100 (440)	100 (440)	100 (440)
Total No. revolutions	100 (2 × 50)	200 (4 × 50)	400 (8 × 50)
Mass of color pigment, g	1.0	0.6	0.75
Mass of dispersing vehicle, g	1.7	1.4	1.8

PIGMENT DISPERSION TECHNIQUES

It should be kept in mind that the techniques described in this chapter pertain to preparing specimens for determination of tinting strength and mass color, and they are not meant for pigment dispersion in general. The general topic of pigment dispersion is discussed elsewhere in this manual as well as in a variety of references [23–31]. There is a vast amount of literature that deals with the surface treatment of organic pigments to improve ease of dispersibility, and interested readers are encouraged to seek such information in the classic work of Hayes [32], the above listed references, and others [33–35]. Detail regarding the surface treatment of inorganic pigments is also in the literature [36–38].

Spatula and Hand Mullers

Grinding pigment/vehicle combinations can be carried out with a spatula or a hand muller[4] by rubbing or mulling the materials over a 3 × 12 in. (8 × 30 cm) strip area on a glass plate. The rubbing is done by pushing the muller up one side and pulling it down the other side of the strip area so that all color particles receive the same amount of rubbing. One rub is one up and down course on the strip area. Early studies by Ayers [39] indicated that the muller gave more reliable results than a spatula and that the rubbing surface may vary a great deal without affecting the results. Stutz's [40] results during investigation of the tinting strength of white pigments also found a muller was superior to a spatula. It was also found that a weighted or un-weighted muller could be used without affecting the results.

Automatic Mullers

Automatic[5] or mechanical mullers have two circular glass grinding surfaces that contain the pigment/vehicle mixture. The grinding surfaces are usually constructed of ground glass with one surface stationary and weighted to exert a pressure of 100 psi (440 N) and the other surface rotary with rotation effected with a motor. Because rotation is about the diskcenters, paste located at the center can receive less mulling than paste located near the edges. To compensate for this effect, it has been found helpful to spread the paste in a ring approximately halfway between the edge and the center. The revolutions per mulling cycle can be adjusted in increments of 1 to 999. Mechanical muller advantages include very good development of tinting strength, the possibility to rapidly mull small quantities of materials, and efficient processing of a large number of samples. The specific way to operate a mechanical muller when determining tinting strength or mass color can be found in the annex to Ref. [17].

LABORATORY MINIATURE MEDIA MILLS

Commercial horizontal or vertical laboratory media mills that can process up to one quart of millbase are available. In a general sense, media can be nonferrous or ferrous as, for example, flint pebbles, sand, ceramic alumina, porcelain, stainless steel, high carbon steel spheres, etc. but for test grinds, specified media must be used. For small grinds, a media mill can be simulated with a laboratory dispenser equipped with a fiber or Telfon 1 5/8 in. disk, a 200 mL tall-form beaker, and media. Equal volumes of millbase to media are used. Grinds may be 60.0 g for carbon black and some organic pigments to 160.0 g for inorganic pigments. The millbase must be carefully prepared to eliminate gross and oversized agglomerates. Peripheral impeller speed should be 2000 feet (610 m) per minute, and the mixture should be ground for a set time or to a set dispersion level such as a Hegman value of 7.0+. Advantages of media mills include development of the highest tinting strength and mass color, simulation of actual factory grinding conditions, and low cost.

LABORATORY ROLLER MILL

Small, three-roller mills have been found useful for grinding small, laboratory-size batches of paint. Rolls of such mills are about 4 in. (10.16 cm) in diameter and 8 in. (20.82 cm) in length. Batches as small as 5 g have been prepared in such mills.

PALL GLASS MILL

Small quantities of metal-free pigment paste can be prepared with the Pall Glass Mill [41]. The mill is a heavy ground-glass stopper in a heavy glass joint. The mixed, un-ground materials (1–8 g) are placed in the joint and the stopper/plunger is inserted. The stopper is rotated with a small motor at about 150 rpm. In this mill grinding pressure ranges from 20 to 30 psi. The Pall Glass Mill is said to be an improvement over hand mulling because it saves time and because it results in greater development of tinting strength.

PIGMENT CONCENTRATION

Paste viscosity has an effect on grinding efficiency, and it is a property that determines the level of tinting strength and mass color that is developed. Ayers [39] investigated iron oxides, and his results indicated that color developed faster as paste viscosity increased. A low-viscosity paste had a reflectance of 26 % at a wavelength of 700 nm, whereas a high-viscosity paste was darker and redder with a reflectance of 23 %. It should be pointed out that there is a point above which viscosity has no effect on grinding efficiency.

MIXING TIME OF LIQUID COLORS

An important property of oil or universal liquid colorants is the ease with which they can be incorporated into white paints. A method for testing the speed of incorporation of such colorants has been described by Paul and Diehlman [42]. Their method involves use of a mechanical rotating bottle that contains a white paint, the liquid colorant, and a grinding media. When the test was first developed, No. 11 lead shot was used as the media; however, today glass beads, zirconia grinding media, and steel shot are among the media used to avoid lead contamination of the paint.

The test is conducted by charging the bottle with 550 g of grinding media, 2 mL of the liquid colorant, and 75 mL of white paint. The bottle is then closed with a cork that is concave on the inner end to match the glass end of the bottle and placed in the holder of the rotating device. The

[4] Hand mullers are implements made of a hard substance such as glass, stone, or similar material and used as a pestle to grind pigment/vehicle (i.e., paint) combinations. These are seldom, if at all, used today.

[5] Automatic in this area of technology means "motor driven."

bottle is then tilted and rotated slightly by hand to wet the container walls.

This is followed by mechanical rotation of the bottle until the paint is homogeneous in that no streaking of the color is seen. The time in seconds for mixing is determined and recorded.

OTHER RELATED TEST PROCEDURES

While the various test procedures cited above each contain reference to a number of ASTM documents, it is worthwhile to list some of these. Table 2 is a partial listing of such potentially useful documents.

Part 11: Physical and Mechanical Properties

47

Adhesion

Gordon L. Nelson[1]

PREFACE

IN PREPARATION OF THIS CHAPTER, THE CONTENTS of the fourteenth edition were drawn upon. The current edition will review and update the topics as previously addressed, introduce new technology that has been developed, and include additional references.

INTRODUCTION

Organic coatings are applied to a variety of substrate materials (woods, metals, plastics, ceramics) for decorative, protective, and functional applications. In each case, it is imperative that the coating adheres well to the substrate. Accordingly, adhesion assessments should be an integral part of the coating development. This may seem a straightforward task, but coating adhesion is, in fact, extremely complex and often poorly understood. The growing use of plastics to replace metals and other "traditional" materials renders the issue even more complex [1,2].

The objectives of this chapter are to briefly review salient concepts of the adhesion process and to discuss currently accepted standard test methods.

FUNDAMENTAL CONCEPTS

While the very definition of "adhesion" is of some controversy [1], adhesion may be loosely defined as the attraction between dissimilar bodies for one another. ASTM D907 on Terminology of Adhesives defines adhesion as "the state in which two surfaces are held together by interfacial forces which may consist of valence forces or interlocking action or both." In discussing adhesion assessment, one may consider the issue from two different aspects: *basic* adhesion and *practical* adhesion. Basic adhesion signifies the summation of all interfacial, intermolecular forces, whereas practical adhesion is used to represent the forces or work required to disrupt the adhering system [3]. The next section will be devoted to theories and concepts of basic adhesion and will out of necessity be brief. The perspective will be from that of a polymeric coating on a plastic substrate [2]. Metal and metal oxide substrates will be discussed where appropriate. The reader is referred to Refs. [4–7] for a more thorough discussion.

BASIC ADHESION

Work of Adhesion

Bonding between polymeric coatings and substrates may be viewed as the union of two contiguous polymer phases, one a solid and the other a liquid that solidifies to form a thin film. The reversible separation of the two phases may be expressed by the work of adhesion

$$W_a = Y_1 + Y_2 - Y_{12} \tag{1}$$

where W_a is the work of adhesion, and Y_1 and Y_2 are the surface tensions of the two phases. The maximum force per unit area, σ^2, to effect this process is the ideal adhesive strength [8]

$$\sigma^2 = [16 / 9(3)^{12}](W_a / Z_0) \tag{2}$$

where Z_0 is the equilibrium separation between the two phases, usually about 5 Å. The average value W_a for polymers is typically 50 ergs/cm^2, yielding a theoretical value for σ^2 of 15 000 psi (103 mPa). For practical purposes this value is never attained, primarily due to the fact that perfect inter-molecular contact is most unlikely. In fact, this is at least an order of magnitude higher than the practical adhesive strength usually observed. This deviation from ideality has led to the promulgation of several theories of adhesion, none of which are universally recognized [9]. This is not unexpected, since most theories deal exclusively with the mechanisms of bond formation and disregard the fact that bond strength is ultimately a function of both the degree of bond formation, the nature of the bond (chemical and physical), and the rheological properties of the bonding phases. The strength of an adhesive bond is, in fact, a function of all of these factors. Summary paragraphs about basic theories of adhesion follow below.

Fracture Theory

The area of interfacial bonding between coating and substrate will, in most instances, contain voids or defects. The result is deviation between the ideal adhesive strength and the practical limit.

Good [10] and Williams [11] have applied the theory of cohesive fracture to coating fracture. The concept that fracture propagates from the weakest point, a defect, is fundamental to fracture mechanics. The strength of a bond, in terms of the energy required to induce fracture, is described as a function of the defect size and the energy dissipated by irreversible processes (plastic deformation, light emission, and electric discharge). The general equation given is

$$f = k(EF/d)^{1/2} \tag{3}$$

[1] *Dean, College of Science, Florida Institute of Technology, 150 West University Blvd., Melbourne, FL 32901-6975.*

Copyright © 2012 by ASTM International

where f is the fracture stress, $k = (4/\pi)^{1/2}$, E the elastic modulus of the material, d the defect length, and F the fracture energy or total work per unit area of fracture surface, which is dissipated. Accordingly, the fracture energy

$$f = W_a + W_i \tag{4}$$

where W_a is the work of adhesion and W_i is the total work for the irreversible processes. For all practical purposes W_i is much greater than W_a therefore [12,13]

$$f = W_i \tag{5}$$

Weak Boundary Layer Theory

Proposed by several workers [14–16], the weak boundary layer theory maintains that true interfacial fracture does not occur, and that fracture usually occurs *cohesively* in a weak boundary layer, which may be near the interface between coating and substrate. Experimental evidence has perhaps disproved the first point [10], that true interfacial failure can occur, but it has been shown that the second is valid in some instances [17,18].

Of practical importance to WBL investigations is the locus of fracture, which can occur in one or more of the zones in Fig. 1. For a strong bond, the boundary layer (layers) must be rheologically sound and chemically durable. The zone of failure may, of course, be studied by scanning electron microscopy (SEM), transmission electron microscopy, and Fourier transform-infrared [19]. In fact, thin layers of coating have been noted where interfacial failure was only thought to occur on visual examination.

Wetting-Contact Theory

The wetting-contact theory states that van der Waals attractive forces alone provide sufficient coating/substrate bond strength given perfect molecular contact, and that the extent of contact and resulting bond strength are functions of wetting energetics [20–28]. No one denies the importance of wetting in adhesion, i.e., the lower the contact angles, the more the interfacial area of contact, which generally yields improved adhesion (Fig. 2).

However, thermodynamic wetting is a necessary but not sufficient condition for the establishment of coating film adhesion. Wetting is a kinetic phenomenon as well. Furthermore, this model does not consider the effects of weak boundary layers or the effects of defects or fracture mechanics. What is the effect of surface contamination on the contact angle?

For guidance on the measurement of contact angle, see ASTM D7334 (WK11928) Standard Practice for Surface Wettability of Coatings, Substrates and Pigments by Advancing Contact Angle Management.

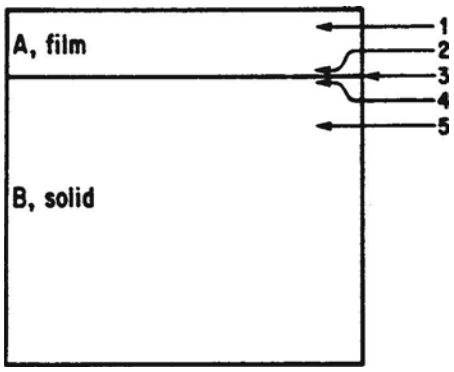

Fig. 1—Weak boundary layer theory. Possible zones of failure (after Good [19]).

Diffusion Theory

Voyutskii and others [29–33] have proposed that coating adhesion between high polymers arises from interdiffusion. This has been validated somewhat by the observation that adhesive strength is a function of polymer molecular weight, structure, and contact time.

Key to this theory is the concept that no clear-cut inter-facial boundary exists, but rather that an interphase exists which consists of polymer chain segments from both contiguous phases. The theory has been criticized for giving insufficient weight to the contribution of van der Waals attractive forces. Nevertheless, for the case of solvent-borne organic coatings applied to plastic substrates, this phenomenon is intuitively appealing.

Interdiffusion of coating and substrate polymer molecular segments is a function of polymer-polymer compatibility. An interphase forms as a result of the blending of the two phases. Although polymer pairs are generally incompatible, Helfand and others [34–38] have utilized statistical thermodynamics to predict that interdiffusion also occurs as a result of the tendency for free energy at the interface to minimize. A useful equation that describes interfacial thickness as a function of the Flory–Huggins interaction parameter as derived from Hansen solubility parameters is [36,38]

$$a_i = 2(m/\mathrm{x})^{1/2} \tag{6}$$

where a_i is the interfacial thickness expressed as the cross-sectional area of a lattice cell, m is a lattice constant directly proportional to nearest-neighbor contacts, and x is the Flory–Huggins interaction parameter. By this equation, interfacial thickness increases by interdiffusion as the solubility parameter difference between the two phases decreases. Although experimental verification is scarce, adhesive strength has been shown to decrease with increasing disparity in the solubility parameters of the two phases [39].

It is important to note that diffusion should occur in the latter stage of bond formation, the first stage being wetting to establish contact. Additional support for the theory comes from the observation that adhesive strength between certain high polymers increases with time [30]. This theory, however, cannot be applicable to systems involving one or more hard solids (metals, glass, or metal oxides).

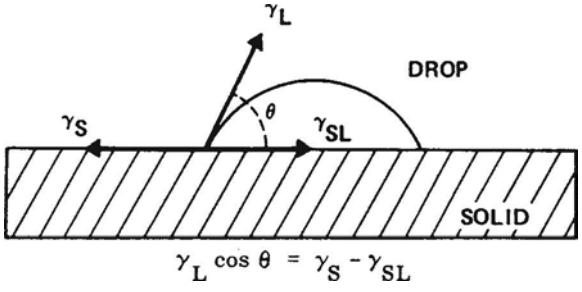

Fig. 2—Contact angle.

Chemical Adhesion

The bond strength of covalent bonds is 1 to 2 orders of magnitude greater than van der Waals attractive forces. There have been numerous applications where interfacial chemical bonds have been employed to promote adhesion. Dramatic increases in bond strength have been reported [40].

Coupling agents such as chrome complexes [41], silanes [42], and titanates [43] have been used effectively, Organic functionalities, including isoeyanates, carboxyls, amides, amines, hydroxyls, and epoxides [43,44], have been reacted interfacially to enhance adhesion.

Adhesive strength has been shown to increase with functional group concentration as expressed by

$$f = kC^n \tag{7}$$

where f is the adhesive strength, C the functional group concentration, and k and n are positive constants [45]. There, however, appears to be an upper limit for functional group concentration above which adhesion may tend to decrease [46,47].

Mechanical Adhesion

In mechanical adhesion substrate roughness is thought to provide a mechanical locking of the coating to the substrate. However, if there is not intimate contact between the coating and the substrate, then increased roughness should lead to a *decrease* in adhesion by producing uncoated voids. In the practical application of electroless metals on polymer substrates, etchants are used that create deep channels, increasing adhesion. Other examples are anchor coats for polytetra fluoroethylene, adhesion to porous anodic films on aluminum, and hot melt polyolefin coatings on metals. Mechanical adhesion is also important for porous substrates such as wood, cloth, and paper. Since good adhesion can be obtained on smooth surfaces such as glass, questions can be raised about the general validity of the mechanical adhesion mechanism. It should also be noted that mechanical abrasive treatment of a solid surface may also yield macroradicals and active secondary chemical products, which if they do not come into contact with atmospheric oxygen, may interact with components of the coating. This has been shown for certain adhesives. Active radicals or functionality would yield adhesion, better described as mechanico-chemical adhesion than just mechanical [7,48,49].

Electrostatic Adhesion

In the theory of electrostatic adhesion, when two dissimilar materials are brought into contact, a charge transfer takes place, which results in the formation of an electrical double layer, much like a capacitor. Work would then be required to separate the two charged layers. This is thought to be particularly applicable to metal-polymer bonds. Indeed, ionizing discharge has been shown to affect a copper to acrylic bond but not copper on salt (NaCl) or glass. This theory would not be applicable to two nonpolymer systems [49,50].

Acid-Base Adhesion

In the acid-base adhesion theory, it is said that the strength of the adhesive bonds is increased significantly by acid base interactions between coating and substrate. Appropriate modification of surface acidity or basicity of the substrate should increase adhesion. Modification of surface acidity or basicity of inorganic solids can increase mechanical properties (modulus, extension to break, and toughness) of coatings on these substrates. It has also been claimed that the reverse is true, however [51,52].

Combination of Phenomena

The preceding theories interpret adhesion in terms of single phenomena, each of which undoubtedly plays some role in interfacial bonding between coating and substrate. One should be cautioned, however, against exclusive use of a single theory to explain the adhesion of a given system. A more logical approach has been proposed by Allen [53].

$$\psi = a\psi_A + b\psi_B + c\psi_C + \ldots \tag{8}$$

which suggests that a combination of phenomena is more realistic, that is, that basic adhesion is the summation of all interatomic or intermolecular interactions at the interface. One would think that systematic studies could be made to assess the contribution of a given variable to the adhesion process, with the others being held constant. This would reveal useful information as to factors critical to coating adhesion for a particular system. Unfortunately, being able to accomplish that task is questionable given that adhesion assessment not only involves factors of basic adhesion but variation in application of the applied external stress (tensile, shear, or peel) and many other factors.

It can be concluded that adhesion is an interfacial phenomenon in which both physical and chemical forces operate when surfaces develop to form an interface. Adhesive strength is a measure of the degree to which the two surfaces are attracted. This is a function of wettability, relative surface energetics of both phases, and of the kinetics of wetting. For integrity of a bond at the interface between a coating and a substrate, one needs to consider the following factors:

1. Thermodynamics and kinetics of the formation of the bond.
2. The forces acting near the interface in both the coating and the substrate.
3. The cohesive forces within the coating layer.
4. Internal stresses in the coating layer.
5. The behavior of the coating layer under stress.

To understand basic adhesion one must understand the surface chemistry, surface physics, surface architecture, coating polymer chemistry and physics, polymer rheology, coating internal stresses, fracture mechanics, and effects of changes in the environment. In fact, it has been noted that spontaneous loss of adhesion can occur due solely to internal strain of the coating [54–56].

Effects of Substrates

ADDITIONAL CHEMISTRY

The adhesion of organic coatings to metals is at a high level of development in the practical sense. The contribution of surface energy, chemical functionality, surface irregularities, and contaminants (oxides, adsorbed water, etc.) have been identified.

On the other hand, coating adhesion to plastic substrates has presented additional complexities. Polymer

surfaces are often more difficult to wet and bond because of low surface energy, incompatibility, chemical inertness, or the presence of contaminants (oils, lubricants, plasticizers, etc.), and weak boundary layers. Surface modification techniques have been developed to enhance adhesion. In the absence of surface preparation, coating adhesion is felt to be a function primarily of van der Waals and/or polar-dipolar attractive forces, mechanical adhesion (from surface irregularities), and interdiffusion. This latter contribution to adhesion has been studied using SEM. In Fig. 3 is presented a scanning electron micrograph of a thermoplastic acrylic coating applied to modified polyphenylene oxide (a blend of PPO and polystyrene), an important engineering thermoplastic. The first coating contains 60 % of the recommended amount of solvent. The interface formed is sharp and well-defined. In this instance, adhesion appears to be due largely to mechanical and attractive forces. Fig. 4 shows the same substrate and coating, which in this case contains 100 % of the recommended amount of solvent. The sharp interface seen in Fig. 3 is no longer present, an intermediate zone or interphase having formed in its place. Diffuse interface formation of this magnitude is undoubtedly unique to coatings applied to plastics. Bond strength will be a function of formulation, solvent content, and drying time [2].

Organic coatings are complex formulations, thus, the polymer chemistry at the developing coating substrate interface will clearly be impacted by the solid surface, whether plastic, metal, or inorganic, that is, the polymer interface may be somewhat different than the bulk coating (i.e., a boundary layer). Fully developed coatings may also be porous or permeable, thus aging and weathering may impact adhesion, as water, oxygen, and other agents penetrate to the polymer coating solid interface [7,57]. Indeed, some coatings that have acceptable adhesion while dry may fail badly when tested under high humidity or after immersion in water for several hours.

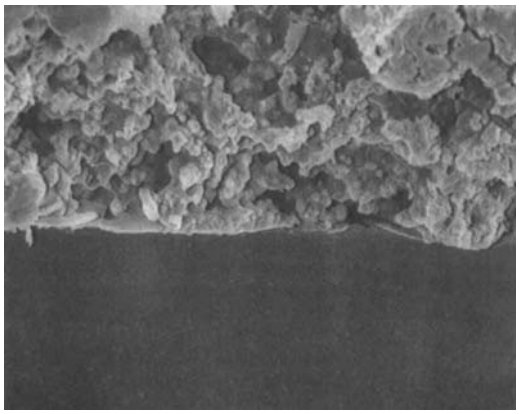

Fig. 3—SEM of sharp interface.

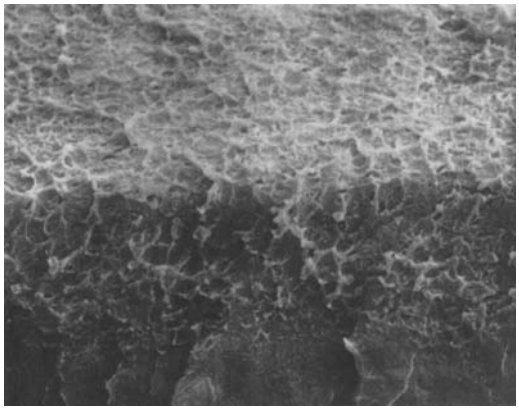

Fig. 4—SEM of diffuse interface.

It has been shown for polyolefin-metal adhesion that oxidation of the polymer attached to the surface occurs through action of oxygen absorbed by the metal and the polymer. The appearance of oxygen-containing groups in the otherwise inert polymer should promote an increase in the extent of interaction with the metal. Adhesion in this case would also be increased by oxygen donor fillers [7,57].

All metals (except gold) are known to exist with an oxide film on their surfaces. The volume of oxide formed may be smaller than the metal reacted, and consequently the oxide film is porous and nonprotective (alkali and alkaline earth metals) or the volume may be larger and therefore protective (transition metals and aluminum). However, in the latter case, migration of metal cations from the surface leaves vacancies, which aggregate to form cavities. Treatment of a metal before coating to produce a preferred or controlled bonding surface is therefore common [7,57]. From the above discussion, it is clear that chemical interaction between coating and solid can occur even when not recognized or anticipated.

Finally, a change in substrate may impact adhesion. Weathering failures such as blistering and scab corrosion are often regarded as adhesion failures by coatings development chemists. Delamination of coatings in the absence of substrate corrosion can also be produced by weathering. A common problem involves the interfacial chalking of an epoxy primer and a topcoat that has a high UV light transmission. In the presence of UV light, moisture, and oxygen, the epoxy primer is degraded at the interface between the primer and topcoat, leading to delamination of the topcoat from the primer.

Delamination of clear or semitransparent exterior wood coatings can also occur by UV, water, and oxygen attacking the wood substrate. Delamination of the intact coating results when the wood substrate coating interface is destroyed. The solution to this problem is to add organic and inorganic UV absorbers to the coating to protect the wood substrate from degradation.

PRACTICAL ADHESION

Given the complexities of the adhesion process, can adhesion be measured? As Mittal [3] has pointed out, the answer is both "yes" and "no." It is reasonable to state that at the present time no test exists that can precisely assess the actual physical strength of an adhesive bond. But it can also be said that it is possible to obtain an indication of relative adhesion performance.

Practical adhesion test methods are generally of two types: *implied* and *direct*. Implied type tests include indentation or scribe techniques, rub testing, and wear testing. Criticism of these tests arises when they are used to quantify the strength of adhesive bonding. But this, in fact, is not their purpose. An implied test should be used to assess coating performance under actual service conditions. Direct measurements, on the other hand, are intended expressly

to measure adhesion. Peel, lap-shear, and direct tensile are common examples. Meaningful tests of this type are highly sought after, primarily because the results are expressed by a single discrete quantity, the force required to fracture the coating/substrate bond under prescribed conditions [2].

Test Methods

In practice, a battery of tests is used to evaluate adhesion by inducing bond rupture by different modes. Criteria deemed essential for a test to warrant large-scale acceptance are: use of a straightforward and unambiguous procedure, relevance to its intended application, reproducibility, and quantifiability, including a meaningful rating scale for assessing performance. Test methods used for coatings on metals are peel adhesion or "tape testing," Gardner impact flexibility testing, and adhesive joint testing including shear (lap joint) and direct tensile (butt joint) testing. These tests do not, in fact, strictly meet the criteria listed, but an appealing aspect of the above tests is that in most cases the equipment/instrumentation is readily available or can be obtained at reasonable cost [2].

A wide diversity of test methods has been developed over the years. In this chapter only selected test methods developed through the consensus process will be discussed in detail. The reader should recognize, however, that numerous test methods have been developed that measure aspects of adhesion [7,58–61] and that there generally is difficulty in relating these to basic adhesion phenomena (Fig. 4).

The Tape Test

By far the most used test to access coating "adhesion" is the peel test. In use since the 1930s, in its simplest version, a piece of adhesive tape is pressed against the paint film. The test consists of observing whether the film is peeled off when the tape is removed. The method can be refined to measure the force required for film removal. In other tests, crosses or a cross-hatched pattern are cut into the coating, a tape applied and removed, and the coating removal assessed against an established rating scale. The current widely used version was first published in 1974 as ASTM D3359, Standard Test Methods for Measuring Adhesion by Tape Test. Two test methods are covered. This is one of the top-selling ASTM test methods, regardless of field.

These test methods cover procedures for assessing the adhesion of coating films to metallic substrates only, by applying and removing pressure-sensitive tape over cuts made in the film. Method A is primarily intended for use at job sites, while Method B is more suitable for use in the laboratory. The cross-hatch test, Method B, is not considered suitable for films thicker than 5 mils (125 μm). Both test methods are used to establish whether or not the adhesion of a coating to a substrate is at a generally adequate level. They do not distinguish between higher levels of adhesion for which more sophisticated methods of measurement are required. In multicoat systems, adhesion failure may occur between coats so that the adhesion of the coating system to the substrate is not determined. In Test Method A an X-cut 1.5 in. (3.8 cm) long is made in the film (to the substrate) with a sharp cutting device. A 1-in. (2.5-cm)-wide pressure sensitive tape is applied over the cut and firmly adhered with a pencil eraser and then removed, and adhesion is assessed qualitatively on a 0 to 5 scale.

In Test Method B, a lattice pattern with either 6 or 11 cuts in each direction is made in the film (to the substrate), pressure-sensitive tape is applied over the lattice and then removed, and adhesion is evaluated by comparison with descriptions and illustrations.

For Test Method A, the following rating scale is used:

5A = No peeling or removal.
4A = Trace peeling or removal along incisions.
3A = Jagged removal along incisions up to 1/16 in. (1.6 mm) on either side.
2A = Jagged removal along most of incisions up to 1/8 in. (3.2 mm) on either side.
1A = Removal from most of the area of the X under the tape.
0A = Removal beyond the area of the X.

For Test Method B, 3/4 in. (1.9 cm) cross-cuts are made.

For coatings having a dry film thickness up to and including 2.0 mils (50 μm), 11 cuts are spaced 1 mm apart.

For coatings having a dry film thickness between 2 mils (50 μm) and 5 mils (125 μm), 6 cuts are spaced 2 mm apart.

For films thicker than 5 mils (125 μm), Method A is used instead of Method B.

For Test Method B, adhesion is rated according to the following scale (as illustrated in Fig. 5):

5B = The edges of the cuts are completely smooth; none of the squares of the lattice is detached.
4B = Small flakes of the coating are detached at intersections; less than 5% of the area is affected.
3B = Small flakes of the coating are detached along edges and at intersections of cuts. The area affected is 5 to 15 % of the lattice.
2B = The coating has flaked along the edges and on parts of the squares. The area affected is 15 to 35 % of the lattice.
1B = The coating has flaked along the edges of cuts in large ribbons, and whole squares have detached. The area affected is 35 to 65 % of the lattice.
0B = Flaking and detachment worse than Grade 1.

Repeatability within one rating unit is generally observed for coatings on metals for both methods, with reproducibility of 1 to 2 units. The method is widely used and is viewed as "simple" as well as low in cost.

Peel Adhesion Testing on Plastic Substrates

ASTM D3359 has drawn fire when used for substrates other than metal, such as plastics. The central issues are that the test may lack reproducibility and does not relate to its intended application. Poor reproducibility is a direct result of several factors intrinsic to the materials employed and the procedure itself. More importantly, in this instance the test is being applied beyond its intended scope. ASTM D3359 was designed for relatively ductile coatings applied to metal substrates, not for coatings (often brittle) applied to soft plastic parts [1].

Nevertheless, the tape test enjoys widespread popularity. The tape test is economical to perform, lends

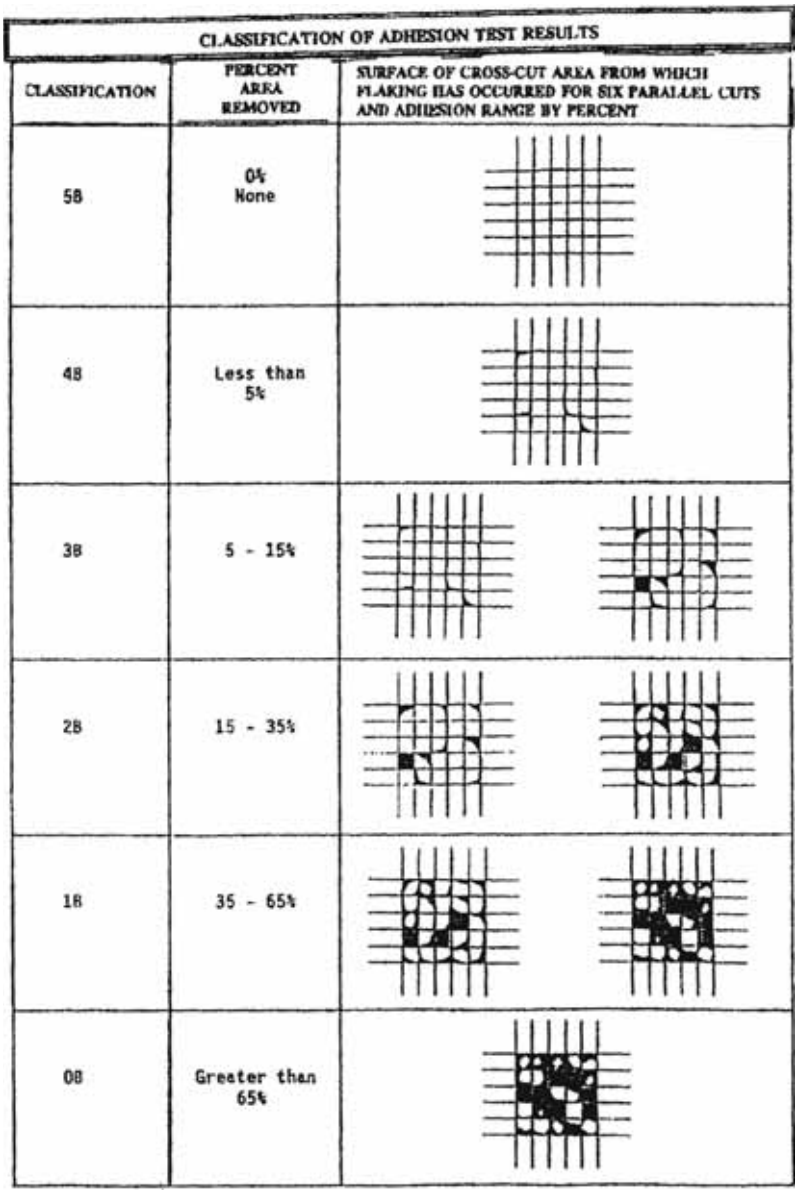

Fig. 5—Classification of adhesion test results. From ASTM D3359.

itself to job site application, and most importantly, after decades of use, people feel comfortable with it [42]. Unfortunately, the often unique functional requirements of coatings on plastic substrates dictate that the tape test as written may not be a satisfactory measure of practical adhesion performance.

When a flexible adhesive tape is applied to a rigid coated substrate surface and then removed, the removal process has been described in terms of the "peel phenomenon," as illustrated in Fig. 6.

Peeling begins at the "toothed" leading edge (at the right) and proceeds along the coating-adhesive interface. It is reasonable to assume that any coating removal is due to a tensile force generated along this interface, which would be a function of the rheological properties of the backing and adhesive layer materials and the strength of the bond between the adhesive layer and the coating surface. Note, however, that in actuality this force is distributed over a discreet distance (0 to A in Fig. 6), which relates directly to

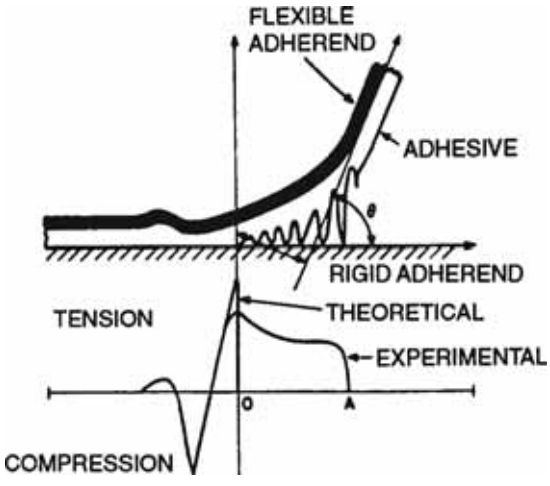

Fig. 6—Peel profile [62].

the properties described [63], not concentrated at a point (0 in Fig. 6) as in the theoretical case, though tensile force is greatest at the origin for both. It is worthwhile to note the significant compressive force which arises from the response of the tape-backing material to being stretched, which precedes the tensile force. Both tensile and compressive forces are involved in tape testing.

Close scrutiny of the tape test with respect to the nature of the tape employed and certain aspects of the procedure itself reveal several factors, each or any combination of which can dramatically affect the results of the test as discussed below.

The Tape Controversy

Beginning in 1991, given the withdrawal of the originally specified tape, 3M-710, ASTM D3359 no longer specified a specific tape. Differences in tapes can lead to different results for reasons noted above since small changes in backing stiffness and adhesive rheology cause large changes in the tension area. It is also important to note that tapes, like most products, are manufactured to meet minimum standards. A given lot may surpass these criteria and be suitable for general market distribution, but a source of serious and unexpected error for tape testing [63]. There was, in fact, a commercially available tape test kit that included a tape with adhesion variations of up to 50 % claimed by the manufacturer [64]. And, of course, tapes age on storage. Bond strengths change over time.

While there are tapes available that would appear to deliver consistent performance, a given tape does not adhere equally well to all coatings. For example, the peel removal force of the tape previously recommended by ASTM (3M-710) was examined with seven coatings. It was found that while peel was indeed consistent for a given coating, it varied by 25 % between the highest and lowest ratings among coatings. This observation could be the result of several factors, notably coating composition and topology, but the bottom line is that no single tape is likely to be suitable for testing all coatings. It is also useful to note the tape test does not give an absolute value for the force required for bond rupture, but serves only as an indicator that some minimum value for bond strength was met or exceeded [1,2].

Procedural Problems

The tape test is operator intensive. By design it was made as simple as possible to perform and requires a minimum of specialized equipment and materials that must meet certain specifications. Therefore, the burden of accuracy and reproducibility relies largely upon the skill of the operator and his/her ability to perform the test in a consistent manner. Key steps that directly reflect the importance of operator skill include the angle and rate of tape removal and the visual assessment of the tested sample. It is not unexpected that different operators might obtain different results [1,2].

PEEL ANGLE AND RATE

The standard requires that the free end of the tape be removed rapidly at as close to a 180° angle as possible. But if peel angle and rate vary, the force required to remove the tape can change dramatically. Nearly linear increases were observed in peel force approaching 100 % as peel angle was changed from 135 to 180°, and similar large differences can be expected in peel force as peel rate varies. These effects are related in that they both reflect certain rheological properties of the backing and adhesive, which are molecular in origin, but the most useful conclusion is that these phenomena can make large contributions and must be minimized to assure reproducibility [65].

VISUAL ASSESSMENT

The final step in the test is visual assessment of coating removed from the specimen, and this can be subjective in nature. This assessment can vary among individuals evaluating the same specimen [65].

Performance in the tape test is based on the amount of coating removed compared to a relative scale. But it was found that the exposure of substrate can be due to factors other than coating adhesion, arising from the requirement that the coating be cut (hence the synonym "cross-hatch adhesion test"). Justification for the cutting step is reasonable; cutting provides a free edge from which peeling can begin without having to overcome the cohesive strength of the coating layer. This might be suitable for coatings applied to metal substrates, but for coatings applied to plastics, the cutting process can lead to false indications of poor adhesion. This is due to the unique interfacial zone mentioned earlier. For coatings on soft plastics, how deep should this cut penetrate? Is it possible to cut only to the interface?

If microscopic examination of panels is included, in several instances it is clearly evident that coating removal results from substrate failure at or below the interface, not from adhesive failure between coating and substrate. At the same time, it is also observed that cohesive failure within the coating layer is a frequent occurrence. The latter observation is significant in that the tape test assessment criteria make no provision for it [1,2].

Mechanized Tape Test

A mechanized tape test was published by ASTM Committee B 8 in 2000. The scope of ASTM B905, Test Methods for Assessing the Adhesion of Metallic and Inorganic Coatings by the Mechanized Tape Test, includes the assessment of adhesion of metallic and inorganic coatings and other thin films to metallic and nonmetallic substrates. A pressure-sensitive tape is applied to the coated surface and then a mechanized device is utilized to remove the tape at a regulated, uniform rate and constant angle while the removal force is simultaneously recorded (Fig. 7). Four methods are described: A1 and A2, which do not involve cuts made to the coating (for use on parts), and B1 and B2, which use a cross-hatch pattern of six lines (plus six at 90°) for laboratory use. Methods 1 and 2 refer to peel angles of 90° and 180°, respectively. Methods B1 and B2 are not recommended for polymeric substrates. For Method A coating detachment (failure) or no coating detachment (pass) are reported versus the maximum registered peel force. For Methods B a classification similar to ASTM D3359 is reported versus the maximum registered peel force. The spacing of cuts, however, is 4 mm versus 1 or 2 mm in D3359. In B 905 a 90° peel angle is preferred "due to the stress strain behavior of the tape," versus the 180° peel angle of D3359.

An interlaboratory study during the development of the test method revealed that the maximum peel force of the tape depends significantly on the type of coating, the type of tape, the peel rate, and the peel angle. The pressure used

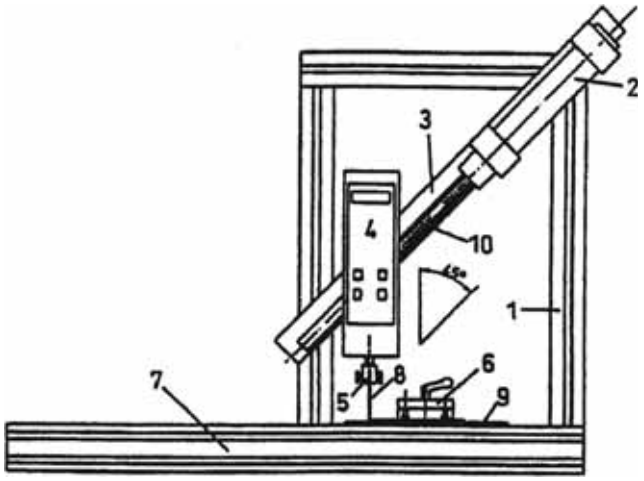

Fig. 7—Mechanized tape tester.

for adhering the tape (a roller is used) was not significant. Results for the four test methods should not be compared. While the methods provide a regulated uniform peel rate and constant angle of test, and most importantly provide a way of measuring peel force, the other underlying issues in tape testing are not overcome. If two different coatings have different peel forces despite a single tape, peel rate, and angle of peel, then the adhesion rating/results are still not directly comparable.

Other Peel Tests

The corresponding test in the International Standards Organization to ASTM D3359 is ISO 2409. The cross-hatch test is used in ISO 2409 up to a coating thickness of 10 mils (250 μm). A single crosscut test is used above 10 mils, versus 5 mils (125 μm) for D3359. A 1-mm cross-hatch spacing is used for a coating thickness up to 60 μm for hard substrates, a 2-mm spacing for soft substrates, a 2-mm spacing for coatings 61–120 μm, and a 3-mm spacing above 120 μm. In ISO 2409 six cuts for the 90° cross-hatch are made in each direction. In D3359 a 1-mm spacing is used for coatings up to a thickness of 50 μm (11 cuts in each direction) and a 2-mm spacing for coatings 50–125 μm (6 cuts), with the single crosscut test applied at higher coating thickness. In ISO 2409 the tape is removed at an angle of 120° (angle away from operator) versus 180° in D3359. The classification scheme is 0 to 5 with 0 meaning no coating detachment in ISO 2409. This is the opposite in D3359, with ratings 5B to 0B, with 0B signifying greater than 65% coating removal. Thus ISO 2409 and ASTM 3359, while both being tape peel tests, differ in many significant ways, not the least of which being that the classification schemes signify opposite results.

Numerous tape peel tests exist in the industry. Examples include the General Motors Engineering Standard GM 9071P-Tape Adhesion Test for Paint Finishes, which is similar to ASTM D3359, and Boeing Specification Support Standard (BSS) 7225, which provides more varied cross-hatch patterns than D3359 and provides specific procedures for tape testing after wet immersion.

Direct Tensile Testing

A long-used approach to coating adhesion testing is the direct tensile test, perhaps "conceptually" the simplest of all methods for measuring adhesion. A dolly or stud is bonded to the coating film. The normally applied force that is required to remove the film is measured. If failure occurs at the substrate-film interface, this force is taken to be the "force of adhesion." An obvious limitation is, of course, the strength of the adhesive bond of the stud to the cured coating. Such methods have been available since the 1930s. Many of these test methods have unfortunately suffered from their own lack of reproducibility. This is not unexpected since the forces involved are not quite as simple as appearance would have it [5,66].

It is essential that the force is applied strictly in the direction normal to the sample and that no bending moment is active across the test area. Deviations from symmetry in the test arrangement, poor alignment, deviations from homogeneity and of thickness of the adhesive (coating), and random variations in the strength of the bond between film and substrate affect test results [5,66].

The stress at locations where the adhesive film is thinner will be higher than the average stress and will be transmitted to the film under test. Another factor may be peeling during the test, which is not easily identified or analyzed.

The adhesive used to bond a stud to the coating has the potential to influence the coating film properties by penetration through the film into microcracks and possibly into the substrate [66]. Test adhesive flexibility may also be an issue, as well as the flexibility of the substrate, if the sample is unrestrained.

There exists now within ASTM both laboratory and field versions of direct tension tests for coatings. Test Method for Measuring Adhesion of Organic Coatings to Plastic Substrates by Direct Tensile Testing. ASTM D5179, while limited to organic coatings on plastics, uses a restrained sample and commonly available tensile test apparatus. The second, Method for Pull-Off Strength of Coatings Using Portable Adhesion-Testers, ASTM D4541, defines a class of portable pull-off adhesion testers for field evaluation of coating adhesion. ASTM D5179 is the successor to numerous attempts to develop a reproducible coating tension test and was approved in 1991. It will be discussed first.

ASTM D5179

This test covers the laboratory determination of adhesion of organic coatings to plastic substrates by mounting and removing an aluminum stud from the surface of a coating and measuring the force required to break the coating/substrate bond with a tensile tester. The test method provides an inexpensive test assembly, which can be used with most tensile test machines. The method is used to compare the pull-off strength (commonly referred to as adhesion) of coatings to various plastic substrates, thus allowing for a quantitative comparison of various coating/substrate combinations.

A carefully prepared 2-cm diameter aluminum stud is bonded directly to a coated, cured panel using a cyanoacrylate adhesive. The adhesive is allowed to cure for 2 h at room temperature. Adhesive buildup is removed from around the stud. The specimen is then subjected to test on a tensile tester equipped with an upper coupling adapter and a restraining device (Fig. 8) to provide for sample alignment and minimal substrate flexing. The sample bearing the stud is installed in the restraining device, with only the stud protruding. The tensile machine crosshead is lowered so the upper coupling adaptor can be attached to the specimen.

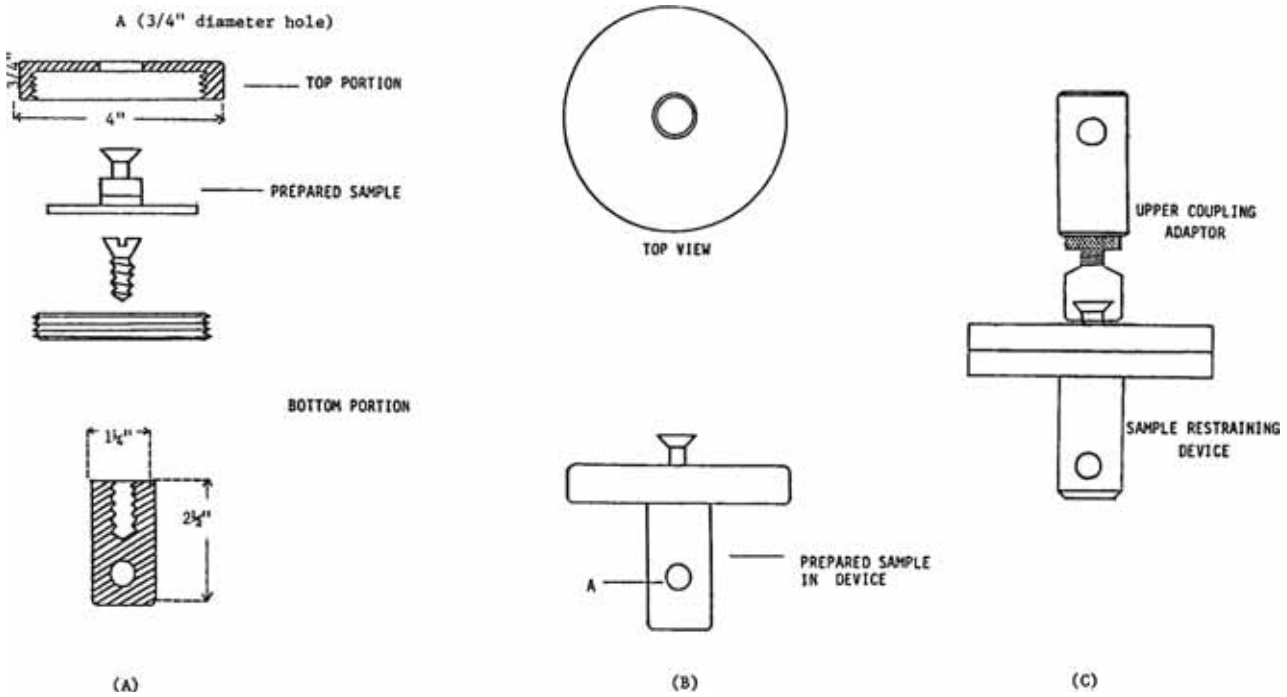

Fig. 8—Direct tensile restraining device. From ASTM D5179.

When testing thin substrates, a piece of plastic is placed in the restraining device behind the specimen to insure a rigid assembly. The tension test is conducted, and pull strength recorded. Each specimen is rated according to type of coating failure, as follows:

A = Adhesive failure of the coating from the substrate.
C = Cohesive failure in the coating.
AC = Combination of adhesive failure at the coating/substrate interface and cohesive failure in the coating.
S = Adhesive failure at the stud.
CS = Combination of adhesive failure at the stud and cohesive failure in the coating.

For multilayer coatings, failure between the layers is noted and labeled as CM. Five specimens of each coated substrate are tested one day and five on a second day. If one specimen differs significantly from the other four tested at the same time, fails because of an uneven (nonplanar) stud, or for another reason performs unlike the other four, a replacement specimen is tested. The stud and specimen are carefully examined. The adhesive should have been applied uniformly to the entire stud surface. Coating should have pulled off uniformly over the *entire* stud surface either with adhesive failure from the substrate (A) or cohesive failure in the coating (C). If failure is less than 90 % A or C (or CM), if the adhesive has failed at the stud, a retest, exercising particular care in the specimen and stud preparation is performed. Pull strength for the ten runs on each coating substrate combination are averaged and reported.

The precision and bias are primarily dependent upon the accuracy of the force measurements, the alignment of the device, and the care exercised in stud and specimen preparation, and in the care in testing. A ten-laboratory round robin on ten samples gave an average standard deviation of 29 % for reproducibility and 22 % for repeatability. A range of pull strengths of 2 orders of magnitude has been observed (Table 1) for diverse coating-plastic combinations.

ASTM D4541

This test method defines a class of portable adhesion testers for measuring the pull-off strength of coatings. The method covers a procedure and apparatus for evaluating pull-off strength by determining either the greatest perpendicular force (in tension) that a surface area can bear before a plug of material is detached or whether the surface remains intact at a prescribed force (pass/fail). Failure will occur along the weakest plane within the system comprised of the test fixture, adhesive, coating system, and substrate and will be exposed by the fracture surface. The method maximizes tensile stress as compared to the shear stress applied by other methods such as scratch or knife adhesion, and results are not comparable. It is recognized that the pull-off strength reflects both material and instrumental parameters and therefore provides a relative, not absolute, measure of adhesion. The pull adhesion testers defined are portable and capable of applying a concentric load and counter load to a single surface so that coatings in the field can be tested even though only one side is accessible. Measurements are limited by the strength of adhesion bonds between the loading fixture and the specimen surface or the cohesive strength of the substrate. The pull-off test is performed by securing a "loading fixture" (dolly or stud) normal (perpendicular) to the surface of the coating with an adhesive. After the adhesive is cured, the testing apparatus is attached to the loading fixture and aligned to apply tension normal to the test surface. The force applied to the loading fixture is then gradually increased (in less than 100 s) and monitored until either

TABLE 1—Representative pull strength for organic coatings on plastics

Sample No.	Coating	Substrate	Failure Mode	Pounds Per Square Inch[a]
1	Lacquer	Polyester/ Polycarbonate	C	58
2	Lacquer	Polycarbonate	A	36
3	Lacquer	ABC	C	82
4	Lacquer	Polycarbonate	A	37

14	Enamel	PPO/Nylon	A	242

[a] To convert to metric, multiply by 6.89 kPa.
NOTE: ABC = acrylonitule-butadiene-styrene, PVC = polyvinyl chloride, PPO = polyphenylent ether.

a plug of coating material is detached or a specified value is reached. The nature of the failure is assessed as to the percent of adhesive or cohesive failure, and the actual interfaces and layers involved are identified. The pull-off strength is computed based on the maximum indicated load, the instrument calibration data, and the original surface area stressed (Fig. 9).

This method is general and is applicable to any portable apparatus meeting the standard's basic requirements for determining the pull-off strength of coatings. Five apparatuses are commonly recognized to meet the requirements of the standard.

It is known that the rigidity of the substrate affects pull-off strength results and is not a controllable test variable in field measurements as defined by this standard. For example, steel substrates of less than 1/8 in. (3.2 mm) thickness show reduced pull-off strength results compared to 1/4-in. (6.4-mm) thick panels.

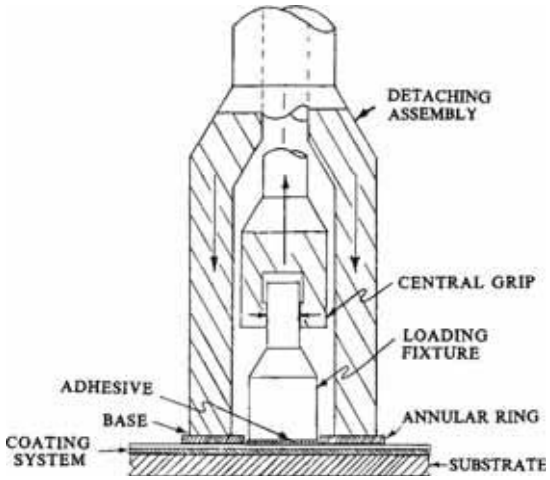

Fig. 9—Portable adhesion tester. From ASTM D4541.

Errors in measurement in this test result from alignment of the apparatus that is not normal to the surface, poor definition of the area stressed due to improper application of the adhesive, poorly defined glue lines and boundaries, holidays in the adhesive caused by voids or inclusions, improperly prepared surfaces, and sliding or twisting of the fixture during the initial adhesive cure. Also, scratched or scored samples may contain stress concentrations leading to premature fractures. Interlaboratory data have been obtained for four commercial test apparatus and are presented in Table 2.

ISO 4624

Similar pull-off test methodology has been approved through the International Standards Organization, and the parameters involved have been carefully studied. ISO 4624, "Pull-off Test for Adhesion," was approved in 1978. ISO 4624 specifies two different tests assemblies (A and B of Fig. 10).

Test Assembly A (Sandwich Method) consists of a substrate painted on one or both sides, with test cylinders (studs) with a specified diameter bonded coaxially to the coated test surface and on the reverse. Test Assembly B consists of a rigid substrate coated on one side, with one test cylinder (stud) applied to that side only. While the latter is the more practical, Test Assembly A on stress analysis shows a smoother stress distribution than B. Test Assembly B shows strong stress peaks at the coating layer periphery. The result is that Test Assembly B shows 20 to 60 % lower breaking strength results than the sandwich method for several organic coatings on metal [67].

TABLE 2—ASTM D 4541 interlaboratory data (psi)[a]

Instrument Loading Fixture Diameter Paint Sample	Patti 13 mm	Elcometer 20 mm	Hate 19 mm (mean of 3 results)	Dyna 50 mm
A	1160	586	1185	201
B	1099	624	1157	185
C	1333	827	1245	190
D	1678	888	1686	297

[a] To convert to metric, multiply by 6.89 kPa.

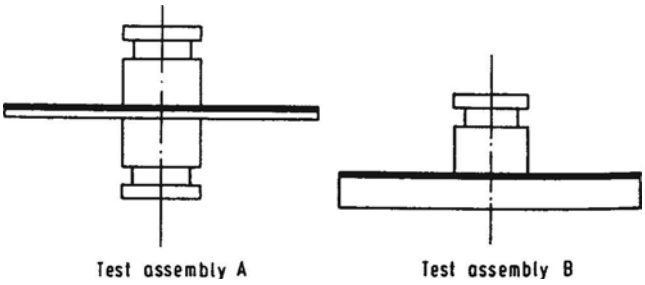

Fig. 10—ISO 4624 test assemblies.

For Test Assembly B, breaking strength values have been shown to be a function of the diameter of test cylinders (studs) as well as their geometry. On the range of 10 to 28 mm diameters, a factor of 2 in breaking strength was seen with a peak at about 14-mm diameter. It was observed that tensile forces only affected the central part of the test area. Even test cylinders of the same diameter, but different shapes, gave different results, up to 45 % lower. It has been noted that while uniform tensile stress can only be approached, the length of the test cylinder (stud) should be no less than half its diameter. When this is done, similar results are achieved regardless of cylinder diameter [67].

Perhaps it is only a coincidence, but it is interesting to note in Table 2 for apparatus meeting ASTM D4541 that the loading fixture diameter and geometry differ significantly and at least partially account for the greater than factor of 4 variation in test results, with the apparatus having a 50-mm loading fixture diameter showing the lowest numerical results.

Substrate thickness (flexibility) has a significant effect upon results. In a study of steel panels in the range of 2 to 30 mm thick, breaking strength increased to a thickness of 15 mm using Test Assembly B. A comparison of results with the sandwich method for substrates above 15-mm thickness, however, still showed breaking strength values about one third higher for Test Assembly A. These observations can be explained in terms of differences in stress distribution. Thinner substrates show increased stress intensity at the periphery, which is distinguishable up to 15-mm thickness [67].

ISO 4624 specifies that tensile stress shall not be increased at a rate greater than 1 MPa/s, so that failure occurs within 90 s of initial stress application. An investigation of the rate of tensile stress increase in the range 0.15 to 1.2 MPa/s yielded indistinguishable results [67].

Sample parameters are important. Coating thickness (and adhesive thickness) is a key factor. The energy stored in a 5-mil (125μm) coating, by virtue of its internal strain, increases as the coating thickness increases and at a particular thickness can be sufficient to overcome the work of adhesion at the interface (spontaneous peeling). The variation is largest at thicknesses below 125 μm (5 mils), which of course is the area of most practical application. It was also observed that at the lowest coating thickness for the coatings studied, cohesive failure occurred in the uppermost parts of the coating, leaving a very thin film of coating on the test cylinder (stud). With thicker coatings, the fracture propagated deeper into the coating. Through study of the locus of failure, one can also study the effects of environmental conditions (aging, solvents, moisture) and of coating resin cure [67].

More recent studies have also looked at instrument and sample parameters. Rocke et al. studied the influence of measured pull-off strength by stud area, adhesive thickness, the thickness of the substrate, as well as coating composition [68]. A comprehensive Norwegian study involved some 1400 pull tests using three different instruments on a three-coat paint system and on thermal arc-sprayed ALMg5 on blast-cleaned steel, with the blast-cleaned steel also assessed as a standard. The parameters investigated included the effect of panel thickness on pull strength (5, 8, and 12 mm), the effect of cure time of the paint system on pull-off strength (8, 15, 28, 37, and 76 days after application of the top coat), the effect of four different brands of cyanoacrylate adhesive on pull-off strength, the effect of different temperatures on adhesive cure or pull-off on pull-off strength (8.5°C, 23°C, and 70°C), the effect of stud diameter on pull-off strength, and the effect of cutting around the edge of the stud on pull-off strength. The data reported were the averages of 10 to 30 runs [69].

Adhesion on blast-cleaned steel using an epoxy adhesive showed a 24–58 % increase in mean pull-off strength in going from 5 to 12 mm thick panels. The increase in pull-off strength for the three-coat paint system increased 30–34 % from 8- to 76-day coating cure time. Four cyanoacrylate adhesives were cured for 1, 2, 5 at 23°C or 8.5°C at 50 % relative humidity on bare blast-cleaned steel. At 23°C (1h) pull-off strength ranged from 25.6 to 35.4 MPa, while at 5 h pull-off strength ranged from 29.1 to 38.2 MPa. Corresponding data at 8.5°C were 21.5 to 27.0 and 22.2 to 30.6, respectively. Testing of arc spray coated samples at different temperatures showed an increase in pull-off strength for one of two cyanoacrylate adhesives and not the other and also a difference in locus of failure was also noted. Some effect of stud size was seen, with higher mean pull-off strength for studs at 1.57 cm^2 versus 3.14 cm^2. Cutting around the stud showed a slight lowering of pull-off strength (under 10 %). A number of experimental factors affect test results. A 5-mm rigid steel panel is not "infinitely thick." Cured coatings may still be undergoing changes over long time periods. Such changes can effect adhesion. Temperatures of cure coatings and adhesives may affect pull-off strength [69].

Clearly, stress distribution changes, as altered by test apparatus and sample parameters, can alter results dramatically. Pull-off strength (breaking strength) is therefore a relative number. Comparisons must be made carefully in concert with an examination of the locus of failure. Practically speaking, while absolute values are only approached, relative values and studies of the locus of failure are sufficient for most purposes.

Scrape Adhesion Testing

Used to a lesser extent than the preceding methods is ASTM D2197, Test Methods for Adhesion of Organic Coatings by Scrape Adhesion.

This test method covers the determination of the adhesion of organic coatings such as paint, varnish, and lacquer when applied to smooth, flat (planar) panel surfaces. The materials under test are applied at uniform thickness to planar panels, usually sheet metal of uniform surface texture. After drying, the adhesion is determined by pushing the panels beneath a rounded stylus or loop loaded in

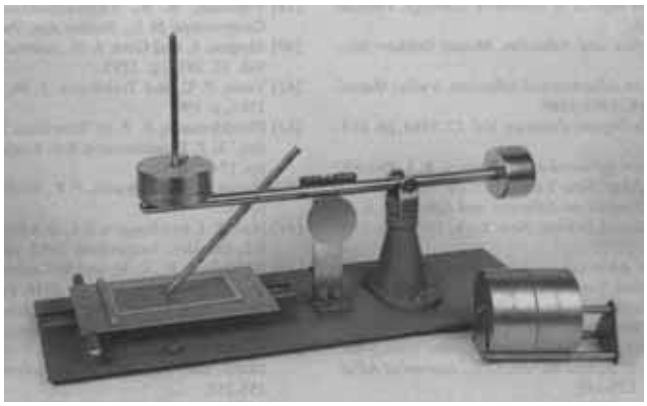

Fig. 11—Balanced-beam scrape adhesion tester.

increasing amounts until the coating is removed from the substrate surface.

The method is most useful in providing relative ratings for a series of coated panels exhibiting significant differences in adhesion. The balanced-beam, scrape-adhesion tester (Fig. 11) consists of a balanced beam to which is secured a platform for supporting weights and a rod at an angle of 45° that holds the scraping loop. The rod is set so that the scraping loop contacts test surfaces directly below the weights. The loop is a 1/16-in. (1.6-mm)-diameter rod bent into a "U" shape with an outside radius of 0.128±0.002 in. (3.25±0.05 mm) hardened to Rockwell HRC 56 to 58 and chromium plated and polished.

At least 1/2 in. (1.3 cm) at the end of a test panel is un-coated. The surface of the substrate must be hard enough so that it is undamaged by the scraping loop. The test procedure is as follows. A test panel on the sliding platform is placed so that it may be moved away from the operator and the uncoated portion is toward the main beam support. Weights are placed on the weight support using an initial amount estimated to be appropriate for the particular coating. The beam is lowered until the loop rests on the uncoated portion of the specimen and the full load is applied; then the sliding platform is slowly pushed away from the operator 1 to 2 s/in. for a distance of at least 3 in. (76 mm). If the coating is removed, the testing is continued using successively smaller loads (0.5-kg increments) until the coating is not removed. If the coating is not removed by the initial scrape, the testing is continued, using successively larger loads (0.5-kg increments) until the coating is removed or until the maximum load of 10 kg has been applied. A new area of the test surface is used each time a scrape is made. When the critical load has been approximately located, the test is repeated five times at each of the three loadings: above, below, and at the load determined in the first trial.

For each applied load, the number of times the coating was removed or adhered is tabulated. The load where the scrape results change from mainly adhering to mainly removed, ignoring the first 1/2 in. (13 mm) of the scratch if the coating was removed, is the adhesion failure end point.

Perhaps the most "practical" approach to paint adhesion is assessment by the use of a paint knife. A test method that provides guidance for such evaluations is ASTM D6677, Test Method for Evaluating Adhesion by Knife.

TORQUE TESTS

While the scope of ASTM D3359 provides for the testing of coatings on metal substrates only, it and other tests discussed previously have been used to assess the adhesion of coatings on wood. Little data have, however, been published with wood as the substrate. Several papers using a torque technique have been published [70–73]. While such methods have not been standardized, it was felt that they might be of interest to readers. In this shear technique, studs are glued on the painted samples using a solvent-free, dual-component epoxy glue. After the glue has dried, a slot is drilled in the paint film around the studs until the wood surface is reached. The studs are removed using a recording torque wrench. The failure load is noted and the locus of failure determined. The shear stress (adhesion value) is calculated using the equation $T = (167I)/(\Pi d3)$ where I is the measured torque (Nm), and d is the diameter of the stud (in this case, 12.5 mm). A minimum of six replicates is used for the calculation of the mean adhesion value. Adhesion values are given in MNm^{-2}. Painted samples have been tested dry and after water immersion [74,75].

UNIFORM DOUBLE-CANTILEVER BEAM TESTS

While not standardized, workers have found success with a uniform double-cantilever beam technique for the testing of the adhesion of coatings on wood [74,75].

Other ASTM Standards

Other ASTM standards that pertain to aspects of adhesion measurements of films and coatings include the following:

ASTM B533 – Standard Test Method for Peel Strength of Metal Electroplated Plastics.

ASTM B571 – Standard Practice for Qualitative Adhesion Testing of Metallic Coatings. (This method includes bend, burnishing, chisel-knife, draw, file, grind-saw, heat-quench impact, peel, push, and scribe-grind tests.)

ASTM C633 – Standard Test Method for Adhesion or Cohesion Strength of Thermal Spray Coatings.

ASTM D3730 – Guide for Testing High-Performance Interior Architectural Wall Coatings. (This guide includes a pull-strength test for adhesion assessment.)

ASTM D4145 – Standard Test Method for Coating Flexibility of Prepainted Sheet. (This method includes a tape pull-off test.)

ASTM D4146 – Standard Test Method for Formability of Zinc-Rich Primer/Chromate Complex Coatings on Steel. (This method is a tape test after dome-shaped deformation.)

ASTM D7234 – Standard Test Method for Pull-Off Adhesion Strength of Coatings on Concrete Using Portable Pull-Off Adhesion Testers.

ASTM D7334 – Standard Practice for Surface Wettability of Coatings, Substrates and Pigments by Advancing Contact Angle Measurement.

ASTM F692 – Standard Test Method for Measuring Adhesion Strength of Solderable Films to Substrates.

ASTM F1044 – Standard Test Method for Shear Testing of Calcium Phosphate Coatings and Metallic Coatings.

ASTM F1147 – Standard Test Method for Tension Testing of Calcium Phosphate and Metal Coatings.

ASTM F1842 – Standard Test Method for Determining Ink or Coating Adhesion on Plastic Substrates for Membrane Switch Applications. (This test is based upon D3359.)

Additional tests exist for electrodeposits, and bending, burnishing, and wrapping tests for coatings on wire. Tests for adhesives have also been applied to coatings as well. Use of reverse impact tests, lap and butt joint tests, and tensile shear tests have been reported [1].

CONCLUSIONS

Basic adhesion is the summation of multiple phenomena. Ideal adhesion is probably neither obtainable nor measurable experimentally. Practical techniques do, however, allow sufficient assessment of relative adhesion for most purposes, if used with care and knowledge. Workers need to understand both basic adhesion concepts and the factors affecting practical adhesion for systems of their interest if they are to make improvements in real world products.

Abrasion Resistance*

Daniel K. Slawson[1]

PREFACE

IN PREPARATION OF THIS CHAPTER, THE CONTENTS of the fourteenth edition were drawn upon. The author acknowledges the authors of the fourteenth edition. The current edition will review and update the topics as addressed by the previous authors, introduce new technology that has been developed, and include up-to-date references.

The problem of resistance to abrasion exists all around us: on floors, walls, furniture, automobiles, farm implements, construction equipment, military gear, appliances, shoe soles, and so on. Because resistance to abrasion is a basic factor in the durability of a coating, its measurement is of practical importance to both producer and consumer.

Abrasion is caused by mechanical actions such as rubbing, scraping, or erosion from wind and water. It can take two general forms: marring or wearing.

DEFINITIONS

Mar abrasion consists of permanent deformations that have not ruptured the surface of a coating. The resistance of a coating to marring is its ability to withstand scuffing actions that tend to disfigure or change the appearance of its surface. Some examples of potential causes of marring of organic coatings are (a) sliding an object across the surface of furniture; (b) rubbing of a belt buckle, button, zipper, or rough fabric on an automobile finish; (c) sliding a toy across a wall or a refrigerator door, etc.

Wear abrasion is caused by mechanical action that removes material from the surface of a coating. In many cases, the removal is gradual or progressive due to repetitive mechanical action.

RELATIONSHIP TO OTHER PHYSICAL PROPERTIES

Abrasion resistance is not a unique or isolated property of a material but is rather related to other physical characteristics such as hardness, cohesive and tensile strength, elasticity, and toughness. Also, from the standpoint of retaining its protective or decorative function, the thickness of a coating can be an important factor.

Hardness, Elasticity, and Tensile Strength

Abrasion resistance is related to hardness, yet the relationship is not simple. A first thought might be that the harder a coating, the better would be the abrasion resistance; however, this is not always true. Steel is much harder than rubber, for example, but steel "tires" on an automobile, in addition to not giving a smooth ride, would not last long on concrete roads in comparison to the service life of a good rubber tire. The ability of a material, such as a rubber tire, to undergo elastic deformation and recover or "to ride with the blow" is associated with good abrasion resistance.

The energy transferred to an elastic material by an impacting object is largely returned to the object, though redirected, instead of being expended in the destruction (separation and removal of material) of the impacted surface. From a fundamental viewpoint, this is a consequence of the smaller deceleration and hence smaller force generated, since force is equal to the product of mass and acceleration, when the impact is with a material that will deform or "give" with the impacting object. If the deformation caused by the object is not elastic, the material will yield and flow, causing damage. Therefore, soft materials with a low tensile strength are not abrasion resistant.

The fact that elastic materials are often abrasion resistant does not mean that hard materials are not abrasion resistant. Theoretically, however, if one is given two materials of equal tensile strength, the material of lower modulus should have the best abrasion resistance. The deceptive factor here is that a hard material usually has a much higher tensile strength than a soft material. Thus, when a rubber is compared with steel, materials with orders of magnitude difference in tensile strength are being considered. The fact that rubber is abrasion resistant emphasizes that the value of a low modulus of elasticity and adequate tensile strength are factors that play a role in obtaining good abrasion resistance.

In theory, a very hard material that has a hardness and cohesive strength adequate to completely resist any impact force it might encounter would not be dependent on rubberlike elasticity to reduce or dissipate impact stresses. It would be more abrasion resistant than the best elastic but weaker material [1].

CORRELATION WITH END-USE PERFORMANCE

From the discussion above, it is apparent that the measurement of abrasion resistance involves measuring a complex combination of interrelated properties among which there is no direct relationship. The task of devising a test methodology that will correlate with end-use performance is, therefore, complex and difficult but not impossible to

* This chapter is an abridged and modified version of the chapter with the same title, written by Mark P. Morse, found in the previous edition of this manual.

develop. If the test method subjects the material under test to a composite of destructive forces similar to those met in service, then the test method will correlate—or predict—the service performance of the material in at least a qualitative or relative ranking respect.

When accelerated tests are being considered, even tests that rank materials in the same sequence as actual service tests, a quantitative correspondence with actual service is seldom expected or obtained. Actual end-use tests, while the most reliable in providing an indication of a material's probable long-term durability, suffer from the difficulties of ensuring equivalent usage and measurement, especially when the comparison of different materials is attempted. Because of such difficulties and because service tests are usually very time consuming, a wide variety of test machines have been developed to provide an accelerated indication of the abrasion resistance of coatings and related materials such as laminate flooring, plastics, linoleum, and wall coverings. In a comprehensive review article by Harper [2], there is a list of no less than 49 different abrasion-causing machines. An investigation by the International Study Committee for Wear Tests of Flooring Performance [3], in which seven commercial, organic flooring materials were systematically tested on 21 abrasion machines of 17 different types, indicated that very few of these machines were capable of providing a reliable comparison of the abrasion resistance of widely different materials that could be correlated with end-use performance. In addition, the different machines did not correlate very well with each other.

On the basis of a round robin conducted in 1956 by ASTM with six different clear floor coatings evaluated by six different abrasion test methods [4], only two of the methods were found to correlate with actual end-use performance and to have the reproducibility necessary for acceptance as ASTM standards. These were ASTM Test Method for Abrasion Resistance of Organic Coatings by Falling Abrasive (ASTM D968) and ASTM Test Method for Abrasion Resistance of Organic Coatings by Air Blast Abrasive (ASTM D658, withdrawn in 1996). The jet abrader (ASTM D658, withdrawn in 1996) offers greater speed and precision of measurement [1]. More recent comparative testing (see Comparison of Wear Abrasion Testers) indicates ASTM D658 is superior to ASTM D968 and that ASTM Test Method for Abrasion Resistance of Organic Coatings by the Taber® Abraser (ASTM D4060) is superior to both of these tests regarding precision and sensitivity in differentiating between coatings.

MECHANISM OF ABRASION

The success of the particle impingement types of abrasion testers in correlating with service performance is perhaps not surprising when one considers the abrading mechanism. Whether or not a particular type of abrasion test correlates with end-use performance depends not only on a similarity of abrading mechanisms and the abradants used in both cases, but also on the extent to which that mechanism is maintained during the course of the abrasion test. It is on the latter factor that many methods fail.

Rubbing (friction) and scraping methods obviously wear away the test surface in a different manner than methods in which abrasive particles are contacted with the surface. One aspect of the mechanistic difference lies in the angle of contact with the surface. Abrasive particles striking the surface of a coating at nearly normal incidence tend to compress, scar, and cut into the coating. As a result, minute portions of the coating eventually should be crosscut and displaced. On the other hand, the rubbing and scraping types of abrasion that take place at near grazing incidence would tend to undercut and to shear through very thin layers of the coating in successive, irregular slices that ultimately wear it away. Different devices might incorporate various degrees of these basic processes, depending on the angle and force of particle attack.

Apart from the nature of the above mechanisms, it should be apparent that whatever the mechanism, it is not maintained uniformly in friction methods. Such methods suffer from changes in the abrading conditions as the testing proceeds, either because of heating of the specimen or clogging of the abradant or other.

If an abrasion test using the direct impingement of particles is chosen so the undesirable frictional effects are avoided, there may be doubt about whether the method correlates well with a type of service in which the coating is, for example, walked upon. Yet, the previously mentioned ASTM round robin of abrasion tests carried out with floor coatings clearly established the validity of particle-impingement-type tests for evaluating this type of end-use service life.

Until the mechanism of abrasion is more completely studied and understood, industry must continue to rely to a large extent on experimentation and even intuition when devising abrasion test methods. In addition, properly designed test programs must be employed to determine the extent to which a given method correlates with actual end-use performance [1]. A side variety of useful abrasion testing procedures are described in sections that follow.

ABRADANTS

The most sophisticated and precise abrasion testing instruments are only as good as the contact point between the test specimen and the abradant used to wear the specimen. A consistent abrasive material to evenly wear the specimen is key to accurate abrasion testing. The abradant must be consistent from lot to lot. The Taber Abraser uses a variety of resin (Calibrase®) and vitrified (Calibrade®) abrasion wheels containing a wide range of silicon carbide and aluminum oxide grains. The scrub abrasion testers use black nylon or black hog bristle brushes, sponges, abrasive paper, and stainless steel/nylon balls. The Linear Abraser uses abrasive plugs (Wearasers®) containing the same abrasive material as the Taber Abraser wheels. The Falling Abrasive Test uses Ottawa silica sand and silicon carbide. The oscillating sand tester uses silica or alumina zirconia abrasive.

Falling Abrasive Test

This widely used abrasion test method has both ASTM and federal counterparts. Originally developed at Gardner Laboratory the method has been studied and further developed by others [5]. ASTM D968 employs an apparatus, Fig. 1, that is simple and inexpensive compared with other more complicated instruments, and the test results correlate reasonably well with various types of service [4]. However, the method is laborious and time consuming since large

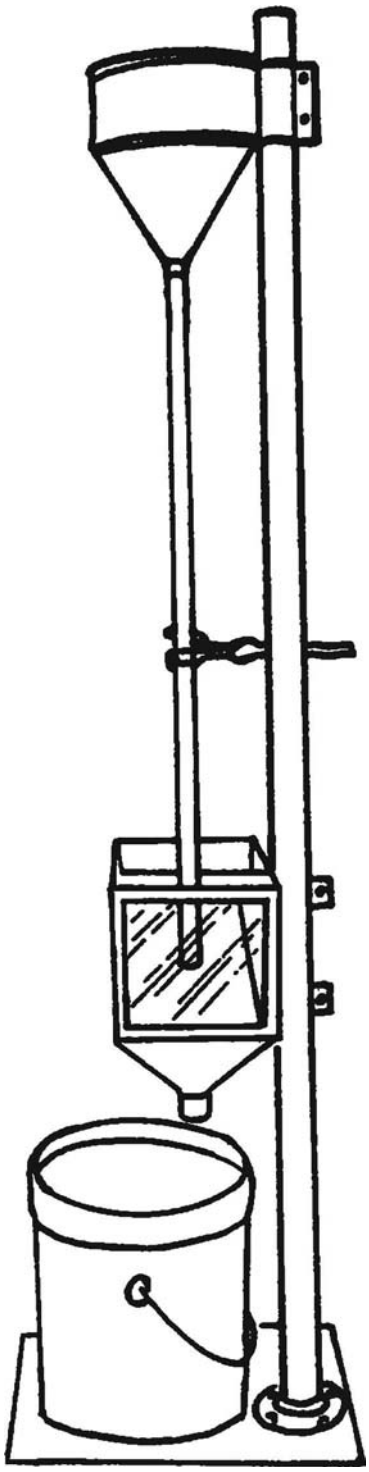

Fig. 1—Falling sand abraser (courtesy of Paul N. Gardner Co.).

quantities of abrasive must be handled due to the slow rate of abrasion, particularly when the material under test is abrasion resistant.

Over the years a variety of abrasives have been used in the basic apparatus. These abrasives include sand, emery, and various grades of silicon carbide. Sand, although having the disadvantage of a slow abrasion rate, is readily available and has given reproducible results at low cost. Therefore, it has been the abrasive of choice in the standard methods. Only sand and silicon carbide are used in ASTM D968, which specifies that a natural silica sand graded to a particular sieve size and known as Ottawa sand is the standard sand abrasive and a silicon carbide of particular sieve size is the other standard abrasive. Abrasion resistance is expressed in terms of the volume of abrasive required to wear through a unit thickness of the coating with the abrasive falling from a specified height through a guide tube. The substrate is supported at a 45° angle to the vertical.

ABRASIVE BLAST METHODS

Air Jet Erosion Tester and Micro-Abrader

These testers shown in Fig. 2 are used to test the erosion resistance of solid materials to a stream of gas containing abrasive particulate. Micro-sized abrasive particles are mixed with pressurized air to generate an abrasive flow. The abrasive flow is propelled and directed through a small nozzle toward the test sample. Material loss, in this case, is achieved via the impingement of small abrasive particles upon the surface of the test sample. Materials such as metals, ceramics, minerals, polymers, composites, abrasives, and coatings can be tested with this instrument. Depending on the test instrument used; the test specimen, temperature, angle of incidence of the jet stream, abrasive particulate speed and flux density, can be varied to best simulate actual conditions.

Fig. 2—Micro-abrader (courtesy of Taber Industries).

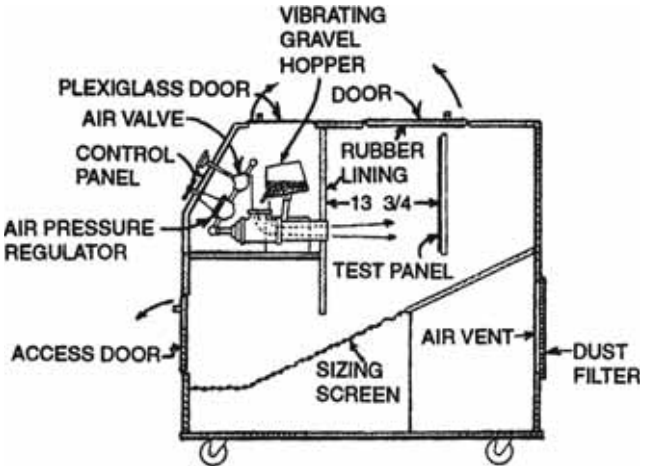

Fig. 3—Interior of a gravelometer (courtesy of the Q-Panel Company).

Gravel Projecting Machine

This machine, which is commonly termed a gravelometer, is a device designed to evaluate the resistance of automotive and railway finishes to abrasion by flying gravel and road ballast. ASTM Test Method for Chip Resistance of Coatings (ASTM D3170) has a description of such a device and provides a procedure for its use. Fig. 3 illustrates the interior components of a device that meets specification given in ASTM D3170. A test chamber is provided in which a coated panel is supported vertically and blasted with a stream of particular gravel. One pint of this gravel is introduced into an air stream having a pressure of 70±2 psi (4.92±0.14 kg/cm^2) over a 10 s period. Tests are usually conducted in a cold room to simulate winter-like driving conditions. At the completion of the test, the coated panel is visually rated for degree of chipping by using a photographic reference standard provided with D3170. SAE Method J400 describes the test procedure used for evaluating the chip resistance of automotive coatings.

METHODS USING ROTATING DISKS

Schiefer Abrasion Testing Machine

(This machine is available from Frazier Precision Instrument Company, Inc., 925 Sweeney Dr., Hagerstown, MD 21740. www.frazierinstrument.com) The machine was designed for measuring wear resistance of textiles such as rugs and fabrics [6–9] but it offers a potentially useful means for evaluating the wear abrasion of organic coatings. It has two unique features: (a) a uniform abrasion pattern and (b) interchangeable steel and Carboloy abradant disks with crosscut and rod patterns that reduce heating and clogging (Fig. 4).

To conduct a wear abrasion test, the specimen is mounted on a motor-driven rotating plate where it is abraded uniformly in all directions by the motion of the offset rotating abradant mounted directly above it. Both specimen and abradant rotate in the same direction with approximately the same angular velocity, 250 rpm, each about its own axis. The axes are spaced 1 in. (2.54 cm) apart and are parallel. The abradant is loaded with a standard weight.

Fig. 4—Schiefer abrasion testing machine (courtesy of Frazier Precision Instrument Company).

METHODS USING ROTATING ABRASIVE WHEELS

Taber® Abraser

(This instrument is available from Taber Industries, 455 Bryant Street, North Tonawanda, New York 14120. www.taber-industries.com) This apparatus, Fig. 5, is widely used for evaluating the wear abrasion resistance of organic coatings. A procedure for its use is given in ASTM Test Method for Abrasion Resistance of Organic Coatings by the Taber Abraser (ASTM D4060), in ISO/DIN Methods 3494 and 4584. ASTM D4060 utilizes a specimen in the form of a 4-in. (10.2-cm)-diameter disk or a 4-in. (10.2-cm)-square mounted on a turntable that is rotated at a fixed speed under a weighted abrading wheel. A wide variety of resin and vitrified abrasion wheels containing a wide range of aluminium oxide and silicon carbide grits create different types of abrasion. An important feature of the Abraser is the wheels traverse a complete circle on the specimen surface. This reveals abrasion resistance at all angles relative to the grain of the specimen. A vacuum pickup is used to remove

Fig. 5—Taber Abraser (courtesy of Taber Industries).

any loose particles generated during actual tests. Wear abrasion resistance is expressed in terms of (a) Wear Index, which is the weight loss per specified number of revolutions (usually 1000) under a specified load (500 or 1000 g), and/or (b) wear cycles per mil, which is the number of cycles required to wear through a 1-mil thickness of coating and is reported as the number of revolutions per mil.

ASTM D6037 Standard Test Methods for Dry Abrasion Mar Resistance of High Gloss Coatings, utilizes two test methods to assess mar resistance by measuring the gloss of abraded and unabraded areas. Mar resistance is directly related to the coating's ability to retain gloss in abraded areas. Test Method A uses a device that contains an abrasive wheel (Taber Calibrase® CS-10 Wheel unless otherwise specified or agreed). Test Method B uses a device that contains a wheel that has been fitted with abrasive paper.

ASTM D1044 Standard Test Method for Resistance of Transparent Plastics to Surface Abrasion describes a procedure for estimating the resistance of transparent plastics to one kind of surface abrasion by measuring the change in optical properties. This test uses Calibrase®, CS-10F Wheels resurfaced on a ST-11 Refacing Stone to create the wear. The abrasive damage is visually judged and numerically quantified by the difference in haze percentage in accordance with Test Method D1003 between abraded and unabraded specimen.

Fig. 6—Taber Grit Feeder Attachment (courtesy of Taber Industries).

Taber® Grit Feeder Attachment

When used with the Taber Abraser, the Grit Feeder, seen in Fig. 6, provides a unique method to evaluate three-body abrasion resistance on a variety of materials. This instrument was originally designed to simulate abrasion caused from grit embedded in leather soled shoes and is typically used to test flooring. Aluminum oxide grit particles are evenly distributed onto the specimen wear path and pass under a pair of leather wheels. This loose grit acts as an abradant and aids in the rolling action that contributes to the physical breakdown of materials. The Abraser Vacuum is attached to the grit feeder, and continuously removes both abraded material and used grit.

In an ASTM round robin, Taber Abraser tests with a series of organic coatings produced abrasion resistance values that exhibited a within-laboratory coefficient of variation of 10 % and an interlaboratory coefficient of variation of 30 %. Another study of the reliability of test results was conducted by Hill and Nick in 1966 [10].

TESTS BASED ON LINEAR MOTION

Straight-Line Reciprocating Machines (Scrub Abrasion Testers)

These machines, as shown in Fig. 7, pull a sled or boat back and forth over the surface of a coated panel. The sled surface can be a brush, a sponge, rubber, or sandpaper. A sled travel of at least 10 in. (25.4 cm) is provided by the machines, and they can provide reciprocating cycles ranging from 35 to 60 per minute.

Both dry and wet surface tests may be performed with these machines. For dry surface tests, wear abrasion resistance is reported as: (a) number of cycles to reach a certain visual end point, (b) degree of abrasion observed after a specified number of cycles, and (c) number of cycles required to abrade through the coating to the substrate.

Procedures for conducting wet adhesion (scrub resistance) tests on interior paints are described in ASTM Test Method for Wet Abrasion Resistance of Interior Paints (ASTM D4213), and ASTM D2486 Standard Test Methods for Scrub Resistance of Wall Paints. Other methods include DIN 52778 and ISO 11998.

In these test procedures, coating films are applied to a plastic substrate and allowed to dry. A sponge surface is mounted on the sled. Both the sled and the coating surface are wet with a soap solution of specified composition. Wet abrasion resistance is reported as: (a) computed rate of

Fig. 7—Scrub Abrasion Tester (courtesy of Byk-Gardner).

Fig. 8—Taber Linear Abraser (courtesy of Taber Industries).

erosion of the wet coating film and (b) number of cycles required to wear through the coating film to the substrate or to produce breaks in the film.

Taber® Linear Abraser

The Taber® Linear Abraser, shown in Fig. 8, utilizes the same abrasive material contained in the Taber Abraser wheels in the form of an abrasive plug (Wearaser®). This instrument is designed to test virtually any size or shape specimen in a wet or dry environment. This instrument can also be modified to evaluate scratch resistance and color transfer. A precision bearing on the spline shaft creates a "free-floating head." As the arm strokes, the abradant follows the contour of the specimen, curved or flat. The user can customize the abradant, stroke length, speed, and weight load. A procedure for its use is given in ASTM Test Method D6279 Test Method for Rub Abrasion Mar Resistance of High Gloss Coatings.

Fig. 9—Taber Large Linear Abraser (courtesy of Taber Industries).

Fig. 10—Taber Reciprocating Abraser (courtesy of Taber Industries).

Taber® Large Linear Abraser

The Large Linear Abraser, shown in Fig. 9, combines a longer test stroke and heavier weight load, than the Taber® Linear Abraser, with a scouring pad to simulate the wear bakeware and cookware receive in extensive home use as it is cleaned.

Taber® Reciprocating Abraser

The Reciprocating Abraser, shown in Fig. 10, referenced in "ISO 1518 Paints and Varnishes—Scratch Test," is used for evaluating resistance to abrasion, scratch, and mar on most flat or slightly contoured objects. A sliding specimen platform moves in a horizontal, reciprocating motion under a stationary tool, generating a linear wear, scratch/mar path.

RCA Abrasion Wear Tester

(This device, is available from Norman Tool and Stamping Co., 15415 Old State Rd., Evansville, IN 47711. www.normantool.com). It is being used for evaluating the abrasion resistance of appliance finishes and of coatings on television set controls. The machine abrades a 2 in. by 2 in. (5.1 cm by 5.1 cm) coated panel surface by passing computer or polyester tape over the surface. A fresh tape surface is presented for each cycle of abrasion. Weights ranging from 55 to 275 g are applied to the tape depending on the nature of the coating under test. Abrasion resistance is reported either as the number of cycles required to produce the onset of visible scuffing or as the number of cycles required to wear through to the substrate.

Oscillating Sand Tester

This testing device, seen in Fig. 11, is used to determine the resistance of transparent plastics and transparent coatings utilized in windows or viewing ports to surface abrasion. The test specimen is mounted in a tray (so that it forms part of the bottom of the tray) and covered with abrasive media to a depth of 12.7 mm. The tray reciprocates in a linear motion at a speed of 300 strokes per minute over a distance of 100 mm. A typical test utilizes a specimen that is 100 nm by 100 mm and is tested for 600 strokes. The results of the test consist of measuring and recording the change in haze

Fig. 11—Taber Oscillating Sand Tester (courtesy of Taber Industries).

and light transmission of the test specimen. This tester is referenced in ASTM F735, Standard Test Method for Abrasion Resistance of Transparent Plastics and Coatings Using the Oscillating Sand Method.

COMPARISON OF ABRASION TESTERS

ASTM Subcommittee D-01.23 conducted a round robin to determine the comparative precision, sensitivity, and correlation of four wear abrasion testing procedures. The procedures were (a) air blast silicon carbide (ASTM D658—discontinued in 1996), (b) falling sand (ASTM D968), (c) falling silicon carbide (ASTM D968), and (d) Taber Abraser (ASTM D4060). The wear abrasion resistance of four coatings with significantly different apparent resistances to abrasion were tested with each device. The results obtained from these tests are recorded in ASTM Report RR D01-1037, which is available at ASTM Headquarters.

From the results, it was concluded that the air blast silicon carbide test and the cycles per mil Taber Abraser test had better sensitivity in differentiating coating abrasion resistances than the other test procedures. The falling sand test, air blast silicon carbide test, and Taber Abraser cycles per mil test ranked the coatings in the same order as the expected performance. The falling silicon carbide test reversed the ranking of two of the coatings. The precision exhibited by the four test procedures are as given in Table 1.

TABLE 1—Comparison of abrasion resistance test method precision

	Coefficients of Variation	
	Within Laboratory	Between Laboratories
Taber Abraser (ASTM D4060)	4 %	16 %
Air Blast Silicon Carbide (ASTM D658)	7 %	10 %
Falling Sand (ASTM D968)	9 %	35 %
Falling Silicon Carbide (ASTM D968)	11 %	45 %

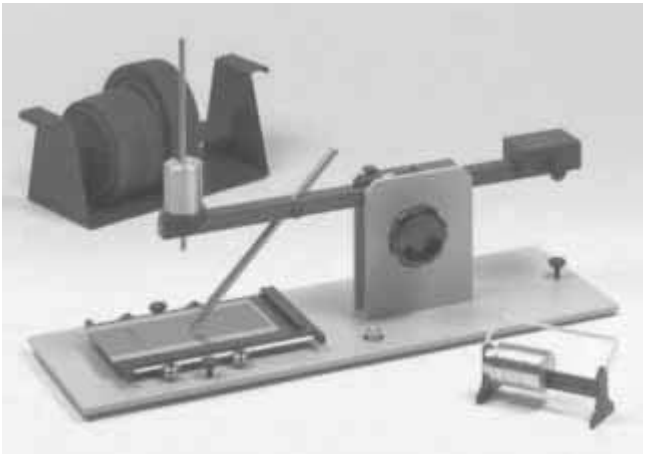

Fig. 12—Balanced Beam Tester (courtesy of Byk-Gardner).

TESTS FOR MAR ABRASION RESISTANCE

Balanced Beam Tester

A useful test for determination of mar resistance involves the use of a balanced beam scrape tester, seen in Fig. 12. ASTM D5178 was developed to determine the mar resistance on smooth, flat surfaces. Results are expressed in terms of force-to-mar films of organic coatings such as paint, varnish, and lacquer when applied to smooth, flat planar panel surfaces. This test is carried out by placing a coated test panel on a movable platform and a weight on the beam. The stylus is lowered gently onto the coated surface and then the platform is pushed against the stylus at a rate of 1/4 in. (6 mm) per second for a distance of at least 3 in. (75 mm). At the end of each stroke, the stylus is raised off the coated panel and the panel is moved slightly to the side to provide a new test surface. The coating is examined for marring. If none is visually observed in the initial scrape, successively greater weights are added to the beam until marring is apparent. If marring is produced in the initial scrape, testing is continued using successively lighter weights until the coating is not marred. The weight required to just produce visible marring is taken as the mar resistance value. Details about the balanced beam tester and its operation can also be found in ASTM D2197, Test Methods for Adhesion of Organic Coatings by Scrape Adhesion, ASTM D2248, Practice for Detergent Resistance of Organic Finishes.

Taber® Shear/Scratch Tester

The Taber Shear/Scratch Tester, seen in Fig. 13, is used to evaluate the scratch and mar resistance of organic coatings, slate, high pressure decorative laminates, and polymeric substrates. A specimen rotates at 0.5 or 5 rpm and the scratching/marring occurs as the specimen comes in contact with either the diamond or carbide tools. An adjustable load is applied to the scratch tool. Mar resistance is reported as the amount of weight required to just produce a barely visible scuffing or loss of gloss. This instrument is referenced in ASTM C217, Weather Resistance of Slate, EN 438-2 Decorative High Pressure Laminates—Resistance to Scratching, ISO 4586-2 High Pressure Decorative Laminates—Resistance to Scratching.

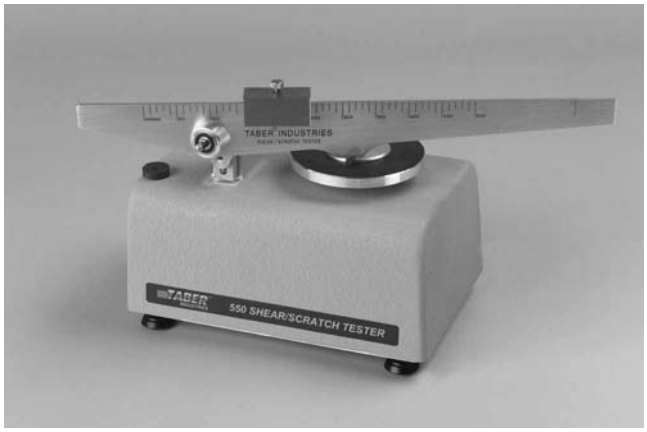

Fig. 13—Taber Shear/Scratch Tester (courtesy of Taber Industries).

Multi-Finger Scratch Tester (5-Finger Scratch Tester)

This testing device, made popular by the automotive industry, can be used for determining the scratch and mar resistance of molded-in-color automotive plastics by use of a linearly oriented, multi-fingered scratching device. Operation involves 1 or 7 mm, individually loaded, hemispherical tips scratching the surface at a constant speed of 100 mm per second. This testing device is seen in Fig. 14.

Coin Mar Test

This test consists of dragging the edge of a coin across the surface of a coated panel and visually determining the degree of marring produced. The procedure can be used as a "pass/fail" test or for comparing the mar resistance of coatings on a relative basis. Results will vary from laboratory to laboratory due to the particular coin used and the pressure used for contact.

Fingernail Test

In this test, the back of a fingernail is dragged across the surface of a coating and the degree of marring is visually observed. The procedure can be used as a "pass/fail" test or for comparing the mar resistance of coatings on a relative basis.

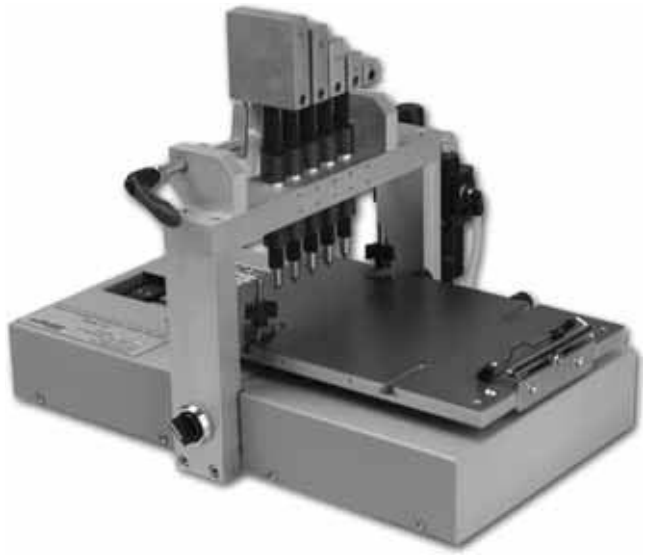

Fig. 14—Taber Multi-Finger Scratch Tester (courtesy of Taber Industries).

Paperclip Mar Test

This procedure is used to determine the ability of a surface to resist scuffing or marring. Scuffing is defined as permanent damage to the coating. An example of scuffing would be a break in the top-coat with visible flakes of coating caused by scraping by the paperclip. A paperclip remains in contact with the test specimen as the specimen is moved in four directions that are parallel to each of the edges of the specimen. The appearance is evaluated for evidence of scuffing or marring.

Nanoscratching

ASTM D7187 Standard Test Method for Measuring Mechanical Aspects of Scratch/Mar Behavior of Paint Coatings by Nanoscratching, covers the nanoscratch method for determining the resistance of paint coatings on smooth flat surfaces to scratch/mar. The loss of appearance is mainly due to surface damages created. This method uses a two step process to quantitatively and objectively measure scratch/mar behavior. Step one is to find the relationship between damage shape and size. Step two is to relate damage shape and size to visual loss of luster.

RAIN OR WATER EROSION

Rain erosion resistance of aircraft coatings has been studied in two types of testing machines [11]—whirling arm and jet. In the whirling arm tester, specimens having an airfoil contour are fastened to the leading edges of the two arms of a propeller-like blade that is rotated at angular velocities equivalent to flying speeds of up to 700 mph. Simultaneously drops of water fall on the whirling arms. Both the simulated air speed and the quantity of "rainfall" can be varied and closely controlled. In the jet-type tester, a high-pressure jet of water impinges on the specimen. A rotating slotted disk in the path of the water jet breaks the stream of water into individual drops to simulate rainfall.

In both of the above methods, having the water in the form of individual drops is a basic principle of the test. This is because the erosion that occurs on the leading edges of the airfoils on high-speed aircraft flying through rain is often the result of cavitation produced by the high-energy impacts of a multitude of individual droplets. At very high velocities, the water droplets, in effect, behave as tiny solid projectiles.

MISCELLANEOUS METHODS

PEI Abrasion Tester

Designed and developed by the Porcelain Enamel Institute to measure the abrasion resistance of porcelain enamels, this tester has also proven to be useful in determining the wet abrasion resistance of organic coatings. It is specified to be used in ASTM C448, Test Methods for Abrasion Resistance of Porcelain Enamels. The tester, which is pictured in Fig. 15, has a gyrating table with positions for nine specimens. Abrasive-retaining rings and lids are clamped over the specimen to form individual test chambers. Each chamber is charged with glass or stainless steel spheres, and a slurry of abrasive particles is added through a

Fig. 15—PEI abrasion tester. (courtesy of National Bureau of Standards).

filling aperture located in the lid. The table gyrates at 300 cycles per minute to cause abrasion of the specimens. The amount of abrasion is evaluated by measuring the loss of gloss or loss of weight in the specimens after a specified time period [12].

Sand on Wheel Tester

This test instrument is used for determining the resistance of metallic materials to abrasion by means of the dry sand/rubber wheel apparatus. The test specimen is pressed against a rotating rubber-rimmed wheel [13]. The test specimen is exposed to three-body scratch abrasion as abrasive grit is introduced between the specimen and rubber-rimmed wheel under a specified load. The intent of this method is to produce data that will reproducibly rank materials in their resistance to abrasion under specified conditions. Test results are reported as volume loss in cubic millimeters for the particular test procedure specified. Materials of higher abrasion resistance will have a lower volume loss. ASTM G65 Standard Test Method for Measuring Abrasion Using the Dry Sand/Rubber Wheel Apparatus.

END POINT MEASUREMENT

Any abrasion test is useless unless an accurate and repeatable endpoint can be reached. Without a precise end, the abrasion test results can be meaningless. The most common methods for determining endpoint are as follows; weight loss of the specimen after the abrasion test, visual loss by inspecting the specimen either with the naked eye or digitally. Those less common methods include gloss loss, haze loss, and change in coating thickness.

Calibration

An important aspect of today's quality systems is the traceability of testing instruments. Verification that the instruments, abradants, and scratch tools are within specification is the core to ensuring repeatable and reproducible test results. Precision testing instruments should be calibrated regularly to ensure accurate results.

Dynamic Mechanical and Tensile Properties

Loren W. Hill[1]

DYNAMIC MECHANICAL AND TENSILE PROPERTIES are determined in all branches of materials science. There is a large body of published structure/property information that can be integrated with coatings research and development. By using structure/property information, coatings chemists can design and optimize chemical structures of the binder components of coatings. Purposeful and enlightened formulation with well-designed components makes it possible to obtain desirable coatings performance in many cases.

Determination of dynamic mechanical and tensile properties requires the use of free films. This requirement is a serious limitation because many, if not most, of the performance properties of coatings are influenced by coating-substrate interactions. Therefore, tests of coatings intact on their end-use substrates must be thoughtfully coupled with free film determinations. The practical utility of basic methods described in this section is greatly enhanced when results are interpreted in relation to results of adhesion, abrasion, hardness, flexibility, toughness, and internal stress tests as described elsewhere in the manual.

Dynamic mechanical analysis (DMA) and stress-strain analysis (SSA) of tensile properties are complementary methods in several ways. DMA involves very small strains, whereas SSA involves the maximum strain that the sample can withstand. Since the small strains used in DMA usually do not exceed the tensile strength or yield strength of the sample, the method is nondestructive. This feature facilitates property determination over a wide temperature range on a single sample, that is, DMA is often used as a temperature-scanning method. In contrast, SSA data are usually obtained at a single temperature, preferably on an instrument located in a controlled temperature and humidity room. Since the sample is broken in each test, it is very arduous to carry out SSA over a wide temperature range, and SSA is not amenable to temperature scanning.

DEFINITIONS

Tensile Versus Shear Tests

Two types of deformation of a block-shaped sample are depicted in Fig. 1. These deformations are used frequently in property determinations because they can be carried out reproducibly and treated by simple mathematics. In a tension test (Fig. 1 (A)), the sample is pulled apart with straight line application of force, called "uniaxial extension." In a shear test (Fig. 1 (B)), one face of the cube is held stationary and the sample is pushed sideways by application of force at the opposite face. Note that different symbols (ε epsilon or γ) are used for strain in these two tests. A single symbol is used for stress (σ sigma), but subscripts indicate the type of test. In Fig. 1, F is force and A, B, and C are initial sample dimensions. The product $A \times B$ is the initial cross-sectional area.

It is evident in Fig. 1 that strain is defined quite differently in tension and shear tests. In a tension test, strain is the fractional increase in sample length. In a shear test, strain is the distance moved by the movable face divided by sample thickness, i.e., the distance between the stationary and movable faces. In both tests, stress is force divided by cross-sectional area, and modulus is stress divided by strain. Since strain is unitless, stress and modulus have the same units (force/area). It is evident in Fig. 1 (A) that cross-sectional area will decrease as ΔC increases. If the initial cross-sectional area is used to calculate σ_t, the resulting E is called "engineering" modulus. If the change in cross-sectional area is incorporated in the calculation, the resulting E is called "true" modulus.

The relationship between tensile modulus and shear modulus is

$$E = 2(1 + \mu)\mathrm{G} \tag{1}$$

where μ is Poisson's ratio [1,2]. For materials that do not undergo change in volume with strain, $\mu = 0.5$, and Eq (1) becomes $E = 3G$. Experimentally, μ is very close to 0.5 for rubbery materials and slightly less than 0.5 for many thermoplastic polymers [1,2].

Definitions of Dynamic Properties

In dynamic testing, an oscillating strain is applied, and the resulting oscillating stress is measured, or conversely an oscillating stress is applied, and the resulting oscillating strain is measured. Definitions and mathematical treatments do not depend on which of these modes of operation is used. Definitions and symbols used here correspond to ASTM Standard D4092, Terminology Relating to Dynamic Mechanical Measurements in Plastics. Relationships between strain, stress, and time are sketched in Fig. 2 for tensile DMA with application of strain and measurement of stress. The maximum applied strain is ε_0. The maximum resulting stress is $\sigma_{t,0}$. Oscillation is depicted as a sine wave, but whether or not the driver of the instrument in use actually delivers a sine wave oscillation may depend on the particular instrument. The sample is held under sufficient tension so that it remains taut (not slack) even when the oscillating strain is at a minimum.

A. TENSILE

ϵ = Tensile Strain

σ_t = Tensile Stress

$$\epsilon = \frac{\Delta C}{C}$$

$$\sigma_t = \frac{F}{AxB}$$

E = Tensile Modulus

$$E = \frac{\sigma_t}{\epsilon}$$

B. SHEAR

γ = Shear Strain

σ_s = Shear Stress

$$\gamma = \frac{\Delta X}{C}$$

$$\sigma_s = \frac{F}{AxB}$$

G = Shear Modulus

$$G = \frac{\sigma_s}{\gamma}$$

Fig. 1—Deformations of test samples: A. tensile, B. shear. The two types of deformation have different definitions and different symbols for strain, stress, and modulus.

The sine waves for strain and stress have the same frequency, but for viscoelastic samples the waves are out of phase by an amount, δ, called the phase lag. Theoretically and experimentally, δ is zero for an ideal (Hookean) elastic solid. If an ideal (Newtonian) liquid could be tested in this way, δ would be 90°. For viscoelastic materials, δ lies between 0 and 90°, and the value of δ is a rather direct indication of viscoelastic character [1–4].

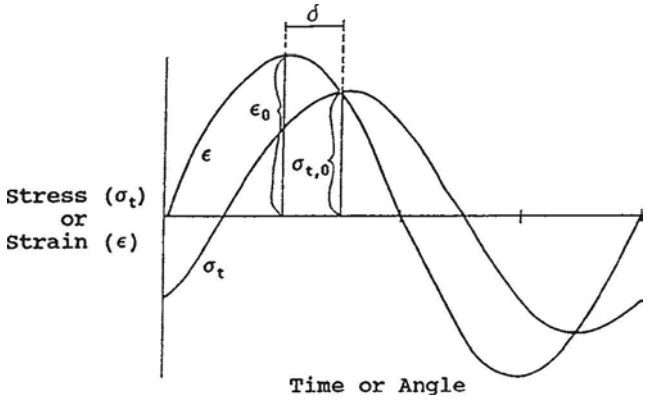

Fig. 2—Applied oscillating strain (ε) and resulting oscillating stress (σ_t) in a dynamic mechanical analysis experiment with tensile deformation. The phase lag (δ) and maximum values of strain (ε_0) and stress ($\sigma_{t,0}$) are indicated.

Definitions of dynamic properties depend on the concept of resolving the stress wave of Fig. 2 into two waves, one that is in phase with strain and one that is 90° out of phase with strain. The in-phase resolved plot represents elastic response, and the 90° out-of-phase resolved plot represents viscous response. In terms of modulus, the separated responses result in the following definitions

$$\text{Tensile Storage Modulus} = E' = \frac{\sigma_{t,0}\cos\delta}{\varepsilon_0} \quad (2)$$

$$\text{Tensile Loss Modulus} = E'' = \frac{\sigma_{t,0}\sin\delta}{\varepsilon_0} \quad (3)$$

$$\text{Loss Tangent} = \frac{E''}{E'}\tan\delta \quad (4)$$

The term "storage" is associated with the elastic part of the response E because mechanical energy input to elastic materials is "stored" in the sense of being completely recoverable. The term "loss" is associated with the viscous part of the response E'' because mechanical energy input to ideal liquids is totally lost through viscous heating. The ratio E''/E' is viscous response expressed relative to elastic response. This ratio reduces to sin δ/cos δ, which is tan δ. Thus, the name "loss tangent" is appropriate.

A check of limiting values of δ is consistent with assignment of elastic and viscous responses in Eqs (2) and (3). When $\delta = 0°$, cos $\delta = 1.0$ and sin $\delta = 0$. By Eq (3), E'' is zero and all of the response is elastic, i.e., E' from Eq (2). When $\delta = 90°$, cos $\delta = 0$ and sin $\delta = 1.0$. Now E' is zero by Eq (2) and all of the response is viscous, i.e., E'' from Eq (3).

DMA relationships in Eqs (2) and (3) relate directly to characterization of samples that are solid or semi-solid. Other objectives of DMA include following viscosity and elasticity changes as the cure of thermoset coatings takes place and determining the melt-flow properties of powder coatings before the onset of cross-linking. When viscous response is the main interest, DMA is often carried out in shear.

The treatment for shear DMA is identical, but with selection of appropriate shear symbols from Fig. 1, the definitions are:

$$\text{Shear Storage Modulus} = G' = \frac{\sigma_{s,0}\cos\delta}{\gamma_0} \tag{5}$$

$$\text{Shear Loss Modulus} = G'' = \frac{\sigma_{s,0}\sin\delta}{\gamma_0} \tag{6}$$

$$\text{Loss Tangent} = \frac{G''}{G'} = \tan\delta \tag{7}$$

Once the experimenters have values of $\sigma_{s,0}$, γ_0, and δ in hand, it is their choice whether to express results in terms of modulus values, Eqs (5) and (6), or in terms of "dynamic viscosity." For dynamic viscosity, the frequency of oscillation, ω in radians per second, is required, but this frequency is usually known. The frequency is required because viscosity is (shear stress)/(rate of shear strain). In a dynamic shear test, rate of shear strain is the product $\omega \times \gamma$. Definitions of dynamic viscosity are:

$$\text{Dynamic Loss Viscosity} = \eta' = \frac{G''}{\omega} = \frac{\alpha_{s,0}\sin\delta}{\omega\gamma_0} \tag{8}$$

$$\text{Dynamic Storage Viscosity} = \eta'' = \frac{G'}{\omega} = \frac{\sigma_{s,0}\cos\delta}{\omega\gamma_0} \tag{9}$$

$$\text{Loss Tangent} = \frac{\eta'}{\eta''} = \tan\delta \tag{10}$$

In the Newtonian liquid limit ($\delta = 90°$), η'' is zero by Eq (9), and all of the response is viscous, η' from Eq (8). Furthermore in this limit, G' is zero by either Eq (9) or Eq (5), and the viscous response could alternatively be expressed in terms of G'' from Eq (6). Thus, in dynamic shear tests, modulus and viscosity determinations are one and the same experiment. Usually experimenters will choose Eqs (5) and (6) when the sample has a lot of elastic character and only a little viscous character, whereas the logical choice for mainly viscous materials having only a little elastic character will be Eqs (8) and (9). In principle, it would be valid to express tensile DMA results in terms of dynamic viscosities as well. This is not done very often, probably because viscosity is strongly associated with shearing experiments, not with tensile experiments. The close association of viscosity with shear is the basis for omitting the word "shear" at the left in Eqs (8) and (9).

The relationships between modulus values defined in Fig. 1 and the dynamic modulus values are [1–4]:

$$E^2 = E^2 + E''^2 \tag{11}$$

$$G^2 = G'^2 + G''^2 \tag{12}$$

Use of complex numbers and quantities such as $i = \sqrt{-1}$ has been avoided here. If readers would like definitions of such quantities as the "complex tensile storage modulus," E^*, they should consult Refs. [1–4]. Complex notation may be convenient for mathematical derivations, but complex modulus values, with their imaginary parts, add little or nothing to the interpretation of structure/property relationships.

Definitions of Tensile Properties

The term "tensile properties" logically refers to all properties that can be determined in tests that involve tensile deformation as depicted in Fig. 1 (A). Common tests that involve tensile deformation include stress-strain tests, creep tests, and stress relaxation tests. Stress-strain tests are used much more frequently than the others. Therefore, the terms "tensile properties" and "stress-strain properties" are often used interchangeably. Creep and stress-relaxation tests are sometimes referred to as "transient tests" because responses, either elongation or stress, change with time and are determined as a function of time [5].

Terminology, definitions, and symbols for stress-strain tests have been taken from earlier editions of the *Paint Testing Manual*. Additional terminology was taken from ASTM standards for various polymeric materials:

D2370	Test Method for Tensile Properties of Organic Coatings
D638	Test Method for Tensile Properties of Plastics
D882	Test Method for Tensile Properties of Thin Plastic Sheeting
D412	Test Methods for Vulcanized Rubber and Thermoplastic Rubbers and Thermoplastic Elastomers—Tension
D883	Terminology Relating to Plastics

In a stress-strain test, the sample is elongated at constant rate. The force, also called "load," required to maintain constant rate of elongation is determined. Force is converted to tensile stress (σ_t) by division by the initial cross-sectional area ($A \times B$ in Fig. 1 (A)). Results are presented as a plot of stress (σ_t) on the vertical axis versus strain (either ε or $100 \times \varepsilon$ = % elongation) on the horizontal axis. A hypothetical example is shown in Fig. 3 [5,6]. The tensile modulus (E) is the slope of the initial, linear portion of the plot (see Fig. 3). If the initial part of the plot is not linear, several calculations for estimating E have been suggested in ASTM D638. Use of the slope for E amplifies the simple definition of tensile modulus given in Fig. 1 (A).

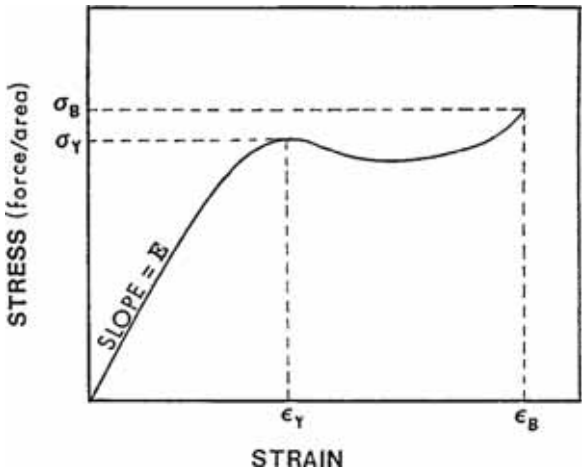

Fig. 3—A hypothetical stress-strain curve for a ductile film. Tensile properties are defined: tensile modulus (*E*), elongation at yield (ε_Y), elongation at break (ε_B), yield stress (σ_Y), and tensile strength (σ_B).

Other terms used for tensile modulus include "elastic modulus," "Young's modulus," and "stiffness."

The first point on the plot of Fig. 3 where the slope is zero is called the "yield point." Strain at the yield point is called "elongation at yield" (ε_Y). Stress at the yield point is called "yield strength" (σ_Y). Elongation is continued until the sample breaks. Strain at the break point is called "elongation at break" (ε_B). Stress at the break point is called "tensile strength" (σ_B) as shown in Fig. 3. However, in some cases (not shown) the stress is higher at the yield point than it is at the break point. In such cases, ASTM standards specify that the "tensile strength" be indicated as the higher value of stress and be designated as "tensile strength at yield." Practice is not uniform with regard to this latter "tensile strength" terminology.

Results of transient tests have not frequently been published for coatings. Such tests clarify viscoelastic character quite directly. Possibly unexpected field failures of coatings could be avoided in some cases if more attention were given to viscoelasticity. Only the most simple form of retardation and relaxation concepts are treated here.

In a tensile creep experiment, the sample is subjected to constant stress, σ_t, and elongation is determined as a function of time, $\varepsilon(t)$. Analysis of dependence of elongation on time yields "retardation time," τ. The simplest mechanical model that permits definition of τ is the Maxwell model as shown in Fig. 4. This model consists of a series connection of an ideal Hookean spring of modulus, E, and a dashpot that contains an ideal Newtonian liquid of viscosity, η. As indicated in Fig. 4, τ is the viscosity of the liquid in the dashpot divided by the modulus of the spring. τ has units of time. Results of the creep experiment for the Maxwell model can be expressed as

$$\varepsilon(t) = \varepsilon(0) + \frac{\varepsilon(0)}{\tau} t \tag{13}$$

When stress is first applied, the spring extends instantaneously by an amount $\varepsilon(0)$. Then retarded further elongation takes place due to flow in the dashpot. It is evident in Eq (13) that the retarded elongation is linear with time. The value of τ can be obtained from the product (reciprocal of the slope) × (intercept) [4,5].

In a tensile stress relaxation experiment, the sample is elongated instantaneously by an amount ε, and thereafter ε is held constant. Stress is determined as function of time, $\sigma(t)$. Analysis of the dependence of stress on time yields "relaxation time," τ. For the Maxwell model, τ values are the same whether from creep or relaxation. For real materials, experimentation is required to determine whether or not retardation and relaxation values are equal. Results of the stress relaxation experiment for the Maxwell model can be expressed as

$$\sigma(t) = \sigma(0) e^{-t/\tau} \tag{14}$$

When the instantaneous elongation is applied, the time zero response is entirely in the spring. Then the dashpot extends with time relieving stress on the spring. It is evident from Eq (14) that the value of τ can be obtained as the time at which stress has been reduced to $1/e$ (0.368) of its initial value. Alternatively, one can obtain the value of τ from the negative of the reciprocal of the slope of a plot of ln $\sigma(t)$ versus t [4,5].

To represent mechanical response of viscoelastic polymeric materials, it is usually necessary to use more elaborate mechanical models and to replace a single value of τ by "a spectrum of relaxation times" [1,2].

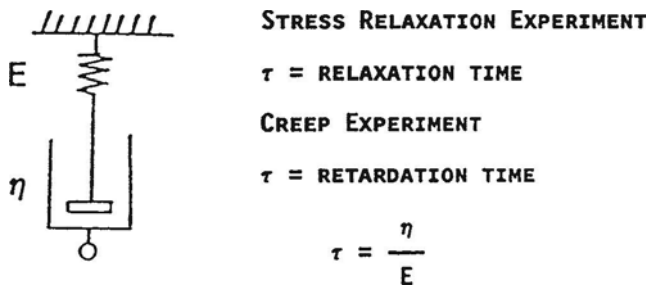

Fig. 4—A mechanical model consisting of a spring and a dashpot permits definition of relaxation time and retardation time.

PREPARATION OF FREE FILM SAMPLES

Methods for preparation and cure of adherent films are described elsewhere in the manual and in ASTM Standard Practice for Producing Films of Uniform Thickness of Paint, Varnish, and Related Products on Test Panels (D823). Since dynamic mechanical and tensile property determinations require free films, ASTM Practice for Preparation of Free Films of Organic Coatings (D4708), is also very useful. Details concerning thickness measurements, which are required for calculation of cross-sectional area, are given in ASTM Test Method for Measurement of Dry-Film Thickness of Organic Coatings Using Micrometers (D1005).

The most widely used method for free film preparation involves application on release substrates, i.e., low surface energy substrates. Four release substrates are described in ASTM D4708. Low surface energy results in poor adhesion so that the coating can be stripped from the release substrate after it is cured. Surface tension differences between the coating and release substrate must be carefully balanced. If the surface tension of the liquid coating is higher than the critical surface tension of the release substrate, the coating will crawl inward from the edges to

give nonuniform thickness. In extreme cases of crawling, the coating will break up into unconnected puddles. There are many types of release paper and many surface treating agents to convert glass or metal panels into low-energy surfaces. It is worthwhile to try several release surfaces to find the balance that will avoid crawling but will still permit separation. Tendency to crawl can be reduced by use of high-viscosity formulations. Viscosities for draw-down application (see ASTM D823) can be quite high compared to those required for spray application.

Thickness is an important consideration in preparation of samples for dynamic mechanical and tensile property tests. Usually tests are more reproducible if samples are thicker than normal coatings thicknesses. However, film formation seldom occurs in exactly the same way for thick films as for thin ones. Several reasons for dependence of cured film properties on thickness have been discussed [5]. In our laboratory, films of 1 mil (25 μm) and up have been analyzed routinely. It has not been possible to analyze or even handle very thin free films such as beverage can coatings, which are approximately 3 to 5 μm thick.

Coatings and thin plastic film samples are usually prepared as rectangular strips, whereas thicker materials are prepared as dogbone-shaped samples. The narrowing in the middle of the dogbone tends to control where failure occurs in tension tests, but for thin samples this narrowing causes the cross-sectional area to be too small for many load measuring cells. The dogbone shape also provides more area for clamping, which facilitates the balance between slip-free clamping and avoidance of rupture at the clamp.

There is extensive literature on the notch sensitivity of polymeric materials in stress-strain tests [7]. The challenge in preparation of high *Tg* coating samples is to avoid undesired notches, nicks, or cracks along the edges. Small edge cracks, which are very difficult to detect even with magnification, can cause premature failure in tension tests. Usually samples are die cut, and the sharpness and condition of cutting edges of the die affect uniformity of sample edges.

DMA

Instruments and Methods Used for DMA

Many DMA practices used for plastics have been applied to coatings as well. The broadest standard practice is:

ASTM D4065 Standard Practice for Plastics—

Dynamic Mechanical Properties: Determination and Report Procedures

Thirteen procedures for applying oscillating strain are diagrammed in D4065, and equations are given for calculating dynamic properties for each.

Other methods are specific to the type of oscillating deformation used:

Test Method for Plastics: DMA

D5023	Flexure—Three Point Bending
D5024	Compression
D5026	Tension (most common for coatings)
D5279	Torsion (sometimes called shear)
D5418	Flexure—Dual Cantilever Beam

One of the reasons for rapidly expanding use of DMA for coatings and other research is a rather long history of improvements in the quality of automation and computer-control of instruments. DMA instrumentation was undergoing rapid change and development in 1995 when the last edition of this manual was published. Eighteen DMA instruments were tabulated for coatings used prior to 1995. A great deal of consolidation has occurred in terms of instruments offered and instrument companies active in DMA. Table 1 lists the instruments used in eleven papers published from 2002 to 2006. A common feature of all these instruments is oscillatory deformation, an example of which is shown in Fig. 2. Variable features include: the type of deformation (tensile, shear, etc.), free versus forced oscillation, frequency scan versus temperature scan versus either, sensitivity for thin film analysis, capability of traversing the entire range of property behavior (glassy to transition to rubbery) during a single temperature scan, breadth and rate of temperature scan, breadth and rate of frequency scan or range and number of frequency settings, versatility of sample holding devices, ruggedness versus flimsiness, amount of attention required once a run has been started, accuracy and versatility of the associated software for control during the run and data treatment and plotting after the run. In several cases, newer models permit determination of properties at several frequencies during a single temperature scan.

TABLE 1—DMA instruments Cited, 2002–2006

Company	Model Number	Number of Citations	References
Rheometrics Scientific	DMTA—3	Four	[29–31,51]
Perkin Elmer	DMTA—7	Three	[35,54,55]
TA Instruments	2980	Two	[32,56]
Polymer Laboratories	PL & (England)	Two	[48,57]

The procedure for carrying out a DMA run on an automated instrument is rather simple, with details depending on the particular instrument. Usually the associated software includes a "run" program that prompts the operator to input sample data (e.g., thickness) and settings for the run such as initial and final temperatures, frequency of oscillation, heating rate, etc. After the input steps, there is usually a cooling period. The instrument takes over when the preset initial temperature is reached. Thereafter nothing is required of the operator until the run is finished. Usually initial and final temperatures are selected to span the glassy region, transition region, and rubbery plateau region. For direct tensile DMA, the run program usually contains a tensioning sub-routine, which provides constant static tension sufficient to avoid slack in the sample in the glassy region and then decreasing static tension as the sample softens in the transition region. Modification of the tensioning sub-routine is often necessary. If tension is too high, films break in the glassy region or are pulled apart in the transition region. If tension is too low, slack results or the oscillatory stress falls below measurable values. Skilled operators soon develop several modified run programs with different tensioning parameters that are suitable for samples of various properties and dimensions. Calibration of DMA instruments is described in E2254 Storage Modulus Calibration of DMA.

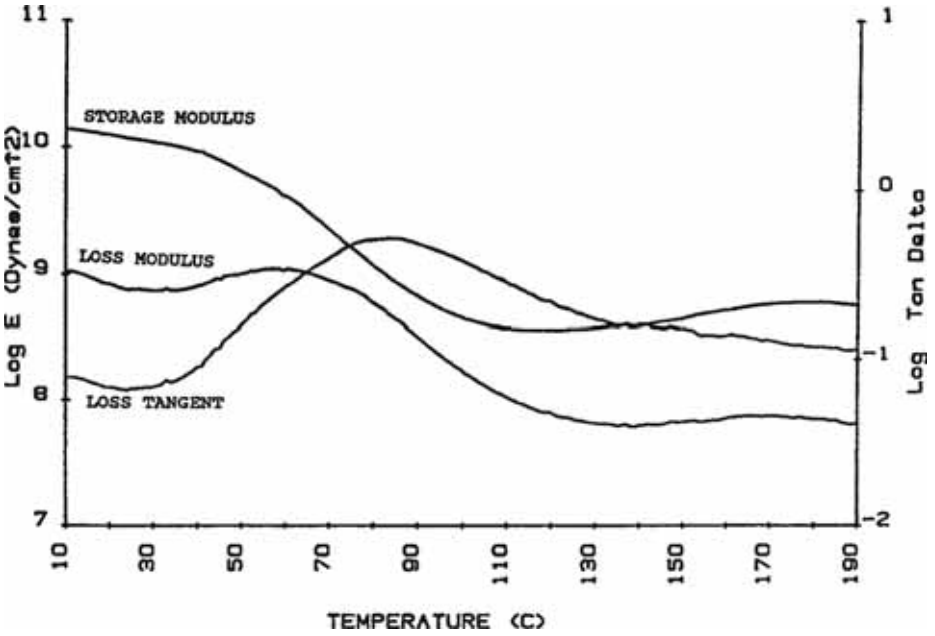

Fig. 5—DMA plots for a clearcoat prepared from an ACR and an etherified MF resin, ACR/MF 70/30. The film was cured before DMA for 30 min at 120°C with 0.5 % para-toluenesulfonic acid. DMA was carried out at 11 Hz. See Table 2 for dynamic properties.

Various support materials, such as glass braids and metal springs or shims, are used when the sample is a viscous liquid and the objective is to follow cure as the coating formulation is converted to a solid. Use of supports makes it difficult to obtain absolute values of E', but relative values are often sufficient for component optimization. The position of peaks in E'' or tan δ plots are usually not shifted when a support is used. When coating samples do not contain solvents, e.g., powder coatings and 100 % active coatings, parallel plate, and cone and plate geometries can be used.

In some cases, DMA is treated as an adjunct to thermomechanical analysis (TMA). The TMA probe is driven up and down in an oscillatory manner as temperature is scanned. General indications of liquid-like character during transitions can be obtained, but quantitative DMA data are not often obtainable in this manner.

Interpretation of DMA Plots

DMA plots are shown in Fig. 5 for a clear film prepared from an acrylic polyol (ACR) and an etherified melamine formaldehyde (MF) cross-linker. Plots are labeled according to Eqs (2)–(4). The storage modulus level at the left is typical of amorphous, unpigmented films in the glassy state. The 25°C data are of interest for comparison with modulus values obtained from the slope of stress-strain plots because SSA is usually carried out at 25°C. The value of E' (25°) from the computer printout corresponding to Fig. 5 is 1.38×10^{10} dynes/cm^2. The same value expressed in other units is 1.38×10^9 Pa or 2.00×10^5 psi (1 pascal = 1 newton/m^2 = 10 dynes/cm^2 = 1.45×10^{-4} pounds-force per square inch). The recommended SI unit is Pa. The value of E'' (25°) is 6.86×10^8 dynes/cm^2. Inserting E' and E'' (25°) values into Eq (11) and solving for tensile modulus, E, we obtain $E = 1.382 \times 10^{10}$. In this case $E = E'$ (25°) to a very close approximation, and the contribution of E'' (25°) to E is negligible. Hard, tough coatings often have tensile modulus values from SSA ranging from 1×10^{10} to 3×10^{10} dynes/cm^2 [5,7,8], in agreement with the DMA value. For a quantitative comparison of E from SSA and E from DMA via Eq (11), the strain rate from SSA would have to be matched with the oscillating frequency from DMA.

The viscous response is not always negligible relative to elastic response, of course. The E'' contribution is highest at the temperature of the maximum in tan δ, 79°C in Fig. 5. Note that E' (79°) is 1.04×10^9 dynes/cm^2, and E' (79°) is 5.15×10^8 dynes/cm^2. From Eq (11), $E = 1.16 \times 10^9$ dynes/cm^2, and E > E' (79°) for this case. If we actually carried out SSA at 79° and a strain rate corresponding to 11 Hz, we would expect to find $E = 1.16 \times 10^9$ dynes/cm^2. During the elongation in SSA, it would not be evident that a significant fraction of the resistance was viscous in nature. However, after the sample broke or was released from the grips, retraction would be delayed (not instantaneous) and part of the deformation would be permanent.

The middle portion of the plots in Fig. 5 represents the transition region where E' drops sharply and both E'' and tan δ go through a maximum. In coatings papers the glass transition temperature is usually taken as the temperature of the maximum in the tan δ plot, and the symbol used for this temperature is T_g. This definition will be used in this chapter. Different assignments and symbols of various transition temperatures are described in ASTM E1640 Standard Test Method for Assignment of the Glass Transition Temperature by Dynamic Mechanical Analysis:

Peak temperature of the loss modulus plot = T_1 (55°C in Fig. 5)

Peak temperature of the tan δ plot = T_t (79°C in Fig. 5)

Intercept of two E′ tangents= T_g (52°C in Fig. 5)

The two tangents in the last assignment are drawn (1) along the glassy portion and (2) through the inflection point in the transition region. The lower transition values

TABLE 2—Dynamic properties of acrylic/MF clearcoat

Frequency, Hz	T_g, °C	Tan δ, max	PW,[a] Δ,°C	E' (min), dynes/cm^2	Temperature of E' (min),°C
3.5	76	0.49	45	3.3×10^8	108
11.0	79	0.49	50	3.6×10^8	112
35.0	83	0.52	55	4.2×10^8	116
110.0	88	0.52	59	4.7×10^8	121

[a]PW is the peak width at half height.

agree more closely with that obtained from differential scanning calorimetry, but the highest value can be obtained with better reproducibility because the tan δ peak is prominent. Coatings often have several binder components, and many coatings are cross-linked. These structural features broaden the glass transition and favor use of the peak in tan δ for assigning T_g. Regardless of the data point selected to represent T_g, it is important to remember that T_g depends on rate of testing for viscoelastic materials.

The effects of changing rate of testing, i.e., frequency in DMA, are shown in Table 2. The 11 Hz data of Table 2 correspond to the run depicted in Fig. 5. A ten-fold increase in frequency results in a 7° to 9° increase in T_g with a slightly stronger dependence on frequency at the higher frequencies. Hartmann [9] noted that a 7°C T_g change per decade change in frequency is used as a "rule-of-thumb." Results of Table 2 are consistent with this generalization. The height of the tan δ peak is nearly independent of frequency, but the width increases with increasing frequency. Very similar dependence of height and width on frequency was observed for lightly cross-linked epoxy films [9]. Values of E' (min) increase slightly with increasing frequency (Table 2). The structural implications of E' (min) will be discussed in the next sub-section.

Height and width of tan δ peaks reflect structural homogeneity and cross-link density. Homogeneous, uncross-linked, noncrystalline polymeric materials of narrow molecular weight distribution usually have tan δ (max) values greater than one and sometimes greater than two. Such tan δ peaks are very narrow. A broader molecular weight distribution results in a wider peak and a lower value of tan δ (max). Introduction of cross-links invariably reduces tan δ (max) and usually increases peak width. For homogeneous cross-linked samples, peak width reflects the broadness of the distribution of lengths of chains between junction points in the network [2,3]. For sound and vibration damping, materials with both high and wide tan δ peaks would be desirable, but height and width cannot be adjusted independently [9]. High peaks tend to be narrow, and wide peaks tend to be low. These observations have resulted in speculation concerning a general comparability of peak areas of the glass transition. Eventually theoretical treatment of peak areas may prove to be useful for structure/property correlations.

Samples that undergo partial phase separation during molecular weight buildup and cross-linking often have very broad transitions [4,9,10]. Manson and Sperling [10] have described the use of interpenetrating polymer networks to limit and control the extent of phase separation. When T_g values of the separate domains are close to one another, a general broadening is observed. When T_g values of the separate domains are considerably different, tan δ plot shapes provide considerable structural information. Observation of two narrow peaks with low tan δ values between them indicates distinct phase separation with little mixing at domain boundaries. Observation to two broad and indistinct peaks with high tan δ values between them indicates diffuse domains with extended regions of varying composition at the boundaries [4,10]. Diffuse domains have also been created in multiblock uncross-linked polymers, and block design has resulted in controlled broadening of tan δ peaks [11].

The relationships between transition width and coating end-use performance have been presented for radiation-cured coatings [12], polyol/melamine thermoset coatings [13,14], gel coats [14], and can coatings [14]. Although the glass transition is emphasized in this section, many polymers are known to have multiple transitions. Low-temperature transitions are observed in DMA as tan δ or E'' peaks that are quite small compared to the glass transition peaks. As discussed in the section entitled "Relationship to Other Mechanical Properties," good impact resistance is often attributed to transitions that produce low-temperature loss peaks.

Interpretation of tan δ peak broadening in terms of structural nonuniformity requires considerable restraint because in some cases broadening is caused by physical or chemical changes that take place during the temperature scan. In some cases, DMA has its own uncertainty principle; the structural features that are under study are changing during the determination. Physical changes include loss of plasticizer or absorbed water and morphological changes such as partial crystallization. Chemical changes include additional cross-linking of thermoset coating during the scan and oxidative or thermal degradation. In general, if the temperature of processing the samples is well above the temperature of the tan δ peak under analysis, there is much less chance that properties are changing during the scan.

Determination of Cross-Link Density

For unpigmented, cross-linked coating films, the level of storage modulus, E', in the rubbery plateau region above T_g is an indication of cross-link density. A wide range of variation has been observed from approximately 4×10^7 dynes/cm^2 for lightly cross-linked films to approximately 2×10^9 dynes/cm^2 for every highly cross-linked films. Increases in E' values in the rubbery plateau have been attributed to increase in cross-link density for many types of studies: increasing cure temperature and cure time [13,16–18], increasing radiation dose in electron beam curing [15],

increasing the stoichiometric balance in epoxy films [2,19] and in polyol/melamine films [13,17,18], increasing the functionality of the cross-linker in radiation cure films [20] and in powder coating [21,22], and increasing the molecular weight of the main film former in acrylic clearcoats [23].

Quantitative aspects of the relationship between E' in the rubbery plateau and cross-link density have been clarified [18]. Cross-link density is defined as

$$\nu_e = \text{moles of elastically effective network chains per cubic centimeter of film} \quad (15)$$

Cross-link density can be calculated using Eq (16)

$$\nu_e = \frac{G'}{RT} = \frac{E'}{3RT} \quad (16)$$

where the storage modulus values, G' or E', are obtained in the rubber plateau, T is temperature in degrees K corresponding to the storage modulus value, and R is the gas constant (8.314×10^7 dynes/degrees K · mole in the cgs unit system). Inserting the 3.5 Hz data from Table 2 ($E' = 3.3 \times 10^8$ dynes/cm^2 and T = 108°C = 381°K) into Eq (16) gives $\nu_e = 3.47 \times 10^{-3}$ moles/cm^3. Since Eq (16) has no correction for frequency dependence of E', a more accurate value would be obtained if frequency were reduced until E' no longer depended on frequency. Extrapolation to zero frequency was used in cross-link density calculations for powder coatings [21]. For a polyurethane film of low T_g but relatively high cross-link density, E' plots were identical in the rubbery plateau at 11 and 110 Hz [18]; thus, no frequency extrapolation was necessary for the is case.

Equation (16) has been called "the ideal network law" with an analogy implied to the ideal gas law [18]. In an ideal network, all chains are elastically effective. Conversion in the network forming reaction is complete, and there are no small loops or dangling ends. For ideal networks formed by functional group reactions of terminally functional (telechelic) starting material, the value of ν_e can be calculated directly from Eq (15). The calculation requires only a balanced chemical equation and an experimental determination of cured film density. For example, consider a tetrafunctional coreactant B_4 (M_n = 3000) cured by a trifunctional cross-linker A_3 (M_n = 300) $4A_3 + 3B_4 \rightarrow$ Ideal Network (density = 1.10 g/cm^3).

The mass of the network formed by this reactions is 10,200 g ($3 \times 3000 + 4 \times 300$), and the volume is 10,2001/.10 = 9273 cm^3. This volume of cured film contains 24 mol of chain ends ($4 \times 3 + 3 \times 4$) coming into junction points in the network. By definition, a chain has two ends; therefore, there are 12 mol of elastically effective chains in 9273 cm^3 of ideal network film. From Eq (15), $\nu_e = 12/9273 = 1.29 \times 10^{-3}$ mol/cm^3.

Equation (17), attributed to Scanlon [18,24], formalizes this type of calculation

$$\nu_e = \frac{3}{2}C_3 + \frac{4}{2}C_4 + \frac{5}{2}C_5 + \ldots = \frac{1}{2}\sum_{f=3}^{\infty} fC_f \quad (17)$$

where C_f is the concentration of *"f"* functional reactant expressed in unusual units, i.e., moles of reactant per cubic centimeter of *final film*. Difunctional reactants contribute to volume but do not increase the number of moles of chains. Therefore, there is no C_2 term in Eq (17).

Ideal network calculations have been carried out for several types of coating such as polyester polyol/melamine films [17], epoxy/diamine films [19], and powder coating films [21,22]. The ν_e values calculated from reactant structures agree remarkably well with experimental ν_e values from Eq (16).

Although ν_e is useful for network characterization, most coating chemists can more easily visualize a network based on the value of M_c

$$M_c = \text{weight of sample in grams that contains one mole of elastically effective chains} \quad (18)$$

If chain lengths in the network vary, one can place a bar over M_c and refer to this quantity as "number average molecular weight of effective network chains." Based on Eqs (15) and (18), the relationship between ν_c and M_c is

$$M_c = \frac{\rho}{\nu_e} \quad (19)$$

where ρ is film density in g/cm^3. For the $4A_3 + 3B_4$ example, M_c =1.10/1.29 $\times 10^{-3}$ = 853 g/mol. For the film of Table 2, the experimental density is 1.12 g/cm^3, and M_c is $1.12/3.47 \times 10^{-3}$ = 323 g/mol. Or course, a high value of M_c corresponds to a loose network and a low value to a tight network.

Equation (16) can be considered empirical or the result of kinetic theory of rubber elasticity [20,24–28]. The theory was developed for networks that have very long chains between junction points. For long chains, conformations can be treated by statistical-mechanics concepts. The chains in networks of greatest interest for coatings are much too short for such treatments. For long chains between junction points, results of the theory are of ten expressed as [20]

$$\nu_e = \nu_c + \nu_p = \frac{G}{gRT} \quad (20)$$

where ν_e is sum of a chemical contribution, is ν_p. The physical contribution is attributed to chain entanglements [28] or physical constraints [25–27]. The factor, g, is related to junction point displacement under stress and is reported to depend on functionality [20,25]. If the reader chooses to use rubber elasticity theory, Eq (16) is obtained from Eq (20) with g = 1.0, $G = G'$, and $\nu_p = 0$ (relative to ν_c). It has been shown that Eq (16) can be derived rather directly for networks made up of short chains such that chain entanglements are minimal [18].

For many years DMA has been used to determine the extent of cure of thermoset coatings. Cross-link density (Eq (16)) and glass transition temperature (from the maximum in the plot of tan δ versus temperature) are used as measures of extent of cure. Recent examples include:

Acrylates cross-linked by hydroxyl alkyl amides [29] (2006)
Catiionic UV curable coatings [30] (2004)
UV cured acrylate/hyperbranched polyester coatings [31] (2003)
Urethane/acrylic hybrid coatings [32] (2005)
Alternative UV cure methods for automotive clearcoats [33] (2004)
High performance all-acrylic coatings [34] (2003)

Pigmented or nanoparticle-reinforced coatings, of course, do not have a direct relationship between E' (min)

and cross-link density. Finely divided particles, as well as cross-links, cause an increase in E' (min). Rodriguez et al. [35] have reported on the effects of varying Pigment Volume Concentration (PVC) on dynamic mechanical properties of epoxy coatings. Soucek and Ni [36] have reported the effect on dynamic properties of varying the content of oligosiloxane ceramer in a polyurethane coating for aircraft.

RELATIONSHIP TO OTHER MECHANICAL PROPERTIES

Knowledge of dynamic properties is useful for optimizing the chemical structure of coating components. When the binder is a copolymer, monomer ratios can be altered to control thermosets, increasing the functionality of the cross-linker is expected to cause an increase in cross-link density. DMA is a very direct method for determining whether purposeful structural changes have actually had the desired effects.

In addition to general structure/property use of DMA, progress is being made in establishing relationships between dynamic properties and the results of paint test methods for hardness, flexibility, impact resistance, and solvent resistance. DMA has some inherent limitations in the establishment of these property/property relationships. The oscillatory deformation, e.g., ε_0 in Fig. 2, is very small. If the paint performance property depends critically on large deformations, a property/property correlation should not be expected. Results of paint performance tests usually depend to some extent on interactions between coating and substrate. When dependence on coating-substrate interactions is dominant, a free film method such as DMA should not be expected to correlate with results of paint tests.

DMA has helped elucidate the causes of reversals in rank orders of hardness among films when different tests are used [5,37]. As described elsewhere in the manual, hardness is determined by penetration, pendulum, and scratch test methods. The most important property for influencing hardness is T_g. However, even for a series of films that have the same T_g, considerable differences are sometimes observed in hardness test results. We have observed that penetration hardness depends more directly on the E' (25°) value than on T_g. Films of the same T_g can have quite different values of E' (25°). Pendulum hardness depends more directly on E'' values than on E' values. This result is expected because damping of the swings of a pendulum depends on conversion of mechanical energy into heat through viscous effects in the coating. As noted earlier, E'' is a measure of viscous response. Films that have nearly the same E' (25°) values and the same penetration hardness can have quite different E'' (25°) values and quite different values of pendulum hardness. The back and forth rolling motion of a Sward Rocker is also damped by viscous effects, and therefore depends strongly on E'' values. In this case, there is also a contribution from sliding friction. Usually pendulum hardness is determined at a single temperature, but Sato [37] describes studies of damping time as a function of temperature. Plots of the reciprocal of damping time versus temperature have exactly the same shape as the tan δ plot for the same films. Both glassy and rubbery materials have low tan δ values as shown in Fig. 5. If a pendulum hardness test is carried out at room temperature on a material that is in its rubbery region at room temperature, a careless interpretation of results is likely to conclude that rubber is very hard. This example illustrates that DMA can be used to understand the results of paint tests more fully.

Among the many scratch tests that have been devised, the most widely used is pencil hardness. Although pencil hardness results are quite reproducible when carried out by one skilled in the art, these results sometimes do not correlate with either penetration or pendulum hardness results. Furthermore, there is no known dynamic property that correlates well with pencil hardness. The plowing action in pencil hardness failures involve large localized deformations. A relation to stress-strain analysis, which also involves large deformation, is more likely.

Flexibility of coatings is often measured by mandrel bend tests and falling weight impact test (see a previous chapter in this book). In thermoplastic polymer studies, good flexibility and impact resistance are often associated with low temperature peaks in E'' and tan δ plots [38]. Rubber-toughened epoxy coatings clearly show the low temperature peak attributable to the rubber phase [39]. Polyester/melamine films have much better mandrel bend performance than do acrylic/melamine films of similar T_g and cross-link density. DMA scans beginning at –100°C show a weak tan δ peak at –70°C for the PE/MF films, but no such peak is observed for the ACR/MF films [18]. In some cases [12,13], extreme broadening of the peak in the E'' plot has been associated with improvements in flexibility of coatings.

Pigments often increase the toughness of coatings without broadening the transition or introducing low-temperature loss peaks [15]. The main effect of increasing pigment volume content (PVC = 0 to 55 %) on DMA plots is to increase E' values moderately in the glassy region and strongly in the rubbery plateau [15]. Values of T_g often increase by about 5 to 10°C at PVC = 0.4 relative to the corresponding clear coatings [15].

Solvent resistance as measured in methyl ethyl ketone (MEK) double rub tests is related to E' values in the rubbery plateau, i.e., to cross-link density [5,13]. MEK resistance also depends on the solubility parameter of the coating. Although the double rub test is widely used to determine the degree of cure of thermoset coatings, the only ASTM method adopted relates to zinc-rich primers (D4752). Relationships between the number of double rubs and E'(min) values are quite reproducible within a coating type but not from type to type. For example, with acrylic clearcoats, 200 double rubs are obtained when E'(min) = 2×10^8 dynes/cm^2 [13]. Films of this type having 50 to 100 double rubs typically have E' (min) values in the range of 5×10^7 to 1×10^8 dynes/cm^2. In contrast, polyester polyol powder coatings, cured with several types of cross-linkers, yielded 200+ double rubs despite having E' (min) values as low as 5×10^7 dynes/cm^2 [22]. The lack of generality in the relationship of MEK resistance to E' (min) for various coatings types is believed to result in part from differences in solvent-polymer interactions. There may also be a weak dependence of MEK resistance on T_g as well as a strong dependence on E' (min).

DETERMINATION OF TENSILE PROPERTIES

Description of SSA

Instrumentation for SSA is described in detail in the ASTM test methods listed in the section of this chapter entitled

"Definitions of Tensile Properties." In most cases, specific instruments are not identified, apparently to avoid commercial implications, but it is generally known than Instron® instruments (Instron Engineering Corp.) are widely used. For organic coatings, the most suitable test method is usually ASTM D2370. However, other tension test methods contain additional useful information. ASTM D638 is useful for selection of metric units and units consistent with SI recommendations. ASTM D882 has rather extensive data on statistical treatments for plastic sheeting, but the statistical methods could be beneficially applied to coatings films. For certain types of coatings, such as flexible primers or coatings for plastic substrates, rubbery behavior is expected, and ASTM D412 provides useful information such as data treatment when a crack moves slowly across the sample as opposed to the more usual instantaneous failure mode. Often stress-strain curves do not start out with constant slope as shown in Fig. 3, but instead have an initial curvature caused by takeup of slack. The initial curved portion is called a "toe," and toe compensation is described in ASTM D638 and in ASTM D882. Some stress-strain curves have no linear (i.e., no Hookean) region from which to calculate the slope for modulus values. In such instances, the "toe corrected" origin and another point on the curve are joined by a straight line. The slope of the line is reported as the "secant modulus." The elongation percentage at the second point selected is always reported along with the value of secant modulus. Graphical illustrations of secant modulus determinations are given in ASTM D638 and in ASTM D882. Among the various test methods, D638 contains the most complete list of definitions and symbols.

Determination of "tensile energy to break" is described in ASTM D882. The area under the stress-strain curve, e.g., see Fig. 3, is divided by sample volume to obtain this quantity, which has also been called "work-to-break" or "toughness" [5]. Recommended units are megajoules per cubic meter. ASTM D882 describes how an integrated chart paper area (distance^2) can be converted to energy/volume by using the ordinate setting (force/distance of chart paper), the abscissa setting (distance of elongation/distance of chart paper), and the sample dimensions. Now that computers are used to control operation and to treat data for SSA [40], numerical integration is nearly instantaneous, and tensile energy to break is likely to be reported more often. This SSA property may prove to be useful for correlations with paint test results.

Interpretation of Stress-Strain Curves

Schematic stress-strain curves for various types of polymeric materials are shown in Fig. 6 [2]. This extremely wide range of property variation is represented in coatings of various types. Scales on the graphs give an order-of-magnitude indication of property values. Brittle materials (6*A*) have high modulus values (initial slope), tensile strengths up to about 8000 psi (5.5×10^7 Pa = 5.5×10^8 dynes/cm^2), and elongations below 10 %. Ductile materials (6*B*) usually have lower initial slopes, tensile strengths in the 4000 to 6000 psi range, and elongations of about 100 %. The upper plot in 6*B* corresponds to yielding with uniform sample deformation between the grips. The lower plot in 6*B* corresponds to a ductile sample that necks down at the yield point, and further elongation (~40 % to 110 % in Fig. 6) occurs with increase in length of the necked part of the sample. Elastomeric (rubbery) samples (6*C*) have much lower initial slopes than brittle materials, tensile strengths of about 2000 psi, and elongations of the order of 400 % to 500 %. The upward curvature near the end of the lower plot in Part C is attributed to strain-induced crystallization [2].

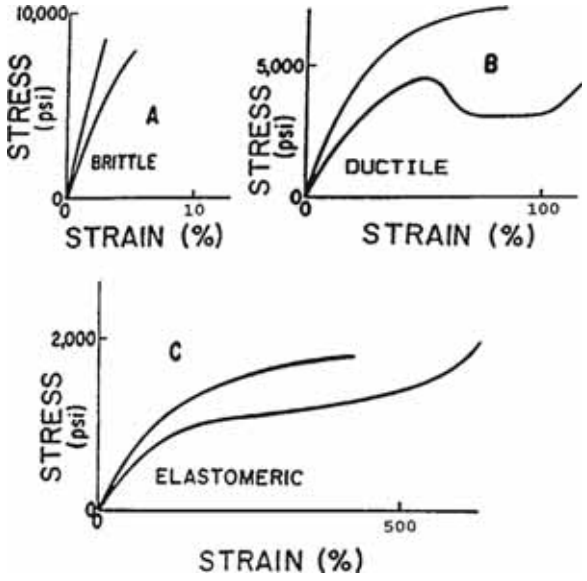

Fig. 6—General kinds of stress-strain curves for various types of coatings. Scales indicate order-of-magnitude values.

Materials represented in 6A and 6B of Fig. 6 have T_g values above the test temperature. Therefore, modulus values depend on secondary interactions of polymer chain segments and partial crystallinity, if any exists. The elastomeric material (6*C*) has T_g well below the test temperature. Therefore, modulus values depend in part on cross-link density, chain entanglements, or both.

Stress-strain curves are carried out at a constant rate of strain and results depend on strain rate selected. In general, a higher rate results in higher modulus. The two curves in 6*A* could represent the same material strained at different rates. In fact a large increase in strain rate could cause the plots of 6*B* to be converted to the plots of 6*A*. Dependence on strain rate is evidence of viscoelasticity. Strain rate dependence in SSA, therefore, has the same origin as dependence on oscillatory frequency in DMA (see Table 2).

A recent study of silicone-epoxy resins cross-linked with amines of various functionality [40] illustrates the extreme range of stress-strain properties exhibited by coating films. Tensile strength ranged from 31 to 4418 psi. Percent elongation ranged from 7 % to 177 %. Unfortunately, neither modulus values nor tensile energy to break were reported. Property variations were attributed to differences in degree of entanglement and to partial phase separation. In a network-forming thermoset system, it would be impossible to get a tensile strength as low as 31 psi unless incompatibility had prevented occurrence of the network-forming reaction.

Examples of all types of behavior shown in Fig. 6 are represented in a single figure for coatings used on naval aircraft [41] (see Fig. 4, Ref. [41]). One plot shows results for a polysulfide sealant that has a tensile strength of about 250 psi and an elongation >130 %. Results for a flexible polyurethane primer are a tensile strength of 3500 psi, a

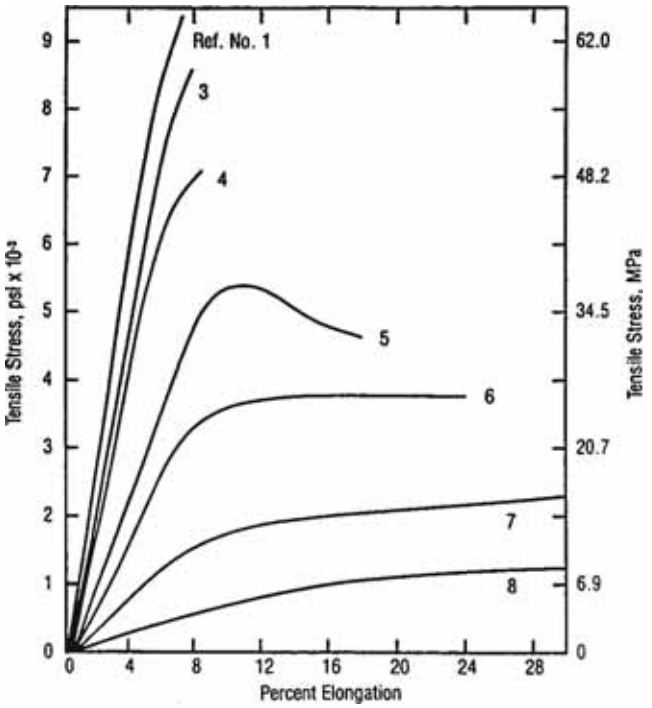

Fig. 7—Stress-strain curves for UV-cured cycloaliphatic epoxide films flexibilized with oligomeric propylene oxide triol. Strain rate is 40 % per minute. See Table 3 for tensile properties.

yield strength of 3200 psi, an elongation at break of 90 %, and an elongation at yield of 40 %. The plot shows that a polyurethane topcoat yields and breaks at about the same point: 4000 psi and 22 % elongation. The plot for an epoxy primer shows brittle behavior (no yield point), a tensile strength of 2300 psi, and an elongation at break of 7 %. The authors [41] report that replacing the epoxy primer by the flexible polyurethane primer eliminated the need for the sealant coat.

SSA has been used extensively to characterize cationic UV-cured cycloaliphatic epoxy/polyol coatings [42–44]. The mechanism of introduction of polyol is a chain transfer step [34], which permits use of a wide range of epoxy:polyol ratio without need for stoichiometric balance. Selection of flexible polyols with this wide formulating latitude permits preparation of cross-linked films with an extremely wide range of mechanical properties. Numerous stress-strain curves have been presented for this type of system with oligomeric propylene oxide polyols [43] and with oligomeric caprolactone polyols [44]. Examples of stress-strain curves for a cycloaliphatic diepoxide (CYRACURE® UVR-6110, Union Carbide) and a propylene oxide triol (*MW* = 702) are shown in Fig. 7 [43]. The corresponding tensile properties are given in Table 3. Films from Compositions 1 through 4 all give brittle failure (compare Fig. 6(A)) and only moderate changes in tensile properties (Table 3) despite a large change in composition. At Composition 5 (70/30 epoxy:polyol, see Table 3) a yield point is first noted, and thereafter very large property changes occur despite relatively small changes in composition. Compositions in the 4 to 6 range (see Table 3) are reported to give excellent post formability, as required for coatings on beverage can ends, while maintaining adequate hardness and solvent resistance [42–44].

Relationship to Other Mechanical Properties

SSA is used in a general way to assess suitability of a binder for various coating end uses. Most coating chemists associate modulus with coating hardness and percentage elongation at break with coating flexibility. Quantitative correlations of these properties are not published very often, however. The lack of published correlations may result from the fact, noted above, that paint tests of adherent coatings depend on coating-substrate interactions, whereas SSA is carried out on free films. ASTM Test Method for Elongation of Attached Organic Coatings with Conical Mandrel Apparatus (D522) describes how to calculate percent elongation from the crack length in a conical mandrel bend test. Comparison of elongation of adherent coatings by the conical mandrel method and elongation of the same coating as a free film from SSA would certainly be of interest, but such comparisons were not found in the literature.

TABLE 3—Tensile properties (strain rate, 40 %/min) of UV-cured cycloaliphatic epoxide films flexibilized with oligomeric propylene oxide triol

Film Number[a]	Composition[b]		Tensile Modulus,[c] psi	Tensile Strength, psi	Elongation, %
	Epoxide, wt %	Triol, wt %			
1	90.0	10.0	3.88×10^5	9.5×10^3	6.6
2	85.0	15.0	3.72×10^5	8.9×10^3	6.6
3	80.0	20.0	3.33×10^5	8.4×10^3	7.4
4	75.0	25.0	2.95×10^5	7.0×10^3	8.1
5	70.0	30.0	2.05×10^5	4.3×10^3	16.2
6	66.7	33.3	1.48×10^5	3.7×10^3	24.3
7	63.4	36.6	0.70×10^5	2.5×10^3	54.0
8	60.0	40.0	0.26×10^5	2.0×10^3	88.4

[a]Keyed to the plots in Fig. 7.
[b]Weight % of polymeric binder. (Films also contain 2.9 wt % photoinitiator and 0.5 wt % flow agent.)
[c]1% secant modulus. (The modulus range expressed in pascals is 2.68×10^9, No. 1, to 1.79×10^8, No. 8.)

The logic of associating yield behavior in SSA with post formability of coil coated metal was noted in 1977 [45].In 1987, Koleske [43,44] confirmed that compositions that exhibited a yield point performed well in the demanding post-forming operations carried out on beverage can ends.

Evans and Fogel [46] provided convincing evidence that gloss retention during abrasion of floor coatings is related to the area under stress-strain curves. This area, divided by sample volume, is called "work-to-break" or "toughness" as noted previously. The authors provide a clear example of the need to match strain rates when attempting to correlate SSA results with paint test results.

The field of Fracture Mechanics was well established for analysis of cracking of plastics by the 1980s, but coatings publications using Fracture Mechanics concepts began in the 1990s. In 1992 Gregorovich and McGonigal [47] reported that "the essential work to break," obtained from SSA plots with notched samples, correlated with resistance to car wash marring of automotive topcoats. In 2005, Sadati et al. [48] analyzed scratch resistance of clear coats based on fracture energy. In 1998 Nichols et al. [49] analyzed the fracture energy of automotive clearcoats using Fracture Mechanics, and in 2002 Nichols [50] used Fracture Mechanics concepts for anticipating paint cracking during weathering. In 2006 Skaja et al. [51] combined DMA and SSA data in analysis of mechanical property changes during accelerated weathering of polyester-urethane coatings. In 2001 Soucek et al. [52] analyzed fracture toughness of inorganic-organic hybrids, and in 2002 Soucek and Ni [36] used SSA and Fracture Mechanics to determine mechanical properties of nanostructured polyurethane ceramer coatings for aircraft.

Failure of attempts to correlate pencil hardness with penetration hardness, e.g., Tukon Hardness, probably result because the former has a strong requirement for toughness, whereas the latter is more dependent on the modulus value at room temperature.

DMA is much more generally applicable to determination of cross-link density (see the chapter subsection entitled "Determination of Cross-Link Density") than is SSA. If the *Tg* of a coating binder is well below the temperature at which SSA is carried out, then the modulus from the initial slope of the stress-strain curve is a rubbery plateau modulus and Eq (16) is valid at least in principle. In practice, curvature in stress-strain curves and permanent deformation usually result in inappropriate modulus values. An innovative approach to avoiding the permanent deformation problem consists of reversing the extension mode of SSA so that a retraction plot is also obtained. Hergenrother [53] has applied this tensile retraction method for determination of cross-link density of elastomeric polyurethanes.

CONCLUSIONS

A wide range of automated and computer-controlled instruments is available for determination of dynamic mechanical and tensile properties. Careful review of variable features is necessary to insure suitability for property determinations on coating samples of normal thickness. Determination of basic physical properties makes it possible to integrate structure/property knowledge from many polymer fields with coatings research and development. Free film coating data are much more useful when thoughtfully interpreted in relation to results from tests carried out with films intact on their end-use substrates. This review includes many examples that illustrate the benefits of combining DMA or SSA data with results from well controlled and documented tests as provided by the ASTM. The goal of much of the discussion provided here is better understanding of hardness, flexibility, post-formability, solvent resistance, and abrasion resistance.

DMA and SSA are often complementary because strains imposed on test samples are very different. SSA provides information on yield behavior and failure at high strains. DMA provides low strain properties and reveals the viscoelastic nature of coatings very directly and quantitatively.

For unpigmented thermoset coatings, values of storage modulus, E', in the rubbery plateau can be used to calculate cross-link density. Determination of cross-link density usually makes it possible to confirm or deny that purposeful reformulation or changes in resin structure have had the desired effects.

Flexibility and Toughness

John Fletcher[1] and Joseph Walker[2]

PREFACE

IN PREPARATION OF THIS CHAPTER, THE CON-tents of the fourteenth edition were extensively drawn upon. The authors acknowledge the author of the fourteenth edition, Mark P. Morse. The current edition will review and update the topics as addressed by the previous author, introduce new technology that has been developed, and include up-to-date references. This chapter is an abridged and modified version of the chapter entitled "Flexibility," written by Garmond G. Schurr, found in earlier editions of this manual.

DEFINITIONS

For a coating to meet its service requirements it must exhibit appropriate properties of flexibility and toughness to withstand cracking when it is subjected to stresses produced by shrinking or swelling, forming, mechanical abuse, and weathering. Flexibility is the ability of a material to be bent or flexed without cracking or undergoing other failure. Toughness is the strength and resilience of a material; it is the material's ability to withstand great strain imposed in a short time period, such as an impact, without tearing, breaking, or rupture.

INTERPRETATION

The flexibility of a coating applied to a substrate depends not only on its ability to expand by pressure from within the film, distensibility, but also on the coating thickness and on the adhesion between coating and substrate. Good adhesion tends to give better apparent flexibility than does poor adhesion. The toughness of a coating is dependent on its hardness, stiffness, resiliency, distensibility, and the existence of an energy dissipation mechanism that operates at temperatures far below room temperature and is discernable by dynamic mechanical measurements made over a broad temperature or frequency range.

Generally, the bend and impact tests used to evaluate flexibility and toughness are much more severe than actual service conditions. This is because the tests are usually performed on relatively fresh, un-aged coating films. Since coating films tend to lose flexibility during use due to the loss through volatilization of free plasticizing components and chemical changes such as degradation, cross-linking, and the like, these severe tests that exceed normal operational expectations are useful in predicting long-term serviceability [1].

BASIC PROPERTIES AFFECTING COATING PERFORMANCE

Both flexibility and toughness depend on very basic properties: the viscoelastic behavior of the coating and its physical transitions and relaxations. The following is a discussion of these properties taken from a paper by Skrovanek and Schoff [2].

Coatings, as the polymers from which they are prepared, are viscoelastic in nature, that is, they behave both as viscous liquids and as elastic solids. The coatings have elastic recovery and yet will flow with time when placed under a stress. In general, viscoelastic behavior and mechanical properties are markedly affected when a coating enters the glass transition, softening point, or other relaxation. To be certain that the properties of a coating will fulfill the needs of its intended use, the viscoelastic behavior of the coating should be measured, controlled, and designed to meet the particular end use.

The softening point of a coating can be used as an index of flexibility. The softening point is between the temperature where the coating changes from being hard and glassy and the temperature where it is leathery or rubbery. For example, if a coating has a softening temperature region near the temperature of the forming operation, the coating is less susceptible to failure by cracking or a similar mechanism than if the softening region is above the forming temperature. Measurement of energy storage (related to elasticity) and energy loss (related to viscous losses) as a function of temperature is a means of predicting impact resistance.

Impact resistance of a paint film can be considered as energy dissipation by vibration or rotation of various molecular segments so that at no time will sufficient energy be focused to cause fracture. Since the impact tests performed on paint films often produce deformations beyond the elastic limit of the films, flow within the films must take place or fracture will occur [3].

To obtain good impact resistance, the paint film must consist of a polymer that has a sufficiently high molecular weight to have strong intermolecular entanglement (and therefore, high tensile strength), but sufficiently low viscosity (by choice of proper molecular constituents and limiting molecular weight) that flow and accompanying energy dissipation will take place.

Polymer viscosity increases as molecular weight increases so that polymers with very high molecular weights will have greater flexibility than those polymers

with intermediate or low molecular weights. At the same time, molecular weights below the critical molecular weight for entanglement lead to very low tensile strengths and the mechanical behavior observed is brittleness. It has been found that modulus is the dominant factor in the relationship between the tensile properties of a coating and its impact resistance [4].

In addition to dynamic mechanical behavior, the relaxation behavior as measured by dissipation or damping of coatings has been determined by application of dynamic electrical tests [5]. In a dielectric relaxation test, a periodic electrical potential is applied to the sample coating situated between a pair of electrodes. The dielectric constant and dissipation factor are measured as a function of frequency and temperature.

TECHNIQUES FOR MEASURING BASIC VISCOELASTIC PROPERTIES

Thermal Mechanical Analyzer (TMA)

This instrument employs transducers to sense the position of a vertical rod that rests on the surface of a coating sample. The instrument is usually equipped with a furnace and program planner so that heating, cooling, and isothermal temperature operations can be employed.

With its use, softening points and glass transitions can be determined from plots of coating indentation as a function of temperature. Also, changes in stresses within a coating at a constant temperature (creep) can be determined from plots of indentation versus time [2].

Dynamic Mechanical Thermal Analyzer (DMTA)

This instrument produces vibrations in a coating film over a wide frequency range and/or temperature range. It can scan a wide range of sample temperatures at different rates. The resulting deformations from the sinusoidal applied stresses are analyzed to compute values related to energy storage and energy loss [2].

Tensile Testing

Tensile testing of organic films can measure tensile strength, modulus and elongation of the coating materials. The area under the stress-strain curve can be used as a measure of the toughness of the coating.

EXTERNAL FACTORS AFFECTING FLEXIBILITY AND TOUGHNESS

Flexibility and toughness are not constant characteristics of a specific coating. A number of external factors affect these properties.

Humidity

Water is a good plasticizer for almost all paint films in that it preserves the flexibility and adhesive power of the film. A change in relative humidity of as little as 2 % can be detected in flexibility measurements. Some paint films, such as those based on latexes, imbibe moisture very rapidly, whereas others reach equilibrium with the atmosphere very slowly. It is imperative that tests for flexibility and toughness are conducted in an atmosphere of controlled relative humidity and that the specimens are conditioned in that atmosphere for a day or more before the tests are performed. Generally, flexibility and toughness tests are carried out at a relative humidity of 50 ± 5 %. The 10 % tolerance is needed because of the difficulty in more accurately controlling relative humidity in most laboratories. If the environment cannot be controlled at this recommended level, then the relative humidity should be measured and reported along with the mechanical properties.

Temperature

The flexibility and toughness of coatings are dependent on temperature. This is particularly true of thermoplastic coatings, but it also is a factor for thermoset coatings. These coatings have a definite second order transition temperature known as the glass transition temperature, T_g. Coatings at a temperature below T_g are hard and brittle with poor flexibility and impact resistance unless there is an auxiliary loss mechanism below T_g or below the temperature at which the coating is used, as exists in polycarbonates that have a high T_g of about 160°C (at 1 Hz) and yet have excellent impact resistance because of a relaxation that occurs at about –90°C (at 1 Hz). If coatings do not have this type loss mechanism, at temperatures just above T_g they are flexible, and at temperatures substantially above T_g they tend to develop viscous rather than elastic properties. There is a tendency for all thermoplastic coatings to have identical flexibility properties if these properties are measured at the same temperature relative to T_g, for example, at 10°C above T_g [1,6].

Flexibility and toughness measurements are usually made at a temperature of 25 ± 1°C after the coatings are conditioned at that temperature. However, there are many instances when test are performed at lower temperatures as might be encountered in cold climates.

Strain Rate

Strain rate is the rate at which a coating specimen is elongated and is usually expressed in percent per minute, in./in./ min or cm/cm/min. This is the rate of extension relative to specimen size. That is, if a specimen 10 cm long is elongated at a rate of 1 cm/min, it is the same as a specimen 1 cm long being elongated at a rate of 0.1 cm/min (1 mm/min). In both cases, the strain rate is 10 % per min.

Strain rate has a great influence on the flexibility and toughness of a coating. In general, the effect of increasing the strain rate is similar to decreasing the coating temperature, that is, as the strain rate is increased, flexibility and toughness decrease.

There can be critical strain rates where flexibility has sharp changes, which are very similar to the effects produced at the glass transition temperature [7]. This means that the strain rate used in a test must be closely controlled. In some tests, such as a bend test, this is difficult to do. This also means that tests performed at a low strain rate (cupping test) are likely to produce different flexibility ratings than those produced by a high strain rate (conical mandrel test) [1,7].

It should also be noted that the temperature and humidity of the test are significant in the results that are obtained and should be noted as part of the test result.

FLEXIBILITY AND TOUGHNESS MEASUREMENTS

Mandrel Bend Tests

Both conical and cylindrical mandrels are used for evaluating the flexibility of coatings. Even though it is difficult to control the strain rate in these manually operated tests,

Fig. 1—A conical mandrel bend tester (Reprinted by permission of Elcometer Inc.).

they can provide very useful flexibility ratings and are often used to evaluate coatings applied to metal test panels.

Conical Mandrel Tests

A conical mandrel test consists of manually bending a coated metal panel over a cone. As described in ASTM D522, Standard Test Methods for Mandrel Bend Test of Attached Organic Coatings, Test Method A, a conical mandrel tester consists of a metal cone, a rotating panel bending arm, and panel clamps. These items are all mounted on a metal base as illustrated in Fig. 1. The cone is smooth steel 8 in. (203 mm) in length with a diameter of $\frac{1}{8}$-in (3.2 mm) at one end and a diameter of 1.5 in. (38 mm) at the other end.

When a coating is applied on a $\frac{1}{32}$-in (0.8 mm)-thickcold-rolled steel panel, as specified in ASTM D522, a bend over the mandrel produces an elongation of 3 % at the large end of the cone and of 30 % at the small end of the cone. The coated panel is bent 135° around the cone in approximately 1 s to obtain a crack resistance rating under simulated abuse conditions. In some instances, longer bend times have been found to be useful. For example, if the percent elongation of the coating at the point of cracking is to be determined, the method specifies a bend time of 15 s. ASTM D6905, Standard Test Method for Impact Flexibility of Organic Coatings, describes a procedure for determining the ability of a coating and its substrate to resist shattering, cracking, or chipping when the film and the substrate are distended beyond their original form by impact. This test method references D522 but states that D6905 is perhaps a better way to apply the test using a rapid application of the force. Since the impact is almost instantaneous the problems associated with time variables in the mandrel tests are eliminated.

Since variations in temperature and humidity can affect mandrel bend tests, it is imperative that the coated panels be conditioned at a standard temperature and relative humidity before performing the test, which is conducted under the same conditions.

Film thickness will also influence the results of the test and therefore the thickness of the film should be reported along with the temperature and humidity conditions.

The crack resistance value of a coating is obtained by measuring the distance from the furthest end of the crack to the small end of the mandrel. This distance is converted to cone diameter by means of a plot given in ASTM D522. The mandrel diameter at which cracking occurs is taken as the crack resistance value.

If the elongation of the coating at the onset of cracking is to be reported, a bend time of 15 s is used and the diameter at which the onset of cracking occurred is converted to percent elongation from a plot given in ASTM D522 Test Methods for Mandrel Bend Test of Attached Organic Coatings.

Cylindrical Mandrel Bend Tests

When executing cylindrical mandrel flexibility tests, a coated panel is bent manually over one or more cylindrical rods or surfaces of different diameters. ASTM D522 Method B states that the testing device should include mandrels with 1-in. (25 mm), $\frac{3}{4}$-in. (19 mm), $\frac{1}{2}$-in. (12.7 mm), $\frac{3}{8}$-in. (9.5 mm), $\frac{1}{4}$-in. (6.4 mm), and $\frac{1}{8}$-in (3.2 mm) diameters. Examples of cylindrical mandrel testers are given in Figs 2 and 3.

The panel should be bent over a mandrel with the uncoated side of the panel in contact with the mandrel surface. The panel should be bent approximately 180° around the mandrel at a uniform velocity in a time of 1 s. If cracking has not occurred, the procedure is repeated using successively smaller and smaller diameter mandrels until cracking is apparent. The cracking-resistance value of a coated panel is the minimum diameter at which cracking does not appear.

Fig. 2—A cylindrical mandrel bend tester (Reprinted by permission of Elcometer Inc.).

Fig. 3—Simple cylindrical mandrels test apparatus. (Reprinted by permission of Elcometer Inc.)

This testing procedure can be applied as a "pass/fail" test by determining whether cracking is produced by bending over a specified mandrel diameter.

A table for converting mandrel diameter to percent elongation is given in ASTM D522. Schuh and Theuerer [8] derived the relationship between the diameter of a mandrel and the elongation of a coating to be as follows:

$$\text{Persent Elongation} = 100(t/(2r + r)) \quad (1)$$

where t is the thickness of the coated panel and r is the radius of the mandrel.

