PHOTOPOLYMERIZATION, FREE RADICAL

Introduction

Photopolymerizations, which use light energy (photons) to initiate chain reactions to form polymer materials, are the basis for a growing, billion-dollar industry (1,2). Applications in which photopolymerization is used include films and coatings, inks, adhesives, fiber optics, and dentistry (2–5). Each of these industries has benefited from the high productivity and lower costs afforded by photopolymerization systems.

Photopolymerization has many advantages over thermal and redox polymerizations in which the reaction system is heated to produce active centers. The solvent-free systems used in photopolymerizations eliminate emissions of volatile organic compounds and reduce material costs. Spatial and temporal control of the polymerization is achieved through control of the initiating light. Photopolymerizations also use less energy to effect cure than do thermal means. They produce a more rapid through-cure so that more films and coatings can be processed in less time. Furthermore, photocuring systems are more compact than thermal curing systems and operate at room temperatures. All these characteristics of photopolymerizations translate into lower production costs for industry.

Photopolymerization systems, like thermally initiated systems, contain initiator, monomer, and other additives that impart desired properties (color, strength, flexibility, etc) (6). The reaction is initiated by active centers that are produced when light is absorbed by the photoinitiator. One important class of active centers includes free-radical species, which possess an unpaired electron (5,7). The highly reactive free-radical active centers attack carbon–carbon double bonds in unsaturated monomers to form polymer chains. Although the kinetic treatment of photopolymer systems is similar to that in thermal systems, significant differences arise in the description of the initiation step, which in turn affect the

description of the rate of polymerization. An overview of the components, kinetics, and applications of these free-radical photopolymerization systems is given in this article. More detailed information may be obtained in the references cited.

Photoinitiators

In order to produce free radicals that initiate polymerization, photoinitiators absorb light of a certain frequency. Upon absorption, the photoinitiator molecule is promoted from the ground electronic state to either a singlet or triplet excited electronic state. This excited molecule then undergoes either cleavage or reaction with another molecule to produce initiating free radicals. Numerous photoinitiators have been developed to meet the needs of a variety of photopolymerization systems, as described in a number of recent papers and reviews (3–6,8–12).

In selecting an appropriate photoinitiator system, several key criteria must be fulfilled. First, the absorption spectrum of the initiator must overlap with the emission spectrum of the light source, be it polychromatic (eg, arc lamp) or monochromatic (eg, laser). Good engineering of the system involves optimizing the light absorption of the initiator and, in many cases, minimizing emission lines that do not coincide with the initiator absorption spectrum (ie, are wasted through absorption by other system components). By matching the absorption of the photoinitiator to the light source output, the initiation efficiency can also be optimized. However, the overlap between the initiator and light source must preferably not coincide with the absorption peaks of other components in the photopolymerization system (monomer, pigments, additives, etc.). In systems where there is overlap, such as highly pigmented systems, higher light intensities and photoinitiator concentrations are often used (13). Figure 1 demonstrates a good match of a photoinitiator with a light source and monomer in that there is a clear optical window for the photoinitiator to absorb light in the 300–400-nm region without competition from the monomer.

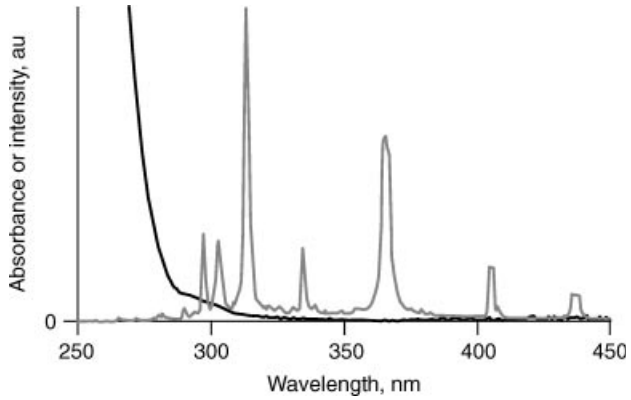

Fig. 1. UV–visible absorption spectra of dimethoxyphenylacetophenone (DMPA) (photoinitiator) and 2-hydroxyethyl methacrylate (HEMA) (monomer) in dichloromethane overlaid with the spectral output of a 200-W Hg(Xe) lamp. ——— DMPA; ——— HEMA; and ——— Hg(Xe) Lamp.

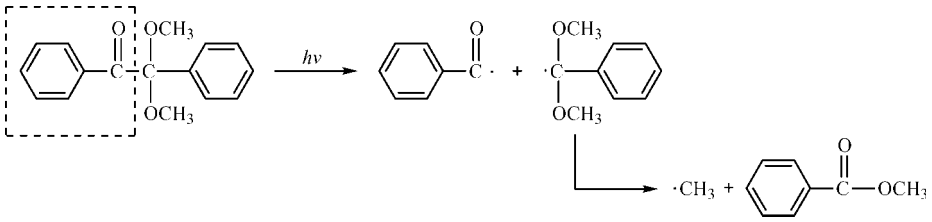
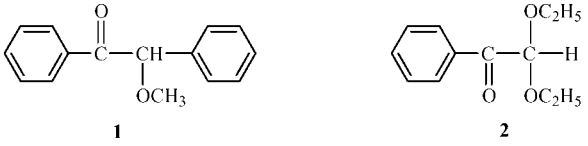
Many free radical photoinitiators are based on the benzoyl chromophore (highlighted in eqs. 1 and 2), which produces free radicals when irradiated with light of the appropriate wavelength. Judicious choice of substituents (R groups) and their placement can alter the absorption spectrum, so that more freedom is available in the choice of lamp (and initiating wavelength) and system components. Secondly, the impact of residual photoinitiator and its photoproducts upon the final products must be considered. This becomes most important in thick films and coatings that must be of a certain color. If the photoinitiator fragments absorb at the same wavelength as the photoinitiator, then light cannot penetrate to the bottom of a thick sample, and full conversion of the monomer will not be attained. Also, some photoinitiator fragments, such as aromatic amines, will "yellow" initially colorless and white coatings and films, especially after long exposure times to sunlight or fluorescent lights (13).

Unimolecular Photoinitiators. Photoinitiators termed unimolecular are so designated because the initiation system involves only one molecular species interacting with the light and producing free-radical active centers. One type includes photoinitiators that form radicals via the cleavage of the initiator molecule. This cleavage may take place at the α or β position with respect to the carbonyl group. Upon illumination, the photoinitiator molecule is excited and undergoes cleavage. In α-cleavage or Norrish Type I, the bond adjacent to the carbonyl is broken to produce two free radicals. Equation 1 demonstrates the α-cleavage of a representative benzyl ketal photoinitiator dimethoxyphenylacetophenone (the dashed box highlights the benzoyl chromophore).



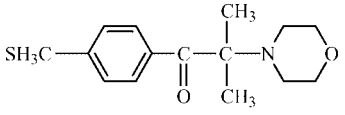
(1)

In this case, the benzoyl radical and a methyl radical produced through the fragmentation of α,α-dimethoxy benzyl radical both initiate polymerization. Other families include benzoin ethers, acetophenone derivatives, amino ketones, and phosphine oxide derivatives (**1–4**) (3,11).

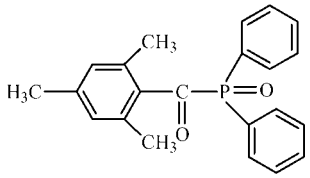


1

2

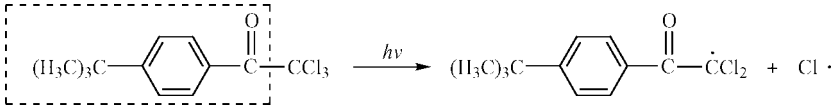


3



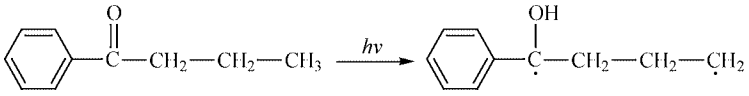
4

β-Cleavage occurs predominately in α-halogenoacetophenones; however, it is also seen in photoinitiators with a C—S or C—O bond adjacent to the benzoyl chromophore, such as β-ketosulfoxides (3,11). Equation 2 demonstrates this cleavage mechanism for the photoinitiator 2,2,2-trichloro-4′-*tert*-butylacetophenone (the dashed box highlights the benzoyl chromophore).



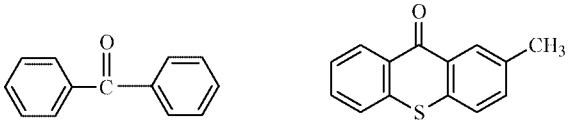
(2)

A second type of unimolecular photoinitiators, also called Norrish Type II, includes those that form biradicals through intramolecular hydrogen abstraction. This occurs in ketones with a γ-hydrogen and is shown in equation 3 for intramoleculer H-abstraction of the photoinitiator 1-phenyl-butan-1-one (14). The resulting ketyl radical participates in termination, while the other radical grows the polymer chain.



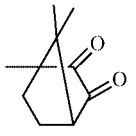
(3)

Bimolecular Photoinitiator Systems. Bimolecular photoinitiators are so-called because two molecular species are needed to form the propagating radical: a photoinitiator that absorbs the light and a co-initiator that serves as a hydrogen or electron donor. Photoinitiator families include benzophenone derivatives, thioxanthones, camphorquinones, benzyls, and ketocoumarins (**5–9**) (3).

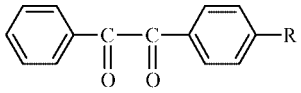


5

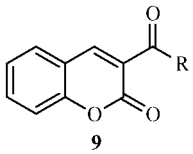
6



7

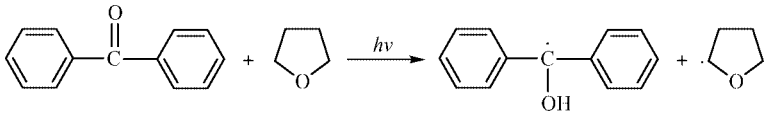


8



9

The abstraction of a hydrogen molecule from the co-initiator or the transfer of an electron between the two initiating molecules takes place once the photoinitiator is in the excited state. In both cases, free radicals result, one or more of which may actually begin the photopolymerization. Initiation by hydrogen transfer is common in diaryl ketones. The co-initiator is usually an ether or an alcohol with an abstractable α-hydrogen, such as 2-propanol. Equation 4 demonstrates the H-abstraction reaction between the photoinitiator benzophenone and the hydrogen donor tetrahydrofuran. In this case, the ether radical initiates polymerization, and the ketyl radical only participates in termination.