Observed elongations are greater than values calculated from the above expression and vary with different types of metal substrates.

Crack resistance of a coating is dependent on its thickness. That is, the thicker the film, the lower the crack resistance. Values of crack resistance obtained by the mandrel bend tests should be corrected for film thickness when comparisons are made between different coatings. ASTM D522 contains corrections to be added to elongation values obtained with coatings having a thickness greater than 1 mil (0.03 mm) when applied to 1/8-in (0.8-mm)-thick steel panels.

Conical mandrel bend test procedures, similar to those given in ASTM D522, are found in ISO 6860 and BS 3900 E11. Cylindrical mandrel bend test procedures, similar to those given in ASTM D522, are found in ISO 1519, DIN 35 152, and BS 3900 E1.

T-Bend Tests

T-bend tests are a means of evaluating the flexibility of coated strip metal that is to be formed during a fabrication process (Fig. 4). Multiple 180° bends of the coated metal are made, and the amount of cracking produced at each bend is visually determined. Ratings are classified as 0T, 1T, 2T, 3T, and so on. The 0T (pronounced zero T) bend consists of making a 180° bend with the paint on the outside of the bend and pressing the bend flat so there is no space between the metal surfaces. This operation is

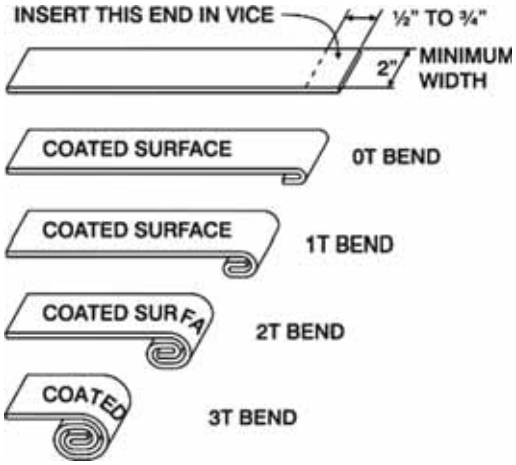

Fig. 4—T-Bend test bending the coated sheet on itself (ASTM D4145: Standard Test Method for Coating Flexibility of Prepainted Sheet).

repeated successively to produce a 1T (pronounced one T), 2T, 3T, etc. bends. These successive bends result in two, three, etc. thickness of the metal around the first bend. It should be apparent that the greater the number of thicknesses around which the coated metal is bent, the less severe the test.

Test results are reported as passing the smallest T-bend on which cracks are observed. In some cases, cracking must be detected by removal of the coating using a pressure-sensitive tape placed on the bend edges and observing the degree of removed coating particles. ASTM D4145, Test Method for Coating Flexibility of Prepainted Sheet, describes this test procedure.

A triangular-shaped specimen has been found to be convenient for making T-bend tests as this shape leaves a portion of each bend exposed for later examination and for permanent record.

Alternatively the T-bend test described in D4145 can be carried out using a die around which the deformation is

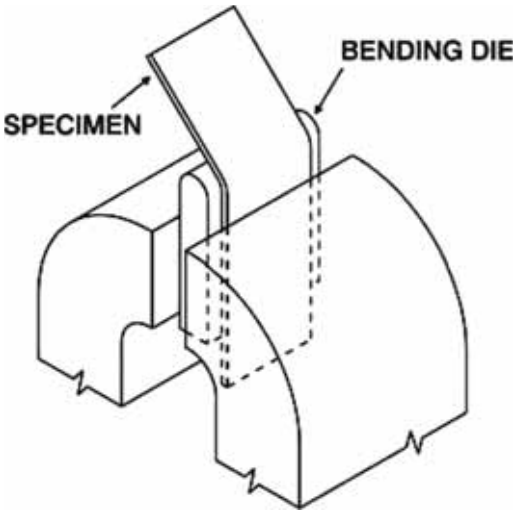

Fig. 5—T-Bend test using a die around which the specimen is bent (ASTM D4145: Standard Test Method for Coating Flexibility of Prepainted Sheet).

Fig. 6—Motorized Cupping Tester fitted with a web-cam to record the onset of cracking in the coating. (Reprinted by permission of Elcometer Inc.)

made (Fig. 5). Progressively larger dies are used to progress the test to the point where no damage to the coating results from the bending.

Cupping Tests

A test using a relatively slow rate of forming can be conducted with a Cupping Tester (Fig. 6) that pushes a punch into the unpainted side of a coated panel until the increasing deformation produces cracks in the coating. Test procedures are given in ISO TC 35, BS 3900 E4, NFT 30–019, SIS 18 41 77, DIN 50 101, and DIN 50 102. Cupping testers can be used to simulate different forming operations. The motorized Cupping Tester uses a spherical punch and a range of cupping speeds can be achieved. The maximum cupping depth is approximately 18 mm (0.7 in.). The cupping action is stopped when cracking in the coating is detected visually. The depth of cupping at that point is indicated on a dial gage and is considered to be the flexibility rating. The cupping tester can be equipped with a magnifier, a stereomicroscope, or a web-cam for observing the onset of cracking.

Forming Tests

In many industrial operations, metal is coated flat and then formed into various shapes by drawing the coated metal. This can be simulated directly or by elongating a coated metal sheet. Any tension-testing instrument capable of rapidly elongating a metal strip can be used for determining the ability of a coating to be drawn (drawability). A coated metal strip is elongated at a high rate of strain until cracking occurs. The elongation can be measured with an extensiometer [1]. Drawability would be reported as the percent elongation obtained just before cracking is observed. Since elongation is rate dependent, the rate of elongation used in the test should be reported.

ASTM D4146 Test Method for Formability of Zinc-Rich Primer/Chromate Complex Coatings on Steel provides a procedure for determining the formability of coated strip metal. An outline of a testing machine that can produce a sufficiently high pressure for pressing a 1 5/8-in (41-mm)-diameter indenter ball into the coated metal is provided. The rate of forming can be adjusted over a range of 0.2 to 1.0 in./min (4.8 to 25 mm/min). A dial gage monitors the movement of the indenting ball. Adhesive tape is applied over the dome formed in the metal, and the tape is rapidly removed. The amount of coating removed is given a rating by comparing it with a set of photographic standards.

Impact Resistance Tests

The most commonly used impact testers drop a weight onto an indenter resting on the surface of a coated panel that is resting on a platform (Fig. 7). A die in an opening in the platform allows the panel to be pushed down by the indenter to form a dimple in the panel. The weight is dropped through a guiding tube whose height is marked in increments.

There are a number of possible combinations of weights, indenter sizes, die sizes, and weight heights that can be used in performing impact tests. The tests can be performed by impacting either the coating directly (coating facing upward) or indirectly (coating facing downward).

Cracking observed on or around the impact-produced dimple is considered failure, and the force to produce the cracking is given in inch-pounds (kilograms-meters), that is, weight times height. The test can be performed either to determine the inch-pounds required to produce cracking or to determine whether a coating passes or fails at a specified inch-pound value. ASTM D2794, Standard Test Method for Resistance of Organic Coatings to the Effects of Rapid Deformation (Impact), describes such a test procedure and offers three procedures for determining the degree of cracking produced in an impact deformation: (a) visual inspection with a magnifier, (b) visual inspection after application of an acidified copper sulfate solution, and (c) use of a pin-hole detector.

The General Electric Impact Flexibility Tool is used for simultaneously making several indentations of different sizes. From these indentations, conclusions can be made regarding crack resistance and the amount of draw that a coating applied to sheet metal can tolerate. This tester consists of a steel cylinder that has knobs (segments of spheres) of different radii machined on each end. The cylinder is dropped onto a coated panel that is supported coating side down by a rubber pad. The height of drop is adjusted so that the boundary of the cylinder is just discernible. This procedure assures that each knob is used to its limit. Eight knobs cover a range of 0.5 to 60 % elongation. See Federal Test Method Standard 141C, Method 6226.

ASTM G14, Standard Test Method for Impact Resistance of Pipeline Coatings (Falling Weight Test), describes a test procedure for determining the impact resistance of pipe coatings. A fixed weight of 3.0 lb (1.36 kg) and having a 5/8-in. nose diameter is dropped through a guide tube onto a coated pipe specimen. The height of the weight is adjusted until the minimum height at which cracking appears is attained. A wet-sponge pinhole detector is used to determine the presence of cracks in the coating on the impacted pipe. An equation is given for calculating the impact resistance from the weight and its height of drop required to just produce cracking.

Fig. 7—Falling weight impact tester. (Reprinted by permission of Elcometer Inc.)

A different type of impact tester was developed and is being used at the Bell Laboratories of AT&T. A coated panel is subjected to repeat glancing blows by a case-hardened steel ball at the end of a short arm that is pivoted to another arm connected to a rotating shaft. During the test, the coated panel is mounted on a platform that moves so that successive blows do not strike the same spot. The energy level of the blows may be held constant, as in a "pass/fail" test, or it can be adjusted by changing the speed of the rotating shaft to determine the onset of cracking. If the hammer energy level required to destroy the coating is desired, a transparent, calibrated scale of shaft speed in revolutions is superimposed over the impact pattern. This tester is not commercially available.

There are a number of other impact testers that have been developed over the years and used to some extent. These include the Parlin-duPont Tester, Camp Impact Test, Hart Impact Tester, Ball Punch, General Electric Ball Drop, and Navy Falling Ball test. None of these testers are commercially available now.

The ISO 6272 standard, Rapid-deformation (impact resistance) tests is made up of two parts, part 1, Falling-weight test, large-area indenter and part 2 Falling-weight test, small-area indenter. Part 1 uses a 1 kg weight with the 20 mm diameter spherical indenter attached, whereas part 2 is based on ASTM D2794-93 (2010) and uses either a 12.7 mm or 15.9 mm indenter.

Testing of Free Films

ASTM D2370, the Standard Test Method for Tensile Properties of Organic Coatings, covers the elongation, tensile strength and stiffness (modulus of elasticity) of organic coatings when tested as free films. The method for preparing the uniform free films of organic coatings is given in ASTM D4708, Standard Practice for Preparation of Uniform Free Films of Organic Coatings using substrates that can be peeled from the cured film. Procedures are given for preparing free films on three alternative substrates. These substrates are treated FEP (fluorinated ethylene-propylene) sheet, silicone coated paper, and halo-silane coated glass plates. (Note: The dental foil that used to be included as one of the substrate has been removed from this practice because it contains mercury and is therefore hazardous.)

Cold Crack Resistance Tests

Tests in which coatings on substrates are cycled through elevated temperature, low temperature, and room temperature environments are called cold crack tests. They have been used in the coatings industry for many years as an indication of the ability of a coating to resist cracking in service and therefore are considered to be tests of coating flexibility.

ASTM D1211 Standard Test Method for Temperature-Change Resistance of Clear Nitrocellulose Lacquer Films Applied to Wood is an example of such a cold crack test, however this Standard Test Method was withdrawn without a replacement in 2006. It described a procedure for testing lacquer coatings applied on wood. The testing cycles consist of 1 h at 120°F (49°C), 1 h at –5°F (–21°C), and ½ h at room temperature. The results were reported as the number of cycles required to produce visible cracking in the coating.

Automotive coatings are subjected to cold crack cycle tests. A typical test for exterior coatings on metal panels consists of (1) equilibration at room temperature, (2) exposure in a humidity cabinet at 100°F (38°C) and 100 % relative humidity for 20 h, and (3) exposure in a freezer at –22°F (–30°C) for 4 h. After removal from the freezer, the coated panels are allowed to stand at room temperature for 2 h. Then the coatings are visually rated for cracking. In some cases, an exposure of 2 h in an oven at 150°F (65°C) is introduced into the above cycle conditions.

A rapid cold crack test that has been developed is based on the use of cooled air entering a transparent, insulated box. Cold air that has been cooled at a rapid controlled rate is introduced into the box, and the coatings are observed for cracking. The coatings are then rated by determining the temperature decrease from room temperature that is required to produce visual cracks in the coatings [4].

Effects of Aging and Weathering

The ultimate measure of satisfactory flexibility and toughness of a coating applied to a substrate is performance under service conditions. Most flexibility and toughness tests are performed on relatively fresh-coated panels, that is, tests are usually performed after the panels have been conditioned in a specified atmosphere for a specified period between 24 h and 7 days. The results obtained are applicable to service conditions if these are concerned with post forming or service indoors without a degrading atmosphere, since most coatings do not change appreciably in their physical service properties under such conditions. However, if the service conditions include exposure to weathering, this factor can cause appreciable changes to occur in the coatings properties.

The effects of moisture, temperature changes, and exposure to sunlight (ultraviolet wave lengths) encountered in outdoor exposure generally reduce the flexibility and toughness of organic coatings. Therefore, it often is desirable to conduct tests for flexibility and toughness after periods of weathering to determine how a coating will perform under actual weather conditions [1].

Understanding Osmotic Activity in Paint Films and Determining Cause by Systematic Analysis of Blister Fluids and Blistered Coatings

George Mills[1]

INTRODUCTION

A PROBLEM OFTEN OBSERVED WITH PAINT FILMS is the development of domed blisters. Usually these "bubbles" in the paint film are the result of osmotic activity. Understanding the osmotic process will be very helpful in the investigation of the cause(s) or driving force with this mode of paint failure. Osmotic blisters may develop between the primer paint and base substrate, between coats of applied paints, or within the matrix of a single layer of the composite (single or multi-coat) paint film. Although in most cases the blisters are easily seen, it is possible to experience osmotic activity under paint films when a domed blister is not elevated enough to be visible. When this occurs on a steel substrate, typically, corrosion will develop under the film. The osmotic process may be represented by the following graphic. It is most important to appreciate that potential solvent molecules will migrate through the paint film "one molecule at a time." One will remember that a collection of single, individual molecules is defined as a gas. For this reason, osmosis follows, and is controlled by, the general gas laws.

A common "definition" of osmotic activity in paint films describes the migration of solvent molecules through the film and dissolving one or more solutes forming the blister fluid solution. This process then continues in an effort to dilute the blister fluid solution to the point that it has the same concentration (actually, same vapor pressure) as the outer contact solvent liquid. It is this differential in vapor pressures that drive the osmotic activity.

Osmosis involves a semi-permeable membrane (as with a paint film), a solvent, and one or more solutes. To understand the potential interventions and investigation of the driving forces, knowledge of the basics of osmosis are extremely useful. Within this chapter we will review the chemistry and physics controlling the osmotic phenomena and present the analytical techniques that will allow one to determine the source, or driving force, of the osmotic activity. After determining the driving force one then has the ability to modify the paint formulation, application procedures, surface preparation, or service restrictions if any of these are shown to be the cause (source). If a coating failure has occurred one may determine where the liabilities lie as well as the extent of remediation that will be required to allow a true long-term fix of the problem. Problems associated with faulty application such as improper surface preparation are frequently claimed as the culprit. But, the inclusion of a water soluble thinner or chemical reaction under, or within, the coating matrix that produce water soluble materials are possible. Examples of some of these will be discussed later. Other potential sources of osmotic problems include deficiencies in the paint specification and unanticipated service conditions. Paint formulations that include pigments, resins, or additives that are soluble, or convert to a form that is soluble in service, can cause osmotic problems. On rare occasions manufacturing anomalies may lead to osmotic activity.

The investigation of osmotic activity in paint films should involve the systematic collection of samples from the site along with attentive observation of the blister location, size, and shape. If within a tank, note if blister predominance is in the liquid or vapor phase of the tank (or at the vapor/liquid interface). Are there temperature differentials that would cause condensation? Data relating to cargo history may be needed in tank lining failures to recognize and explain unusual solutes found in the blister fluid and/or coating dome analysis. The collected samples should include blister fluid withdrawn from blisters, recovered paint chip film blister domes, paint film samples collected away from blistered areas, and, for internal tank lining failures within non-aqueous tank lining failures, a sample of the material within the tank leading to the osmotic problem.

Sometimes, solutes found in the blister fluid are the result of chemical reaction products. These reaction products may be generated in the blister fluid over time or generated within the coating matrix itself producing a solute *in situ*. Examples of these include the highly alkaline fluid on an underground pipeline or ship's ballast tank caused by the reduction of oxygen in systems under cathodic protection (CP). This high *pH* fluid may hydrolyze bound chlorine from an epoxy resin or bromide from the blue-green pigment in the fusion bonded epoxy (FBE). Tank linings exposed to chlorinated solvents will experience generation of hydrochloric acid (HCl) from hydrolysis of the material within the coating film. Hydrolysis of acetate solvents

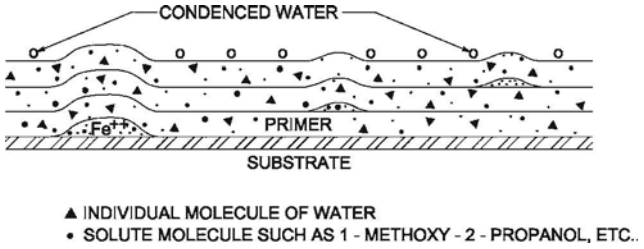

Fig. 1—Osmotic blisters can form at various interfaces. This includes under the initial primer coat at the substrate or between intermediate coats. Individual molecules of the solvent migrate through the polymer forming the paint film. Some of these molecules of solvent coalesces to a liquid forming the blister and disolves one or more solutes. The difference in vapor pressures between the fluid in the blister and the migrating solvent controls the direction of solvent flow. (Graphics done by George Mills, Jr.; Building Design Solutions, LLC.)

generates acetic acid. When blister fluids are low *p*H, often there will be an iron corrosion product as a solute as well. These will be discussed later (Fig. 1).

Chemical analysis of the blister fluid along with thermal out-gassing of the blister dome film, usually, will define the cause of the osmotic activity. When "strange" or unexpected solutes are seen, the investigator may be required to review some of the chemical reactions that could produce these solutes in the blister fluid. While the solvent is often water, tank linings and internal pipe coatings in non-aqueous service may experience osmotic activity wherein the solvent of the osmotic blister is the product of the contact service media. The solutes may be occluded previous cargo materials or lower molecular weight polymer fractions generated by the cargo material. These will be discussed in detail later.

Most domed paint blisters will be present with the liquid that caused the blister, although some blister domes may be found after the liquid has escaped from the coating. The disruption in the paint film often leads to severe corrosion of the substrate as seen in Fig. 2 within a ballast tank of a large ocean going tanker.

As discussed previously the cause (driving force) of osmotic blister formation may originate as a result of numerous sources. While the applicator often is accused of improper surface preparation, the service conditions encountered and the paint's formulation may be responsible. The real driving force, and hopefully a correction in the future, may be determined by systematically analyzing the blister fluids and understanding some of the complex chemistry that may be operative.

The physical development of osmotic blisters in a paint film requires that a solvent be available having marginal transmission within the paint film. This solvent will dissolve one or more solutes under the film at the substrate, between applied coats, or within the matrix of a single layer of the paint film. Usually the source of the solvent is not a mystery. Typically, it is water from condensation or immersion when water contact is possible. For tanks in non-aqueous service, the linings may experience osmotic blister formation wherein the materials in the tank constitute the solvent. For these situations, the contact solvent will be known or discovered upon chemical analysis. The identification of the solutes, and the source of these solutes, may present the investigator with a challenge. While in some cases, salts over-coated during application have been cited as the driving force, the real picture, usually is considerably more complicated. The solutes may involve the generation of ions, with time, under the film. A good example is the osmotic blisters often discovered in the lining of potable water tanks at the "one year" guarantee inspection after use of hypochlorite as the purification agent. Through multiple chemical steps, hydrochloric acid is generated at the steel interface leading to iron chloride salts under the blisters. Fig. 3 depicts the blisters formed in such a way within the potable water tank onboard a very large passenger cruise ship.

The blister fluid may have become strongly acid or strongly alkaline by generating an acid or alkali under the film after gas phase transmission of the acid or alkaline precursors. Acids and alkalis are both strong ionic solutes and may drive osmotic blister enlargement once initiated. Water soluble solvents included in the paint formulation by the manufacturer, or added at application, are another source of solutes in which there is no additional ionic activity.

Fig. 2—Osmotic blisters in the ballast tank of a large marine tanker. Note that many blisters have broken open and corrosion of the substrate is substantial. Some of these may be driven by cathodic protection anodes installed in the tanks that are operative only when the tank is with ballast water.

Fig. 3—Osmotic blisters in a potable water tank within a large cruise ship. Notice rust staining coming from broken blisters. Often these initiate from water soluble solvents formulated into the epoxy or added during application. Analysis of the blister fluid will indicate the source of the osmotic blister formation.

OSMOSIS IN PAINT FILMS

When a practitioner is asked to define an "Osmotic paint failure," the typical response is "… the passage of water through a semi-permeable membrane to dissolve salts under the paint thereby forming blisters under the film." While this might describe a portion of such failures, the picture is much broader than this description might imply. The term "semi-permeable" is in common usage although, often, there is little, or no, thought as to the considerable significance of the numerical value of the "semi-" in this common definition. This is true as it relates to the material acting as the solvent as well as the materials acting as the solutes driving the osmotic activity. It is important to appreciate that this variability in migration rate/ability through the paint film applies to both the solvent and (the often neglected) solute(s), when these solutes are water-soluble solvents included in the paint formulation, added during application, or generated in service.

In this chapter on methods of determining the source of osmotic activity in paint films, the terms "blister fluid" and "blister solution" represent the mixture of the solvent and one or more solutes found in the blister. By convention, the material present in this solution in the largest amount is considered to be the solvent. Generally speaking, the value of the vapor pressure of the solvent in the blister fluid solution as compared to the vapor pressure of the solvent outside the blistered film dictates the direction of the solvent flow. One must remember that a solvent's vapor pressure will always be depressed when the solvent has any solutes added. In the production of pickles, the cucumber is soaked in a strong salt brine solution wherein the water of the brine has a lower vapor pressure than the water inside the cucumber. In this case, the water flows out of the cucumber causing it to shrivel to a much smaller size.

Within the blister fluid, all of the dissolved materials are considered as the solutes and will act to depress the solvent's vapor pressure. Many only think of salts, over-coated at the time of application or included in the formulation, as potential solutes and water from either surface condensation or immersion service as the solvent. While water soluble salts are a common and strong osmotic driving force, water soluble solvents, such as oxygenated alcohols, have been shown to present a serious osmotic driving force. Oxygenated alcohols are alcohols (already containing at least one oxygen atom) that contain additional oxygen in the form of ethers or ketones. These materials are excellent solvents for the epoxy coatings as they cure and may be employed in the paint formulation, but they are typically not very volatile and remain within the coating matrix for long periods of time. Their added oxygen in the molecule as ether linkages (–COC–) usually render them water soluble. Their water solubility also aides in displacing moisture at the interface during application over damp surfaces. Unfortunately, since most are totally water soluble, they can become the osmotic driving force when liquid water condenses on, or comes into contact with the coating, especially when insufficient time is available to allow escape during the drying stage [1].

Water soluble reaction products such as acetic acid remaining after hydrolysis of acetate solvents or microbial digestion of sugars have also been seen as solutes. Acid solutes usually cause additional corrosion of steel substrates under coatings with the initially formed iron salts becoming solutes in the osmotic process. The ferrous (Fe^{+2}) corrosion product soon converts to an insoluble ferric (Fe^{+3}) corrosion product after reaction with oxygen in the air. If the adhesion is good and the blister dome breaks from internal pressure, osmosis cannot continue at that blister location since osmosis requires movement of one molecule at a time.

There are a number of factors that dictate the degree and speed of damage to a coating system that is experiencing osmotic activity. This communication is intended to present some important aspects useful in understanding the process of osmosis, its damaging effects upon paint films, and a methodology that has proven useful in the systematic elucidation of the source of the osmotic driving force. Osmotic activity in paint films is a very common failure mode. This chapter is intended to assist the coatings formulator, the application contractor, the failure analysis practitioner, and the end user in understanding the operative driving forces and demonstrate methodology useful in determining the source of the osmotic activity after coating failure.

Osmotic activity in paint films will be addressed in the following steps: (1) discuss the chemistry/energetics of the osmotic process and other chemical processes that may accompany and exacerbate this coating failure mode; (2) discuss some of those factors causing, or accelerating, osmotic activity in paint films; (3) discuss a proven methodology employed in the systematic chemical analysis of the osmotic blister fluids to identify the source of the activity and the significance of the analytical data as it relates to potential problems with the paint formulation, the specific application, and/or the service leading to the paint failure; and (4) present some case history examples to demonstrate the data developed in identifying the source of the osmotic activity.

Water is the most common solvent encountered in paint film osmotic activity. For this reason, water systems, primarily, will be discussed in this communication. It is important to appreciate that other solvent/solute systems may be encountered and are just as damaging. A common example exists with marine epoxy tank linings containing benzyl alcohol or nonyl-phenols and cargo materials having marginal transmission coefficients such as the fuel additive methyl-t-butyl ether (MTBE) and some lower molecular weight alcohols sequenced with the presence of water.

THE CHEMISTRY OF THE OSMOTIC PROCESS

In simpler terms, osmosis is the natural process of *individual* solvent molecules migrating through the film, condensing, and dissolving some solute to form a solution. For osmosis to be possible, molecules of solvent MUST travel through the paint film ONE MOLECULE AT A TIME. By definition, this makes the process a "Gas Phase Transition" since a "gas" is a collection of individual molecules. For this reason osmotic activity follows the general gas laws of chemistry.

It is more understandable to say that the vapor pressure of the pure solvent (outside the coating film) is greater than the vapor pressure of the diluted solvent in the blister fluid solution. This difference in vapor pressure thereby forces the solvent towards the osmotic solution. This is due to the depression in vapor pressure of the blister fluid caused by

the solutes present as opposed to the pure solvent. Just as dissolved solutes will depress the freezing point, or elevate the boiling point of a solvent (by depressing its vapor pressure), the energy required to perform the chemical work, or, simply, the osmotic driving force, has its origins in the similar basic laws of chemistry [2].

This then leads one to the more common "definition" of osmotic activity. The solvent molecules migrate through the film and dissolve into the blister fluid solution in an effort to dilute that solution to the point that it is the same concentration (same vapor pressure) as the outer contact liquid. More precisely, the process continues until the vapor pressure of the blister fluid solution equals the partial vapor pressure of the solvent outside the blister. (The physical chemistry purist will speak of equating the chemical potential of the two.)

Because osmotic activity is a "colligative property" of the solution, the driving force is based on the number of individual species dissolved in the solution rather than the individual solute's molecular weight, size, or chemical structure. In general, this means that the effect of one mole (90 g) of 2-butoxy ethanol/liter has the same damaging effect as a half "mole" (about 29 g) of sodium chloride/liter since the sodium and the chloride ions are each separated in the osmotic solution and the total sum of the number of individual species dissolved (ions) are equal to the number of the 2-butoxy ethanol molecules in solution.

Individual movement of molecules of the solvent through the paint film is an important concept to appreciate. By definition, this is a gas phase transition since a gas, also, exists as individual molecules. For osmotic blisters to form in the first place there must be sufficiently compromised adhesion for a condensed (liquid) phase to exist, even if over an extremely minuscule area. Once a liquid solution is present, at an interface (base substrate, inter-coat interface, particle inclusion, etc.), the volume and, usually, the pressure of the condensing fluid will continue to increase until two conditions exist collectively.

In osmotic activity, the first condition is that the concentration of the solute within the blister fluid decreases as the volume of pure solvent passing through the film increases. When this concentration of driving solute in the blister fluid equals that in the external contact fluid, the process will stop. More precisely stated, the osmotic driving force diminishes as the partial pressure (chemical potential) of the solution in the blister and the partial pressure of the liquid outside the film approach the same value.

The second condition occurs when the actual pressure that is gradually created in the osmotic blister reaches the value that will force the pure solvent (or solutes) back through the film. This is the process of reverse osmosis used to purify water in certain desalination systems.

When the adhesion of the paint film is good and the film cannot be peeled easily from the substrate by the internal osmotic pressure generated, the pressure may become sufficient to rupture the blister. When this occurs, if the crack remains open and liquid solvent can pass, osmotic activity is no longer possible. This is because liquid phase movements (as opposed to gas phase) are now operative since there is no semi-permeable membrane. Osmosis requires that individual molecules (i.e., separated from each other) move through the semi-permeable membrane (paint film) thus acting as a vapor phase transmission.

FACTORS CAUSING VARIATION IN OSMOTIC ACTIVITY IN PAINT FILMS

While most osmotic activity in paint films is clearly visible, osmotic activity can, and does, occur without the appearance of visible domed blisters. The development of osmotic blisters at the coating/substrate interface, whether visible or not, depends on a large number of factors. A few of these include: (1) the value of the paint's adhesion force at that location; (2) the degree of the depression of the glass transition temperature, T_g, and/or plasticity of the paint film caused by the water (or other solvent) and any migrating solutes; (3) the concentration, and location, of available solutes; (4) the transmission coefficients of the solvent, and solutes, within the paint film at that location and under the local ambient cure conditions.

For coatings like epoxies, the actual variation in transmission rates are possible within a single formulation and depend on numerous application variables. Solvent and molecular solute transmission coefficients within a paint film will depend on variations in the degree of mixing prior to application, closeness to true mixed chemical stoichiometry of the base and converter resins, temperature of the substrate (and, therefore, the reacting paint mixture) during curing, ultimate cross-link density of the formulation, amount of carbon dioxide (CO_2) stripped from the air by the amino functional converter during mixing and application, and a myriad of other variables.

Although rare, osmotic activity can occur within the matrix of the paint film as opposed to an interface. When this happens, bubbles of liquid will form within the coating matrix, usually from condensation of water (or the solvent) on the surface of some occluded particle. This requires the osmotic pressure to develop to a value greater than the tensile strength of the paint matrix at the location of the formed bubble. Osmotic activity in this form is typically present as very small bubbles within the paint film. The bubbles are not spherical in nature, and they are best viewed under a microscope. It is important to emphasize that osmotically driven bubbles have nothing to do with any air or gas bubbles or voids that may have been trapped during application and are present in the applied film [3]. Osmotically generated voids or bubbles within the coating matrix will show, microscopically, a fractured edge as opposed to a smooth surface for air trapped bubbles. The size of the bubbles formed from osmotic activity that occur within the coating matrix depends largely on the tensile strength of the coating matrix at the inclusion and the distribution of water soluble inclusions, either salts, pigments, or converter fractions. Water soluble low molecular weight amine converters have been seen in blister fluid when application occurred at cold temperatures. Typically, these are usually at an interface as opposed to within the film matrix and occur as a result of reaction of the alkaline amine functional cross-linker and the acid gas carbon dioxide.

From the above discussion, it is evident that for osmotic activity to occur at an interface where adequate solute is available, the value (strength) of adhesion is the major factor that will dictate the size of the blisters formed. When blisters form, areas having very good adhesion will yield small blisters. Areas having compromised or lower values of adhesion will yield larger blisters. Very large blisters (16 in. diameter and greater) have been observed when CP produced alkali salts *in situ* under FBE pipe coatings.

Fig. 4—Blisters as large as 20 in. have been seen on cathodically protected pipelines. The fluid from the blister on the FBE coated pipe above was highly alkaline from the reduced oxygen production of hydroxide.

These coatings were applied over salt contaminated areas of a pipe and developed within a few years time. This very common example typically is the result of applied cathodic protection and the production of hydroxide ion (salts) from reduction of oxygen gas passing through the coating and dissolving into the blister fluid. See Fig. 4.

All amorphous (i.e., non-crystalline) organic coatings and plastics will allow small molecules to migrate within, or diffuse through, the plastic matrix. This is the same mechanism that allows a freshly applied coating, after gelling, to lose most of its included solvents as it cures and dries. The rate, or speed, of passage of these individual molecules through a coating film is called its transmission coefficient for that material and depends on numerous factors. These include the solute size and molecular weight. Ficks Law dictates that the diffusion rate through a polymer matrix is inversely proportional to the square root of the molecular weight of the migrating molecule. Diffusion rate is also impacted by the cross-link density of the film. The transmission coefficient of migrating molecules is often related to the glass transition temperature, T_g. Migration rates are also impacted by the chemical and structural nature of the matrix as well as the migrating specie's polarity, polarizability, and chemical stability. This migration within a coating matrix is normal and to be expected, although sometimes it is undesirable. When sufficient volumes are lost after reaching the gelled state in its curing process, cracking of the coating from shrinkage stress development may occur. No coating stresses can develop from volume loss before the gel point is reached since liquid mechanics are operative within the freshly applied paint. The inclusion of these migrating species within a coating matrix causes a decrease in the cured film's glass transition temperature, T_g. This dynamic, constant movement within the coating film is the same as experienced with migrating plasticizers, chemically blocked cross-link accelerators/enhancers, molecular catalysts, as well as binder extenders such as benzyl alcohol, nonyl-phenols, etc.

The past experience of the author has shown that the water-soluble solutes causing osmotic blisters can come from a number of sources. Some typical sources include the following:

1. Water-soluble solvents purposefully formulated into the paint by the manufacturer. The most common are oxygenated alcohols such as 1-methoxy-2-propanol and 2-butoxy ethanol. Some are listed in the product's material safety data sheets (MSDS) while some paint manufacturers are reluctant to identify their presence.
2. Water-soluble solvents added at application (thinners). While the paint or the manufacturer's recommended thinners may not contain the oxygenated alcohols, the manufacturer's recommended wash thinners may contain these solvents. These have been detected in applied paint films in past blister fluid analyses, apparently from inadvertent inclusion by the applicator when the wash thinner was used to thin the paint at application.
3. Salts remaining on the substrate at the time of application. All water-soluble salts, whether sodium chloride, sodium/potassium/lithium hydroxide, or whatever the ionizable water-soluble salts may be, these can become solutes in the osmotic blister fluid. Most water based zinc silicate formulations use a binder that originates as a water glass. This is a silicate dissolved by alkali hydroxide. Shop primers often are not formulated above the critical pigment volume concentration (CPVC) and allow the hydroxide salts to become trapped within the matrix of the shop-primer coating. These are slowly released when used in immersion or damp, water-condensing service. Usually, efforts are made to water rinse any soluble salts from the primers prior to over-coating but with systems formulated below the CPVC, this cannot be done effectively. Even with systems formulated above the CPVC, extended curing times are always required to minimize the availability of the soluble alkali hydroxides. Rinsing should continue until the dampened surface has a *p*H equal to the rinse water. The lack of porosity makes this task difficult (or impossible). In these cases, the blister fluid will be of a high *p*H, high conductivity, and the ion analysis will indicate the presence of the alkali metal (Na, K, or Li) from the water based zinc silicate primer. Ethyl silicate based zinc primers are not as prone to the blistering in this way, although the mineral acids used to stabilize the silicate binder in the storage container may present a problem if not rinsed away prior to over-coating and immersion.
4. Hydroxide salts generated in the blister fluid. The continuous generation of hydroxide ion in blister fluid will occur when two conditions are met: (a) a liquid water filled area exists at the steel or zinc primer interface irrespective of how small (as opposed to intercoat delaminated areas) allowing oxygen to migrate in; (b) a cathodic potential exists of sufficient voltage to reduce any oxygen that migrates into the blister fluid. The oxygen is converted to hydroxide as it migrates into the blister fluid.

$$2H_2O + O_2 \rightarrow 4OH–$$

This represents the in situ production of a salt that will drive osmotic blister activity. The blister fluid will present with high conductivity and a high *p*H but may also contain dissolved organic and inorganic moieties from the paint. Benzyl alcohol is more soluble in alkaline blister fluid than in neutral *p*H water and has been seen in high *p*H blister fluid.
5. Hydrolysis of formulated, or cargo absorbed, materials such as ester solvents or chlorinated solvents. Esters are the reaction product of an acid and an alcohol.

Hence, butyl acetate is the reaction product of butanol and acetic acid. When this has been a cargo in a lined tank, after washing with water we have seen hydrolysis within the coating matrix. The butyl alcohol and acetic acid are regenerated by soponification reaction with a water molecule. Acetic acid that migrates to the steel interface may produce a corrosion product with iron that is itself somewhat soluble and becomes one of the osmotic driving solutes. Chlorinated solvents hydrolyze to HCl. The rate of hydrolysis is a function of the specie undergoing hydrolysis and the alkaline strength of the nucleophilic centers (nucleophilicity) within the coating matrix that catalyze the hydrolysis. The blister fluid will be of a low *p*H (less than 7 depending on acid content). Fermentation of sugars, as in molasses cargoes aboard ships, also produces acetic acid. Acetic acid will migrate through the coating and initiate corrosion at the steel interface. Analyses of the solid iron corrosion product recovered from under ruptured blisters will give a strong indication of acetic acid when utilizing the pyrolysis function of the gas chromatograph mass spectrometer (GC/MS) if this has occurred.

6. Production of sulfuric acid (H_2SO_4) within the slime layer of an internal lined sewer pipe caused by the bio-oxidation of hydrogen sulfide (H_2S). This leads to low *p*H blister fluids, and often perforation of the pipe.
7. Low molecular weight amine functional curatives that have been blocked from the epoxy reaction by carbon dioxide (CO_2) or other blocking agents. For CO_2 blocked converters, this is typically the result of cold temperature application wherein the epoxy-amine reaction slows or stops and the acid gas CO_2-amine reaction continues reasonably fast. During mixing of the amino side of the epoxy coating or the "A" + "B" mix, if a vortex is drawn on the mixing paint and air is mixed into the paint, most of the CO_2 in the air will be stripped and the resulting blocked curative will not be available for reaction with the epoxy. This is one of the sources of variability in the ultimate T_g of the cured coating. Inclusion of ketones in the amino side of an epoxy curatives is another potential source of failures. This happens when the amino functionality is blocked by the formation of ketimines in the can during storage. In this case, the length of time since curative manufacturer and the past thermal history will influence the amount of ketimine that has developed in the can. Ketimines require moisture from the atmosphere to cure and are the curatives used in "moisture cured" epoxy systems.

The data developed by the blister fluid analysis, on occasion, will indicate additional tests useful in confirming the source of the water soluble solutes found. This is true when their presence cannot be explained by the MSDS of one of the paint products involved. The MSDS for the coating material does not always include non-hazardous water-soluble solvents. Evidence developed from work by this laboratory on ship-bottom paints has shown that solvents from any coat of applied paint will migrate throughout all prior applied old layers allowing blisters to form at the steel interface. This was demonstrated after the fresh application of a topcoat containing an oxygenated alcohol was applied to a ship's hull over three layers of five year old, pre-existing paint that never blistered. The analysis of the blister fluid collected from below the original paint system indicated the water-soluble alcohol that was present in the new paint application. On occasion, chemical reactions in or about the osmotic blister area will be producing the solutes. For this reason, to establish liability, the investigator must be prepared to accept the data from the blister fluid analysis and seek the true chemical pathways to these solutes, even if he must revisit his chemistry textbooks.

THE SYSTEMATIC CHEMICAL ANALYSIS OF OSMOTIC BLISTER FLUIDS AND BLISTERED COATINGS

A systematic analysis of the fluids removed from osmotic blisters will provide the answers as to what drives the osmotic activity and therefore assist in establishing liability. In addition, the analysis often will indicate ancillary chemistries occurring within the blister fluid itself and/or within the coating matrix forming the blister dome. The following analytical methodologies have been found to provide sufficient data to identify the material(s) initiating the activity and any additional driving forces that might be developed after blister formation.

The collection of blister fluids is best done using a hypodermic syringe after first producing a small hole through which the needle may be placed as seen in Fig. 5. Usually, the coatings are too hard and brittle to force the needle through the coating film itself. For this reason, to minimize the chance of destroying, bending, or plugging the needle, drilling or puncturing with a sharp nail at the edge of the blister may be best. The solution should be collected and stored in glass vials since many of the solvents will migrate through plastic containers if the chemical analysis is not done timely.

Ideally, many answers are provided by using a GC/MS having the ability, first, to out-gas and identify the lower molecular weight volatiles followed by a separate, second, analysis of the fragments after pyrolysis at elevated temperature of the residues. The pyrolysis, then, is done without opening the thermal extraction (TE)/pyrolysis (Pyro) oven. This is useful in solving some of the mysteries when the solutes are organic in nature. Higher molecular weight water soluble materials may be identified that are not seen on direct injection. When this type of equipment is not available, gas chromatograph/mass spectrometers utilizing

Fig. 5—Blister fluid is being removed under water using a small hypodermic syringe. This is in the coating within a large concrete pool at a state aquarium. Note sharp wood chisel used to first produce a very small hole in the coating at the edge of the blister.

direct injection of the blister fluid is an alternative that will provide good definitive data for some of the cases, but the solvent portion is always much greater than the molecular solutes. The ionic solutes will not volatilize and cannot be seen by the GC. These are identified by ion chromatography or by scanning electron microscope (SEM) with energy dispersive x-ray (EDX) after drying the blister fluid residues (Fig. 6).

Knowing potential sources of osmotic activity allows narrowing the search. The sequence of procedures followed in the blister fluid analysis yielding the most data will include the following steps.

1. GC/MS analysis by low temperature TE/desorption (water soluble solvents).
2. GC/MS analysis by pyrolysis analysis of non-volatiles remaining after TE (higher molecular weight, water soluble reaction products); Done without opening TE/ Pyro oven.
3. Determination of electrical conductivity and *p*H
4. Ion chromatography to identify the specific ions other than OH^- and H^+ ions seen in the *p*H determination. When not available, SEM/EDX analysis of the dried blister fluid residue will reveal the inorganics present.

While the mass spec detector suffers in its being more difficult to perform finite concentration determinations, its ability to provide the identity of unknown water soluble organic solutes from their specific mass fragment fingerprint is excellent. Although it may be useful in some cases, the absolute concentration of the specific solutes in the blister fluid is not required to determine the source of the osmotic activity.

After analysis of the blister fluid, additional analyses of related coating materials will allow determining the source of the water soluble solvents. These analytical techniques include thermal extraction and pyrolysis analysis of the coating materials forming the dome of the blister, as well as coating material in the near vicinity of the blister. Testing wet, un-applied, un-mixed coating materials from the can will pinpoint specific problems if these are from the paint formulation. If a water soluble solvent is found to be the osmotic driving force, the comparison of the analyses of the applied coating and the unapplied coating material will indicate whether this bad solvent was added during application or was included by the manufacturer in the paint formulation. Occasionally a review of the MSDS for the coating product will indicate the water-soluble solvent, though from experience we have seen that the paint manufacturer often does not identify these solvents (Fig. 7).

GC/MS Analysis by Low Temperature Thermal Extraction/Desorption (TE/GC/MS)

Often, the amount of available blister solution is small. Because of the large amount of data provided by the GC/MS thermal desorption and pyrolysis techniques, these analyses should be performed first if only one drop of blister fluid solution is available. When salts are the primary osmotic driving force, usually there will be ample blister fluid sample available (Fig. 8).

The ideal GC/MS analytical instrument used for the thermal extraction and pyrolysis analysis is a combination of four instruments linked together. It has been described in detail previously [4,5]. Briefly, it is a late-model GC with a mass spectrometer used as the detector. Integrally attached to the GC inlet is a heated transfer line of deactivated fused silica maintained at about 325°C (620°F) connecting the computer controlled TE/ Pyro oven. The very small TE/ Pyro oven has a stream of Helium sweeping any volatilized materials into the cryogenic trap in the GC. The separation

Fig. 6—The ideal analytical instrument configuration for identifying the source of osmotic activity in paint films is a gas chromatograph having a mass spectrometer as a detector, a thermal out-gassing/pyrolysis attachment, and a liquid nitrogen trapping section at the head of the GC column. To the right is the pyrolysis and thermal out-gassing attachment. The liquid nitrogen cryogenic focusing on capillary column is within the GC oven as seen in Fig. 6. The components of the analytical system are as follows: 1. Gas chromatograph; 2. Mass spectrometer; 3. Pyrolysis-outgassing controller for solid samples; 4. Liquid nitrogen cryogenic controller; 5. Heated crossover line from pyrolysis oven to cryogenic trap in the GC oven; 6. Liquid nitrogen supply line from outside LN2 storage.

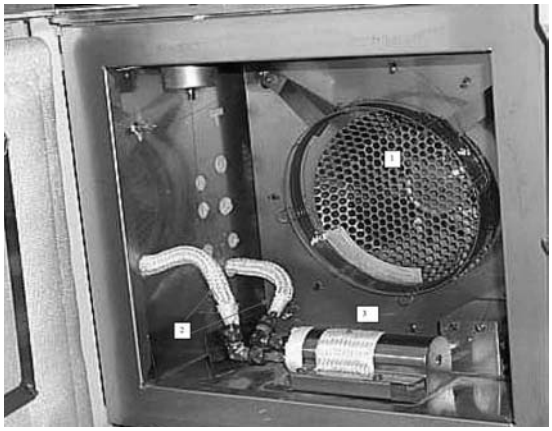

Fig. 7—Oven of gas chromatograph housing quartz capillary column (30 m) and quartz cryogenic focusing chamber. The components are: 1. 30 m capillary column passing through liquid nitrogen (LN2) cryogenic trap; 2. LN2 inlet and outlet fed by thermostat control of LN2 valve; 3. Quartz LN2 cryogenic chamber with electrical resistance heater to flush trapped components onto the column at the start of the GC analysis. Capillary column passes through the LN2 cooled cryogenic trap. An alternative "home-made" cryogenic trap is a simple styrofoam cup containing liquid nitrogen. This is placed in the GC oven allowing a short section of the capillary column to be manually submerged during sample out-gassing. The LN2 is removed at the start of the GC analysis.

Fig. 8—A conductivity meter requiring only one drop of blister fluid is used to determine electrical conductivity. Conductivity of the blister fluid solution is a measure of the total number of ions or salts present. Specific identification of the ions is provided by SEM/EDX or ion chromatography. (Photo provided by HORIBA Instruments, Inc., www.horiba.com)

Fig. 9—A *p*H indicating a paper strip is used to determine the *p*H of the blister solution. The fluid from the conductivity meter is adequate for this determination. If there is minimal blister fluid available, a very small spot from the hypodermic syringe will suffice.

column used is a 30 m DB-5 capillary column. About 4 in. of the front end of the column passes through a quartz chamber plumbed to receive liquid nitrogen. This chamber also contains a wire resistance heater capable of heating the frozen column to 275°C (527°F) very quickly. A separate computer controller is programmed to maintain –125°C (–193°F), initially to cryogenically trap the volatilized components or thermally degraded fragments from the heated polymer. The thermal desorption/pyrolysis oven operates for about 6.5 min, going from ambient to 125°C (257°F) for TE or ambient to 500°C (932°F) for pyrolysis. This drives off any materials volatile at these conditions. The cryogenic trap maintains its cold –125°C (–193°F) temperature for 10 min. At the end of the 10 min. collection period, the controller shuts off the LN2, the resistance heater quickly takes the cryogenically cooled trapped section of the column to 275°C (527°F), the GC is automatically switched on, and the mass spectrometer starts to collect data. An alternative cryogenic trap that works very well is a simple styrofoam cup placed in the GC containing liquid nitrogen. A loop of the GC column is then submerged under the LN2. To start the analysis the cup of LN2 is removed and the GC started after the out-gassing/ pyrolysis. This provides –190°C (–310°F) cryogenic trapping. At this temperature, all products of interest will be stopped, including carbon dioxide and acetone.

Frequently, solutes identified by the low temperature TE analysis include the oxygenated alcohols (2-butoxy ethanol, 1-methoxy-2-propanol, etc.), the butanols, benzyl alcohol, the xylenes, ketones, acids (both organic and mineral), and any solutes volatilized at the 125°C (257°F) TE condition. If the blister is being driven by hydroxyl ion being leached from the substrate (as with some water based zinc silicates) or generated from CP impressed currents, the *p*H will be high. For high *p*H blister fluids, the solubility of any benzyl alcohol binder extender and other alcohols become much greater. These may then be seen. Typically, their concentrations will not be sufficiently great to continue the development of the blisters in neutral (water) blister fluid. Tank linings used in organic solvent service can generate blisters from the alcohol extenders depending on the coating and service (Fig. 9).

GC/MS High Temperature Pyrolysis (PYRO/GC/MS)

To identify the higher molecular weight solutes, without opening the TE/Pyro oven system after the TE run, the TE/Pyro oven controller is set for the pyrolysis programmed conditions. The cryogenic trap is brought back down to –125°C (–193°F) or the cup of LN2 is re-inserted. When the cryogenic section of the separation column reaches the low trapping temperature, the pyrolysis oven containing the dried blister fluid sample is heated to 500°C (932°F). Any organic materials that were dissolved in the blister fluid but did not volatilize during the warming thermal extraction procedure are now subjected to the potential thermal degradation temperature of 500°C (932°F). Any heavy organic solutes will degrade to volatile components. The identification of these components allows one to visualize their precursors.

Determination of Electrical Conductivity and pH

If there is sufficient blister fluid, one drop is used to determine the electrical conductivity and *p*H. When the conductivity is high, there is ionic activity. If the *p*H is alkaline, the ionic source could be from applied CP, or a source of stray current potential sufficient to reduce molecular oxygen to the hydroxide. The coating may have been applied over a water based zinc shop primer wherein all of the sodium or potassium hydroxide could not be rinsed away. There is a very low probability that some of the amine curative may have been solubilized.

If the conductivity is high and the *p*H is neutral, as may be the case between coating layers, the salts may be organic acid or carbonated amine curatives. An exception is in areas where wind blown salts are available, as on offshore facilities and in marine applications.

If the conductivity is high and the *p*H is low, there is some source of acid causing the *p*H depression. Unlike the clean, non-corroded metal seen under high *p*H blister

fluids, typically, the low *p*H fluids cause the steel to corrode. The source of acid must be determined from past history or pyrolysis of the iron corrosion product. For cargo tank linings, this is a common problem and may be deduced from cargo histories that are available. Acetic acid is especially problematic. Cargoes of molasses and natural sugar products often contain acetic acid that is the result of bio-degradation. The transmission coefficients for acetic acid through most tank linings are such that it often becomes the primary solute in the osmotic activity. After desolution of iron, additional soluble iron (II) complexes add to the solute mix dissolved in the blister fluid. As oxygen transports across the paint film to the blister fluid, the soluble iron (II) complex is converted to iron (III) and precipitates out of solution. Analysis of the rusty iron scrapings from under the blister area by pyrolysis GC/MS will often reveal which acid has been operative, even if it is hydrochloric acid. Hydrochloric acid results from the hydrolysis of chlorinated solvents. There are many different chlorinated organic solvents stored in coated tanks as well as transported in coated marine tankers. All will hydrolyze to some degree to produce the HCl. The most problematic chlorinated solvent seen by this laboratory is the cargo material allyl chloride, $CH_2{=}CH_2CH_2Cl$. This material absorbs into the tank lining and within hours after water washing, liberates HCl.

Hydrogen sulfide, H_2S, may be generated within sewer systems that are not properly treated to control the condition. Since this is an anaerobic action (occurs in the absence of oxygen), to stop this H_2S formation, sewer operators will sometimes attempt to maintain a sufficient amount of dissolved oxygen (DO) in the effluent to disallow attack of the sulfates. Another practice is the addition of nitrates into the effluent, since the bacteria prefer nitrates to sulfates as their hydrogen acceptor in the energetics of their life cycle. If the sewer system has not been properly controlled for the production of hydrogen sulfide, sulfuric acid will be produced from any H_2S after reaching aerobic conditions. This occurs readily in the crown of partially filled pipes where air is available above the wastewater. The resulting corrosion is called "Crown Corrosion" for this reason [6]. This can destroy both steel and concrete pipe systems after loss of coating by osmotic blister formation.

Ion Chromatography

The use of ion chromatography usually will identify the specific ions causing the high conductivity in blister fluids. Past experience of this laboratory has shown that the presence of hydroxyl ions from a CP induced high *p*H blister fluid often will cause an increase in additional ionic species in the blister fluid. Under blue or green coatings, bromine may be hydrolyzed from the phthalo blues and greens pigments. Chlorides may be hydrolyzed from epoxy resins in high *p*H blister fluids. For this reason, the presence of the chloride or bromide ion in the blister fluid is NOT, conclusively, indicative of salts over-coated during application although these may have contributed to the diminished adhesion exacerbating the osmotic activity. Sulfates will be seen in oxidation of the H_2S in sewer pipes. Sea water evaporation and blown sea salts will contain chlorides, bicarbonates or carbonates (depending on *p*H), sulfates, and all other ions typically seen in seawater.

CASE HISTORIES OF OSMOTIC ACTIVITY PAINT FAILURES

Case Number 1: A series of barges employed in fresh water river trade developed blisters after being in service a number of months. The time to discovery was about a year. The paint system included the use of a water based potassium silicate zinc shop primer applied to the steel plate upon arrival at the fabrication facility. After application of the shop primer, the steel was fabricated into barges within about a month. After fabrication of the barge, and just a few days before launch, the finished barge was high-pressure fresh water rinsed, allowed to dry, and over-coated with an epoxy coating. Blisters were discovered during dry-docking about a year later. There were no cathodic protection anodes used. The declaration was made that there had been no cathodic protection potentials applied to the vessel during its moorings. Grounding a vessel to the CP system of a dock is a practice that often occurs with vessels that trade in flammable cargo. These barges traded in dry cargo.

Fluid was collected from a number of the blisters on the bottom of a barge. The blister fluid was clear, the *p*H of the fluid was about 13, the conductivity was measured at 19 200 μS (microsemins). Chemical analyses of the fluid by GC/MS TE followed by PYRO indicated that a small amount of organic solubles was present in the fluid. These were all alcohols that had migrated from the epoxy paint topcoat. There were no heavier molecular weight materials seen during the pyrolysis analysis.

The analyses indicated that the water based zinc silicate still contained sufficient water-soluble potassium hydroxide to become the solute in the osmotic blisters. It is extremely difficult to extract all alkali from these types of silicate films in one short rinsing. Additionally, the curing of the silicate film may require months to fully bind the potassium and allow loss of the excess alkali to become minimally soluble-salt free. (It cannot become salt-free.) The driving force to produce blisters is just as strong for the salt potassium hydroxide as it is for the salt sodium chloride. One would never consider over-coating high concentrations of sodium chloride salt. Because zinc metal is amphoteric (i.e., can be dissolved by either acid or base) the tetrahydroxy zinc (II) ion is just another solute driving the osmotic activity. The organic solutes seen in the GC/MS analysis are, in part, because of their increased solubility as the pH of the blister fluid increases. The butanol and benzyl alcohol have limited solubility in neutral water. The 1-methoxy-2-propanol is 100 % water-soluble and can be a problem in certain scenarios. This water soluble solvent is sensitive to length of drying time and ventilation. The transmission coefficient for this oxygenated alcohol is greater than the 2-butoxy ethanol and often will not be sufficient to generate visible osmotic blisters. The exception is in well cross-linked epoxy systems where its mobility is more restricted. This is an example of the importance of the numerical values of the "semi" in the "semi-permeable membrane" part of a typical definition of "osmosis." In this case, although the concentrations were relatively small for all alcohols, the 1-methoxy-2-propanol exacerbated the blister formation and the hydroxide ion provided the driving force for the continued osmotic activity (see Fig. 10 and Fig. 11).

Case Number 2: Blisters developed within the coating system of a large floating offshore drilling platform. The

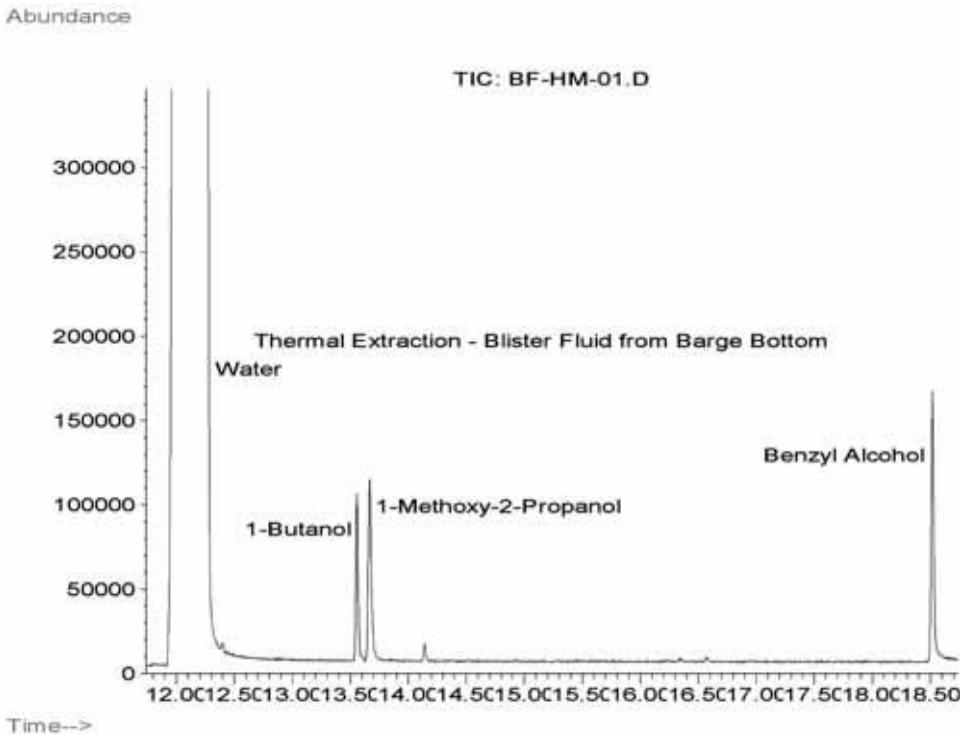

Fig. 10—GC/MS response from the thermal extraction of blister fluid collected from the bottom of a barge. Alcohols that normally are not appreciably soluble in water are more soluble in alkaline blister fluid. The scan is magnified to reveal the small amounts of organic solutes.

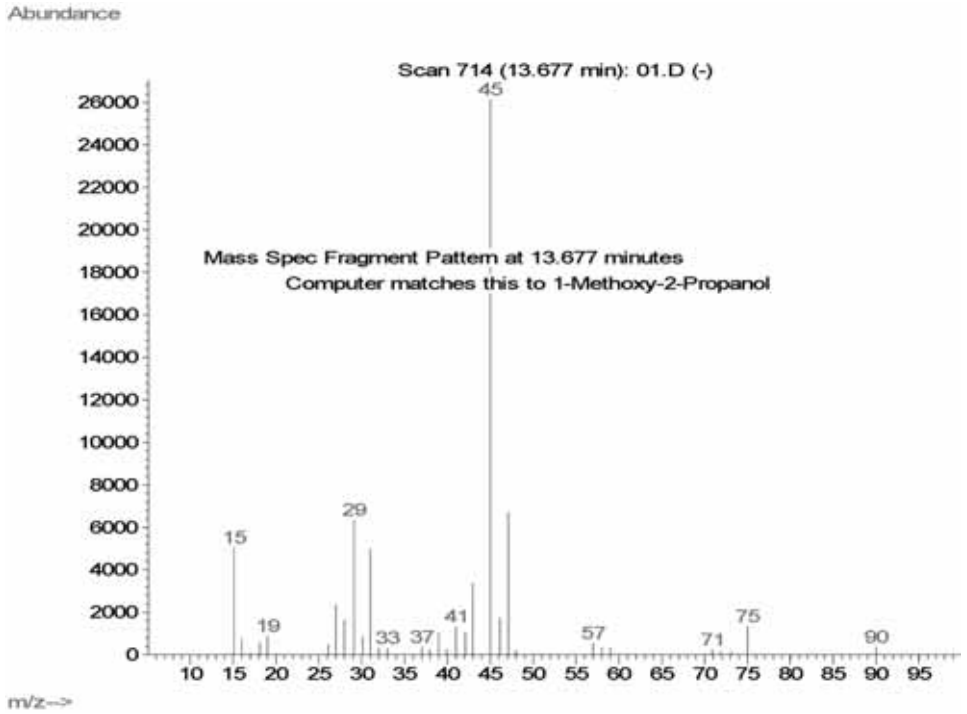

Fig. 11—Fragment pattern collected by the mass spectrometer at 13.677 min. The computer matched this pattern to 1-Methoxy-2-Propanol, a water soluble epoxy thinner. This "oxygenated" alcohol can cause osmotic blisters when condensed water is possible.

paint system was similar to Case Number 1 with the exception that the zinc silicate was applied as a holding primer after construction. It was a solvent based, ethyl silicate zinc coating. The two-coat epoxy topcoat was applied during colder months in Europe. Severe blistering occurred after flooding the tanks for testing. The drilling platform was delivered to the US for completion and an investigation of the cause of the osmotic activity was done [7].

Blister fluids were collected from two types of blisters based on their development location. Type one were blisters that originated at the metal interface and were under the full thickness of epoxy paint. Type two blisters were between the layers of the epoxy coating. Both blister fluids were clear as they were removed using hypodermic syringes. These fluids were analyzed separately. The blister fluid removed from the metal interface had a relatively high *p*H of greater than 12. The *p*H of the fluid extracted from blisters between layers of epoxy was neutral, *p*H of 7.

The GC/MS chemical analysis of the two blister fluids was very similar even though there was a large difference in their *p*H. There was a very large peak of 2-butoxy ethanol in each. It was very evident that the driving force for the blister formation was the oxygenated alcohol, 2-butoxy ethanol. A review of the MSDS for the reported coating material did not indicate the presence of this alcohol in the coating formulation. For this reason, it was first suspected that the applicator might have used this water-soluble solvent during application. This was shown to not be the case when retained samples of the actual coating materials used became available for GC/MS analysis. These were tested and found to contain the 2-butoxy ethanol as part of the paint formulation. The coating manufacturer was able to determine that there was a difference in the solvent system of the European produced material as opposed to that manufactured in the US. The high *p*H of the blister fluid removed from contact with the metal substrate was the result of sacrificial anodes installed during the construction of the platform. Oxygen that migrates into the blister fluid at the metal interface experienced sufficient electrical potential to cause the oxygen to be converted to hydroxide ion producing the high *p*H. For blisters formed between paint layers, there could be no electrical potential felt between layers, although there was compromised adhesion that allowed the delamination between coats of epoxy at the blister site [8].

Stress Phenomena in Organic Coatings

Dan Y. Perera[1]

PREFACE

THIS CHAPTER REVIEWS AND UPDATES THE TOPICS addressed by the previous authors, including up-to-date references and expanded to include stress in multi-layer systems and stress in physical aging.

Interest in the stress phenomena in organic coatings is relatively new. The importance of understanding and measuring this stress became evident as facts accumulated about its role in coating degradation [1–10]. This is also supported by the fact that many coatings used today (e.g., thermosets) are more susceptible to developing high stresses than traditional ones (e.g., alkyd paints). It is now quite clear that stress can affect coating adhesion and/or cohesion and provoke delamination and/or cracking.

Since the development of stress is involved in practically all stages of coating life (film formation, exposure to various climatic conditions), its measurement is essential for a better understanding of coating behavior.

In addition, the measurement of stress can be used to evaluate other important characteristics of a coating, such as the glass transition temperature (T_g) and the critical pigment volume concentration (CPVC).

ORIGINS OF STRESS IN ORGANIC COATINGS

Stresses originate in organic coatings as a result of their adhesion to the substrate. Good adhesion is, on the one hand, indispensable for adequate substrate protection, but on the other hand prevents the normal movement of a coating.

The three main causes which provoke stress in an organic coating are [11]:

1. Film formation.
2. Variation in temperature.
3. Variation in relative humidity (RH).

The stresses induced by film formation, variation in temperature, and variation in RH are known, respectively, as internal, thermal, and hygroscopic. The latter two stresses are also referred to as hygrothermal (S^{HT})

It is important to realize that, due to the coating adhesion to its substrate, stress exerts its action mainly in a plane parallel to the substrate [6,12,13]. Therefore, one can write

$$S = \frac{E\varepsilon}{1-\nu} \tag{1}$$

where

S = stress,
E = elastic modulus,
ε = strain,
ν = Poisson's ratio.

This relationship represents the stress equation for an uni-axial deformation adapted for a bi-axial deformation by dividing it with $1 - \nu$. It is therefore considered that the coating can contract or expand only through its thickness. In practice this might not always be so, i.e., in addition to tangential stresses, the coating can also be subjected to normal stresses.

Stresses are especially damaging at edges [14] where they cannot cancel each other or in the middle of the plate if defects or heterogeneities are present.

Film Formation

During film formation and regardless of the mechanism involved (evaporation of solvent, coalescence, chemical reaction, or their combination), in almost all cases the coating tends to contract. If this contraction is prevented by coating adhesion to its substrate and/or the mobility of macromolecular segments is hindered, a tensile stress will develop in the coating.

In the literature certain confusion reigns about the denomination of the stress arising during film formation. For example, for solvent-based coatings an author may use these terms: cure stresses, solvent removal stresses, residual stresses, shrinkage stresses, internal stresses. For simplification, I suggest referring to the stress arising during film formation as internal stress (S^F).

If a liquid paint is applied on a substrate [8] and the development of stress is measured as a function of time, a number of stages can be observed (Fig. 1).

In Stage 0, the coating is still liquid and is mobile enough to permit volume contraction, and consequently no stress develops.

In Stage 1, the film starts to form, the volume contraction is restricted, and stress develops.

In Stage 2, a number of processes can occur. Depending on the coating composition, the evolution of stress can include various combinations of increasing, decreasing, and stationary stress levels. If no damage occurs to the film (cracks, microfissures, loss of adhesion), a decrease in stress results from relaxation processes which occur from the moment the stress develops but only become evident at this stage. It also follows that the measured stress values are a result of two opposite processes, one tending to develop stresses in the coating (in this case due to the volume shrinkage) and the other tending to decrease them (due to stress relaxation).

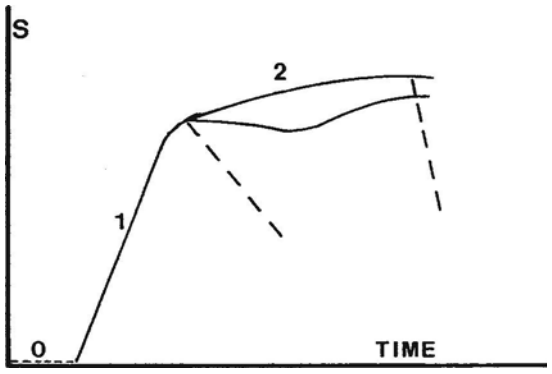

Fig. 1—Schematic description of stress (*S*) dependence on time.

Examples of stress development as a function of time for latex coatings [15] above and below the CPVC are shown in Fig. 2.

It is important to add that stress starts to develop in a coating when its T_g is at least equal to the experimental temperature [6]. For solvent-based coatings (Fig. 3), this is also confirmed by the fact that stress appears when Phase 2 of the evaporation kinetics (the diffusion process) starts [16]. At this point in the evaporation, referred to as solidification, the solvent volume fractions are equal to the solvent concentration necessary to bring the T_g of the coating to a temperature equal or higher than the experimental one [6,17].

The stresses arising in the different stages of the film formation of the polymer lattices are also discussed in Ref. [18]. The paper provides evidences of lateral dilatation stress occurring during the initial stage that is attributed to the capillary pressure.

If Eq (1) is extended to accommodate the specific effect of internal strain, ε^F [6], then

$$\varepsilon^F \approx \frac{V_s - V_t}{3V_s} = \frac{\Delta V}{3V_s} \tag{2}$$

where

V_s = volume of coating at solidification, and
V_t = volume of coating at time t after solidification.

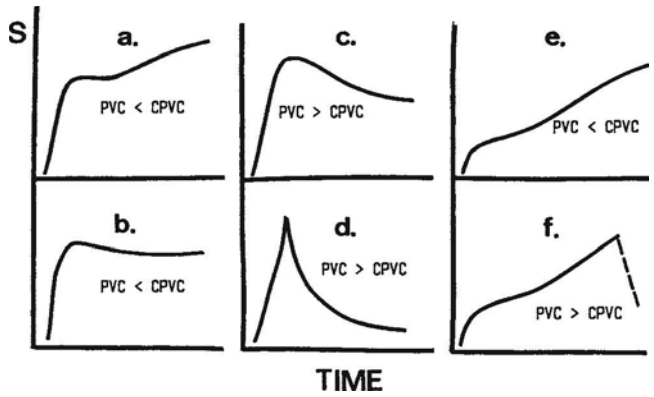

Fig. 2—Schematic description of stress (*S*) dependence on time for latex coatings: (a) and (b) PVC < CPVC; (c) and (d) PVC > CPVC; (e) PVC < CPVC in the presence of a poor coalescent; (f) PVC > CPVC in the presence of a poor coalescent.

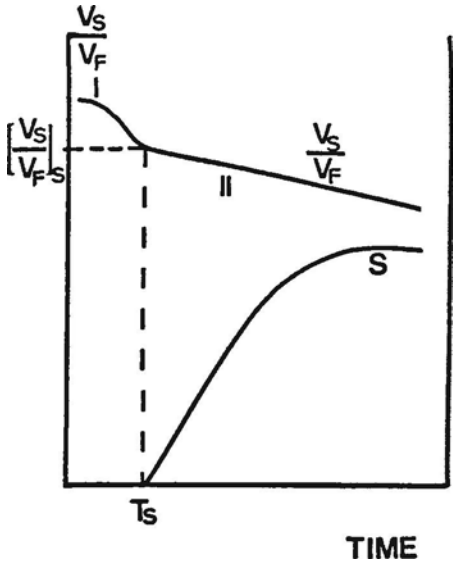

Fig. 3—Schematic representation of the dependence of V_S/V_F and stress (*S*) on time, V_S = volume of solvent present in the film; V_F = volume of the dry film.

One can write [19] that

$$S^F = \int_{V_t}^{V_S} \frac{E}{1-\nu}\frac{1}{3V_s}dV \tag{3}$$

Despite the limitations of Eq (2), which assumes that the strain is isotropic and linear, Eqs (2) and (3) enable one not only to better understand the factors affecting the S^F but eventually to calculate it approximately.

Variation of Temperature

When coated substrates are exposed to variations in temperature, dimensional changes are induced. If the thermal expansion coefficients of the coating $\left(\alpha_F^T\right)$ and the substrates $\left(\alpha_S^T\right)$ are different, which is usually the case, a thermal stress (S^T) will develop in the coating [2,7,11,20,21].

Since the thermal strain, ε^T is given by

$$\varepsilon^T \approx \left(\alpha_F^T - \alpha_S^T\right)\Delta T \tag{4}$$

the combination of Eqs (1) and (4) gives

$$S^T = \int_{T_2}^{T_1} \frac{E}{1-\nu}\left(\alpha_F^T - \alpha_S^T\right)\, dT \tag{5}$$

Determination of T_g

A schematic description of the stress dependence on temperature [19] is represented in Fig. 4.

Such dependence indicates the possibility of determining the T_g of a coating from the stress measurement. This is due to the fact that E, α_F^T, and ν (see Eqs (1) and (5)) also show a profound change at T_g.

Below temperature ***a*** the coating is in the glassy region, and above temperature ***b*** the coating is in the rubbery region.

The linear dependence of S on temperature in the glassy region greatly facilitates the measurement of T_g. This linearity is due to the fact that in this region E, α_F^T, and ν are practically independent of temperature.

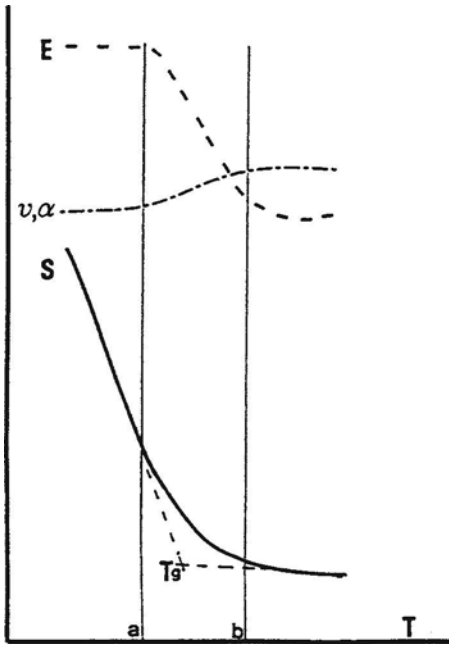

Fig. 4—Schematic representation of dependence of S, *E*, α, and *v* on temperature (*T*).

Three examples of the stress dependence on temperature and T_g determination by thermal stress measurements [19] are shown in Fig. 5.

When the stress magnitude in the rubbery region is small (e.g., elastomers, coatings with a low degree of cross-linking), the T_g can be determined with fair accuracy just by carrying out a few measurements in the glassy region and then extrapolating the straight line to $S^T = 0$.

For coatings subjected to a significant stress in the rubbery region (e.g., highly cross-linked thermosets), the measurement of stress in this region might provide a way to approximately determine the cross-link density, v_e [22].

Since in accordance with the molecular theory of rubber elasticity in its simplified form [23,24]

$$E_r = 3v_e RT_r \tag{6}$$

and

$$S_r = 2E_r\varepsilon_r \tag{7}$$

giving

$$v_e = \frac{E_r}{3RT_r} = \frac{S_r}{6RT_r\varepsilon_r} \tag{8}$$

where R, S_r, E_r, and T_r are, respectively, the gas constant, the stress, the elastic modulus, and the temperature at the beginning of the rubbery region. If S_r is measured and ε_r is known or determined from separate measurements (e.g., by thermomechanical analysis), v_e can be calculated.

Others have used the evaluation of T_g by stress measurements to investigate the effect of a pretreatment on certain pigments [25], the state of cure of baking enamels [22], and the modification of epoxy coatings [20,26].

Variation of Relative Humidity

Dimensional changes induced by absorption and desorption of water as a result of variation in RH is another cause of stress development in a coating [11,27,28]. As in the case of temperature, if a mismatch between the expansion coefficients of the coating and the substrate exists, a hygroscopic stress (S^H) will arise in the coating.

Since the hygroscopic strain ε^H is given by

$$\varepsilon^H \approx \left(\alpha_F^H - \alpha_S^H\right)\Delta H \tag{9}$$

one can write that

$$S^H = \int_{RH_1}^{RH_2} \frac{E}{1-\nu}\left(\alpha_F^H - \alpha_S^H\right) dRH \tag{10}$$

where α_F^H and α_S^H are, respectively, the hygroscopic expansion coefficients of the coating and the substrate.

Some examples of the S^H dependence on RH are given in Fig. 6.

INTERDEPENDENCE OF STRESSES

While in previous sections the various stresses (S^F, S^T, S^H) were discussed separately, in practice they can act together in such a way that the total stress (S_{tot}) is small or, as in many cases, very important [11]

$$S_{tot} = S^F \pm S^T \pm S^H \tag{11}$$

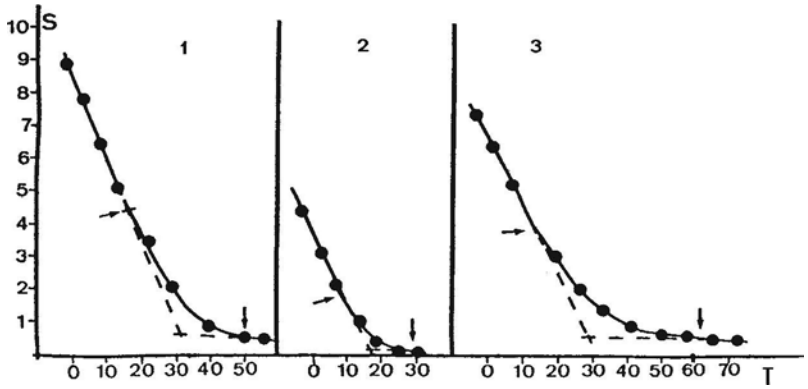

Fig. 5—Stress (*S*, MPa) dependence on temperature (*T*, °C) for three coatings at RH ≅ 0 % [an epoxy (1), a polyurethane (2), and an epoxy/melamine system (3)].

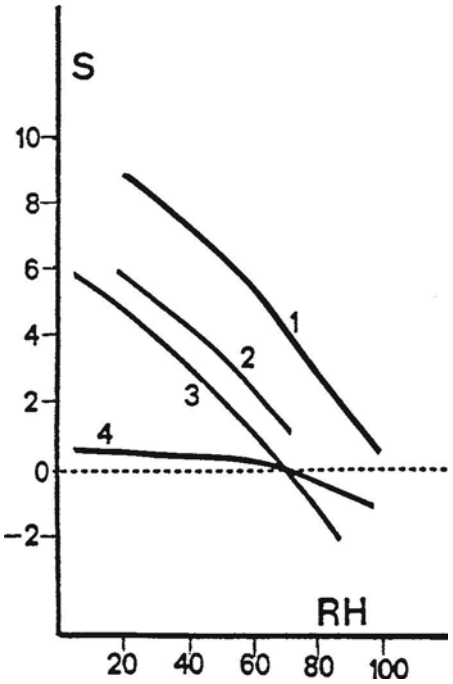

Fig. 6—Stress (*S*, MPa) dependence on relative humidity (RH, %) for a polyester powder coating (1); an epoxy (2); a polyurethane (3); and a latex coating (4).

The positive and negative signs are arbitrarily chosen. The positive sign denotes a coating tendency to contract (tensile stress) and the negative sign a coating tendency to expand (compressive stress). S^F is practically always positive.

Equation (11) indicates the existence of two climatic conditions which might provoke a high stress in a coating:

1. Low temperatures and RH's induce high tensile stresses (e.g., a dry, cold winter).
2. High temperatures and RH's induce high compressive stresses (e.g., a humid, warm summer).

According to Eq (11) and depending on the type of coating and the way it was cured, a number of situations can arise. For example, for a thermosetting coating cured at a high temperature (i.e., at $T > T_g$, RH = 0 %) and then exposed to different RH's, since $S^F \approx 0$ (except for highly cross-linked coatings), the S_{tot} is given by

$$S_{tot} \approx S^T - S^H \tag{12}$$

In Fig. 6, for one coating, the stress is positive regardless of RH, meaning that S^T is always higher than S^H; but cases where negative stress values are obtained are not rare.

It could be demonstrated [11] that the same coating conditioned in an identical environment but with different previous histories can develop different values of stress. Thus, a coating cured under isothermal and constant RH conditions (e.g., 21°C and 50 %) will develop a total stress given by

$$S_{tot} \approx S^F - S^H \tag{13}$$

Now, if the coated substrate is first heated at $T > T_g$ for sufficient time to enable a maximum stress relaxation and then brought back to the initial conditions (i.e., 21°C and 50 % RH)

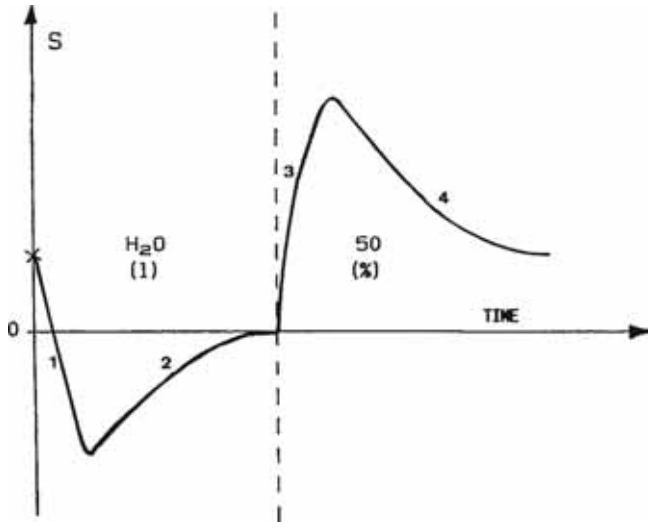

Fig. 7—Schematic description of the stress (*S*) dependence on time at two experimental conditions (water and 50 % RH). *X* = the initial stress.

$$S_{tot} = S^T - S^H \tag{14}$$

The results obtained [11] show that in certain cases (e.g., for an epoxy coating), the S_{tot} can be very different [S_{tot} (Eq (13)) = 5 MPa; S_{tot} (Eq (14)) = 0.4 MPa].

Interesting cases are those where the T_g of a coating is close to or below the experimental temperature once they are immersed in water or exposed to a high RH [29]. Under such conditions S^F or S^T can relax and therefore $S_{tot} \approx S^H$.

Such a situation is illustrated schematically in Fig. 7 and for a particular epoxy coating in Fig. 8.

Once a coated substrate is immersed in water one can observe first the development of a hygroscopic compressive stress followed by its decrease. The time necessary to reach zero stress is mainly dependent on the type of coating. The withdrawal of the coated substrate from water provokes first the development of a relatively high tensile hygroscopic stress followed by its decrease. The decrease in stress (Curves 2 and 4 in Fig. 7) is due to relaxation processes facilitated by the low T_g of the coating. The much higher stress values attained after the immediate withdrawal of the

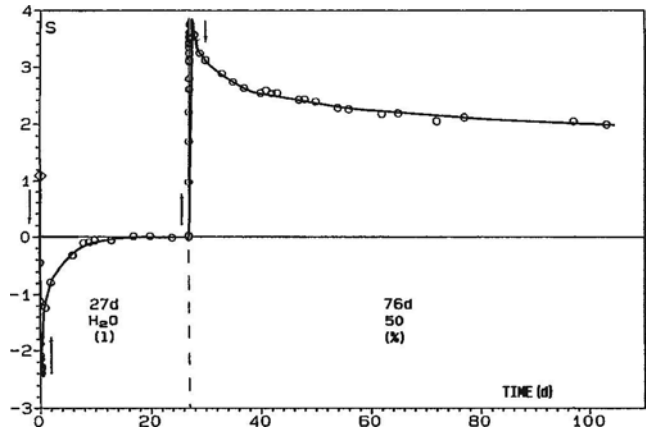

Fig. 8—Epoxy coating. Stress (*S*) dependence on time (*t*) at two experimental conditions (water and 50 % RH).

coated substrate from water (Curve 3 in Fig. 7), in comparison with the initial stress ($S_{tot} \approx S^F - S^H$ or $S_{tot} \approx S^T - S^H$) are due to the high hygroscopic tensile stress $\left(S_{tot} \approx S^H\right)$.

The above findings are important not only for understanding the mechanism of the stress development in organic coatings but also for practical reasons such as choosing the experimental conditions of natural or accelerated weathering tests, i.e., the magnitude of stress developed in a coating might depend as much on natural climatic conditions as on the type and order of cycle selected in the laboratory.

STRESS MEASUREMENT

Equations (1), (3), (5), and (10) show that, if one knows the values of E, ε, and v of a coating, then in principle the various stresses can be calculated. However, except for relatively simple cases, this is difficult because the above coating characteristics can be time, temperature, and relative humidity dependent.

Therefore, efforts were made to directly determine the stress arising in a coating. Among the methods one can find in the literature are: optical [30–33], strain gages [20,34,35], brittle lacquer materials [36], x-ray diffraction [37], and cantilever (beam) [2,4,8,11,27,38–45].

The cantilever (beam) method appears to be the most widely used and is suitable for determining the stress in an organic coating. This method makes use of the fact that for a coating under stress, applied on a substrate, the coated substrate will deflect in the direction which relieves the stress. Since the deflection can be measured and the elastic properties of the substrate are known from separate determinations, the stress can be calculated.

Two variations of the cantilever (beam) method are described in the literature: a one-sided coated substrate either (1) fixed vertically at one end [4,8,27,38] (Fig. 9) or (2) freely supported on two knife edges [2,11,43,45] (Fig. 10).

The stress analysis of (1) is more complicated and shows that to eliminate the effect of clamping on the coated substrate deflection, its measurement should be made at a distance higher than 80 mm from the clamping point [8]. Variation (2) is much simpler to analyze and can be designed to eliminate the effect of weight loss on the coated substrate deflection by choosing the right distance between the two knife edges [45].

Each variation has its advantages, but if correctly used they should give identical results. For example (1) is more suited to evaluate stress in water [29] and (2) to determine the effect of temperature [2,11].

Among the techniques used to measure the deflection of coated substrates, one can mention: capacitive transducers [44,45], laser [46], traveling microscope [4,8,27], automatic micrometer [11]. A variety of flexible substrates can be used, such as cold laminated steel, stainless steel, aluminum, copper, and silicon wafers.

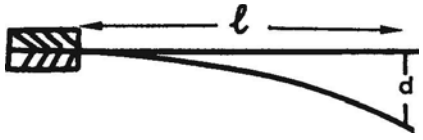

Fig. 9—Schematic description of the vertically fixed at one end cantilever (beam) method.

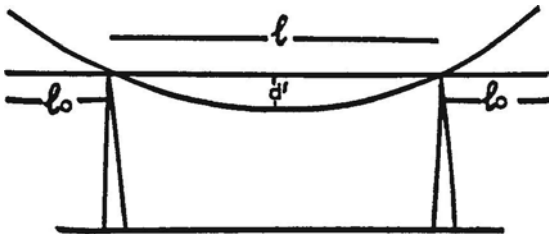

Fig. 10—Schematic description of the freely supported beam method.

A commercial apparatus, the CoRI Stressmeter (Fig. 11), is based on variation (2) and the mathematical analysis described in Ref. [45]. This apparatus is almost completely automatic and enables one to measure the stress from about –5 to 110°C under a variety of RH's. This instrument requires the use of substrates that are electrically conductive, e.g., cold laminated steel, stainless steel, aluminum, and copper.

In certain cases, such as for investigating the stress arising in ultraviolet cured coatings, the stress measurement might necessitate an elaborate set-up. In this case the set-up might include, among others, a UV lamp, a controlled flow gas and temperature device, an application chamber and a video camera monitoring the deflection of the coated substrate [47].

Mono-Layer Systems

A number of mathematical equations are proposed in the literature to calculate the stress in a mono-layer system [41,42], but in the author's opinion those proposed by Corcoran [41] are the closest to the real situation (e.g., considers the fact that stress develops in two directions)

$$S = \frac{dE_S t^3}{3l^2 c(t+c)(1-v_S)} + \frac{dE(t+c)}{l^2(1-v_S)} \tag{15}$$

$$S = \frac{4d'E_S t^3}{3l^2 c(t+c)(1-v_S)} + \frac{4d'E(t+c)}{l^2(1-v_S)} \tag{16}$$

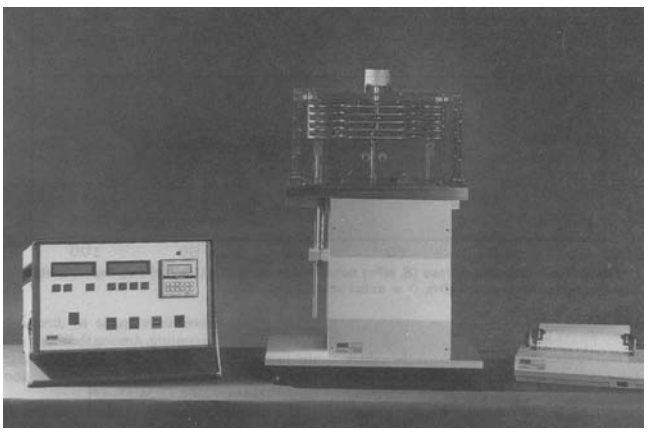

Fig. 11—CoRI Stressmeter apparatus (Courtesy of Elcometer, Liège, Belgium).

where

d = deflection of the substrate (Fig. 9),
d' = deflection in the middle of the substrate (Fig. 10),
E_s = elastic modulus of the substrate,
E = elastic modulus of the coating,
ν_s = Poisson's ratio of the substrate,
t = thickness of the substrate,
c = thickness of the coating,
l(Eq 15) = length of the coated substrate between the point at which it is clamped and the point at which the deflection is measured (Fig. 9), and
l(Eq 16) = distance between the two knife edges (Fig. 10).

Equations (15) and (16) assume, among other things, good adhesion between the coating and the substrate, isotropic elastic properties of the coating and the substrate, the elastic limit of the substrate is not exceeded, and the stress is constant throughout the coating thickness. If the last condition is not fulfilled it means that the coating is heterogeneous through the film thickness. Therefore, the measurement of stress as a function of film thickness might enable one to determine, depending of the film composition, the distribution of the solvent, cross-link density, pigmentation, etc., through the film thickness [8,15,16,68,76(a),76(b),77,79–81].

The second term in Eqs (15) and (16), which contains a number of coating properties difficult to determine, can be neglected if $E_S \gg E$ and $t \gg c$.

Since the substrate is flexible and deflects during a stress measurement, in principle, part of the stress relaxes. This relaxation is however negligible with respect to the stresses arising in the coating. An approximate calculation, by considering even a high elastic modulus ($E \approx 2$ MPa) and strain ($\approx 6\times10^{-6}$) values, induces a negligible stress relaxation (0.01 MPa $\ll$) with respect to stresses usually arising in the coating.

Most commonly, stainless steel or cold laminated steel [4,8,11,27,44,45] shims are used. Other substrates such as aluminum and copper can also be used.

The elastic modulus, E_s, of each shim can be determined prior to use with the CoRI Stressmeter by applying Eq (17)

$$E_S = \frac{Pl^3}{4d't^3b} \tag{17}$$

where

P = weight placed in the middle of the substrate,
b = width of the substrate, and
d', l, t = as in Eq (16).

It is important to add that, although it is not difficult to make the measurements, nevertheless great care is necessary. One should always use the correct substrate thickness, adequately condition it, and precisely calibrate the apparatus.

Multi-Layer Systems

In many cases multi-layer systems are applied on substrates to protect them against a variety of aggressive factors. Since the mechanical characteristics of each layer are usually different, one can expect that the stresses arising in each layer be also different. Furthermore, a monolayer system might become a multi-layer one if part of it acquires mechanical characteristics different from that of the bulk. This is typical of coatings subjected to chemical changes when submitted to natural or accelerated weathering.

To the author's knowledge, all the relationships for calculating the stress in multi-layer systems found in the literature [48–52] necessitate the determination of elastic properties of each layer, coating characteristics not always easily measurable.

To enable the determination of stress in each layer of multi-layer systems mathematical equations that do not necessitate the knowledge the elastic characteristics of each layer were derived [53]:

$$S_2 = \frac{4E_S t^3}{3l^2c_2\left(t+2c_1+c_2\right)\left(1-\nu_S\right)}\left(d_2-d_1\right) \tag{18}$$

$$S_3 = \frac{4E_S t^3}{3l^2c_3\left(t+2c_1+2c_2\right)\left(1-\nu_S\right)}\left(d_3-d_2\right) \tag{19}$$

where

c_1, c_2, c_3 = thickness of individual layers,
d_1, d_2, d_3 = deflection of the coated substrates (d′ in Fig. 10) with one, two, and three layers,
S_2 (Eq (18)) and
S_3 (Eq (19)) = stress in a top coat of two- and three-layer systems, respectively.

For a three-layer coating system whose composition is unaffected by multiple applications and curing, the determination of stress in each layer is as follows:

—application of the first layer and its curing,
—measurement of the deflection d_1 and of the thickness c_1,
—calculation of stress S_1 from Eq (16),
—application of the second layer and its curing,
—measurement of the deflection d_2 and of the thickness c_2,
—calculation of stress S_2 from Eq (18),
—application of the third layer and its curing,
—measurement of the deflection d_3 and of the thickness c_3,
—calculation of the stress S_3 from Eq (19).

Procedures for coatings affected by successive applications and curing are described in Ref. [53].

Two examples by applying Eqs (18) and (19) are presented in Figs. 12 and 13, respectively. Fig. 12 shows that for a three-layer system the highest thermal stresses are arising in the primer. Fig. 13 illustrates the case when a single layer system of 77 μm becomes a multi-layer one, due to its exposure in an accelerated weathering device. After seven days of weathering the thermal and hygroscopic stresses arising in the first 27 μm are much higher than in the bulk.

STRESS AND PHYSICAL AGING

We are associating the stress development with physical aging because both phenomena are mainly occurring in the glassy region, and they are therefore unseparated.

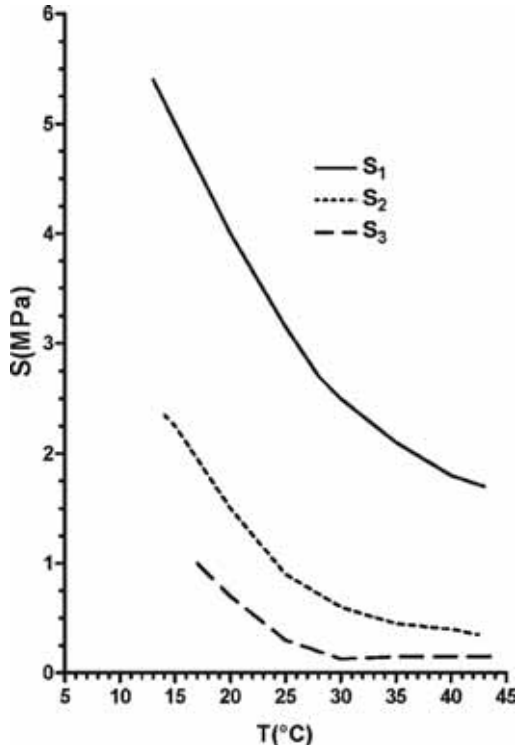

Fig. 12—Stress (*S*) dependence on temperature (*T*) for a three layer acrylic/melamine system. S_1, S_2 and S_3 indicate the stresses arising in the primer, middle, and top layers, respectively [53]. (With kind permission of Springer Science + Business Media.)

Physical aging is a general term that includes relaxation processes of a material in the glassy state, caused by its non-equilibrium state [54]. This process is easily explained by considering the dependence of volume (*V*), enthalpy (*H*), and entropy (*S′*) on temperature (*T*) above and below T_g (Fig. 14) [54–58]. During cooling at $T > T_g$, due to the great mobility of polymer chain segments, *V*, *H*, and *S′* can follow the decrease in temperature. Below T_g the

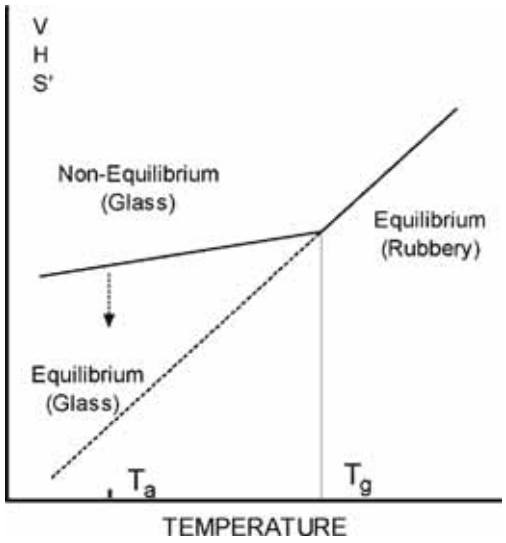

Fig. 14—Schematic description of the dependence of volume (V), enthalpy (H), and entropy (S′) on temperature. T_a = physically aging temperature.

mobility of polymer chain segments is reduced, and *V*, *H*, and *S′* cannot follow any more the decrease in temperature, meaning that the material departs from its equilibrium state. The values of these thermodynamic quantities being higher than in equilibrium state they will continuously decrease until the equilibrium state is reached. The closer the aging temperature to T_g the higher the aging rate and the smaller the change in property. Since the studies made by Struik [54], this relaxation toward equilibrium is known as physical aging.

In contrast with chemical aging that induces irreversible changes, physical aging is a reversible process. It can be eliminated by heating the samples to $T > T_g$ for sufficient time. More than 800 studies have been dedicated to various aspects of physical aging. While certain phenomenological models (e.g., Kohlrausch—Williams—Watts) describe

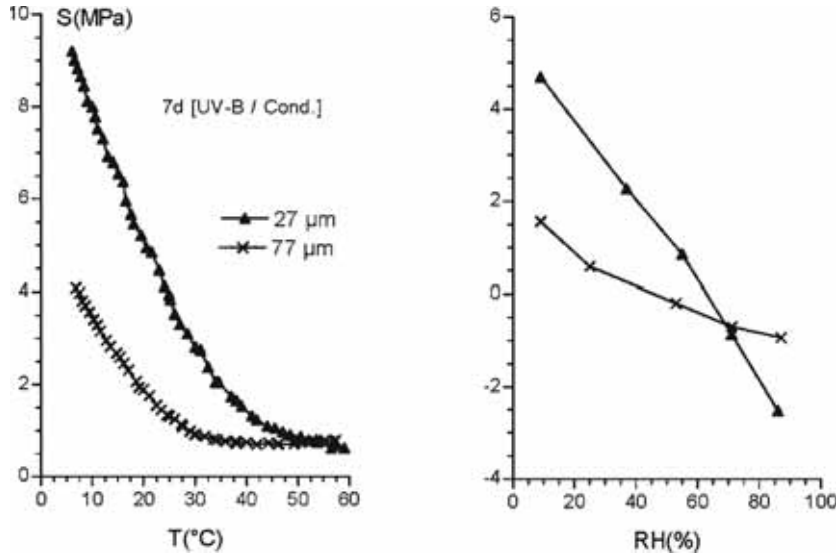

Fig. 13—Stress (*S*) dependence on temperature (*T*) (left) and on relative humidity (RH) (right) for an acrylic/melamine system after an exposure of 7 days in a Q-Lab Corporation (QUV) device.

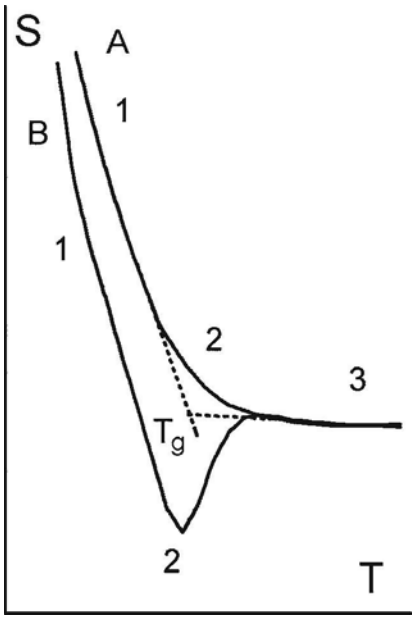

Fig. 15—Schematic description of the stress (*S*) dependence on temperature (*T*), for physically unaged (A) and aged (B) organic coatings. Segments 1 and 3 represent the glassy and the rubbery regions, respectively. Segment 2 represents the glass transition region [59].

well its kinetics, this process is not very well understood on a molecular scale. Nevertheless, it is associated with increased molecular packing and densification, processes that can greatly affect important coating properties like mechanical, thermal, and electric. Concerning mechanical properties, which directly affect coating integrity, densification causes the coating to become harder and more fragile.

To describe the interdependence between stress and physical aging the thermal stress will be considered. This interdependence was discussed in detail in Refs. [59,60] and is schematically described in Fig. 15. Curves A and B are typical of physically non-aged and physically aged coatings obtained during their heating. The U-shape curve is mainly due to the increase of E with physical aging which in turn induces higher compressive thermal stresses (see Eq (5)). The right side of the trough represents the decrease of this stress with temperature due to the stress relaxation in the rubbery region.

Studies made with thermoplastic (e.g., latex paints) and thermosetting (e.g., waterborne, powder coatings) systems show that the coating composition (type of binder, presence of coalescents, degree of film cross-link density, presence of pigments) affects the physical aging process [61,62]. Physical aging also influences the coating durability by increasing the stress magnitude and by decreasing the stress relaxation rate. There are indications that physical aging affects the late stages of coalescent process.

EFFECT OF COATING COMPONENTS

Since E, ε, and ν (Eqs (1), (3), (5), and (10)) are known to be affected by the coating components, one should expect the same to hold for stress development. This section will briefly review the influence of pigmentation, solvents, and binder.

Pigmentation

It has been shown that pigmentation, both the pigment volume concentration (PVC) and the type of filler (i.e., pigments and extenders), affects the development of internal stress [7,43,63–68]. To illustrate this, examples are presented in Figs. 16–21.

Figs. 16 and 17 show, respectively, the stress dependence on time for a thermoplastic binder in solution and a latex, filled with a titanium dioxide (TiO_2). Some PVCs are above the CPVC, and some are below the CPVC.

The different stages occurring during the film formation, discussed previously, can be recognized. In Stage 1 stress increases relatively rapidly. For latex coatings, this stage corresponds to the transition phase of the evaporation kinetics when the greatest part of the coalescence occurs.

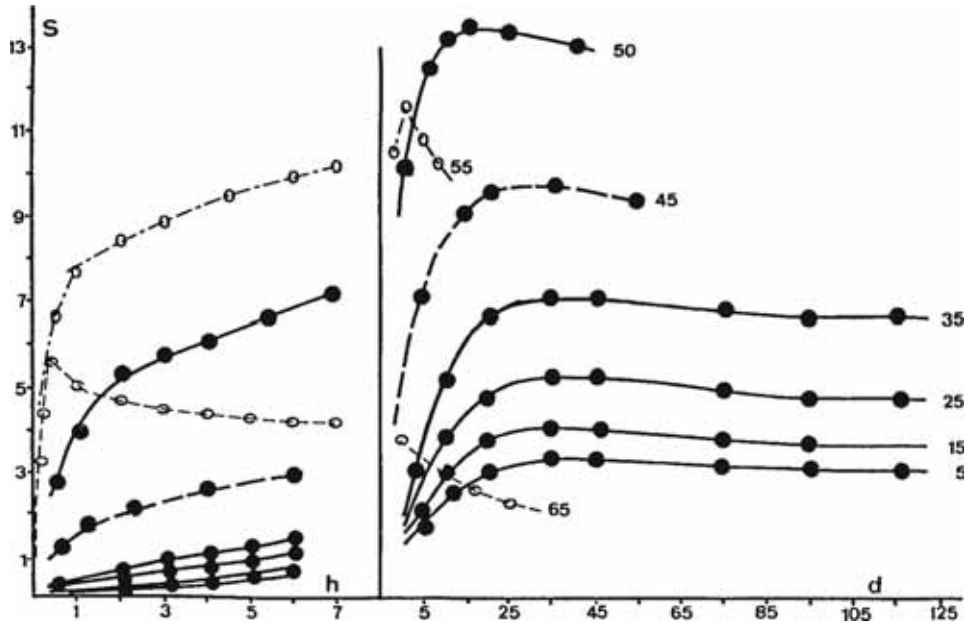

Fig. 16—Stress (*S*, MPa) as a function of time [hour (h) and day (d)] for a polyisobutyl methacrylate filled with TiO_2. The numbers in the figure indicate the different PVCs (%) investigated. CPVC = 51 %.

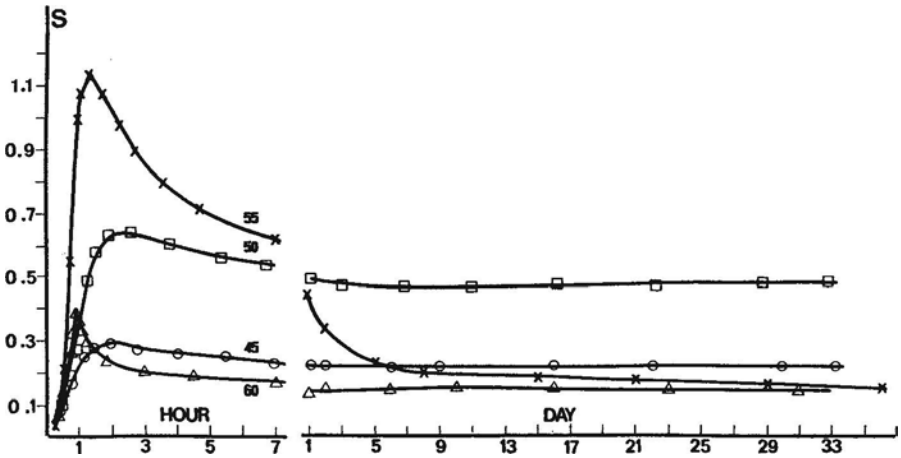

Fig. 17—Stress (*S*, MPa) as a function of time for a latex (vinyl acetate/vinyl versatate copolymer filled with TiO_2):45 % (○); 50 % (□); 55 % (X); 60 % (Δ). CPVC = 52 %.

In Stage 2 (which corresponds to Phase 2 of evaporation kinetics), depending on the PVC and the type of filler, the stress can decrease or first decrease and then increase. For PVC < CPVC, this decrease is mostly due to the relaxation process, but for PVC > CPVC is mostly due to relief processes such as filler/binder dislocations and/or formation of microfissures.

DETERMINATION OF THE CPVC

The plot of the maximum internal stress (*Sm*) as a function of PVC enables one to determine the CPVC of a coating. Some examples are presented in Figs. 18 and 19.

These figures, as well as other results presented in Refs. [66,67], clearly indicate that *Sm* is a function of PVC. *Sm* increases with PVC up to a certain PVC and then decreases. This PVC corresponds to the CPVC, indicating the possibility of accurately determining this characteristic [69,70] from stress measurements, and agrees well with the CPVCs calculated or determined by other methods (density, various mechanical properties).

The dependence of *Sm* on PVC can be understood if one considers Eq (1) and the way E, ε, and ν are affected by the PVC.

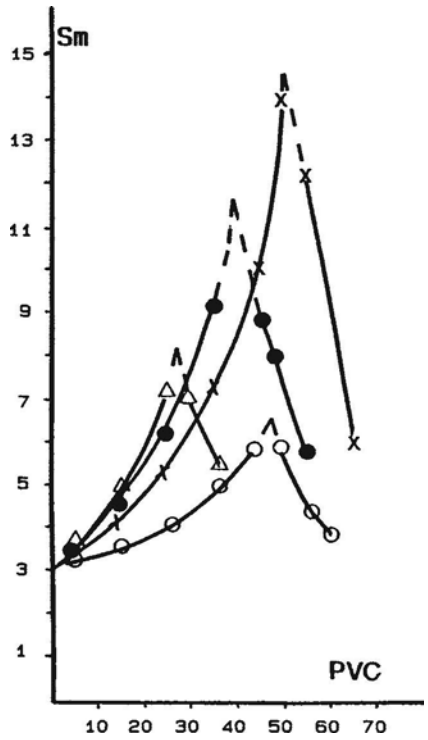

Fig. 18—Maximum internal stress (*Sm*) as a function of PVC (%) for a solvent-based thermoplastic binder filled with a TiO_2 (X),a red iron oxide (■), a yellow iron oxide (Δ), and a talc (○).

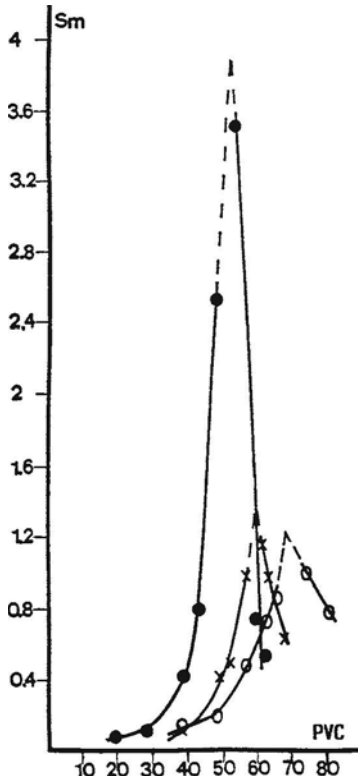

Fig. 19—*Sm* as a function of PVC (%) for a styrene acrylic copolymer filled with a TiO_2 (■), a calcium carbonate (X), and talc (□).

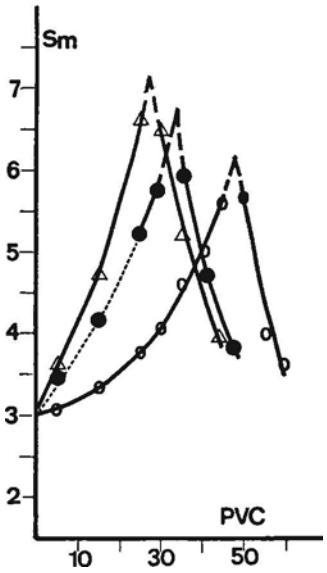

Fig. 20—*Sm* (MPa) as a function of PVC (%) for a thermoplastic binder in solution containing a yellow iron oxide (Δ), a talc (□), and their mixture (n = 0.5) (●); *n* = pigment volume fraction.

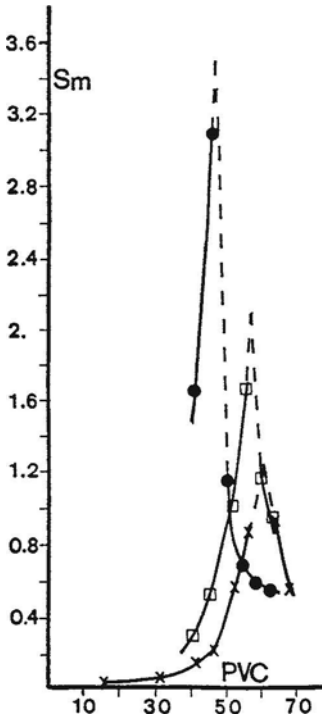

Fig. 21—*Sm* (MPa) as a function of PVC (%) for a latex binder containing a TiO_2 (●), calcium carbonate (X), and their mixture: TiO_2 (n = 0.4)/$CaCl_3$ (n = 0.6) (□).

For PVC < CPVC, E increases with increasing PVC because the E of an inorganic filler is in general higher than that of an organic binder [71]. For PVC > CPVC, E decreases as a result of the increasing film discontinuity [23,72]. Since in general ε and v are decreased (or are little affected) by the PVC, it follows that the increase of Sm with PVC is mainly due to the effect of PVC on E.

Figs. 18 and 19 also show that the magnitude of Sm is dependent on the type of filler. There are fillers which induce a higher stress (e.g., TiO_2, red iron oxide) than others (e.g., $CaCO_3$, talc). This is due to the filler/binder interaction (reinforcing effect), which is determined by the nature and, in particular, by the surface area and the acid/base character of the binder [73].

Examples of $Sm = f(\text{PVC})$ for coatings containing a mixture of fillers are presented in Figs. 20 and 21.

An examination of the results obtained with binary and ternary filler coating systems indicates that the stress Sm_t can be calculated approximately by means of an additive rule

$$Sm_t \approx n_1 Sm_1 + n_2 Sm_2 + \cdots + n_i Sm \approx \sum_{x=1}^{x=i} n_x Sm_x \qquad (20)$$

where

n_1, n_2, n_i = volume fraction of different fillers present in the mixtures, and

Sm_1, Sm_2, Sm_I = maximum stress of different single filler systems at a given A below or equal to 1 (A = reduced PVC, PVC/CPVC).

For organic coatings cured at high temperatures, such as baking paints, the CPVC can be determined by measuring the stress as a function of temperature of paints formulated at different PVCs. The representation of stress arising at a temperature (in the glassy or rubbery regions) as a function of PVC enables one to determine the CPVC (Fig. 22). As in the case of coatings formed at room temperature, the CPVC corresponds to the PVC that develops the highest stress.

In the literature one can also find simplified methods to determine the CPVC of latex coatings based on the same principle. They simply compare the force [74] or the deflection induced by the internal stress for flexible plastic substrates [75](Fig. 23) coated with paints of different PVCs.

These methods can be useful, but one has to be aware that they are valid only if both the thickness of the various paints and the time necessary to reach the maximum stress are the same.

Solvents

The presence of solvents in a coating can affect the magnitude and especially the rate of development of internal stress. This is illustrated in Fig. 24.

For thermoplastic binders in solution, the slower the evaporation of a solvent from a coating, the slower is the development of internal stress. The converse also is true. One should note that the coating cast from fast-evaporating solvents (Curve 1, Fig. 24) produces slightly higher stress values than those cast from more slowly evaporating ones (Curves 3 and 4, Fig. 24).

The results obtained were explained by using Eq (1), the principle of plasticizing effectiveness of solvents and the stress relaxation favored by the presence in the coating of the slower evaporating solvent [16].

For coatings containing a mixture of solvents (Fig. 25), both the development rate and the stress magnitude are mainly determined by the presence in the film of the less volatile solvent(s).

The situation may be different if the film formation is a result of solvent evaporation and cross-linking

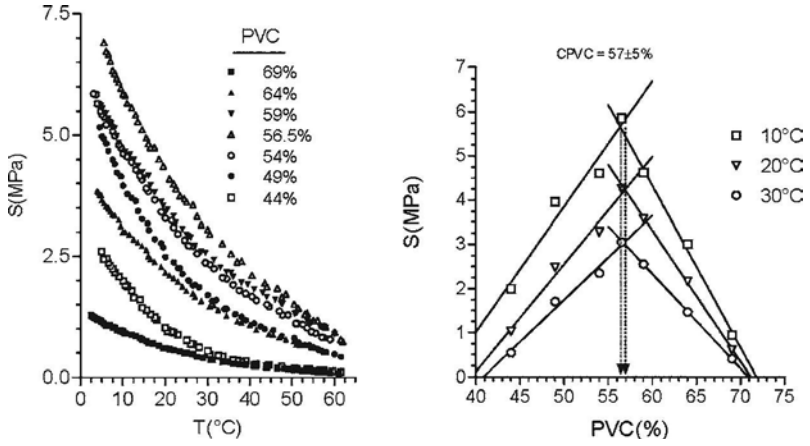

Fig. 22—A polyester/melamine system filled with a mixture of pigments cured at 150°C for 30 min. Left: Stress (*S*) as a function of temperature (*T*) at 0 % RH of 7 PVC formulations. Right: Stress (*S*) as a function of PVC at different temperatures determined during heating or cooling. CPVC (%) = 57±0.5.

processes (e.g., epoxy and polyurethane coatings). Under such circumstances the coating containing faster evaporating solvents can develop smaller stress values [76]. For such coatings, the volume of solvent present in the film after most of the cross-linking has occurred (Eq (2)) and which determines the magnitude of ε^F will increase the slower the solvent evaporates. If the stress relaxation process is negligible, it follows that for such coating systems the faster the solvent evaporates the smaller the internal stress.

The influence of solvents on internal stress is also evident for latex coatings where certain solvents, for example the coalescing agents, play an important role in the film formation process [15,52,77].

Examples of how the level and the type of coalescent affect internal stress are presented in Figs. 26 and 27, respectively.

Fig. 26 shows that: (1) the coalescent level affects the time necessary to reach the maximum stress, and (2) for each formulation, there is an optimal coalescent level to obtain a tight continuous coating developing the lowest internal stress.

In Fig. 27, the results obtained with three solvents used in latex coatings are given. One can see that the type of solvent influences both the value and the development rate of the internal stress.

As in the case of thermoplastic coatings, the influence of solvents on internal stress development in latex coatings was explained [15,68,75] by taking into consideration the plasticizing effectiveness [18,78], the molar volume, and the steric hindrance of solvents. The plasticizing effectiveness affects the internal stress magnitude, while the molecular dimensions affect the evaporation kinetics and consequently the rate of the stress development.

Binder

The binder is a key component of an organic coating with regard to stress development. To understand the role of the binder, one must consider the general Eq (1) (see also Eqs (3), (5), and (10)) and/or the T_g of a coating with respect to the experimental temperature.

Equation (1) indicates that the stress is directly affected by the magnitude of E, ε, and ν of the binder. The smaller the values of E, ε, and ν, the smaller the magnitude of stress.

With respect to T_g, it should be remembered that the binders having their T_g below or close to the film formation temperature (T) develop a negligible internal stress, while those having their $T_g > T$ develop a significant one. This is due to the fact that at $T > T_g$, the mobility of the binder molecular segments is high and the stress arising during film formation can partially or totally relax. Moreover, it can be shown that for a thermoplastic binder in solution

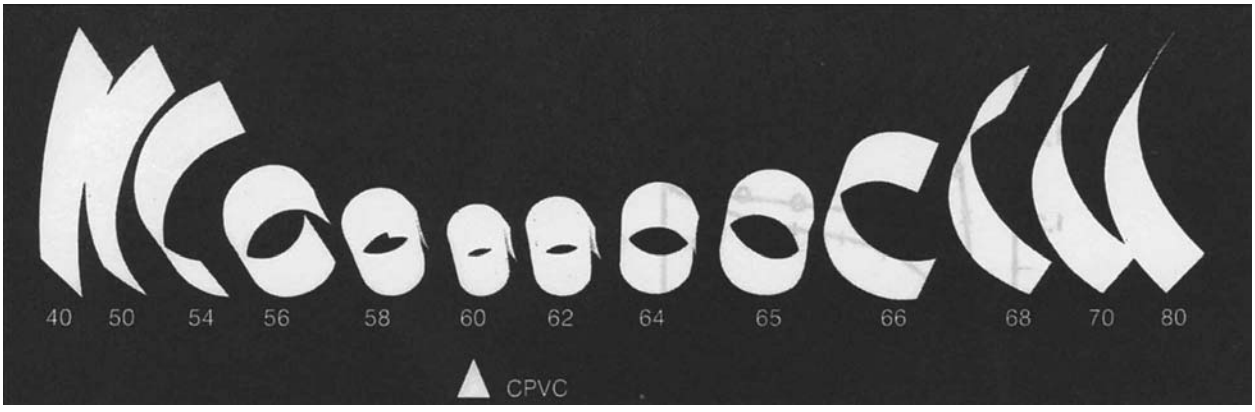

Fig. 23—Determination of the CPVC by comparing the curvature of painted plastic substrates.

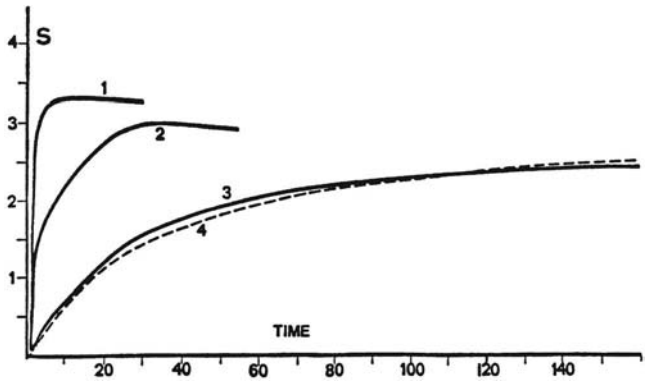

Fig. 24—Stress (*S*) as a function of time in a thermoplastic varnish cast from methyl ethyl ketone and ethyl acetate (1); toluene (2); xylene (3), methyl isobutyl ketone and isobutyl acetate (4), at 52 % RH and 21°C.

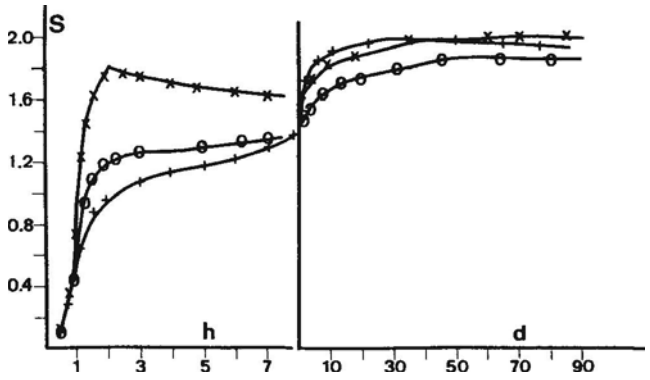

Fig. 26—Stress (*S*, MPa) as a function of time (h, hour; d, day) for a styrene acrylic latex paint containing different amounts of Texanol 5 % (X);10 % (○);15 % (+); percent of Texanol calculated by weight of binder solids.

having a $T_g > T$, the lower the T_g of the binder, the less will be the solvent in the film after its formation (see Eqs (2) and (3)) and therefore the smaller the internal strain and stress in the dry coating [16].

Studies carried out with polyimide coatings, materials usually developing high stresses, indicated that the stress level is determined by morphological and backbone structure [82], polymer chain rigidity and molecular orientation [79]. Ultraviolet-cured coatings, materials that also develop high stresses, were also investigated. It was found that the stress magnitude is mainly affected by photo-initiator concentration, light intensity [80], monomer functionality, monomer chain length [47,83], degree and distribution of cross-linking, and temperature at solidification point [81]. For multifunctional methacrylate coatings a lower stress can develop through lowering light intensity, lowering monomer functionality, [82] raising monomer chain length and plasticizer concentration, and using acrylate monomer instead of methacrylate [83]. Stress development in thermosetting coatings, below and above T_g, is discussed in Ref. [84]. Investigations designed to decrease the stress magnitude by forming low T_g polymer domains [85] or introducing soft polymeric inclusions [86] in the film have been performed.

In brief, any change occurring in the molecular structure of a binder (e.g., cross-linking, crystallinity, molecular weight, steric hindrance) may induce a change in E, ε, ν, and T_g and thus affect stress development.

STRESS VERSUS ADHESION AND COHESION

It is accepted that the stress arising in a coating can reduce the adhesion and cohesion, two crucial properties of an organic coating for obtaining durable coatings [1–10,87–91].

The way the stress affects adhesion is described in detail in Refs. [87,88].

Equation (21) will be used to demonstrate how the stress affects adhesion. This relation describes the factors affecting a measurement of adhesion regardless of the method used (pull-off, peel, torsion, etc.)[91].

$$W_T \approx \gamma_{adh} + W_P - \beta \tag{21}$$

where:

W_T = total measured work (energy) used to separate the coating from the substrate, where the substrate can be another coating. In the literature W_T is also known as *adherence* and the *measured* or *practical adhesion*;

γ_{adh} = the interfacial work of adhesion, a consequence of a variety of chemical and/ or physical interactions between the coating and the substrate. It represents the actual physical strength of adhesive bonds, and is known in the literature also as the *adhesion* or *basic and fundamental adhesion*;

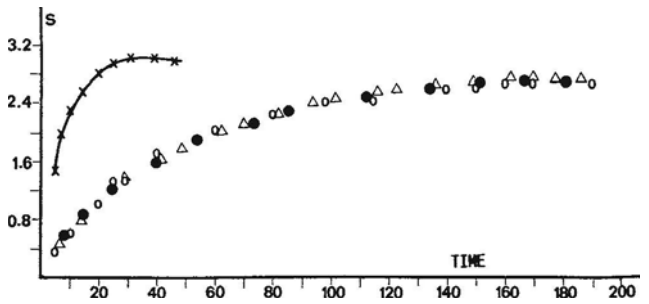

Fig. 25—Stress (*S*, MPa) as a function of time (day) for a thermoplastic varnish cast from toluene (X); isobutyl acetate (○), and their mixtures [1/1 (W/W) (●) and 1/3 (W/W) (Δ)].

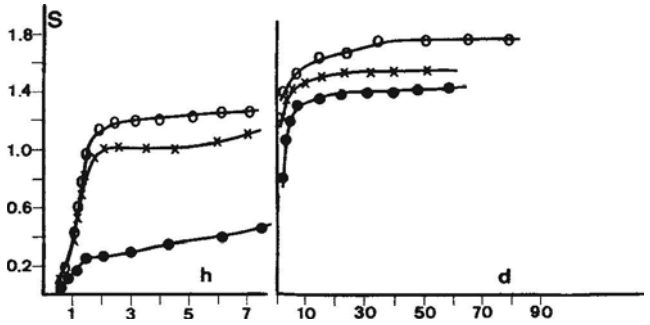

Fig. 27—Stress (*S*) as a function of time (h, hour; d, day) for a styrene acrylic latex paint containing Texanol (○); Dalpad A (X); Dalpad A + propylene glycol (●).

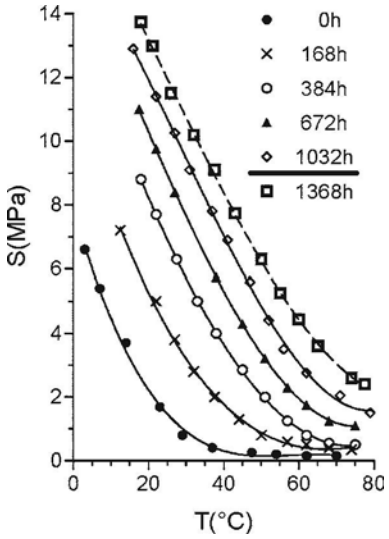

Fig. 28—Stress (*S*) as a function of temperature (*T*, °C) for a primer/clearcoat system after different periods of weathering (4 h UV-B at 60°C and 4 h condensation at 50°C) [100].

W_P = work (energy) expanded in plastic deformation and viscous dissipation occurring during the adhesion measurement. Depending on the viscoelastic character of the coating this work might be important;

β = elastic energy acting against adhesion.

It is shown that the application of an energy balance analysis [92] leads to the factor β

$$\beta = cU_r = \frac{cE\varepsilon^2}{1-\nu} \tag{22}$$

where U_r, c, and ε are the recoverable strain energy, the film thickness, and the strain.

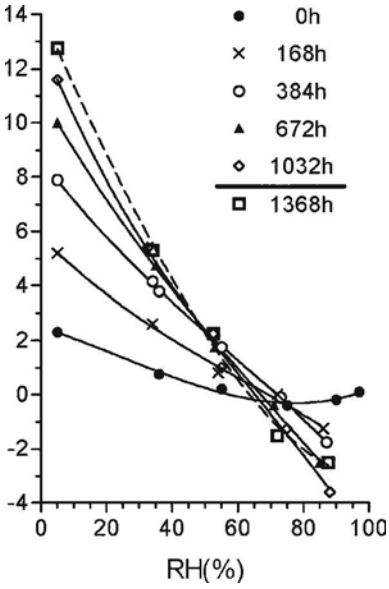

Fig. 29—Stress (*S*, MPa) as a function of RH (%) for a primer/clearcoat system after different periods of weathering (4 h UV-B at 60°C and 4 h condensation at 50°C) [100].

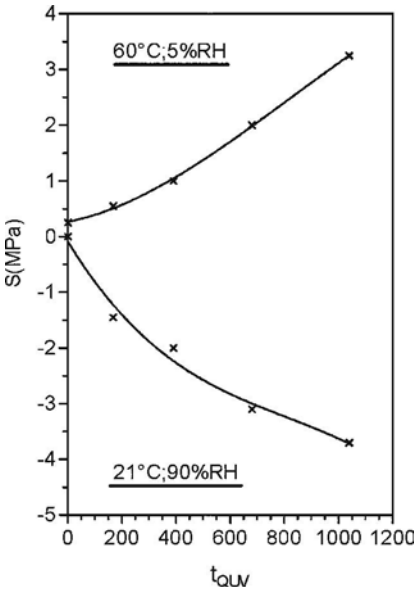

Fig. 30—Stress (*S*) as a function of time of weathering (t_{QUV}, hour) for a primer/clearcoat system at two climatic conditions [100].

To accommodate the effect of stress [19,28,93], Eqs (1) and (22) are combined to give:

$$\beta = cS\varepsilon \tag{23}$$

and the combination of Eqs (21) and (23) leads to

$$W_T \approx \gamma_{adh} + W_P - cS\varepsilon \tag{24}$$

Equation (24) shows, among others that: (1) that in most cases the measured adhesion (W_T) is not identical with inter-facial work of adhesion (γ_{adh}) one normally expects to measure, and (2) when the product "$c\ S\ \varepsilon$" overcomes γ_{adh} the coating will spontaneously detach from the substrate; thus, if a high stress arises in a coating, in order to prevent its detachment, it should be applied in a thinner layer.

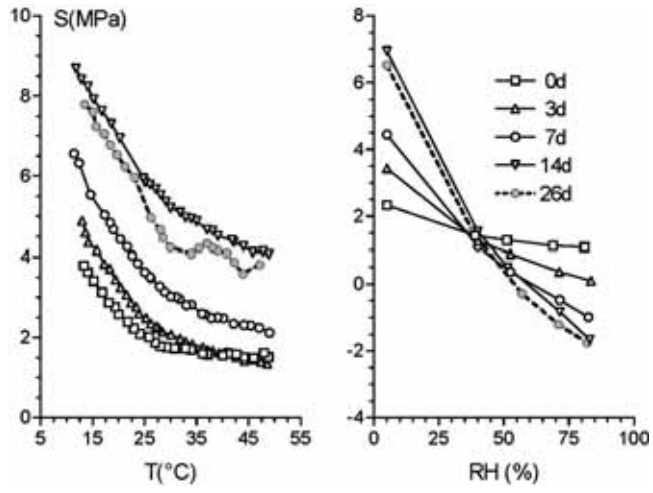

Fig. 31—Stress (*S*) as a function of temperature (*T*) at 5 % (left) and of RH at 21°C (right) for a polyester/melamine system after different periods of weathering (d, day) (4 h UV-B at 60°C and 4 h condensation at 50°C) [100].

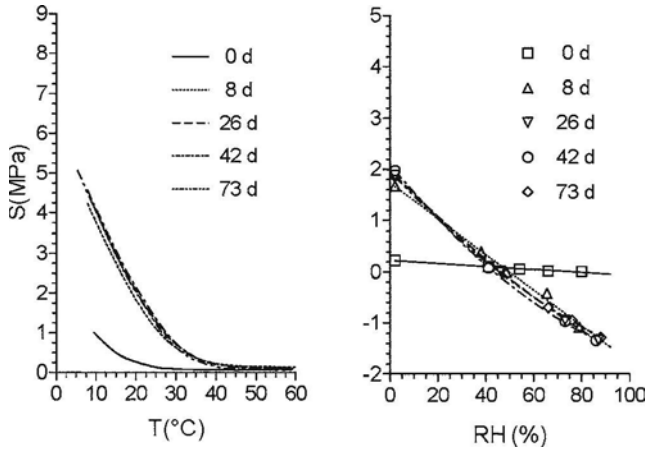

Fig. 32—Stress (*S*) as a function of temperature (*T*, °C) at 5 % (left) and of RH at 21°C (right) for an acrylic latex paint containing coalescing agents after different periods of weathering (d, day) (4 h UV-B at 60°C and 4 h condensation at 50°C).

Because it is energy that expresses the effect of e, tensile or compressive strains are identical in their effect [87].

Since stress develops in most organic coatings, the product "$c\ S\ \varepsilon$" should also be considered in adhesion tests performed in laboratories. This fact is taken into consideration in mathematical equations (25) and (26) for pull off and peeling at 90°, respectively [87].

$$\sigma \approx \left[\frac{2K}{c}(\gamma - cS\varepsilon)\right]^{1/2} \tag{25}$$

$$\frac{F}{b} \approx \gamma - cS\varepsilon \tag{26}$$

where

σ = stress applied to pull the coating from the substrate,
K = bulk modulus of the coating,

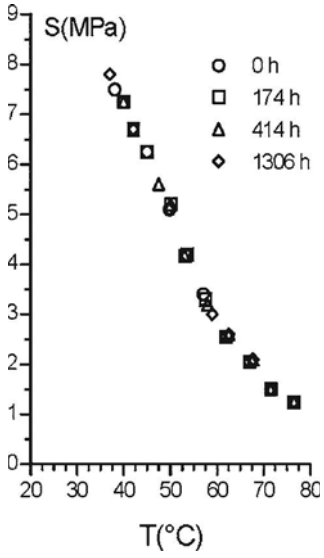

Fig. 33—Stress (*S*) as a function of temperature (*T*, °C) at 5 % for a polyester/TGIC powder coating after different periods of weathering (d, day) (4 h UV-B at 60°C and 4 h condensation at 50°C).

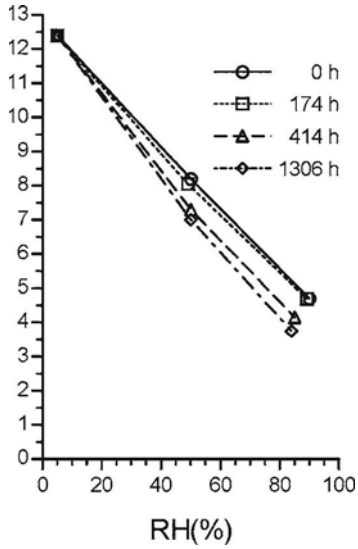

Fig. 34—Stress (*S*, MPa) as a function of RH at 21°C for a polyester/TGIC powder coating after different after different periods of weathering (d, day) (4 h UV-B at 60°C and 4 h condensation at 50°C).

γ = interfacial work of adhesion,
F = force applied to peel the coating, and
b = width of the coating.

Equation (27)(for pull-off measurements of coatings having $\nu = 0.4$) is interesting because it takes into consideration the work expanded in plastic deformation (W_p) [94].

$$\gamma = \frac{c}{4.286E}\left(\sigma^2 + 2.572S^2\right) \tag{27}$$

In addition, the study demonstrates the difference between adhesion and adherence [94] and the wrong interpretation of data that might result if only one of them is considered.

Equations (22)–(24) also indicate the possibility of determining the adhesion of a coating (i.e., factor γ) without applying any external force. This is due to the fact that at a particular film thickness a spontaneous detachment should occur [87]. Unfortunately, this method can only be used for badly adherent coatings. For all other coatings, extremely high film thicknesses, difficult to apply and cure, would be necessary. When necessary, the product "$c\ S\ \varepsilon$" can also be increased by submitting the coated substrate to high stresses, e.g., thermal stresses.

If the adhesion forces exceed the cohesive strength of a coating the stresses arising in the coating can provoke cracking, Assuring rather than loss of the coating from the substrate. Such damage can occur at low stress values due to stress concentration in the film, a consequence of the presence of heterogeneity in the coating (e.g., bad pigment/binder dispersion, presence of impurities, air voids, and variation in film thickness). The verification of this principle can be realized very approximately by determining the stress and the ultimate properties of a coating. Since most organic coatings are viscoelastic, it is essential that these properties be evaluated under the conditions (strain rate, temperature, RH) corresponding to the stress development in the coating. A more quantitative approach of the failure mechanism in organic coatings, but also more difficult to

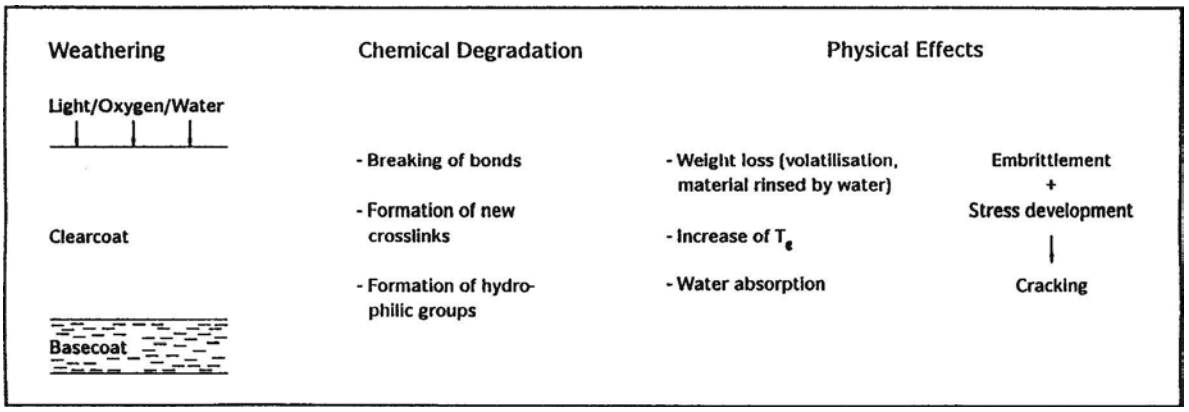

Fig. 35—Schematic representation of processes causing crack formation in a coating.

realize, mainly due to relatively low thickness of the films, is the application of fracture mechanics principles [95]. According to certain publications these difficulties are partially solved both theoretically [96,97] and experimentally [98,99].

It is important to add that fatigue processes (e.g., due to variation of temperature and RH) are factors decreasing the overall stress at which the coatings are damaged (delaminates and/or cracks).

DURABILITY AND STRESS DEVELOPMENT

Weathering

In most cases when organic coatings are exposed to weathering (accelerated or natural), they undergo chemical and physical modifications which are expressed in the change of T_g, E, α, ν, and cross-link density. Under such circumstances and according to Eqs (1), (3), (5), and (10), one can also expect to see changes in stress development.

A more detailed discussion of the role played by stress in the coating deterioration is given in Refs. [9,100]. It is shown that depending on the type of coating the weathering can affect the stress development in different ways.

In one case weathering provokes: (1) a shift of the curves $S = f(T)$ to higher temperatures indicating an increase of T_g, which in turn induced higher thermal stresses (Fig. 28), and (2) an increase of the slope of the curves $S = f(\text{RH})$ due to an increase of the coating sensitivity to moisture, which induced higher hygroscopic stresses (Fig. 29).

The representation of the stress as a function of time of weathering for two experimental conditions similar to those present in the accelerating apparatus (Fig. 30) indicates that every time the experimental conditions changed (every 4 h) the coating was exposed to an increasing hygrothermal stress (tensile thermal stresses under dry conditions and compressive hygroscopic stresses under wet conditions).

Another case often met in practice is represented in Fig. 31. In this case weathering induced a relatively small increase of T_g and a significant upward shift of the curves $S = f(T)$ to higher stress values. This upward shift is a consequence of oxidative cross-link reactions the coating undergoes, a fact confirmed by infra red spectra measurements and the stress increase in the rubbery region (Eq (8)). The $S = f(\text{RH})$ curves are similar to the case described above, showing an increase of coating hydrophylicity with weathering.

Fig. 32 is often observed with (acrylic) latex paints containing coalescent solvents. The shift of the curve $S = f(T)$ to higher temperatures, observed during the first days of weathering, is mainly due to loss of coalescent solvents present in the coating. The stress dependence on RH of the unweathered coating is negligible. This is due to its T_g (about 21°C at 0 % RH), close to the experimental temperature (21 ± 1.5°C), a fact that enables a fast relaxation of hygroscopic stresses induced by variation of RH. With coalescing solvents departing from the coating, T_g increases (to about 31°C at 0 % RH) and the hygroscopic stresses become measurable.

For organic coatings possessing a good durability it is expected that $S = f(T)$ and $S = f(\text{RH})$ to be little, or not at all affected by weathering. This is illustrated in Figs. 33 and 34. Contrary to other coatings, for this one (a polyester/triglycidyl isocyanurate (TGIC) powder coating), the dependencies $S= f(T)$ and $S = f(\text{RH})$ are not changing or changing very little with weathering. These results are in agreement with the behavior of the coatings mentioned above under tropical conditions. While the acrylic/polyurethane and the polyester/melamine coatings are cracking after a few years, for the same period, the powder coating is still undamaged.

The processes thought to lead to fissuring of the clearcoat are described in Fig. 35. Briefly, the chemical degradations induced by UV, water, and oxygen, which decrease the coating cohesion, combined with the fatigue process at steadily increasing hygrothermal stress levels are the causes of the coating degradation.

Hygroscopic Stress and Corrosion

Due to the heterogeneous nature of most of organic coatings, which possess regions of different hydrophilicity [101], hygroscopic stresses are arising in a coating exposed to a high RH or immersed in water [102]. They participate in formation and/or enlargement of pathways through which water and electrolyte can reach the metallic substrate and thus provoke corrosion. This affirmation is based on the observation that the coatings developing low hygroscopic (compressive) stresses or able to relax them fast, protect well the substrate against corrosion. Among the coatings investigated in one study (Fig. 36), the powder coating and Plexigum developed the lowest hygroscopic compressive stresses and protected well the substrate against the aggressive action of 0.5M NaCl electrolyte. The polyurethane,

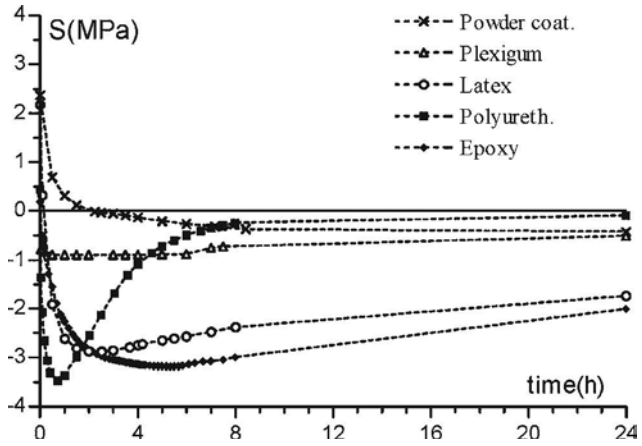

Fig. 36—Stress (S) as a function of immersion time in water at 21°C for five organic coatings [102]. (With permission from Marie-Odile Barkallah, AFTPVA-EUROCOAT.)

a system which developed high hygroscopic compressive stresses but which relaxed relatively fast, provided only an average protection.

Friction and Slip Resistance

Joseph V. Koleske[1]

PREFACE

In preparation of this chapter, the contents of Chapter 50 Slip Resistance in the fourteenth edition were drawn upon. The author acknowledges the author of the chapter in the fourteenth edition, Paul R. Guévin, Jr. The current edition will review and update the topics as addressed by the previous author, introduce new technology, and include up-to-date references.

INTRODUCTION

FRICTION IS AN INTERESTING PROPERTY THAT IS often taken for granted. For example, it would not be possible to walk if there were no friction between shoe soles and the ground or other surfaces. There is also an awareness that friction varies with the nature of the shoe bottoms—rubber, plastic, leather, etc.—and of the surface—ground, concrete, painted concrete, ice, wood floor, polished floor, steel, etc. Automobiles would not move if it were not for the friction between tires and road surface, would not slow down if it were not for the friction between brake discs or drums, and would not stop if it were not for the friction between tires and road surface. Without friction, dishes would not stay on a table and the slightest jostling would cause items to slide. Many other examples could be given of friction and slip.

At times, conditions of high friction are desirable and other times low friction is needed. If a heavy object is to be slid, low friction is useful. Skiers want low friction between their skis and snow or ice and use waxes as a lubrication to decrease friction. In the cases of polished, wet, or icy surfaces, frictional forces are quite small and automobiles, people, and animals have a tendency to slip. In the case of dry concrete, neat or painted, or wood, the frictional forces are quite high and the surface is stable and with it less chance for slipping. It should be kept in mind that there is a need for material combinations that result in high friction, as in a painted or otherwise coated walkway area where a person walking or running on the surface does not want to slip and fall, and in low friction, as when an object is to move smoothly and evenly by another object of similar or different composition, as when sheets of paper move by one another in a copy machine. Friction can be increased by use of additives such as sand on an icy surface and decreased by the use of lubricants such as oil, water, graphite, and the like.

Slip is a word that has many meanings [1–3], but it is obvious that slip occurs when friction is low. In certain areas of the coating industry, slip is considered to be the ability of an object to move in a relatively free or unencumbered but controlled manner as when one sheet of coated or uncoated metal passes over another in a coating-line feeding operation, when such sheets move along a conveyor system in coating, printing, fabrication, or packaging operations, and the like. The material or coated material must have proper "slip" or "lubricity" to allow passage through various sections of the coating fabrication or packaging section of the line. Slip is also important in fabricating operations wherein the coated object is in contact with a tooling system as in fabrication of bottle caps, in bending or forming operations, and so on. In various textile lines, proper slip is need for threads to flow smoothly and uniformly through fabrication systems and not cause thread or yarn breaks and defective final products or lost production.

CONCEPTS OF FRICTION

In a technical sense, *friction* is the force between contacting objects that resists the relative motion of the objects. Starting or static friction is the frictional force between stationary objects, and dynamic, kinetic, or sliding friction is the frictional force between objects that are sliding with respect to one another. Consider a block resting on a solid surface as in Fig. 1. The upward force, F_U, of the solid surface, counterbalances the weight or mass of the block, F_N, and the block is at rest. F_N is usually referred to as the perpendicular or normal force. If a force, F_A, is applied to the block and parallel to the solid surface, the force of friction, F_F, resists it. If F_A is slowly increased, at some point the block will begin to move and slide along the solid surface without further increase in F_A and actually with a small decrease in it [4,5]. Thus, the force required to move an object from rest is greater than the force required to continue the movement at constant velocity. At this point,

$$F_A = F_F \tag{1}$$

By sliding blocks of the same material with equally smooth surfaces but different sizes (i.e., different contact areas) across the same surface, it has been found that the ratio of the frictional force to the mass of the block or F_N is constant. The proportionality factor between the frictional resistance force and the normal force is known as the *coefficient of friction,* μ, with a distinction made between the coefficient of static friction, μ_S, and coefficient of kinetic friction, μ_K, as indicated in the following relationships:

$$F_F = \mu_S F_N \quad \text{stationary} \tag{2}$$

$$F_F = \mu_k F_N \quad \text{sliding} \tag{3}$$

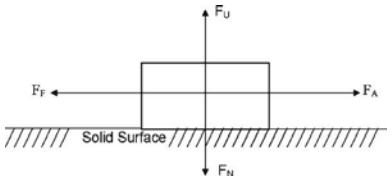

Fig. 1—A solid block resting on a solid surface with an upward force, F_U, and a normal or downward force, F_N, acting on it. A force, F_A, acting parallel to the solid surface is applied to the block and a friction force, F_F, opposes the force F_A.

This points out that it should be stated whether a measured or cited coefficient of friction is for the static or the kinetic condition, however, quite often this is not done in the literature as will be illustrated below.

The friction force is often discussed in terms of an object sliding down a solid inclined surface as indicated in Fig. 2. When the angle of incline, θ, is 0°, the situation is that of Fig. 1, which becomes Fig. 2 as the angle of incline is increased from zero to some finite value less than 90°. As the angle of the incline increases, the force component tending to move the object down the incline, F_A, also increases. At some point, the slightest increase in the angle will sufficiently increase the force component parallel to the plane of the incline, F_A, to a value such that F_F is overcome and, if unrestrained, the object begins to move down the incline at constant speed. Thus, the object does not slide until the force parallel to the incline, F_A, reaches a certain value that is equal to the frictional force, F_F. The mass of the object represented by vector F_M can be resolved into vectors F_A and F_N parallel and normal to the plane of the incline, respectively. At the described condition of sliding at constant speed, $F_A = F_F$. Since $F_F = \mu_K F_N$, substitution leads to $F_A = \mu_K F_N$ or

$$\mu_K = F_A/F_N \tag{4}$$

From the vector diagram in Fig. 2, it is apparent that

$$F_A/F_N = \tan \theta = \mu_K \tag{5}$$

and

$$\theta = \text{arc}\tan \mu_K \tag{6}$$

Thus, if μ_K is known, the angle of incline, at which a block placed on the incline will slide regardless of the weight or mass of the block, can be determined. Note that the coefficient of friction can take on values from zero to extremely high values, but usually it has a value of between zero and one unless special conditions are involved as, for example, in the case of gage blocks, which are ultrasmooth, and in contacting spectroscopically pure metals such as copper that were outgassed in a vacuum prior to admitting other gases such as nitrogen, oxygen, or hydrogen.

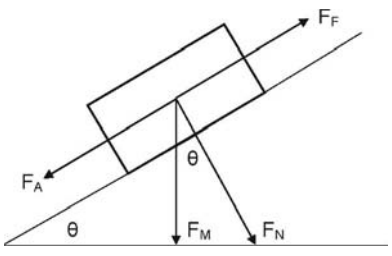

Fig. 2—A solid block resting on an incline. As the angle θ increases, the force, F_A, increases until the friction force, F_F, is overcome and the block will begin to slide.

In physics, the study of friction is called *tribology*. In a physics sense, friction is the resisting force that takes place when two surfaces contact and rub against each other. When investigating the causes of friction, it should be accepted that the surface of materials is microscopically irregular and is not flat on an atomic scale. Although surfaces may appear to be smooth, on a microscopic scale they are covered with asperities and are jagged and rough. The uneven or rough surfaces of the touching objects are thought to be one of the main causes of friction. As the surfaces move or tend to move, the rough surfaces interlock and offer resistance to being moved over one another until a certain value of applied force is reached.

From this model of rough surfaces interlocking, friction would be expected to decrease as the surfaces are smoothened. This is the actual state of affairs—up to a point. If the surfaces are made increasingly smoother, at some point friction will increase.[2] This phenomenon, which is another of the main causes of friction, is thought to be due to the bonding or interaction between surface atoms and these bonds must be broken before friction is overcome and sliding can take place. Such bonding will only take place where the surface atoms can come sufficiently close so as to be within each other's force fields. Thus with usual surfaces, it is only asperities on one surface that make contact with asperities on the other surface that can "bond" and interact through van der Waals or other chemical forces with adhesion bonds. The entire normal force is carried on the tips of the asperities and the true or actual area of contact is much less than the apparent or measured area. Local stress on the contacting asperities may result in a flattening of the asperities and produce an area of minute but intimate contact. With metals, the deformation may be within the elastic limit, but with plastics the viscoelastic deformation may be permanent or a hysteresis effect may be involved. As the surfaces are made increasingly smoother, at some point the overall contact area between them increases and as a result, bonding and resultant friction forces will increase. To move a surface over another surface, the adhesive bonds at the interface must be broken in a shear plane near the surface of one of the materials.

The shear fracture at the minute interaction areas or area of true contact between the dry contacting surfaces is a part of the mechanism of dry friction theory. If it is assumed that the interaction areas are more or less randomly distributed over the apparent contact area, the friction force can be expressed as

[2] Gage blocks are probably the best example of smooth surfaces that have high friction. These devices are used to provide linear dimensions to within given and very small tolerances—reference blocks that can have a high tolerance of ±0.000 002 in. or ±0.000 05 mm are built up to make the desired linear dimension. To develop a particular length, the appropriate blocks are slid together and held together by "forces" akin to the forces between molecules or atoms. Assembled blocks cannot be left together for long periods of time or they will become permanently joined through the forces. See www.claymore.engineer.gvsu.edu or www.ptb.de/en/org/5/54/543/parendm_e.htm as well as other sites for detailed information.

$$F_F = \sigma_G \cdot A \quad (7)$$

where A is the actual area of contact and σ_G is the average shear strength of the interaction areas. Since it is the interaction areas that actually carry the normal force, F_N, between the surfaces, the following relationship also exists.

$$F_N = \rho_m \cdot A \quad (8)$$

where ρ_m is defined as the flow pressure or shear stress of the softer material in the vicinity of local areas of actual contact. If the last two equations are combined, the coefficient of friction is obtained as

$$\mu = F_F/F_N = \sigma_G/\rho_m \quad (9)$$

and the coefficient is independent of the contact area.

Friction coefficients involving true area of contact have also been expressed in accord with the following relationships [6]. For metals, the deformation of asperities to form the true area of contact is approximately proportional to the normal force, F_N. In the case of polymeric materials, rubbers undergo an essentially elastic deformation and the area of contact increases with $(F_N)^{2/3}$ indicating that the coefficient of friction decreases with increasing F_N. When polymers that deform in a viscoelastic manner, the friction force follows a relationship that has the form

$$F_F = k(F_N)^X \quad (10)$$

with k a constant. Since $F_F = \mu/F_N$, the coefficient of friction may be expressed as

$$\mu = k(F_N)^{X-1} \quad (11)$$

with $2/3 < X < 1$. In the case of polytetrafluoroethylene, ithas been found that X has a value of 0.85 for over ten orders of magnitude change in F_N.

In a general sense, both mechanisms, the interlocking and the bonding mechanisms, play a major role in causing friction. Other mechanisms that may be involved in friction forces include, a gouging effect in which asperities on a hard material may gouge a grove in a softer material as moving objects drag and grind against each other; a roughness effect wherein the asperities interlock and there is a need to lift some asperities over other asperities; electrostatic effects in which work must be done to separate charged regions on the sliding surfaces—an effect that may be seen with electric insulators; and hysteresis effects in elastic and plastic deformations at the touching points or near them that take place with not all of the deformation work recoverable. Heat generation and dissipation account for the non-recoverable work.

Values for the coefficient of friction for plastics will depend on test conditions such as humidity, material degree of cure, moisture content, and temperature. For example, the coefficient of friction for nylon will vary from 0.91 to 1.19 when the moisture content is varied from 0.2 to 10 % [7]. Table 1 has coefficients of static friction, μ_S for various synthetic and natural polymers when in contact with the same polymer and with steel. In general, μ_S is greater for these polymers when sliding on the same polymer than when sliding on steel. The values are abstracted from a handbook [8] that contains many more values of the coefficients of friction including the static coefficients for a variety of polymers when in contact with wet and dry snow at 0°C as given in Table 2. In general, the coefficients are lower on dry snow indicating that it should be easier to move an object on dry snow than on wet snow. As the temperature of dry snow decreases from 0°C to –32°C, Table 2, μ_S increases with the effect dependent on the nature of the polymer. A range of values for the coefficient of sliding friction for a number of polymers sliding on a variety of unnamed substrates is given in Table 3.

Examination of the data in Tables 1–3 indicates that polytetrafluoroethylene has a very low coefficient of friction, and it is widely used to make slippery or low friction surfaces. But, the polymer can quite easily erode and wear when used in systems that have repetitious operation. The wear factor can be improved without compromising its frictional properties when it is filled with certain hard particulate solids. However, hard fillers can have a deleterious effect on an opposing surface. It has been found the improved wear while maintaining low friction or a high degree of slipperiness can be obtained without affecting the opposing surface if the polymer is irradiated with an electron beam [9].

Table 4 has values of the coefficients of kinetic friction for Nylon 6-6 in two states of smoothness (molded or machined surface) sliding against the same surface, against the opposite surface, or against mild steel as well as mild steel sliding against itself or the two nylon surfaces. The data indicate the machined nylon surface, $\mu_K = 0.46$, is smoother than the molded nylon surface, $\mu_K = 0.63$. It also appears that friction is less when the smoother machined nylon surface is moving on the rougher molded nylon surface than vice versa. There is very little, if any, difference in friction when either nylon surface is moving on mild steel, $\mu_K = 0.31$ and 0.33, or when a mild steel surface in moving on either nylon surface, $\mu_K = 0.41$. The strong effect of

lubricants, which will be discussed later in this chapter, is apparent from certain data in Table 4.

Shearing processes as described above depend on the viscoelastic nature of polymers and therefore are a function of strain rate (sliding speed) and temperature. It has been demonstrated that the coefficient of friction for crystalline polymers such as polyethylene, polypropylene, and Nylon 6-6 depends markedly on sliding speed and passes through a maximum [6,11]. Amorphous polymers such as poly(methyl methacrylate) and polystyrene only show moderate increases in μ_K and only a slight maximum as strain rate increases. As the temperature is increased, the dependency of friction coefficient curves is shifted to the right or to higher sliding speeds. Grosch [12] found similar effects for μ_K when a variety of rubbers (natural, butyl, styrene-butadiene, and acrylonitrile-butadiene elastomers) sliding on glass was examined as a function of sliding speed over a broad range of temperatures. The viscoelastic nature of friction is further demonstrated by subjecting the μ_K, sliding speed, temperature data to the Williams–Landel–Ferry reduced variables analysis [13]. The shift factor, log a_T, fits a continuous master curve when reduced to a reference temperature. Others [14–16] have obtained similar results that demonstrate the frictional characteristics of elastomeric materials behave in a viscoelastic manner.

Polymers are used in many facets of the electronics industry, and frictional characteristics can play an important role in their usage. Coefficients of friction for some polymers used in this industry and for two lubricants used are given in Table 5 [17]. Friction can cause tribolelectric charging of polymers by contact and rubbing. Since polymers have high resistivity, electrostatic charge can accu-

TABLE 3—Ranges of coefficients of sliding friction, μ_K, for various materials sliding on various unnamed surfaces [6].

Styrene-butadiene copolymer	0.5–3.0

mulate in large amounts and represent serious, hazardous consequences. For example, discharge between dissimilar pairs can cause a spark and a resultant fire or destruction of electronic equipment. A tribolelectric series for a number of widely used polymers is given in Table 6 [6]. Antistatic additives can decrease resistivity, and leakage currents can be used to dissipate an accumulation of electrostatic charge from friction.

ASTM DEFINITIONS/TERMINOLOGY

Table 7 contains a number of specific definitions or terminology that can be found in the ASTM publications indicated in the table. Although the definitions may differ in the exact wording, they are in basic agreement with each other and with the information given above. Terminology related to that in Table 7 may be found in ASTM D1436 Test Method for Application of Emulsion Floor Polishes to Substrates for Testing Purposes in ASTM D2825 Terminology Relating to Polishes and Related Materials, as well as in ASTM and other standards.

ASTM G115-10 Standard Guide for Measuring and Reporting Friction Coefficients contains schematic diagrams for more than 20 device/test configurations for friction testing, the applicable materials for the particular test, and the measured parameters for the standards listed in Table 8. It is a useful guide for those involved in a friction and its measurement. Two other definitions included in this standard are:

triboelement—one of two or more solid bodies that comprise a sliding, rolling, or abrasive contact, or a body subjected to impingement or cavitation. Each triboelement contains one or more tribosurfaces; and

tribosystem—any system that contains one or more triboelements, including all mechanical, chemical, and environmental factors relevant to tribological behavior.

SLIPPERINESS

In a general sense, slipperiness can be defined as the tendency of something to suddenly or involuntarily slide. In many cases, an organic polymer surface such as a coating is involved when slipperiness in considered. In terms of the flooring market area, for which the above definition was written, the flooring surface could be an alkyd or polyurethane enamel on a porch or deck, a vinyl- or polyurethane-coated gymnasium floor, a waxed vinyl composition floor, an epoxy-coated concrete floor, structural steel and coated structural steel, and so on. Slipperiness can be considered as involving of two factors—skid resistance and slip resistance. Skid may be defined as an act of sliding without rota-

tion, and slip can be defined as a slide that occurs suddenly or involuntarily. The coefficient of friction is a measure of slip with a high coefficient of friction denoting poor slip and a low coefficient of friction denoting good slip [5]. Slip resistance is something that is not really measurable in common terms and is often defined by different people in different ways— but everyone realizes that it does exist and the importance of testing for it remains regardless of the difficulty in defining the term [18].

The importance of slip and slipperiness is evidenced by a recent scientific symposium that was entitled "The Measurement of Slipperiness—an International Scientific Symposium" [19]. The seven papers in this symposium dealt with concepts and definitions [20], occupational slip injuries [21], biomechanics [22], human-centered approaches to slipperiness measurement [23], the role of surface roughness [24], and the role of friction in slipperiness [25,26]. For example, Chang and coworkers [26] studied friction mechanisms at the shoe-floor interface under a variety of conditions that included dry surfaces, liquid- and solid-contaminated surfaces, and icy surfaces. They concluded that static friction measurements determined by the traditional use of a drag-type device are only suitable for dry, clean surfaces. Dynamic and stick-slip measurements are needed to properly evaluate contaminated and icy surfaces and to estimate potential risk on such surfaces. Miller [27,28] has presented interesting discussions related to the measurement of slip resistance and to slip resistance standards. These discussions are readily available on the Internet. Di Pilla [29] has also discussed the measurement of slip resistance and the state of the technology, as it existed in late 2001.

DETERMINATION OF THE COEFFICIENT OF FRICTION (COF)

Three types of instruments are used to measure the COF, and these are illustrated in Fig. 3 [30]. These devices are drag-type meters that are based on $\mu = F_F/F_N$, pendulum-type meters that measure the energy loss of the pendulum as an indirect indication of dynamic friction, and articulated-strut devices that are based on the direct and fundamental principle of the resolution of forces that take place when as object slides down an incline as described above wherein $\mu_K = \tan \theta$.[3] Other instruments include torque (ASTM E510 and G99), ball-rolling (ASTM G123), roller (ASTM D3412 and G143), and other devices (see Table 8 for Standard titles). Short descriptions of various devices for studying friction and related properties that are available nationally and internationally can be found on the Internet [18].

Recently [31], sliding experiments were performed on amorphous polystyrene of various molecular weights using an atomic force microscope equipped with a nanotip probe. Friction coefficients were found to range between 0.2 and 0.45 and were similar to those found with other devices. Velocity effects on the dynamic coefficients were slight to nil, but there were marked effects involving the force at which the tip is unstuck as a function of polystyrene molecular weight. As molecular weight decreases, the applied force to overcome friction increases. Overall the results suggest that untangling of polymer molecules plays a role in describing breakage of the contact between interacting

[3] Although the COF from inclined plane testing is often referred to as a dynamic COF, μ_K, Section 10.1 of ASTM G115, Standard Guide for Measuring and Reporting Friction Coefficients, indicates that such testing only yields the static coefficient of friction. The standard recommends that the term static friction coefficient, μ_S, be used to describe a coefficient calculated using a breakaway force in a friction test rig that moves a specimen with a mechanism other than gravity.

TABLE 7—Definitions/Terminology for friction and slip properties taken from two ASTM publications.

ASTM G115-10 Standard Guide for Measuring and Reporting Friction Coefficients	ASTM D2047 Test Method for Static Coefficient of Friction of Polish-Coated Floor Surfaces as Measured by the James Machine
Coefficient of friction—The dimensionless ratio of the friction force between two bodies to the normal force pressing these bodies together.	*Coefficient of friction*—The ratio of the horizontal (shear) component of force required to overcome friction, to the vertical (normal) component of the force applied.
Kinetic coefficient of friction—The coefficient of friction under conditions of macroscopic relative motion between two bodies.	*Dynamic coefficient of friction*—The ratio of the horizontal component of force required to cause a body to continue to slide at a constant velocity, to the vertical component of the force applied.
Friction force—The resisting force tangential to the interface between two bodies when, under the action of external force, one body moves or tends to move relative to the other.	*Friction*—The resistance to relative motion developed between two solid contacting bodies at, and parallel to, the sliding plane.
Static coefficient of friction—The coefficient of friction corresponding to the maximum friction force that must be overcome to initiate macroscopic motion between two bodies.	*Static coefficient of friction*—The ratio of the horizontal component of force required to a body that just overcomes the friction or resistance to sliding, to the vertical component of the force applied.
. . .	*Slip resistance*—The frictional force opposing movement of an object across its surface, usually with reference to the sole or heel of a shoe on a floor. A surface having a static coefficient of friction of 0.5 or greater as measured by this test method is considered to have adequate slip resistance. That is, it will provide the required traction for preventing or markedly reducing the probability of slipping while walking.
Stick-slip—A relaxation oscillation usually associated with decrease in coefficient of friction as the relative velocity increases	. . .

bodies. Scratch testing with a spherical indenter has been used to measure the friction coefficient of polydimethylsiloxane on stainless steel [15]. These results indicated that the dynamic friction coefficient decreased with increasing normal load suggesting that the viscoelastic character of the coating influenced its frictional behavior.

Another technique involving scanning-probe microscopy and known as friction-force microscopy measures the lateral force on a sliding probe caused by sliding friction [32]. The technique allows frictional processes to be examined on a nanometer scale. It has been found that the velocity dependence of friction has a maximum in the friction-velocity interaction and this is related to the glass transition temperature, T_g. Hammerschmidt and coworkers [33] have summarized some of these studies when they used temperature-controlled friction-force microscopy to investigate viscoelastic relaxations of polystyrene, poly(methyl methacrylate), and poly(ethylene terephthalate) and their effect on friction. They concluded that for polymer films the main contribution to friction was viscoelastic mechanical loss.

SLIP RESISTANCE

One may think of slip as the antithesis of friction. While both high and low friction are important, in the sense of walkways, working surfaces, sidewalks, swimming pool, bathing, and other tiled areas, and similar surfaces, there must be sufficient friction to ensure that slipping and/or tripping with subsequent falling and potential injury will not occur. There are many different slip resistance testing specifications and standards. OSHA (Occupational Safety and Health Administration) has a standard [34] that deals with the slip resistance of skeletal structural steel. A subpart of this standard, Standard Number 1926.754(c)(3), indicates that after July 18, 2006, workers will not be permitted to walk on the top surface of structural steel that has been coated with paint or similar material unless documentation or certification indicates that the coating has achieved a minimum average slip resistance of 0.5. This value must be achieved when measured with an English XL tribometer [35] or equivalent tester on a wetted surface at a testing laboratory. The certification or documentation is to be based on the appropriate ASTM standard test method in a laboratory that is capable of performing the test. The cited ASTM test methods [36] are:

ASTM F1677-96 Standard Test Method for using a Portable Inclinable Articulated Strut Slip Tester (PIAST). This method is approved for dry and wet testing. The method, which simultaneously applied the horizontal and vertical forces, can be used on nearly all surfaces. The device used with this method is the Brungraber Mark II.

ASTM F1679-00 Standard Test Method for using a Variable Incidence Tribometer (VIT). The literature suggests that this is an excellent testing method that is approved for both dry and wet testing on essentially all surfaces. As in the previous method, the horizontal and vertical forces are applied in a simultaneous manner. The device used with this method is the English XL tribometer [35], and operators using this equipment should be certified for such use.

With the above said, it must be pointed out that ASTM has found that these methods lack a precision and bias statement and have a reference to proprietary apparatus

TABLE 8—ASTM Standards for measuring friction coefficients and related technology (other standards exist).

[a]Withdrawn, but these standards are referenced and therefore included in above listing.

that violates certain ASTM requirements [37]. A deadline of September 30, 2006 had been set for correcting the deficiencies, but it was felt that this deadline would not be met. As a result, a decision was made to withdraw ASTM F1677 and ASTM F1679 as well as two related test methods.[4] At the same time the above was taking place, OSHA [38] reopened and sought comments and information regarding its Standard Number 1926.754(c)(3) and attendant Appendix B [34,36]. OSHA's purpose of reopening this matter was to consider whether to retain, amend or revoke the provision regarding test methods for slip resistance on skeletal structural steel and whether slip-resistant coatings meeting the requirements could be available by July 18, 2006. Since OSHA ascertained that no progress would be made toward meeting these goals[5] by the "to-be-effective" date, the group decided in early 2006 to revoke a provision within the Steel Erection Standard that addresses slip resistance of skeletal structural steel [39]. Readers interested in this matter would do well to follow proceedings that probably will be found in the Federal Register and/or ASTM literature.

English [40] has a listing of slip resistance standards that are in wide use. Included in the compilation are the above test methods as well as other standards from ASTM, American National Standards Institute (ANSI), National Fire Protection Association (NFPA), and Underwriters Laboratories. The standards are separated by their suitability for wet or dry testing. English also has a description of other tribometers based on pendulum and drag-sled principles.

SENSOR MATERIALS

Materials that may be used as sensors or test pads include a broad range of known items [41]. Of course, sensors are used in context with the tests being conducted. For friction testing, two surfaces are required for any measurement—one is the surface of the specified material to be tested and the other is a sensor material or the surface against which the specified material is to be tested. The specified material and sensor material may be the same or different, but both must be defined and specified.

To obtain meaningful and reproducible results, it is essential that the sensor material be selected to represent use conditions and be well defined. Properties such as uniformity (surface character including flatness, roughness, chemical composition, resilience, and shear modulus), permanence in that chemical and physical characteristics do not change with time, and availability in a usable form that does not require excessive preparation should be considered when selecting a sensor. Many feel that a major concern in sensor selection is choosing a material that will not change as a function of time. Both sensor material and

[4] The "other two" test methods are ASTM F1678-96 Test Method for Using a Portable Articulated Strut Slip Tester and ASTM D5859 Test Method for Determining the Traction of Footwear on Painted Surfaces Using the Variable Incidence Tester.

[5] Comments received by OSHA prior to the deadline suggested that no significant progress had been made regarding the suitability of the test methods referenced in the provision for testing slip resistance or the availability of coatings that would need the slip resistance requirements of the provision [39]. The final revocation rule was effective January 18, 2006.

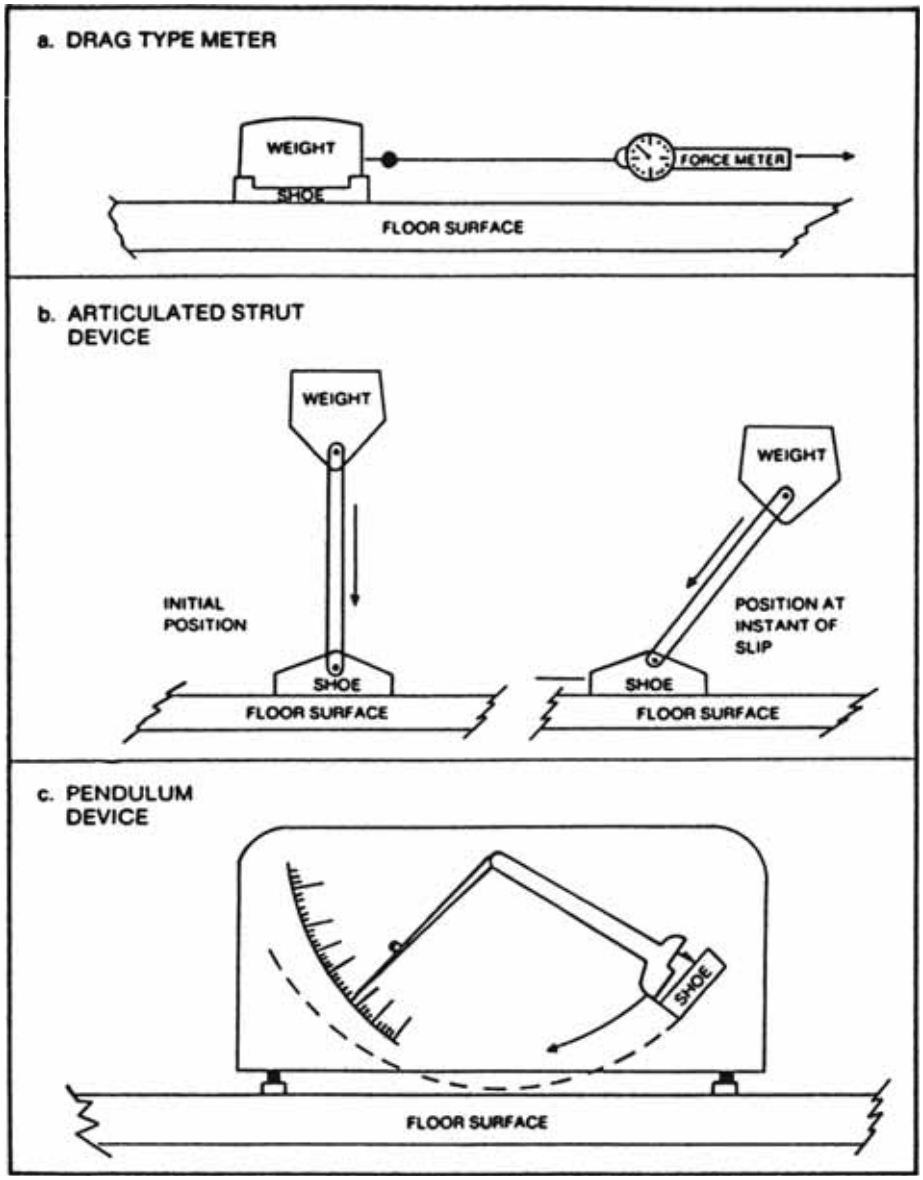

Fig. 3—Schematics of different friction measurement devices (courtesy of the National Institute of Standards and Technology).

test material may be the same or different and both should be reported when the coefficient of friction is stated.

Sensors might be exemplified by leather that is used as a primary source material when friction of flooring is studied. For interlaboratory and specification testing, shoe materials such as leather conforming to Federal Specification KK-L-165C[6] [42] are used. When leather is used as a sensor or as a test material, it should be kept in mind that leather soaks up water and becomes somewhat sticky which will result in high coefficients of friction being measured. Also, leather is not homogeneous in character and can vary from piece to piece. It is important that the appropriate materials are used when specific testing is done. In the case of rubber, it is recommended that a rubber conforming to Section 7.1 of ASTM D1630-06 Test Method for Rubber Property—Abrasion Resistance (Footwear Abrader) be used. Neoprene, nitrile, and styrene-butadiene rubbers have been used in many investigations. In another study [43], three leathers with three levels of oil content, two Kraton® thermoplastic elastomers, and 15 different rubbers were used to generate statistical data for ASTM F609-05 Test Method for Using a Horizontal Pull Slipmeter (HPS). Neolite® is also used as a test pad material that does not change regardless of moisture or wear conditions.

LUBRICANTS

For those instances where friction is to be decreased (slip increased), a variety of lubricants, slip agents, or slip additives are available. These compounds include micronized polyethylene, polytetrafluoroethylene as well as various waxes, oils, and silicones. Water can also act as a lubricant when it is present on many solids. Persson [44] and coworkers have studied the effect of water on the loss of braking power and rubber skidding on a wet highway (tire asphalt). They reported that rubber can seal water-filled pools or

pockets and effectively smooth the rubber surface. This effect reduces the viscoelastic dissipation that surface asperities induce in bulk rubber, and decreases friction. High molecular weight polyoxyethylene has remarkable properties for reducing the friction or drag characteristics of water [45] on objects such as pleasure/racing boats, naval craft, and torpedoes when used in various forms, for reducing the friction of ski waxes on snow when compounded into the wax, and increasing volume output of water under constant pressure through hoses and ducts.