(4)

In photoinitiation by electron transfer, the photoinitiator, after absorption of the initiating light, forms an excited-state complex (exciplex or charge-transfer complex) with the co-initiator, typically an amine. Electron transfer from the amine to the photoinitiator occurs in this exciplex, immediately followed by proton transfer of an α-hydrogen from the amine to the photoinitiator. This results in two radicals: an amine radical that will initiate polymerization and a ketyl-type radical that will most likely terminate by coupling with another free radical species. Figure 2 demonstrates this type of photoinitiation process between benzophenone and an amine co-initiator (3,15).

Bimolecular photoinitiator systems utilize longer wavelengths (thereby requiring less energy) than the unimolecular systems, which are typically constrained to use in the ultraviolet (UV) because of the absorption characteristics of the benzoyl chromophore. However, the production of active centers in bimolecular photoinitiator systems decreases in vitrifying systems (ie, systems in the later stages of conversion where the reaction temperature is less than the glass transition temperature) because diffusion of the initiator and co-initiator molecules

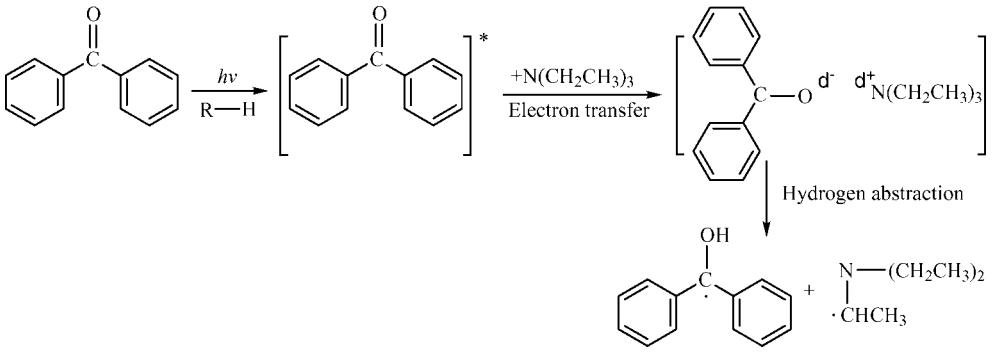


Fig. 2. Electron-transfer reaction with subsequent proton-transfer reaction between the photoinitiator benzophenone and the co-initiator triethylamine.

is strongly suppressed. During this stage in the polymerization, formation of the polymer chains occurs through reactive diffusion.

Photosensitizers. In the bimolecular initiation reactions described above, the co-initiator will not absorb light to initiate polymerization. In contrast, photosensitizers are able to absorb light and are used to enhance the photopolymerization (ie, the photoinitiator is normally able to function without the photosensitizer) (3,4,16). A visible light photosensitizer may be chosen when ultraviolet light is undesirable, such as when working with biological systems or white pigmented systems. If pigments or monomers absorb in the same region as the photoinitiator, a photosensitizer may be used to extend the optical window of the system. A photosensitizer may also be used to improve initiation efficiency by absorbing photons from the light source that the photoinitiator cannot absorb or may do so with a low efficiency.

Two mechanisms have been identified to describe the interaction between photosensitizers and photoinitiators: *energy transfer* and *electron transfer*. In the energy transfer process, the photosensitizer absorbs the light and transfers that energy to the photoinitiator which will then go through either a unimolecular or bimolecular scheme to produce initiating free radicals.

$$PS \xrightarrow{h\nu} PS^*$$

$$PS^* + I \xrightarrow{\text{energy transfer}} PS + I^*$$

$$I^* \longrightarrow R_1^{\cdot} + R_2^{\cdot}$$

In this case, the photosensitizer is not consumed by the reaction and reverts back to its ground state upon transferring its excitation energy to the photoinitiator. For example, the photoinitiator 2-methyl-1-[4-(methylthio)-phenyl]-2-morpholinopropane-1-one (TPMK) absorbs light in the 275–325-nm region, wherear the photosensitizer 3-ethylacetate-2′-methylthioxanthone (ETX) exhibits an absorption peak between 380–420 nm (3). Thus, ETX absorbs light in the visible region of the spectrum and transfers that energy to TPMK, which then undergoes α-cleavage to form the free-radical active centers. In order for this process to occur, the triplet excited electronic state of the photosensitizer must be higher than that of the photoinitiator. Because these states are difficult to match, the energy transfer mechanism is not extensively used.

In the electron transfer mechanism, which is more common, the photosensitizer becomes excited upon illumination and forms an excimer with the photoinitiator. Electron transfer from the photoinitiator to the photosensitizer then occurs, with a subsequent proton transfer. This results in the formation of two radicals. The photosensitizer radical is capable of initiating polymerization, while the photoinitiator radical may not unless it undergoes further reaction (3,13,17). Figure 3 demonstrates this for a representative α-amino ketone photoinitiator and a thioxanthone being used as a photosensitizer.

Specialty Photoinitiators. Photoinitiator systems continue to be developed to meet the needs of industrial applications. Driving forces include increasing reaction speed with higher quantum yields and higher active center reactivities, improving shelf life with greater solubility and stability in the formulations, and

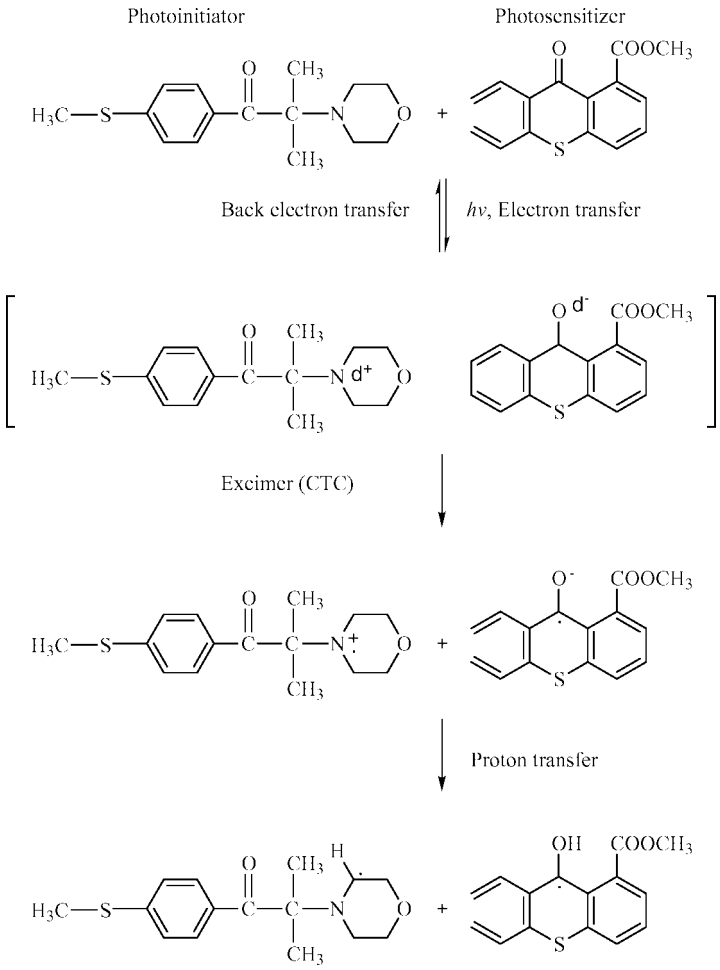

Fig. 3. Electron transfer reaction between the photoinitiator 2-methyl-1-[4-(methylthio)-phenyl]-2-morpholinopropane-1-one and the photosensitizer 9-oxo-9*H*-thioxanthene-1-carboxylic acid methyl ester.

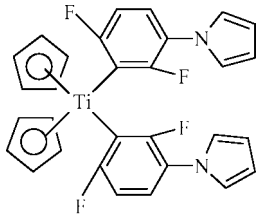
optimizing the absorption spectrum to meet the requirements of the light source and application. Minimizing toxicity of the initiators and yellowing due to photoproducts and sunlight exposure also is important for many applications.

Visible Light Photoinitiators. Visible light photoinitiators are desirable for many applications. Visible light is safer than UV light in that it does not cause cell damage in biological systems. Many common, inexpensive light sources, such as halogen or fluorescent lamps, have strong lines in the visible, which could be used for efficient and cost-effective photoinitiation. In addition, visible lasers are used in photoimaging applications, such as lithography and holography (5). Visible light photoinitiators can also enhance polymerization in systems with pigments, fillers, and UV absorbers (18).

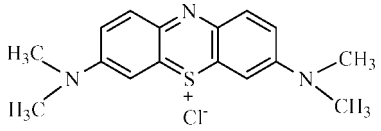
Visible light photoinitiators based on metal salts and complexes have been explored (3,10,12). Some systems generate ionic active centers unless

combined with another molecule (such as a dye or halogenated compound) that will react to produce the initiating free radical. Titanocene complexes, an example of which is bis(η^5-2,4-cyclopentadien-1-yl)-bis-[2,6-difluoro-3-(1*H*-pyrrol-1-yl)phenyl]titanium (**10**), are metal-based photoinitiators that undergo cleavage upon illumination in the 400–550-nm region, with the aryl radical initiating polymerization (12).



10

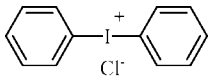
Dyes comprise a large fraction of visible light photoinitiators because their excited electronic states are more easily attained. Co-initiators, such as tertiary amines, iodonium salts, triazines, or hexaarylbisimidazoles, are required since dye photochemistry entails either a photoreduction or photo-oxidation mechanism. Numerous dye families are available for selection of an appropriate visible initiation wavelength; an example of a thiazine dye (with an absorption peak around 675 nm) is methylene blue (**11**).