In some instances, a material of construction can have an internal lubricant as is the case with the acid- and chemical-resistant wood from the tree *lignum vitae*[7] (*Guai-acum Officinale*), an extremely hard wood that find use in noiseless underwater bearings and as saw guides. McLaren and Tabor [46] found that in the dry state this self-lubricating wood has friction characteristics comparable to those of polytetrafluoroethylene. Experimental evidence indicated that the lubricity is due to wood waxes that exude from the wood during sliding operations. Formulation with solid lubricants has made great strides in recent years for industrial operations that impose severe sliding conditions [47]. Nanostructured or nano-composite forms are coupled with micro-texturing, micro-patterning, or other smart surface engineering strategies [48] to achieve very high levels or durability and performance.

Many lubricants also function as abrasion resistance and mar-reduction agents. In certain instances, they can be used as antiblocking agents. They are often used in the plastics processing industry where they function as melt viscosity reducers and flow agents to improve flow onto metal surfaces and, at times, as co-stabilizers. The use of lubricants to reduce wear and power consumption is well known.

Factors that should be considered in selecting a lubricant include absorptivity, melting point, polarity, solubility, effect on adhesion, potential reactivity from friction thermal energy developed, volatility, and similar characteristics. Common lubricant families as well as selected specific lubricants are listed in Table 9. Polyethylene and polytetrafluoroethylene are available in powdered or micronized form in a variety of particle sizes [49]. Silicones are available as formulated products designated for use in the coating industry [50,51]. The powdered and micronized products are incompatible and function as filler when incorporated into the coating where they act as tiny "ball bearings" that decrease friction and often improve abrasion and mar resistance.

[7] A small tree that is native to the Netherlands Antilles and St. Johns in the Virgin Islands and that has been cultivated in Argentina. The wood from this tree is very dense and will sink in water. In addition to its self-lubricating frictional properties, the tree s sap and bark are said to have medicinal properties.

Part 12: Environmental Resistance

54

Prevention of Metal Corrosion with Protective Overlayers

William H. Smyrl[1]

THE PREVENTION OF CORROSION BY SURFACE processing enjoys significant economic leverage, and, as evidence, one may cite the widespread use of coatings, films, and inhibitors for metals and semiconductors in many service environments. All engineering metals used in modern technological societies are unstable with respect to corrosion, and the result is a loss of properties. Natural oxide films provide protection against continued attack for some metals, and alloying extends the life of other metals by developing highly stable passive films. Where metals may not be protected by oxide films, other modification methods have been developed to reduce corrosive attack. In reality, the improvement of corrosion resistance of metals by modification of the surface has been practiced since the invention of metal tools. Some of the earliest techniques to prevent corrosion involved coating with greases or natural oils. More modern methods were developed in the 19th and 20th centuries and include multiple coatings, zinc galvanizing, electroplating of other pure metals, and vacuum physical vapor deposition of mostly pure metal coatings by electron beam and sputtering techniques. The metal coatings are better barriers than organic films because of the lower permeability of the former to moisture, oxygen, and ions. Inhibitors or conversion coatings and primers for paints are cheaper than metal coatings and are used widely by paint manufacturers even though they remain highly proprietary in nature.

The use of organic coatings to protect metal surfaces is practiced widely. Much of the use is for atmospheric exposure of motor vehicles as well as for structural units such as bridges and buildings. The successful implementation of existing technologies has greatly reduced the effects of corrosion of automobiles, for example, in the past decade in response to consumer demand. Despite many recent advances, coating technologists and scientists acknowledge that much is unknown and that new processes and understanding are the keys for further progress [1]. Defects in the metal substrate and in the overlayers are among the primary concerns because they are the source of localized corrosion phenomena. Defects may occur on length scales from atomic-level lattice vacancies to arrays of defects at grain boundaries (for crystalline materials) or to random pores or cracks (for example, in noncrystalline films). Avoiding such defects by proper quality control is a major concern in coatings science and technology.

In the discussion that follows, aspects of corrosion that involve thermodynamics and kinetics will be developed as a basis for the description of the specific nature of corrosion of metals under protective films and overlayers. Some emphasis will be given to protection of thin metal films and micro-structures that are particularly sensitive to corrosion and whose successful protection provides a basis for advancing protection technology in general.

CORROSION IN AQUEOUS SOLUTIONS

The driving force for a reaction is the change in Gibbs free energy, AG, for reactants to products. Mathematically, this may be expressed by

$$\Delta G = \sum_{\text{products}} G - \sum_{\text{reactants}} G \qquad (1)$$

The summation signs are used as a general notation to indicate that all reactants and products are included in the calculation. From the nature of the free energy function, this calculation applies to initial (reactants) and final (product) states and is independent of intervening states. The reaction may be investigated under controlled reversible conditions such as in an electrochemical cell or under irreversible conditions such as in corrosion, and the same total free energy change (ΔG) will be appropriate. A quite general predictive capability may be applied to specific corrosion reactions since all the available thermodynamic data may be used for corrosion calculations directly. This enables the position of final equilibrium of the corrosion system to be established. The thermodynamic calculations have the limitation that no information concerning the *rate* of the reaction is provided, only what the final state will be for the process.

The value of ΔG for reactions of elements to form a compound, all in their standard states at a particular temperature, is the standard free energy of formation of the compound, $\Delta G^0_{f,T}$. Here, the subscript T denotes the temperature. Description of the detailed calculations are beyond the scope of this discussion, but several excellent textbooks are available [2,3].

The most extensive tabulations of thermochemical data for chemical compounds in their standard state at 25°C are in a series of National Bureau of Standards publications [4]. These are NBS Technical Notes 270-3, 270-4, and 270-5, which supersede the older NBS Circular 500 for the elements they cover. These tabulations also update the older

data of Latimer [5]. The book by Latimer [5] remains a valuable reference because of the description of techniques to estimate thermodynamic quantities where reliable data are sparse. Lewis and Randall [3] tabulated thermodynamic data, including data for aqueous solutions of a number of electrolytic solutions that are valuable for corrosion calculations. There is overlap between this tabulation and the JANAF thermochemical tables [6], but the latter also tabulate the standard enthalpy and free energy of formation of chemical compounds at several temperatures along with $-(G^0 - H^0_{298})/T$.

Oxide and hydroxide solubility are strongly influenced by the pH of the aqueous phase. Pourbaix recognized this and summarized the thermodynamic stability of metal-aqueous systems by the use of potential-pH diagrams. The thermodynamic data tabulations already quoted [3–6] should be utilized for detailed calculations, however.

Usually when studying corrosion, one is not concerned with the conditions for thermodynamic stability, but rather with the rate of attack and how it may be altered in basically unstable conditions because only a limited number of systems have absolute or *thermodynamic stability*. As a practical matter it is necessary to accept some rate of corrosion and/or to control or mitigate the rate of attack. Thus *kinetic stability* is always relative and subject to interruption if control is not maintained. Controlling the rate of degradation may be accomplished, for example, by the use of cathodic or anodic protection, the use of inhibitors, the maintenance of protective surface films, or buffering the composition of an otherwise aggressive solution. All these techniques are used widely to extend the life of metallic structures with continuing improvement.

Corrosion reactions are electrochemical in nature. The kinetics of the corrosion reactions are then related to the kinetics of the electrochemical reactions that occur during the corrosion process. The reactions involve not one but at least two electron transfer reactions, and the reactions are not in series but are in parallel. Coupling of parallel or simultaneous reactions is a fundamental feature of the corrosion process. Each of the simultaneous reactions may consist of multiple steps, respectively, as described above, but the simultaneous, independent reactions are coupled electrically. The independent reactions occur on the same surface at the same time, but also at the same potential. The reactions may be coupled chemically as well, e.g., through pH effects, but this is not essential. The specific relation that defines the coupling of simultaneous corrosion reactions on an isolated metal surface is

$$\sum_{\text{anodic}} I_a = -\sum_{\text{cathodic}} I_c \tag{2}$$

There will then be zero net current to the corroding metal electrode. The relationship is written in terms of currents (I_a and I_c) rather than current densities for reasons which will be discussed. The potential at which the balance is satisfied is the mixed or corrosion potential. It is determined by the rates of the simultaneous reactions and is not defined by the state of the system in a thermodynamic sense. The corrosion potential always lies between the equilibrium potentials of the anodic and cathodic processes, respectively.

As a summary, the general corrosion of metallic materials in aqueous solutions is well understood. The anodic or oxidation reaction of the metal is superimposed on a cathodic reaction, and the two are balanced locally on a homogeneous surface. The rate of the reaction is a function of both the rate of metal dissolution and the rate of the cathodic (reduction) reaction. Each reaction may be influenced in general by the composition of the solution, especially the pH and the electrolyte anion, and by the nature of the (oxide) films, if any, which may be formed at the metal/electrolyte interface. If several oxidizing species are present in the solution, each may act in parallel so that the total rate of metal dissolution is increased. For example, most metals will react directly to displace hydrogen from water and to produce an oxide of the metal or some other corrosion process. The addition of oxygen will increase the rate of corrosion of the metal, usually in direct proportion to the concentration of the oxygen added. The specific details will vary with each metal to reflect the thermodynamic, kinetic, and mass transfer driving forces that are acting [7].

Heterogeneous surfaces are commonly observed in corrosion situations and are of the three general classes: (1) the inclusion of foreign metal impurities on the metal surface, (2) the nonuniform coverage of the surface by a film, either an oxide film or an artificial coating in aqueous solutions, and (3) nonuniform conditions in the electrolyte environment. All these are of great importance because localized, or nonuniform, corrosion of metals may be caused by any of the three. A form of galvanic corrosion and pitting corrosion is caused by the first type of heterogeneity, while crevice and pitting corrosion are produced by both (2) and (3).

Restrictions of geometry, e.g., in crevices and corners, prevent mixing of solutions everywhere, and local buildup of reaction products or the exhaustion of an oxidant may occur. The local kinetics will be relatively independent of that in other regions except that there may be coupling through the electric field and electrical current may flow between a localized corrosion site and the surrounding surface. This may lead to nonuniform corrosion, particularly where the buildup of products increases the aggressiveness of the local solution. In this case, corrosion will be most severe, not where the concentration or flux of the bulk solution oxidant is highest but where it is lowest. Crevice corrosion is considered to be an example of this type of attack, and the aggressive solution within a crevice or pit is one which is more acidic than the external solution.

Anodic dissolution, plus hydrolysis of the product metal ion, causes an increase of hydrogen ion concentration. On the other hand, reduction of either hydrogen ions or dissolved oxygen reduces the hydrogen ion concentration. If the net corrosion reaction plus hydrolysis would lead to an increase of hydrogen ion concentration, the process may occur independently of any other process and would accelerate with time to some steady state where diffusion out of the occluded region would limit the buildup. If the corrosion reaction plus hydrolysis leads to no net change in H^+ concentration, an acid solution in a crevice or pit could only be created by separation of the anodic and cathodic regions. Concentrating the cathodic reaction on the outer surface would occur naturally if dissolved oxygen, for example, were the primary bulk oxidant. Coupling this with a net anodic reaction (plus hydrolysis) in the inner region for an overall current balance would lead to a steady state crevice or pit.

For separation to occur as described above, a quite general condition imposed on the corrosion kinetics must be

obeyed. The outside surface must support a cathodic reaction, and it must be supported at a potential that is positive of the potential of the anodic reaction in the crevice. The direction of current flow through the solution establishes this criterion. A qualitative laboratory test may be used to identify metal solution combinations that could cause localized attack by the mechanism described above. The test involves the corrosion kinetics on the metal of interest. Cathodic currents must be observed on the metal in the exterior solution at potentials that are positive of the anodic region for the crevice conditions or the separated reactions will not support increased anodic dissolution in the isolated region. This is a very definitive test, and very few metal-environment combinations match the criterion.

Ohmic drop restricts the penetration of current into a small-gap, occluded region [8]. This causes the anodic reaction to be distributed over a relatively small region, which concentrates the attack. At greater depths in the gap, the metal is isolated from the external surface reactions. Newman [9] calculated the limited depth to which a reaction may penetrate inside a circular geometry, in this case a cathodic protection reaction. The reaction is concentrated near the opening.

Composition gradients are considered to be important for pitting and differential aeration corrosion as well. For pitting corrosion, similar conditions to those for crevice corrosion are considered important. Pits may be initiated in ways that are different from crevice corrosion, e.g., at foreign metal inclusions. However, the propagation of pits depends largely on a locally aggressive solution. Stirring to eliminate concentration effects will stop the growth of pits. Differential aeration could also drive corrosion at locally variable rates under an electrolyte film of nonuniform thickness. The diffusion-limited flux of oxygen through the film would be directly proportional to the film thickness. If the local corrosion rate is limited by the oxygen flux, the attack will be most severe at low film thicknesses. For active/passive metals, increase of the oxygen flux may exceed the peak current for active dissolution and cause the metal to adopt the passive state. In this case, then, thin films of electrolyte will *reduce* the corrosion rate.

ATMOSPHERIC CORROSION OF METALS

Most atmospheric corrosion tests have been conducted in environments such as indoor atmosphere, outdoor atmosphere, and laboratory tests under simulated conditions. Indoor corrosion studies have been performed for the electronics, computer, and communication industries for the development of more durable materials with desirable structural, magnetic, and electrical properties. On the other hand, outdoor studies aimed at understanding corrosion behavior are highly dependent on atmospheric weather factors, especially in marine and urban areas. The latter studies have been performed in the automobile, marine, and aircraft industries. Laboratory tests attempt to use accelerated methods under simulated atmosphere or aqueous conditions. Electrochemical methods have been used extensively in such tests to analyze and monitor the corrosion behavior of metals.

Several weather factors are known to influence outdoor corrosion [10–13]. Precipitation, ambient and dew-point temperatures, atmospheric pollutants, wind direction and wind velocity, and solar radiation can be considered as weather factors in outdoor and/or urban corrosion tests. Among these factors, moisture or relative humidity, temperature, and pollutants such as sulfur dioxide and chlorides are the most important variables.

Relative humidity is known to be the most important factor in determining the atmospheric corrosion rate. It has been reported that rapid acceleration of corrosion occurs beyond a certain value of relative humidity, defined as the critical humidity [14,15]. The period in which the relative humidity exceeds the critical humidity is called the time-of-wetness, and this factor is quite significant in determining atmospheric corrosion rate of metals [16]. In addition, in the presence of a pollutant such as sulfur dioxide, the critical humidity at which corrosion is enhanced to a significant extent will decrease with increasing pollutant concentration [17,18].

It has been reported that comparatively large aggregates of water are present on oxyhydroxide surfaces at humidities below 40 % [19]. Even on clean metal surfaces obtained under ultrahigh vacuum or reducing conditions, significant quantities of water are adsorbed on air-formed films when exposed to the environments containing only oxygen and water vapor for more than a microsecond [13]. As a result, monolayers of adsorbed water may provide the medium for electrochemical microcells that may drive a heterogeneous corrosion process. Water may also exist in the form of complex mixtures with oxides, hydroxides, and mixed oxyhydroxides [19,20].

The corrosion rate of metals is accelerated by the presence of air pollutants such as sulfur dioxide, nitrite, nitrate, hydrogen sulfide, chloride, and some kinds of salts [10,15]. These species may derive from gas-borne particles or from reactions at the surface. Reaction with adsorbed water monolayers yield electrolyte films that facilitate further corrosion processes. Among these pollutants, sulfur dioxide, chlorine gases, sulfur gases, and ozone are important species that promote corrosion in the presence of water [21].

The corrosion-accelerating effect of sulfur dioxide with humidity has been reported by many investigators [10,13,15]. Vernon [15] suggested that sulfur dioxide may change the pH in electrolyte films present on metal surfaces and enhance the corrosion rate. Rice et al. [13] also suggested that sulfur dioxide is readily soluble in water to form sulfurous acid; these local acidic regions accelerate oxide formation, and the corrosion rate is also enhanced by other electrochemical effects. It has been reported that wetting of the metal surface is promoted in the presence of ammonia, and the water droplets contain higher concentrations of sulfates than for the same concentration of sulfur dioxide with no ammonia [10,22].

The effect of chlorine gas or chloride on atmospheric corrosion has been reported [10,13]. In aqueous electrochemical corrosion studies, the chloride ions usually enhance pitting corrosion of many metals and also degrade the oxide surfaces. Rice et al. [13] reported that chlorine gases reduce the surface pH and yield hygroscopic corrosion products that influence the amount of adsorbed water. A direct relationship between the amount of chlorides in corrosion products and atmospheric corrosion rates was reported by Sereda [10].

The effect of ozone gas on copper and silver corrosion has been known to be significant, while cobalt, nickel, and iron are insensitive to ozone [13]. It has been reported that

ozone may enhance the corrosion rate of metals sensitive to H_2S.

The atmospheric corrosion rate can be measured either in field tests in different atmospheres or with accelerated tests in the laboratory. The field tests require long exposure times and yield complicated data that prevent detailed analysis. Accelerated tests are performed under simulated atmospheric conditions, and they are the easiest way to acquire more information with various setup conditions. However, it may not be possible to simulate practical service conditions.

There are several methods to monitor and control the corrosion rates by means of either field or laboratory tests. The conventional method is the weight loss determination, which requires long-term exposure unless a continuous method is used that involves the quartz crystal microbalance [23,24]. Another method is the electrical resistance method and measurement using electrochemical cells. Electrical resistance methods use the changes in the electric resistance of thin wires or foils to monitor failure, but they cannot be used for determination of the instantaneous corrosion behavior [25–27].

Electrochemical methods have been developed to take advantage of the electrochemical basis for atmospheric corrosion [28,29]. Corrosion currents can be monitored electrochemically, and the instantaneous value of current can be detected. One way to monitor atmospheric corrosion with an electrochemical method is to design a cell that will work under thin electrolyte layers (less than 500 μm) with consideration of the effects of corrosion products and dilute pollutants [30].

Electrochemical methods for monitoring atmospheric corrosion have been well reviewed by Mansfeld [30,31]. Most of the studies have been aimed at macroscopic measurement of time-of-wetness that is associated with electrochemical corrosion [10,12,16,17]. Galvanic cells with electrodes of different metals have been commonly used [16,32]. Sereda [10] has developed galvanic cells of platinum-iron and platinum-zinc couples to determine the time-of-wetness. Time-of-wetness was arbitrarily defined as the interval during which the external potential exceeded 0.2 V. This figure was the period during which the relative humidity was greater than 85 % [12,16]. Tomashov [33] has used sandwich-type galvanic cells of iron-copper, iron-zinc, iron-aluminum, and copper-aluminum. They concluded that the method was suitable for fast determination of the corrosivity of the atmosphere and that the direct measurement of corrosion rate for testing metals was possible.

Several investigators [17,34–36] have used galvanic cells consisting of steel-copper and electrolytic cells consisting of individual metals (steel, zinc, or copper) to which an external potential was applied. They concluded that the cell current gave qualitative agreement with the weight-loss data. Recently, extensive studies have been performed by Mansfeld and his coworkers [30,31,37–39]. They used galvanic cells and electrolytic cells which consisted of two electrodes and three electrodes. Galvanic cells such as copper-steel, copper-zinc, steel-zinc, steel-aluminum, and aluminum-zinc couples were used to study the effects of pollutants, relative humidity, and so on. They used the electrolytic cells such as two- and three-electrode cells for studies of the corrosion kinetics and for the measurement of corrosion currents. The polarization resistance method was used to determine atmospheric corrosion kinetics under thin electrolytic layers. Mazza et al. [40] have used a galvanic cell that consisted of a sandwich formed of bronze covered by its artificial corrosion products on which a high-porosity gold film was applied. They monitored the corrosion current with a zero resistance ammeter and obtained instantaneous and continuous information on the corrosion rate of the bronze. Tosto and Bruco [41] used galvanic cells of copper-steel to obtain the relation between the corrosion content and relative humidity. They found that the corrosion current depended on relative humidity (RH).

As a rapid electrochemical method for monitoring atmospheric corrosion, measurements of electrode potential using a suitable reference electrode have been developed by several investigators [42,43]. Although the method gives no absolute data on corrosion rates, it is a fast and easy method for on-site investigations. Thin film methods to measure corrosion rates were discussed by Howard [44]. Pourbaix and his coworkers [42,45] developed an accelerated electrochemical wet and dry method that was designed to use alternate immersion cycles in an electrolyte bath. The electrode potential was monitored when the steel electrode was in the wet part of the cycle. They concluded that their method was selective and yielded reproducible data.

Electrochemical cells designed to simulate thin electrolytic films formed during atmospheric corrosion have been developed by several investigators [46,47]. Fishman and Crowe [47] have studied the thin film of electrolyte with a potentiostatic polarization technique. The corrosion current increased with an increase of RH. They concluded that the resultant corrosion rates were consistent with those reported from long-term weight loss measurements. Fiaud [46] created a thin electrolytic film (80 μm thickness) using the device similar to one developed in the field of thin layer electrochemistry [48]. Platinum and nickel were used as electrodes and sodium sulfate (Na_2SO_4) solution was used as the electrolyte with change of pH by addition of sulfur dioxide (H_2SO_4). SO_2 gas was introduced into the electrolyte through a membrane. They observed the depolarization effect of SO_2, oxidation of SO_2, and reduction of SO_2 with use of cyclic voltammetry and linear polarization techniques.

CORROSION OF THIN METAL FILMS AND MICROSTRUCTURES

Corrosion of a metal occurs by the same fundamental reactions whether it is used in a large structure like an automobile, a bridge, or a heat exchanger, or in a small structure characteristic of magnetic, optical, or microelectronic devices, or under a protective layer [49]. The uniqueness of each application is tied up in the definition of the environment to which the metal is exposed or which develops with time, as well as the definition of a characteristic size of the corroding material. Since the time to failure of a material (i.e., its lifetime) is normally inversely proportional to the corrosion rate and directly proportional to the thickness of the corroding material (its characteristic size), small dimensions are more susceptible to corrosion failure and loss of properties. For example (see Fig. 1), a 50 nm cobalt magnetic film may be corroded completely in about 38 h at a corrosion rate of 1 $\mu A/cm^2$. The desired lifetime is about five years, so a protective film (e.g., diamond-like carbon) must be used to moderate the rate of attack. The protective layer

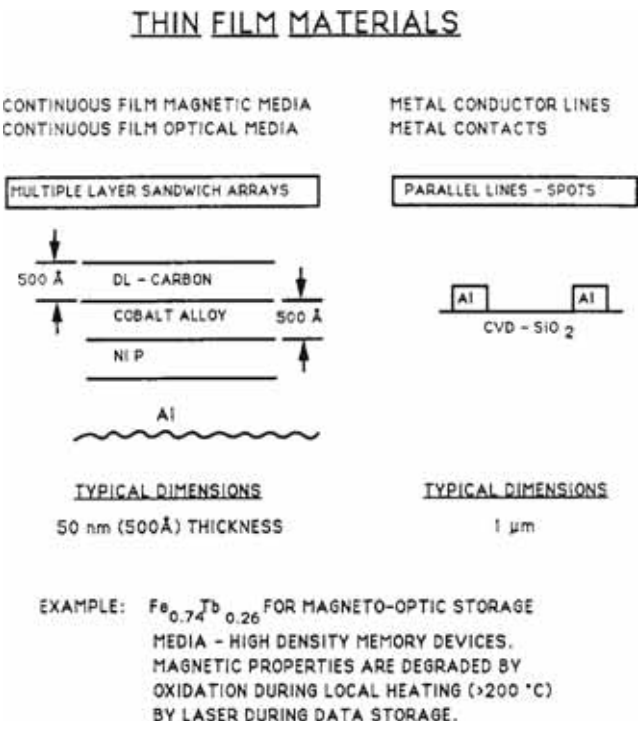

Fig. 1—Thin film materials for magnetic, optical, metal conductor lines and microelectronic contacts make them highly susceptible to have small dimensions that are highly susceptible to corrosion.

must be thin to read or write to the cobalt film with the magnetic head, and defects in the protective layer will lead to localized corrosion attack. Wear and friction are mechanical processes that result from the relative movement of the disk and head. The head is designed to fly very close to the disk to take advantage of the magnetic properties [50], but it comes to rest on the disk surface when the system is idle. Humidity and other factors affect wear and friction, and layers or films may be added to lubricate the magnetic film. Of more interest here, however, are the chemical effects that cause corrosion. Accelerated tests have been used to determine disk reliability [51], tests that measure the affects of wear, friction, atmospheric contaminants, humidity, oxygen diffusion, and galvanic corrosion. Also described by Antler and Dunbar et al. [51] is the comparison between field test experience and laboratory simulated corrosion test results. Earlier results on microelectronics failures are reviewed by Schnable et al. [52], Comizzoli et al. [53], Wood [54], and Stojadinovic et al. [55]. Whatever the mode, the result is a loss of information at the site of degradation and the loss of properties. Better preparation and processing, or better design, may reduce flaws and defects that cause mechanical failure, but they may not reduce corrosion that is the result of the natural instability of the metal in an aggressive environment. Rarely are the thin film metals stable in the environment, so techniques must be found to stabilize the structures and extend the lifetimes.

In the other example of Fig. 1, aluminum interconnects in microelectronic devices have characteristic widths of 1 μm or smaller. Ionic conduction along adsorbed water layers at the silicon dioxide (SiO_2) surface can lead to electrochemical corrosion and "breaks" in the Al conductor. If the corrosion rate were 1 $\mu A/cm^2$, the lifetime of the Al interconnects would be about 48 days, rather than the 10 to 20 year lifetime desired. A protective layer is required for this application as well.

The corrosion phenomena of thin films chosen for magnetic, optical, or electrical applications have unique characteristics, but they are often similar to those observed for bulk materials [35,50,56]. Thin films have bulk metallurgical properties in thicknesses larger than 1–3 nm and have the same chemical reactions as well. Both observations lead to the general conclusion that both bulk metals and films 30 nm or thicker will have similar corrosion behavior. On the other hand, thin film materials have small grain size and are prepared for magnetic disk applications in "tracked" or grooved geometries. The small grain size causes films to have more homogeneous properties, with fewer inclusions and smaller chemical segregation effects than ordinary bulk materials. The tracks have sharp edges and dimensions to generate unique morphologies in the films. The homogeneous properties would make the films less susceptible to corrosion, but the defects generated at edges could be sites for enhanced attack. The dimensions and geometry of the tracks may lead to nonuniform chemical composition in the recesses, which would produce localized corrosion effects as well. Atmospheric corrosion has been studied under simulated conditions for thin magnetic films [35], and, as in other cases, it was found that the affect of humidity and atmospheric pollutants was synergistic. The level of humidity may influence the condensation of thin moisture films on surfaces, which will facilitate transport across surfaces and may cause the accumulation of water in microscopic domains. In the latter, the concentrations of dissolved contaminants may approach saturation conditions. The contamination may come from dust or inclusions of other layers [49]. The conditions are difficult to simulate in the laboratory because of the lack of knowledge of local conditions in the microscopic regions that are relevant to the problem. In addition, it has been difficult to make in situ measurements for conditions that simulate atmospheric-corrosion measurements, which would give a direct indication of the processes responsible for corrosive attack. Several standard tests have been developed to assess atmospheric corrosion damage ASTM Practice for Conducting Atmospheric Corrosion Tests on Metals (G50–76 (1990)); ASTM Practice for Rating of Electroplated Panels Subjected to Atmospheric Exposure (B537-70 (1992)) without addressing the mechanism of the attack.

The second topic relates to protective layers and encapsulants. Pore-free conventional protective layers over magnetic films are too thick to be compatible with the magnetic properties of thin film disk materials. In addition, polymer films can change the adhesion properties of the surface and interfere with the operation of the magnetic head. Highly resistive but electroactive overlayers could lead to galvanic attack of the substrate through holes in the thin film. Sputtered diamond-like carbon films [51,57–60] could fall into this category (see Fig. 1).

A protective layer plated or sputtered over an active metal may have pores and defects that will permit the corrosive medium to contact the active substrate metal and thereby promote galvanic corrosion. The holes or defects may be present on a heterogeneous surface in the geometry of either regular arrays or random arrays. The mathematical

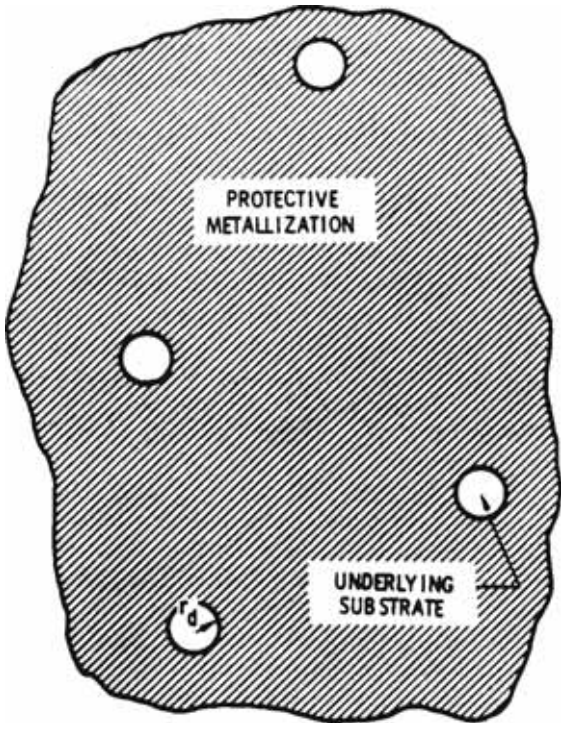

Fig. 2—Multilayer "sandwich" arrays may have underlayers exposed through holes or holidays in the overlayer, and galvanic interactions may enhance the corrosion rate in such systems.

modeling of galvanic behavior in plating corrosion systems has been discussed by Smyrl and Newman [21], where earlier work was also reviewed. They determined the current and potential distributions of galvanic corrosion system, which consisted of anodic disks in a cathodic plane as shown in Fig. 2. They solved the Laplace equation for potential with nonlinear (Butler-Volmer) boundary conditions with the use of finite difference method. The numerical modeling of galvanic corrosion in which the geometry consists of various array forms has been performed by Morris and Smyrl [61–63] in this laboratory. Either regular or random arrays of disks in the cathodic plane were used for the simulation of a heterogeneous surface. Most treatments of the regular array use the symmetry element derived from symmetrical geometry of the system. For mathematical simplicity, a particular hexagonal symmetry element can be approximated by a circular geometry, thus eliminating any angular dependence. For random arrays, the arrays simulated using a Voroni tessellation of the plane into random polygons as shown in Fig. 3 were used for the disk-cathodic plane geometry. The Voroni tessellation has proven to be useful for modelling the transport and mechanical properties of disordered or composite media. The geometrical properties of the Voroni tessellation and algorithms for generating the tessellation have been described by Winterfeld [64]. The model established by Morris and Smyrl included the Laplace equation for potential distribution with nonlinear boundary conditions, and it was solved by a finite element method. The potential distribution of the system was obtained from numerical simulation of a regular array of disks over a cathodic plane. The disks were of alternating sizes (disks with two different diameters) distributed on

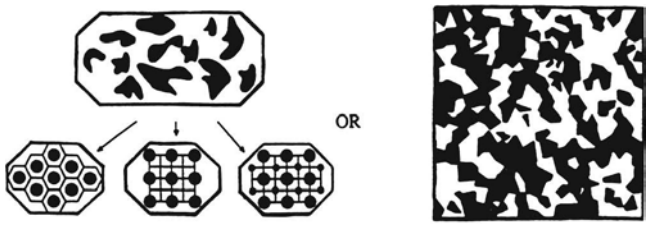

Fig. 3—Simulations of galvanic interactions in multilayer arrays have been carried out with regular patterns or with (more realistic) Voronoi tessellation representations.

the surrounding plane. The models for the tertiary current distribution, which includes both potential distribution and mass conservation with use of a geometry of the random array, are in progress in our laboratory.

Since the total anodic current must be equal to the total cathodic current, the area ratio between anodic and cathodic components of the total area is an important parameter in galvanic corrosion. If the currents to each area were uniform, the area ratio is the *only* parameter that would affect the galvanic interaction for a particular combination of metals. On the other hand, Smyrl and Newman [21] found that ohmic effects in the electrolyte may cause a nonuniform galvanic current distribution on the component areas, and this leads to the conclusion that under such conditions some parts of the cathodic area are not important in determining the total galvanic current. The effect is even more pronounced under circumstances where the electrolyte phase is very thin, that is, galvanic current from cathode to anode flows only near where they join, and more remote areas of each are relatively unaffected by the galvanic coupling. It has recently been found that the *active perimeter* measure of the interactions is more relevant than the area ratio, and the former may be used to correlate the behavior of several geometries [61–63]. The nonuniform current distribution is also obtained if the cathodic surrounding plane is highly resistive but electroactive. For example, resistive sputtered carbon films would cause the cathodic galvanic current to flow only to areas at the periphery of holes and defects [65], and the total area would not be important in determining the galvanic current. However, smaller holes would increase the galvanic current at a constant area ratio because the active perimeter would increase.

In summary, investigations in bulk solution provide a basis on which to begin to analyze atmospheric corrosion behavior. As the electrolyte phase decreases in thickness, ohmic and diffusion effects become more dominant and galvanic coupling is strongly affected. The more remote areas will show the behavior expected for uniform exposure to an aggressive environment. Effects of local composition and local physical geometry then will become more dominant. Behavior in the local areas would be expected to be very similar to the behavior in bulk electrolyte at the same composition conditions. Further general comparisons must be developed as further research is conducted.

COATINGS AND OVERLAYERS FOR CORROSION CONTROL

In the past 15 to 20 years, an explosion of interest in surface modification techniques has mostly involved the deposition

of thin films, the application of coatings, and the formation of surface alloys. The development of many of the techniques has been driven by the need for the semiconductor electronics industry to create improved processing procedures. As a spin off of the advancing technology, other fields, such as corrosion protection, have benefited from the new processes. A recent panel report [66] has summarized the general surface modification techniques that are used. The techniques are divided into three broad categories:

- Low-energy inorganic coating techniques. For the most part these are mature technologies that have been used for many years.
- Polymer coatings include traditional paints, thermoplastics, poly(vinyl chlorides), epoxies, urethanes, and poly (methylmethacrylate).
- Techniques involving the use of energetic ions. The techniques have developed rapidly in the last 10 to 15 years; several have neither reached maturity nor found use for corrosion protection. Only those designated as low cost and scalable for widespread use are viable for corrosion protection, except in critical applications. In addition, most techniques that require vacuum processing are too costly for most applications.

Inorganic sol-gel films are formed from a sol through continuous stages of increasing concentration of a solid precursor. Typically, the sol is a solution of polymeric species or a suspension of "oligomers" including particles in the colloidal size range. During deposition through states of increasing solids concentration, the sol might gel, but the gel state is often a fleeting transient that quickly empties of liquid. Nevertheless, the structures formed during this stage have varying amounts of porosity and influence the structure of the final film. This processing offers good control of composition and homogeneity at low temperatures. It is not directional nor equipment intensive. Complex shapes of arbitrary size can be coated with good uniformity. The cost of high-purity liquid precursors may be high, but for thin-film applications the materials cost would be acceptable.

Films deposited using energetic deposition techniques are dense, highly adherent, have few pinholes, and can be laid down at low temperatures. They are attractive for corrosion protection. Ion-beam-assisted deposition and ion implantation have the best adhesion properties, while RF sputtering has the best throwing power. Three important factors affecting the performance of films are porosity, adhesion, and stress. Although there are compressive stresses, in ion-implanted surfaces, for example, delamination by buckling is practically unknown. Effective porosity in the treated layer could exist due to shadowing of the surface from the beam by contaminating particles. The problem has not been observed, but the exact reason is not known. With the exception of ion implantation [67], only a few studies on corrosion have been done on films deposited using energetic deposition methods. Ion-beam-assisted deposition coatings are adherent and more ductile than bulk materials due to the microcrystalline or amorphous structures. The adhesion is better for the films deposited by energetic beam techniques as compared to films derived from physical vapor deposition. More details may be found in the cited report [66] or in the original literature.

Polymeric materials are widely used as protective coatings because they are transport barriers which limit access of reactive species (i.e., water, oxygen, ions) to the substrate surface. Leidheiser and Granata [68] have discussed the roles that each of these species may play in degradation processes on metal surfaces, and, in particular, the role of ion transport through bulk films and "ion channels" in films. Several techniques are discussed in this paper for characterizing ion transport: d-c measurements, electrochemical impedance analysis, under-the-coating sensing, and radio tracer measurements. Characteristic d-c resistances of 10^{11} ohm-cm^2 are observed for films without continuous aqueous pathways through the coating, as first described by Asbeck and Van Loo [69]. The resistance drops to the order of 10^8 ohm-cm^2 if continuous aqueous pathways exist where such pathways have high rates of transport. It is also clear that films and coatings are heterogeneous and the aqueous pathways are surrounded by regions of lower transport rates. The resistance of films may also decrease with time as the ion channels or pathways equilibrate with an external aqueous environment.

For films with high resistance and no ion channels, the impedance of the film is dominated by its geometric capacitance. For films of lower resistance, the low-frequency impedance is dominated by the sum of the resistance of the film and the resistance of the electrolyte. If corrosion proceeds under the coating because of ingress of the aqueous environment, the low-frequency impedance decreases in value. It has been argued that there is a strong correlation between the sites for corrosion under the film and the intersection of the ion channels with the underlying surface, but it has been difficult to confirm the correlation with direct observations.

The nature of the easy pathways for transport appears to be related to several factors. One of the factors is the presence of pigment and filler particles, which could facilitate the formation of aqueous pathways adjacent to the pigment or filler and would be influenced by the interaction of the particles with the polymer matrix [68]. The channels could also form by coalescence of voids or pores in the polymer matrix, and this would be influenced by the formation processes of the films. Aggregation of solvent in the film could be influenced by the prior history of the film, by the presence of impurities, and by retained solvent.

The presence of channels has been demonstrated to be a function of the glass transition temperature (T_g) of films as well. That is, below T_g, the polymer will be brittle unless a secondary, low-temperature relaxation exists, and this will favor the formation of microcracks and defects. Above T_g, the film will be more flexible and less susceptible to formation of fracture channels. Armstrong et al. [70] have investigated the influence of T_g on ion transport and permeability in chlorinated rubber films.

Pigment and filler particles can have a beneficial influence because of the reduced transport of water, oxygen, and ions. The effect will depend on the pigment volume fraction, the chemical composition, the geometry, and the dispersion as noted by Burns and Bradley [71]. Equilibrium water uptake may cause plasticization and subsequent depression of T_g, as well as swelling, which counteracts the effects of reduced transport rate caused by the solid particles [72]. Pigments that have oxidizing character can induce passivation of the underlying metal, as observed for chromate or vana-date additives [73]. Other pigments may inhibit the cathodic reaction and thus suppress corrosion as well [74].

De-adhesion of organic coatings is responsible for enhanced corrosion rates on one hand and is the result of corrosion on the other hand. Leidheiser [75] has discussed de-adhesion processes which include: loss of adhesion when wet, cathodic delamination, cathodic blistering, swelling of the polymer, gas blistering by corrosion, osmotic blistering, thermal cycling, and anodic undermining. With few exceptions, the loss of adhesion processes requires that reactive species such as water, oxygen, and ions penetrate through the coating. Bonds of the coating with the surface of a steel substrate may be attacked by high pH conditions, which are the result of corrosion reactions or imposed cathodic protection conditions. In either case, OH" ions are particularly aggressive and cause disbonding on steel. In a recent investigation by Stratman [76], disbonding was followed by monitoring the surface potential of a polymer-coated steel surface with a scanning Kelvin probe technique.

A recent international meeting [1] reviewed the unsolved problems of corrosion protection By organic coatings, described the current understanding of the technology, and outlined some focus for further progress. In addition to the principles of barrier layer transport that have been described above, there was discussion on the effects of (1) pre-treatment of surfaces, (2) the contribution made by surface inhomogeneities of the substrate, (3) the critical size of a water phase which may be responsible for corrosive attack, (4) stress in the film and stress in the substrate, and (5) incorporation of corrosion inhibitors in protective films. Funke [77] later summarized the continuing uncertainties that exist in studying corrosion protection properties of organic coatings. Some scatter of behavior is caused by the age and history of the coating—fresh coatings are more susceptible to swelling and changes in composition. Disbonding may initiate at defects, but it may also occur in the absence of holidays or defects. The water that is associated with disbonding could be transported along the surface and not by permeation through the film. Ions may also move along the interface. All these considerations have considerable implications for electrochemical characterization techniques. A review of various types of organic coatings and their applications in various service conditions is provided by Tator [78].

SUMMARY

The atmospheric corrosion of metals is one of the most important single problems facing corrosion science and technology. From small nanostructures to large buildings and bridges, coating techniques are being developed to moderate the rate of degradation with some success. The use of low-cost coatings continues to increase as the coatings are made more impermeable and more adherent to the protected substrate. Higher-cost films applied by high-energy methods are finding wider use in critical applications where conventional coatings are inadequate. In all systems where protection is necessary, the early detection of corrosion is desirable in order to plan replacement and maintenance measures and to avoid catastrophic failures. Detection of the presence of corrosion can be accomplished in two ways: detection of the agent that causes corrosion or detection of the results of the corrosion process either on the material of interest or on a specimen of the material. Sensors and monitors are receiving greater attention in accelerated life testing of materials, and eventually they will be developed more widely for operating systems or in portable monitoring systems. The savings to industry and the public at large would be in the billions of dollars if the onset of failure processes could be detected prior to their culmination in a catastrophic event [79].

Types of Metal Corrosion and Means of Corrosion Protective by Overlayers

Kenneth B. Tator[1] and Cynthia L. O'Malley[2]

INTRODUCTION

THIS CHAPTER WILL PROVIDE A GENERAL OVERview of the cause of metal corrosion, and its prevention by the use of protective coatings, or overlayers.

It must be understood, however, that a thorough discussion of corrosion and corrosion mechanisms can extend far beyond the summaries provided in this chapter. In fact, there are numerous books written solely on corrosion, manifestation of the different types of corrosions, and the reasons why such corrosion occurs.

Similarly, the use of protective overlayers over a metal to prevent corrosion is likewise a quite varied and extensive topic. The literal interpretation of the word "overlayers," as used herein, means anything applied, or overlaid on a metal to prevent, retard, or reduce corrosion. This would include monomolecular layers of gasses, oxides, or other materials that may slow or stop the corrosion process under very specific conditions. Moreover, it includes all of the possible metals and organics that can be applied to a surface. Some of the more common overlayers will be discussed herein.

Accordingly then, the discussion regarding metal corrosion consists of the following sections:

- Definitions
- Extractive metallurgy in reverse
- Electrochemical corrosion
- Forms of corrosion
- Uniform corrosion
- Galvanic corrosion
  - Sacrificial anode cathodic protection
  - Impressed current cathodic protection
- Crevice corrosion
- Pitting corrosion
  - Microbiologically influenced corrosion
- Intergranular corrosion
- Selective leaching
- Erosion corrosion
  - Cavitation
  - Fretting
- Stress corrosion
- Hydrogen damage

The sections on corrosion protective overlayers consist of:

- Conversion coatings
  - Phosphate
  - Chromate
  - Chromate free
- Hot dip galvanizing
  - Batch
  - Continuous
- Cementitious linings
- Glass and porcelain enamels
- Electroplating
- Thermal spray
- Rubber linings
- Paints, coatings, and linings

DEFINITION OF CORROSION

Corrosion, as defined by NACE, the Corrosion Society, is "the destruction of a substance 'usually a metal' or its properties because of a reaction with its environment." This definition does not make use of the terms chemical or electrochemical because such terms would define corrosion only as it relates to metals and would not allow its application to many other materials which disintegrate due to environmental exposure [1]. The American Society of Materials (ASM) defines corrosion as a "chemical or electrochemical reaction between a material and its environment that provides a deterioration (change) of the material and its properties" [2]. ASTM defines corrosion with the same definition. Skorchelletti (translated from Russian) [3] states "the spontaneous oxidation of metals, which is detrimental in industrial practice (reducing the service life of articles) is termed "corrosion" (from the Latin "corrodere," which means to eat away.

If we consider corrosion as a deterioration of a material under the influence of an environment, the discussion of corrosion mechanisms and the effects of such deterioration are many and varied. If, however, the definition is restricted to corrosion of metals, the subject becomes more manageable and limited in scope. The mechanisms of metallic corrosion are relatively well understood.

The fundamentals of corrosion, as they relate to metallic corrosion, can be summarized in the following sections.

EXTRACTIVE METALLURGY IN REVERSE

Extractive metallurgy consist of mining metallic bearing ores from the earth, such as "iron" ore, "bauxite" (aluminum ore), and the ores of other metals, such as nickel, tin, copper, etc. These ores consist of the metal in combination with oxygen and other elements. They are relatively stable

TABLE 1—Metals in order of energy required for conversion from their ores. (Courtesy of NACE Publication.)

Common Metals	Energy Required for Conversion
Potassium	Most
Magnesium	
Beryllium	
Aluminum	
Zinc	
Chromium	
Iron	
Nickel	
Tin	
Copper	
Silver	
Platinum	
Gold	Least

[SOURCE: Corrosion Basics—An Introduction, LaQue, F. L, Chapter 2, Basics of Corrosion, NACE, Houston, TX, p. 23, 1984.]

and nonreactive in the ground, as the metal in the ore has already oxidized and reacted during the passage of time until no further reactions occur. After mining, and during refining purification, large amounts of energy, usually in the form of chemical dissolution, electrolytic separation, and smelting heat, are used to convert the ore into its pure, or alloyed metal. The energy used during the conversion process is indicative of the reactivity of the metal in the environment. The more energy used to extract the metal from its ore, the greater the propensity of the purified metal to react with the environment and return to its former oxidized ore-like state.

Some metals exist in nature in a relatively pure metallic form and need little if any energy to extract them from nature. Gold, for example, in nature is found in pure nugget form, and after shaping (into jewelry, a tooth filling, or other product), it can be placed into a variety of aggressive environments and show little, if any, corrosion or oxidation. Similarly, platinum, silver, and copper are relatively pure metals that require little refining energy compared to other metals such as iron or steel. Table 1 entitled "Metals in Order of Energy Required for Conversion from Their Ores" [4], illustrates the amount of energy required for conversion of the ore to the pure metal.

If the refining of metal from a metallic ore requires the input of energy, metallic corrosion can be described as the reverse of that process—the metal's release of energy as it naturally oxidizes and reverts to its ore-like status. Using iron as an example, the process can be illustrated, as in Fig. 1.

However, the corrosion of some metals is not necessarily bad. In fact some oxidation reactions are beneficial to a metal. For example, aluminum will quickly oxidize (corrode) forming a layer of aluminum oxide (Al_2O_3) on the aluminum surface. The aluminum oxide that is formed is a thin, impervious, tightly adherent layer that seals and protects the underlying aluminum from further oxidation and environmental reaction. Only if the oxide layer is broken down in aggressive environments will further reaction of the aluminum occur. Anodizing (the imposition of an electrical current on aluminum or other light metals in a bath to form an oxide layer) is used to provide a thicker, more

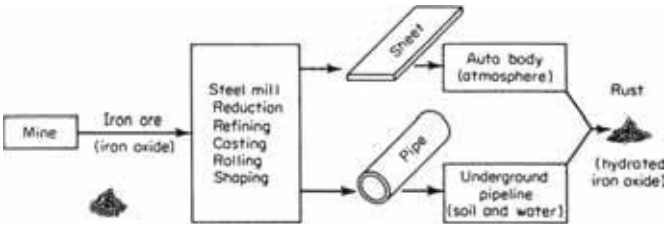

Fig. 1—Metallurgy in reverse. (Courtesy of McGraw-Hill.)

protective oxide layer coating on the metal surface than that which results from atmospheric oxidation.

Copper is another example of a metal that forms a protective oxide layer—in this case, the oxide is a characteristic color that forms as the copper oxidizes by weathering to form a patina. The main constituent of patina is a mixture of basic copper carbonates, sulfates, and chlorides. In rural areas, or areas where there are no chemical contaminates, the patina is predominately basic copper carbonate (green). In industrial areas basic copper sulfate (blue) predominates. In coastal areas where chlorides are present, copper chlorides (brownish-yellow) prevail. Patina color variations from greenish to blue-gray occur, depending on differences in chemical composition. Regardless of color, the patina-oxide surface layer slows or prevents further reaction of the copper metal.

Alloying constituents of stainless steel also enable the formation of a tightly adherent oxide layer that protects the underlying steel from further corrosion. The numerous varieties of stainless steel that exist are due to the variations of metal alloy constituents (carbon, manganese, copper, chromium, nickel, and others) that comprise the oxide layer, and composition of the alloy steel. Conversely, the oxidation of carbon steel, the common low-alloy steel most common for use in structural steel, automobiles, pipelines, and for most industrial and commercial applications, forms a brown or black oxide (rust) that is porous and nonadherent. The rust layer from carbon steel is not protective, and does not prevent further corrosion of the underlying ferrous metal as a result of atmospheric exposure. Progressive oxidative deterioration occurs in a weathering or chemical environment resulting in pitting, general corrosion, and deterioration of the steel substrate.

ELECTROCHEMICAL CORROSION

Electrochemistry involves an electric current in conjunction with a chemical reaction. Electrochemical corrosion will occur when four required elements are present: (1) anode, (2) cathode, (3) metallic pathway connecting the anode and cathode, and (4) electrolyte. Most metals already have three of the four required elements: anode, cathode, and metallic pathway. The anode and cathode form from the metal and this process is discussed subsequently. The metallic pathway is present in all metals as they are ready conductors of electrons. Only the electrolyte is missing. Once an electrolyte is present, corrosion will proceed. An electrolyte is a liquid that contains ions or "charged particles." Most electrolytes consist of water containing dissolved inorganic salts. Inorganic salts, in water solution dissociate into their respective ions (for example sodium chloride dissociates into sodium cations and chloride anions). These electrically charged species provide an excellent pathway for

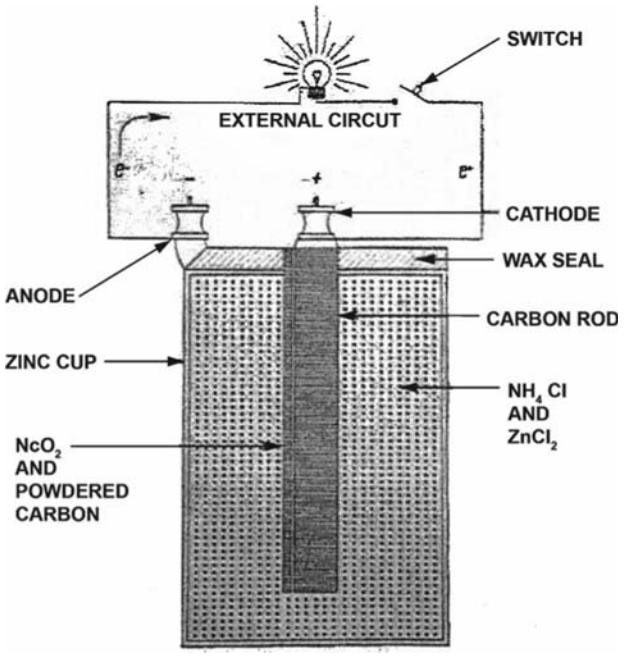

Fig. 2—Dry cell battery. (Courtesy of KTA-Tator, Inc.)

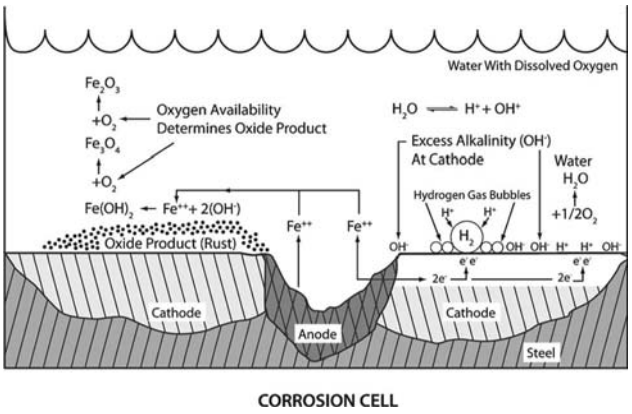
the transmission of electric currents generated during the corrosion process. Almost all water, including that in the oceans, rivers, and lakes contains dissolved mineral salts which dissociate. Rainwater, while relatively pure, forms around a small dust mote, or other particulate matter, and leaches ionic material from that particle. Furthermore, freshly condensed rainwater, which initially is "pure" water, will react with carbon dioxide from the air to form weak carbonic acid [5]. This weak acid dissociates into the hydrogen ion (H^+) and carbonate (CO_3^{-2}) ions. Pollutants in the air such as nitrogen and sulfur oxides will absorb in water, and will result in further electrolytic dissociation. Thus, when a metal is wet with water, or most chemicals, it is virtually always wetted with an electrolyte.

A common dry cell battery shown in Fig. 2 provides a good illustration of how the four elements of a corrosion cell work together to produce a beneficial form of corrosion to generate an electric current and provide power [6]. The battery is essentially a corrosion cell. The anode, and its counterpart, the cathode, are the positive and negative terminals of the battery, respectively. During the electrochemical reaction process, electrical current (or electrons) flows from the anode to the cathode via the metallic pathway or connection (see external circuit). The electrolyte carries ions from the cathode to the anode to complete the electrical circuit. The anode (negative terminal) decays during this process and generates the electron flow, while the cathode (positive terminal) remains intact and is not deteriorated. The only difference between a corrosion cell and a manufactured dry cell battery is that the battery reaction process is designed to produce an electrical current for a productive use. When the anode is depleted in a manufactured battery, the reaction will stop and the battery will "die" since it cannot produce more energy. The battery is replaced with a new one, and electric current is again generated.

In a corrosion cell, the anode is often a material that cannot be replaced readily. Corrosion of an automobile



CORROSION CELL

Fig. 3—Corrosion cell. (Courtesy of KTA-Tator, Inc.)

means deterioration of the metal body of the vehicle; structural steel rusting is deterioration of the structural member; tanks, pipelines, ships, offshore platforms, building steel and other structures that corrode cannot be as easily replaced as a dry cell battery!

An illustration of a corrosion cell is shown above in Fig. 3 [7].

The corrosion cell also consists of anode and cathode coupled by a metallic pathway in an electrolyte. During the corrosion process, the anode deteriorates by going into ionic solution.

The anodic reaction, in every case consists of the metal going into ionic solution as follows: $M \rightarrow M^+ + e^-$ where M is a metal, M^+ is the metal in ionic form, and e is the number of electrons liberated by the metal going into ionic solution. For example, the ionic reaction for steel is $Fe \rightarrow Fe^{+2} + 2e^-$ and that for aluminum is $Al \rightarrow Al^{+3} + 3e^-$.

The cathodic reaction, however, consists essentially of the neutralization of the electrons that are created as the metal goes into ionic solution. These electrons can be neutralized through one of three reactions, depending upon the cathodic environment:

Alkaline, neutral, and near-neutral chemical environments: $2H_2O + O_2 + 4e^- \rightarrow 4OH^-$

Acidic, with oxygen: $H^+ + e^- \rightarrow H$, then $2H + \frac{1}{2}O_2 \rightarrow H_2O$

Highly acidic: $2H^+ + 2e^- \rightarrow H_2$

The electron movement in a corrosion cell (the chemical concept) is defined as moving from the anode through the metallic pathway to the cathode. At the cathode, electrons are neutralized by chemicals in the electrolyte. Conversely, current flow, used in the electrical industry and for cathodic protection (the electrical concept) is opposite, and by definition, electrons comprising the electric current flow from the anode through the electrolyte to the cathode.

Fig. 4 "Chemical Concept of Electron Flow" and Fig. 5 "Electrical Concept of Current Flow" [8] illustrate the differences between the electron and current flow in the chemical and electrical concepts.

While the illustrations of the dry cell battery (electrical concept) and corrosion cell (chemical concept), as shown above, depict the anode and cathode as separate entities, in practice, anodes and cathodes are not isolated entities. For example, all metals consist of crystals, or "grains" that precipitate when molten metal is cooled from a hot melt. Grain boundaries form between grains, and are anodic

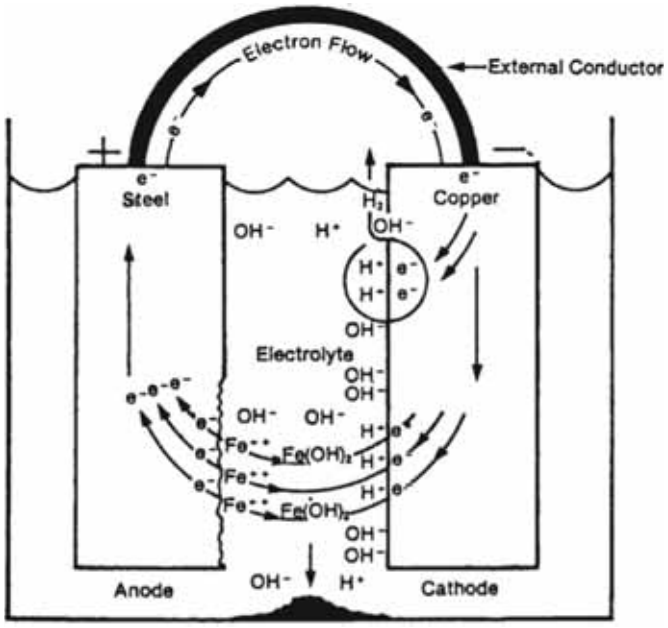


Fig. 4—Chemical concept of electron flow. (Courtesy of NACE International.)

relative to the cathodic grain. Areas of stress concentration, in a formed metal, are anodic to unstressed areas. Where temperature differentials exist, hot areas are anodic relative to cool areas. A scratch, nick, or abraded area on a metal, or mechanically worked area is anodic to adjacent unscratched or unworked areas. Oxygen concentration differences can also result in the formation of anodes and cathodes (the lesser oxygen concentration generally becomes anodic, relative to an adjacent area of greater oxygen concentration). An example of this is corrosion at the waterline of a steel piling or on the wall of a dam gate. Corrosion within a crevice occurs as an anode develops within the sheltered area within the crevice relative to the more exposed areas, which become cathodic.

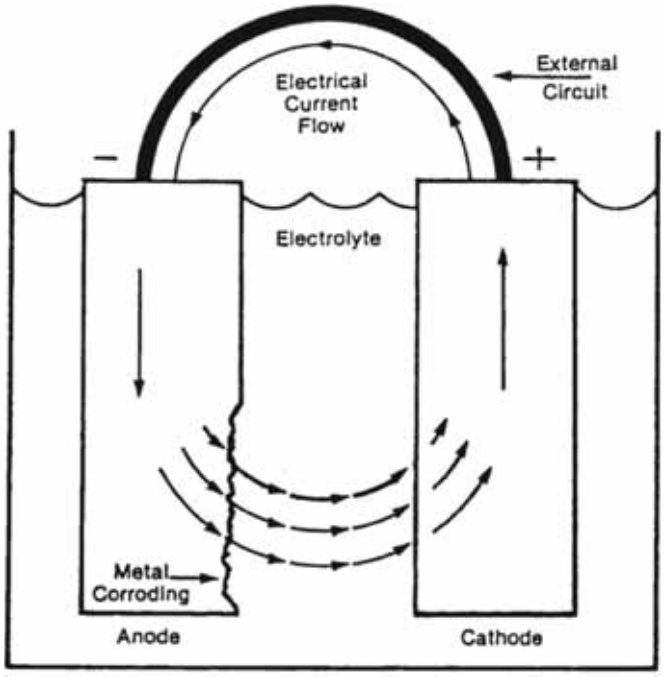

Fig. 5—Chemical concept of electron flow. (Courtesy of NACE International.)

Accordingly, to a greater or lesser extent, all metals will develop anodic and cathodic areas, and will have a comparative potential to corrode. Moreover, as corrosion proceeds and pits and crevices develop in a metal substrate, the anodic and cathodic areas may switch, and the anodes will become cathodes, and vice versa.

A metal in contact with another metal may also become an anode with the other metal becoming the cathode. The tendency of a metal to become an anode or cathode in combination with other metals in a given immersion environment is its corrosion potential. The comparative corrosion potential of a series of metals can be tabulated as the electromotive force (EMF) series. EMF corrosion potentials will vary from environment to environment, and the standard EMF series is that for sea water. Hydrogen is used as an arbitrary reference element, with elements above hydrogen more reactive, while those listed below hydrogen are increasing, inert with a lesser tendency to ionize or go into ionic solution. The EMF series for metals and solutions of their own salts is presented in Table 2 [9], while the EMF series in sea water is shown in Table 3 [10]. If two metals in the galvanic series are coupled, the greater the potential difference between the two metals, the greater the driving force for the more negative metal (anode) to corrode. Note the similarities between the EMF and galvanic series tables with that of the order of metals in order of energy required for conversion from their ores (see Table 1).

Thus, all metals, when wetted, either by immersion, precipitation, condensation, or even high relative humidity (generally 50 % RH or more) have an inherent ability to corrode, as the anode, cathode, metallic pathway, and electrolyte are all present.

Although, not a prerequisite for the initiation and early commencement of corrosion, oxygen is critical, as without it, the corrosion reaction will slow or stop. Oxygen is a depolarizer in that it removes hydrogen from the cathode and allows additional electrons to be neutralized, enabling the process to proceed. If oxygen is not present, the hydrogen accumulation at the cathode may result in a hydrogen surface film, essentially isolating the electrons migrating to the cathode from the electrolyte and slowing or stopping their electron neutralization process.

FORMS OF CORROSION

The appearance or a manifestation of corrosion has been categorized in various schemes by a number of authors. Categorization by environmental condition (immersion, atmospheric, hot, wet, dry, etc.) is one means of grouping corrosion. Covino and Cramer [11] sub-categorize "forms of corrosion" into six subsections. Four of those forms, "uniform corrosion," "localized corrosion," "metallurgically influenced corrosion," and "microbiologically influenced corrosion" fit under the classification of corrosion that is not influenced by any outside process. The remaining two, "mechanically assisted degradation" and "environmentally induced cracking" address corrosion as influenced by another process (Table 4).

Fontana [12] describes eight forms of corrosion that can be identified by visual observation, in most cases with

the naked eye, but sometimes magnification is necessary. The listing is arbitrary, and the eight forms are more or less interrelated, but they cover practically all corrosion failures and problems. The eight forms of corrosion are described in summary below, with some modifications by the writers.

The eight forms are:

1. Uniform corrosion;
2. Galvanic corrosion;
3. Crevice corrosion;
4. Pitting;
5. Intergranular corrosion;
6. Selective leaching;
7. Erosion corrosion;
8. Stress corrosion.

Hydrogen damage—Fontana discusses this last form but does not consider it a corrosion phenomena. Fig. 6 depicts each of the corrosion forms itemized above.

UNIFORM CORROSION

Uniform corrosion is the most common form of corrosion and it is characterized by a chemical or electrochemical reaction that proceeds relatively uniformly over a large area. The metal is relatively uniformly attacked, and the rateofdeterioration of relatively uniform over all areas where corrosion occurs.

TABLE 4—Forms of corrosion—adapted from Covino and Cramer
1. Uniform Corrosion
a. Aqueous corrosion
b. Atmospheric corrosion
c. Galvanic corrosion
2. Localized Corrosion
a. Pitting corrosion
b. Crevice corrosion
c. Filiform corrosion
3. Metallurgically Influenced Corrosion
a. Stainless steels
i. Austenitic
ii. Ferritic
iii. Duplex
iv. High Performance
b. Nickel Alloys
c. Aluminum (1xxx through 7xxx series alloys)
d. Weldment Corrosion
i. Steel
ii. Stainless steel
iii. Non-ferrous alloys
4. Mechanically Assisted Degradation
a. Erosion
b. Fretting corrosion
c. Fretting fatigue
d. Cavitation erosion
e. Corrosion fatigue
5. Environmentally Induced Cracking
a. Stress corrosion cracking
b. Hydrogen damage
c. Liquid metal embrittlement
d. Solid metal embrittlement
6. Microbiologically Influenced Corrosion

GALVANIC CORROSION

This type of corrosion occurs when two metals are in contact, and there is a potential difference between the metals when they are immersed or in a wet environment. The less resistant metal becomes anodic and the more resistant metal becomes cathodic (see Table 3). The anodic metal goes into ionic solution as previously described.

In a service environment where two metals are in contact in a corrosive environment, galvanic corrosion can be readily detected, as one of the metals (the anode) will be aggressively attacked, with the most extensive deterioration closest to the other metal (the cathode). If possible, it is best to avoid dissimilar metal contact in immersion or wet environments unless the consequences of galvanic corrosion are known and anticipated. However, there are many instances of inadvertent contact between dissimilar metals in tanks, pipelines, heat exchangers, and other fabricated items. To prevent unwanted corrosion, sometimes the dissimilar metals are both painted in an attempt to stop galvanic attack. However, this usually makes the situation even worse, because if any defect develops in the coating, the galvanic attack will be concentrated at the small defect in the coating on the anodic metal. This may lead to rapid

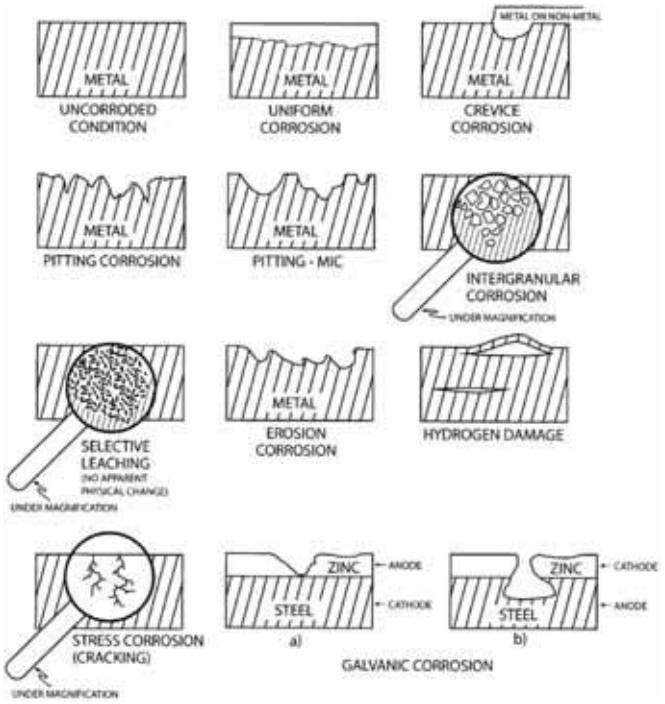

Fig. 6—Depiction of forms of corrosion.

pitting and perforation. Painting, however, may work if only the cathode, or more resistant metal, is painted. This reduces the cathodic area and with a small defect in the coating on the cathode the corrosion current will be distributed over the much larger unpainted anode. Accordingly, pitting does not occur due to the small cathode/large anode relationship.

Cathodic protection is the beneficial use of galvanic corrosion. There are two types of cathodic protection: (1) use of the sacrificial anode and (2) use of impressed current.

Both types of cathodic protection utilize an anode that is designed to deteriorate and protect the cathode, which is, by design, the metal that is to be protected.

Cathodic Protection by Sacrificial Anode

Zinc, in the form of a zinc-rich coating, or as a galvanize layer on steel, corrodes preferentially as the anode, and protects the steel, which becomes the cathode in the galvanic couple. The steel is usually a pipeline, tank, ship hull, or another steel item in immersion or in the soil. For pipelines, tank interiors, and ship hull exteriors, zinc, magnesium, or aluminum alloy anodes in the form of blocks or ribbons of metal, are attached or connected to the steel to be protected.

Irrespective of whether the anode is a piece of metal or a coating, when it becomes exhausted due to sacrificial galvanic protection, it is replaced by either a new metal anode or a new sacrificial coating system. The costs of replacement of the sacrificial anode are designed to be substantially less than the cost of replacement of the structure being protected. Fig. 7 [13] illustrates a pipeline being protected by a sacrificial anode system.

Impressed Current Cathodic Protection

In this means of corrosion protection, the normal corrosion current is reversed beneficially to make the structure being protected the cathode and the anode an inert material.

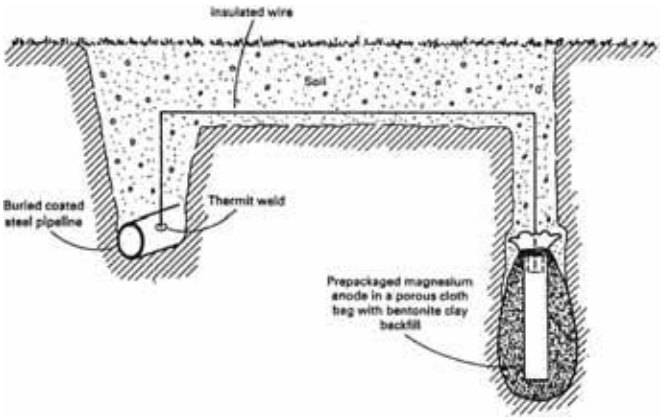

Fig. 7—Cathodic protection of a buried pipeline using anodes. (Courtesy of ASM International.)

Usually, an ordinary AC current is rectified to direct current (DC) with the negative terminal of the DC supply connected to the structure being protected, and positive terminal to the inert anode. The choice of the inert anode depends upon the service environment and the associated current demand for protection. Commonly used inert anodes consist of high silicon cast iron, graphite, conductive polymers, lead alloys, precious metals (platinized titanium or tantalum), and mixed metal oxides, or ceramic oxides. Fig. 8 [14] depicts a pipeline being protected by an impressed current cathodic protection system.

Cathodic protection, using either a sacrificial anode or impressed current, is almost always done in conjunction with coating the object being protected. If the object being protected is uncoated, the current demand required to protect the entire surface would be quite high, and accordingly, the rate of consumption of the sacrificial anode, or the power demand for the impressed current protection system, would be quite high also. However, if the structure being protected is coated with an appropriate coating system, cathodic protection would be needed only at defects in the coating system, such as pinholes, scratches, impact, and other mechanical damage, and, as such defects usually make up only a very small percentage (generally much less than 1 %) of a coated structure's surface, the current demand and the anode consumption is proportionally reduced.

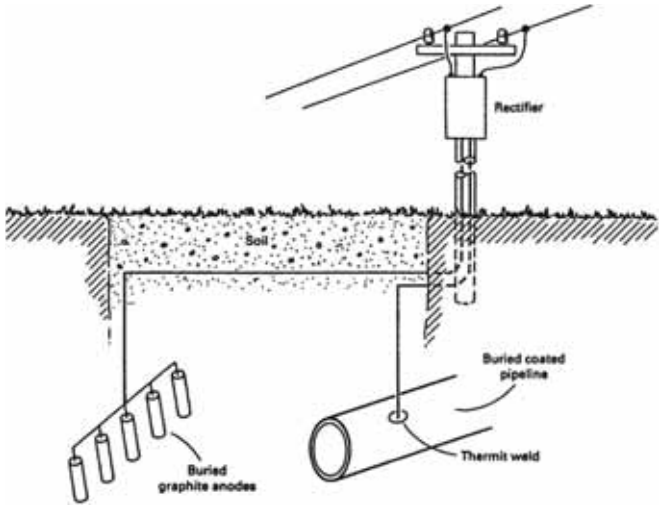

Fig. 8—Cathodic protection of a pipeline using impressed current. (Courtesy of ASM International.)

CREVICE CORROSION

Intensive, localized pitting can occur within crevices or other areas shielded by corrosion products, dirt, or other materials that enable the creation of a stagnant condition beneath the shield. This often occurs between metals and nonmetallic surfaces in contact. As with most forms of corrosion, the environment must be wet or highly humid, resulting in wetness. In general, the tighter the crevice, the more severe the crevice attack. Crevice attack exists principally on passive metals (stainless steel, nickel, titanium, and aluminum-based alloys). This is because there is a need for a large cathode (the passive surface of the metal) to support the high rate of anodic pitting activity within the shielded area.

Initially, crevice corrosion initiates as general corrosion over all surfaces of the metal. The corrosion reaction consists of oxidative dissolution of the metal, and reduction of oxygen to hydroxide ions as shown below:

$$\text{Oxidation:} \quad M \rightarrow M^{+} + e^{-}$$

$$\text{Reduction:} \quad O_2 + 2H_2O + 4e^{-} \rightarrow 4OH^{-}$$

After a short time, the oxygen within the crevice is depleted, and oxygen reduction ceases. However, the metallic oxidation process continues, building up an excess of positively charged metal cations. As these cations cannot be neutralized by oxygen reduction, they draw anions, often chlorides, a ubiquitous highly mobile anion, into the crevice. Chlorides are particularly aggressive compared to most other anions in breaking down protective oxide passivation and accelerating corrosion. This results in increased concentrations of metal chloride within the crevice. The metal chlorides hydrolyze in water, precipitating a metal hydroxide and forming hydrochloric acid, as shown below:

$$M^{+} + Cl + H_2O \rightarrow MOH + HCl$$

The metal hydroxide precipitation drives the metallic oxidation reaction, resulting in a rapidly accelerating, or autocatalytic corrosion process.

Filiform corrosion (a special type of crevice corrosion occurring beneath protective coatings or films) and pitting corrosion of metals are related phenomena.

PITTING CORROSION

Pitting is an aggressive, insidious, destructive form of corrosion that results in holes, or pits in a metal that is otherwise unattacked, or has only general corrosion. Pits are generally small in diameter, with a depth generally exceeding the pit diameter, but in some cases (notably microbiologically induced corrosion) the pits may be broad and bowl shaped in appearance. Pits generally grow downward in the direction of gravity. Pitting on vertical surfaces is less common, and on overhead surfaces (where the growth would be upward), is rare.

Pitting may occur within weeks, or may take years to form. Pits are hard to detect and measure because they are often hidden by general corrosion, and are filled with

corrosion product. The most common form of pitting failure is perforation. Structural strength of the member (plate, tube, pipe, etc.) is otherwise unaffected, except that the pitted item has a small hole in its cross-section.

The mechanism of pit growth is essentially identical to that for crevice corrosion—the pit bottom is anodic, and rapid metal dissolution into ions occurs there, while the sides of the pit are cathodic where oxygen reduction takes place. As metal ions build up in the bottom of the pit, the excess of positively charged ions attract chloride ions and form metal chlorides. The metal chlorides hydrolyze and precipitate, as illustrated previously under for crevice corrosion, driving more metallic dissolution, and accelerating pit growth. Most pitting is associated with chlorides, bromides and hypochlorites. The best means of preventing pitting are to use a metal alloy resistant to pitting in the environment of service, or to isolate the metal from the environment by a resistant overlayer.

Microbiologically Influenced Corrosion

Bacterial induced corrosion can cause pitting in immersion conditions. Sulfate reducing and oxidizing bacteria are responsible for corrosion in sewage piping, and many petrochemical environments (in tanks, and downhole) where sulfur compounds are present. Sulfates are ubiquitous in the environment, as sulfur comprises 0.06 % of the earth's crust. Sulfur is important in the building of plant and animal tissues. It is found in combination with many other elements, and is a constituent of coal and petroleum, and the cause of acid rain. Sulfates are found in most soils and waters.

Anaerobic (oxygen deficient) sulfur reducing bacteria *Desulfovibrio desulfuricans* reduce sulfate to sulfide as follows:

$$SO_4^{-2} + 4H^2 \rightarrow S^{-2} + 4H_2O$$

For steel, the corrosion product is iron sulfide, which precipitates when ferrous (steel) ions and sulfide ions react. The FeS precipitate film forms on exposed steel, and where continuous, is protective. However, FeS is cathodic to steel, and where the film is broken, aggressive galvanic corrosion may occur, resulting in pitting.

Conversely, aerobic (oxygen present) bacteria *Thiobacillus thioxidans* can oxidize elemental sulfur or sulfur containing compounds to sulfuric acid, as follows:

$$2S + 3O_2 + 2H_2O \rightarrow 2H_2SO_4$$

The sulfuric acid so formed will aggressively attack metals and concrete. The cycle of anaerobic sulfate reduction to sulfides, and sulfide oxidation to sulfuric acid is a major problem in the corrosive deterioration of concrete sewage piping, and buried steel piping. Metallic attack by this process will result in somewhat distinctive bowl shaped pits. There are other oxidizing and reducing families of bacteria, but those cited above are perhaps the best known and most prolific. Other metals pitted by bacterial action can include aluminum, stainless steels, and copper.

INTERGRANULAR CORROSION

As previously mentioned, grain boundaries are anodic with respect to the grain. As a rule, this is not a problem, as the grain boundary is only slightly more anodic than the grain matrix. However, under certain conditions, such as in highly acidic environments, the interface between the grains becomes very reactive, and aggressive intergranular corrosion results. With most forms of intergranular corrosion, only the grain boundary deteriorates, and there is little, if any, corrosion to the grain matrix.

Intergranular corrosion can be caused by impurities at a grain boundary, enrichment of one of the alloy elements, or depletion of one of these elements in the grain-boundary area. Depletion of chromium in the grain-boundary regions of stainless steels results in intergranular corrosion. Austenitic (18-8) stainless steels are particularly susceptible, particularly when heated within a temperature range of 950 to 1,450°F. Chromium carbide precipitates from the solid solution, depleting a zone near the grain boundary. This leads to corrosion because the chromium-depleted zone does not have sufficient resistance in a given corrosive environment. The appearance of intergranular corrosion results in a "sugary," granular appearance due to attack of the grain boundaries, leaving small, protruding "grains" (appearing like sugar granules) of metal. Intergranular corrosion sometimes occurs when austenitic stainless steels are welded and not annealed by water quenching after heating. Annealing, a rapid cooling by quenching, does not give sufficient time for chromium carbide precipitation.

SELECTIVE LEACHING

Selective leaching is the removal of one element from a metal alloy. The removal of zinc from brass alloys, or the removal of iron or steel from a cast iron alloy, are perhaps the two most common examples of selective leaching. The mechanism of dezincification of brass alloys is that initially, the brass dissolves in the corrosive environment; the zinc ions stay in solution; and the copper from the brass (approximately 30 % zinc and 70 % copper) plates back onto the brass, resulting in a copper-rich, zinc-deficient plug or layer.

Dezincification of brass is usually prevented by using a less susceptible brass alloy (for example, 15 % zinc, 85 % copper) or adding small amounts of arsenic, antimony, or phosphorus as dezincification inhibitors.

Graphitization of gray cast iron occurs because the iron is anodic to graphite and dissolves, leaving a porous mass consisting of graphite (a form of carbon) with little or no iron. There is no dimensional change to the cast iron, and graphitization is visually hard to detect, even though the metal has lost its ductile strength and becomes very brittle because the structure (often a pipe) looks the same as it did before graphitization occurred.

Many old, buried sewer and water pipes are made from gray cast iron, which after graphitization, crack due to soil settlement, movement of heavy equipment over them, excavation, or impact.

Graphitization may be prevented by using ductile (nodular) cast iron, because the graphite agglomerates in nodes and a graphite network is not present in the malleable cast iron to hold the residue together in the original form after loss of iron from the alloy.

EROSION-CORROSION

Erosion-corrosion is the acceleration or increase in the rate of deterioration by the relative movement between a corrosive fluid and a metal surface.

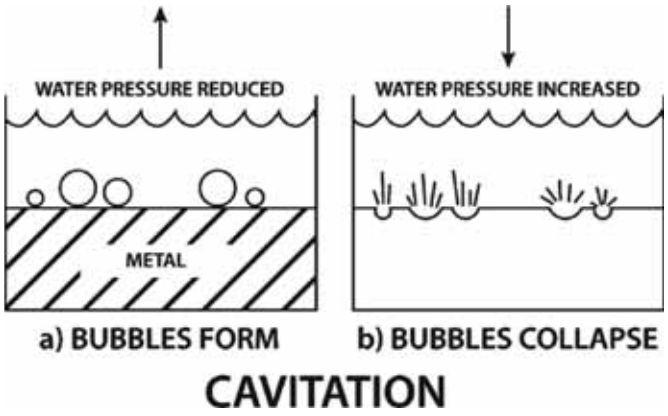

Fig. 9—Depiction of cavitation. (Courtesy of KTA.)

The appearance of erosion-corrosion is distinctive as grooves, gulleys, waves, and rounded holes and valleys appear on the surface in a directional pattern. An Illustration is shown above.

Velocity, either of the metal through the corrosive fluid or the corrosive fluid over the metal, increases the rate of attack, as a general rule. However, in some cases, increased velocity will reduce corrosion if it prevents deposition of materials that may cause crevice corrosion, or exposes the metal to inhibitors (chromates and sodium nitrite) in the fluid. Many stainless steels have a tendency to pit and suffer crevice corrosion in relatively stagnant water, but with movement or increased fluid velocity, that same metal can be used successfully because the motion prevents formation of deposits on the surface that could cause the initiation of pits and crevice corrosion. Metals that form a passive layer on their surfaces, such as stainless steels, aluminum, lead, copper, and brass, are susceptible to erosion-corrosion, because the eroding fluid may wear away the passive layer, exposing the metal to the corrosive immersion environment.

Erosion-corrosion can be prevented or minimized by the choice of more resistant materials; design to slow flow or turbulence; removal of entrained solids; the addition of inhibitors; and the use of coatings, including hard, abrasion resistant metallic coatings or soft, energy absorbing rubberlike coatings to isolate the metal from the environment.

Cavitation is a special form of erosion-corrosion caused by the formation and collapse of vapor bubbles in the liquid adjacent to the metal surface. If pressure on water is reduced sufficiently, it will boil at room temperature. Similarly, any dissolved air or other gases, will form bubbles at reduced pressure. When these bubbles are formed on or adjacent to a metal surface, and then subjected to rapidly increasing pressure, the bubble will collapse and cause an explosive shock to the surface. The surface shock causes a localized deformation and pitting, resulting in removal of the surface metal and a general roughening of the surface. Cavitation produces rounded microcraters on the metal surface. Sharp pressure pulses caused by collapsing bubbles are highly localized and can remove weak or soft portions of microstructural phases of an alloy. Fig. 9, depicts cavitation corrosion.

Examples of cavitation can occur when pumping water with a piston. When a cylinder is full of water and the piston is raised away from the water, pressure is reduced and the water vaporizes, forming bubbles. If the piston is again pushed toward the water, pressure is increased and the bubbles condense or collapse. In a similar fashion, the turning of a pump impeller through a liquid draws the liquid into the flowstream, reducing its pressure. As the impellor pushes the liquid downstream, pressure on the liquid is increased at the impellor surface, collapsing any bubbles that may have formed. A ship's propeller, pushing the ship through the ocean, is subject to cavitation for the same reason. Calculations have shown that rapidly collapsing vapor bubbles produce shock waves with pressures as high as 60,000 pounds per square inch [15].

Fretting corrosion is related to erosion-corrosion and occurs at contact areas between materials under load subject to vibration and slip. Fretting corrosion appears as pits or grooves in the metal surrounded by corrosion products. Fretting occurs in the atmosphere rather than under aqueous conditions.

STRESS CORROSION

Stress corrosion results in cracking caused by the simultaneous presence of tensile stress and a specific corrosive medium. Stress corrosion cracking (SCC) is particularly insidious, as it is not predictable in many cases, and may result in a catastrophic loss of metal strength. The metal surface is generally unattacked, but fine cracks progress through it as a result of the SCC. For SCC to occur, the metal must be stressed and be in a corrosive environment. Metallic stress alone may result in creep, metal fatigue, and ultimately tensile failure; and a corrosive environment alone will cause deterioration of a metal, the simultaneous presence of both stress and a corrosive environment will sometimes produce disastrous SCC.

Both intergranular (between grains) and transgranular (through grains) occur with SCC. Cracking generally proceeds perpendicular to the applied stress. Increasing the stress decreases the time before cracking occurs. As is the case with most chemical reactions, SCC is accelerated by increasing temperature.

Most metal alloys are subject to SSC in specific environments. Carbon steel, high-strength steels, austenitic stainless steels, high nickel alloys, aluminum, titanium, magnesium, and zirconium will all crack under stress in certain specific environments.

Environments that cause SCC are usually aqueous, and an environment that causes SCC in one alloy may not cause SCC in other alloys. Changing the temperature, degree of aeration, and/or the concentration of ionic species within the corrosion solution may change an innocuous environment into one that causes aggressive SCC failure. Also, an alloy that is immune in one heat treatment may be susceptible in another. As a consequence, the listing of all possible alloy environment combinations that may cause SCC is virtually infinite.

SCC can initiate and propagate with little evidence of corrosion until catastrophic failure occurs. Cracks frequently initiate at surface flaws or defects in the metal as a result of rolling processes, corrosion, or wear. The cracks, under stress, grow with little evidence, even in metals that are normally quite ductile. Often, microscopic examination is necessary to verify the presence of SCC.

Corrosion fatigue is a related form of SCC and is the tendency of a metal to fracture under repeated cyclic stressing.

Because SCC is hard to predict, it is also difficult to anticipate means for prevention. However, some generalized methods for reducing SCC are reducing the stress of the metal (perhaps by stress-relief annealing); changing the metal alloy to one more resistant in a given environment; the use of coatings (to isolate the metal from the corrosive environment); work hardening by shot-peening to produce residual compressive stresses on the metal surface; the use of inhibitors such as phosphates in water solution; application of cathodic protection, where it is positively known that SCC is the cause of failure.

HYDROGEN DAMAGE

The penetration of nascent hydrogen (atomic hydrogen) into a metal structure may cause blistering and embrittlement of that metal. Hydrogen penetration may be accelerated by cathodic protection using either impressed cathodic currents or sacrificial anodes. Acid pickling or corrosion in environments containing hydrogen and sulfide, typically that in vessels handling sour [hydrogen-sulfide containing hydrocarbons], may also increase the incidence of hydrogen damage to steel.

Atomic hydrogen (H), because of its extremely small atomic size, is capable of diffusing through steel and other metals. The reduction of hydrogen ions involves the production of hydrogen atoms that can be in contact with a metal surface prior to their combination into a hydrogen molecule. The application of cathodic protection, electroplating, and other processes are sources for introduction of nascent or atomic hydrogen into a metal. Certain substances such as phosphorus, arsenic compounds, and sulfide ions reduce the rate of hydrogen ion reduction by decreasing the rate at which hydrogen combines to form molecules. Accordingly, in the presence of these materials, there is a greater concentration of atomic hydrogen on a metal surface.

Because of its small size, the hydrogen atom can penetrate into a metal. Hydrogen pick-up can result from welding, heat treating, corrosion, or during melting of the alloy. Once in a metal, the hydrogen atoms may accumulate at voids or other internal surfaces within the alloy to form molecular hydrogen. As the concentration of molecular hydrogen increases at these micro-structural discontinuities, high internal pressure is created that can initiate cracking or blistering.

The presence of atomic hydrogen in a metal matrix has been theorized to lower the cohesive force between metal atoms such that local tensile stress perpendicular to the plane of a crack becomes equivalent to or greater than the lattice cohesive force, causing fracture and cracking.

At high temperatures (400 to 1,110°F; 200 to 595°C), hydrogen can react with carbon in the metal alloy to form a hydrocarbon—typically methane. This can result in a surface or internal decarburization, whereby carbon is removed from the alloy, leading to embrittlement of the metal.

With all hydrogen permeation, higher strength alloys are more susceptible to hydrogen cracking, and higher stresses caused by nascent hydrogen penetration cause cracking to occur more rapidly.

Hydrogen embrittlement (penetration of atomic hydrogen at low temperatures) is a reversible process, as opposed to hydrogen attack (penetration of high temperature, high-pressure hydrogen). Baking at 190°C (375°F) for four hours will usually suffice in removing hydrogen from most steels. Cadmium coatings on steel require a longer baking time because atomic hydrogen diffuses more slowly through that metal. Baking times up to 24 hours at 190°C (375°F) are common for cadmium-plated parts.

USE OF PROTECTIVE OVERLAYS TO PREVENT CORROSION

Corrosion Prevention with Protective Overlayers

A number of overlays on a metal surface (in the form of coatings) can be used to isolate the metal from a corrosive environment (barrier coating), provide galvanic sacrificial protection, or inhibit corrosion by the use of passivating pigments. The common type, of coatings used as overlays on a metal surface are discussed herein: conversion coatings (phosphate, chromate, and chromate–free); cementitious linings; glass and porcelain enamels; electroplating; thermal spray coatings; rubber linings; and paints, coatings, and linings.

CONVERSION COATINGS

Conversion coatings can be defined as a material applied to a metal surface that chemically reacts and converts the surface of the metal into a compound that becomes part of the coating. There originally were two principal kinds of conversion coatings: those based on phosphate chemistries and those on chromate chemistries. Because of chromate toxicity, a third type of conversion coating is emerging—those based upon chromate-free chemistries.

Phosphate Conversion Coatings

A phosphate layer $M_3(PO_4)_2 \cdot (nH_2O)$ is formed on a metal substrate by exposure to a phosphating bath. M stands for a metal and represents divalent metallic cations of one or more metallic alloying elements in the phosphating bath that deposit onto the metal being phosphated. n is the number of waters of hydration attached to the metal phosphate molecule comprising the phosphate layer. Steel, aluminum, copper, and magnesium, and their alloys are most commonly phosphated. Zinc phosphate is by far the most commonly used phosphate solution and it is applied usually by immersing the work piece in a bath or by spraying in a cabinet or tunnel.

For painting purposes, crystalline zinc phosphate layers are formed on steel, zinc galvanized steel, and aluminum. The weight of the phosphate coating ranges from 1 to 7 g/m² (0.0033 to 0.023 ounces per square foot).

The phosphate solution consists of a primary phosphate dissolved in a dilute solution of phosphoric acid. When a metal component is immersed in the solution or sprayed with the solution, the acid attacks the metal surface. The attack to the metal reduces the concentration of the acid in the localized area of the attack at the metal interface. With a less acidic environment, the primary phosphate decomposes into a sparingly soluble secondary phosphate and an insoluble tertiary phosphate, both of which precipitate onto the surface at the areas of lower acid concentration. In the process, they are molecularly bonded to the metal. The resulting phosphate layer consists principally of phosphate crystals, but may have amorphous phases between crystals.

The decomposition of the primary phosphate to the secondary tertiary phosphates release hydrogen ions that restore the acid level in the acid-depleted region. The process continues until the desired thickness of the phosphate layer is attained. This mechanism of coating formation is the same for both zinc and iron phosphatizing processes. Manganese phosphate baths are used for heavier coatings. Most conversion coatings used for painting pretreatments consist of zinc in combination with various amounts of Fe^{++}, Ni^{++}, or Mn^{++} ions.

The major advantage of phosphating pretreatments are an increase in surface area for paint bonding provided by the crystalline phosphate layer and a significant reduction of underfilm corrosion at scribes, discontinuities, and mechanical damage when the phosphate-treated steel is exposed to a corrosive, aqueous environment compared to an unphosphated metal.

Most automobile bodies are zinc phosphated prior to painting to increase corrosion resistance and paint adhesion.

Chromate Conversion Coatings

Chromate conversion coatings are formed by chemical or electrochemical treatment of metals or metallic coatings in solutions containing hexavalent chromium (Cr^{6+}). The process results in the formation of an amorphous protective coating comprised of the substrate, complex chromium compounds, and other components in the chromating bath. The most common chromating solution is zinc chromate, and the film formation is similar to that for phosphatizing. The metal being passivated is attacked by the acid (chromic acid and some sulfuric acid), bringing about a decrease in acidity at the metal surface as the acid is consumed during the attack. The hexavalent chromate is reduced to trivalent chromium, which precipitates as a complex chromate gel, bonding itself to the metal. The reduction of the hexavalent chromium results in the formation of hydrogen ions, raising the acidity level at the metal/liquid interface after precipitation of the chromate gel. It is believed that the gel film is formed with chromic hydroxide, providing an insoluble matrix with basic chromic chromate absorbed in it as a soluble component. The gel is soft for the first 24 h or so, after which it hardens and becomes relatively abrasion resistant. Chromate films can be produced on steel, cadmium, copper, and magnesium substrates. Aluminum and aluminum alloys are passivated principally by an acid process consisting of chromate-fluoride and chromate-fluoride-phosphate treatments. Chromate conversion coatings are most frequently applied by immersion or spraying, but can be brushed, roll coated, dipped, squeegeed, or applied in other ways. Chromate conversion coatings are applied primarily to enhance bare or painted corrosion resistance to undercutting and underfilm corrosion, and to improve the adhesion of paint or other organic coatings.

Galvanized steel is passivated by immersing or spraying the freshly prepared galvanized strip in a chromating solution for one to three seconds immediately before removing excess chromate by squeegee rolls. The conversion coating is applied to a weight range from 0.01 to 0.02 g of chromium per square meter (1 to 2 mg of chromium per square foot). Chromium passivation of galvanized steel can be classified as clear, iridescent, and colored (yellowish), depending upon its thickness. Corrosion protection provided by these coatings increases with color (thickness).

Chromate-Free Conversion Coatings

Because hexavalent chromium (Cr^{6+}) is a carcinogen and toxin, there has been an attempt to replace chromate-containing products with safer and more environmentally acceptable alternatives.

However, chromate conversion coatings have been successfully used for a long time and the chromating process consists of both cleaning and deoxidizing/desmutting prior to application of the conversion coating. These preparation procedures, prior to application of the chromate conversion coating, have been developed and refined over the years to optimize the performance of the chromate conversion coating. For chromate-free substitutions, the development and optimization of surface preparation and cleaning methods is not as nearly perfected. However, there are technologies under development that may be promising for chromate-free conversion coatings used in various industries. Some of the chromate-free conversion coatings currently under development or evaluation are based on the following technologies:

Titanium and zirconium fluorocomplexes—These systems consist of an acidic hexafluoro metal complex (H_2ZrF^6 or H_2TiF^6) compound, and commonly a polymer. The added polymers improve corrosion resistance and adhesion of subsequent coats. Titanium and zirconium fluorocomplex conversion coatings are in use on sheet stock for the canning industry and are being evaluated by the automotive industry.

Cerium-based conversion coatings—These coatings are being developed for use on aluminum, both for architectural and aerospace applications. The coating generally consists of cerium chloride ($CeCl_3$) or cerium nitrate [$Ce(NO_3)_3$] and a silicate (SiO_2) seal coat.

Cobalt-based conversion coatings—A cobalt nitrate [$Co(NO_3)_2$] bath produces layers of cobalt oxides over an aluminum substrate. Cobalt-based conversion coatings are being developed for the marine, automotive, and aerospace industries.

Molybdenum-based conversion coatings—These coatings are being developed for use on tin plate and zinc for galvanized surfaces. They have met with little success on aluminum.

Hydrotalcite coatings—These consist of clay-like mineral compounds such as hydromagnesite compounds in conjunction with an alkaline lithium salt solution. A system of polycrystalline compounds is formed on aluminum and aluminum alloy substrates that has good corrosion resistance. Subsequently applied organic coatings adhere well to the hydrotalcite coating surface.

Siliane coatings—Silanes form a silicate layer on a metal surface; they tend to have good corrosion resistance due to a lack of organic groups, and the ability of surface silanol groups to form siloxane bonds as they age. These are being developed for the automotive industry.

Conductive polymer coatings—Conductive polymers, including polyaniline, polypyrroles, and polythiophene-based coatings dispersed in a polymer matrix react with iron on a steel surface and form an iron oxide coating from 0.04 mils to 0.8 mils (1–20 μm thick). These coatings are being developed for ferrous metals.

HOT-DIP GALVANIZING

Hot-dip galvanizing consists of immersing an object to be protected in a bath of molten zinc. The protective coating so developed consists of zinc-iron alloy of variable composition on the surface of the steel. Closest to the surface, the iron content is high relative to the zinc, and proceeding through the protective layer cross section, the zinc content increases in the alloy until the surface layer is all zinc with no iron. Fig. 10 [16] shows a photomicrograph of the cross section of a hot-dip galvanize coating. At the zinc/steel interface, there is an alloying and diffusion of the zinc into the steel and a gradual transition of iron-zinc intermetallics until a relatively pure zinc layer is reached at the outer layer. The outer zinc layer is relatively soft, but the iron-zinc alloy layers are quite hard and from four to six times more resistant to abrasion than the pure zinc layer. The compositions of the various alloy layers are shown adjacent to the photomicrograph.

Galvanizing is applied by either of two methods: batch galvanizing or continuous galvanizing. Batch galvanizing involves cleaning of the steel to be protected, applying a flux to the surface of the zinc bath, and immersing the steel item through the flux into the molten bath of zinc for various periods of time. Thickness of the coating is controlled by the composition of the steel substrate, immersion time, and bath withdrawal rate. (Fast withdrawal rates result in thicker galvanized films.) Batch galvanize thickness is usually between 2 and 4 oz/ft², or 1.7 to 3.4 mils per side (610 and 220 g/m² and 43–86 μm in thickness).

Continuous galvanizing consists of moving a steel sheet, strip, or wire through a tank of molten zinc in a continuous flow. Continuous galvanize coatings are applied at speeds of over 90 m/min (300 ft/min). Coating weights vary from 90 to 1100 g/m² (0.29 to 3.6 oz/ft²). Coating thickness equivalents are from 6 to 78 μm; 0.24 to 3.1 mils.

The zinc coating may be on only one side of the sheet, of equal weight on both sides of the sheet, or of different weights on each side of the sheet. Most sheet coating lines use a gas-wiping technique in which a stream of air or nitrogen gas is directed against the emerging sheet, blowing off excessive zinc and cooling it. A coated galvanized sheet is often oiled or coated with a chromate conversion coating to inhibit white rusting and superficial corrosion during storage in transit. Application of a wax on galvanized wire serves as a white rust preventative and facilitates handling during subsequent processing.

All galvanized coatings on steel protect by acting both as a barrier and providing cathodic protection to the underlying steel. A fresh galvanized surface reacts with oxygen to form zinc oxide (ZnO). In the presence of moisture, zinc oxide converts to zinc hydroxide ($ZnOH_2$) and further reaction with carbon dioxide in the air results in the formation of zinc carbonate ($ZnCO_3$), which is relatively insoluble and provides a gray patina on the surface of weathered galvanize. Cathodic protection is provided to the steel at discontinuities, scratches, and mechanical damage due to the fact that zinc is anodic to steel in most environments.

Layer	Alloy	Iron, %
Eta (η)	Zinc	0.03
Zeta (ζ)	$FeZn_{13}$	5.7-6.3
Delta (δ)	$FeZn_7$	7.0-11.0
Gamma (Γ)	Fe_3Zn_{10}	20.0-27.0
Steel Base Metal	Iron	99+

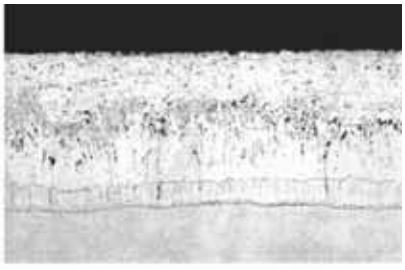

Fig. 10—Photomicrograph of galvanized steel cross-section, and alloy layer compositions. (Courtesy of GalvInfo Center.)

CEMENTITIOUS LININGS

Linings based upon cement are used as sprayable linings, as centrifugally-cast linings for water pipe interiors, and to add weight to submersed pipelines. For corrosion protection purposes, the high alkalinity (pH of 12) of the cement, due principally to calcium silicates and some aluminum silicates, prevents corrosion of steel. Additionally the great thickness (1/2 to 2 in. or more) and inorganic nature of the lining renders it highly abrasion resistant, and resistant to mechanical damage. Ductile and steel water pipes sometimes have a Portland cement lining centrifugally cast to their interior as part of the manufacturing process. Centrifugal casting provides a more dense cement lining making it more resistant to leeching of alkalinity and more abrasion resistant than sprayed linings.

Sprayed cement linings, are more porous, but still provide good corrosion resistance, abrasion resistance, and heat resistance. Spray application is necessary on in situ structures. Often polymers, such acrylic, styrene-butadiene, and polyvinyl acetate latexes, and epoxy emulsions are added to the cement mixture in percentages up to about 20 % to provide better moisture impermeability, acid resistance, tensile strength, and adhesion.

Cement is also added to pipeline exteriors as a coating or as a casting to provide weight to keep the pipe from rising when buried or submersed in water.

GLASS AND PORCELAIN ENAMELS

These coatings are based on complex borosilicate glasses that are produced by quenching a molten glassy mixture. Frits are formed by shattering the glass into small granules by mechanical means. The composition of the frits will vary widely depending upon the intended use for the enamel coating. Porcelain enamels are used widely for chemical processing vessels, agricultural storage tanks, piping and pipe components, and as well for water heater tanks, cookware, and as appliance coatings. They can be formulated to have excellent chemical resistance, particularly to alkalis (at room temperature) and many acids. Water resistance is excellent at room temperature and decreases somewhat at elevated temperatures. Weather resistance, even in highly corrosive, polluted, industrial environments, is excellent. Solvent resistance to common organic solvents, greases, and oils is also excellent. High temperature resistance, depending upon formulation, is excellent up to 2,000°F (1,095°C). However, as might be imagined, glass and porcelain enamels do not have good flexibility and will crack when subjected to bending or twisting. Additionally, when impacted, the thicker coatings may fracture and chip.

ELECTROPLATING

Electroplating involves the electrodeposition of a metallic coating onto a base metal to improve the corrosion resistance, appearance, or properties of that base metal.

Electroplating is commonly done to improve corrosion resistance, and examples are: chrome-plated steel automobile bumpers; electrogalvanizing or zinc plating of steel strip and sheet metal; zinc and cadmium plating of screws, nut, bolts, and other small hardware items; tin plating of steel strip for food packaging and other container uses.

Electroplating consists of the deposition of a layer, usually a thin metal, on an object by passing an electric current, usually DC, through a bath within which the object being plated is immersed. The object being plated is one of the electrodes, usually the cathode. The anode is the metal being deposited, and it dissolves as the plating process proceeds. The plating bath contains dissolved salts of the metals that are being deposited. The bath also contains appropriate acids, bases, and buffering salts to hold the pH to the desired level. Addition agents, such as boric acid, glycine, urea, and gelatin may be added to the bath to regulate plating texture to give, for example, a smooth mirror-like finish. To plate out metals above hydrogen from an aqueous solution, the concentration of hydrogen in the cathodic film must be low. Hence, a basic solution such as that provided by a cyanide bath may be used.

To plate out monovalent ions such as silver (Ag^{+1}) will require one electron per ion. Multivalent ions such as gold (Au^{+1} and Au^{+3}) will require one and three electrons per ion, respectively. In theory, one Faraday of electricity will deposit one equivalent weight of any metal; 107.868 grams of silver, 196.967 grams of Au^{+1}, and 196.967/3 = 65.66 grams of trivalent gold. However, this ideal is almost never realized and the current efficiency is defined as the actual mass of metal deposited/the theoretical mass of metal that would have been deposited using the same amount of electrical current.

Metals commonly plated are copper, chromium, nickel, iron, cadmium, zinc, indium, tin, lead, silver, and gold. Brass, bronze, zinc-iron and zinc-nickel alloys are also plated. Each of these metals require a different bath, and different bath operating parameters (temperature, cathode current density, voltage, pH, addition agents, etc.).

THERMAL SPRAY COATINGS

Thermal spray utilizes heat to melt a material (usually a metal, ceramic, organic polymer, or combinations thereof) for corrosion protection. Steel surfaces are by far the most widely used substrate for thermal spray coatings, although any metal or non-metal compatible with the coating may be coated. The heating methods used are flame (combustion), electric arc, and electric plasma spray processes. In all cases, a feed stock, usually consisting of a powder or wire, is heated, atomized, and propelled onto a suitably prepared substrate where, upon impact, it consolidates for form a protective, adherent coating. For purposes of corrosion protection, often metallic and ceramic coatings are sealed with one or more layers of a polymeric topcoat. Sealers are typically thinned coatings including epoxies, polyurethanes, phenolics, and silicones. Thermally sprayed coatings can be readily built to thicknesses from 0.004 to 0.08 in. (0.1 to 2 mm). Thermally sprayed metals for protection of steel substrates are most commonly metallic zinc, aluminum, and zinc-aluminum alloys (85/15 zinc-aluminum). Other metals can be thermally sprayed such as stainless steel, bronze, nickel, tin, and other exotic metals.

Ceramics are usually applied over a thin, metallic bond coating. Glass frits, ground to a powder for easier melting, based on borosilicate glasses and other ceramics, can be applied.

Polymer coatings, including polyethylene, polypropylene, nylon, polyethylene-tetrafluoroethylene copolymers, as well as thermoplastic acrylics and thermoset epoxies, can be thermally spray applied. These polymers are ground into a powder and fed into the combustion zone by a carrier gas where, upon heating, they melt and as droplets, are transported to a preheated substrate. The molten particles impinge on the substrate, flattening and solidifying into an interlaced network of "splats." The thickness of the coating is governed by the number of spray passes.

RUBBER LININGS

Rubber, in the form of prefabricated sheets, have been used successfully as a lining material in a variety of immersion environments such as storage tanks, flue gas desulfurization units, chemical scrubbers, pipelines, valves, and pumps. Because of superior impact, abrasion, and chemical resistance, rubber linings in the range of 3–6 mm (1/8–1/4 in.) can often outperform conventional liquid-applied linings.

A steel or other metal surface is thoroughly cleaned, usually by solvent cleaning and abrasive blast cleaning. An adhesive system, designed to adhere the rubber to the metal, is then applied. The adhesive may be a single or multicoat system. The rubber sheet is then cut to fit and applied to the surface using rollers and stitchers to press out air pockets and to press the sheet into the adhesive. The applied rubber must then be cured or vulcanized by steam in an autoclave, by heating with exhaust steam, or by a chemical curing agent applied to the rubber surface.

The seams where adjacent rubber sheets join are of particular concern, as most rubber lining failures occur at the seams.

Rubber sheets used for corrosion protection usually comprise two or more different types of rubbers laminated together to form the finalized sheet. Natural rubbers derived from latex-producing plants (principally in Malaysia, Indonesia, and Thailand) account for nearly 90 % of the global production of raw, natural rubber.

Synthetic rubber is made principally from petroleum feedstock. Principal synthetic rubber compounds used for linings are neoprene or chloroprene rubber (CR); butyl rubber (IIR—a blend of isoprene and isobutylene copolymers); chlorobutyl rubber (CIIR—manufactured by the chlorination of IIR); ethylene-propylene rubber (EPDM—a copolymer of ethylene and propylene with the addition of a diene monomer); nitrile rubber (NBR—a copolymerization of acronitrile and butadiene); styrene-butadiene (SBR—formed by copolymerization of styrene and butadiene); and chlorosulfonated polyethylene (CSM—marketed as Hypalon by DuPont).

Each of the rubbers, including the various types of natural rubbers, has advantages and disadvantages, along with specific chemical and temperature resistances, and hardness and flexibility.

Rubber lining systems are chosen for their resistance to the intended service, and are applied, cured, and inspected for defects prior to placing the rubber-lined structure in service.

TABLE 5—Advantages and limitations of principal coating resins. (Courtesy of ASM International.)

Resin type	Advantages	Limitations	Comments
Autooxidative cross-linked resins			
Alkyds	Good resistance to atmospheric weathering and moderate chemical fumes; not resistant to chemical splash and spillage. Long oil alkyds have good penetration but are slow drying: short oil alkyds are fast drying. Temperature resistant to 105°C (225°F)	Not chemically resistant; not suitable for application over alkaline surfaces, such as fresh concrete, or for water immersion	Long oil alkyds make excellent primers for rusted and pitted steel and wooden surfaces. Corrosion resistance is adequate for mild chemical fumes that predominate in many industrial areas. Used as interior and exterior industrial and marine finishes
Epoxy esters	Good weather resistance; chemical resistance better than alkyds and usually sufficient to resist normal atmospheric corrosive attack	Generally the least resistant epoxy resin. Not resistant to strong chemical fumes, splash, or spillage. Temperature resistance: 105°C (225°F) in dry atmospheres. Not suitable for immersion service	A high-quality oil-based coating with good compatibility with most other coating types. Easy to apply. Used widely for atmospheric resistance in chemical environments on structural steel, tank exteriors, etc.
Thermoplastic resins			
Acrylics	Excellent light and ultraviolet stability, gloss, and color retention. Good chemical resistance and excellent atmospheric weathering resistance. Resistant to chemical fumes and occasional mild chemical splash and spillage. Minimal chalking, little if any darkening on prolonged light exposure.	Thermoplastic and water emulsion acrylics not suitable for any immersion service or any substantial acid or alkaline chemical exposure. Most acrylic coatings are used as topcoats in atmospheric service. Acrylic emulsions have limitations described under "Water emulsion latex."	Used predominantly where light stability, gloss, and color retention are of primary importance. With cross-linking, greater chemical resistance can be achieved. Cross-linked acrylics are the most common automotive finish. Emulsion acrylics are often used as primers on concrete block and masonry surfaces.
Water emulsion latex	Resistant of water, mild chemical fumes, and weathering. Good alkali resistance. Latexes are compatible with most generic coating types, either as an undercoat or topcoat.	Must be stored above freezing. Does not penetrate chalky surfaces. Exterior weather and chemical resistance not as good as solvent or oil-based coatings. Not suitable for immersion service	Ease of application and cleanup. No toxic solvents. Good concrete and masonry sealers, because breathing film allows passage of water vapor. Used as interior and exterior coatings
Asphalt pitch	Good water resistance and ultraviolet stability. Will not crack or degrade in sunlight. Nontoxic and suitable for exposure to food products. Resistant to mineral salts and alkalies to 30 % concentration	Black color only. Poor resistance to hydrocarbon solvents, oils, fats, and some organic solvents. Does not have the moisture resistance of coal tars. Can embrittle after prolonged exposure to dry environments or temperatures above 150°C (300°F), and can soften and flow at temperatures as low as 40°C (100°F)	Often used as relatively inexpensive coating in atmospheric service, where coal tars cannot be used. Relatively inexpensive. Most common use is as a pavement sealer or roof coating.
Coal tar pitch	Excellent water resistance (greater than all other types of coatings); good resistance to acids, alkalies, and mineral, animal, and vegetable oils	Unless cross-linked with another resin, is thermoplastic and will flow at temperatures of 40°C (100°F) or less. Hardens and embrittles in cold weather. Black color only; will alligator and crack on prolonged sunlight exposure, although still protective	Used as moisture-resistant coatings in immersion and underground service. Widely used as pipeline exterior and interior coatings below grade. Pitch emulsions used as pavement sealers. Relatively inexpensive
Cross-linked thermosetting resins			
Bisphenol-F epoxies	Lower volatile organic compound (VOC) content than Bis-A epoxies. Better temperature and chemical resistance than Bis-A types. Intermediate temperature and chemical resistance between Bis-A and novolacs	Less flexible; requires thorough blast cleaning surface preparation	Increasing use due to high reactivity and low VOC content

TABLE 5—Advantages and limitations of principal coating resins. (Courtesy of ASM International.) (Continued)

Resin type	Advantages	Limitations	Comments
Epoxy novolacs	Greatest chemical resistance and highest temperature resistance of all epoxy resins used for most severe immersion service	Least flexible of epoxy resins. Costly	Used for high-temperature chemical immersion service
Polyamide, cured epoxies	Superior to amine-cured epoxies for water resistance. Excellent adhesion, gloss, hardness impact, and abrasion resistance. More flexible and tougher than amine-curved epoxies. Some formulations can cure on wet surfaces and underwater. Temperature resistance: 105°C (225°F) dry; 65°C (150°F) wet	Cross-linking does not occur below 5°C (40°F). Maximum resistances generally require 7 day cure at 20°C (70°F). Slightly lower chemical resistance than amine-cured epoxies	Easier to apply and topcoat, more flexible, and better moisture resistance than amine-cured epoxies. Excellent adhesion over steel and concrete. A widely used industrial and marine maintenance coating. Some formulations can be applied to wet or underwater surfaces.
Polyurethanes (aromatic or aliphatic)	Aliphatic urethanes are noted for their chemically excellent gloss, color, and ultraviolet light resistance. Properties vary widely, depending on the polyol coreactant. Generally, chemical and moisture resistance are similar to those of polyamide-cured epoxies, and abrasion resistance is usually excellent.	Because of the versatility of the isocyanate reaction, wide diversity exists in specific coating properties. Exposure to the isocyanate should be minimized to avoid sensitivity that may result in an asthmatic, like breathing condition on continued exposure. Carbon dioxide is released on exposure to humidity, which may result in gassing or bubbling of the coating in humid conditions. Aromatic urethanes may darken or yellow on exposure to ultraviolet radiation.	Aliphatic urethanes are widely used as glossy light-fast topcoats on many exterior structures in corrosive environments. They are relatively expensive but extremely durable. The isocyanate can be combined with other generic materials to enhance chemical, moisture, low-temperature, and abrasion resistance.
Amine-cured epoxies	Excellent resistance to alkalies, most organic and inorganic acids, water, and aqueous salt solutions. Solvent resistance and resistance to oxidizing agents are good as long as not continually wetted. Amine adducts have slightly less chemical and moisture resistance.	Harder and less flexible than other epoxies and intolerant of moisture during application. Coating chalks on exposure to ultraviolet light. Strong solvents may lift coatings. Temperature resistance: 105°C (225°F) wet; 90°C (190°F) dry. Will not cure below 5°C (40°F); should be topcoated within 72 h to avoid intercoat determination. Maximum properties require curing time of approximately 7 days.	Good chemical and weather resistance. Best chemical resistance of epoxy family. Excellent adhesion to steel and concrete. Widely used in maintenance coatings and tank linings
Epoxy powder coatings	Good adhesion, chemical and moisture resistance. Allows cathodic protection in shielded areas on pipelines	Color change is difficult due to extensive cleanup of old powder. Like all epoxy resins, chalks on ultraviolet exposure. Must be applied in shop. Hard to field repair	Applied by electrostatic spray/ fluidized bed. Increasing use because of VOC used as pipeline, original equipment manufacturer coatings
Coal tar epoxies	Excellent resistance to saltwater and freshwater immersion. Very good acid and alkali resistance. Solvent resistance is good, although immersion in strong solvents may leach the coal tar.	Embrittles on exposure to cold or ultraviolet light. Cold weather abrasion resistance is poor. Should be topcoated within 48 h to avoid intercoat adhesion problems. Will not cure below 10°C (50°F). Black or dark colors only. Temperature resistance: 105°C (225°F) dry; 65°C (150°F) wet	Good water resistance. Thicknesses to 0.25 mm (10 mils) per coat. Can be applied to bare steel or concrete without a primer. Low cost per unit coverage
Epoxy phenolics	Excellent hot water resistance and acid resistance. More flexible than phenolic. Better alkali resistance than phenolics	Not as alkali resistant as other apoxy resins. Applies in thin films: somewhat brittle	Linings for food and beverage processing and storage tanks

(*Continued*)

TABLE 5—Advantages and limitations of principal coating resins. (Courtesy of ASM International.) (Continued)

Resin type	Advantages	Limitations	Comments
Phenolics	Greatest solvent resistance of all organic coatings described. Excellent resistance to aliphatic and aromatic hydrocarbons, alcohols, esters, ethers, ketones, and chlorinated solvents. Wet temperature resistance to 95°C (200°F). Odorless, tasteless, and nontoxic; suitable for food use	Must be baked at a metal temperature ranging from 175 to 230°C (350 to 450°F). Coating must be applied in a thin film (approximately 0.025 inch, or 1 mil) and partially baked between coats. Multiple thin coats are necessary to allow water from the condensation reaction to be remove. Cured coating is difficult to patch due to extreme solvent resistance. Poor resistance to alkalies and strong oxidants	A brown color results on baking, which can be used to indicate the degree of cross-linking. Widely used as tank lining for alcohol storage and fermentation and other food products. Used for hot water immersion service. Can be modified with epoxies and other resins to enhance water, chemical, and heat resistance
Polyureas	Extremely fast curing, highly elastic thick film coatings with good strength. Abrasion resistance, chemical resistance	Requires specialized spray equipment due to fast curing Not resistant to strong acids.	Concrete coatings for use in secondary containment of chemical tanks. Elastomeric roof coatings

PAINTS, COATINGS, AND LININGS

The application of a pigmented coating to a metal surface to provide corrosion protection, and as well to provide color and appearance is by far the most common means of corrosion protection of steel and most other metals. The reason for this is that coating materials are relatively inexpensive and can be inexpensively and quickly applied as a liquid by brush, roller, or spray to an irregular, complex surface. The applied liquid coating wets and conforms to the shape of a complex surface and, upon drying or curing, form a protective layer, sealing the object from a corrosive environment.

Sometimes the words "paint," "coating," and "linings" are used to describe a liquid blend of resins and pigment that will dry or cure into a protective layer on a metal. In general usage, however, "paints" are usually materials that are used primarily for decorative purposes, "coatings" are used for corrosion protection purposes in atmospheric environments, and "linings" are used for corrosion protection purposes in immersion or subsoil environments. As can be seen by these general categories, there is much overlap and, under many circumstances, the terms can be used interchangeably.

Coating materials generally consist of a resin (or resin blend), pigments, and solvents or water. Most resins are

TABLE 6—Advantages and limitations of zinc-rich coatings. (Courtesy of ASM International.)

Resin type	Advantages	Limitations	Comments
Organic zinc-rich	Galvanic protection afforded by the zinc content, with chemical and moisture resistance similar to that of the organic binder. Should be topcoated in chemical environments with a pH outside the range 5–10. More tolerant of surface preparation and topcoating than inorganic zinc-rich coatings	Generally have lower service performance than inorganic zinc-rich coatings, but case of application and surface preparation tolerance make them increasingly popular.	Widely used in Europe and the Far East, while inorganic zinc-rich coatings are most common in North America. Organic binder can be closely tailored to topcoats (for example, epoxy topcoats over epoxy-zinc-rich coatings) for a more compatible system. Organic zinc-rich coatings are often used to repair galvanized or inorganic zinc-rich coatings.
Inorganic zinc-rich	Provides excellent long-term protection against pitting in neutral and near-neutral atmospheric, and some immersion, services. Abrasion resistance is excellent, and dry heat resistance exceeds 370°C (700°F). Water-based inorganic silicates are available for confined spaces and compliance with regulations regarding volatile organic compounds.	Inorganic nature necessitates thorough blast-cleaning surface preparation and results in difficulty when topcoating with organic topcoats. Zinc dust is reactive outside the pH range of 5-10, and topcoating is necessary in chemical fume environments. Somewhat difficult to apply; may mudcrack at thicknesses in excess of 0.13 mm (5 mils)	Ethyl silicate zinc-rich coatings require atmospheric moisture to cure and are the most common type. Widely used as a primer on bridges, offshore structures, and steel in the building and chemical-processing industries. Used as a weldable preconstruction primer in the automotive and shipbuilding industries. Use eliminates pitting corrosion.

organic polymers, although some, notably the silicones, silanes, and silicates (used principally for inorganic zinc-rich coatings) are inorganic.

Pigments provide color, moisture impermeability, strengthening, and reinforcement of the dried film, and in some cases, inhibition (chromates, molybdates, borates), and sacrificial protection (zinc). Pigments are ground or mixed into the resin blend and either dissolved in the solvent mixture or emulsified in water (sometimes with a solvent coalescing aid).

The principal characteristics of a coating are derived from the resin or resin blend. Proper choice of pigments must be made for the intended service, as the pigment must have the appropriate acid, alkali, moisture, temperature, and weatherability resistances for the environment of intended use.

In order for any coating system to perform properly in a given environment, the metal must be cleaned of oils, grease, salts, and contaminants that may compromise its performance. Common surface preparation methods include hand and tool scraping, brushing and grinding; abrasive blast cleaning; solvent cleaning; water washing; and high pressure water jetting. Often, more than one layer of coating is used, with primers formulated for adhesion, corrosion inhibition, and sacrificial protection. Topcoats are formulated for environmental resistance, and intermediate coats (when used) provide a means for the topcoat to adhere to the primer and provide additional thickness and resistance to the coating system.

Coating systems are usually chosen for their environmental resistance, and the surface preparation and specific coating design are dependent upon the desired environmental service and anticipated service life.

Table 5 [17,18] describes the advantages and limitations of principal coating resins used to formulate coatings and linings.

Zinc-rich primers, and when untopcoated, zinc-rich coatings, consist of an organic (commonly epoxy, or polyurethane) or inorganic (silicate) binder highly loaded (75 % solids by volume or higher) with zinc dust. The zinc in the zinc-rich is anodic to the underlying steel, and corrodes preferentially to the steel which is the cathode in the galvanic couple. Accordingly, in time, when the zinc dissipates, it can be replaced by reapplication. This is usually much safer and less expensive than steel replacement. Zinc-rich primers are widely used in aggressive neutral and near-neutral marine industrial and atmospheric environments as they virtually eliminate pitting corrosion.

Table 6 lists the advantages and disadvantages of organic and inorganic zinc-rich coatings.

CONCLUSIONS

Metallic corrosion, its mechanisms, and forms have been summarized in the preceding paragraphs, along with some of the more common means to prevent corrosion by use of protective overlayers. A more exhaustive treatment of either subject is beyond the scope of this chapter.

As knowledge of corrosion increases as a result of research into corrosion mechanisms and the means to detect and study corrosion, new methods to combat corrosion will be discovered, along with new corrosion protection materials and methods. When one considers the state of the art of corrosion knowledge, and the methods used to deter corrosion 50 years ago, it is evident we have come a long way baby! It is almost unimaginable to think where the science will be in another 50 years. What an exciting future for workers, technicians, scientists, and technologists in the field of corrosion, and corrosion protection!

Accelerated Weathering

Valerie S. Sherbondy[1]

PREFACE

IN PREPARATION OF THIS CHAPTER, THE CON-tents of the fifteenth edition were drawn upon. The current edition will review, clarify and update the topics as addressed in the previous edition. New technology and reference materials are acknowledged and included to update the reader with the advances in this industry.

Paints and coatings are used both to protect substrates and to provide an aesthetically pleasing appearance. In an outdoor environment, both of these functions can be affected by weathering. The four major factors involved in weathering are solar radiation (sunlight), moisture, oxygen, and heat. Sunlight, especially in the short wavelength/high energy ultraviolet (UV) region, has been proven to lead to discoloration, loss of gloss, scaling, embrittlement, and chalking. Moisture, in the form of rain, dew and humidity can cause blistering, flaking, loss of adhesion and promote the growth of mildew and algae. Heat exposure may cause embrittlement, cracking, peeling, and checking. Oxygen in the atmosphere participates in the oxidation of the surface of the coating, which may eventually lead to oxidation of internal layers, causing embrittlement, softening, cracking, or crazing. The oxygen is often left out of the discussion since it is more constant than the other factors, but this degradation process is a contributing factor to the other three factors of weathering. These elements contribute individually as well as in combination to cause coating failures.

Naturally occurring and man-made chemicals in the environment also contribute to coating degradation and could be considered a fifth element of weathering. However, the type and levels of chemicals can vary dramatically, even over short distances. Therefore, they cannot be considered as universal in influencing the degradation process as the four factors mentioned previously. Perhaps as a consequence of this, and also partly due to tradition, chemical resistance testing is usually considered to be separate from artificial weathering. Although the effects of chemicals cannot be ignored, they are discussed elsewhere in the manual. One of the most common chemical exposure tests that is often grouped with accelerated weathering continues to be salt fog or salt spray testing, which is discussed in the corrosion section of this manual. In summary, this chapter will consider only devices that incorporate an UV light source, temperature control or monitoring, and moisture exposure monitoring.

Accelerated or artificial weathering involves the use of laboratory equipment (either indoors or outdoors) to simulate the degradation that occurs during actual outdoor exposure [1–3]. Accelerated weathering is the term most often applied to artificial weathering because at least one of the elements of light, heat, and moisture are either longer in duration or more intense than the actual time and conditions encountered in outdoor exposure. This increased exposure causes the coating to weather or degrade more rapidly than when placed in an environment without the intensified weathering factor. However, in an attempt to accelerate the effects of natural weathering, the laboratory conditions may be overly aggressive and thus cause results that are not attained during natural weathering. In some cases, the modes of failure identified by accelerated weathering do not occur in natural conditions, which is at least partially due to the unpredictability of the exposure environment. To evaluate the applicability of the results from any accelerated test, background information about the material being exposed and actual field results of similar materials may be referenced. Internal controls, consisting of materials with known performance characteristics, provide helpful information and can be used to predict expected service life expectations.

Artificial weathering devices should be designed to produce test conditions that are controllable and reproducible, so that data are reproducible on a day-to-day basis and comparable on a laboratory-to-laboratory basis. This differs from outdoor or natural weathering where there is natural variation and no control over environmental factors. Due to this variability of conditions, the results of short-term natural weathering often are not reproducible. For example, weathering factors are different for various parts of the world and for different countries and can be broken down to represent various known climates, which are further addressed in the "Natural Weathering" chapter of this book. Some locations receive more sunlight and heat, while others are cloudy and cool. There are also seasonal variations. Even for long-term testing, the data for a specimen placed outside during January would not necessarily concur with data for a duplicate specimen placed outside in July because of initial exposure effects. When considering short term exposure, even if the same location and time of year are used, the natural weathering factors change from year to year. It should be noted that the longer term outdoor weathering does settle into a pattern and exposures of greater than 3 years have shown correlation to other samples exposed over a similar time. The long term outdoor exposure monitoring has indicated that the variations within particular climates vary within a characterized range. In contrast to natural weathering, data produced

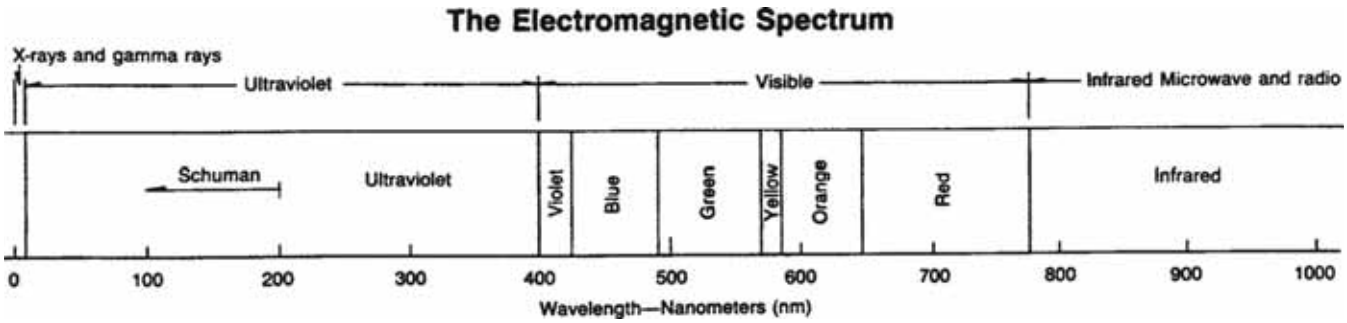

Fig. 1—The electromagnetic spectrum.

under controlled laboratory conditions can be used as comparative data (assuming the same equipment, equally aged lamps, etc.) even if testing was conducted during different times of the year or over several years.

In addition to reproducibility, a great advantage of accelerated weathering is that the results are available more quickly than with natural weathering, which is a phenomenon that may take years. The time saved on testing can translate into cost savings when developing new products or when choosing a new coating system for buildings, tanks, or equipment where historic data about coating performance is not available. This acceptance of data should be used cautiously since not all accelerated data is representative of natural weathering degradation processes.

Even though there are many advantages to accelerated weathering, it is important to recognize that the data is most often used for comparative purposes only. Although there are correlation tables available for many devices for a variety of materials, the correlation between artificial and natural outdoor results should be validated before using the results as a basis for business decisions. One reason an accepted overall correlation has not been developed is that the data obtained through artificial weathering has been produced by subjecting the sample to unnatural conditions, and the results may or may not duplicate those that occurred during natural weathering. If similar failure modes are experienced in an accelerated weathering device and at an outdoor test site, a direct correlation may be developed for that product. The calculated correlation would be valid only for the tested material under the stated, specific conditions. Note that the correlation is often extended to a variety of similar environments, making further estimates of service life possible, but this correlation is not a universal correlation and should not be represented as such.

Although the previous information makes it sound like the only way to get reproducible data is accelerated weathering devices, it should be noted that not all results obtained by accelerated weathering devices are as reproducible as those using and producing the data would like [3]. Studies have concluded that even though the settings may be the same, the maintenance of the device—including light source, filters, and gages—affect the exposure levels and thus the results of the testing. The cleaning and disposal of light filters is often subjective and a major source of variation that changes the amount of light at critical wavelengths. The intensity of the light is also dependent on the changing of, rotation of, and power supplied to the light source. These factors may speed up or slow down the degradation process due to changes in both temperature and UV light exposure. Since this is known to occur, testing specifications are sometimes written to include a standard material be exposed with the test specimens or to include an actual measurement of the light during the testing. This measurement is discussed later in this chapter. Updates to methods and equipment are decreasing the variability by increasing the requirements for monitoring, ease of monitoring, and required documentation. [See ASTM G151 "Standard Practice for Exposing Non-metallic Materials in Accelerated Test Devices that Use Laboratory Light Sources" for an example of care. The manufacturer of the device should provide exact information.]

Even if the light source was not changing with time, each device has regions of more intense exposure. For this reason, most devices have recommended manual rotation procedures for the exposed specimens. These procedures should be performed at regularly spaced intervals to decrease the effects of increased or decreased light intensity on the specimens during the duration of the exposure. These effects would be greater on short-term tests, where the specimens would not be moved through the different exposure zones.

Aside from the conditions of the device, the conditions surrounding the device also affect performance. Most devices require a surrounding area that is ventilated and able to maintain ambient conditions, so that temperature changes within the device can be maintained or obtained. For example, a relatively high ambient temperature may reduce the amount of condensation on some devices, while high amounts of ventilation may slow the temperature recovery after water spray in other devices. It should be noted that ambient conditions are not specified by all of the accelerated weathering ASTM standards, although the manufacturers of the testing equipment often recommend general guidelines. Ambient conditions could vary between laboratories, adding an unknown variable that may affect the results.

ELEMENTS OF WEATHERING

There are many component factors that contribute to the weathering of a coating. The general components are light, moisture, heat, and oxygen, which are always present in various amounts. This section concentrates on these general components and on how they are simulated and intensified.

Light

Sunlight is composed of radiation from the visible, UV, and infrared regions of the electromagnetic spectrum

(Fig. 1) [4]. The most damaging region of sunlight for polymeric materials has been determined to be the UV light region, especially the shorter wavelengths ranging from 400 to 295 nm. The portion of sunlight in the UV region is relatively small, only 5 to 7 %, due to the filtering effects of the atmosphere. The UV region has been divided into three domains: UV-A, UV-B, and UV-C. The UV-A region is 315 to 400 nm, the UV-B region is 280 to 315 nm, and the UV-C region is 100 to 280 nm. Although the high energy/short wavelength UV-C is the most damaging region, these wavelengths are essentially filtered out by ozone in the upper levels of the atmosphere. Therefore, if light sources produced output only in this region, they would cause abnormal degradation unless the coating was to be used for aerospace applications.

Radiation in both the UV-A and the UV-B regions cause degradation of coatings. The energy of the shorter wavelengths present in the UV-B region, ~91 to 102 kcal/mol (3.8 to 4.3 J/mol), cause more severe and rapid degradation of coatings than the wavelengths in the UV-A region. In the UV-B region, the energy levels are high enough to break carbon-nitrogen, carbon-carbon, nitrogen-hydrogen, carbon-oxygen, and carbon-hydrogen bonds in the polymeric portion of the coating. In the UV-A region, the longer wavelengths do not have sufficient energy, (~71 to 91 kcal/mol) (3.0 to 3.8 J/mol), to break certain bonds, namely carbon-hydrogen. Thus, it is important to characterize the output of the light source used in the weathering device and determine if the spectral power distribution adequately correlates to the electromagnetic spectrum of sunlight and the actual exposure of the product being evaluated.

One type of degradation caused by exposure to solar radiation is classified as erosion. The breaking of chemical bonds first leads to a degradation of the coating surface layers and is manifested by chalking, fading, and loss of gloss. Once the protective outer layer of polymer is lost, pigments are exposed. Without the protective polymeric binder, the pigments can fade and erode, causing a change in color and/or appearance. Although pigments can and do fade even in intact polymer films, this example is provided to show one of the possible effects of solar radiation on the polymer which can lead to a visual performance defect. This is by no means the only mode of degradation, or even the most common. The modes of degradation are variable and are determined by the UV light resistance of the individual components of the coating formulation.

Sunlight has been simulated in accelerated weathering devices by filtered and unfiltered mercury arcs, open and enclosed carbon arcs, xenon arcs, and fluorescent lamps, as well as concentrated onto the paint surfaces by reflection of collected sunlight. However, as the results produced by early accelerated testing devices were compared to the results obtained from natural weathering, the light sources were modified to attempt to achieve results more similar to the natural weathering defects. Depending on the exact coating type and the service environment, several different specifications have been developed that indicate which light source should be used. Most of these test specifications require the use of open or "sunshine" carbon arcs, xenon arcs, or fluorescent lamps. These light sources were chosen based on their ability to more closely simulate the degrading UV light range of sunlight or to rapidly produce dramatic changes in the coating. Each of the light sources provides benefits as will as pitfalls to the testing process. The source chosen will depend on the current research at the time, the light sources currently available, the material being tested, the expected environmental conditions, and historical testing of competitive compounds. Since these factors will vary with each exposure and the advances in the exposure devices, a recommendation of source cannot be made in this chapter and the manufacturers of the devices and current literature should be referenced.

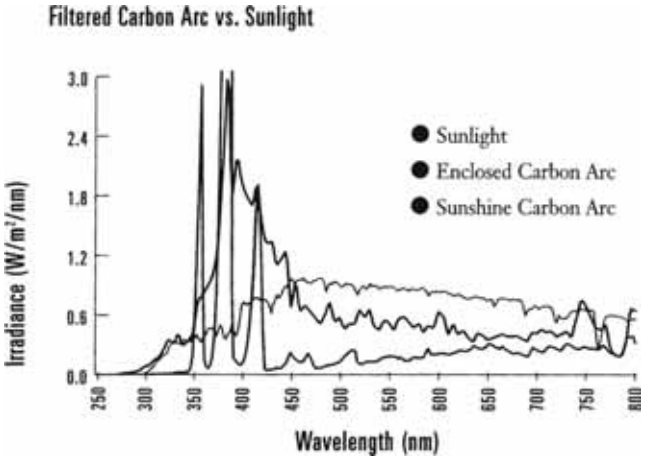

Fig. 2—Spectra of light produced by an enclosed carbon arc and a sunshine carbon arc. Used with permission of the Atlas Electric Devices Co.

ENCLOSED CARBON ARC

Originally, these lamps were used to test the light fastness of textiles. They were then combined with a water spray to be an industry-wide artificial testing device. Although mercury and carbon arc sources have been in use for over 75 years, when they were used to test paint products, it was discovered that they produce light that accelerates chalking and fading more than cracking and further testing of light sources was initiated. The carbon arc source consists of neutral solid and cored carbon electrodes. The flame portion of the lamp is enclosed in a borosilicate globe. The globe creates a semisealed atmosphere that sustains the arc and filters out UV light below 275 nm. The lamps produce two large spectral peaks that center near 350 and 380 nm, but they deliver essentially no emission below 340 nm, where the light is more severe in its degradation capabilities and more damaging to polymeric materials (Fig. 2). In addition, even the light in the visible region, 400 to 800 nm, was also low compared to sunlight, meaning that any visible color change due to the change of the pigment would require a lengthy exposure. As a result, there was incentive to produce a light source that provided a better simulation of natural sunlight, especially since more durable materials were being developed. In addition, a rigorous maintenance routine was essential for consistent operation. The rods and globe need to be cleaned daily, and the globe checked for deterioration and replacement.

OPEN-FLAME CARBON ARC

Innovation of the open flame carbon arc, or sunshine carbon arc, from the basic carbon arc was a welcomed change

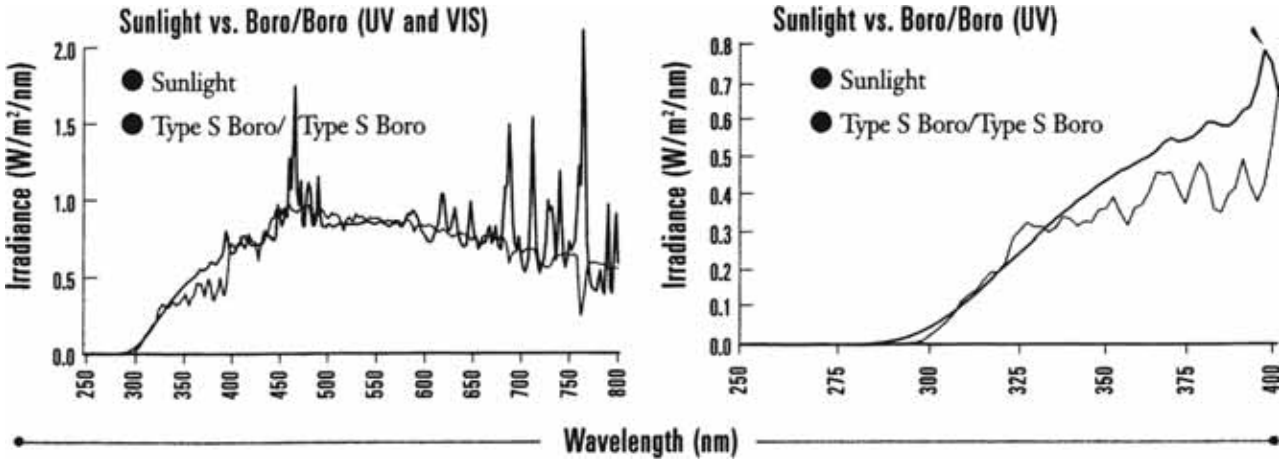

Fig. 3—Spectrum of light produced by a xenon arc with Boro/Boro filters. Used with permission of the Atlas Electric Devices Co.

since the industry saw the need for a special distribution spectrum closer to that of sunlight. The lamp operates in a free flow of air instead of in a globe. The lamp is composed of copper-coated electrodes and a central core of rare earth. The lamp is surrounded by a stainless-steel filter frame that also acts as an air duct. The frame holds flat, optical, heat-resistant, borosilicate glass panels that filter portions of the lower wavelength light from the spectrum. The spectrum produced by this light source is more similar to that of sunlight in the region between 310 and 370 nm (Fig. 3). However, there was still a spectral imbalance due to large bands between 370 and 450 nm, but the region between 450 and 800 nm was closer to natural sunlight than the enclosed carbon arc lamp shown in Fig. 3. The disadvantage of this light source is the emission between 260 and 310 nm, which includes a portion of the undesirable UV-C region. Although this light source was an improvement, the industry requested the spectral distribution of the light be even closer to that of sunlight. Maintenance issues could lead to variability since the carbon rods need to be replaced daily and the filters need to be cleaned daily and replaced periodically. A good laboratory will perform these functions as a matter of the daily routine; however, fewer laboratories are offering this service. The current use of the filtered carbon arc sources to simulate the effects of outdoor weathering has been widely deprecated by the weathering science community due to the poor simulation of the spectral distribution of the terrestrial solar radiation.

XENON ARC

The adoption of the filtered xenon arc solar radiation sources for accelerated weathering devices was the next improvement in artificial weathering equipment. The xenon lamp consists of a burner tube and a light filter system. There are two types of xenon arc lamps. One type of xenon arc lamp is cooled by water circulated through the lamp housing. The cooling water also filters out a portion of the long-wavelength infrared light. The other type of xenon lamp is air-cooled. Both lamp types produce a spectrum closer to sunlight when filtered and set at the correct irradiance setting. There are several filters and combinations of filters that can be used. The three common filter combinations used for artificial weathering of paint are quartz/borosilicate, borosilicate/borosilicate, and quartz/quartz. The first combination allows the UV region to extend down to 270 nm (Fig. 4). The borosilicate/borosilicate combination is the most common combination and has a cutoff at 280 nm, which makes the spectrum closer to that of natural sunlight, which cuts off at 295 nm. The quartz/quartz combination produces a spectrum that extends to below 250 nm, i.e., into the undesirable UV-C region, and although used to test coatings, it is the least popular of the three filter combinations. If a more precise match for the solar cutoff and full UV spectrum match is needed, an option of lower temperatures is available with a coated infrared absorbing (CIRA) quartz/soda lime filter combination. With all of these combinations there is an increased spectral output in the 450–500 nm region when compared to the spectral output of natural sunlight.

Recently, an additional filter has been introduced to the market [5]. The spectra distribution of this filter used as an inner filter with a quartz or CIRA filter provides a spectral distribution of xenon light that matches the spectral distribution of sunlight more closely than any testing light source to date (Fig. 5).

Since the xenon arc source decays as the lamp ages, the irradiance of the light source should be monitored and can be controlled by adjusting the lamp wattage. All modern devices have a monitoring system that adjusts the lamp power to compensate for the decay. The settings for the lamps are referenced in many of the standards and should be referenced depending on the exposure required. Common settings produce a spectrum with approximately the same cutoff wavelength (determined by the filter) as natural sunlight. The settings are chosen to be within the range of natural sunlight. Note that a variance in the wattage settings results in changes of the degradation rate of the coatings.

FLUORESCENT UV LAMPS

Another development in light sources is the fluorescent UV lamp [6,7]. These lamps were not developed to simulate the entire spectral range of natural sunlight. Rather, they simulate only the damaging UV region found in sunlight. Currently there are three types of fluorescent UV bulbs. The QFS-40 and UVB-313 produce light with a maximum output at 313 nm (Fig. 6). The UVB-313 has a higher

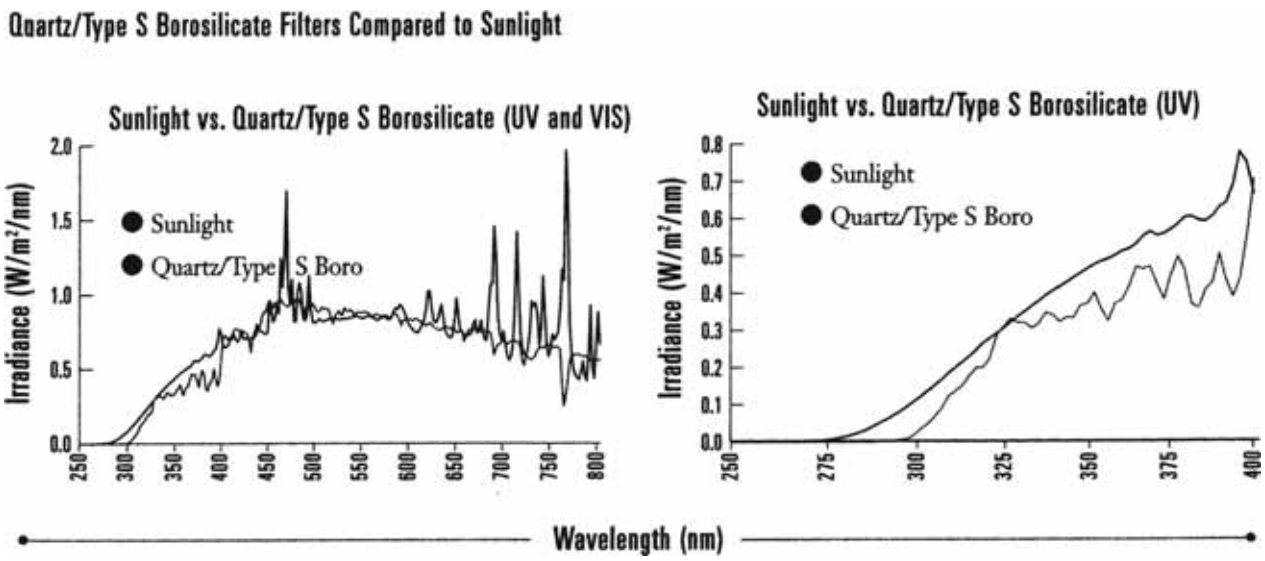

Fig. 4—Spectrum of light produced by a xenon arc with Quartz/Boro filters. Used with permission of the Atlas Electric Devices Co.

intensity and thus a greater weathering acceleration rate than the QFS-40. Since the UVB-313 has a higher, more stable output than the QFS-40 and the devices can now be adjusted to lower the irradiance, the QFS-40 bulb is being phased out of production. Both of these lamps have outputs down to 275 nm, which is below the cutoff of natural sunlight, and can lead to anomalous results [8]. The third type of fluorescent lamp is the UVA-340 lamp that produces a spectrum very similar to that of natural sunlight (Fig. 7). The spectrum is made up of wavelengths in the UV-A region with a small amount of the UV-B region wavelengths. The cutoff matches that of natural sunlight, but provides little exposure to light above 390 nm. Although the results produced by the UVA-340 lamp are closer to that of sunlight, the UVB lamp had been a widely used fluorescent light source because of the rate at which degradation occurred. In some cases the degradation produced by the higher output UVB-313 bulbs was not found to match the actual degradation that occurred in actual application. The bulbs continued to be used

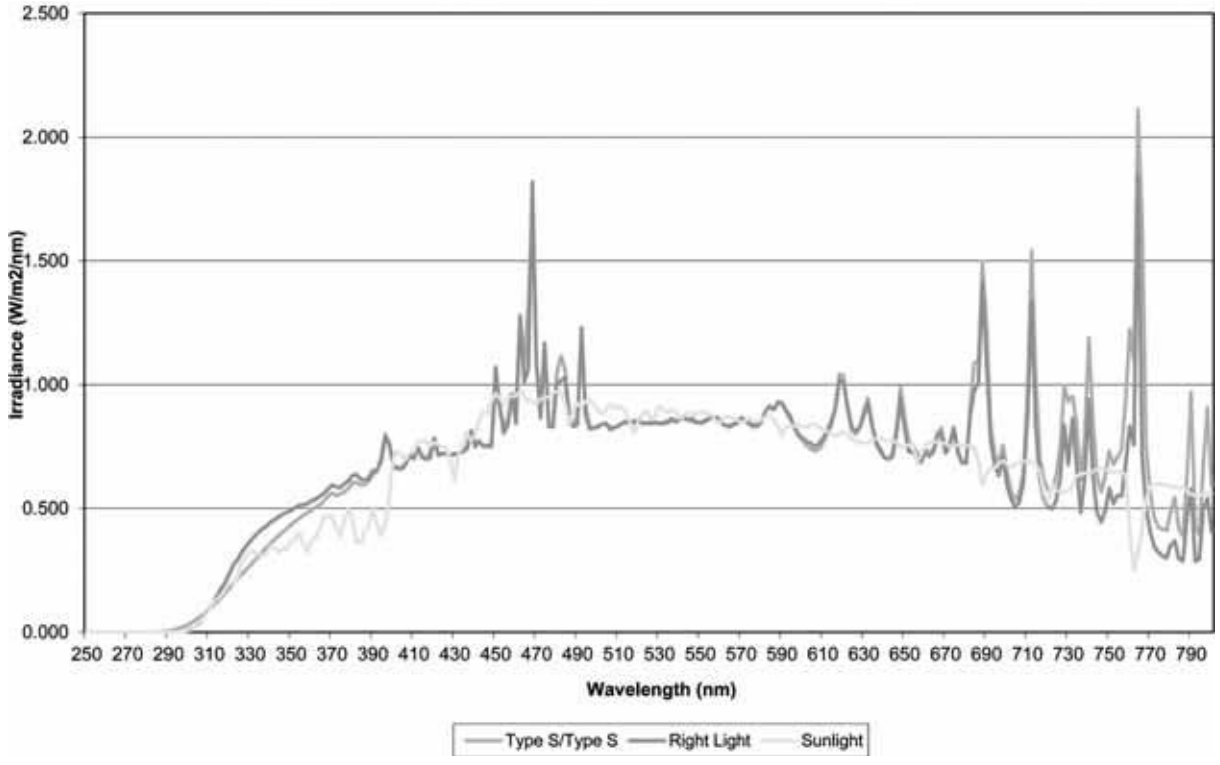

Fig. 5—Right light filter system versus sunlight. Used with permission of the Atlas Electric Devices Co.

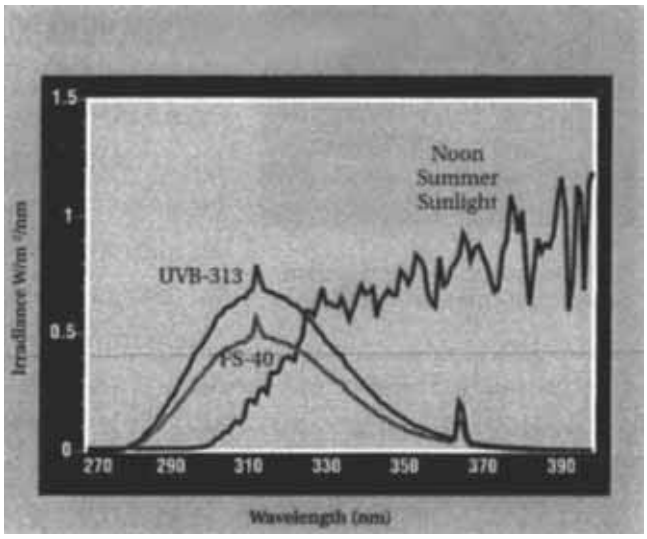

Fig. 6—UVB-lamps versus summer sunlight. Used with permission of the Q-panel Co.

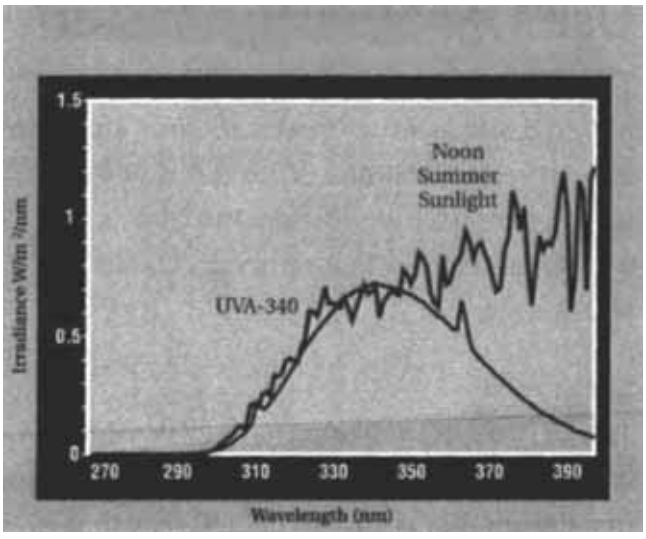

Fig. 7—UVA-340 lamps versus summer sunlight. Used with permission of the Q-panel Co.

since so much of the historical comparative data had been obtained using the UVB-313 bulbs. The change to the UVA-340A bulb has taken time, but these bulbs are currently the most used fluorescent bulb. Since the UV cutoff of the UVA-340 lamp is higher, the degradation process takes a longer period of time than with the UVB lamps, but often more closely matches the degradation seen in the field and is still accelerated when compared to outdoor exposure tests. The degradation of the coatings produced by the fluorescent bulbs may be significantly different from those of natural weathering due to the lack of long wavelength radiation. Beyond the peak output for these lamps, the spectrum is much weaker than the visible light spectrum. Due to the lack of output in the visible light region, coatings of different colors do not vary much in surface temperature, unlike variations produced by natural sunlight.

Changes in instrument technology and uses of monitoring devices have been used to increase the irradiance of the fluorescent bulbs. The bulbs can be operated at up to 1.75× the normal level to increase the intensity of the light, without changing the spectral distribution. In this way, the UVA-340 bulbs, set at a higher irradiance, can be used to produce quicker results without introducing an unnatural wavelength as produced by the UVB-313 bulbs. The bulbs used at the higher irradiance level should be monitored to evaluate bulb aging and decay in irradiance output [8].[2]

METAL HALIDE

New technology and testing requirements are pushing manufacturers to perform additional exposure tests on all of the products offered to the consumer. One of the other advances in artificial weathering is the use of metal halide lamps. These do not have a continuous spectrum, but a large number of individual spectrum lines over a wide spectral range. Several rare earth metals are present and when used together produce a spectrum similar to sunlight. These lamps have to be used with filters, measuring devices to stabilize the irradiance, and electronic power supplies to provide a spectral power distribution that matches solar radiation. These lamps are high efficiency and thus suited for use in large-scale chambers. Several different radiation units are used for the large-scale exposure and can be moved around the testing area to simulate different light exposure conditions, such as sunrise, sunset, and other incident angles of interest. While it has been determined that the metal halide devices can reproduce the relative energy with a defined range, these are not known to be good overall simulators of sunlight. Additionally, the current lamps vary in output from one to another, which means that each lamp must be measured to determine the suitability to the exposure project. The temperature of the environment surrounding the lamps must also be monitored since the spectral distribution will vary with temperature changes.

LAMP STABILITY

Once a light source has been selected, it is assumed that several tests run over a period of months or years can be used to evaluate the relative performance of the paints. However, this assumption is not always true. Essentially all new accelerated weathering devices are now sold with irradiance control. Even with this control, the output of the light source may vary depending on the care and maintenance of the device. All of the devices should be cleaned and the light sources changed as recommended to ensure the most reproducible and even spectral distribution and irradiance. The newer devices have the option of monitoring and adjusting the light output, or irradiance, for all of the different light sources. Many of the methods used for testing now recommend monitoring the irradiance. In the future, these settings may become a required part of the report for the testing results. The monitoring devices take the guesswork out of determining exactly when to clean or change a light source. The monitoring can lead to

[2] ASTM has found suitable devices available and used by DSET Laboratories, Inc., Box 1850 Black Canyon Stage 1, Phoenix, AZ 85029 and at Sub-Tropical Testing Service, 8290 S. W. 120th St., P.O. Box 560876, Miami, FL 33156.

extended service of the light source, increased reproducibility of results and better overall maintenance of the testing devices. In summary, the maintenance of the device according to sound practices and manufacturers recommendations is required for reliable operation and consistent data for comparison purposes.

There are several monitoring instruments available to measure the light output including pyranometers, radiometers, spectroradiometers, and light-sensitive materials. However, each of these devices may be used to measure different characteristics of light. Two different-colored light sources could produce the same response if a pyranometer is used to measure the light. These devices measure the amount of radiant power regardless of the spectral distribution. Even when filtered to restrict the wavelength of light being measured, it was found that the response was not sufficiently sensitive for the UV range.

Radiometers have been modified with filters to select areas of the spectral distribution. These are classified as wide band, broad band, or narrow band. The wide-band instruments measure the light output over a range of several hundred nanometers. Broad-band instruments function over a range of 20 to 100 nm, while narrow-band instruments measure less than 20 nm. The most commercially successful radiometer measured the total UV light using a wide-band UV filter. However, when these devices were used to measure natural sunlight in comparison to the light sources, it was found that sensitivity to shorter wavelength UV was less than its peak sensitivity to visible light, which could be affected by temperature changes.

The currently used radiometer, developed for exterior monitoring, has a narrow band filter and a thermoelectrically cooled detector. This is suited for long-term use and is easily operated in the field or laboratory by relatively inexperienced personnel.

For internal use and for the most accurate measurements, spectroradiometers are available. These would not withstand external use and normally require operation by skilled personnel.

In contrast to actual light measurements, there are industries, other than the paint industry, that rely on the use of light-sensitive reference materials. The reference material is placed in the cabinet at the same time as the test samples and monitored, usually for color changes, to evaluate the effectiveness of the light source. These materials must be inherently unstable to achieve the desired result. This instability should be considered when choosing a reference material. The reaction of some materials may vary widely, and the sensitivity is often a result of the total environment, so all of the other factors of exposure must remain constant. One of the major problems with using this technique in the paint industry is the short life of these materials relative to the more durable paint systems.

Even with all of the variability of light sources, proper care of the instrument can yield consistent results between laboratories. Most of these instruments have been run for many years with less monitoring and fewer quality-control procedures than are in use today, and the data have been acceptable over many years. This is due to the fact that most companies understand that the test results can vary, and to that end often include several competitive materials in the test protocol.

Moisture

Another important characteristic of weathering is moisture. Moisture is commonly overlooked as a significant factor of paint degradation because it is a common belief that structures are only wet when it rains, when they are splashed, or when they are immersed in fluids. Actual time-of-wetness studies have shown that samples placed outside in several different locations in the United States and Canada were wet approximately 30 % of the time [9]. This averages to approximately 8 h per day. The water in a natural environment is caused by dew (high relative humidity), rain, or melting snow or ice. During contact, the water may be absorbed or pass through the coating and several types of degradation may be initiated. One example is the liquid passing through the coating and interacting or reacting with a water-soluble material resulting in the formation of an osmotic cell. Another process could be initiated if moisture passes through the coating and reacts with the substrate, for example wood; the interfacial bond between coating and substrate may be destroyed or weakened. The process that affects most coatings is the cyclic absorption and desorption of water.

The theory behind cyclic moisture exposure is based on the permeation, or absorption, of the liquid into the coating, which may cause certain coatings to swell. During the drying, cycle desorption, evaporation will occur, causing the coating to shrink, resulting in cyclic stressing of the system. Inner layers of the coating material may be at different points in the cycle, relative to the top surface, adding additional stress within the coating system. The cyclic changes can lead to flaking and surface stress cracking, as well as cracking and peeling of the entire coating system.

The process by which degradation takes place and how fast it will occur is influenced by the permeability of the coating and the contact time required to initiate water penetration. Additionally, the rate of water and chemical degradation is increased by increased temperature and UV light exposure.

The temperature of the coating when the exposure to moisture occurs can change the way the moisture affects the coating. Rain in particular can cause thermal shock and lead to erosion of the paint surface. If the surface of the paint is warm, the rain striking the surface initiates an evaporation process, which quickly cools the surface and may lead to surface degradation. Freeze-thaw cycles and frozen rain or hail can also cause surface degradation to occur more rapidly, but are not addressed in this chapter.

For testing purposes, moisture can be simulated by water spray, condensation, fog, or immersion. Depending on the device used, degradation acceleration is possible by increasing the number of wet/dry cycles or increasing the time of exposure. Since accelerated weathering devices run around the clock (and day after day for that matter), it is possible to cycle the specimen through several wet and dry periods and still meet or exceed the 8 h of average wetness found in natural weathering. Another way to accelerate the damage caused by moisture is to increase the time period of exposure to moisture. Prolonged exposure may degrade coating just as much as the stresses caused by wet/dry cycling.

Although the time of wetness is a big factor in the initiation and perpetuation of the degradation process, it is important to consider the purity of the water itself. The

water used for testing should be clean and meet the specifications outlined in the device manufacturer's instructions. Introduction of chemical contamination through the water source could greatly change the degradation of the exposed coating and lead to corrosion within the exposure device, thus altering the exposure even more. The contaminant may initiate the degradation prematurely, or enhance color changes. Even small amounts of a contaminant can be of great influence since heat is applied and evaporation is induced. The heat and evaporation may concentrate the contaminant before it can be diluted or washed away by another cycle of moisture exposure. Recommendations for purification and consistency in the water supply include distillation or a combination of deionization and reverse osmosis. The cleanliness of the water supply can also determine the life of the testing equipment, which often contains items susceptible to corrosion.

Temperature

The third factor of weathering is heat or temperature. Testing performed over the years has indicated that degradation of coatings occurs more rapidly at elevated temperatures and temperature variation can lead to expansion and contraction stresses in the coating. These stresses may be magnified by the expansion and contraction of the substrate itself, which can lead to cracking, peeling, checking, or loss of adhesion. Temperature can also accelerate the effects of other weathering factors such as light and moisture. In accelerated weathering, cyclic testing at only slightly elevated temperatures can produce accelerated results. The temperature chosen for testing should be within the expected temperature range of the service environment. Drastic increases in temperature are not necessary to produce noticeable effects and in fact should be avoided. Testing at excessive temperatures can either cause premature or unreasonable failures or even enhanced performance that would not be realized under actual use condition. High temperatures may cause the coating to bake or cure excessively and cause it to become brittle with decreased impact resistance, or it may become more resistant to the environment than would occur if it were only air dried under ambient conditions. To prevent these occurrences, temperatures near those of actual or expected exposure should be used. The temperature should be monitored so the data have meaning relative to other test results.

Oxygen

Changing the degree of oxygen exposure of specimens by introduction of ozone or pure oxygen is possible with a few testing devices, but this modification in technique is not commonly practiced. Oxygen exposure is usually inadvertently changed in artificial weathering devices. The condensation, fog, immersion, or water spray used to create moisture can introduce oxygen to the test environment and the surface of the panels. Even in natural weathering, oxidation of a coating surface usually occurs in the presence of moisture.

Oxidation involves breaking bonds within a cured coating. Either primary or secondary bonds may be affected by oxidation. Since the oxidation process is different for different chemical types (acrylic, epoxide, vinyl, etc.) of coatings, the results of oxidation can range from embrittlement to softening, along with crazing, cracking, or discoloration. Oxidation usually begins as a surface phenomenon that breaks down the outer polymeric binder layers. Water can then pass through the film to the inner layers and cause further breakdown (often at an accelerated pace) of binder and additives.

Other Factors

Although light, heat, moisture, and oxygen play important roles in the deterioration process, it should be recognized that there are other factors that affect coating stability. Weather resistance is dependent on the curing or drying process, the substrate being painted, and application methods. These conditions cannot be fully simulated under controlled laboratory conditions since, as with natural weathering, these conditions are seldom consistent.

In actual service, most coatings experience environmental factors that often continually change, are not reproducible, or are unforeseeable at the time of application. Examples include acid rain or other transient environmental pollutants. Chemical exposure, particularly in the vicinity of chemical plants or other heavy industrial environments, can also contribute to degradation. Testing for chemical resistance would be relevant when such factors can be identified and is discussed elsewhere in the manual.

ACCELERATED WEATHERING DEVICES

Carbon Arc and Xenon Arc

Carbon arc and xenon arc lamp devices are used to expose specimens to UV radiation, elevated temperature, and water spray. The test conditions for paint and coatings are outlined in ASTM Standard Practice for Filtered Open Frame Carbon Arc Exposures of Paint and Related Materials (D822). The basic principles and operating procedures for xenon arc devices are found in ASTM Standard Practice for Operating Xenon-Arc Light Apparatus for Exposure of Nonmetallic Materials (G155). Additional information for these devices can be found in Standard Practice for Operating Open Flame Carbon Arc Light Apparatus for Exposure of Nonmetallic Materials (G152) and ASTM Standard Practice for Operating Enclosed Carbon Arc Light Apparatus for Exposure of Non-metallic Materials (G153).

There are several devices manufactured by several companies that use either carbon arc or xenon arc light sources. The light source for these devices should be chosen by the chemical nature of the material to be tested since the spectra of the various light sources are different and produce different weathering results. For both the carbon arc- and the xenon arc-based devices, it is very important to monitor the levels of irradiance at a selected wavelength if the data are to be used for comparison purposes. This is required because there is a progressive decrease in radiation intensity as the lamp ages. This can be overcome by progressively increasing the lamp wattage, thereby minimizing the changes in intensity, and by monitoring the radiation output as described in the corresponding ASTM procedure. The newer devices include the monitor and automatically adjust the wattage to keep the intensity constant.

Both carbon arc and xenon arc procedures include four test methods:

1. Continuous exposure to light and intermittent exposure to water spray.

2. Alternate exposure to light and darkness and intermittent exposure to water spray.
3. Continuous exposure to light without water spray.
4. Alternate exposure to light and darkness without water spray.

A typical cycle used for evaluating coatings with these devices is 102 min of light at 145 ± 5°F (63 ± 3°C) and 18 min of light and water spray at 60 to 63±2.5°F (15.5 to 17±1.5°C).

Fluorescent UV/Condensation

With fluorescent UV bulb devices as described in ASTM Standard Practice for Operating Fluorescent Light Apparatus for UV Exposure of Nonmetallic Materials (G154), specimens are cycled between exposure to UV light and condensation in a heated environment.

The light source for the QUV[3] and UV2000[4] is composed of eight fluorescent lamps that produce light in the UV range. The light source may be any of the UV fluorescent bulbs produced for accelerated weathering. The particular bulb used will determine the nature of and speed at which the results are acquired. The exterior of the specimen rack is exposed to room temperature, and the inside is exposed to heat and humidity produced by the lights and a heated water bath. The condensation is caused by the temperature differential that exists between the front and back of the mounted specimens. The exposure can be varied by changing the temperature, the length of the light, and/or the condensation segments of the cycle. A few models are also available with a spray option. The spray option can be used to simulate thermal shock or erosion by water.

The samples are mounted in brackets, which form the cabinet wall. The panels are stationary and set at an angle so condensate can run off the test surface and be replaced by fresh condensate in a continuous manner. Vents along the bottom of the chamber permit an exchange of ambient air and water vapor to prevent oxygen depletion of the condensate. The specimens are placed approximately 50 mm from the lamps. In instruments with irradiance control, the lamps and samples do not need to be rotated and the lamps are changed only when irradiance drops below the set point. In instruments without the irradiance control, both the lamps and the panels have to be manually rotated at specified intervals to ensure even UV exposure.

Various tests can be selected. If no conditions are specified, ASTM G154 suggests 4 h of UV light at 60°C and 4 h of dark condensation at 50°C. Test temperatures of 50, 60, and 70°C are widely used.

Fluorescent UV-Salt Fog

The Mebon Prohesion Cabinet [10], a cyclic corrosion chamber, was originally developed as an alternative to the standard salt fog cabinet, ASTM Standard Practice for Operating Salt Spray (Fog) Apparatus (Bl17) for conducting corrosion resistance studies. Further studies revealed that when used in conjunction with a device providing a light source, there was use as an accelerated weathering device. The procedure is outlined in ASTM Standard Practice for Cyclic Salt Fog/UV Exposure of Painted Metal, (Alternating Exposures in a Fog/Dry Cabinet and a UV/Condensation Cabinet) (D5894).

The cyclic corrosion chamber introduces a spray or fog by means of an external reservoir and a peristaltic pump operating at a flow rate of from 0.5 to 1.5 ml/h. Although a variety of solutions can be used, one consisting of 0.35 % ammonium sulfate and 0.05 % sodium chloride (Harrison's solution) is recommended for corrosion studies. A series of experiments with this device indicated that, at least for corrosion rate studies, this solution provided more realistic results than the warm, 5 % sodium chloride solution used in salt fog cabinets[2] [11,12]. The conclusion that these test results were more realistic was based on an analysis of the corrosion products. This analysis revealed that the amount of sulfur and chloride salts on panels exposed to the particular salt solution was similar to the amount and type found on the panels that had been corroded at an outdoor location. Due to the nature of the instrument, almost any exposure solution can be used to customize the testing for the location.

The fog, introduced at ambient temperature, is eliminated by forcing air through the device at 23 to 55°C. Not only does this assist in drying the panels, it also replenishes the oxygen. The wet-dry cycles can be varied from 1 to 10 h. Since the cabinet is not outfitted with a light source, it is necessary to manually move the panels from the cyclic corrosion chamber to a fluorescent UV/condensation device to incorporate the element of light into the test. The standard practice outlined in ASTM D5894 involves weekly rotation between the two instruments.

Fresnel Reflector

There are three methods for accelerating natural weather exposure: black box, heated black box, and Fresnel reflector. These are described in ASTM Practice for Conducting Black Box and Solar Concentrating Exposures of Coatings (D4141). The first two methods accelerate the weathering by increasing the temperature of the exposed surface and are discussed in the natural weathering section. The Fresnel reflector is the only method that collects and intensifies natural sunlight to accelerate weathering. The basic principles for this method are found in ASTM Practice for Performing Accelerated Outdoor Weathering of Nonmetallic Materials Using Concentrated Natural Sunlight (G90). It is performed in the desert region of Arizona using Sun-10, FRECKLE, EMMA, EMMAQUA, or other similar devices that involve the use of a mirror array [7, 13]. A more detailed description of this device is presented in the chapter that deals with natural weathering.

The concentration of sunlight is achieved by collecting sunlight on ten mirrors and focusing the reflected light onto the specimen. The assembly is designed to actually follow the track of the sun as it moves through the sky. The device is equipped with a blower to regulate the surface temperature of the specimen. The maximum surface temperature that can be reached is limited to no more than 10°C above the maximum temperature normally achieved by natural

[3] ASTM has found suitable devices available from Atlas Electric Devices Co., 4114 Ravenswood Ave., Chicago, IL 60613 and from Quartzlampen GmbH, 6450 Hanau/Main, Germany (domestic distributor is Batson Machinery, Inc., P.O. Box 3978, Greenville, SC 28608).

[4] ASTM has found suitable devices available from Q-Panel Co., 26200 First St., Cleveland, OH 44145 and from Atlas Electric Devices Co.

weathering. The test may be performed with or without water spray. The water spray is provided by an oscillating nozzle assembly, which supplies deionized water as a fine, dense mist. The water spray provides a thermal shock effect and is sprayed on the samples for set cycle times. A common cycle is 8 min of water spray per hour. Exact cycles are given in ASTMG90.

Since this method uses natural sunlight, the spectrum produced follows that of natural sunlight but at a higher intensity level. The testing can be performed for specific levels of solar exposure or for specific time periods. The quantity of light is measured by a radiometer, and it is expressed as total solar radiant exposure. The preferred method is based on solar exposure since this quantification accounts for the natural seasonal variations of sunlight. This allows, for example, results obtained in January to be directly compared to those obtained in July.

Newer technology has permitted better temperature control during cloud cover and night time exposures. Additionally, changing the number of mirrors used at different times of the year can control the irradiance levels throughout the exposure time and lead to results that may be correlated to results obtained in the future [13].

Ultrafast Weathering

In contrast to all of the above methods, this technique of ultrafast weathering does not wait for visual changes to occur on the surface. At the present time, this method is still being evaluated to determine if there is any correlation between the information gathered using electron spin resonance (ESR) spectroscopy to monitor radical formation and natural weathering results [2]. The theory behind ultrafast weathering is based on the assumption that the radicals, which form within the first several hours of the test, will reveal the relative stability of the coating. For this testing, the process of radical formation is induced by UV radiation greater than that of sunlight. The light is filtered to remove unwanted shorter wavelengths and also focused on the sample using a cooled mirror. The sample is placed between the poles of a magnet in the microwave resonator of the spectrometer. The radical formation is plotted as a function of light-exposure time. Each paint will produce a characteristic curve. If a correlation is found to exist, the curves of different paints are then to be compared to determine which exhibits the best UV light stability. This testing could be completed over several hours instead of days, months, or years.

Chemical Resistance

Latoska N. Price[1]

THE ABILITY OF A COATING TO RESIST CHEMICAL deterioration or staining is an essential element in its evaluation [1]. Aesthetics play a key role in the decoration of a coated object. Certainly more purchasers of coated products are moved initially by appearance than by price. It has been said that a coating is a complex material that is often a component of a coatings system, which in turn provides added value to a final product.[2] What follows is a review of established test procedures with various levels of complexity and equipment sophistication that provide standardized tools for evaluation of potential flaws such as discoloration, softening, swelling, adhesion loss, gloss reduction, and pitting of the paint finish. Some methods include visual standards such as those for blister size and density or for corrosion which offer a common ground for communication or performance properties between the manufacturer and the end user of a coating. Other tests are less definitive, and while they can give insight as to how the paint may function during service, they do not necessarily correlate precisely with real life conditions. Yet, since these tests are to function in lieu of actual field exposure to predict ultimate performance, it is crucial that accelerated or simplified test parameters reproduce both the chemical as well as the physical effects of field exposure.

STAINING

Staining tests provide a thorough method of determining the ability of a coating to resist discoloration from household chemicals, chemical reagents, and other materials common in today's environment. The tests generally expose the coating surface to a spot of the reagent on the coating surface or by immersion of a coated test panel in the reagent for a specified period with timed checkpoints.

Staining from Household Chemicals

ASTM D1308, Test Method for Effect of Household Chemicals on Clear and Pigmented Organic Finishes, encompasses the evaluation of discoloration, change in gloss, blistering, softening, swelling, loss of adhesion, or other phenomena resulting from a variety of household chemicals such as distilled water, ethyl alcohol, or vinegar. Materials or chemicals suggested as reagents are outlined in Table 1.

Other materials can also be used as specified by the customer or seller. The procedure utilizes open and watch glass covered spot tests with the reagent at ambient temperature as well as immersion tests in the reagent.

Staining in the Transportation Industry

ASTM D1308, as previously mentioned, was the supplement to ASTM D1540, Test Method for Effect of Staining Agents on Organic Finishes Used in the Transportation Industry. The latter document has been withdrawn, but is available from Internet sources. Some materials or chemicals suggested as reagents are listed in Table 2.