11

Other examples include acridine dyes (with absorption peaks around 475 nm), xanthene dyes (~500–550 nm), fluorone dyes (~450–550 nm), coumarin dyes (~350–450 nm), cyanine dyes (~400–750 nm), and carbazole dyes (~400 nm) (12,19–21). The oxidation or reduction of the dye is dependent on the co-initiator; for example, methylene blue can be photoreduced by accepting an electron from an amine (22) or photo-oxidized by transferring an electron to benzyltrimethylstannane (12). Either mechanism will result in the formation of a free-radical active center capable of initiating a growing polymer chain. For a more detailed discussion of the mechanisms, see Reference 12.

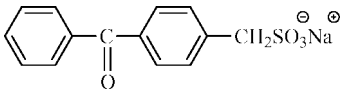
Three-component visible light photoinitiator systems exhibit faster polymerization rates than those seen in the dye-electron donor systems mentioned above. The third component is usually a sulfonium or iodonium salt (an example is diphenyliodonium chloride) (**12**), but may also be a bromocompound, ferrocenium salt, or thiol derivative (3,12,21–24).



12

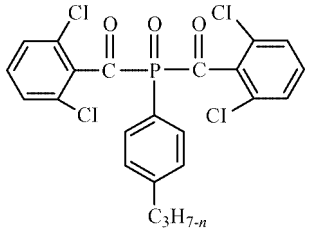
The incorporation of the third component has been shown to provide pathways to scavenge oxygen molecules that inhibit free-radical polymerization, to regenerate the dye photoinitiator, and to produce a free-radical active center in place of a terminating dye radical (3,12,13,21). In addition, the wide selection of dyes available for use in three-component systems allows more flexibility in initiating wavelength selection, and the photopolymerization of thick parts is possible if a photobleaching dye is chosen (21).

Water-Soluble Photoinitiators. Water-soluble photoinitiators are needed for systems such as printing inks and emulsion processes, where the reaction system is an aqueous solution rather than simply a monomer. Since free radical photoinitiators are based on the aromatic benzoyl chromophore, the molecules are generally nonpolar and therefore incompatible with water. Research has focused on developing photoinitiators with hydrophilic substituents that increase water solubility (3,25). Both unimolecular and bimolecular systems have been successfully demonstrated. An example of a unimolecular photoinitiator is sodium 4-benzoylbenzenemethane sulfonate (**13**).



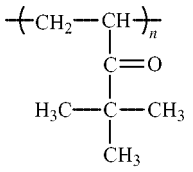
13

Photobleaching Initiators. Photobleaching initiator systems are designed such that the absorption of the photoinitiator byproducts is lower than that of the photoinitiator (13,26). Thus, as the active centers are formed, more light may pass through the system. This is crucial in thick films, where light penetration to the bottom of the sample is hindered by the absorption characteristics of the upper layers. Insufficient light penetration will result in low conversions at the bottom, wrinkling of the surface, and decreased production speeds. Photobleaching is also necessary for colorless or white films and coatings to prevent yellowing. Acylphosphine oxides and bisacylphosphine oxides (**14**), which undergo α-cleavage, are examples of photobleaching initiators widely used today. These photoinitiators absorb well into the visible spectrum; however, once cleavage occurs, the absorption peaks in the visible spectral region disappear.



14

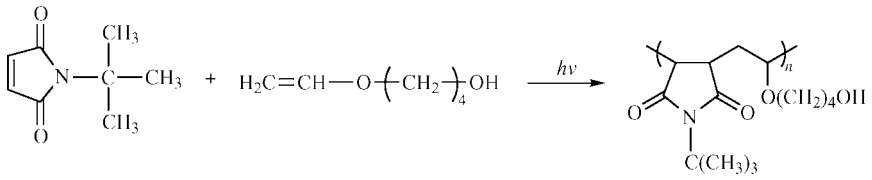
Polymerizable and Polymeric Photoinitiators. Growing interest in polymerizable and polymeric photoinitiators is seen in several industries. An example is poly(4,4-dimethyl-1-penten-one) (**15**).



15

In the food-packaging industry, species that migrate from a film or coating may contaminate foods. In the film and coating industries, migrating species may cause yellowing at film surfaces. Thus, tethering or incorporating the photoinitiator on the main polymer chain is an effective means of reducing migration by photoproducts and unreacted photoinitiator (27). These types of photoinitiators exhibit other practical benefits, such as improved compatibility with monomers, longer shelf life, increased reactivity, and reduced volatile emissions (28,29). Polymeric photoinitiators have been synthesized by grafting the initiator molecule onto the backbone of the polymer chain (3,27,30). They have also been created by terminating polymer chains with the initiator molecules (3,27,29,31,32). Polymeric photoinitiators may become entangled within the polymer product or attached to the main polymer chain or network, depending on whether the active center cleaves from or is part of the polymeric photoinitiator chain (27). Polymerizable photoinitiators may be formed by attaching the photoinitiator on a polymeric or oligomeric chain that has one or more functional groups that can enter into the polymerization as well (3). Thus, the photoinitiators become copolymerized with the main polymer chain or network.

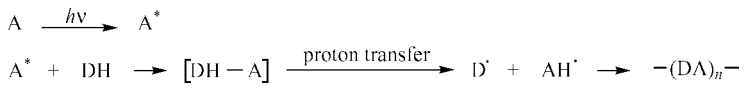
In some cases, a monomer may function as a photoinitiator and become incorporated into a copolymer chain. This has been shown for styrene and other conjugated monomers when exposed to deep-UV light; however, the initiation efficiency in these systems is substantially less than when a photoinitiator is present (p. 223 of Ref. 33, and Ref. 34). A better polymerizable initiator scheme is illustrated by the acceptor-donor chemistry of maleimide-donor systems (35–37). Maleimide acts as both photoinitiator and comonomer in the presence of hydrogen donors such as vinyl ethers or vinyl esters (38,39); an example of this copolymerization is shown in equation 5. It shows the molecular structure of the acceptor *tert*-butylmaleimide (left), the donor 4-hydroxy-butyl vinyl ether (right), and their corresponding copolymer repeat unit.



(5)

In these systems, illumination with a subsequent hydrogen abstraction or electron/proton transfer process results in the production of two radicals, both of

which may start a propagating chain by adding either monomer (35–37):



These systems have the added advantage of being photobleaching, as well as less inhibited by oxygen.

Monomers

Unsaturated monomers, which contain a carbon–carbon double bond (C=C), are used extensively in free radical photopolymerizations. The free-radical active center reacts with the monomer by opening the C=C bond and adding the molecule to the growing polymer chain. Most unsaturated monomers are able to undergo radical polymerization (qv) because free-radical species are neutral and do not require electron-donating or electron-withdrawing substituents to delocalize the charge on the propagating center, as is the case with ionic polymerizations. Commercial consideration in formulation development is therefore given to the final properties of the polymer system, as well as the reactivity of the monomer.

(Meth)acrylate Systems. Acrylate and methacrlate monomers are by far most widely used in free-radical photopolymerization processes. The generalized structure of these monomers and their corresponding polymer is shown in Figure 4.

These monomers have very high reaction rates, with acrylates having an even faster reaction rate than their methacrylate counterparts (4). This makes them especially amenable for high speed processing needed in the films and coatings industry. (Meth)acrylate systems are also easily tailored using the ester linkage to obtain the desired chemical, mechanical, and optical properties for a variety of applications (see ACRYLIC ESTER POLYMERS; METHACRYLIC ESTER POLYMERS). Monoacrylates, which have only one C=C group, are generally used as reactive diluents with multiacrylates, which have two or more C=C groups per molecule (Fig. 5). Multiacrylates increase the mechanical strength and solvent resistance of the ultimate polymer by forming cross-linked networks rather than linear polymer chains, whereas monoacrylates reduce the viscosity of the prepolymer mixture for ease of processing (4,6).

One of the drawbacks of acrylate and methacrylate systems is their relatively large polymerization shrinkage. Shrinkage is caused by the formation of covalent

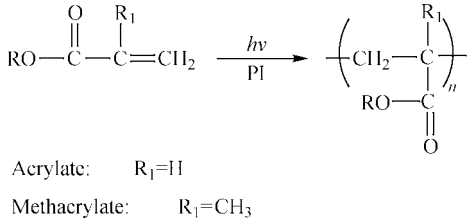


Fig. 4. Molecular structure of a generalized acrylate monomer and its corresponding polymer repeat unit.

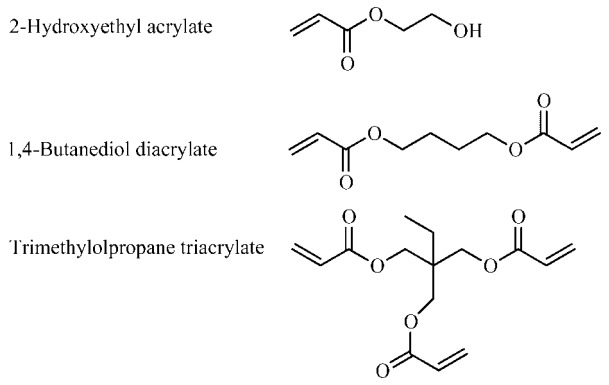

Fig. 5. Molecular structures of monomers with a varying number of acrylate reactive groups: a monoacrylate (top), diacrylate (middle), and triacrylate (bottom).

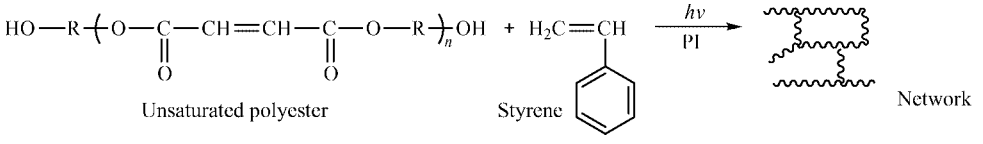
bonds between monomer molecules. When a covalent bond is formed between two monomer molecules, the distance between them is approximately half as much as that between two molecules experiencing van der Waal's forces in solution. In addition, because the number of conformations that a polymer chain can achieve is less than that for the individual monomer molecules, monomer conversion results in a negative entropy of polymerization and less free volume. Thus, volume shrinkage of 5–25% is observed in these systems (4,40–42). This shrinkage causes stresses in the polymer parts, which can affect their ultimate performance, especially in applications such as stereolithography, dentistry, and coatings. One way to overcome this disadvantage is to develop oligomeric acrylates. These oligomers contain 1 to 12 repeat units formed through step-growth polymerization; the ends are then capped with two or more (meth)acrylate functional groups. Commercially available oligomeric families are shown in Figure 6.

In addition to reducing shrinkage, oliogomeric acrylates offer improved properties of wear resistance and chemical and moisture resistance. They also enable the use of these functional groups in rapid processing applications, which would not be possible using the slower step-growth polymerization mechanism. Because of their size, these oligomers must be combined with other monomers to reduce the resin viscosity. Examples of coating formulations incorporating multiacrylates and oligomeric acrylates are shown in Table 1.

Unsaturated Polyester Systems. Coatings in the furniture industry rely heavily upon resin formulations containing unsaturated polyesters, styrene, and photoinitiator (3,4,13,43,44). The unsaturated polyesters are synthesized using step-growth polymerization (see POLYESTERS, UNSATURATED). Upon illumination, the carbon–carbon double bond in the unsaturated polyester and styrene copolymerize to form a cross-linked network (eq. 6). Equation 6 shows a generalized reaction scheme for an unsaturated polyester system.



(6)

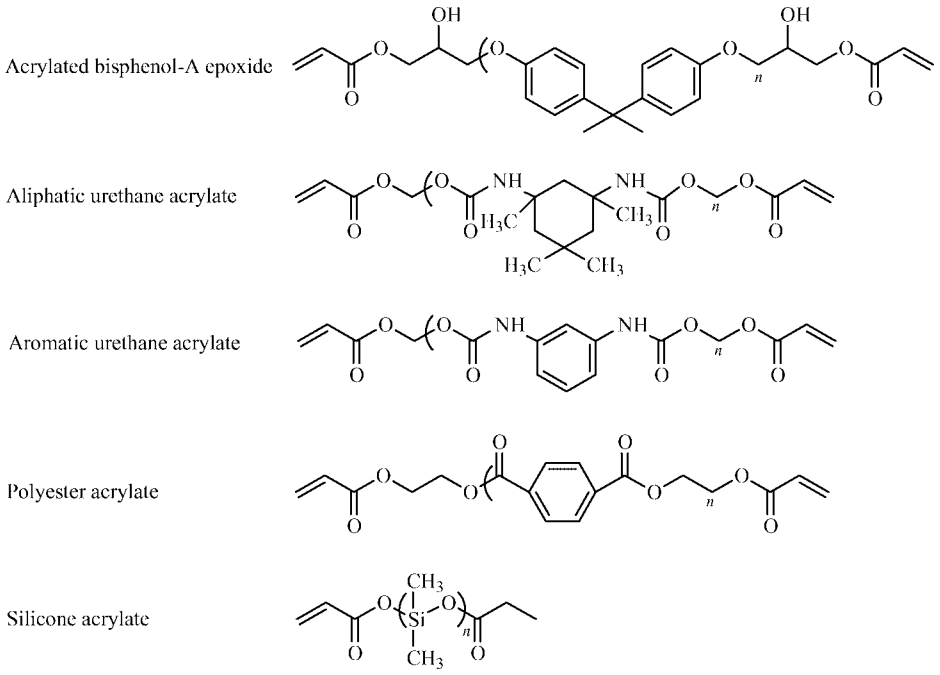


Fig. 6. Molecular structure of some generic acrylated oligomers.

Although these systems polymerize much slower than the acrylate systems, they are low cost and can still polymerize at ambient temperatures.

Thiol–Ene Systems. Systems that combine thiols [such as a trithiol (**16**)] with ene comonomers, such as allyl ethers [like trimethylol propane diallyl ether (**17**)] or acrylates, were first considered in the 1970s; however, because of their unpleasant odor, thiols were abandoned, and acrylates became the monomer of choice for industrial implementation.

Table 1. Sample (Meth)acrylate Formulations

Basic coating	Wood-flooring topcoat	Adhesive resin for dentistry	Resin composite for dentistry
Acrylated epoxy oligomer, 45%	Urethane acrylate, 60%	Dimethacrylated epoxide, 60–70%	Silica filler, 77–87%
Triacrylate, 20%	Diacrylated polyether, 24%	Monomethacrylate, 30–40%	Dimethacrylated epoxide, 5–9%
Diacrylate, 20%	Polyester tetraacrylate, 10%	Camphorquinone, <1%	Dimethacrylated polyether, 5–9%
Amine, 10%	Amine, 10%	Amine, <1%	Camphorquinone, <1%
Benzophenone, 5%	α-Hydroxyketone, 5%		Amine, <1%

17

Several factors have led to renewed interest in thiol systems. First, the systems require little or no photoinitiator in order to polymerize (45,46). This reduces the cost of formulations (since the photoinitiator is generally the most expensive component), as well as decreases toxicity and purity concerns. In addition, photoinitiator fragments do not interfere with the physical properties of the polymers, such as color and strength. The thiol functions as photoinitiator by producing a thiyl and a hydrogen radical pair through a sulfur–hydrogen bond cleavage when exposed to light (47,48):

$$RSH \xrightarrow{h\nu} RS^{\cdot} + H^{\cdot}$$

Thiol systems are also less sensitive to inhibition by oxygen, a major disadvantage of free-radical polymerizations. The inactive peroxy radical formed through interaction of oxygen and a growing chain end can undergo chain transfer to the thiol to regenerate the active thiyl radical. However, this still results in the incorporation of oxygen into the polymer, which will affect its performance properties. Because most of the double-bond conversion occurs in the liquid state, these systems undergo less volume shrinkage and establish an infinite network (gel point) later in the reaction so that higher conversions, even in systems with multiple functional groups on each monomer, may be reached (49). This is a result of extensive chain transfer during the free-radical chain polymerization, which leads to the formation of very short chains. Long polymer chains and networks are formed through a step-growth mechanism (46–48,50).

Other Monomer Systems. The above sections are by no means an exhaustive list of monomers that are used in free radical photopolymerizations. Diallyldiglycolcarbonate (**18**) has been used for many years in optical components such as lenses (51). Acrylamide (**19**) is used in stereolithography and to prepare holographic materials (52–54). *N*-vinylpyrrolidinone (**20**) is copolymerized with acrylates and methacrylates for cosmetic and biomedical applications (55). Norbornene (**21**) is copolymerized with thiols for optical fiber coatings (56). Liquid crystal polymers (**22**) based on acrylates and thiol–enes are being developed to produce mirror coatings, polarizing films, and liquid crystal displays (57,58).

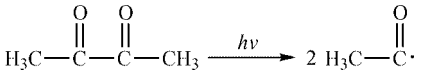
Kinetics

The description of free-radical chain polymerization kinetics must take into account four basic steps: *initiation*, which creates free-radical active centers; *propagation*, which grows the polymer chains; *termination*, which destroys the active centers and ends chain growth; and *chain transfer*, which ends a growing chain and begins another. These classical steps also describe thermal polymerizations; however, different descriptions are required for thermal- and photoinitiation.

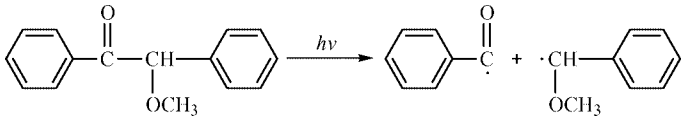
Initiation. In both thermal- and photopolymerizations, the rate of initiation depends on two processes: the *dissociation* of the initiator and the *initiation* of the propagating chain. The decomposition rate (k_d) of thermal initiators strongly depends on temperature, with the half-life of many thermal initiators at the reaction temperature on the order of minutes or hours. In contrast, for photopolymerizations, the rate at which photons are absorbed at a specific wavelength will determine the decomposition rate of photoinitiators. This process is not temperature-dependent. Thus, in the classic initiation mechanism, the interaction between light of a specific wavelength and a photoinitiator molecule is considered. For a unimolecular photoinitiator, this reaction step can be written as follows:

Either one or both of the radicals may then initiate polymerization. Biacetyl is an example of a photoinitiator that generates two identical free-radical groups (eq. 7) (59).



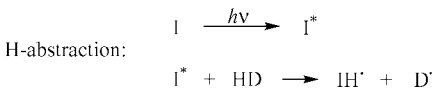
(7)

Benzoin methyl ether is an example of a photoinitiator that generates two dissimilar free radicals, each with a different initiation efficiency (ie, benzoyl radical is more likely to start a propagating chain than the ether radical) (eq. 8) (60).



(8)

A similar mechanism may be developed for radical production by electron transfer or hydrogen abstraction:



Generally, the donor radical (such as an amine or alcohol) is the initiating species. The reactive radical species ($R^{\bullet}$) then goes on to attack a nearby monomer molecule, thereby starting a propagating chain ($R{-}M^{\bullet}$):

where k_i is the initiation rate constant, usually expressed in L/mol·s. Taking into account these two reactions (production of the free-radical active centers and initiation of the propagating chain), the rate of photoinitiation (R_i), which describes the change in propagating center concentration with respect to time, may be expressed as (33)

$$R_i = \frac{d[R{-}M^{\bullet}]}{dt} = 2f\varphi I_a$$

Here, I_a is the amount of photons absorbed by the photoinitiator molecules expressed in mol photon/L·s or Einstein/L·s; f is the photoinitiator efficiency calculated by determining the moles of propagating chains ($R{-}M^{\bullet}$) started per mole of free-radical active centers ($R^{\bullet}$) generated; and φ is the photoinitiator quantum yield which relates the moles of active center pairs ($R^{\bullet}$) produced per moles photons absorbed (φ is defined such that it is ≤ 1). The integer 2 is included in the expression when both radical species initiate polymerization. If only one of the radical species is active, it is omitted.