As with ASTM D1308, discoloration, change in gloss, blistering, softening, swelling, loss of adhesion, or other phenomena are examined after testing. With some reagents, exposure to sunlight or UV radiation for a specified time is required. Elevated temperature is also used to more closely simulate surface conditions in hot, sunny climates. Gasoline resistance tests combine dripping of fuel at ten drops per minute at a 20° angle with a UV lamp trained on the surface at a 90° angle. Adequate ventilation and safe handling of the dispensing and collecting vessels are essential to safety when working with gasoline. The staining potential of solid materials requires close contact of the reagent with the surface and heat exposure before evaluation.

Staining Resistance of Furniture Finishes

Decorative finishes for wood and metal furniture can include substrates such as wood, multi-density fiber board, steel or aluminum which require more from coatings to withstand normal use. Coatings for these substrates can be waterborne or solvent borne and used for such painting techniques as marble and stone replication, the creation of visual and physical textures, painted distressed finishes, glaze effects, one of the various crackle techniques or simply to provide color. One detail these finishes all have in common is that they require a high degree of stain resistance in order to preserve the decorative surface.

Staining resistance of furniture finishes is covered as part of ASTM D3023, Standard Practice for Determination of Resistance of Factory-Applied Coatings on Wood Products to Stains and Reagents. This procedure is concerned with materials such as cosmetics, alcohol (ethanol), boiling water, and coffee. Cosmetics contain a number of waxes (e.g., candelilla, carnauba, microcrystalline) and/or oils (e.g., olive, castor) that are particularly staining. Ethanol, the alcohol found in liquors, can do particular damage since ethanol can oxidize in the air to produce acetic acid while coffee, rich in phenol acids (tannins), will wreck havoc on a furniture finish if left in contact with the surface for a period of time. Think of the dreaded coffee ring

TABLE 1—Staining from Household Chemicals		
Item	**Contains**	**Found in**
Alkali solution	Sodium hydroxide	Oven cleaners
Acid solution	Acetic acid	Vinegars
Soap and detergent solutions	Sodium percarbonate based bleaching systems, antimicrobial agents	Laundry detergents, soap scum removers, degreasers
Lighter fluid	Petroleum distillates	Starter for charcoal briquette fires
Fruit cut	Citric acid, tartaric acid, malic acid	Oranges, apples, grapes
Oils and fats	Simple or mixed glycerol esters of organic fatty acids	Meats, salad dressings, margarines, butter, cooking oils
Condiments	Turmeric, ascorbic acid	Mustard, ketchup, grape jelly
Beverages	Phosphoric acid, food dyes	Colas, wines, Kool-Aid
Lubricating oils and greases	Petroleum distillates	Furniture polish

left by a coffee cup, sans coaster, in direct contact with the furniture surface.

Boiling water and hot coffee, prepared by various methods, are poured on a horizontal panel surface and allowed to dry, and the surface is examined for graying, spotting, softening, staining, or other film deterioration. Cosmetics are applied to the coating surface and placed in a 50°C oven overnight and examined for discoloration or film failure. Fifty percent alcohol or 100 proof vodka is trapped on the coating surface using a 25-mm (1-in) square of double acid washed quantitative filter paper to maintain a longer wet contact with the surface of the finish.

SOLVENT/FUEL RESISTANCE

ASTM D2792, Test Method for Solvent and Fuel Resistance of Traffic Paint, relates a method of evaluating the resistance of a coating to solvent and fuel that causes blistering, wrinkling, loss of adhesion, and loss of hardness. The coating is applied to tin panels and air dried for 90 h. Half the panel is immersed in the test liquid, and the vessel is covered for a period of 4 to 18 h as may be specified by the customer. The panels are then removed and examined for defects. The panels are allowed to dry for another 24 h and re-examined for film defects and softening as compared to the unimmersed portion of the control panel.

If subtle differences between coatings are important such as comparative research and development efforts, then the panels can be examined more often without drying at intervals such as 1, 2, 4, 6, 24, and 48 h.

Battelle Chemical Resistance Cell

Several advantages over other immersion methods are claimed for this cell [2], which was developed in the course of research sponsored by Steel Shipping Container Institute, Inc. at Battelle Memorial Institute:

- Panels may be flat or indented
- Edge effects area voided
- Simultaneous testing in liquid and vapor
- Wider range of temperature

The cell consists of a Pyrex glass tube, open at both ends, held horizontally between coated test panels (Fig. 1). A convenient glass tube size is 2 in. (5.08 cm) in diameter and 3 in. (0.762 cm) in length with the ends ground flat. Gaskets are used between tube and panels to give a liquid-tight seal. The frame has screw adjustments for tightening the assembly. A sponge rubber pad behind one panel evens the pressure. A glass ring is used to surround the dimple when an indented panel is under test. The cell is filled through a hole in the middle of the tube. In use, the cell is half filled and stoppered tightly.

Bratt Conductivity Cell for Chemical Resistance

This cell [3], was designed to use conductivity of a film during chemical resistance tests as a measure of its chemical resistance. The cell proper is a 2-oz vial from which the bottom has been removed, in effect becoming a short piece of glass tubing. The cell is formed by the base plate and an additional plate with a hole that fits over the top of the vial and rests on the shoulder.

TABLE 2—Sources of stains	
Reagent	**Examples**
Glycol-based antifreeze up to 100 %	Glycol ethers
Acid, alkali, and salt solutions	Roads salts like sodium chloride or calcium chloride
Polish abrasives, creams, and waxes	Carnauba wax
Road oils and tars	Binders for asphalt, road dust control
Gasoline	Petroleum distillates
Water	Minerals
Hydraulic fluids	Glycols or silicones
Alcohol windshield washing solutions	Isopropyl alcohol
Sunscreen	Cinnamates, benzophenone, anthranilates or para-aminobenzoic acid
Insect spray	N,N-diethyl-m toluamide (DEET)

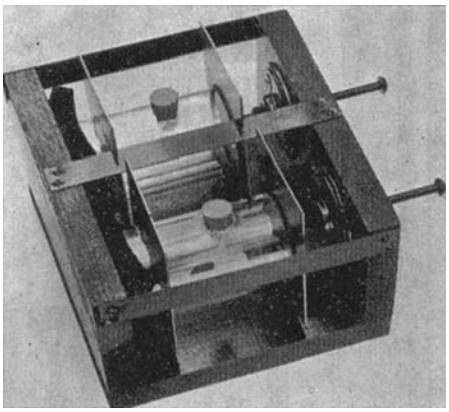

Fig. 1—Battelle chemical resistance cell. (Courtesy of Battelle Memorial Institute.)

During a test, a potential of 15 V is applied to the cell. The metal substrate serves as the positive electrode. The external resistance is selected to produce a voltage drop of about 14 V across the cell.

Resistance

Gearhart-Ball [4] solvent resistance tests utilize free coating films. The cup test employs a free film fastened over the top of a beaker or dish. Approximately 20 ml of solvent is poured over the film, and the length of time required to puncture the film is noted. This test would be considered a crude screening test. More precise data can be derived from the Distensibility test where a tensile strength strip (see ASTM D2370) is clamped with either a tensile tester jaw or an alligator clip on the upper end, and the bottom end is clamped with an alligator clip with a 12-g weight and immersed in a clear beaker containing the solvent reagent. The beaker is immediately marked with the initial length, and the time required to elongate the strip one inch is recorded.

Solvent Rub Resistance

Although solvent resistance can be evaluated using ASTM D1308, many use or adapt a solvent rubbing technique with a gauze cloth soaked in a solvent (MEK is common) and rubbing with the thumb back and forth in 2-in. (5.08-cm) strokes. This procedure, ASTM D4752, Test Method for Measuring MEK Resistance of Ethyl Silicate (Inorganic) Zinc-Rich Primers by Solvent Rub, is imprecise because the person's strength and the size of the thumb are variable. Nevertheless, it provides a quick relative test without having to wait for exposure results. The MEK resistance of some two-component ethyl silicate zinc-rich primers has been shown to correlate well with the cure of the primer as determined by diffuse reflectance infrared spectroscopy.

ACID RESISTANCE AND ACID ETCH RESISTANCE

Acid resistance is determined by exposing a coated panel to freshly prepared mortar as well as a hydrochloric acid solution and is fully described in ASTM D3260, Test Method for Acid and Mortar Resistance of Factory-Applied Clear Coatings on Extruded Aluminum Products. The acid resistance test is performed by first sealing the edges of a specially coated panel with a paraffin and beeswax mixture and then immersing the panel in a 10 vole % solution of 31.6 % solution of HCl at ambient temperature for 6 h, followed by rinsing, drying, and examination for blistering, peeling, lifting, crazing, flaking, or discoloration. Acid resistance however, should not be confused with "acid etch" resistance which is a completely different chemical resistance property. The acid etching of an exterior coating results from sulfur dioxide emissions from the atmosphere. In an automotive clearcoat, for example, etching appears as a non-removable water spot. The physical damage of etch is associated with a localized loss of material resulting in visible pitting of the surface. Evaluation of acid etch resistance is typically evaluated through the use of field testing usually in Jacksonville, Florida. While there is no definitive ASTM test for acid etch resistance, several laboratory tests have been developed.[3,4] Mortar resistance is performed by applying a fresh mortar patty, prepared to a specified formula, to both sides of the specially coated panel and then placing it in a high relative humidity cabinet for seven days. The mortar is then carefully removed and the panel wiped off with a damp cloth followed by examination as with the acid test.

ALKALI AND DETERGENT RESISTANCE

ASTM D1308, Test Method for Effect of Household Chemicals on Clear and Pigmented Organic Finishes, is also recommended for evaluating alkali and detergent resistance. It is a simple common sense technique that can be used for many materials or chemicals that can stain or discolor a coating. The choice of testing materials should be related to the coatings end use. As previously mentioned, ASTM D1308 describes techniques for either immersing the coated substrate in the reagent, putting a small amount of the material on the coated surface and covering with a small watch glass, or just leaving the material on the surface uncovered. The coating is then checked for staining after a period of time or at 1, 2, 4, 6, 24, and 48 h intervals.

For detergent resistance of appliance finishes, a solution of a specified detergent containing a high percentage of sodium phosphate is applied and the temperature maintained at 165°F (73.8°C) for the duration of exposure, usually 250 to 500 h. The test panel is submerged at least six inches into the solution. This is a more severe test than a spot test, but it is more representative of actual service conditions. Examination is done after rinsing and blotting the panel and looking for any manifestation of coating failure.

ASTM D154, Standard Guide for Testing Varnishes, and related but withdrawn ASTM D1647, Test Method for Resistance of Dried Films of Varnishes to Water and Alkali, describes an alkali resistance immersion test using coated test tubes. The use of test tubes coated by dipping into the coating prevents the reagent from creeping under the edge of a flow-on film. As many as 20 tubes are prepared for this test, allowing examination after 1 to 8, 16, and 24 h. The exposed specimens are rinsed with water and allowed to dry for 30 min before examining for whitening, blistering, or removal of the film.

[4] Holubka, J.W., Schmitz, P.J., Xu, L. "Acid Etch Resistance of Automotive Clearcoats II, Comparison of Degradation Chemistry in Laboratory and Field Testing," Journal of Coating Technology, Vol. 72, No. 902, March 2000, pp. 53–61.

WATER AND MOISTURE RESISTANCE

Resistance to water/moisture is potentially affected by many variables such as water source (deionized, tap, pH, saltwater, fresh), exposure format (water vapor or liquid), immersion conditions (static or stirred, stagnate or refreshed), application schedule (cyclic or continuous), temperature (heat/ drying; freeze/thaw). A number of exposure chambers are commercially available including salt fog cabinets, humidity cabinets, and cyclic chambers, that test moisture resistance as well as other resistance criteria, especially weathering.

For resistance to continuously wet conditions, a simple practical test is to partially immerse a coated sample in a glass beaker containing water. The water is maintained at 100°F (37.7°C) for an extended period of time, and panels are periodically checked for discoloration, whitening, or blistering of the film. The test results are compared to a specification or standard sample run concurrently. The procedure for this test is ASTM D870, Standard Practice for Testing Water Resistance of Coatings using Water Immersion.

SALT FOG TEST

Salt fog resistance is important for marine, automobile, and aircraft coatings and any other exterior coating exposed to salt spray by being near the ocean or exposed to salted road conditions. The severe corrosion caused by salt is well known. Salt Fog testing (ASTM B117) is popular because it is simple to run and powerfully accelerates corrosion. However, reproducibility is highly dependent on strict process control of the equipment operating parameters. The use of replicate panels plus positive and negative controls is likewise critical.

Caution is required when comparing salt fog resistance among various coating/substrate combinations in order to predict service life. Certain substances are notorious for poor resistance to salt fog, yet have an excellent record of field exposure corrosion resistance. Additional factors such as sample configuration (especially the presence of moisture traps such as hem flanges or coach joints) also strongly influence corrosion.

Familiarity with ASTM G1 Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens and G16 Guide for Applying Statistics to Analysis of Corrosion Data will also be beneficial. Communication of corrosion results will be facilitated by reference to visual standards such as those for blister size and density (ASTM D714 Standard Test Method for Evaluating Degree of Blistering of Paints) and for corrosion (ASTM D610 Standard Test Method for Evaluating Degree of Rusting on Painted Steel Surfaces).

The test requires a salt fog cabinet and coated panels. The coating is scored to the bare substrate with an X shape (Fig. 2). The edges are sealed with a weatherproof tape, and the panel is placed in the cabinet for a specified period of time. The metal panels are exposed to the settling fog of an atomized neutral (pH 6.5 to 7.2) sodium chloride solution consisting of five parts by weight sodium chloride and 95 parts distilled or deionized water. The sample is then periodically checked to see if the rusted exposed metal has propagated under the coating causing coating failure (Fig. 3). As with water resistance, the results are compared to a standard or a specification.

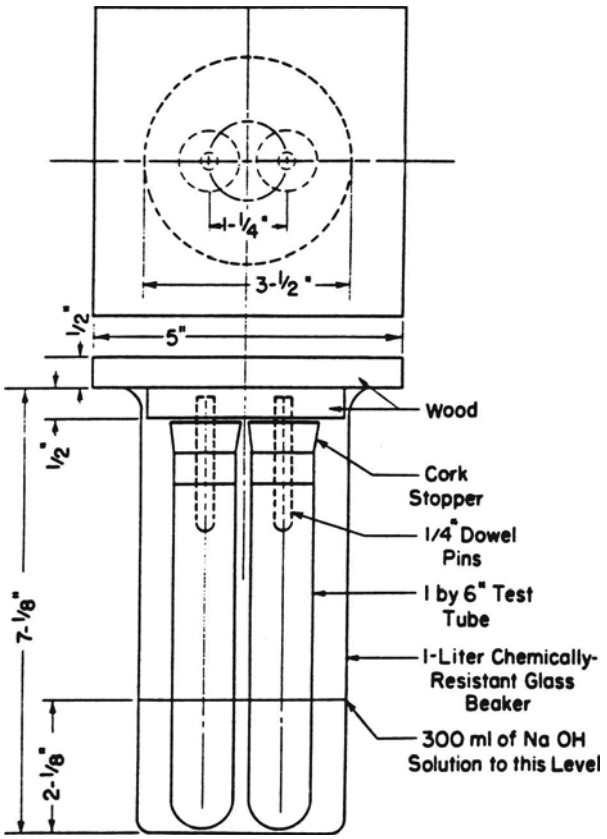

Fig. 2—Apparatus for alkali resistance test.

A typical salt spray cabinet as shown in Fig. 4 incorporates a basic chamber, an air saturator tower, a salt solution reservoir, atomizing nozzles, specimen supports, a heater, and controls for maintaining specified temperature. Such chambers are available commercially from several suppliers. The testing procedure, ASTM B117, Practice for Operating Salt Spray (Fog) Apparatus, describes this method in more detail.

HUMIDITY EXPOSURE

Humidity exposure tests are widely used to test paint film integrity. Exposure to humidity can cause deleterious effects to a coating which can manifest as blisters, or delamination. In ASTM D2247 Practice for Testing Water Resistance of Coatings in 100 % Relative Humidity, the panel face is exposed to 100 % relative humidity at 38°C while the back of the panel is exposed to room temperature conditions. This allows for water to continually condense on the panel surface. ASTM D1735-08 Standard Practice for Testing Water Resistance of Coatings Using Water Fog Apparatus covers the basic principles and operating procedures for testing water resistance of coatings in an apparatus similar to that used for salt spray testing. Alternative practices for testing the water resistance of coatings include ASTM D870 Practice for Testing Water Resistance of Coatings Using Water Immersion and ASTM D4585 Practice for Testing Water Resistance of Coatings Using Controlled Condensation.

PHOTOCHEMICAL WEATHERING

Virtually all exterior field service on earth includes exposure to UV radiation and photochemically induced changes are a key factor in reproducing changes in chemical resistance during use. ASTM D4141, Conducting Black Box and Solar Concentrating Exposures of Coatings, describes several procedures for use in evaluating the degradation of coatings as a result of outdoor exposure. Environmental factors such as acid rain or alkaline bird droppings, as well as repeated heating and cooling, also contribute to a loss of coating film integrity which can result in loss of adhesion and a decrease in gloss. For these reasons, accelerated weather testing now frequently includes cyclic exposure to elevated temperatures and moisture as well as UV radiation. ASTM G155 Operating Xenon Arc Light Apparatus for Exposure of Non-Metallic Materials describes a frequently used artificial weathering method.

Cyclic Testing

The recognition that a warm, continuously wet environment does not accurately simulate the field exposure condition for many coatings/substrate systems, has led to implementation of cyclic test methods. The objective is to shorten test length while preserving the chemical degradation that occurs in the actual field service as well as replicating damage to coating and substrate. Research has documented the transitions from wet to dry more accurately replicated forms of corrosion such as pitting observed in the field. Similarly, cycling above and below the Tg of the coating also accelerates degradation.

ASTM D6675 Practice for Salt-Accelerated Outdoor Cosmetic Corrosion Testing of Organic Coatings on Automotive Sheet Steel, GM 9504P General Motors Accelerated Corrosion Test, JASO M610 Cosmetic Corrosion Test

Method for Automotive Parts, SAE J1563 Guideline for Laboratory Cyclic Corrosion Test Procedures for Painted Automotive Parts, and SAE J2334 Cosmetic Corrosion Lab Test describes practice and schedules for various moisture, heat and electrolyte exposure combinations for automotive products. Other cyclic methods are oriented to the specifics of other application and expected field conditions.

Apparatus for cyclic test can be fully or partially automated. Equipment may or may not include exposure to radiation. In partially automated systems, samples may manually move between different test chambers such as in D5894 Practice for Cyclic Salt Fog/UV Exposure of Painted Metal, Alternating Exposures in a Fog/Dry Cabinet and a UV/ Condensation Cabinet.

Water-Resistance Testing of Coatings

John Fletcher[1] and Joseph Walker[2]

PREFACE

IN PREPARATION OF THIS CHAPTER, THE CONTENTS of the fourteenth edition were drawn upon. The authors acknowledge the author of the fourteenth edition, Wayne Ellis (Deceased). The current edition will review and update the topics as addressed by the previous author, introduce new technology that has been developed, and include up-to-date references.

Other chapters in this manual cover the influence of water on the formulation and durability of organic coatings. Recent ASTM publications about the moisture effects in building materials are listed in the Bibliography at the end of this chapter. These publications describe moisture problems and solutions involving coatings and their uses. Although this chapter is intended to describe only the principal testing and evaluation of water resistance, some general remarks may be helpful in understanding the test conditions.

EFFECTS ON COATINGS OF EXPOSURE TO WATER AND WATER VAPOR

The adhesion of coatings to substrates is strongly influenced by the absorption of water and by the permeability of the coating to water vapor. The mechanism of this influence proceeds as follows [1]:

1. Absorption of water molecules in the coating film.
2. Inclusion of water in the interface between film and substrate.
3. Blister formation.
4. Corrosion/erosion of the substrate.
5. Flaking or peeling of the film.

Although there is no fixed relationship between water absorption and water vapor permeability, generally the higher the water absorption the more permeable the film is to water vapor. Normally the permeability measurements are made on freshly applied films. It should be noted that with progressive aging and weathering, films become more cross-linked, and in the case of water-sensitive binders, the water-soluble additives are washed out by exposure to rain and dew. Hence such films will show decreasing permeability with time.

Water resistance is defined by ASTM as "measured ability to retard both penetration and wetting by water in liquid form" [2]. It is a required property for coatings in almost all cases. Water resistance generally is measured on specimens of coatings applied to nominally impermeable substrates such as metal, wood, or masonry. (Water vapor permeability, on the other hand, is evaluated on free films.) Water resistance may be evaluated as part of other test regimes, such as exposure testing, water repellency, corrosion, chemical resistance, salt-fog resistance, and cycling tests such as humidity-cycling and light-and-water-exposure testing.

Water repellency is defined as the property of some materials which makes water hardly stick to them (hydrophobic). Chapter 67 of the Gardner Sward Coating Handbook deals with water repellent coatings.

Water-repellent coatings appear in some ASTM test methods for coatings on concrete and wood. D6489, Standard Test Method for Determining the Water Absorption of Hardened Concrete Treated with a Water Repellent Coating, describes a procedure for the determination of the water absorption by a core of concrete taken from a surface treated with a water repellent. The specimen is dried to a constant weight and the portions of the specimen not treated with the water repellent are sealed with an impervious sealing material. The specimens are weighed and immersed in water. The specimens are removed from the water, weighed, and percent water absorption is calculated.

Water repellent coatings on wood are described in D4446 and D5401. D4446, Standard Test Method for Anti-Swelling Effectiveness of Water-Repellent Formulations and Differential Swelling of Untreated Wood When Exposed to Liquid Water Environments, describes measurement of the swelling after immersion. Wood samples in the form of elongated slats that represent the timber species or product/treatment combination to be evaluated are exposed in soak containers. The elongated slats are immersed in the water-repellent formulation, conditioned with appropriate weighing, and then subjected to immersion in distilled water for a prescribed period. The untreated slats omit the immersion in the water-repellent formulation. The swelling resulting from immersion for the selected time period is determined by reading a dial gage calibrated in increments of 0.025 mm (0.001 in.). A water repellent efficiency of 60 % is required to pass this test.

D5401, Standard Test Method for Evaluating Clear Water Repellent Coatings on Wood, evaluates the effectiveness of clear water repellent coatings on wood before or after exterior exposure. Five ponderosa pine specimens are treated with the clear water repellent under test and allowed to dry for seven days. Five untreated specimens serve as controls. The treated and untreated specimens are each weighed and then allowed to float in water for 30 min. The specimens are removed, the excess water is wiped off, and each is reweighed. The effectiveness of the water repellent coating is then calculated.

PERMEABILITY CUPS

ASTM E96, [3] Standard Test Methods for Water Vapor Transmission of Materials and D1653 [4], Standard Test Methods for Water Vapor Transmission of Organic Coating Films, both include wet cup methods using the Payne Cup (Fig. 1). A free film of paint is created on a surface that can be peeled off the film when it is cured, for example, silicone paper is suitable for some types of paint. This film is used to cover the aluminum cup, which contains a quantity of water. The film is tightly clamped with a sealing gasket to the lip of the cup and the cup together with the film and the water are carefully weighed. The cup is left for the period of the test so that the water evaporates and the cup and its contents are weighed and the weight loss is noted. The permeability of the film can be calculated from the weight loss, the area of the cup and the duration of the test.

There is a useful paper describing problems with the wet cup method for films with moderate to high water vapor permeability and how to improve results [5].

There are instruments on the market that measure the water vapor transmission of films more easily and rapidly than the methods described in ASTM E96 and D1653. However, it appears that no side-by-side tests have been run comparing such instruments to the wet cup methods for precision and accuracy. It is probable that instrumental methods offer considerable advantages where water vapor transmission measurements must be carried out often and/or in large numbers, but where only occasional measurements are needed, Payne Cups are adequate and economic.

TRADITIONAL TEST METHODS

Spot tests and immersion tests of coatings applied to substrates traditionally have been used as "quick and dirty" techniques to compare specimens. Criteria for evaluation include softening, blistering, solvation, color change, loss of adhesion, and rusting or other deterioration of the substrate. These observations should lead to further and more comprehensive testing related to intended conditions of product use. Such testing may include immersion, exposure to controlled condensation, 100 % relative humidity, or water fog to evaluate moisture-blistering resistance. Even more intensive testing may involve washability and scrub resistance.

SPECIMEN PREPARATION

Careful preparation of coated specimens is essential to assure a proper and meaningful relationship to field exposure and to avoid false test results. The substrate composition and surface preparation, specimen preparation, and the number of specimens should be agreed upon between involved parties prior to testing. Applicable methods for the preparation of test panels are given in ASTM Methods D609 [6], D1734 [7], and Practice D1730 [8]. Test Methods D823 [9] cover application techniques for the production of uniform films.

EVALUATION

ASTM D1654, Standard Test Method for Evaluation of Painted or Coated Specimens Subjected to Corrosive Environments describes the evaluation in terms of the blistering associated with corrosion, the loss of adhesion at scribe marks on the specimen, softening of the film or other film failure.

IMMERSION TESTING

ASTM Practice for Testing Water Resistance of Coatings Using Water Immersion (D870) describes basic principles and operating procedures for testing water resistance of coatings by the partial or complete immersion of coated specimens in distilled or demineralized water at ambient or elevated temperatures. Coated specimens are partly or wholly immersed in water in a container that is resistant to corrosion (Fig. 2). The exposure conditions are varied by selecting the temperature of the water and the duration of the test.

Failure may be caused by a number of factors, including a deficiency in the coating itself, contamination of the substrate, or inadequate surface preparation. Any effects such as color change, blistering, loss of adhesion, softening, or embrittlement are observed and reported. These test results typically are a pass or fail determination, but the degree of failure also may be measured.

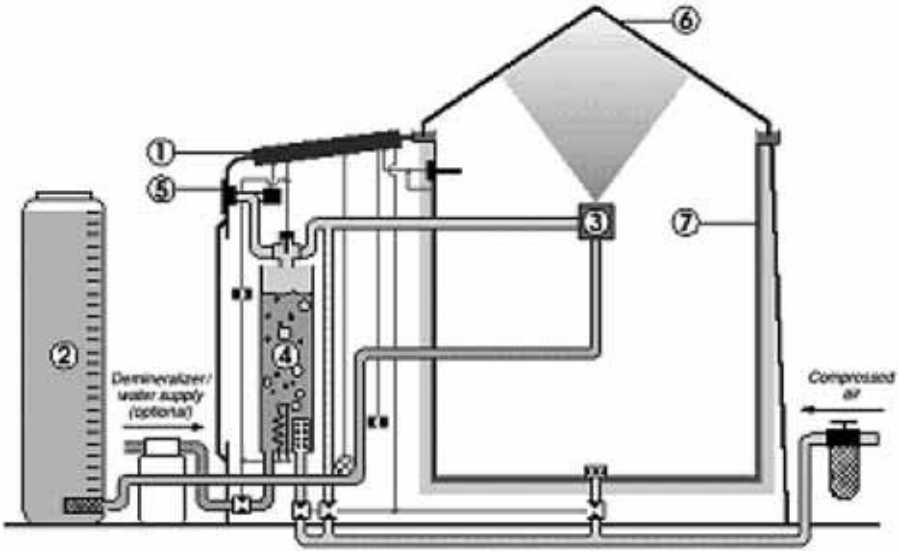

Fig. 3—Typical Salt-spray Cabinet. (Reprinted by permission of Elcometer Inc.)

WATER FOG TESTING

ASTM Practice for Testing Water Resistance of Coatings Using Water Fog Apparatus (D1735) covers the basic principles and operating procedures for testing water resistance of coatings in an apparatus similar to that used for salt spray testing [10]. The apparatus required (Fig. 3) consists of a fog chamber, a water reservoir, a supply of suitably conditioned compressed air, one or more atomizing nozzles, specimen supports, provision for heating the chamber, and necessary means of control. Coated specimens are placed in an enclosed chamber where a water fog surrounds them. The temperature of the chamber is usually maintained at 100°F (38°C). The exposure condition is varied by selecting the duration of the test.

Failure in water fog tests may be caused by a number of factors, including a deficiency in the coating itself, contamination of the substrate, or inadequate surface preparation. Any effects such as softening (measured by pencil hardness), color change, gloss change, blisters, loss of adhesion, embrittlement, and rusting or corrosion of substrate are observed and reported.

100 % RELATIVE HUMIDITY TESTING

Practice for Testing Water Resistance of Coatings in 100 % Relative Humidity (D2247) covers the basic principles and operating procedures for testing water resistance of coatings by exposing coated specimens in an atmosphere maintained at 100 % relative humidity so that condensation forms on the specimens. The apparatus (Fig. 4) consists of a test chamber, a heated water tank, and suitable controls. Heated water vapor is generated at the bottom of the chamber, causing saturation of the air immediately above the water tank. As the saturated mixture rises, it cools below the dew point temperature, causing condensation on the specimens suspended above. Condensation is uncontrolled. (For testing at 100 % RH with controlled condensation, see ASTM D4585, described below.)

Effects of exposure at 100 % relative humidity may be color change, blistering, loss of adhesion, softening, or embrittlement. Any such effects are observed and reported. They may be caused by a number of factors including a deficiency in the coating itself, contamination of the substrate, or inadequate surface preparation.

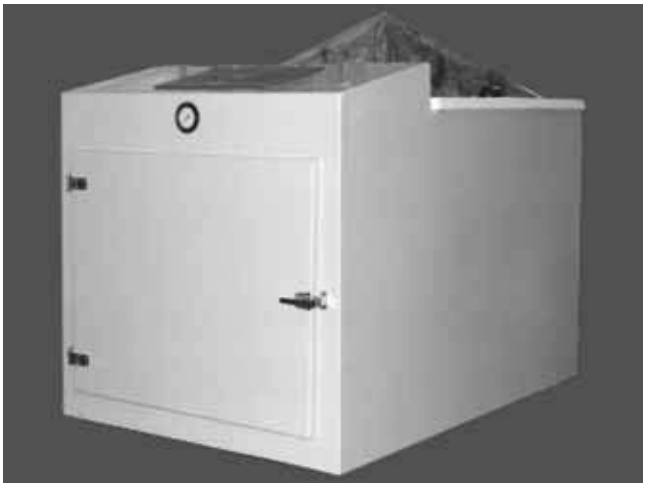

Fig. 4—Humidity Cabinet. (Reprinted by permission of Elcometer Inc.)

CONTROLLED CONDENSATION TESTING

Practice for Testing Water Resistance of Coatings Using Controlled Condensation (D4585) differs from D2247 in that the coated specimens are mounted with the uncoated face exposed to room temperature air. The apparatus (Fig. 5) consists of a test chamber in which the specimens form the roof of a chamber that is fitted with suitable water supply and controls.

Water vapor is generated by heating a pan of water at the bottom of the test chamber. The specimens form the roof or walls of the test chamber so that the reverse sides of the specimens are exposed to the cooling effects of room temperature air. The resulting heat transfer causes water

Fig. 5—Controlled Condensation Apparatus. (Reprinted by permission of Elcometer Inc.)

vapor to condense on the coated specimens as liquid water saturated with air. The temperature and amount of condensate forming on the specimens are controlled by the test temperature and room temperature.

The specimens are inclined so that the condensate runs off the test surface by gravity and is replaced by fresh condensate in a continuous process during the condensate cycle. Exposure conditions are varied by selecting the temperature of the test, the duration of the test, and periodic drying of the specimens. Failure may be caused by a number of factors including a deficiency in the coating itself, contamination of the substrate, or inadequate surface preparation. Any effects such as color change, blistering, loss of adhesion, softening, or embrittlement are observed and reported.

CYCLE TESTING

Test Method for Finishes on Primed Metallic Substrates for Humidity-Thermal Cycle Cracking (D2246) covers an accelerated means for determining the tendency of an organic coating to fail by cracking when exposed to humidity-thermal cycling. Although this method was withdrawn in 1992 without replacement it describes evaluation alternate exposure of prepared specimens in a cabinet maintained at 100°F (38°C) and 100 % relative humidity (with continuous condensation on the specimens), then in a cold box at –10°F (–23°C), allowing only a maximum of 30 s for transfer. Specimens are rated (using a grid overlay) by counting the number of grid squares within which one or more cracks is visible. Evaluation before and after exposure may be done for checking (D660 [11]), for cracking (D661 [12]), for erosion (D662 [13]), and sometimes for water beading (D2921 [14]).

ASTM test method for Humid-Dry Cycling for Coatings on Wood and Wood Products (D3459) was withdrawn without replacement in 2007 but describes a procedure for evaluation of coatings designed for use on interior wood and wood products by exposure alternately to low and high humidity at an elevated temperature. Test panels having a minimum area of 12 × 12 in. (300 × 300 mm) are exposed in 48-h cycles in exposure chambers maintained at 97 ± 2 % relative humidity and 122 ± 3.5°F (50 ± 2°C); the other chamber maintained at 50 ± 5 % relative humidity and 73.5 ± 3.5°F (23 ± 2°C). At each change of conditions during cycling, the panels are inspected under strong light for possible damage or change, which may be in the base material or in the coating. The 1998 version of D3459 is still available from ASTM.

Testing for the effect of water exposure combined with other exposures is not described in this chapter. Such testing includes light-and-water exposure apparatus using carbon-arc ultraviolet [15], Xenon-arc [16], and fluorescent UV [17]. It should be noted that UV or other weathering degradation (accelerated or natural) may impact coating water resistance characteristics. This is especially critical for substances that tend to be subject to dimensional instability (such as wood) or for coatings that are not opaque where the substrate can be affected by UV light.

ACCELERATED MECHANICAL EXPOSURE

In recent years efforts have been made to simulate real life conditions such as the effects of repeated automated washing of automotive paints. Such tests use a water, abrasive, detergent mix with rotating brushes to simulate the damage caused by worn, contaminated brushes to be found in automated car washes in commercial use.

The Car Wash Simulator (Fig. 6) is an example of such a test, utilizing a rotary brush, which can be set up using the same filaments that are used on commercial car washes.

WASHABILITY TESTING

Combination abrasion and scrub testing (D2486, D4213 and D3450) can be undertaken in wet conditions using individually controlled dosing units to introduce water between the abrasive brush or sponge to test paint on test panels or small components (Fig. 7).

Part 13: Specific Product Testing

59

Aerospace and Aircraft Coatings

Charles R. Hegedus,[1] Stephen J. Spadafora,[2] Anthony T. Eng,[3]
David F. Pulley,[4] and Donald J. Hirst[5]

ORGANIC COATINGS ARE PRIMARILY APPLIED TO aircraft for environmental protection and appearance. Reference [1] concludes, "The rate controlling parameter for the corrosion of aircraft alloys, excluding the mechanical damage factor, is the degradation time of the protective coating system." This clearly indicates the importance of the coating system's durability and its ability to control corrosion and erosion. Relative to appearance, commercial aircraft benefit from the aesthetic characteristics of the coating system, while military aircraft rely on camouflage properties to minimize enemy detection and tracking during mission operations.

To meet operational requirements, aircraft coating systems traditionally consist of a primer and a topcoat. Primers inhibit corrosion of the substrate and enhance adhesion of subsequent topcoats, while topcoats are applied for appearance and to enhance overall durability of the coating system. Self-priming topcoats, which perform as both primer and topcoat in a single coating, have recently been introduced [2,3]. In addition, specialty coatings are strategically applied to perform various functions such as protection against rain erosion, chafing, immersion in fuel, and high temperature. References [4–6] provide more detail on the formulation and properties of aircraft coatings.

A number of factors affect the performance of aircraft coatings, including the substrate material, the aircraft's operational environment, and flight conditions. Aircraft structures and skins are manufactured from numerous metallic alloys and polymeric composites with a variety of pre-paint treatments, thus complicating the adhesion and corrosion inhibition characteristics of the coating system. Environmental conditions also can vary dramatically (arctic, tropical, marine, industrial, desert, etc.). Skin temperatures during flight can range from –54 to 177°C (–65 to 350°F) while ground conditions may be relatively benign or highly corrosive. Aircraft type and mission also play important roles in coating system performance. A commuter aircraft that hops from island to island in the tropics sees frequent pressurization and depressurization along with high temperature, humidity, and salt water. In contrast, a military tactical aircraft may fly far fewer hours but will experience extreme structural loads during flight conditions. These flight conditions place environmental and mechanical stresses on the aircraft coating system. Therefore, selection of appropriate test and evaluation procedures is an essential component for determining acceptable coatings for aircraft application [7].

VISCOSITY

The viscosity of aircraft coating components, component mixtures, and raw materials is valuable to the formulator, manufacturer, and applicator for assessment of rheological characteristics. These characteristics affect paint application properties such as atomization, leveling, sagging, and brushability.

Cup Methods (Cup Viscometers)

In aircraft coating specifications and at application sites, Zahn and Ford cup viscometers are used for admixed paints because they are inexpensive, easy to use and maintain, and produce practical quantitative data. Although the stand-mounted, standard Ford cup is more accurate due to its stability, deeper capillary orifice, and larger volume, the dip-type Zahn cup is preferred since it is easiest to use and maintain. Zahn and Ford viscometers are described in ASTM Test Method for Viscosity by Dip-Type Viscosity Cups (D4212) and ASTM Test Method for Viscosity by Ford Viscosity Cups (D1200), respectively.

Brookfield and Stormer Methods

Brookfield and Stormer viscometers are rotation-type viscometers described in ASTM Test Method for Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield) Viscometer (D2196) and ASTM Test Method for Consistency of Paints Measuring Kerbs Unit (KU) Viscosity Using a Stormer-Type Viscometer (D562), respectively. The Brookfield viscometer, which measures absolute viscosities in centipoises (cP) using a rotating spindle, is particularly effective in determining viscosities of non-Newtonian fluids due to its ability to measure shear stress (that is, torque of rotating spindle) at various speeds and shear rates. Since the cup viscometers described above offer relative simplicity and ease of use, the Brookfield viscometer is not used at application sites. However, it is frequently used as a research tool to characterize the viscosities of polymeric resin materials and dispersions.

The Stormer or Krebs-Stormer viscometer uses a rotating paddle to measure relative viscosity expressed in Krebs units. It is designed to provide controlled, uniform, and relative data based on a paddle-stirring motion. This type of viscometer is rarely used in the laboratory or required in current specifications due to the ease of use and maintenance of cup methods and to the accuracy of the Brookfield method.

DENSITY

Wet coating density measurements provide a check on the theoretical density value and on the uniformity of the manufactured product. Determination of density by any convenient or suitable method in this Manual is acceptable; however, a weight-per-gallon cup is normally used due to the ease of use of this instrument. Typically ASTM D1475, Density of Liquid Coatings, Inks and Related Materials is followed.

FINENESS OF GRIND AND COARSE PARTICLES

Fineness of grind and presence of coarse particles are determined to assess the quality and uniformity of the pigment dispersion and coating finish. In order to produce a high gloss coating of good appearance, a paint should be free of coarse particles. However, the extremely low gloss requirements of some aircraft camouflage paints require relatively large particle sizes. Fineness of grind is determined by ASTM Test Method for Fineness of Dispersion of Pigment-Vehicle Systems by Hegman-Type Gage (D1210), commonly referred to as the Hegman scale. The coarse particle content is determined by the weight retained on a 325-mesh sieve as specified in ASTM Test Methods for Coarse Particles in Pigments (D185).

SOLID AND VOLATILE CONCENTRATION/ CONTENT

General

Several analysis techniques are used to determine the total solids, pigment concentration, and volatile concentration of aircraft coatings. This information can be used as a check on the coating composition when compared to the theoretical value as determined from the formulation. It can also be used to determine the quality of an as-received product and its potential surface coverage per volume of paint. In addition, restrictions on the volatile organic compounds (VOC) content of coatings increase the importance of determining the volatile concentration, and methods to determine this value are continuously being developed and refined. The following methods are currently used to determine these compositional properties for aircraft coatings.

Total Solids Content

The total solids content of a coating, often referred to as its nonvolatile content, is a measure of the combined polymer and pigment content in a paint. It is typically represented as the weight fraction or percentage of these "solid" components relative to the as-received "wet" coating. For aircraft coatings, this is determined by subtracting the volatile fraction of the coating from the total to determine the nonvolatile content. The method specified in ASTM Test Method for Volatile Content of Coatings (D2369) is used. A method that provides a volumetric assessment is ASTM Test Method for Volume Nonvolatile Matter in Clear or Pigmented Coatings (D2697).

Pigment Concentration

Three methods are available to determine the pigment weight concentration within a coating: ASTM Test Method for Determination of the Pigment Content of Solvent-Reducible Paints by High Speed Centrifuging (D2698); ASTM Practice for Separation of Vehicle from Solvent-Reducible Paints (D2372); and Federal Standard 141 Method 4021, Pigment Content (Ordinary Centrifuge). These methods use the fact that pigment particles, generally being more dense than the vehicle, will settle under centrifugal force. One distinction between these methods is the variation in rinsing solvent(s) used to separate the polymer from the pigment. Although each method utilizes a different solvent blend, it is common to deviate from the specified method by using solvents which are appropriate for the specific paint under analysis. All three methods result in a quantitative determination of pigment weight concentration in the paint; however, the latter two methods lend themselves to chemical analysis of the pigment sample after this determination.

Volatile Concentration

ASTM D2369 is a standard experimental method to determine the total volatile content of a coating. In contrast, ASTM Practice for Determining Volatile Organic Compound (VOC) Content of Paints and Related Coatings (D3960), offers a method of calculating the VOC using the nonvolatile content, the water content (if any), and the density of the coating. These latter values are predetermined using referenced ASTM methods, and they are subsequently used in the calculations to determine VOC of the paint. It should be noted that in solvent-borne coatings the VOC is the volatile content; however, water-borne coatings obviously have a nonorganic volatile component which must be taken into account when performing these calculations. The VOC is typically recorded in units of grams of organic volatiles per liter of paint with pounds per gallon used as an alternate.

Chemical Analysis

A variety of methods are used to analyze the chemical composition of aircraft coatings and their components. The specific technique that is selected is determined by the material being analyzed and the level of quantitative or qualitative data required. Some of the more common techniques to analyze polymer and solvent systems are gas chromatography, infrared and ultraviolet spectroscopy, and nuclear magnetic resonance (NMR). Atomic absorption and x-ray spectroscopy are common techniques for determining the chemistry of inorganic pigments. Table 1 provides some of the common ASTM methods used to analyze aircraft coatings.

TABLE 1—Analytical methods for aircraft paint components

Compound	ASTM Method
Ketones	D2804
Isocyanate	D3432
Water	D4017
Lead, cadmium, and cobalt	D3335
Chromium	D3718

Because of growing concerns over potentially toxic materials, restrictions are being placed on the lead and chromium content of many aircraft paints. These restrictions are in direct conflict with corrosion control requirements since chromate salts, such as strontium chromate, barium chromate, and zinc chromate, have been shown to be excellent corrosion inhibitors for many metals. Therefore, many specifications require analysis for these pigments to ensure either their presence or their absence. Specific methods to determine lead and chromate content are listed in Table 1.

STORAGE STABILITY

General

The effects of long-term storage on aircraft coating performance are a major concern. Long durations of time and extreme temperatures can have drastic effects on the chemical and physical nature of paints, causing them to have different properties than when they were originally manufactured. Since many aircraft manufacturing, rework, and maintenance activities have paint storage facilities that have only moderate environmental controls, determining the effects of these conditions is necessary. Of primary importance are chemical stability and pigment dispersion. These properties are assessed in the laboratory following long-term and accelerated storage conditions.

Long-Term Evaluation

Methods typically used for determination of stability of aircraft coatings are specified in ASTM Test Method for Package Stability of Paint (D1849), and Federal Test Method Standard (FTMS) 141 method 3022.1, Storage Stability (Filled Container). In these methods, the packaged coating is allowed to sit undisturbed at ambient conditions for an appropriate period of time. (One year is typical for aircraft coatings.) At that time, the coating is reevaluated to compare its physical and optical properties with those originally found for the as-manufactured material. Other methods may be used to evaluate specific aspects of the material at that time, such as FTMS 141 method 3011.2, Condition in Container; method 3021.1, Skinning; or method 4208, Evaluating Degree of Settling of Paint. In most cases, it is essential that (1) the paint be free from skinning, (2) the pigment has not reagglomerated or formed a compacted cake at the bottom of the container and it can be easily redispersed to form a consistent mixture, and (3) the applied coating has properties similar to when it was manufactured.

Accelerated Conditions

To speed the evaluation of a coating's behavior under storage conditions, methods have been devised to accelerate this behavior by subjecting the coating to extreme conditions. One common example is specified in FTMS 141 method 3019.1, Storage Stability at Thermal Extremes, which subjects the coating to 49°C (120°F) or –12°C (10°F) for 168 h, depending on the type of storage suspected. Methods involving cyclic exposure to high and low temperatures have also been used. With the development of high-performance water-borne coatings for aerospace applications, one major concern is the freeze-thaw stability of these coatings. ASTM Test Method for Freeze-Thaw Resistance of Water-Borne Coatings (D2243) is used to evaluate coating consistency and performance after 17 hat –18°C (0°F).

Another technique for predicting storage stability of coatings is by evaluating the settling properties of pigments under accelerated conditions. Aircraft coating specifications rarely contain this type of evaluation; however, centrifugation is often used as a research tool to evaluate the tendency of various pigments to settle and compact in specific vehicles. The centrifugal force and the duration are selected on a case by case basis to ascertain differences between systems.

FLASH POINT

General

The flash point of a coating is the minimum fluid temperature at which the solvent vapors are ignited by a spark or flame. It can be predicted roughly as the weighted average of the individual flash points for each of the solvents in a coating formulation. The closed-cup technique is generally preferred since container breakage during shipment and storage often leads to flammable vapors being trapped in a confined space. Naturally, these flash points tend to be lower than the corresponding open-cup values.

Pensky–Martens

The Pensky-Martens test is a closed-cup method that can be conducted on an admixed coating or on one of the separate components in the liquid (uncured) state. The material may be refrigerated to bring it to a temperature below the expected flash point. It is then placed in a closed metal cup, heated slowly while stirring, and periodically exposed to a pilot flame through a shutter mechanism. A thermometer immersed in the fluid measures the coating temperature. The flash point is the minimum temperature at which the solvent vapors ignite, yielding a large flame that propagates over the surface of the fluid. The procedure is covered in ASTM Test Methods for Flash Point by Pensky–Martens Closed Cup Tester (D93), Method A for clear coatings and Method B for pigmented coatings.

Setaflash

The Setaflash test uses an enclosed apparatus with automatic controls to determine the flash point. It is easier to operate than the Pensky-Martens tester and utilizes an electric heater for efficient heat transfer and greater accuracy. ASTM Test Methods for Flash Point of Liquids by Small Scale Closed-Cup Apparatus (D3278), Method B describes the test procedure.

Tag

The Tag tester is similar to Pensky–Martens, except that the cup is placed in a bath containing a mixture of water and ethylene glycol. Only coatings with no suspended solids (such as, fillers) can be evaluated. ASTM Test Method for Flash Point by Tag Closed Cup Tester (D56) is the applicable test method.

POT LIFE

Pot life is the length of time in which the flow properties (such as, viscosity) of catalyzed paints will not change within an acceptable range for application. Acceptable coating conditions can vary from no change up to gellation. Pot life requirements in the aerospace industry tend to be controlled by production limitations. Since a normal production work shift is 8 h, many paints have been required to

have a pot life spanning this period. More recently, restrictions on the volatile organic content compounds (VOC) of paints have resulted in high solids coatings that tend to inherently possess higher viscosity and shorter pot life (2–6h). Pot life of aircraft coatings is usually determined by measuring viscosity as a function of time after mixing the paint for application. Substantial increases in viscosity are an indication that the pot life is nearly expended.

It should be noted that the issue of pot life can be circumvented via the use of plural-component spray equipment, which is becoming more common in the production painting of aircraft. This equipment stores the various components of a multi-component paint separately and then mixes those components at the desired ratio immediately before or at the spray gun. This equipment not only negates pot life as a factor but also minimizes the amount of catalyzed multi-component paint that is wasted due to unused material. The only drawback is that the equipment is most effectively and efficiently used when large volumes of paint (5 gal or more) are used as opposed to small quantities (1 gal or less), which are typical of touchup maintenance operations.

DRYING TIME

ASTM Test Method for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature (D1640) defines drying times of paint films. As many as eight stages of the paint drying process are recognized by coatings authorities. Determination of a particular set of drying properties is important for aerospace coatings due to the strict time and processing constraints placed on production and maintenance painting facilities. No particular drying time parameters are universal throughout the aircraft industry. Each paint facility has acceptable limits for these drying properties depending on their function, schedule, and climatic conditions. For example, set-to-touch time may be more important to a small parts shop where components are handled shortly after painting. In contrast, dry-hard times may be paramount at a production facility for painting entire aircraft that must be flown shortly after painting.

Set-to-Touch

A film is set-to-touch when it clings weakly to the finger under gentle pressure but none of the film transfers to the finger. This property indicates that the painted piece can be handled gently, but excessive contact will diminish the quality of the coating. This property may be considered important to shops painting small aircraft components which must be moved from the application area.

Tack-Free

Basically, tack is the tenacity of the film to cling to foreign objects. This component of drying is not considered of major importance in production painting; however, it may be used to ascertain the overall drying characteristics of a coating.

Dry-to-Recoat

This stage of drying is considered to be the most important for painting of aircraft because it is one of the major factors controlling the production rate. Dry-to-recoat is the time at which a second coat, or specified overcoat (such as, topcoat), can be applied without developing irregularities in the coating system, such as lifting, blistering, or loss of adhesion. If overcoated prior to the recoat time, these defects can be caused by a number of factors, one of which is the trapping of solvent in the original coat.

Dry-Hard

The most common technique is to squeeze or pinch the coated surface with the thumb and forefinger with maximum pressure. The dry-hard time is when this procedure can be performed without leaving a permanent mark on the coating surface. This drying stage is also important in production painting of aircraft since painting is usually the last stage of maintenance and the aircraft can be flown after the coating is dry-hard.

FILM THICKNESS

Aircraft coatings are developed and manufactured to be applied within acceptable thickness limits. Coatings which are applied outside of these limits will not exhibit their optimum performance properties. For example, thin coatings may not have the required tensile and shear strength, making them susceptible to cracking and chipping, especially around fastener heads and at panel seams. In contrast, coatings which are too thick may lack flexibility and can exhibit excessive internal stresses. Another important consideration is the excessive weight that coatings add to an aircraft, causing additional fuel consumption. Therefore, coating thickness is diligently controlled and measurements are performed in both the wet and dry states.

Wet coating films are checked for thickness during aircraft application processes using various wet film thickness gages according to ASTM Test Method for Measurement of Wet Film Thickness of Organic Coatings (D1212). A tooth gage is commonly used in the aerospace industry since it is simple to use, inexpensive, and can be used to obtain good approximations of dry film thickness. These approximations are made by multiplying the wet film thickness by the coating volume percent solids.

The thickness of cured aircraft coatings can be determined either destructively or nondestructively. Destructive methods involve the chipping or cutting of dry films from a substrate and subsequent measurement of the coating thickness with a gage. This approach is typically not taken for aircraft coatings since the coating-substrate bond must be destroyed. Nondestructive techniques include micrometer, eddy current, magnetic induction, and a magnetoresistor/ thermistor system. These are the most desirable methods of dry film thickness determination used in the aerospace industry, both in the field and in the laboratory due to their accuracy and ease of use. One problem encountered is that aircraft are constructed of a number of types of materials. Therefore, the method used to determine coating thickness may depend on the substrate material, especially if a nondestructive method is used. One method for film thickness testing is ASTM D7091, Practice for Nondestructive Measurement of Dry Film Thickness of Nonmagnetic Coatings Applied to Ferrous Metals and Nonmagnetic, Nonconductive Coatings Applied to Non-ferrous Metals.

OPTICAL PROPERTIES

General

The appearance of an applied coating is determined by a number of optical properties (color, gloss, opacity, etc.).

In the commercial aerospace industry, where public opinion is a consideration, these optical properties can strongly affect the initial impression of the aircraft and are considered to be important with respect to customer recognition. The optical properties of coating systems for military aircraft affect the detectability of these aircraft and thus effect their survivability in potentially threatening scenarios. In both the commercial and military sectors, optical properties are specified with strict tolerances and are closely monitored with instrumentation as well as with the naked eye.

Color

The colors used on commercial aircraft tend to be strong and vibrant for recognition and attraction. The colors of military aircraft coatings are empirically selected in order to achieve either theater-specific (desert, forest, arctic, etc.) or multitheater (world-wide) camouflage paint scheme requirements. In either case, paint color is considered to be important. In addition, color change is often used to assess the effects of environmental exposure (weathering, immersion in fluids, etc.) on aircraft coatings. Means of characterizing aircraft coating colors range from qualitative visual assessment to quantitative measurements with instruments, the latter providing the obvious advantage of consistent, numerical results. For the latter, ASTM Standard Practice for Calculation of Color Tolerances and Color Differences from Instrumentally Measured Color Coordinates (D2244) is followed, resulting in a color description in either the XYZ or Lab color coordinates. Color differences, as qualified by a delta E value, are determined by using these color coordinates as described elsewhere in this manual to determine delta E.

One additional note must be made with respect to color measurement of aircraft coatings. Colorimeters and spectrophotometers can both be used to quantitatively measure color. Colorimeters use a specified light source with defined radiation wavelengths and intensities, typically resulting in a direct output of XYZ and/or Lab color coordinates. Spectrophotometers measure light reflected from the coating surface over an entire wavelength region. (In the case of color characterization, this is the visible region of the spectrum.) Of the two, colorimeters are less expensive and easier to use. However, colorimeters do not account for metamerism. Metamerism is a phenomenon that occurs when an object appears to be different colors under different light sources. This effect is observed with some coatings for military aircraft, which use unconventional pigments to obtain camouflage properties. In order to confirm that two colors are the same, their total reflectance over the entire visible spectrum must match. These data are obtained using a spectrophotometer. In addition, spectrophotometers are frequently used for military aircraft coatings to determine their reflectance characteristics outside of the visible region, most commonly the infrared and ultraviolet regions.

Opacity (Contrast Ratio)

Opacity or hiding power is the ability of a coating to mask the underlying substrate. Opacity of aircraft coatings is usually quantified by its contrast ratio according to ASTM Test Method for Hiding Power of Paints by Reflectometry (D2805). In this method, the coating is applied over white and black substrates. (Contrast ratio or Leneta charts are typically used.) A colorimeter is used to measure the coating's luminous reflectance (Y) on the black and white surfaces. Contrast ratio is then determined by:

$$\text{Contrast ratio} = Y(\text{black})/Y(\text{white})$$

Contrast ratio is a function of coating dry film thickness. The method must define the coating thickness at which the contrast ratio is determined; 2.0 mils is common for aircraft topcoats. Applying a coating to a precise thickness is difficult and may require several attempts. An alternative approach is to determine the contrast ratio at several coating thicknesses and subsequently fit the data to a quadratic equation. This equation can then be used to determine the contrast ratio at the desired coating thickness.

Reflectance and Gloss

Incident light which is reflected from a surface has two components, specular and diffuse. Specular reflectance or gloss represents light that has been reflected off a surface when the angle of incidence equals the angle of viewing. Diffuse reflectance is light reflected in all directions other than specular. Specular reflectance data are usually obtained via glossmeters whereas diffuse reflectance data are obtained by the use of goniophotometers.

Gloss of aircraft coatings is measured by instruments that have been standardized to either 60° or 85° incident angles according to ASTM Test Method for Specular Gloss (D523). Commercial aircraft coatings have high gloss and are usually characterized at 60°. In contrast, many military aircraft are painted with low gloss coatings for camouflage purposes. In addition to gloss analysis at 60°, military coatings are also analyzed at 85° in order to minimize glare at grazing angles.

Directional reflectance represents the optical data that are obtained from analyzing reflected diffuse light. This type of data is normally obtained via goniophotometric equipment. Several methods describe procedures for these measurements, including ASTM Test Method for Color and Color-Difference Measurement by Tristimulus Colorimetry (E1347) and Practice for Goniophotometry of Objects and Materials (E167). The use of diffuse reflectance of aircraft coatings is typically limited to those for tactical military functions that require camouflage properties.

ADHESION

General

For aircraft coatings to provide maximum protection against degradation, they must firmly adhere to their substrate. Because of the complex nature of adhesion, various techniques have been devised to determine the adhesive characteristics of coatings. Since a coating's adhesion to its substrate can be significantly affected by environmental conditions, these tests are often performed after exposure to accelerated conditions such as immersion in water at elevated temperature. Common adhesion tests used to evaluate aircraft coatings are tape and scrape tests. Other techniques, such as mechanical peel, tensile, and shear tests, are used less frequently.

Tape Tests

Adhesion tape tests are described in ASTM Test Methods for Measuring Adhesion by Tape Test (D3359). These are

the easiest and most versatile of the adhesion tests because they can be conducted in both laboratory and field environments. Tape tests are performed by cutting through the applied coating, into the substrate. A variety of scribe patterns can be used. One common pattern (described in the "A" method of D3359), which is used to evaluate aircraft coatings, is two scribes forming an "X." An alternative pattern (described in the "B" method of D3359), is formed by scribing eleven parallel lines through the coating, followed by a second set of eleven lines which are perpendicular to the first set. These scribe lines create a matrix of 100 squares. Adhesive tape is firmly applied over the scribe area and is subsequently removed with a quick upward motion. Coating adhesion is then characterized using standard ratings for the amount of coating removed according to the ASTM method.

As mentioned above, the coated specimens can be subjected to a specific environment prior to testing adhesion characteristics. This practice is most commonly performed with the tape tests. A typical exposure for aerospace coatings is a 24 h immersion in water at 21°C (70°F). More severe exposures are becoming common as coating technology advances. One example is immersion in water at 65°C (150°F) for seven days. Immediately upon removal from the water, the coating is scribed and tested.

Scrape Adhesion Test

The scrape adhesion test is described in ASTM Test Method for Adhesion of Organic Coatings by Scrape Adhesion (D2197). Scrape adhesion is used to characterize the adhesive and shear strength properties at the primer-substrate interface. The instrument used for this test is the Gardner Labs Scrape Adhesion Test Apparatus (Model SG-1605). The specimen for this test has an area which is uncoated with the substrate exposed. The test is performed by guiding a weighted stylus at a 45° angle to the specimen along the exposed substrate into the coating system. The scrape adhesion value is recorded as the heaviest weight used without shearing the coating from the substrate. Typical scrape adhesion values for aerospace primers fall into the 3 to 5 kg range.

The scrape adhesion test is also used to determine the intercoat adhesion between a topcoat and a primer. When testing this property, a specimen with a section of primer exposed is used and the stylus is guided across the primer into the topcoat. Typical scrape adhesion values for aerospace topcoats also fall into the range of 3 to 5 kg. This test can also be performed after exposure to severe environmental conditions.

Peel and Tensile Tests

Peel test methods are rarely used for aircraft coatings. Instead, a modified version of an adhesive peel test is occasionally used. In this test, two thin metal strips are bonded together using the coating as the adhesive. One end of the specimen is left unbonded, and the metal strips at this end are separated to form a "T." They are subsequently pulled apart in a tensile machine, and the force needed to pull the two strips apart is recorded as the adhesive peel strength of the coating. The type of failure (adhesive or cohesive) is also recorded. An adhesive failure indicates that the coating strength exceeds that of the coating-substrate adhesive strength.

The most common tensile adhesion test used on aerospace coatings is a tensile pull-off test, also referred to as a button test. In this test, a flat head paten is bonded to the surface of the coating with an adhesive. A tensile force is then applied to the paten perpendicular to the coating surface until the paten is removed. The location at which the paten is removed from the surface must be carefully examined. In many cases, the adhesive which bonds the paten to the coating will fail or the coating may fail cohesively. In these cases, it can only be stated that the adhesive strength of the coating exceeds the tensile strength recorded. Only if the coating fails adhesively is the recorded tensile strength that of the coating-substrate adhesion.

FLEXIBILITY

General

Flexibility is an important property for aerospace coatings, particularly at low temperatures (–51°C), which is common for aircraft cruising at high altitudes. Cracking of coatings at skin joints and around fastener heads can lead to corrosion of exposed areas. Corrosion inhibiting epoxy primers used on aircraft tend to be brittle and exhibit poor flexibility, whereas the urethane topcoats are generally more flexible, especially at low temperatures. Sealant materials and elastomeric primers occasionally are used to improve the overall flexibility of the paint system.

Mandrel Bend

The flexibility of high-performance coatings is commonly characterized by the mandrel bend test method outlined in ASTM Test Methods for Mandrel Bend Test of Attached Organic Coatings (D522). This test is normally conducted at low temperatures such as –51°C and is performed by bending a painted specimen 180° around mandrels of various diameters with the coating aligned away from the mandrel. After allowing the specimen to return to room temperature, the coating is examined for cracking along the bend. The smallest (most severe) mandrel diameter that the coating can withstand without cracking is recorded. One standard military specification requirement for this test on low gloss coatings is a 2-in. mandrel bend while more flexible coatings can withstand mandrel bends of 1/8 to 1/4 in. at low temperatures without cracking.

Impact Tests

The most universal test for measuring impact flexibility of aerospace coatings is Method 6226 (G.E. Impact) of Federal Test Method Standard 141B. The test apparatus consists of a solid steel cylinder weighing 1.69 kg (3.7 lb), which has spherical knobs protruding from the end. These knobs are designed such that the coating system is subjected to elongations of 0.5, 1, 2, 5, 10, 20, 40, and 60 %. The impact is accomplished by allowing the steel cylinder to fall freely from a height of 1.05 m (42 in.) through a hollow cylinder guide, striking the reverse uncoated side of the specimen. The imprints formed from the knobs are examined, and the impact elongation is recorded as the highest deformation without cracking of the coating. A standard requirement for this test on aircraft topcoats is 40 % elongation.

Another commonly used test is the Gardner impact test specified in ASTM Test Method for Resistance of Organic Coatings to the Effects of Rapid Deformation (Impact)

(D2794). This test is performed in a similar fashion to the G.E. impact test described above; however, the weighted cylinder has a rounded end and is dropped from various heights. The weight of the impact cylinder and the highest height that causes no cracking or disbondment of the coating are used to calculate an impact strength, usually in inch-pounds. This test can be performed directly on the coated side of the panel or, like the GE impact test, on the reverse, uncoated side.

Tensile (Elongation) and Fatigue Tests

For aerospace coatings, free films of the coating generally 5 mils thick or greater are prepared and tested for tensile characteristics. Epoxy primers have relatively high tensile strengths (>2500 psi) but very poor elongations (<10 %), whereas flexible primers can have elongations exceeding 100 %. It should be noted that the rate of deformation has a significant effect on mechanical properties, including tensile, and this must be clearly specified as part of the testing procedure. For this reason, elongations obtained from impact tests cannot usually be directly correlated with those from tension tests.

Fatigue tests are not usually performed to study coating performance. However, fatigue testing of coated specimens with fasteners has been performed to study cracking of aircraft paints around fastener heads. In these studies, increased flexibility of the coating generally leads to less cracking and better overall performance. Isolated studies [8] have been reported in which coatings were used as a variable in fatigue testing of metal test fixtures. In these studies, a series of specimens were exposed to a corrosive environment to induce corrosion fatigue. In these cases, flexibility and corrosion inhibition are essential characteristics of the coating.

WEAR RESISTANCE

General

Aircraft coating systems can experience wear due to a number of causes and mechanisms. The most obvious of these is abrasion at leading edges of wings, antennas, and radomes caused by impingement of rain, sleet, dirt, and other debris. Since these leading edges are critical to flight dynamics, special wear-resistant coatings are often applied to these areas to protect the underlying substrate from damage. Another form of wear can be caused from the movement of adjacent parts such as flaps and stabilizers. In addition, internal parts such as bearings may be coated to prevent excessive wear. Since all of these types of wear cause different mechanisms of coating degradation, a number of varying tests are performed to simulate in-service conditions. For example, coatings that protect against rain erosion do not usually protect well against erosion from sand. Specifications for aircraft coatings (other than those for rain erosion) typically do not contain wear tests; however, development and selection of new aerospace coatings often require that characterization of wear properties be performed. Therefore, careful evaluation of wear mechanisms and selection of suitable evaluation methods is essential for these types of coatings.

Rain Erosion

There are a number of facilities throughout the United States that have built equipment to evaluate rain erosion. Some of these facilities are discussed in Refs. [9,10]. In general, coatings are applied to a small specimen that is subsequently secured to a test fixture arm. The test is performed by spinning this arm in a chamber with falling water droplets that impinge upon the coated surface. Parameters of the test include:

1. Substrate material, thickness, and geometry.
2. Coating type and thickness.
3. Water droplet size and falling rate.
4. Testing arm speed (specimen-water droplet impact).

Although attempts to correlate data from various test rigs have been unsuccessful at obtaining quantitative relationships, trends in coating performance have been observed. These trends generally agree with rain erosion performance on aircraft.

Taber Abraser

ASTM Test Method for Abrasion Resistance of Organic Coatings by the Taber Abraser (D4060) is a frequently used test throughout the coatings industry because it is well defined and relatively easy to perform. As such, it is often used for aircraft coatings to assess their wear characteristics. Care must be taken in interpreting Taber abraser results since reproducibility of data from lab to lab is not consistent.

HARDNESS AND MAR RESISTANCE

Pencil Hardness

The most frequently used test for hardness of aircraft coatings is the pencil hardness test, ASTM Test Method for Film Hardness by Pencil Test (D3363). Briefly stated, it is performed by guiding pencils of various hardness across a coating surface to determine the hardest pencil that will not scratch or mar the coating. The test is used on aircraft coatings for several reasons, including:

1. To assess coating cure and cure rate.
2. To evaluate the coating's ultimate hardness.
3. To evaluate damage caused by weathering and operational fluids (such as, by comparing coating hardness before and after exposure).

Shore Hardness

The Shore hardness test [ASTM Test Method for Rubber Property-Durometer Hardness (D2240)] is inappropriate for thin coatings (thickness <6.4 mm or 0.25 in.). However, for thicker coatings such as sealants, ablative, and intumescent materials it can be used to evaluate hardness, cure, and environmental effects.

Arco Microknife

Although the arco microknife test was originally designed to evaluate adhesive strength of coatings, it has been used to determine hardness. This can be performed by placing a specified weight on the diamond stylus and determining the number of scratch cycles required to cut through the coating. It can also be performed by determining the weight needed to get through the coating with a specified number of cycles.

Mar Resistance

Mar resistance is not usually considered a critical property for aircraft coatings. One method is the balance beam test that uses the scrape adhesion apparatus described in ASTM

Test Methods for Adhesion of Organic Coatings by Scrape Adhesion (D2197). The method determines the weight required to mar a coating surface with a stylus.

CORROSION INHIBITION

Salt Spray

Corrosion resistance is an important property for aerospace coatings, and numerous tests have been developed to evaluate the corrosion preventive properties of coatings, ranging from simple exposure studies to sophisticated electrochemical analysis.

Salt spray tests are commonly used as accelerated corrosion resistance tests for coatings. The two primary methods used for aircraft coating systems are the 5 % NaCl neutral salt spray test covered by ASTM Practice for Operating of Salt Spray (Fog) Apparatus (B117) and the acidified SO_2/salt spray test covered by ASTM Practice for Modified Salt Spray (Fog) Testing (G85—Annex 4). Specimens coated with an aircraft finishing system are usually scribed with an "X" through the coating into the substrate and then exposed for various times (usually 2000 to 4000 h for ASTM B117 and 500 to 1000 h for ASTM G85—Annex 4). Exposure periods for coatings vary for different substrate materials and can be selected either as a specified duration or as the point where significant differences in finishing system performance are observed. After exposure, the panels are inspected for corrosion in the scribe area and blistering or uplifting of the coating across the specimen. Subsequently, the coatings can be carefully removed from the surface without disturbing the underlying substrate by using a chemical stripper, and the specimen surface can be examined for evidence of corrosion.

Standard aircraft epoxy primer/polyurethane topcoat systems perform well on aluminum substrates in the neutral test, normally exhibiting no significant corrosion products in the scribe or any blistering of the coating after 2000 h. These materials may last up to 4000 h without any evidence of corrosion. The SO_2/salt spray environment simulates stack gases, such as those found in industrial areas and on diesel-powered aircraft carriers, and aircraft engine exhausts found on the flight deck of all aircraft carriers. It is an extremely aggressive environment, and aircraft systems exposed to this environment tend to fail at much shorter times than in the neutral test. A system exhibiting no significant corrosion products or blistering after 500 h is normally considered acceptable in this acidified environment.

Because numerous materials are used in the construction of aircraft, the contact of dissimilar conductive materials is common. When this occurs, the potential for galvanic corrosion is high if the two dissimilar conductive materials are not insulated from each other. In many cases, organic coatings are applied to provide this insulation. Therefore, it is becoming common to assess the ability of aircraft coatings to inhibit galvanic corrosion by painting and exposing specimens containing dissimilar conductive materials. One example is a graphite-epoxy composite coupled to aluminum.

Immersion Studies

Total immersion corrosion tests can be severe depending on the immersion solution, duration, and exposure temperature. Again, blistering or uplifting of the coating or corrosion of the underlying substrate constitutes failure in this test. Although this type of evaluation is not typically performed on aircraft paints, coatings requiring a high degree of impermeability, like those used in or around aircraft bilge areas, galley, lavatories, and other areas where water can be entrapped, would be evaluated with this type of test.

Filiform Corrosion

Filiform corrosion occurs on painted aluminum, steel, and magnesium in a high-humidity and elevated temperature environment containing oxygen and chloride ions. Filiform initiates at points where the coating ruptures (commonly around fastener patterns or panel seams) and propagates as filaments under the coating. If unchecked, damage of the coating system can allow other corrosion mechanisms such as stress corrosion cracking, exfoliation, and crevice corrosion to ensue. Typical filiform corrosion tests involve exposing coated specimens to hydrogen chloride vapors and then placing them into a high-humidity (85 % to 95 % RH) and elevated temperature (85 to 140°F) environment for a specified duration such as 1000 h. It should be noted that this type of corrosion is prominent on pure aluminum. For this reason, the test is performed on aluminum clad specimens in lieu of aluminum alloy.

Electrochemical Analysis

Reference [11] provides a thorough review of electrochemical methods used to evaluate the performance of corrosion protective coatings. Of these methods, electrochemical impedance spectroscopy (EIS) is one of the most promising techniques because it provides both qualitative and quantitative information about the corrosion resistance properties of the coatings and the substrates to which they are applied. In addition, EIS can give insight on the nature of their interfacial adhesion. References [12,13] provide detailed descriptions of EIS and its application for analyzing organic coating/metal substrate systems. EIS measurements can be made using a system consisting of a computer interfaced to a frequency-response detector and a potentiostat/galvanostat. Test cells consist of a glass o-ring joint clamped onto a coated metal specimen [12]. Electrolytes used for specimen exposure can range from distilled water to neutral or low pH salt solutions.

For an EIS experiment, the test cell described above is filled with the selected electrolyte solution. A reference electrode (such as, Calomel) and a counter electrode (such as, platinum or graphite) are immersed in the cell with the metal substrate serving as the working electrode. The EIS cell is allowed to reach equilibrium as indicated by its open circuit potential or steady-state rest potential. Small excitation amplitudes, usually in the 5- to 10-mV range, are introduced to the system, and the response signal is measured. These data can be correlated to an electrical circuit consisting of resistors and capacitors. The information from this electrical circuit is a model depicting the electrochemical reactions occurring in the coating-substrate system. Because of the detailed quantitative information that is obtained from EIS analysis, its use as a tool to research high-performance aircraft coatings is growing. In many cases, attempts are made to correlate EIS data with results from other corrosion studies such as salt spray. This approach provides a detailed assessment of coating integrity, durability, and corrosion inhibition.

WEATHERING AND ENVIRONMENTAL EXPOSURE

Outdoor Exposure

Outdoor exposure tests are normally conducted over periods of one year or more. In an effort to produce timely results, these tests are not frequently performed on aircraft coatings. However, older specifications, such as MIL-C-83286, did require a one year exposure of coated panels on an outdoor test rack in Florida. It was specified that the panels must be at a 45° angle and facing south. After this exposure period, the coating is evaluated for changes in color, gloss, and flexibility.

The U.S. Navy has instituted a program to evaluate the exterior durability of coatings in its operational environment by placing exposure racks on aircraft carriers and other ships. Results of these exposures have resulted in identification of successful aircraft coatings. Details of this effort are provided in Ref. [14].

Accelerated Weathering

The components of outdoor natural weathering that have the most significant effects on coatings and other materials are ultraviolet radiation and water (humidity, condensation, rain, etc.). It has been proposed that these conditions can be simulated and that the resulting effects can be accelerated by subjecting coatings and other materials to high-intensity light (including ultraviolet wavelengths) and water.

The most common accelerated weathering methods used for aircraft coatings are the xenon-arc Weatherometer and the QUV accelerated weathering tester. The former method is described in ASTM Standard Practice for Operating Xenon Arc Light Apparatus for Exposure of Nonmetallic Materials (G155). Again, there is a number of test variables that have significant effects on coating performance, and various laboratories have adopted slightly different procedures and parameters. Since there are no precise correlations between natural weathering and any of the accelerated methods for aircraft coatings, it is especially important that the test variables are well defined. One common approach that is used in military and federal specifications (MIL-PRF-85285, Coating, Polyurethane, High Solids and TT-P-2756, Polyurethane Coating: Self-Priming Topcoat, Low VOC) follows ASTM G155 as a guideline. The exposure is performed in a 6000-W, xenon arc weatherometer with a continuous cycle consisting of 102 min of high-intensity light only and 18 min of light and water spray. The conditions in the chamber are as follows:

1. Black body temperature 60°C (140°F)
2. Relative humidity 50 %
3. Intensity of the arc wavelength 0.55 W per m^2 at 340 nm.

The exposure period is 500 h, and the coating is subsequently evaluated for changes in gloss, color, and flexibility.

The second common method for accelerated weathering is described in ASTM Standard Practice for Operating Fluorescent Light Apparatus for UV Exposure of Nonmetallic Materials (G154). In this case, specimens are subjected to periods of ultraviolet light and condensation, respectively. During the condensation period, the coating surface is exposed to 100 % relative humidity at elevated temperature, while the backside of the specimen is exposed to cooler air, thus producing water condensate on the coating. Exposure parameters include UV intensity, duration of exposure to each condition, and temperature of the chamber and condensate.

Humidity

Since high temperature and humidity can cause coating disbondment and substrate corrosion, extreme humidity exposure is often performed on aircraft coatings to evaluate their resistance to such environments. Again, exposure parameters vary and must be clearly specified for reproducibility and interpretation of results. ASTM Practice for Testing Water Resistance of Coatings in 100 % Relative Humidity (D2247) is usually followed. The chamber conditions are 49°C (120°F) and 100 % relative humidity with constant condensation on the coated panels. A typical exposure period can range from 30 to 90 days.

FLUID RESISTANCE

Aircraft coatings are frequently subjected to aggressive operational and environmental fluids. Several examples are hydraulic fluids, engine oils, fuel, de-icing solutions, and cleaners. In order to assess the resistance of aircraft coatings to these fluids, a number of exposure tests are performed. The exposure can range from a simple wiping action to long-term immersion. The temperature of the exposure is also a critical variable. Following exposure, the specimen is usually evaluated for degradation of the coating (discoloration, softening, blistering, etc.) and substrate (corrosion).

Water Resistance

Resistance to water is usually performed by total immersion. The severity of the exposure can range from 24 h at ambient temperatures to seven days at 65°C (150°F). Since water can play a significant role in coating disbondment [15], adhesion tests are frequently performed immediately upon removal of the coated specimen from water immersion.

Another technique is to measure the water absorption (up-take) of a coating as a function of immersion time. This is performed by simply weighing the coated panel (or free film) as a function of immersion time. Water up-take values for high-performance aircraft coatings can range up to 20 %.

A third technique to characterize the effects of water on a coating is to determine its water vapor transmission rate (WVTR). WVTR is a measure of the rate at which water will permeate through a coating. ASTM Test Method for Water Vapor Transmission of Organic Coating Films (D1653) describes two methods to determine WVTR. In Method "A," a free film of the coating is sealed to the open mouth of a cup containing distilled water. In Method "B," the free film is sealed to a cup containing desiccant. These fixtures are exposed to controlled environments (temperature and humidity), and they are weighed periodically to determine the rate of water vapor diffusion through the coating. Aircraft coatings must exhibit low WVTRs to maintain their adhesion and corrosion inhibition.

Organic Solvent Resistance

Resistance to organic solvents is usually performed by rubbing a coated panel with a cloth dampened with a specified

solvent. Since toluene and methyl ethyl ketone (MEK) are both harsh and have been frequently used in the aerospace industry, they are common solvents. After rubbing the surface, the coating is inspected for color change, dissolution, or any abnormality which may have been caused by the solvent. The cloth can also be inspected for residue which may be apparent by a color change.

Hydraulic Fluids and Engine Oils

Hydraulic fluids and engine oils are frequently used at elevated temperatures, and therefore their attack on aircraft coatings can be accelerated and more severe. Table 2 describes typical immersion tests using these fluids.

HEAT RESISTANCE

Aerodynamic heating can produce skin temperatures of 121°C (250°F) in level flight and 176°C (350°F) during high-speed maneuvers. Painted components adjacent to engines and exhaust tracks may experience unusually high temperatures. This heat may exceed the maximum service temperature of some organic coatings, which may cause darkening, embrittlement, and/or premature aging. The heat resistance of a coating is determined by subjecting a coated panel to a constant temperature for a specific period of time. For example, specification MIL-PRF-85285 requires that a polyurethane topcoat withstand exposure to a 121°C (250°F) oven for 1 h without a significant color change (maximum delta E value of 1.0).

Thermal Fatigue

Thermal fatigue refers to the resistance of a coating to stresses induced by rapid temperature changes. Often called thermal shock, this simulates the effect of take-off from hot (and sometimes humid) ground temperatures to the cold atmosphere at high altitudes and then back again. The MIL-C-81945 intumescent coating used on weapons must withstand 60°C (140°F), 95 % relative humidity for 24 h followed by –40°C (–40°F) for 24 h. The coating is then cycled between the two chambers for 28 days. Cracks extending deep into the coating indicate failure in this test. Method 503.1 ofMIL-STD-810 provides further guidance.

Thermal Conductivity

Stored weapons (bombs, missiles, etc.), including those used on military aircraft, must be protected from accidental fuel fires. This is accomplished with exterior, insulating coatings on those weapons that delay ordnance reactions and provide fire fighters sufficient time to extinguish the fire. The efficiency of these coatings is measured by a unique test, originally developed by NASA [16]. It uses a small furnace burning JP-4 or JP-5 aviation fuel to produce a constant heat-flux of 10 btu/ft²-s at a flame temperature of approximately 1800°F (982°C). A coated panel is mounted to an open port above the furnace, and the temperature of the uncoated backside is recorded as a function of time. The thermal efficiency is calculated from these data. It is expressed as the number of seconds/mil of coating thickness for the backside temperature to reach either 500°F (260°C) or 1000°F (537°C). (Most explosives and propellants react between these two temperatures.) Specification MIL-C-81945 requires that intumescent coatings have a minimum thermal efficiency of 2 s/mil to 500°F (260°C).

TABLE 2—Aircraft operational fluid immersion tests

Material	Duration	Temperature
Lubricating oil (MIL-L-23699)	24 h	250°F
Hydraulic fluid (MIL-H-83282)	24 h	150°F
Jet fuel (JP-5)	7 days	70°F
Jet fuel (JP-8)	7 days	70°F

STRIPPABILITY

Aircraft are periodically returned to depot maintenance facilities for inspection and overhaul. At this time, the aircraft's exterior coating system is removed by chemical and/or mechanical means. In order to ensure that this procedure can be adequately performed, strippability tests are conducted in the laboratory as part of the coating evaluation procedure. One common testing procedure is accomplished by applying a chemical paint stripper, such as MIL-PRF-81294, onto the surface of a coated specimen. After a specified period of time (usually 1 h), the panel is abraded with a stiff bristle brush and rinsed with water to remove loosened paint. Usually, 90 % removal of the coating from the substrate is considered acceptable. Other non-methylene chloride and non-phenolic strippers, such as TT-R-2918, will require up to four hours to remove similar amounts of coating. MIL-PRF-81294 is a methylene chloride based stripper TT-R-2918 is a benzyl alcohol based stripper.

CLEANABILITY

Low-gloss aircraft coatings, such as those used in camouflage schemes on military aircraft, become dirtier and are more difficult to clean and restore than high-gloss coatings. This is primarily due to the increased surface roughness of low-gloss coatings, which entraps carbonaceous and oily soils as discussed in Refs. [17,18].

The cleanability or the ease at which dirt and soil can be removed from a coating surface can be quantified by consistently soiling a coating and using a standard cleaner and cleaning motion in attempts to remove this soil. Measuring the color difference of the coating prior to soiling and subsequent to cleaning provides an indication of the coatings cleanability. The following is a detailed procedure for the evaluation of the cleanability of aircraft coatings. The soil in this procedure was generated using a hydraulic fluid. This soil is representative of that found on operational aircraft. Other soils can be derived from greases and lubricating oils.

APPARATUS REQUIRED

1. Test panels 7.62 by 15.24 by 0.05 cm (3 by 6 by 0.02 in.) of 2024 T3 aluminum alloy chromate conversion coated with materials conforming to military specification MIL-DTL-81706 to produce a coating meeting MIL-C- 5541.
2. One-liter, wide-mouth, glass jars.
3. Balance, accurate to 0.1 g.
4. High shear mixer.
5. Hog bristle brush (Gardner WG-2000-B).
6. Acid brushes.

7. Rubber roller, 2270 g (5lb).
8. Forced draft oven capable of 105°C (221°F).
9. Wear tester (Gardner Heavy Duty Wear Tester).
10. Template for positioning and holding test panels on the wear tester.
11. Cellulose sponge backed with nylon web (Scotch Brite 63).

PREPARATION OF SOIL

1. Place 50 g of carbon black (such as Raven 1040 manufactured by Columbian Chemical Company) in 500 g of hydraulic fluid meeting military specification MIL-PRF- 83282.
2. Homogenize the carbon black and hydraulic fluid mixture using a high shear mixer for 15 min. Prior to application of the soil to the specimen, thoroughly stir or shake the mixture to obtain a thorough dispersion.

PREPARATION OF THE CONTROL FORMULA CLEANER

1. Any desired aircraft cleaned can be used. However, the following is a control formulation meeting a common aircraft cleaner (MIL-PRF-85570, Type II) as listed in Paragraph 4.6.13.1 of the specification.
2. Mix the first five ingredients listed below, then neutralize the mixture to a pH of 8.0 with acetic acid. Mix the last two ingredients together and then add that to the initial mixture.
3. Igepal CO-630 (1) 10.0 parts by weight
4. Monamid 150 CW (2) 5.0
5. Dipropylene glycol methyl ether 10.0
6. Deionized water 71.5
7. Benzotriazole 0.5
8. Hostacor 2098 (3) 2.0
9. Morphaline 1.0
10. (1) GAF Corporation, or equivalent.
11. (2) Mona Industries Inc., or equivalent.
12. (3) American Hoechst Corp., or equivalent.

PREPARATION OF TEST PANELS

1. To the chromate conversion coated aluminum specimens described, apply a suitable primer for the desired topcoat. One such material is epoxy primer conforming to MIL-PRF-23377 Type I or II to a thickness of 15.2 to 22.9 μm (0.6 to 0.9 mil). Allow drying for 4–6 h at ambient conditions. Apply the desired topcoat to the intended thickness. Allow the coating to cure under the appropriate conditions.
2. After allowing the desired cure time and conditions, use a bristle acid brush to coat the painted surface of a test panel with the soil described in the "Preparation of Soil" section. Remove excess soil by covering the test panel surface with tissue and exerting pressure by rolling the tissue with the roller. Repeat this blotting three times using fresh tissue each time. Brush the soiled surface ten times in one direction only, parallel to the long dimension of the test panel, using the hog bristle brush. Bake the test panel at 105°C (221°F) for 60 min.
3. Measure the L, a, and b tristimulus values on a suitable colorimeter and record the values as L_i, a_i, and b_i, respectively.

CLEANING PROCEDURE

1. Dilute the control cleaner by one part cleaner with nine parts distilled water (by volume).
2. Clean the test panel within 4 h using the wear tester as follows. Cut the sponge with any texture "ribs" running perpendicular to the cleaning stroke. When the dry sponge is attached to the cleaning head on the wear tester, the combined weight shall be between 1350 and 1400 g. Place the soiled test panel in the template at an angle 45° to the cleaning stroke. Saturate the sponge and cover the test panel with the diluted cleaner. After 55 to 65 s, clean the test panel using 5 cycles (10 strokes) of the wear tester, then immediately turn the test panel 90° in the template and clean for an additional 5 cycles. Rinse the test panel under a flowing stream of tap water at room temperature for 2 min and allow to fully dry.
3. Measure L, a, and b values on the same colorimeter used prior to the cleaning procedure and record them as L_f, a_f, and b_f, respectively.
4. Calculate the change in color due to soiling and cleaning according to the following equation.
5. A minimum of three replicates should be tested for each coating at each condition.

Architectural Coatings

Neal Rogers[1]

INTRODUCTION

ARCHITECTURAL COATINGS ARE THE PAINTS AND coatings used to coat buildings and homes. Most are designated for specific uses such as roof coatings, wall paints, or deck finishes. No matter its use, each architectural coating must provide certain decorative, durable, and protective functions. Different test protocols may be applied in the evaluation of an architectural coating depending on its intended end-use.

For the purpose of this testing manual, the definition of the term *Architectural Coating* is most distinctly stated by standards ASTM D5146-10 and D5324-10 [1]. These two standards share the following definition of architectural coatings: "Organic coatings intended for on-site application to interior or exterior surfaces of residential, commercial, institutional, or industrial buildings, in contrast to industrial coatings. They are protective and decorative finishes applied at ambient temperatures." Although factory-applied coatings for building products such as vinyl siding or aluminum window frames may ultimately be used for architectural end-uses, these coatings will not generally follow all of the testing schemes described herein.

Substrates

The substrate that a paint is applied to determines the needed testing scheme. Here are several examples. First, painting over fresh stucco or masonry surfaces requires a paint that has resistance to the alkaline nature of the substrate. A tinted paint with marginal alkaline resistance may show quick color fading. Second, a paint designed to be applied to drywall should efficiently seal the surface to allow for the second coat to be nice and uniform. Finally, a coating that is designed for application directly over wood must be able to block tannins and extractives in the wood from bleeding through into the coating. Table 1 shows examples of common substrates for architectural coatings.

Because substrate conditions can affect end performance of a coating, development of an architectural coatings test program should take substrate differences under consideration. For instance, freshly milled wood panels that are used as test surfaces for coatings will behave differently than wood that has been exposed to natural elements before being painted. The natural processes of sunlight, moisture through humidity and precipitation, and temperature change causes the surface of wood to degrade. These differences in wood substrate can affect both short and long term adhesion performance of a coating.

Many tests for coatings are conducted on very uniform substrates such as lacquer-sealed paper charts or glass plates. These tests can help distinguish performance differences between several similar coatings, but may or may not be predictive of performance when applied on a real-world substrate. Application of a paint to real-world substrates is critical to identify performance differences from laboratory work in drying characteristics, adhesion, and film durability.

DO-IT-YOURSELF PAINTERS VERSUS PROFESSIONAL PAINTERS

The do-it-yourself (DIY) paint industry grew significantly in the late 20th century with the emergence of big box hardware chains who distribute their own high performance paint lines. DIY'ers are typically concerned with decorative aspects but also require some performance durability as well. For instance, a homeowner who wishes to change the color of a room may simply paint a new color but they still want the finished paint to resist color and gloss change with aging or abrasion. In order to get this performance level with the appropriate color, the DIY painter may be willing to trade off easy application if they are not as experienced as a professional painter to recognize the best application qualities and are happy with the finish when the job is complete.

Professional painters tend to be most sensitive to the application characteristics of a paint. It is important for the paint to have a certain open time so a painter can easily repair brush or drip marks during application. It is more critical for a professional painter than a DIY painter to have ease of flow and wetting from the application tool to the surface. Poor flow or wetting can cause additional effort to achieve a uniform appearance. A professional painter would not likely continue to recommend or select a paint with poor flow and wetting for future projects.

Architectural Coating Categories

The general class of architectural coatings can be broken down into a number of categories depending on a coating's end application. Each category calls for a testing scheme of common tests that can be customized depending on what features are the most important for the coating to be tested. ASTM offers several standard testing guides that list and briefly describe test methods that are relevant to broad categories of coatings (Table 2).

The following is a brief description of some of the most common architectural categories.

- Interior wall paints—interior wall paints are typically used for coating primed or previously painted surfaces. High performance interior wall paints are tested for film toughness characteristics such as the ability to withstand scrubbing, ease of stain removal, and resistance to blocking.
- Exterior paints—exterior paint films are designed to resist elements such as sunlight, dirt pickup, and attack by mold and mildew. They typically need a certain degree of flexibility to withstand expansion and contraction fluctuations of the building products they cover.
- Primers—primers are basecoats used to prepare the surface for subsequent topcoats. They need to have good adhesion to their recommended substrates, good sealing properties, and other characteristics that will protect the topcoat.
- Floor paints—floor paints typically need good abrasion resistance characteristics. They also need to withstand fluid spills without discoloring or losing hardness.
- Wood stains and clear wood topcoats—although not all wood stains are film-forming coatings, the clear finishes that cover them typically are. Clear topcoats must have good hardness development and be resistant to wear and tear from handling or daily contact with people.
- Deck finishes—deck finishes must be resistant to sunlight and provide good abrasion resistance and flexibility over the deck surface. Deck finishes must also prevent wood tannins from migrating through the finish and affecting appearance.
- Faux finishes and metallic/specialty finishes—these coatings are typically decorative in nature and have limited expectations of durability. Like wood stains, they often require a subsequent clear topcoat to achieve a more protective finish. Finishes that are intended to be durable without an additional topcoat require similar characteristics to the interior and exterior paint categories.

ASTM D6763-10	Standard Guide for Testing Exterior Wood Stains and Clear Water Repellents

PROPERTIES OF LIQUID COATINGS

Density

Density measurements are commonly used in quality control laboratories of paint manufacturers to ensure consistency of the finished paint. Density is typically measured by a type of pycnometer called a weight-per-gallon cup. In the United States, a weight-per-gallon cup is usually found as a stainless steel cylinder with a volume of 83.45 mL so that the weight in grams required to fill the cup divided by 10 is the density of paint in pounds per U.S. gallon.

Viscosity

Like density, viscosity is a second characterizing test commonly used in quality control laboratories of paint manufacturers. Viscosity for architectural coatings is typically measured by Stormer viscometer and/or a cone and plate viscometer.

The Stormer viscometer has a paint paddle that turns at a fixed rotational velocity in a paint. The instrument measures resistance to the rotation and provides a viscosity value in Krebs Units (KU). Most Stormer viscometers in service today have digital readouts, however older models have a falling weight attachment that uses gravity to provide power to spin the paddle. For these older models, the test technician uses a stopwatch to time how long it takes for the weight to drop a certain length and charts provided by the instrument manufacturer are used to calculate the KU viscosity measurement. Interior and exterior house paints typically have Stormer viscosities in the range of 90–110 KU. Stormer viscosities are considered a low shear rate viscosity. It can be thought of as the feel of the liquid paint as it is stirred in the can before application.

The cone and plate viscometer, often referred to as an ICI viscometer, uses a cone spindle and a flat plate to measure viscosity at a higher shear rate. The test paint is placed on the plate and then the spindle is pressed onto the plate and prompted to spin. The resulting shear force on the spindle determines the viscosity measurement. In architectural coatings, cone and plate viscosity is often suggested as an estimation of the brush drag of a coating. When a fully-loaded paintbrush is applied to a surface, the painter feels resistance to the flow of paint from the movement of the brush. Solvent-borne alkyd based paints often have ICI viscosities in the range of 4–7 Poise; water-borne 100 % acrylic latex paints have ICI viscosities typically below 2.5 Poise.

A rheometer is a more sophisticated rheologymeasurement instrument that measures fluid response over a range of shear rates. With experienced technicians, this type of instrumentation can be used to predict settling or separation of a paint when it is still in a liquid state. It can also be used to estimate how thixotropic a paint is. A thixotropic fluid displays a decrease in viscosity over time at a constant shear rate. Some thixotropy can be desirable for a coating, especially if it may be applied by spray in the field. Complete rheometric analysis is more often used as a development or stability investigation tool.

A more complete explanation of theory behind the use of rheometric and flow characterization of liquid coatings

can be found in Chapter 33 of this manual [2], "Rheology and Viscometry."

Stability

Stability of a liquid paint is often associated with physical phase separation or settling of solid components of the paint itself. Stability of the liquid paint is typically tested under one of three conditions: hot (oven stability), cold (freeze-thaw stability), or standard room temperature (shelf stability). Stability observation intervals vary with the test. For oven stability, observations are typically made at weekly intervals up to 4 weeks; for freeze-thaw stability, observations are often made after a 16-hour freezing cycle followed by 8-hour thaw cycle.

The key observation factor in a stability test is whether or not the paint fluid maintains its uniformity when stirred back together. Acrylic latex paints that are not freeze-thaw stable will develop a gelled structure and will not be able to be stirred back into a uniform liquid state. Paints appearing to have a uniform consistency in the liquid state might also be evaluated for the presence of grit or gloss changes in a film drawdown, viscosity changes, or pH changes. Long term-storage may also effect the persistency of some defoamers used in paint formulations making evaluation of foam on application testing another possible criteria by which to judge stability. ASTM D1849-95 (2008), Standard Test Method for Package Stability of Paint [1], and ASTM D2243-95 (2008), Standard Test Method for Freeze-Thaw Resistance of Water-Borne Coatings [1], provide methods for evaluating uniformity of liquid samples after storage at a wide range of potential temperatures.

Syneresis or settling may form during the course of a stability evaluation. Both properties are judged by assessing physical character of the liquid paint. Syneresis is a liquid/liquid separation normally characterized by a clear liquid layer at the surface of the liquid paint. The depth of a syneresis layer may be measured and compared with other samples. Settling is a solid separation where solid material from the paint settles to the bottom of the container. Observations of any grits or caked material at the bottom of the can are conducted by dipping a spatula into the paint and stirring gently. ASTM D869-85 (2011), Standard Test Method for Evaluating Degree of Settling of Paint [1], provides descriptions and rating scales for reporting the degree and type of settling found in a liquid paint sample.

Fineness of Dispersion

The fineness of pigments dispersed in a paint film are an important characteristic especially for semi-gloss to high gloss finishes. The most common method employed to assess fineness of pigment dispersion is by using a Hegman-type gage. The Hegman gage is a steel block with a path machined out such that the path is tapered uniformly in depth lengthwise from about 100 μm at 10 mm from one end to zero depth at the other end. Because a Hegman gage is often used in paint manufacturing during the pigment dispersion, or "Grind," process, the Hegman test is often referred to as a Hegman Grind or simply a Grind check.

ASTM Standard Test Method D1210-05 (2010) [3] describes the proper use of the Hegman-type gage to evaluate fineness of dispersion. Semi-gloss to high gloss coatings typically require Hegman Grind ratings above 6. For matte to satin coatings, the need for the Hegman tool to define the fineness of dispersion is not as critical, however, it can be used to confirm the consistency of a pigment dispersion for multiple batches.

Colorant Compatibility

Colorant compatibility with a tint base paint system is a key feature to ensure a formulation will retain its appearance properties when tinted with colored pigment dispersions, or "Colorants," at the point of sale. ASTM D5326-94a (2009) [1] provides a test method for assessing the effectiveness of color development in tinted latex paints. In this method, a film drawdown of uniform thickness is brushed into with a hand-held paintbrush. The higher shear forces of the brush can affect color development. If there is a tendency for a dark colorant to agglomerate or flocculate in a liquid paint system, colors may appear darker if the higher shear application forces of the brush cause more of the pigment to de-agglomerate. Similarly if a white pigment such as TiO_2 is flocculating, the color upon higher shear application would appear lighter.

Another way to simulate high-shear forces on a drawdown is by gently rubbing the uniform thickness drawdown with a finger. The most effective time to conduct this "rub-up" test is as the drying stage of solvent evaporation advances. As solvent initially evaporates from the paint film during the first stage of the drying process, a rub-up will not produce much shear on the paint except for pigment particles that are crushed by the rubbing finger. By allowing the paint to begin to dry, a gentle rubbing action will generate more stress and strain applied to the paint film.

Aside from color variation, viscosity differences may also develop when tinting a base paint, especially for accent and deep base tint systems that may require up to 8–10 % of colorant by volume to achieve the desired end paint color. At the time of writing this chapter, there were several rheology modifier product lines being promoted as polymer-based thickeners that are developed specifically for the benefit of maintaining viscosity and preventing viscosity loss upon tinting.

Volatile Organic Contents (VOC)

VOCs for architectural coatings in the U.S. are typically reported in terms of grams volatile organic compounds per liter of liquid paint less water and other exempt solvents. The definition of VOCs in other parts of the world have different definitions or different methods by which to judge VOC of a liquid paint. In the European Union zone, for instance, common coalescing solvent 2,2,4-trimethyl-1,3-pentanediol-1-monoisobutyrate used in acrylic emulsion paints is exempt because of its high boiling point of around 255°C compared to other glycol ethers and solvents used as coalescing agents.

A complete discussion of volatile organic content measurement related to paints, is found in Chapter 1 of this manual [2], "Regulation of Volatile Organic Compound Emissions from Paints and Coatings."

FILM-FORMATION PROPERTIES

Drying Times

In general, drying time assessment of a paint system is critical to understanding its performance. However, for most acrylic emulsion-based architectural paints, drying profiles tend to be very similar. Set to touch times are typically less

than 20–30 min with through dry achieved in less than a few hours. Many acrylic emulsion paint systems are ready for subsequent topcoats in under 2 h of drying at standard conditions of 75°F and 50 % relative humidity.

With solvent-based alkyd paints, dry time assessment can be more critical to predict early film performance. Alkyds rely on an internal oxidative cure mechanism to build molecular weight through cross-linking between polymer chains. Additives used to catalyze the oxidative cure reactions can alter the drying performance of an alkyd based paint. Typical long-oil alkyd trim enamel paints applied by natural spread rate have dry set to touch times in the range of 45–120 min and maintain a good flow and leveling profile during these early stages of dry. This flow profile helps alkyd paints achieve better open time than acrylic latex paints during early stages of dry. However, the slower oxidative drying character of an alkyd paint can cause slower development of film toughness properties such as block resistance and hardness.

The most common methods of dry time testing for architectural paint films are by dry time recorder or by finger touch methods. Although both types of testing are used often in practice, most laboratories have a preference on which method to rely. Laboratories that use dry time recorder methods typically run dry testing very frequently and become very good in the art of comparing and interpreting dry time recorder results. Laboratories that insist on running dry by finger touch methods often believe the touch methods are more sensitive to slight differences in dry that might go undetected by interpretation of a dry time recorder result.

Both dry time methods are valid, however, one must be aware that they may give different interpretations of a coating's drying profile. It is typically not valid to compare Dry Hard time as measured on a dry-time recorder compared to a thumb-imprint judgment of Dry Hard.

Although there are surely many others, here are a few resources that can be used as guides in the assessment of drying times and film-formation processes in coatings. A few suggestions are as follows.

- Paint and Coating Testing Manual, Chapter 36, "Cure: The Process and Its Measurement" [2].
- Paint and Coating Testing Manual, Chapter 39, "Drying Time" [2].
- ASTM D1640-03 (2009), Standard Test Methods for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature [3].

Holdout

Holdout is a property that indicates the ability of a paint to seal a surface to allow subsequent topcoats to maintain their ideal appearance. Typically, holdout of a paint is related to developing the desired gloss level for an enamel topcoat. If a gloss enamel paint is applied directly to a porous surface such as drywall, or a porous flat paint finish, its gloss potential could be significantly diminished. Because of this, a primer with good holdout properties is often selected to be a basecoat for a gloss enamel paint.

There are two methods typically used to assess holdout. The first method is by simple gloss measurement. In this method, the test paint is applied to the substrate or surface where holdout properties are of concern. A separate film application of a topcoat paint is made to a well-sealed surface to determine its full gloss potential. Finally, the topcoat paint is applied to the test paint using the same application method used on the well-sealed surface. Gloss is measured for each of the two topcoats and the holdout result is reported as a percentage of gloss over the test paint system relative to gloss over the well-sealed substrate.

Holdout can also be assessed by measuring porosity of a topcoat paint applied over a test paint compared with the porosity of a topcoat paint over an ideal surface. Porosity measurements are discussed in the following section.

Porosity

The porosity of a coating impacts film toughness properties such as stain resistance, washability, and abrasion resistance. For instance, the less porous the coating surface, the more difficult the coating will be to stain. Accurate measurement of porosity can thus give an indication of ultimate film performance.

Porosity testing can be an indication of good film formation. Even if film formation visually seems complete, a porosity test has the potential to identify differences in film formation. The uniformity of a substrate also affects porosity of a topcoat finish. Although a film may appear uniform, a porosity test on the substrate of choice can indicate ultimate porosity.

There are two key test methods for evaluating porosity of paint films, one that involves staining of the surface, and one involving weight gain. The staining test method is presented in ASTM D3258-04 (2010), Standard Test Method for Porosity of White or Near White Paint Films by Staining [1]. A test paint is first applied as a uniform film to a non-porous surface, such as a lacquer-sealed paper drawdown chart. When dry, a dark staining medium is applied on the test paint and allowed to stand for a specified time interval. The staining medium commonly used is compatible with Mineral Spirits. This allows the stain to be rinsed away with a solvent that is not expected to significantly affect the surface film. After the staining medium is rinsed away, the panel is allowed to dry and reflectance measurements are taken between the stained and unstained areas. The porosity of the test coating is reported as the difference in reflectance between the stained and unstained areas.

The weight gain method presented in ASTM D6583-04 (2010), Standard Test Method for Porosity of Paint Film by Mineral Oil Absorption [1], is similar to the staining method but uses mineral oil absorption to achieve a weight difference rather than staining medium absorption to achieve a measurable visual difference. Mineral oil is applied to a dry uniform film-thickness coating over a non-porous substrate. Excess mineral oil is wiped off and the panel is weighed. The difference in panel weight before and after the mineral oil application allows the calculation of how much mineral oil was trapped in pores of the coating.

Penetration

Penetration is the ability of a coating to flow into and permeate the surface of its substrate rather than form a simple film at the surface. Penetration is a significant factor on porous substrates such as natural woods or some wood composites. A coating that penetrates in addition to forming a film at the surface often offers enhanced adhesion

characteristics. For wood finishes such as film-forming semi-transparent stains, improved penetration can also assist in enhancing water resistance and ultimate durability of the coated wood. These benefits are often most realized in exterior coatings applied to substrates such as chalky or previously uncoated weathered wood. Penetration into wood may be hindered if a paint film forms too quickly or if binder particle sizes are too large.

Although penetration is a significant consideration in designing an exterior wood coating system, there is not an abundance of standardized test methods available by which to evaluate penetration. One common laboratory practice involves using filter paper or blotting paper to represent a porous substrate. Several layers (5–10) of paper are stacked and the test coating is applied by a dropper to the top layer of the paper. As the coating migrates into the layers of filter paper, it can spread out within the layer or penetrate into successive layers. The end result is how many layers the coating penetrates. This test is most successfully used as a comparison between two similar coating systems.

A more challenging test method involves application of a test coating to its desired substrate. After the coating penetrates the surface and is allowed to dry, small cross-sectional areas of the coated substrate are cut and evaluated using standard microscopic techniques. By viewing several cross-sectional areas, a technician can judge the overall ability of a coating to penetrate into the substrate. This method can be difficult to judge depending on the coating system. In a clear system, the color differences may not be readily visible. Even for pigmented systems, if the pigment particles are inhibited from penetration and the binder penetrates more deeply, a false analysis may result.

Low Temperature Film-Formation

The ability of a paint to form a uniform defect-free film at low temperatures is an important characteristic of coatings that are designed for new construction or those designed for exterior application. These types of coatings are more likely than others to experience cold ambient air conditions or cold surface substrates during application. Low temperature film formation is usually assessed at temperatures just above the freezing point of water, 4°C (39°F), but may be tested as low as desired for the end application.

The test paint, substrate, and application tools are all pre-conditioned at the designated low temperature. If possible, the paint application is conducted at the same conditions, however, if the application tools must be removed from the cold environment to create a suitable sample for analysis, the sample should be immediately returned to the cold environment as soon as possible after the paint is applied. After several hours or other suitable dry time, the paint is removed from the cold chamber and assessed visually for any film defects or poor gloss development. An acrylic emulsion-based paint that does not have sufficient coalescing solvent for low temperature film formation will often crack when applied on a paper drawdown chart and placed in a 4°C temperature environment.

There are two ASTM methods for assessing low temperature film formation. ASTM D7306-07 [1] involves visual assessment of the film after testing and ASTM D3793-06 [1] requires a porosity measurement once the film is removed from the cold temperature conditions.

APPLICATION PROPERTIES

Liquid paints may be applied by brush, roller, or one of a variety of spray methods. The final appearance of a painted surface is a result of a combination of a paint's early drying profile, application tool selection, and flow and leveling characteristics of the liquid paint. The following sections describe test methodologies used to assess the application performance of a paint.

Rheology Effects on Application

Viscosity of liquid paints was discussed in an earlier section but this topic extends quite distinctly to application characteristics. For instance, a paint does not necessarily need a high ICI viscosity to have a good spray application profile. A paint ideal for brushing or rolling might have a moderate to high Stormer viscosity but still spread evenly on a given surface.

Ultimately, testing of real-world application techniques in a field environment or in a laboratory with substrates representative of field surfaces is necessary to completely assess application characteristics. It is possible to predict field application behavior based on rheometric analysis of liquid paints, but such correlation must be developed through an extensive study of real-world application techniques.

Anti-Sag Resistance

One of the benchmark tests in predicting flow characteristics of an architectural paint is assessing its tendency to sag when applied to a vertical surface. The most common way to do so is by using a specially designed film application bar called an Anti-Sag meter. The Anti-Sag meter creates a series of uniform films with increasing thickness that come from the drawdown clearance indicated on the bar. One common anti-sag meter, see Fig. 1, has drawdown clearances ranging from 4 to 24 mils clearance in 2-mil intervals. When a drawdown is made from this application tool and the panel is immediately hung in a vertical orientation with the thickest stripe at the bottom of the panel, a technician visually assesses and reports the highest drawdown clearance where the paint did not "sag" into the next stripe. Fig. 2 shows a finished Sag test drawdown. This type of Sag resistance determination is detailed in ASTM D4400-99 (2007) [1].

Sag may also be determined more subjectively on any vertical surface using any application tool such as a brush or roller. The laboratory test technician would take the base of a paintbrush, a spatula, or any other suitable tool to mark a horizontal or wavy line in the wet finish. This type of test results in a pass or fail result depending on how much of the paint sags across the line.

Fig. 1—Example anti-sag meter drawdown tool.

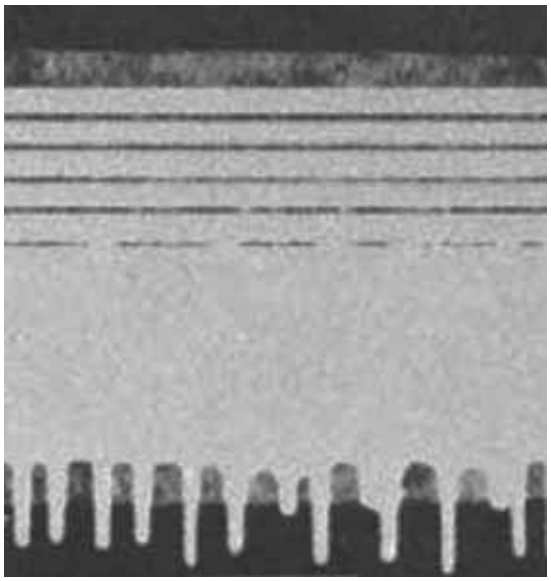

Fig. 2—Typical Sag pattern.

Fig. 3—Pocket wet-film thickness gage.

Leveling

The ability of a paint to level into a uniform finish is typically assessed on a horizontal surface. It is often more of a challenge for lower gloss and sheen finishes to level completely compared to higher gloss finishes which contain lower levels of pigment to inhibit flow-out of the polymer system.

A leveling evaluation may be done with any application tool other than tools designed to create uniform wet-film surfaces such as clearance drawdown bars. For a paint roller, the rheology and additives in a paint formulation and the nap size and construct of a paint roller will affect appearance in a rolled-out finish. The ability of the roller nap patterns to flow out into a smooth uniform finish represents the leveling capability of a paint. A paintbrush can also be used for leveling evaluation. Instead of nap mark patterns, the brushstroke marks must flow out smoothly to form a uniform film. When comparing multiple test paints for leveling, the same application tool should be used across different samples because different application tools may leave slight variations in film appearance.

There are a couple of specially designed paint-application drawdown bar tools that are used to assess leveling ability of a paint. The NYPC leveling bar applies five sets of two uniform stripes of paint to a test panel. Each group of two stripes is at a different drawdown clearance: 10, 20, 40, 80, and 160 mils. As the paint flows out, the gap between the stripes is overcome and the paint flows together. The rating is assigned based on what film thickness produces a result where one paint stripe is no longer able to flow into the stripe of its pair.

The second type of leveling drawdown bar that is used consists of a rounded bar that creates a pattern of uniform ridges across the drawdown area for a paint. This drawdown is rated by allowing the paint to dry in a horizontal orientation and then comparing the drawdown appearance to a set of levelness standards where 10 is completely smooth and standard number 1 shows very distinct ridges. Evaluations using this tool should be done in a controlled light environment and all test specimens viewed at the same angle or series of angles to ensure consistent interpretation and rating of results. Similar levelness standards may be used in practice to assess leveling resulting from paint brushouts.

Applied Spread Rate

Spread rate of an architectural paint is reported in units of area covered per unit volume of paint (sq. ft/gallon or sq. m/L). In some regions, spread rates are alternately reported in area per unit mass (typically sq. m/kg). The desired spread rate is set by paint manufacturers in order to achieve a certain dry film thickness that will give the end user of paint the durability properties needed for the paint to perform as it was designed.

Rather than target a spread rate, painters who apply by spray application methods typically assess spread rate in the field by using a wet-film thickness gage, see Fig. 3. This pocket tool quickly tells a painter if the speed of delivery of the liquid paint is sufficient to achieve the needed film thickness. Use of notch gages for measuring wet film thickness are detailed in ASTM D4414-95 (2007) [3]. A painter or laboratory technician can measure the spread rate applied to a test panel by measuring its area and the weight of paint applied. The weight applied can be converted to volume using the known density of the test paint and then area per unit volume can be calculated.

Rather than target a spread rate, painters who apply by spray application methods typically assess spread rate in the field by using a wet-film thickness gage, see Fig. 3. This pocket tool quickly tells a painter if the speed of delivery of the liquid paint is sufficient to achieve the needed film thickness. Use of notch gages for measuring wet film thickness are detailed in ASTM D4414-95 (2007)[3]. In a laboratory testing environment, it is often useful to measure spread rate applied to a test panel by measuring its area and the weight of paint applied. The weight applied is converted to volume using the known density of the test paint and then area per unit volume can be calculated. Example calculations for spread rate and wet film thickness are provided here for reference.

Spread rate

Area of test panel = 20 by 30 cm = 600 cm^2 = 0.060 m^2

Weight of applied paint = 8.0 g = 0.0080 kg

Density of liquid paint = 1.3 kg/L

$$\text{Applied spread rate} = 0.060\ m^2 \div (0.008/1.3)L$$

$$= 9.8\ m^2/L \text{ or } 400\ ft^2/gal$$

Wet film thickness calculation (assuming uniform coverage)

$$\text{Volume applied} = (0.0080/1.3)L = 0.00615\ L = 6.15\ cm^3$$

$$\text{Area of test panel} = 600\ cm^2$$

$$\text{Wet film thickness} = (6.15/600)\ cm = 0.010\ cm = 100\ \mu m$$

For design of a laboratory test or field test of a given coating system, a laboratory technician must decide whether to control the spread rate by forcing the coating to be applied at a desired weight, or to apply the coating at a natural spread rate from a given application tool. If natural spread rate is selected, it is still considered a best practice for the technician to measure the amount of paint applied to the testing area at least for the first few samples to make sure the amount being applied is close to the desired result. Applying too much or too little paint to a test panel can greatly affect test results such as exterior durability, flexibility, and stain-blocking.

Applied Hiding Power

The ability of a paint to hide defects in the background can be a critical requirement. Very white or brightly colored paints sometimes do not have the pigmentation necessary to hide different or varying background colors they are intended to cover. Because of this, it is necessary to be able to assess hiding power using conventional laboratory methods.

ASTM D5150-92 (2009) [1] describes a method for evaluating hiding power for paints applied by roller. In this method, a standard sealed chart with varying degrees of light gray to dark gray to black stripes over a white background is used as the application substrate. Test paints are applied by roller and the result is visually assessed to judge which colored stripe is the last one to be barely visible under the topcoat. Although D5150 is for evaluation of roller-applied paints, the same type of panel can be used as a substrate for applied hiding power evaluation using any application tool such as a paint brush or airless spray equipment.

An alternate method for assessing applied hiding power differences between two paints is given in ASTM D344-97 (2004), Standard Test Method for Relative Hiding Power of Paints by the Visual Evaluation of Brushouts [3]. This method uses a black and white sealed chart as the substrate and requires the user to measure the amount of paint applied so it is applied at a known spreading rate. The method requires some practice of brushing technique because the visual assessment of hiding assumes uniform application across the entire brushout. In ASTM D344, the hiding power of the test paint relative to the control paint is defined as the spread rate of the test paint needed to achieve equivalent visual applied hide contrast divided by the spread rate of the control paint.

Hiding is often assessed on paints that are applied to achieve a uniform film thickness as with a drawdown method. This type of hiding assessment is described in the section on Appearance Properties.

Application Foam

Many architectural paints use defoamers as additive ingredients to suppress foam formation during manufacturing as well as during application. Foam can be particularly noticeable for application with a paint roller. As paint transfers between the roller and substrate, the fibers of the roller pull paint from the painted surface and back to the roller. The result of this repeated process can be foam in the form of un-popped bubbles along the path of the roller. In some cases the foam will pop before the paint is able to completely dry; however, in other cases the foam can be relatively stable and remain in the film after the surface has dried. This leads to an undesirable appearance. Foam can also be generated by brushing or spraying. Foam resulting from spraying applications may manifest itself as very small pinholes in the coating.

To test for application foam, a technician must simply choose the application tool and substrate of choice and then observe how foam develops after application. The final judgment of the presence of foam should be conducted after the surface of the film has dried. Microscopy may be used for verifying that the surface is free from foam, pinholes, or other defects.

Spatter Resistance

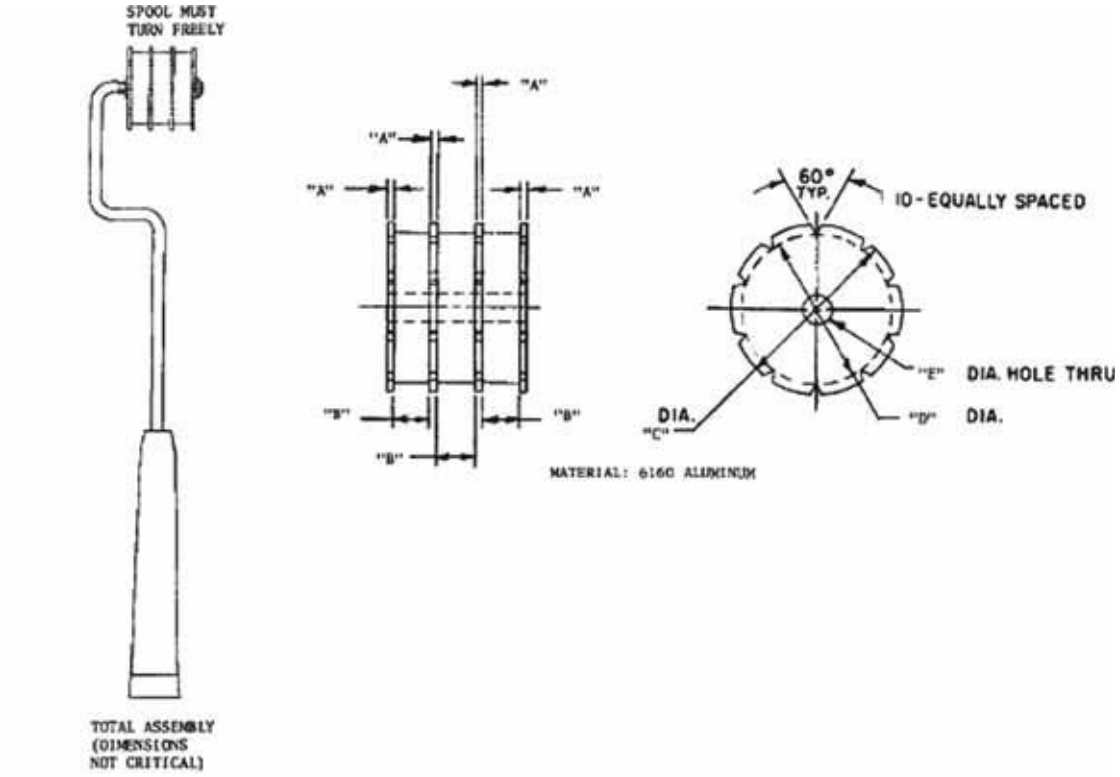
Spatter resistance is generally a property considered for interior wall paints. Although drop cloths are used in most painting scenarios to protect flooring or surrounding furniture, there is still a desire to prevent paint from spattering onto the person applying the paint. As with application foam, spatter resistance of a paint is most often associated with hand-held roller application tools. Spatter may be evaluated by choosing a substrate and application tool that will best represent what is used in the field.

ASTM D4707-09 [1] was developed to provide a systematic test method for evaluating and rating spatter resistance. This method calls for a specially designed "notch-spool" roller (see Fig. 4) to artificially generate spatter for any test paint selected. Each notch on the spool roller catches the paint and flings it downward during the application. The spatter is caught on a black panel (or a white panel for dark colors) and evaluated versus a set of visual standards also provided in ASTM D4707-09 to give a 0–10 rating scale. Even if the notch-spool roller is not used for the test, the visual standards are often used in rating spatter resistance using any suitable application tool.

Applying Uniform Paint Films for Testing

Much of the testing done on paint films in a laboratory environment requires the application of a uniform paint film. There are many ways to apply uniform paint films for testing which are detailed in ASTM D823-95 (2007), Standard Practices for Producing Films of Uniform Thickness of Paint, Varnish, and Related Products on Test Panels [3] (Table 3), as well as in Chapter 40 of this manual, "Film Preparation for Coating Tests" [2].

The most important of these standard practices for an architectural coatings laboratory are the blade film application practices. Spray application practices are occasionally used for architectural coatings projects, however, these techniques are much more common for application of industrial coatings to metal panels or other substrates. Architectural coatings manufacturers that do maintain



Dimensions			
		in.	mm
A	Flange thickness	0.063± 0.005	1.60 ± 0.13
B	Space between flanges	0.343 ± 0.005	8.71± 0.13
C	Total diameter	1.600± 0.015	40.16 ± 0.38
D	Diameter under notches	1.400 ± 0.015	35.56 ± 0.38
E	Hole diameter	0.281 ± 0.005	7.14 ± 0.13

Fig. 4—Notched spool roller and dimensions from ASTM D4707.

laboratory capabilities for spraying typically use these to assess characteristics using airless spray equipment that would be used by professional painters in the field.

Blade film applicators are more commonly referred to as "drawdown bars." They come in many dimensions, shapes, and have varying clearance gaps. Some are one-sided, some are two-sided (top and bottom have different clearance gaps), some are multi-sided (for instance, a square drawdown bar with four clearance gaps on one side and four clearance gaps on the other side), some are even adjustable to various clearances. The use of drawdown bar tools is quite simple—a test panel or substrate is affixed to a flat surface; a small amount of paint is placed at the top of the test panel just in front of the drawdown bar; and finally, the bar is drawn down leaving behind a uniform thickness of the liquid paint.

TABLE 3—Practices of ASTM D823-95 (2007) [3]

Practice	Description
A	Automatic Spray Machine Application
B	Motor-Driven Dip Coater Application
C	Motor-Driven Blade Film Application
D	Hand-Held Spray Gun Application
E	Hand-Held Blade Film Application

A common best practice to ensure a uniform film thickness drawdown on a sealed paper test chart is to use a vacuum plate as the flat surface beneath the test panel. The use of a vacuum will prevent the paper chart from having small bumps or bends which might lead to non-uniform film thickness in those areas. A representative vacuum plate is shown in Fig. 5. The nozzle attachment of the vacuum plate is connected directly to a vacuum pump.

Motor-driven drawdown bar film applicators are typically designed with a vacuum plate included. The potential advantage of using a motor-driven drawdown applicator rather than hand-held drawdown bar is that the speed of application is constant and there are no shakes or wiggles that could happen during a hand-held application. A practiced technician can become as good as a motor-driven drawdown applicator for producing consistent uniform films, but repeatability between different operators can cause minor differences.

One common type of drawdown bar is called a "Bird" bar. A 3-mil Bird bar is one of the most common pieces of equipment found in an architectural coatings laboratory. It is important to note that Bird bars are graduated differently

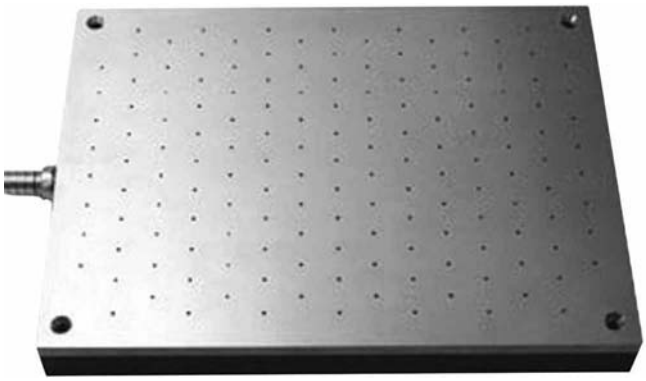


Fig. 5—Vacuum plate. (Courtesy of Paul N. Gardner Company.)

than standard clearance drawdown bars. A Bird film applicator labeled as 0.003 in. or 3 mils actually has a clearance of 6-mils. This is confusing to many paint technicians who do not recognize the distinction. The idea of the Bird bar when it was introduced was to allow a laboratory technician to apply a wet film of approximately 3 mils. The final wet-film thickness of the paint drawdown will vary depending on rheological character of the paint and the speed of the drawdown.

In the U.S., film thicknesses in the coatings industry are still typically reported in units of mils with 1 mil being equal to 0.001 in. Drawdown bar tools are also specified in units of mils. In the rest of the world, drawdown tools are typically specified in units of microns or μm. Because there are 25.4 μm per mil, a 100 micron drawdown bar is roughly equivalent to a 4 -mil clearance gap drawdown bar (Table 4).

Open Time

Regulatory pressures to formulate coatings at low solvent levels have caused open time to become an important property of interest for coatings formulators. Without consideration for solvent amounts or solvent selection, there are a broad range of ways to extend or reduce open time for a given coatings system. Restrictions on the use of solvents classified as volatile organic compounds have resulted in polymer design to play a much more significant role in how a coating behaves during early stages of dry.

In terms of brush application, open time is the amount of time after a coating is applied where the coating film can be re-brushed into without leaving any noticeable difference in the film appearance. After the additional brushing, the coating must still flow out to match surrounding areas in order to still be considered "open." This property allows a painter flexibility to return to an area already painted and repair any drips or marks left behind by the original coat. If a paint has a short open time and closes quickly, there are only a few minutes before the paint can be re-wet by brushing into it. After the open time has elapsed, re-brushing into the film adds an additional coat to the surface rather than repairing the original coat.

For interior and exterior paints, open time is tested in the laboratory by brushing into a uniform film at varying time intervals. For short open time paints, 2-min intervals are often used. For long open time paints, 10–15 min intervals are often more appropriate. To accentuate the appearance of open time, the initial film drawdown is disturbed by marking the surface which will be repaired by re-brushing into the film at the designated interval. The open time is the last time where the marks on the film surface are able to be re-incorporated into the film without being visible.

This same method can be extended to film-forming wood stain finishes by applying the coating directly to a wood substrate. At various time intervals, additional wood stain is applied on adjacent areas and lapped into the original application of stain. Here a laboratory technician is observing the visibility of overlap marks between adjacent areas. Open time for non-opaque wood finishes is often referred to as lapping time because the assessment focuses on the visibility of lap marks in the overlapping application areas.

TABLE 4—English Unit Approximation of Metric Drawdown Clearance Gaps

Metric	Equivalent in Mils	U.S. Drawdown Bar Equivalent
50 μm	1.97	2 mils
75 μm	2.95	3 mils; 1.5-mil Bird
100 μm	3.94	4 mils
150 μm	5.91	6 mils; 3-mil Bird
300 μm	11.8	12 mils; 6-mil Bird

Touch Up

Touch up is the ability of a paint to maintain its original appearance when a small area is re-painted with the same paint after the original coat has dried. This is an important characteristic because small imperfections are often found upon inspection of a newly painted wall or surface resulting in the painter wishing to repair them to improve uniformity of appearance for the overall paint job. In new construction, the ability to touch up paint is critical as there is a lot of traffic through a building or home while it is being completed for occupancy. Touch Up can be important for both interior or exterior paints but it is normally more important for paint on interior wall surfaces due to higher visibility at close distances.

To establish a laboratory test protocol for touch up, the field touch up scenario should be considered in selecting application tools and environmental conditions for the test. For a paint designed for a DIY consumer, roller or brush touch up over a roller base coat is the most common scenario. For professional painters, touch up with a brush or roller over a sprayed basecoat is common. Different application tools—which can cause a paint to experience varying shear stress during application—can cause differences in color development especially if surfactant and pigment loadings in the paint have not been optimally formulated. Environmental conditions can also change between the time of applying a basecoat and a topcoat. For example, during cold-weather months for new residential construction, the main paint application might be completed in cool conditions before heating systems in the new house are fully on-line. However, final touchups may be completed at the end of the construction process when environmental conditions would be normal room temperature.

A simple visual assessment is the most common observation criteria for a touch up test. ASTM D3928-00a (2010), Standard Test Method for Evaluation of Gloss or Sheen Uniformity [1], describes a laboratory procedure for providing a visual assessment rating for touch up by paintbrush of a paint sprayed on a test panel. Gloss and color measurements of touched up and non-touched up areas may be taken to assist a coatings formulator in differentiating performance of paint systems that appear visually similar.

APPEARANCE PROPERTIES

Color and Gloss

The measurement of color and gloss for architectural coatings is the same as measurements of color and gloss for other types of coatings. In an architectural coatings laboratory, film drawdowns over lacquer-sealed paper charts are typically used to assess color and gloss. In the production of architectural coatings, samples from paint batches are often force dried in an oven deemed suitable to speed the curing process without affecting assessment of the finished appearance. It is common for paints to be manufactured as white bases of varying strengths which are subsequently tinted using standard universal colorant dispersions based on standard recipes at the point of sale. To ensure accuracy of tinting across multiple batches it is important to measure and control the tint strength of the coating in production.

Tint strength is measured by adding a pre-determined amount of a specific colorant or blend of colorants to a white paint and measuring it against a standard. If the color matches within a pre-defined tolerance limit, the paint batch may be approved. The tolerance limit varies depending on what is the acceptable variation for the end customer. ASTM D3134-97 (2008)e1 [3] provides a standard practice for establishing acceptable color and gloss tolerances.

Gloss measurement for architectural coatings are important in order to define the finish for painters or consumers. Flat or matte finishes are measured for gloss using a higher viewing angle of 85°; mid-gloss paints, such as satin and semi-gloss, are measured at a viewing angle of 60°; and high gloss finishes are often measured at both 20° and 60°. A viewing angle of 85° is sometimes referred to as "sheen" instead of gloss.

A detailed discussion of color and gloss measuring instrumentation is found in optical properties sections of this testing manual such as Chapter 43, "Color and Light," or Chapter 44, "Gloss" [2].

Hiding Power

Hiding power is measured by comparing the color of a coating over a black background to the color of the same coating over a white background. This measurement is called contrast ratio and is often expressed as a percent. If a coating is completely opaque, the two colors will be the same and the contrast ratio will be 100 %. In practice, the contrast ratio is reported as the ratio of reflectance (Y-tristimulus) value of a white paint over black background to the reflectance value of a white paint over white background. Many lacquer-sealed drawdown charts are manufactured with white and black backgrounds in order to enable measurement from a single drawdown. Contrast ratio can be measured for any paint film thickness but in practice is often conducted over a 3-mil Bird drawdown.

Uniformity of Finish

Uniformity of finish is an important parameter for a coatings formulator. In a typical production environment, the uniformity of finish of a coating is expected to be perfect and is judged on a pass/fail scale. However, in a laboratory environment where modifications in additives or formulation parameters result in different film-formation characteristics, a 0–10 rating scale with 10 being a perfectly uniform film is often more useful. Film defects that result in non-uniformities of film appearance include things like cratering, orange-peel appearance, and pinholes. One key resource that offers a variety of examples of film defects is the FSCT Pictorial Standards of Coatings Defects Handbook [4].

DRY FILM PERFORMANCE PROPERTIES

Adhesion

An architectural coating system must be designed to have good adhesion on its intended substrate. Many architectural coatings are intended primarily for recoat of previously painted surfaces. Adhesion in this case is straightforward and can be easily verified using a simple cross-hatch adhesion tape-pull test as described by method B of ASTM D3359-09e2, Standard Test Methods for Measuring Adhesion by Tape Test [3].

Because previously painted surfaces can vary in porosity and compatibility with the topcoat, an architectural coatings laboratory often chooses to evaluate adhesion of a paint over an aged gloss alkyd enamel finish. Use of aged gloss alkyd enamels for an adhesion substrate became a standard for a couple of reasons when the first-generation of acrylic emulsion latex paints were emerging. First, the early acrylic emulsion latex paints were often used to paint over alkyd enamels because the alkyd enamels were the predominant paint used in construction at the time. Second, this was a challenging test for many of the acrylic emulsion paints to withstand. A practice for preparation of aged gloss alkyd panels can be found in ASTM D6900-10, Wet Adhesion of Latex Paints to a Gloss Alkyd Enamel Substrate [1].

Exterior coatings and primers often are subject to more challenging adhesion performance standards than interior wall paints. These coatings are subject to be directly applied to not only previously painted surfaces, but also to wood, masonry, and various metals such as steel, galvanized steel, and aluminum. Testing to these different substrates may also follow ASTM D3359 [3] or any other method as described in Chapter 50 of this manual [2].

Exterior coatings are often exposed to wet and humid conditions and must maintain their adhesive character when paint films are wet. One common laboratory practice for evaluating wet-film adhesion is to submerge the test panel in water or place a saturated paper towel or cheesecloth on the test area of the surface until the film is saturated. When the film is sufficiently wet, the coating can be tested using cross-hatch adhesion by tape methods. Another practice is described by ASTM D6900-10 [1]. In this test, the coating is applied to an aged gloss alkyd panel and allowed to cure at an agreed interval. The panel is then soaked, cross-hatched, and placed on a linear abra-

sion machine using a standard wet scrub brush attachment. After 100 or other agreed upon number of cycles, the percentage of squares removed is determined by visually examining the panel.

Scrub Resistance

The intent of a scrub resistance test is to demonstrate the ability of a coating to resist film deterioration and erosion during cleaning. Scrub resistance testing is considered most applicable to interior wall paints. It is generally not as important for exterior coatings because they are more likely to be washed down with water spray rather than with a scrubbing mechanism. Scrub resistance tests are typically done with a household cleaner or a laboratory-prepared cleaning solution. The cleaner selected may be abrasive or non-abrasive depending on the desired harshness of the test. The cleaner is applied to a wet bristle brush which scrubs the surface of the paint film. A linear washability machine tester is typically used to conduct the test.

There are two types of scrub resistance tests. In the first, the coating is tested to a failure point as described by ASTM D2486-06, Standard Test Method for Scrub Resistance of Wall Paints [1]. In this test method, the test paint is applied by drawdown to a uniform film thickness and allowed to dry for a week at standard conditions or at other agreed upon drying interval and conditions. A 12.7 mm by 0.25 mm shim is placed behind the test panel to create an artificial but consistent bump in the path of the scrub brush. As the scrub brush passes over the raised area during the test, the film will show failure here. A bristle brush is wet and applied with an abrasive scrub medium that speeds erosion failure of the test. In this method, it is often a best practice to conduct a comparative test between two coatings. This way any variability in setup of the test is minimized because the two coatings are scrubbed on the same machine simultaneously.

In the second type of scrub test, the coating is tested for a pre-set number of cycles and then measured to determine the amount of film that eroded during the test. Methods of this type include ASTM D4213-08, Standard Test Method for Scrub Resistance of Paints by Abrasion Weight Loss [1] and ISO 11998:2006[E], Determination of Wet-Scrub Resistance and Cleanability of Coatings [5]. In contrast with the scrub to failure methods which use a bristle brush with an abrasive scrub medium, this test requires use of an abrasive pad used with a non-abrasive medium. Additionally, no shims or raised area is necessary for this test. Instead, the coating to be tested is weighed before and after the test. The difference in weight is used to calculate the volume of film displaced or the amount of film thickness lost during the test.

Burnish Resistance

Burnish resistance is the loss of uniformity of finish when a paint film is rubbed during normal use. As with scrub resistance, burnish resistance is a test for interior wall paints rather than exterior paints. Flat and low sheen paints typically burnish more than semi-gloss or gloss paints and sometimes burnish resistance is not even evaluated for higher gloss finishes. The relatively high pigment content of flat paints makes them more susceptible to gloss increases due to burnishing.

In the laboratory, burnish resistance is tested using the same linear washability machine as the scrub tester. However, burnish resistance is typically evaluated under dry conditions. A dry abrasive pad may be used, or a cheesecloth-wrapped piece of wood is attached to the washability machine to provide the mechanism for burnishing. A test method for Burnish Resistance of Latex Paints is offered in ASTMD6736-08 [1].

For very low sheen paints, burnish resistance is typically reported as units of sheen increase. However, in the case of higher sheen flats or satin finish paints, a percentage of units of gloss increased may be more critical in differentiating two test paint systems in performance.

A preliminary assessment of burnish resistance differences between two test paints can be made by simply swiping the back of a fingernail across a drawdown of two test finishes while applying a little pressure. If one of the finishes shows the mark more, it will generally rate lower for burnish resistance. The end resulting panel from a wet-scrub test may also be used to estimate burnish resistance. Simply take gloss measurements on the panel in the path of the scrub brush and in the unscrubbed areas after the paint is allowed to dry.

Stain Resistance, Stain Removal, and Washability

The properties of stain resistance and stain removal are often confused during discussion of coating performance. Stain resistance is the ability of a coating film to resist staining from the specified medium. Stain removal on the other hand, is a rating of how easy it is to remove the stain once it is already present on a coated surface. Because semi-gloss and high gloss coatings tend to be relatively non-porous compared to flat finishes, they are inherently better at stain resistance. This often leads to a higher rating for stain removal because if the stain is trapped on the surface and not in the pores or crevices in the coating, a household cleaner will be able to more easily access the stain and wash it away.

The terms stain removal and washability are essentially equivalent. The term washability is often considered a more practical oriented test designed to mimic actual washing of an interior wall coating with a sponge and household cleaner. Alternatively, standard stain removal tests often have artificial removal methods such as scrubbing with a laboratory benchtop linear washability tester.

Stain resistance can be measured in a couple of different ways. The varieties of stains to use are highly dependent on the end application and what the person designing the test believes are the most critical stains to evaluate. A simple spot test can be used to assess stain resistance for any staining media. An effective test method is described in ASTM D1308-02 (2007), Standard Test Method for Effect of Household Chemicals on Clear and Pigmented Organic Finishes [3]. This method covers not only household chemicals, but also food items such as beverages, cooking oils or fats, and common condiments.

ASTM D1308 provides a wide latitude for an experimenter to choose the most critical parameters for study. Chemical spots can be covered or uncovered and allowed to stand on the test panel for any desired time interval before evaluating. At the end of the test, the stained film area is evaluated for staining or discoloration. Typically a rating scale (such as 10 = excellent, 0 = poor) is designed within

a laboratory to indicate relative performance. Alternatively, stains can be rated simply as pass or fail or, if the stained area is large enough, a color reading can be taken and reported as color difference versus an unstained reference area.

There are two primary ASTM methods that encompass methods used to assess architectural coating performance for stain removal and washability. ASTM D3450-00 (2010)e1, Standard Test Method for Washability Properties of Interior Architectural Coatings [1], utilizes a carbon black dispersion in mineral oil and odorless mineral spirits as the soil-ant medium. After the stain is applied to the test film, a scrub media solution is applied to a wet sponge and affixed to an attachment to the linear washability machine—the same machine used for scrub resistance testing. The sponge is allowed to pass over the soiled area for a set number of cycles. The final result is reported as the ratio of reflectance of the washed soiled area and the reflectance of the unsoiled dry film.

ASTM D4828-94 (2008), Standard Test Methods for Practical Washability of Organic Coatings [1], more closely represents a practical stain removal situation. In this method, soil and staining media include stains from common household items such as lipstick, ink pens, or crayons. The reporting method is a visual assessment and grading of the stain removal rather than a measured reflectance. Otherwise, the mechanics of this method are similar to ASTM D3450 both use a wet sponge with scrub medium and the linear washability machine for a set number of cycles.

Block Resistance

Block resistance is a test intended to measure the ability of a coating to withstand sticking to itself when under pressure. In a field environment, this is represented by a newly painted window and frame or a door and the surrounding molding. Most architectural trim enamel coatings are expected to stand up to block resistance at normal room temperature after only a day after being painted. Block resistance is not typically an issue for flat or satin finish paints—the higher pigmentation level of these classes of coatings usually enable good block resistance performance.

A block resistance test can be done in many ways in a laboratory environment but all block resistance tests follow the same basic procedure. Any two flat substrates, at least one of which is painted with the test paint, are placed face-to-face and a weight placed on top for a certain time interval. After the agreed upon time interval, the flat surfaces are separated from each other. The testing technician can rate the paint for any film separation that happens as well as how tacky the surfaces were to each other during attempted separation.

ASTM method D4946-89 (2008)e1, Standard Test Method for Blocking Resistance of Architectural Paints [1], gives instruction for one standard way to conduct this test. The ASTM method calls for a specific size rubber stopper (#8 stopper) and a 1-kg weight to be placed on top of each test sample. Each test sample consists of a paint drawdown that has been cut into square pieces with two squares placed face to face. The drawdown stays under the 1-kg weight block for 30 min, and then is allowed to rest at room temperature for an additional 30 minutes before separation. The separation is rated based on a 0–10 rating scale with ratings of 4–10 (no tack between samples) grading how tacky or difficult the separation, and the lower ratings of 0–3 (0 = complete separation) being reserved for paints where varying degrees of film sealing are observed.

Block resistance tests can be run at room temperature, but are often also run at elevated temperature of around 110–120°F. The elevated temperature makes a more challenging test and can simulate more challenging field conditions that coatings may face.

Print Resistance

Print resistance is related to block resistance, but instead of the coated paint sticking to another flat surface, another object is allowed to sit on the coated paint and evaluated for the imprint left on the painted surface. This would be tested most typically for high gloss enamel finishes. A typical print resistance test requires a cheesecloth to be placed on the surface and under a weight for a set time period. At the end of the time period, the weight and cheesecloth are removed. The tester then evaluates how much of the imprint is showing on the surface and does not recover. A detailed test protocol for print resistance is found in ASTM D2064-91 (2008), Standard Test Method for Print Resistance of Architectural Paints [1]. Examples of heavy, medium and slight print resistance are shown in Fig. 6 which can also be viewed in ASTM D2091-96 (2003), Standard Test Method for Print Resistance of Lacquers [1].

Architectural Primers and Stainblocking

Architectural primer coatings are designed to be recoated by durable topcoats, so they do not necessarily need to have the best scrub resistance, stain resistance, or high gloss appearance that are requirements for certain topcoat paints. Overall, primer performance is often judged based on properties of adhesion and holdout that were discussed in previous sections. One performance property that is a unique requirement of primers is stainblocking.

Stainblocking is the ability of a coating to prevent staining media present within or on top of a surface from penetrating into a subsequent topcoat. Stains that need to be primed originate from a variety of sources. Some of the more common sources are ink pens or markers on interior walls, water leaks on ceiling tiles, or tannins and other extractives that naturally occur in wood.

The basic steps for testing stainblocking are the same for all. Simply coat the stained substrate with the test primer, allow it to dry then topcoat it with a paint representative of the topcoat that would be used in a field environment. In order to ensure the stainblocking performance is a result of the primer, the topcoat that is chosen often has marginal inherent stainblocking on its own. The drying time of the primer system is a key variable in setting up the test; shorter dry times for the test primer can show more stainblocking performance differences than longer dry times.

For tannin blocking evaluation, wood boards being tested are typically exposed to a humid environment in order to stimulate the tannins within the boards to migrate through the primer. ASTM D6686-01, Standard Test Method for Evaluation of Tannin Stain Resistance of Coatings [1], provides a test procedure for evaluating tannin bleed-through.

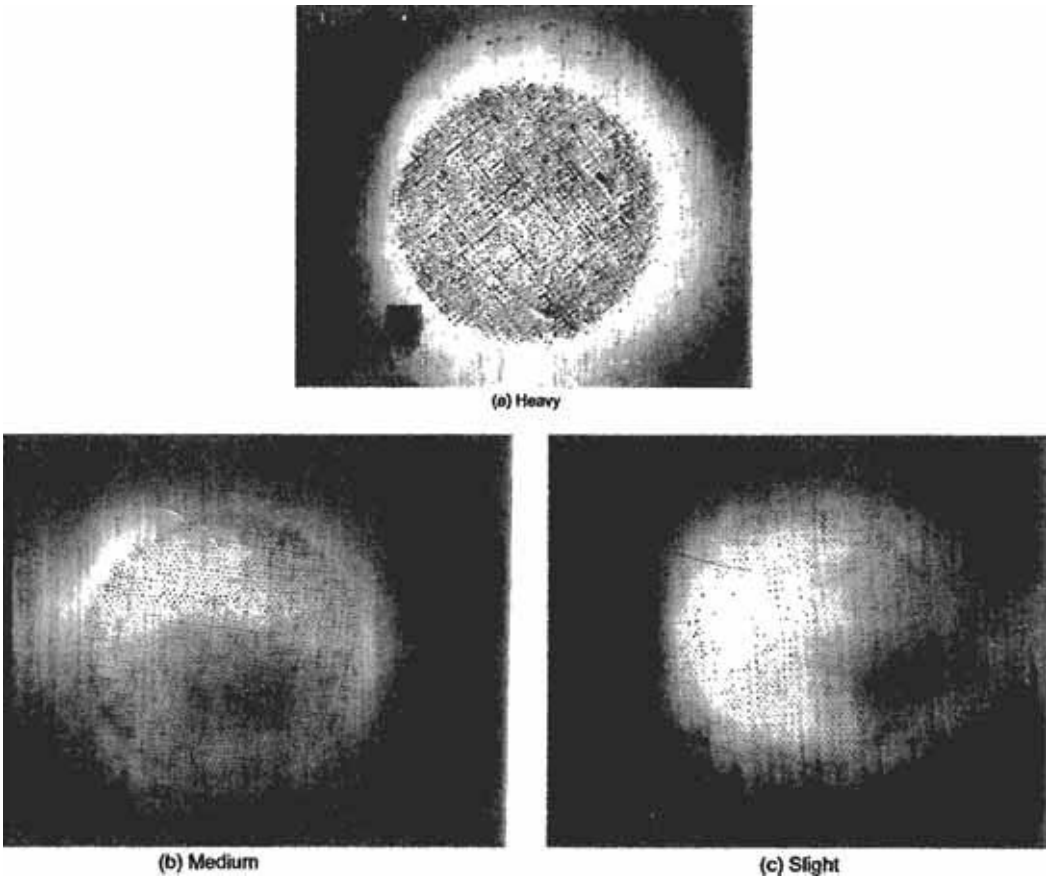

Fig. 6—Print resistance examples. Top panel represents heavy imprint (poor print resistance). Lower left panel represents medium imprint. Lower right panels represents slight imprint.

The results of a stainblocking evaluation are often evaluated by visual assessment and comparison of test primer versus control. For more differentiation, a spectrophotometer can be employed to measure the difference in color that the use of a stainblocking primer achieves. This allows for more precision in differentiating between multiple test systems.

Floor Coatings

Some architectural coatings are designed for application to wood or concrete floors. In general, floor coatings must be considered for their ability to withstand abrasion from light foot traffic. Abrasion Resistance is discussed in detail in Chapter 49 of this testing manual [2]. Any of the abrasion methods described there are applicable to architectural coatings; Taber abrasion or falling sand are most commonly used in practice.

Garage floor coatings have special requirements for testing such as the ability to resist automotive fluid chemicals and to withstand hot tires. Automotive fluid or other chemicals of interest can be tested in accordance with ASTM D1308-02 (2007) [1]. Additional detail on chemical resistance testing of coatings is also found in Chapter 55 of this manual [2]. Hot-tire pickup resistance of a coating can be simulated in a laboratory environment with a section of tire tread. The tire tread is heated to the desired temperature to simulate heat gained from road friction; the tire tread may also be heated while submerged in water to simulate a tire on a rainy day. The tire tread is then clamped to a concrete test panel that is coated with the test paint to generate a desired pressure. After a certain time period, the tire tread is separated from the test panel which is evaluated for film removal or disfigurement as a result of contact with the tire.

Deck Finishes

The architectural coatings category of deck finishes covers several types of coatings including paints, solid color stains, semi-transparent stains, and clear waterproofing coatings. Like floor coatings, deck finishes must also be considered for wear resistance and light foot traffic tests described in the previous section. Natural exposure to elements such as sunlight, temperature variation, and water/humidity are also critical for deck finishes. Because deck finishes on horizontal surfaces must hold up to standing water, they are often evaluated for water repellency. A discussion of water-repellent coatings and related test methods is included in Chapter 67 of this testing manual [2].

Environmental Effects

Many architectural coatings are designed for application to exterior structures. Each exterior coating must be able to withstand sun, moisture, and temperature variations in its designated environment.

For natural exposure, architectural coatings companies typically use a practice similar to ASTM D1006-01 (2008), Standard Practice for Conducting Exterior Exposure Tests of Paints on Wood [3], to evaluate exterior performance.

Although this test practice refers specifically to wood substrates, the basic principles of ASTM D1006 for exposure orientation, test fixtures, use of control or reference materials, application of paints, and inspection may be applied to any type of substrate. When D1006 was developed, wood substrates were once the most common siding material for residential construction, however, many other composite materials and finishing systems now predominate new construction markets.

For accelerated exposures, different methods can be selected. Three of the most commonly used accelerated methods for architectural coatings evaluation are:

1. UV-Condensation exposure—described in ASTM D4587-05, Standard Practice for Fluorescent UV-Condensation Exposures of Paint and Related Coatings [3].
2. Xenon-Arc exposure—described in ASTM D6695-08, Standard Practice for Xenon-Arc Exposures of Paint and Related Coatings [3].
3. Fresnel reflector rack exposure—described in Procedure C of ASTM D4141-07, Standard Practice for Conducting Black Box and Solar Concentrating Exposures of Coatings [3].

There are different reasons to select among these accelerated testing practices. Typical decision criteria on what accelerated protocol to use are decided by cost, ease of maintaining the test equipment and test fixtures, and experience as to which method most accurately duplicates natural exposure for the intended exposure environment. A detailed discussion of accelerated exposure testing for coatings is found elsewhere in this manual [2].

Inspection of coatings on exposure tests are related to maintaining the original appearance and integrity of the paint film. Common exposure evaluation criteria for architectural coatings include the following:

- Gloss and Color Retention
- Film Integrity: Cracking, Checking, Flaking, Erosion
- Chalking
- Mildew growth
- Dirt Pickup

Chapter 52 of this manual [2] describes general inspection practices for natural weathering tests and provides test reference standards to the items listed above.

CONCLUSION

This chapter has provided a broad review of test methods used for the assessment of architectural coatings performance. Sections of this chapter have described tests relevant to several subsets of architectural coatings as well as performance testing categories including liquid paint and film formation, application characteristics, appearance, dry film performance, and environmental effects.

Ultimately, an architectural coatings formulator must design test criteria that take into account changing regulatory requirements, various field application techniques and substrates, and environmental exposure factors. It is the author's intent that the contents herein prove useful to a formulator or testing technician to establish criteria, guidelines, and references for evaluating architectural coatings systems.

Artists' Paints

Benjamin Gavett[1]

INTRODUCTION

AS COATINGS, ARTISTS' PAINTS ARE DECORATIVE in nature and are intended to endure for decades or centuries under conditions of indoor storage and display. Relative to other coatings, they are highly loaded, most often with a single pigment. Thickness of application ranges from transparent washes to thick, textural builds. Typical tools used include the airbrush, paintbrush, and palette knife, but paints are also often applied by other means, such as rags, sponges, or with the hands. They are often modified at the time of application to change sheen, texture, color, flow, or other characteristics. The substrate used is usually paper or a cotton or linen duck stretched over an open frame, but may be almost anything else, including solid or compressed wood panels, paperboard, metal, synthetic fabric, glass, figurines, clothing, or walls.

Artists' paints are categorized according to their vehicle or binder. Most common are oil (alkali-refined linseed oil), acrylic (acrylic emulsion), and water color (gum arabic). Variations of these include several types of vegetable-based drying oils, such as cold-pressed linseed oil, safflower oil or stand oil, and acrylic emulsion copolymers. Other natural and synthetic materials that are in more limited current use are acrylic solutions, poly(vinyl acetate), casein, egg, wax, and various gums.

Although an artist will use almost any paint, those formulated for such use are expected, above all else, to be as permanent as possible. However, paint is only one element in the process of manipulating materials to transform vision and ideas into art. Stability of the finished work is a function not only of the paint used, but also of application technique, substrate, age, storage, handling, and ambient environmental conditions.

TESTING OF ARTISTS' PAINTS

Testing of artists' paints is done to ensure quality and consistency in their manufacture, as well as to determine the performance parameters a user should expect from the paint, such as flexibility, durability, and adhesion to various substrates. Some performance criteria, light fastness, for example, are similar among different types of paints. Others can be quite different, such as flexibility, or drying time. It is up to the manufacturer to perform tests necessary to ensure that the paints are of a quality consistent with or exceeding that which is expected and historically true for the type of paint being produced. The artist, through experience and education, must be aware of the particular limitations inherent with each type of paint. When new applications are explored, as is often the case with art, it becomes necessary to select and perform tests that will provide confidence that the finished artwork will have the desired physical integrity.

The tests described in this section have been found to be useful to quantitatively and qualitatively describe various characteristics of artists' paints. Acceptability of quality is determined between buyer and seller. In practice, it is largely dependent on what is considered characteristic of the particular paint type. Many of these test methods are ASTM standards that the reader should consult for further details. It is important to note that there are ASTM standard specifications for several types of artists' paints, including acrylic emulsion, watercolor, gouache, oil, resin-oil, and alkyd. These represent the current consensus, between producers, consumers, and other interested parties, of minimally acceptable performance characteristics and other criteria. Most of the following test methods were not developed for artists' paints in particular. Due to the wide spectrum of types of artists' paints and potential uses, this listing does not include all test methods that may be relevant, but several ASTM documents pertinent to artists' paints and not given herein are given in Table 1. Each method described is not relevant for all types of paint. Those included are of varying importance and applicability. They are grouped loosely into several categories: Shelf Stability, Working Properties, Film Properties, and Safety and Compliance.

SHELF STABILITY

It is common for art materials to languish for years on store shelves prior to being purchased. Once purchased, a container is typically opened and closed many times during a life cycle that may take months or years. Stability is evaluated to help ensure endurance of the product through foreseeable conditions of storage and use.

Appearance

The appearance of the undisturbed paint in the container creates an impression of quality, regardless of the ease of restoring it to a homogenous condition. Evaluations for appearance in the retail container are most accurate when based on true conditions of storage and use. However, this is not practical when developing new products. Potential failure may be more quickly realized by placing samples in a laboratory oven at a moderately elevated temperature. As the difference between normal and test temperature increases, accuracy in predicting potential problems may decrease because higher temperatures may exaggerate changes. In a study of latex paints published in the *Journal of Coatings Technology* [1], the authors concluded that an oven temperature of approximately 50°C most accurately predicted shelf-life performance. Items to note regarding

TABLE 1—ASTM documents useful to artists' paints interests and not used in text

ASTM	Document Title
D1535	Standard Practice for Specifying Color by the Munsell System
D1968	Standard Terminology Relating to Paper and Paper Products
D3424	Standard Practice for Evaluating the Relative Lightfastness and Weatherability of Printed Matter
D3730	Standard Guide for Testing High Performance Interior Architectural Wall Coatings
D4236	Standard Practice for Labeling Art Materials for Chronic Health Hazards
D4941	Standard Practice for Preparing Drawdowns of Artists' Paste Paints
D5010	Standard Practice for Testing Printing Inks and Related Materials
D5067	Standard Specification for Artists' Watercolor Paints
D5181	Standard Test Method for Abrasion Resistance of Printed Matter by the GA- CAT Comprehensive Abrasion Tester
D5724	Standard Specifications for Gouache Paints
D6043	Standard Guide for Selection of Permanent and Durable Artists' Papers
D6801	Standard Test Method for Measuring Maximum Spontaneous Heating Temperature of Art and other Materials
D6901	Standard Specification for Artists' Colored Pencils
D7188	Standard Terminology for Printing Inks, Materials and Processes
E308	Standard Practice for Computing the Colors of Objects by Using the CIE System

appearance may include skinning, surface cracking, or separation. Parameters of acceptability will vary depending on expectations of the customer for the particular type of paint.

Color Change

Sometimes the color of a paint film produced from a container of paint changes during storage, for example, as can happen when a pigment is not compatible with the pH of the formulation. This may be determined by preparing a fresh batch of the paint to be tested and immediately preparing a drawdown from it. Subsequent drawdowns at the same thickness may be periodically prepared from the same batch after the paint has aged in the container. The subsequent drawdowns are compared against the original. Using a laboratory oven may accelerate the results obtained from this test.

Consistency

During storage and use, it is desirable that the paints maintain their intended texture and body. Evaluations are based on visual observation and workability with typical application tools. Items to note include mealiness, tackiness, elongation, and break. as well as other body characteristics. Conclusions may be drawn by comparing batches of the same formula, made at different times and that have been stored and otherwise similarly treated. It is useful to evaluate both full and partially empty containers.

Flocculation

To determine if the pigment is fully dispersed or has remained dispersed over time, a tint of the color is prepared with a compatible white. A drawdown is made and the excess paint is recovered and set aside until the drawdown is dry. Next, a small amount of the original wet mixture is placed on top of the dried paint film. This paint is then rubbed under pressure in a circular motion (a gloved thumb is suitable) in an effort to cause further dispersion of the pigment. If it has become more fully dispersed, the rubbed paint will appear as a stronger tint against the original drawdown.

Freeze-Thaw Stability

Shipping and storage often expose artists' paints to extreme temperature fluctuations. Water-based paints can be quickly ruined if not formulated for protection from freezing. ASTM Specification for Artists' Acrylic Emulsion Paints (D5098),in Volume 6.02 of the ASTM Book of Standards, describes the procedure used for testing acrylic paints. The same procedure is used for watercolors. To meet the requirements of the standard, the paints must pass five freeze-thaw cycles while retaining proper consistency.

Package Integrity

The expected life and use of the package containing the paints should be considered when designing appropriate tests. Consider, for example, how the container will be shipped or how many times a tube will be flexed. Potential interactions between the paint and packaging should also be evaluated. For example, solvents may migrate through the walls of plastic containers, causing them to become drawn inward. Real time evaluations are best, but potential failure can be accelerated by increasing temperature or solvent load.

Seeding

Over time, ingredient incompatibilities or reactive pigments may result in seeding, the formation of small, undesirable particles or granules in paint, varnish, or lacquers [2]. This can be readily observed by preparing drawdowns of the paint, as described in ASTM Practice for Preparing Drawdowns of Artists' Paste Paint (D4941) and examining the dried paint film. ASTM Test Methods for Coarse Particles in Pigments (D185) may also be used.

Settling

In low-viscosity formulations, it is common for pigments to exhibit some settling. Ideally this would not happen, but if it does, it is important that the pigments are easily remixed. Settling that occurs over time may be evaluated according to ASTM Test Method for Evaluating Degree of Settling of Paint (D869).

Spoilage/Putrefaction

It is necessary to protect against microbial contamination from raw materials and packaging or that may be introduced during manufacturing. Also, since artists' paints

are typically opened, used, and re-closed many times, it is important that they be formulated to resist microbial growth from contamination occurring subsequent to purchase by the consumer. ANSI Z356.5, American National Standard for Art and Craft Materials—Paints and Inks, Section 4.2, describes a test method for evaluating the effectiveness of preservatives used in paint formulations. Paints to be tested are inoculated with pieces of bread that have been covered with a sugar solution and allowed to mold. After 2 weeks, the paints are inspected for decomposition.

Viscosity Changes

Paint stability is quickly and quantitatively evaluated by monitoring viscosity. Viscometer type and method have not been standardized for artists' paints. If needed, a method may be agreed upon between buyer and seller. For most purposes, it is sufficient to ensure consistency of test conditions and equipment when doing periodic rechecks. Accelerated aging with the use of a laboratory oven is usually predictable of real-time viscosity stability of water-based paints.

WORKING PROPERTIES

Many attributes of importance to the consumer of artists' paints are difficult to measure and report with repeatability. This subjectivity is often coupled with varying preferences among users. An ideal paint for one artist may be lacking in certain qualities for the next. It is not as important to standardize these characteristics, as it is to determine them and transfer this knowledge to the buyer.

Brushing Characteristics

Paints are brushed out on standard substrates by experienced technicians and rated as being smooth, sticky, tacky, or fluid, as described in Section 6.6 of Commercial Standard (CS98) for Artists' Oil Paints [3]. This was the original quality standard for artists' paints and was the base from which the subsequent ASTM artists' paint quality standards were developed. It is also common to describe artists' paints for their tendency to flow and level or hold brush strokes and peaks.

Color Variation

If batch-to-batch constancy of color is desired, it may be determined by placing samples next to each other on a test card and drawing them down together using a thin film applicator. Comparisons of masstone, undertone, and tint are useful. For quantification and reporting, spectrophotometric measurements and CIE L*a*b* color difference may be obtained according to the practices described in ASTM Practice for Calculation of Color Tolerances and Color Differences from Instrumentally Measured Color Coordinates (D2244).

Drying Time

ASTM D5098, Specification for Artists' Acrylic and Dispersion Paints and ASTM Specification for Artists' Oil, Resin-Oil, and Alkyd Paints (D4302), specify drying time requirements. Dust-free drying time of these and other types of paints are determined by following the procedures described in ASTM Test Methods for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature (D1640).

Fineness of Dispersion

Finely dispersed pigments are important for smooth brushing, realizing tinting strength potential, and maximizing encapsulation of pigment within the binder. ASTM Test Method for Fineness of Dispersion of Pigment-Vehicle Systems by Hegman-Type Gage (D1210) may be followed to measure this characteristic.

Odor

Evaluation of odor may be important in determining potential consumer acceptance of artists' paints. The different vehicles have characteristic odors and what is objectionable to some may not be to others. Formula variations may be rated, based on the acceptability of their odor, by a panel of intended users.

Opacity

Opacity is not standardized for artists' paints. It is expected to vary depending on the pigment and vehicle used. The artist benefits if opacity ratings are reported on the container or in manufacturers' literature. This characteristic is typically evaluated by applying a drawdown over a test panel that has adjoining areas of black and white. A scale is then established and colors are assigned values relating to a range from highly transparent to fully opaque.

Tinting Strength

The potency of a color is indicative of its value to the user, particularly when blending with white (absorption tinting strength). Depending on chemical composition, pigments are expected to vary accordingly in strength. Identically pigmented paints may exhibit differences due to degree of processing or loading. It would not be appropriate to critically compare paints of different vehicles because of differences in the loads they will tolerate. ASTM Standard Test Method for Determining the Relative Tinting Strength of Chromatic Paints (D4838) may be followed to arrive at instrumentally derived determinations of tinting strength relative to that of a standard or reference paint. Simple comparisons between paints can be made by using a white paint of standard composition and strength to prepare tints, which are then drawn down alongside of each other. The tints are most accurately prepared using a weight-based ratio of the standard white to the test color. A ratio based on volume, using syringes, may be useful if an accurate balance is not available or if it otherwise suits the purpose of the user.

Viscosity

Artists' paints are available in a wide range of viscosities, from pourable ink-like to heavy impasto. Oil paints are typically expected to maintain definition of the brush stroke, provide sharp peaks, and retain their shape as they emerge from the tube. Water-based vehicles are highly manipulative, and the desired viscosity is dependent on the intentions of the user and manufacturer. Viscosity, thixotropy, and dilatancy may be determined with the equipment and techniques described in ASTM Test Methods for Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield Type) Viscometer (D2196).

FILM PROPERTIES

Adhesion

Intercoat and substrate bonding of artists' paints are extremely important. They become especially critical to

evaluate when determining surface preparation techniques for new or unusual substrates or when considering multi-media applications. There are many types of adhesion testing apparatuses, but a useful and inexpensive test involves cutting the paint films and attempting to lift them with pressure-sensitive tape. This is described in ASTM Test Methods for Measuring Adhesion by Tape Test (D3359).

Bleeding

Artists' paintings are typically created in a manner that results in overlapped or layered films. The tendency for color of an underlying dry paint film to migrate through to subsequently applied paint is an occasional but usually unwelcome occurrence resulting from the pigment exhibiting some solubility in the vehicle. The tendency for bleeding may be determined by applying an opaque white overstripe onto a smooth, dried paint film. The white is extended off the paint film and onto the uncoated portion of the test support. Discoloration due to bleeding will be readily apparent. This test is described as Test Method B of ASTM Test Methods for Bleeding of Pigments (D279).

Block Resistance

Artists' paintings are not typically produced, used, or stored in a manner that will cause them to come into contact with and stick to other surfaces. However, there are times when this does occur, such as in production situations or when there is inadequate storage space. If block resistance is important to the user, the paint in question should be evaluated because many artists' paints exhibit inherently poor block resistance. A case-specific test should be designed to simulate worst-case scenarios of pressure, temperature, and humidity fluctuations. Anticipated drying and storage times should also be considered in the test design.

Chemical Resistance

Resistance to the various liquids with which a painting may be expected to come into contact is an important characteristic. These include varnish vehicles, solvents used in varnish removal, and cleaning solutions that may be used on the paint film. Chemicals to be tested with a particular paint vary depending on the type of paint and what is expected of it. A procedure for designing appropriate tests may be based upon the Spot and Immersion Tests described in ASTM Test Method for Effect of Household Chemicals on Clear and Pigmented Organic Finishes (D1308).

Flexibility

Paints applied to flexible supports, such as stretched cotton or linen canvas, may be susceptible to potentially destructive forces. The different types of artists' paints vary in the degree they will flex without failure. Although there are no established standards, they have different thresholds of expectation and, therefore, acceptability.

During storage or shipping, paintings are often rolled up. ASTM Test Methods for Mandrel Bend Test of Attached Organic Coatings (D522) describes equipment and methods for determining and rating flexibility. Relevancy is increased by testing the coatings over the intended substrate and primer. Combined with the use of accelerated aging techniques, the mandrel test will help predict natural embrittlement of the paint film.

Paintings must also endure expansion and contraction of the fabric due to changes in environmental humidity and temperature. Sometimes these conditions become extreme, as when a painting is shipped during freezing weather. Failure will occur more quickly if the individual components of the painting have greater relative differences in their moduli of elasticity. Use of a temperature and humidity-controlled environmental chamber programmed to expose paintings to repeated cycles of extreme conditions will accelerate the failure that might be observed over time under normal conditions.

Another force of concern is mechanical impact against the film that may occur during handling. For example, when a painting is mounted on an open-back stretcher, fingers may inadvertently press into it as it is being carried. The risk of damage increases as temperature decreases and the glass transition temperature is approached. The rate at which external forces are applied also influences susceptibility to damage.

Gloss

Some manufacturers of artists' paints will add inert flatting agents to control the gloss values of the various colors so that they are similar within a line. Others will allow a color's gloss to be dictated by the characteristics of the colorant, i.e., tolerable load and particle size. Gloss values for artists' paints have not been standardized. It is a matter of preference and manufacturing philosophy. When required, gloss may be specified between the buyer and seller, with measuring parameters identified.

Lightfastness

ASTM Test Methods for Lightfastness of Colorants Used in Artists' Materials (D4303) describes three methods used to determine resistance to fading of acrylic, watercolor, alkyd, and resin-oil artists' paints. Included are conditions of exterior exposure under glass, artificial daylight fluorescent lamps, and xenon-arc apparatus. Prior to exposure, samples to be tested are tinted with white until they reach 35–45 % reflectance at their wavelength of maximum absorption, between 420 and 620 nm. With each method, exposure is continued until specimens have been exposed to a total radiant dose of 1260 MJ/m^2. To meet the ASTM standard specifications for use in artists' paints, the pigments must be tested under at least two of the three methods and exhibit a mean color change of less than eight color difference units (CIE 1976 L*a*b* color difference equation). These test methods are designed to predict performance of artists' paints displayed in typical household or museum environments. Results may not be indicative of performance if the intended use is more rigorous, such as in exterior mural applications.

There are also ASTM practices for determining the lightfastness of artists' materials by exposing samples indoors to sunlight filtered through window glass while simultaneously exposing a series of eight ISO Blue Wool Reference materials to control the duration of exposure. One half of each specimen and control is shielded from exposure during the test. This test takes longer to run, but it is relatively inexpensive. It is intended for artists' materials that are not specifically covered by other ASTM standard test methods. For details, see ASTM Standard Practice for the Visual Evaluation of the Lightfastness of Art Materials

by the User (D5398) and ASTM Standard Practice for the Visual Determination of the Lightfastness of Art Materials by Art Technologists (D5383).

Yellowing

While oil or alkyd paint vehicles may be expected to yellow to some degree, this may be considered a serious flaw if encountered in the newer generation of synthetic media. To determine the relative potential for yellowing of a vehicle, a standard titanium dioxide white pigment may be formulated into the test vehicle and into one of known stability. They are then exposed to the accelerated methods described in ASTM D4303, Test Methods for Lightfastness of Colorants used in Artists' Materials, and the amount of yellowing is determined with ASTM Practice for Visual Evaluation of Colors and Color Differences of Diffusely-Illuminated Opaque Materials (D1729) or Test Method D2244, Practice for Calculation of Color Tolerances and Color Differences from Instrumentally Measured Color Coordinates. It is also useful to subject films of the unpigmented vehicles to the same tests.

SAFETY AND COMPLIANCE

Flash Point

Solvent-based paints may require flash point determination for label warnings and to determine applicability of shipping regulations. The prescribed test method can vary depending on the authority. ASTM Test Methods for Flash Point of Liquids by Small Scale-Closed-Cup Apparatus (D3278) is usually applicable.

Toxicological Evaluation

The Federal Hazardous Substances Act (FHSA) requires all art materials to be evaluated by a board-certified toxicologist for potential to cause acute and chronic health effects. This law was incorporated into the FHSA with the Labeling of Hazardous Art Materials Act (LHAMA), the basis of which is ASTM Practice for Labeling Art Materials for Chronic Health Hazards (D4236). A wide assortment of test methods provides the information required for the toxicological assessment. These are not specified by the Standard Practice or LHAMA, but include all which are embodied in the field of toxicology as well as compositional analysis of the paints and their constituents. The evaluating toxicologist determines any testing that may be required to supplement the information that exists for the raw materials in a product. Appropriate precautionary label information is then assigned. The toxicologist must supply the criteria used in making these determinations to the Consumer Product Safety Commission, the enforcement agency of the FHSA.

One ASTM method developed to provide analytical data useful in a Toxicological evaluation is D5517, Standard Test Method for Determining Extractability of Metals from Art Materials. This method was adopted from the European Toy Standard, EN71-3. Test conditions are designed to simulate the acid potential of gastric juice, at body temperature.

Volatile Organic Compounds (VOC)

Artists' paints are sometimes applied to substrates that are covered by VOC regulations. Architectural, sign painting, and furniture application are examples. ASTM Practice for Calculating Formulation Physical Constants for Paints and Coatings (D5201) provides equations to calculate the theoretical VOC content of paints, based on the formula and exclusive of water and exempt solvents. EPA Test Method 24 is the standard analytical approach used to quantify VOC in coatings applied to architecture.

BIBLIOGRAPHY

The following books provide additional reading on the subjects of artists' materials, their uses, history, and characteristics. These books also contain extensive reference sections.

Can Coatings

Joseph V. Koleske[1]

PREFACE

IN PREPARATION OF THIS CHAPTER, THE CONTENTS of the fourteenth edition of this manual were drawn upon. The author acknowledges the author of the chapter in the fourteenth edition, Martin B. Price. The current edition will review and update the topics as addressed by the previous author, introduce new technology, and include up-to-date references.

INTRODUCTION

The container industry is a major user of coatings with functional coatings used on the internal surfaces and protective, decorative, informative coatings used on the external surfaces. Internal coatings are often sanitary in nature and meet Food and Drug Administration requirements. In 2005, about 100 billion (also see Tables 1 and 2) cans were manufactured in the United States. Each can contains very little coating in a mass sense, but to point out the obvious, with a multiplier of ten to the eleventh power, very large amounts of materials are involved.

Cans are used to package a wide variety of materials including beverages (beer and soft drinks), food products (baby food, coffee, dairy products, fruit and fruit juices, meat and poultry, soup, vegetables, and others), pet foods, and nonfood products such as aerosols, automotive products, paint, and clear coatings. Beverage packaging is by far the largest user of cans with an annual usage of about 100 billion units in the USA and about 200 billion units worldwide. In a general sense, beverages are packaged in aluminum containers and food and other products in steel containers.

The majority of the cans are coated individually with most having different coatings on each side—i.e., internally and externally—and on the ends. These coatings provide corrosion resistance under a variety of conditions, compliance with strict food and taste requirements, and attractive, long lasting identification characteristics to each container. During storage, a long shelf life is required for internal beverage coating materials that are in contact with liquids that range from being quite alkaline to quite acidic in nature. The processes required for the efficient and economically acceptable manufacture of two- and three-piece cans and can ends involve complex engineering. Unique physical coating characteristics are required to conform to machinations of these complex mechanical systems that manufacture an article that is well known and broadly used at an extremely rapid rate and in large volume. A majority of the tests currently in use to ensure that all the requirements are met are discussed in this chapter. A brief description of the process for can production is included. Because it represents the largest volume of cans, most of the discussion will be directed toward beverage cans.

DESCRIPTION OF THE CAN INDUSTRY

Brief History of Beverage Cans[2]

The first flat top beverage can was made by American Can Company to contain Krueger's Beer.[3] The beverage went on sale on January 25, 1935 in Richmond, Virginia. When the year was over, 200 million cans had been sold. In the next year, the Felinfoel Brewery located in Wales, Great Britan sold canned beer outside the United States. The following year 23 breweries in the United Kingdom were marketing 40 brands of beer in cans. The Schmalbach Brewery became aware of the growing popularity of canned beer and introduced its first canned beer in 1937 using a three-piece can and a crown-cork closure rather than a flanged can end.

The early process for beer can construction was complicated and after a fast start in the mid-1930s, the technology did little until the early 1950s. Americans stationed in Frankfurt, Germany, became accustomed to using and liked the three-piece, tinplated-steel can, and in 1951 the German brewery marketed its export beer in this type of can. In addition, during WWII, beer was shipped to military personnel on overseas duty in steel cans. Even though the can required punching a hole with a special opener on the flat topped can, military personnel returning home brought a strong desire for this type of packaging and the metal-can beverage industry grew quite rapidly.

In 1959, Coors brewery became the first to introduce a two-piece, lightweight, aluminum can, but the special opener was still required. Later a pull-tap was devised, but it separated from the can and became an additional litter problem as well as a sharp item wherein people could be cut. Later, in 1963 Alcoa invented the easy open, pull-tab that stayed attached to punch a drinking opening in the can top and the litter and sharp hazard from the tabs disappeared. The two-piece aluminum can was here to stay in the United States, and it has grown to its current level of about a hundred billion cans with the volume about two soft drink cans to one beer can (Table 1).

Even with the new attached pull-tab, the aluminum can represented an environmental litter problem that would not

TABLE 1—United States production of beverage cans (number rounded to the nearest billion cans) [2]

	Billions of Cans					
	1980	1985	1990	1995	2000	2005
Beer Cans						
Aluminum	26	36	39	36	33	32
Steel	4	0.1	0.4	0	0	0
Total Beer Cans	30	36	39	36	33	32
Soft Drink Cans						
Aluminum	16	30	49	63	67	68
Steel	10	4	4	Nil	0	0
Total Soft Drink Cans	26	34	53	63	67	68
All Beverage Cans						
Aluminum	42	66	88	99	100	100
Steel	14	4	4	0	0	0
Total	56	70	92	99	100	100

go away by a rusting process. Cans were quite prevalent throughout the countryside. Further, aluminum, though abundant in nature as bauxite ore, was and is produced by a relatively expensive process and beverage can cost was and is important. To combat these problems, ways to decrease the amount of aluminum used in each can have been devised by using thinner and stronger designs. Since the early 1980s, aluminum cans have decreased in weight by about 30 %. By developing a good recycling program for the empty containers, the littering factor has been markedly diminished while obtaining overall cost savings for the industry. As described in Table 2, 63 % of beverage cans are recycled in the USA and in Japan 78.5 % are recycled. Elsewhere the number of cans recycled is less, but recycling is still growing in importance. During this time, internal and external coatings were developed to safely contain both beer and soft drinks and to present an attractive, decorative outer appearance.

The Can Coating Industry

The volume of coatings consumed by coating cans for food and beverages in the United States places the container industry among the highest users of finishes by all industries. However, the consumption has not been growing because the number of cans is relatively constant and there have been efforts through the years to increase formulation solids or to switch to essentially 100 % solid systems as represented by radiation-cure coatings. Although the United States is the largest user of cans and coatings for cans, the European market [1] certainly has a significant volume and manufactured over 38 billion units in 2005. South America is another growth area.

TABLE 2—Recent aluminum beverage can production in various countries [2,3]

Country	Year	~Billions of Cans	% Recycled
Australia	2005	3	. . .
Europe	2005	38	. . .
Japan	1999	17	78.5
United Kingdom	1999	7.7	31
United States	1999	102	63
World	2001	200	. . .

Can Production Process

Two-Piece Can Production

As late as 1990, about 400 million beer cans and 4 billion soft drink cans were made of steel in the United States (Table 1).[4] Five years later there were no steel beer cans and only a few soft drink cans made of this material. Currently, all of the beverage containers are constructed of aluminum and comprise what are commonly called "two-piece cans." Fig. 1 is a simplified schematic of the process used to prepare these cans from aluminum or steel. The can is manufactured by punch pressing cups from sheets or coils of either metal, though mainly from aluminum. The cups are then forced through a series of rings to "iron out" and form the domed bottom and to form a full-length can. At this stage, the product is a container with sides, a bottom, and an open-ended top that represent one of the two pieces of a two-piece can. The can lid, with pull-tab opener, is sealed and secured after filling and is the second piece of the can.

Decoration, identification, and, often, descriptive and informative consumer information are applied to the containers with exterior inks and coatings. Increased manufacturing speed and smooth movement on the production lines requires the proper lubricity of the coating. The containers and attendant coating require a high degree of abrasion resistance to maintain aesthetics and prevent can failure

[4] Annual production details for beverage and food containers can be found in Ref. [2].

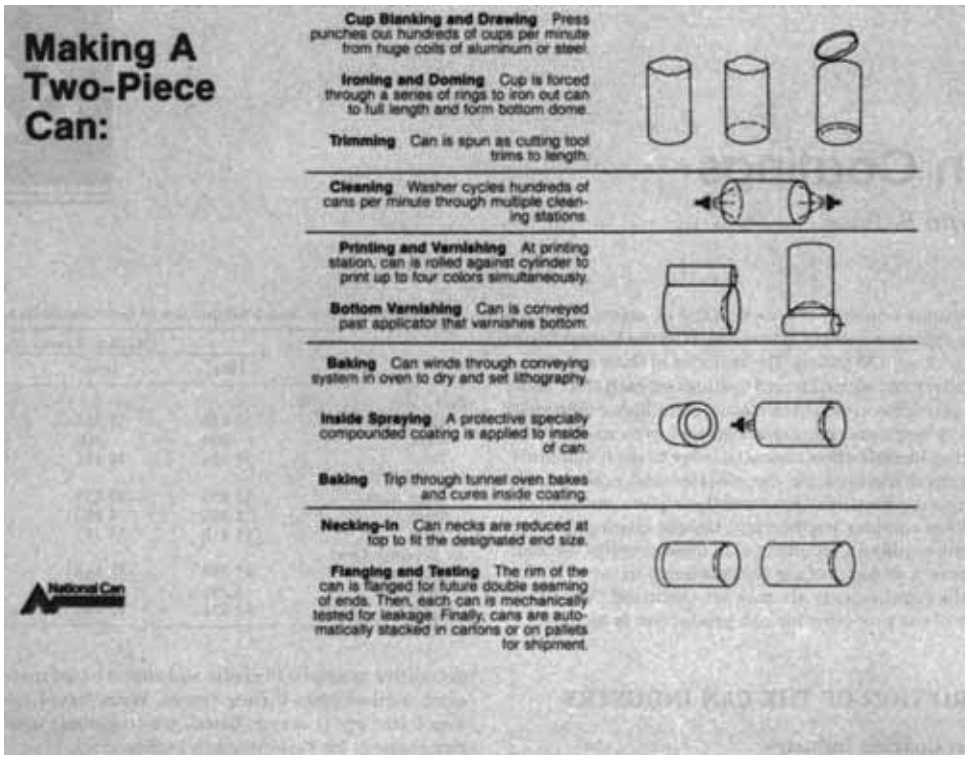

Fig. 1—Two-piece can production process.

during processing and shipping. Cans rubbing against one another during movement in any of the production process steps and shipping can cause scratches. These are often unacceptable for aesthetic reasons and, in extreme cases, can result in the actual rupture of the increasingly thinner stock from which the cans are manufactured.

In 1992, average aluminum cans weighed 16.55 g and by 2005 the weight had been decreased to 14.7 g—a reduction of 11.2 % [3]. Savings such as this, coupled with recycling, have reduced costs and made aluminum containers competitive. Cans are often so thin that filling before sealing is required to give the container adequate rigidity for the crimping/sealing operation. Further, the level of flexibility in the container and coatings must be inherently sufficient so that the severe crimping operation, which is critical to securing the lid onto the container, can be accomplished without coating failure or delamination.

Coatings are usually applied to the interior of these cans by spray techniques. Rapid application is obtained by using short bursts of airless spray from a lance positioned opposite the center of the open end of horizontally held cans. This process or a similar one is used when coating most food and drink containers. If the intended can content is acidic in nature, as is the case with most soft drinks, uncoated containers can corrode. Thus, an internal coating that presents an adequate barrier to this corrosion must be applied. Although beer is not strongly acidic in nature and corrosion is less a problem than with soft drinks, a major concern exists regarding taste-alteration potential due to contact of the beer with the metal container walls. Thus, the protective inner coating protects from metal contact and in itself must not alter the taste of the packaged product. To achieve this end, the coating must have a low level of extractables.

Coatings suitable for food and beverage use (a) must be Food and Drug Administration (FDA) compliant, (b) must pass subjective taste tests to ensure there is no adverse contribution of the flavor of the product, and (c) must meet demanding toughness and flexibility requirements. Both the interior and exterior coatings must pass most of these tests for production of the can to be acceptable. For a majority of the cases, after the can is packed and sealed, it is subjected to a thermal treatment to complete processing of the contents. Many of the commercial beer products require pasteurization that is normally carried out at 150 to 180°F (65.5 to 82.2°C). Higher temperature exposures are required for processing other food products in many packaging operations. Coatings on the crimped edges of the can that have survived the actual crimping and sealing procedure must maintain adhesion, clarity, color, and abrasion resistance after these thermal treatments.

Three-Piece Can Production

Fig. 2 is a simplified schematic of the three-piece can production process. In a typical manufacturing process for this type of can, a large metal coil is sheared into sheets. An "inside" container coating is placed on one side of these sheets usually by roll-coater application and the coating is cured. When an exterior can coating is required in lieu of paper or plastic labeling, the "exterior" or other side of the sheet is coated with the decoration and information as defined by the customer. This decoration is often overcoated with a clear coating and the sheets are cured for a second time to form the coated can body sheets. On low-rust potential metal when paper or plastic is the customer chosen labeling technique or when ultraviolet radiation cured coatings are used, the second oven-cure operation may not be required. (The ultraviolet radiation

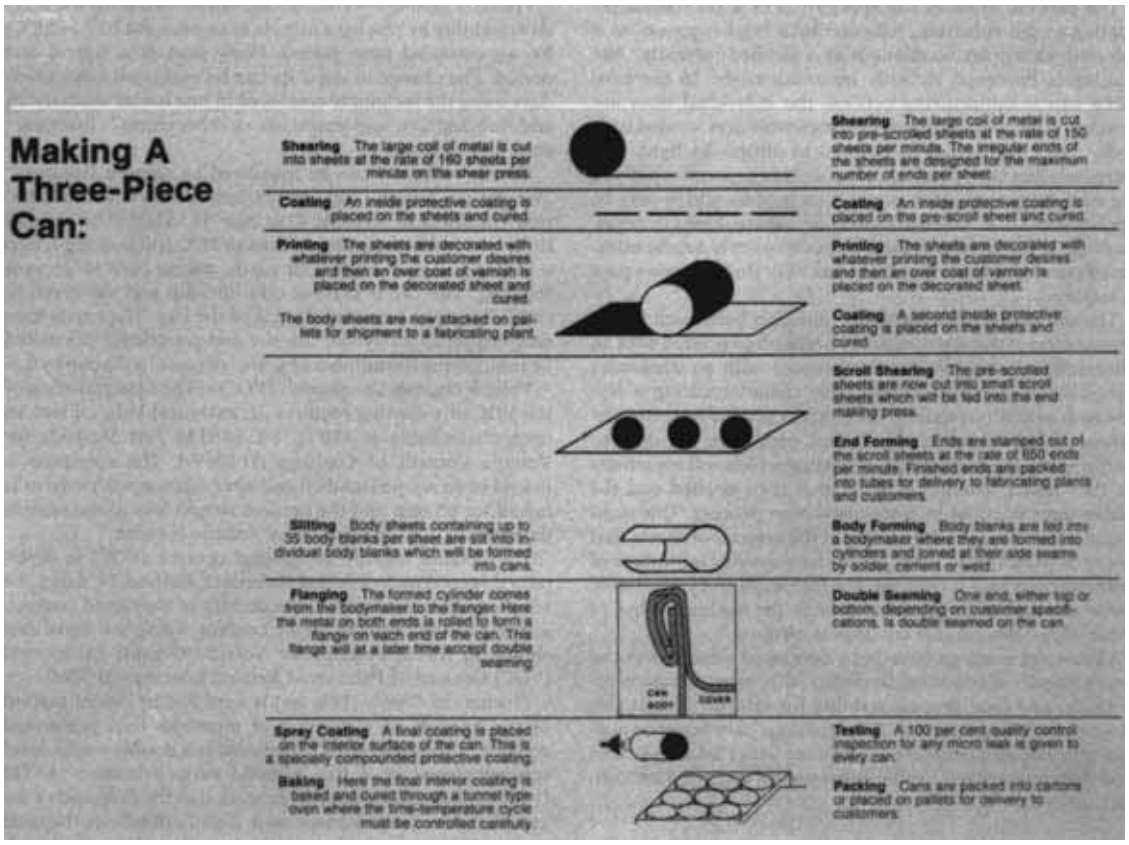

Fig. 2—Three-piece can production process.

curing process will be discussed later.) The coated sheets are stacked and shipped to the fabrication section or plant where they must easily slide over one another during the subsequent processing steps. To achieve the desired degree of lubricity, specific lubricants may be applied after the final baking process. The coated surfaces are often tested to evaluate the nonbonding characteristics of the sheets during stacking.

For can fabrication, the coated can body sheets are slit into individual body blanks. Usually about 35 body blanks are obtained from each sheet. The blanks are coiled into a cylindrical shape and flanged to permit formation of a seam. The seam is then welded, soldered, or cemented to form the can body. A coating is required to cover the seam, since the initially applied coating is usually destroyed or deformed during the seaming process. A coating, either liquid or powder, is applied to the seam and thermally cured or fused. This coating must have all of the requirements of the main body coating, including FDA compliance, and cause no detectable alteration to taste of the contained product.

Preparation of Can Ends

Can ends are stamped from sheets that are already coated on the side to be in contact with the packaged product. With some metals, the side destined to become the exterior will also be coated to impart corrosion resistance. Can-end coatings must have the proper combination of mechanical properties, particularly flexibility, to withstand the crimping necessary to secure the end to the top or bottom of the container. The coatings, including the crimped sections, must maintain their integrity through the elevated-temperature, food-processing steps as required for two-piece cans (Table 3).

Some can ends have been coated by the electrocoating or electrodeposition process. Early descriptions of the use of electrocoating process can be found in the literature in, for example, the United States Patent 3,847,786, "Roll-Through Method and Apparatus for Electrocoating Can Ends," Nov. 1974. The process provided for quickly coating the surface and, in particular, for covering any sharp

TABLE 3—United States production of food cans for human and pet consumption [2]

	Approximate Number of Food Cans (Billions)

or raw edges from the forming process. More recently, in April 2007, United States Patent Application 20070080065, "Methods for Electrocoating Full Panels of Easy Open Ends," was filed by Oravitz and co-workers who applied for a patent that involved the electrodeposition process. The full panel of easy-open ends is essentially uncoated prior to electrocoating.

Ultraviolet Radiation-Cured Coatings

Ultraviolet radiation curing [4] is a relatively new technology that is being used to cure beverage can coatings [5–9] as well as in other areas of packaging [10]. The process has several distinct advantages over more traditional oven-bake systems. Among these are essentially the elimination of solvents and related volatile organic compound pollutants, improved production, efficiency, working conditions, low-cost plant installations as well as more rapid, simplified change-over from one decoration and set of colors to another. Presently, industrial production using this technique involves external clear and colored coatings.

This cure process involves the application of a formulated, photosensitive, low viscosity coating to a substrate followed by brief exposure to a selected ultraviolet wavelength range at a defined intensity. The coating is hardened or cured virtually instantaneously at high line speeds. In the two-piece manufacturing process, the individual cans are printed, often with ultraviolet radiation-curable inks, coated with a clear coating, and then exposed to the radiation. The extremely rapid cure permits the process to proceed rapidly to the next stage in the can production process, which may be application of a water-dilutable or solvent-based sanitary interior coating. Since this interior coating requires an oven bake, the radiation-cured coating is oven baked as well. Only one oven pass is required to achieve full cure.

The ultraviolet radiation cure technique has also been used in the preparation of three-piece cans. Sheets, often printed with a radiation curable ink, are overcoated with an ultraviolet radiation-curable overprint coating. After exposure to ultraviolet radiation, the dry-to-touch condition required for efficient production usually develops in a fraction of a second permitting the can-stock sheet to be flipped over to the reverse side. A coating that will eventually be the "inside" coating of the can is then applied and the entire sheet is cured by a standard oven process. This technique is also used for the coating of exterior sheets that are to be used for can ends. Again, the economic advantage of only one oven pass is realized. The importance of inclusion of some measure of the speed of cure in the quality control of these ultraviolet radiation-cured coatings is obvious.

Radiation cured coatings have been developed that meet the requirements of adhesion, flexibility, slip, gloss, abrasion resistance, and food process stability for exterior use. In general, these coatings are not used as interior coatings.

Testing of Can Coatings

Tests Conducted on Liquid Coating

Viscosity—As discussed in the previous section, speed of production is a critical aspect of an economically successful can production plant. The speed of application of paint required for the satisfactory coating of two-piece can bodies or of three-piece can sheets places unique requirements on the flow characteristics of the liquid coating. To ensure complete coverage with the standard thin layer of coating, outstanding flow must be assured. The usual means for viscosity determination is the use of a Brookfield Viscometer as described in ASTM D2196, Standard Test Methods for Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield-Type) Viscometer.

Alternate methods for measuring viscosity include use of the Ford Cup or the Zahn Cup as described in ASTM D1200, Standard Test Method for Viscosity by Ford Viscosity Cup, and ASTM D4212, Standard Test Method for Viscosity by Dip-Type Viscosity Cups, respectively. These procedures relate flow to the length of time required for a test liquid to flow through a calibrated orifice at the tapered, bottom end of a cup. The Ford Technique is generally considered more accurate, though less convenient than the Zahn cup technique.

Viscosity Stability—The coating can be evaluated for long-term stability by placing a sample in an oven at 120°F (48.8°C) for an extended time period. Forty days is a typical test period. The change in viscosity can be evaluated every seven days using the technique employed to rate initial viscosity. In addition, settling, agglomeration, or other changes in appearance can be noted and taken into account when considering the evaluation.

Density—Density can be measured by using a Gardner™ "Weight per Gallon" cup as described in ASTM D1475, Standard Test Method for Density of Liquid Coatings, Inks, and Related Products. The process involves equilibrating the product at 25°C and pouring it into an appropriately cleaned cup up to the fill mark while taking care to prevent foaming. The cap is pressed onto the cup and the overflow is carefully wiped from the outside of the cup. The cup is then weighed on an analytical balance and pounds/gallon are calculated by multiplying the number of grams of coating in the cup by 0.1. When needed, the liquid coating thickness of an applied coating may be determined with ASTM D1212, Standard Test Methods for Measurement of Wet Film Thickness of Organic Coatings.

Volatile Organic Content (VOC)—The determination of the VOC of a coating requires an analytical balance and an oven controllable at 110±5°C, ASTM 2369, Standard Test Method for Volatile Content of Coatings. The liquid specimen is placed in an aluminum dish, and after dilution with a solvent is baked for 60 min at the indicated temperature. The percent weight loss of the sample is then determined as the percent volatile content.

The VOC is determined according to EPA Federal Reference Method 24, Determination of Volatile Matter Content, Water Content, Density, Volume Solids and Weight Solids, of Surface Coatings. This is done by using the weight percent volatile content, the density of the liquid coating, and the weight percent water content in concert with equations given in ASTM D3960, Standard Practice for Determining Volatile Organic Compound (VOC) Content of Paints and Related Coatings.

Fineness of Grind—This test is used to determine the fineness of dispersion of pigments in a pigmented coating. A Hegman Grind Gage with a double-wedge steel scraper is placed on a flat, nonskid surface as described in ASTM D1210, Standard Test Method for Fineness of Dispersion of Pigment-Vehicle Systems by Hegman-Type Gage. A sample of the coating is applied at the deep end of the groove on the gage surface so it slightly overflows the total groove. The

scraper is then drawn down over the entire length of the gage with sufficient pressure to clean the sides of the gage. A reading should be made at this point without delay. The reading consists of a visual observation made by viewing the side of the gage perpendicularly to the drawn coating: the point where the sample shows a definite speckled pattern is read from the numbers of the side of the gage. The quality of the dispersion is a measure of the effectiveness of the grinding operation in dispersing pigments for pigmented coatings or of additives, such as wax, for transparent samples.

Flash Point—The flash point of a coating is the minimum temperature at which vapor given off by the coating will ignite when exposed to a spark or flame. The Department of Transportation standards for shipment places a minimum flash point requirement for such coatings as these. A method to determine what is referred to as a "closed-cup rating flash point" involves use of a Seta Flash apparatus, ASTM D3278, Standard Test Methods for Flash Point of Liquids by Small Scale Closed-Cup Apparatus. For an open flash point, a tag open-cup method is often used, ASTM D56, Standard Test Method for Flash Point by Tag Closed Cup Tester. In both methods, the substance under test is heated at a controlled rate, for example 2°C/min, and a flame is passed over the surface. The flash point is defined as the temperature at which definite ignition is observed.

Cure Speed—A variety of methods have been devised for determination of this difficult to ascertain and even difficult to define characteristic of a thermoset coating. One practical definition of cure adequacy is the development of sufficient hardness in the coating that allows the can manufacturing process to advance to the next stage without marring the coating. Often, the customer and the coating supplier will agree on an empirical test to satisfy cure speed requirements. A simple technique may involve the use of cotton balls dropped onto the "cured" surface. Non-adherence of fine fibers or wads of fibers to the surface is often rated as an adequate cure because it relates to the ability to permit continuation of the manufacturing process. Frequently a higher degree of cross-linking than afforded by this empirical test is needed, especially for the development of resistance properties encountered by the coating at a later stage of its use. Rubbing the cured surface with a cloth moistened with a strong solvent is a method frequently employed. Determination of coating hardness using the pencil hardness test described later is a means of assigning a numerical rating to the relative degree of cure.

In the case of radiation cured coatings, ASTM D3732, Standard Practice for Reporting Cure Times of Ultraviolet-Cured Coatings, can provide guidance related to degree of cure and to cure speed attainable with such systems.

Tests Conducted on Cured Surfaces

Hardness—the hardness of a coating can be determined with the use of a series of pencils as described in ASTM 3363, Standard Test Method for Film Hardness by Pencil Test. The series of pencils have leads of various, known hardness—that is, lead with the following increasing harness—5B, 4B, #B, 2B, B, HB, H, 2H, 3H, 4H, and 5H. The cited test method describes the technique used to sharpen the leads and the way to perform the test. ASTM D1474, Standard Test Methods for Indentation Hardness of Organic Coatings, has other methods used for hardness determination.

Film Thickness—ASTM D7091, Standard Practice for Nondestructive Measurement of Dry Film Thickness of Nonmagnetic Coatings Applied to Ferrous Metals and Nonmagnetic, Non-conductive Coatings Applied to Non-Ferrous Metals can be used to determine film thickness of both steel and aluminum substrates. A variety of gages are described that are based on eddy current measurements. The information in this Standard Practice is meant to supplement and not to replace any manufacturer's instructions. As an example, a device may be calibrated with standard sheets of known film thickness placed on an uncoated surface of a similar substrate test section. After standardization, the head of the gage is placed on the coated sample and coating thickness is reported, usually in mils. The film surface is measured at several locations on the specimen and then averaged for the final, reported result.

A StrandGage® [11] is often employed in the metal decorating industry because it is easy to use when determining the thickness of very thin coatings (up to about 0.003 in or 0.076 mm) that are characteristic of the can industry. The device is calibrated to give results in milligrams or grams per area.

Film Continuity—Freedom from voids is a most important characteristic of beverage can interior coatings. Basically, the interior coating must be free of pinholes or other discontinuities. If such defects exist, they will lead to corrosion and contamination that will result in taste or color degradation and may result in destruction by rapid cathodic corrosion in certain instances. One of the accepted methods for evaluating the coating for such imperfections is an "enamel rater" instrument. Such devices electrically test the coating coverage and report an index of the amount of metal exposed.

One device for this purpose is the WACO Enamel Rater [12] in which a container such as a beverage can to be evaluated is filled with a conductive solution and placed on a platform. Electrical contact is made on a cleaned area of the can exterior, an electrode is placed in the center of the can's contents, and the amount of current flowing through the system is measured. The current flow will be impeded by the interior protective coating. Flaws, breaks, pinholes, or other defects in the coating are areas that will permit current flow. Suppliers and customers usually agree on a maximum acceptable value of current on time and result.

An alternative test technique for determining film voids is the copper sulfate solution immersion test. In this test, a sheet of coated metal is immersed in a solution of acidified copper sulfate for 2 to 4 min. After removal, a careful visual or magnifying glass examination of the coated metal will reveal copper-plated areas where inadequate coating protection permitted the copper to plate out onto the metal surface. The presence of such detectable flaws is an unacceptable condition for most commercial products.

Stability to Food Processing and Pasteurization Conditions—Many foods are packaged into containers in an uncooked state. Cans are sealed and the entire can is processed at an elevated temperature for the period required to complete the food processing. A characteristic test period is 1 h at 250°F (121°C) in an autoclave. Determination of the ability of a coating to withstand this treatment is often made by careful examination of a section of coated

substrate that has been mandrel bent [13]. The section so treated is then permitted to cool and next exposed to 100 % humidity at 100°F (37.7°C) for 16 to 24 h. After cooling, visual examination of the surface for discoloration, for film rupture, and for adhesion—especially in those areas where film extension has occurred—presents a useful appraisal of the ability of the coating to withstand food-processing conditions.

A less severe test is available for the pasteurization process. This process is required for some foods and for some beer packaging. The temperature used is 150 to 180°F (65.5 to 82.2°C) for 3 h. A similar visual examination of the surface of the coated steel or aluminum substrate is conducted for discoloration, blushing, adhesion loss, or film failure.

Abrasion Testing—A critical characteristic of an acceptable exterior film is its ability to protect cans from marring and scratching the decoration and identification. As mentioned earlier in the "Can Production" portion of this chapter, occasionally abrasion resulting from cans rubbing against each other—especially in shipping—can be sufficiently severe so as to cause metal rupture.

Various tests are employed to measure the coatings ability to resist abrasion. A simple technique involves rubbing the coated surface with a standard pencil eraser, counting the number of rubs or double rubs required to remove the coating, and reveal the uncoated surface. Often times an companies will devise proprietary, in-house techniques to test individual can, plastic bound can assemblies, and fully carton-packaged cans.

The TABER ABRADER TESTER™ is a commercial device in common usage for abrasion testing and preliminary evaluation of abrasion resistance [14]. In this test, coated panels are rotated under selected weighted abrasive wheels. The result value is usually reported as weight loss in "Milligrams/cycle × 1000."

Another abrasion test involves the use of the Gavarti GA-CAT device [15]. The instrument has a provision for mounting a limited number of specimens and can rapidly evaluate coated metal abrasion resistance. The device vibrates the cans or coated strips at a rate and for a duration that can be controlled thus emulating the abrasion received during transportation. The cans are visually examined after the allotted exposure time and rated according to individual company or customer defined standards.

Pack Testing—A requirement for the packaging of many food products is that no undesirable effects on the appearance of the container or the taste or color of the contents take place when the product is stored on a shelf for three years or more. An accelerated test to evaluate this characteristic involves the actual packaging of the substance in question in a test can. The can is sealed and exposed to the food processing conditions previously described, after which the product is aged at an elevated temperature for an extended period of time. Typical conditions for this test are 120°F (48.8°C) with a generally accepted estimate that one-month exposure at this temperature relates to one year of room temperature exposure. The coating product can be periodically examined by initiating several containers at zero time and withdrawing them selectively at one-month intervals. The test is useful for new product evaluation. A three-year actual test is usually required by most customers before they will accept a new product or a significant compositional change in a coating formulation. At the end of the test period, evaluations include can appearance, food taste, and vacuum testing. The latter is accomplished by piercing the container with a device such as a hand-held vacuum unit that pierces the can and seals a vacuum gage around the opening. Chemical reaction of the food product with coating or exposed container walls can result in a pressure change.

Adhesion Test—This test is similar to one used throughout the coatings industry. It involves pressing Scotch Brand™ Tape to the surface and examining the surface and the adhesive side of the tape after removal. The surface of the coating is scored with a razor in an "X" pattern or a crosshatch pattern before the tape is applied as described in ASTM D3359, Standard Test Methods for Measuring Adhesion by Tape Test.

Flexibility—A test known as the "T-Bend" test is commonly used throughout the metal coating industry [16]. The test evaluates the flexibility characteristics of a coating on a substrate by deformation of the coated substrate and subsequent evaluation of the adhered coating. A Zero-T (0-T) bend is a bend in a section of metal turned back on itself through a 180° bend. The examination after the bend can be visual, microscopic, or it can use Scotch Brand® tape adhesion or copper sulfate solution exposure for evaluation. This type of examination is usually dependent on a customer's stated requirements.

A second 180° bend around the bend already made represents a lesser level of flexure requirement. A coating that satisfactorily passes examination on this surface, and that already failed the 0-T test, will be considered a 1-T flexibility coating. A third bend represents 2-T, etc.

Another method of evaluating the flexibility of the coating involves the use of an impact testing device as described in ASTM 2794, Standard Test Method for Resistance of Organic Coatings to the Effects of Rapid Deformation (Impact). In this test, flexibility is evaluated by dropping a large, bullet-shaped weight from a measured height down through a cylindrical guide tube onto the uncoated surface of a test sheet placed on a die that has a depression analogous to the shaped weight. The test is termed a "reverse impact test." Microscopic examination of the impacted area is employed for evidence of cracking in the coating. The coating can be tested to the point of metal failure, a factor that depends on the thickness and strength of the substrate used. The test can also be carried out with the coated surface of the test sheet placed on the die. In this case the test is called a "forward impact test."

A test that is more specific to the can industry is the Erichsen Lacquer Testing Instrument. This device is a cupping and deep-drawing cup test machine that is used for testing coated ferrous and non-ferrous metals. In use, a cup is actually formed from a section of coated metal and the corners of the formed cup are examined for signs of inadequate flexibility.

Extraction Testing—Coating components capable of being extracted by the container contents must be below defined concentration limits. The Food and Drug Administration has established a series of limits and has defined certain liquids to be used for testing based on the planned contents of the container. These can be found in Code of Federal Regulations (CFR) 21, Section 175.300, Resinous and Polymeric Coatings. An extraction technique is also described in detail in this U.S.A. government publication.

Gloss Measurement—The specular gloss of a coated sample is measured using a 60° gloss meter as described in ASTM D523, Standard Test Method for Specular Gloss. The gloss meter should be equilibrated and calibrated against standard panels. The meter is placed over the panel to be tested, several readings are taken at different places on the panel, and an average of these readings is recorded. Care must be taken to control film thickness on test panels, since deviation in gloss level will be observed at varying thicknesses.

Color Measurement—Customers will assign an acceptable level of deviation of the final color or colors of the can-stock sheets or the cans based on a defined standard. Spectrophotometric analysis using appropriate ranges is reported. ASTM D2244, Standard Practice for Calculation of Color Tolerances and Color Differences from Instrumentally Measured Color Coordinates, describes techniques used for the analysis.

Blocking Resistance—Sheets of coated product are frequently stacked and stored before being transported to the next processing station. Such storage can often occur after an oven operation, which means that the sheets are stacked at an elevated temperature. As sheets are fed to the pile, the pressure imposed on the lower members of the stack can become considerable, and the sheets must resist adhering to each other. Efficient and rapid movement of these sheets individually for subsequent processing is essential to achieve an economical container-production rate. Simple tests are commonly developed between customer and supplier to evaluate the ability of coatings to resist this sticking phenomenon.

In one such test, a series of coated sheets or panels are stacked face to back. Pressure, usually imposed by means of a properly placed block of metal, is imposed on the top sheet or panel of the stack. The stack, which can be stored at controlled temperatures for defined periods of time, is examined after cooling for ease of separation. The weighted block of metal is usually of such physical dimension that the resistance to sticking can be determined and reported in appropriate pressure units.

Although there are a number of ASTM tests for blocking resistance, none are specifically designed for the can coating area. However, readers may be interested in reviewing ASTM D3003, Standard Test Method for Pressure Mottling and Blocking Resistance of Organic Coatings on Metal Substrates, which deals with the sticking of coatings applied to coil-coated substrates prior to fabrication.

Testing of Industrial Maintenance Coatings

Dwight G. Weldon[1]

INDUSTRIAL MAINTENANCE COATINGS COVER A diverse range of coatings for use in a wide variety of industries. For example, coatings such as alkyds, acrylics, vinyls, epoxies, urethanes, polyureas, silicones, and silicates can be used to coat structures of such variety as bridges, railroad cars, chemical process vessels, elevated water tanks, and concrete floors. Therefore, it is obvious that because of the many different coating chemistries and the vast range of environments to which they might be exposed, the testing of industrial maintenance coatings can be a broad topic. Furthermore, a particular physical property which may be important in one application, such as temperature resistance for a stack coating, may be of little importance for a different coating in a different environment. Therefore, it is important to know not only what type of tests can be run, but to appreciate the relative importance of various tests, realizing that their ranking may change from project to project.

In broad terms, the testing of coatings falls into one of two categories: determining the properties of the liquid paint, and determining the properties of the dried film. The testing of liquid paint can involve not only determining compositional related parameters such as density or solids content, but also application related parameters such as dry time and sag resistance. Although dried films can certainly be subjected to a barrage of analytical techniques to investigate chemical composition, this would generally be considered a separate topic, and in the context of this chapter most of the testing on dried films is done to determine performance or physical properties, such as abrasion resistance or adhesion.

In the past, much emphasis, not only in testing but in specification writing, was placed on the chemical composition of the coating. In the last decade or so, the emphasis has shifted more toward performance based requirements. Although the performance of the coating on the substrate is certainly of more fundamental importance than which ingredients are in the can, the latter should not be ignored. Indeed, it is fairly common when screening coatings for a Qualified Products List (QPL) to base acceptance on their performance characteristics, but also to do some basic compositional testing of the specific batch which was submitted. The results of these compositional tests are then used to define the characteristics of any future batches which may be provided for specific jobs, to help insure that production batches have similar composition (and therefore hopefully similar performance characteristics) to the batch which passed the QPL testing.

TESTING OF LIQUID COATINGS

Density

The density, or weight/gallon, of a liquid coating is a rapid, inexpensive test which, when combined with a few other simple tests, provides a measurement indicative of the types and relative amounts of ingredients making up the coating. Indeed, a significant variation in density is a sign that a production error has probably occurred.

The density of a material is generally performed with a pycnometer, which is simply a device which has a specific, known volume at a certain temperature. In the paint industry, the pycnometer is known as a "weight-gallon cup," and the test is performed in accordance with ASTM D1475 (Standard Test Method for Density of Liquid Coatings, Inks, and Related Products). Briefly, a slight excess of material is placed in the cup, such that when the lid is attached the excess is forced out through a small hole in the center of the lid. This assures that the cup is completely filled. The cup and lid are weighed before and after, and the grams of liquid paint can then be used to determine the density of the paint, in lbs/ gal. Often, the density of the paint in lbs/ gal is simply the weight of the paint contained in the cup, in grams, divided by 10.

Solids by Weight

The percent solids by weight of a coating, often referred to as its percent nonvolatile by weight, is usually determined in accordance with ASTM D2369 (Standard Test Method for Volatile Content of Coatings). Basically, a liquid coating consists of four types of ingredients: resins or polymers, pigment, additives, and solvents. By determining the solids by weight, one is determining the combined amount of the first three ingredients. Since these are the ingredients left behind in the dried film, it is important that a particular production batch have the correct solids content.

Basically, the test method involves weighing a certain amount of liquid coating into a previously weighed thin, disposable aluminum dish, baking this in an oven for 1 hour at 105 to 115°C, and dividing the weight of solid material left behind by the initial weight of liquid material used.

The procedure is simple and straightforward, although the precision and accuracy for thick, high solids multicomponent coatings is not quite as good as for simple low solids coatings such as alkyds. In some such cases, these coatings contain curing agents which are volatile at the temperature of the test, meaning that they can evaporate in the oven before they get a chance to cross-link and become "nonvolatile." This possibility is recognized by ASTM, and

[1] *Weldon Laboratories, Inc., 1188 Route 30, P.O. Box 40, Imperial, PA 15126.*

Copyright © 2012 by ASTM International

for such coatings it is recommended that they be allowed to air dry for one hour after mixing and prior to placing them in the oven. Single component reactive coatings, such as moisture cured urethanes, are not specifically addressed by ASTM. However, it would seem logical to treat them in a similar fashion to the reactive two component coatings.

Volume Solids

The percent solids by volume of a coating, often referred to as its volume solids, is determined in accordance with ASTM D2697 (Standard Test Method for Volume Nonvolatile Matter in Clear or Pigmented Coatings). This is a somewhat more complicated test than either the density or weight solids tests described above, and indeed requires that these two tests be done in order to perform the necessary calculations. Essentially, the liquid coating is applied to small metal disks and allowed to dry. The disks are then weighed in air, and again while suspended in water, and the appropriate calculations are done to determine the percent, by volume, of the nonvolatile material in the coating.

Not only is volume solids an important property relating to the composition of the coating, but it has important practical significance. If the coating is supposed to be 70 % solids by volume and is to be applied at 10 mils wet, it will dry to a thickness of 7 mils. If a batch were low in solids, say 50 % versus 70 %, and if the applicator still applied it at the recommended 10 mils wet, he would only get a dry film thickness of 5 mils, rather than the expected 7 mils.

Viscosity

There are many ways to measure the viscosity of a coating. These include determining the time it takes for a coating to drain from a cup of known volume through an orifice of known size (ASTM methods D4212—Standard Test Method for Viscosity by Dip-Type Viscosity Cups, and D1200—Standard Test Method for Viscosity by Ford Viscosity Cup), the use of rotational viscometers using spindles, such as Brookfield viscometers (ASTM D2196—Standard Test Methods for Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield type) Viscometer), and rotational viscometers using paddles, such as the Stormer viscometer (ASTM D562—Standard Test Method for Consistency of Paints Measuring Krebs (KU) Viscosity Using the Stormer-Type Viscometer). Brookfield viscometers can produce a much more accurate viscosity profile than a Stormer viscometer, because they allow one to obtain viscosity data over a wide range of shear rates. In contrast, a Stormer viscometer (Fig. 1) provides only a single data point, with the viscosity (expressed as Krebs Units, or KU) being determined under a single, low shear condition. Nevertheless, partly because of its simplicity, the standard quality control test for viscosity is done with the Stormer type viscometer.

When performing viscosity testing, it is important that the temperature requirements be observed, as this can significantly affect the results. It is also important to realize that the viscosity of a multi-component coating can change over time, and that viscosity should be determined as soon after mixing as possible.

Pigment Content

The weight solids test described above provides a measure of the total amount, by weight, of solid material in the liquid coating. It says nothing, however, about the ratio of pigment to vehicle, which can have a significant influence on the performance of the coating. The common procedures for determining percent pigment are ASTM D2371 (Standard Test Method for Pigment Content of Solvent-Reducible Paints) for solvent borne coatings, and ASTM D3723 (Standard Test Method for Pigment Content of Water-Emulsion Paints by Low-Temperature Ashing) for water-borne coatings. The first procedure involves using a centrifuge to separate the pigment from the vehicle and solvents, while the latter involves ashing a dried film of coating after first determining its weight solids. Once a sample has been analyzed for percent pigment and weight solids, the percent vehicle can be calculated simply by taking the difference between the two. The only error in this procedure, which is usually quite minor, is the inclusion of any additives as vehicle.

Sag Resistance

Sag resistance provides a measure of how thick a coating can be applied to a vertical surface before it begins to sag. This is important, because if the coating is intended to be applied at 10 wet mils but sags at 5, it will have to applied in two coats rather than one.

Sag resistance is commonly tested in accordance with ASTM D4400 (Standard Test Method for Sag Resistance of Paints Using a Multinotch Applicator). This involves preparing a drawdown using a notched applicator (Fig. 2) which applies the coating in a pattern of stripes covering a range of thicknesses. The drawdown is then immediately hung vertically, with the thinnest stripe at the top and the thickest at the bottom, and subsequently evaluated to determine the heaviest thickness which does not sag into the stripe below it.

Fig. 2—A multinotch applicator used to evaluate sag resistance. (Photograph courtesy of Weldon Laboratories.)

Drying Time

How long it takes a coating to dry to touch, or dry hard, can be an important practical consideration. Furthermore, if the drying time of a particular batch is very much longer than expected, it could be an indication of a compositional problem. Drying time is commonly measured in accordance with ASTM D1640 (Standard Test Methods for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature). The tests are simple but subjective, and involve such techniques as touching with one's finger to determine set to touch times, or using a twisting motion with one's thumb to determine dry to handle times.

Infrared Spectroscopy

Most of the above tests are rapid, require relatively inexpensive equipment, and provide a quick screening method to determine if a particular batch of coating falls within specification requirements. However, they essentially measure some type of bulk property which, although dependent to some extent on the specific ingredients of the coating, does not in any way actually identify these ingredients. A powerful tool for providing compositional information on paints and coatings, whether in the solid or liquid state, is infrared spectroscopy.

Infrared spectroscopy is described in great detail elsewhere in this volume. Simply put, it allows a material to be identified by measuring the amount of infrared light absorbed (or transmitted) at various frequencies. Indeed, a spectrum is simply a graph showing the amount of absorbed (or transmitted) infrared light as a function of frequency. Two examples of infrared spectra are shown in Fig. 3. Even without understanding the underlying theory of the process, it is obvious that the spectrum of the vinyl latex is much different in appearance than the spectrum of the

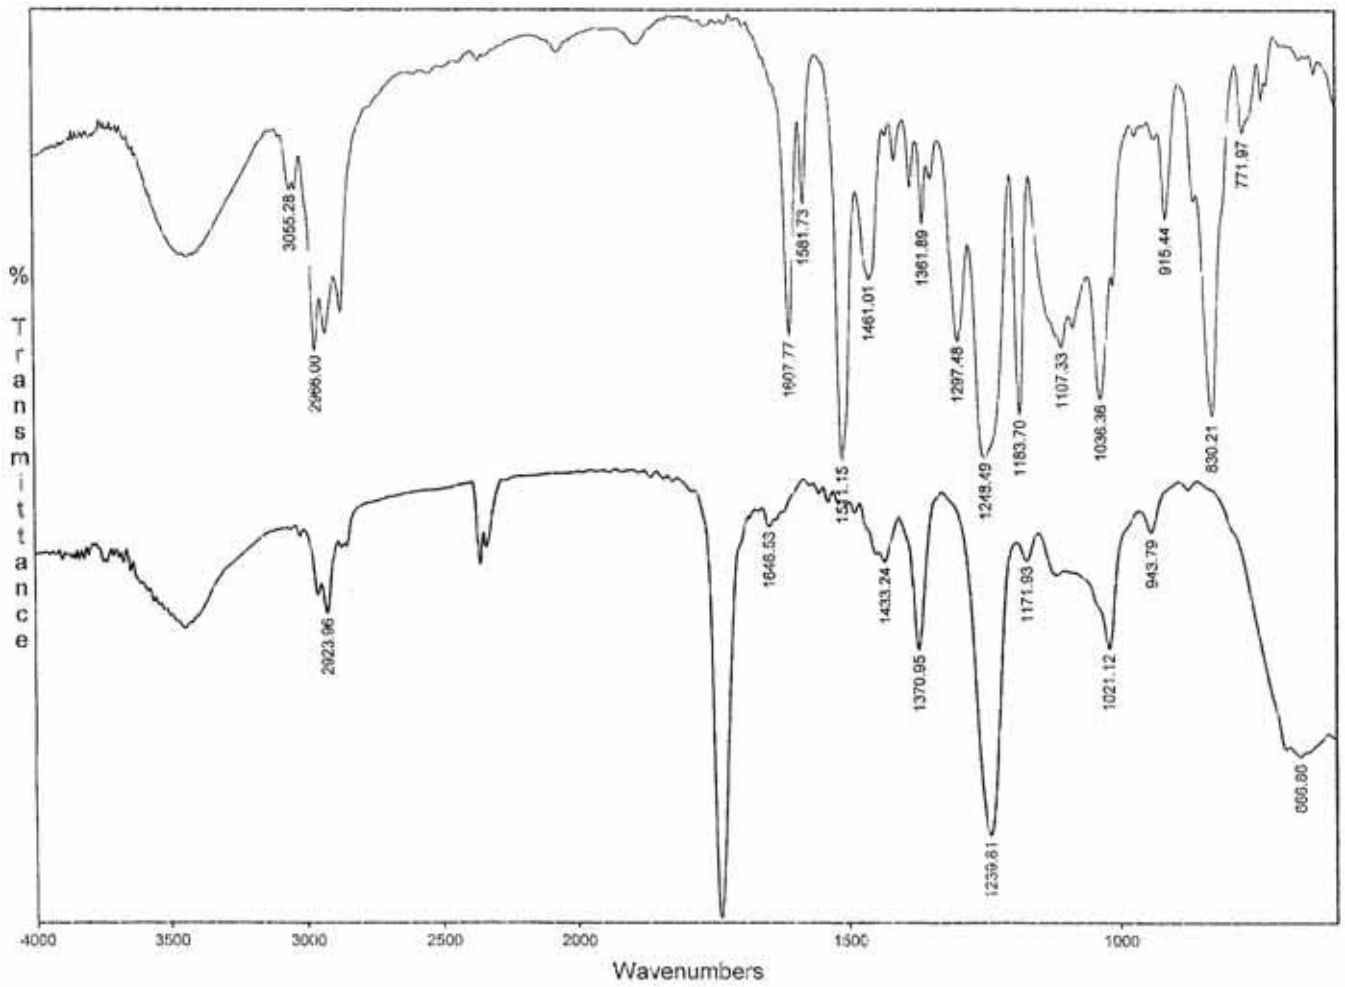

Fig. 3—Infrared spectra of an epoxy (top) and a vinyl latex (bottom). (Photograph courtesy of Weldon Laboratories.)

epoxy. The fact that different materials each have their own unique infrared spectrum has led to them being referred to as "fingerprints."

In recent years there has been a trend in product testing to obtain an infrared spectrum of the batch of coating submitted for testing. If the batch passes all the testing requirements and is approved, the spectrum is kept on file in the event that a problem occurs with a later, production batch of coating. If the spectrum shows a marked deviation in composition from the originally approved batch, it is likely that the problem is a coating one. On the other hand, if the various bulk properties are consistent, and the spectrum is a good match to the spectrum of the approved batch, it is likely (but not certain) that the problem lies elsewhere.

Although an extremely useful technique, infrared spectroscopy is not without its limitations. First of all, there is more than one way to actually obtain a spectrum of a sample, and the analyst must be consistent in his methodology in order to obtain reproducible spectra. Secondly, infrared spectroscopy generally cannot detect ingredients which are present at less than 4 % or 5 % unless they are somehow separated or at least partially isolated from the mixture. Therefore, a minor additive which might have a crucial bearing on the performance of a coating, such as an ultraviolet light absorber, would not even be detected by this technique.

TESTING OF APPLIED COATINGS

Because of the diversity of coating types, structures, and environments encountered in the industrial maintenance field, there are numerous tests which could be appropriate for a given situation. Because of this, the first question to ask when putting together a testing program, or evaluating the manufacturer's published literature, is "what is this coating going to be used for?." This simple question will help greatly in deciding which tests are appropriate, and how much emphasis to place on each test. The following is a list of many of the common tests which could be appropriate for evaluating the performance of an industrial maintenance coating. ASTM D6577 ("Standard Guide for Testing Industrial Protective Coatings") provides a good list of the many tests available.

Adhesion

Of all the physical and chemical properties of a coating, this one is arguably the most important. The best coating will offer little protection if it does not stick to the substrate. There are several methods to measure adhesion, including such subjective, "unofficial" techniques as prying with a hammer and chisel to rubbing with the edge of a coin. The three more widely used standardized ASTM techniques, however, include D3359, D4541, and D6677.

ASTM D3359 (Standard Test Methods for Measuring Adhesion by Tape Test) is often referred to as "tape adhesion." There are two methods to choose from, A and B, depending on the thickness of the coating. Method A is recommended for films greater than 5 mils thick, and involves using a cutting tool to scribe an "X" cut into the specimen, followed by the application of a special pressure sensitive adhesive tape. The tape is then rapidly removed, and the adhesion is assessed in accordance with the method's descriptive rating system. The ratings range from a 5 for no peeling or removal, to a 0 for removal beyond the area of the X. Method B, for thinner films, involves scribing a cross-hatch pattern into the specimen, again followed by the application and removal of tape. The ratings, which also range from 5 to 0, are assessed in accordance with pictorial representations of the percentage of coating removal.

The technique has the advantage of being quick, simple, and inexpensive, and can even be done on curved surfaces. However, occasionally problems can be encountered with the tape not adhering well to the paint, resulting in artificially good results. A more common problem, however, especially with thick, tough coatings, is not being able to scribe completely through to the substrate.

ASTM D4541 (Standard Test Method for Pull-Off Strength of Coatings Using Portable Adhesion Testers) is often referred to as "tensile adhesion." It involves using an adhesive to attach aluminum or steel dollies or stubs to the coating, and then using some sort of portable adhesion tester (Fig. 4) to measure the force required to pull the stub from the surface, hopefully taking the coating along with it. The result is reported in psi. A variation of this test is currently being evaluated for use on coated concrete.

The advantages of this method compared to D3359 include less subjectivity and less operator error associated with not cutting completely through the coating. It has several potential drawbacks, however, not the least of which is the fact that the various instruments on the market can produce widely varying results. Thus, it is critical, when performing the test, to report which instrument was used, and results between one coating and another should only be compared if they were tested using the same type of instrument. It is also not uncommon for the precision to be relatively poor, at least for certain types of instruments, so it is advisable to perform testing in duplicate or triplicate.

The method can usually not be used on curved surfaces, as this changes the degree of contact and hence the surface area tested, and, once the stubs are applied, it can take from a few hours to overnight before the adhesive has cured enough to test. Furthermore, some adhesives do not bond well to the surfaces of some coatings, resulting in glue failures rather than coating delamination. It should also be pointed out that it is not unusual for tensile adhesion and tape adhesion results to appear to be inconsistent. This is

Fig. 4—A type of commonly used portable adhesion tester. (Photograph courtesy of Weldon Laboratories.)

likely because tape adhesion applies a significant degree of shear stress to the coating, which is absent in the tensile testing. Thus, the coating adhesion, when assessed by tape adhesion, can sometimes appear to be worse than the tensile adhesion values would indicate.

A third, relatively new ASTM method for assessing adhesion, is D6677 (Standard Test Method for Evaluating Adhesion by Knife). This method involves using a knife to cut an "X" into the sample, and then uses the tip of the knife to pick or probe at the intersection of the cuts. There is a rating system based on the ease with which the coating can be removed. Investigators and inspectors have used similar methods for years in subjectively determining coating adhesion, and one of the main reasons for establishing D6677 was to try to standardize, at least to some extent, the various subjective methods in use.

Corrosion Resistance

When the structure being painted is made of steel, assessing the corrosion resistance of the coating is very important. By far the most commonly used procedure is the salt spray test, ASTM B117 (Standard Practice for Operating Salt Spray (Fog) Apparatus). The test involves placing the painted panels in a salt spray cabinet (Fig. 5), which essentially produces a fog of warm (95°F) saltwater (5 % sodium chloride). After an agreed upon period of time, such as 1000 h, the panels are evaluated for such things as blistering (ASTM D714—Standard Test Method for Evaluating Degree of Blistering of Paints), rusting (ASTM D610—Standard Practice for Evaluating Degree of Rusting on Painted Steel Surfaces), and undercutting at the scribe (ASTM D1654—Standard Test Method for Evaluation of Painted or Coated Specimens Subjected to Corrosive Environments), if the panels were scribed (an option) before placing them on test.

Fig. 5—An ASTM B117 salt fog cabinet. (Photograph courtesy of Weldon Laboratories.)

The procedure has been used for decades, and is firmly entrenched in many specifications. Over the last ten years or so, however, it has become somewhat controversial, and there is a body of evidence that salt spray results do not correlate very well with real world performance.

A second commonly used test procedure which has increased substantially in popularity over the last several years is what is known as Prohesion testing, which is described in ASTM D5894 (Standard Practice for Cyclic Salt Fog/UV Exposure of Painted Metal). The terminology, however, is somewhat confusing, as Prohesion testing refers to a procedure involving a cyclic salt fog test, which is only one component of D5894 (the other component being accelerated weathering).

In D5894, the test panels (either scribed or unscribed) are placed in a cyclic salt fog cabinet (sometimes referred to as a Prohesion cabinet), which introduces a fog of dilute salt water (0.05 % sodium chloride/0.35 % ammonium sulfate) at room temperature for one h. After one h, the cabinet is purged with warm, dry air for one hour, and the cycle is repeated. The panels remain in the cyclic salt fog cabinet (also described in ASTM G85, Standard Practice for Modified Salt Spray (Fog) Testing) for a specified period of time (typically one week), after which time they are manually transported to an ASTM G154 accelerated weathering cabinet, which uses ultraviolet light, heat, and moisture to weather the panels, again typically for one week. The panels alternate between the two cabinets, typically for a total duration of 1000 h, and are then evaluated in the manner described above for salt fog testing.

It is generally felt that D5894 gives better correlation to the real world performance of coatings than does B117. However, in both cases, and indeed with all accelerated laboratory test methods, it is extremely difficult to use the tests to actually predict the service life of a coating system. The tests are primarily used to compare one coating with another, allowing them to be ranked as to which can be expected to perform the best. There is also concern that D5894 gives artificially poor results for zinc-rich primers.

Accelerated Weathering

A commonly asked question of a coating is "how durable is it," or "how well does it weather." The best, but also the slowest way, to answer this question is to expose painted panels outdoors in an environment similar to what might actually be expected. As this can take years, there have been various accelerated laboratory test methods developed. All of these methods employ a combination of heat, ultraviolet light, and moisture to weather or degrade the coating. Broadly speaking, they fall into two categories, depending on the source of ultraviolet light: arc devices, and fluorescent tube devices.

Arc devices produce ultraviolet light by passing an electrical current through an electrode. Devices include enclosed and open-flame carbon arcs described by ASTM G153 (Standard Practice for Operating Enclosed Carbon Arc Light Apparatus for Exposure of Nonmetallic Materials) and D822 (Standard Practice for Filtered Open-Flame Carbon-Arc Exposures of Paint and Related Coatings), and

xenon arc machines described by ASTM G155 (Standard Practice for Operating Xenon Arc Light Apparatus for Exposure of Non-Metallic Materials). In all cases, water is sprayed intermittently onto the specimens as a fine mist, and exposure to light and darkness is alternated. A commonly used cycle is 102 min of light at 145°F and 18 min of light and water spray at 60°F. The xenon arc devices have become much more common than the carbon-arc devises.

Fluorescent UV bulb devices are described in ASTM G154 (Standard Practice for Operating Fluorescent Light-Apparatus (for UV) Exposure of Nonmetallic Materials), formerly known as ASTM G53. Briefly, they use fluorescent tubes to provide the ultraviolet light, and moisture in the form of condensation is produced by heating a trough of water located in the bottom of the instrument. Many different types of bulbs are available which have different spectral characteristics, although most fall into what is known as either the UV-A or UV-B region of the electromagnetic spectrum. The UV-B region is more aggressive and can produce results in less time, but the UV-A region is generally felt to be a more realistic test.

Regardless of which type of test is selected it must be kept in mind that it is very difficult, if not impossible, to predict an actual lifetime for a coating based upon accelerated weathering data. Weather varies dramatically from geographic region to geographic region, and even from year to year in the same region. Therefore, the primary use of accelerated weathering is to compare or rank one coating versus another.

Chemical Resistance

When one considers all the industrial environments that painted structures can be exposed to, as well as the fact that coatings are used to protect such things as waste water treatment plants, off shore oil platforms, secondary containments, and even the interiors of railroad tank cars and chemical process vessels, it is apparent that chemical resistance is an extremely important property. The two relevant test methods for determining chemical resistance are ASTM D1308 (Standard Test Method for Effect of Household Chemicals on Clear and Pigmented Organic Finishes), and ASTM C868 (Standard Test Method for Chemical Resistance of Protective Linings).

The title of D1308 is somewhat misleading, as the methodology can be applied to harsh industrial chemicals as well as mild household ones. The method is broadly written, and covers such possibilities as simple room temperature spot testing, where a small amount of chemical is applied to a test panel and covered with a watch glass for an hour or so, to high temperature immersion testing. The method does not go into much detail as to apparatus, time, or temperature, and basically leaves these decisions up to the investigator. Obviously, chemicals should be chosen which could reasonably come into contact with the coating, and realistic, although perhaps slightly elevated, temperatures should be chosen. Although in service the coating may be expected to perform for several years, laboratory testing is usually carried out for no more than a few months, with the panels being evaluated for such things as rusting, blistering, cracking, softening, or delamination. If the coating goes for a few months with little or no sign of deterioration, it is generally assumed to be acceptable for that chemical, even though it is not possible to predict the actual service life in years.

While D1308 involves immersion testing, C868 is often referred to as "one-sided" immersion testing, or sometimes "Atlas Cell" testing, even though there may be a number of companies which manufacture the equipment. A virtually identical test is described in NACE TM-01-74 (Laboratory Methods for the Evaluation of Protective Coatings and Lining Materials in Immersion Service). The apparatus used in C868 (Fig. 6) consists of a glass cylinder, typically 5 to 7 in. in diameter, fitted with ground glass take offs for such things as condensers, thermometers, or immersion heaters (one variety jackets the outside of the cell with a flexible heating element). The gasketed test panels actually form the two ends of the cell. The cell is then filled halfway to two thirds full with the chemical of interest, and the heating element set to maintain the desired test temperature. The test duration is typically from 3 to 6 months.

One of the main advantages to C868 testing is that, since the test panels are not immersed, there are no edge effects to worry about. Sometimes it is difficult to seal sharp edges, and failures can occur near edges which are more application related than coating related.

Another advantage to C868 testing, which depending on circumstances may be more perceived than real, is the belief that it mimics the "cold wall effect." The cold wall effect has been observed numerous times, and occurs when the outside, non-immersed surface of the steel is colder than the inner surface which is exposed to the contents of the vessel. This is a more aggressive condition than if the inner and outer temperatures are the same, and can more readily cause blistering of the interior coatings.

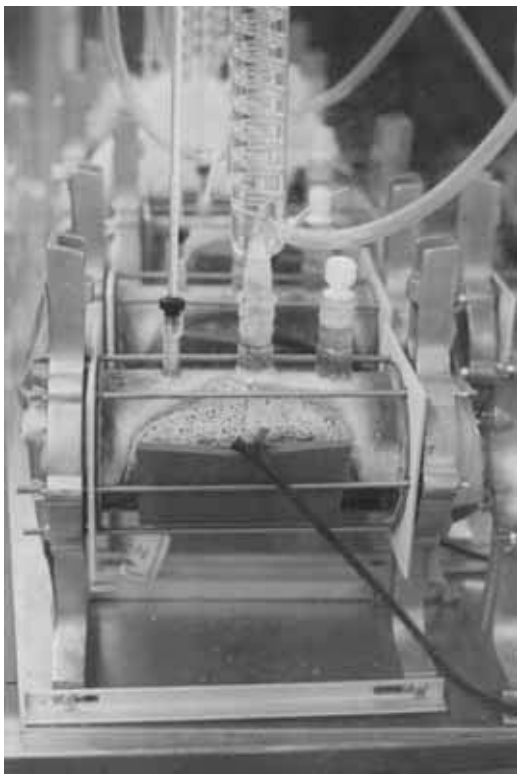

Fig. 6—An ASTM C868 chemical resistance cell. (Photograph courtesy of Weldon Laboratories.)

At first glance, this condition would appear to be simulated in Atlas Cell testing. However, unless the steel test panels are rather thick, there is actually very little difference in temperature between the inner and outer walls. A temperature gradient can be imposed by jacketing the outer surface with a cell containing circulating water, but in practice this is rarely done.

When doing chemical resistance testing, it is tempting to choose a temperature much higher than the actual, expected temperature, in order to accelerate the test. Care must be taken, however, not to choose too high of a temperature. If the coating is below its glass transition temperature when in actual service, but has been artificially raised above its glass transition temperature during laboratory testing, the possibility exists that it will have been made more permeable as a result. Thus, it could fail in the laboratory, yet in actual service it could perform very well.

Abrasion Resistance

Coatings used to protect handrails or used in areas subjected to heavy foot traffic need to be resistant to abrasion. By far the two most popular methods to evaluate abrasion resistance include Taber abrasion and falling sand.

Taber abrasion testing is described by ASTM D4060 (Standard Test Method for Abrasion Resistance of Organic Coatings by the Taber Abraser). The test panels, which are 4×4 in.^{2} with a hole in the middle, are mounted on a device called a Taber abrader. This is essentially a turntable with a pair of weighted abrading wheels which rest on the panel. As the panel rotates, the abrasive wheels turn along with it, resulting in removal of some or all of the coating. The panels are weighed before and after testing, and the result is usually reported as a weight loss per so many cycles (usually 1000 cycles). Coatings with better abrasion resistance lose a smaller amount of weight. When evaluating Taber abrasion results, it is important to know the number of cycles, the load on the wheels, and the type of wheels. CS-17 wheels are the most common, but wheels of lesser and greater abrasiveness can be used.

The falling sand test is described by ASTM D968 (Standard Test Methods for Abrasion Resistance of Organic Coatings by Falling Abrasive). Essentially, the test panel is mounted at a 45° angle beneath a tube which is attached to a hopper. A known quantity of sand is dumped into the hopper and impinges upon the test panel. The amount of sand required to wear through the coating is reported. On relatively thin, ordinary coatings such as an acrylic latex or an alkyd, the test is relatively simple to do. On a thick, high performance coating such as an epoxy or an elastomeric urethane the test can be extraordinarily time consuming, and requires large quantities of sand (an individual quantity of sand is to be discarded after a certain number of uses).

Impact Resistance

Examples of coatings which would require good impact resistance would include coatings for overseas shipping containers, and coatings for use on locks and dams. Most-impact resistance tests involve dropping a weight onto a coated panel and looking for cracking or disbonding. The most common procedure is ASTM D2794 (Standard Test Method for Resistance of Organic Coatings to the Effects of Rapid Deformation (Impact), where a hemispherical tup is rested on the panel, and a falling weight, housed in a guide tube, is dropped from varying heights to determine the greatest force, expressed in in-lbs, which will not crack or disbond the coating (Fig. 7). The procedure calls for the use of a thin gage steel panel which will deform under the conditions of the test, although many users prefer to use thicker steel representative of the actual article to be coated. If the weight is dropped on the coated face, the result is referred to as direct impact. If it is dropped on the back of the panel, it is referred to as indirect or reverse impact. Coatings nearly always have lower reverse impact than they do direct impact resistance.

Flexibility

A certain amount of flexing or movement is common with many structures. Electrical transmission towers flex and move in the wind, thin galvanized decking can flex when walked upon, and metal can change dimensions slightly upon freezing and thawing. Furthermore, instantaneous flexing can occur when a surface is subjected to a sharp impact. Indeed, it is difficult to imagine a case where flexibility would not be a desirable property of a coating. The fact that not all coatings are flexible is because to impart flexibility to a coating, one must often sacrifice other properties, such as chemical resistance or resistance to permeation.

Coatings are commonly tested for flexibility by bending a coated, thin gauge steel or aluminum panel over a mandrel and examining the coating for cracking, in accordance with ASTM D522 (Standard Test Methods for Mandrel Bend Test of Attached Organic Coatings). The method

Fig. 7—A variable impact tester used to measure the impact resistance of coatings. (Photograph courtesy of Weldon Laboratories.)

Fig. 8—A conical mandrel tester used to determine per cent elongation. (Photograph courtesy of Weldon Laboratories.)

describes two procedures, one using a conical mandrel, and one using cylindrical mandrels.

The conical mandrel consists of a metal cone, 8 in. in length, with a diameter of 1/8 ft at the narrow end to 1 1/2 in. at the wide end (Fig. 8). There are clamps for mounting the panel, and a rotating arm which is used to bend the panel around the mandrel. If the coating is being evaluated for percent elongation, it is bent slowly (over a period of 15 s). If it is being evaluated for crack resistance it is bent quickly (approximately 1 s). If cracking occurs, the distance which the cracking extends from the small diameter end towards the large diameter end is measured and used to determine the coating's percent elongation. If no cracking occurs, the percent elongation is greater than approximately 32 percent. When using cylindrical mandrels, one usually simply reports the smallest diameter mandrel over which the panel can be bent without cracking, although % elongation can also be estimated.

The mandrel testing described in D522 is usually sufficient for testing most industrial maintenance coatings. However, for very flexible elastomeric coatings it is of little use, since these coatings will have elongations of 100 % or more, far above the maximum 32 % which can be determined by D522. In such cases, it may be desirable to test such coatings using the so-called "universal testing machines," which essentially use clamps to hold free, unsupported films of coatings between the jaws of the machine. The sample is then stretched apart at a known rate and a stress-strain curve obtained. Such properties as percent elongation, tensile strength, and modulus (essentially the "stiffness" of the sample) can be determined. Applicable test procedures include D2370 (Standard Test Method for Tensile Properties of Organic Coatings) and D638 (Standard Test Method for Tensile Properties of Plastics). It is often difficult, however, to test very thin free film coatings by these methods, although coatings thicker than about 5 mils can usually be tested.

Moisture Resistance

A coating intended to line the interior of a potable water tank obviously requires good moisture resistance. While salt spray and accelerated weathering tests have a moisture component to them, they introduce other elements which the potable water lining would not be exposed to. Since water could certainly be considered a chemical, some type of water immersion test could certainly be carried out in accordance with the general chemical resistance testing previously described by ASTM D1308. However, water or moisture resistance is more commonly done in accordance with either ASTM D4585, D2247, or D1735.

ASTM D4585 (Standard Practice for Testing Water Resistance of Coatings Using Controlled Condensation) involves generating water vapor by heating a pan of water located in the bottom of the chamber. The test panels form the roof or walls of the chamber, and since their back side is exposed to the cooler air of the laboratory, condensation forms on the coated front surfaces. Although this sounds like a relatively gentle test, it is actually quite aggressive since the condensing water is relatively pure and it is conducted at a slightly elevated temperature. Coatings typically fail by blistering. ASTM D2247 (Standard Practice for Testing Water Resistance of Coatings in 100 % Relative Humidity), is somewhat similar, except that the cabinet is designed differently and the specimens are completely suspended inside the chamber.

Considerably different than the above methods is ASTM D1735 (Standard Practice for Testing Water Resistance of Coatings Using Water Fog Apparatus). This method uses a chamber similar to an ASTM B117 salt fog cabinet to expose the panels to an actual mist of water.

Hardness

Industrial maintenance coatings are commonly rated for hardness using the pencil hardness method described in ASTM D3363(Standard Test Method for Film Hardness by Pencil Test). In this method, a series of pencils is used to determine the hardest pencil lead which will not scratch or gouge the coating. The pencil ratings, from softest to hardest, are as follows:

6B-5B-4B-3B-2B-B-HB-F-H-2H-3H-4H-5H-6H

The test is somewhat subjective, not only because of operator variability, but also because of possible variations among different sets of pencils. ASTM lists a reproducibility of plus or minus one pencil.

For thick coatings, hardness is sometimes determined using some type of indentation tester. The two most commonly used are the Barcol (D2583) and Durometer (D2240—Standard Test Method for Rubber Property-Durometer Hardness) types. In both cases, hand pressure is used to drive a spring loaded indenter into the coating, and the ease of penetration is reflected on the scale (higher numbers indicate harder coatings).

Water Vapor Permeability

It is not surprising that a coatings resistance to the permeation of water vapor can have a significant bearing on its ability to protect the substrate. In many cases, this is tested in a very practical way by subjecting painted test panels to wet or humid environments, such as the salt spray, accelerated weathering, and humidity tests described above. A more direct way to actually measure the rate of water vapor permeation, however, is described in ASTM D1653 (Standard Test Methods for Water Vapor Transmission of Organic Coating Films). In this test method, free films of coating (or films attached to a thin, porous paper substrate) are sealed to the open mouth of a cup or dish, and essentially form the lid of the cup (Fig. 9). In Method A the cup

Fig. 9—A permeability cup used to determine water vapor transmission. (Photograph courtesy of Weldon Laboratories.)

contains a desiccant, and the assembly is placed in a humid environment. The cup is weighed periodically to measure the amount of moisture which has passed through the coating and into the desiccant. In Method B, which is the more common procedure, the cup contains water, and is placed in a dry environment. It is then weighed periodically to determine the amount of moisture which has passed through the coating and out of the cup.

Theoretically the procedure sounds very simple and straightforward. In practice, however, it is not quite so simple. It can sometimes be extremely difficult to obtain, as the method calls for, "smooth and completely continuous films of uniform thickness throughout the test area." Furthermore, if the coatings are very thin, or very brittle, it can be a frustrating task to remove them from the release paper or even mount them on the cups without tearing or fracturing them.

Pipeline Coatings

Alfred Siegmund[1]

IN PREPARATION OF THIS CHAPTER, THE CONTENTS of the fourteenth edition were drawn upon. The author acknowledges the authors of the fourteenth edition. The current edition will review and update the topics as addressed by the previous authors, introduce new technology that has been developed, and include up-to-date references.

INTRODUCTION

Energy and its availability continue to drive the industrialization of nations. America uses a very large volume of energy based on fossil fuels. Many times, the usage point is a great distance from the source. Carbon-steel pipelines continue to be the most economical means of transporting fuel from the source to the consumption point. Many thousands of miles of pipelines crisscross the landscape. As with all carbon-steel pipe, corrosion is a major concern. Pipeline failures [1] always make big headlines, cost large amounts of capital to repair, and frequently disrupt needed service.

Building a major pipeline is a costly, time-consuming project. First, an abundant source of fossil or other fuel must be located and combined with a provider who will service an end user. Federal, state, and local permits must be obtained, rights-of-way purchased, and financing obtained. From start to finish, this can be a multi-year project. To protect the investment and to provide for safe operation, every possible means of protection must be considered over the life of the pipeline. The most economical means of protection continues to be a combination of cathodic protection and protective coatings. This chapter focuses on the role of coatings and their design, selection, and use.

MARKET

The United States Department of Commerce estimates that loss of steel due to corrosion costs in the billions of dollars each year in the United States alone. The market for pipeline coating products varies each year and depends on the number of permits issued. At about the turn of the twenty-first century, this market was estimated to exceed $350 billion per year—an amount that grows each year. The market is divided between repair and rehabilitation products and new construction products. There are five basic product groups available for such uses.

- Asphalt enamels and asphalt mastics . . . 7 %
- Coal tar and coal tar modified products . . . 14 %
- Fusion Bonded Epoxy (FBE) powder coatings . . . 32 %
- Polyolefins, including both bonded and extruded products . . . 17 %
- Tape products . . . 30 %

The distribution of product use size will vary from year-to-year depending on the active projects in particular areas as well as developments and improvements within the product areas. Table 1 contains a listing of some considerations that are pertinent for such coatings.

WHY USE COATINGS?

Control of steel pipeline corrosion is a complicated process that involves several different techniques. Internal corrosion protection may be accomplished with organic coatings and/or inhibitor coatings. External corrosion protection is almost always a combination of cathodic protection and organic coatings. Careful selection of the coating material in combination with proper application can result in many years of trouble-free service. In certain regions where permafrost is encountered, special considerations regarding the environment need to be made [2].

Coatings are required to provide a wide range of protective properties that vary from excellent mechanical characteristics to elevated temperature resistance. On a per-square-foot basis, coatings have proven to be the most economical corrosion control system for steel pipelines. The United States Department of Transportation (DOT) recognizes the protection provided by coatings. It is a DOT requirement that a bonded coating protect all new steel pipelines involved in intrastate commerce.

PRODUCT DEVELOPMENT, COMPARATIVE TESTING, AND QUALITY CONTROL

Product testing utilizing procedures or methods published by ASTM, NACE, SSPC, and others takes place in three distinct time frames. Several pipeline specifications, methods, and practices are given in Table 2. The technologist will use a broad spectrum of tests to learn everything possible about the product. The goal is to determine the strong points of the product and possibly to correct any product deficiencies. The basic properties of an external coating are resistance to cathodic disbondment, adhesion, impact resistance, flexibility, and resistance to moisture penetration. Such failure modes have been described in the literature [3]. Defining these properties will provide the technologist with information used to decide whether or not a potentially useful product is being considered. Many other properties must be defined to generate a product specification list.

The pipeline engineer will use a series of tests to choose between comparable products and will use some of these tests to establish an in-process quality program.

TABLE 1—Considerations for repair and rehabilitation coatings	
Adhesion and compatibility	Time to pipe burial
Coating cure time	Two-component, cold-damp surfaces
Inspection	Transition to existing coatings
Materials and workmanship	Weather for over-the-ditch repair
Surface preparation	Weather, temperature, rock shields

The application, along with an outside quality team, will use a limited number of in-process tests to assure product quality.

INTERNAL PIPE COATINGS

Most of the information in this chapter refers to external pipeline coatings. Internal pipe coatings are used, but their use is far more complicated than the external coatings [4]. Internal coatings not only provide corrosion protection, they can impart minimized erosion, fouling, friction, and wear—all of which are dependent on what is flowing in the pipe. Thus, internal coatings can provide improved flow rates (~ 5 – 15 %) and greater productivity, factors that will result in decreased maintenance costs. The internal coating will be in contact with liquid or gaseous substances such as crude and refined oil, water, air, food products, oxygen, nitrogen, natural gas and so on. Three common systems used are two-component epoxy polyamide/amine combinations that cure under ambient conditions, fusion bonded materials that are thermally cured, and air-dried, field applied coatings based on either epoxides or urethane chemistry.

With this strong dependence on what is being carried in the pipeline, only this brief mention will be made of the coating technology for internal coatings. In a general sense, the topic is too complex for this particular chapter.

TABLE 2—Pipeline coating specifications, practices, and standard methods	
Test Designation	**Title**
API RP 5L2	Recommended Practice for Internal Coating of Line Pipe for Non-Corrosive Gas Transmission Service

EXTERNAL COATINGS FOR REPAIR AND REHABILITATION

The existing pipeline infrastructure is aging. Many lines have 20, 30, or 40 years of service and are in need of repair and maintenance, which poses a unique set of problems [5–8]. First is that the pipeline will remain in service during the work effort. This can cause problems with temperature—hotter close to compressor stations and variable in other locations. Access to buried pipe is limited due to the confines of the associated ditch. This limits surface cleaning and can markedly affect the choice of coating and the long-term performance of the selected product.

Application techniques are limited to spray equipment that is tractor mounted and travels along the pipeline or traveling equipment that actually rides on the pipe. Weather conditions are a significant consideration in the selection and performance of the coating. Cold damp surfaces are not uncommon as well as hot days during summer and in desert areas. Cure time, or time to bury, becomes an important factor as maintaining an open ditch during certain weather condition can pose serious difficulties.

The previously mentioned concerns limit the coating that can be effectively utilized. Waxes, oils, and greases are still utilized as protection for elbows, valves, and other short runs. They are generally protected by a layer of Kraft paper or felt to allow them to be quickly buried.

Coal tar and coal tar modified products are well suited for rehabilitation and over-the-ditch applications. There is a wide choice of products that include but are not limited to modified epoxides, urethanes, and associated mastics and enamels [9]. The moisture resistance of these coatings along with their relative ease of application makes them a good choice for this service. Tests used for coal tar and related products are listed in Table 3.

TABLE 3—ASTM test methods for analyzing coal tar and related products (a partial listing)	
Designation	**Standard Test Method for**
ASTM D4	Bitumen Content
ASTM D5	Penetration of Bituminous Materials
ASTM D36	Softening Point of Bitumen (Ring-and-Ball Apparatus)
ASTM D71	Relative Density of Solid Pitch and Asphalt (Displacement Method)
ASTM D2415	Ash in Coal Tar and Pitch
ASTM D3143	Flash Point of Cutback Asphalt with Tag Open-Cup Apparatus
ASTM G17	Penetration Resistance of Pipeline Coatings (Blunt Rod)

Cold-applied tapes that are applied by equipment that rides the pipe are popular. Machines have been utilized that clean and coat the pipe in a short time span allowing for quick return of the pipeline to service.

Table 4 contains a listing of typical tests used to determine the acceptability of external pipeline coatings.

FACTORY OR PLANT APPLIED PRODUCTS

The majority of new pipeline construction projects use plant-applied coatings. This allows for thorough evaluation of the coatings before they are put in service. This involves a coordinated effort between the coating supplier, applicator, and end user. A comprehensive quality control plan can be implemented along with in-process quality checks. All of this leads to a project with a longer life before repairs are needed. A variety of coatings will meet such an effort to develop factory-applied products.

- Extruded polyolefins
- FBE powder coatings
- Multi-layer products
- Tape and wrap products

Table 5 is a listing of in-process tests that might be used to determine coating quality. It should be pointed out that some of the products can be field applied as indicated.

Tape and Wrap Products

These coatings mainly consist of polyolefins applied in tape form. They are comprised of an adhesive layer and an outer protective layer. In some instances, the two layers are co-extruded and applied as a single tape. Most tape and wrap products are cold applied, but there are some that are "heat fused" to bond the layers together. These coatings provide added moisture protection and resistance to handling damage.

Extruded Polyolefins

The next step in process improvement was to use a thermally extruded polyolefin as the outer layer of polyolefin and thus provide for a continuous protective outer film. This added even more moisture protection and handling damage control. As in the tape and wrap system, an adhesive prime coat comprised of a mastic, two-part epoxy, fusion bonded epoxy, or rubber-based material is employed [10–12].

Coal Tar Enamels

Coal tar enamels are particularly suitable for coating steel pipe. They are generally hot applied either in the yard or in the field. In use, they are virtually unaffected by long periods of water immersion, soil stress, punctures, or bacteria, and they provide a relatively high electrical resistance. These coatings work best in the temperature range of 1.1 to 82°C (30 to 180°F). The enamels are degraded by ultraviolet radiation and therefore should be wrapped with Kraft paper when exposed to sunlight. Coal tar enamels

frequently are reinforced with a fiberglass mat or embedded with a felt mat as a means of protection. The products do provide for many years of service and were the first commonly used external protective coatings.

Coal Tar Mastic

Coal tar mastic is heavily filled with clays, silica, fiberglass, or similar materials. The resultant material is a highly viscous mass that is cold applied to a thickness of 1.27 to 1.6 cm (1/2 to 5/8 in.). Coal tar mastic can be applied as a hot extrusion, seamless coating. The material can be applied to a wide range of pipe diameters for buried pipeline service.

Coal Tar Epoxides

Coal tar epoxides are two-component materials that require mixing just prior to application. Coal tar plays two important roles in this type of coating: (1) cost reduction and (2) improved water resistance. The two components are designed to air cure and provide a harder film than neat coal tar products. Excellent adhesion is provided by the epoxy component if optimum cure is achieved.

Coal Tar Urethanes

As with coal tar epoxides, coal tar is used primarily as a cost reducing material. With the coal tar urethanes, the base components are polyols and multifunctional isocyanates. The systems can be spray applied to yield very rapid cure speeds. This feature reduces out-of-service time for the pipeline.

These coatings have the advantages of lower cost, excellent water resistance, a wide range of application techniques, and long proven service lives. They can be plant applied or over-the-ditch applied. They comprise one of the largest group of coatings used for repair and maintenance of existing pipelines.

In general, coal tar products have limitations in protection when combined with cathodic protection. Temperature service is limited to 66°C (150°F).

Fusion Bonded Epoxy Powder Coatings (FBE)

This relatively new technology now is dominant in the United States new pipe-construction protective-coating market. Refinements in this technology have taken place over the past 35 years as it grew in popularity. Drawbacks to this coating technology are moisture absorption by the basic epoxy powder and transportation damage due to the film thickness specifications for this product line [13–17].

Specialty products have been formulated within this coating type. Abrasion resistant products exist for pulling pipe under roads and rivers. Surface texture products with improved adhesion of heavy weight cement coatings are available [18]. In many instances, a combination of two coats of the powder coating applied dry-on-dry are used to gain the desired combination of end-use characteristics.

There are three levels of temperature performance products within the FBE product type. The "standard" FBE is rated for 66°C (150°F). A second generation of the coating provides for resistance to 82°C (180°F) is available, and a third generation that is rated for 93°C (200°F) has been qualified.

Multi-layer Products

The multi-layer or three-coat systems currently dominate the external pipeline coating market outside the United States [19–21]. The system was designed to take the best properties of each system and combine them into one product. The product normally consists of an epoxy primer followed by an adhesive tie-coat and then a polyolefin topcoat.

The epoxy primer provides for excellent adhesion to the metal surface and gives excellent cathodic disbanding resistance. The epoxides coating can be either in the form of a liquid or an FBE powder, but the trend is toward a powder application and thermal curing. The adhesive tie-coat is designed to adhere to both the epoxy primer and the polyolefin topcoat and thus provide the tie between the coatings. The outer polyolefin topcoat gives excellent resistance to water penetration and mechanical damage during transportation and installation. Application of the outer layer is by extruder, which will effectively increases the cost of the overall system.

Specialty Coatings

By definition, specialty coatings are those that have been developed and successfully applied to meet specific needs. They have not generated sufficient business/use to determine their survival rate or their place in the market. There are three specialty products with sufficient merit to mention.

The first of these coatings is a three-layer system based entirely on powder coating products. The outer layer is a polyethylene powder that depends on residual heat to thermally fuse and flow the powder into a continuous film. This limits the total film thickness that can be applied, but it meets all of the other characteristics of a multi-layer product.

The second product uses thermal sprayed aluminum with a seal coat as the applied product. This system has been applied to several offshore pipelines. The product has an estimated life of more than 35 years. This is a totally different coating system that utilizes sacrificial metals for protection as opposed to the normal practice of using a barrier product.

The third specialty system is designed for hot product lines that operate between 93°C (200°F) and 149°C (300°F). The desire is to provide protection on hot product lines in areas close to compressor station where elevated surface temperatures are encountered. The system is based on an epoxides base coating with a composite inter membrane and is applied as a multi-layer wrap.

Girth-Weld Products

All pipelines have connections at the welds and at other components that cannot receive coatings at the plant [8]. They must be protected after the pipe is welded together to form a pipeline. These are the weakest links in the system. The coating that is on the body of the pipe may not be the best choice for field application to the weld areas.

The most popular girth-weld products are based on two-component epoxy products or heat-shrink sleeves. All of the products have a corresponding girth-weld material. Logistics, weather, and cost may prevent them from being the product of choice for the girth-welds.

Sealants

Saul Spindel[1]

SEALANTS ARE PRODUCTS INSTALLED INTO AN opening to prevent the intrusion of air, water, dust, heat, cold, and other materials such as gases, e.g., radon. The liquid-applied sealant is installed into the opening by gun or knife. It is then expected to function even though the space (joint) it occupies is stressed because of movement of the joint to which the sealant is applied due to expansion and/or contraction due to temperature changes, thereby placing significant strain upon the adhesive forces that bond the sealant to the substrate to which it is attached. The sealant is also expected to function regardless of whether it is applied to a horizontal opening or a vertical one or whether it is applied to a building facade subject to rapid expansion and contraction or to a plaza or deck where it is subject to puncture by spiked heels.

The opening, or gap, into which a liquid-applied sealant is installed is usually called a joint. The sides of the joint (substrates) may be made of similar or dissimilar materials, generally varying in width from 0.250 to 2.00 in. (0.64 to 5.08 cm) with the depth of the installed sealant usually about one half the width. When required, sealant backing (preformed joint fillers) made of materials such as open or closed cell rubber or polyurethane foam are installed to control the joint depth. Primers are sometimes used to improve adhesion of the sealant to the substrate.

Typical building materials that sealants are used with are glass, steel, concrete, mortar, granite, marble, aluminum, various painted or coated surfaces, or wood. When the sealant is installed into the joint, the surfaces the sealant contacts must be clean, dry, sound, and free of contaminants or loose particles to provide an opportunity for the sealant to perform as intended [1].

Caulks or sealants are fomulated based on oils, latex polymers, butyl, acrylic and blocked styrene solvent-release polymers, and polysulfide, polyurethane, and silicone elastomers. The oil-based products exhibit relatively little movement capability, generally 5 % or less, and thus they are traditionally installed in relatively static joints. Acrylic latex polymers can be formulated to possess significant movement, as much as ±25 %, whereas the solvent-release butyl, acrylic, and blocked styrene sealants can move about ±10 %. The elastomerics exhibit significant movement capability, with silicones moving as much as +100 %, –50 %. (+100 % refers to 100 % expansion whereas –50 % refers to 50 % compression based upon the original dimensions of the installed sealant).

Though this chapter provides an overview and general description of sealants, test methods, and specifications, it does not address the suitability of the test methods or specifications discussed nor does it differentiate between cured short-term performance and actual long-term performance and effectiveness of sealant products on buildings and/or other structures [2].

POLYMERS USED IN SEALANTS

Oil-Based Caulks

Oil-based caulks are generally composed of drying oils, mineral fillers, thixotropes, and driers. The oil oxidizes and thereby dries slowly, though the caulk usually sets up to become paintable within a 24 to 48 h period. Oil-based caulking compounds are easy to apply, easy to tool, and are available in a range of qualities. Generally, oil-based caulks exhibit movement of about 5 %. Oil-based caulking compounds are used primarily by do-it-yourselfers [3].

Butyl Sealants

Butyl sealants are based on polyisobutylene or polybutene, fillers such as talc and/or calcium carbonate and additives such as adhesion promoters, antioxidants, and thixotropes. Butyl sealants dry by solvent release.

Butyl sealants can be formulated to move at about $\pm 7\frac{1}{2}$ to $\pm 12\frac{1}{2}$ %. They are widely used in mobile home applications. In addition, another class of butyl sealants that are prepared without volatile solvents are extensively used as the primary seal in dual-sealed insulated glass because of their very low moisture vapor permeation properties [4].

Acrylic Solvent Release Sealants

These sealants are similar to butyl sealants; however, they are based on polymethylacrylate polymers (or polyethylacrylate or polybutylacrylate polymers), resulting in medium-high molecular weight products that, when formulated with colorants, thixotropes, and additives, are used as sealants [5].

Acrylic solvent-release sealants exhibit movement similar to butyl sealants, namely up to $\pm 12\frac{1}{2}$ %. Acrylic solvent-release sealants are versatile in that they adhere to a wide variety of surfaces and, in addition, exhibit excellent resistance to sunlight. Two prime disadvantages of acrylic solvent-release sealants are: (1) they often require heating in the cartridge when applied at lower than room temperatures because their viscosity may become too thick to allow them to be easily applied and (2) they may emit acrylic monomer, which is somewhat odiferous and may be toxic in enclosed areas [6].

Block Copolymer Sealant

Elastomeric block copolymer sealants, usually based on either styrene, styrene-butadiene, or isoprene, are another class of solvent-release sealants. These polymers exhibit excellent resistance to ultraviolet light, are effective as clear sealants, generally adhere to a wide variety of substrates, and are readily paintable. The sealants can be formulated to move about $\pm 12\frac{1}{2}$ %.

Polyurethane Sealants

Polyurethane sealants are available as either single or multi-component products. The one-component sealant is derived from an in situ reaction of an isocyanate with a hydroxyl component. These components cure by the reaction of the isocyanate (NCO) with atmospheric moisture, forming a polyurea. The sealants contain fillers, thixotropes, additives, and adhesion promoters.

Two-component polyurethane sealants are usually based on an isocyanate-terminated polyether reacted with a hydroxyl-terminated polymer. As with other sealants, two-component polyurethane sealants are combined with fillers, adhesion promoters, and other additives and stabilizers.

Polyurethane sealants exhibit good movement capabilities, easily exhibiting ±25 % movement. They generally adhere well to a variety of surfaces and are widely used in commercial applications, especially where abrasion resistance, i.e., traffic applications, is a prerequisite [7].

Polysulfide Sealants

Polysulfide sealants are sold as both one-component and two-component materials. Two-component sealants are formulated with polysulfide polymers, hiding and color pigments, clays, and mineral thixotropes. The second, or reactive component, consists of a curing agent (e.g., lead peroxide), adhesion promoters, fillers, and stabilizers. Both components are mixed just prior to use [8].

The one-component polysulfide sealants are formulated with ingredients similar to the two-component material except that the cure chemistry is different. One-component polysulfides cure by reaction with atmospheric oxygen and moisture and are generally relatively slow to attain full cure.

Polysulfide sealants can be formulated to move at ±25 % and are used on a wide variety of surfaces. Polysulfides are used widely in insulated glass applications [9].

Silicone Sealants

Silicone sealants are primarily used as one-component products usually referred to as RTV (room temperature vulcanizing) materials. They are polysiloxane prepolymers that react with atmospheric moisture and ultimately cure to form an elastomer. Silicone sealants are cured generally by one of three mechanisms, namely:

1. *Acetoxy cure*—A reaction between methyltriacetoxy silane with polydimethylsiloxane to form an acetoxy-terminated polymer "intermediate." This material is then reacted with atmospheric moisture in order to cure. Acetic acid is liberated during cure, and its odor can readily be noted.
2. *Neutral cure*—These sealants are the result of a reaction between polydimethyl siloxane with methyltrimethoxysilane to form the "intermediate." This "intermediate" then reacts with atmospheric moisture in order to cure. Alcohol is generally liberated during the cure process.
3. *Oxime cure*—In this cure mechanism, methyl triethylmethyl ketoxime silane is reacted with ethyl methyl ketoxime to form an "intermediate" that cures when reacted with atmospheric moisture. Cyclohexylamine, a heavy musty-odor material, is released during cure.

Silicone sealants can be formulated to have a movement capability of as much as 100 % and are used in many applications, especially where long-term durability is required. Silicone sealants are the primary sealants used in structural glazing [10].

Acrylic Latex Sealants

Acrylic latex sealants are essentially formulated from relatively high molecular weight acrylic polymers prepared by emulsion polymerization in an aqueous media and include fillers, surfactants, additives, and thixotropes. Acrylic latex sealants dry by evaporation to form easily applied, highly weatherable products that exhibit good adhesion.

These acrylic sealants can be formulated to move as much as ±25 %; however, they should not be applied at low temperatures and are not recommended for use in continuous damp or wet environments [11].

TEST PROCEDURES

The following is a brief summary of the test methods and procedures used to evaluate sealants. Where appropriate, reference is made to specific specifications and/or procedures where these tests are covered.

Extrusion Rate

This test is performed to measure the discharge rate of single and multi-component sealants (ASTM C603). Single-component sealants are extruded through a cartridge of known volume and predetermined orifice at 50 psi air pressure. The time to empty the cartridge is recorded. Multi-component systems are mixed and allowed to stand for 3 h before being extruded in order to develop information on their application properties after mixing.

Rheological Properties (Flow and Sag)

This test is employed to determine the horizontal or vertical flow properties of the sealant under conditions of extreme variations in temperature (ASTM C661). Stainless steel channels, open ended for testing vertical (non sag) sealants and close ended for testing horizontal (self leveling or pourable) sealants, are filled with the sealant and exposed at an elevated temperature (122°F, 50°C), and at a low temperature (40°F, 4.4°C). Sag (vertical displacement) is measured, and horizontal deformation is noted.

Hardness

This test is used to measure the indentation hardness of a cured sealant using a Shore A Durometer (ASTM C661). If a sealant is too hard, it may be indicative of future problems that can result in a loss of resiliency, thereby resulting in either cohesive breaks or adhesive loss.

Effects of Heat Aging After Cure

Exposure to the atmosphere may cause loss of volatile components after cure, resulting in shrinkage, hardening, or cracking, which may affect the durability of the sealant. This test can be used to predict premature failure (ASTM C792). Sealant specimens are cured for 7 days at standard conditions, then heat aged for 21 days at 158°F (70°C) and evaluated for volatility (weight loss), cracking, and hardness [12].

Tack-Free Time

This is the time required for the surface of a sealant to attain a tack-free state (ASTM C679). This time may be indicative of the time interval required for the sealant to resist damage from light surface contact, job-site or airborne dirt pickup, or impinging rainfall.

Staining of Porous Substrates

This test method is useful to determine possible staining by the sealant on porous substrates (ASTM C1248). The sealant is applied to standard-size joint specimens made of porous materials such as white marble or granite. The specimens are compressed and clamped and then stored for 28 days at various conditions including room temperature, elevated temperature, and ultraviolet-fluorescent weathering. Upon completion of the exposures, the specimens are evaluated for changes in surface appearance and depth of any stain.

Adhesion and Cohesion Under Cyclic Movement (Durability)

The primary intent of an elastomeric sealant is to fill joints in buildings and other structures and thereby render them impervious to the elements. These joints are considered active, meaning that they will expand and contract with temperature change and building movement.

This test method is designed to evaluate the ability of the sealant to withstand expansion and contraction with temperature change and not develop any loss of adhesion to the substrate or any cohesive cracks (ASTM C719). When adhesion loss to the substrate or cohesive cracks within the sealant develop, water can penetrate, thereby resulting in damage to the structure.

Joints are prepared using two similar substrates. The sealant is extruded between the joints (substrates), cured, and then immersed in water for seven days. The specimens are then hand flexed and evaluated for adhesion loss. If no adhesion loss is noted, the specimens are compressed and subjected to elevated temperature (158°F, 70°C) for 7 days to determine whether any heat set or deformation occurs. These test joints are then subjected to 10 cycles of extension at room temperature and examined for loss of adhesion or cohesive breaks in the extended state. If there is no loss of adhesion or cohesive break, the test joints are then cycled for 10 cycles of compression at elevated temperature (158°F, 70°C) and expansion at low temperature (–15°F, –26°C) to simulate joint movement during extreme temperature changes. (Buildings contract when cold, thereby opening up or expanding the joints. On the other hand, buildings expand when hot, thereby closing or compressing the joints.) Upon completion of this cycling, the specimens are examined for the presence of any adhesive bond loss or cohesive breaks.

Adhesion-in-Peel

This test is used to evaluate the adhesive characteristics of a sealant and its ability to maintain a bond to a substrate (ASTM C794). The sealant is applied to the substrate, cured, and immersed in water for 7 days. After the immersion period, the 180° peel strength of the sealant is measured and the amount of adhesive loss to the substrate is determined. An additional set of specimens is prepared on a glass substrate, exposed to UV radiation to simulate sunlight, and then evaluated for the effect of the actinic radiation on the interface of the sealant-to-glass bond by once again measuring peel strength and adhesion properties of the sealant.

Effects of Accelerated Weathering

This procedure is used to evaluate the effects of exposure to ultraviolet radiation and water spray to simulate weathering on the sealant (ASTM C793). After exposure, the sealant is evaluated for surface cracking. After 24 h cold exposure specimens are then bent over a 0.5 in. (1.27 cm) diameter rod under cold (–15°F, –26°C) temperature to evaluate low-temperature flexibility and brittleness.

The following section lists specifications and standards for sealants, as well as their sources.

SEALANT SPECIFICATIONS

Federal Specifications

TT-S-00227E	Sealing Compound Elastomeric Type, Multicomponent (For Caulking, Sealing, and Glazing Building and Other Structures)
TT-S-00230C	Sealing Compound Elastomeric Type, Single Component (For Caulking, Sealing and Glazing Building and Other Structures)
TT-S-01543A	Sealing Compound, Silicone Rubber Base (For Caulking, Sealing, and Glazing in Buildings and Other Structures)
TT-C-598B	Caulking Compound, Oil, and Resin Base Type (For Masonry and Other Structures)
TT-S-001657	Sealing Compound, Single Component-Butyl Rubber Based, Solvent Release Type (For Buildings and Other Types of Construction)

OTHER SEALANT STANDARDS

Insulating Glass

ASTM E774	Standard Specification for the Classification of the Durability Sealed Insulating Glass Units.

Highway/Bridges

SS-S-200E	Sealing Compounds, Two Component, Elastomeric, Polymer Type, Jet Fuel Resistant, Cold Applied.

(American Association of State Highway and Transportation Officials [AASHTO]).

LIST OF ASTM STANDARDS

C509	Standard Specification for Elastomeric Cellular Preformed Gasket and Sealing Material
C510	Standard Test Method for Staining and Color Change of Single- or Multi-Component Joint Sealants
C542	Standard Specification for Lock-Strip Gaskets
C603	Standard Test Method for Extrusion Rate and Application Life of Elastomeric Sealants
C639	Standard Test Method for Rheological (Flow) Properties of Elastomeric Sealants
C661	Standard Test Method for Indentation Hardness of Elastomeric-Type Sealants by Means of a Durometer

Pavement Marking Materials

James R. Swisher[1]

PAVEMENT MARKINGS GO RELATIVELY UNNOTICED by most people but affect almost everyone every day. They are used not only on city streets, highways, and interstates but also at airports, parking lots, and many commercial and industrial sites. A variety of materials are used for these applications. Some have specific uses, but all must adhere to the surface on which they are applied, show resistance to abrasion and weathering, and perform adequately over their expected life-times [1].

The following discussion will focus on the different types of marking materials being used and the testing of these materials for acceptability.

TYPES OF PAVEMENT MARKING MATERIALS

There are three general materials used for pavement markings. These include liquid coatings, thermoplastics, and tapes. All pavement markings fall into one of these general categories and cover a range of thickness from 8–150 mils. Glass beads or other reflective materials are used with each of these pavement marking materials to provide for night visibility.

Liquid Coatings

SOLVENT-BORNE MARKING

This was the standard material in use for traffic marking for decades. These one-component materials are usually alkyds or chlorinated rubbers that dry by the evaporation of their solvents, followed by oxidation of their binders. They are usually applied hot and under pressure with conventional spray equipment to achieve fast-drying markings. The advantages of using solvent-borne coatings are the vast body of knowledge and experience with these materials—they can be applied over a wide range of environmental conditions and have a low cost. The major disadvantages are the need for frequent applications, especially in high-traffic areas, the release of large quantities of solvent to the atmosphere during drying, and the need for solvent to clean equipment. These solvents contribute to air pollution and become hazardous waste when used to clean equipment.

WATER-BORNE MARKING

Water-borne markings are composed of high molecular weight acrylics and styrene-acrylic latex binders that allow them to be successfully applied on concrete and asphalt surfaces and over several other older markings [2]. Water-borne materials are also one component and must be applied under more stringent environmental conditions than solvent-borne materials. For example, low air and surface temperatures and high relative humidity, lengthen the film formation and dry time of the coating. In addition, due to their corrosive nature, water-borne materials should be handled in stainless steel equipment. However, even with these application requirements, the reduction in solvent emission and associated hazardous waste has enabled these materials to be the choice of many pavement marking entities.

These materials are used in a variety of wet thicknesses from 15 mils for standard lines to 30 mils for "High Build" lines depending on their chemical compositions.

EPOXY

This is a two-component, very durable, high-quality pavement marking material. The two components (pigmented resin and hardener) are stored separately and mixed at the time of application. A variety of cure times can be achieved through formulation adjustments. Close attention must be paid to the mix ratio of the components to obtain optimum performance and durability. Due to their durability, epoxies are used in higher traffic areas where repeated application of coatings would be disruptive to traffic. One disadvantage of epoxies is the loss of color retention due to degradation from ultraviolet (UV) sunlight exposure.

POLYESTER

Polyester is a two-component system used mainly on Portland cement concrete surfaces since proper adhesion is a concern on asphalt concrete surfaces. This coating is a durable, high-quality material that has a useful life of three years or more. Polyester is also very durable and is useful in high traffic areas. Adjusting mix ratios of resin and catalyst gives appropriate cure times. Some disadvantages include monomer emission, hazardous waste generated from solvents used in equipment clean up.

POLYUREA, URETHANES, METHYL METHACRYLATE

These two-component materials are composed of pigmented resins and a hardener. While similar to epoxies, these products are more durable and may contain color or UV stabilizers. These products are relatively new to the pavement marking industry and show good potential.

Thermoplastic

Thermoplastic (also known as hot melt) pavement markings are another durable, high-quality, single-component marking material. They are composed of a mixture of either maleic-modified glycerol resin esters or hydrocarbon resins with plasticizers, pigments, and glass beads. The material is normally melted between 400–425°F and is either sprayed

[1] *VDOT Materials Division, 1401 E. Broad St., Richmond, VA 23219.*

Copyright © 2012 by ASTM International

or extruded on the road to form a durable material of thickness from 90–125 mils [3]. During the melting process constant stirring of the thermoplastic is very important for the following reasons:

1. To prevent localized burning.
2. To prevent potential color changes in the pigments.
3. To keep the intermixed glass beads suspended.

Thermoplastic may be applied to hydraulic concrete cement or asphalt concrete cement. Thermoplastic performs best when applied on asphalt concrete cement due to thermal bonding. If thermoplastic is being applied to hydraulic concrete cement a primer/sealer is normally required for proper adhesion and durability. Application thicknesses for new stripes are usually 90–125 mils, while re-stripe thicknesses are 30–60 mils.

Traditional yellow, lead chromate pigments are being replaced with organic yellow pigments that require careful formulation to ensure color continuity in both day and night-time environments.

Thermoplastic is also used as a preformed (pre-shaped) material for arrows, stop bars, pavement signs and text markings. The preformed markings are melted to the road surface using heating torches.

Pavement Marking Tapes

Pavement marking tapes can be used as a durable, long-life marking material or as a removable or temporary marking in construction areas. All tapes are composed of three layers: an adhesive layer, a backing material usually made of plastic or aluminum foil, and a pigment and glass bead layer. Application of these tapes will vary between manufacturers with primers being used for some tapes. While most tapes are installed with a weighted roller, some tapes are pressed (inlaid) into the hot asphalt. This inlay method produces a recessed tape that is less susceptible to abrasion from traffic and snowplow blades.

PERMANENT TAPES

These tapes can be divided into plastic-backed and foil-backed tapes. Plastic-backed tapes are 60–90 mils thick and are used as stop bars, crosswalks, arrows, long lines, and skip lines. These tapes may be flat or profiled. Foil-backed tapes are greater than 20 mils in thickness and are used in areas that are free of curves, turns, or stops.

TEMPORARY/REMOVABLE TAPE

This tape is used on construction sites or projects that require the tape to be removed or paved over. To facilitate removal, a plastic mesh or similar material may be added between the adhesive layer and the backing material of the tape. Film thicknesses are from 25–30 mils.

Glass Beads (Retroreflective Optics)

Glass beads are used with pavement markings to increase night visibility. Without the beads, most markings would be invisible at night. Fig. 1 gives an excellent explanation of how glass beads improve visibility. Glass beads must be round to work. Irregular or broken beads will not retroreflect light efficiently back to the driver. Beads vary in refractive index (RI) from 1.50 to 1.90. The 1.50 RI beads are most commonly used for highways, while the 1.90 RI beads are more efficient in light return and found on airport runways or in markings that are visible when wet.

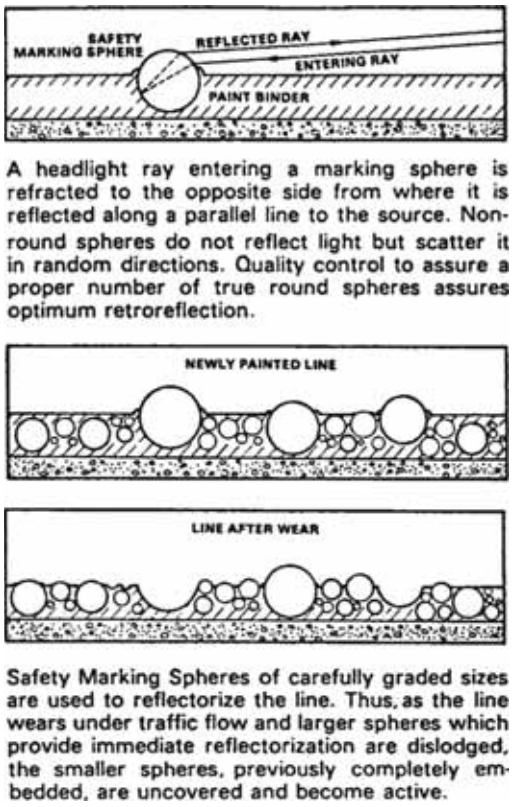

Fig. 1—How do glass spheres work? (from *Potters Safety Marking Spheres,* Potters Industries Inc.)

Glass beads also come in a variety of sizes with a specific size distribution usually being specified. Glass beads are applied to the binder material at the time of application to the road surface. This is usually done by a pressurized spray nozzle so that many of the beads (about 70 %) are initially buried in the marking material. The quantity of beads added to a line will vary with the marking material from 6-25 lb./gal. Some marking materials like thermoplastics have intermixed glass beads in addition to surface-applied beads. Other products—pavement marking tapes—have the glass beads pre-applied at the time of fabrication. Some pavement markings require the application of two separate bead sizes with two separate bead guns. This "double-drop" system is known to improve the visibility of the pavement marking. Other retroreflective optics such as ceramics and bead clusters are also being used to enhance night-time visibility in both dry and wet (rain) environments.

MATERIAL TESTING

Pavement marking materials are tested for conformance to specification in the laboratory and for performance in field evaluations.

Laboratory Testing

LIQUID TRAFFIC MARKINGS

Many of the tests performed on liquid marking materials are standard coating tests and are referenced where applicable.

Liquid Properties

1. **Skinning**—Paints that contain binders that dry by oxidation can form skins in a partially filled container.

These must be removed before use. This test can be performed in accordance with ASTM D154, Guide for Testing Varnishes and ASTM D2805, Standard Test Method for Hiding Power of Paints by Reflectometry, for Water-Bornes.

2. **Fineness of Dispersion**—Commonly called "fineness of grind," this test is not generally specified for traffic marking except in the case of some application equipment [4]. The test is performed in accordance with ASTM D1210, Test Method for Fineness of Dispersion of Pigment-Vehicle Systems by Hegman-Type Gage.
3. **Density or Weight/Gallon**—The density is determined for unbeaded paint by using ASTM D1475, Test Method for Density of Liquid Coatings, Inks, and Related Products.
4. **Consistency**—Determine the consistency using a paddle type viscometer in accordance with ASTM D562, Test Method for Consistency of Paints Measuring Kreb Unit Viscosity Using a Stormer-Type Viscometer.
5. **Stability**—Traffic paints should remain stable in the container for at least six months. Heat-age stability and freeze-thaw stability are often required and can be checked by heating and cooling a specimen through several cycles. Use ASTM D1849, Test Method for Package Stability of Paint, for heat-age stability and ASTM D2243, Test Method for Freeze-Thaw Resistance of Water-Borne Coatings, for freeze thaw stability of water-borne paints. Use ASTM D1309, Test Method for Setting Properties of Traffic Paints During Storage, for the accelerated test and ASTM D869, Test Method for Evaluating Degree of Setting of Paint, for aged paints.
6. **Chemical Analysis**—Identification and quantification of traffic paint components can be made by several means. Infrared spectroscopy can be used for resin identification. Use ASTM D2621, Test Method for Infrared Identification of Vehicle Solids from Solvent-Reducible Paints, to aid identification of solvent reducible resins. Oils and oil acids can be identified by gas chromatography. ASTM D2245, Test Method for Identification of Oils and Oil Acids in Solvent-Reducible Paints. White titanium pigment concentration can be determined using either the Jones Reduction method or the Aluminum Reduction method found in ASTM D1394, Test Methods for Chemical Analysis of White Titanium Pigments. Chrome yellow may be quantified using atomic absorption spectroscopy or by wet chemical methods using ASTM D126, Test Methods for Analysis of Yellow, Orange, and Green Pigments Containing Lead Chromate and Chromium Oxide Green. X-ray fluorescence (XRF) can be readily used to quantify lead chromate and titanium dioxide content. While expensive initially, XRF is generally much quicker than wet methods. Many epoxy traffic markings specify an epoxy content. Use ASTM D1652, Test Methods for Epoxy Content of Epoxy Resins, for this determination. The amine value is also specified on many epoxy traffic markings. Use ASTM D2074, Test Methods for Total, Primary, Secondary, and Tertiary Amine Values of Fatty Amines by Alternative Indicator Method for this determination.
7. **Pigment Content**—ASTM D2371, Test Method for Pigment Content of Solvent-Reducible Paints, is used for solvent reducible coatings and ASTM D3723, Test Method for Pigment Content of Water Emulsion Paints by Low-Temperature Ashing is used for water emulsion paints. ASTM D4451, Test Method for Pigment Content of Paint by Low Temperature Ashing (450°C), is a low-temperature ashing method useful for all coatings that do not contain organic pigments.
8. **Non-Volatile Content**—Sometimes referred to as "total solids," use ASTM D2369, Test Methods for Volatile Content of Coatings to determine the non-volatile content of the paint.
9. **Volatile Organic Content**—can be determined using ASTM D2369, Test Method for Volatile Content of Coatings
10. **Total Volume Solids**—can be determined using ASTM D2697, Test Method for Volume Nonvolatile Matter in Clear or Pigmented Coatings.
11. **Lead Content**—can be determined using ASTM D3335, Test Method for Low Concentrations of Lead, Cadmium, and Cobalt in Paint by Atomic Absorption Spectroscopy.

Appearance and Physical Properties

1. **No-Pick-Up Time**—A quality control test that is useful in the laboratory uses a steel cylinder fitted with two replaceable O-rings that is rolled down a ramp over a test stripe as shown in Fig. 2. This is a control test and shows little correlation with field applications. The no-pick-up time can be determined using ASTM D711, Test Method for No-Pick-Up Time of Traffic Paint.
2. **Dry-Through Dry Time**—This test is conducted at 50 % and 90 % relative humidity.
3. **Scrub Resistance**—This is a wet abrasion test often specified using ASTM D2486, Standard Test Methods for Scrub Resistance of Wall Paints.
4. **Flexibility**—This test evaluates the sample after being bent 180° over a 1/2 in. mandrel per ASTM D522, Standard Test Methods for Mandrel Bend Test of Attached Organic Coatings.
5. **Water Wash-Off**—This is a new test issued in 2008 as ASTM D7377, Standard Practice for Evaluating the Water Wash-Off Resistance of Traffic Paints Using a Water Faucet.
6. **Bleeding**—This test measures the amount of material that passes from an asphalt pavement through the traffic marking material. An arbitrary scale of photographic standards are used, where 10 shows no bleeding and

Fig. 2—ASTM D711 equipment.

2 shows considerable bleeding. Use ASTM D868, Test Method for Determination of Degree of Bleeding of Traffic Paint, contains the photographic standards.

7. **Hiding Power**—Hiding power (or dry opacity) is the measure of the ability of the coating to hide the substrate. Use ASTM D2805, Test Method for Hiding Power of Paints by Reflectometry.
8. **Color**—The color of traffic markings are usually compared to a specified standard. Color differences can be determined visually between the product and a standard. This comparison is fast and acceptable although numerical values are not obtained. The advantage of using color difference instruments are that they provide numerical values that can be compared to future measurements. Visual color comparison can be made in accordance with ASTM D1729, Practice for Visual Appraisal of Colors and Color Differences of Diffusely-Illuminated Opaque Materials.

   To determine the color in terms of tristimulus values or chromaticity coordinates, use ASTM E308, Practice for Computing the Colors of Objects by Using the CIE Systems. Color difference measurements are instrumentally obtained by following ASTM D2244, Practice for Calculation of Color Tolerances and Color Differences from Instrumentally Measured Color Coordinates. To determine the day and nighttime colors of pavement markings use ASTM D6628, Standard Specification for Color of Pavement Marking Materials.
9. **Reflectance and Retroreflectance**—Reflectance is the measure of light reflected from the surface of a material. Many pavement markings are visible during daytime illumination due to their reflectance of light or Luminous Reflectance Factor (Y). This reflectance of light makes the pavement marking material appear lighter than the pavement. To measure the Luminous Reflectance Factor (Y), the beadless sample is generally illuminated at a 45° angle and measured at a 0° angle using the standard CIE illuminant D65. Determine the Luminance Reflectance Factor in accordance with ASTM E1347, Standard Test Method for Color and Color-Difference Measurement by Tristimulus Colorimetry.

   Retroreflectance is a measure of light reflected back close to the light source. In practice, it simulates the car headlights reflecting off of the pavement marking back to the driver. In the laboratory, retroreflectance can be measured on a beaded sample in accordance with ASTM D4061, Test Method for Retroreflectance of Horizontal Coatings. Portable retroreflectometers are used to test pavement markings in field evaluations in accordance with ASTM E1710, Test Method for Measurement of Retroreflective Pavement Marking Materials with CEN-Prescribed Geometry Using a Portable Retroreflectometer. The Delta LTL-2000 portable retroreflectometer (used by several state Departments of Transportation) is shown in Fig. 3. It is designed to simulate the driver geometry and the visual distance of 30 meters. After the instrument is zeroed and calibrated, it is placed over the test line and the reading is obtained. Retroreflectivity can also be measured on the road with a mobile vehicle equipped with measurement instrumentation. Testing has indicated

Fig. 3—Delta, LTL-2000 portable retroreflectometer.

there is similarity between readings obtained with portable retroreflectometers and those obtained in the laboratory using ASTM Test Method D4061.

10. **Resistance to Wear**—This is a measure of a pavement markings' ability to withstand wear from traffic [5]. The test procedure involves dropping an abrasive sand on a dry test specimen until the material is worn away. The test is usually performed on an unbeaded material that is the appropriate thickness. A variation of the test is to drop a specific volume of sand on the specimen and calculate the amount of material lost by weight. The abrasion resistance can be determined by using ASTM D968, Test Method for Abrasion Resistance of Organic Coatings by Falling Abrasive.

THERMOPLASTIC

Thermoplastic material (including hot melt) is supplied in a powdered form or in block form. The material is prepared for testing by melting a sample at its application temperature under constant agitation. A guideline for testing thermoplastics can be found in the American Association of State Highway and Transportation Officials (AASHTO) Standard Test Method T-250. Two methods should be followed when sampling and preparing the thermoplastic: ASTM D7307, Standard Practice for Sampling of Thermoplastic Traffic Marking Materials and ASTM D7308, Standard Practice for Sample Preparation of Thermoplastic Traffic Marking Materials.

Gravimetric and Chemical Analysis—The amount of binder, glass beads, titanium dioxide, or lead chromate or other pigments can be determined in accordance with ASTM D4797, Test Methods for Chemical and Gravimetric Analysis of White and Yellow Thermoplastic Traffic Marking Containing Lead Chromate and Titanium Dioxide.

Appearance and Physical Characteristics

1. **Reflectance**—Measuring reflectance on thermoplastic is the same as for liquid coatings except a patty is used instead of a drawdown coating [6]. Use ASTM D4960, Test Method for Evaluation of Color for Thermoplastic Traffic Marking Materials, to determine reflectance.
2. **Softening Point**—Thermoplastic marking material does not have a distinct melting point but will become gradually softer as the temperature rises. The softening point is useful in predicting the tendency of the

material to flow at elevated temperature. To measure the softening point, melted thermoplastic is cast into brass rings and allowed to cool. The ring of thermoplastic, which is supporting a steel ball, is placed in a liquid bath and heated at a controlled rate. The softening point is reported as the temperature at which the steel ball falls a distance of 1 in. The softening point can be determined in accordance with ASTM D36, Test Method for Softening Point of Bitumen (Ring-and-Ball Apparatus).

3. **Specific Gravity**—The specific gravity of the thermoplastic is determined on the premelted sample. The material is ground so it will pass through a No. 30 sieve. The thermoplastic is tested in accordance with ASTM D153, Test Methods for Specific Gravity of Pigments, Method A.
4. **Bond Strength**—The bond strength of thermoplastic marking material is determined instrumentally using concrete bricks and steel blocks. A melted specimen is applied to a concrete brick with a drawdown blade. Two steel cubes are placed in the hot thermoplastic, and the excess thermoplastic is scraped away from the cubes. After trimming, the steel cubes are removed and the material is allowed to cool. A heated steel cube is bonded to the thermoplastic square with an epoxide adhesive and allowed to cure before the bond strength can be determined on a dynamometer. The bond strength is determined in accordance with ASTM D4796, Test Method for Bond Strength of Thermoplastic Traffic Marking Materials.
5. **Impact Resistance**—Impact resistance is determined on blocks of thermoplastic using an Izod-type impact apparatus. The procedure given in ASTM D256, Test Methods for Determining the IZOD Pendulum Impact Resistance of Plastics, is used except the specimen is not notched.
6. **Flowability**—This test is a measure of the thermoplastic marking materials' ability to flow. It is closely related to the viscosity of the material. The test involves melting a weighed sample in a pint can for 4 h with constant agitation. The can is suspended at a 45° angle, allowing material to flow over the edge until the flow ceases. The residue is weighed and the flowability is calculated. Test the material in accordance with AASHTO Test Method T-250.

PAVEMENT MARKING TAPE

1. **Film Thickness**—The adhesive layer is removed from the tape with a suitable solvent, and the thickness is measured with a micrometer. The glass beads are included in this measurement, which is in contrast to films from liquid coatings where the glass beads are not included.
2. **Reflectance and Retroreflectance**—Reflectance and retroreflectance are measured in the same manner as liquid coatings. For information, see No. 9 under "Appearance and Physical Properties," of Section B, "Material Testing."
3. **Glass Bead Adhesion**—A qualitative test to check glass bead adhesion is to firmly scratch the surface of the tape with a thumbnail. Acceptable adhesion for this test is noted when beads are not easily removed from the surface.
4. **Tensile Strength**—A 1 -in.-wide strip of tape is tested in accordance with ASTM D638, Test Method for Tensile Properties of Plastics, at a test rate of 0.25 in. /min.
5. **Adhesive Shear Strength**—The adhesive shear strength is a measure of the adhesive strength between the tape and the pavement. A 1 × 3 in. piece of carborundum extra coarse emery cloth is applied to the adhesive face of a 1 × 6 in. strip of tape with a 1 in. overlap. A pressure of 50 psi is applied to this overlapped area. The specimen is then tested in accordance with ASTM D638, at a speed of 0.50 in./min.
6. **Skid Resistance**—The skid resistance of tapes are measured on a British Pendulum Tester. This pendulum impact tester measures energy loss as a rubber slider travels over the specimen. The test can be used in the laboratory or in the field. The values are measured in British Pendulum Numbers. The test should be made in accordance with ASTM E303, Test Method for Measuring Surface Frictional Properties Using the British Pendulum Tester.

GLASS BEADS (RETROREFLECTIVE OPTICS)

1. **Gradation**—Gradation of glass beads is a measure of the sphere diameter. AASHTO specification M-247 gives three gradations of glass beads. Type 1, Type 2, and Type IM. Additional types (III, IV, and V) will be added as larger size glass bead sizes are specified. To perform the test, the beads are hand sieved through standard sieves starting with the largest opening and progressing through to the smallest opening sieve. The glass beads are removed from each sieve, weighed and the percent passing each sieve is calculated. The test is performed in accordance with ASTM D1214, Test Method for Sieve Analysis of Glass Spheres.
2. **Roundness**—The roundness of glass beads is another measurable indication of how well a pavement marking will perform as a retroreflective media. As mentioned earlier, only round spheres can reflect light back toward the light source. To test for roundness, the glass beads are mechanically separated by controlled vibration of a glass plate held at a fixed slope as shown in Fig. 4. The glass spheres that are round will roll down the slope while irregular-shaped particles will roll to the side or vibrate to the top. After testing the complete sample, the percent rounds can be calculated by weighing the amount of spheres that have rolled down

Fig. 4—Glass bead roundness apparatus.

Fig. 5—Paint truck.

the slope. The test is performed in accordance with ASTM D1155, Test Method for Roundness of Glass Spheres.

3. **Refractive Index**—To determine the refractive index of glass beads, the beads are treated as a pigment and are tested in that manner. Most pigments are tested using the liquid immersion method (Becke Line method or equivalent) at a temperature of 25°C.

Optical Particle Analyzers are now being used to determine bead size and gradation. While expensive, the optical particle analyzer allows for much quicker testing and a higher degree of precision and quantification of bead samples. ASTM is currently investigating the use of optical particle analyzers.

Note on other retroreflective optics testing: Specific test methods to characterize ceramic materials and bead clusters have not been promulgated (Fig. 5)

FIELD EVALUATION OF MARKING MATERIALS

Field evaluation of traffic marking materials is useful in determining the relative service life of these materials under actual road conditions using transverse lines (Fig. 6). Two evaluation methods are described below:

ASTM D713, Standard Practice for Conducting Road Service Tests on Fluid Traffic Marking Materials

This ASTM method is excellent for performing field evaluations. It is broken up into two parts—Application Process and Performance Criteria.

Fig. 6—Applied test stripes.

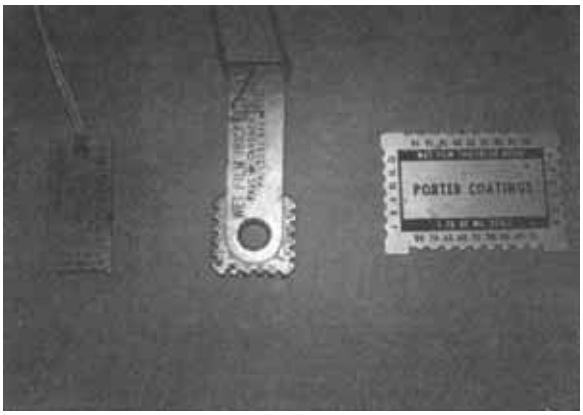

Fig. 7—Wet film thickness gages.

APPLICATION PROCESS

Location for Tests—Pavements should be selected where traffic is free flowing without grades, curves, intersections, or other phenomena that would cause excessive braking or turning. The area should have uniform wear, full exposure to sunlight throughout the day, and have good drainage. Interstate highways are usually excellent choices for testing.

Wet Film Thickness Measurement—Wet film thickness is measured with a wet film thickness gage consisting of a piece of metal with calibrated notches cut at various mil thicknesses as shown in Fig. 7. The gage is placed in a freshly applied line on a test plate and withdrawn. The notch with the highest reading that has paint on it is the wet film thickness. The wet film thickness is measured and adjusted before the test line is applied to the pavement.

Film thickness for thermoplastic is usually measured with calipers on a cooled test panel.

Glass Bead Measurement—There are two methods that can be used to quantify the weight of glass beads applied. The first involves weighing a freshly applied stripe without beads on a test panel and a test stripe with beads. The difference in weight is used to calculate the quantity of glass beads. This procedure is described in ASTM Method D713.

The second procedure involves collecting the beads from the bead gun during a preset time period. The weight of beads collected is determined and used to calculate the application rate for the beads.

Glass bead distribution is checked on a beaded test panel or the road surface. The beads should be evenly distributed across the width of the stripe, approximately 70 % of the beads should be buried in the material, and the remaining beads should be 50 % embedded in the material.

Application Procedures—Before applying any test lines, wet film thickness, line width, glass bead application rate, and glass bead distribution should meet the specification. Several test lines are usually applied. One line is for the Auto-No-Track Time determination (see next section), while the others are for additional evaluations.

PERFORMANCE CRITERIA

Field No-Track Time—The field no-track time is determined by driving a standard passenger car over a freshly applied line. This is usually done at 25–35 mph at the specified no-track time. Any deposit of paint on the roadway or exposure of the pavement under the test line is considered as not meeting the no-track requirement. No track times

range from 90 s to 2 min and are dependent upon air and road temperature, wind speed, sunlight, and humidity. The general correlation between the laboratory no-track time described in ASTM D711 and the field results is that a 7 min dry time by D711 will indicate a 90 second dry time in the field.

Appearance—This is the general condition of the test lines when viewed from a distance of 10 ft. It takes into consideration color, bleeding, darkening, fading, dirt collection, etc. This is done for each wheel track. A numerical value is usually assigned from 0 to 10 with 10 being the highest quality.

Durability—The durability of the material in each wheel track is rated from 1 to 10 (10 indicating no material has worn away). ASTM D913, Practice for Evaluating Degree of Traffic Paint Line Wear, can be used as a guideline.

Retroreflectivity—Retroreflectivity measurements are made in each wheel path using a portable retroreflectometer as previously described. Two ASTM methods should be followed:

ASTM E1710, Test Method for Measurement of Retroreflective Pavement Marking Materials with CEN-Prescribed Geometry Using a Portable Retroreflectometer.

Periodic Field Evaluation

Periodic inspections of the test stripes are made, usually monthly. At each inspection, daytime appearance, durability, color, and retroreflectance values are recorded.

Special Considerations for Pavement Marking Tapes

Application of pavement marking tapes will vary with the type of tape and manufacturer. Many tapes require primers or adhesives to be applied to the pavement before applying the tape. Most are rolled with a weighted roller after application to assure good contact between the adhesive and the pavement. The manufacturer's instructions for application should be followed closely.

In addition to the previously discussed evaluation criteria, removable tapes are also evaluated for their ability to be easily removed. About 90 days after application, a test line is removed by lifting a corner with a putty knife and pulling up the line. An acceptable tape should be removed in large sheets and not small pieces.

AASHTO'S NATIONAL TRANSPORTATION PRODUCT EVALUATION PROGRAM (NTPEP)

In an attempt to improve traffic marking materials throughout the country, the Federal Highway Administration (FHWA) sponsored a research project to evaluate the feasibility of Regional Test Centers for the testing of pavement marking materials in the lab as well as in the field. This study paved the way for the current pavement marking evaluation program, NTPEP. While this program is administered by the NTPEP coordinator, all lab and field testing is conducted by participating State DOT's and other research facilities.

The intent of the program is to provide testing results so users can make the determination of acceptance. Manufacturers submit pavement marking materials to the program for laboratory testing and 2 year field (actual road) testing. The field testing procedures are based on ASTM D713, Standard Practice for Conducting Road Service Tests on Fluid Traffic Marking Materials. As described previously, portable reflectometers are used in lieu of the night-time visibility evaluation. Field testing sites are chosen based upon their environmental conditions. The manufacturers submit their materials for laboratory testing and then apply their materials to concrete and asphalt cement road test sites. Laboratory tests of the materials are conducted in a designated DOT or contracted facility. Field tests of the applied materials are conducted initially and every 30 days thereafter for the first year and every 4 months for the second year. Laboratory and field test results are published periodically in the web-based AASHTO, NTPEP, Data Mine Program.

Laboratory Testing Includes the Following:

Solvent-Borne Paint
- Viscosity
- No Track Dry Time
- Total Solids
- Pigment Content
- Opacity
- Settling Properties
- IR Scan on Vehicle
- Density
- X-ray Diffraction

Water-Borne Paint
- Viscosity
- No Track Dry Time
- Total Solids
- Pigment Content
- Heat Stability
- Freeze-Thaw Stability
- Water Resistance
- Dry Opacity
- Density
- Degree of Settling
- X-ray Diffraction

Thermoplastic
- Specific Gravity
- Bond Strength
- Flowability
- Softening Point
- Low Temperature Stress Resistance
- Bead Content and Grading
- Impact Resistance
- Daylight Reflectance
- Yellowness Index

Preformed Thermoplastic
- Softening Point
- Low Temperature Stress Resistance
- Bead Content and Grading
- Impact Resistance
- Daylight Reflectance
- Yellowness Index
- Color
- Whiteness Index

Epoxy
- Drying Time
- Epoxide Number
- Adhesion to Concrete
- Hardness
- Abrasion Resistance
- Color
- Yellowness Index

Preformed Tapes
Tensile Strength
Ultimate Elongation
Retroreflectivity
Whiteness Index
Adhesion
Skid Resistance
Wear Index

Field Testing—Information and Tests:

Site Location, ADT, Weather Conditions
Pavement Marking Material Description
Application Information
Retroreflectivity
Durability
Appearance/Color
Snow Plow Damage
Removability

More detailed information can be obtained through the AASHTO/NTPEP website at www.aashto.org [7].

Water-Repellent Coatings

Victoria Scarborough[1], and Thomas J. Sliva[2]

INTRODUCTION

WATER REPELLENTS ARE TRANSPARENT COATINGS formulated for the purpose of protecting porous substrates by preventing the penetration of liquid water. Unlike waterproofing materials and sealers, water repellents allow the passage of water vapor and generally are not designed to prevent the intrusion of liquid water under hydrostatic pressure.

Water is known to penetrate porous materials and contribute to their deterioration [1–3]. Examples include warping and swelling of wood as well as cracking and spalling of concrete and masonry caused by freeze/thaw cycles and dissolved salts. Further, chloride ions in de-icing salts can accelerate the corrosion of reinforcing steel in concrete. Water repellents are used to provide protection against such damage.

Water repellents provide protection by depositing hydrophobic compounds on the substrate, thus modifying the surface tension of the treated area. With some treatments, water may bead on the treated surface.

Compositions

Most water repellents are composed of 1 to 65 % monomeric or polymeric hydrophobic compounds suspended or dissolved in a carrier solvent. The type of compounds used to deliver the water repellency, e.g., acrylic, silconate, silane, siloxane, metallic stearate, etc., generally classifies the products that produce the repellency.

The carrier solvent is selected based on its compatibility with the hydrophobic compounds. Organic solvent carriers can be aliphatic, aromatic, or chlorinated compounds that can be derived from petroleum distillation. These carriers are considered volatile organic compounds (VOC) and, in recent years, have been subject to restricted use by state and federal air emission control regulatory agencies. In reality, solvent borne water repellents are restricted in many parts of the United States. Reformulation efforts have resulted in water borne repellents that are offered by most, if not all, manufacturers.

Classification

Water repellents also are classified as either film formers or penetrants. As film formers, the substrate pores are filled and there is a continuous film on the surface. Examples of film formers include acrylic polymers or silicone elastomers. In most cases, the film-forming portion of the water-repellent is a blend of several different hydrophobic compounds.

Water repellents that are penetrants line the pores of the substrate and generally do not visibly alter the surface of the substrate. Examples of such materials include solutions of metallic stearates or paraffinic waxes. Penetrants also include reactive chemicals such as silanes and siloxanes that covalently bond to the silicate minerals in cementitious substrates. Moisture and/or alkaline material present within the substrate may catalyze this reaction.

SCHEDULE OF TESTING

Most of the laboratory tests used for the evaluation of water repellents are outline in the following sections, Tests on Physical Properties, Tests for Water Repellency of Treated Wood, and Tests for Application on Treated Masonry. All of the listed tests described may not be required for each water repellent examined, and the selection of tests to be conducted may be guided by the type and recommended use of the treatment or as agreed on by buyer and seller. Other tests, as agreed on, may be added.

Tests on Physical Properties

Typical physical properties tested on a liquid water repellent prior to application include weight per gallon, viscosity, drying time, color, flash point, pH, storage stability, total solids, percent nonvolatile content, and VOC content. Many of these tests are outlined in Section 8 of this manual on "Physical Characteristics of Liquid Paints and Coatings" and are summarized in Table 1.

Tests for Water Repellency of Treated Wood

Dimensional Stability

The relative ability of water repellents to retard dimensional changes in wood submerged in water is measured using the "wood swellometer test" and is detailed in Federal Specification TT-W-572, Paragraph 3.7, "Water Repellency" [4]. This test compares the swelling of untreated control specimens with the swelling of treated specimens after each has been submerged in water for 30 min. Similar procedures are described in the National Woodwork Manufacturers Association Test Method NWMA-M-2-81 [5]; in ASTM D4446, "Standard Test Method for Determining the Anti-Swelling Effectiveness of Water-Repellent Formulations and Differential Swelling of Untreated Wood When Exposed to Liquid Water Environments"; in American Wood Preservers Association Standard M-18, "Standard Method of Testing Water Repellency of Pressure-Treated

TABLE 1—Physical property tests involved in water-repellency testing

Property	ASTM	Title—Standard Test Method(s) for
Weight per gallon	D1475	Density of Liquid Coatings, Inks, and Related Products
Viscosity	D1200	Viscosity by Ford Viscosity Cup
Viscosity	D2196	Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield Type) Viscometer
Drying Time	D1640	Drying, Curing, or Film Formation of Organic Coatings at Room Temperature
Color	D1544	Color of Transparent Liquids (Gardner Color Scale)
Flash Point	D56	Flash Point by Tag Closed Cup Tester
Storage Stability	D2243	Freeze-Thaw Resistance of Water-Borne Coatings
Storage Stability	D1849	Package Stability of Paint (Heat Aging)
% Nonvolatiles	D2369	Volatile Content of Coatings
% Nonvolatiles	D5095	Determination of the Nonvolatile Content in Silanes, Siloxanes, and Silane-Siloxane Blends Used in Masonry Water Repellent Treatments
VOC Content	D3960	Determining Volatile Organic Compound (VOC) Content of Paints and Related Coatings
Total Solids	D2834	Nonvolatile Matter (Total Solids) in Water-Emulsion Floor Polishes, Solvent-Based Floor Polishes, and Polymer- Emulsion Floor Polishes
pH	E70	pH of Aqueous Solutions with the Glass Electrode

Wood;" [6] and in ISO/DIN 4496, "Wood Test Method Determination of the Radial and Tangential Shrinkage" [7].

In Federal Specification TT-W-572b, water repellent effectiveness is measured on treated Ponderosa pine sapwood that is cut into 6 by 38 by 254 mm (0.25 by 1.5 by 10 in.) wafers. The wafers are cut from two adjacent specimens from each of five different boards. Specimen pairs of ten wafers are required to make a set for testing, one for the treated wafers and one for the untreated controls. Five wafers (one from each board) are immersed in the test water repellent for 30 s. The wafers are cured under standard conditions for four days or until constant weight is attained.

The wafers are inserted into a holding device fitted with a micrometer at one end that is known as a swellometer gage. One end of the wafer touches the base of the gauge and the other end just touches the plunger dial of the micrometer. The wafer apparatus is immersed in water for 30 min, and a dial reading is made before and after immersion.

The difference between the dial reading of the treated and the untreated control wafers is divided by the dial reading of the untreated control wafers and multiplied by 100. The average of these five readings represents the water-repellent effectiveness in percent of the product. Federal Specification TT-W-572b requires that a water repellent exhibit a minimum of 60 % water-repellent effectiveness. ASTM D4446 differs from the federal specification in that it requires a 3 min dipping time for water-based water repellents, and it specifies that all control untreated specimens must swell a minimum of 0.8 cm (0.32 in.).

Water Absorption

Water-repellent effectiveness can also be measured gravimetrically using ASTM D5401, "Standard Test Method for Evaluating Clear Water Repellent Coatings on Wood." Water absorption is tested by cutting matched 50 by 100 by 305 mm (2 by 4 by 12 in.) Ponderosa pine sapwood boards. Five boards are treated with the test water repellent by immersing for 30 s. Five boards serve as untreated controls. After curing, the boards to constant weight under standard conditions, they are weighed, immersed in water for 30 min, removed, and reweighed. The difference between the absorption of the treated and the untreated boards is divided by the absorption of the untreated boards and multiplied by 100. The average of the five treated boards represents the water repellent effectiveness in percent of the product.

Unlike with Federal Specification TT-W-572b, the boards used in this test can be exposed to exterior weathering cycles, returned to the conditioning room to attain constant weight, and water repellent efficiency can be determined over periodic exterior exposure intervals to determine long-term effectiveness.

Beading

Water repellents for application on wood substrates can be evaluated for their ability to form and hold a water bead [8]. A suitable test is described in ASTM D2921, "Standard Test Method for Qualitative Tests for the Presence of Water Repellents and Preservatives in Wood Products." After the wood has been treated and allowed to cure, several water droplets are placed on the wood with an eyedropper or other device. The time required for the droplets to lose their spherical shape and flatten out is recorded. The test can be used to compare water-beading ability before and after either artificial or natural weathering. The ability to bead water does not prevent water absorption as described in ASTM D5401 nor does it necessarily correlate with the ability to retard dimensional changes in wood as described in Federal Specification TT-W-572b.

Paintability

If wood is to be painted and a water repellent is used as an undercoat, it may be necessary to evaluate the effects of the

water repellent on the primer or topcoat. Evaluations can include checking the adhesion of the topcoat to the substrate, observing any changes in color to the topcoat, and measuring the drying characteristics of the topcoat. These evaluations may also be made after a periodic weathering of the water repellent-treated surface before the topcoat is applied.

Weathering

Substrates treated with water repellents can be subjected to artificial or outdoor weathering, e.g., using ASTM G151, "Practice for Exposing Nonmetallic in Accelerated Test Devices That Use Laboratory Light Sources;" ASTM G154, "Practice for Operating Fluorescent Light Apparatus for UV Exposure of Nonmetallic Materials;" ASTM G90, "Practice for Performing Accelerated Outdoor Weathering of Nonmetallic Materials Using Concentrated Natural Sunlight;" and ASTM D4141, "Standard Practice for Conducting Accelerated Outdoor Exposure Tests of Coatings." The substrate is evaluated for appearance properties such as cracking (as shown in the pictorial standards of ASTM D661, "Standard Test Method for Evaluating Degree of Cracking of Exterior Paints"), discoloration, mold, and mildew as well as dirt pickup. The substrate may also be evaluated for beading ability or water-repellent effectiveness.

Tests for Application on Treated Masonry

Water Repellency

Water repellency on masonry is determined following procedures described in Federal Specification SS-W-110c, Paragraph 4.3.2 [9], ASTM D6489, "Standard Test Method for Determining the Water Absorption of Hardened Concrete Treated with a Water Repellent Coating," and ASTM D6532, "Standard Test Method for Evaluation of the Effect of Clear Water Repellent Treatments on Water Absorption of Hydraulic Cement Mortar Specimens." Generally, cement or mortar specimens are prepared as described in the method. These are weighed, immersed in water, and the amount of weight gain recorded. The same specimens are dried to constant weight and then immersed in the test water repellent. Three specimens are tested for each of the water repellent under evaluation.

After the water repellent has cured, the specimens are immersed in water for 72 h. The percent water absorbed by the treated specimens is calculated based on the weight of the dry treated specimens.

Other test methods related to the examination of water repellency include ASTM C67, "Standard Test Methods for Sampling and Testing Brick and Structural Clay Tile;" ASTM C97, "Standard Test Methods for Absorption and Bulk Specific Gravity of Dimension Stone;" and ASTM C140, "Standard Test Methods for Sampling and Testing Concrete Masonry Units and Related Units."

Chemical Resistance

The resistance of a water repellent to the intrusion of various chemicals is determined following methods modified from procedures described in ASTM C267, "Standard Test Method for Chemical Resistance of Mortars, Grouts, and Monolithic Surfacings and Polymer Concretes;" ASTM C67, "Standard Methods for Sampling and Testing Brick and Structural Clay Tile;" Report 244 of the National Cooperative Highway Research Program, "Concrete Sealers for Protection of Bridge Structures [10];" and ASTM C672, "Standard Test Method for Scaling Resistance of Concrete Surfaces Exposed to Deicing Chemicals." Cubes of mortar are prepared and then treated, cured, and immersed in a specified chemical solution. Uncoated control cubes are included in the immersion. Typical chemicals used in this test include fuels and oils, various salt solutions, and acid and alkaline solutions.

Differences in weight gain or loss as a function of time are measured and plotted as compared to the untreated control. The rate of weight gain or loss over time during immersion may be more significant than the actual difference. By charting the weight gain or loss over time, the rate of deterioration may be determined.

Chloride ion penetration resistance is of particular interest in testing for the resistance of water repellent-treated masonry, since reinforcing steel in concrete will corrode and deteriorate after prolonged exposure to salt and/or salt solutions. A method for determining the resistance of concrete to chloride ion penetration is described in AASHTO Method T259 [11].

Freeze/Thaw Resistance

Freeze/thaw resistance is determined by means of ASTM D5860, "Standard Test Method for Evaluation of the Effect of Water Repellent Treatments on Freeze–Thaw Resistance of Hydraulic Cement Mortar Specimens." Treated specimens are subjected to cycles of freezing and thawing and then evaluated for weight loss and physical deterioration such as cracking and spalling after each series of cycling.

Moisture Vapor Transmission

Because the passage of moisture vapor through masonry may affect the long-term performance of a structure, water repellents applied to masonry structures may be required to demonstrate their ability to allow the passage of moisture vapor. Several methods are available to measure moisture vapor transmission of the applied film. These methods include ASTM D1653, "Standard Test Methods for Water Vapor Transmission of Organic Coating Films;" ASTM D6490, "Standard Test Method for Water Vapor Transmission of Non-Film Forming Treatments Used on Cementitious Panels;" and ASTM E96, "Standard Test Methods for Water Vapor Transmission of Materials." In a general sense, these methods measure the rate at which water vapor passes through a coating film. The specimen is sealed to the open mount of a cup or dish that contains desiccant. This assembly is then placed in a test chamber with a controlled atmosphere. The cup or dish is exposed to a specified relative humidity and periodic weightings are made to determine the rate of water vapor transmission through the film. With penetrants, the treatment is applied to a masonry substrate and testing is conducted on treated and untreated test specimens. The percent retention of water vapor transmission is reported. Another method is described in NBS Technical Note 883, Paragraph 2.2.2, "Moisture Vapor Transmission on Brick [12]," a method that measures the moisture vapor transmission of the treated brick rather than the film.

Efflorescence

Efflorescence is a usually white, undesirable, powdery deposit that appears on the surface of masonry and concrete products [13]. It is formed by salts dissolved in water

that is passing through the concrete and masonry products by capillary action. When the solution reaches a surface, the water evaporates and leaves the salt on the surface as efflorescence. Although usually white in appearance, it may have other colors that depend on the nature of the salt involved. Although harmless in itself, the deposit often detracts from the appearance of the substrate.

There are two types of efflorescence—the powdery type mentioned above that is easy to remove and a crystalline form that comes about when the deposits are repeatedly dissolved and dried out a number of times. In this cyclic process, the crystalline form of efflorescence is formed, and it is tightly adhered to the surface. It is more difficult to remove than the powdery deposit and removal may require special cleaners or acids. Factors such as low temperatures, ground water, humidity, rain, and other water sources such as sprinklers facilitate efflorescence formation.

Water repellents may be used to prevent the formation of efflorescence. The efficiency at preventing efflorescence can be measured using the method described in NBS Technical Note 883, Paragraph 2.2.2 [12]. ASTM C1400-1, "Standard Guide for Reduction of Efflorescence Potential in New Masonry Walls," ASTM D7072-04, "Standard Practice for Evaluating Accelerated Efflorescence of Latex Coatings," and ASTM C67, "Standard Test Methods for Sampling and Testing Brick and Structural Clay Tile" are useful when investigating this phenomenon.

Part 14: Analysis of Paint and Paint Defects

68

Analysis of Paint

Darlene Brezinski[1]

SAMPLING

THE IMPORTANCE OF APPROPRIATE SAMPLING FOR analytical work cannot be overemphasized. Unfortunately, this topic is often not given sufficient thought, and there is often not enough training on the subject. A clear understanding of the nature of the problem or the reason analysis is needed must be established prior to obtaining a sample. It is extremely important to know the compositional makeup of the bulk material from which the sample is being taken. Without this knowledge, improper sampling can very easily occur. The homogeneity or heterogeneity of the sample along with its stability is very important to consider. The composition of a sample may change once it is removed from its natural matrix or environment due to interactions with a container, ultraviolet light, or air, for example. One should also know in advance what level of precision is required of the analysis and what compositional information is required.

Development of a sampling plan is one of the most important steps in providing reliable samples and consequently accurate and reliable data. The types of samples usually encountered are as follows:

Representative Sample: A sample considered to be typical of the bulk material and whose composition can be used to characterize the bulk with respect to the parameter measured.

Systematic Sample: A sample taken according to a systematic plan with the objective of investigating systematic variability of the bulk. Systematic effects due to time or temperature are typical matters of concern.

Random Sample: A sample selected by a random process to eliminate questions of bias in selection and/or to provide a basis for statistical interpretation of measurement data.

Composite Sample: A sample composed of two or more increments that are combined to reduce the number of individual samples needed to average compositional variability [1].

There are basically three kinds of sampling plans that can be used in a measurement process. Intuitive sampling plans may be defined as those based on the judgment of the sampler. General knowledge of similar materials, past experience, and present information about the bulk material, ranging from knowledge to guesses, are used in devising such sampling plans. Because the samples are based on judgment, only judgmental conclusions can be drawn when considering the data. In the case of controversy, decisions on acceptance of conflicting conclusions may be based on the perceived relative expertise of those responsible for sampling [1].

Statistical sampling plans are those based on statistical sampling of the bulk materials and ordinarily can provide the basis for probable conclusions. Hypothesis testing can be involved, predictions can be made, and inferences can be drawn. Ordinarily, a relatively large number of samples will need to be measured if the significance of small apparent differences is of concern. The conclusions drawn from such samples would appear to be noncontroversial, but the validity of the statistical model used could be a matter of controversy [1].

Protocol sampling plans may be defined as those specified for decision purposes in a given situation. Regulations often specify the type, size, frequency, sampling period, and even location and time of sampling related to regulatory decisions. Not specifically following any part of the protocol could be reason for discrediting a sample. The protocol may be based on statistical or intuitive considerations but is indisputable once established [1].

When decisions are based on identifying relatively large differences, intuitive samples may be fully adequate. When relatively small differences are involved and the statistical significance is an issue, statistical sampling will be required [1].

General Sampling Techniques

It is obvious that the sample submitted for analysis must accurately reflect the bulk material from which the sample was taken. Personnel taking samples should be trained in proper protocol for obtaining samples from bulk material. Equally as important as training is the use of proper containers necessary for storing samples. Many types of containers can alter the integrity of the sample. A paint sample submitted in the original container is not necessarily a representative sample as frequently volatile components may have already been lost or the contents may have been adulterated. Assumptions regarding the integrity of the sample are extremely difficult to make, and good analysts need to constantly bear in mind the history of the sample itself.

Detailed procedures regarding sampling of all sorts of coatings would be impossible to write; however, ASTM Practice for Sampling Liquid Paints and Related Pigmented Coatings (D3925) and ASTM Practice for Sampling Industrial Chemicals (E300) should be examined for detailed recommendations.

All the precision in weighing, measuring, calculating, and so forth has absolutely no meaning if the sample is not

[1] *Consolidated Research, Inc., P.O. Box 2190, Kingsford, MI 49802.*

Copyright © 2012 by ASTM International

a valid and representative sample. The sample taken for analysis must totally and accurately reflect the composition of the bulk material from which it was taken. If there is any doubt about the integrity of the sample *as a representative sample,* the analysis should not be conducted as the data has no meaning. This becomes extremely important when dealing with samples where the bulk is large and perhaps not always completely homogenous [1]. In the real world of sampling, it is often very difficult to even know if the sample was obtained properly and if it is representative. The analyst usually has no control over the sampling step itself. In these cases, it becomes important for the analyst to stress that the data are only representative of the sample that has been analyzed and not necessarily representative of the bulk. Rather serious management decisions can be falsely made if the decision is based on data that is not representative data.

Care should be taken to assure that all containers, agitators, and sampling apparatus are clean and that they can in no way contribute to contaminating the sample. Reusable syringes in particular can pose problems, particularly in trace analysis, if they are not cleaned extremely well. Contaminant materials will lead to erroneous test results as the contaminate will be assumed part of the sample. For pigmented coatings that are dispersions, finely divided pigment particles may settle upon standing. Consequently, very thorough agitation is necessary at every stage of the sampling and analysis procedure.

Airtight storage containers are necessary to prevent evaporation of sample material. Volatile solvents may also diffuse through the walls of plastic containers. The loss of volatiles subsequently introduces significant error in such tests as viscosity, weight per gallon, and nonvolatile content. If cap liners are used for samples, they must be made of a nonreactive material. It is also very important in all stages of sampling/analysis that the samples be kept at fairly constant and consistent temperatures. Extremes of temperatures may change the properties of some coatings.

Proper labeling of the sample cannot be stressed enough. Labeling should be done in accordance with prior established standard operating procedures (SOPs) for the laboratory. The more information available on the label, the less likely error will be introduced either in the handling of the sample or in the analysis. Formula composition, if known, can be an asset to the analyst in choosing the best analytical methods and save valuable and costly analytical time.

Laboratory Protocol

The analytical laboratory today must have SOPs. This is standard, acceptable practice today, and laboratories that have not implemented these procedures will find it more difficult to maintain credibility of the data with their clients. SOPs define clearly how each step of the laboratory operates. Clear SOPs are necessary for training, logging samples, calibration, quality assurance, receipt of samples, chain-of-custody, report formats, analytical methods, handling of hazardous materials, etc.

Whatever kind of sampling plan is developed, it should be written as a protocol containing procedures (SOPs) that must be followed. It should address the following:

- when, where, and how to collect samples
- sampling equipment, including its maintenance and calibration
- sample containers, including cleaning, addition of stabilizers, and storage
- criteria for acceptance and/or rejection of samples
- criteria for exclusion of foreign objects
- sample treatment procedures such as drying, mixing, and handling prior to measurements
- sub-sampling procedures
- sample record keeping such as labeling, recording, and auxiliary information
- chain of custody requirements [1]

Appropriate laboratory protocol has established SOPs in place for every facet of the operation. Sample control has to include not only the receipt and handling of the sample but the handling and storage of the data.

Implementation of a chain-of-custody plan for each sample is most critical to good operating practices in the analytical lab today. It provides traceability for the sample upon receipt and distribution of the sample for analysis. The purpose of chain-of-custody is to ensure control of the sample and corresponding data and that the data are verifiable. The flow of samples for analysis and the associated paperwork must be clear to everyone involved in the laboratory.

Analytical Quality Assurance

The validity of analytical data must be clearly established through the documentation of quality assurance practices. This is particularly important because often analytical determinations and the subsequent data may be used as evidence in a court of law. Standard operating procedures should be established and encompass the following: record keeping, sample homogeneity, calibrations, reference standards, calculations, laboratory housekeeping, the statistics of inter-laboratory studies, and practical quality control.

Laboratory accreditation is becoming increasingly important in today's environment to provide a level of confidence in the laboratories' capabilities, personnel, testing procedures, and equipment. It establishes integrity and reliability in the testing and the data. As regulatory requirements become more demanding, the nature of the analytical methodology has been changing to more sophisticated analyses and, along with these changes, there has been an increased emphasis on quality assurance and quality control. Successful laboratories have made major commitments to quality products and quality data. Therefore, the process of verification of laboratory procedures is becoming more important for providing precise and accurate data.

GENERAL TESTING

Before any tests are run on the coating and prior to separation, testing to establish some basic parameters or conformance properties should be run. Among these are flash point, density, water content, nonvolatile content by weight and/or volume, and pigment or ash content. Reference should be made to elsewhere in this manual for more information regarding determination of density, specific gravity, and so forth.

Flash Point

The flash point of a material is defined as the lowest temperature, corrected to a pressure of 760 mm Hg (101.3 kPa, 1013 mbar) at which application of an ignition source

causes the vapor of the specimen to ignite under specified conditions of test. Flash point is one of the properties used to classify liquids according to their flammability by governmental regulatory agencies. Several different flash point methods are available. The analyst must determine which one of these methods is appropriate for the sample to be analyzed and then follow the recommended ASTM procedures. Both Tag open cup and closed cup methods, Pensky-Martens closed cup, and Setaflash tester methods are commonly used in the coatings industry. [ASTM Test Method for Flash Point and Fire Points of Liquids by Tag Open-Cup Apparatus (D1310); ASTM Test Method for Flash Point by Tag Closed Tester (D56); ASTM Test Methods for Flash Point by Pensky-Martens Closed Cup Tester (D93); ASTM Test Methods for Flash Point of Liquids by Small Scale Closed-Cup Apparatus (D3278).] Open cup flash points are only required in the rare customer specification. Department of Transportation regulations specify closed-cup. Laboratories need to be certain of the shipping requirements and the appropriate methods prior to analysis of the sample.

Density

Density is weight per unit volume. It is a key property in the identification, characterization, and quality control of a wide range of paint materials. The density of water at various temperatures is used to calibrate the volume of the container. The weight of the paint liquid contents of the same container at the standard temperature is then determined and density of the contents calculated in terms of grams per milliliter, or pounds per gallon, at the specified temperature.

Density measurements in terms of weight per gallon are commonly used to check paint quality. If the density is not within specification, there is a good chance that there was a mischarge or other serious problem. This could indicate further chemical analysis is required to determine the nature of the problem. ASTM Test Method for Density of Liquid Coatings, Inks and Related Products (D1475) is suitable for the determination of density of paint and related products and components when in liquid form.

ASTM D1475 provides for the maximum accuracy required for hiding power determinations. Automatic equipment for measuring density is available from several manufacturers [see ASTM Test Method for Density, Relative Density and API Gravity of Liquids by Digital Density Meter (D4052)]. For higher precision if working with nonpigmented materials, ASTM Test Method for Specific Gravity of Drying Oils, Varnishes, Resins and Related Materials at 25/25°C (D1963) can be used to determine specific gravity and the corresponding density.

Water (Content) Determination

Control of water content is often important in controlling the performance of paint and paint ingredients and is certainly critical in determining and controlling the volatile organic compound (VOC) content. ASTM Test Method for Water in Paints and Paint Materials by Karl Fischer Method (D4017) is applicable to all paints and paint materials, including resins, monomers, and solvents, with the exception of aldehydes and certain active metals, metal oxides, and metal hydroxides. The Karl Fischer Method has been evaluated for pigmented products containing water in the 30 %–70 % range; however, it is believed that the method is also applicable for higher and lower concentrations. The method consists of dissolving the sample in pyridine, or other appropriate solvent, and titrating directly with standardized Karl Fischer reagent to an electrometric end point.

ASTM Test Method for Water Content of Coatings by Direct Injection into a Gas Chromatograph (D3792) is also used for determining water in many latex systems. That method has not been evaluated for other water reducible paints, but is believed to be applicable. The established working range of the method is from 40 % to 55 % water, but there is no reason to believe that it will not work outside of this range. In this method, a suitable aliquot of whole paint is internally standardized, diluted, and injected into a gas chromatograph. By choosing the correct column and conditions, water can be separated from the other volatile components.

Water content in pigments may be determined in accordance with ASTM Test Methods for Common Properties of Certain Pigments (D1208).

SEPARATION OF SOLIDS AND VOLATILE CONTENT

Separation of solids is routinely performed for determining the percent composition of the coating, i.e., % NVMs (nonvolatile materials), % pigment, and % solvent. In many cases, however, separation of these materials is also necessary for further identification purposes, to check formulation related problems, and for general problem solving.

Nonvolatile Content by Weight

Nonvolatile measurement is one of the most widely used tests for coatings characterization. It determines the quantity of coating remaining after all solvents or water and other volatiles have been removed. When used in conjunction with volume nonvolatile content, the area covered by a gallon of paint or coating can be determined.

It has become customary to determine the amount of NVM, or solids, in a coating and that information is useful to producers, users, and to environmental and health and safety interests in comparing the coverage of competing products and in estimating the volatile organic content. Standard practice has been to accurately weigh by difference from a syringe a small sample of paint into a tared aluminum foil, flat-bottomed dish. The dish is heated for a specified temperature and time (usually to constant weight at 105°C), cooled in a desiccator, and weighed. From this weight and the original weight of the empty dish the weight of NVM may be calculated. The procedure is not as simple as it first appears, and different types of coatings require different methods. ASTM Guide for Determining Volatile and Nonvolatile Content of Paint and Related Coatings (D2832) is intended to aid in the selection of the proper standard for determining the volatile and nonvolatile content of coatings. This guide should be examined carefully and followed prior to determining nonvolatile content.

Perhaps the most commonly used method is ASTM Test Methods for Volatile Content of Coatings (D2369). This method is the procedure of choice for determining the volatiles in coatings for the purpose of calculating the volatile organic content (VOC) in coatings. Correspondingly,

the nonvolatile (NVM, or solids) is used to determine the weight percent solids content.

Another commonly used procedure is ASTM Test Method for Nonvolatile Content of Latexes (D4758). This method should not be used for determining VOC of formulated coatings; however, it is appropriate for obtaining the weight percent of a commercial latex product that, when incorporated into a coating product, constitutes the binder content of the coating.

The nonvolatile content of resin solutions is useful to coatings producers and users for the determination of the total solids available for film formation and for the estimation of VOC. ASTM Test Methods for Nonvolatile Content of Resin Solutions (D1259) provides the detailed procedures.

Nonvolatile Content by Volume

A measure of the volume of dry coating obtainable from a given volume of liquid coating is considered by some to be a better measure of value than percentage of nonvolatile matter by weight. ASTM Test Method for Volume Nonvolatile Matter in Clear or Pigmented Coatings (D2697) is applicable to the determination of the volume of nonvolatile matter (volume solids) of a variety of coatings. This method is intended to provide a measure of the volume of dry coating obtainable from a given volume of liquid coating. This value is useful for comparing the coverage (square feet of surface covered at a specified dry film thickness per unit volume) obtainable with different coating products.

The value obtained may not be equal to that predicted from simple additivity of the weights and volumes of the raw materials in a formulation. One reason is that the volume occupied by a solution of resin in solvent may be the same, greater, or less than the total volume of the separate ingredients: such contraction or expansion in resin solutions is governed by a number of factors, one of which is the extent and direction of spread between solubility parameters of the resin and solvent. The spatial configuration of the pigment particles and the degree to which the spaces between the pigment particles are filled with the binder also affect the volume of a dry coating formulation. Above the critical pigment volume concentration, the apparent volume of the dry film is significantly greater than theoretical due to the increase in unfilled voids between pigment particles. The use of volume nonvolatile matter values in such instances should be carefully considered as the increased volume is largely due to air trapped in these voids.

In methods, the weight and volume of a stainless steel disk are determined. After the disk is coated with the material being tested, the weight and volume of the disk plus dried coating is determined by weighing in air and then by weighing in a liquid of known density, the volume being equal to the quotient of the weight loss of the coated disk (due to the Archimedes buoyancy effect) divided by the density of the liquid displaced. The liquid may be water or an organic liquid, such as low solvency mineral spirits, depending on the nature of the coating being tested. From the measured weights and volumes of the disk before and after coating, the weight and volume of the dried coating film are calculated. Based on the density of the liquid coating and the weight percent nonvolatile matter, the volume of the liquid coating deposited on the coated disk is calculated. The volume of the dried coating divided by the volume of liquid coating, multiplied by 100, provides the volume percent nonvolatile matter in the total liquid coating.

Pigment Content

For most water emulsion paint systems, the pigment content (often called ash) is most often determined following the determination of the weight percent nonvolatiles. ASTM Test Method for Pigment Content of Water-Emulsion Paints by Low Temperature Ashing (D3723) covers a procedure for the pigment content determination. After weighing the dishes for NVM, the dishes are transferred to a muffle furnace and heated at a low ashing temperature of about 450°C for 1 h. Of course the analyst must keep in mind that the method is only applicable to pigments that do not decompose or lose weight at temperatures below 500°C. This would include most metal oxides, silicates, and a majority of anhydrous inorganic salts.

A note of caution is advised, as this may be too low an ashing temperature for some paints. Each system is different, and one cannot assume that this temperature will be sufficient.

To separate pigment from solvent-based paints, ASTM Test Method for Determination of the Pigment Content of Solvent-Reducible Paints by High-Speed Centrifuging (D2698) should be followed. Also ASTM Test Method for Pigment Content of Solvent-Reducible Paints (D2371) provides a centrifugation method for separation of pigment from the vehicle.

Vehicle Separation

Separation of the vehicle from the pigment in solvent-reducible paints is desirable and often required in order to further characterize paint vehicles by chemical or instrumental methods of analysis. ASTM Standard Practice for Separation of Vehicle from Solvent-Reducible Paints (D2372) covers the procedure for separating the vehicle from the pigment by centrifugation.

Solvent Separation

If it is desirable to separate the solvents from the vehicle, ASTM Standard Practice for Vacuum Distillation of Solvents From Solvent-Reducible Paints for Analysis (D3272) details a vacuum distillation procedure. For analysis purposes, however, most people prefer direct injection of paint sample into the gas chromatograph for solvent identification.

Sample Preparation

For many types of analysis, the previously discussed separation techniques are sufficient. Many chemical analyses require further sample treatment in the form of either extractions or digestions. The standard analytical techniques are always applicable in these cases. Extractions are often more attractive techniques for separating inorganic species than precipitation methods, which are more time consuming. Of course the extent to which inorganic and organic species distribute themselves between two immiscible solvents differs greatly depending on the species and the extraction solvents.

Decomposition of the organic material for further analysis requires rather drastic sample treatment and typically involves oxidation techniques. Wet ashing makes use of liquid oxidizing agents such as sulfuric, nitric, and

perchloric acids. Dry ashing usually implies ignition of the organic compound in air or in a stream of oxygen.

Sample dissolution is one of the most common operations in analytical chemistry. Because most quantitative techniques require that samples be introduced in liquid form, thousands of sample dissolutions are performed every working day in analytical laboratories. Despite the importance and widespread applicability of sample dissolution, most conventional digestion procedures are tediously labor-intensive, and a number of them, such as perchloric acid digestion, are potentially hazardous to laboratory personnel [2].

New microwave dissolution techniques make it possible to speed the preparation of solid samples by combining the rapid heating ability of microwave energy with the advantages inherent in the use of sealed digestion vessels. Researchers have found microwave dissolution to be faster, more controlled, more elegant, and more amenable to automation than conventional open-beaker or closed-vessel techniques [2].

The advantages of microwave dissolution include faster reaction rates that result from the high temperatures and pressures attained inside the sealed containers. These containers are made of polymers that will not contaminate or adsorb the sample and do not absorb microwave energy. The caps are designed to safely vent container gas in case of excess internal pressure buildup [2].

The use of closed vessels also makes it possible to eliminate uncontrolled trace element losses of volatile molecular species that are present in a sample or that are formed in the course of dissolution. Such losses can easily destroy the integrity of a measurement. In the field of elemental analysis, significant percentages of elements such as arsenic, boron, chromium, mercury, antimony, selenium, and tin are lost at relatively mild temperatures with some open-vessel acid dissolution procedures. Several of these elements have already been shown to be retained when closed vessels are used [2].

Another advantage of closed vessels is a decrease in blank values as compared to open-beaker work because contamination from the laboratory environment is lower and smaller quantities of reagents are used. The blank value incurred in sample preparation is an important parameter because it frequently determines the limit of detection [2].

Many laboratories, however, have abandoned closed-vessel microwave digestions because of vessel ruptures. Thus safety concerns must be of primary importance and analysts should consult closed vessel suppliers.

CHARACTERIZATION AND CHEMICAL ANALYSIS

Analytical instrumentation has advanced significantly in recent years primarily due to advancements in the field of nanotechnology. Analysts constantly need to be aware of current literature for the most appropriate method of analysis. It is strongly recommended that particular topics be searched on the Internet for relevant literature and state-of-the-art analytical techniques, methodology, and instrumentation.

Analytical Data

The reporting of analytical data is exceedingly important, and every effort must be taken to ensure that the data are sound, defensible, and meaningful. Most basic texts on analytical chemistry discuss the appropriate statistical methods used in dealing with data, standard deviation etc., as well as significant figures. An excellent text by Taylor [1] deals with all aspects of chemical measurements and should be examined thoroughly by all analysts. Also available is ASTM Procedure for Intralaboratory Quality Control Procedures and a Discussion on Reporting Low-level Data (D4210).

In the analytical laboratory, a method of measurement (procedure) is usually followed that specifies the equipment, reagents, sample handling, etc., and the instructions to be followed. The analyst who carries out the method is following what is called a measurement process. The most important attribute of a measurement process is whether it can be made to run in a state of "statistical control." Although repetition of measurement is subject to variability, the achievement of statistical control implies that the statistical properties of this variability are uniform over time, so that it becomes meaningful to use measurements over a limited time span to predict limits of variation for both those and future measurements and to assign the level of confidence to be associated with the limits. To achieve statistical control, all assignable causes of significant variation are removed from the process [3].

Given the existence of statistical control, the two most important other attributes of the process are generally the precision and the accuracy of the results. Precision is universally considered to be the mutual agreement of individual measurements about some mean value (not necessarily the true value), while accuracy refers to the degree of agreement of individual measurements with some true or accepted reference value of the property being measured. When the mean value is not identical with the reference value, the systematic difference is called the bias. We should avoid using the terms accuracy and bias interchangeably; accuracy has to do with the difference between individual measurements and some reference value, while bias represents the systematic difference between the process mean and the reference value [3].

Structural Analysis

All aspects of coatings manufacture, from the screening of raw materials to finished product quality assurance, depend on analysis data. The ultimate goal of analyses is to identify the chemical species contained in a sample and then determine the amount of each species. As such, both qualitative (what) and quantitative (how much) analyses must be performed. It is extremely important to try and obtain all the background information regarding the sample to be analyzed as this information can often save time and expensive analysis costs.

Organic Structural Analysis

A. Instrumental Methods

Spectroscopy is the study of the interaction of electromagnetic radiation with matter, that is, the interaction of wave lengths of visible light, infrared light, ultraviolet light, X-rays, and radio waves and their effect on chemical substances. Spectroscopy allows the study of these effects with instruments that give an enormous amount of information in a short period of time with less stringent sample requirements than is needed with classical chemical techniques. All of the wavelengths in the ultraviolet, visible, and

infrared regions provide valuable information about the structural makeup of molecules.

Infrared Spectroscopy (IR) provides a unique fingerprint useful in the identification of a wide variety of chemical species [4]. Certain infrared wavelengths are absorbed in the sample by the bonds between the atoms, and the absorbance is measured and plotted as a function of wavelength. Since each chemical material has its own particular and unique arrangement of atoms and bonds, its absorbencies are slightly different from those of all other chemicals.

Normally specific functional groups will give characteristic absorbencies, and these groups can be recognized. Thus, there are very specific absorbencies for groups such as carbonyls, amines, alcohols, nitro groups, and isocyanates. Although it may not always be obvious from a spectrum which chemical is being examined, the analyst will recognize these functional groups and know something about the chemical structure.

In addition, IR can be a very valuable tool for reaction kinetic studies, hydrogen bonding, dipolar attractions and solute-solvent interaction studies, examination of the nature of hydration and the nature of inorganic lattices at various temperatures, and for studying the surface of a material by attenuated total reflection (ATR) and variation of composition with depth by variable angle ATR. These are but a few of the numerous applications of IR in the coatings field [4].

If more detailed information is desired and if the sample has some degree of solubility, then *nuclear magnetic resonance* (NMR) analysis can be extremely valuable. NMR spectrometry not only provides information regarding the functional groups that are present but it also provides information about the location of those functional groups relative to each other. In other words, the placement of the functional groups in the molecule can be discerned from NMR data [5].

If the compound is volatile and has some degree of thermal stability, *gas chromatography* (GC) can be very useful for identification purposes as well as for determining purity/ impurities of materials. If a material is identified qualitatively by GC, then that material can be further analyzed quantitatively. If the compound is not very volatile or is unstable under GC conditions it may be possible to analyze it by *high performance liquid chromatography* (HPLC). Here, as in GC, both qualitative and quantitative determinations can be made [5].

For both GC and HPLC, if the peak of interest cannot be readily identified, it can be trapped and further analyzed by either IR or NMR techniques. Current instrumentation allows the analysis of materials like this quite readily by offering instrument capabilities such as the following: HPLC-MS (mass spectrometry), GC-IR, and GC-MS. These instruments allow accurate separation of components followed by subsequent identification.

MS can be applied to the quantitative analysis of organic, organometallic, inorganic and ionic compounds and materials including metals, and alloys. It is used both to confirm the presence of known compounds and to identify compounds of unknown structure. Volatile or gaseous samples, usually organic compounds, can be examined using electron impact (EI) or chemical ionization (CI) to give positive or negative ion mass spectra. Nonvolatile samples can be examined by fast atom bombardment (FAB) or thermospray ionization for inorganic and organic salts, while plasma discharge ionization is used for metals and refractory materials.

The value of MS, of course, is absolute identification of either known or unknown compounds, particularly when combined with information from other spectroscopic techniques. Pyrolysis can also be carried out prior to ionization inside the spectrometer and thus used for characterizing both linear and cross-linked polymers.

Raman spectroscopy [5] is used to determine molecular structures and compositions of organic and inorganic materials. Raman, like infrared, provides characteristic frequencies of various functional groups. However, since the selection rules governing the allowable transitions are different, some frequencies may be observed in the Raman spectrum that do not appear in the infrared and vice versa. Some applications include:

- Examination of aqueous solutions of inorganic compounds. While water gives rise to intense absorptions in the infrared, making unavailable major regions of the spectrum for identification purposes, it is a poor Raman scatterer, thereby allowing the observation of vibrational transitions in the regions obscured in the infrared.
- Structural identifications of water-soluble organic compounds such as amino acids.
- Detection of weak infrared frequencies, such as the stretching vibrations of the following groups: —C=C—, —C=C—, —S—S—, —C— S—, —N=N—, and —O—O—.
- Determination of configurational isomers in both the solid and liquid state [4].

B. Chemical Methods

The techniques used in chemical analysis are of two general types: gravimetric and titrimetric. In a titrimetric analysis, the volume of known solution required to completely react with a functional group is measured. This volume is then related to the concentration of reacting species in the sample. The primary criteria for titrimetric analyses are that the sample is soluble in a suitable solvent and a reagent is found which fully reacts with the species of interest. Determinations of acid, hydroxyl, and oxirane functional groups, as well as elemental analysis for nitrogen content, utilize titrimetric techniques. Titrimetric analyses are quite sensitive, and measurements of concentration at the 0.1 % level are routine. During gravimetric measurement, the weight of material formed during analysis is used to determine the composition of the original sample.

Classical chemical analyses can be further divided into two categories depending upon the type of information desired: functional group determination and the measurement of elemental composition.

The presence of functional groups in polymers and coatings can normally be determined using a combination of chemical and instrumental measurements. Building upon qualitative functional group information obtained from spectroscopic techniques, quantitative analysis can begin. In some cases specific chemical tests are also required to confirm the presence of species indicated by other techniques. The quantitative measurement of the

following chemical species is routinely performed in the laboratory:

Acid (mg KOH/g sample) $COOH + KOH \rightarrow COO^{-}K^{+}$
Amine (meq/g sample) $NH_2 + HCl \rightarrow NH_3 + Cl^{-}$
Hydroxyl (mg KOH/g sample)
Epoxy or oxirane (meq/g or g/eq)
Isocyanate (%)
Acrylate (%)
Olefinic unsaturation
Thiol or mercaptan (meq/g) $SH + Ag^{+} \rightarrow S{-}Ag + H^{+}$

Many of the above are chemical functional groups that may be part of a large molecule or polymer. The level of these species provides information regarding a polymer or coating. For example, many of the polymers used in coatings are formed using multi-step reactions, and the reactions are monitored by functional group analysis. In addition to monitoring polymerization processes, the levels of species in coatings are of importance. When two coatings components are designed to be blended prior to application, functional group determination is needed to insure that the components are mixed in proportions that give optimum physical and durability properties.

Inorganic Structural Analysis

A. Instrumental Methods

Most inorganic compounds are not sufficiently volatile or soluble to allow identification by either gas or liquid chromatographic techniques. *Ion chromatography* can, however, play a major role in inorganic analysis. *Infrared* analysis (IR) is notable for pigment identification as is discussed in a subsequent section.

X-ray fluorescence (XRF) [5] and other emission techniques are used for elemental analysis of inorganic compounds. *X-ray diffraction* (XRD) analysis [5] is an important tool not only in compound identification but also in identifying crystal structures and in crystalline phase analysis.

Thermal analytical techniques such as *differential thermal analysis* (DTA), *differential scanning calorimetry* (DSC), and *thermal gravimetric analysis* (TGA) are all used on a routine basis for identifying and analyzing inorganic compounds, as well as organic compounds. These techniques provide information about the melting points, other phase transition temperatures, and thermal stability of both inorganic and organic compounds. Also, particle size, surface area, and porosity analyses provide useful characterization information about inorganic materials [6].

Inductively coupled argon plasma spectroscopy (ICAP) [5] allows the determination of numerous elements in aqueous and organic solvent solutions. ICAP methods rely on the emission of light by atoms in the sample as opposed to the absorption of light, the principle behind atomic absorption (AA) spectrometry. Liquid and/or solid samples are readily analyzed using inductively coupled plasma (ICP) techniques after appropriate sample preparation steps are taken. ICP analytical procedures employ classical sample preparation methods such as acid digestion, fusion, dry ashing, dilution, and extraction. In practical applications, AA and ICP are quite similar. The major differences are the speed with which ICP handles samples and most importantly its relative freedom from interferences. The technique is desirable for: quantitative determination of trace elements in aqueous and organic solvent solutions, quantitative analysis of pigments in paints and coatings, evaluation of waste materials and total metals content, and detection of trace metallic impurities in polymers.

The surface upon which a coating is deposited plays an important role in the protective properties of a coating system. A single molecular layer of oily contamination can interfere with proper bonding and result in coating adhesion failure. In addition, the oxide layer that forms in a clean metal surface is often mechanically weaker than the bulk of the metal. Under stress, this layer may flake off and carry with it the coating. Techniques for the examination of surfaces may take many forms, but all involve bombarding the sample with atomic or subatomic particles. The bombardment excites the surface of the sample, releasing energy, which can be used to determine elemental or molecular composition. Depending on the technique chosen, the "surface" examined will vary between the first several atomic layers of a sample down to the first several micrometers.