Beer's Law, which relates the absorption of light to the concentration of the absorbing species, is used to define I_a for a specified wavelength of light. It is

derived from the partial differential equation used to describe the change in amount of photons as the light passes through an absorbing medium of thickness b:

$$\frac{dI}{db} = -kI \tag{9}$$

where I is the amount of photons in mol photon/(L·s) and k is the absorption coefficient (cm^{-1}), which can also be expressed in terms of the absorbing species concentration and its molar absorptivity as shown below. A bulk-averaged I_a may be obtained by integrating equation 9 over the sample depth:

$$I_a = I_0 - I_t = I_0(1 - e^{-2.3\varepsilon b[I]}) \tag{10}$$

where I_0 is the amount of photons incident upon the sample [mol photon/(L·s)]; I_t is the amount of photons transmitted through the sample [mol photon/(L·s)]; ε is the molar absorptivity of the photoinitiator [L/(mol·cm)]; b is the thickness of reaction system (cm); and [I] is the photoinitiator concentration (mol/L). If the quantity εb[I] is small (<0.01), then equation 10 may be approximated by the first term of its Taylor series expansion (61):

$$I_a = 2.3 I_0 \varepsilon b[I] \tag{11}$$

In systems where the quantity εb[I] is not small, typically in thick systems, equation 10 must be used such that R_i increases proportionally with I_0, but not with [I]. Thus, simply increasing [I] does not result in a homogeneous reaction rate: the upper layers will absorb the largest fraction of the incident light, limiting initiation near the bottom of the system. Therefore, in these systems, conversion at the bottom of the sample is generally much less than at the top unless the initiator concentration and initiating wavelength have been properly chosen.

Several groups have developed models to describe photoinitiation and photopolymerization in thick films or films with high optical densities (62–66). The latest models (62,63) take into account variations in the initiator concentration by solving partial differential equations that describe [I], I_a, and photolysis product concentration as a function of depth and time. If the molar absorptivity, photoinitiator quantum yield, and diffusion properties are known for an initiator system, then these equations can be solved to describe the light intensity gradient in a thick sample and to determine the effects of the initiator absorption characteristics on the efficiency of active center generation for different wavelengths of initiating light.

Propagation. Since chain polymerization kinetics are usually followed for free radically photoinitiated polymerizations, the propagation mechanism involves the addition of monomer to the growing polymer chain:

$$R - M_n^{\cdot} + M \xrightarrow{k_p} R - M_{n+1}^{\cdot} \tag{12}$$

The rate of polymerization (R_p) obtained from this mechanism is as follows:

$$R_p = \frac{d[M]}{dt} = k_p[M][R - M_n^{\bullet}] \tag{13}$$

where k_p is the propagation rate constant [L/(mol·s)] and is generally assumed independent of chain length n. [M] is the reactive group concentration (mol/L), which is equal to the monomer concentration if only one reactive group is present on the monomer molecule.

Termination. Termination of the free-radical active centers may occur either by combination or by disproportionation. In termination by combination, two propagating chains unite to form one long polymer molecule:

$$M_n^{\bullet} + M_m^{\bullet} \xrightarrow{k_{tc}} P_{n+m} \tag{14}$$

In termination by disproportionation, one propagating chain abstracts a hydrogen atom from a neighboring propagating chain, resulting in two polymer molecules, one of them having a terminal double bond:

$$M_n^{\bullet} + M_m^{\bullet} \xrightarrow{k_{td}} P_n + P_m \tag{15}$$

When developing a rate expression for termination, the rate constants for these mechanisms are often lumped in a single termination rate constant, k_t [L/(mol·s)]. The rate of termination, which is generally assumed independent of chain length n, equals the rate of destruction of the propagating active centers ($M^{\bullet}$):

$$R_t = \frac{-d[M_n^{\bullet}]}{dt} = 2k_t[M_n^{\bullet}]^2 \tag{16}$$

Rate of Polymerization. The concentration of growing chains ($R{-}M_n^{\bullet}$) is difficult to measure experimentally; thus, for simplicity, it is often assumed that the change in the concentration of propagating chains over time is very small in comparison to the change in the monomer concentration. According to this pseudo–steady-state assumption, ($d[M_n^{\bullet}]/dt$) is approximated as zero, and the rate of initiation is then equal to the rate of termination. When this is invoked, the rate of polymerization may be written as:

$$R_p = k_p[M]\sqrt{\frac{f\varphi I_a}{k_t}} \tag{17}$$

Similarly, the kinetic chain length (ν), which describes the average number of monomer molecules (or reactive groups for multifunctional monomers) that are consumed per initiating radical, can be calculated as follows:

$$\nu = \frac{R_p}{R_i} \approx \frac{R_p}{R_t} = \frac{k_p[M]}{2\sqrt{k_t f \varphi I_a}} \tag{18}$$

The actual chain length will be shorter if chain transfer reactions occur.

Autoacceleration, where the rate of polymerization increases with conversion in isothermal conditions, is observed in both thermal- and photoinitiated free-radical polymerizations because the termination mechanisms are the same for both. As the chains grow longer, it becomes more difficult for the active centers to diffuse and undergo bimolecular termination; thus, termination frequency decreases and active centers at the chain ends can become trapped. In cases where termination is controlled by diffusion, the pseudo–steady-state assumption is no longer valid and chain length dependent termination (CLDT) may occur (67). As is discussed for chain cross-linking photopolymerizations below, more complicated kinetic treatments must then be considered, including unsteady-state kinetics.

Inhibition. One of the major disadvantages of free-radical photopolymerization is its susceptibility to oxygen inhibition. This is especially troublesome in thin-film and coating applications where oxygen diffusion plays a significant role in increasing cure times and results in incomplete conversion on the surface. When oxygen, which is essentially a biradical in its electronic ground state, reacts with a free-radical active center, it forms a peroxy radical, which is much less reactive (Refs. 3,4, and p. 264 of Ref. 33):

$$\mathrm{M}_\mathrm{n}^\bullet + \mathrm{O}_2 \rightarrow \mathrm{M}_n\text{—O—O}^\bullet$$

$$\mathrm{M}_\mathrm{n}\text{—O—O}^\bullet + \mathrm{M} \rightarrow \text{No reaction}$$

Thus, oxygen effectively acts as a chain terminator and reduces the rate of polymerization until the oxygen in the system has been consumed.

The cost of preventing or minimizing oxygen inhibition is high. In industry, an inert gas such as nitrogen or carbon dioxide may be used to blanket the system. Waxes or shielding films may also be used to prevent oxygen from entering the system. Other methods involve adding oxygen scavengers, dye sensitizers, or antioxidants to capture oxygen and prevent it from reacting with the propagating chains. High photoinitiator concentrations or increased light intensity may also be used to produce a larger number of active centers in order to consume the oxygen in the system faster. However, very close to the surface, it is difficult to consume the oxygen faster than it diffuses into the sample, which can result in tackiness (or incomplete cure) in the surface layers.

Techniques for Measuring Rates and Reactive Intermediates. Kinetic parameters for photopolymerizations may be measured using many different methods or combinations of methods (9,68). Photodifferential scanning calorimetry (PDSC) is a standard technique for obtaining the rate of polymerization (R_p) and conversion (69–73). The conversion of monomer C=C bonds to polymer C—C bonds is an exothermic reaction. The heat flow from the sample (ΔH in W/g) is directly proportional to R_p:

$$R_\mathrm{p} = \frac{\rho \Delta H}{\Delta H_\mathrm{p}}$$

where ρ is the density of the monomer (g/L) and ΔH_p is the heat of polymerization for the reactive group of the monomer (J/mol). The conversion of the sample is

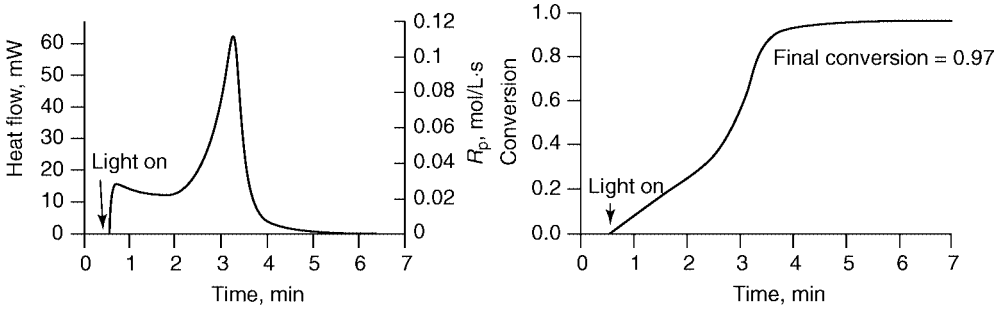


Fig. 7. Photodifferential scanning calorimetry profiles for photopolymerization of 2-hydroxyethyl methacrylate initiated with 2 mmolal dimethoxyphenylacetophenone at 50°C and light intensity of 60 mW/cm^2 with nitrogen purge: polymerization rate (left) and degree of conversion (right).

calculated by integrating the area under the R_p versus time curve, as shown in Figure 7.

Conversion and R_p data may also be obtained using spectroscopic techniques such as Raman spectroscopy (73–75) and infrared spectroscopy (15,50,73,75–77). Here, peaks in these spectra correlate to functional groups within a molecule. As the monomer is converted to polymer, the peaks associated with the C=C bonds decrease. The conversion in the system may be calculated by ratioing this peak height or area at any point in time to the initial peak height or area, as shown in Figure 8:

$$Conversion = 1 - \frac{[M]}{[M]} = 1 - \frac{P_{rxn}(t)/P_{ref}(t)}{P_{rxn}(0)/P_{ref}(0)}$$

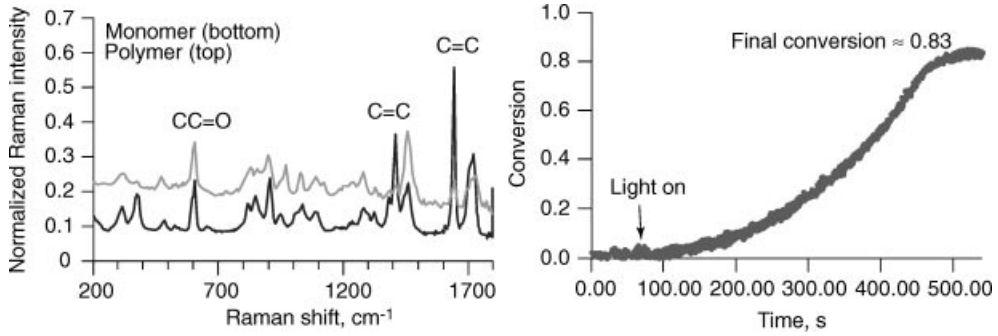

Fig. 8. Raman spectra for photopolymerization of 2-hydroxyethyl methacrylate initiated with 2 mmolal dimethoxyphenylacetophenone at 50°C and light intensity of 75 mW/cm^2: Raman spectra of the monomer and its polymer (left) and degree of monomer conversion based on monitoring the C=C bond depletion at 1640 cm^{-1} (in this system, the internal reference band at 605 cm^{-1} is constant throughout the reaction and cancels out in the conversion ratio) (right).