Electron beam X-ray analysis (microprobe) is one of the capabilities generally included with a *scanning electron microscope* (SEM) [5]. High-energy electrons that strike a sample during the image forming process interact with the atoms comprising that surface. Among the species formed during this interaction are X-rays having specific energies depending on the elements present in the sample. Once detected and analyzed, X-ray spectra can yield information on the elemental composition of the sample, as well as indicate the quantity of each element present. Two types of X-ray detectors are in general use. The energy dispersive detector is useful for detecting elements above sodium in the Periodic Table but is not suitable for low-level quantitative analysis. A wavelength dispersive detector observes all elements more massive than carbon and has significantly improved quantitative analysis capabilities. An instrument that contains all the imaging ability of the SEM and has full quantitative analysis capability is called a microprobe. This instrument has sufficient resolution to allow the elemental analysis of a particle less than 1 μm in diameter. The primary disadvantage of the microprobe is that X-rays can emerge from atoms several micrometers below the surface of the sample. Consequently, the signal from a thin layer of surface contamination can be lost in the signal from the substrate.

Ion scattering spectrometry (ISS) and *secondary ion mass spectrometry* (SIMS) techniques involve bombarding the sample with gas ions and analyzing the products removed from the surface [5]. Both methods exhibit very high sensitivity for all elements, including hydrogen, and can analyze a few atomic layers of exposed surface at a time. Resolution is normally on the order of millimeters with the exception of specialized instruments known as microprobes. These techniques are very useful for hazing and chalking problems where very minute amounts of material cause appearance problems at the surface of the coating. ISS and SIMS readily determine the nature and extent of the contaminating material. Cases of substrate contamination leading to adhesion problems are also more easily solved using the data provided by these analytical methods.

Electron spectroscopy for chemical analysis (ESCA) and *scanning auger microscopy* (SAM) are techniques in which

a sample is irradiated with a beam of X-rays (ESCA) or electrons (SAM) to liberate electrons from the top 2 to 5 nm of the surface [5]. The energy of the liberated electrons is then analyzed to provide information regarding the composition of the surface layers in the sample. In addition to elemental composition, information can be obtained on the chemical environment of the elements present on the surface. Through comparison of spectral fingerprints with the spectra of standard materials or a library of reference spectra, compounds present on the surface can be readily identified. ESCA has the capability of observing particles approximately 1 mm in diameter and is well suited to paint films on a variety of substrates. SAM has the ability to study much smaller particles (approximately 0.2 μm in diameter), but the surface must be conductive, limiting its utility to metal surfaces.

B. Chemical Methods

In conjunction with titrimetric and gravimetric measurements, analysis of elemental composition provides important information on coatings systems. Among the many elements determined are: carbon (%), hydrogen (%), nitrogen (%), sulfur (%), chlorine (%), bromine (%), phosphorous (ppm).

The level of nitrogen in an industrial coatings system is an important analytical value because nitrogen is present in melamine, urea, and benzoguanamine oligomers, which are used as cross-linking agents in many coatings. Correct levels of cross-linking agent are essential since physical, chemical, and performance characteristics are directly related to cross-linker levels. Low concentrations of cross-linking agent yield coatings that are soft, water sensitive, and do not resist detergent solutions and the weather. Elevated levels of curing agent have equally undesirable effects since coatings become brittle and lack sufficient adhesion to the substrate. In addition to cross-linking agent, nitrogen content provides information on the presence of polyamide and urethane polymers, which also contain nitrogen.

C. Microscopic Methods

In general, microscopic techniques are overlooked in the coatings industry. This is a significant omission as microscopy can be a wonderful tool for solving problems. The instrumentation is readily available but, unfortunately, trained microscopists are lacking. In many instances of coating failure and/or customer complaint the first step should be a microscopic examination. The following describes the more common and readily available techniques for the coatings laboratory.

Light Microscopes Low-power Magnifiers

Large magnifying glasses, jewelers loupes, linen testers, lenses that can be swung into place over a spectacle lens, and other magnifiers that provide assistance to the naked eye are all occasionally used in coatings analysis. Applications range from inspecting raw materials for inhomogeneities to scrutinizing a defect in a finished, coated surface [7].

The purpose of using a magnifier such as this is to provide an enlarged image so that the viewer can see the problem and/or the surface. For instance, it may become apparent that a fiber is the source of a defect surface problem. Also observable would be a particle at the center of a crater.

Stereomicroscopes

Stereo or stereobinocular microscopes are the next step up from simple magnifiers. They actually consist of two compound microscopes of relatively low magnification that are mounted side-by-side at the correct visual angle, so that the images of objects viewed through them are observed as a true, upright, fused stereo pair. These microscopes are sometimes referred to as dissecting microscopes [7].

Magnification ranges for these microscopes are usually from 2.5× to 200×. Samples can be viewed using various lighting conditions and in most instances sample preparation is minimal.

Polarizing Microscope (PLM)

The polarizing microscope is the chemical microscopist's primary tool. With it, the microscopist can study the morphology of fibers, crystals and particles. Accurate and precise measurements can be made of the optical properties of these substances by which they can be identified and characterized [7].

The majority of the analytical work undertaken with a polarizing microscope is performed by transmitted light. To look at a paint film by transmitted light, the microscopist must prepare a thin section using a device called a microtome. The sections range in thickness from tens of micrometers to a few angstroms and can be cut and mounted for microscopical observation [7].

Other Light Microscopes

Certain problems may require the use of other microscopes such as: interference microscopes, fluorescence microscopes, hot-stage microscopes, or an infrared microspectrophotometer. The latter is a microscope with an infrared spectrophotometer attached and is often used to identify the composition of multilayer paint films.

The use of Fourier transform infrared microspectroscopy (IMS) has increased greatly in the last several years. Utilization of IMS often eliminates or reduces the need for sample preparation techniques since a defect area can be analyzed directly without physical or chemical extraction. Samples can be analyzed by:

- Transmission, where the IR beam passes through the sample
- Reflection, where the IR beam reflects from the sample surface
- Attenuated total reflection (ATR), where the IR beam typically penetrates from 0.5 to 2.0 μm into the sample [8].

These three basic methods for IMS have been utilized for years and recent improvements have focused on the use of automation features such as mapping and autofocus to speed up analysis. Today's instrumentation features simultaneous view and collect features, which provides significant improvements in data collection time and efficiency. There is a continuous, full view of the sample area and a real-time spectrum preview to quickly find the optimum sample point [8].

Electron Microscopes

Scanning Electron Microscope

The SEM is the most useful electron microscope for the coatings lab. It provides a large range of magnifications, great depth of field, and the ability to obtain elemental analysis when it is equipped with an X-ray (EDS) analysis system.

SEMs are used for a variety of analyses, including pigment characterization, surface morphology measurements, and paint-film formation examination. The real strength of SEM is the ability to provide high magnification images of a sample and detailed chemical information on a micrometer-size scale [9].

The only requirement for SEM examinations is that samples are able to withstand the vacuum conditions in the microscope and are thermally stable during electron-beam irradiation. Most components used in coatings, such as resins, pigments, fillers, and other additives, are insulating materials. These materials need to be coated with a thin metallic film to render the sample surface electrically conductive, so that the specimen can be examined in the SEM [9].

X-Ray Microanalysis

Most SEM work is done using electron beam voltages of 10 – 30 keV. At these voltages the electron beam has enough energy to knock out inner-shell electrons, which leads to X-ray emission. X-rays are produced for all chemical elements using an accelerating voltage of at least 10 keV and X-ray spectra can be obtained from any area, line, or point on the sample [9].

It is important to remember that while the instruments are capable of performing quantitative analysis with these techniques, it is generally not advisable for paint samples. This is because the typical paint film is not homogenous and therefore the elemental data may be indicative of only the spot that is being scanned. A better estimate of the elemental composition of any paint sample is obtained by choosing several different areas on the sample for examination and comparison purposes.

Transmission Electron Microscope

This microscope is a transmission scope as opposed to the SEM, which is a reflection microscope. The samples for analysis must be very thin for TEM work, which may be difficult. The TEM is a great tool for examination of pigments and extenders as their size is suited for easy sample preparation.

Scanning Probe Microscopy

Scanning probe microscopes (SPMs) are powerful tools for surface metrology—measuring surface features whose dimensions range from interatomic spacing to 100 μm. The common feature of all SPMs is that the measurements are performed with a sharp probe scanning over the surface while contacting or maintaining a very close spacing to the surface. Like SEMs, SPMs image and measure the sample surface; however, SPMs measure surfaces in all three dimensions—x, y, and z. SPMs, like optical microscopes, are easy to use with little or no sample preparation and no vacuum required. They also provide the highest magnifications and resolution [10].

Atomic Force Microscopy

The first commercial AFM was introduced in 1989 and, therefore, this technique can be considered relatively new. It is ideal for providing high resolution, three-dimensional imaging of the surface structure of a film. For coatings, atomic force microscopy (AFM) can be used to understand the properties of a substrate and the effect of a coating on that substrate.

SEM has limitations, in that three-dimensional information is not available, and SEM resolution and contrast are very poor. Other techniques, such as TEM, also provide only two-dimensional data. AFM can be applied to any material, offers a much higher resolution (i.e., to the atomic level), and causes far less surface damage due to the reduction of size and forces involved. The probe tip, which interacts with the sample, is mounted onto a cantilever that translates the forces acting upon the tip in a measurable quantity. AFM can provide the following four main advantages in visualization.

- Precision. The AFM can see structures at various length scales with ease and minimal sample preparation, from subnanometer to hundreds of microns.
- High resolution. It can see the surface with very high vertical resolution and provide detailed three-dimensional visualization.
- Reduced damage. The AFM can image samples in a relatively nondestructing manner.
- Real-time monitoring. Changes in morphology as conditions are varied can be achieved in real-time [11].

AFM images can reveal critical information about surface features and can examine any rigid surface. Differences between supposedly equivalent and smooth surfaces can be seen rather dramatically using this technique. AFM can resolve very tiny features (even down to the atomic level) that are unseen by other means. The technique also allows the analyst to examine a large field of view (over 100 μm) so that comparisons can be noted with visual or optical microscopic examinations. AFM is also useful for rough surfaces, as its vertical range is more than 5 μm. Large samples can fit directly in the microscope without cutting.

AFM works by means of a tiny stylus (probe or tip) that is in contact with the surface of the sample. The most basic component is the scanner that may move the sample or can move the probe over the sample. As the instrument scans in a raster pattern, the stylus rides up and down the surface hills and valleys. The computer stores information at all points and assembles an image. This technique provides extraordinary topographic contract compared to SEM analysis. Various modes of operation can be conducted depending on the analysis required.

Vehicle Identification

Infrared Spectroscopy

Qualitative infrared spectroscopy is a valuable analytical tool that allows the examination of the multitude of materials utilized in the coatings industry. It is the primary tool for vehicle/resin identification in a coating. An infrared spectrum indicates the overall composition of any unknown material in terms of its functional groups. With a minimum of background knowledge, substantial information can be gained from an infrared spectrum by simple functional group identification. However, beginners should be cautioned against making unfounded conclusions based strictly on this technique. As one becomes more acquainted with infrared spectroscopy, the limitations and real complexity of this analytical technique will become more apparent. All laboratories involved in the infrared analysis of any aspect of coatings should have available a copy of "An Infrared Spectroscopy Atlas for the Coatings Industry" published by the Federation of Societies for Coatings Technology [4]. This atlas (inclusive of a 2500-spectra library) is

an invaluable tool and a true benefit to the spectroscopist in the coatings industry.

Occasionally, it is possible to obtain some qualitative information from the infrared spectrum of a pigmented binder system if the system is relatively simple. However, a binder free from pigment should be obtained for an infrared analysis. This means prior separation of pigment, vehicle, and solvent, and a further breakdown of these fractions, if possible. The elemental composition of the fraction should be obtained because in some cases the presence of certain elements will not be obvious from the infrared spectrum [4].

In most cases, band positions are indicative of the functional groups present. The shape of the bands also gives information concerning the functionality of a molecule. The relative intensity of a band in comparison to the intensity of other bands provides information pertaining to the amount and identity of a specific functional group present in a molecule. Functional groups that give rise to a large change in the dipole moment of a molecule, upon undergoing a vibration will have very intense absorption bands. Excellent examples of this phenomenon are the carbonyl and ether groups [4].

Once it is known which bands are characteristic of certain functional groups, the absence of these bands from a spectrum can be used to establish which functional groups are not present in detectable amounts. This method of analysis is important since the spectroscopist is frequently requested to establish the presence or absence of a particular functionality. If there is absorption present in a particular region, no information can be obtained from that region by negative interpretation. Positive interpretation or other techniques must then be relied upon [4].

The simplest method of interpretation is to consider the entire spectrum as though it were a picture and compare this picture with the spectrum of known materials that have been physically or mentally cataloged. If the spectra are the same, or very similar, it is a reasonable assumption that the materials are nearly identical. As experience is gained and more spectra are committed to memory, many materials can be recognized by inspection. Reference spectra prove invaluable in this type of interpretation, especially when a definite identification must be made [4]. There are also very extensive collections of reference spectra with which one tries to match "fingerprints" of unknown materials in order to make positive identifications.

In most cases, the limit of detectability of one material in another by infrared spectroscopy is 5 %. However, depending on the type of material, it may be less than 1 % or as high as 30 %. The limit of detection will depend on the phase, the absorptivity of the particular absorption being used, and the proximity of this band to other strong absorptions. Therefore, it is important to rely upon previous knowledge of the system and to use other confirmatory methods to verify the infrared analysis [4].

In addition to determining polymer type and concentration, the detection of contaminants in complex matrices and the examination of residual reactive functional groups can be done by infrared. The technique has advantages over other analytical techniques in that literally any type of sample can be examined by IR: solids, liquids, or gases. Special techniques are also available to examine surfaces.

Extension of an ultraviolet and visible spectroscopy (UV-VIS) experiment into the near-infrared region allows examination of materials that absorb in that region. Wavelengths in the near-IR region are those longer than visible wavelengths and occur below the red portion of the visible spectrum. A special source and detector are needed to extend into the near-IR, but instrumentation is available that will automatically switch to these at the proper wavelength. A special technique is utilized in the near-IR called diffuse reflectance and is used to measure the total reflected light off of a painted surface. This is done with a device called an integrating sphere that collects all of the reflected light from a surface and focuses it to the detector. In this way, one not only measures the amount of light a sample will absorb, but how much is reflected as well.

Infrared has great utility for the quantitative analysis of polymers, inorganic pigments, solvents, and additives. Solubility of the sample is not a requirement, and many complex mixtures can be determined in this fashion. With the increased utilization of Fourier transform and computer-assisted dispersive infrared spectroscopic techniques, quantitative applications have been further enhanced. The basis for quantitative analysis is, of course, the Beer-Lambert Law [4].

Nuclear Magnetic Resonance Spectroscopy

NMR spectroscopy permits the qualitative and quantitative analysis of many organic materials. When certain nuclei are placed in a strong magnetic field, their nuclear spin states are split into two or more levels due to the magnetic properties of these species. Transitions between these magnetically induced energy levels can then be brought about by the absorption of radio frequency energy. The specific frequencies of the radiation subsequently re-emitted depend on both the chemical and magnetic environment of each nucleus, such that detailed structural information is possible. NMR, as an analytical technique, provides information about how the atoms in a molecule are arranged. It is possible to determine which carbons are present as methyl groups, methylene groups, and so forth. The number of hydrogen atoms attached to oxygen and nitrogen can also be determined, and with these pieces of information the analyst is able to generate a molecular structure.

Samples that are soluble in a variety of solvents can be examined using NMR spectroscopy. It is ideal for structural identification of organic compounds. Qualitative and quantitative analysis of polymer composition, quantitative measurement of polymer mixtures, analysis of copolymer sequence distribution and tacticity, analysis of type and degree of polymer branching, and polymer end group analysis can all be done with NMR. An NMR spectrum of a typical polyester would show each of the dibasic acids and the polyols used in the synthesis of the polyester. NMR can be a superb asset to the analyst along with other tools such as IR for identification of true unknowns and for assisting polymer synthesis identification work.

Miscellaneous Testing

A host of chemical methods exist for further identification of resin components by chemical treatment of the resin to break it down into its original starting components, which can then be analyzed by conventional methods. For

example, a resin may be subjected to aminolysis to form amides of the carboxylic acids and to release the polyols. Upon further treatment, these materials can be readily identified. Scanning of available ASTM methods and Official Methods of Analysis of the Association of Official Analytical Chemists (AOAC Methods) [12] will provide insight into other useful techniques and procedures.

Thermal analytical data can also aid in the identification and characterization of a polymer. DTA or DSC can be used to obtain a melting point, a T_g, and a measure of the thermal stability of the polymer. XRD analysis of the polymer will determine if the polymer is partially crystalline, help to identify the chemical structure of the polymer, and provide information on the preferred conformation of the polymer chains in the crystalline regions [6].

Electron microscopy and XRD techniques describe the submicron morphological features of polymers such as lamellae and crystallites, while optical microscopy is used to study large morphological features such as the size and nature of spherulites in a polymer [6].

Electron probe microanalysis (EPMA) is an elemental identification technique associated with SEM. When materials are bombarded by a high-energy (10 to 50 keV) electron beam, characteristic X-ray fluorescence radiation is produced. By incorporating either energy dispersive or wavelength dispersive spectrometers directly into the instrument, it is possible to obtain X-ray spectra directly on the area as seen by the electron beam. Thus, it is possible to obtain qualitative and quantitative elemental data from a small volume of material for the elements boron through uranium. EPMA has been used extensively for impurity and inclusion identification in polymers [6].

Some unique vehicles may be particularly difficult to analyze, and the determination of residual monomer by gas chromatography often can shed some light on the resin system.

Pigment Identification

The following sections discuss the qualitative and quantitative identification of pigments.

Infrared Spectroscopy

As noted in the discussion on vehicle identification, IR analysis for the qualitative identification of pigments is most common. Procedures and reference spectra may be found in the Infrared Atlas [4]. Infrared is also used for identification of extender pigments.

Inductively Coupled Argon Plasma Spectroscopy

Inductively coupled argon plasma spectroscopy, often referred to as ICP or ICAP, is a technique used to determine the concentration of various elements present in any sample or material. The instrument can provide qualitative and quantitative information and can complete an analysis on numerous elements simultaneously and in a matter of a few minutes. The major strength of the technique, aside from speed, is the ability to detect trace amounts of elements.

A solution is aspirated into the instrument, where a fine aerosol is formed. This aerosol is then introduced into a high-energy argon plasma, where the elements present in the sample are raised to an excited state. When these elements return to ground state, they emit light at wavelengths characteristic of the elements present. The intensity of the light is proportional to the concentration of the element present in the sample. Generally, sensitivity is in the low parts-per-million range for most elements.

The plasma is a highly ionized, chemically inert, hot gas that achieves a temperature estimated to be 10,000°C. A radio frequency generator provides energy to the plasma torch by creating an oscillating magnetic field. A sample introduction device, known as the nebulizer, converts the sample solution into fine droplets or aerosol mists that are transported to the torch by means of argon carrier gas. The high temperature of the plasma dries the droplets and decomposes the sample into individual atoms that are excited and emit light as they return to the ground state. The wavelength of the light produced differentiates one element from another. The intensity of the light produced is a measure of the concentration of the element present in the sample.

The light emitted from a sample containing many elements passes through an optical path that separates the spectrum of light into discrete wavelengths. A detection system, made from many photomultiplier tubes, each representing a wavelength of an element, measures the intensity of light and converts it to electrical energy. The electrical energy is converted into concentration by means of a dedicated computer. The computer performs all instrumental control functions and prints the data.

Some applications of ICP are the following: pigment composition in coatings, industrial influent and effluent analysis, soluble cations and anions in electrocoat baths, organometallic additives in coatings, driers and catalysts in coatings, competitive product analysis, quality control of raw materials, and industrial hygiene analysis.

Inductively coupled plasma-mass spectrometry (ICP-MS) techniques were commercialized in 1983 and it is a very fast growing trace element technique. This is because of its ability to carry out rapid multielement determinations at the ultra-trace level. As a technique it determines the same elements as other spectroscopic methods such as atomic absorption but its speed of analysis and detection limits are highly desirable.

Atomic Absorption Spectroscopy

Atomic absorption spectroscopy, commonly referred to as AA, is designed for measuring the concentration of metallic elements in solution at the parts-per-million level. Atomic absorption is an efficient and sensitive method for performing routine quantitative analysis with a high degree of precision and accuracy. Unlike ICP spectroscopy, this instrument is only capable of analyzing the concentration of one element at a time. Thus, it is more often recognized for its quantitative power rather than its qualitative capabilities.

Atomic absorption methods rely on the absorption of light by atoms. If a solution containing metal ions is aspirated into a heat energy source, such as a flame, the high temperature and environment of the flame causes the formation of free, ground-state atoms in the flame. These free atoms are capable of absorbing light of a particular frequency. If a beam of light having the appropriate frequency or energy passes through the flame, the free atoms in the flame will absorb some of this energy. The decrease

in the intensity of the light beam can then be taken as a measure of the concentration of that particular element in the sample solution.

Atomic absorption instrumentation requires a light source, an atomizer, a monochromator, and a detector. The normal light source used in AA is a hollow cathode lamp. It consists of a hollow cup made from the element to be analyzed. Application of a high potential causes formation of positively charged ions which bombard the cathode, forming excited metal ions which emit light. AA is important since free, uncombined atoms must be formed before light absorption occurs. A solution containing the metal ions is heated to a temperature sufficient to dissociate the ions into atoms. The heat energy can be provided using an air-acetylene or nitrous oxide-acetylene flame. The primary function of the monochromator is to isolate a single atomic resonance line from the spectrum of lines emitted by the light source and direct it through the flame and onto the detector. Photomultiplier tubes are employed as detectors. They measure the changes in light intensity and convert them to electrical signals.

Sample preparation is an essential part of AA. Solid and pigmented samples are ashed to remove organic species. The inorganic components are dissolved in acid and diluted with deionized water prior to introduction into the flame. Non-aqueous AA is an ideal way of determining organometallic compounds to prevent sample loss or conversion of the metallic species into insoluble components.

Atomic absorption complements ICP techniques for the analysis of paints, resins, UV-curable coatings, and other materials. It is also a very useful tool in analyzing waste materials, pigment composition, pollution studies, raw material evaluation, and analysis of organometallic compounds.

Several pigment analysis procedures using AA are standard ASTM methods. Typical procedural examples of AA analysis for pigments can be found in the following:

Standard Test Method for the Determination by Atomic Absorption Spectroscopy of Titanium Dioxide Content of Pigments Recovered from Whole Paint (D4563).

Test Method for Detection of Lead in Paint by Direct Aspiration Atomic Absorption Spectroscopy(D4834).

X-Ray Fluorescence Spectroscopy

XRF is a relatively simple and, in general, nondestructive method for the analytical determination (qualitative and quantitative) of elements. This method is extremely useful because of the ease of sample preparation and its ability to "scan" the periodic table for all elements down to aluminum and sometimes boron. The technique allows for rapid qualitative determination of the elements present. ASTM Test Method for Determination by X-Ray Fluorescence Spectroscopy of Titanium Dioxide Content in Paint (D4764) is a typical application for the technique.

X-Ray Diffraction

The XRD pattern obtained from a material is characteristic of that material. The intensity of a diffraction peak is entirely due to one component of a mixture and is dependent upon the amount of that substance in the mixture. To a minor extent the peak intensity of the component is also dependent on the mass absorption coefficient of other materials present. Since the method utilizes the ratio of diffraction maxima of two chemically similar materials, it is expected that the effects of other constituents will be the same for both materials.

Diffraction measurements can be made on single pigments, pigment mixtures, on films of pigmented coatings and on films prepared from liquid coatings if interfering materials are not present. ASTM Test Method for Ratio of Anatase to Rutile in Titanium Dioxide Pigments by X-Ray Diffraction (D3720) is an application well suited to this technique.

Chemical Methods

The typical chemical methods using titrimetry and gravimetric procedures are always appropriate for quantitative pigment determinations. Some of these techniques have been replaced in recent years by more efficient (not necessarily more accurate) and time saving instrumental methods; however, there are situations where the traditional testing methods are still most appropriate.

Numerous ASTM methods exist for these types of analysis, and one needs to check the index of available test methods. By way of example, the following are noted:

ASTM Test Methods for Chemical Analysis of White Titanium Pigments (D1394).

ASTM Test Method for Arsenic in Paint (D2348).

Additive Identification

Additives can often be the most difficult components to analyze and identify in a coating. They frequently are present in small quantities (often at a few percent or less), and their presence can be masked by major components. In addition, the number of possible additives is large and includes surfactants, plasticizers, defoamers, thickeners, anti-oxidants, etc. It takes a skilled and experienced coatings analyst plus good deductive problem-solving ability to become adept at additive analysis. The volatile nature of some co-solvents, coalescing agents, and some plasticizers makes their identification by gas chromatography fairly straightforward.

Infrared Spectroscopy

For samples containing mixtures, the IR spectrum generally gives information only about the major component(s). However, computerized infrared instrumentation allows one to subtract spectra of the major constituents from a mixture and get the resultant spectrum of minor materials such as additives and contaminants. Thus, it is possible to do a spectral "separation" in just a few seconds rather than a true chemical separation that may take hours. Water and hexane extractions of dried films followed by IR can point to some of the following, for example:

- Cellulosic thickener (which can be confirmed by spot test).
- Long chain aliphatic hydrocarbon "oil" is indicative of defoamers.
- Carboxylate containing component may indicate a polyacrylate salt.
- Nitrile component may indicate mildewcide.
- Dialkyl sodium sulfosuccinate is indicative of a wetting agent.
- Inorganic sulfate may be a possible persulfate polymerization catalyst.

High Performance Liquid Chromatography

High performance liquid chromatography is frequently referred to as HPLC or just often as LC. This technique is used to separate components from mixtures, especially nonvolatile components that are not amenable to GC analysis. Since these nonvolatile components represent about 90 % of all organic compounds, HPLC separation techniques offer extraordinary versatility and capability. Components may be separated either by size or subtle differences in molecular configuration and solubility. Separations based on size are commonly called gel permeation chromatography (GPC) or size exclusion chromatography (SEC). Separations based on subtle differences in molecular configurations and solubility are called partition chromatography. Both quantitative and qualitative information can be obtained by using HPLC techniques.

Samples to be analyzed by HPLC are dissolved using an appropriate solvent or a combination of solvents before they are introduced into the liquid chromatograph. Samples that are not soluble in HPLC solvent(s) are not suitable for analysis using this technique. The actual separation process takes place on a packed column or a series of packed columns through which solvent is constantly pumped. The separated components elute from the column(s) directly into a detector. The detector is connected to a recording device that produces a trace of the separated components versus time, i.e., a chromatogram.

The three most common detectors in HPLC are the differential refractometer, the UV spectrometer and the evaporative light scattering detector. The refractometer measures the difference in refractive index of the solvent and the component being analyzed. The ultraviolet spectrometer measures a compound's absorbance at various wavelengths in the ultraviolet (or sometimes visible) region of the light spectrum. The refractive index detector is most commonly used with size separations, while the ultraviolet detector is usually used in conjunction with partition chromatography. The ultraviolet detector is capable of detecting components in the part-per-million range. The refractive index detector, on the other hand, can only detect components down to the 2 to 4 % ranges. It is referred to as a universal detector because it is not dependent on the sample components absorbing at a particular wavelength of light.

Typical applications include: surfactant evaluation, polymer characterization, additives in polymers, air and water pollution, raw material evaluation, multi-functional acrylates, plasticizers, coalescents, and cross-linking agents.

Ultraviolet and Visible Spectroscopy

UV-VIS examines the absorption of UV and visible wavelengths of light by a sample. This type of analysis is often used as a quantitative measure of a material. Materials that possess aromatic rings such as polystyrene, alkyd resins, and many paint additives will absorb UV light and can be examined. Materials that absorb in the visible region of the spectrum are those which possess color. Chemicals such as dyes can be examined in that region. UV-VIS is very sensitive for the species that absorb in these regions, and concentrations in the low parts-per-million range can usually be determined.

The visible region of the spectrum consists of wavelengths seen through the eye. In a visible instrument, a tungsten filament light is used as a source of visible wavelengths. Wavelengths are separated by a grating and examined one at a time. A photocell detector is used to measure absorbance at each wavelength and a spectrum is recorded.

Ultraviolet wavelengths are shorter than visible wavelengths and occupy the region above the blue end of the visible spectrum. To observe ultraviolet absorbencies, a mercury lamp is used as a source of UV light. Wavelengths are separated by a grating and detected, again by a photocell. An ultraviolet spectrum looks similar to a visible spectrum. Modern instruments combine UV and visible detection, and as the spectrum is being scanned the instrument will automatically switch from one source to another. Observed absorbencies are directly proportional to concentration of the component of interest.

Materials which do not absorb in the UV or visible region can sometimes be measured by complexing them with an absorbing reagent, usually to develop a colored species. Very sensitive methods of this type are used for the determination of formaldehyde, phosphorous, and sulfate.

Solvent Identification

Gas Chromatography

GC is a technique for the separation of any species exhibiting a measurable vapor pressure at a temperature up to approximately 300°C, as well as any compounds for which a stable, volatile derivative may be formed. Both qualitative and quantitative information can be obtained.

Most GC samples are liquids or solutions at room temperature, although instrumentation may be adapted to analyze solid and gaseous samples. Liquid samples (approximately 0.001 mL) are introduced to the instrument using a syringe into a flash-heating chamber called an injection port. There, the volatile sample components are quickly and evenly vaporized. In some cases, however, decomposition of sensitive components can occur when they come in contact with the hot metal surface. The analytical chemist may be able to minimize or circumvent this problem if proper precautions are taken. The vaporized components are then carried onto the column and through the gas chromatographic system using an inert gas, such as helium or nitrogen, flowing at a constant rate.

The column is the portion of the chromatograph where the actual separation of components is achieved. A packed column consists of narrow tubing made from stainless steel, nickel alloy, glass, or a number of other materials, filled with fine particles of a packing material. This packing material may consist of polymeric beads or an inert solid material supporting a thin film of a non-volatile liquid. It is the varying degree of interaction between each of the sample components with the packing material that causes the components to become separated in the column. A large number of packing materials of varying chemical composition are available. Columns containing other packing materials are easily interchanged so that different separations can be obtained.

Occasionally, samples will contain a number of components of similar volatility and/or chemical composition that are difficult to separate on packed columns. In these instances, capillary columns are used. Capillary columns are extremely long (100 to 300 ft, 30.48 to 91.44 m), narrow bore tubes made from glass, metals, or fused silica. They are internally coated with a thin film of a nonvolatile liquid

to effect separation. A variety of detectors used alone or in combination can be strategically mounted at the end of the column to monitor the separated components as they exit the column. The detectors available in GC have varying sensitivity and specificity. If needed, some may be operated to detect materials in the sub parts-per-million level.

The response of the detector to an eluting component is electronically converted into a visual representation called a chromatogram. A chromatogram is a plot of detector response versus time elapsed since sample injection. Eluting components are represented as peaks in the chromatogram. The time needed for a component (peak) to elute can be used to help identify the component. The area produced under the peak is related to the concentration and is used in the quantitative determination of the component.

Typical applications include: qualitative and quantitative solvent analysis, odor analysis, pollution studies, purity determinations, determinations of residual monomers, and determination of airborne organic contaminants.

Additional information on gas chromatography may be obtained from ASTM Practice for Packed Column Gas Chromatography (E260). ASTM Test Method for Direct Injection of Solvent-Reducible Paints into a Gas Chromatograph for Solvent Analysis (D3271) describes the techniques used in many situations. Note should also be made of ASTM Test Method for Determination of Dichloromethane and 1,1,1-Trichloroethane in Paints and Coatings by Direct Injection into a Gas Chromatograph (D4457) for exempt solvent analysis for VOC calculation purposes. ASTM Committee E19 on Chromatography is focused on chromatographic techniques. There are numerous ASTM GC test methods for the determination of the purity of specific solvents and for the determination of specific impurities such as benzene.

GC—Mass Spectrometry

GC has been well established as an excellent tool for the separation of volatile species in complex mixtures. A significant limitation of GC, however, is the relative inefficiency and lack of certainty in this technique when the identification of unknown components is required. Mass spectrometry is an excellent tool for qualitative analysis. However, if a complex mixture is introduced into the instrument, the resulting mass spectra of all components are superimposed on one another, making analysis difficult, if not impossible. These limitations are overcome by a combination of GC and mass spectrometry. Sample constituents are separated into pure components using the gas chromatograph; these pure components are then introduced into the ion source of the mass spectrometer for identification. Generally, samples are liquids; however, gases and solids can also be examined.

As the sample components enter the mass spectrometer, they are immediately ionized. Electrons are removed from the sample molecules resulting in the formation of positively charged ions. This is normally accomplished through electron impact or chemical ionization. Each of these ionization techniques has unique properties for providing useful analytical information.

Electron impact ionization occurs when electrons emitted from a hot filament collide with sample molecules causing the loss of one or more electrons. This results in the formation of positive ions that contain excess energy. The excess energy causes many of the resulting ions to break apart or fragment, thus providing the fragmentation patterns used to determine chemical structure.

In chemical ionization, the mass spectrometer's ionization source is pressurized with a reagent gas such as methane, ammonia, or butane. Electrons from the filament collide with, and impart energy to, the reagent gas. The energetic reagent gas molecules subsequently collide with the sample molecules causing the sample molecules to become positively charged. Ions formed in this manner do not contain as much excess energy as ions formed via electron impact ionization. Consequently, very little fragmentation occurs and intact ions containing molecular weight information are obtained.

Following ionization, the sample and fragment ions are sorted according to their respective masses. An appropriate detector measures ion intensities at each mass, and the corresponding signals are transmitted to a computer for further processing and data storage. Results can then be displayed in graphical or tabular form. Interpretation of the spectra and comparison with a library containing thousands of reference compounds allows sample composition to be determined by the analyst.

Typical problems examined using GC-MS include: the qualitative identification of volatile organic species and contaminants in coatings and coatings raw materials, quantitative analysis of volatiles at the parts-per-million and parts-per-billion level, evaluation of potential odor causing species, and determination of polymer composition following pyrolysis and chemical degradation. Other uses include: characterization of complex solvent systems; monitoring of waste streams and ground waters; characterization of polymer products, by-products, and intermediates; identification of odor problems; and monitoring of raw materials for potential contamination.

TRACE ANALYSIS

With the development of sophisticated instrumentation over the past two decades, the ability to increase sensitivity in lower detection limits for many materials has increased. This is particularly true in the areas of metals analysis. As a result, many regulatory and compliance agencies have changed their detection limits to reflect this increased capability. For EPA (Environmental Protection Agency), OSHA (Occupational Safety and Health Administration), and FDA, and FDA (Food and Drug Administration) compliance, trace analysis is extremely important. Many manufacturers require trace analysis to identify contamination, to verify product purity, and so forth. Analysts must be prepared to provide data in the parts per billion (ppb) and sub ppb range when necessary, and this frequently involves good concentration techniques as well as good methodology and instrumentation.

Certainly techniques such as GC, MS, and HPLC are capable of measuring components in solution well below the ppm range. The specificity of MS and its sensitivity for organic compounds has made it a common tool used in EPA protocols for pollutant-related analysis. Coupled techniques such as GC-MS, LS-MS, and ICAP-MS are also available today and can provide very low-level analysis. Commonly

used trace element procedures such as AA, ICAP, ion selective electrode analysis, neutron activation analysis, and optical emission spectroscopy all offer low-level analysis. ICP-MS detection capabilities are comparable to those of graphite furnace atomic absorption spectrometry. For many elements ICP-MS provides quantitative analyses down to the parts per trillion level.

In addition, for inorganic compounds, scanning electron, microprobe, and transmission electron microscopy are useful for trace analysis. Surface techniques such as X-ray photoelectron, Auger, and SIMS are also useful as qualitative and quantitative measurement techniques.

At the very small concentrations that characterize trace and ultratrace analysis, and with the minute samples employed in microanalysis, the limit of detection, a new criterion of performance, becomes important. Because noise itself now becomes limiting, many questions arise. For example, how large must the reading from a sample be compared with that from a blank for a person to report that analyte is present?

At the detection limit, statistics and chemistry become intimately mixed and statistical procedures must be used to interpret chemical results. The detection limit is simply the smallest concentration of analyte that can be certified as statistically different from a blank. To determine the limit, two sets of measurements are necessary. In addition to a regular set, many measurements (10 to 20 are recommended) must be made on a blank under the same conditions. It must simulate regular samples but be without analyte.

To calculate the limit of detection, one begins by observing the limiting response. For a given measurement procedure, it is the smallest response that can indicate with reasonable probability that a particular analyte is present. To obtain the limit of detection from the limiting response requires a calibration curve or a standard addition curve. A usable curve will be one based on quite pure standard solutions of extremely low concentration. The alternative, a long extrapolation of a calibration curve beyond the lowest points for standards even in those favorable cases in which the curve is linear, will invite substantial error.

Actually, as quantitative measurements at the trace level have become more important than simple detection, a limit of quantification or *limit of determination* is recommended by IUPAC for comparison of the relative merits of different trace methods rather than the limit of detection.

The future of analysis will become more sophisticated with the development of more sensitive instrumentation and computer technology. Robotics and autosampling will also enhance the development of analysis and reduce the amount of error that is introduced in analysis. These changes tend to impose more sophisticated demands in analysis from customers and regulatory agencies. There is a tremendous burden on the analyst to be conscious of extraordinarily good laboratory techniques, the limitations of the instrumentation, and the reporting of sound data.

FORENSIC PAINT ANALYSIS

Forensic science is the application of the natural sciences, such as chemistry, biology, physics, and biochemistry to criminal and civil laws that are enforced in the criminal justice system. The field of forensics is very broad, encompassing medicine, pathology, dentistry, and even paint.

Coatings are routinely analyzed in local crime laboratories along with hair, fiber, blood, and other evidentiary materials. Paint is often transferred from the surface of one object to another when a crime is committed. Tools that are used for breaking and entering, such as screwdrivers or crowbars, often have tiny particles or smears of paint that have transferred from the point of entry to the tool. A tool can also be the source of paint that is transferred to a victim. Devices containing explosive charges, vehicles used to transport explosives, and objects removed from the scene of an explosion often contain paint. Fragments of wood at a crime scene can also be coated, and the coating can prove to be a valued piece of evidence.

Each year literally thousands of vehicular hit-and-run cases occur, resulting in personal injury and death. Consequently, automotive coatings are frequently and routinely analyzed in most crime labs around the world. The analysis is often very difficult for forensic examiners because the sample size available to the analyst—the paint chip—is extremely small, often less than 1 mm. Many times only a paint smear is transferred to the clothing of a hit-and-run victim. Forensic paint examiners might be called upon to identify the make, model, and color of the automobile involved and/or compare the available paint evidence to another sample to establish a common origin or match to a suspect vehicle.

For the forensic examiner, the analytical examination of paint is quite different than it is for the paint chemist in a manufacturing facility. The forensic paint examiner is often presented with very small paint chips or fragments, or even smears of paint. They are dealing with a dried paint film and consequently have no knowledge of whether the source of the paint was from solvent or waterborne coatings or a powder coating. The job of the forensic examiner is to try to determine from the paint chip an identification of the polymeric resin system or binder, the pigment composition, both organic and inorganic, and the additives if possible. Identification of additives is particularly difficult in most instances because the level of additive used in paint manufacture is very low and is usually on the order of 5 % or less. There are some additives, however, that are very unique in chemical composition and can often be an aid to identify similar paint systems. A concise monograph on coatings additives is recommended as a useful guide for paint analysts [13].

Paint chips or smears may be examined for comparison and/or identification purposes. Comparative analysis subjects two or more samples from different sources to the same rigorous analytical testing to determine if there is a common origin. For example, how does the paint smear that is transferred to a victim's clothing in a hit-and-run compare to paint obtained from a suspect vehicle? By contrast, the purpose of the identification process is to identify the chemical composition of the paint particles with as much certainty as current analytical methods and instrumentation will allow.

The analysis of paint chips by the crime laboratory usually includes microscopy; infrared spectroscopy (FTIR);

some type of elemental analysis, such as energy dispersive X-ray analysis (EDX); and quite often pyrolysis gas chromatography-mass spectrometry (PGC-MS). For the forensic paint examiner, other than visual examination, a microscopic analysis is the first approach to identifying the sample.

Optical and stereo microscopic techniques are extremely important in paint examination because they determine the number of paint layers, the thickness and color sequences of the layers, and pigment features such as texture, particle size, shape, and distribution. IR is also widely used to identify the polymeric resin (binder) and, depending on the instrumentation, provide a great deal of information regarding pigment identification. The greater the analytical capability of the laboratory, the more data is available to determine with a great deal of certainty whether the paint recovered from a crime scene is different from (or similar to) that of suspect samples.

Analyzing automotive paint chips is, in some ways, easier than analyzing other types of paint (such as architectural) that are found at crime scenes because of the multilayer nature of automotive coatings. For automotive systems, it is fairly typical for automotive original equipment manufacturers (OEMs) to use four distinct paint layers particularly for the steel body frame. There is an electrocoat layer, a primer layer, a colored basecoat layer, and a final clear topcoat. Each of these layers is distinct in terms of resin and pigment composition. This layering, along with the thickness and subsequent identification of each layer and the components in each layer, can become very useful in determining a possible make, model, and color of a suspect vehicle or in determining a match to a suspect vehicle. Analysis is conducted on all the layers: clearcoat, colorcoats, primer-surfacer, and electrocoat.

Sometimes unique colors and/or pigments in the primer-surfacer and colored basecoat layers can provide the analyst with distinct and discriminatory information. Color becomes important for the forensic paint examiner if a known and questioned sample is present. There are hundreds of different colors and shades used in the paint industry and a spectrophotometric analysis can often shed a great deal of information about the samples. Microspectrophotometers provide an objective color measurement as opposed to subjective visual comparisons. Spectrophotometers measure the light that is transmitted, reflected, or absorbed by a sample in the visible and ultraviolet ranges.

Consumer demand has driven the pigment industry to develop many unusual and special effect pigments. This is particularly noticeable in the automotive industry. There are the conventional or absorption pigments where light is absorbed and scattered. A completely different optical behavior can be observed with the group of effect pigments including pearl luster and metal effect pigments. Metal effect pigments consist of small metal platelets (for example aluminum, titanium, copper) which operate like little mirrors and almost completely reflect the incident light. The dominant class of pearlescent pigments is based on platelets of natural mica coated with thin films of transparent metal oxides [14].

Interference and angle-dependent color effects can also be achieved by layers or particles based on liquid crystal polymers. Another new technology involves the use of holographic pigments that are prepared from grinding of holographic films to small particles. All of these new technologies place an added level of difficulty on the analyst but they also provide some discriminating characteristics for pigment and layer analysis. This can be a significant advantage for the forensic paint examiner. It is also wise for the paint examiner to study the pigment paint literature for developments in this area.

Pyrolysis gas chromatograph and PGC-MS analysis can be a valuable tool for comparing many paint formulations. Very small paint chips can be used (on the order of a few micrograms). As the chip is heated the polymeric decomposition products are recorded. This pattern of decomposition product (or pyrogram) can often be used to compare paint samples and distinguish one from another. Pyrolysis techniques have been quite successful for acrylics in particular.

As technology has shifted toward lower-molecular-weight materials, waterborne and powder-coating systems, there have been an increasing number of additives used in formulating. Newer pigment technology, particularly in automotive coatings, also places an increasing burden on analysts.

Forensic paint analysts are faced with grave responsibilities in analysis and interpretation of data. Scientists must be extremely well trained and capable in the area of analytical techniques and also must be qualified paint examiners, possessing a fair amount of knowledge regarding paint composition and the raw materials used within the industry. It is a serious responsibility because the analytical results used in a courtroom may significantly affect the outcome of a trial and a person's life.

The most ideal situation occurs when there is a physical match between a paint chip recovered from a crime scene and a suspect vehicle. The majority of paint analysis will not be sufficiently different or unique such that the sample can be matched to a single source.

For more information regarding the forensic analysis of paint, one should refer to the following: ASTM Practice for Receiving, Documenting, Storing and Retrieving Evidence in a Forensic Laboratory (E1492) and ASTM Guide for Forensic Paint Analysis and Comparison (E1610).

The Analysis of Coatings Failures

George D. Mills[1]

THE TESTING OF COATINGS ALWAYS HAS A RELA-lationship to coating failures, either directly or indirectly. Testing before failure helps to ascertain serviceability, establish the best formulation variables, maintain quality assurance of coating products during manufacture, develop storage and application parameters, ensure specification viability, and, in essence, prevent early failure. Testing after failure assists in determining cause, hopefully prevents future coating failures of a similar nature, and aids in placing liability.

Failure modes run the full gamut. Coating failure can originate from within, as with deficiencies in a coating's formulation or its manufacturer. Anomalies in the coating's film-forming chemistry from competing atmospheric side reactions are very common with some urethanes and epoxies. Failures can originate external to the coating material from improper specification, inappropriate or inadequate surface preparation, and application deficiencies. When a failure occurs and is investigated, the coatings practitioner must maintain an open mind. Often there are multiple causes impacting the failure.

The analysis of coating failures should follow a systematic program based on the "scientific method." Briefly this translates to (1) investigate, (2) hypothesize, (3) test, and (4) conclude or reconsider. Test programs after failure are often a part of the failure analysis process and have the purpose of establishing viability of a proposed failure mechanism. Designing the test and evaluation program requires knowledge of the total process from specification to paint manufacturing to paint application. In part, it requires knowledge of the laws of physics and chemistry that are controlling what is happening at interfaces. The coating system contains many types of interfaces including the substrate/coating interface, emulsion resin particle/carrier surfaces, inter-coat interfaces, and the interfaces between the pigments and binder in the coating formulation. The chemistry and physics of solutions controls apparent viscosity and can impact osmotic failure modes. Polymer curing and weathering reactions, corrosion, and dimensional stability after cure are just a few of the other sources of coating failures often reported. As a preliminary to designing test programs to determine failure modes, the investigator must appreciate not only the processes of surface preparations, cleaning, and pretreatments, but coating application techniques as well. He must be knowledgeable about the different types of coatings and their typical degradation and stabilization mechanisms.

Coating failures may manifest themselves as a change in physical or chemical properties. Changes in gloss, color, extensibility, chemical resistance, and vapor/gas transmission coefficients are common problems. Failures associated with delamination of a coating from its substrate are usually classed as "adhesion" failures, although they are often a delamination through a weak boundary layer (WBL) near the interface. Osmotic activity from solvents or coating constituents within the film or salts beneath the film is a common failure mode in some environments. Under film corrosion is often considered as a coating failure and may result in substrate damage.

Coating failure analysis is extremely important for various reasons. One of the most important is simply to "ensure" that the failure does not happen again. While this sounds noble, the experience of most investigators is to the contrary, for one sees the same problems occur repeatedly. Paints and coatings are very sophisticated chemical systems. Since all of the natural forces impacting the chemistry and physics of the system are operative, the total picture is seldom known. Most often, a very naive conception of the situation is developed and action is taken for one particular reason while failing to consider a multitude of other less familiar causations.

Truly successful investigations of coating failures necessitate knowledge of the coating system's chemistry and the many applicable evaluation and test procedures available. To appreciate which test regime would be appropriate for a specific failure situation, the investigator must understand much about the coating itself. This includes knowledge of the components formulated into the coating, its curing chemistry, the chemistry and physics of interfaces associated with the coating, and any interfering and competing atmospheric side reactions. These side reactions include the impact of ambient application temperature and relative humidity as they impact curing, inter-coat adhesion, and the total coating matrix as applied. One must consider application equipment and procedures, with a host of related potential problems. This might include considerations such as off-ratio mixing (including "zone curing" from insufficient mixing), use of thinners that are non-solvents or that may be contaminated with water from storage outside. There is the possibility that paint formulation and manufacturing problems are potential typical sources of coating failure problems.

Designing the proper test regime before a coating failure occurs is very important. It is difficult, if not impossible, to assess all of the variables that will be seen in the field after the coating is applied. Reconstruction of a failure situation is even more difficult, and it is usually impossible to match the original application situation totally.

[1] *President, George Mills and Associates International, Inc. 322 Manchester La., Foley, Alabama 36535.*

Copyright © 2012 by ASTM International

This is particularly true in off-ratio mixing problems or the problem of "zone curing". Zone curing occurs when the two-part coating is not mixed totally. For epoxy systems cured through amino functional curatives, over stirring of the curative where air is allowed to be drawn into the coating material, carbon dioxide (an acid gas) in the air is reacted with the curative. This effectively blocks the curative and does not allow reaction with the epoxy. The final "hardened" epoxy will display various degrees of cure even when the prescribed "mixing ratio" was followed. Advanced instrumental techniques using cryotrapping of pyrolyzed polymer fragments followed by gas chromatography using a mass spectrometer as a detector have proven extremely helpful [1].

The design of a test program to demonstrate feasibility of a particular failure mode is best accomplished by considering five basic questions. These questions guide the investigator through the logic that assists one in understanding the potential failure modes. The basic questions are as follows:

1. What is the actual coating failure?
2. What is the coating system?
3. What was the desired property of the coating that failed?
4. How was the coating applied?
5. What evidence is presented by the samples of failed coating?

There are many chemical instrumental techniques of analysis available to the investigator. The data from some of these laboratory instruments allows one to know the actual coating failure. The task sounds so simple, but it is remarkable that past experience has shown that many of the failure, are not as first thought as will be pointed out in the ensuing material. To aid the reader, a few of the instrumental analysis techniques and their common abbreviations along, with selected web addresses, are given below.

WHAT IS THE ACTUAL COATING FAILURE?

A coating failure exists when a coating fails to accomplish all of its intended tasks during its engineered design life (EDL). Usually, a failure in a particular primary property prompts the investigation and leads to the declaration that a coating failure exists. The first step in analyzing a failure is to clearly define the problem. While this appears at first glance to be an easy and straightforward task, it is not. A typical example is the mistake of identifying a delaminated coating automatically as lost adhesion. Loss of adhesion, by definition, is a delamination between two dissimilar surfaces, as with a primer and substrate or two coats of paint. In contrast, a cohesion failure is delamination through one material in the coating system. This results in splitting a layer leaving two surfaces that are the same material. One must appreciate that a splitting layer may be only a few molecules thick and appears to be a true adhesive failure.

There can be numerous reasons for a coating to break away from its substrate. While adhesive loss is possible, cohesive delamination within a WBL is very common. A good example is a coating applied over improperly prepared zinc galvanizing where cohesive failure occurs in the zinc oxide-zinc carbonate layer and is automatically written off as a saponification problem, even though the coating may not be susceptible to (or capable of) saponification. Another very common cohesive failure is the apparent delamination of an amine-cured epoxy applied over an amine carbonate that has formed on (or exuded from) an earlier applied epoxy coating. This cannot usually be seen with the unaided eye. Splitting within a "transparent" layer

near the interface will appear as if the problem is adhesive rather than cohesive failure. Interrogation of the coating interfaces by the proper instrumental technique is the only way to determine the locus of failure in delamination failures.

Many tests associated with coatings may be brought to bear in providing answers. While most of these tests are established ASTM procedures, some are related to task-specific, chemical analysis. These include auger spectroscopy, X-ray photoelectron spectroscopy (XPS), and other surface analysis techniques that are limited to "seeing" only the outer few angstroms of the surface. Ion bombardment, which ablates the surface, allows "seeing" an elemental analysis as a function of depth into the outer layer. Techniques such as energy dispersive X-ray (EDX) will evaluate the surface but are much more energetic, thus giving an average elemental analysis much deeper into the sample being evaluated [2].

Osmotic blister formation is another area often misunderstood. The analysis of osmotic paint failures is addressed in depth within this book. Osmosis requires one solvent (by definition, the specie present in the greatest concentration) and one or more solutes. Analysis of the blister fluid is required to determine the source of the driving force. While water is often the source of solvent with inorganic salts or dissolvable organic solutes, other organic solvents are seen in some industrial tank-lining problems. Analysis of the blister fluid is best accomplished by gas chromatography/mass spectrometer (GC/MS) for organic solutes [1] and ion chromatography or EDX (after evaporation) for inorganic solutes [2]. To the contrary, "blister-like" formations in inorganic zinc-rich or flame-sprayed metallic coatings may look like osmotic blisters, but they are usually caused by the production of powdered corrosion products (typically oxides and/or carbonates) under or within the film [3]. It is safe to say that the problem cannot be solved and proper liability placed until the true coating failure problem has been identified.

WHAT IS THE COATING SYSTEM?

Failures are often related to the generic type of coating under investigation. As such, the failed coating should be identified as a preliminary step in understanding the potential failure modes that exist leading to the failure. Alkyds have failure modes different from acrylic latex systems. Epoxies will often fail differently from urethanes. Alkyds over vinyl primers are susceptible to differential water vapor transmission problems causing alkyd delamination from the vinyl in damp climates. Moisture-cured systems such as urethanes, epoxies, and ethyl silicate zinc-rich systems when applied in very dry atmospheres cannot cure properly. Urethanes and some latex systems present problems in wet atmospheres.

Although a coating is any material applied to another surface, each coatings practitioner will have a view of coating systems shaped by his/her experiences. While most coatings are paint-like in nature, many have strikingly different appearances and characteristics with correspondingly different failure modes and different required test regimes. The coatings manager at an automobile factory might work with inorganic metal pretreatments, electrodeposited primers, and robotically applied color coats with wet-on-wet ultraviolet (UV)-resistant clear topcoats followed by water-repellant surface modifications. The pipe corrosion specialists will encounter conventional liquid paints, fused powders, flame/arc-sprayed metallic powders such as zinc, aluminum, or high alloys, and/or plastic tapes wrapped around the pipe with or without primers for external protection. Internal pipe coatings may be the conventional liquid and powdered coatings as well as thin cement linings like those found in many potable water supply lines or fused polyethylene mixtures. Because of this great diversity, the coatings analyst will address coating failures of many generic types of films including organic, inorganic, and metallic.

Paints form the largest subgroup of coatings and, as such, will be the focus of this section. Analyzing coating systems before and after failure requires many different testing procedures. Many of these standardized procedures can be found in Volume 6.01 through 6.04 of the *Annual Book of ASTM Standards* [4]. To be efficient, the investigator must have knowledge of the paint formulations of many generic types. Knowledge of the polymer's typical failure mechanisms, individual polymer chemistries with their respective degradation mechanisms, and typical stabilization methods are also very helpful [5]. An efficient investigation requires an appreciation of the tools and instrumentation that can be brought to bear and is tremendously important in determining the testing regime best suited to a particular type of failure problem. This includes knowledge of the capabilities and, equally important, limitations of the analytical instruments being used. One must be able to interpret and challenge test data when necessary. It is this necessity that requires knowledge of the chemistry and physics operative for the system under investigation.

Typically, paint may be considered as being composed of four "subsystems," any one (or combination of them) may produce a coating failure. These are (1) the resin or binder system, (2) the pigment system, (3) the solvent or carrier system if a liquid, and (4) the additives package.

The resin or binder system holds the pigments together and provides physical characteristics such as electrical resistance, flexibility, water and gas permeability resistance, adhesion, etc. The pigment system serves to provide coating strength, vapor transmission resistance, anticorrosive properties at a metal interface, abrasion resistance, color and restricted light transmission as well as other film property enhancements. For less than 100 % solids systems, the carrier system is usually a solvent or dispersing media. For 100 % solids liquid coatings, the dispersing media may be air or the pressure from an airless application system. For powder coatings, super dry air is the delivery system, transporting the fluidized powder through the delivery lines.

The additive package is meant to produce specific effects to the coating system when included in low concentrations. Additives may address potential problems with the pre-applied paint "in the can" or address potential film problems after application. Coating failures may originate from problems associated with quality control of the paint's manufacture as well as problems associated with long-term storage or application. Each type of coating will have some characteristic failure modes, although certain modes will be common to all.

Failure Modes Associated with a Generic Type of Coating

Failure modes tend to follow generic types of coatings. In a very broad sense, coatings may be grouped into three categories based on the final film. These are coatings with organic binders, those with inorganic binders, and those composed of metallic films. The largest category of coatings is those utilizing an organic binder. Organic binders use polymers based on carbon as the primary atomic makeup of their backbone. The paint film at application includes polymer precursors using functional groups such as epoxies, urethanes, vinyls, acrylics, and alkyds. These must polymerize to reach some high molecular weight at which they are capable of forming protective films. Generally, inorganic coatings are those that utilize elements other than carbon for forming a film. These may be silicates, sulfates, or cementations coatings based on calcium. As a coating, each will have some typical failure modes. Metallics may be very thin films used on plastics for affecting gas molecule transmission, esthetics, and abrasion resistance characteristics. They may be thick as with galvanizing or flame/arc-sprayed metallics used for corrosion protection or thin as the aluminum coatings on a potato chip bag.

ORGANIC RESIN BINDERS: POLYMERS BASED ON CARBON

Paints and coatings using organic binders are by far the largest category and will provide the greatest challenge to the failure analysis investigator. These will include binders derived from vegetable oils, petroleum, and cellulose. They can be separated further into groups based on their curing functionality or their polymer origination such as epoxies, urethanes, alkyds, acrylics, chlorinated rubber, or vinyls. They may also be classed by their dispersion system such as solvent, emulsion, powder, waterborne, or 100 % solids.

Organic resin binders will utilize some mechanism for producing the protective film. This film forming/curing mechanism is a potential source of failures. A failure may manifest itself as a film with poor flexibility, poor weather ability, poor chemical resistance, adhesion deficiency, or a host of other shortcomings.

The formation of a paint film may come about by various mechanisms, each having distinctive failure modes. Some typical examples include (1) lacquers, (2) oxidative binders requiring oxygen from the atmosphere, (3) moisture-cured binders requiring water molecules from the atmosphere, (4) chemically reactive cross-linking binders, (5) heat-activated binders, and (6) non-thermal, high-energy cured binders such as UV initiated curing and electron beam.

Lacquers are coatings containing polymers dissolved in a suitable solvent system that evaporates to yield a film. While these coatings are called "lacquers" in the United States, in Europe and other parts of the world, the word "lacquer" is often used interchangeably with the word "paint." Film testing may address sanding characteristics, abrasion resistance, drying times, gas or water vapor permeability, gloss, and color retention, among other film properties. With essentially no chemical cross-linking occurring after application, the solids deposited on each coat will be determined by the percent of dissolved solids. Unfortunately, the viscosity increases as the dissolved solids increases. As such, the maximum lacquer viscosity that allows application will dictate solids content. Since this is related to the polymer's average molecular weight, which must be high for toughness and strength, films of low dry film thickness (DFT) are often seen, and the applied solids will be low. Lacquer film properties are strongly impacted by the solvent system, humidity and other ambient conditions, the application methodology used, and many other factors. Investigation of these type failures, as with most, requires inquiries as to application conditions.

Common failure modes encountered are often associated with thin films and the water susceptibility of the "tailing solvents" used in the formulation, occluded water caused by the use of fast evaporating active solvents producing fogging and cloudiness at application, and others. In acid-modified solution-vinyl systems, reaction with basic pigments will cause viscosity increases and possibly gelation in the can during storage. Other problem areas leading to failures include the "strength" of the solvent system, temperature of the coating solution at application, interaction of solute binder polymer with certain pigment particles, and interaction of some pigment particles with other pigment particles.

Typical failure modes for lacquers include production of cloudiness during application (blushing), use of improper (non-solvent) thinner, "fisheyes" (a surface tension problem), lifting of solvent-sensitive undercoats, and delamination from overcoating sanding sealers containing excessive sterates, among others. Coating softness is often related to the inclusion of non-solvents entrapped in the film if their evaporation or migration rate is less than the true solvents for the coating system. To address this problem, the coating formulation will often have a small "tailing" of slow-evaporating true solvent to allow the escape of these non-solvent diluents.

Because of the large amounts of solvents required and the typically low solids content, this type of coating system is not considered to be environmentally friendly. As such, lacquers are not as popular as they were in the past. Most states have enacted laws that control the maximum value of the volatile organic content (VOC) of the paints, and this has greatly limited their use.

Oxidative binders are polymers that usually require the pressure of atmospheric oxygen to cross-link sufficiently to form a strong film. Paints based on unsaturated vegetable oils such as linseed, soya, tung, tall oil, and others as well as modified vegetable oils, such as alkyds, fall into this category. These coatings require metal catalysts called "dryers" to be included in the formulation. The most common metallic dryers are lead, cobalt, manganese, iron, barium, calcium, zirconium, zinc, cerium, and vanadium. To allow solubility in the paint binder these metals, typically, are added as the octoate. An excess of cobalt dryer in a batch of alkyd paint may result in a surface wrinkling upon curing such as seen in Figs. 1 and 2. These dryers assist in the curing mechanism by increasing the coating's ability to react with atmospheric oxygen. A common failure mode for some alkyd coatings containing organic pigment would be a slow or nondrying paint after application. This occurs when dryers are either left out at manufacture or prematurely bound to a formulated pigment in the coating during can storage. In-can aging will allow adsorption onto the organic pigment particles, causing a loss of activity before application. Some carbon blacks are particularly susceptible to binding

Fig. 1—Alkyds that contain an excess of the cobalt metallic dryer may develop "wrinkles" on its surface.

some dryers. This leads to slow or retarded drying of some black paints that have aged. The in-can age is often available from the coded paint's batch number stamped on each can. The paint manufacturer, usually, will explain how to read the code.

Increased viscosity within the can is often caused by reaction with the oxygen contained in the air space above the coating. Frequently, with highly reactive oxidative binders, a small amount of inert gas may be placed in the head space of the can prior to shipping. Skinning and gelling are problems frequently encountered with this type of curing system. Retardation is controlled by the use of additives such as volatile ketimines. These volatile inhibitors interfere with the cross-linking mechanism, thus extending the life of the coating material after the can has been opened. Often, upon reopening a can of an oxidative type of coating, one will notice that a vacuum has developed. This is due to the reaction with (and consumption of) the oxygen that was in the air in the head space of the can.

Moisture-cured binders constitute a class of organic polymeric materials that require water vapor from the air to cause polymerization. Curing problems can arise with these when the application is done in closed areas with dehumidification (DH) equipment. While the most common of these are the moisture-cured urethanes, epoxies cross-linked by ketimines form another important class of moisture-cured epoxy coatings. Inorganic silanol binders, found in many zinc-rich systems, must have water to complete the hydrolyzation required in forming the cured inorganic silicate binder. Typical failure modes include application of the coating in conditions providing insufficient moisture to complete the cure. Application to surfaces that are damp or excessively wet can create bubble formation in urethanes. Overcoating inorganic zincs before complete hydrolyzation interferes with curing by stopping the reaction with moisture. This produces a zinc-rich primer layer with low tensile strength. Such films will often fail by cohesive failure (splitting) within the inorganic layer, especially after application of an epoxy that shrinks slightly on curing.

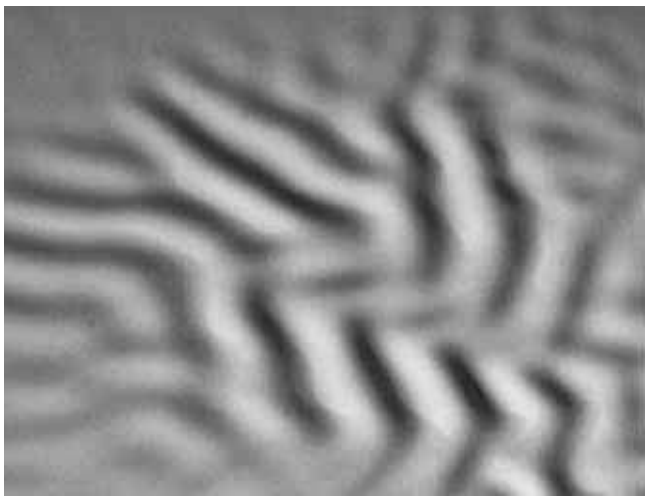

Fig. 2— The microscopic view of an alkyd having an excess of cobalt dryer additive seen in Fig 1.

Failures associated with thinners that contain water as a contaminant present a different kind of problem. For urethane coatings, inclusion of excessive water in the coating matrix will generate gas bubbles of carbon dioxide caused by reaction with the isocyanate groups. In a worst case, the applied coating will be rough with bubbles through the film. In slight contamination cases, this will be evidenced by viewing a chip of the coating from the side through a microscope. Small bubbles will be seen through the coating thickness. When the bubbles are mostly located at or near the interface, there is probable cause to suspect application over a damp surface. Water picked up on the pigmented side of a two-part urethane during the pigment-grinding process during manufacture is a common problem. A Karl Fischer water analysis of the polyol side may reveal the source of the problem.

Water contamination introduced into an ethyl silicate binder can cause premature gelation and shortening of the pot life. Water reaction of zinc and aluminum-metal-containing coatings still in the can often produces gas of sufficient pressure to explode the container.

Chemically reactive cross-linking binders include all two-part systems. This includes epoxies and urethanes that have appreciable reaction rates at room temperature as well as single-package, cross-linking systems that require heating or some other energy source to increase the reaction rate significantly and allow a cure to be attained. Some systems will contain all the reactive polymeric binder precursors

Fig. 3—Large natural gas tanks that were painted during cold weather.

that cross-link with each other to produce the final film. Some systems may generate the required energetic cross-linking specie by a reaction brought about by an outside energy source such as UV radiation, electro-deposition, or high-energy electron beams.

Ambient-cure, two-component, or catalyzed binders such as epoxies and urethanes require a proper mixing ratio to allow the finished film to have its desired properties. Improper ratio mixing can lead to a host of final film problems. These problems include inadequate curing, brittleness, loss of extensibility, loss of chemical resistance, early extensive chalking, and many more. Off-ratio coating systems may be investigated using GC/MS pyrolysis [1].

Epoxies are often cured by amine functional polyamides, amine adducts, or aliphatic amines. Polyamides, being manufactured from long-chain fatty acids, are very aliphatic in nature and, typically, not particularly soluble in the "more aromatic" epoxy side. Because of this poor solubility, it is often necessary to allow extra time after mixing for the reaction products to gain solubility characteristics more closely related to each other. This extra time is called the "induction period" or "sweat-in time" and allows time for the two resins to partially co-react. The partially reacted resin solution eventually changes the solubility characteristics of the binder system sufficiently to completely solubilize all resin components. A failure to reach complete solubility will lead to "zone curing" with macro islands of un-reacted polyamide and potentially un-reacted epoxy resin. Additional failure modes include osmotic blister formation (where the low molecular weight amine is the solute, with condensed water being the solvent), increased amine carbonate formation and exudation to create intercoat delamination problems, film brittleness, poor weatherability, and others.

Application of epoxies cured with amine and polyamide systems in cold weather can present future delamination problems. In cold weather, when the epoxyamine curing reaction slows down, the amine reaction with carbon dioxide and water vapor from air does not slow very much. The formation of an amine carbonate "bloom" develops on the coating surface. See Figs. 3–5.

Additional amine carbonate within the coating matrix formed during spray application exudes to the surface over time. This leaves a weak boundary layer on the surface. When overcoated, the insoluble "greasy" amine carbonate

Fig. 4—Tank after one year showing mildew on areas of constant moisture condensation.

Fig. 5—The urethane top coat over the epoxy primer is peeling as the result of applying coating over the thin layer of amine carbonate formed (and exuded) after primer application.

will not allow adhesion of the next coat and usually results in delamination in less than a year. The interface will be moisture sensitive and potentially provide the solute for osmotic blister formation. The author has found a simple test to evaluate for the presence of the amine carbonates. This is done by applying a drop of 6 *M* hydrochloric acid to a suspected surface while watching the edge of the drop under a microscope. The HCl will liberate the carbon dioxide at the edge of the "wetting front" as the droplet wets the surfaces. The bubbles of gas can be seen in the edge of the drop of liquid. The experiment should be conducted under a microscope since the reaction is rather fast and because often only a small amount of gas is liberated. The gas may present itself as a tiny bubble within the drop of acid solution. To test the amine side of the curing agent for preexisting carbonate salts, add about 1 ml of the resin component to a test tube. Tilt the test tube at about 45°, add a drop of the 6 *N* HCl, allowing it to run down the inside of the tilted tube, and note the production of any bubble formation of carbon dioxide at the acid solution/resin interface. The amount of foam produced is a quantitative indication of the amount of carbonates existing. Grinding pigment into the amine side, in open tanks, often introduces the carbonate and causes variability in the degree of cure of the catalyzed coating.

Heat-activated binders have a cross-linking reaction rate that is too slow at room temperature to allow complete cure. These systems require heating to provide a forced cure. This is true for liquid systems as well as for most thermoset powder coating systems such as fusion bonded epoxy (FBE) coatings. Typical failure modes include abnormal brittleness, discoloration, lack of design physical properties, lower chemical resistance, and other problems. Causes may stem from formulation problems such as batch-to-batch variation in catalyst level or incorporation, as well as problems associated with variable temperatures within the pass-through ovens or heating equipment. Low temperatures caused by variations in metal heat capacity due to variations in metal mass of a coated part are seen often in powder coating systems as producing curing anomalies. Since the cured coatings will typically have elevated glass transition temperatures, T_g, the differential scanning calorimeter (DSC) is the instrument of choice in determining quality of cure [6].

Non-thermal, high-energy-cured binders require an energy source other than heat. These coating systems are typically employed on fast-moving, automated industrial lines. The coatings include both ultraviolet radiation curing systems as well as electron and other high-energy beam curing. Because the energy source must be "felt" through the polymer layer, UV-cured systems must be fairly transparent to the energy source and preferably have little or no pigmentation. However, UV-curable colored inks and coatings are commercially available. This usually necessitates that the films be of low DFT.

INORGANIC BINDERS—THOSE BASED ON NON-CARBON POLYMERS

Inorganic coatings are those that do not rely on carbon as the primary atomic composition of the polymer. These include those systems that ultimately end up with an inorganic binder after application. The most common include zinc-rich systems using alkali silicates as the binder. Generally speaking, inorganic coatings are formed from the oxides of specific elements. The silicates are formed from the oxides of silicon. Cement coatings and linings for water pipes rely on the oxides of calcium or variations thereof. Some high-temperature coatings used in flue gas desulfurization stacks are based on calcium sulfate.

A different class of inorganic coatings is those that are chemically reacted onto a metal surface. These include the colored anodized coatings commonly seen on aluminum window and door frames, precipitated zinc and iron phosphate coatings used as anticorrosives on pretreated steel and acid phosphate treatments to zinc and galvanized surfaces, among others. Typical failure modes with these types of coatings will include under-film corrosion and spalling of the coating, especially with cement that has become carbonized from reaction with carbon dioxide and, therefore, lacks the higher pH required to disallow corrosion of embedded steel. Corrosion testing methods such as given in ASTM B117 "Practive for Operating Salt Spray (Fog) Apparatus" (see Table 1) are used often to determine coating quality.

Precipitation-type coatings are usually done from a water solution. Because of this, the surfaces must be able to be wet-out by the water solutions. A typical problem is "spottiness" caused by incomplete thermodynamic wetting of the substrate. This lack of wetting disallows water-based chemical reactions that must occur at the metal interface. The reason for a lack of wetting is usually from oil or other low-energy contaminants on the surface. Investigation of the pre-cleaning system is indicated in these cases. Surfactants are usually added to overcome this problem, but these may then cause an even worse problem if they are not totally removed. One must remember that surfactants are called "surfactants" because of their ability to displace, usually thermodynamically, most adsorbed species on the surface of the substrate. When overcoating a substrate that has been wet with surfactant, these surfactants must be displaced. This can often be difficult or impossible and often leads

TABLE 1—Frequently Used ASTM Standard Documents for Evaluating Paints For Specific Properties

Designation	Document Title
B117-09	Practice for Operating Salt Spray (Fog) Apparatus
D522-93a(2008)	Test Methods for Mandrel Bend Test of Attached Organic Coatings
D523-08	Test Method for Specular Gloss
D570-98(2010)	Test Method for Water Absorption of Plastics
D610-08	Practice for Evaluating Degree of Rusting on Painted Steel Surfaces
D660-93(2005)	Test Method for Evaluating Degree of Checking of Exterior Paints
D661-93(2005)	Test Method for Evaluating Degree of Cracking of Exterior Paints
D662-93(2005)	Test Method for Evaluating Degree of Erosion of Exterior Paints
D714-02(2009)	Test Method for Evaluating Degree of Blistering of Paints
D772-86(2005)	Test Method for Evaluating Degree of Flaking (Scaling) of Exterior Paints
D869-85(2011)	Test Method for Evaluating Degree of Settling of Paint
D968-05(2010)	Test Methods for Abrasion Resistance of Organic Coatings by Falling Abrasive
D1014-09	Practice for Conducting Exterior Exposure Tests of Paints and Coatings on Metal Substrates
D1186-93	Test Methods for Nondestructive Measurement of Dry Film Thickness of Nonmagnetic Coatings Applied to a Ferrous Base Withdrawn 2006-Replaced D7091
D1200-10	Test Method for Viscosity by Ford Viscosity Cup
D1210-05(2010)	Test Method for Fineness of Dispersion of Pigment-Vehicle Systems by Hegman-Type Gauge
D1400-94	Test Method for Nondestructive Measurement of Dry Film Thickness of Nonconductive Coatings Applied to a Nonferrous Metal Base
D1475-98(2008)	Test Method for Density of Liquid Coatings, Inks, and Related Products
D1653-03(2008)	Test Methods for Water Vapor Transmission of Organic Coating Films
D1654-08	Test Method for Evaluation of Painted or Coated Specimens Subjected to Corrosive Environments
D2196-10	Test Methods for Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield Type) Viscometer
D2243-95(2008)	Test Method for Freeze-Thaw Resistance of Water-Borne Coatings
D2244-09b	Practice for Calculation of Color Tolerances and Color Differences from Instrumentally Measured Color Coordinates
D2621-87(2005)	Test Method for Infrared Identification of Vehicle Solids from Solvent-Reducible Paints

D6577-06	Guide for Testing Industrial Protective Coatings
D7091-05	Standard Practice for Nondestructive Measurement of Dry Film Thickness of Nonmagnetic Coatings Applied to Ferrous Metals and Nonmagnetic Nonconductive Coatings Applied to Non-Ferrous Metals
G8-96(2010)	Test Method for Cathodic Disbonding of Pipeline Coatings
G14-04(2010)	Test Methods for Impact Resistance of Pipeline Coatings (Falling Weight Test)
G42-96(2003)	Test Method for Cathodic Disbonding of Pipeline Coatings Subjected to Elevated Temperatures
G95-07	Test Method for Cathodic Disbondment Test of Pipeline Coatings (Attached Cell Method)

to eventual delamination or water sensitivity. A short-term test frequently used is the Hot Water Boil Test. This is also called the "Crock Pot Test" since a standard kitchen electric crock pot has been found to work very well. Samples are cut from coated specimens that have been through the cleaning system. These are placed in the crock pot under deionized water for 24 h (or less, depending on type of coating), and the coating is evaluated against a standard of known cleanliness.

METALLIC COATINGS

Metallic coatings are very thin layers of pure metal, usually applied to a substrate for appearance, modification of wear characteristics, corrosion protection, or to disallow the transport of migrating gas molecules through plastic film. They are important because of their ability to modify physical properties of the substrate such as stopping the migration of oxygen, carbon dioxide, and other small molecules through plastics. An example most are familiar with is the shiny metalized coatings seen on food wrappers containing oxidizable vegetable oils. It is usually assumed that these shiny packages are for "aesthetics only," however, these thin metalized films serve to stop the migration of oxygen into the food package. With the trend to eat more unsaturated oils in our foods, the oxygen would react with the unsaturated bonds in the oils to produce a rancid taste. This is associated with the product being old and stale. The bad taste is due to the formation of aldehydes during the oxidation process. One might note that this chemical reaction is the same as the curing reaction of oil-based paints.

FAILURE MODES ASSOCIATED WITH THE PIGMENT SYSTEM, CARRIER SYSTEM, OR ADDITIVE PACKAGE

Some common failure modes associated with the pigment system include: heavy settling; flocculation; lack of wet-out during manufacture; insufficient grind or dispersion development; adsorption of additives such as driers, UV stabilizers, and surface-active agents during storage; and poor color stability with some pigments. Improper use of the anatase titanium dioxide can lead to chalking. Accelerated ageing tests of the formulated coating usually include storage at elevated temperatures with intermediate observations of settling and grind measurements.

The carrier system assists the binder system in forming a film and in developing adhesion during application. For liquid coatings that are sprayed, rolled, brushed, flow coated, or dipped, the viscosity must be within certain limits dictated by the application equipment, final film build desired, and ambient conditions. Additionally, there must ultimately be intimate contact between the binder polymer and the substrate. While this may appear to occur automatically and instantaneously, it does not. Development of adhesion between binder polymer and the substrate is a time-dependent function. Thermodynamic wetting is controlled by the energetics in existence between the actual surface encountered on the substrate by the coating system and the binder. We typically do not expect that the surface being painted to be coated with a material forming a WBL. Thermodynamic wetting is a necessary, though not sufficient, condition for adhesion. Unfortunately, since adhesion development is a dynamic process requiring time for the many "molecular realignments and adjustments" to occur as well as the displacement of molecular species lightly bound to the substrate, high-solids coatings with little or no solvent have a formidable job before them. Displacement of surfactant-type molecules at the interface will usually present a severe challenge and frequently present delayed adhesion failures.

There are always adsorbed species on the surface. Depending on the "sticking" strength of the adsorbed surface species, the binder may not make intimate (molecular) contact with the substrate as its viscosity is increasing to a gel. Adsorbed species include such molecules as vapor-phase water, oxygen, and other gases from the air, oily contaminants, and surfactants from cutting oils or coolants. In thermodynamics, this sticking is related to the heat of wetting. Failure to displace these compounds often results in eventual adhesion problems. One of the roles of the solvent is to assist in wetting out the substrate by displacing the adsorbed species followed by deposition by the binder. The coatings formulator will design the solvent system to assist the polymeric binder in displacing any interfering adsorbed species. But, since desorption/adsorption is a time-dependent process, extremely fast solvents and viscous, high-solids systems may not be able to respond in the time during which the polymer system cures and approaches a gel state. Increases in viscosity after application also present additional problems. There must be sufficient time for adhesion to develop between the binder polymer and the substrate. In some instances, changes to the polymer backbone have been done to produce a more negative heat of wetting [7]. The use of additional mechanical energy as from brushing is always helpful. It is for this reason that brush striping of welds in tanks and critical areas is often required prior to spray application of the first coat.

Solvents are the most common of the paint system carriers. Typical problems encountered might include use of the wrong solvent, allowing water to contaminate proper thinners that have been stored outside, transfer of solvents to oily or contaminated containers, etc. Water, which has been drawn into a solvent container due to temperature changes, is a common work-site occurrence.

Air suspension of powders is an example of a non-liquid carrier system. Powder coatings are usually applied electrostatically by fluidizing the powder with compressed air in a porous bottom chamber. The air-suspended particles are then drawn into an air stream via a venturi nozzle and transported to the point of application. Surfaces being powder coated may or may not be heated before application. With application to hot substrates, the powder melts and flows to produce a relatively thick coherent film. Depending on melt viscosity, flow characteristics, gel time, and thermal transfer characteristics of the melted polymer, air bubbles may be in evidence throughout the film. Due to the poor thermal transfer of the powder coating, the bubbles will be concentrated closer to the heat source, i.e., the substrate. These bubbles have not been a problem with FBE pipe coatings other than to cause a decrease in lateral cohesive film strength. Failure modes common to powdered pipe coatings stem from the use of wet air, plugged ventures and spray nozzles, and irregular heating of the metal surfaces for various reasons. Long-term adhesion problems may develop when application to the steel surfaces occurs at too low temperatures. High steel temperatures favor enhanced thermodynamic wetting although exceeding the

recommended application temperature of powdered coatings may result in foaming or loss of properties.

Variations in adhesion often follow variations in steel surface temperature. When powder coatings are applied to cold surfaces followed by heating through conveyor ovens, film build is usually limited to no more than 2 to 4 mils. Because of the short time allowed for flow and wet-out to occur, surfaces must be very clean and receptive to the applied coating. Typical failure modes are associated with surface pre-treatments, poor adhesion over unclean surfaces, contamination with other non-compatible or off-color powders from the same application system, compatibility with specific surface pretreatments, "wet" air used as the carrier, as well as curing difficulties resulting from catalyst deactivation or poor incorporation during extrusion. Gel particles may result with some catalyst systems during extrusion of the powder coating when the catalyst is "too reactive." This produces bumps in the otherwise smooth, glossy coating.

It is not practical to assume that the practitioner will have experience in all areas necessary to address the multitude of potential problems. Knowledge of application equipment, an in-depth chemical knowledge of the formulations and specific curing mechanisms and the physics of adhesion including the energetics controlling adsorbed molecular displacement, among other things, are required to thoroughly understand the potential problems one will encounter in the field. This should be developed through continued study, close observation, and by asking questions.

Tapes and extruded polyolefin thermoplastic coatings are popular pipe coatings. Sheeted rubbers find use on the risers of off-shore platforms and as acid tank linings. These will have specific failure modes. Rubber must be vulcanized in ovens after application to the tank wall or pipe. Failure modes usually will be associated with the improper cure of the polymer. This could stem from catalyst inactivation caused by the use of improper curing temperatures. Tapes of PVC with various types of adhesive binders are popular pipe coating materials. These may be applied in the cleanliness of a factory or as a "railhead operation" at the point of pipe construction or over the ditch. Extruded polyethylene and polypropylene pipe coatings are usually applied in a factory setting. Sheeted rubber coatings are frequently applied to the interior of carbon steel tanks that will see acid service. This is done both in the fabrication facility and in the field when it is possible to provide sufficient heat to cure the vulcanizable adhesives and coatings used. A common problem often encountered with these systems is the inadvertent inclusion of air bubbles or air pockets under the coating material. Bubble inclusion followed by eventual under film corrosion and perforation of the steel is a major failure mode for this type of coating.

Was the Specified Coating Material Used?

Often it is necessary to determine that the specified coating was used. Typically, Fourier transform infrared (FTIR) analysis of the binder is the analytical method of choice due to the widespread availability of the instrumentation. There is often considerable difficulty in gaining a positive identification of the coating due to interference from the pigments that produce an instrument response added to that of the polymer. The presence of silicates in paints is very common. A silicate peak often obliterates an informative section of the FTIR scan used to identify the polymer in question. Additional problems can stem from the specific technique used. The use of a "diamond anvil" attachment to a FTIR microscope has proven very beneficial in getting good polymer scans in the presence of interfering pigments but on rare occasions introduces some uncertainty when the binder is not totally homogeneous or well dispersed. An expected peak may appear to be missing. A good example is the presence of a crystalline, non-soluble cross-linker containing the cyano functional group in a fusion-bonded epoxy powder coating that is not seen using the FTIR diamond anvil in microscopic transmission mode but that is seen using the typical FTIR attenuated total reflectance (ATR) mode of surface analysis. GC/MS techniques provide a definitive analytical technique for identifying the coating used years after an application [1].

Was the Coating Material Properly Formulated and Manufactured?

Determining the "as applied" quality of a coating years after application can be a difficult task in some respects. On the other hand, it is usually surprising to most that the solvents used in a coating typically remain in the applied coating material for many years. A good example is the trapping of alcohols in cured epoxy coating systems for years after application. Normal-butanol, a very common solvent used in epoxy-polyamides formulations, can be extracted three to five years after application. High-molecular-weight oxyalcohols and glycols are also present for long times and are often found as the solute in an osmotic coating failure. Gas chromatography using thermal extraction (TE) with liquid nitrogen "cryo-trapping" before starting the GC run and a MS for the detector (GC/MS) allows for a positive identification of trapped solvent molecules. The vapor transmission coefficient within the cured coating system dictates the rate of solvent loss after application. The technique is also very useful for identifying the generic type of coating used years after application by pyrolyzing a very small coating chip at a higher temperature. By doing this in a stream of helium and trapping the fragments with liquid nitrogen, an analysis of the fragments will allow one to identify the original polymer [1].

Quality in the manufacture of the coating products includes both the proper formulation for use in the environment intended as well as the eventual commercial manufacturer. There is usually a lengthy testing program required to evaluate the coating formulation before a product is commercialized. A few typical failures seen in the formulation and manufacture include systems formulated to contain low vapor pressure, water-soluble solvents in coatings to be used under water, formulation without required UV or thermal stabilizers for exterior coatings, gelation of acidic binders by reaction with basic pigments, loss of dryer catalysts from a oxidizable coating system, inclusion of carbon dioxide and water vapor into the amine side during the manufacturer of an adduct for a two-part catalyzed coating, and failure to exclude water contaminants during the manufacture of the non-isocyanate side of a urethane coating system.

WHAT WAS THE DESIRED PURPOSE OF THE COATING?

Before designing the test regime to evaluate a specification or starting the investigation of a failed coating, the analyst should ask why the coating was applied. Often it will be intuitive or would be stated in the specification. The design of the testing and evaluation program should include elements encompassing these objectives. Table 1 lists some of the ASTM standard test methods used to evaluate a coating's specific serviceability relative to a particular property. Table 2 lists some of ASTM's standard practices for accomplishing the objectives.

Coatings provide a renewable surface and allow the engineer to use materials that are more economical or provide a physical characteristic not attainable from the uncoated surface. While coatings frequently provide a variation in appearance, most coatings serve to protect more than to beautify. When the protection is not provided for the full design life of the coating, including the maintenance of all expected and desired protective properties, a coating failure has occurred. Frequently the coating will be evaluated for a particular service through a series of tests. These evaluation programs are designed to assist in predicting failure modes and to assist in the preparation of specifications. Problems often develop when the service does not match the initial testing program.

A major reason for applying coatings to many different types of substrates is to protect the substrate from deterioration. Coatings on steel, when applied properly, have the ability to stop corrosion in hostile environments for a period of time. Coatings applied to wood have the ability to prevent fungus growth and rotting, even in damp environments. Hard metalized coatings protect softer metals from wear. Highly active metalized coatings such as zinc and aluminum have the ability to prevent corrosion of steel in adverse conditions [3]. When coatings are applied to protect the substrate and the substrate sustains premature damage, a coating failure has occurred. Test regimes usually address the perceived problem. Sophisticated a-c impedance and d-c polarization techniques have the ability to measure actual corrosion currents and represent a very sensitive test method for metal substrates. A-C impedance testing is also used to evaluate and compare coating performance in specific environments.

Coatings are often applied to the inside surfaces of pipes, tanks, plastic and paper food packages, food and beverage cans, and rail cars to protect the contents from contamination and/or spoilage. This contamination may originate from the metal container, which leads to discoloration of the product by allowing metal ions to enter.

Contamination in the form of bacteria or degrading reactive gases is frequently a problem in food packaging. Tank coatings may fail by allowing components of the coating to migrate into the products carried within the tanks. Loss of coating components will then lead to coating shrinkage that will stress relieve in various ways leading to failures by cracking, increased osmotic activity, etc., depending on the products carried and the coating polymer fragments remaining. A coating failure that allows product contamination is usually very costly. See Figs. 6 and 7.

Coatings are frequently applied to enhance a substrate's appearance. Because of this, any undesired change in the coating's visual attributes will constitute a coating failure. This would include not only changes in color, gloss, and texture, but appearance failures due to growth of algae and mildew as well. Failure modes related to a loss in aesthetics are usually adverse reactions to the environment, often due to ultraviolet radiation or delamination of the coating.

Small molecules such as water and the acidic gases carbon dioxide, hydrogen sulfide, and sulfur dioxide have the ability to migrate through a polymer film. When this occurs, the possibility of corrosion of the substrate is great. Frequently, coatings are used to interfere with this process. The rate at which these small molecules can pass through a coating or polymer membrane is called the vapor transmission coefficient for that specie. Metal coatings applied to food wrappers inhibit or stop migration of oxygen, thereby disallowing reaction with oils containing double bonds. This maintains freshness. A failure to prevent these molecular migrations in an amount based on the original design parameters constitutes a coating failure. Often this failure mode is closely related to cross-link density or changes in cross-link density after coating degradation.

Fig. 6—Loss of non-bound components such as benzyl alcohol in an epoxy tank lining in a ship leads to considerable coating shrinkage stress followed by cracking to relieve the stress.

Coatings are applied to stair treads and slick surfaces to provide nonslip characteristics. On the contrary, internal pipe coatings should be very smooth so as to provide decreased resistance to flow. This allows increased volumes of fluids with less pressure drop and lower power requirements for the pipeline. Many coatings provide abrasion resistance to a substrate, thereby increasing the substrate's life indefinitely since coatings are a renewable entity. Failure of the coating to accomplish any of these design goals constitutes a coating failure.

Fig. 7—Poor surface preparation and shrinkage of epoxy tank lining that leads to loss of coating in the corner of the tank.

Coatings are frequently applied to metal substrates to modify electrical flow characteristics. Coatings are naturally dielectric, though conductive pigments and additives may decrease internal electrical resistance for special requirements. The electrical resistance becomes an important attribute in accomplishing a particular circuit requirement. A very good example are those coatings applied to metal surfaces that are placed under cathodic protection such as underground pipelines, metal bulkheads at a shoreline, ship bottoms, offshore underwater structures, as well as internal tank linings. ASTM G8, G42, and G95 (see Table 1 and Ref. 4) are methods for evaluating the cathodic disbondment properties of coatings. Because of the generation of large concentrations of hydroxyl ion at coating defects, if the coating is chemically reactive to hydroxyl ion, delamination may occur. If phosphoric acid had been applied to clean the steel, saponification of the pretreatments can be a dominant failure mode with some coating systems.

Conductive coatings are used to dissipate electrical charge. These are found in laser printers and some copy machines. Conductive coatings are also applied to bags, plastic mats, and other articles used around electrical equipment sensitive to the discharge of static electricity. A failure to provide the desired low electrical resistance or conductivity over its planned lifetime constitutes a coating failure.

For materials that expand and contract extensively with changes in absorbed materials such as water and carbon dioxide, minimizing absorption will allow the substrate to remain dimensionally stable. Wood, when "dry," is about 10 to 15 % water. Depending on the type of wood, absorption of water, especially through open-end grain, causes huge changes in the size of the piece of wood. Other characteristics such as flexibility, warping, and cracking are a common occurrence when wood coatings fail. The peeling of coatings on wood usually starts at some break in the film and slowly radiates from the site of moisture ingress. As moisture enters the wood, it expands greatly and pulls the coating from the surface. As it dries out, the wood shrinks. This continual expansion and contraction is a major source of problems for wood coatings. See Figs. 8 and 9.

Paper products must be protected from moisture pickup to maintain strength and integrity. Paper cartons containing milk and other food products are usually protected by surface coatings of wax, polyethylene, or vinyl thermoplastics. Sizing or starch-type coatings are frequently applied to paper to provide a degree of stiffness if "wet strength" is not required.

While gloss is frequently considered an aesthetic property, coatings that have the ability to reflect or absorb specific wavelengths of light are functional coatings. Pigmented coatings engineered to reflect very little radiation are often applied to thermal adsorption devices such as solar heat exchangers. Coatings with adsorption efficiencies approaching 95 % have been developed. Changes in reflection or adsorption characteristics over the coating's planned lifespan constitute a coating failure.

Coatings containing voids or small bubbles have the ability to adsorb and deflect mechanical wave energy such as sound. Changes with time in these adsorption or dampening abilities usually constitute a coating failure. Some of these unique physical properties are impacted by the adsorption of liquids such as water from condensation and may be the subject of test programs when evaluating this type of failure. Knowledge of the physics of wave energy transmission and point reflection through elastic media is necessary to design test programs evaluating these parameters.

Fig. 8—Expansion and contraction of wood occurs when water is absorbed and lost from the wood. The paint film cannot follow the dimension of the wood. This results in peeling paint that pulls fibers from the wood surface.

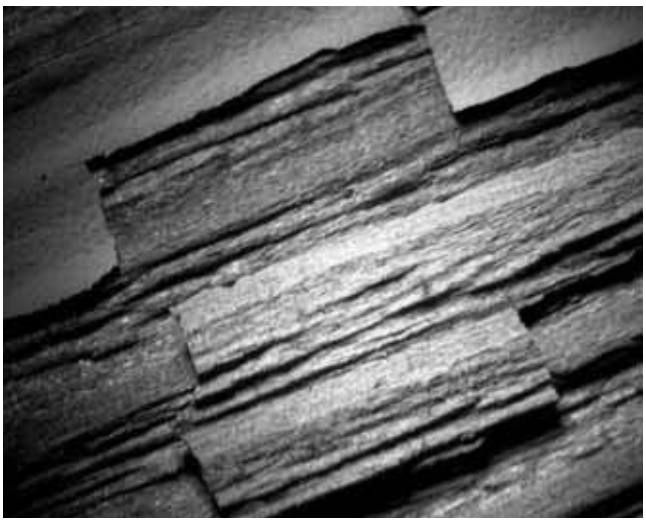

Fig. 9—Microscopic view of wood/paint surface in Fig. 8. Note wood fibers attached to the backside of the delaminated paint chips.

HOW WAS THE COATING APPLIED?

Many coating failures can be traced to problems associated with the procedures surrounding the coating's application. For this reason, each step of the process must be considered. Getting a particular coating applied can be thought of as having been accomplished through a series of steps with multiple responsibilities. These broadly include the following:

1. Preparation and follow through of the specification.
2. Preparation of the surface/substrate.
3. Physical application techniques and equipment.
4. Third-party inspection.

The specification, type of coating being applied and its particular mixing and curing requirements, variations in ambient weather conditions, variations in the condition of the substrate, surface preparation techniques, pretreatments, equipment used during the application, the quality of third-party inspection as well as the applicator's knowledge and ability all play a major role in getting the coating properly applied and minimizing coating failures.

Preparation and Follow Through of the Specification

The specification should serve as the "blue print" for getting the coating properly applied. Its existence implies that someone has surveyed the site to determine any abnormalities that might exist, evaluated the service requirements, reviewed the particular problems unique to the structure and service demands, identified a particular coating with the required service characteristics through prior testing, and provided an adequate application procedure that, theoretically, will meet the use requirements. The specification assists the applicator in knowing what is expected of him and serves as a legal document in times of dispute.

Frequently a coating will be specified by a specific manufacturer's product numbers. Failures in the specification, either in the type of recommended coating or the application procedures, can result in early failure. As such, the specification must be reviewed when investigating a coating failure. Coating materials may have been used that were not on the approved list. Most applicators are not in possession of proper knowledge to make substitutions and usually do not want that responsibility. Coating failures in many forms have resulted from attempts to circumvent the specification. Analysis of very small coating chips by FTIR or GC/MS and compared with known samples can demonstrate compliance or lack thereof [2].

Before specifying a particular coating system, it is usual to evaluate specific candidates in a test program that closely simulates the use environment. This is accomplished either within the owner's organization or by subcontracted third party testing organizations. While most of the required test procedures are found in Volumes 6.01 through 6.04 of the *Annual Book of ASTM Standards,* specific custom-designed procedures may be desired in some unique applications.

Often a particular coating material will require specific mixing and application procedures dictated by its formulation. The coating manufacturer is in the best position to determine this since he is knowledgeable about the components of the coating. Requirements placed on the curing regime, mixing times with requisite induction periods, strainer mesh sizes, and other requirements will be specified by the manufacturer.

Preparation of the Surface/Substrate

The quality of the surface preparation done prior to coating application will strongly influence the life, and quality, of the applied coating. Some contaminants are very harmful and lead to early failure in certain services. Some contaminants can be tolerated, and, while coating life may be somewhat adversely impacted, long-term longevity can be realized. Displacement of some surface contaminants may be addressed by variations in the ability of the solvent system to affect coating wet-out. Contaminates that interfere with adhesion or promote under-film corrosion are particularly troublesome to paints. There are potential problems with all types of surface preparations. The Steel Structures Painting Council (SSPC) has produced specifications addressing some of the most common surface preparations for steel [8]. These specifications will usually dictate the specific surface cleanliness required for service and should reflect that used during the original test sequences. Surface contaminates can impact the surface tension of freshly applied coatings. In one case the concrete floor at a power station was "mopped clean" using a mop that had been used to spread a silicone sealer. The result was a serious surface tension (fisheye) problem in the applied epoxy floor coating. See Fig. 10.

For coatings that have an extended design life, as with automobile bodies, the surface preps are extremely sophisticated. Unique electrodepositing primer coatings require a very clean and totally wet-out surface. Coating failures on this scale have resulted in multimillion-dollar claims. Chemical pretreatments present potential failure problems as well. Cleanliness of the substrate and its impact on adhesion is the topic of many testing programs. But since one must be looking at the surface at a depth of no more than a few angstroms, the analytical techniques required include auger spectroscopy and XPS. The use of EDX to analyze a "surface" is not proper because the area being analyzed will include a depth well below the surface where "adhesion" will occur. While this technique is usually defined as a surface technique, it does penetrate well below the actual surface encountered by the coating as it attempts to "wet-out" the substrate.

Improperly operating equipment is a source of coating failures. A very common problem is the abrasive-blast-

Fig. 10—"Fisheyes" in an epoxy floor coating contaminated with a silicone sealing agent is a surface tension problem. The coating was intended to be smooth and shinny.

cleaning air compressor that passes oil. Oil contamination can be a long-term, serious problem with certain coating systems. While pure aliphatic oil residues, being low-energy compounds, are usually displaced by the active solvents of the coating system such as ketones and esters, oil based systems can present a serious problem. Adhesion between the binder of the coating and the substrate takes time to develop. It is highly probable that adhesion problems will develop with the ingress of water vapor if the interface has been contaminated with strong surfactants and the solvent system does not have time (or ability) to displace them before the coating gels and its glass transition temperature reaches ambient temperature. Analysis of the interface surfaces by XPS can allow a definitive identification of the structure of the molecules forming the interface and is required to identify the locus of failure.

Profile and surface conditions existing at the time of coating application are difficult to evaluate after a coating has been in service for a while. Frequently, though, it is necessary to inspect the substrate under a coating. Paint may be removed by using commercial paint stripper, allowing inspection of substrate profile and the current surface condition. This may include the presence of corrosion products. Mill-scale deposits may be found where the specification calls for complete removal. While the actual profile is not as critical as the original molecular contaminants that could interfere with the thermodynamic wetting process, one can gain insight into the history of the surface being inspected.

For submerged services, a "white metal" abrasive degree of cleanliness is usually specified. If a metal sample may be removed and is bendable, the sample may be subjected to extreme cold, as with liquid nitrogen or carbon dioxide followed by rapid bending. The coating will usually pop from the substrate if chemical bonding has not occurred, allowing a clear measure of the debris that remained at the time of application.

Physical Application Techniques and Equipment

The physical application techniques employed as well as the equipment used can lead to many types of coating failures. Coating defects can range from delamination between coats caused by exceeding the recoat window and pinholes caused by small compressed air bubbles whipped in during highspeed stirring and applied by airless application systems, to curing problems originating from improper ambient field conditions, off-ratio mixing, or inclusion of water contaminants from "bad" solvent. Some defects such as orange peel, sags, and runs will be evident at the time of application, but improper curing of a coating may not become evident until a failure occurs months or years later. The analytical techniques useful in evaluating off-ratio mixing of catalyzed paints depends on the coating matrix, but typically include thermal methods such as DSC, FTIR, gel permeation chromatography (GPC)/high-pressure liquid chromatography (HPLC) of solvent extracts from the failed coating, and GC/MS are typical analytical methods for evaluating cure.

The specific application technique will often present typical failure modes. Test programs that evaluate a particular coating before it is specified will usually utilize the expected application techniques. Application by spray, roller, brush, flow coater, dipping, or trowel requires that the coating material have certain physical properties. Ambient conditions expected at the time of application should be considered. Application may use electrostatics with some powders and liquid paints.

Was the coating properly cured? Was the temperature and relative humidity in the required range? Some moisture-cured ethyl-silicate, zinc-rich systems as well as moisture-cured epoxies and urethanes require that there be sufficient moisture available to allow binder-curing reactions to occur. Overcoating these paint systems before there has been sufficient water pickup can lead to premature coating failure due to insufficient coating strength development. Too much water can cause blushing with high flash lacquers and foaming with urethanes.

The curing of a coating is usually by chemical reaction with the polymer precursors in the paint. All physical laws controlling chemical reactions will be in effect. This means that the reaction rate will be controlled by the substrate temperature since the heat capacity of the coating will usually be considerably less than the substrate. Potential side reactions with atmospheric constituents such as water and carbon dioxide may be a problem with some binders. For moisture-cured systems such as urethanes, epoxies, and ethyl silicate systems, air that is too dry will interfere with polymer curing and the use of DH equipment may present a problem. Excessive humidity may leave surfaces with a microscopic layer of water. With solvent-borne paint systems, this may not be as critical as with the super-high solids or 100 % solids systems. The solvent system is usually engineered to assist in moisture removal by displacement, dissolution, and selective azeotrope formation. Coatings that cannot displace these interfering surface-adsorbed species with properly engineered solvent systems may experience delamination shortly after application. With most coating systems, this may be demonstrated by the addition of thinners of varying "strengths" and noting the delamination sensitivity caused by water vapor. When a coating delamination problem exists with a particular coating system and the "adhesive" qualities may be enhanced by adding active thinner only, one may suspect problems with the thermodynamic wetting of the substrate.

Third Party Inspection

An important part of the professional application program will often include third party inspectors. These are usually required by the owner and serve as monitors and record keepers for the job. Should a failure occur in the future, the records frequently provide the only link to the daily happenings. Data will include paint batch numbers, ambient weather data for each day, humidity and temperatures, wet- and dry-film builds, the thinners used, logging of equipment problems, names of operators, substrate temperature, and a multitude of other data. Very important information useful to the solution of coating failures is often found in the inspection reports. Organizations such as SSPC and National Association of Corrosion Engineers (NACE) can provide lists of certified coating inspectors.

WHAT EVIDENCE IS PRESENTED BY THE FAILURE?

To successfully diagnose the causes of failures in coating systems, the investigator must be fully cognizant of all of the factors affecting the coating's longevity. This includes, but is limited to, (1) a thorough knowledge of the chemistry

of the coating systems being used; (2) factors affecting the cross-linking, cure, or film-forming characteristics of the binder; (3) factors affecting adhesion and potential adverse chemical reactions between the substrate, binder, and environment; (4) corrosion fundamentals and protective techniques; (5) potential formulation problems; (6) potential application problems; (7) the suitability of the specified coating for the service; and (8) the instrumentation that can provide sophisticated answers to the complex questions that exist.

It is rare for all of these disciplines to be found in a single individual and the investigator must be willing to continue their study. New coating polymers are being developed routinely and are being incorporated into coating systems. Their reaction chemistries both with the cross-linkers used to produce the final film and the interfering side reactions with ambient, local, or solvent species may produce unexpected results. Because of this, the successful investigator must be aware of his/her limitations and be willing to seek knowledgeable assistance when necessary.

Those with experience in the formulation of paints and coatings will often have a distinct advantage over others. Understanding the potential shortcomings of the polymers used, the problems forced by the use of environmentally friendly solvent systems, the functions of the additives, the physics of adhesion, and the limitations of the analytical "tools-of-the-trade" will assist in understanding failure mechanisms. Even still, the challenge is tremendous and true solutions may be elusive. It is important to know when to ask for help.

While the investigation of a coating failure requires all of the knowledge discussed, a systematic approach offers the best chance for a successful conclusion. Before beginning the investigation, it is important to follow a preconceived procedure that will ensure that each phase of the investigation is addressed. Since each failure may be somewhat different, there will be opportunities to veer from the path as evidence is produced. The investigation should contain the follow elements as a minimum:

1. Gather background information.
2. Conduct the field investigation.
3. Conduct the laboratory investigation.
4. Consider potential failure modes and test the hypothesis.
5. Report the findings.

Gather Background Information

Inquire as to the nature of the problem. While the first reports coming in from the field will usually lack details necessary for a definitive conclusion, they do provide a picture of the problem as it is perceived. There is little standardization of the descriptions of failures. As an example, coating delamination can occur at the interface or within the coating or substrate. The observer usually will know only that "the coating fell off."

Obtain a copy of the specification. This will provide insight as to potential problems perceived at the initial documentation. The type of coatings and typical failure modes will prompt additional questions.

Obtain relevant daily inspection reports. These will provide data as to the current weather conditions at the time, equipment malfunctions, types of paints used, as well as any problems encountered out of the ordinary. Batch numbers of the coating material will allow queries to the manufacturer as to similar problems that may have been seen with the coating in other situations.

Conduct the Field Investigation

Talk to the applicator if possible, not just the foreman. Inquire as to any recollections about the application. Was the weather at the time of application cold, wet, dry? What was the time of day, direction of surfaces relative to solar heating, surface preparation, blast medium used, and condition of equipment?

Ensure that field test instruments are properly calibrated. The data must be reliable and relatable to other data available from original testing done prior to specification writing and the coating manufacture.

Gather all relevant samples. Representative paint chips from the "bad" area should be matched with representative samples from a "good" area. Fluid from under blisters may be withdrawn with hypodermic syringes and stored in glass bottles. Empty cans, samples of shot/grit from the automatic abrasive cleaning machines, sample debris from the dust collector, liquid samples from degreaser/phosphating baths, etc. will hold clues to potential problems.

Perform adhesion checks if indicated. ASTM D3359 (Test Methods for Measuring Adhesion by Tape Test) describes methods for determining the degree of apparent adhesion of the coating. Frequently, poor or marginal adhesion causes other problems to surface although the coating appears to be intact. Under-film corrosion is a common occurrence when contaminants remain on the steel interface after coating application. Fig. 11 depicts a good use of the tape peeling test. In this case the concrete floors a new auto dealership were painted. The dealer specified their color and the specification was not followed. This required the paint application contractor to then repaint with a different color epoxy. After being occupied the new coating peeled with little difficulty from the original coating due to

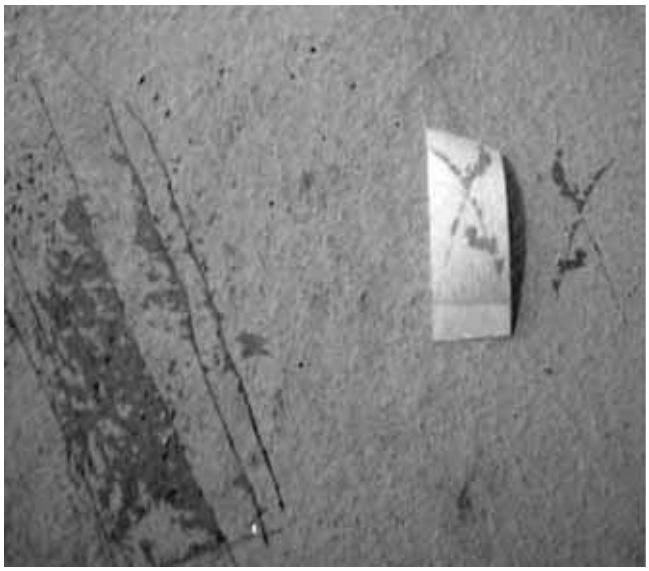

Fig. 11—ASTM D 3359 "Test Methods for Measuring Adhesion by Tape Test" applied to a peeling top coat epoxy soon after applying over the first cured coat epoxy. The first coat was the wrong color. The peeling is occurring in a weak boundary layer (WBL) of carbonated amine that formed on the first coat during application.

the amine carbonate WBL that had formed on the surface of the original coat. While none of the original empty paint buckets were available to test for trapped CO_2, it is probable that a portion of the interfering carbonated amine exuded from the original coating as a result of aggressive stirring of the curative. Discussions with the paint applicator revealed that he was under the misconception that the more he stirred the individual components before mixing the "A" and "B," the better the mixed paint would be.

Inspect surface profile and cleanliness of substrate. The depth and intensity of the abrasive cleaning will determine whether the surface contains "new metal." Profile depth alone is not sufficient to describe the surface. For high-solids coatings with limited active solvents, wet-out of the interface, a requirement for the development of adhesion, may not be possible as the coating increases its viscosity to a gel. As the coating cures to a film and internal stresses began to grow across the outer surface, some coatings can literally pull themselves from the surface. The inability of the coating to encapsulate debris encountered on the surface exacerbates the problem and decreases its total adhesion.

Field test for cure by MEK rubs (ASTM D4752). This test is useful for catalyzed coating systems such as epoxies and urethanes, though not suited for alkyds or latex systems due to active solvent swelling and delamination. If the coating can be resolubilized, there is a high probability that there is a problem with the curing. Off-ratio catalyzation, severe zone curing from inadequate induction time, and deactivation of one reactive component are but a few of the reasons for failure of the MEK rub test. One must remember that the fourth most abundant component in air is carbon dioxide (CO_2) and CO_2 is an "acid gas." As such, carbon dioxide will react with any alkaline epoxy curative such as amines and polyamides while in contact with air. This is the typical amine blush that creates adhesion problems like that seen in Fig. 9. The application of amine/polyamide-cured epoxies will often require mixing. If a vortex is pulled during the stirring of the amine/polyamide curative, carbon dioxide will be stripped from the air and will chemically block that site from reaction with epoxy. For epoxy polyamides with 1:1 mixing ratios, there may be pigments ground into the polyamide side of the paint. Depending on the manufacturing equipment used by the paint producer, there will be some carbon dioxide blocking some of the amine functionality. Most manufacturers do not use a nitrogen blanket during pigment dispersion into the curative side of the epoxy. This amine carbonate will exude from the catalyzed epoxy as it cures and over time to produce delamination problems. This laboratory has developed a test to determine if there is CO_2 blocked amine in the can before mixing at the application site. To test for the presence of carbonated amine a small sample (about one ml) of the curative is placed in a test tube. A drop of six molar hydrochloric acid is carefully deposited below the curative using a pipette or hypodermic syringe. The acid will force the CO_2 from the amine functionality as the hydrogen ion reacts with the amine. This assumes that no calcium carbonate is formulated into the paint.

Photograph document observations. Include relevant data in each photograph. This might include the observation number, test location, film build, highlight of suspect area (both good and bad), and some point of reference. The point of reference might be a pencil, coin, or even the investigator's finger. Cracks in a tank lining may be 1 cm long or 1 m long. A photograph without reference may be impossible to distinguish against a background (wall) of white paint.

Observe all activity in the area that may impact coating application or longevity. When inspecting the coating facility, look about to determine if other activities may present problems. Is the grit blast machine near the degreaser? Is metal shot and grit getting into the phosphating bath, increasing the chance for leaving loose iron particles in the phosphate on the surface to be overcoated? Is automatic welding equipment nearby using silicon sprays as a wire lubricant? Is grit or shot blasting near a powder coating fluid bed or phosphating bath introducing contaminates into the powder or sticking to the steel substrate prior to coating application? These have been the source of coating failures in the past.

Conduct the Laboratory Investigation

After gathering the samples, the analysis may be planned depending on the nature of the problem. In answering those questions posed before, some analytical laboratory work is usually required. Some of the instrumentation and the answers they provide may be summarized in the following discussions about each instrument.

Infrared analysis of coating samples is sometimes useful in determining whether the specified coating was used. Operator technique is very important in obtaining totally definitive information, and results are often marginal. The method is very useful in testing the coatings prior to application when there is a desire to ensure compliance. Microscopic FTIR provides greater sensitivity when analyzing filled polymer solutions, as most paints are [2].

GC is very useful for solvent identification. Solvent retention that leads to osmotic blister formation may be demonstrated by GC analysis of the blister liquid. Because of the migration of the solvent molecules into plastics such as polyethylene, glass collection bottles will provide a more accurate system for sample transportation.

A tremendously useful system of instruments is the "hyphenated" system made up of a pyrolysis/GC/FTIR/MS. In this "instrument" which, in essence, is a laboratory on a bench, paint chips can be analyzed with little or no preparation. Positive identification of generic coating and polymer types, polymer degradation studies, solvent-retention analysis after years in the field, determination of catalysis levels in oil-free polyesters from field sample chips, and numerous other tasks are very easy with the instrument [1].

Ion chromatography is a very useful tool for the analysis of osmotic blister liquid when the problem stems from salts under the film. Analysis of soluble salts taken from a surface is also easy to accomplish by dissolution followed by ion chromatography or after evaporation onto a suitable substrate via energy dispersive X-ray.

Thermal analysis techniques such as differential scanning calorimetry and thermal gravimetric analysis (TGA) are useful in determining some physical properties of coatings. DSC has been used to monitor curing profiles of powder coatings and other thermosets for many years [6]. TGA systems, set up to allow a flowing gas stream to sweep the escaping molecules through a heated gas cell of an infrared spectrophotometer, are now available. This system

of instruments allows studies of the thermal stability of polymers used in coatings.

Surface analysis such as XPS, auger, scanning electron microscopy (SEM), and EDX are analytical techniques that look at the surface of the coating or substrate. Auger and XPS are tremendously important in determining the locus of failure when investigating coating delamination [8]. A major failure mode is the development of, or application over, a WBL. These are not easy to identify with the naked eye. What may appear to be an adhesive failure could be the splitting of an organic layer only a few molecules thick at the interface. This could be due to the loss of reaction caused by a rogue metal specie. Zinc is such a culprit when overcoated with oil-free, polyester-based systems cured by a free radical mechanism. This has been seen when a zinc-rich coating had been applied by mistake and then removed by abrasive blasting. This left trace amounts of metallic zinc alloyed into the steel surface. The zinc interfered with the curing mechanism of the polyester.

Atomic absorption (AA) spectroscopy is useful in determining the concentration of metals in coating systems. While lead, chromium, and other metals are controlled to protect workers and the environment, low concentrations of catalytic levels may be determined as well.

UV weathering characteristics are evaluated in simulated weathering cabinets. When failures are thought to have originated from UV degradation, test regimes may be designed to evaluate the coatings using UV of different wavelengths.

Physical and application characteristics such as percent solids, viscosity, pot life, and others are usually monitored as a quality assurance/quality control (QA/QC) procedure during or prior to application. The requirement to monitor these variables is often included in the specification, and the values can be found on the daily reports of the inspectors.

Liquid chromatography such as GPC and HPLC are useful in evaluating a polymer used as a binder of coatings. Failures associated with the migration of the smaller-molecular-weight fraction to an interface, causing the development of a WBL, is a typical example. QA/QC of incoming resins for use in a coating is another typical use.

X-ray diffraction (XRD) is useful in the analysis of any crystalline material. Since most pigments found in paint are mineral in nature and possess crystalline structure, they may be identified using this technique. Even when a coating system may be lacking an identifying collection of crystalline materials, the "amorphous signature" of the XRD scan has been used to provide information about unknown coating specimens.

Consider Potential Failure Modes and Test the Hypothesis

At some time after starting the investigation, a hypothesis can be drawn. A testing program incorporating this hypothesis may be developed that will assist in proving or disproving the possibility of a failure mode.

REPORT THE FINDINGS

After a conclusion has been reached, a full report should be written. This would include all of the data gathered including pictures. The report should contain sections such as (1) Introduction, (2) Executive Summary, (3) Background Information, (4) Discussion and Laboratory Analysis, and (5) Conclusions. Since a primary reason for failure analysis is to prevent similar problems in the future, the report should be written with that objective in mind. It should also serve as a teaching aid to others.

CONCLUSION

Coating failure analysis will draw from a multitude of disciplines. To increase effectiveness, one must be willing to have an open mind during observation and study the basic chemistry and physics controlling the processes. Do not enter an investigation with preconceived ideas so strongly set so as to be swayed from seeing the small details that will define the actual failure mode. Do not be afraid of the "heavy" chemistry associated with the sophisticated analytical instrumentation that can give one very powerful insight into the systems. This will be a learning experience for all.

While there are some coating mistakes that are commonly made, the reasons for coating failures appear to be limitless. Just as a good mechanic must know how an engine works to diagnose its problems, so too must the coatings failure practitioner know how paints work and the tools available for use in any required investigation. This knowledge of potential failure mechanisms can be extremely helpful to others, as well, including the owner, specifier, paint manufacturer, and applicator. By appreciating potential coating problems, an awareness of many important details is naturally obtained. Learning the complex chemistry of urethanes may be beyond the average applicator, but the knowledge that bubbles in urethanes may be the result of painting over dampness or condensed water on the surface forces an awareness that is very helpful.

Part 15: Instrumental Analysis

70

Atomic Absorption, Emission, and Inductively Coupled Plasma Spectroscopy

Dwight G. Weldon[1]

A PAINT, EVEN ONE AS SEEMINGLY SIMPLE AS A red-lead alkyd, is actually a very complex system wherein a variety of components such as polymers that may or may not contain reactive functionality, pigments, plasticizers, additives, and solvents must interact in such a way that the dried film offers expected protection. In addition, quite often, the film is expected to provide an aesthetic appeal. Because of this complexity, it is not surprising that the complete chemical analysis of a coating can be a complicated and time-consuming task. Indeed, a complete analysis of all the components may require the use of several analytical techniques, many of which are discussed in this manual.

The intent of this chapter is somewhat more limited, as it pertains only to the analysis of coatings for metallic constituents and more specifically, elements. Such compounds are widely used in the coating industry. Many pigments and extenders are inorganic compounds that may contain metals, and many driers, catalysts, and ultraviolet (UV) light absorbers are metal-containing compounds as, for example, cobalt naphthenate and dibutyltindilaurate. It should be pointed out that in theory inductively coupled plasma spectroscopy can be used to analyze all elements except argon. However, in actual practice, it applies to approximately 70 elements, many of which are not typically considered metallic by most paint chemists.

Classical wet chemical techniques are valuable in determining several of the above-mentioned paint-component compounds. However, a generally simpler, more efficient, and, in some cases, more sensitive way to achieve this involves the use of the related techniques of atomic absorption (AA), atomic emission (AE), and inductively coupled plasma (ICP) spectroscopy. It is the purpose of this chapter to briefly describe the underlying principles of these techniques and to discuss their usefulness within the coating industry.

ELECTROMAGNETIC RADIATION

A useful definition of spectroscopy is the study of the interaction of light, or more generally, electromagnetic radiation, with matter. Therefore, a logical starting place in the discussion of spectroscopic methods is a brief introduction into the nature of electromagnetic radiation.

Simply put, electromagnetic radiation is energy traveling through space at enormous velocities that are effectively the speed of light. The classical interpretation of this radiation ascribes to it a wave-like character with the propagation of the radiation likened to the ripples caused by tossing a pebble into a quiescent pond. However, certain electrical phenomena such as the photoelectric effect are more readily explained by the quantum mechanical interpretation of electromagnetic radiation which describes the radiation as small, discrete wave packets or bundles called "photons." These dual views of radiation as bundles and waves are complimentary and not mutually exclusive.

The classical, wave-like interpretation of electromagnetic radiation characterizes it by either the wavelength (λ) or the frequency (ν). Fig. 1 is a simple representation of electromagnetic wave radiation wherein light is an oscillating vector with a wavelength, λ. From this, wavelength is defined as the length of a cycle, the distance between two successive maxima or minima, and the frequency as the number of cycles that take place per second. The relationship between wavelength and frequency is

$$\lambda = \frac{V}{\nu}$$

where V is the velocity of the wave front. In a vacuum, this velocity is equal to the speed of light, $c = 2.99 \times 10^{10}$ cm/s. Thus, for the radiation traveling in a vacuum, the equation is

$$\lambda = \frac{c}{\nu}$$

The electromagnetic spectrum is described in Fig. 2. The spectrum varies from high-frequency gamma rays, through the visible light region, all the way to low-frequency radio waves. The various regions of the spectrum have different energies, and therefore they interact differently with matter. The relationship between radiation frequency and its energy, E, that arose from quantum mechanics is given by the simple expression

$$E = h\nu$$

where h is Planck's constant, 6.624×10^{-10} ergs-s. Thus, the higher the frequency or conversely the shorter the wavelength, the more energetic the radiation. As described in Fig. 2, the lower energy end of the electromagnetic spectrum involves low-energy processes such as rotation of molecules, whereas the higher-energy ultraviolet and visible light region involves higher-energy processes such as outer electron transitions. It is these transitions that form the basis of AA, AE, and ICP spectroscopy.

ATOMIC ABSORPTION SPECTROSCOPY (AA)

Atomic absorption spectroscopy probably is the most widely used of the three methods to be discussed. Basically, samples of coatings are chemically treated and introduced into a spectrometer that has been calibrated with known samples. For example, paint that is analyzed for lead is weighed, ashed at an elevated temperature to remove organic material, and then digested in hot nitric acid. The acid solution is diluted and fed into the spectrometer flame.

A simple, but not entirely accurate, picture of atomic structure involves negatively charged electrons rotating in orbits around a positively charged nucleus. The greatest population of electrons will reside in the lowest energy or ground state. If the atom is exposed to light of an energy exactly matching the difference between a ground-state orbital and an orbital of higher energy, a portion of this light can be absorbed and the electron can be excited such that it moves from the ground-state orbital to the higher-energy orbital. Thus, if a light source of appropriate frequency is available and is coupled with a detector capable of sensing attenuation of this light source, the concentration of a particular atomic species can be determined. This is the basis for AA spectroscopy.

Fig. 3 is a simple block diagram of an AA spectrometer. It consists of an aspirator, which is used to deliver the liquid sample into a flame, and an appropriate light source that is usually a hollow cathode lamp. The cathode is made from the element of interest, encased in a glass sleeve, and maintained at a low pressure with an inert gas such as argon. The light source is positioned so that it can be focused through the flame into a monochromator (prism or grating) and onto a phototube or other suitable detector.

When an electric current is passed through the lamp, it excites the inert gas, which then impinges on the cathode and sputters off atoms of the metallic cathode material. Collisions between these neutral metal atoms and the gas ions result in promotion of the metal atoms to an excited state. When these excited atoms relax back to the ground state, they emit light which is characteristic of the cathode element, and this light is then focused through the flame.

Intuitively, it would seem that there must be a relationship between the amount of light absorbed and the concentration of analyte atoms in the flame. Indeed, it has been found that if I_0 is the intensity of the incident beam originating from the source lamp and I is the intensity of the beam after it has passed through and been attenuated by the atoms in the flame of thickness or path length b, that the following relationship exists:

$$\log(I_0/I) = (k/2.303)b$$

where k is a constant. This relationship is known as Lambert's law. Beer found that increasing the concentration of

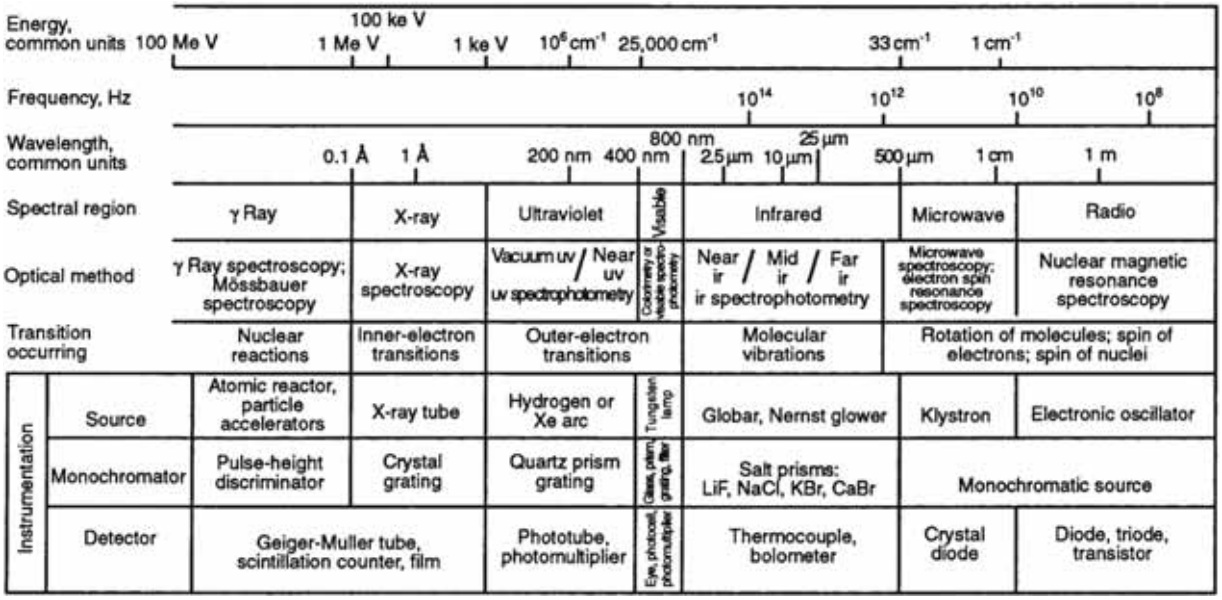

Fig. 2—The electromagnetic spectrum and corresponding spectroscopic methods [1]. (Printed with permission of The McGraw-Hill Companies, Inc., from Olsen, E.D., *Modern Optical Methods of Analysis,* 1975.)

analyte had the same effect as a proportional increase in path length. Therefore, the constant k is proportional to the concentration C of analyte and the relationship may be written as

$$\log(I_0/I) = abC$$

where a is the new proportionality constant. The expression is known as Beer's law.

The ratio I/I_0, which is dimensionless, is called the transmittance, T. In practical work, the terms "percent transmittance" [$\%T = (I/I_0)\ 100$] and "absorbance" [$A = \log(I_0/I) = -\log T$] are the parameters most often used, and Beer's law is often expressed as

$$A = abC$$

Because the relationship between absorbance of an analyte and its concentration depends on the constant, a, and the path length, b, each instrument must be calibrated before a quantitative analysis can be performed. Methods of calibration are discussed in the references to this chapter and in many other analytical texts. Often calibration involves measuring the absorbance of a series of standards of known concentration and constructing a calibration curve, or the use of internal standards [1].

One of the inherent drawbacks to AA is the need to use a different lamp for each element to be detected, although some multi-element lamps that contain as many as five or six metals exist. Since specific cathode tubes are needed, AA is quantitative and not qualitative in nature.

Flame Characteristics

Although the processes taking place within a flame are very complex, the flame serves three basic functions:

- sample volatilization
- decomposition of molecular compounds to the elements of interest
- excitation of the individual atom (AE only)

The flame consists of three regions: an inner core, an interconal zone, and an outer cone. The analytical measurement is generally carried out in the interconal zone, which is the hottest part of the flame. The height of this zone above the burner varies with the type of gases being burned, their flow rate, and the burner type.

A very important property of the flame is its temperature, since thermal energy is responsible for decomposing samples into individual atoms and, in the case of AE, for exciting the atoms thus formed. The most common flame type is the air-acetylene flame, which achieves an interconal-zone temperature of approximately 2200°C. If a nitrous oxide-acetylene flame is used, the temperature is approximately 2900°C.

Hotter flames are usually more advantageous because they reduce the number of chemical interferences. One primary source of chemical interference is compound formation within the flame, resulting in broad-band absorption and emission. As flame temperature is increased, many of these compounds are decomposed into the free atoms and the problem is eliminated. Also, hot flames are desirable in AE since they will provide more energy for the excitation of an increased number of elements. Too high a temperature should be avoided since it is possible that a significant portion of the neutral atoms may become ionized rather than simply excited.

Graphite Furnace

A modification of AA involves the use of a graphite furnace rather than a flame to achieve excitation. Small graphite tubes or boats that have electrical contacts through which an electrical current can be passed are the basis of this technique. A small amount of sample is precisely measured into the graphite furnace, the current flow is begun, and a very high temperature is achieved, resulting in the production of an atomic vapor.

The graphite tubes are usually about 5 cm in length and about 1 cm in diameter. The sample is introduced with a micropipette through a hole in the top of the tube. The radiation from the hollow cathode lamp is focused through the axis of the tube. Heating is usually accomplished in stages. The first stage is a low-temperature step that has the purpose of volatilizing any water or solvent in the sample. The second, somewhat higher temperature step, is used to ash the sample, and this is followed by a rapid increase in current to achieve temperatures of 2000 to 3000°C and atomization of the unknown elements whose absorption is then measured.

The main advantage of the graphite furnace technique is improved detection limits due to greater sampling efficiency. Flames have low efficiency because flow down the drainage tube (see Fig. 3) results in most of the sample never getting to the flame, and also because the residence time of the atoms in the analytical portion of the flame is very brief. In contrast, graphite furnace atomizers utilize almost all of the sample and residence time is greatly increased.

Cold Vapor and Hydride Generation

Some elements, such as mercury, arsenic, tin, and antimony, are best analyzed in the vapor state. In this technique, the elements (except mercury) are converted to their gaseous hydrides with sodium borohydride in a reaction vessel. The gaseous hydrides are swept by an inert gas, such as argon, into a heated quartz cell that is located over the burner assembly area heated by the flame. A cold vapor technique is used for mercury.

An example where this technique might be useful is the case of tin. Organotin compounds are often used at very low levels as catalysts in certain urethane coatings. The typical detection limit for tin by conventional flame AA is 0.1 part per million (ppm), whereas the detection limit for the hydride method is 0.0002 ppm [2].

ATOMIC EMISSION SPECTROSCOPY (AE)

Instrumentation for atomic emission spectroscopy is very similar to that used for AA. In fact, the same instrument can usually be used for both methods. AE relies on detection of energy emitted from excited atoms as they relax to their ground state configuration as opposed to measuring the decrease in signal strength due to absorption of energy by ground state atoms being raised to an excited state. Since in AE the source of the measured light is the analyte itself, there is no need for an external light source such as the hollow cathode lamp used in AA. For this reason, the technique is more readily adaptable to multi-element analysis than AA. However, the number of elements readily analyzed by AE is considerably smaller than that detected by AA.

SOURCES OF INTERFERENCE

Spectral interference can affect AA and AE results. It can be caused by the overlapping of a line or band originating from an impurity element with the line being measured. For example, in emission analysis of sodium, the presence of calcium can give rise to spectral interference since thermally stable calcium hydroxide can form in the flame. This compound emits a band of radiation that overlaps the characteristic 590-nm line of sodium. This can be reduced to a certain degree if a monchromator of high resolution is used in AE.

Such spectral interferences are less common in AA than in AE. In AA the line source is the extremely narrow line produced by the hollow cathode lamp, and, therefore, monochromator resolution is less important in AA. However, there are still a few cases of spectral interference in AA. For example, both iron and platinum have absorption lines very near 272 nm, and manganese and gallium have lines near 403 nm.

Problems can be caused by chemical interference, which can decrease the population of free metal atoms and thereby yield an artificially low result. For example, many elements form stable oxides or hydroxides within a flame. Lithium is known to form a hydroxide in the flame. Such interferences can be minimized by increasing flame temperature.

Other types of interference include broad-band absorbance that is caused by molecules that have either formed or not been completely dissociated in the flame or by particulate matter in the flame.

Background Correction

Instrument manufacturers have devised a variety of instrumental methods for background correction. Background correction with a deuterium lamp relies on the fact that this lamp provides broadband continuous radiation in the ultraviolet region. By having a relatively wide slit width, the fraction of this radiation absorbed by the analyte is very small compared to the broadband absorbance due to molecular species in the flame or by scattering. Therefore, this type of interference can be corrected by simply subtracting the absorbance of the deuterium lamp from the absorbance of the hollow cathode lamp.

Another type of background correction utilizes the Zeeman effect. When vapor phase atoms are subjected to a strong magnetic field, a splitting of the electronic energy levels occurs. This produces, in the simplest case, three lines separated by a fraction of a nanometer and is termed the "Zeeman effect." The central, strongest line only absorbs radiation that is plane-polarized with the magnetic field, while the two weaker lines do not absorb radiation of this polarity. By mounting a rotating polarizer after the hollow cathode lamp, absorption by the analyte occurs only during the proper orientation of the polarizer. When the polarizer is in the opposite orientation, no analyte absorption occurs. Since background absorption and scattering occur during both cycles, it can now be subtracted to give only the absorbance due to the analyte.

The Smith-Hieftje technique relies on the observation that when hollow cathode lamps are briefly and cyclically pulsed at high currents, the emission band of the excited species is significantly broadened. The total absorbance from analyte plus background is obtained during the low current cycle, whereas the total absorbance during the high current pulse is primarily due to background. The signals can be subtracted from one another to obtain the corrected, analyte signal.

INDUCTIVELY COUPLED PLASMA SPECTROSCOPY (ICP)

Inductively coupled plasma spectroscopy is another technique for elemental analysis. As with conventional AE, the technique relies on measurement of light emitted when excited state atoms relax to their ground state. The major difference is that ICP accomplishes this through the use of a plasma rather than a flame. The plasma is formed as a result of argon gas being excited by an inductively coupled radio-frequency generator. One of the key elements in the instrument is the plasma torch into which the sample is carried by a rapid flow (~1 L/min) of argon.

The plasma is roughly 2 cm in diameter and is maintained within a water-cooled induction coil at the top of the torch. The torch consists of concentric quartz tubes through which argon flows. The plasma has a very intense, brilliant core. The temperatures in the plasma reach anywhere from 5000 to 7000°C, which is over twice that of most conventional flames used in AE. This higher temperature allows excitation of a greater number of elements than would be possible in a conventional flame, thereby extending the scope of the technique. Furthermore, it shares the advantage of AE over AA in that individual hollow cathode lamps are not required. Therefore, when coupled with either a rapid scanning or a multi-channel monochromator, ICP is a very efficient technique for conducting simultaneous multi-element analyses.

The higher temperature of the plasma in comparison to the flames results in more complete atomization and reduction in chemical interference. Although it would seem that the higher temperature of the plasma would result in increased sample ionization and therefore poorer determination limits, this is not the case because of the suppression effect caused by the large amount of argon ions [3]. Detection limits are typically an order of magnitude better than AA, and the calibration curves are also linear over a much wider range.

Although the various instrument manufacturers have their own designs, there are basically two types of ICP spectrometers: sequential and simultaneous.

In most sequential spectrometers, the light dispersed by a movable diffraction grating is focused on a fixed detector, allowing emission intensities to be measured over a wide range of frequencies. Alternatively, the grating can be kept at a fixed position and the detector moved [4]. Since the scan speed is relatively fast and since there is no need to install and change hollow cathode lamps, the technique is much faster than AA when more than five or six elements per sample are being determined. Indeed, current instruments have throughputs ranging from 20 to 50 elemental determinations per minute [5].

In simultaneous spectrometers, a series or bank of detectors, such as photomultiplier types or diode arrays, are positioned at fixed points about the grating so that light at several, preselected frequencies is measured simultaneously. This is a much faster technique than the sequential method, especially if ten or more elements are being determined per sample. A disadvantage with the simultaneous instruments

is their lack of flexibility. Since only a limited number of detectors can be used, only a limited number of preselected analytical lines can be measured. Typically, instruments can be set up to determine approximately 30 to 40 elements, although some can accommodate more than this.

Therefore, although able to detect more elements at somewhat better detection limits with an extended linear calibration curve compared to AA and AE, the biggest advantage of ICP spectroscopy is speed and especially so when multi-element analyses are performed. However, speed comes at a price. Conventional AA/AE spectrometers can be purchased for $15,000 to $30,000, whereas sequential ICP instruments are typically $50,000 to $75,000, and simultaneous instruments are well over $100,000. Therefore, if only a few samples are being analyzed per day for two or three elements, which is often the case in most coating laboratories, AA or AE is probably the most cost-effective choice.

APPLICATIONS

Approximately 70 elements can be detected in a practical sense with either AA or AE. Detection limits are typically subpart per million. Thus, the techniques are both versatile and sensitive. Although several hours may be required for sample preparation, the actual analysis step is usually extremely rapid. Samples must be introduced into the instruments as liquids of low viscosity with the material to be analyzed in a dissolved state. Some limited work has been done on fine suspension samples.

One of the most common uses of AA spectroscopy in the coating industry is determination of lead. Lead had become a major health concern, and its presence can greatly impact the cost of removal and disposal of old paint from various structures. The commonly accepted method for lead determination is ASTM Test Method for Low Concentrations of Lead, Cadmium, and Cobalt in Paint by Atomic Absorption Spectroscopy (D3335). In this method, the dried paint is ashed to burn off the organic materials and then digested in hot nitric acid. The method is also used to determine cadmium pigments and cobalt contained in some driers.

ASTM Test Method for Low Concentration of Mercury in Paint by Atomic Absorption Spectroscopy (D3624) is used for the determination of mercury that is contained in many common fungicides used in paint. The sample is decomposed at elevated temperature, dissolved in sulfuric and nitric acids, diluted, and analyzed using a cold-vapor AA technique.

ASTM Test Method for Low Concentrations of Chromium in Paint by Atomic Absorption Spectroscopy (D3718) involves ashing dried paint followed by digestion with potassium permanganate and sulfuric acid, dilution, and analysis.

ASTM Test Method for Low Concentrations of Antimony in Paint by Atomic Absorption Spectroscopy (D3717) involves ashing dried paint followed by refluxing with hydrochloric acid and stannous chloride.

Other ASTM atomic absorption and emission tests include:

- ASTM Test Method for Analysis of Aqueous Leachates from Nuclear Waste Materials Using Inductively Coupled Plasma-Atomic Emission Spectrometry (C1109)
- ASTM Test Method of Determining Elements in Waste Streams by Inductively Coupled Plasma-Atomic Emission Spectrometry (C1111)
- ASTM Test Method for Major and Minor Elements in Combustion Residues from Coal Utilization Processes (D3682)
- ASTM Practice for Flame Atomic Absorption Analysis (E663)
- ASTM Determination of Additive Elements in Lubricating Oils by Inductively Coupled Plasma Atomic Emission Spectrometry (D4951)
- A method for determination of zinc in cured films of inorganic zinc-rich primes that has been used in the author's laboratory involves digestion of the sample in 1:1 hydrochloric acid: water for 20 to 30 min followed by filtration and dilution. Results in good agreement with the manufacturer's published values have been obtained for a variety of coatings.

It should be pointed out that the usefulness of AA and AE spectroscopy is not limited to published ASTM test methods. The techniques are versatile, and in-house methods can often be devised to perform a variety of analyses. An excellent source of published test methods can be found in the journal *Analytical Chemistry*, "Application Reviews," usually published in the June 15 edition of every odd-numbered year since 1987 and in the April editions prior to 1987. For instance, the 1989 review [6] listed ten AA and AE methods for coatings and related products. These included determination of lead content in household paints, of nickel and cobalt in coatings for brass, of sodium and silicon in surfactants, and of metallic elements in poly(vinyl chloride). The 1993 review [7] lists 13 AA/ICP methods.

Chromatography

Rolando C. Domingo[1] and updated by Rey G. Montemayor[2]

CHROMATOGRAPHY IS A TERM THAT DENOTES A myriad of laboratory separation processes based on a differential migration phenomenon. It is particularly effective for the resolution and separation of complex mixtures; hence, it can be used as a chemical preparatory method or, more importantly, as an analytical tool. This potent analytical technique has been widely used in the paint industry for a broad range of coating applications from everyday routine analysis to fundamental research into the nature of organic coating systems. Its use has been so extensive that virtually every type of material used in paint has been affected by chromatography.

Chromatography possesses certain inherent features that offer distinct advantages over conventional analytical techniques: complex mixtures, including isomers and homologs, can be separated; most of the equipment is relatively simple and inexpensive; chromatographic procedures are applicable to a broad spectrum of chemical types and are adaptable to both micro- and macro-size samples; and chromatography is capable of both qualitative and quantitative functions even when applied to multicomponent systems.

The term chromatography was coined by Tswett [1] who, in 1906, used powdered chalk and petroleum ether to separate plant pigments into colored zones of isolated pigment. The technique, as described by Tswett was largely ignored for a long time, and it was not until the late 1930s and early 1940s that Martin and Synge [2] applied the technique successfully to colorless materials, but the name has persisted. The term is currently used to signify a broad group of separation techniques, most of which are independent of color.

GENERAL PRINCIPLES

Chromatography is a separation process that is achieved by distributing the components of a mixture between two phases: a stationary phase and a mobile phase. Those components held preferentially in the stationary phase are retained longer in the system than those that are distributed selectively in the mobile phase. As a consequence, solutes are eluted from the system as localized concentration in the mobile phase in the order of their increasing distribution coefficients relative to the stationary phase. Considered simply, the chromatographic process involves the differential migration of sample components as they are moved through a chromatographic system. The rates of migration for the various components are related to their unequal distribution between two phases, a moving phase and a stationary phase. Distributions are determined by driving and resisting forces that are exerted between the two phases and the components in the sample. These forces are influenced by the chemical structure and the size and shape of molecules present in the chromatographic system and in the sample. Generally, the stationary phase is a finely divided solid serving as an adsorbing surface or a liquid supported by some inactive porous media; the mobile phase is usually liquid or gas. The effectiveness of a chromatographic separation depends upon proper selection of phases, and, although the choice is often made on an empirical basis with heavy reliance on experience, the best results are obtained by the application of established theoretical principles. Phases are selected so as to take advantage of some functional incremental differences in the properties of the compounds to be separated; for the most part, these are differences in molecular size, solubility in the liquid phase, and adsorption to the solid phase. In today's capillary gas chromatographic columns, solid supports are no longer used. Instead, the liquid or stationary phase is coated on to the wall of the capillary tubing. To improve thermal stability, the stationary phases are oftentimes chemically bonded to the tubing wall.

In practice, there are certain basic fundamentals that apply to all differential migration techniques, regardless of the separation media used: flow rates must be slow enough to allow equilibrium to occur between phases; solute concentration must not exceed the adsorption capacity of the stationary phase; and the greater the difference in partition ratio between phases, the shorter the migration path required for resolution. Since the efficiency of all chromatographic processes is governed by the above factors, these concepts should be kept in mind when a system to be used for a given separation is being considered.

Chromatographic separations are conducted usually in columns of carefully graded sorptive powders, in sheets, or strips of porous media such as paper, or in thin layers of powdered adsorbents spread on rigid surfaces. After a suitable system has been selected, a small quantity of the mixture is placed at one end of the chromatographic column and transported through the stationary phase with solvent or gas. Isolated compounds are detected "on column" if they are visible or "off column" by chemical or electronic means after leaving the column. A permanent record of the

separation may be obtained by photographing the column, by plotting some property of the separated components against elution volume on graph paper, or by electronic recording. Such records are referred to as chromatograms.

GENERAL CLASSIFICATION OF CHROMATOGRAPHY

As all chromatographic separations are carried out using a mobile and stationary phase, the primary classification of chromatography is based on the physical nature of the mobile phase. The mobile phase can be a gas or a liquid giving rise to the two basic forms of chromatography, namely gas chromatography (GC) and liquid chromatography (LC). The stationary phase can also take two forms: solid and liquid, thus providing two subgroups of GC and LC, namely; gas–solid chromatography (GSC) and gas–liquid chromatography (GLC), together with liquid–solid chromatography (LSC) and liquid–liquid chromatography. The different forms of chromatography are summarized in Table 1.

GENERAL METHODS

Frontal, displacement, and elution analysis are the three basic methods for conducting chromatographic separations, and each has its own unique function. Separations are determined by adsorption or partition interplay between sample, stationary phase, and moving phase.

Frontal Analysis

Frontal analysis separations are made by the continuous addition of the sample onto a column containing an adsorbent. As the sample passes through the column, the component having the lowest adsorption affinity for the adsorbent emerges first. After the most strongly adsorbed component has saturated the column, the sample flows through the column unchanged. Only a limited portion of the least adsorbed component can be obtained in pure form. Frontal analysis is not an effective method for resolving mixtures, but it does provide a means of treating solutes having strong adsorption characteristics. This means of separation is seldom used in the coatings industry because of the advances in column technology for both liquid and gas chromatography.

Displacement Analysis

In this method, a concentrated portion of a sample is adsorbed onto a column, followed by the addition of a solvent (developer) that is adsorbed more strongly than any of the components in the sample. As the developer passes through the column, the components are displaced and forced ahead of it. Components will also displace one another so that the one least strongly adsorbed emerges from the column first, followed by the others in the order of increasing adsorption affinity. The component with the greatest adsorption affinity elutes last, immediately ahead of the displacing solvent. Under optimum conditions, each component will move through the column as a "belt" of pure material. A graph, obtained by plotting volume against some physical property of the effluent, will contain a series of steps. Under optimum conditions, each component will move through the column as a "belt" of pure material. A graph, obtained by plotting volume against some physical property of the effluent, will contain a series of steps. Under standardized conditions, the height of each step is used for identification, and the length of each plateau is used to determine relative amounts. When put to practice, all reversibly adsorbed components are moved through the column, but they are not resolved completely. The trailing edge of one component will overlap the leading edge of the following component, and, although it is not possible to completely separate each component in its pure form, normally a relatively pure fraction of each is attainable.

Elution Analysis

Elution processes are conducted by introducing a concentrate of the sample onto a column followed by the addition of an unadsorbed moving phase. As the sample mixture is washed through the column, components are selectively retarded and separated into discrete zones that are isolated by the presence of the moving phase between zones. This procedure contrasts with displacement and frontal methods by having the eluting solvent pass through the sample. Theoretically, complex mixtures can be completely resolved; hence, elution chromatography has the potential of being a good procedure for qualitative and quantitative analysis.

Of the three processes discussed, elution chromatography is the most efficient method for resolving mixtures, which accounts for its being the most widely used form of chromatography.

Adsorption Chromatography

Chromatography can be further classified as adsorption and partition chromatography. In adsorption chromatography, the stationary phase is a solid, most often a powder or granular adsorbent, and the mobile phase is either a liquid or gas. Sample components are separated according to their relative adsorption on active surfaces as they are percolated through an adsorbent bed. For any particular component, the degree of adsorption is related to the competitive attraction exhibited by the adsorbent and developing phase. Thus, if a component is attracted strongly by an adsorbent and attracted weakly by the moving phase, it shows little or no movement through the column. Conversely, if it shows a greater affinity for the moving phase than for the adsorbent, it will tend to move along with the moving phase. Hydrogen bonding, dielectric constants, and dipole moment of the sample and the two phases are factors that greatly influence adsorption separations. In general, strong adsorption is favored by the presence of highly polar compounds in weakly polar moving phases.

LSC denotes the use of a liquid moving phase, whereas GSC indicates a gaseous moving phase. Prior to the introduction of partition chromatography by Martin and Synge in 1941 [2], adsorption chromatography was used exclusively. A vast selection of adsorbents and mobile phases are available, providing a great deal of flexibility for separating mixtures. Various aspects of adsorption chromatography, including technique and equipment, will be discussed in greater detail during the treatment of specific methods such as "classical column chromatography," thin layer chromatography, etc.

Partition Chromatography

Partition chromatography is distinguished from adsorption chromatography by the presence of a liquid that is positioned in the system by sorption to an inactive solid support. The liquid layer is the stationary phase, and the solid merely serves as a support. Separation of compounds is related to their differential solubility in two immiscible phases. Hence, a compound demonstrating a solubility preference for the stationary liquid phase will have its passage through the column retarded. Those that are less soluble in the stationary liquid phase, but readily soluble in the mobile phase, tend to move unimpeded through the column. In a static experiment with a given set of phases, a compound will be distributed between phases in a characteristic manner. This property is referred to as its partition coefficient, *k,* and may be defined as follows:

$$k = \frac{[\text{concentration of compound in stationary liquid phase (g/ml)}]}{[\text{concentration of compound in moving phase (g/ml)}]} \quad (1)$$

Since components are separated by virtue of differences in their partition coefficients, conditions of a test are adjusted so as to take advantage of some factor peculiar to each component that magnifies quality differences in k values. Fortunately, only slight differences are required for separation, and such differences can be achieved by proper selection of stationary liquid phase.

Although partition chromatography is historically more recent, it has surpassed adsorption chromatography as a method for separating complex mixtures. In partition chromatography there is a more rational relationship between the chemical character of materials and their chromatographic behavior, which accounts for its effectiveness when applied to the separation of closely related compounds such as isomers and members of a homologous series. Adsorption chromatography, however, is more limited in its applications; it will distinguish between classes of compounds, but there is little sub fractionation within classes.

LIQUID CHROMATOGRAPHY

Of the various forms of chromatography, the form using a liquid eluent came first. LC is characterized by the employment of a liquid moving phase; the stationary phase may be either liquid or solid. The separation of molecules is based on their preference for a liquid or solid stationary phase relative to a liquid moving phase. LC encompasses established techniques such as paper, thin layer, "classical column," and gel permeation chromatography, all of which have been used extensively for routine and research purposes. For the purpose of clarity and continuity, the different chromatographic techniques will be discussed as separate entities, but, in some cases, there has been a fusion of techniques. For instance, papers have been impregnated with ion exchange materials; gels, the material commonly associated with gel permeation chromatography, have been spread on thin plates for thin-layer separations.

"Classical Column" Chromatography

The term "classical column" chromatography is used here to define procedures usually associated with older forms of chromatography. The method involves the introduction of a sample onto a column packed with adsorbent; separations are facilitated by the addition of a displacing or eluting solvent.

Apparatus and technique—The essential equipment consists of container, adsorbent, and developing solvent. The container for the column of adsorbent is usually a glass tube, from about 5 to 50 mm in internal diameter, with a working height of from 5 to 25 times the diameter. Columns prepared from plastic and metal tubes have also been used. Fritted glass disk, perforated plastic, cotton, or glass wool may be used at the base of the column to support adsorbents such as silica, magnesium and aluminum oxides, calcium phosphate, charcoal, and cellulose. Adsorbents vary in their capacity and activity, with activity increasing with decreasing particle size and water content. If practical flow rates are to be realized, it is necessary to use relatively large particles, but not so large as to reduce the capacity below reasonable limits. In addition, narrow mesh ranges provide more uniformly packed columns and columns of higher efficiency. Adsorbents may be packed in two ways, as a dry powder or as a slurry. To ensure uniformity, the tube should be vibrated frequently and a vacuum or pressure applied during addition of packing material.

Although the activity and capacity of different adsorbents are not the same, the sequence of eluting power for different solvents is the same for any given adsorbent. In order for separation to occur, the eluting solvent must be appropriate to the packing material and sample. For example, a very polar solvent will displace the sample completely with little or no separation of components; on the other hand, a very nonpolar solvent may cause all of the components to adsorb on one section of the column with little migration or separation of components. A general practice is to start the analysis with the most nonpolar solvent and gradually change to solvents of increasing polarity. The process of systematically changing the composition of eluting media during a chromatographic analysis is referred to as gradient elution [2]. Strain [3,4] lists absorbents according to their absorptive strength and solvents in the order of their eluting power.

An analysis is conducted by introducing a sample in a few milliliters of nonpolar solvent and allowing it to flow onto the column. The eluting solvent is added, in small increments at first, and then in large quantities. At no time during the analysis is air drawn through the column. If colored compounds are chromatographed, they are detected visually on the column or in the effluent. Certain

colorless compounds may be examined by fluorescence when exposed to ultraviolet radiation, or the packing may be extruded and the components detected after treatment with reagents. Eluted components are identified by dividing the effluent into aliquots and determining such properties as refractive index, nonvolatile content, *p*H, optical density, etc: Automatic fraction collectors, actuated by weight of fraction or a timing device, can be used to avoid manual collection of effluent.

Classical chromatography, as it is commonly used, is relatively simple but lacks detector sensitivity and is time consuming. The latter is particularly true when a fresh column is required for each analysis. Nevertheless, this type of chromatography has contributed to the general knowledge of organic coatings and to paint analysis.

Applications—ASTM Test Method for Hydrocarbon Types in Liquid Petroleum Products by Fluorescent Indicator Adsorption (D1319) describes the determination of hydrocarbon types in petroleum products. A column is packed with activated silica gel containing a mixture of fluorescent dyes. A hydrocarbon mixture is introduced onto the gel, and isopropyl alcohol is added to desorb the sample down the column. The hydrocarbons are separated according to their adsorption affinities; aromatics are retained the most tenaciously, immediately followed by olefins, and finally by saturated hydrocarbons. The fluorescent dyes are also separated selectively with the hydrocarbon types and make the boundaries of the aromatic olefin and saturate zones visible under ultraviolet radiation. The volume percent of each type of hydrocarbon is calculated from the length of each zone. A separation of this type is an example of adsorption chromatography by displacement; the developing solvent in this case is isopropyl alcohol. Hydrocarbon types in mineral spirits and VM&P naphtha have been determined using this method.

Loeblich and Lawrence [5] used partition chromatography for the qualitative and quantitative analysis of rosin and modified rosin products. The column is packed with 2-aminopyridine-furfuryl alcohol on silicic acid. The alcohol serves as the stationary liquid phase; isooctane is the eluting solvent. Fractions are collected and titrated with 0.01 N sodium hydroxide solution.

Swann et al. [6] used carbon black and asbestos to separate phthalate plasticizers from phthalate resins. Phthalate resins were retained selectively on the column, and phthalate plasticizers were detected and measured by saponification of the effluent.

HIGH PERFORMANCE (OR HIGH PRESSURE) LIQUID CHROMATOGRAPHY

In recent years the term liquid chromatography has acquired new significance by being used to denote a completely integrated column-detector-recorder system. New developments in instrumentation make use of the principles and practices commonly associated with gas chromatography, the object being the attainment of rapid and high-efficiency separations. Traditional methods, out of necessity, employ large samples, slow flow rates, and short columns, conditions that are not conducive to rapid, efficient analysis. With the advent of high-pressure flow systems and highly sensitive continuous flow detectors, operating conditions closely approaching those used in gas chromatography may now be used. The total unit consists of thermostated columns, solvent reservoir, degasser, metering pump, detector, and strip chart recorder/electronic integrator.

The resurgent interest in liquid chromatography has prompted an ever-increasing number of instrument manufacturers to produce highly sophisticated instruments that are capable of multiple modes of operation including adsorption, partition, and gel permeation separations. The term high performance (or high pressure) liquid chromatography (HPLC) will be used in this section to designate adsorption and partition separations based on advanced liquid chromatography technology. Descriptions of liquid chromatographs have been presented by Lambert [7], Stouffer et al. [8], and Jentoft and Gouw [9], the principal differences being in the techniques used to monitor the sample stream.

HPLC has already reached the level of acceptance enjoyed by many other chromatographic techniques. Its potential as an analytical tool is still creating an enormous amount of interest. In the past, most publications were concerned with the refinement of instruments with less emphasis on applications. Presently, publications are now focusing on the applications of HPLC in the paint and coatings industry. HPLC complements other forms of chromatography. For example, HPLC can be used for the analysis of compounds having a broad range of molecular weight, whereas thin-layer and paper chromatography are limited to nonvolatile compounds and GC is limited to those that can be vaporized. HPLC is usually regarded as a relatively slow method when compared to other chromatographic techniques. However, the time necessary to produce a separation is related directly to the resolution required. HPLC can make separations of simple mixtures at speeds comparable with GC; complex samples may still require several hours. Readers are encouraged to read ASTM Practice for Liquid Chromatography Terms and Relationships (E682).

Apparatus and technique—Fig. 1 shows the pertinent components of a liquid chromatograph. Solvent from one of the reservoirs is moved through a degasser by a pulse-free pump that is capable of delivering flow over a wide range of pressures. The flow is split into two streams; one is directed to the reference side of a differential detector, the other is allowed to pass through a sample injector, fractionating column, and finally to the sample side of the same detector. The sample is introduced with a syringe, or sample loop, located at the entrance to the column, and the effluent from the column is generally monitored by a continuous flow differential detector.

Most column packings used in traditional methods for both adsorption and partition separations may be used for HPLC, for example, silica gel, alumina, diatomaceous earth, etc. There have been, however, newly developed packings that greatly extend and enhance the use of HPLC. In the past, the development of LC was impeded by hydraulic difficulties and detector problems, but with the advent of improved solvent transport equipment and high-performance continuous flow detectors, HPLC has been elevated to a position of new prominence. At this point, it is needless to belabor the importance of each of these two factors. However, the performance characteristics of the various detectors should be carefully considered since the type used directly influences the effectiveness of the total system. Some detectors are selective, responding to only certain classes of compounds,

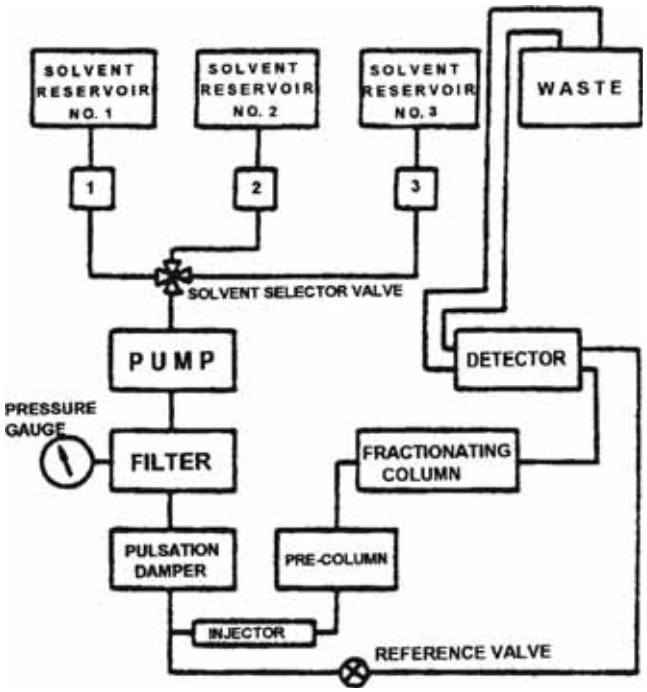

Fig. 1—Schematic diagram of high-pressure liquid chromatograph.

while others are applicable to a wide range of classes and have broader application. For this reason the best use is made of detectors in the context of the complete system and sample to be analyzed. Photometric, refractometric, calori-metric, radiometric, polarographic, and ionization detectors have been evaluated by Huber [10]. He concluded that all of them can be used for HPLC, but that a universal, all-purpose detector is not yet available. Some of the more conspicuous detectors will be discussed briefly so as to provide background regarding principle of operation and area of usefulness.

At the present time, refractive index comes closest to being the universal detector for liquid chromatography. Detection depends on the difference in the refractive indexes of pure solvent flowing through the reference side of the detector and of the effluent from the analytical column; measurement is nondestructive to the sample, the level of sensitivity is good, and operation is simple. Use of the refractive index detector in liquid chromatography is discussed in ASTM Practice for Refractive Index Detectors Used in Liquid Chromatography (El303-95 (2009)). As with other nondestructive detectors, when used in conjunction with an automated fraction collector, the sample can be isolated and subjected to further treatment.

The heat of adsorption detector is also applicable to a wide range of materials since it responds to an almost universal property of materials, heat of adsorption. Thermal changes, induced by the desorption and adsorption of the sample, are sensed, amplified, and recorded as positive and negative peaks on a chromatogram.

The flame ionization detector, also called chain, cord, and belt detectors, combines high sensitivity and quantitative analysis with wide dynamic range. In flame ionization detection, all of the carrier leaving the column can not be directed through the detector; instead, a small wire or belt is passed continuously through the eluting stream collecting a portion of the sample. The carrier solvent is flash evaporated in one chamber, and the sample residue is then moved into a pyrolysis zone where the sample is decomposed thermally and detected with a flame ionization detector. Since the carrier solvent is removed completely, this type of detector is not affected by gradient analysis, but at the same time, its use is restricted to nonvolatile compounds. Obviously, this type of detector is well suited for the analysis of resins, polymers, and oils.

Photometric detectors measure the difference in ultraviolet light adsorption between a sample and reference stream. Since ultraviolet adsorption is parameter-specific, this type of detector is limited to chromophores. This property, of course, can be advantageous when non-ultraviolet and ultraviolet adsorbing compounds emerge from a fractionating column together.

Applications—Bombaugh et al. [11] were able to separate ethylene glycol, cdiethylene glycol, and triethylene glycol using a column packed with porous silica beads; the eluting solvent was water in methyl ethyl ketone, and the eluted compounds were detected using a differential refractive index detector. Poulson and Jensen [12] used an adsorption column composed of 100 to 200-mesh silica gel for the separation of alkene-alkane hydrocarbons. Diatomaceous earth coated with various liquids was used to separate and determine aromatic hydrocarbons [13]. The compounds were sensed with a differential photometric detector. ASTM Practice for Testing Fixed-Wavelength Photometric Detectors Used in Liquid Chromatography (E685-93 (2005)) discussed the use of the fixed wavelength photometric detectors in liquid chromatography.

SUPERCRITICAL FLUID CHROMATOGRAPHY

Supercritical fluid chromatography (SFC) is a relatively recent chromatographic technique, having been commercially available since only about 1982. What differentiates SFC from other chromatographic techniques (GC and HPLC) is the use of a supercritical fluid such as liquefied CO_2 as the mobile phase. As such, the entire chromatographic flow path must be pressurized. Compared with HPLC, SFC provides rapid separations without the use of organic solvents. With the desire for environmentally conscious technology, the use of CO_2 as the mobile phase contributes to efforts to reduce the introduction of environmentally harmful organic chemicals. In addition, SFC separations can be done faster than HPLC separations because the diffusion of solutes in supercritical fluids is about ten times greater than that in liquids. Although solute diffusion in supercritical fluids is about three times less than in gases, SFC allows high resolution at a much lower temperature thus allowing fast analysis of thermolabile compounds. SFC is compatible with both HPLC and GC detectors. As a result, optical detectors, flame detectors, and spectroscopic detectors can be used. Because of the high pressures of SFC, care has to be taken such that detector components are capable of withstanding the usual range of pressures used in SFC systems. This chromatographic technique is not used in the paints and coatings industry.

PAPER CHROMATOGRAPHY

Paper chromatography, as the name implies, uses paper as the separation media. A strip of filter paper is spotted

with the sample near one edge and is arranged so that developing solvent can move by capillary action through the sample. The differential distribution of components between phases (paper and developing solvent) causes them to migrate at characteristic rates. If compounds are colorless, reagents may be applied to reveal them as circular or elliptical spots.

The popularity of paper chromatography can be attributed to several desirable qualities. The method is extremely versatile and simple, it allows for simultaneous analysis of several samples on one paper, and optimization of the developing solvent is easily controlled. On the other hand, one should be cognizant of certain disadvantages. The sample must be non-volatile or be capable of conversion to a nonvolatile derivative before analysis, the length of the migration path is limited, and quantitative analysis is moderate. Most important, extraordinary precautions must be taken to reproduce conditions of test in order for retention data to be reproducible and significant.

Apparatus and technique—The equipment necessary to conduct paper chromatography involves materials common to most laboratories. Whatman No. I filter paper has been the type most widely used, but for many analyses, other types of filter papers are adequate and sometimes preferred. A large assortment of containers has been employed as developing chambers: glass jars, test tubes, graduated cylinders, specimen tanks, and pipes can all be used if thev are provided with tight-fitting lids. An unlimited number of liquid mobile phases are available; the type used is dictated normally by the polarity of the sample.

Capillary action is the principal dynamic force involved in ascending, lateral, or radial paper chromatography. However, in the case of descending chromatography, the movement of solvent is initiated by capillary action and finished by gravity. Occasionally, particularly when complex mixtures are encountered, it may be necessary to employ, a two-dimensional technique. In this type of analysis the separation is carried out using one solvent in one direction. drying the sheets, and finishing the separation at right angles with another solvent. In all paper chromatographic separations, it is essential that the internal volume of the developing chamber be saturated with vapors from the eluting solvent.

If cellulose papers are exposed to water vapor, they will adsorb about 22 % of water that may serve as the immobile liquid phase for reverse phase chromatography. Where water is impractical as an immobile phase because of sample insolubility, papers can be impregnated with other liquids such as kerosene, silicone oil, and olive oil. It is sometimes necessary, for the solution of special problems, to alter the composition of the paper. This can be done by direct chemical treatment or by the addition of a material having special properties, such as an ion exchanger. Paper of this type represents a departure from conventional paper chromatography since principles based on other techniques are involved.

Under stringently controlled conditions, compounds may be identified by their R_f values. The R_f value is the ratio of distances traveled by a compound and the solvent front, expressed as follows:

$$R_f = \frac{\text{distance traveled by compound}}{\text{distance traveled bt solvent front}} \qquad (2)$$

Although the use of R_f values is well documented in the literature, they are often difficult to reproduce and should be used with caution. When R_f values are reported, detailed information concerning all of the operating parameters must be stated.

Since it is possible to conduct multiple analyses on one sheet, an unknown mixture can be identified by analyzing it in parallel with standard compounds; direct comparison can be made with respect to the retention characteristic of both the sample and standard. If standards of known concentration are run simultaneously with the unknown, the amounts of each isolated component can be estimated from their relative intensities.

For additional information regarding the theory and practice of paper chromatography, the reader is referred to books by Hais and Macek [14] and Block et al. [15].

Applications—Dicarboxylic acids and polyols have been identified in polyesters [16] by paper chromatography. Following dissolution of the resin with alcoholic potassium hydroxide, isolated dipotassium salts were converted to their corresponding acids and separation was accomplished by ascending technique. Polyols recovered from the saponification filtrate were separated by a two-dimensional technique; chloroform-ethanol mixture, used first in one direction, was followed by elution at right angle with ether saturated with water. Dicarboxylic acids were visualized with bromcresol purple, and polyols were detected by spraying with ammoniacal silver nitrate. Tawn and May [17] identified dicarboxylic acids and polyols in alkyd resins using a similar procedure.

Mills and Werner [18] identified various types of natural resins using reverse phase chromatography. Papers were wet with kerosene and were blotted to remove excess kerosene. Samples were chromatographed with a liquid moving phase consisting of isopropanol-water-kerosene. The papers were dried, sprayed with a carbon tetrachloride solution of phenol, and exposed to bromine vapor. Colors varied according to the type and amount of resin.

THIN-LAYER CHROMATOGRAPHY

In thin-layer chromatography (TLC) an aqueous slurry of a finely divided adsorbent mixed with a binder is spread on a glass plate so that a uniform, coherent film adheres to the glass. Coated plates are dried and activated by baking in an oven for a prescribed length of time. An analysis is conducted in much the same manner as in paper chromatography. A plate is spotted with a sample and placed in a chamber containing solvent. After the developing solvent has irrigated the TLC plate, the plate is removed from the tank, dried, and compounds are detected with appropriate reagents. As in paper chromatography, the vital driving force exhibited by the mobile phase is that supplied by capillary action; separation is due to adsorption or partition processes.

Paper chromatography and TLC are similar, and both share some of the same advantages such as high sensitivity, selectivity, and low cost. TLC, however, provides sharper zone separation and increased speed, 20 or 30 min for most TLC analyses as opposed to several hours for paper chromatography. TLC is subject to most of the disadvantages described for paper chromatography, for example, compounds must be nonvolatile, have a limited elution path, etc.

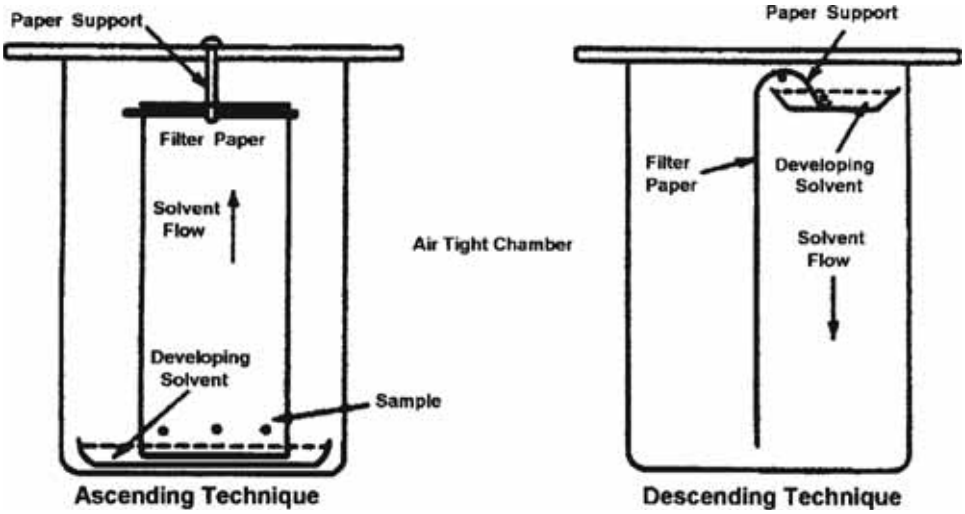

Fig. 2—Apparatus for paper chromatography.

Apparatus and technique—Equipment requirements for TLC are minimal. The basic materials, as shown in Fig. 2, consist of a tank, plate, adsorbent, visualization reagent, rack, and adsorbent applicator. Relatively inexpensive equipment can be purchased from distributors of chromatographic supplies; if necessary, however, apparatus can be usually improvised from material found in most laboratories. A developing tank must have a tight-fitting lid, and it should be large enough to receive 2 × 8 in. (5.08 × 20.32 cm) or 8 × 8 in. (20.32 × 20.32 cm) plates, but not so large as to require a large solvent reservoir. A "tankless" system can be arranged by sandwiching the thin layer between two plates and placing the sandwiched layer in a shallow trough containing solvent. The nature of the adsorbent plays a major role in determining the type of separation that will be obtained. In a broad sense, any of the adsorbents used in column chromatography can be used to prepare thin films provided they are available as powders of uniform particle size. Silica gel and aluminum oxide are used most frequently. The homogeneity and quality of adsorbent powders are important factors to be considered if well-defined results are to be obtained. For a given adsorbent, the migration of components in a mixture is determined by the choice of mobile liquid phase; its polarity can be altered to enhance or suppress the movement of the components. For example, if a sample moves with the solvent front, the polarity of the mobile phase should be reduced by choosing a solvent of lower polarity or by mixing solvents of different polarity. Conversely, if a sample shows little tendency to move, the polarity of the eluting solvent is increased by selecting a solvent occurring lower in the eluotropic series or by changing the ratio of polar and nonpolar solvents, favoring the polar solvent. The eluotropic series, solvents arranged in order of polarity, and other solvent activity have been described in books [19,20]. The preparation of chromatoplates is relatively easy and can be accomplished by using several techniques: pouring, dipping, spreading, or spraying, The first two methods require no special equipment, but they lack the refinement needed to provide uniform films. The spray technique is messy and does not always yield films of uniform thickness. By far the most popular technique is that which uses a draw bar. Films are prepared by mixing adsorbent, binder, and water until a homogeneous slurry is obtained. Glass plates, usually 2 × 8 in. (5.08 × 20.32 cm) or 8 × 8 in. (20.32 × 20.32 cm), are aligned on a perfectly flat surface. A spreader is positioned on the end plate, charged with the slurry, and drawn across the plates with constant pressure and speed. For analytical purposes, film thickness should be in the range of 0.2 to 0.5 mm. Chromatoplates are air dried and, if desired, activated by heating at elevated temperatures. Although glass is the most common substrate, plastic and fiber glass sheets have been used successfully. TLC sheets from plastic and fiber glass can be cut and shaped with scissors. Pre-coated glass plates and plastic sheets can be purchased from several commercial sources, and, although the price per plate is increased substantially, the cost is still within the budget of most laboratories. A solution of the sample may be transferred to the chromatoplate with a micropipette or syringe. After the diluting solvent has evaporated, the plate is transferred to a developing chamber where it is irrigated with the developer solvent. If a two-dimensional technique is necessary, the plate is turned 90° and treated with another solvent. The plates are dried and then sprayed with an appropriate visualization reagent.

Methods of identification are similar to paper chromatography; R_f values or "parallel analysis" are standard techniques for TLC. Additional information may be obtained by removing spots with a spatula and subjecting them to chemical or instrumental analysis. Visual comparison with standards of known concentrations run simultaneously is often sufficient for estimating the amount of a component. If more precise quantitative information is required, instrumental methods are used. Densitometric techniques measure the density of color or acid char on the plate and relate this property to the amount of sample present. With all quantitative TLC procedures, it is important to rigidly control sample application, adsorbent quantity, and solvent composition. For an in-depth treatment of TLC theory and practice, the reader is referred to books by Truter [19], Bobbitt [20], Randerath [21],and Stahl[22].

Applications—the utilization of TLC for paint research and routine applications has been illustrated by Privett

and Blank [23] and Rybicka [24]. The former dwells on the many general applications to fats and oils that are important to the paint chemist. Privett and Blank also demonstrated the use of TLC for the determination of total saturated fatty acids in oils, and an investigation of a more basic nature illustrated the usefulness of thin films for elucidating mechanisms involved in the auto-oxidation of oils. An interesting application, as described by Rybicka, illustrates the utility of TLC for monitoring glycerolysis reactions. Periodic sampling and TLC analysis on silicic-acid-coated plates were used to show how triglyceride content is decreased, accompanied by an increase in mono- and diglycerides. Similar studies with other polyols and oils were described.