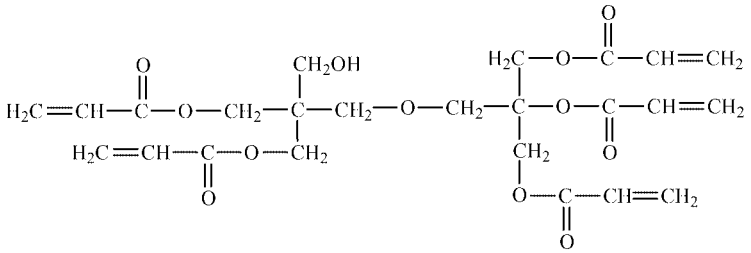
where P_{rxn} is the peak height or area associated with the reactive functionality and P_{ref} is the peak height or area associated with an internal reference. R_p is then calculated by differentiating the conversion curve over time.

Fluorescence spectroscopy has been used to measure conversion by adding fluorescent molecules to the system that are sensitive to physical parameters (such as polarity or viscosity) that can be correlated to conversion (78–80). Both fluorescence (23) and absorption (35) spectroscopy have been used to follow changes in the photoinitiator spectrum as it absorbs light and produces free radicals. More complicated techniques are used to observe the free-radical active centers generated during polymerization. Since the lifetime of a free-radical active center is very short (typically 10^{-1}–10 s) (p. 274 of Ref. 33), sensitive techniques are needed to determine the structure and concentration of initiating or propagating free radicals. These include the addition of trapping agents that ensnare the free radicals through radical combination or hydrogen abstraction, as well as electron spin resonance (ESR) spectroscopy that allows differentiation of radical species, environment, and concentration during reaction (71,81). Other specialized methods include laser flash photolysis (82–84) and photo-chemically induced dynamic nuclear polarization (photo-CIDNP), which provide information on excited state lifetimes and free-radical intermediates (17,84).

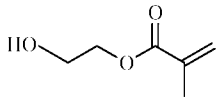
Complex Photopolymerization Systems. Kinetic modeling of free-radical photopolymerizations becomes more complicated as comonomers are added to the reaction system and as different polymerization methods are used to tailor the polymer properties. Although free-radical reaction mechanisms still hold true, rates of propagation and termination must be reconsidered to account for variables such as differences in double bond reactivities, reaction diffusion, and chain transfer.

Chain Cross-Linking Photopolymerizations. In many applications, polymer networks rather than linear chains are desired. The conversion of double bonds in cross-linked systems is often lower because a fraction of the functional groups becomes trapped in areas inaccessible to the active centers. However, polymer networks show improved strength and chemical resistance because degradation of the polymer requires breaking multiple bonds. In order to achieve these types of structures, multifunctional monomers are needed to connect polymer chains together. The monomer itself may then have more than one functional group, as shown in the example (70). Dipentaerythritol pentaacrylate (**23**), a cross-linking monomer, has five reactive sites and is used in protective coating formulations.

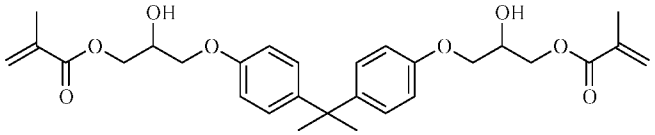


23

Other systems incorporate a monomer with one functional group, which forms the polymer chains, and another monomer with multiple functional groups, which contributes to the chains as well as forming bridges (cross-links) between the chains. For example, 2-hydroxyethyl methacrylate (**24**) and bisphenol A glycidyl methacrylate (**25**) are used in adhesive resins for dental composites:

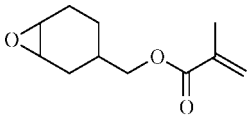


24



25

Cross-linked systems may also be developed in stages. These monomers have one reactive group that undergoes free-radical polymerization and a second reactive group that undergoes cross-linking by another mechanism, such as cationic photopolymerization. One example is the hybrid monomer (3,4-epoxycyclohexyl) methyl methacrylate (**26**) where the acrylate moiety forms the polymer chains first using free-radical photopolymerization and the epoxy moiety forms the cross-links second using cationic photopolymerization (85):



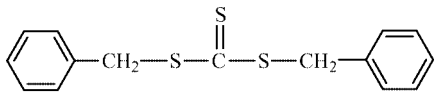
26

The properties of these cross-linked photopolymers are strongly influenced by the cross-link density (ie, the length of the polymer chain between cross-links and the length of the cross-linking molecule itself) (p. 521 of Ref. 33). As the cross-link density increases, hardness and solvent resistance increases, while flexibility decreases (43). The cross-link density can be adjusted by the choice and concentration of the monomers. If different reactive groups are present, then the reactivity ratios of the monomers will determine the rate at which one monomer will react with itself versus the other monomer(s). This will dictate how often a monomer capable of forming a cross-link is added to the main chain. However, in most commercial formulations, mono- and multifunctional monomers with the same type of reactive group (eg, acrylates) are mixed to obtain desired performance properties. Thus, the concentration and number of reactive groups for each monomer will determine the cross-link density.

Kinetic modeling of cross-linked systems is significantly more difficult than for linear systems. Termination mechanisms are more complex because active center trapping (first order or unimolecular termination) and effects of reaction–diffusion must be considered (69,86). Monomers with multiple reactive groups used in highly cross-linking systems may exhibit increased rate of consumption for the pendant reactive groups after the molecule has been included in the polymer chain, resulting in the formation of microgel regions. These structural inhomogeneities are manifested by densely cross-linked regions within a looser polymer

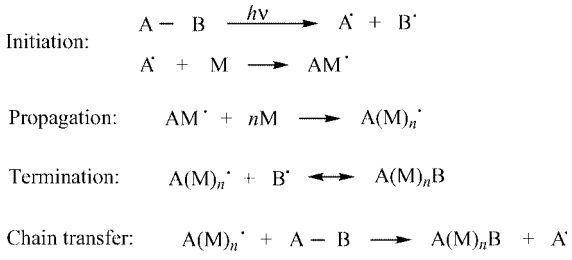
network. Other differences include delayed volume shrinkage with respect to reaction rate (leading to excess free volume) and immediate autoacceleration in the polymerization rate (leading to an increase in radical concentration). Modeling efforts have focused on simulating termination in these systems through incorporating chain-length–dependent termination (67,75,87), combining unimolecular and bimolecular termination equations (69), and considering the impact of diffusion-controlled behavior on the rate constants (72,88,89).

"Living" Free-Radical Photopolymerizations. The ability to control polymer architecture, molecular weight, polydispersity, and end groups enables the development of polymers with improved and specified properties. Living polymerizations, in which propagating chains do not undergo termination or chain transfer reactions and continue to grow until the monomer supply is exhausted, is one way to gain such control (90). Living polymerizations have been successful in systems with ionic active centers; however, bimolecular termination reactions make this difficult to achieve in free-radical polymerizations. Processes such as atom transfer radical polymerization (ATRP) are used in free-radical thermal polymerizations to produce living polymers (91–93) (see LIVING RADICAL POLYMERIZATION). Light-initiated free-radical living polymerizations can be accomplished using iniferters (94). An iniferter participates in the polymerization by serving as an initiator, chain transfer agent, and chain terminator. Photoiniferters generally contain a carbon–sulfur linkage, which cleaves upon illumination to produce a carbon radical and a sulfur radical. Dibenzyl trithiocarbonate (**27**) is an example of such an iniferter (93):



27

The carbon radical ($A^{\bullet}$) is more reactive and serves as the initiation radical, while the sulfur radical ($B^{\bullet}$) is less reactive and serves only as the termination radical (95):



Since termination and chain transfer are still present in iniferter-assisted photopolymerizations, these systems are sometimes described as controlled, rather than living, free-radical polymerizations. Regardless, this approach enables control of bulk free-radical photopolymerizations that is not otherwise

obtainable. Examples of applications include surface modification of substrates (91), three-dimensional nanoscopic patterns (96), and block copolymers (93,97).

Photopolymerization in Microemulsion Systems. Free-radical photopolymerization in microemulsion systems can be used to form stable microlatexes with controlled molecular weight and polydispersity. Microemulsions are two-phase systems, usually consisting of monomer droplets in an aqueous solvent (termed *oil-in-water*) (98,99). Acrylates, methacrylates, and styrenes are typical monomers for microemulsion photopolymerizations. Surfactant molecules are used to stabilize the monomer droplets in solution and to prevent their coalescence. In microemulsions, co-surfactants such as alcohols are often needed to reduce the surface tension of the monomer droplets. This enables further curvature, producing droplets with diameters on the order of 10–50 nm (100). Because of their small size, they do not scatter visible light as do macroemulsions, which are opaque since they contain droplets on the order of 100–1000 nm (101). Thus, microemulsion systems are transparent and allow light to penetrate throughout the system to initiate polymerization within the droplets. Traditional photoinitiators such as benzophenone (102) may be used to generate the free-radical active centers, as well as photoinitiators developed to function as surfactants (103). The kinetics of microemulsion photopolymerizations deviate from the classical bulk kinetics discussed above. Although kinetic expressions for macroemulsions have been developed, a general understanding of microemulsions has not been attained. The surfactant concentration plays an important role in determining the rate of polymerization, along with the light intensity and monomer and photoinitiator concentrations. Termination reactions are suppressed because of the low radical concentration in the droplets and because of diffusional limitations within the droplets, resulting in higher molecular weight polymers (104,105).

Hybrid Photopolymerizations. Hybrid resin systems consist of monomers possessing two different functional groups—one that photopolymerizes by a free-radical active center (such as an acrylate) and the other by a cationic active center (such as an epoxide) (85,106–109). The two functional groups may be combined in one formulation either as separate monomers or as one monomer with both functionalities. If the functional groups are on different molecules, entangled chains or interpenetrating networks will be produced; cross-linked structures will result if the functional groups are on the same molecule because the polymer chains can be connected via either reactive bond.

The systems are designed in order to improve the reaction rate of the mixture and the physical properties of the photopolymer. The flexibility of the two photoinitiation schemes in one system allows for numerous possibilities in achieving greater control of viscosity, conversion, shrinkage, adhesion, and ultimate strength. The kinetics of hybrid photopolymerization systems are more difficult because two reactive systems (free-radical and cationic) must be resolved from one another. Cationic photopolymerization kinetics are more difficult to analyze than free-radical kinetics because the pseudo–steady-state assumption is often not valid for the cationic active center concentration, and the nature and concentration of the cationic active centers is difficult to determine (p. 376 of Ref. 33, see also Photopolymerization, Cationic).

Applications

Free-radical photopolymerizations have been traditionally applied to thin films and coatings where the light penetration is less of an issue (εb[I] is more likely to be small), high production speeds can be achieved, and formulations free from volatile emissions are desirable. In this way, the disadvantages of free-radical photopolymerization, such as poor conversion in thick or strongly absorbing systems, in the presence of oxygen, and in vitrifying systems at ambient temperatures, may be minimized. Despite these limitations, applications of free-radical photopolymerization are far-reaching and encompass the automotive, electronic, medical, optical, graphic arts, flooring, and furniture industries, to name a few. Photopolymerizations continue to expand into previously uncontemplated areas such as topcoats for automobiles, thick parts and composite structures, and biomedical implants as more industries begin to appreciate the advantages these light-induced reactions have over traditional, thermal polymerization methods (1,2,110,111).

Films, Coatings, and Adhesives. Photopolymers may be used as coatings (qv) for a wide range of substrates, including wood, glass, paper, metals, and plastics (2–4,44,110,112–115). These coatings serve to protect surfaces from scratches and chemical exposure, to provide decoration and color, and to allow modification of surface properties. At present, most coatings are applied as a liquid monomer formulation and then photopolymerized; however, photocurable powder coatings are being developed and are expected to have a huge impact in metal-, paper-, and wood-coating applications (2,4). Free radically photopolymerized adhesives provide bonding between laminates, such as glass panes or plastic films. Pressure-sensitive adhesives and release coatings are used to make tapes, labels, and stickers (116,117). Photocurable inks are used on packaging materials and magazines, and photocurable varnishes provide glossy coatings for graphic media.

Optics and Photoimaging. Advanced applications of free-radical photopolymerizations include development of optical devices (118–120). The rapid reaction rates afforded by free-radical photopolymerizations have been able to incorporate liquid crystal order in polymers used for displays, waveguides, and holographic gratings (121,122). Films and coatings for optical components, optical fibers, and eyeglasses also benefit from the flexibility and transparency of these photopolymer materials. In the optical fiber industry alone, several photopolymer coatings are used (123–126). A soft, rubbery primary coating is applied to glass fibers as a cushion against stresses and as a barrier against moisture. A hard secondary coating is applied over the primary coating to prevent damage to the fiber during use. Photoimaging techniques are based on the advantage of spatial control over photoinitiation. This has led to tremendous growth in holographic and lithographic applications and even to rapid prototyping of three-dimensional parts through stereolithography (3,127,128). Patterns for gratings, printed circuit boards, and integrated circuits may be created in photoimageable or photoresist materials using photomasks or computer-controlled lasers (129,130). Microlithography can also be used to develop photopolymer membranes on microfluidic chips to perform chemical separations (131,132).

Biomaterials. In recent years, photopolymerizations have become more prominent in biological applications because these systems can provide superior

products with rapid reaction rates at room temperature. Photopolymerizations for biological applications are more challenging because of the numerous considerations with regard to safety and health. For example, resin formulations and final products must have zero toxicity when introducing these systems into a biological system. Since the migration of small molecules may cause health problems, high conversions of monomer and low concentrations of residual photoinitiator are desirable. When photopolymerizations are conducted *in vivo*, the formulations must be polymerizable by visible light (to prevent cellular damage), and the reactions must not be hampered by atmospheric oxygen or high water concentrations. If the polymers are designed to biodegrade, then the degradation products themselves must not cause health complications (see BIODEGRADABLE POLYMERS, MEDICAL APPLICATIONS). In addition, polymers that will be used *in vivo* must be biocompatible, as well as sterilizable (133). Scaffolding for bone and tissue engineering (qv), bioadhesives for wound closure, and microchips for biochemical analysis are examples of biomaterials produced using free-radical photopolymerizations (134,139).

Hydrogels. Free-radical photopolymerization can be used to produce cross-linked hydrophilic polymer networks that have numerous applications as biomaterials. These hydrogels (qv) are insoluable, but can swell with water to produce soft polymers that have mechanical integrity. Biomedical applications of hydrogels include delivery systems for drugs, enzymes and proteins (140–143); wound dressings (133); and biosensors for detection of glucose and other bioproducts (144). Soft contact lenses are optically transparent hydrogels produced by photopolymerization of mono- and dimethacrylates in a mold (145,146).

Dental Composites. Photopolymers are quickly replacing traditional amalgams for the repair of tooth caries and defects (147) (see DENTAL APPLICATIONS). The photopolymers may be matched to the color of the tooth, and treatment does not require the cutting away of natural tooth structures for bonding. A resin adhesive, which contains a mono-(meth)acrylate as a reactive diluent and a multi-(meth)acrylate as a cross-linker, is applied to the prepped tooth to provide a bond between the tooth and filling. The resin composite, which contains multi-(meth)acrylates for cross-linking and silica fillers to reduce shrinkage stresses, is photopolymerized in incremental layers upon the adhesive base to form the tooth filling. Both the adhesive and composite resins use a visible light free-radical photoinitiator system (camphorquinone with an amine co-initiator) with a blue light source (139,148). Photopolymerization of each layer takes place in less than one minute.

PLASTICS PROCESSING

Introduction

Plastics are classified as thermoplastic or thermosetting resins, depending on the effect of heat. Thermoplastic resins, when heated during processing, soften and flow as viscous liquids; when cooled, they solidify. The heating/cooling cycle can be repeated many times with little loss in properties. Thermosetting resins liquefy when heated and solidify with continued heating; the polymer undergoes permanent cross-linking and retains its shape during subsequent cooling/heating cycles (see THERMOSETS). Thus, a thermoset cannot be reheated and molded again. However, thermoplastics can be melt-reprocessed, and hence readily recycled (see RECYCLING, PLASTICS).

Thermoplastic Resins. Almost 85% of the resins produced are thermoplastics (1,2). Although a number of chemically different types of thermoplastics are available in the market, they can be divided into two broad classes: amorphous and crystalline. Amorphous thermoplastics shown in Table 1 (3) are characterized by their glass-transition temperature T_g a temperature above which the modulus decreases rapidly and the polymer exhibits liquid-like properties; amorphous thermoplastics are normally processed at temperatures well above their T_g (see AMORPHOUS POLYMERS). Semicrystalline resins shown in Table 2 (3) can have different degrees of crystallinity ranging from 50 to 95%; they are normally processed above the melting point T_m of the crystalline phase (see SEMICRYSTALLINE POLYMERS). Upon cooling, crystallization must occur quickly, ie, in a few seconds. Addition of nucleating agents increases the crystallization rate (see CRYSTALLIZATION KINETICS). Additional crystallization often takes place after cooling and during the first few hours following melt processing.

Over 70% of the total volume of thermoplastics is accounted for by the commodity resins: polyethylene, polypropylene, polystyrene, and poly(vinyl

Table 1. Glass-Transition Temperature of Amorphous Thermoplastics[a]

Polymer	T_g, °C
Polyamideimide (PAI)	295
Polyethersulfone (PES)	230
Polyarylsulfone (PAS)	220
Polyethermide (PEI)	218
Polyarylate (PAR)	198
Polysulfone (PSU)	190
Polyamide, amorphous (PA)	155
Polycarbonate (PC)	145
Styrene–maleic anhydride (SMA)	122
Chlorinated PVC (CPVC)	107
Poly(methyl methacrylate) (PMMA)	105
Styrene–acrylonitrile (SAN)	104
Polystyrene (PS)	100
Acrylonitrile–butadiene–styrene (ABS)	100
Poly(ethylene terephthalate) (PET)	67
Poly(vinyl chloride) (PVC)	65

[a] Ref. 3.

chloride) (PVC) (1) (see ETHYLENE POLYMERS, HDPE; ETHYLENE POLYMERS, LDPE; ETHYLENE POLYMERS, LLDPE; PROPYLENE POLYMERS (PP); STYRENE POLYMERS; VINYL CHLORIDE POLYMERS). They are made in a variety of grades and because of their low cost are the first choice for a variety of applications. Next in performance and in cost are acrylics, cellulosics, and acrylonitrile–butadiene–styrene (ABS)

Table 2. Melting Temperature of Semicrystalline Thermoplastics[a]

Polymer	T_m, °C
Polyetherketone (PEK)	365
Polyetheretherketone (PEEK)	334
Polytetrafluoroethylene (PTFE)	327
Poly(phenylene sulfide) (PPS)	285
Liquid crystal polymer (LCP)	280
Nylon-6,6[b]	265
Poly(ethylene terephthalate) (PET)	260
Nylon-6[b]	220
Nylon-6,12[b]	212
Nylon-11[b]	185
Nylon-12[b]	178
Acetal resin[c]	175
Polypropylene (PP)	170
High density polyethylene (HDPE)	135
Low density polyethylene (LDPE)	112

terpolymers (see ACRYLIC ESTER POLYMERS; ACRYLONITRILE AND ACRYLONITRILE POLYMERS; CELLULOSE ESTERS, INORGANIC). Engineering thermoplastics (qv) such as acetal resins, polyamides (qv), polycarbonates (qv), thermoplastic polyesters (qv), and poly(phenylene sulfide), and advanced materials such as liquid crystal polymers, polysulfones (qv), and polyetheretherketones are used in high performance applications; they are processed at higher temperatures than their commodity counterparts.