A very comprehensive survey of TLC methods as applied to lipids has been made by Mangold [25]. Included are details for the separation of glycerides, fatty acids as methyl esters, and cis- and transisomers along with other facets of lipid analysis. Many of the methods are capable of yielding information relevant to the analysis of organic coating materials. Knappe [26] demonstrated the application of TLC to a broad spectrum of coating materials including polyols, dicarboxylic acids, fatty acids, and hydrolysis products from nitrogen resins. Numerous chromatograms and comprehensive retention data were presented to illustrate applications. Techniques for the fractionation of materials used by the plastic industry, but of importance to the paint chemist, have been described [27–29]. These data include tables of R_f values of polyhydric alcohols, dicarboxylic acids, and plasticizers. An impressive list of 40 plasticizers is presented in Ref. [29]. Separations were performed on silica gel layers using methylene chloride as the mobile phase. Antimony pentachloride was the primary visualizing agent.

Potentially, TLC promises to be an extremely valuable tool for research and quality control problems, and wider acceptance by the paint industry should be seen in the near future. The commercialization of precoated TLC plates from several manufacturers should alleviate some of the reproducibility problems associated with "homemade" TLC plates prepared in the past. Used to its fullest potential, TLC techniques can be used to screen and/or separate a wide variety of relatively nonvolatile materials prior to HPLC analyses.

GAS CHROMATOGRAPHY

Of the various forms of chromatography, that using a gaseous moving phase has proved to be the most effective for the analysis of organic coating materials. As in most chromatographic processes, the separation of compounds may occur by partition or adsorption activity—GLC and GSC, respectively. The equipment for, and the execution of, both forms are similar; however, due to its versatility and effectiveness, GLC has made a much greater impact on paint analysis, and for that reason it will be emphasized and discussed at considerably greater length. A glossary of GC terms can be found at the end of this chapter.

The primary object of this discussion is to impart to the reader a basic concept of GC processes and to focus attention on the many applications to paint analysis. Within the scope of the discussion, it will be only possible to etch the surface of present GC knowledge. If the references appear to be numerous, it is because the technique has such broad application and not because it has been exhaustively investigated.

GC is a separation technique that uses a gaseous moving phase to transport volatilized components of a sample through a small diameter tube containing a solid adsorbent or a liquid fixed to an inert porous solid. As the components advance through the column, they are retarded selectively by sequential adsorption on a solid stationary phase or by solubilization in a liquid stationary phase. A sensing device, located at the exit of the column, detects the various components by responding electronically to some physical or chemical property. From the time of appearance and the magnitude of the signal furnished by the detector, information regarding the number, type, and concentration of components can be usually ascertained.

Since the advent of GC, many time consuming and laborious test procedures have been reduced to routine methods of short duration. In addition, the unique responsive capability of GC permits the accumulation of analytical information, much of which cannot be obtained by conventional techniques. In short, GC is characterized by versatility, reliability, and speed.

The outstanding popularity and performance of GC can be attributed to features that are inherent in this type of analysis. Any material that is volatile or can be converted to a volatile derivative will respond to GC. GC is extremely sensitive—as little as one nanogram of some materials can be detected. Rapid and efficient analysis is made possible by the low density and viscosity of carrier gases, which permits rapid mass transfer between phases, thereby allowing rapid flow rates. Columns can be used repeatedly; several hundred analyses on one column are not unusual. The production and interpretation of data are relatively uninvolved. On the other hand, GC has certain disadvantages. Materials remaining on a column are not detected. Owing to the empirical nature of the technique, chemical or instrumental confirmatory tests may be necessary to verify the presence of a compound, particularly when background information concerning the sample is lacking.

Ever since its introduction by James and Martin [30] in 1952, a wealth of GC information has appeared in the literature that has swelled to mammoth proportions. The retrieval of such information is readily made possible through the use of compiled classified indices such as bibliographies [31,32] and annual volumes of Gas Chromatography Abstracts [33,34]. In addition, for current developments, Preston Technical Abstract Company [35] offers a weekly abstract service consisting of tides of papers and abstracts. Reviews [36–46] reflecting specific application to organic coatings have also been published. ASTM Committee E19 on Chromatography's Chromatographic data compilations [47–50] are arranged according to compound and liquid phase; data include relative indices for a vast number of compounds obtained in different columns. Committee E19 has also been responsible for the publication of two general methods, ASTM Practice for Packed Column Gas Chromatography (E260) and ASTM Practice for Gas Chromatography Terms and Relationships (E355). ASTM Committee D01 on Paint and Related Coatings, Materials, and Applications also published Practice for Direct Injection of Solvent-Reducible Paints Into a Gas Chromatograph for Solvent Analysis

(D3271-87 (2006)) and ASTM Test Method for Analysis of Dichloromethane and 1.1,1-trichloromethane in Paints and Coatings by Direct Injection Into a Gas Chromatograph (D4457-85).

Gas-Liquid Chromatography

Various terms such as gas-partition, vapor-phase-partition, gas-liquid-partition chromatography, and vapor fractometry have been used interchangeably when referring to GLC. However, the name GC is probably the most commonly used.

GLC is characterized by the presence of a stationary liquid phase, usually a nonvolatile liquid or solid that is liquid at the operating temperature, supported by the wall of a tube or by sorption to an inert porous material such as diatomaceous earth. In GLC, the components to be separated are vaporized at the entrance of a partition column and moved through the column by a continuous flow of inert gas. For the most part, the rate of migration exhibited by components is dependent upon their degree of solubility in the immobile liquid phase. Very soluble molecules are dissolved readily by the stationary phase, and their passage through the column is retarded. Compounds that have poor or moderate solubility in the liquid phase spend more time in the carrier gas and move through the column rapidly. Ideally, the multiplicity of variable conditions can be regulated so that each compound will reach the end of the column at different times where they are detected electronically as they leave the column.

The distribution of a compound between phases is referred to as its partition coefficient. Although the partition coefficient difference may be very small in a static experiment where only one equilibrium occurs, separation is possible through magnification of that difference by a continuous series of equilibria that is the normal occurrence during chromatographic separation. Since the partition coefficient is affected directly by the solubility characteristics of the liquid phase, the equilibrium for a given compound can be shifted by using stationary phases at different chemical structures. Liquid phases of varying polarity are available in great number, and it is the exploitation of their different selectivities that accounts for the tremendous flexibility and effectiveness of GLC.

Apparatus and technique—the essential components of a gas chromatograph are shown schematically in Fig. 3. In the following discussion of equipment, it will be convenient to explain the process under its operational stages, which may be briefly summarized as follows. The flow of gas, usually from a compressed gas cylinder, is adjusted to desired levels with a series of pressure and flow regulators and split into two streams; one is allowed to flow through the reference side of a differential detector and the other is directed to the injection system, which is located immediately ahead of the column. This segment of the chromatograph, the injection port or flash vaporizer, is maintained at a temperature sufficiently high to cause instantaneous vaporization of the sample in the flowing carrier gas. Introduction of liquids and solids in solution is accomplished most often by injection through a self-sealing silicone rubber septum with a hypodermic syringe. The sample is carried immediately onto the column where the various components are separated by virtue of their different partition coefficients. As the components emerge from the partition column, they pass through a sensing device that transmits an electronic signal proportional to the concentration of the sample to a potentiometric strip recorder or an electronic integrator.

To provide maximum performance and flexibility, the injection port, column oven, and detector should all be individually thermostated. A rule of thumb is that the temperature of the injection system and detector should be at least 25°C higher than that of the column.

The choice of carrier gas is limited to a few inert gases, and this is restricted even more by the type of detector used. The most widely used carrier gases are helium, nitrogen, hydrogen, and argon.

A GC detector must be capable of sensing minute changes in the composition of the carrier gas in a reproducible and precise manner. In order to perform effectively, GC detectors must have high sensitivity, linear response, and low noise level. Secondary factors such as low cost, simplicity, and ruggedness are also desirable. The two most prominent detectors are thermal conductivity (TC) and flame ionization (FID). TC detectors, also called katharometers, consist of two filaments heated electrically and arranged in a Wheatstone bridge circuit; one filament is exposed to pure carrier gas and the other is located in the carrier gas stream emerging from the analytical column. When the carrier gas from the column is diluted with the sample, the temperature and resistance of the sensing filament increases, thereby causing a

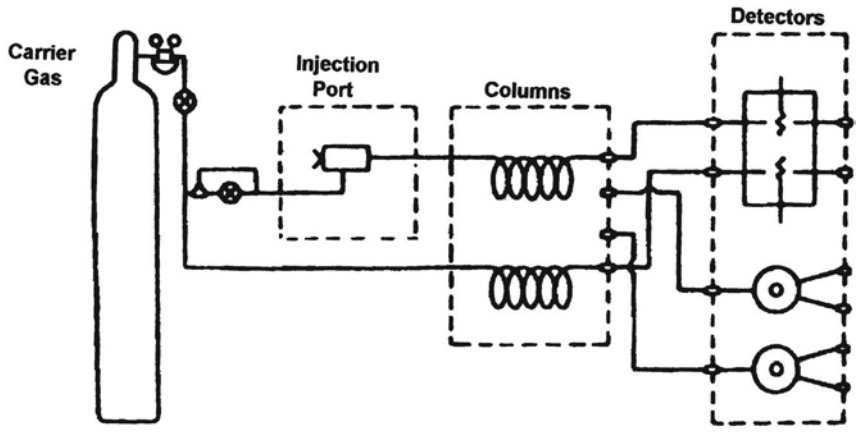

Fig. 3—Schematic diagram of a gas chromatograph.

voltage drop across the bridge, which is shown as a peak on the chromatogram. FID detectors operate on the principle that relatively few ions are formed when hydrogen is burned in air; but when organic compounds are present, ions proportional to the carbon concentration are formed. By applying a potential across two electrodes surrounding the flame, the ion current produced from the sample molecules is fed to an electrometer amplifier, the output of which is sent to a recorder. TC and FID detectors are both durable and relatively trouble free. TC detectors will respond to virtually all compounds, whereas FID detectors are sensitive to organic compounds only. One of the principal virtues of FID detectors is its high sensitivity, about 1000 times that of thermal conductivity. Testing of thermal conductivity and flame ionization detectors used in gas chromatography are discussed in ASTM Practice for Testing Thermal Conductivity Detectors Used in Gas Chromatography (E516-95a (2005)) and ASTM Practice for Testing Flame Ionization Detectors Used in Gas or Supercritical Fluid Chromatography (E594-96 (2006)), respectively.

There are other high-performance detectors that are used in conjunction with GC. Beta-ray ionization detectors use a radioactive source to ionize the argon carrier effluent from the column. Metastable argon ions collide with sample molecules, inducing a current flow that is amplified and measured. Glow discharge detectors operate on the principle that the composition of the effluent can be measured in terms of voltage across a gaseous discharge. In an electron capture detector, nitrogen is passed through an ionization chamber containing tritium as the source of ionizing radiation. All ions formed by the ionizing radiation can be collected by applying a small potential across the chamber. When the effluent from a gas chromatograph contains electron-attracting compounds, a decrease in current flow proportional to the electron affinity of the compound is observed [51,52]. The detector is highly selective for compounds containing halogen, conjugated carbonyl, nitriles, nitrates, and organometallic compounds. The function and performance of various detectors have been discussed in detail [53,54]. The use of electron capture detectors in GC is covered in ASTM Practice for Use of Electron-Capture Detectors in Gas Chromatography (E697-96 (2006)). Testing of nitrogen/phosphorous thermionic detectors for use in gas chromatography is discussed in ASTM Practice for Testing Nitrogen/Phosphorus Thermionic Ionization Detectors for Use in Gas Chromatography (El 140-95 (2005)).

Most modern instruments are equipped for linear programmed temperature operation, which consists of increasing the column temperature at a uniform rate throughout an analysis. Programmed temperature gas chromatography (PTGC) is particularly useful for the examination of complex mixtures and wide-boiling-range samples, where a single analysis of high and low boiling components at constant-temperature isothermal analysis is not practical. Generally, when the range of boiling points in a mixture is 100°C or more, temperature programming is recommended. If low temperature isothermal analysis is used, low boiling compounds will usually be separated effectively but high boiling compounds emerge as broad peaks. At high isothermal temperatures, light components emerge rapidly, causing peaks to be crowded; high boiling compounds produce favorably shaped peaks. When temperature-programmed operation is employed, a low initial temperature can be used for the separation of low boiling materials, and, by steadily increasing the column temperature, intermediate and high boiling components can be eluted in a reasonable length of time as sharp, well-defined peaks.

Although PTGC has greatly enhanced the usefulness of gas chromatography, its practice is somewhat restricted by the type of liquid phase employed. During temperature programming, a temperature is reached at which volatilization or decomposition of the liquid phase occurs, thereby causing a positive deviation of the recorder pen from the baseline. This effect is referred to as column bleeding, and in the event of severe bleeding the recorder pen may travel off-scale, obscuring any component peaks that may be present. Column bleed may be suppressed by favoring thermally stable liquid phases and through the use of short and low-loaded columns. These remedies are not always practical since a specific problem may dictate the use of conditions contrary to those described previously. A more direct way to compensate for column bleed is through the use of a dual column gas chromatograph. In this type of system, a column matching the one used for analysis is mounted in the oven compartment and connected to the reference side of the detector. As the temperature is increased, a signal is generated in the reference cell equivalent to that in the sample cell, thereby cancelling out any signal due to substrate bleeding.

Columns

The successful practice of GLC depends primarily on the proper selection and preparation of a suitable column. The availability of hundreds of liquid phases and numerous solid supports, in addition to parameters such as length, diameter, amount of liquid phase, and mesh size, offers an almost infinite number of possibilities. Fortunately, most separations can be performed on relatively few columns involving only a few liquid phases. Columns are divided into two major classes, packed and open tubular. Packed columns consist of tubing filled with size-graded support material impregnated with a nonvolatile liquid. Generally, higher-column performance is obtained with small-column-diameter and light-stationary-phase loading. Four to ten-foot (1.22 to 3.048 m) columns of 1/8 or 1/4 in. (3.175 or 6.350 mm) outside diameter containing 10 to 20 % liquid phase are common.

With Golay's development of the capillary column or open tubular column [55], the separations possible in GLC were greatly increased. These columns are prepared by coating the inside surface of small-diameter tubing with a thin layer of nonvolatile liquid. Capillary columns are generally much more efficient than packed columns, but, owing to their low capacity, high-sensitivity detectors and special sampling techniques are necessary to accommodate the small samples used. Fortunately, the split/splitless injector ports introduced by GC manufacturers in the late 1980s and early 1990s are able to handle normal-sample-size injections without much difficulty.

The readers may find the chemically cross-linked and surface-bonded stationary phases made using fused silica capillary tubing (30 m by 0.25 mm ID) quite useful to have in their gas chromatography laboratory (see Table 2).

Tubing

Tubing materials should be stable with respect to the sample, packing, and carrier gas, and be of uniform diameter. Tubing made of copper, stainless steel, monel, glass, and plastic have all been used for the construction of packed columns. The two most widely used materials are stainless steel and copper-stainless steel for its inertness and copper for its low cost. The most common tubing material used in capillary column gas chromatography is fused silica, primarily due to its flexibility and inertness. Special attention was given to the wide-bore, 0.53-mm inside-diameter columns because they have been reported [47] as a packed column alternative. Readers are also referred to a 1991 review covering the fundamentals, characteristics, and selection of open tubular columns in gas chromatography [48].

Solid Support

The function of the support material is to provide a large surface area for holding the liquid phase; it should be chemically inert to the sample and partition liquid and have good handling characteristics. The principal support materials are those derived from diatomaceous earth (Table 3). They are relatively inert, have adequate mechanical strength, and will adsorb up to 40 % of the liquid phase without losing their free-flowing character. Diatomaceous earth supports can be broadly classified as to color: white or pink. White supports contain fewer active sites and therefore are considered superior for the analysis of polar compounds. Pink supports, on the other hand, are less fragile and have greater capacity for holding the liquid phase. Schuppe and Lewis [49] group the various commercial diatomaceous earth supports according to color and ASTM code.

Ideally, a support should be completely inert, but unfortunately diatomites exhibit a certain amount of surface activity. The interaction with polar compounds, usually hydrogen bonding, is mainly attributed to the presence of silanol (–Si–DH) groups located at the surface of the support. Attempts to deactivate supports have been practiced in several ways: washing with acid and alkali, saturating with polar liquids, and reacting silanol groups with reagents. Although acid and base washing have been widely practiced, both techniques are of questionable value. In fact, acid treatment has sometimes proved deleterious by promoting isomerization of certain compounds and the decomposition of the liquid phase. By far the most effective way to reduce support reactivity is by reacting the silanol groups with a silylating reagent. This treatment is more effective with white supports; the degree of deactivation varies with the type of reagent and the technique employed.

Other support materials of notable importance are glass beads, Teflon, and porous polymers. Since porous

polymers are generally used without a liquid phase, they will be discussed in detail under gas solid chromatography. Teflon has found its greatest use in the separation of very polar compounds such as water, acids, alcohols, and amines, but Teflon has poor handling properties and produces columns that are much less efficient as compared to columns from diatomaceous earth. Because of their low surface area, glass beads cannot hold much liquid phase, less than 0.5 %; it is this low volume of liquid phase that is responsible for some of its advantages, namely, speed of analysis and low operating temperatures. They are, on the other hand, substantially less efficient than diatomite columns. For information concerning support technology, such as types, physical properties, chemical structure, pore structure, treatment, etc., the reader is referred to detailed articles [56–58] on the subject.

Stationary Liquid Phase

The selection of liquid phase is one of the most vital judgments made in selecting a chromatographic system, for it is the degree of selectivity of the partitioning liquid that most strongly influences the separating capability of a GLC column. Theoretically, any liquid can be used as a liquid phase, but there are some limiting factors. A liquid phase must be nonreactive to the system and sample, have reasonable thermal stability, and be liquid at the operating temperature. Although materials of low vapor pressure are favored, the main criterion regarding volatility is that the liquid phase be relatively nonvolatile (vapor pressures 0.01 to 0.10 mm) at operating temperature. Finally, a liquid phase must be soluble in some volatile solvent to allow coating of the support. Terms such as substrate, partition liquid, stationary phase, and solvent are synonymous with liquid phase. Considerable effort has been expended in an attempt to permit advance prediction of the most suitable liquid phase for a given problem, but most often the analyst must rely on experience, published procedures, and certain generalizations. Although solute-liquid phase activity such as chemical interaction, hydrogen bonding, and other cohesion forces all affect the selectivity of the liquid phase, in practice the most distinguishing characteristic is polarity. The polarity of the liquid phase is determined by the ratio of polar or polarizable groups to nonpolar groups, with the retention of solutes depending on the relative polarities of solutes and liquid phase. The greater the polarity of the stationary phase, the greater is the solubility (retention) of polar solutes relative to nonpolar solutes. The solubility or lack of solubility of sample components in the liquid phase can be used to make group separations or to accelerate or retard components with respect to others in the sample. In general, nonpolar liquid phases separate nonpolar solutes by order of volatility and polar solutes by structural type; whereas, polar phases separate polar solutes by order of relative volatility and polarity and nonpolar solutes by structural type.

An enormous number of liquids, semisolids, and solids have been recommended for use as liquid phases. Schupp [54] listed over 300 materials along with their maximum temperatures, chemical names, and trade names. The seventh edition of Guide to Stationary Phases for Gas Chromatography [59] contains over 700 literature references to liquid phase use in order of application to different classes of compounds. Lists of liquid phases, arranged alphabetically in chemical classes, are available from suppliers of chromatographic equipment, and they usually include maximum temperatures and solvency. Although there are a vast number of liquid phases available, the majority of problems encountered in most laboratories can be resolved with five or six stationary liquid phases provided they represent a wide range of polarities. The following list, arranged in order of descending polarity, is representative of such a group: N,N bis(2-cyanoethyl) formamide; diethylene glycol succinate; dodecyl phthalate; polyethylene glycol (molecular weight 20 000); and apiezon grease. Books on GLC generally contain chapters devoted specifically to the discussion of partition liquids, and it is recommended that the reader consult the previously mentioned books [54] for a more complete study of liquid phase technology.

Column Efficiency

Column efficiency may be defined by considering the narrowness of a peak relative to time spent in the column. Provided there are no instrumental deficiencies, column

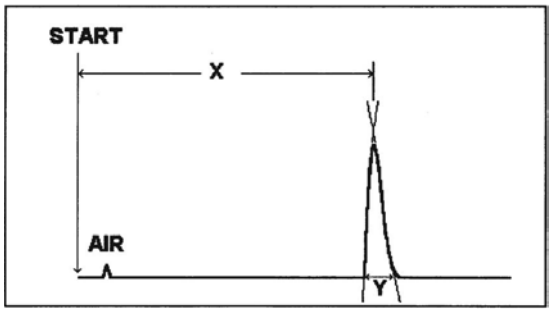

Fig. 4—Graphic calculation of column efficiency.

efficiency is a function of packing type, packing technique, and operating conditions and is usually expressed in terms of the number of theoretical plates. The plate concept, a carryover from counter-current extractions, implies a series of complete equilibria or "theoretical plates." The better the performance of a column, the higher is its number of theoretical plates. Inasmuch as distinct stages are not observed in chromatographic separations, the number of theoretical plates for a column is calculated from the relative peak sharpness shown on the chromatogram. A good packed column should have an efficiency of at least 400 plates, and it is not uncommon for a well-prepared column to have over 1000 plates. The number of theoretical plates, *N,* equals $16(x/y)2$, where x is the distance in millimeters from injection to peak maximum, and y is the baseline in millimeters cut by the two tangents as shown in Fig. 4.

Column efficiency can be expressed per unit of column length. The height equivalent to a theoretical plate (HETP) is calculated by dividing L, the length of the column in centimeters, by N; thus, HETP = L/N. High HETP indicates that the column has been poorly prepared or is not being operated under ideal conditions.

Theories [60–62] have been developed to elucidate mechanisms that cause spreading of the component molecules as they pass through the column, and an understanding of such processes is important to efficient operation of a chromatograph. Such theories take into account the interrelated multiple effects of parameters such as column diameter, column length, carrier gas, temperature, gas velocity, support size and shape, and sample size, and their ultimate effect on N. A summary and comparison of these theories have been presented [63]. A brief discussion to shorten analysis time while maintaining or improving resolution was published in 1993 [64].

Interpretation of Chromatograms

Fundamentally, the object of a chromatographic analysis is the resolution of sample components for identification and quantitative measurement. Fortunately, GC has tremendous capacity for resolving mixtures, but, unlike many other instrumental techniques, the record of an analytical run tells very little about the chemical nature of separated compounds. In addition, components in a sample mixture may not completely separate on a given column; consequently, the number of peaks on a chromatogram is not always an indication of the number of compounds in a sample. When background information concerning the sample is available and when sample components are few, the interpretation of GC data is fairly simple. However, the interpretation of a chromatogram from a multicomponent sample, where background information is limited, is a formidable task. In this section, qualitative and quantitative analysis will be briefly discussed; for a more complete treatment of the subject, the reader is referred to the work of others [65,66].

Qualitative Analysis

For a given set of operating conditions, the amount of carrier gas required to elute a compound from a column is characteristic for that compound and is not influenced by the presence of other compounds.

Accordingly, the time from injection to peak maximum is a property peculiar to a compound. This type of information, represented as retention volume (VR) and retention time (tr), has been the basis for most schemes of qualitative analysis. The use of such information may be greatly assisted by the considerable amount of published retention data such as ASTM compilations [49,50].

One of the weaknesses of gas chromatography is in the identification of unknown compounds. Dutoit [51] examined the retention indices of 135 solutes representing most chemical families on pure polar phase and pure nonpolar phase. This 1991 publication should aid the readers in the qualitative identification of GLC peaks. Another recent study regarding qualitative analysis by GLC using retention indexing was completed by Sun et al. [52]. The programmed temperature retention value databases compiled in various laboratories are listed along with reproducibility data under different chromatographic conditions.

For the purpose of illustration, the description of retention parameters will be confined to retention times; this does not, however, imply the use of retention volume to be inferior. Retention time measurements are shown on the chromatogram presented in Fig. 5. The adjusted retention time (t_R), time measured from air peak to peak maximum, corrects for instrument dead volume.

The first impulse would be to conclude that absolute retention times are adequate for identification purposes, but absolute retentions are comparable only when obtained on the same column using identical operating conditions. Instead, most retention times are calculated relative to some other compound that is used for reference. Relative retention time (r) is obtained as follows:

$$r_{c,s} = t'_{R,c} / t'_{R,s} \tag{3}$$

where c refers to component in the sample, and s indicates the reference standard. Relative retention times are independent of column length, liquid loading, and flow rate, but they are dependent on the type of liquid phase. The reference material may be one that is known to be in the

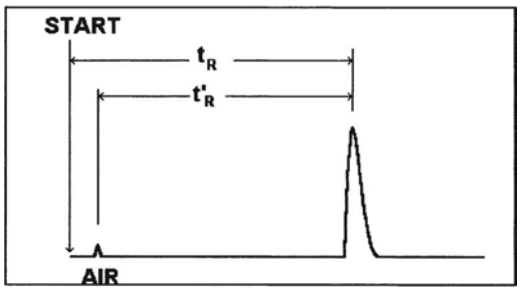

Fig. 5—Retention time (t_R) and adjusted retention time (t'_R).

original sample, or it can be mixed prior to the chromatographic analysis. In practice, relative retentions are usually obtained by computing the ratio of the distance from air peak to standard and air peak to component.

Once a peak has been tentatively identified from its retention time, the sample may be "spiked" with the suspected compound to see if it superimposes and shows up as one peak. If the two materials emerge together, this is good evidence of its presence in the original sample, but this does not constitute positive identification since more than one compound may have the same retention time for a given column. The next step is to go through the same procedure using a different column having a packing of completely different polarity. It is not likely that two materials will have the same retention time on widely different columns, but, if doubt still persists, the compounds can be trapped at the exit of the GC unit, and the isolated materials can be subjected to instrumental or chemical analysis. Walsh and Merritt [67] trapped eluted materials in a neutral solvent and applied a battery of chemical tests to determine chemical functionality. Methods have been described for direct trapping of fractions on a disk of potassium bromide and fraction trapping with subsequent transfer to a microcell; the isolated components were then subjected to infrared (IR) analysis. Although somewhat limited in versatility and flexibility, table top GC-mass-spectroscopic and GC-Fourier transform infrared units do an outstanding job of routine identification and for quality control purposes. Prices of these integrated instruments vary from $60,000 to approximately $100,000.

Success in any research laboratory is highly dependent on the timing upon which unknown chromatographic peaks are identified. While lR and mass spectroscopy (MS) have been proven to be important qualitative tools, each has its inherent weaknesses. When used together, these techniques reinforce each other, producing a richer body of useful information than either technique used alone [68]. The use of mass spectrometers as detectors for capillary column gas chromatography has also been discussed by Clement [69] in his 1992 publication. Another 1992 review [70] with several references is given on gas chromatography, including column types, injection methods, detection means, data systems, supplementary apparatus, and future prospects.

Quantitative Analysis

The analog signal generated by the presence of a compound in the carrier gas is proportional to its concentration, and quantitative analysis is obtained by conversion of this signal to some form of digital data. For the most part, quantitative data are obtained from peak area measurements, but significant use has been made of peak heights.

Peak areas can be measured by: (1) use of a planimeter, (2) cutting and weighing chart paper, (3) triangulation (A = WH/2), (4) height times width at half height (H × W at H/2), (5) ball-and-disk type of integrator, and (6) electronic digital integrator. The planimeter yields good results, but its use is tedious, and accuracy is dependent on the shape of the peak and the skill of the operator. Cutting and weighing peaks from chart paper is time consuming, and it is practically impossible to accurately cut and weigh cutouts of narrow peaks. Triangulation and height times width at half height are both relatively simple methods, and each will yield satisfactory results with symmetrical peaks, but the methods are unsuitable with asymmetric or very narrow peaks. The ball-and-disk type of integrator, which is attached to the drive mechanism of the recorder pen, has found widespread application. Since peak areas are integrated as they are recorded, the operator need only count the integrator units under the appropriate peak. With an electronic integrator, the output from a gas chromatograph is fed to the measuring unit that converts the analog signal to digital, which is eventually converted to peak areas using an appropriate algorithm. The integrated peak areas are read directly from the printer/plotters of most electronic integrators. Of the various methods for integrating peak areas, ball-and-disk and electronic integration provide the best results for applications requiring reasonable speed and precision of quantitative data. However, ball-and-disk integrators are extremely difficult to find because of the popularity of electronic digital integrators. Where cost permits, particularly in the case of routine analyses, the electronic digital integrator is preferred. Most electronic integrators made in the late 1980s and early 1990s have the capability of plotting the chromatograms in real time. Thus, a separate strip chart is no longer necessary to monitor the progress of the analysis.

Area normalization and internal standardization are methods used for converting digital data to percent composition. In the normalization procedure, the area of the component being measured is divided by the total area of all other peaks. This method assumes that all of the sample is eluted from the column.

$$\text{Percent component } C = \frac{\text{Area of } C}{\text{Total area of all peaks}} \times 100 \qquad (4)$$

If a portion of the sample remains on the column, an error proportional to the amount of material remaining on the column will be conferred on all the compounds measured.

The internal standard method is used more widely for the quantitative interpretation of a chromatogram. In this method, peaks of interest are calculated relative to a known amount of internal standard that has been added prior to chromatography. It is not necessary to determine all peaks as in the normalization method, and this can be advantageous particularly when one compound is to be determined in a complex mixture. The following calculation is used with internal standardization determinations:

$$\text{Percent component } C = \frac{CW}{BS} \times 100 \qquad (5)$$

where:
C = peak area of component,
B = peak area of internal standard,
W = weight of internal standard, and
S = weight of sample.

If the determination is to be calculated on a volume basis, simply substitute volume for weight in W and S. Complete elution of all components is not necessary; in fact, the percent of sample hang up can be determined by calculating the total percent represented by all the peaks eluted and subtracting the total from 100.

A direct weight-to-area relationship does not exist for all compounds. Detector response is a function of structure and molecular weight; the detector response for a

given compound is not the same with all detectors since various detector types operate on different principles. Once determined, however, response factors are generally interchangeable between instruments having the same type of detector. Messner et al. [71] published thermal conductivity factors for a large variety of compounds and also provided a formula for calculating factors. Deitz [72] tabulated a lengthy list of TC and FID detector response factors for various classes of compounds. For certain applications, peak height measurements are more convenient and reliable than peak area. Such is the case when peaks are tall and narrow and where errors in area measurements are likely to be maximized. Peak height determinations are affected to a greater extent by variations of operating conditions than are peak area determinations. This effect is greatly diminished through the use of an internal standard.

To increase accuracy and precision of peak area measurements, the use of electronic integrators is highly recommended. The initial cost for such an investment can easily be recovered within a short period of time primarily through labor cost savings. Current integrators are so versatile that they can perform difficult peak integration that normally would take a less experienced analyst a lot of time to perform. Some can perform reintegration and recalculation using a variety of methods. In the 1990s, most integrators are capable of being interfaced to a personal computer to enhance data crunching and for information storage and retrieval purposes. This is especially useful where data documentation is critical.

Applications—applications for GLC in the paint industry exist at almost every level of manufacture and product development. Its rapid acceptance by the industry is due to several inherent features, principally, versatility and speed. Initially, analyses were solvent oriented, but applications to virtually every class of material used in surface coatings have been reported in the literature. At present, GLC is used for a variety of analytical operations including both routine and research functions. It is unexcelled as a routine quality control tool for defining raw materials to be used for the manufacture of paint products. Batches of solvent, plasticizers, polyols, fatty acids, and other materials can be examined simply and rapidly to determine conformance to acceptable standards. Information regarding vehicle composition of a whole paint can be obtained in great detail and with reasonable accuracy.

Moreover, GLC can be used to monitor drying processes, solvent release from films, and the chemical curing of polymeric materials. In a 1991 publication, K. Takahashi [42] described a simple and sensitive method for the measurement of the leaching rate of tributyltin and triphenyltin compounds from antifouling paint by gas chromatography using flame photometric detection. Static headspace analysis by combined gas chromatography-mass spectrometry for the analysis of organic solvents in printing inks was recently studied [43].

Because of the multiplicity of published papers relevant to GC coatings analysis (well over 1000), complete coverage of all applications is beyond the scope of this chapter. A review [46] describing basic GC processes and applications includes approximately 150 references to coatings analysis. In his monograph on GC application to polymer analysis, Stevens [44] refers to several hundred analytical procedures and, in many cases, presents operating conditions, tables of retention times, and chromatograms. Readers are directed to the second part of a 1992 article by Ettre [45] on the evolution of chromatography since the development of GLC by Martin and James 40 years ago and HPLC by Moore and Horvath 25 years ago.

Miscellaneous	[43,135–137,139–145]

A partial list of references is shown in Table 4; examples were selected to illustrate the variety of coating problems amenable to GLC analysis. Methods directed to the analysis of oils and fats are listed separately, but most are also applicable to fatty acids isolated from alkyd resins. A compilation of ASTM methods that have been evaluated and accepted as standard or tentative procedures is presented in Table 5. Other GLC procedures are currently being evaluated for ASTM acceptability.

One facet of GLC that often goes unrecognized is the pretreatment of substances to alter their structure, thereby permitting the examination of materials that would not respond normally to GLC analysis.

Such is the case with the analysis of paint binders and very polar materials such as polyols and dicarboxylic acids. Many of the methods of sampling and techniques for preparing derivatives described by Cavagnol and Betker [73] and Schupp [74] have application to the analysis of surface coatings. Beroza and Coad [75] attack the same general problem but in a different way; for the most part, samples are altered within the instrument and not externally.

In the following discussion of analytical methods, special emphasis will be directed to the broad range of usefulness within the paint field, and, wherever possible, basic principles and equipment will be stressed.

Solvents

A major consideration in GLC is sample volatility. Materials to be analyzed must possess sufficient vapor pressure to permit vaporization at the point of sample introduction. Since enamel and lacquer solvents fulfill this requirement, it is only natural that GLC would be rapidly utilized in

Table 5—Summary of ASTM test methods for paints, related coatings, and aromatics using GC

ASTM	Title of Test Method or Practice
D2245	Test Method for Identification of Oils and Oil Acids in Solvent-Reducible Paints
D2360	Test Method for Trace Impurities in Monocyclic Aromatic Hydrocarbons by GC
D2743	Practices for Uniformity of Traffic Paint Vehicle Solids by Spectroscopy and GC
D2804	Test Method for Purity of Methyl Ethyl Ketone by GC
D3257	Test Method for Aromatics in Mineral Spirits by GC
D3271	Practice for Direct Injection of Solvent-Reducible Paints into a GC for Solvent Analysis
D3329	Test Method for Purity of Methyl Isobutyl Ketone by GC
D3362	Test Method for Purity of Acrylate Esters by GC
D3545	Test Method for Alcohol Content and Purity of Acetate Esters by GC
D3760	Test Method for Analysis of Isopropylbenzene (Cumene) by GC
D3792	Test Method for Water Content of Coatings by Direct Injection into a Gas Chromatograph
D3797	Test Method for Analysis of o-Xylene by GC
D3798	Test Method for Analysis of p-Xylene by GC
D3876	Test Method for Methoxyl and Hydroxypropyl Substitution in Cellulose Ether Products by GC
D3893	Test Method for Purity of Methyl Amyl Ketone and Methyl Isoamyl Ketone by GC
D4367	Test Method for Benzene in Hydrocarbon Solvents by GC
D4457	Test Method for Analysis of Dichloromethane and 1,1,1 Trichloroethane in Paints and Coatings by Direct Injection into a GC
D4492	Test Method for Analysis of Benzene by GC
D4735	Test Method for Determination of Trace Thiophene in Refined Benzene by GC
D4747	Test Method for Determining Unreacted Monomer Content of Latexes Using GC
D4773	Test Method for Purity of Propylene Glycol Monomethyl Ether, Dipropylene Glycol Monomethyl Ether, and Propylene Glycol Monomethyl Ether Acetate
D4794	Test Method for Determination of Ethoxyl or Hydroethoxyl Substitution in Cellulose Ether Products by GC
D4827	Test Method for Determining Unreacted Monomer Content of Latexes Using Capillary Column GC
D5008	Trace Method for Ethyl Methyl Pentanol Content and Purity Value of 2-Ethylhexanol by GC
D5060	Test Method for Determining Impurities in High-Purity EthylBenzene by GC

Table 5—Summary of ASTM test methods for paints, related coatings, and aromatics using GC (*Continued*)

ASTM	Title of Test Method or Practice
D5135	Test Method for Analysis of Styrene by Capillary GC
D5310	Test Method for Tar Acid Composition by Capillary GC
D5399	Test Method for the Boiling Point Distribution of Hydrocarbon Solvents by GC
D5713	Test Method for Analysis of High Purity Benzene for Cyclohexane Feedstock by Capillary GC
D5910	Test Method for Determination of Free Formaldehyde in Emulsion Polymers by LC
D5917	Test Method for Trace Impurities in Monocyclic Aromatic Hydrocarbons by GC and External Calibration
D5974	Test Method for Fatty and Rosin Acids in Tall Oil Fractionation Products by Capillary GC
D6133	Test Method for Acetone, p-Chlorobenzotrifluoride, Methyl Acetate, or t-Butyl Acetate Content of Solvent-borne and Waterborne Paints, Coatings, Resins, and Raw Materials by Direct Inhection into a Gas Chromatograph
D6142	Test Method for Analysis of Phenol by Capillary GC
D6144	Test Method for Analysis of AMS (Alpha Methyl Styrene) by Capillary GC
D6229	Test Method for Trace Benzene in Hydrocarbon Solvents by Capillary GC
D6387	Test Method for Composition of Turpentine and Related Terpene Products by Capillary GC
D6438	Test Method for Acetone, Methyl Acetate, and p-Chlorobenzotrifluoride Content of Paints, and Coatings by Solid Phase Microextraction GC
D6526	Test Method for Analysis of Toluene by Capillary Column GC
D6563	Test Method for Benzene, Toluene, Xylene (BTX) Concentrates by GC
D6886	Test Method for Specification of the Volatile Organic Compounds (VOCs) in Low VOC Content Waterborne Air-Dry Coatings by GC
D7011	Test Method for Determination of Trace Thiophene in Refined Benzene by GC and Sulfur Selective Detection
D7057	Test Method for Analysis of Isopropylbenzene (Cumene) by GC (External Standard)
D7090	Test Method for Purity of Isophorone by Capillary GC
D7266	Test Method for Analysis of Cyclohexane by GC (External Standard)

this area. Solvents may be encountered in two forms: as raw material to be formulated into a surface coating or as an ingredient of a coating. In the latter event, the analysis is complicated by the presence of pigment and binder, which usually necessitates the isolation of solvent through distillation. To alleviate problems associated with solids or nonvolatile components of the paint or coating,

a removable glass liner or glass insert can be installed in the injection port of the gas chromatograph. Such glass liners can be occasionally solvent-cleaned or oven-cleaned overnight at 400°C. Another, but less desirable alternative. is through the use of a precolumn. The pre-column should be made from the same stationary phase as the analytical column [76].

An important aspect of production control is the analysis of individual solvents for impurities. Relatively small amounts of impurity may seriously affect the performance characteristics of a paint, and such impurities can be easily detected and determined using GLC. Batches of solvent can be rapidly screened by subjecting them to GLC analyses and comparing the resulting chromatograms to those obtained from reference materials of acceptable quality [77]. Relative amounts of each solvent can be quickly ascertained from ratios of peak heights or peak areas. If significant deviation from the reference material is observed, a more thorough and precise GLC analysis can then be conducted. In 1993, Vonk [78] described the use of wide-bore fused silica columns for the analysis of solvents.

Petroleum fractions, such as mineral spirits and VM&P naphtha, are extremely complex mixtures of hydrocarbons, and it is virtually impossible to completely separate all the components. Nevertheless, valuable information regarding the nature and identity of such solvent systems may be obtained by comparison with reference chromatograms obtained using identical operating conditions. No attempt is made to identify the individual peaks; instead, observations are made to determine if the unknown and control have similar distillation ranges and if peaks are proportional. Chromatograms of this type are referred to as "fingerprints" and will often suffice for quality control purposes.

The percentage of aromatic species in mineral spirits may be determined by using columns prepared from highly selective liquid phases such as N,N-bis(2-cyanoethyl) formamide and 1,2,3-tris(2-cyanoethoxy) propane. These very polar liquid phases are capable of eluting high boiling aliphatic solvents well in advance of low boiling aromatics, thereby providing the means for aliphatic-aromatic group separation. Such columns provide the basis for the analysis of aromatics in enamel thinners and solvents [79,80] yielding information that relates to the photochemical reactivity of hydrocarbon solvents, a factor of importance in air pollution studies.

The problem of determining solvents in whole paints and lacquers by GLC is compounded by the presence of non-volatiles, and special provisions must be made for sampling. No universal method for isolating solvent from paint and lacquer is available [81–85]. Vacuum distillation and collection in a cold trap [86] works well in many cases, but this scheme is time consuming and difficulties arise when very light or very heavy solvents are present. Introduction of a coating from a syringe onto an adsorbent pad [36] in the injection port has been used, but viscous samples require dilution, and thermally unstable resins are decomposed in the injection port, resulting in the appearance of extraneous peaks on the chromatogram. To avoid or significantly minimize thermal degradation of certain resins, it is advisable to decrease the injection port temperature below its decomposition temperature. A good injection port temperature for most solvent analysis is 200°C. As previously indicated, use of a removable glass liner or insert is a must if direct injection of the whole paint is to be performed. Again, the glass insert can be occasionally cleaned using an appropriate solvent or by overnight oven cleaning at 400°C. Precipitation of lacquer resins with pentane and subsequent analysis of the supernatant liquid by GLC works well with most automotive lacquers [77], but the nonuniform occlusion of certain solvents has been reported. For the most part, the means of sample handling will be determined by the type of material encountered and the extent of analytical information desired.

Several comprehensive schemes have been proposed that are particularly useful for the analysis of unknown samples. Haken and McKay [87] used GLC in conjunction with solubility tests in various media along with functional group analysis for the characterization of solvent systems. The New York Society for Paint Technology published a paper [81] on the subject of solvent analysis that included a comprehensive tabulation of retention data for a broad spectrum of solvents. A procedure for the identification of plastic and lacquer solvents was described by Haslam et al. [86]. The solvents were isolated by vacuum distillation in a sealed "H-tube" and subsequently separated on tritolyl phosphate and paraffin wax columns. Chromatographic data were supplemented by infrared spectroscopy where necessary.

Since no single column will separate all solvents, separation on one liquid phase can be very misleading. When examining an unknown solvent mixture, it is best to conduct the analysis on at least two liquid phases of different polarity, and in some cases supplementary chemical or instrumental testing will also be necessary.

GLC has also been used to study the retention of solvents in paint films during drying processes [88,89]. It has been demonstrated that solvent retention is related to the chemical structure of the film and solvent, as well as the boiling point of solvents. Perrone [90] also described a GC method for the determination of residual solvents in pressure sensitive tapes as a quality control step in the manufacturing process [91–99].

Oils

The drying and nondrying oils used in the production of paints and varnishes can be identified through the application of GLC. The GLC analysis is preceded by the saponification of sample and isolation of the fatty acids. Free fatty acids may be examined directly [100], but they are generally analyzed as their methyl esters, which are more volatile, less polar, and less susceptible to isomerization. Any of the several acid-catalyzed esterification techniques, for example, hydrochloric acid (HCL), sulfuric acid (H_2SO_4), or boron trifluoride (BF_3) in methanol, will provide adequate conversion to the ester; the BF_3-methanol reagent, however, offers the advantages of a high yield combined with rapid ester conversion. The difficulty in handling BF_3 gas can be circumvented by using boron trifluoride etherate in methanol. The reagent is easy to prepare, stable, and will convert fatty acids to their corresponding methyl esters within a few minutes.

Many of the fatty acids found in oils are of the same carbon chain length, differing only in position and number of double bonds [101–104]. Most polyester liquid phases will differentiate between C_{18} fatty acids, but polyesters

having the highest oxygen-to-carbon ratio provide the best separations. Of the polyester liquid phases, diethylene glycol succi-nate has received the most attention. Six- to-eight-foot (1.83 to 2.44 m) columns containing 10 to 20 % polyester on white diatomaceous earth supports are most common.

Zielinski et al. [105] considered the analysis of reacted and unreacted oils and made provisions for their complete analysis. Fatty acids were identified from the relative retention time ratio (RTR) values. RTR values were defined as the numerical ratio of the corrected retention time of a given methyl ester peak to that of the methyl palmitate peak. With the exception of licanic and eleostearic acids, all the fatty acids can be readily separated and identified.

Linseed, soybean, tall, safflower, and cottonseed oils can be identified from their characteristic fatty acids distributions. With other oils, identification may be achieved from an inspection of only one or two acids. For example, marine oils contain respectable amounts of palmitoleic and myristic acids, castor oil consists mostly of ricinoleic acid, coconut oil is rich in lauric acids, and oiticica and tung oils contain appreciable amounts of licanic and eleostearic acids, respectively.

Complete details for the identification of oils in organic coatings by GLC may be found in ASTM Test Method for Identification of Oils and Oil Acids in Solvent-Reducible Paints (D2245) [106].

A further extension of GLC to fatty acid analysis is demonstrated in a method for dimer acids [107]. Dimers are relatively nonvolatile, but their elution as methyl esters is made possible by using a short column acid composed of a thermally stable liquid phase, silicone grease, on silanized Chromosorb W. Monomeric fatty acids are eluted as one peak, while dimer acids emerge further along the column as a well-defined Gaussian peak.

Resins

The GLC analysis of resins constitutes a special problem inasmuch as the analyst must rely on some means of forming volatile products, either by derivative formation or through thermal decomposition [108–114]. Thermal decomposition techniques will be discussed in greater detail in the following section; this section will be concerned with methods for converting nonvolatile resinous materials to volatile derivatives.

Alkyd and polyester resins account for a large portion of polymeric material used in organic coatings. The identification of the oil component in alkyd resins by GLC has already been described. The remaining classes of material, dicarboxylic acids and polyols, can be analyzed by chemically degrading the resin so as to regenerate the acids and alcohols, which are then derivatized and subsequently analyzed by GLC. If butylamine is used to degrade the resin, polyols may be analyzed qualitatively [115] as their acetates or qualitatively [116] and quantitatively as trimethylsilyl ethers [117]. The latter method involves a minimum of sample manipulation, and it is applicable to all of the polyols normally found in alkyd resin. Both procedures are relatively uninvolved and capable of analyzing more than one polyol simultaneously.

When alkyd or polyester resins are subjected to a catalyzed equilibrium reaction in a large excess or methanol, methyl esters of mono- and dicarboxylic acids are formed in good yield.

MeOH(large excess) + alkyd or polyester + methyl ester + glycol

A method [111] has been developed for the identification of mono- and dicarboxylic acids in alkyd and polyester resins where lithium-methoxide was employed as the transesterification catalyst. Two columns, one polar and the other nonpolar, were used to obtain retention data. Identification was made possible by comparing the relative retention times of peaks from a sample to those obtained from pure compounds. Percival [108] reported a similar method using sodium methoxide as the catalyst; semiquantitative results for polyols and dicarboxylic acids were presented.

Pyrolysis

Thermal degradation, when used in conjunction with GLC, can be applied to the analysis of a wide range of polymeric materials. This technique, commonly referred to as pyrolysis, has been the subject of numerous papers. One of the most recent reviews regarding pyrolysis gas chromatography, their advantages and problems in polymer characterization, was published in 1992 by Ahmadi et al. [109]. Pyrolytic GLC is a most convenient way of analyzing small quantities of high-molecular-weight material without the necessity of resorting to chemical pretreatment. Under proper conditions the products of thermal degradation are unique for the material being analyzed, and if conditions are controlled carefully, highly reproducible results are obtained. Data, however, are sometimes difficult to interpret, and reproducibility between laboratories is not always good.

Early pyrolysis work was conducted in a system external to the gas chromatograph, with the pyrolyzate being collected in a cold trap. Pyrolysis products were introduced into a gas chromatograph and chromatographed by conventional means. Ever since its inception, pyrolytic GLC has undergone a series of refinements with the ultimate development of integrated pyrolytic-GLC systems. Curie point pyrolysis coupled with GC-MS, headspace GC-MS, and preparative HPLC were used to determine the compounds of an uncured polyester resin containing a cross-linking accelerator, an acrylate copolymer, surfactants, additives, and marble powder [110]. Of the many techniques described in the literature, two are most prominent.

In one method, a filament of high-resistance wire is coated with the sample resin, and the sample is pyrolyzed by energizing the filament with a predetermined amount of current. In a modification of the "filament technique," a quartz or ceramic sample holder is placed inside the heating coil to prevent catalysis, which may occur at the surface of the wire. In both variations, pyrolysis products are carried onto the column as they are formed, thus preventing the occurrence of secondary reactions between highly reactive chemical species. Pyrolysis temperature can be controlled by calibrating various settings of a variable voltage source with a thermocouple [118].

The second type of pyrolysis [119] employs a microoven to decompose the sample. In this technique the oven is preheated to the desired reaction temperature and the sample is then introduced by means of a moveable boat or cup. The unit can be designed so that several samples

can be readied for analysis and introduced one at a time by external sample manipulation. Generally, the carrier gas is not allowed to flow over the sample until pyrolysis is complete, at which time valves are positioned so as to direct the carrier gas flow over the boats, thereby carrying the pyrolysis products onto the column.

As compared to the filament technique, the micro-oven offers better reaction temperature control and a means of weighing the sample and residue, but it is more susceptible to secondary reaction of pyrolysis products.

Since polymer composition may vary over a wide range, it is difficult to choose column and chromatography conditions to cover all substances. Some polymers yield highly polar species (for example, acetic acid from polyvinyl acetate or amines from nitrogenous resins) that may be lost by adsorption on the column. Columns that perform well with polar substances are not always suitable for the separation of less polar materials. Therefore, optimum conditions should be determined for different classes of polymers. When samples are completely unknown, best use is made of pyrolysis when the general type of resin is determined by prior chemical or instrumental testing. Kim [120] reviewed the fundamentals of gas chromatography and pyrolysis and their applications in the analysis of fibers and polymers. Generally, the fragmentation of polymers will proceed by three basic pyrolytic reactions. Cross-linked polymers tend to carbonize, and as a result they produce pyrograms that are very difficult to relate back to the starting material. Such is the condition with alkyd resins. Secondly, some linear polymers will rupture between the side chain and the polymer backbone. This type of pyrolysis can be useful if the decomposition products are characteristic of the side chain. Pyrolysis of polyvinyl acetate typifies this type of bond schism; acetic acid is the principal decomposition product. The final and most useful type of pyrolysis occurs when the polymer backbone ruptures, producing monomers of the polymer. This type of decomposition is favored by quaternary-substituted carbons on the polymer backbone. For instance, good yields of methacrylate monomer are formed from the pyrolysis of polymethacrylate polymers, whereas polyacrylate polymers give low yields of acrylate monomer.

If experimental conditions are controlled carefully, the reproducibility of pyrolysis patterns is good. Thus, if sufficient reference chromatograms are developed, an unknown resin can be identified by matching the sample pyrogram with one from a reference library. Since, in many cases, decomposition produces a pattern of peaks that are not individually identified, the resulting chromatogram is employed as a "fingerprint." Jain et al. [121] demonstrated the use of pyrolytic GLC for the identification of small samples of paint. Characteristic pyrograms were obtained from different types of paint vehicles and those with the same vehicles but different pigments. The method was recommended for use in the forensic field where, very often, chips or traces of paint are the only physical evidence. Groten [122] investigated a broad spectrum of polymeric materials and found that they all produced characteristic pyrograms. McKinney [123] compiled a bibliography on pyrolysis gas chromatography for the period 1960 to 1963 that includes a subject and author index. A comprehensive treatment of pyrolysis chromatography, with special reference to paint resins, was presented by Hillman [124]. The study included 22 pyrograms of various types of coating materials in addition to a discussion of the effects of operating conditions and polymer structure on the resulting chromatograms.

As mentioned before, alkyd resins do not yield well-defined pyrograms that can be used for compositional analysis. Pyrolysis of alkyd resins is most useful for the examination of minute chips or flakes of paint. If an adequate amount of wet sample is available, alkyd resins may be examined best by gas chromatography of the fatty and dibasic acid methyl esters [105,111] and the trimethylsilyl ethers of the polyhydric alcohols [117]. Styrenated and acrylated alkyds, however, give good yields of monomer from the modifying resin, and with proper calibration the concentration of modifying resin can be ascertained.

When the pyrolysis is limited to certain classes of resins, for example, methacrylate and polystyrene, high yields of monomer are obtained that can be equated with the copolymer composition of the polymer through the use of calibration mixtures. Since copolymers do not give the same pyrograms as physical mixtures of the same composition, physical mixtures cannot be used for the quantitative analysis of copolymers. A random rupture of bonds occurs when acrylate is pyrolyzed; yields of monomer are low, accompanied by the esterification alcohol and gases. A scheme for the identification of copolymer composition of thermosetting acrylic resins has been presented [108]. In this method, a filament was coated with the resin solution and dried prior to decomposition. Twelve monomers were identified by combined analysis on polar and nonpolar columns [126].

Plasticizers

One of the most desirable properties of a plasticizer is low volatility, and for this reason it would be expected that the analysis of such materials by GLC would not be easy. Indeed, the vapor pressures of many plasticizers are so low that they have been recommended as stationary liquid phases for GLC analysis where moderate operating temperatures are adequate. However, by a suitable choice of operating conditions, most nonpolymeric plasticizers may be chromatographed without great difficulty.

In general, reasonable emergence times of high boiling compounds may be achieved by the use of short columns, rapid flow of carrier gas, high operating temperatures, or low-liquid-phase concentration. Since each of these operating conditions can produce undesirable effects such as poor resolution, reduced column longevity, and tailing, a compromise must be reached that will allow the resolution of high boiling mixtures within a reasonable time span. A 9 in. (22.86 cm) silicone grease column [127] was found to be adequate for the quality control of incoming stocks of butyl benzyl phthalate. Differences in the manufacturing processes of this plasticizer leads to products of variable composition, and, although a high yield is the desired end product, appreciable amounts of dibutyl and dibenzyl phthalate are sometimes encountered. When incorporated with acrylic resins, dibutyl phthalate tends to distill out of a lacquer on exposure, a condition that may ultimately lead to resin embrittlement.

A method for the analysis of plasticizers was presented [128] in which a 6 ft (1.82 m) silicone grease column was used to separate a broad range of plasticizers. A rapid flow of carrier gas, 120 mL/min, and a high terminal column temperature, 290°C, were used in conjunction

with temperature programming for the separation of low, medium, and high boiling plasticizers [129–134].

Miscellany

Ghanayem and Swann [135] separated glycols on polar columns without resorting to derivative formation. A method of this type is useful where the purity of low-boiling, uncombined polyol is under consideration. High-boiling polyols, however, normally require derivatization prior to the chromatographic step. The ever-increasing popularity of aerosol packaging has generated considerable interest in methods for the chemical analysis of aerosol propellants. The performance characteristics of various propellants may vary over a broad range; flammability, toxicity, vapor pressure, and solvency are some of the factors that determine their usefulness. It is practically impossible to identify propellants using conventional methods; they are, however, susceptible to GLC analysis. A two-column method [136] has been devised for the identification of propellants in aerosol-packaged paint. In this method, a 22 ft (6.70 m) silicone grease column is used at ambient temperature for the separation of fluorinated compounds, chlorinated hydrocarbons, and aliphatic hydrocarbons. A 6 ft (1.82 m) porous polymer column is used for the separation and identification of carbon dioxide. The concentration of each propellant may be approximated from the ratios of peak heights or peak areas. Obtaining a representative sample from an aerosol can could, prior to solvent analysis, present some difficulties to inexperienced analysts. Rastogi [137] suggested freezing the aerosol can in liquid nitrogen, puncturing the can, and allowing the propellant to evaporate as a sample preparation method.

The many applications of GLC to paint analysis are too numerous to mention; indeed, the number is vast and continues to grow. Eiceman et al. [138] reviewed the fundamental developments in gas chromatography for the period 1990 and 1991 and noted the attention given to the characterization of liquid phases and prediction of retention behavior. A review of the usual methods of quantification by headspace gas chromatography for liquid samples was presented by Nagai [139] in 1991.

In today's laboratory environment where analysts are required to multitask, autosamplers are helpful not only for productivity reasons but also for increasing accuracy and precision. The design, operation, and troubleshooting of GC autosamplers was discussed by Hinshaw [140]. Moreover, the labor cost associated with troubleshooting could be prohibitive when the analytical laboratory relies solely on the GC instrument manufacturer. It is critical for the analysts to be fully informed and educated about all aspects of problem solving, including the chromatographic hardware. A paper [141] covering trace-level sampling, principles of splitless injection, post-injection effects, and troubleshooting splitless injection was published in 1991.

Gas—Solid Chromatography

GSC represents a gas chromatographic technique where components are separated on a solid rather than on a liquid phase. Its application to the analysis of coating materials has been extremely limited, and for this reason only a very brief description of GSC processes will be presented with special emphasis being directed to new developments and potential applications to paint analysis.

Instrumentation and interpretation of data are basically the same as in GLC, the only departure from GLC convention being the absence of a liquid stationary phase. Initially, GSC methods were used primarily for the analysis of very volatile, inert materials, but with the introduction of new packing, the technique has been extended to the analysis of a much broader spectrum of chemical types. Alumina, silica gel, molecular sieve, organoclay, and porous polymers are the most widely used GSC packing materials. GSC with silica gel, alumina, or organoclay preclude the analysis of polar solutes since polar solutes are irreversibly adsorbed on surface-active groups. Of the GSC packing mentioned, porous polymers are the most recent, and, owing to their versatility, they offer the best potential for GSC analysis of coating materials [142–145].

Porous Polymer Packings—porous polymer beads represent a unique advance in column technology by making use of polymer synthesis to produce columns for specific applications. Porous polymer beads are derived from the same family of polymers used in gel-permeation chromatography; they were first introduced as a GC packing by Hollis [146], who demonstrated their application to various chemical species.

The porous polymer beads used by Hollis were prepared from styrene, t-butylstyrene, and ethylvinylbenzene cross-linked with divinylbenzene. By varying the monomer ratios and polymerization conditions, the properties of the polyaromatic beads can be varied with regard to chemical structure, pore structure, particle size, and surface area. Consequently, beads of different performance characteristics can be synthesized. Porous polymer beads from different sources have been studied [147]; their physical properties and performance characteristics have been described in great detail.

Technically, the use of porous polymer beads packings should not be classed exclusively as GSC since partition and diffusion, as well as adsorption, all contribute to their effectiveness. Most likely, adsorption predominates at low temperatures and partition at high temperatures. Porous polymer beads have good mechanical strength, which permits their being packed by conventional vibration techniques. Most beads can be used up to 250°C with little or no bleeding, and this characteristic is particularly important when high-sensitivity detectors are used in conjunction with temperature programming. Unlike diatomaceous earth packings, porous polymer beads are hydrophobic, eluting water very rapidly with little or no adsorption. The potential uses of such packings are still being explored, but excellent results have already been achieved for the analysis of polar compounds [148], these chemical types being difficult to chromatograph on conventional GLC columns [149].

Finally, the readers may find the list of ASTM practices relevant to chromatography shown in Table 5 useful in their practice of chromatography [150].

GAS CHROMATOGRAPHY GLOSSARY

The following definitions of terms used in GC were compiled by Brenner and Olson [149] and the International Union of Pure and Applied Chemistry under the Chairmanship of Dr. Ambrose [150].

adsorbent (active solid)—Solid, granular material used to pack columns and on the surface of which sample components are held by adsorptive forces.

adsorption chromatography—See gas-solid chromatography.
adsorption column—Column used in gas-solid adsorption chromatography. The column material consists of an active solid (adsorbent).
air peak—The peak of a substance that is not retarded by the column material, thus indicating the time necessary for the carrier gas to travel from the injection point to the detector.
attenuator—An electrical element containing a series of resistances that may be selected by a switch to produce the reduction of input voltage to a recorder by a fixed factor.
band—See peak.
band area—See peak area.
baseline—The line drawn by the recorder pen when no sample is being measured in the detector.
capillary column (open tubular column)-Tubing of small diameter, usually 0.25 to 1.0 mm inside diameter, in which the inner walls of the tube are used to support the stationary liquid.
carrier gas—The gas, usually inert, that constantly flows from a pressurized source through the chromatograph, impelling the sample through the system.
chromatogram—The graphic recording of the detector response versus time or volume of carrier gas.
column—A metal or glass tube packed or internally coated with the column material through which the sample and carrier gas flow and in which the chromatographic separation is performed.
column material—The material contained in the column. In adsorption chromatography, the column material is the adsorbent itself; in partition chromatography, the column material consists of a stationary phase distributed on an inert solid support or coated on the inside wall of the column.
component—A pure compound contained in the sample mixture.
detector—A measurement device, usually electrical, that emits a signal in the presence of a component that is eluted from a chromatographic column.
elution—The "washing" of a component through and out of the column by the carrier gas.
filament element—A type of thermal conductivity device in which a fine tungsten or similar wire is used as the variable resistance element in the cell chamber.
flow programming—A technique in which the carrier gas flow rate is gradually increased in order to expedite the elution of the higher boiling components.
gas chromatography (GC)—Collective noun for all chromatographic methods in which the moving phase is a gas. The term "chromatography" implies that a stationary phase is present in addition to the moving phase. These methods are also called vapor-phase chromatography (VPC).
gas-liquid chromatography (GLC)—Chromatographic method in which the stationary phase is a liquid distributed on a solid support. The separation is achieved by partition of the components of a sample between the phases. This method is also called gas-liquid partition chromatography (GLPC).
gas-solid chromatography (GSC)—Chromatographic method in which the stationary phase is an active solid (adsorbent). The separation is achieved by adsorption of the components of a sample. This method is also called gas-solid adsorption chromatography.
integrator—A mechanical or electromechanical device for producing a continuous summation of detector output with respect to time, yielding a measurement of included area of a chromatographic band.
ionization detectors—Chromatographic detectors in which the measurement of a sample is derived from the current produced by the ionization of sample molecules induced by thermal, radioactive, or other excitation sources.
katharometer (catharometer)—See thermal conductivity cell.
Liquid phase—A liquid that is relatively nonvolatile at the column temperature and is sorbed on the solid support where it acts as a solvent for the sample. The separation achieved differs with differences in solubility of the various components of the sample in the liquid phase. This is also called the stationary phase or substrate.
moving phase (mobile phase)—The carrier gas within the column, in which sample component molecules progress down the length of the column.
partition chromatography—See gas-liquid chromatography.
peak—The portion of the chromatogram recording the detector response while a single component emerges from the column. (If the separation of a mixed sample is incomplete, two or more components may appear as one peak.)
peak area—The included area formed by the ascending and descending arms of a chromatographic-recorded band and the baseline of the chart.
potentiometric recorder—A readout device in which a pen, whose deflection is proportional to the voltage output of the chromatographic detector, writes on a paper chart that is moving at a constant speed.
pyrolysis—A technique in which nonvolatile samples are thermally decomposed in the absence of oxygen in the inlet system and the volatile products are admitted to the chromatographic column.
relative retention—The ratio of the retention time of a component to the retention time of a second component chosen as a standard.
resolution—The degree of separation between peaks.
retention index—The number of carbon atoms (multiplied by 100) of a hypothetical normal paraffin, which under the given conditions would have a retention time identical to that of the substance of interest.
retention volume—The product of the retention time of a component and the volumetric flow rate of the carrier gas.
retention time—The elapsed time from injection of the sample to recording of the peak maximum of a component band.
sample—The gas or liquid mixture injected into the chromatograph for analysis.
sample injector—A device by which a liquid or gaseous sample is introduced into the apparatus. The sample can be introduced directly into the carrier gas stream or into a chamber temporarily isolated from the system by valves that can be changed so as to

instantaneously switch the gas stream through the chamber.

separation—The elapsed time between elution of two successive components, measured on the chromatogram as the distance between the recorded bands.

solid support—The granular material upon which the thin layer of liquid in a partition column is held.

solute—The individual fractions of the sample dissolved in the liquid phase during their travel through the column. This is also used as another term for the sample itself.

solvent—Synonym for the liquid phase.

span of a recorder—The signal level (number of millivolts) required to produce a change in the deflection of the recorder pen from zero to 100 % on the chart scale.

splitter—A T-fitting attached to the column to divert a portion of the flow. An inlet splitter allows introduction of very small samples to a capillary column. An effluent splitter may be used to permit parallel operation of two detectors.

stationary phase—See liquid phase.

substrate—See liquid phase.

tailing—A form of band distortion in a chromatogram in which the trailing edge returns to the baseline relatively slowly, producing an asymmetrical band.

temperature programming—A technique in which the column temperature is gradually increased in order to expedite the elution of the higher boiling components.

thermal conductivity—A physical property of materials that is the ability to conduct heat from a warmer to a cooler object.

thermal conductivity cell—A chamber in which an electrically heated element is contained that, by its change in resistance, will reflect changes in thermal conductivity within the chamber atmosphere.

thermistor bead element—A type of thermal conductivity detection device in which a small glass-coated semiconductor sphere is used as the variable resistive element in the cell chamber.

vapor-phase chromatography (VPC)—See gas chromatography.

Electron Microscopy Overview with Coating Applications

David R. Rothbard[1] and John G. Sheehan[2]

INTRODUCTION

ELECTRON MICROSCOPES ARE FREQUENTLY USED in the analysis of coatings and their components because of their high resolution and multifunctional capabilities. The two common types are the scanning electron microscope (SEM) and the transmission electron microscope (TEM). In various operating modes and with specialized detectors, these instruments can be used to examine surface texture and internal structure, determine particle size and shape, provide elemental analysis, and reveal crystallographic orientation and identity.

The resolving power of electron microscopes is orders of magnitude greater than that of light-optical microscopes, partly due to the shorter electromagnetic wavelength (higher energy) of electron illumination. Modern SEMs with field-emission electron guns have the ability to resolve better than 1 nm between objects and commercial TEMs can resolve better than 0.2 nm. However, the actual resolution obtained is highly dependent on the nature and preparation of the sample. Contrast develops in SEM by electrons emitted at or near the surfaces of bulk specimens and, therefore, topography and composition are examined. Contrast develops in TEM by electrons transmitted through thin specimens and, therefore, variations in structure and composition are examined. Due to the improved resolution of modern SEMs, TEMs are no longer needed to see coating components 50 nm or smaller. In this chapter, SEM will receive more attention than TEM for this reason, along with its greater availability and documented coatings applications.

Types of signals generated in a sample by a vertically incident electron beam are illustrated in Fig. 1. An SEM typically has detectors for secondary electrons (SEs), backscattered electrons (BSEs), and X rays positioned above the surface of bulk specimens. The TEM collects elastically and inelastically scattered electrons, and sometimes X rays from thin (ca. 100 nm) specimens. Hybrid TEMs have some SEM capabilities. They may collect BSEs and SEs from the incident-beam side of thin specimens, a variety of transmitted electron signals from the opposite side of the sample, and X rays from both sides. These are known as scanning transmission electron microscopes (STEMs) or analytical electron microscopes. Their greatest strength is their ability to focus a fine electron probe on very thin samples, achieving high spatial resolution in elemental and structural analysis.

SEMs and TEMs were both invented in the 1930s in Germany [1]. Ernst Ruska shared the 1986 Nobel Prize in Physics for designing the transmission electron microscope and improving electron optics. Soon after its invention, TEM became widely used to image replicas of surfaces at resolution far better than was possible with the first SEM and, therefore, further development of SEM continued at a slow pace. An important step was the invention of an efficient secondary electron detector by Everhart and Thornley in 1960. In 1965, the Cambridge Instrument Company introduced the first commercial SEM. SEM was quickly applied to the study of coatings, as evidenced by American Chemical Society Symposia on SEM of polymers and coatings in 1970 [2] and 1973 [3].

Some of the greatest recent improvements in SEM and TEM design and operation were made possible by the rapidly increasing power and decreasing cost of personal computers. Manufacturers (and after-market suppliers) have moved to using standard personal computer (PC) interfaces and operating systems to control microscope functions. Better computers and software have driven an almost complete transition from analog to digital beam control, correction, and acquisition. Image archiving, processing, and analysis functions are common options. Intensive image processing and crystallographic computations are performed quickly during an imaging session. One or more PCs can integrate these and other functions, such as energy dispersive spectrometer (EDS) analysis and motor stage control.

This chapter has three main parts: SEM, TEM, and further applications to coatings. The SEM section begins with a description of the electron-optical column including the electron gun, lens system, and scan coils. This is followed by a discussion of image formation and signal collection. The function of these components must be understood in order to create ideal operating conditions for SEM and to correctly interpret SEM images. Also included is a discussion of X-ray microanalysis, used to identify and measure the elements present in a sample. The SEM section also has an overview of sample preparation, including conductive coatings and cross-section analysis. In the TEM section is a brief discussion of contrast and electron optics. The last section discusses some additional applications of electron

microscopy to coatings, from pigment sizing and identification to structure and wear.

SCANNING ELECTRON MICROSCOPY

The main specifications that control the performance of an SEM are the type of electron gun and whether the sample chamber will have variable pressure capabilities (in addition to the standard high-vacuum sample environment). In configuring an SEM, there are a wide variety of choices in signal detection systems. These have to be balanced against the size and geometry of the sample chamber. Vacuum systems for SEMs have become more complex due to the need for higher vacuum in the electron gun and lower (weaker) vacuum levels in the sample chamber. Two excellent texts are available to the reader desiring more detail on SEM and X-ray microanalysis [4,5].

The SEM can image surfaces at magnifications from about 10 to 200,000 times. Depth of focus is large, so rough surfaces may be fully focused. The types of signals that can be collected include SE, BSE, and characteristic X rays. As the electron beam scans the sample, the signal from each spot is collected, amplified, and synchronously displayed on the monitor with intensity proportional to the collected signal. The same scan generator deflects the electron beam across both the sample and the monitor and therefore the image displayed is a magnified view of the scanned area. In digital SEMs, the scans are digitally stepped with control over step size and dwell time per pixel.

To clearly see a feature of interest requires sufficient contrast, magnification, and resolution. Each of the signal types noted above has its own contrast mechanisms. Although SEMs commonly have magnification ranges above 100,000 times, obtaining a useful image at those magnifications requires sufficiently fine resolution. Spatial resolution is the ability to differentiate two closely spaced objects, measured by their distance of separation. An instrument with 3 nm spatial resolution will not provide sharp images of 3 nm objects. Instead, it will be able to differentiate larger objects spaced as closely as 3 nm apart, if they respond ideally under the electron beam.

A schematic diagram of the SEM is shown in Fig. 2. Electrons are drawn out of the gun by the electric field between the source and the anode. The condenser lenses form the beam into a finely focused probe. The scan coils cause the probe to scan across the sample in a raster. The final lens focuses the beam on the sample. Any combination of BSE, SE, and characteristic X rays can be detected. Details of the function of each component in the SEM are discussed below.

Electron Guns

The ultimate resolution of an ideal sample imaged in the SE mode of SEM is substantially controlled by the type of cathode in the electron gun, or source. The resolution is improved by making the probe diameter at the specimen surface smaller. This beam diameter can be expressed in nanometers as

$$d_{\min} = KC_s^{1/4}\lambda^{3/4}(1 + i_p/B\lambda^2)^{3/8}$$

where K is a constant near one, C_s is the spherical aberration of the lens, λ is the electron wavelength in nanometers, i_p is the probe current in amperes, and B is the electron gun brightness (in amperes per centimeter squared—steradian) [4]. To decrease the beam diameter (improving resolution) one can use an electron gun with higher brightness (current density). In any SEM, lowering the probe current (using condenser lens controls) and decreasing wavelength (by increasing accelerating voltage) should decrease probe size.

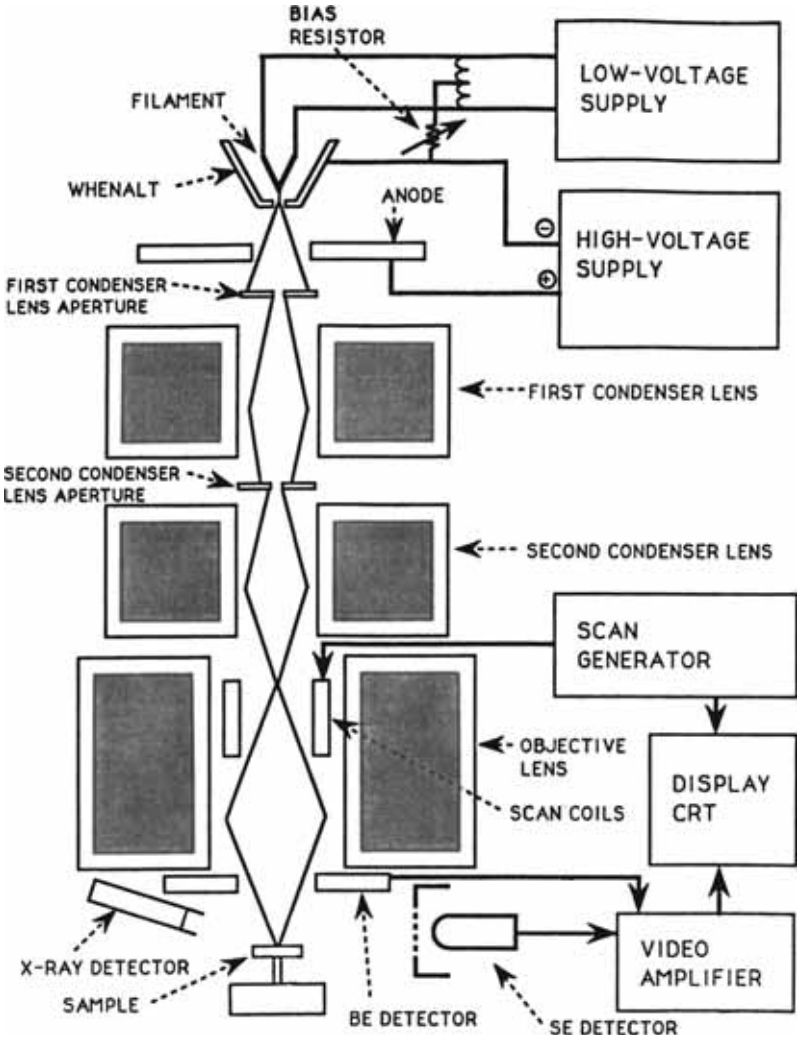

Fig. 2—Schematic diagram of an SEM with a thermionic electron gun. The "objective" lens is actually a final condenser lens. Adapted from Thomas [6] with permission from John Wiley and Sons.

An SEM can be designated conventional or field emission (abbreviated FESEM or FEG SEM), depending on which gun type is incorporated. Characteristics of electron sources are summarized in Table 1. A conventional SEM may have either a tungsten filament or a lanthanum hexaboride (LaB_6) crystal cathode, the most common thermionic cathode materials. Thermionic excitation occurs when a filament is heated to near its potential-energy barrier, allowing electrons to overcome their work function and eject themselves into the vacuum. Tungsten cathodes consist of a wire bent like a hairpin. They are easy to operate and need only moderate vacuum to prevent oxidation. However, they require frequent replacement (ca. 50–100 h). LaB_6 cathodes consist of a crystal of that compound mounted in refractory metal strips or an intermediate carbon-ceramic support. Compared to tungsten, LaB_6 has higher current density, and a smaller diameter of the first crossover, resulting in better resolution (Table 1). Another advantage of LaB_6 cathodes is their significantly longer lifetimes. However, LaB_6 guns require a somewhat higher vacuum to prevent contamination and reactions of LaB6 with oxygen-containing residual gases [5]. This adds to the expense and complexity of the gun vacuum system.

Field emission electron guns deliver orders of magnitude higher current density (brightness) than conventional SEM sources, but require a larger capital investment. FESEMs are made with either cold or thermal field emission design. Field emission occurs when a huge potential gradient ($>10^7$ V/m) is applied to a tungsten tip of about 0.1 μm in diameter, causing electrons to tunnel through their potential barrier. No thermal energy is needed to lift the electrons over the barrier. The combination of high current density and small diameter of the first crossover in field emission (FE) guns makes possible ultrahigh resolution (<1 nm) SEM imaging. The diameter of the first crossover from a field emitter is only about 10 nm and therefore only one condenser lens is needed to demagnify the probe enough for high-resolution imaging. Gas molecules that strike the tip cause the work function to rise and the emission to fall. Field emitters that operate at room temperature (known as "cold field" emitters) require vacuum better than 10^{-8} Pa. Even in a clean vacuum, gas molecules eventually cover the tip. The tip is cleaned by rapid heating (flashing) at about 2300 K.

A second type of high current density source is thermal field emission, including the Schottky design. This cathode

TABLE 1—Performance parameters for electron sources in SEM[a]

	Tungsten	Lanthanum Hexaboride	Cold Field Emission	Schottky Thermal Field Emission
Gun vacuum, Pa	10^{-3}–10^{-4}	10^{-5}	10^{-8}	10^{-7}
Lifetime, hours	50–100	≥1000	thousands	thousands
Source size	50 μm	10 μm	2 nm	20 nm
Brightness, A/cm^2-sr	10^5	10^6	10^8	10^8
Signal stability, (% drift/hour)	1	2	5[b]	1–2
Maximum probe Current, A	2×10^{-5}	2×10^{-5}	5×10^{-9}	5×10^{-7}
Energy spread, electron-volts	2	1	0.1	0.2
SE resolution @ 30 kV, nm	3.5	2.5	0.5	1

[a]Approximate values. Adapted from sources including Goldstein et al. [4] with permission from Springer-Verlag.
[b]Stability commonly improved by correction circuitry.

contains a zirconium oxide (ZrO) coated tungsten crystal maintained at 1800 K. The high temperature avoids the flashing required to clean cold FE tips and accommodates a slightly weaker gun vacuum. The ZrO coating lowers the work function, easing electron emission [4]. Schottky emitters can produce higher beam currents, valuable in some backscattering and x-ray analysis applications.

SEM at low accelerating voltages (below 5 kV) has the advantages of less specimen damage and less surface-charge buildup, when lower beam currents are used. There is improved representation of surface details because the primary electron beam does not penetrate as deeply, and there is a smaller region of secondary electron emission. Low-voltage SEM had been limited in resolution mainly by large chromatic aberrations in final lenses, which arise from the large energy spread of electron beams from thermionic cathodes. This problem has been overcome by FE cathodes, whose energy spread is an order of magnitude smaller than in thermionic cathodes (Table 1). The merits of low-voltage SEM for surface imaging and EDS were discussed by Boyes [7].

Magnetic Lenses and Scan Coils

The purpose of the condenser lens system in the SEM is to deliver electrons from the first crossover to the specimen plane in a small-diameter, high-intensity beam. SEMs with thermionic electron guns have two demagnifying condenser lenses plus a final condenser lens (Fig. 2). The first condenser is placed halfway between the second condenser and the electron gun, and the second is placed halfway between the gun and the specimen. Two condenser lenses instead of one are advantageous because more electrons are collected and focused into the probe, and the probe diameter is smaller. The spray aperture in each condenser lens intercepts scattered electrons and decreases spherical aberrations. The first spray aperture is usually fixed and the final aperture is selectable to varying diameters. While a smaller probe diameter improves resolution, it is not always advantageous because it reduces both the probe current and the signal-to-noise ratio. Higher probe currents are needed for EDS and some BSE detectors. The operator must decide which combination of aperture and condenser lens currents fits the requirements of resolution and signal detection.

The lens closest to the sample is often incorrectly called the "objective" lens. It is more accurately called the final condenser lens. There is no objective lens in an SEM because, unlike a TEM and compound light microscope, all SEM lenses are on the same side of the sample as the illumination source (electron gun). The purpose of the final lens is to provide the operator with a fine control for the focus of the beam at the sample surface.

The scan coils, located within or above the final lens, deflect the electron beam across the sample in a raster pattern. The image signal from a selected detector is simultaneously displayed on the monitor in the same positional coordinate system. Magnification is the ratio of a feature's length in the image to the length of that same feature in the sample. The distance between the bottom of the final lens and the top of the sample is known as the working distance. The depth of focus is inversely proportional to the working distance. Probe diameters are small when the beam is focused at short working distances. Therefore, high-magnification imaging should be done at short working distances, and low-magnification imaging should be done at long working distances (if more depth of focus is desired).

Image Formation

Most SEMs are equipped to detect SEs, BSEs, and characteristic X-rays as the electron beam scans across sample surfaces. The SE signal is produced when bound electrons are removed as a result of inelastic scattering of the electron beam. The intensity of the SE signal depends partly on the orientation of the sample feature with respect to the primary electron beam, which is why SE images provide topographic contrast. X-ray detection is discussed in a later section.

BSEs result from elastic scattering of the primary electron beam. Electrons are elastically scattered when they penetrate the electron clouds of target atoms and change direction without losing energy. An electron is backscattered after a series of direction-changing elastic events that cause the electron to exit the sample. The probability of a backscatter event depends on the size of the nuclei and, therefore, backscatter contrast depends on the distribution of an average atomic number in the sample. BSE images of flat specimens show higher atomic number phases as brighter. The depth in a sample from which BSE information emerges ranges from about 80 nm for gold to about 600 nm for aluminum if the accelerating potential is 20 kV [5]. Since BSEs can come from deep in the sample (lower

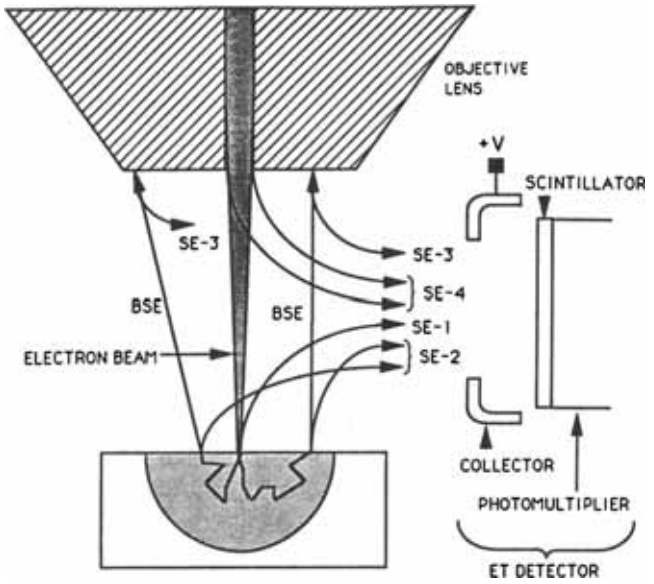

Fig. 3—Types of secondary electrons collected by the ET detector. SE1 carries high-resolution topographic information. Adapted from Reimer [5] with permission from Springer-Verlag.

in the teardrop in Fig. 1), the spatial resolution is generally poorer than in SE images. The BSE signal strength drops rapidly below 10 kV, and its behavior changes significantly below 5 kV.

Although some BSEs reach the Everhart–Thornley (ET) detector used for SE collection, it is an inefficient way to collect BSEs. BSE detectors are generally either of the solid-state or scintillator design. They are retractable or permanently mounted above the sample (labeled "BE Detector" in Fig. 2). A solid-state detector is a disk-shaped detector placed just below the final lens with a hole in the center for the electron beam. Scintillator-type detectors have an aluminized layer on a light pipe connected to a photomultiplier. They take up more space but respond better at fast scan rates.

Most SEM images are acquired with secondary electrons using the ET detector, shown in Fig. 3. SEs have low energy (<50 eV) and escape from the near-surface to provide more surface-sensitive data with higher resolution than BSEs. The ET detector collects mainly SEs, with a small contribution of BSEs. The major components of the ET detector are a collector grid, a scintillator, and a photomultiplier. SEs are pulled toward the scintillator by a small positive potential on the collector grid. A 10 to 12 kV bias on the scintillator coating accelerates SEs enough to cause photon emission when they strike the scintillator.

Secondary electrons are classified into four types, shown schematically in Fig. 3. SE1s are generated by direct interaction with the primary beam and therefore carry the highest resolution information. SE2s are generated by backscattered electrons as they exit the sample surface and therefore contribute subsurface atomic number contrast. Since SE2s come from a large electron diffusion zone around the primary beam, they degrade spatial resolution. SE2s cannot be detected separately from SE1s, but operating parameters (like lower accelerating potential) can lower their contribution.

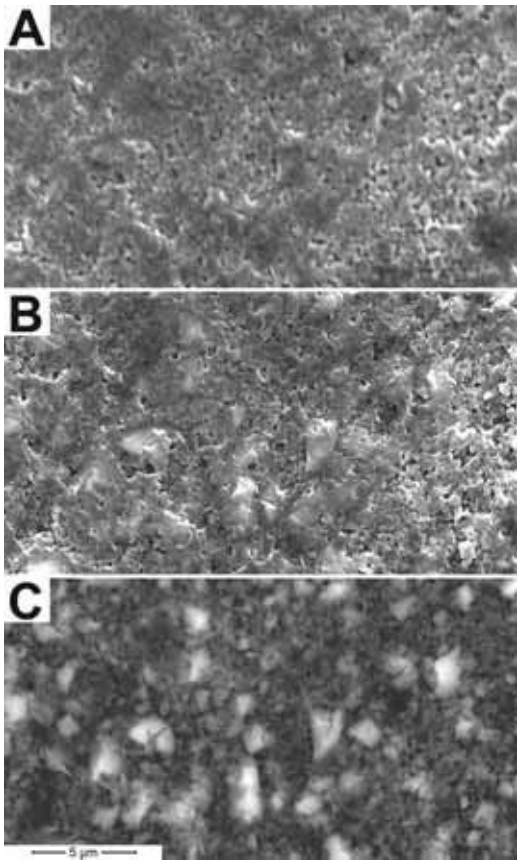

Fig. 4—Three SEM images of the same area of a coated paperboard used for food packaging. (A) SE image at 5 kV; (B) SE image at 20 kV; (C) BSE image at 20 kV. Bar = 5 μm. Photos by S. A. Wight, National Institute of Standards and Technology (NIST).

SE3s are generated by backscattered electrons that strike the final lens pole piece and the specimen chamber walls. SE4s are generated when the primary beam strikes internal column parts. SE3s generated at the final lens pole piece can be reduced with a shield made of low SE-emitting material, such as carbon-coated aluminum, placed just below the final lens. A +50 V bias applied to the shield prevents the escape from the shield of any SE3s. Reimer [5] discussed these signal types in detail. Peters [8] reviewed procedures for high-resolution SE image formation.

To demonstrate the importance of SEs and BSEs in generating contrast in the SEM, three micrographs of the same area of a coated paperboard used in food packaging are shown in Fig. 4. The coating contains kaolin clay and calcium carbonate pigment in an organic binder. Micrographs in Figs. 4(*A*) and 4(*B*) were recorded at 5 and 20 kV accelerating potential, respectively, with an ET detector. In Fig. 4(*A*) at 5 kV, the surface looks porous but uniform with pigment particles barely visible in the binder due to the low energy BSEs, therefore weak signal from SE2 and SE3, and dominance of SE1. In Fig. 4(*B*), pigment particles are becoming visible from within the coating blend due to a combination of SE2, SE3, and BSE. This is possible because of the greater exit depth of BSE at 20 kV. Comparison of Figs. 4(*A*) and 4(*B*) demonstrates the strong dependence of accelerating voltage on the appearance of SEM

images. Sometimes more than one accelerating voltage is needed for coating characterization.

The micrograph in Fig. 4(*C*) shows the same area as Figs. 4(*A*) and 4(*B*), this time recorded with a solid-state BSE detector at 20 kV. Since no SEs were detected, the binder near the sample surface generated little signal. Instead, contrast was mostly generated by the distribution of pigment particles within the coating. This example illustrates the importance of understanding signal generation in the SEM in order to correctly interpret images. Observation of only Figs. 4(*B*) and 4(*C*) might lead one to the false conclusion that the binder does not cover the pigment particles. The SEM was operated at normal (high) vacuum, with a thin gold coating added to the sample for electrical conductivity.

X-Ray Microanalysis

Inner shell ionization is the event that triggers characteristic X-ray production. An X-ray photon is produced when an electron from an adjacent shell drops to an inner shell to replace the ejected electron. Each element has its own set of characteristic X-rays and therefore elements present in a sample can be identified by their wavelength or energy if a spectrum of emitted X-rays is collected. That is the basis of X-ray microanalysis.

There are two common types of X-ray detectors: the wavelength dispersive spectrometer (WDS) and the EDS. In WDS, a small portion of the emitted X-rays hit a crystal. X-rays that satisfy Bragg's law for the crystal are diffracted to a proportional counter. X-ray spectra are collected by varying the crystal type and its position on the focusing circle. The advantages of WDS are excellent energy resolution (avoiding elemental overlaps), lower limit of detection (about 100 ppm instead of 1000 ppm), and high a signal-to-noise ratio. However, WDS uses higher beam currents than EDS (more sample damage and larger probe size), and is very sensitive to surface roughness. Also, simultaneous multielement acquisition requires more than one detector.

Before EDS was introduced to SEM in 1968, X-ray microanalysis was primarily done with WDSs using dedicated electron microprobes. EDS has poorer energy resolution than WDS (ca. 140 eV versus 20 eV), but the whole energy spectrum can be recorded simultaneously and therefore the elemental components can be quickly identified. Today, EDS detectors are routinely installed on SEMs. In EDS, X-rays pass through a thin window to a lithium-doped silicon crystal. The energy of incoming X-rays is measured from the number of electron-hole pairs generated in the crystal by each X-ray photon. A beryllium (BE) window (ca. 8 μm thick) usually separates the vacuum in the microscope from that around the liquid nitrogen cooled Si(Li) crystal. The BE window blocks out most X-rays from elements lighter than atomic number 11 (sodium). Windowless and ultra-thin window detectors extend the range down to $Z = 4$ (BE). Since the 1990s, durable atmospheric thin windows have been replacing Be windows, allowing full-time light element detection [9]. Silicon drift detectors have now become the preferred choice over Si(Li) for new EDS detectors because of their rapid acquisition speed, ability to handle high count rates, and freedom from liquid nitrogen cooling.

Accurate quantitative analysis requires careful control of conditions and an understanding of the beam interaction volume. In quantitative X-ray analysis with EDS, the X-ray intensities of each element in a sample are measured and compared to the measured intensities of well-characterized standards. The concentration of each element in the sample is the ratio of the X-ray intensity of each element in the sample to that in the standard. Still, corrections are needed to account for the different ways X-rays are generated in the sample compared to the standard. These include backscattering and the stopping power (Z), X-ray absorption (A), and fluorescence (F). Together, these corrections are known as the ZAF correction. EDS analytical systems available from commercial vendors have computer programs that calculate ZAF corrections, or the alternative $\phi(\rho z)$ corrections [9]. Quantitative EDS analysis without standards has its limitations, but has been effectively applied [10].

In X-ray mapping a compositional image is created with elemental windows selected from an EDS or WDS detector. Labana and Wheeler [11] mapped the spatial distribution of elements in a corroding metal-coating interface of painted phosphated steel using an electron microprobe. Elemental concentrations were determined quantitatively from individual spot analyses using the wavelength dispersive detectors. With modern EDS hardware and software, full spectrum mapping allows extensive re-display and quantification of chemical data.

EDS elemental X-ray maps can be very useful in tracing production defects or failures in coatings. Fig. 5 from Germani [12] shows a cross-section of paint that was applied to a metal sign. The SEM/BSE image (upper left) reveals the location of the primer, white ink, and clear topcoat layers. The clear topcoat suffered delamination upon outdoor exposure. The failure at the ink-topcoat interface was attributed to chlorine migration into the clear coat from the ink (see the chlorine X-ray map). The titanium signal is from titanium dioxide pigment. Silicon in the primer may come from a mineral pigment and from a deglossing agent in the topcoat.

Crystal Orientation by SEM

Electron diffraction in the TEM is an established approach to the determination of crystal structure in electron microscopy. However, BSEs in an SEM can also be used to generate diffraction patterns. As with X-ray diffraction and other forms of electron diffraction, Bragg's Law controls the constructive interference of energy waves from a crystalline material. Electron diffraction from the focused beam on a poly-crystalline sample generates light and dark Kikuchi bands containing information on the crystal orientation and identity. Reimer et al. [13] compared approaches such as high energy electron diffraction, electron channeling patterns, and electron backscatter diffraction (EBSD).

EBSD holds great potential for the study of coatings. The patterns come from within tens of nanometers of the surface [14]. They can be used to map the orientation of crystallites and their grain boundaries and to identify the crystalline phase. Modern EBSD systems include a tilted mount, retractable camera, and specialized software to enhance and analyze the patterns. Low-cost high-speed computers allow rapid automated calculations and integrated image displays.

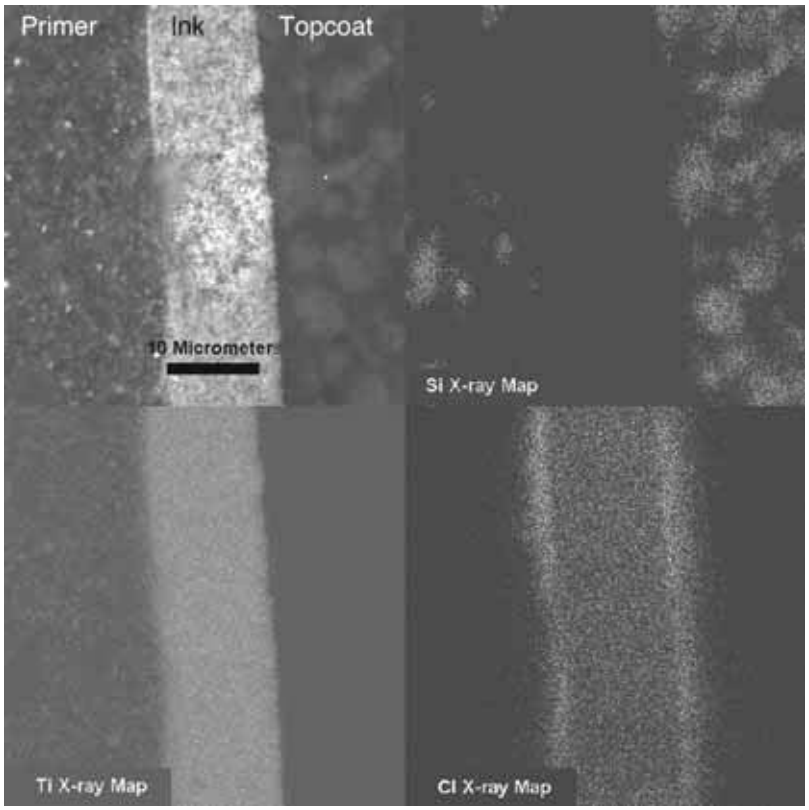

Fig. 5—SEM/BSE image and three elemental X-ray maps of a paint cross section. Bar = 10 μm. Reproduced with permission from M. S. Germani, Ph.D., Micro Materials Research, Westmont, IL, [12].

Conductive Coatings

Historically, all electrically nonconductive materials have been given a thin conductive coating prior to SEM analysis. Application of a 10 to 20 nm coating, after mounting the sample on a conductive base, provides a pathway for electron flow to prevent charge buildup. Metal coatings also increase SE yield and signal strength, indirectly improving feature resolution. With the advent of variable pressure SEMs (VPSEMs) and the operation of SEMs at low accelerating potential, there are now some situations in which a conductive coating may not be needed at all.

For routine SEM imaging with secondary electrons, gold or gold-palladium coatings are applied. When the main objective is analysis using the X-ray or BSE detector, carbon coating may be more appropriate. Carbon has low X-ray (and electron) absorption and its low-energy characteristic X rays are normally not in the range of sample peaks. Metal coatings can generate their own X-ray background and characteristic peaks in critical ranges. They can also suppress the BSE contrast inherent in the specimen. Carbon coatings will generally not produce the level of feature resolution or charge dissipation obtained with metal coatings. Carbon is usually deposited by thermal evaporation under high-vacuum, but some low-vacuum methods are also available.

Coating techniques for SEM include thermal evaporation, plasma-magnetron sputtering, and dc glow discharge. Films are formed by thermal evaporation when a metal wire or carbon rod is heated to its melting point in a high vacuum ($<10^{-3}$ Pa). Films formed by thermal evaporation have large grains compared to other techniques and may not reach areas of the sample that are shadowed from this point source. As the resolution of SEMs improved, the grain size of metal coatings became a limit to resolution. Coating techniques that produce thinner, continuous films with smaller grains were needed. Plasma-magnetron sputtering is one of them.

In magnetron sputtering, films are formed when ionized, inert gas atoms strike a metal cathode to eject metal atoms, which deposit on the sample. Ionization efficiencies and, hence, sputtering rates are increased with an annular magnetic field that surrounds the cathode to concentrate electrons in the cathode area [15]. Films made with magnetron sputtering have smaller grains than thermally evaporated films. The magnetron sputter-coater is now standard equipment in most SEM labs. Care should be taken not to allow rotary-pumped coaters to reach their ultimate vacuum. Otherwise, pump oil can disrupt nucleation when it contaminates the target and the sample. State-of-the-art magnetron coaters are evacuated with oil-free turbomolecular pumps and equipped with cold stages because low sample temperatures decrease grain size. Au/Pd alloy targets produce finer grain coatings than pure gold, but some users avoid them due to the additional peaks that appear during X-ray microanalysis.

Metal film thickness can be measured to ensure that only enough metal is deposited on the sample to form a continuous film. The quartz microbalance is the most widely used instrument to measure film thickness on electron microscopy specimens. Methods of film-thickness determination were discussed by Flood [16].

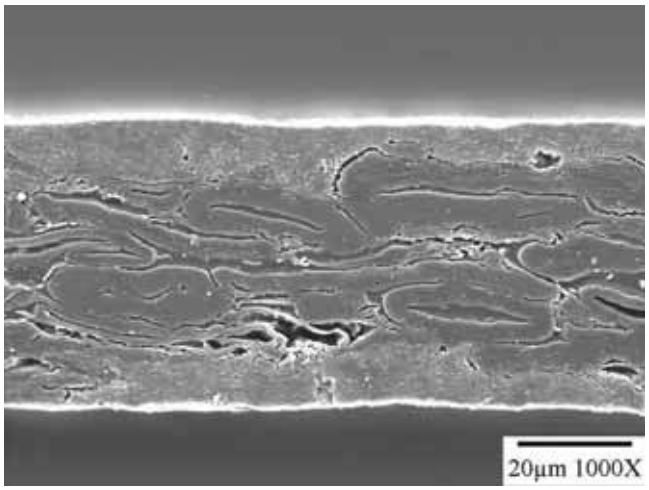

Fig. 6—Polished and etched cross section of lightweight clay-coated paper. Secondary electron SEM image. Bar = 20 μm. Photo by G. Maghiari, IPST.

Extra care is required to coat samples with ultrathin (1 to 4 nm) continuous films needed to take advantage of the high resolution at magnifications over 50,000 times, available from FESEMs. Magnetron coaters made to accommodate a chromium target and a greater range of controls are commercially available. More recently, a method of osmium coating through DC glow discharge has proven to provide excellent high-resolution images [17]. The osmium tetroxide dissociates in the glow discharge and ionized osmium molecules form an amorphous metal film on the sample surface. Safety considerations for the toxic osmium tetroxide have been addressed in the design.

Sample Preparation and Cross Sections

If samples are not dry and a cryogenic or variable pressure SEM is not available, some method of stabilization and drying will be necessary. This might simply entail drying in an oven or vacuum oven. If such drying will alter the microstructure, then freeze-drying or critical point drying may be used. Other approaches include exchanging the solvent with epoxy or making a cast/replica of the surface. Dry samples are trimmed to a size adequate for the microscope stage and attached to a planchet (mount) with conductive paint or tape.

When cross-sectioning is needed for analysis of internal structure or composition, several methods are available. Sometimes a broken or fractured edge is sufficient. Cut faces are usually too rough or smeared to reveal essential features. If the material is soft or plastic, freeze-fracturing in liquid nitrogen may work. The best sections are usually prepared with a microtome or by grinding and polishing. Dried paint and other coatings are normally embedded in epoxy prior to microtomy or metallographic polishing.

Microtomes are designed to cut sections of specified thickness ranges. Depending on the design, they may have metal, glass, or diamond knives. Rotary microtomes cut thick sections (ca. 20 μm) for light microscopy. Some ultra-microtomes have "thick" settings for sections approximately 2 to 10 μm thick, and "thin" settings for 50 to 200 nm TEM sections. Although microtomes do not generally work well on very hard materials, ultramicrotomes can be used to prepare ultrathin TEM sections of silicon wafers and ceramics [18]. For SEM, one only needs a cleanly cut block face, although the sections cut from it can be analyzed. Improved resins and microtomes have made cross-sectioning of paints less difficult. Derrick et al. [19] used glass knives in an ultramicrotome to produce 5 μm-thick paint sections.

Cross sections are often used to determine the thickness, composition, and structure of coating layers with SEM. Coated papers have historically been sectioned by microtome, but grinding and polishing (after epoxy embedding) have become more common due to improved procedures and the larger sample area exposed [20]. Fig. 6 shows an SE image of a polished and etched section of coated paper with excellent detail. Sometimes BSE imaging is used to display the compositional contrast of coating layers and components. ASTM Test Method D5235 [21] (method withdrawn) describes a grinding-polishing method for preparing and measuring cross sections of coatings on wood, using light microscopy. With modification, this procedure might be used for SEM, especially VPSEMs that do not require dry specimens.

On the leading edge of cross-section technology is focused ion beam (FIB) preparation for TEM and SEM. These systems are quite expensive but have been extensively used in semiconductor analysis. Typically, the FIB workstation has a gallium ion source that is used to thin and shape a small area of interest. This method has enabled the production of well-resolved images of thin ink layers on printed paper [22]. Dual beam FIB/SEM instruments allow the operator to guide and observe the sectioning of a sample. Layered fuel cell electrodes were prepared and analyzed this way [23]. By imaging the surface during progressing ion milling, the authors were able to build a three dimensional model of the structure. In another FIB/SEM study [24], structural components and defects in carbon fiber composites for nuclear fusion devices were characterized.

Cryogenic SEM

Electron microscopes operating in the normal high-vacuum mode have a pressure lower than 10^{-3} Pa in their specimen chambers. This limits conventional SEM to dry samples. When volatile samples like paints are placed in the SEM specimen chamber their solvents quickly evaporate, contaminating the electron column, damaging the vacuum pumps, and causing the electron beam to scatter. One solution is to lower vapor pressures by freezing and examine samples in an SEM equipped with a stage cooled by liquid nitrogen. The technique is known as cryogenic SEM (cryo-SEM), described by Sheehan [25–27] for examining paper-coating formulations. The reader is also referred to Echlin [28] for more on techniques of cryo-electron microscopy.

The procedure of cryo-SEM is to fast-freeze each sample and transfer it into a vacuum chamber attached to the SEM specimen chamber. There each sample is fractured, sometimes etched, and then coated with a thin metal film. Then the sample is transferred to a cold stage in the SEM. The challenges of high-resolution cryo-SEM are to freeze fast enough to prevent noticeable growth of ice crystals, transfer without condensing water vapor on the fracture

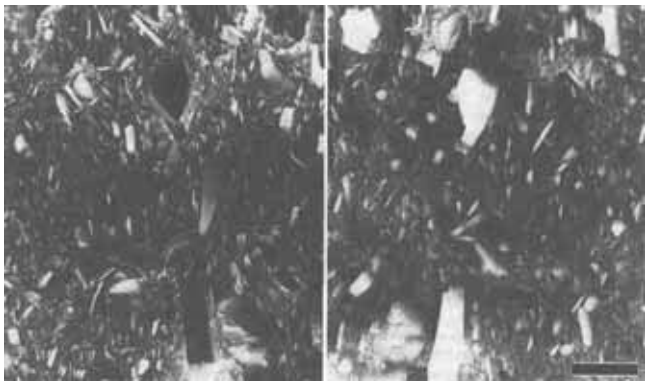

Fig. 7—Cryo-SEM image of complementary fracture faces of a coating formulation. Bar = 1 μm [26]. Reproduced with permission from Microscopy Society of America.

surfaces, coat frozen-hydrated samples with an ultrathin, continuous metal film, and image in the SEM without too much buildup of contaminants.

Wet microstructures of coating formulations can be examined with cryo-SEM after freezing and fracturing. Complementary fracture faces of a frozen-fractured pigment/latex coating formulation are shown in Fig. 7. Kaolin and calcium carbonate particles can be identified by their morphologies. The dark areas between the particles are ice. Close examination of the complementary faces shows that fractures propagated around the pigment particles.

Environmental and Variable Pressure Scanning Electron Microscopy

Cryo-microscopy is one approach to imaging volatile samples in the SEM. VPSEM, including the environmental SEM (ESEM), is another. Before the advent of the ESEM, some operators mechanically limited the vacuum level (ca. 20–200 Pa) in the SEM sample chamber and imaged their materials exclusively with a BSE detector. Usually a scintillator-type BSE detector was used because of its greater topographic contrast and better response at high scan speeds than solid-state detectors. In recent years, SEM vendors began to offer variable pressure capabilities on many microscope models, some advertising a resolution of 5 nm in variable pressure mode.

A revolutionary development in SEM in the 1980s allows the imaging of wet, volatile specimens without freezing. It is known as ESEM [29]. With the ESEM, samples are imaged in a gaseous environment at pressures up to 2.7 kPa. This is made possible by a combination of a differentially pumped vacuum system, small travel distances for the electron beam in moderately pressurized gas, and (most importantly) a biased current detector known as the gaseous secondary electron detector. The gas in the specimen chamber promotes SE signal multiplication and neutralizes charge buildup on samples. Therefore, a conductive coating is not required for imaging electrically insulating samples. ESEM SE resolution approaches that of conventional high vacuum SEM operation. To obtain optimum images from some samples, a conductive coating may still be needed to boost SE contrast. EDS elemental analysis can be performed in VPSEM/ESEM modes, but the spread of the electron beam in the gaseous environment makes spot analysis by EDS more difficult to control and quantify [30].

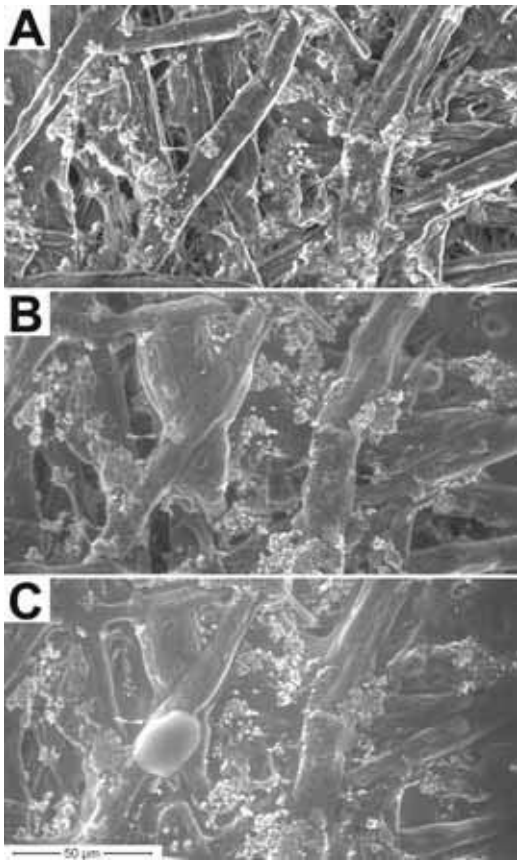

Fig. 8—ESEM micrographs of the same area on uncoated writing paper as water condenses. (A) ambient dryness, 20°C, 293 Pa; (B)condensation and fiber damage, 7°C, 933 Pa; (C) water drops and films, 7°C, 1093 Pa. Bar=50 μm. Photos by S. A. Wight, National Institute of Standards and Technology (NIST).

The main advantage of ESEM compared to conventional SEM is that hydrated samples can be examined in their natural states at water-saturated vapor pressures. This also makes possible dynamic imaging of wetting and drying by controlling sample temperature and water vapor pressure. Other experimental gases can be used in the ESEM sample chamber instead of water vapor.

Care must be taken with ESEM of hydrated specimens to avoid specimen damage by radiolysis products of water. Water molecules are radiolyzed by the electron beam into mainly hydrogen and hydroxyl radicals, which diffuse into specimens and sometimes damage them [31,32]. Radiation damage from free radicals in hydrated specimens was documented in TEM by Leapman and Sun [33]. Molhave et al. [34] concluded that water vapor enhanced irradiation induced destruction of carbon nanotubes in both SEM and TEM.

Fig. 8 demonstrates real time water condensation in an ESEM sample chamber. Fig. 8(*A*) is an ESEM image of writing paper (with wood pulp fibers) in its natural state at 20°C and 293 Pa pressure. Accelerating potential was 10 kV and no conductive coating was used. Water was condensed in the same area by raising the pressure to 933 Pa and lowering the stage temperature to 7°C (Fig. 8(*B*)). Beam damage, perhaps enhanced by radiolysis, can be seen in the prolonged exposure used for this demonstration. In

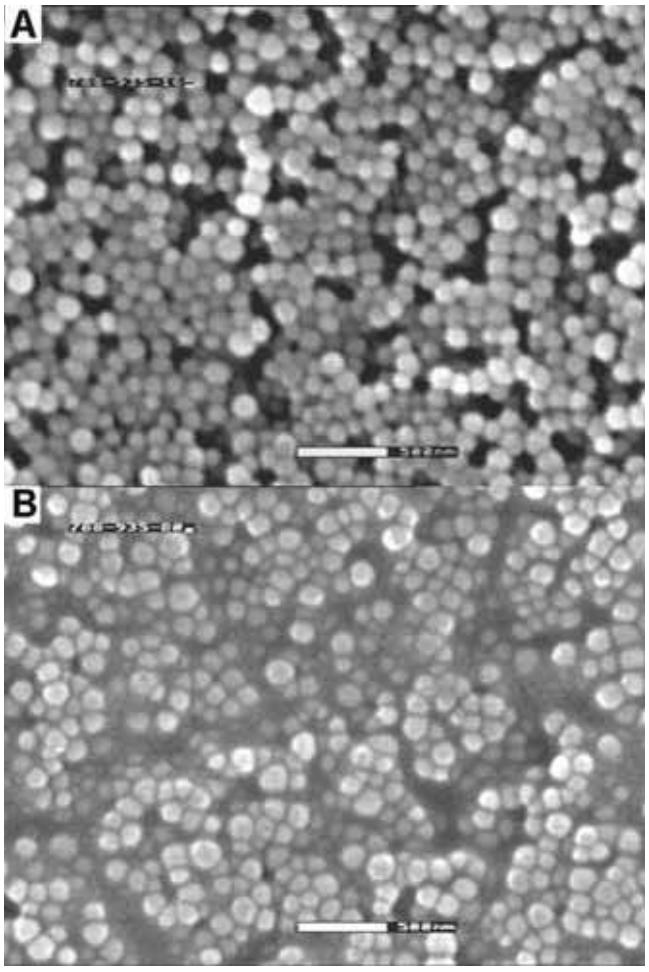

Fig. 9—ESEM micrographs of two coatings containing 0.10 μm plastic pigment with latex levels of (A) 14 wt. %; (B) 44 wt. %. Bar = 500 nm. Reproduced from Xiang and Bousfield [35] with permission from JPPS.

Fig. 8(*C*), at 7°C and 1093 Pa, water droplets and films can be seen.

A paper coating formulation with plastic pigment and a high latex content is susceptible to damage and difficult to image in a conventional SEM [35]. ESEM images in Fig. 9 compare 0.10 μm plastic pigment in mixtures with 14 % and 44 % latex binder by weight. They show the packing of pigment particles and filling of interparticle pores. Few pigment-size pores are open at the 44 % binder level.

TRANSMISSION ELECTRON MICROSCOPY

The TEM produces images from electrons that have been transmitted through ultrathin sections of samples, or naturally thin particles. The spread of the beam in a sample is minimized by the thin specimen, allowing a higher spatial resolution than SEM. Modern TEMs can resolve better than 0.2 nm. Contrast mechanisms include scattering, diffraction, and phase contrast. The useful thickness of amorphous samples at 100 kV is 100 to 3000 nm. For metal foils and crystalline materials at 100 kV, it is about 50 to 200 nm [36]. With added STEM capabilities, compositional and structural data can be collected from a spot 1 nm or less in diameter.

Types of Contrast

Electron beam interactions that lead to contrast in the TEM are shown in Fig. 1. In ultrathin samples, the beam does not spread into the teardrop shape shown for a bulk specimen. Electrons are elastically scattered by coulombic interactions with positively charged nuclei as they travel through TEM specimens. Scattering contrast is also known as amplitude contrast, or mass-thickness contrast, because the amount of scattering depends on specimen thickness and atomic number. Scattering contrast in TEM can be imaged in the bright-field mode and in the dark-field mode. In the bright-field mode, electrons that are scattered at larger angles are intercepted by the objective aperture. Others pass through the objective aperture and form the image. In the dark-field mode, only the electrons that are scattered at large angles are used to form the image. This is accomplished by tilting the electron beam off axis or by moving the objective aperture off axis. In STEM, an annular dark-field detector collects that signal.

Another type of contrast caused by elastic scattering is known as phase contrast, the result of interference between the scattered and the unscattered electrons. Phase contrast varies as the objective lens focus is varied above or below the specimen. Diffraction contrast results when Bragg reflections from crystalline planes interfere with the primary beam. The interference image gives information about crystal structures. A TEM can be switched to diffraction mode to provide electron diffraction patterns for phase analysis.

Inelastic interactions in TEM include plasmon excitations and inner-shell ionizations. Some TEMs are equipped with electron spectrometers that measure the energy loss spectrum, known as electron energy loss spectroscopy. Electronic structures are indicated by plasmon losses, whose energies are less than 50 eV. Chemical compositions are indicated by losses from inner shell (K, L, and M) ionizations [36].

Optics

A schematic of an electron-optical column of a TEM is shown in Fig. 10. It is similar to an upside-down view of a compound light microscope, with the illumination source being an electron gun. The electron-optical column of the TEM differs from the SEM in several ways. First, the electron beam is not scanned across the sample (except in STEM mode). The condenser lens system illuminates the entire area to be imaged. Second, the TEM has a projector lens system that focuses the transmitted electrons onto a phosphor screen, where the image can be viewed. Third, higher accelerating potentials (80 to 500 kV) in TEM are needed to transmit electrons through thin samples. Accelerating potentials in SEMs range from about 300 V up to 30 kV.

The two condenser lenses work together in the normal TEM imaging modes. The first condenser lens (C1) controls the spot size, while the second condenser lens (C2) is used to adjust brightness. In the STEM mode, where a finely focused probe is required, C2 is essentially turned off, and the upper part of the objective lens is used as a third condenser lens to focus the beam.

The objective lens forms, focuses, and initially magnifies the image. In most TEMs the specimen is inserted

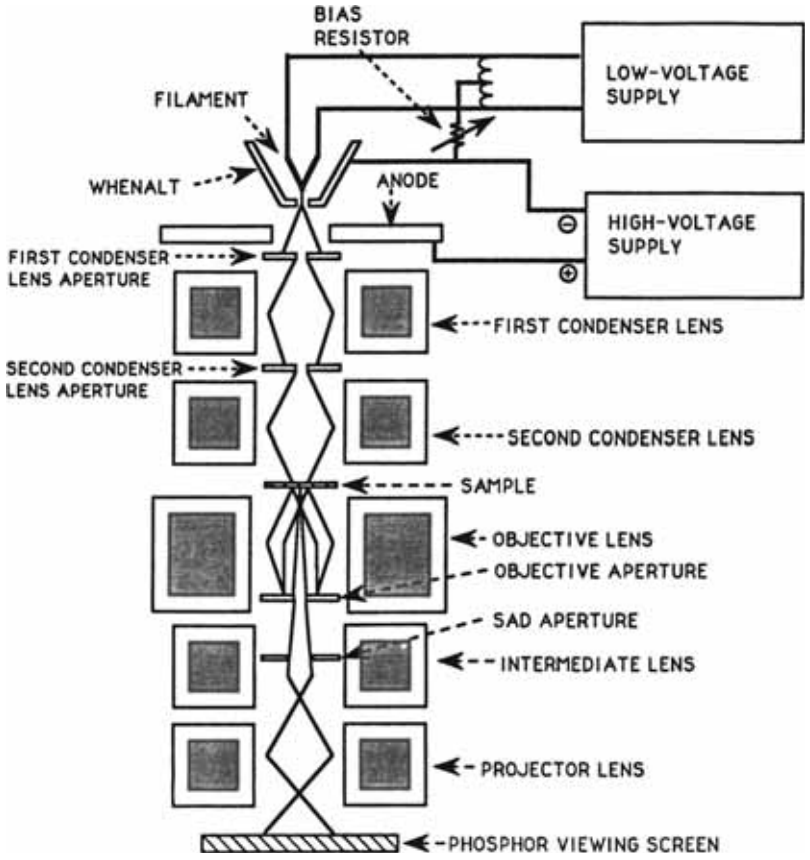

Fig. 10—Electron-optical column of the TEM. Adapted from Thomas [4] with permission from John Wiley and Sons.

into the objective lens section of the column. The objective aperture blocks scattered electrons in the bright-field mode, discussed earlier. Contrast is increased if a smaller objective is selected, but the signal strength will decrease accordingly.

The projector lens system projects the transmitted electrons onto the phosphor viewing screen or photographic emulsion. A wide variety of digital cameras are now available for image collection below the column or through a side-mounted camera port. Digital image collection has all but replaced film photography in TEM.

ADDITIONAL COATING APPLICATIONS

Pigment Particle Size and Identification

There are numerous non-microscopic methods for determining particle size distribution. Given a large, well-dispersed pigment population, these automated methods generate statistically valid measurements in very little time. Each approach, including microscopy, measures "size" differently and is likely to generate somewhat different results. Microscopic size measurement is a powerful approach when the shapes of particles need to be determined or when they are fixed in a dry coating. Particle-size measurements are more fully explored in a separate chapter of this manual.

The microscope is especially useful for measurement of plate-like and needle-shape particles that do not obey Stokes' law on which the sedimentation sizing methods are based. However, microscopic methods can be slow and laborious. In the past, particle-size analysis was performed by manually measuring particles with the aid of a reticle or grid on the microscope display or with a ruler using printed micro-graphs. Today, with size-calibrated digital images collected on electron microscopes, selected dimensions can be easily measured with the click of a mouse. Automated image analysis is possible if individual particles can be made to stand out unambiguously from their background by a combination of the right sample preparation, signal selection, and image processing. It must be understood that the particle images represent two-dimensional projections or slices of three-dimensional objects. True diameters may not be presented, and preferred orientation of particles in a coating will affect their shape within the section.

Pigments of known morphologies can be identified easily with both SEM and TEM. Some pigment particles are smaller than 0.1 μm and therefore conductive coatings must be ultrathin in order not to blanket morphologies of the particles before SEM imaging. Pigment particles can also be identified in SEM by their EDS spectra if the particles are larger than a few micrometers. Identification of smaller particles in SEM with an EDS is hampered by the large generation volume of X rays.

Fig. 11 shows images of kaolin clay taken with SEM (Fig. 11(*A*)) and TEM (Fig. 11(*B*)). The different contrasts in the SE mode with the SEM and in the bright-field mode with TEM are clear. The SE contrast is topographical and the TEM contrast depends on mass-thickness. In both, the pseudohexagonal, plate-like habits of particles are indica-

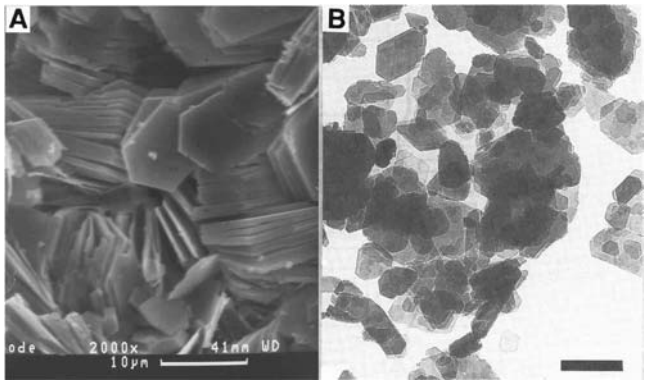

Fig. 11—Different kaolin clays imaged in (A) SEM. Bar = 10 µm. Photo by D. R. Rothbard; TEM. Bar = 0.5 µm. Photo by R. P. Gursky.

tors of the presence of kaolin. Clay identifications should be confirmed using other detection modes that provide chemical and structural data.

Contact diameters of various sizes of latex have been measured with SEM [37] and TEM [38], and compared to theoretical predictions. Demejo et al. [39] imaged with high-resolution SEM extents of latex deformation resulting from particle-substrate adhesion and compared their results to theoretical predictions.

Failures and Defects

Pits, cracks, and loss of adhesion can be readily examined with SEM. Some contaminants can be identified by their morphologies and others by their characteristic X rays using EDS. Here are some examples: SEM examination of a paint film that failed rapidly in a salt spray test revealed a textured surface that rusted rapidly in the pitted areas. When the paint was applied with a smooth finish, it passed the salt spray test. Poor scrubbability in a latex paint was due to lack of coalescence, readily apparent after SEM examination revealed many cracks in the film. Loss of adhesion on metal reflectors was due to insect eggs that pulled the paint off as the eggs dried. A glossy varnish, which turned out flat, was found to be laden with diatomaceous earth from a broken filter [40].

Quach [41] used SEM with EDS to identify contaminants responsible for adhesive failures. Welding splatter was identified as a cause of chipping of paint on a steel building chord. EDS was also used to identify plaster dust, fly ash, and sulfur dioxide as contaminants that caused adhesive failure in other samples.

Structure and Wear

Bishop and Silva [42] examined leaching of pigment in cross sections of antifouling paint films. Cross sections were made by fracturing in liquid nitrogen. They found a linear correlation between the leached matrix thickness and the volume fraction of pigment. Examination of complimentary fracture faces was required to see if leached pigment or fracture was responsible for voids. They also showed that the insoluble matrix of microtome-sectioned films was distorted.

Fay et al. [43] used SEM and EDS in an investigation of antifouling paints, to monitor the concentration and distribution of biocides. SEM images were used to document paint erosion after synthetic seawater exposure, in terms of texture and film porosity. The authors assumed they were obtaining quantitative EDS elemental analysis to the hundredths of a weight percent, which is an overinterpretation of standardless EDS analysis in an inhomogeneous medium.

SEM examination of weathered paint films showed the onset of chalking when binder wears away from between pigment particles [44,45]. However, the conclusion was that SEM images point to the cause of chalking, but gloss measurements are a more quantitative and economical method for routine weatherability evaluation.

Nylon coatings are used in such applications as printing rollers and marine hardware because of their wear and weather resistance. Thermally sprayed nylon 11 coatings with 7 and 12 nm silica pigment were sectioned and analyzed by SEM [46]. SEM was used to determine the structure of the raw materials and finished coating. Cross-section images, supported by EDS, showed nylon polymer cells surrounded by bead-like silica-rich interfaces.

FIB sectioning was mentioned earlier with respect to SEM preparation. It is used as much, if not more, for TEM. The method was applied in a TEM study of plasma spray coatings on aluminum and the interface between them [47]. Oxidative wear of a nano-structured TiAlN/VN coating was studied by TEM and EDS after FIB preparation [48]. The authors were able to detect a 20–50 nm thick wear induced tribofilm on the surface.

A combined analytical approach was used to examine the structure and composition of thermal barrier coatings (TBCs) designed for engine and turbine components [49]. Light microscopy, SEM, TEM, EDS, and X-ray diffraction methods were applied. Thick TBCs are commonly modified to increase their lifetime. The modification methods and their effects on structure and performance were compared.

Infrared Spectroscopy

Dwight G. Weldon[1]

INFRARED (IR) SPECTROSCOPY IS ONE OF THE most powerful analytical methods available in the coatings industry. It can be applied to both liquid and solid samples, and can be used to analyze both bulk samples and surfaces. Although perhaps the most fundamental uses of infrared spectroscopy are the elucidation of molecular structure and the identification of unknowns, it has great utility in the coatings industry as a problem solving tool. For instance, IR spectroscopy can be used not only to determine if the specified epoxy coating was actually used on a project experiencing coating failure, but can also be used to determine if the coating was mixed in the proper ratio of Part A to Part B, and maybe even to determine if it was applied over an organic contaminant such as grease or oil. In some cases, it can be used to determine a coating's degree of cure, or to examine surfaces for exudates, or to determine if the correct amount of plasticizer is present in a brittle lacquer. In short, IR spectroscopy is an essential component of the modern coatings laboratory.

THEORY OF INFRARED SPECTROSCOPY

Spectroscopy can be simply defined as the study of the interaction of light with matter. Since there are many different types of light, or electromagnetic radiation, it stands to reason that there must also be many types of spectroscopic techniques.

The classical interpretation of the nature of electromagnetic radiation, put forth by Christian Huygens in the late seventeenth century, ascribed to it a wavelike nature. In this view, light (radiation) consists of oscillating electric and magnetic fields moving through space at right angles to one another, with a characteristic frequency and wavelength (see Fig. 1). The wavelength (λ) is defined as the distance between successive maxima or minima (a cycle), while the frequency *(ν)* is the number of cycles per second. For electromagnetic radiation moving through a vacuum, the relationship between wavelength and frequency is as follows:

$$c = \gamma\nu$$

where c is the speed light (3.0×10^8 m/s). From this relationship, it can be easily seen that wavelength and frequency are inversely proportional to one another. In other words, as frequency increases, wavelength decreases, and vice versa. Although frequency is often expressed in cycles per second, or hertz, in infrared spectroscopy it is usually expressed in wavenumber, or reciprocal centimeter units, abbreviated cm^{-1}.

The wave theory of light was able to explain many, but not all, phenomena. This lead to the development in the early to mid twentieth century of quantum mechanics, which provided the very useful relationship that the energy of light *(E)* is directly proportional to its frequency, as follows:

$$E = h\nu$$

where h is Planck's constant (6.6×10^{-34} Js).

The electromagnetic spectrum is depicted in Fig. 2. As shown in this figure, the different types of electromagnetic radiation have different frequencies, and hence different energies. As a consequence of this, they interact differently with matter. For example, the very high frequency gamma rays, shown at the far left of the table, are sufficiently energetic to disturb the structure of the nucleus of an atom and cause radiation sickness, while the low frequency microwaves are only able to affect the rotation of molecules, and are useful for less destructive tasks such as heating water. Infrared radiation is roughly in the middle of the table, and is energetic enough to interact with the internal vibrations occurring in molecules.

Molecules are in a constant state of motion. Not only does this include translational motion through space, but it also includes the stretching and bending of the chemical bonds holding the various atoms of a molecule together. These stretching and bending vibrations occur within very discrete ranges of frequency, depending on the type of atoms and the type of chemical bonds holding them together. For example, Fig. 3 depicts some of the vibrations which can occur in a simple fragment of a molecule consisting of a carbon atom bonded to two hydrogen atoms. As shown in Fig. 3, if the carbon–;hydrogen bonds stretch in and out together, this occurs at a frequency of about 2850 cm^{-1}. If the bond lengths stay the same, but the angle of the bonds change in a bending or scissoring type action, this occurs at a frequency of about 1470 cm^{-1}.

If the frequency of infrared light focused through or on a sample identically matches the frequency of one of these molecular vibrations, the sample can absorb some of this light. In practice, the sample is scanned over a wide range of frequencies, typically from about 4000 to 400 cm^{-1}, and a spectrum is produced showing the frequencies at which the infrared light is absorbed. Since these correspond to the frequencies of the internal molecular vibrations occurring

in the sample, and since these vibrations are indicative of the type of atoms and how they are bonded together, an infrared spectrum provides a great deal of information on the chemical structure of the molecule.

The infrared spectra of methyl ethyl ketone (MEK) and toluene, two common solvents used in the paint industry, are shown in Fig. 4. Since MEK and toluene have dramatically different molecular structures, their spectra are also dramatically different. Indeed, every compound has a unique infrared spectrum, which is sometimes referred to as a "fingerprint." Sometimes differences are dramatic and sometimes they are subtle, but as Fig. 4 demonstrates, infrared spectroscopy can be a very powerful tool in the identification of unknowns.

A quick examination of the spectra in Fig. 4 shows that they have many bands, including those near 2900 cm^{-1} due to the carbon–hydrogen stretching vibrations discussed above. The very strong band near 1720 cm^{-1} in the spectrum of MEK is due to a carbon atom double bonded to an oxygen atom (a carbonyl group). While all of these bands correspond to one type of vibration or another, and therefore provide a great deal of information about the structure of the molecule, it is not always necessary to be able to assign every single band to a particular type of molecular vibration. Indeed, in some cases this would be extremely difficult. There are many excellent collections of infrared spectra, such as "An Infrared Spectroscopy Atlas for the Coatings Industry" [1], which enable one to identify a compound without having to laboriously assign every single peak to a particular vibration. There are also electronic databases available which allow spectral searching on the computer.

Although many compounds can be positively identified simply by matching up the spectrum of the unknown to a spectrum contained in a reference collection, it is still desirable to have at least a general understanding of where the major bands from the more common functional groups

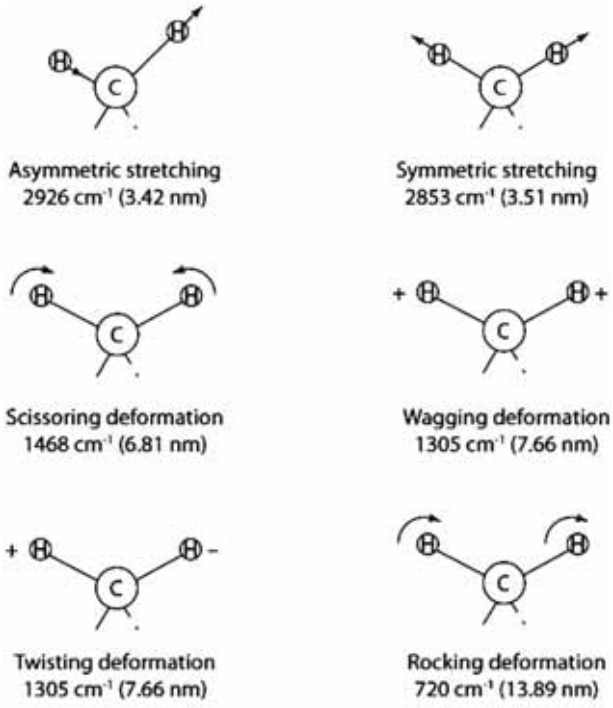

Fig. 3—Bending and stretching vibrations of a CH2 group. Courtesy of Spectroscopy Atlas.

absorb infrared radiation. This would be a very formidable task were it not for the fact that it has already been done. Because the frequencies of the stretching and bending vibrations of any pair of atoms is only modestly affected by their proximity to other atoms in the molecule, one can always expect, for instance, that the C═O stretching vibration will occur between roughly 1650 to 1750 cm^{-1} and the carbon-hydrogen stretching vibrations will always occur between approximately 2950–2850 cm^{-1}, regardless of the structure of the rest of the molecule. Because of this, and after a great deal of research, tables known as correlation charts have been developed which show where the various functional groups absorb infrared light. These tables are indispensable in the interpretation of infrared spectra, and can be found in many texts on infrared spectroscopy [1,2].

Not only do correlation charts tabulate where certain vibrations occur, they often provide information about

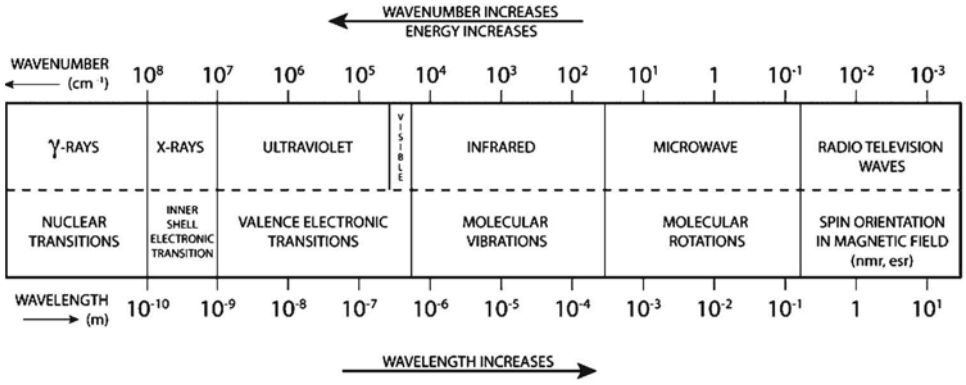

Fig. 2—Electromagnetic spectrum. Courtesy of Spectroscopy Atlas.

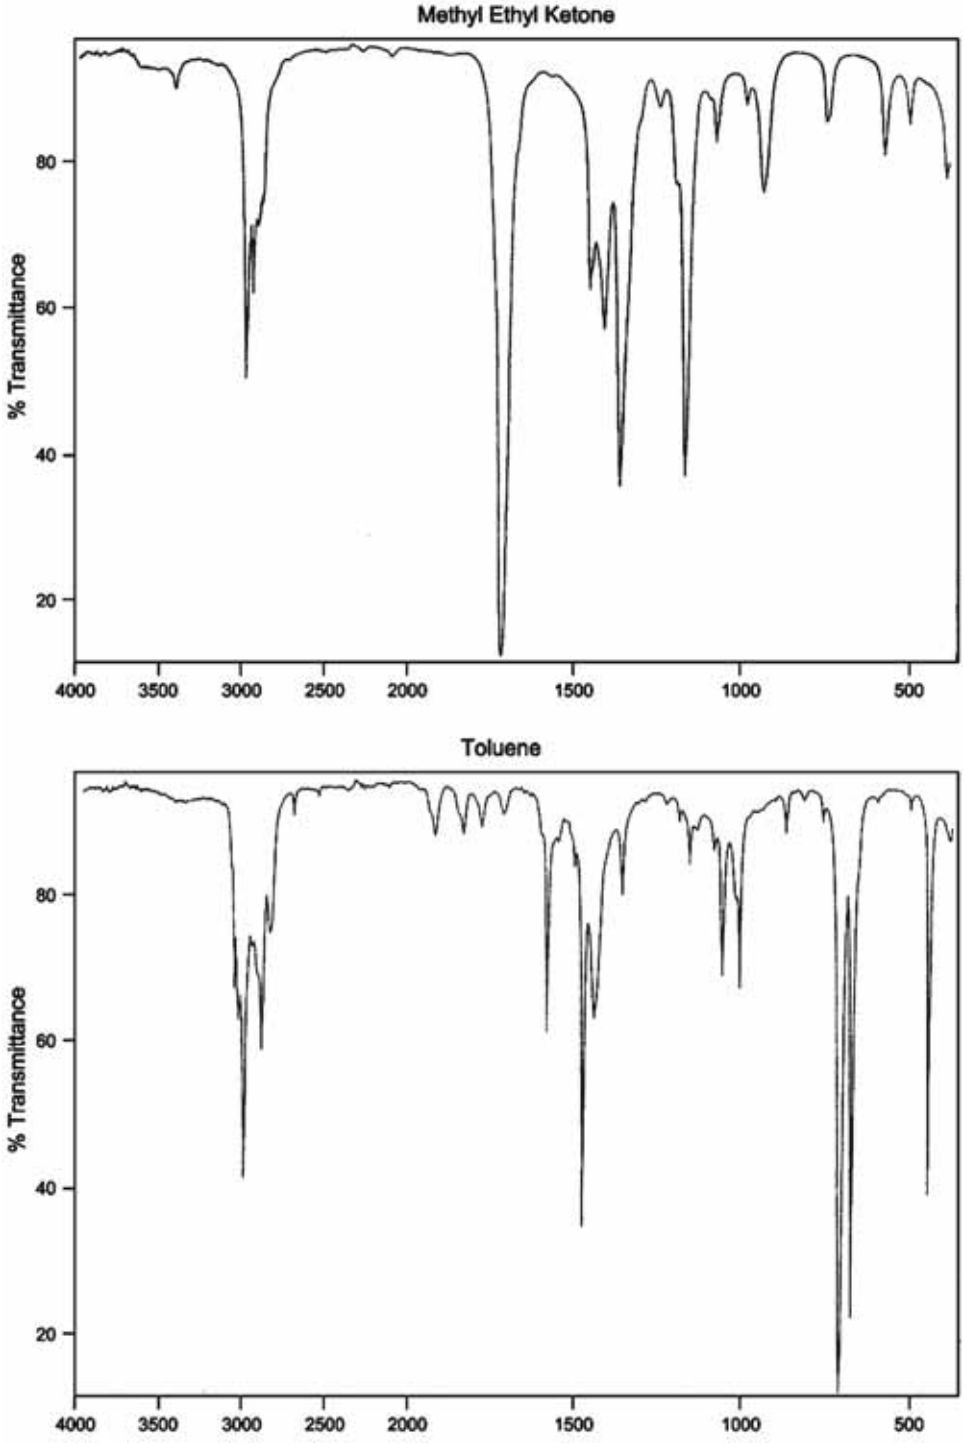

Fig. 4—Infrared spectra of methyl ethyl ketone (top) and toluene (bottom). Courtesy of Weldon Laboratories.

the strength of the absorption band. Indeed, not every vibration in a molecule is "infrared active," and there are various rules, called "selection rules," which can predict whether or not a particular vibration will actually absorb infrared radiation. While the selection rules are beyond the scope of this chapter, a simplification of them is that, for a particular vibration to absorb infrared light, and hence result in a band in the infrared spectrum, the vibration must produce a change in the molecule's dipole moment. A dipole moment arises from a partial separation of electric charge, and is related to the difference in electronegativity (the tendency of an atom to hold on to an electron) between the vibrating atoms. The dipole moment will not change during a symmetrical vibration of a symmetrical molecule, and no infrared band will result. If the change in dipole moment is small, the corresponding band will be weak. If it is large, the corresponding band will be strong. Many times, the intensity of a particular band is nearly as important as its frequency in assigning it to the correct structure or functional group.

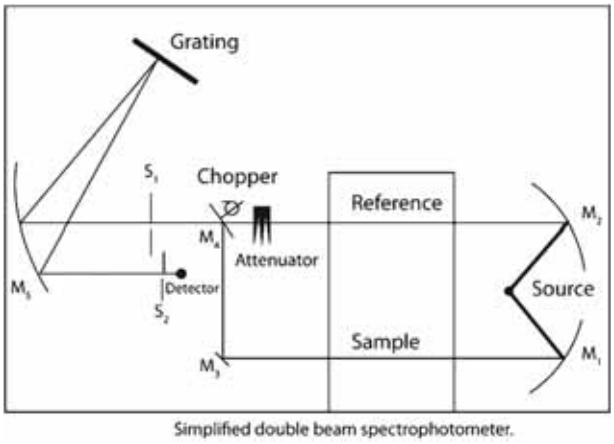

Fig. 5—Simplified double beam dispersive spectrometer.

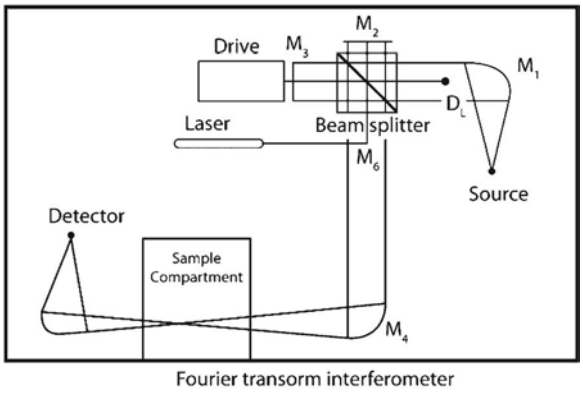

Fig. 6—Simplified fourier transform interferometer.

INSTRUMENTATION

There are two basic types of infrared spectrometers, dispersive and fourier transform. Dispersive instruments are seldom used anymore, but may still be available in some laboratories.

Dispersive Spectrometers

The development of dispersive spectrometers in the 1940s brought infrared spectroscopy into everyday use in the analytical laboratory. A simplified version of such an instrument is shown in Fig. 5. This design directs an infrared beam through the sample, and compares its intensity to that of a reference beam which bypasses the sample. The source of infrared light is an electrically heated wire or ceramic rod, which produces a continuum of infrared light spanning a wide range of frequencies. The two spherical mirrors, M_1 and M_2, direct this radiation along two paths, one of which goes through the sample (the sample beam), and one which bypasses the sample (the reference beam). The beams are "chopped" so that the detector alternately views one beam and then the other, such that the intensity of radiation in the sample beam, at any frequency, can be ratioed to that of the reference beam. The means of selecting a certain frequency of infrared light to examine is the monochromator, which consists of narrow slits (S_1 and S_2) and some type of dispersive element (either a prism or a diffraction grating).

For decades, dispersive instruments were employed for infrared spectroscopy. However, they tended to be slow (the author can well remember waiting 20 min for a spectrum to be completed), and detection limits were somewhat poor. Because of the loss of energy in the monochromator, certain accessories were often difficult to use, limiting the type of samples which could be run. Fourier transform units addressed these problems.

Fourier Transform Spectrometers

Nondispersive, or Fourier transform spectrometers, started becoming popular in the 1970s, and are by far the most common type in current use. Although they still require a source of infrared radiation and a detector, they do not disperse the radiation into individual frequencies, and hence do not require a monochromator. Instead, all of the infrared radiation is simultaneously passed through the sample, after having passed through an interferometer, as shown in Fig. 6.

As shown in Fig. 6, mirror M_1 collimates the energy from the IR source onto a beamsplitter, where the energy is divided between a stationary mirror M_2 and a moving mirror, M_3. The location of the moving mirror is tracked by a small helium neon laser, such that the difference in path length between the two beams is accurately known. The two beams are then recombined, and subsequently focused through the sample compartment and then on to the detector.

The output of the detector is not an infrared spectrum as we know it, but rather what is known as an interferogram (Fig. 7), which is basically a plot of detector response versus mirror travel, and contains all the information about constructive and destructive interference as a function of path length difference. It also contains all the spectral information concerning the sample, since the different frequencies of light will have been attenuated to one degree or another by the sample. In order to convert the abstract interferogram into the more commonly recognized infrared spectrum, a mathematical procedure known as the "Fourier transform" is employed by the instrument's computer. It took the advent of small, fast computers to bring the advantages of Fourier transform spectroscopy into the commercial laboratory.

Fourier transform infrared (FTIR) has some important advantages compared to dispersive IR, not the least of which is speed. Rather than taking several minutes to acquire a spectrum with a dispersive instrument, an FTIR can obtain a reasonably good spectrum in a few seconds.

Perhaps an even more important advantage of FTIR is sensitivity. Because there is no monochromator, all of the infrared radiation is passed through the sample at once, as opposed to a small amount at a time with a dispersive instrument. As a result, detection limits are roughly 10 to 100 times better with FTIR. As a consequence of this, certain types of samples can be run with FTIR which could not be run on a dispersive instrument. Furthermore, there are certain accessories which "waste" considerable amounts of energy, and were therefore difficult to use with dispersive instruments. These accessories, such as attenuated total reflectance attachments, are easily used with FTIR equipment, and greatly enhance the versatility of the technique.

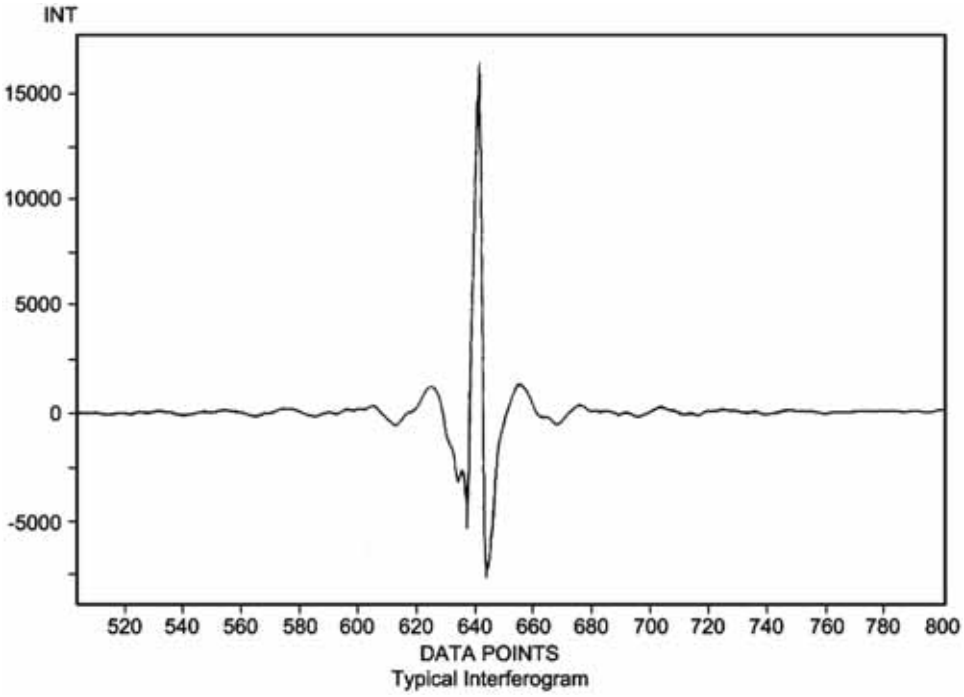

Fig. 7—Typical interferogram.

SAMPLE HANDLING

In the coatings industry, samples will usually be run in the form of a solid, although liquid samples will occasionally be encountered. There are several ways of obtaining spectra of both solids and liquids, and the choice will often depend on the type of question being asked of the analyst.

A common way of obtaining an infrared spectrum of a solid sample is by the use of the pressed pellet technique. Shavings or scrapings of the sample, such as a dried paint chip, are ground in a mortar and pestle, or by the use of a small mechanical grinding mill, along with a carrier which is essentially transparent to infrared radiation in the region desired. Two very common carriers are potassium bromide and sodium chloride powder. A ratio of roughly 1 mg of sample to 100 mg of potassium bromide is common. The ground sample is then placed in a special die and subjected to perhaps 10 000 lbs of pressure in a laboratory hydraulic press (inexpensive hand presses can also be used for the occasional sample). This fuses the sample into a relatively transparent pellet, which is then placed in the optical path of the spectrometer for analysis.

The pellet technique is extremely useful and can be used for a variety of samples. It works best for samples which are relatively hard and brittle, since they are easiest to grind. However, even relatively flexible samples can be run by this method, with enough patience. Sometimes the use of a few drops of a fast evaporating solvent, such as methylene chloride, during the grinding operation can help to break apart stubborn samples.

Often, especially in a laboratory dealing with failure analysis, or even for routine identification of paint samples from a jobsite, the samples will consist of more than one coat of paint. Care must be taken in the analysis of such samples. Usually, if the chips are thick enough, or if the various coats are of different colors, scrapings of the individual coats can be obtained with the use of a low power stereo microscope. However, if the samples are very small and/or brittle, this may not be possible.

Potassium bromide pellets can result in good quality spectra, require little sample, and can often be made in a few minutes. Since the sample as a whole is being analyzed, the spectrum will be representative of all of the ingredients in the sample, such as resins, cross-linkers, additives, and pigments. However, it must be kept in mind that potassium bromide and sodium chloride are hygroscopic. Even if stored in a desicator (a highly recommended practice), a small amount of moisture is almost inevitable. This will result in a band near 3300 cm^{-1}, and a much weaker one near 1620 cm^{-1}. Bands due to water are usually only a minor problem so long as one is cognizant of them.

A more intractable problem with pellet spectra is light scattering due to small, opaque particles dispersed in the pellet as a result of certain types of pigmentation in the coating. Some of the most difficult samples to analyze include zinc-rich primers and coatings pigmented with aluminum flake or carbon black. These particles act like minute mirrors, resulting in light scattering and severely sloping baselines.

Another way to obtain a transmission spectrum of a solid is by the mull technique. In this technique, a small amount of sample is dispersed by grinding it in a high purity mineral oil, such as Nujol. The paste is then spread across a salt plate, or sandwiched between two plates, and a transmission spectrum is obtained. Mulls do not suffer from the disadvantage of trace water, but the oils used will have bands of their own which will show up in the spectrum. Often, two different types of dispersing media are required to obtain spectra over the entire region of interest.

The pellet and mull techniques discussed above result in a spectrum of the bulk sample, since the infrared radiation is passing through the sample (a transmission spectrum). In many cases this is exactly what is needed to characterize the coating or solve the particular problem. However, sometimes it is desirable to obtain a spectrum of a surface, rather than of the bulk sample. This might be the case if one is concerned about the possibility of oil on the back of a delaminated coating, or of a surfactant exudate on the surface. The technique of choice for investigating these types of problems is attenuated total reflectance (ATR).

In ATR, the sample is pressed firmly against the face of a special crystal having a high index of refraction. The infrared radiation is focused into this crystal at such an angle that total internal reflection takes place at the sample/crystal interface, resulting in what is called a "standing wave." This standing wave penetrates and interacts with only the first few microns of the sample surface, resulting in a reflectance spectrum (as opposed to a transmission spectrum) which is very sensitive to the surface composition of the sample. The technique works best with soft, flexible samples which can be easily pressed against the face of the crystal, and can be difficult to do with hard, brittle samples, especially if they have uneven surfaces. The technique is described in more detail by Mirabella [3].

ATR is one of those "energy guzzling" techniques which has greatly benefited by the use of modern Fourier transform spectrometers. While ATR spectra have been collected for decades using traditional dispersive spectrometers, the sample size had to be relatively large, and the process was rather lengthy. With FTIR instruments, samples as small as 1mm^2 can be rapidly analyzed.

One of the most obvious advantages to the ATR technique is not having to grind the sample. Therefore, inconsistent particle size and light scattering effects are eliminated, as are bands due to moisture in the grinding medium. Soft, flexible samples, which would be difficult to grind, are usually routine for ATR. Furthermore, sometimes valuable information can be obtained from a surface spectrum which can not be obtained from a transmission spectrum.

There are, however, several disadvantages to ATR. For one thing, most collections of reference spectra are in transmission, not reflectance. While similar, there can also be substantial differences between the two types of spectra.

Furthermore, ATR spectra can be influenced by such things as the angle of the incident beam of infrared radiation, and the degree of contact between the sample and the crystal. The angle of incidence will affect the depth of penetration of the standing wave into the sample, and hence the appearance of the spectrum. The degree of contact between the sample and the crystal will also affect not only the depth of penetration, but also the strength of the signal. And, as mentioned above, brittle, wavy samples can be difficult to analyze. An additional complication is the possibility of a layering, or stratification, of the various ingredients in the coating. Although this does not happen often, it is possible that the ATR spectrum of the front of a sample will look different than the spectrum obtained from the back of the sample due to this stratification effect.

Although the above techniques are the most common ones for obtaining spectra of solid samples, they are certainly not the only ones. Diamond anvil cells can be used to produce very thin films of small samples for transmission spectroscopy, extremely thin films on very reflective surfaces can be investigated by specular reflectance techniques, and spectra can also be obtained of samples based on the acoustic vibrations they emit from the heating effects of the infrared beam (photoacoustic spectroscopy). FTIR microscopes even allow spectra to be obtained from samples as small as a few microns. Again, Mirabella's text [3] is recommended for additional information on these techniques.

While paint chips are a common staple of the modern analytical coatings laboratory, liquid samples are also routinely encountered. By far the simplest technique for obtaining a spectrum of a liquid sample, provided it does not contain water, is to spread a small amount on a salt plate (such as a potassium bromide crystal), allow the solvent to evaporate, place the crystal in the optical path of the instrument, and obtain a transmittance spectrum. This is generally referred to as a "cast film" spectrum. A similar technique is described in ASTM Standard Test Method for Infrared Identification of Vehicle Solids From Solvent-Reducible Paints (D2621).

If one wishes to obtain a spectrum which is representative of the sample as a whole, including solvent, a drop of sample may be sandwiched between two crystals and a so-called "neat" spectrum easily obtained. A neat spectrum is a very simple, rapid tool for quality control, allowing a spectral library to be easily made of all batches of a particular coating. If the sample contains fast evaporating solvents, the procedure should be accomplished as quickly as possible. Both fixed and variable path length cells can also be used to obtain spectra of liquid samples, but they are more difficult to clean.

Obtaining spectra of water based samples in the above fashions can be difficult, as water dissolves most of the common crystal materials, as well as contributing bands to the spectrum. Silver chloride discs, which are insoluble, can be used, but it is often difficult to acquire high quality spectra with them. Some of the suppliers of infrared equipment produce what are essentially thin "plastic" disposable cards to which liquid samples, both solvent based and water based, can be applied. One should, of course determine which bands the cards themselves contribute to the spectrum.

Sometimes it may be desirable to obtain an infrared spectrum of a liquid sample after first removing the pigment. Certain inorganic pigments have very strong, broad bands which can obscure much useful information from the resin components of the coating. The pigment can usually be removed by centrifugation, which is often made easier by diluting the sample with a volatile solvent such as acetone or methyl ethyl ketone. The clear supernatant contains the resin and solvent. A small drop of this is spread across a salt plate, the solvent removed, and a transmission spectrum obtained of the cast film.

The above technique does not work so well with latex samples, even if they are thinned with water. It may be possible to first break the emulsion by sonication, or to obtain a good separation using a very high-speed centrifuge. However, a technique which works well for many types of latex

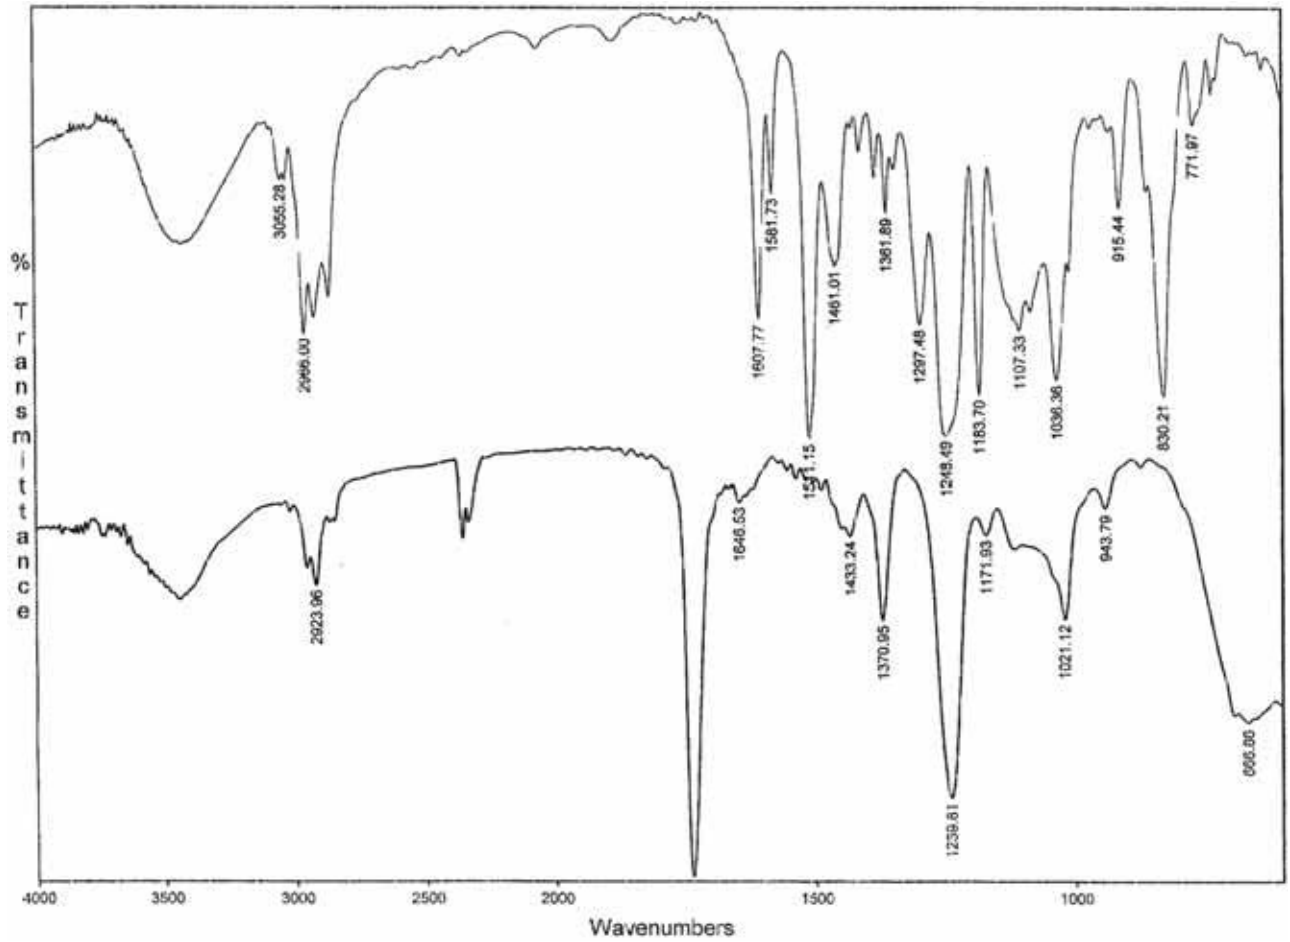

Fig. 8—Infrared spectra of epoxy (top) and a vinyl latex (bottom). Photograph courtesy of Weldon Laboratories.

samples is to first apply them to a glass slide and allow a brief time (perhaps 15–60 min) for the bulk of the water to evaporate. Usually, scrapings of the dried coating can be easily re-dissolved in a suitable organic solvent, which is then centrifuged as described above. The technique described by ASTM Standard Practice for Qualitative Identification of Polymers in Emulsion Paints (D3168) may also be useful in certain situations.

While the ATR technique previously described is usually associated with solid samples, liquid samples, especially if they are viscous, can often be applied directly to the ATR crystal. There are also other ATR accessories available from various vendors which allow liquid samples to be conveniently analyzed.

INTERPRETATION OF INFRARED SPECTRA

By far the most important component in the interpretation of infrared spectra is the experience of the spectroscopist. However, whether experienced or a novice, correlation tables are indispensable in the process of spectral interpretation. These tables list the locations of infrared bands due to the various functional groups, and often provide information into the relative intensities of the various bands. There are many texts which contain such tables [1,2], and the operational software which is supplied with many spectrometers contains digital versions. One simple but important rule is that, while the presence of an expected peak may indicate the presence of a certain functional group, the absence of an expected peak almost certainly indicates the absence of the functional group. It should also be kept in mind that a coating is not a pure compound, but can be a complicated mixture of several ingredients, each of which is contributing its own unique spectrum to the overall spectrum of the coating. Thus, although the Spectroscopy Atlas [1] is an indispensable reference collection, it is not a collection of spectra of paints and coatings, but rather of the raw materials which go into making them. ASTM D2621 also contains many useful reference spectra of alkyds, but again these spectra are of unpigmented resins.

In addition to digital correlation tables, there are also software packages which allow the spectrum of an unknown to be searched against a digital database. These databases provide a quick way to eliminate the majority of possibilities, and can often rapidly point the investigator in the right direction. Although there are various algorithms employed, the goal is to generate the best matches to the spectrum of the unknown. While sometimes very helpful, one should never blindly accept the result of such a computer search, since even matches with a high score of similarity can be wrong. One reason for an erroneous match is that most of the digital libraries only contain spectra of pure compounds or raw materials, whereas the actual coating sample may contain several such ingredients.

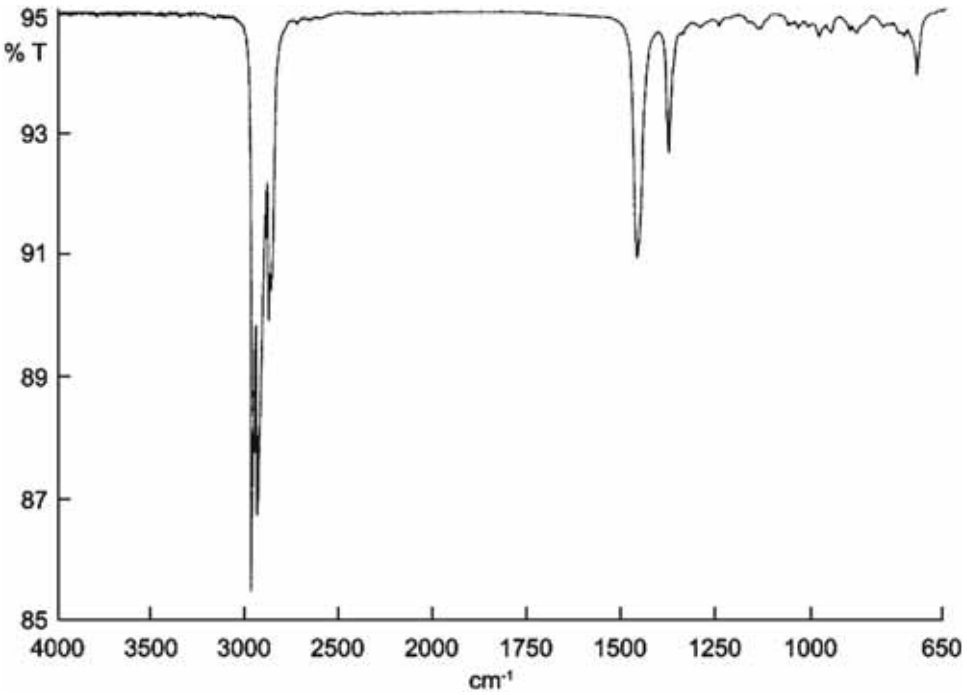

Fig. 9—Infrared spectrum of the layer found floating on top of paint.

Many instrument software packages contain some form of spectral subtraction, or "difference" spectroscopy capability. The developers of this software like to point out its ability to remove or subtract the spectral features of known or unwanted components, such that small amounts of hidden or "masked" materials can be identified. The procedures are usually interactive in nature, ideally allowing bands from known constituents to be eliminated to reveal the spectral features of a contaminant or other minor ingredient otherwise obscured.

While spectral subtraction may be very useful in certain circumstances, when applied to most coating problems the results should be viewed with a great deal of caution, especially when attempting to detect compounds at low concentrations. One of the major fallacies underlying the technique is the unspoken assumption that the spectral features of all of the ingredients in a complex, concentrated mixture are purely additive in nature, and that the presence of one compound does not interact with another and therefore affect the shape or locations of bands. Sometimes this is true and sometimes it is not.

APPLICATIONS OF INFRARED SPECTROSCOPY

There are many uses of infrared spectroscopy in the coatings laboratory, ranging from routine quality control procedures to sophisticated problem solving investigations.

Quality Control Applications

It is not unusual for a paint manufacturer to run some simple quality control checks on their incoming raw materials, such as the viscosity of a resin solution or the refractive index of a solvent. Some manufacturers extend this QC monitoring to include infrared spectra of certain raw materials, particularly resins. As discussed in the section on sample handling, it is a very easy matter to obtain a spectrum of a resin or resin solution, especially if it is unpigmented. Establishing acceptance or rejection criteria is another matter, however, and unless there is a substantial difference in appearance of the spectra, it would probably take some time until the manufacturer has acquired enough data to begin to establish these criteria for a particular product. Nevertheless, the analytical procedure is very simple and rapid, and if problems did crop up later with a certain product, one would then be able to examine the spectrum of the resin which went into that particular batch and compare it for deviations against other such resins which resulted in successful batches.

In addition to obtaining spectra of raw materials, some manufacturers also obtain spectra of the finished product. While an infrared spectrum of a finished paint sample will not be able to provide information about very slight differences in formulation, such as the type or level of an additive, it will certainly reveal any major errors very quickly. While not foolproof, it certainly provides another level of quality control over the more traditional approach of simply obtaining the sample's viscosity and weight per gallon. Indeed, a system for testing incoming raw materials, manufactured intermediates, and finished products has been developed [4].

Problem Solving Applications

The technical service department of any paint company is routinely faced with such problems as "what are these gel particles in the paint?," "why does this batch take so long to cure?," "why did this furniture lacquer crack?," or "why did this epoxy delaminate?." Infrared spectroscopy is an excellent tool in helping to solve these types of problems, and many more.

One of the simplest, most direct uses of infrared spectroscopy is in the generic identification of a coating. Many

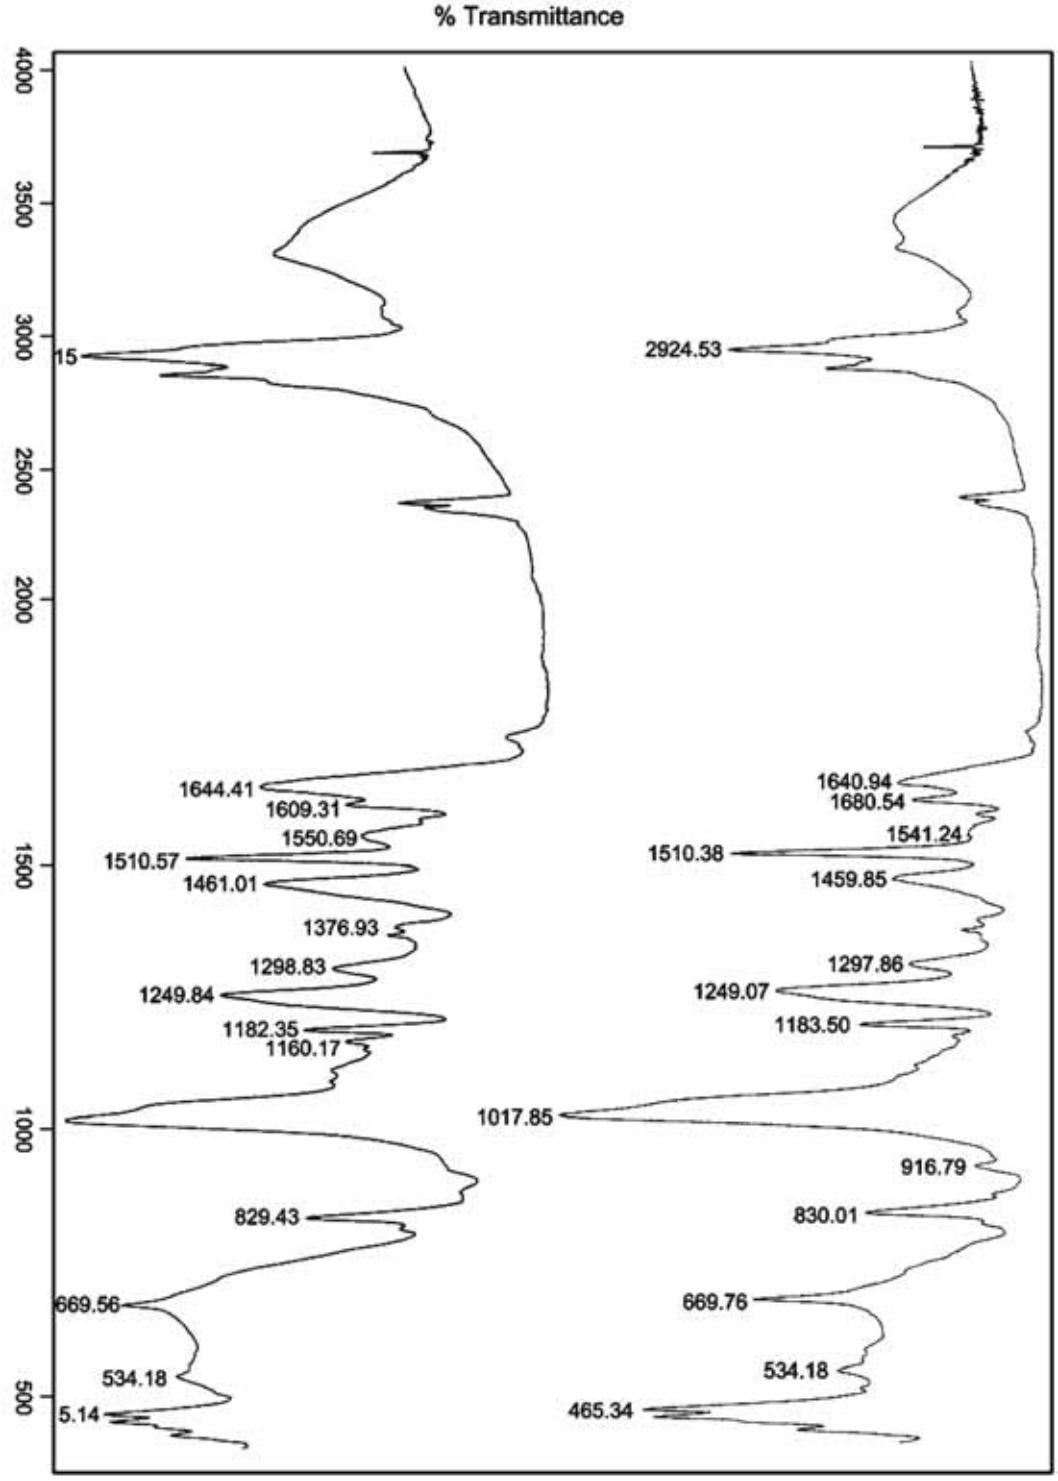

Fig. 10—Spectra of a polyamide epoxy at the proper mix ratio (top) and with an excess of Part B polyamide component (bottom). Note the difference in relative intensity of the 1640 and 1610 cm-1 bands. Courtesy of Weldon Laboratories.

times a coating does not perform as expected because the wrong paint was used, or perhaps because the "correct" paint was unknowingly applied to an existing coat of paint with which it is not compatible. Fig. 8 shows the spectra of an epoxy and a vinyl latex. It is obvious that the spectra are quite different. Therefore, if an epoxy was to have been used but an alkyd was applied instead, or if an epoxy was applied over an acrylic latex with which it is not compatible, such problems can be easily and rapidly detected by infrared spectroscopy.

Another common problem results when a component separates while standing in the shipping container. Fig. 9 shows the spectrum of such a "float" found on the surface of a paint can. Using a micropipette, the material was

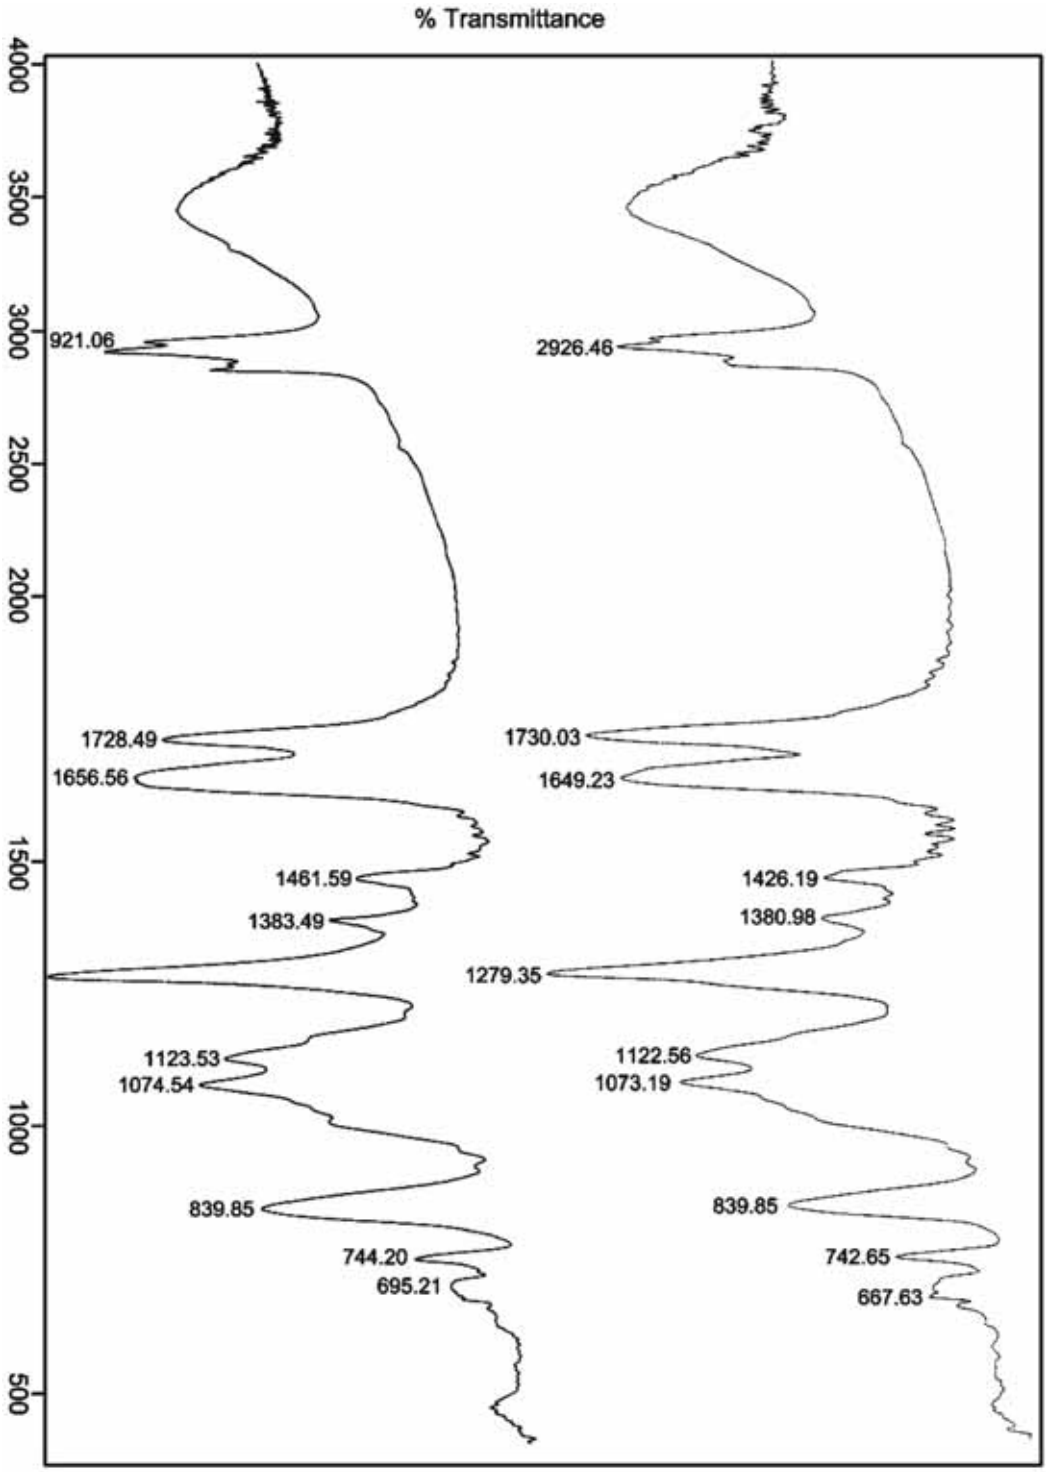

Fig. 11—Spectra of nitrocellulose lacquers with correct amount of plasticizer (top) and with inadequate plasticizer (bottom). Note the difference in relative intensity of the 1730 and 1650 cm-1 bands. Courtesy of Weldon Laboratories.

removed and spread onto a potassium bromide plate. Even though there was only a small amount of material, the spectrum was good enough to identify the layer as a mineral oil. This clue led to the discovery that a shipment of cans had not been adequately degreased prior to use [5].

A common failure mode involving two component coatings, such as a polyamide cured epoxy, is failure of

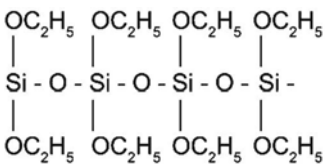

Fig. 12—Structure of ethyl silicate pre-polymer.

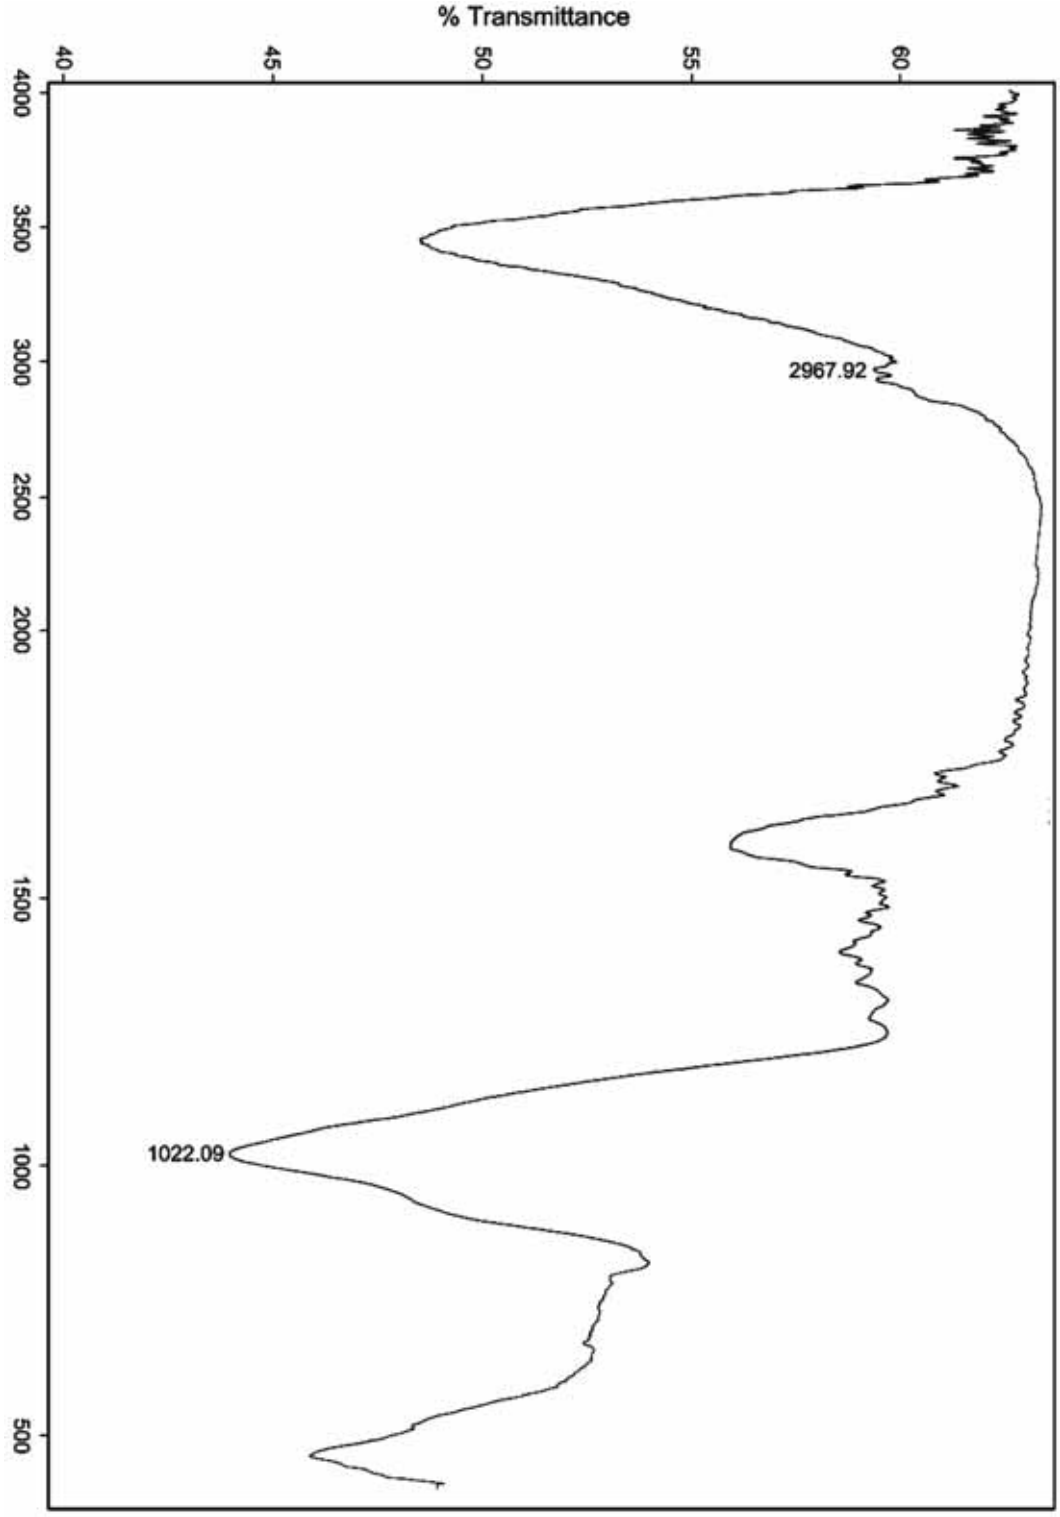

Fig. 13—Spectrum of an ethyl silicate inorganic zinc-rich primer. Courtesy of Weldon Laboratories.

the applicator to mix the Part A and Part B components in their proper ratio prior to applying the coating. One of these components will contain the epoxy resin, while the other will contain the polyamide curing agent. Failure to mix the components in their proper ratio, often 1:1 by volume, can result in coatings which do not cure properly and which have inferior physical and chemical properties. Infrared spectroscopy can often determine the approximate mix ratio of such a coating. The procedure involves preparing drawdowns in the laboratory of the coating at different mix ratios, and examining the spectra to see if there are any pairs of bands which change in relative intensity in a consistent fashion with changes in mix ratio. As Fig. 10 shows, as the mix ratio of this particular epoxy changes,

the relative intensities of several bands change, including those near 1640 and 1610 cm^{-1}. The 1640 band is due to the carbonyl vibration from the polyamide curing agent, while the 1610 band relates to the epoxy resin. It is not surprising that the ratio of these two bands changes as a function of mix ratio. The spectrum of the jobsite sample is then compared to the spectra of the standards to determine its approximate mix ratio.

It should be pointed out that, based on the author's experience, the above technique for obtaining mix ratios of two component coatings is only approximate, being good to only two significant figures. Not only is there an error associated with precisely mixing various volumes—or even weights—of viscous coatings to prepare the standards, and errors associated with reproducibly grinding the various samples for preparing potassium bromide pellets, but Beer's law, which relates the intensity of a band to the concentration of the species responsible for it, is only strictly valid for analytes in dilute solutions. This is certainly not the case in failure analysis, where the samples are at high concentrations in a solid matrix.

Another problem where infrared spectroscopy proved useful was that of a nitrocellulose furniture lacquer which developed long, hairline cracks. Nitrocellulose is an excellent resin for lacquers, as it dries quickly and produces a hard finish with good gloss and clarity. Unfortunately, it is also brittle, and usable coatings are only made by the addition of a plasticizer. Although there are many types of plasticizers available, one of the most common for nitrocellulose lacquers is a non-drying alkyd such as a coconut oil alkyd.

Fig. 11 shows the spectrum of a satisfactory lacquer which did not develop cracks, and the spectrum of the brittle, complaint batch. Nitrocellulose has a very strong, characteristic band in the infrared near 1650 cm^{-1}, while the band near 1730 cm^{-1} is due to the coconut oil plasticizer. In comparing the relative intensity of these two bands, it is apparent that the good lacquer contains a much greater ratio of plasticizer to nitrocellulose than does the brittle sample.

In certain cases, infrared spectroscopy can be a very effective tool in problems involving the lack of cure of a coating. Urethane coatings are very amenable to cure studies by infrared spectroscopy [6] since the isocyanate structure has a very distinctive band near 2300 cm^{-1} which disappears upon curing as the isocyanate reacts with the polyol component, or with atmospheric moisture.

Inorganic zinc-rich primers are another coating type whose cure can be monitored by infrared spectroscopy. Such primers consist of roughly 80 %–90 % zinc dust pigment dispersed in a binder which is usually based on a low molecular weight ethyl silicate (actually an ethoxy silicate), as shown in Fig. 12.

Because of their very high loading of zinc dust pigment, which is actually above the coating's critical pigment volume concentration (CPVC), the primers provide outstanding corrosion protection due to their galvanic effect (the zinc pigment will oxidize to protect the underlying steel, in much the same fashion as galvanizing). However, failures in the form of delamination or splitting of such primers have occurred when topcoated with such coatings as epoxies, often due to inadequate curing of the zinc-rich primers prior to topcoating [7].

Fig. 13 shows the infrared spectrum of a typical inorganic zinc-rich primer. It is dominated by a strong, broad band near 1000 cm^{-1} due to the stretching vibrations of the silicon-oxygen bonds in the inorganic polymer. There are also much weaker bands near 2900 cm^{-1} due to the carbon-hydrogen stretching vibrations of the ethoxy groups on the low molecular weight prepolymers. When these coatings cure they do so by reaction with atmospheric moisture, which cleaves the oxygen-silicon bond holding the ethoxy groups to the silicate backbone, resulting in the formation of silanol groups which subsequently condense with one another to form the high molecular weight, cured inorganic polymer. The bottom line is that as the coating cures the ethoxy groups are cleaved and evaporate in the form of ethyl alcohol. Since these groups are the only source of carbon-hydrogen functionality, as the coating cures the intensity of the carbon-hydrogen bands will decrease relative to the intensity of the silicon-oxygen band. This fact can be used to follow the degree of cure of such coatings [8], including the analysis of failed jobsite samples.

The above are just a few examples of the power of infrared spectroscopy as a problem solving tool in the coatings industry. Even if the technique does not unequivocally solve the particular problem at hand, it can often eliminate certain possibilities and point the investigator in the right direction.

SUMMARY

Infrared spectroscopy has been a powerful technique for organic and analytical chemists for over 50 years. Modern computer controlled fourier transform instruments and associated sampling accessories have made the technique increasingly rapid and sensitive, and have extended its capability to samples which would have been difficult if not virtually impossible to analyze many years ago. Although the technique has applications in quality control, its real utility is as a problem solving tool. Depending on the experience and ingenuity of the analyst, IR spectroscopy can provide solutions to a wide variety of problems concerning the composition of materials and systems in the coatings industry.

Methods for Polymer Molecular Weight Measurement

Thomas M. Schmitt[1]

THE BINDERS USED IN COMMERCIAL COATINGS are organic polymers, the molecular weights of which greatly influence the properties of the final coating [1]. As a necessary result of the manufacturing processes, synthetic polymers are mixtures of compounds of similar molecular structure but varying molecular weight. For an exact understanding of the system, one must know the molecular weight and weight (or mole) fraction of each species, in other words, the molecular weight distribution. For many practical purposes, an average value of molecular weight suffices. The final cured paint film is a cross-linked system resembling a single massive molecule, where the concept of molecular weight has little meaning. Molecular weight determination is thus applied only to coating formulation ingredients.

Many procedures have been used to determine molecular weight. We limit our discussion to the most practical methods, for which commercial instrumentation is available at reasonable price. Archaic methods and research methods are omitted, as are those techniques which are suitable for determination only of low molecular weight compounds.

MOLECULAR WEIGHT DEFINITIONS

While the molecular weight of a single molecule is a simple concept, there are several ways to calculate the molecular weight of a mixture. The most useful values are number average molecular weight, $\overline{M}_n$ and weight average molecular weight, $\overline{M}_w$

$$\overline{M}_n = \frac{\sum_i n_i M_i}{\sum_i n_i}, \quad \overline{M}_w = \frac{\sum_i w_i M_i}{\sum_i w_i}$$

where M_i denotes the molecular weight of component i, n_i is the number of moles of component, i and w_i symbolizes the total weight of component i and is thus equal to $n_i M_i$. Weight average molecular weight is necessarily equal to or higher than number average molecular weight. A mixture of equal numbers of two molecules, one weighing 100 and the other weighing 1000, has a $\overline{M}_n$ of 550 and a $\overline{M}_w$ of 918. The polydispersity of this mixture, $\overline{M}_w / \overline{M}_n$, is 1.7. This indicates that most of the mass of the example mixture consists of higher molecular weight material, but that comparatively small molecules are also present. The higher the value of $\overline{M}_w / \overline{M}_n$, the broader is the distribution of weights of molecules in the sample. Two other measures of molecular weight have found acceptance because they can be directly measured by certain techniques: z-average molecular weight, $\overline{M}_z$, and viscosity average molecular weight, $\overline{M}_v$

$$\overline{M}_z = \frac{\sum_i w_i M_i^2}{\sum_i w_i M_i}, \quad \overline{M}_v = \left[\frac{\sum_i w_i M_i^a}{\sum_i w_i M_i}\right]^{1/a}$$

For the above-mentioned mixture of molecules of weight 100 and 1000, the z-average molecular weight is 991. Clearly, if the actual distribution of M_n, M_w, or M_z is known, the distributions and average values of the other two parameters may be calculated. The exponent a is obtained from the Mark–Houwink equation and is specific to polymer type and branching as well as the temperature and solvent of the measurement system [2].

Which molecular weight value is of greatest significance, number average, weight average, z-average, or viscosity average, depends upon the particular application of the polymer mixture. Knowledge of M_n and M_w is sufficient for most purposes. M_n is often critical to stoichiometry of curing reactions and controls some properties. For coatings, many of the properties of the final product are controlled by M_w, with M_w/M_n also playing an important part.

METHODS FOR DETERMINATION OF NUMBER AVERAGE MOLECULAR WEIGHT

End Group Analysis

Some polymers used in coatings have reactive end groups which participate in the curing reactions. Assuming that the degree of branching is known and that the end of each polymer chain has such a group, methods for routine quality control may be based on determination of end groups. Since each molecule has the same number of end groups, the result is a number-average molecular weight. Polyurethane raw materials fit this description, and "wet chemical" methods are well-established for rapid and accurate analysis of these compounds. Hydroxy-terminated compounds are analyzed by determination of hydroxyl number [ASTM Method for Testing Polyurethane Raw Materials: Determination of Hydroxyl Numbers of Polyols (D4274)]. Isocyanate-terminated prepolymers are analyzed by ASTM

[1]*Manager, Analytical Chemistry & Chemical Engineering, BASF Corp., 1609 Biddle Ave., Wyandotte, MI 48192.*

Copyright © 2012 by ASTM International

Test Methods for Polyurethane Raw Materials: Determination of Isocyanate Content of Aromatic Isocyanates (D5155). End group analysis is not limited to polyurethane raw materials. Amine or carboxylic acid functional groups may be determined by acid–base titration, often in nonaqueous solvents, but the parameters of solvent, titrant, and apparent pH at the end point must be worked out for each compound.

End groups may also be determined by spectroscopic methods, usually infrared, near infrared, and nuclear magnetic resonance spectrometry. For example, see ASTM Test Methods for Polyurethane Raw Materials: Determination of Primary Hydroxyl Contents of Polyether Polyols (D4273), and ASTM Standard Practice for Polyurethane Raw Materials: Determining Hydroxyl Number of Polyols by Near Infrared Spectroscopy (D6342).

Even polymers which are not usually thought of as possessing functional end groups may be analyzed. This is because molecules are often terminated by fragments of the catalyst which initiated the reaction. An example is polyacrylonitrile, which may be terminated by a sulfate or sulfonate group. The analyst familiar with the mechanism of polymerization can sometimes devise a way to measure molecular weight based on determination of these residues.

Accurate measurement of $\overline{M_n}$, by end group analysis is limited to polymers of molecular weight less than about 20 000, since the end group concentration is too low for precise measurement above this range.

Colligative Properties Analyses

$\overline{M_n}$ may be determined based on colligative properties, i.e., based on measuring changes in solvent properties which are due to the number of molecules dissolved. These properties include vapor pressure, freezing point, boiling point, and osmotic pressure. By derivation from fundamental equations [2–5], it can be shown that, at low concentration, the relationship between a colligative property and molecular weight reduces to

$$\overline{M_n} = \frac{KC}{\Delta X}$$

where K is a constant specific for the solvent, C is the weight/volume concentration of the polymer, and ΔX represents the observed change in the colligative property.

K is best determined experimentally, rather than calculated. For the best accuracy, several measurements are made so that the value of

$$\frac{\Delta T}{C}$$

can be extrapolated to find the limit at zero concentration. These techniques are more often used in research laboratories than for quality control purposes. Boiling point elevation and freezing point depression are rarely used for polymers since instrumentation suitable for observation of small temperature differences is not commercially available.

Small molecules have a disproportionate effect on the number average molecular weight. For example, the presence of 0.1 wt % water contaminating a 20 000 $\overline{M_n}$ polymer will result in return of a colligative property value of 9500 for $\overline{M_n}$. This effect is amplified as polymer $\overline{M_n}$ increases. Thus, moisture and solvent must be completely removed prior to analysis. Commercial polymers are first purified by extraction or by dissolution and precipitation to remove additives such as stabilizers and lubricants.

For determination of molecular weight by membrane osmometry, a solution of the test substance is separated from pure solvent by a semi-permeable membrane, i.e., a membrane which is permeable to low molecular weight solvent molecules but impermeable to molecules of the test substance. Because of the lowered activity of solvent containing the polymer, solvent molecules will tend to travel across the membrane from the pure solvent. The pressure which must be applied to the solution to equalize this flow is equivalent to the osmotic pressure. Because the change in osmotic pressure is dramatic compared to the small temperature changes observed with the other colligative property methods, membrane osmometry is useful for higher molecular weights, up to about $\overline{M_n} = 10^6$, although accuracy fades at the highest values. The technique cannot be used for low molecular weights because commercial membranes are not sufficiently selective: typically, manufacturers quote cutoff values of 5000 to 20 000 for various membranes, indicating that molecules below that value can permeate the membrane. This property can actually be an advantage in that it is not necessary to purify the polymer to remove low molecular weight additives: their concentration is quickly equalized on each side of the membrane, so that their presence does not affect the molecular weight value. Elevated temperatures may be used with less soluble polymers, but choice of membranes becomes limited as the temperature is increased and as less common solvents are selected.

Vapor pressure osmometry actually is unrelated to osmometry, consisting simply of the measurement of vapor pressure depression in order to determine molecular weight. Commercial instruments measure the vapor pressure indirectly: the vapor pressure difference between a dilute polymer solution and pure solvent is measured by monitoring the temperature difference between drops of each liquid in equilibrium with solvent vapor. Although in principle this is an absolute measurement, in practice these instruments are calibrated with standards of known $\overline{M_n}$. Vapor pressure osmometry complements membrane osmometry in that it is suitable for materials with $\overline{M_n}$ in the range below 20 000, with accuracy dropping off at higher molecular weights because of the very small temperature differences observed.

The experimental procedure is described in ASTM standard D2503 (Test Method for Relative Molecular Mass (Molecular Weight) of Hydrocarbons by Thermoelectric Measurement of Vapor Pressure), although the manufacturer's instructions for the specific apparatus must be considered definitive.

DETERMINATION OF WEIGHT AVERAGE MOLECULAR WEIGHT BY LIGHT SCATTERING

Unlike $\overline{M_n}$, $\overline{M_w}$ is not affected much by the presence of small quantities of low molecular weight impurities. The only common method for direct determination of $\overline{M_w}$ is light scattering. Light is scattered by polymer solutions in a manner which is well understood theoretically and which depends upon the size of the polymer molecules in solution. Classical measurement of $\overline{M_w}$ by light scattering

is described in an ASTM standard [Standard Test Method for Determination of Weight-Average Molecular Weight of Polymers by Light Scattering (D4001)]. Until the 1980s, this technique was performed only by specialists because of the attention to detail required for accurate values: (1) Traces of dust and other particles needed to be laboriously filtered from the solutions; (2) Measurements needed to be taken manually at several scattering angles.

Modern laser light sources make possible measurement of light scattered at angles less than ten degrees [2]. At such low angles, the equations defining the relation of M_w to scattered light are reduced such that measurement at a single fixed angle is sufficient. Simple measurement of a set of dilute solutions of the polymer to determine scattered light and the concentration dependance of the solution refractive index (RI) suffice to determine M_w. Instruments are also available which make measurements at multiple angles automatically, so that the radius of gyration as well as the molecular weight of the substance may be determined. With either the low-angle or multiple-angle instruments, operation is no more tedious than if a single measurement were made on each solution. An advantage of the laser light sources is that their intensity makes the sample size requirement lower, so that much less solution need be filtered free of particulates. If the instrument is designed so that the sample solution flows through the cell, interference from particulates is apparent as random sharp spikes, which may be corrected electronically before performing molecular weight calculations.

Light scattering is not suitable for analysis of polymers of M_w lower than about 20 000. However, the low-range sensitivity increases as the RI difference between solvent and polymer increases. Methods for molecular weight determination for light scattering are well described in the literature [2–5], but the instructions of the instrument manufacturer are most relevant.

SIZE EXCLUSION CHROMATOGRAPHY

Size exclusion chromatography (SEC) is a type of high performance liquid chromatography (HPLC) in which separation is made on the basis of the size of the molecules in solution [6, 7]. It is often called gel permeation chromatography (GPC) since the separating medium was historically a swollen polymer gel. The stationary phase is now most often a rigid packing containing pores of the same order as the size of the molecules in the sample. As a sample of a disperse polymer is pumped through the HPLC column, smaller molecules penetrate further into the stationary phase than do larger molecules, with the result that smaller molecules elute after those that are larger.

SEC determines size in solution versus standards. Because the interaction of a polymer with a solvent changes as a function of molecular weight, size in solution does not necessarily have a constant relationship to molecular weight over a large molecular weight range. Thus, SEC is not an absolute method for determining either M_n or M_w. In spite of this, it is today the most widely used procedure for determination of both. SEC has the very great advantage that the polymer need not be purified of additives, oligomers, and residual monomers before analysis. Indeed, SEC can sometimes be used for the determination of these components simultaneously with the characterization of the polymer itself.

SEC Instrumentation

SEC instrumentation consists of a basic HPLC system, including a constant volume pump, injector, column set, detector, and computerized data handling system. (HPLC is discussed in detail in Chapter 71.) The *pump* must be capable of delivering solvent with greater precision than is necessary for ordinary HPLC, preferably within 0.1 %. This is because the SEC calibration curve is semilogarithmic, with small differences in elution volume resulting in large differences in apparent molecular weight. Alternatively, some device may be used to continuously monitor flow rate so that experimental data may be replotted in terms of elution volume rather than elution time. Another approach is the use of an "internal standard," usually of very low molecular weight, to permit correction of experimental retention times. Such devices are rarely used nowadays, since the variations they introduce are of the same magnitude as the variations in flow of modern, well-maintained HPLC pumps. Control of the *temperature* of the system is very desirable since fluctuations in ambient laboratory temperature add variation to retention times and, more seriously, cause drift in the baseline of the refractive index detector. Ideally, the entire unit is encased in a constant temperature chamber. Unfortunately, these enclosures usually must be constructed by the user because of the limitations of commercial units. Many users make do with temperature control of only the column chamber and the detector, which suffices if the laboratory temperature remains reasonably constant.

SEC *columns* are usually filled with styrene/ divinylbenzene copolymer and are always purchased prepacked. Several instrument manufacturers supply columns of a uniform high performance. For increased resolution, more than one SEC column is used in series, with as many as four or five 30 cm columns being preferred by many operators. These may consist of diverse columns, each containing packing of a specific pore size, or each may contain packing of broad pore size distribution.

Various *detectors* are used in SEC. The most common is based on detection of changes in RI of the solvent as the solute elutes. This property is closely related to concentration and such a detector is suitable for any material with an RI which differs from that of the solvent. Commercial detectors are designed to minimize temperature fluctuation since RI is strongly dependent upon temperature. Temperature control can be either active (electronic heating devices) or passive (massive metal block surrounding the cell). The mass response of the refractive index detector varies by only a few percent with molecular weight, and it is thus assumed to be a linear concentration detector. It is well to check this assumption if analyses will straddle a broad molecular weight range, particularly at the low end of the range. Caution must be used in the analysis of copolymers since the RI of copolymers varies with composition.

Other detectors are used for special purposes. A UV absorbance detector, usually in series with an RI detector, is suitable for analysis of polymers with strong chromophores, such as those containing styrene, terephthalate, or bisphenol A groups. Infrared absorbance detectors are

used to track particular components of the polymer, but limitations in useful wavelengths and solvents prevent their general application. Another detector is based on "evaporative light scattering." In this instrument the solvent is evaporated as the SEC effluent passes through a gas stream. Any nonvolatile solute is converted to a fine aerosol, which is detected by its ability to scatter a light beam. The evaporative light scattering detector can be surprisingly sensitive, but the calibration curve is usually nonlinear. A detector based on differences in dielectric constant between solvent and solution has many of the advantages of the RI detector, but is not widely available. Caution must be used when applying any detector, since, if the response is not linearly proportional to concentration over a wide molecular weight range, calculation of molecular weight distribution from experimental data may result in serious errors.

Two specialized detectors are worthy of mention: A viscosity detector gives an instantaneous readout of the viscosity of the solution eluting from the chromatograph. It is used in series with an RI detector so that both concentration and viscosity of the eluent are determined, permitting estimation of intrinsic viscosity and hence molecular weight. There are low-angle and multiple-angle laser light scattering instruments designed for use as SEC detectors. Like the viscosity detectors, they are used together with a mass sensitive detector, usually an RI detector. A characteristic shared by both detectors is their intrinsically greater sensitivity as the M_w of the solute increases. Thus a trace of high polymer or undissolved material that might be undetected by refractive index appears as a major component to a light scattering detector. Whether or not this sensitivity is advantageous depends on the application. Viscosity and light-scattering detectors are commercially available, reasonably priced, and reliable. Still, they remain very much the province of the research and development laboratory. This is because the additional information which they provide is not essential for most practical applications. They are not used for routine analysis of paint components nor are they typically used by synthetic chemists.

An *autosampler* is a valuable accessory for GPC, more so than for other forms of HPLC. This is because the long analysis times typical of SEC and the rigorous calibration procedures make it difficult to attain high sample throughput unless the usual 8 h day can be extended. If the column and mobile phase are rarely changed so that calibration is required infrequently, manual injection is practical.

Calibration and Calculations

SEC is a relative technique which requires calibration with standards of known molecular weight. The calibration curve is semilogarithmic, with the SEC columns chosen such that retention volume is linearly proportional to the logarithm of molecular weight over a broad range. Calibration is greatly simplified if specially prepared standard materials of low polydispersity can be used.

The choice of standards is critical since the relationship of retention time to molecular weight varies with different polymers, even those in the same chemical family. Since it is the size of the solvated polymer rather than its molecular weight which determines elution volume, significantly different calibration curves are obtained from branched and linear molecules. The most easily obtainable standards are of polystyrene. Polystyrene has a higher molecular weight for the same chain length than do aliphatic polymers, so a polystyrene calibration curve will give high results for the molecular weight of many common polymers. The method of calibration should always be reported when SEC molecular weight values are given.

A universal calibration system has been devised based on the relationship between viscosity and SEC retention time, since each is a function of the size of the solvated polymer. When using universal calibration, standards and samples may be quite different polymers; it is only necessary that the Mark–Houwink coefficients for standards and samples be known. Of course, the Mark–Houwink coefficients must be known for the polymer in the particular SEC solvent at the temperature used. Obtaining these coefficients is not as demanding a task as preparing narrowly distributed standards of a new polymer, and universal calibration is used in many research laboratories.

Almost all analysts use computerized data systems for evaluation of SEC results. These systems are reasonably priced and aid the operator in all phases of data treatment, from calibration to determination of molecular weight averages to preparation of attractive graphs of molecular weight distribution. Caution must be used in their application; not all systems will give the same results as an intelligent operator performing manual calculations. The greatest difficulty is in mathematical representation of the calibration curve of retention time versus molecular weight. Use of high order polynomials to represent the calibration can introduce large errors compared to simply connecting the experimental data points.

SEC data for narrow molecular weight distributions must be corrected for dispersion contributed by the instrumentation. This correction is not significant for the broad molecular weight distributions typically found in coating raw materials. Band broadening corrections become more important if a molecular weight-sensitive detector is used, such as a viscometer or light-scattering instrument.

SEC procedures and calculations are described in ASTM Test Method for Molecular Weight Averages and Molecular Weight Distribution of Polystyrene by High Performance Size-Exclusion Chromatography (D5296).

Application of SEC

SEC may be performed with either aqueous or organic solvents. Nonaqueous systems are more reliable, but, of course, water-soluble compounds such as polyacrylates are more readily analyzed in aqueous solvents. Nonsize exclusion interactions between the column and sample are more common with aqueous systems. These undesirable interactions include adsorption and ion exclusion/ion retardation and can often be controlled by adding salts or a low percentage of organic solvent.

Elevated temperature is necessary for the analysis of some polymers because of their low solubility or because of the high viscosity of the solvents which they require. In general, this is not a consideration for the relatively low molecular weight polymers used in coatings raw materials.

SEC has long since spread from the specialized central laboratory to the laboratory of the synthetic and formulating chemist. Central analytical laboratories select the SEC column set and mobile phase for optimum resolution of a particular polymer and molecular weight range. Central laboratories also typically perform extensive calibration. Practice in synthesis laboratories is usually different, with a single system used in a comparative fashion for all analyses. Indeed, when SEC is used routinely by resin chemists to follow polymerization reactions, the fine details of calibration are typically ignored and molecular weight is estimated by simple comparison to polystyrene standards, either by visual estimation of "peak" molecular weight or by uncritical acceptance of the default computer-generated report. For most troubleshooting applications, it is enough to overlay the chromatograms of a "good" and a "bad" polymer in order to determine whether differences in molecular weight distribution contribute to a problem. In the case of a product which does not have a single smooth molecular weight distribution but rather consists of two or more discrete distributions, visual comparison of peaks is often more valuable than comparison of numerical values. To monitor a polymerization reaction, it may be enough to watch the gradual disappearance of the peaks due to monomers.

VISCOMETRY

Rheology of paint components is discussed in Chapter 33. We discuss here only viscosity measurement to determine molecular weight.

Solution viscometry is the method of determining molecular weight most suitable for routine quality control. The viscosity/concentration relationship of a polymer solution is a function of the chain length of the polymer, so viscosity can be used as a measure of molecular weight.

As with other methods, determination of true molecular weight by solution viscosity requires purification of the polymer and extrapolation to zero concentration of a series of ratios representing measured values. The zero intercept, representing the limit of the viscosity/concentration relation as zero concentration is approached, is the intrinsic viscosity, [η]. It is related to $\overline{M}_v$ by the relationship expressed in the Mark-Houwink equation

$$[\eta] = K\overline{M}_v^a$$

The constants for the Mark-Houwink equation must be determined experimentally using well-characterized polymer standards of narrow $\overline{M}_w/\overline{M}_n$. ($\overline{M}_w/\overline{M}_n$ must be small for valid calibration since $\overline{M}_v$ is numerically different than $\overline{M}_n$ or $\overline{M}_w$.)

Since viscosity is determined by the hydrodynamic volume of the polymer, the relationship with molecular weight is specific for the polymer, the solvent, the temperature, and, of course, the concentration. A relationship determined for a linear polymer will not be accurate if branched molecules are also present. This means that the constants in the Mark–Houwink equation change with various solvents and with polymers having various degrees of branching. Measurements are made at high dilution to minimize the effect of variables other than molecular size. Capillary viscometers, used to measure the solution flow rate at a specific pressure differential, are most generally suitable. Procedures for determination of solution viscosity are contained in ASTM Standard Practice for Dilute Solution Viscosity of Polymers (D2857), as well as in the other ASTM standards referenced in D2857.

It is unfortunately not possible to discuss this subject without defining a number of viscosity relationships.

Relative viscosity is the parameter which is actually measured when viscosity is determined. It is the ratio of efflux times for the polymer solution versus pure solvent:

$$\eta_{rel} = t/t_0$$

where t and t_0 are the efflux times for polymer solution and pure solvent, respectively. Reduced viscosity takes concentration into account:

$$\eta_{red} = \frac{t - t_0}{t_0 C}$$

where C represents the polymer concentration, usually in grams per 100 mL. Intrinsic viscosity is determined by plotting against concentration several values of reduced viscosity, extrapolating to obtain the intercept at zero concentration:

$$[\eta] = \lim_{C \to 0} \eta_{red}$$

where [η] represents intrinsic viscosity.

Some workers determine Mark-Houwink constants with unfractionated polymers of measured $\overline{M}_w$, thus relating viscosity to $\overline{M}_w$ rather than $\overline{M}_v$. This nonrigorous approach is viable because $\overline{M}_v$ is usually rather close to $\overline{M}_w$.

Solution viscosity is an excellent method for routine QC of relatively uniform polymers. A single analysis at a fixed concentration and temperature will indicate that the product falls into the stated molecular weight range. For example, ASTM Test Method for Determining Inherent Viscosity of Poly(Ethylene Terephthalate) (PET) by Glass Capillary Viscometer (D4603), describes a method for determining inherent viscosity (natural log of relative viscosity, divided by concentration). ASTM Test Method for Intrinsic Viscosity of Cellulose (D1795) describes a one-point procedure for estimating intrinsic viscosity. The results of such measurements can be related to molecular weight and are useful for predicting properties of different batches of well-understood commercial resins. Many polymer chemists routinely make one-point viscosity measurements to monitor synthesis experiments, reserving more sophisticated molecular weight measurements for products chosen for commercialization.

Melt viscosity, the viscosity of the pure polymer, is correlated with $\overline{M}_w$. Equations developed to relate degree of polymerization with melt viscosity use a temperature-dependent function which differs for each polymer system. As a practical matter, polymer melts are nonideal fluids, and their true viscosity can rarely be measured with simple equipment. Thus, melt viscosity is usually determined because of its relation to polymer processability, rather than as an estimate of $\overline{M}_w$. Melt viscosity is a useful tool for rapid comparison of suspect resin batches to controls, especially with resins which are suspected of changing during storage or when there are difficulties in analyzing by SEC. Pour point, the temperature at which the polymer begins to flow, is similarly related to molecular weight, and may be used to estimate it.

X-Ray Analysis

A. Monroe Snider, Jr.,[1]

X-RAY DIFFRACTION (XRD) AND X-RAY FLUORES-cence spectrometry (XRFS) are powerful, well-established tools used by analytical chemists in many areas of technology. They have great utility in the coatings industry. In areas where they are applicable, they are frequently the quickest and easiest techniques available. XRD is convenient for the identification of diverse crystalline solids encountered in paint research laboratories and production plants. It is particularly well suited for use in the identification and quantitative analysis of crystalline pigments and extenders, either when they are alone or present in paste or paint. XRFS is useful as a stand-alone technique for elemental analysis and as a complementary tool for use with other analytical techniques. X-ray spectrometers typically can analyze all elements with an atomic number of about 11 (sodium) and higher, but some units can reach as low as atomic number 5 (boron). XRFS can span the concentration range from parts per million to high percentages for most elements in liquid or solid samples. Dedicated XRFS units, much lower in cost than scanning spectrometers, can be set up to detect and quantify one or a few specific elements. Portable XRFS units are available for field investigations. The present section summarizes the principles and methodology of XRD and XRFS.

RADIATION SAFETY

Although operation of modern X-ray instruments involves little risk to the operator when proper safety practice is followed, it is imperative that the operator knows and follows proper practice. Exposure to excessive quantities of X-ray radiation is injurious to health. Therefore, users should avoid exposing any part of their bodies, not only to the direct beam, but also to secondary or scattered radiation that occurs when an X-ray beam strikes or passes through any matter. It is strongly recommended that users check the degree of exposure by film badge or dosimeter carried on them. X-ray instruments should not be operated with safety interlocks, shielding, or other protective devices removed or deactivated. Before using the equipment, all persons designated or authorized to operate X-ray instrumentation or supervise its operation should have a full understanding of its nature and should also become familiar with established safe exposure factors by careful study of the American National Standards Institute Standard N43.2-2001, "Radiation Safety for X-ray Diffraction and Fluorescence Analysis Equipment" [1]. Inquiries should be made of state agencies about existing requirements.

Application

TYPES OF SAMPLES

XRD is widely used for the analysis of analytes that are crystalline or polycrystalline solids, i.e., solids comprised of atoms or ions arranged in a three-dimensional lattice pattern [2]. The sample may be totally crystalline or may contain one or more crystalline components interspersed with noncrystalline material. Common types of materials analyzed include pigments and extenders (alone, in grind pastes, in liquid and powder paints, or in dried paint chips), miscellaneous crystalline solids, and pretreatment on metal. XRD also has important uses in the study of amorphous materials such as polymers and inorganic glasses [2]. In the case of scanning X-ray diffractometers, a flat surface of the specimen must be presented to the X-ray beam.

Types of Information Provided

X-ray diffraction analysis permits qualitative and quantitative analysis of crystalline components. It can indicate the degree of crystallinity, crystallite orientation, and long-range order in polymers. Long-range order in liquids has also been studied [2].

Range of Concentrations

As a rule, crystalline components can be analyzed by routine methods at concentrations ranging from 100 % down to approximately 1 % or 2 %. However, the limit of detection varies widely with the identity of the analyte of interest, the number and identity of other components, the quality of the instrumentation used for analysis, and the instrument operating conditions. Analysis of components at concentrations as low as 0.01 % has been reported [3].

Physical Principles

XRD experiments are performed by irradiating a specimen of crystalline or polycrystalline material with a beam of X-rays of known wavelength and determining the angle 2θ between the incident beam and each diffracted beam of X-rays and measuring the intensity of each diffracted beam. Diffraction occurs only at discrete angles defined by the Bragg equation [2,4,5]

$$n\lambda = 2d\sin\theta$$

where

n = a positive integer (usually one),
λ = the wavelength of the X-rays used,

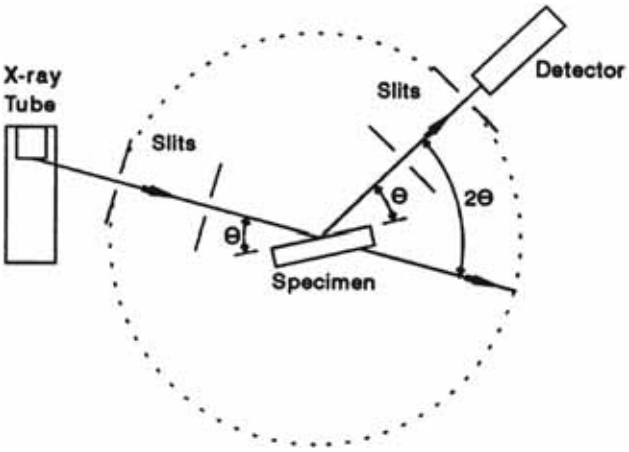

Fig. 1—X-ray diffraction goniometer system.

d = the distance between layers of atoms of a set of lattice planes, and
θ = the angle between the incident X-ray beam and the lattice plane [5].

The wavelength of the X-rays is determined by the choice of the x-ray tube target material, usually copper, and is thus known. The wavelength of copper K_α radiation, the principal component of X-rays from a copper target, is 1.541 84Å. It is common practice to use a crystal monochromator or absorption filter to prevent unwanted wavelengths of X-rays from contributing to the diffraction pattern. Angle θ is half of the diffraction angle 2θ that is determined experimentally. The distance between layers of atoms in a set can be calculated by using the Bragg equation. The distance, d, is determined by the diameter of atoms comprising the crystal, the three-dimensional arrangement of the atoms in the crystal, and the set of lattice planes in the crystal that produced the "reflection" of X-rays. Thus, crystallites of different compounds or different crystal modifications of a single compound will give different sets of d-spacings. Each crystalline phase will produce a unique XRD pattern that can be used as a "fingerprint" for identification. Detailed discussions of the Bragg equation and the physical basis of XRD are available in various treatises on XRD, such as the classic work by Klug and Alexander [2].

Analysis by XRD requires that a specimen be placed in the primary beam of a diffractometer and the diffraction angle and the intensity of each diffracted beam be measured.

Diffractometers use either an electronic detector or photographic film to indicate the position of the diffracted beams of X-rays. Most diffraction units in industrial laboratories today use an electronic detector, usually a proportional counter. Fig. 1 is a simplified diagram of a diffractometer.

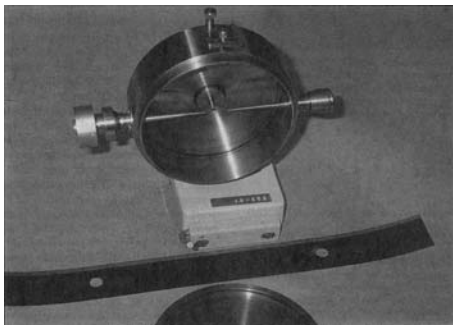

Fig. 3—Debye-Sherrer camera with the front cover removed displayed with a developed X-ray film.

The specimen is placed in a holder at the center of a goniometer system. The goniometer system is a mechanical device that permits accurate measurement of the angle between the primary beam and the surface of the specimen (θ) and the angle between the primary beam and the detector (2θ). A receiving slit and detector slowly sweep around an arc at a fixed distance from the center of the goniometer, facilitating determination of the intensity of X-rays scattered at each angle, 2θ, on the arc. While the detector moves through angle 2θ, the specimen rotates about the same axis through angle θ. A plot of the intensity of scattered radiation as a function of 2θ, a diffractogram or diffraction pattern, is thus produced. Fig. 2 shows the diffraction pattern of the rutile form of titanium dioxide.

A relatively new variation of the electronic detector is the position-sensitive detector (PSD) that uses an arc-shaped solid state detector to sense both the position and intensity of the diffracted radiation [6,7]. The PSD is stationary during data collection, but may be moved to different locations on the goniometer circle, as required, so that its surface can intercept X-rays at all 2θ positions of interest. Compared to a conventional scanning unit, a PSD can markedly shorten the time required to collect data.

The oldest method for collection of diffraction patterns, photographic, is still useful today, with the Debye-Sherrer camera being the most commonly used camera [2]. The Debye-Sherrer camera (Fig. 3) uses a strip of film mounted on the inner surface of a cylindrical holder. The film records XRD over a 2θ range of 360°. The d-spacing of arcs caused by exposure of the film to diffracted X-rays can be calculated from the position of the arcs on the film. Relative intensities of the diffracted x-ray beams can be evaluated by measuring the degree of darkening of the corresponding arcs on the film by an optical density

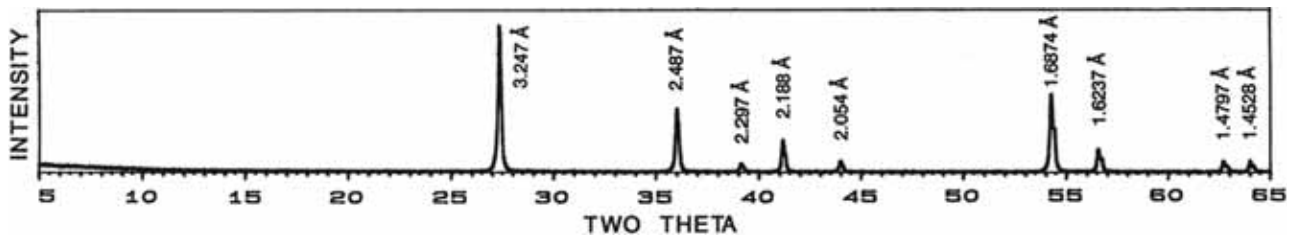

Fig. 2—X-ray diffraction pattern of rutile TiO_2 with the peaks labeled with the d-spacing of the corresponding sets of crystallographic planes.

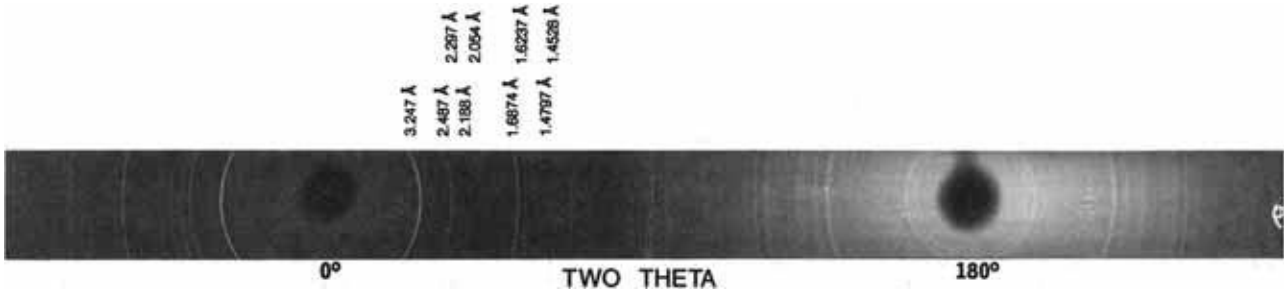

Fig. 4—Debye-Sherrer film with diffraction pattern of rutile TiO_2. The *d*-spacings of selected diffraction arcs are marked for comparison with peaks shown in Fig. 2.

measurement or by visual comparison to standards. Fig. 4 shows the diffraction pattern of rutile TiO_2 recorded with a Debye-Sherrer camera.

Experimental Procedure

SPECIMEN PREPARATION

Specimens for XRD can be any crystalline containing solid that can be mounted to permit collection of a diffraction pattern. For scanning diffraction units, the surface of the specimen should be flat and must be positioned in the focal plane of the instrument's x-ray optical system. The latter requirement can be met by mounting the specimen with its surface flush with the face of the specimen holder designed for the instrument. Failure to do so causes a systematic error in the observed 2θ angle and *d*-spacing of all peaks in the diffraction pattern. Fig. 5 shows a photograph of specimen holders used in some commercial XRDs.

Common types of samples encountered in the coatings industry and the recommended modes for mounting them in a scanning diffractometer are summarized in Table 1.

A Debye-Sherrer camera is useful for analysis in cases where there is too little sample for analysis using a conventional scanning diffraction unit. For small amounts of powder, the specimen is prepared by loading the powder into a thin-walled glass capillary or by mixing the powder with noncrystalline glue and rolling the mixture to form a filament. The capillary or filament after hardening is mounted in the center of the camera on a motor-driven rotating stub. Rotation presents a more nearly random orientation of crystallites to the incident X-ray beam. A single small chip or crystal may be analyzed by attaching it by glue to the end of a glass capillary and exposing it to X-rays in the Debye-Sherrer camera. In Fig. 3, the

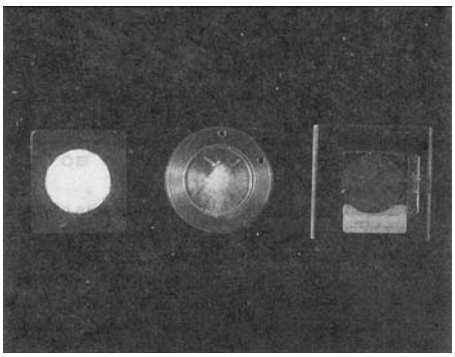

Fig. 5—Specimen holders for three common commercial X-ray diffractometers, each with a different type of specimen: (left) powder in a depression, (center) powder sprinkled on petroleum jelly smeared on a zero background quartz plate, and (right) disk cut from a drawdown of paint.

TABLE 1—Common samples and methods of mounting for XRD analysis

Sample	Method of Mounting
Powder	Put directly in holder or sprinkle on film of petroleum jelly or amorphous glue on zero background plate.
Liquid paint or grind paste	Prepare drawdown film on amorphous plastic sheet. Cut specimen to fit holder. Attach specimen to holder using double stick tape.
Paint chip	(1) Cut specimen to fit holder or (2) scrape off portion of interest, pulverize, and run as powder.
Paint on panel	Cut specimen to fit holder or cut to same dimensions as holder and run without holder.
Pretreatment on metal	Cut specimen to fit holder or cut to same dimensions as holder and run without holder.
Paint with low pigment content	(1) Remove pigment from paint by centrifugation. Dry and grind the pigment plug. Mix the ground material. Run as power.[a] (2) Pour paint into crucible, dry, ash, mix, and run as power.[b]
Suspension in liquid	Isolate solids from liquid by decantation, filtration, or centrifugation. Dry, grind, and mix. Run the resultant powder as described above.[a]
Sludge	(1) Run as drawdown on amorphous plastic sheet or (2) dry, grind, mix, and run as powder.
Gel	(1) Run as smear on plastic sheet, (2) dissolve organic portion with solvent and then handle sample as suspension, or (3) ash and handle as powder.[b]

[a]Caution: The composition of the plug may be heterogeneous because of stratification of the pigments during gravity settling or centrifuging.
[b]Caution: Ashing may change the crystalline composition of a sample by causing decomposition, vaporization, or transformation of phases that are present. Ashing at mild temperature, 450°C, in accordance with ASTM D4451 may prevent or lessen the amount of change of crystalline components [10].

capillary can be seen mounted along the axis at the center of the camera.

Specimens suitable for a Debye-Scherrer camera are equally suitable for XRD units equipped with a PSD and a holder for capillary specimens.

A thin-film XRD, a variation of the scanning diffractometer, can be extremely useful in the analysis of thin films of crystalline coating or contaminant on flat surfaces [8,9]. They also give better results than conventional diffractometers when only a small amount of powder is available. Thin film units operate exactly as conventional scanning diffractometers except the surface of the specimen is irradiated with X-rays at a fixed but selectable grazing angle. In comparison to conventional XRD analysis, this approach reduces the depth of penetration of the X-ray into the specimen and enhances the strength of the signal from crystalline components on the surface [9].

To achieve best results, some types of paint samples require modification before they are mounted in the specimen holder. Procedures such as ashing or centrifuging may be helpful.

Chips or drawdowns of paint that have low pigment-to-binder ratio may yield diffraction patterns with weak intensity and unacceptable signal-to-noise ratio. This problem is common with wood stains and varnishes. The resultant poor quality diffraction patterns may prevent complete and reliable identification of the crystalline constituents and may prevent accurate quantitative analysis. In such cases, the strength and quality of the diffraction pattern can be greatly improved if the organic binder is removed before the diffraction pattern is recorded. Low temperature (450°C) ashing in a muffle furnace can burn away the organic matrix of a sample, with minimum alteration of the chemical composition or crystalline phase of crystalline components. Details of the procedure are provided in ASTM Standard Test Method for Pigment Content of Paints by Low-Temperature Ashing (D4451) [10] and Standard Test Method for Pigment Content of Water-Emulsion Paints by Low-Temperature Ashing (D3723) [11]. Ashing leaves a powdery residue of crystalline material that will yield a much improved diffraction pattern, compared to one obtained directly from the original sample.

The analyst should be aware that the advantages of ashing are accompanied by potential risks. First, ashing, even at low temperature, destroys organic pigments and causes loss of water from hydrated components, if such materials are present. Second, unintended temperature excursions substantially above the intended 450°C may cause chemical changes such as the conversion of metal carbonates to metal oxides, metals to metal oxides, or lower oxides of metals to higher oxides. Analytical results from an overheated sample can be badly misleading.

In the case of liquid samples, high-speed centrifugation can be used to remove crystalline material, generally pigment, from the paint vehicle and concentrate it as a "plug" at the bottom of the centrifuge tube. Details of the procedure are given in ASTM Standard Test Method for Pigment Content of Solvent-Reducible Paints (D2371) [12] and ASTM Standard Method for Determination of the Pigment Content of Solvent-Reducible Paints by High-Speed Centrifuging (D2698) [13]. Noncrystalline particles, if present in the sample, are also incorporated into the plug. If a liquid sample has high viscosity, then pigment separation by centrifugation may be very slow, unless solvent is added to thin the sample. Separation of pigments by centrifugation can be helpful in the case of very low solids paints, such as electrodeposition paints, which tend to give poor quality drawdowns. Centrifugation must be done with sufficient speed and time to remove fine, low-density particles which, if present, tend to settle slowly. The following two cautions should be noted: (1) incompletely precipitated crystalline components will be underreported in the analysis of the resultant plug; (2) centrifugation causes stratification of the various particulate phases in the plug on the basis of density and particle size. The stratified, inhomogeneous plug must be fully retrieved, homogenized, and properly sampled to ensure that subsequent analyses are not biased. Material from the plug may be mounted using one of the methods listed in Table 1.

INSTRUMENT OPERATION CONDITIONS

Operating conditions should be based upon recommendations of the manufacturer of the XRD unit, requirements of the analytical method being used, and practical laboratory considerations. As a general rule, x-ray tubes with copper targets are commonly operated with a potential of about 40 to 45 kV and a filament current of about 35 to 45 mA. If other factors are held constant, then higher power settings can be used to shorten analysis time, lower the limit of detection, and improve signal-to-noise ratio, but at the expense of shortened tube life. For routine, general-purpose analysis by scanning XRD units, the common choice for slits used to define the dimensions of the x-ray beam illuminating the specimen and reaching the detector are as follows: 0.15° for the receiving slit and 1.0° for all other slits. If other factors are held constant, then larger slits can be used to shorten analysis time, lower the limit of detection, and improve signal-to-noise ratio, but at the expense of reduced ability to resolve closely spaced peaks. Conversely, smaller angle slits should be used if higher resolution is required. For analysis of unfamiliar paints, pigments, and other materials, diffraction patterns should be collected over a range scanning at least from 5 to 65° 2θ. Use of a shorter scan range may cause the omission of important diffraction peaks. However, scans spanning a narrow 2θ range may be satisfactory for routine tests based on peaks located within a chosen portion of the diffraction pattern. For routine qualitative and semiquantitative analysis, satisfactory results can be achieved with most step scanning instruments by progressing in steps of 0.02° 2θ, with 1.0 to 1.2 s per step. Longer count time may be required for quantitative analysis. In the case of older diffractometers with analog scanning motors, a scan rate of 1°/min is satisfactory for routine qualitative and semiquantitative analysis.

When analysis of minor components is required, especially in the case of samples that tend to yield weak XRD patterns with poor signal-to-noise ratio, the analyst may find it necessary to resort to the following instrument operating conditions to improve the diffraction pattern: (1) the widest slit set that can be used without producing unacceptable broadening of the diffraction peaks, (2) increased count time per step (slower scan rate), and (3) increased x-ray tube power output (increased filament current and acceleration potential). Of these three factors, wider slits

usually should be tried first, since this option will give the greatest benefit. Signal-to-noise ratio (S/N) will increase with the square root of the count time or scan time (e.g., quadrupling the time to collect a scan will double the S/N). Adding or averaging the signal collected during multiple scans is an alternative to—and generally preferable to—use of a single long scan. Increases in x-ray tube power should be done in accordance with the recommendations of the instrument manufacturer.

Qualitative Analysis

INTERPRETATION OF XRD PATTERNS

Preparation of d-Spacing Intensity Table—after the XRD pattern of a test sample is recorded, the analyst must obtain a list of all diffraction peaks with their *d*-spacing and relative intensity. The peaks should be listed in descending order of *d*-spacing. The intensity is expressed as a percentage of the strongest peak, taken as 100. If the x-ray unit lacks data processing capability, then the analyst must read the 2θ of each peak from the pattern and calculate the *d*-spacings from the 2θ values of the peaks using the Bragg equation. Likewise, the height of each peak must be measured by hand and the relative intensity determined. However, *d*-spacing-intensity tables can be obtained automatically from diffraction units equipped with even the most basic computer capabilities.

General Comments—identification of pigments, extenders, and other crystalline phases by XRD is accomplished by matching the peaks of the diffraction pattern of a sample under analysis with the sets of diffraction peaks exhibited by reference samples of known composition [2,14,15]. XRD provides no chemical information about a test sample other than the identification of each component that is achieved when a full match of its set of peaks is found. Either manual or computer-assisted searches can be done. Manual methods rely on the numerical comparison of *d*-spacings and intensities of diffraction peaks. Computer search methods also begin by matching the *d*-spacings of peaks, but rely in part on the analyst to do visual matching of peaks on a video screen.

Several instrument manufacturers and after-market suppliers offer excellent computerized search-match programs. Operated on personal computers, these programs use diffraction data files stored on compact disk or magnetic medium. The data files are available from the International Centre for Diffraction Data (ICDD), formerly known as the Joint Committee for Powder Diffraction Standards (JCPDS) [16]. Use of these computer programs and data files can greatly speed up qualitative analysis [17].

Manual Search Procedures—diffractionists who are experienced in the analysis of paints, but who do not have computerized search-match capabilities, usually employ a qualitative analysis procedure that has the two following steps. First, the diffraction pattern is inspected for the presence of sets of peaks that are characteristic of commonly used pigments and extenders, or other phases suspected of being present. Sets of peaks found in the pattern that are suspected of resulting from common components are compared to the peaks on reference diffraction patterns. The comparison may be done directly by comparing diffraction patterns or indirectly by comparing the *d*-spacings and relative intensities calculated from reference patterns. Partial or even complete identification of components may be achieved by this procedure. Second, peaks that were not identified by the first approach are subjected to a systematic search using compilations of XRD data, such as the Powder Diffraction File from ICDD. The first approach is most useful when the analyst, because of information available from other sources such as elemental analysis, the appearance, knowledge of the intended use of the paint, or experience, suspects the presence of certain crystalline components.

Fig. 6 shows the XRD patterns of several common paint pigments. For brevity, the term pigment will be used to mean both pigments and extenders. The pigments are readily distinguished from each other and from all other crystalline material by the positions of the peaks on the 2θ scale and by the relative intensities of the peaks. Since the diffraction pattern of each crystalline phase is unique, it may be used as a "fingerprint" for identification. The patterns in Fig. 6 were collected under identical conditions from powder specimens. Although some pigments originally gave patterns with greater peak heights, they are all plotted to about full scale for convenience.

Fig. 7 shows diffraction patterns of dried paint films from two test paints of known composition. Each crystalline component in the paint film contributes its own set of peaks to the pattern, with the position and relative intensity unaltered by the other components. Resin and other noncrystalline components produce only a broad, weak hump in the baseline. Some crystalline components of the two paints represented by Fig. 7 can be identified by comparison with the diffractograms of individual pigments in Fig. 6.

Table 2 lists 37 pigments and extenders commonly used in paint, with the *d*-spacings and relative intensities of their five most intense diffraction peaks. This table, compiled from the Powder Diffraction File of ICDD, may aid the paint analyst in identifying common components. The table may be helpful to analysts regardless of whether they have access to a computerized search-match system. The pigments are listed in order of the d-spacing of the strongest peak. The *d*-spacing of the strongest peak is listed in the first column on the left. The next four strongest peaks of each phase are listed in decreasing order of their *d*-spacings. The subscripts state the relative intensity of each peak rounded off to the nearest integer, with the intensity of the strongest peak taken as 10 and represented by "x."

To use Table 2 in a systematic manner in interpreting a diffraction pattern, the analyst determines the *d*-spacing of the peaks at the high d-spacing end of the pattern of the sample under analysis and then searches the first column of Table 2 for apparent matches. When an apparent match is found for a peak, the pattern of the test sample is inspected for the presence of the remainder of the peaks listed in the same row of Table 2. The absence from the pattern of any one of the listed peaks is usually sufficient reason for rejection of the suspected component. However, in the case of materials consisting of platelet or acicular-shaped particles such as clays, mica, and aluminum flake, preferred orientation may greatly decrease the intensity of some diffraction peaks compared to the intensities listed in Table 2. If the pattern of the test sample has all the peaks listed for the candidate component, then the analysts should note the ICDD file number listed for the phase in the last column. The file number may then be used to

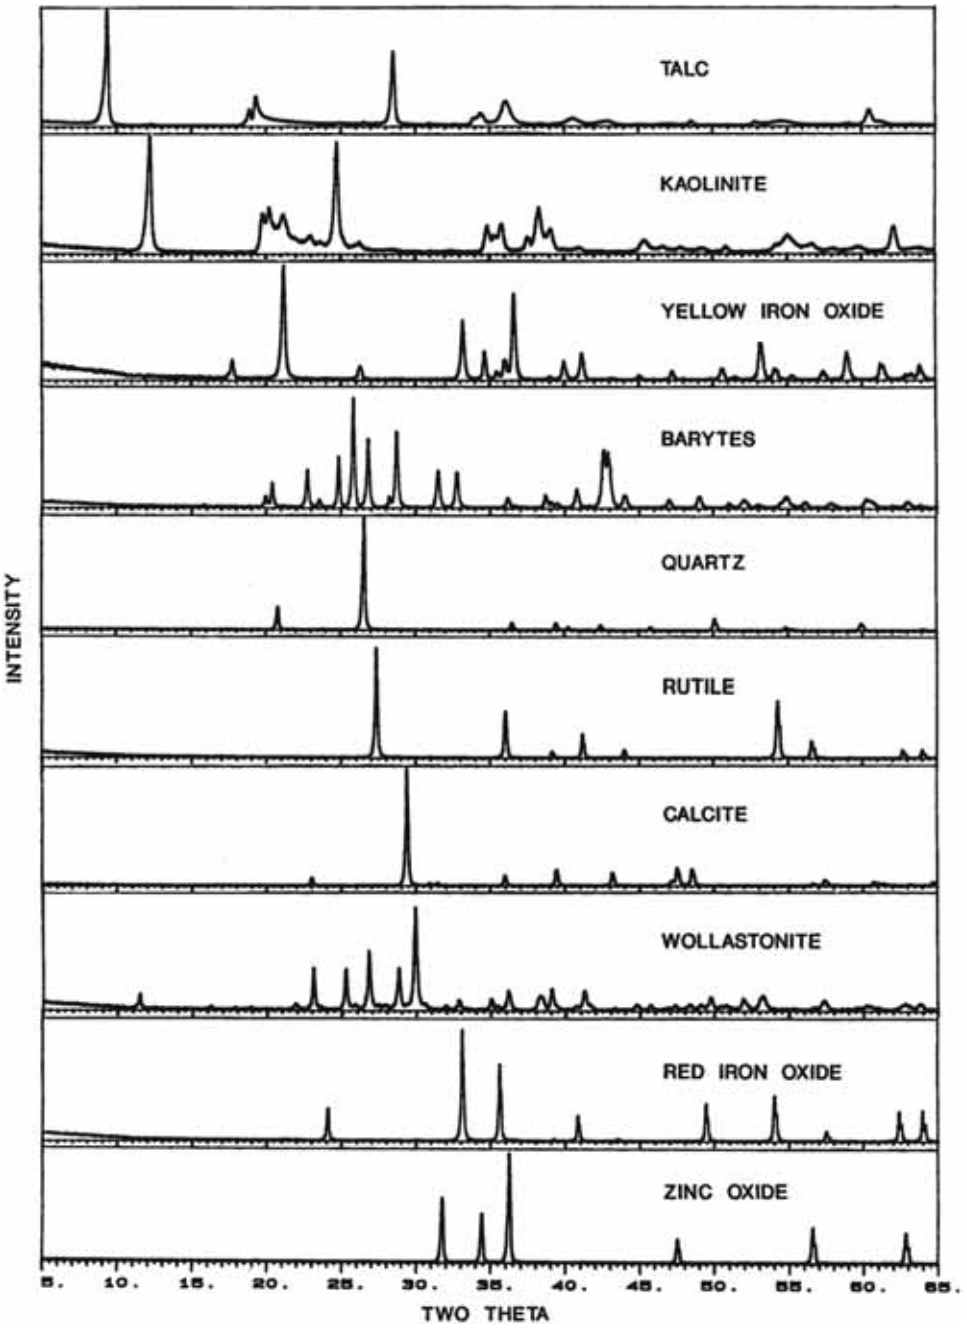

Fig. 6—X-ray diffraction patterns of several common pigments and extenders run as powder.

locate the full set of diffraction data provided by ICDD (and JCPDS) compilations. Using the ICDD data, all peaks attributed to the identified component may be marked on the pattern of the test sample. The identification process is then repeated with unassigned peaks in the pattern, working progressively from the peaks with the highest *d*-spacing, particularly the strongest ones, to the peaks with low *d*-spacing.

In an alternative use of Table 2, the analyst searches the list for crystalline phases that he suspects may be present in the test sample. If the strongest peaks listed in Table 2 for the suspected component are present in the diffraction pattern of the test sample, then the analyst notes the ICDD file number and proceeds as described in the previous paragraph.

Analysis of extraneous deposits may be aided by use of ASTM Standard Practices for Identification of Crystalline Compounds in Water-Formed Deposits by X-ray Diffraction (D934) [18]. Standard D934 contains a table, analogous to Table 2, which lists commonly encountered extraneous materials and their strongest diffraction peaks.

The printed Alphabetical Index and Search Manual and its computer compact disk counterparts from ICDD provide an alphabetical listing by name of a large collection of crystalline phases, their formula, the d-spacing and relative intensity of the three strongest peaks, and their ICDD file number. These references are an extremely useful starting point in peak identification when the analyst knows or suspects the presence of certain phases in the test sample. If the three strongest peaks of a candidate are found in the

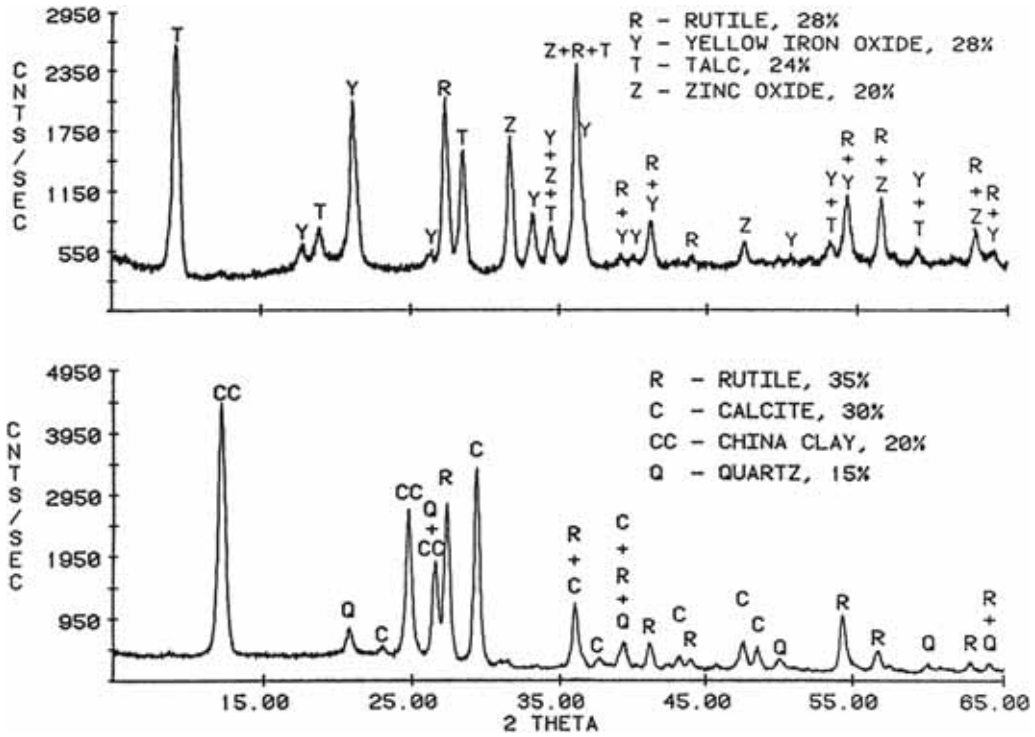

Fig. 7—X-ray diffraction patterns of drawdowns of two paints with the principal peaks of the constituent pigments labeled.

pattern of a test sample, then the analyst should use the ICDD file number to locate the full set of diffraction data on the compact disk or in the equivalent printed volumes. For positive identification, all peaks listed for the candidate in the full data set must be present with appropriate intensity in the test pattern. However, the weaker peaks of low-concentration components may be unobservable.

Peaks that remain unassigned after the information in Table 2 and the alphabetical files has been used must be identified by using the ICDD Powder Diffraction Files and either the Hanawalt or Fink search methods, or other search system. The Hanawalt method is based on the three strongest peaks in the diffraction pattern. The Fink method is based on the eight strongest diffraction peaks of each phase without use of intensity information. The Fink index lists each phase eight times with a cyclic permutation of the eight peaks. Instructions in the Hanawalt and Fink search manuals should be studied carefully before attempting to use either method [16]. Although still used in many laboratories, sale of Fink search manuals has been discontinued.

Computer-Assisted Searches—analysts using computer programs for qualitative analysis must rely on instruction from the program supplier. In general, computer search routines provide a list of crystalline phases that have peaks that match, or approximately match, the 2θ positions of the peaks of the test sample. Unfortunately, since more than one phase, perhaps many, may have peaks at the same 2θ position as the test sample, a search-match program may suggest phases that are not actually present. "False hits" are especially common when the diffraction pattern of the test sample is complex. Computer search routines provide the opportunity for the analyst to include information about elemental content of the sample and a variety of additional physical and chemical data to exclude implausible candidates. They also permit the analyst to adjust the *d*-spacing range spanning each test sample peak to account for possible error in the *d*-spacings of test sample and reference data. The analyst can widen the d-spacing "search window" to reduce the possibility of missing a component of the test sample or narrow the window to reduce the number of false hits. When analyzing "difficult samples," the analyst may benefit from comparing the results of searches run with a variety of search window widths. Some search routines assign a figure of merit to each candidate on the list based on similarity between data for the test sample and the candidate. Most programs permit the analyst to suggest candidates for consideration and exclude specific noncandidates. The analyst may draw on his knowledge of the origin of the sample and use Table 2, when appropriate, to suggest candidates. Visual matching on a video screen of the 2θ positions and intensities of peaks of candidate components, represented by "sticks," with the position and intensity of actual diffraction peaks is a key part of computer-assisted analysis. All candidate components with "extra" peaks not found in the diffraction pattern of the test sample must be rejected unless there is reason to suspect that preferred orientation of the particles can account for the discrepancy. (Preferred orientation exists when platelet or needle shaped crystalline particles are not randomly oriented, but instead have tended to align parallel to one another as may occur when liquid paint film dries, bulk powder is compressed in one direction during specimen preparation, or falling particles settle onto a surface.) Candidates with badly mismatched peak intensities must be considered suspect except when preferred orientation could account for the discrepancy. Relative intensities are especially unreliable for mineral pigments, especially clays, mica, and silica. Complete analysis ideally requires that a set of crystalline components can be identified that can account for all peaks, both their position and intensity, observed in the diffraction pattern of the test

TABLE 2—Strongest XRD peaks of common pigments and extenders for paint

[a]Subscripts represent the relative intensity (rounded to the nearest integer) of the diffraction peaks of a phase, with the most intense peak taken as 10 and represented by "x."
[b]Particles of this material frequently exhibit preferred orientation in paint films, thus causing the observed relative intensities to differ from intensities listed in this table.

sample. In reality, whether the search-match is done manually or with the aid of a computer, it may not be possible to identify all peaks in a diffraction pattern and therefore not all crystalline components in the corresponding sample.

Although computer search-match programs are valuable aides for interpretation of diffraction patterns, common programs that are presently available may suggest the presence of components that are absent and fail to show the presence of phases that are truly present. Therefore, results thus obtained should always be verified and, if necessary, corrected by the analyst.

Limitations—Qualitative analysis by XRD has four principal limitations. First, only crystalline phases can be identified. Noncrystalline components must be identified by other means. Second, different substances can be encountered that have similar diffraction patterns, at least in part. Misidentification can occur when the sample contains several crystalline phases producing a complex pattern and diffraction is the only technique being used for analysis. Examples of potentially confusing coincidences or near coincidences are the strongest peaks of red lead, quartz, and zinc sulfide, with *d*-spacings of 3.38, 3.34, and 3.31 Å, respectively, a secondary peak of barytes at 3.319 Å, and a strong peak of mica at 3.36 Å. The 3.247 Å peak of rutile may conceal the 3.260 Å peak of strontium chromate. The 3.445 Å peak of barytes may conceal the 3.452 Å peak of strontium chromate. Many other similar peaks can be found for common pigments in Table 2. Third, low concentration components may be overlooked, especially if they scatter x-rays weakly or if their strongest peaks are overlapped by peaks of major components. For example, small amounts of zinc oxide may be overlooked if its strongest peak at 2.476 Å is overlapped by a peak of rutile at 2.487 Å or talc at 2.476 Å, particularly when the latter phases are major components. Fourth, the relative intensity of peaks in the pattern of certain phases may differ significantly depending on their history, the degree of preferred orientation of the particles, the specimen preparation techniques, and the instrument used to collect the pattern. Anomalies arise especially from pigments that consist of platelet or acicular particles that exhibit preferred orientation and from clays that have been changed by chemical, thermal, or mechanical processing.

The analyst should not rely upon XRD alone when analyzing unfamiliar samples. Information from all sources should be reconciled before XRD results are reported. The speed and reliability of analyses can be greatly improved if information is available about what elements and functional groups are present in the sample. XRFS and optical emission spectroscopy are convenient techniques for qualitative elemental analysis. Plasma emission, atomic fluorescence, and atomic absorption spectrometry can also be used for elemental analysis. Infrared spectroscopy can provide functional group information and, through spectral matching, may provide independent corroboration of pigment identification. Elemental analysis data are particularly useful in detecting and identifying crystalline components that are present at low concentrations. Elemental analysis and infrared spectroscopy results are useful for identifying noncrystalline pigments. Color, solubility in selected liquids, chemical reactivity, magnetic properties, or response to ashing can sometimes give clues to the presence or absence of suspected components.

Identification of crystalline materials, especially complex mixtures of crystalline materials, is more difficult if the analyte concentrations are low and the XRD pattern is weak and "noisy." In such cases it may be necessary to collect a new diffraction pattern under instrument operation conditions that improve the signal-to-noise ratio (refer to the "Instrument Operation Conditions" section) and then interpret the improved pattern. Complete and reliable analysis may also require that the analyst prepare a fresh test specimen in a manner that increases the amount of crystalline material relative to noncrystalline material (refer to the "Specimen Preparation section").

Quantitative Analysis

THEORY OF QUANTITATION

Quantitative analysis by XRD is based on the principle that the intensity of a diffraction pattern of a crystalline substance is directly proportional to the concentration of that substance in the sample. This relationship and several complicating factors are discussed in detail by Klug and Alexander [2]. The intensity of X-rays diffracted from a given set of crystallographic planes in component *i* in a mixture is given by the equation

$$I_1 = K_i' f_i / \mu$$

where

I_i = the intensity of diffracted X-rays,
K_i' = a constant that depends on both the nature of component *i* and the characteristics of the apparatus,
fi = the volume fraction of component *i*, and
μ = the absorption coefficient of the mixture.

Since the absolute intensity I_i is influenced by the composition of the matrix, the absolute concentration of an analyte cannot be determined unless a calibration curve is established with an internal standard.

However, using the "matrix flushing" method described by Chung, the *relative* concentration of crystalline components in a mixture can be determined without knowledge of the absorption coefficient [19,20]. This approach is based on the fact that all components under analysis are in the same matrix and thus are equally influenced by x-ray absorption. The intensity of x-rays diffracted from a component *i* is given by the equation

$$I_i = k_i X_i$$

where

k_i = a constant that depends on component *i* and the apparatus, and
X_i = the mole fraction of component *i*.

The ratio of the intensity of X-rays diffracted from two components *i* and *R* is given by the equation

$$\frac{I_i}{I_R} = \frac{k_i}{k_R}\frac{X_i}{X_R}$$

where

k_R = a constant that depends on component *R* and the apparatus, and
X_R = the mole fraction of component *R*.

The constants k_i and k_R indicate the relative efficiency of two materials in diffracting X-rays from given sets of

crystallographic planes into the detector of the diffractometer. The relative value of k_i and k_R can be determined from the equation

$$\frac{k_i}{k_R} = \frac{I_i}{I_R}$$

by measuring the intensity of X-rays diffracted from two crystalline components *i* and *R* in a 1:1 binary mixture. Peak area, rather than height, should be used to represent intensity since the former is less influenced by differences in particle-size distribution. Quantitative analysis of a multicomponent mixture requires that the identity of all components be known. One component is arbitrarily chosen as an internal reference, *R*. Binary 1:1 by weight mixtures are prepared with the reference component and each of the other components. The intensity ratio Ii/IR of a peak, usually the strongest, of each component is then measured. The ratio of the intensities of the diffraction peaks defines the k_i/k_R of each pair of components. The ratio k_i/k_R is called a reference intensity ratio RIRs or RIR [21–25]. Corundum, the most commonly used reference material, is the basis of all RIR values given in ICDD Powder Diffraction Files. Davis, Smith, and coworkers published RIR values for some common materials, including several that are used as pigments or extenders in paint [25,26]. Published reference intensity ratios must be used with care since material other than corundum may have been used as the reference and intensity may have been measured as peak height instead of area.

MANUAL CALCULATION OF COMPOSITION

The relative weight percent of each crystalline component in a multicomponent mixture can be determined by the following procedure:

1. Determine the intensity of the diffraction peak chosen for quantitation of each component. (Integrated intensity based on peak area is recommended. Intensity may be expressed in counts per second, relative intensity compared to the most intense peak in the set, or any other consistent system.)
2. Determine the reference intensity ratio (RIR) for every crystalline component in the sample if the information is not already available. (Once a RIR has been determined, it may be saved and used in future analyses conducted under the same experimental conditions.)
3. Divide the intensity of the chosen peak of each component by the corresponding RIR.
4. Normalize the set of quotients so that their sum is 100.
5. The normalized quotients correspond to the relative weight percent of each crystalline component.

EXAMPLE

The diffraction pattern of a sample indicated the presence of three components: rutile, quartz, and tan iron oxide. The analyst determined that the RIRs for these phases are:

3.20 for the 3.247 Å peak of rutile

2.96 for the 3.342 Å peak of quartz

2.32 for the 2.543 Å peak of tan iron oxide

The intensity of the corresponding peak for each component in the diffraction pattern of the test sample is:

Component	Intensity
Rutile	100.0
Quartz	19.1
Tan iron oxide	1.8

The data and calculated values may be organized as follows:

Component	Intensity	RIR	Quotient	Percent
Rutile	100.0	3.20	31.3	81.1
Quartz	19.1	2.96	6.45	16.8
Tan iron oxide	1.8	2.32	0.78	2.1

Two important points about quantitation by XRD analysis should be noted. First, the results do not include noncrystalline components such as carbon black, amorphous silica, or highly processed clays. Second, the results do not represent percent by weight on either a dry film or a liquid paint basis.

The absolute weight percent of crystalline pigments and extenders can be determined by either

1. Using a variation of the above method that includes an internal standard [19,20,27] added in known concentration to the paint.
2. Taking into account the total percent pigment in the paint if no amorphous pigment is present. The percent pigment in dry coating or water-reducible paint can be determined by ASTM Test Method for Pigment Content of Water Emulsion Paints by Low-Temperature Ashing (D3723) [10]. The percent pigment in solvent-reducible paint can be determined by ASTM Method for Determination of Pigment Content of Solvent-Reducible Paints by High Speed Centrifuging (D2698) [13] or ASTM Test Method for Pigment Content of Solvent-Reducible Paints (D2371) [12].

The accuracy and precision of quantitation by XRD are strongly dependent on the number and type of crystalline components present, the accuracy of the RIRs used, the amount of preferred orientation of crystallites, and the instrument-operating conditions. Published studies reported that the "matrix flushing" method described above yielded results that agree with known composition within 4.2 % relative for all components [20]. Standard deviations of about 0.4 % and 5 % have been reported for components comprising 90 % and 5 %, respectively, of three-part mixtures of NiO, μ-Fe_2O_3, and Fe_3O_4 [28]. Smith et al. reported relative error ranging from 0 to 12 % [24]. Dyakonov et al., in a study with seven laboratories, reported relative standard deviations of interlaboratory determinations ranging from 5 to 20 %, but cited relative standard deviations of 60 % for low-concentration components [29]. An approach for dealing with preferred orientation in mica has been suggested by Kamarchik and Ratliff [30].

COMPUTER-ASSISTED CALCULATION OF COMPOSITION

Some computer programs for processing XRD data include a quantitative analysis program that, in principle, can be

used to determine the weight percent of each crystalline component in a mixture of crystalline components. (The results are the percent of total crystalline content, not the percent of total solids.) These programs calculate composition using a computerized version of the manual calculations described and illustrated in the paragraphs above. Because of their simplicity and speed, they can be very helpful if used prudently, but most commercially available quantitation programs have two serious shortcomings. First, they assume that all crystalline materials have a RIR of unity, a markedly inaccurate assumption. Second, they base quantitation on the strongest diffraction peak of each crystalline component, even though the strongest peak may be overlapped by peaks of other components. Consequently, if the strongest peak of a minor component, a peak that would be weak if it stood alone, is overlapped by a strong peak of a major component, then the calculation algorithm gives a much inflated apparent weight percent for the minor component. Thus, careless or uninformed use of these programs may yield results that are wildly inaccurate. Analysts should not rely upon results produced by a quantitative XRD program without investigating and understanding the assumptions and limitations of the program.

Some quantitation programs permit the analyst to replace the default value of unity in the internal RIR table by user-installed RIR values. Ideally, the substituted RIR values have been determined experimentally using the same diffractometer operating under similar conditions, especially with the same slit widths. Less reliable than the foregoing approach, but still far better than using unity, would be entry into the internal RIR table the RIR values obtained from an external source, such as those stated in the ICDD Powder Diffraction Files or in other published literature [16,25,26]. The analyst should consult the user manual to determine the nature of the RIRs used in calculations and the procedure to install alternative RIR values, if changes are desired.

When proper RIR values are used and there is no overlap of the strongest diffraction peak of any component in the sample, computerized quantitation programs give satisfactory results quickly. Under these conditions, the accuracy and precision are similar to those achievable by manual calculations. In the case of samples in which one or more of the components have their strongest peak overlapped by a peak of another component, the analyst probably must resort to manual calculation based either on a weaker, non-overlapped peak or on the strongest peak after overlap contribution has been subtracted.

LIMITATIONS

Quantitation of pigments by XRD is sometimes handicapped by one or more of the following problems. First, the degree of crystalline regularity within particles of some pigments, especially silica and clays, may differ depending on the source and the nature of the processing that they have received. A factor contributing to variability of the apparent crystallinity is the amount of substitution of "foreign" ions in the crystalline lattice. An example is the substitution of magnesium for calcium in calcite and strontium for barium in barytes. Thus, a given amount of pigment in a test sample may diffract X-rays more or less strongly than the supposedly equivalent pigment sample used to establish the RIR. An article by Davis et al. provides a valuable listing of RIRs (versus corundum) for many common pigments and illustrates the variability of reference intensity ratios for pigments from different sources [22]. Second, pigment particles that are platelet or acicular in shape tend to assume preferred orientations in a paint film as the paint dries. If the extent of preferred orientation of the particles in the specimen and the reference specimen used to establish the RIR differs, then quantitation based on the RIR is incorrect. Mica and aluminum flakes commonly exhibit preferred orientation. Third, the strongest peaks normally used for quantitation may be overlapped by peaks of other components, thus requiring the use of weaker and less reliable peaks as the basis of quantitation.

Examples of XRD Analysis

PIGMENT ANALYSIS

XRD analysis is the most direct way to determine the identity and purity of pigments, whether in assessing the quality of pigments from established suppliers or in evaluating pigment from potential new suppliers. Crystalline impurities contribute "extra" peaks to diffraction patterns, differences that may be readily seen in patterns of pigment powders alone or in grind pastes. X-ray analysis has long been established as the method of choice for determination of the amount of anatase in rutile [ASTM Test Method for Ratio of Anatase to Rutile in Titanium Dioxide Pigments by X-ray Diffraction (D3720)] [31]. The widespread use of diffraction in the pigment industry attests to its utility in that field.

Questions concerning the identity or amount of pigments in paint can be more conveniently and definitively answered by XRD than by any other technique. Visual comparison of diffraction patterns or, when necessary, quantitative analysis can be used to determine whether errors in pigment composition account for the difference in performance, color, or gloss of "good" and "bad" paint. Diffraction analysis is a basic tool that may be used to verify whether a paint that exhibits poor performance is the correct paint and comes from the correct supplier. The differences in the two patterns in Fig. 8, one for a good paint and one from a poorly performing suspect paint, coupled with differences in resin and solvent determined by other techniques, proved that the suspect paint was an unauthorized substitute.

METAL PRETREATMENT AND OTHER THIN COATINGS

XRD can be used to determine the identity and amount of pretreatment on metal or, in general, crystalline coatings on substrate. Fig. 9 shows the characteristic part of the diffraction patterns of two common types of pretreatment, hopeite [$Zn_3(PO_4)_2 \cdot 4H_2O$] and scholzite [$CaZn_2(PO_4)_2 \cdot 2H_2O$], on zinc-galvanized steel. Coating thickness or pretreatment weight on test samples can be determined by comparison of the intensity of one or more peaks of the species of interest with the same peaks exhibited by standard samples scanned under identical conditions.

X-RAY FLUORESCENCE SPECTROSCOPY

Application

TYPES OF SAMPLES

XRFS is applicable to any liquid or solid that can be placed at the focal point of the X-ray optics system. Permissible specimen size differs widely with instrument type. Common commercial laboratory units can accept

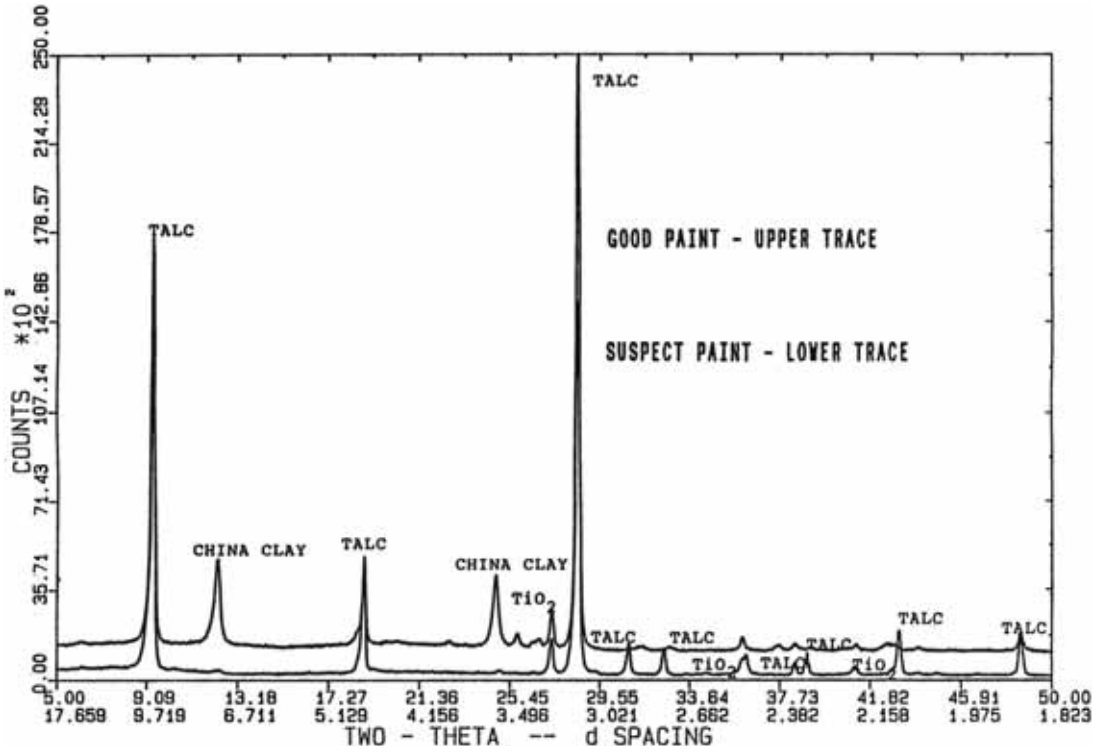

Fig. 8—X-ray diffraction patterns of drawdowns of two paints: one known to be good; one of suspect identity.

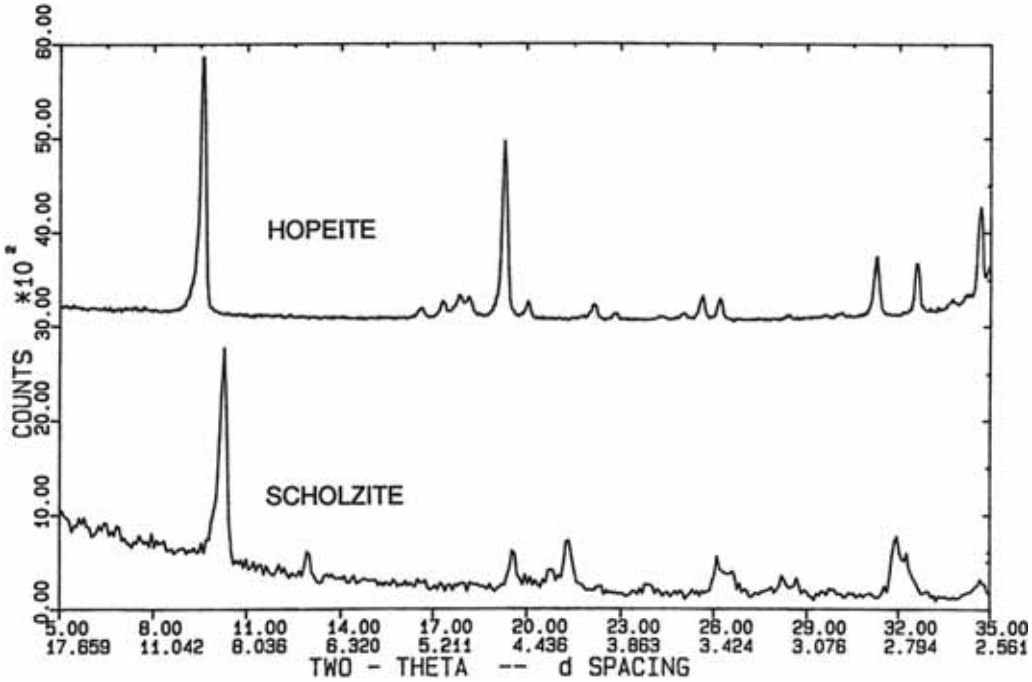

Fig. 9—X-ray diffraction patterns of hopeite and scholzite pretreatment on zinc-galvanized steel. (The principle peaks of zinc metal are beyond the right end of the pattern.)

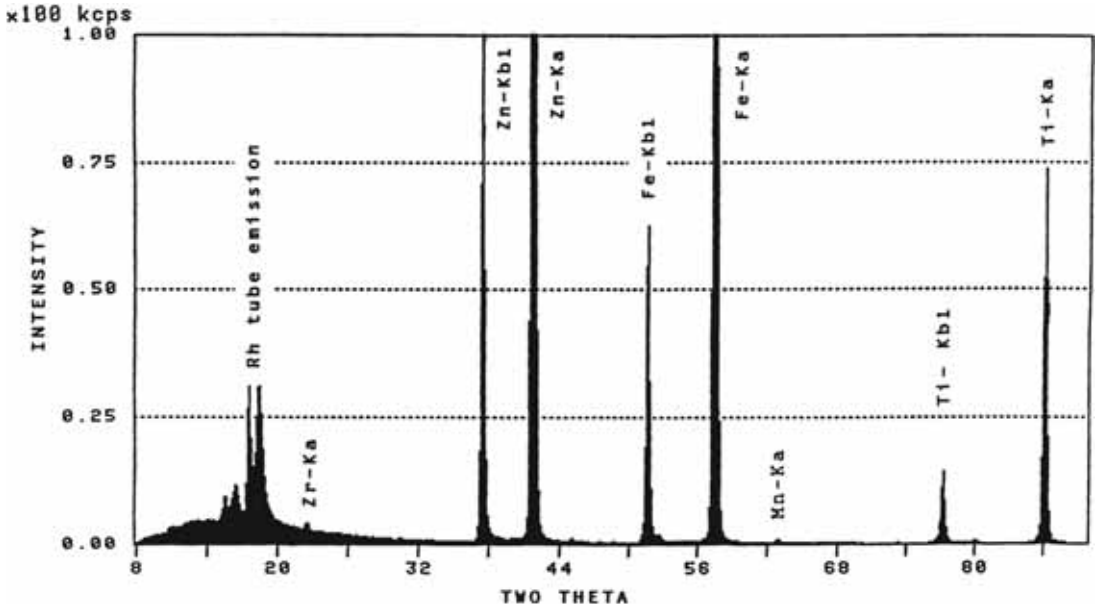

Fig. 10—Part of an X-ray fluorescence spectrum, recorded using a wavelength-dispersive spectrometer, of paint containing rutile, yellow iron oxide, talc, and zinc oxide.

specimens as large as a cylinder about 4.0 cm in diameter and 2.5 cm in height to as small as 1 or 2 mg of powder. Some laboratory models can analyze specimens up to several centimeters in each dimension. There is no maximum size limit for bench top or portable units with hand-held X-ray probes.

TYPES OF INFORMATION PROVIDED

The most sophisticated and costly X-ray spectrometers can be used for qualitative and quantitative analysis of all elements in the atomic number range from 5 (boron) to 92 (uranium). Lower-cost instruments span fewer elements and offer less versatility.

RANGE OF CONCENTRATIONS

Analysis can be performed on elements ranging in concentration from 100 % down to a few parts per million in favorable cases. The limit of detection differs widely with the model of spectrometer, the element of interest, and what other elements are present. The limit of detection rises rapidly with decreases in atomic number, especially below 11 (sodium).

Physical Basis

When X-ray photons of sufficient energy are directed onto a specimen, some photons are absorbed in a process that causes ejection of electrons from core atomic orbitals. The vacancies thus created in the inner orbitals are then filled by electrons from outer orbitals. The transitions of electrons from outer to inner orbitals are accompanied by the release of X-rays in a process called X-ray fluorescence [32,33]. The wavelengths of the fluorescent x-rays are greater than the wavelengths of the incident X-rays. Of key importance in analysis is the fact that every element emits fluorescent x-rays at characteristic wavelengths. The spectra are plotted as intensity as a function of 2θ angle (as in Fig. 10), wavelength, or photon energy (as in Fig. 11). Angle 2θ refers to the position of the X-ray detector that moves at twice the angle of the diffraction crystal used in some instruments to separate different wavelengths to produce a spectrum.

Types of X-Ray Fluorescence Spectrometers

SCANNING

Scanning X-ray fluorescence spectrometers permit the acquisition of spectra spanning a broad wavelength or energy range. These spectrometers, usually floor-standing, are versatile instruments for both qualitative and quantitative analysis. Scanning spectrometers, most using X-rays from Coolidge-type tubes, can be further classified as either wavelength or energy dispersive.

Wavelength-dispersive (WLD) instruments produce a spectrum by using a crystal to diffract the fluorescent X-rays, a single wavelength at a time, onto a detector that measures their intensity. By rotating the crystal through an angle defined as θ as the detector moves around an arc through angle 2θ, only those X-rays that satisfy the Bragg equation reach the detector. The resultant spectrum is usually plotted as intensity as a function of 2θ angle, but could in principle be plotted as intensity as a function of wavelength. By use of several crystals, each effective for a certain span of wavelengths, a broad range of wavelengths can be scanned. Instruments based on energy-dispersive X-ray spectroscopy (EDXS) permit all wavelengths of the fluorescence to reach the detector simultaneously and use a pulse-height discriminator to electronically classify the energy of the X-ray photons that strike the detector.

Descriptions and comparisons of the two types of scanning spectrometers have been provided by Campbell [34]. Compared to EDXS units, the WLD spectrometers generally offer far superior spectral resolution and lower limits of detection. High resolution eases the task of achieving reliable quantitative analysis of elements present at low concentration in the presence of high concentration elements of adjacent atomic numbers. EDXS instruments

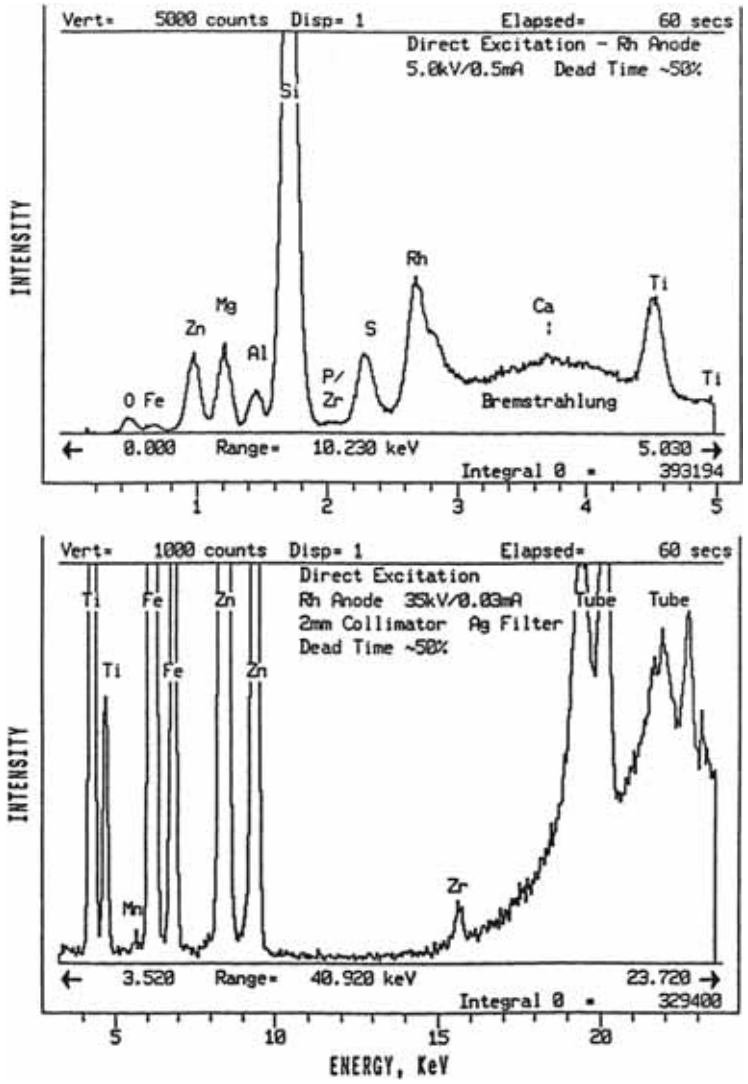

Fig. 11—X-ray fluorescence spectrum, recorded using an energy-dispersive spectrometer, of the paint used for Fig. 10.

provide much faster acquisition of spectra and are usually lower in cost. Scanning spectrometers are convenient for qualitative elemental analysis and are broadly versatile for quantitative analysis [35].

Generally, the large scanning spectrometers offer greater versatility, greater accuracy, greater precision, and lower limits of detection than do less expensive, smaller, dedicated bench-top and portable units. However, recent models of the smaller units have narrowed the performance gap.

DEDICATED (SPECIALIZED APPLICATION)

Dedicated X-ray fluorescence spectrometers, available at much lower cost than the scanning spectrometers, permit quantitative analysis of a single element or a few selected elements. Most of the dedicated units, and all the lowest priced units, use a radioactive isotope instead of an X-ray tube as the source of radiation to excite the specimen [36]. In single element analyzers, the isotope source, detector composition, and operating conditions are chosen to give best performance for analysis of a specific element of interest. Dedicated x-ray spectrometers are typically small bench top units with simple operating procedures. They are well-suited for routine analysis [35].

ON-LINE

Products and process materials may be analyzed on-line by specially adapted dedicated X-ray fluorescence units with remote analyzer heads [37]. The heads house the X-ray source and detector. Flow-through heads can be used for liquids. Fixed or moving heads can be used for moving sheet stock or other solid material. Bulk composition or the composition or thickness of a coating on a substrate can be determined by this method. The apparatus and methodology are custom-designed for each application.

XRFS analysis is well suited for on-line use in production facilities because of its nondestructive nature, high degree of automation and reliability, real-time output of analytical results, ease of interface with computerized data storage systems, and ease of integration with process control systems. On-line XRFS units can function directly in both quality monitoring and process control. These units can be rigged to give an immediate alarm if a process goes out of acceptable operating limits.

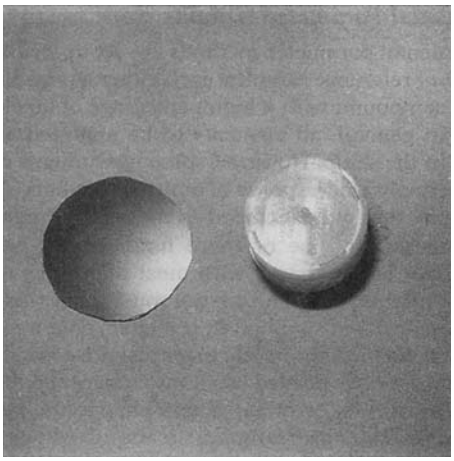

Fig. 12—Two examples of specimens: (left) a disk cut from a painted steel aluminum; (right) a plastic cup covered on the bottom with metal-free plastic film and on the top with a plastic cap. Suitable for liquids and powders.

PORTABLE

Portable X-ray fluorescence units with self-contained power supplies and either single or multiple element capability are available for uses that require mobility. Some of these devices are only a little larger than a cordless telephone handset. They are well suited for rapid analysis in off-line applications, in factory yards, and in field studies [38]. There is growing use of portable units for determining lead content in paint in situ in old residential buildings [39]. However, the operator is cautioned against using calibration curves established with one type of paint on one type of substrate for analysis of other formulations of paint or other substrates.

ELECTRON BEAM EXCITED X-RAY SPECTROSCOPY

Spectroscopic analysis can be performed with X-rays generated by bombardment of a specimen with an electron beam, as in a scanning electron microscope (SEM) or an electron microprobe (EMP) [32]. The spectrum may be produced by either energy-dispersive or wavelength-dispersive means. SEM units, commonly equipped with energy-dispersive X-ray capabilities, are extremely useful tools for the study of surfaces and small features, especially defects such as craters, voids, pinholes, mars, and stains. In addition to providing images, such instruments can perform qualitative and quantitative elemental analysis. EMP units, usually equipped with both energy-dispersive and wavelength-dispersive capabilities, are used when the emphasis is on quantitation rather than imaging. Both SEM and EMP permit elemental analysis as point analysis, line scan, area analysis, or mapping. Present technology permits analysis of all elements with atomic number 4 (beryllium) and higher.

Experimental Procedures

Specimens may be any solid or liquid that can be presented to the X-ray beam. The size of the specimen holder of the spectrometer is the principal practical limitation. Sample preparation methods have been discussed by Bertin and Leyden [32,40]. Fig. 12 shows two types of specimens.

Many of the recommendations given in Table 1 for XDR also can be used to prepare specimens for qualitative analysis by X-ray fluoresence spectroscopy. However, the analyst is cautioned that the X-rays used for X-ray fluorescence spectroscopy are commonly more penetrating than those used for diffraction analysis. Unless care is taken, the fluorescence spectrum may show elements in the backing material used to support the intended specimen material. The analyst must either use a specimen that is sufficiently thick to prevent X-ray fluorescence from the backing from reaching the detector or use a backing (such as a metal-free polymer) that is free of conflicting elements. It is common practice to place liquid or powder in a disposable plastic cup, the bottom of which is covered with a thin plastic film that transmits X-rays. (Liquids and powder are most conveniently analyzed in spectrometers that irradiate the specimen from below. For instruments of the opposite configuration, the specimen cup must be filled so that there is no bubble when the cup is inverted in the analysis chamber.) Paint chips may be placed directly in the specimen cup, and drawdowns of paint on metal-free plastic sheets such as Mylar may be cut to fit the specimen holder.

For quantitation, powders may be pressed into disks in a binding agent such as orthoboric acid, granular cellulose, or graphite or cast as pellets after dissolution in molten flux such as lithium tetraborate or lithium metaborate. Ashing or extraction with acid or organic solvent is sometimes useful to remove analytes from bulky matrices, thus lowering the limit of detection and perhaps increasing analytical accuracy. Dissolution with acid or other solvent may make the sample more amenable to quantitation methods described under "Quantitative Analysis." Detailed procedures for briquetting, fluxing, and ashing are available in the *Spex Handbook of Sample Preparation and Handling* [41]. Powders and liquids can be analyzed in disposable cups, as mentioned above. Disk-shaped specimens cut from solid samples may be handled in a similar manner. Bertin provides valuable information about specimen preparation [32].

Specimens are analyzed under vacuum whenever possible to minimize absorption of X-rays by the atmosphere in the analysis chamber. However, liquids and powders must be run under helium or air to prevent spatter. Portable analyzers and certain models of bench top units can operate without the specimen in vacuum or purge gas because of the short distance between the specimen and critical instrument parts.

Operating procedures differ widely with the make and model of X-ray spectrometer. Manufacturer instructions on safety and operation should be consulted.

Qualitative Analysis

Qualitative elemental analysis can be conveniently done using a scanning X-ray fluorescence unit. Elements in a specimen can be identified by the position of the peaks on the spectrum expressed as photon energy (kilovolts), 2θ angle, or wavelength. Peak identification tables can be found in manuals provided by manufacturers of the spectrometers or in treatises on X-ray spectrometry [32]. Modern X-ray spectrometers have computer programs that can indicate what elements are present in a specimen. For instruction in use of these programs, the analyst should refer to the instrument operation manual.

Fig. 10 shows part of an X-ray fluorescence survey spectrum (collected using a WLD instrument) of a drawdown of a tan paint, the same one used to produce the diffraction pattern in Fig. 7(*a*). Note the corroborative nature of element content indicated in Fig. 10 and the identity of

the pigments determined from the diffraction pattern in Fig. 7(*a*). For comparison, Fig. 11 is an X-ray fluorescence survey spectrum, recorded by an energy-dispersive instrument, of the same sample.

Quantitative Analysis

GENERAL PRINCIPLES

The principles of quantitative analysis by XRFS have been discussed in detail by many workers including Bertin [32,33]. The basic equations show that the intensity of the fluorescent X-rays is proportional to the amount of element that produced the X-rays, but is influenced by other factors such as the density and absorption coefficient of the specimen. Nevertheless, the linear proportionality between analyte concentration and fluorescence intensity shows that common analytical methods such as standard addition can be readily employed in X-ray spectrometry. Direct comparisons of concentration can also be made between samples that differ only in the amount of analyte of interest. Analyses by these simple methods can be done with small, low-cost, bench-top analyzers. Analysis of more than one element, especially in a matrix of variable composition, is best done with more sophisticated scanning spectrometers with suitable computers and software. Yet, some bench-top analyzers equipped with computers can determine the concentration of more than one element in matrices of variable composition. X-ray spectrometers must be programmed and calibrated by the analyst or the manufacturer for each analytical application before reliable quantitative analysis can be done. Recalibration must be done periodically.

DIRECT COMPARISON METHOD

Quantitation by direct comparison is done as follows. The analyst prepares or collects a set of three or more reference specimens that contain an element of interest at a range of known concentrations, but are otherwise essentially identical. Equal amounts of each specimen are placed in specimen cups or otherwise prepared for analysis. The analyst collects fluorescence intensity data for the element of interest from the set of samples and establishes a calibration plot of intensity versus concentration. Modern X-ray spectrometers with integrated computer capabilities can store the calibration plot for convenient use. When the spectrometer lacks computer capabilities, the analyst can construct the plot manually or use an external computer. Test samples of unknown composition are then run on the spectrometer under conditions identical with those used when the calibration samples were run. Intensity data from each test sample can be converted to concentration through use of either a manual or computer-stored calibration plot. To avoid extrapolation error because of unexpected plot curvature or other reasons, the range of concentration of the reference specimens should span the concentration of the specimens being analyzed. If the test specimen lies outside the range, then either the specimen should be diluted by a known amount to bring it "on scale" or the calibration plot should be extended with additional reference specimens. Operating instructions from the supplier of the spectrometer should be followed.

When applicable, direct comparison is usually the simplest, most convenient element quantitation method available. It can be done with even the simplest X-ray spectrometers. Most modern X-ray spectrometers can store several, perhaps many, calibration plots suitable for different applications.

Note the following three cautions. (1) If a test specimen differs in matrix composition or physical state from the reference specimens used to establish the calibration plot, then the analytical results may be incorrect. Error can be large if the matrices of the test sample and the reference samples differ widely in absorptivity of X-rays. Thus, in general, a calibration plot established with one type of sample should not be used to analyze other types of samples. (2) The calibration curve may show a significant amount of curvature if the analyte and the matrix differ widely in absorptivity (e.g., tin in resin) and a wide range of concentrations is spanned. If the intensity versus concentration plots shows curvature, then either a polynomial fit must be used or another method of analysis must be employed. (3) Calibration plots tend to lose accuracy with time and must be replaced or corrected following manufacturer instructions. As a consequence of aging, progressive changes in the output of the x-ray source and in the sensitivity of the detector contribute to calibration "drift."

STANDARD ADDITION METHOD

The method of standard addition can be used when no suitable reference samples are available to permit analysis by direct comparison. In this method, the analyst divides the test sample into at least three equal portions of known volume or weight. One of the divided specimens is retained for analysis with no further change. Each remaining specimen is "spiked" with the element of interest in a series of different known amounts. This method has convenient application only to liquids, and perhaps to powders, because of the need to mix uniformly the added component with the original material. The concentration of *added* analyte in each specimen is then calculated. The intensity of x-ray fluorescence of the analyte in each specimen is measured under identical conditions. The intensity of the analyte fluorescence signal is plotted as a function of added analyte concentration, as in Fig. 13. The data line of the graph is extrapolated to the point of interception (a negative number) on the concentration axis. The absolute value of the concentration intercept corresponds to the concentration of the original unspiked sample. Many modern X-ray spectrometers have computer programs that do the calculation.

EMPIRICAL METHODS

The empirical methods require the use of a set of reference samples that span the concentration range of all elements of interest. All modern high-priced and most mid-price X-ray spectrometers can perform analyses using one or more variations of this approach when equipped with suitable software. The analyst must follow the instructions from the instrument supplier. Empirical methods are well suited for routine multielement analysis of large numbers of samples of the same type. A different program, with its own set of reference samples, must be established for each class of samples and choice of elements. High accuracy and precision are achievable when the reference samples properly represent the test samples.

FUNDAMENTAL PARAMETER METHODS

Fundamental parameter methods are set up by the analyst with a set of reference samples, each either a pure element

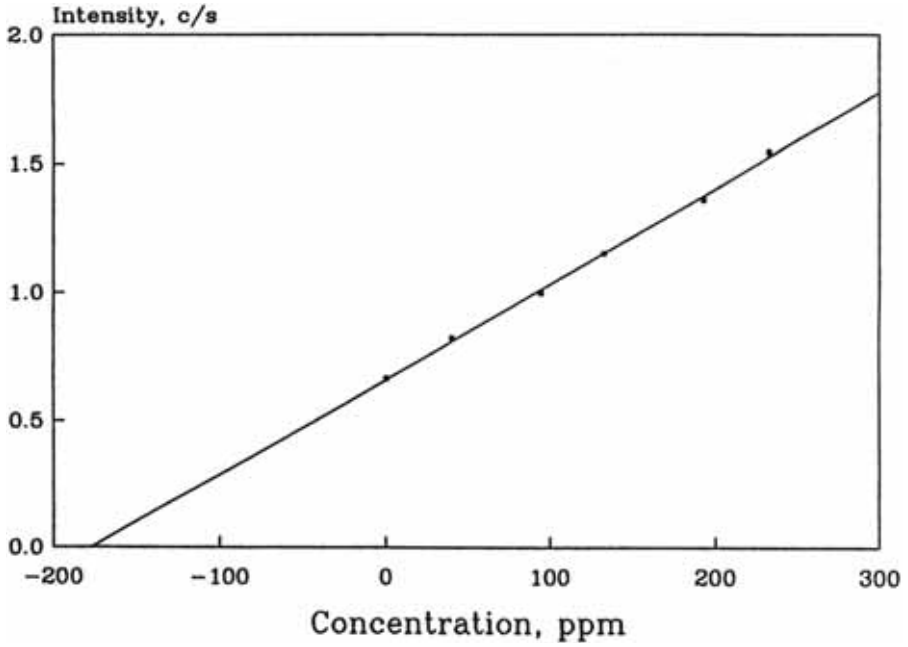

Fig. 13—A plot of the intensity of the sulfur, K_α, peak as a function of the concentration of sulfate in the analysis of an aqueous solution by a standard addition method.

or a simple compound with a high percentage of an element of interest. In general, all elements to be analyzed should be included in the setup. However, some instruments can interpolate the analytical response of omitted elements from similar elements that were included in the setup. Programs that permit analysis by one or more fundamental parameters methods can be purchased with all high-price and some mid-price instruments. The analyst must follow instructions from the instrument supplier. In principle, once a program is established, no further reference samples are needed. In practice, recalibration is needed when instrument repair, maintenance adjustments, or other factors change the instrument response. No standard samples, in the usual sense of the word, are needed for calibration. Fundamental parameters programs can be used to perform multielement quantitative or semiquantitative analysis of test samples of widely varied composition and unfamiliar nature. If an analyst must perform a quick semiquantitative analysis of an unfamiliar sample, then the fundamental parameter program is the method of choice. Accuracy varies with the task and the sophistication of the instrumentation and software.

COMPARISON TO OTHER TECHNIQUES

In quantitative analysis of liquid samples, XRFS, compared to atomic absorption or plasma emission spectrometry, offers the advantage of being able to handle samples with (1) higher concentrations of analyte without use of large dilution factors and attendant inaccuracy, (2) matrices that are ill-suited for aspiration into nebulizers, and (3) elements that are not easily detected by flame or plasma photometric techniques.

Applications of X-Ray Fluorescence Spectroscopy

ANALYSIS OF ELEMENTS IN SOLUTION

Fig. 13 shows a plot of data used in the quantitation of sulfur in an acidic aqueous solution by a standard addition method. The sample resulted from flushing a steel panel retrieved from outdoor exposure with citric acid and then concentrating the solution by evaporation. This example illustrates a general-purpose method. ASTM Standard Test Method for Sulfur in Petroleum Products by Wavelength Dispersive X-ray Fluorescence Spectrometry (D2622) could be adapted for analysis of sulfur in other organic liquids or solutions [42]. ASTM Standard Test Method for Determination of Elemental Content in Polyolefins by Wavelength Dispersive X-Ray Fluorescence Spectrometry (D6247) is applicable to a variety of elements and could be adapted for use with other types of organic samples [43].

SURFACE ANALYSIS

Foreign substances may sometimes be detected on surfaces by X-ray fluorescence spectroscopy, eliminating the need to resort to X-ray photoelectron spectroscopy and other "surface analysis" techniques. To be detectable, the contaminant must contain an element that is not present in significant amounts in the surface itself. Fig. 14 shows a silicon peak in the high-resolution X-ray fluorescence scan of the surface of a piece of aluminum extrusion from which poorly adhering paint was peeled. Comparison of Figs. 14(*a*) and 14(*b*), respectively, prove that washing the peeled surface with hexane significantly reduced the amount of silicon present. The elevated silicon signal on a substrate to which paint adhered poorly and the ready removal of the silicon material by hexane suggested the presence of silicone oil. This suspicion was confirmed using analysis by micro-infrared spectroscopy of residue left by evaporation of the hexane washings.

METAL PRETREATMENT

XRFS provides a quick and convenient way to determine the amount of pretreatment on metal surfaces. Once reference samples have been used to establish a calibration plot

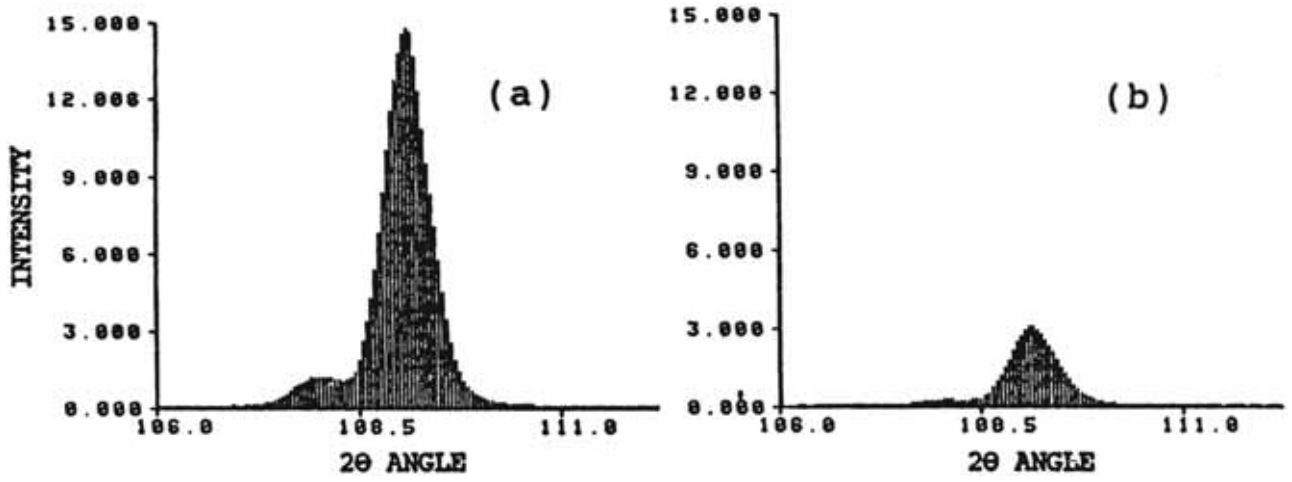

Fig. 14—The K_α peak of silicon on extruded aluminum from which poorly adhering paint has been peeled: (a) peeled only; (b) peeled and washed with hexane.

that relates fluorescence intensity, expressed in convenient units such as counts per unit time, to coating weight, which was determined by an independent method, the instrument can be used to determine pretreatment weight on test samples. Fig. 15 shows a calibration plot for the weight of chromium conversion coating on aluminum sheet [44]. Even low cost bench-top or portable units can give quick direct readout of pretreatment weight using internally stored calibration plots. ASTM Standard Practice for Determination of Chromium Treatment Weight on Metal Substrates by X-Ray Fluorescence (D5723) details the procedure for chromium-containing pretreatment [45]. With suitable instrumentation, the method can be adapted for phosphorus of phosphate or for other types of thin surface coatings.

DETECTION OF BULK CONTAMINANT

The low limit of detection of X-ray fluorescence spectroscopy makes it well suited for the detection of trace impurities, some of which may not be detectable by any other means. There is the tacit requirement that the contaminant contain an element that is not a normal component of the sample. Although small amounts of impurity may have no perceptible impact on the performance of a material, knowledge of the presence and amount of an impurity may be crucial in determining the cause of substandard performance. Table 3 summarizes data collected by XRFS in the investigation of a case in which silicone contamination was suspected as the cause of cratering exhibited by certain batches of waterborne paint. Quantitation was by a standard addition method. Although XRFS cannot distinguish between different silicon-bearing species, the higher level of silicon in batches of resin used in the crater-prone paint supports the suspicion that silicone caused the cratering. The data also suggest that a threshold concentration between 7 and 13 parts per million silicone in the resin, based on the silicon signal, is needed to produce cratering in the paint produced from it.

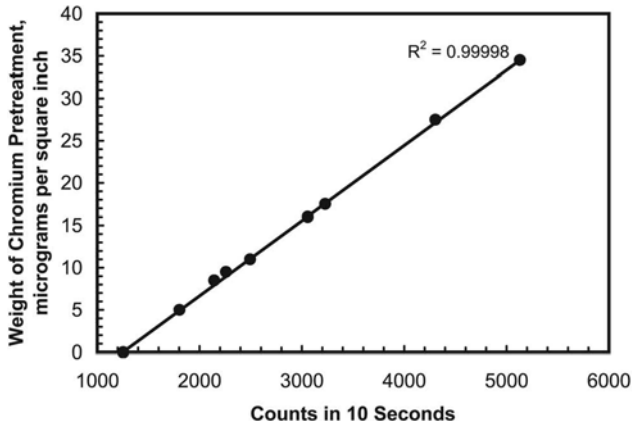

Fig. 15—Plot of weight of chromate conversion coating on aluminum sheet as a function of fluorescent signal intensity. Each point is an average of three 10-s measurements.

QUALITY CONTROL

Dedicated X-ray fluorescence units that can determine the concentration of a single element have great utility in production plants for monitoring the composition of raw materials, intermediates, and products. Fig. 16 shows a calibration "curve" that was established to permit monitoring the percent cobalt in a cobalt drier solution used in the manufacturer of paint [46]. Similar results have been demonstrated for calcium, zinc, and zirconium driers [47]. Driers are metallic salts of carboxylic acids used to catalyze the curing of paint films.

TABLE 3—Concentration of silicone, determined by XRFS, in batches of resin used in batches of paint of known extent of cratering

Extent of Cratering	Concentration of Silicone, ppm
None	3
None	4
None	7
Bad	13
Bad	13
Worst	40

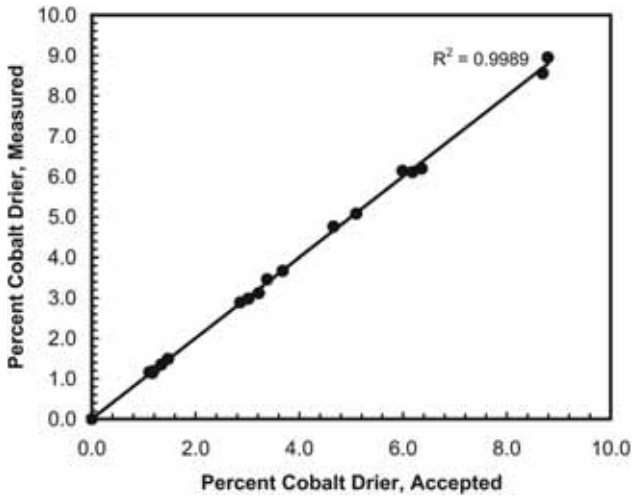

Fig. 16—Plot of the amount of cobalt in a drier solution as measured by a benchtop XRFS unit versus the accepted amount.

Dedicated x-ray analyzers have also been used to monitor the amount of rutile in batches of paint in production plants [48]. Caution: A different calibration plot must be established for each paint formulation to be monitored, unless the compositions of the dried paints films are essentially identical in all respects other than rutile content.

Guidance on the use of X-ray analyzers to determine the coating thickness is given in ASTM Standard Test Methods A754/A754M, Coating Weight (Mass) of Metallic Coatings on Steel by X-Ray Fluorescence [49], and B568, Measurement of Coating Thickness by X-Ray Spectrometry [50].

ANALYSIS IN THE FIELD

Concern over the potential adverse health effects of lead in paint in residential buildings has prompted an interest in convenient, nondestructive methods of testing for lead. Fully portable X-ray analyzers that can detect lead in paint on walls and other surfaces are commercially available. The analyzers can detect lead-containing paint beneath layers of lead-free paint, and some can provide direct readout of the amount of lead per unit area of paint surface [51]. The accuracy and precision are not well documented. The Department of Housing and Urban Development established a limit of 1.0 mg of lead per cm^2 of painted surface, a level detectable by portable analyzers [52]. Caution: In accordance with the constraints of all X-ray fluorescence spectrometers, matrix differences between test samples being analyzed and reference samples used to establish instrument calibration curves may compromise the accuracy of the apparent lead concentrations reported by portable units.

Other uses of portable analyzers include determination of the weight of pretreatment on metal, the thickness of paint, and the concentration of key elements in samples at environmental cleanup sites.

SUMMARY

XRD and XRFS, used alone or in combination, can provide valuable information about coatings, coating ingredients, impurities, and substrates. Sample preparation effort is minimal for both techniques. XRD offers easy qualitative and quantitative analysis of crystalline materials in general and pigments in particular. XRFS is widely useful for qualitative analysis and, when suitable standards are used, for quantitative analysis. Attractive features of XRFS for quantitative analysis include its suitability for all elements except a few with lowest atomic number, applicability over a broad concentration range, tolerance of chemically reactive specimens, and applicability to samples of diverse physical states. Both XRD and x-ray spectrometry are suitable for applications including basic research, product and process development, quality control, and practical problem solving. The area of greatest potential growth is the use of dedicated x-ray fluorescence spectrometers in production plants for quality control, particularly for on-line monitoring.

Part 16: Specifications

77

Paint and Coating Specifications and Standards

Joseph V. Koleske[1]

INTRODUCTION

COATING AND PAINT SPECIFICATIONS ARE A COM-monality established between a customer and a supplier. They define what a customer can expect from a supplier and what the supplier is required to do to meet the customer's expectations. Often such agreements are between organizations that purchase the products in large volume for construction and maintenance projects, for resale to distributors, or to end-use consumers. Details of how to carry out the testing required to meet such specifications is left to the devices or procedures (often termed standards or test methods) of a third, uninterested party such as ASTM International or similar groups that are listed elsewhere in this chapter. Purchasing organizations may be federal, state, and local governmental agencies and departments, large industries as for example the automotive, petroleum, and pipe industries, public utilities, railroads, retail companies such as Sears and Wal-Mart, universities and other educational institutions, as well as others. However, in certain instances, the standards used to meet the specifications can carry down to the final consumer as sometimes evidenced on certain products, for example the listing of volatile organic compounds on a can of paint.

Simplistically, a specification is a precise, though detailed, statement of requirements that must be satisfied by a material, product, system, or service that indicates the procedures—standards or test methods—to be followed when determining whether each of the requirements is satisfied [1]. Paints and coatings used in industrial new construction may be specified in construction documents, while such materials used in maintenance finishes or sold through retail outlets may be described in the particular specifications of the purchasing organization. Engineering departments often specify finishes applied by large manufacturing industries, as, for example, the automotive industry, the appliance industry, and the packaging industry. Those who develop the specifications for large quantities of original equipment, maintenance or other finishes, such as public utilities, transportation organizations, and government agencies, purchase on a specification basis and most often by competitive bidding.

Coating specifications set by, for example, the United States Navy and other government agencies will sometimes specify that a coating or paint be manufactured according to a specific formula or recipe that passes the requirements stated in particular, delineated test methods (www.nstcenter.com). If one goes to the "Technical Resources" tab at this site and clicks on "Standards and Specs," items that are used to specify many products can be found.

Federal Test Method Standard 141D, "Paint, Varnish, Lacquer, and Related Materials: Methods of Inspection, Sampling and Testing" is a document[2] that describes a number of coating test methods used by various Federal agencies in their specifications for a number of products. The test methods include coating material characterization tests, volume solids, nonvolatile content, density/weight per gallon, drying time, spectroscopic analyses, chemical resistance, corrosion resistance, as well as other coating performance characteristics such as adhesion, abrasion resistance, accelerated weathering, hardness, impact resistance, and the like.

An example of a detailed specification used by the United States Navy that specifies a paint formula is MIL-DTL-15090D, November 6, 1996, *Enamel, Equipment, Light Gray* (*Navy Formula 111*). To illustrate the complexity of the requirements, within this specification, two particular Federal and two particular Department of Defense specifications as well as two Federal Standards are included along with two Environmental Protection Agency documents and a reference to the Federal Register. The requirements do not stop with these inclusions. Also included in the specification are 28 ASTM standard test methods and standard practices and one Steel Structures Painting Council specification. The actual formula for this paint specifies 16 specific ingredients by weight and weight percentage and a variety of quantitative requirements for the liquid paint and the final paint film. Military specifications such as this one may be altered and may be superseded, as was the case with the above-cited MIL-DTL, which superseded MIL-E-15090C, March 30, 1982. Those interested in supplying or bidding on contracts for the various products should maintain an awareness of such changes.

[1]*1513 Brentwood Rd, Charleston, WV 25314-2307*

[2]Federal specifications and standards discussed in this chapter refer to documents of the United States of America government and are available through the U. S. General Services Administration, Federal Supply Service, FSS Product Acquisition Center, Supply Standards Division, Arlington, VA 22202. Downloadable versions of the documents are available on the Internet. When international or specific country documents are discussed, they will be noted by country designation (see Table 1 for some examples).

Copyright © 2012 by ASTM International

The United States General Services Administration has a "Numeric List of Federal Standards" available on the Internet (www.fss.gsa.gov/pub/fedspecs/). This site has both numeric and alphabetical listings of Federal Standards, Federal Qualified Products, and other publications. Also included are ways to download the publications, costs, addresses, and other useful information.

SPECIFICATION CONSIDERATIONS

The Construction Specifications Institute (CSI) [2] indicates that the following items should be considered in a project construction specification: scope, related sections, referenced documents, definitions, performance requirements or properties, submittals, quality assurance, delivery-storage-handling project considerations, and sequence scheduling. Submittals also cover paint and coating product data as well as color samples.

Material specifications in the ASTM format [3] usually include terminology, ordering information, chemical composition, physical and mechanical properties, performance requirements, sampling, physical and analytical test methods, inspection, packaging and marking, and, if needed, quality assurance.

Donlin [4] has an excellent description of the complex military standards system. His study summarizes information from government manuals, standards, specifications as well as other documents. It represents an effective way to become familiar with the government's documentation system that was in place when the study was developed and make its complexity easier to understand. It is pointed out that the federal documents were developed with government funds, and, if unclassified, are readily available for public use. The article also contains listing of many "milspecs" as they are often termed.

Some paint and coating specifications (for example, those for military use) require prequalification of the products described. Such a requirement exists when the time to conduct tests will exceed 30 days, when quality conformance inspection would require special equipment not commonly available, or when the specification deals with life survival or emergency life-saving equipment. The specifications for such products include the requirements for qualification, the qualification tests, and the name of the activity responsible for qualification. Products that are so qualified are listed on Qualified Products Lists.

SOURCES OF SPECIFICATIONS AND STANDARDS

International Sources

International specifications and standards for paints and coatings are of interest in these days of international or global commerce. For example, Canadian standard 1-GP-71, *Methods of Testing Paints and Pigments,* is available from the Canadian General Standards Board (CGSB). This particular standard contains about 80 methods of analysis in the category termed "Paints and Related Products." In Germany, the German Institute of Standardization (DIN) develops standards. The International Organization for Standardization[3] (ISO) is a nongovernmental network of the national standards institutes of 146 countries who contribute to the development, manufacturing, and supply of products and services in an efficient, clean, safe manner. ISO standards may be obtained from the American National Standards Institute (ANSI). Table 1 is a listing of the address and other pertinent information about these organizations and about several other organizations that deal in specifications and standards.

The Asian Forum for the Standardization of Information Technology (AFSIT) is an organization that has 16 Asian country members. It deals in the promotion of the active information exchange of technology and its standardization. It can be accessed on the Internet at www.cicc.or.jp/ where one can find routes to the standards department of their member countries, such as India, Republic of Korea, Sri Lanka, Vietnam, and several others.

In the summer of 2004, ASTM International (www.astm.org) announced that they had signed a Memorandum of Understanding (MOU) with the national standards body of China, the Standardization Administration of the People's Republic of China (SAC). This is expected to accelerate development of product and testing standards in China, encourage greater access to ASTM standards in China, and give a greater voice to Chinese experts in the content of ASTM standards. This interaction furthers a history of ASTM involvement with Asian standards organizations such as the Chinese National Institute of Standardization (CNIS) and the Shanghai Institute of Standardization (SIS). A similar MOU was completed in June 2001 between ASTM Committee D01 on Paints and Related Coatings, Materials, and Applications and ISO TC 35 on Paints and Varnishes [5]. The purpose was to reduce the duplication of standards activities.

Automobile manufacturers have developed their own standards, which may incorporate many standards and methods of organizations such as ASTM International. Such private industry standards can and often do differ from one manufacturer to another and are known by their own in-house designations. Usually these standards are available to the public or to vendors so they can develop products that meet the requirements of the industry. Other, usually large scale, manufacturers also have their own standards.

Although the list given in Table 1 is not complete, it should provide guidance to interested parties. Wide varieties of standards can be obtained (purchased) from SAI Global (www.sai-global.com), Beuth Verlag (www.beuth.de), British Standards (www.StandardsUK.com), and many others at international and national sites.

Non-Government Sources

TECHNICAL SOCIETIES

Committee D-1 on Paint and Related Coatings, Materials, and Application of ASTM (See Table 1) has developed an extensive number, more than 670 standards, test methods, practices, and procedures that are concerned with paints and coatings. These standards are published as Vols. 6.01 to 6.04 of the *Annual Book of ASTM Standards.* They are also available as separate standards. Standards that relate to the ASTM test methods, procedures, and guides related to the radiation curing of coatings have been published and are

[3]ISO is a nongovernmental organization. This is a network of the national standards of 157 countries with one member per country. The organization is coordinated by a Central Secretariat in Geneva, Switzerland, and it acts as a bridging network that can obtain consensus on solutions that meet both the requirements of business and needs of society.

available in soft-cover book or CD-ROM format [6]. Other ASTM committees have developed a myriad of tests, some of which are related to or have an impact on the paint and coatings industry and are available in other volumes of the *Annual Book of ASTM Standards*. Many specifications and standards of other national and international organizations list ASTM documents as the necessary requirement for approval.

The American Architectural Manufacturers Association (AAMA) publishes standards for architectural products including organic coatings for aluminum. The American Association of State Highway and Transportation Officials (AASHTO) has developed standards that deal with highway-marking materials, highway materials of construction, bridge construction and maintenance, and other related products. The Maple Furniture Manufacturers Association (MFMA) publishes specifications and standards for wood flooring and a list of conforming floor-finish products.

The National Association of Corrosion Engineers (NACE) has developed standards that deal with corrosion testing, selection of corrosion-resistant materials, and the use of coatings to reduce corrosion. Their documents include standards for surface preparation, corrosion control, coating materials, and selection, application, and testing of coatings and paints. They also develop standards in cooperation with the Steel Structures Painting Council (SSPC). This latter group deals in the same type tests as NACE and includes quality control and contractor qualification standards and specifications.

The Construction Specifications Institute (CSI) has developed several "SpecGuides" that are used as part of construction documentation that deals with the preparation of technical specials for paints, coatings, and application [2]. The National Institute of Building Sciences (NIBS) has developed a powerful electronic database termed the *Construction Criteria Base* that includes the complete construction guide specification of most federal government departments and agencies as well as those of many nongovernment organizations. Model building codes are also accessible in this database, which is available in CD-ROM format from NIBS (Table 1). This consolidated system includes full copies of supporting documentation and the software needed to develop contract specifications for projects including:

Applicable codes and regulations.

Construction guide specifications of major military departments and civil agencies.

Design and estimating guidance documents.

Materials, testing, and processing documents.

Product data, available in full-color graphics.

Built-in software for search and processing functions. Military and federal specifications and standards, commercial item descriptions, and referenced nongovernment specifications and standards are accessible in the *Construction Criteria Base*.

AUTOMOTIVE INDUSTRY

The automotive specifications and testing area is complex, and numerous standards have been either adopted from standards developed by private, technical, or governmental organizations or developed within their own companies. Snowwhite [7] has given an overview of the performance requirements for automotive coatings and presents a general specification for interior and exterior automotive coatings in North America. The general requirements include physical properties, general film and coatings properties, durability, and chemical resistance and these are specified by 60 tests or test methods to meet these requirements. The listing is of documents by ASTM International, Society of Automotive Engineers, Chrysler, Ford, and General Motors.

TESTING LABORATORIES

Although it is left to individuals to decide on which laboratory to use and what standards to measure them by, one method is to determine if a given laboratory has a quality assurance program and the management to meet international standards is to ascertain their accreditation. There are two accrediting agencies for testing laboratories, and these are:

- NVLAP, National Voluntary Laboratory Accreditation Program, that is carried out under the auspices of the United States Department of Commerce
- A2LA, American Association of Laboratory Accreditation

It is beyond the scope of this chapter to describe the many testing laboratories that exist nationally and internationally. Readers can find many such organizations by sourcing the Internet or the open literature.

Part 17: New Coating Technology

78

Radiation Curing of Coatings

Joseph V. Koleske[1]

INTRODUCTION

RADIATION CHEMISTRY AND ITS RELATIONSHIP TO the coating and paint technology industry involves the application of a low viscosity mixture principally comprised of reactive monomers and oligomers but containing, as well, conventional coating additives such as fillers, colorants in the form of dyes or pigments, surfactants, and so on to a substrate and exposing them to a radiation source—particularly ultraviolet (UV) or electron beam (EB) radiation—for very short periods of time. When required, as in UV radiation curing, a small amount of photoinitiator is included in the formulation. When exposed to the radiation source, the mixture of materials is almost instantaneously converted into an effectively cross-linked, high quality coating or other product [1].

Radiation technology, as applied to coatings, had its infancy in the late 1960s and early 1970s when governmental regulation began requiring that solvent emissions from paint and coatings be decreased and regulated. At that time, most coatings were formulated with high molecular weight polymers and large amounts (often 80 % or more) of inexpensive solvents and cosolvents that for the most part were emitted to the atmosphere. Regulation increasingly forced companies to decrease these emitted solvents, and it was in this environment that new technologies such as high solids, powder, and radiation-cured coatings were born. Changes were slow to come into being in the stodgy (at that time) paint and coatings business, but today each of these methods of formulation and curing has become an important part of the coating and paint business.

RADTECH International[2] is an association for ultraviolet and electron beam technology as related to radiation-cured products for the adhesive, coating, ink, paint, and related industries. This group publishes a report (RadTech Report) five times a year, conducts UV/EB technology expositions and conferences and publishes the conference proceedings, has various publication and information available, and maintains a link between the various facets of the UV/EB industry (see www.radtech.org).

CURING EQUIPMENT

Electron Beam Systems

An electron beam is a stream of electrons that is emitted from an electron beam gun and in which the electrons are moving at essentially the same speed and in the same direction. Almost all substances absorb electrons, which are small atomic sized, high energy, negatively charged particles. Such radiation is known as ionizing radiation. The electrons are capable of penetrating into and through a substrate and/or a coating to reach, for example, an adhesive, a pigmented paint, or other opaque liquid and thus effect polymerization and cure of the appropriate chemical formulation [2,3].

Basically, the sequence of events in the cure process is as follows. While the stream of electrons is passing through the material to be cured, individual electrons are able to collide with an electron that is in a molecule of the uncured compounds. This collision can result in removal of an electron from the molecule and thereby generate a free radical. Such free radicals are able to react with ethylenic unsaturation in the formulation, as is found in acrylates, and initiate the sequence of polymerization, propagation, and termination with the result a cured, cross-linked material. A photoinitiator, which is required in ultraviolet radiation polymerization systems, is not required to initiate polymerization when electron beam technology is used.

In a general sense, there are two types of electron beam processors used in curing systems [4]. The swept or scanned beam type processors involve generation of a relatively narrow beam of electrons that are accelerated in a vacuum that is maintained in the high voltage section of the device. The beam of electrons is then moved, swept or scanned, across a metal foil window by means of an electric or magnetic field. From the window, the beam is sent to the process area where it contacts the reactive, liquid coating and polymerization is induced. The curtain or filament beam processors are single or multiple linear filament emitters with the filament(s) located parallel to the direction of "to-be cured" product movement. A broadband or curtain of electrons is sent to the process area where polymerization is initiated and polymerization, as well as termination, takes place. Since oxygen can inhibit polymerization of free radical systems, it is important to inert the process area with a compound such as nitrogen to obtain good surface and through cure [5].

Ultraviolet Radiation Systems

One of the distinctions between electron beam curing and ultraviolet radiation curing is the requirement for a photoinitiator to be used in the later curing method. Photoinitiators are compounds that are stable until exposed to ultraviolet radiation of one or more wavelengths. When

Benzil dimethyl ketal	White solid	220, 254–335

exposed the compounds absorb the radiation and degrade to form a species that is capable of initiating polymerization—usually free radicals or cations, the type depending on the nature of the system employed. Recently, Lapin [6] developed a comparison of UV and EB for printing and packaging applications and described in detail the fundamental differences in the two technologies.

If coatings are to be cured on flat stock, the curing equipment is relatively simple in nature. An ultraviolet radiation source and a means of cooling the lamp or lamps that serve as the source. The system is comprised of a power supply, radiation source, reflectors, and a conveyor [7]. The power supply is the control device within the system and either stepped or variable ballast systems are used for energy and intensity comparisons [8]. If three-dimensional objects are to be coated, special configurations of the radiation source and reflectors and/or a means of rotating the object when in contact with the radiation are used [9].

There are two general types of ultraviolet radiation sources [10], namely mercury vapor lamps and xenon lamps. Mercury and mercury-doped vapor lamps are widely used because when mercury is vaporized and ionized, it is one of the richest sources of ultraviolet radiation. Doping the mercury alters the transmission spectrum produced by the lamp or bulb, and it is used to efficiently interact with particular photoinitiators. Compounds such as the halides of antimony, cobalt, iron, silver, and others are used alone or in combination as the materials for doping mercury. The lamps are sealed, transparent quartz bulbs that are of three general types—low pressure, medium pressure, and high pressure. Medium pressure electrode and electrodeless lamps are the most widely used industrial ultraviolet radiation sources in the paint and coating industry.

The reflectors [11] have a variety of geometries such as elliptical, diverging, converging, parabolic, and others. The reflectors may be interfocused wherein the radiation is spread over a relatively large area or they may be focused wherein the radiation is concentrated into areas of high intensity. The large area systems are often used when three-dimensional objects are cured.

CHEMISTRY

Photoinitiators

Compounds that absorb ultraviolet radiation and are raised to an excited level from which they photolyze or degrade directly or indirectly into free radicals or cations are termed photoinitiators. The free radicals or cations become the polymerization initiating species and cause very rapid polymerization of photocurable formulations based on a variety of chemistries such as acrylates and methacrylates, polyenes/thiols, and styrene/unsaturated polyesters, all of which are cured by a free radical mechanism and cycloaliphatic epoxide/polyol and vinyl ether systems which are cured by a cationic mechanism. Vinyl ethers can be polymerized with either free radicals or cations and thus are ingredients that can be used in combination-cure systems.

TABLE 2—Examples of hydrogen abstraction type photoinitiators

Compound	Appearance	Absorption, (nm)
Benzophenone	White solid	250–350
Isopropylthioxanthone	Pale cream solid	~320–340
2-Chlorothioxanthone	Pale yellow solid	360
4-Methylbenzophenone	White solid	—
Thioxanthone	Solid	—

Free Radical Photoinitiators

The two main types of photoinitiators that form a species capable of initiating polymerization of ethylenically unsaturated compounds are the homolytic fragmentation process type (Norrish Type I) and the hydrogen abstraction process type (Norrish Type II). The homolytic fragmentation or α-cleavage compounds directly form free radicals capable of initiating polymerization [12]. The absorbed radiation causes bond breakage to take place between a carbon atom and an adjacent carbonyl group and a free radical is formed. Hydrogen abstraction type compounds function through a bimolecular reaction process [13]. They are activated with radiation and form free radicals by electron extraction or hydrogen abstraction from a second compound that is termed a synergist. After this process, the second compound becomes the actual initiating species. Examples of the homolytic fragmentation type compounds are given in Table 1 and of the hydrogen abstraction type are given in Table 2.

Synergists are compounds that have a carbon atom with at least one hydrogen atom in the alpha position to a nitrogen atom. For example, dimethylethanolamine has an alpha carbon atom in the methylene group next to the nitrogen group. Triethylamine has three alpha carbon atoms located on the three methylene groups next to the nitrogen group. Synergists are usually tertiary amines, but ureas and amides have been used as well as particular alcohols and

TABLE 3—Some common low molecular weight synergists

Specific Compounds
2-Ethylhexyl-p-dimethylaminobenzoate
Dimethylethanolamine
N,N-Dimethyl-p-toluidine
Triethanolamine
Triethylamine

ethers. As mentioned earlier, after the bimolecular reaction, the synergist becomes the initiating species. Examples of synergists are given in Table 3.

Oxygen Inhibition

Radiation excited or activated molecules are quenched and markedly decreased in activity or made inactive by oxygen which, of course, is present in all air environments [14]. Such quenching results in inhibition of polymerization in formulations that involve fragmentation-type photoinitiators. Free radicals will react with propagating molecules and termination with accompanying low molecular weight and poor properties result. Oxygen inhibition can be circumvented by curing in an inert atmosphere, addition of oxygen scavengers or waxes, use of shielding films, dye sensitizers, surface active initiators, or high photoinitiator concentrations, and increasing ultraviolet radiation intensity [1].

Cationic Photoinitiators

Cationic photoinitiators are onium compounds that are excited by ultraviolet radiation and then photolyze to form Lewis or Bronsted acids that will rapidly polymerize cycloaliphatic epoxides. In the photolysis process of these compounds, free radicals are also formed and therefore, both epoxides and ethylenically unsaturated compounds can be polymerized in a dual-cure process. Watt [15] has published a detailed study of the cationic curing of epoxides, particularly cycloaliphatic epoxides, over the period of 1965 to 1981.

Diazonium Salts—Lewis Acids

Although presently cationic photoinitiators are used to generate Bronsted or protonic acids from sulfonium or iodonium salts, cationic curing of coatings began with the use of diazonium-type photoinitiators that generated Lewis acids. A variety of anions were used including PF_6^-, $SbCl_6^-$, SbF_6^-, BF_4^-, and AsF_6^- [16]. In a general sense, when radiated with ultraviolet radiation sensitive compounds such as aryl hexafluorodiazonium phosphorous, will photolyze and form gaseous nitrogen, an aryl fluoride, and phosphorous pentafluoride. The latter compound is a Lewis acid and it will initiate the polymerization of epoxides, particularly cycloaliphatic epoxides, into a highly crosslinked network.

Diazonium salt-based radiation cure was developed by American Can Corporation and was known as "Americure." At the time, the early 1970s, this technology was considered a major breakthrough in high solids coatings development. However, the technology had two major deficiencies that inhibited large-scale commercial development. As noted above, during photolysis nitrogen gas was generated. If the coating films formed were greater than about 5 to 10 μm in thickness, nitrogen bubbles were trapped in the "instantaneously" cured film and they were readily visible to the naked eye. The second deficiency involved an instability of the diazonium salts in formulated systems that comprised cycloaliphatic epoxides, other epoxides, and optional additives such as polyols, surfactants, etc. These two factors were serious deterrents to commercial development, and when this was coupled with the onium salt introductions the demise of Americure was assured.

Iodonium and Sulfonium Salts—Bronsted Acids

Compounds that contain an element with an unshared pair of electrons, such as sulfur and phosphorous, can form onium salts. For example, a sulfide, R_2S, can react with an alkyl halide, CH_3I, to form a sulfonium salt, $R_2CH_3S^+I^-$. The commercial onium salts are known as aryl sulfonium and aryl iodonium salts and have the counter ion MF_6^-, where M is antimony or phosphorous [17,18]. Usually, the sulfonium salts were known as triarylsulfonium salts which was a misnomer, since these compounds are complex mixtures of sulfonium salts with the prominent species and have the following generalized structures:

$$Ar - S - (Ar_3)S^+(MF_6)^- \text{ and } (MF_6)^-S^+(Ar_3) - S - (Ar_3)S^+(MF_6)^-$$

The iodonium salts are diaryl compounds with the same counterions and the generalized structure of $I^+(Ar_2)^-$ and $I^+(MF_6)^-$. When these compounds are radiated with ultraviolet radiation, they photolyze and form Bronsted or protonic acids, $(PF_6)^-$ or $(SbF_6)^-$. The protonic acids cause rapid polymerization of cycloaliphatic epoxides alone or in combination with hydroxyl bearing compounds such as polyols, glycols, and alcohols. Although both protonic acids cause very rapid polymerizations, the antimony compound causes the most rapid polymerization and iodonium salts are more rapid in their cure ability than sulfonium salts.

The onium salt photoinitiators are available in the United States, Europe, and Asia under a variety of trade names from both manufacturers and distributors. Various physical and chemical characteristics, as well as ultraviolet radiation absorption maxima for these compounds and other cationic photoinitiators, has been published by Gaube [19]. While free radical systems can be inhibited by atmospheric oxygen, the cationic systems are not inhibited in this manner and thus do not require an inert atmosphere to cure well.

Acrylates—Monomers and Oligomers

Although other free radical-based formulations involved with ethylenically unsaturated molecules can be used for radiation curing of coatings, this brief chapter will be concerned with radiation curing of molecules such as acrylates and methacrylates—preferably acrylates. Other chemistries that are in use or that have been used in free radical initiated systems [1] include unsaturated polyester/styrene systems [20,21], polyenes/thiol systems [22–24], and vinyl ethers [25].

Acrylates are ethylenically unsaturated compounds of the general form

$$CH_2 = C(R)COOR'$$

where R is hydrogen for an acrylate and methyl for a methacrylate and R′ can be any one of a number of groups such as linear and branched alkyl, 2-phenoxyethyl, isonorbornyl, hydroxyalkyl acrylate, and many more. The term acrylate is often taken to mean both acrylates and methacrylates, but since acrylates cure more rapidly than methacrylates, in radiation cure it should be stated as one or the other. There are many types of acrylates and related compounds than can be used in radiation-cure formulations and these include:

- Monofunctional acrylates as described above.
- Difunctional and higher functionality acrylates.

- Oligomeric acrylates of varying molecular weights and viscosities.
- Reactive diluents such as N-vinyl-2-pyrrolidone and vinyl ethers.

Each type has a particular function [1] in the formulation. Monofunctional acrylates are used to decrease viscosity; di- and higher functionality acrylates are used to provide crosslinking and to give rapid molecular weight build; oligomeric acrylates provide flexibility and toughness to the final cured films; and the reactive diluents provide a way of decreasing viscosity with reactive compounds that co-cure into the final product.

Difunctional acrylates include products such as 1,4-butanediol diacrylate, diethyleneglycol diacrylate, neopentyl glycol diacrylate, tripropylene glycol diacrylate, and many others. Higher functionality acrylates include compounds such as ethoxylated trimethylolpropane triacrylate, pentaerythritol triacrylate, trimethylolpropane triacrylate, pentaerythritol tetraacrylate, and so on.

Oligomeric acrylates are of two types, epoxy acrylates or urethane acrylates. These compounds are of quite high molecular weight and viscosity and for this reason are often modified with low molecular weight mono or difunctional acrylates to reduce viscosity and thus improved handling characteristics during formulation and application to a substrate. Urethane acrylates are of two basic types that depend on whether an aliphatic or an aromatic isocyanate is used in preparation. These can be subclassified by the type of polyol that is used to make the oligomeric compounds—polyester or polylactone polyols are more weatherable than poly(propylene oxide) polyols. Poly(tetramethylene oxide) polyols can offer other specific and useful characteristics.

Other oligomeric and/or polyfunctional acrylates include the acrylated oils that can be prepared from what are known in the coating industry as drying oils (see Chapter 4 of this Manual). The oils are epoxidized triglycerides as are found in linseed oil, palm oil, soybean oil, sunflower seed oil, palm oil, and others. Some of these oils and their epoxidized versions have uses other than in radiation curing as in plasticization of poly(vinyl chloride) and other polymers.

Acrylates can be eye and skin irritants, toxic, and, in certain instances, human sensitizers. These factors vary with the particular acrylate and with molecular weight and it is important that Material Safety Data Sheets and other information be consulted regarding specific hazards and precautions about these and any other chemicals that are used in coating, paint, adhesive, ink, and other formulations. Suppliers should have, or can obtain, any desired information about their products and usually represent an important, up-to-date source of safety and handling data.

Cycloaliphatic Epoxides

Cycloaliphatic epoxides form the basis of almost all cationic curing formulations. They are used in combination with the above described onium salt photoinitiators, polyols of various molecular weights, and other typical formulation ingredients. Such systems offer certain advantages over free radical curing acrylate systems. They have improved adhesion because there is low shrinkage of about 2 to 4 % during the photopolymerization reaction that takes place during cure. Also, the systems are all relatively low viscosity liquids that are miscible—factors that lead to easy handling characteristics. There is no oxygen inhibition exhibited with cationic systems.

The main cycloaliphatic epoxide used is 3,4-epoxycyclohexylmethyl-3,4-epoxycyclohexanecarboxylate. A moderately higher viscosity diepoxide that is also used is bis(3,4-epoxycyclohexylmethyl)adipate. This latter epoxide can add a degree of flexibility to a final product. Epoxidized oils such as soybean oil epoxides, Vernonia oil (a naturally occurring epoxidized oil), and others can be used. Monoepoxides are also useful as viscosity reducers, and they do not act as chain-growth terminators because after the epoxide reacts into a growing chain, it leaves a hydroxyl group on the residue and this group is capable of reacting with other epoxide groups to maintain the integrity of the growing chain. There are other available and developmental products that can be found in the literature.

The polyols are added to formulations to provide flexibility and toughness. Most, if not all, polyols can be used and these include polyester polyols, polyether polyols, poly(tetramethylene oxide), glycols, and so on. By balancing end-use requirements and the amount of polyol used, a wide variety of physical properties can be achieved.

Vinyl Ethers

Vinyl ethers are interesting in that they can be cured by either free radical [25] or cationic means [26]. These compounds have the general structure

$$CH_2 = C(H)ORX$$

wherein R can be alkyl, ethylene glycols, cyclohexanedimethanol, and similar compounds and X can be another vinyl ether, hydroxyl, propylene carbonate, etc. Examples are butanediol divinyl ether, diethylene glycol divinyl ether, hydroxybutylvinylether, dodecylvinylether, etc. One very useful attribute of vinyl ethers in cationic systems was its function as an effective reactive viscosity reducer. Other advantages include good miscibility with other compounds, high conversion rates of the vinyl functionality, high cure speeds, low odor for many of the vinyl ethers, usually low toxicity, and no oxygen inhibition [27].

Vinyl ethers have also been investigated in donor/ acceptor or charge-transfer polymerizations [28], been developed into oligomeric urethane vinyl ethers [29] and ester vinyl ethers [30], and used in silicone-vinyl ether blends [31].

Radiation-Curable Powder Coatings

This topic is dealt with in another chapter of this manual (see Chapter 80). Also, generalized information can be found in Ref. [1].

Testing

A broad variety of tests that are useful in testing radiation-cured coatings, adhesives, and inks have been consolidated into one publication by ASTM International [32]. Specific ASTM documents that have been developed for the radiation-cure area include topics such as package stability, cure times, and volatile content along with standard terminology related to radiation measurement and dosimetry and a practice for exposing adhesive specimens to ionizing radiation. These documents are listed in Table 4.

There is a ten-day test requirement for a moisture resistance test in Military Specification-I-46058C (Method

TABLE 4—Methods for examining and testing radiation-cured coatings, adhesives, and inks

ASTM	Standard
E170	Terminology Relating to Radiation Measurements and Dosimetry
D1879	Practice for Exposure of Adhesive Specimens to Ionizing Radiation
D3732	Practice for Reporting Cure Times of Ultraviolet-Cured Coatings
D4144	Test Method for Estimating Package Stability of Coatings for Ultraviolet Curing
D5403	Test Methods for Volatile Content of Radiation Curable Materials

106 of Mil Std 202F). This long time period is tedious and time consuming when a number of potential candidates are screened. An in-house screening test was developed to examine and ascertain strong, potential candidates that could be examined with the long test period of the Mil Spec [33]. In the test, a Soxhlet extraction apparatus is modified and a raised glass platform is placed inside a Soxhlet extraction chamber. The test specimen is placed in a vertical position on the glass platform. Test specimens used were radiation-cured "Y" pattern boards as specified in the Mil Spec for conformal coatings, but other types of specimens could be used for other end uses. Water and a few boiling chips are placed in the flask portion of the device and heated. When the water boils, the exposed test specimen is subjected to a condensing humidity at a temperature of about 95 to 98°C. The test can be carried out for as long as desired and successfully screened candidates can be tested according to the military specification. The test is harsh, but useful in eliminating many unsatisfactory candidates. Details of the test and test equipment are explained in the cited reference.

End Uses

Some of the early successes of radiation curing of coatings were in the printing and packaging areas. That area remains of great importance to the radiation curing because it is a high volume end use, and the technology is easily adaptable to the packaging and printing area. End use industries served by ultraviolet and electron beam radiation curing include adhesives, aerospace and defense; automotive OEM, collision repair, refinishing and components; building products, composites; electronics including conformal coatings, printed circuit board coatings, component adhesives; metal finishing, medical devices, plastics, packaging including food packaging, UV inkjet inks, UV powders, and wood finishing. Today, a listing of many particular end uses can be found on the Internet and specifically at RADTECH's website (www.radtech.org).

Powder Coating

Joseph V. Koleske[1]

INTRODUCTION

ALTHOUGH THE FIRST POWDER COATING WAS developed in the late 1950s, it was not until the early 1970s that governmental regulations and the "80 % solids rule" brought about what was termed the "powder explosion." Requirements indicated that liquid coatings were to have markedly decreased volatile organic content, and this provided the impetus for companies to look into new coating technologies—powder coating, radiation cure, and high solids. It was a difficult task for entrenched companies to change and product manufacturing, equipment costs, and lethargy slowed progress. Solvents were inexpensive and it was easy to apply low-solids, solvent-based coatings. But, a number of old and newly established companies continued with development of the new systems, and today these three new technologies have a strong position in the coatings industry. Numerous industrial, consumer, and automotive finishes, for a broad range of products, are applied with powder coating technology. Powder coating has grown over the past few decades, and today it is a widely used technology that has captured about 12–15 % of the finishing market.

Powder coatings are dry, effectively 100 % solids materials that are supplied as free-flowing powders. The final coatings are either thermoplastic or thermoset in character. They differ from conventional coating systems in that a solvent is not needed to keep the polymeric binder, pigment and/or filler, and additives in a combined state for application and film formation. They are mainly applied by a thermal (fluid bed) method, an electrostatic (spray) method, or a combination of thermal and electrostatic methods. After application, the powder is heated and the particles melt and flow to form a hard protective and/or decorative coating for a wide variety of consumer and industrial end uses.

Although powder coatings provide very high quality finishes for metal, plastic, and wood substrates, they have other important advantages in today's marketplace. These advantages are often described within the industry as the Five E's, and they should be kept in mind when contemplating the use of powder coatings:

- Economy
- Efficiency
- Energy savings
- Environmental compliance
- Excellence of finish.

POWDER PREPARATION

Powder coatings in a general sense are prepared by a melt-mix, grind, and sort operation. The appropriate polymer, pigments, and additives along with cross-linking agents, if thermoset coatings are involved, are weighed into a premixer that ensures a homogeneous dry blend. At this point in the process, adjustments for color matching or other properties can be made. The premix is sent to an extruder wherein component dispersion and melt mixing take place. The extruder barrel can be heated and additional thermal energy is supplied to the mass through viscous heat generated from the mechanical screw system that drives the extruder.

The melt blended extrudates are usually discharged from the extruder in the form of a thin sheet, rapidly cooled, and then crushed or kibbled into small chips that are suitable for grinding. The chips, and usually a dry-flow additive, are then ground in a pin-disk mill, for example, to form a fine powder. This powder may be sieved to remove large-size particles or classified to remove particles below a selected size. Powders are usually processed into specified particle size distributions or ranges for specific applications and then packaged.

Although not practiced commercially, powders have been prepared by spray drying a solution of the premix into an inert atmosphere and, optionally, into a nonsolvent [1]. Such a process requires particular safety considerations including carrying out the operation in an inert atmosphere, properly grounding, etc. The powder produced by this process was micronized in a fluid energy mill to reduce particle size and yields a free flowing powder—again a process that currently has only limited usage. Recently, a "minisuspension" polymerization process that directly forms particles with spherical morphology and narrow particle size distributions has been described [2]. Such a direct process eliminates the numerous energy intensive steps involved in conventional powder preparation. This process quite probably is not widely used.

POWDER APPLICATION

Fluid Bed Technology

Fluidized-bed powder coating technology involves dipping preheated objects into a vat or tank that has a porous bottom plate. Low pressure air is supplied by means of a plenum located below the plate. The rising air suspends the powder in a liquid-like state. The fluidized powder adheres to the heated part and begins to flow and coalesce. After a predetermined immersion time, the part is removed and the melt–flow process continues. Usually the coated part is placed in an oven and the melt–flow process is completed resulting in a smooth, continuous, durable coating.

ISO 8130-11	Coating Powders—Part 11: Inclined-plane Flow Test

Coatings applied by this process are thicker than those from other powder application processes. Part complexity plays a role in coating quality, since areas that trap excess powder or entrap air can lead to excessive build-up or uncoated/thin regions. Often dedicated fluid beds are used for each color, since color changes involving clean up may be time consuming. Thermoset or thermoplastic coatings can be used with the fluid bed process.

Electrostatic Fluidized Bed

This process involves dipping a grounded part into a vat of air-fluidized powder [3–5]. The fluidized bed in this case has a high voltage, direct current grid installed within the plenum. A cloud of electrostatically charged powder particles is generated in the tank [3]. These particles are attracted to and wrap around a part that is at ground potential. Thinner coatings than those obtained with conventional fluid bed technology are obtained with the electrostatic fluidized bed, and they are similar in thickness to those obtained with the electrostatic spray process. The parts to be coated can be un-heated or preheated, but usually preheating is not required. Small parts can be coated with this process.

Electrostatic Spray

Electrostatic spray powder coating involves air fluidization of the powder in a small bed, transporting the fluidized powder by means of a hose to a spray gun, and imparting an electrostatic charge to the powder by means of a high voltage, direct current or by frictional forces in the gun. The charged powder is directed at the part to be coated, which is at ground potential. Such guns can be manually or automatically controlled and can be fixed or reciprocating in nature. The part may be at ambient temperature or heated prior to coating, though it usually is not necessary to preheat the part. The charged powder will wrap around the part and thus coat the entire object. The coated part is then sent to an oven and heated to a melt flow temperature to develop the final coating. If the coating is thermoset in nature, the heating step is conducted in such a manner that melt flow takes place before substantial cross-linking to ensure a smooth coating results. Overspray powder is collected, filtered, and reused. As a result, high material usage of greater than 95 % can result. Electrostatic spray applied coatings are thinner than fluid bed coatings because the charged particles are self-limiting in thickness build-up.

Basically, there are three types of electrostatic spray guns. Corona charging guns are the most widely used. These guns use either internal or external charging to generate a negative charge on the powder. "Tribo" guns charge the powder particles by friction or more specifically by acquiring a triboelectric charge. The positive charge is acquired when the powder rubs along a fluoropolymer tube located in the barrel of the gun. Electrostatic disk or "Bell" guns apply the charge to the particles in the nozzle area as they are fired from the gun toward the grounded part.

CHEMISTRY

A wide variety of polymers can be used to prepare powder coatings. Both thermoplastic and thermoset powders are used. Thermoplastic powders, as well as the films formed from them, can be remelted and reformed, if desired. They are subject to attack by solubilization in the presence of certain solvents. Thermoset powder coatings are formulated with a cross-linking agent, often termed a hardener, that will react with functional groups present on the polymer and an insoluble coating results. Although they are insoluble, thermoset coatings may be swellable in the presence of certain solvents. Once reacted, thermoset powder coatings cannot be remelted and reformed.

A variety of additives can be used in powder coatings, and these usually are dependent on the particular polymer involved. Additives include accelerators, plasticizers, colorants, fillers, extenders, flow control agents, thermal and ultraviolet radiation stabilizers, and the like. Flow control additives are used to facilitate dry powder handling as well as others for melt flow improvement. Melt flow control agents include polyacrylates, silicones, surfactants, and fluorinated alkyl esters.

Thermoplastic Coatings

Thermoplastic polymers include poly(vinyl chloride), vinyl chloride copolymers (see Chapter 15), polyamides, polyesters, poly(vinylidene fluoride), fluoropolymers [2], and polyolefins. Many thermoplastics require base coating with a primer to achieve good adhesion to metal substrates.

Vinyl Powder Coatings

Coatings prepared from poly(vinyl chloride) have excellent chemical and corrosion resistance, hardness, and tensile and dielectric strength. Plasticizers are added to the mix to improve flexibility and toughness and to allow flow-out for smooth films. End uses include dishwasher baskets, lawn furniture, fence posts, shelving, and various wire items such as chain-link fencing. Fluoropolymers include fluorinated ethylene-propylene copolymers, ethylene–tetrafluoroethylene copolymers, poly(vinylidene fluoride) and vinylidene fluoride/hexafluoroproplene copolymers. These polymers can impart good weatherability as well as chemical, dielectric, and heat resistance to a substrate. Some of these polymers can provide coatings that may be cost-effective alternatives to stainless steel and glass linings [6].

Nylon Powder Coatings

Nylon powder coatings have very good abrasion, chemical, and solvent resistance, impact resistance, low coefficient of friction (good lubricity), low toxicity, good thermal resistance, and toughness. Such coatings have relatively poor acid resistance. Nylon coated metal parts are used in rotating and sliding bearing systems and other bearing systems that are used in appliances, farm and textile machinery, relay plungers, and similar items. Other end uses include coatings on meat and other types of hooks, baskets used for degreasing and meat smoking, surgical equipment, and valves. Because of nylon's ability to withstand sterilizing temperatures, hospital equipment coated with nylon can be sterilized numerous times without destructive effects. In the United States, Nylons 11 and 12 are commonly used in these coatings.

Polyolefins

Powder coatings formed from polyethylene and polypropylene have excellent chemical and corrosion resistance to most acids, bases, alcohols, and salts up to temperatures of about 95°C, however, this type of chemistry can be softened by certain greases and oils. Moisture absorption is effectively nil. Properties of polyolefin coatings are dependent on polymer density/degree of crystallinity with properties, in general, improving as density increases. End uses include coatings for a variety of holding racks, glass bottles, pipe hangers, tank lids for containers holding chemicals, certain laboratory tools, and covers for a variety of items.

Thermoset Powder Coatings

Thermoset powder coatings contain a polymer with functional groups such as oxirane, hydroxyl, or similar reactive sites. The cross-linking agent that is to react with these groups must be sufficiently stable to withstand the thermal rigors of compounding and not be reactive until the melt–flow process has taken place during the curing cycle. The compounded powder must also be storage/shipping stable.

Polymers used for thermoset coatings include epoxides such as the diglycidyl ethers of Bisphenol-A, epoxy-polyester hybrids, functionalized acrylics, urethane polyesters, polyester triglycidyl isocyanurate (polyester TGIC), functionalized vinyl chloride copolymers, methacrylate terminated polyesters, vinyl ether capped polyurethanes, and the like. Curing agents include dicyandiamide, solid di- and polyanhydrides, phosphonium compounds, blocked isocyanates,

adipic and succinic acid dihydrazides, as well as many others.

Epoxy powder coatings are often termed "fusion bonded epoxy coatings" (FBE). These are used to coat products such as concrete reinforcement bars (rebars), steel pipe and connections, valves and similar items and thus provide corrosion protection and chemical resistance. Typically, these coatings cure at temperatures of about 150 to 230°C (300 to 450°F).

Radiation-Cured Powder Coatings

In 2001, a publication indicated that a new line of radiation-curable powder coatings was available [7]. The coatings would cure by oven baking at low temperatures of about 100°C for 2 min to melt-flow the coating followed by a five-second ultraviolet radiation exposure to cross-link the coating. These coatings were considered as hybrids of two new technologies—powder coating and radiation curing—since they combine features of both [8–12]. The coatings formed are thermoset in nature. They allow powder coatings to be used on heat sensitive substrates such as plastics and wood. Smooth, adherent, hard, functional and decorative coatings result through two independent processes with flow being promoted by moderate heating and cure by means of cross-linking through ultraviolet radiation.

Chemistries used include unsaturated polyesters based on fumaric or maleic acid and vinyl ether functional polyurethanes, methacrylated urethanes, methacrylated polyesters and epoxy acrylates. Both cationic and free radical ultraviolet radiation cures have been investigated [13]. Benefits, advantages, and chemistry have been detailed in various literature articles [14]. The technology is relatively new, but has current and future promise especially for temperature sensitive substrates such as wood and plastic.

CURING

Thermoplastic powder coatings only require a single heating to melt and flow or "cure" the coating. Thermoset coatings require thermal treatment to effect the cross-linking reaction that insolublizes the final coating.

Four methods are used to cure powder coatings. Gas or electric powered convection ovens that operate at about 140 to 220°C are used to cure coatings on metal substrates. Curing times vary from 30 to 45 min. Infrared ovens operate at higher temperatures of about 160 to 250°C for coated metal substrates and cure times vary from about 1 to 15 min. Combinations of infrared and convection ovens operate at about 140 to 220°C and cure times can vary from about 10 to 25 min. In such curing lines, convection heating follows infrared heating.

The fourth method is used for ultraviolet radiation-curable powder coatings and involves heating in an infrared/ convention oven for about 1 to 3 min at a temperature of about 90 to 120°C to cause melting and flowing. This is followed by ultraviolet radiation for a second or two. The process is used for metal, plastic, and wood substrates.

TESTING

ASTM D3451, Standard Guide for Testing Coating Powders and Powder Coatings, is a summary of numerous ASTM, ISO (International Organization for Standards), and PCI (Powder Coating Institute) documents that are of interest to the powder coating community. The guide does not address test methods developed specifically for the powder coating market, but it does provide guidance to over 100 test methods of general interest.

Specific ASTM documents devoted to powder coating and others that are used by some laboratories are listed in Table 1. Certain of these documents offer options to an investigator. For example, ASTM D5965, Standard Test Methods for Specific Gravity of Coating Powders, has three methods:

- A—for testing coating powders excluding metallic powders. This is a less expensive and less precise determination than that of Method B.
- B—for testing that requires greater precision than test method A, including metallic powders and using helium pycnometry.
- C—for theoretical calculations based on raw material specific gravity. This is a method often used to estimate powder coating coverage at a given thickness.

ASTM D7378, Standard Practice for Measurement of Thickness of Applied Coating Powders to Predict Cured Thickness, has three procedures for measuring dry coating powder thickness:

- A—a procedure that uses rigid metal notched (comb) gages.
- B—a procedure that uses magnetic or eddy current coating thickness gages.
- C—a procedure that uses non-contact ultrasonic powder thickness instruments.