With few exceptions, thermoplastics are marketed in the form of pellets. They are shipped in containers of various sizes, from 25-kg bags to railroad hopper cars. Resins are conveyed to silos for storage and from there to the processing equipment. Colored resins are available, but frequently it is more convenient and economical to buy uncolored resins and blend them with color concentrates. Using concentrates avoids handling dusty pigments and ensures uniform color distribution.

The packaging requirements for shipping and storage of thermoplastic resins depend on the moisture that can be absorbed by the resin and its effect when the material is heated to processing temperatures. Excess moisture may result in undesirable degradation during melt processing and inferior properties. Condensation polymers such as nylons and polyesters need to be specially predried to very low moisture levels (4,5), ie, less than 0.2% for nylon-6,6 and as low as 0.005% for poly(ethylene terephthalate) (PET), which hydrolyzes faster.

Thermoplastic Processing. A variety of processing equipment and shaping methods are available to fabricate the desired thermoplastic product (6–10). Extrusion (qv) is the most popular. Approximately 50% of all commodity thermoplastics are used in extrusion process equipment to produce profiles, pipe and tubing, film, sheet, wire, and cable (1). Injection molding (qv) follows as a preferred processing method, accounting for about 15% of all commodity thermoplastics. Other common methods include blow molding (qv), rotational molding (qv), thermoforming (qv), calendering, and, to some extent, compression molding. Details on the amounts of resins converted annually in the United States in terms of processes and products can be found in the following year's January issue of *Modern Plastics*. Computer-aided design software for molds and extruder screws is commercially available. These programs assist in the selection and fabrication of processing equipment, thereby saving research and development time. Modeling and simulation of polymer processing is described in specialized textbooks (11–17).

The range of processes that may be used for fabricating a plastics product is determined by the scale of production, the cost of the machine and the mold, and the capabilities and limitations of the individual processes. For example, complex and precise shapes can be achieved by injection molding, hollow objects via blow molding and rotational molding, and continuous lengths by extrusion.

Thermoplastics processing operations produce emissions into the air, wastewater, and solid waste resulting from both polymers and additives. Most important are volatile organic compounds emitted from heated cylinders and molds. The identification of such volatiles and the development of analytical techniques for measuring their concentration in the workplace are of paramount importance to establish or revise threshold limit values that would minimize exposure to hazardous chemical substances. Environmental issues in polymer processing are reviewed in References 18 and 19.

Extrusion

Extrusion is defined as continuously forcing a molten material through a shaping device. Because the viscosity of most plastic melts is high, extrusion requires the development of pressure in order to force the melt through a die. Manufacturers of plastic resins generally incorporate stabilizers and modifiers and sell the product in the form of cylindrical, spherical, or cubic pellets of about 2–3 mm in diameter. The end-product manufacturers remelt these pellets and extrude specific profiles, such as film, sheet, tubing, wire coating, or as a molten tube of resin (parison) for blow molding or into molds, as in injection molding.

To provide a homogeneous product, incorporation of any additives, such as antioxidants (qv), colorants (qv), and fillers (qv), requires mixing them into the plastic when it is in a molten state. This is done primarily in an extruder. The extruder, as shown in Figure 1, accepts dry solid feed (F, E, J) and melts the plastic by a combination of heat transfer through the barrel (B, C) and dissipation of work energy from the extruder drive motor (I). In the act of melting, and in subsequent sections along the barrel, the required amount of mixing is usually achieved. Venting may also be accomplished to remove undesirable volatile components, usually under vacuum through an additional deep-channel section and side vent port. The final portion of the extruder (L) is used to develop the pressure [$\leq$50 MPa (7500 psi)] for pumping the homogenized melt through a filtering screen (optional) and then through a shaping die attached to the end of the extruder.

Extruders are defined by their screw diameter and length, with the length expressed in terms of the length-to-diameter ratio (L/D). Single-screw extruders

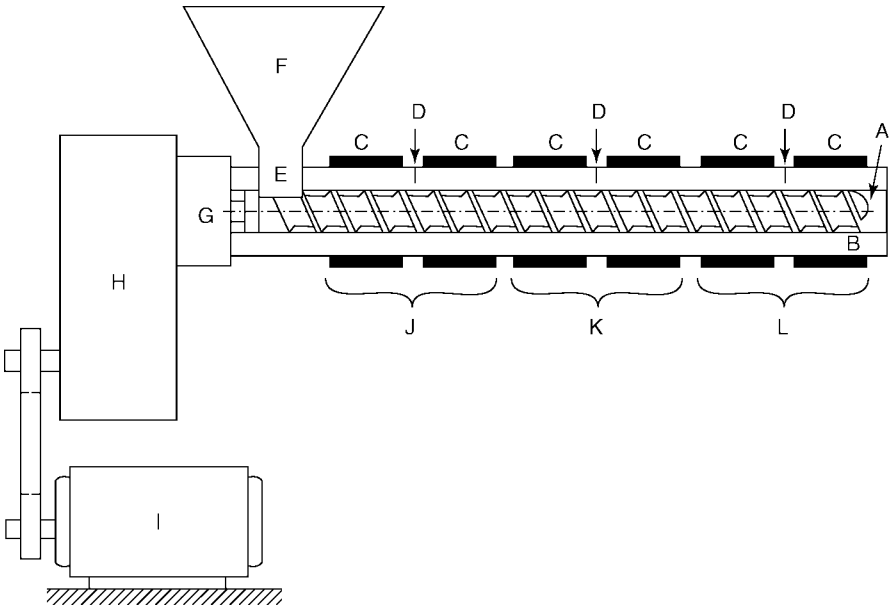

Fig. 1. Parts of an extruder: A, screw; B, barrel; C, heater; D, thermocouple; E, feed throat; F, hopper; G, thrust bearing; H, gear reducer; I, motor; J, deep-channel feed section; K, tapered channel transition section; and L, shallow channel metering section (20).

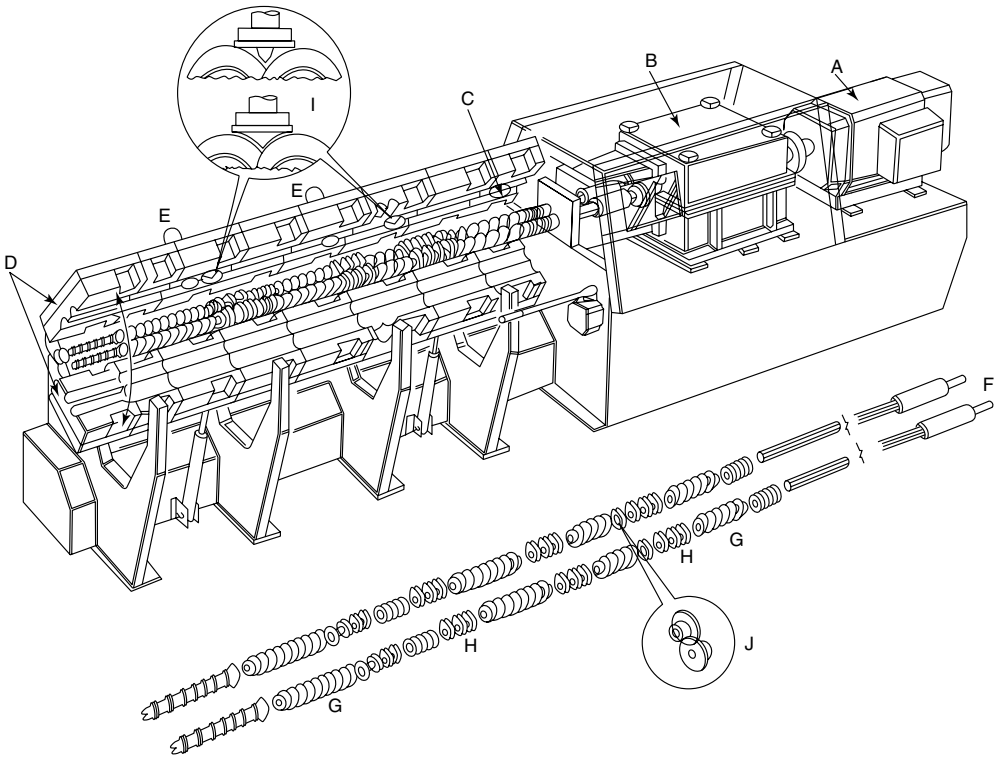

Fig. 2. Intermeshing corotating twin-screw extruder: A, motor; B, gear box; C, feed port; D, clam shell barrel; E, vent port; F, screw shafts; G, conveying screws; H, kneading paddles; I, barrel valve; and J, blister rings. Courtesy of APV Chemical Machinery Inc.

range from small laboratory size (6 mm diameter) to large commercial units (450 mm diameter) capable of processing up to 20 t/h. Melt-fed extruders run at a L/D of about 8; solids-fed extruders run at a L/D of about 20–40 depending on whether intermediate venting is provided.

Varieties of twin-screw extruders are also utilized, particularly when the ingredient mixing requirements are difficult to fulfill or require multiple staging, as in reactive extrusion. Twin-screw extruders are classified as being tangential or intermeshing, and the latter as being counter- or corotating. These extruders are generally supplied with slip-on conveying and kneading screw elements and segmented barrels. These elements, shown in Figure 2, give the processor improved mixing and pumping versatility. Single-screw extruders are usually flood-fed, with the feed rate determined by screw speed. Twin-screw extruders are generally starve-fed. Starve feeding permits greater flexibility in operation as screw speed now becomes a process control variable, independent of feed rate.

Reactive extrusion is the term used to describe the use of an extruder as a continuous reactor for polymerization or polymer modification by chemical reaction (21,22). Extruders are uniquely suitable for carrying out such reactions because of their ability to pump and mix highly viscous materials. Extruders readily permit multiple process steps in a single machine, including melting, metering, mixing, reacting, side-stream addition, and venting.

Recent developments in extrusion equipment include the increased use of microprocessor control systems and a variety of on-line monitoring systems for product quality assurance.

Mechanism of Extruder Operation. An extruder employs drag flow to perform a conveying action that depends on the relative motion between the screw and the barrel. With higher friction on the barrel than on the screw, the solids are conveyed almost as solid plug in the deep-feed channel section. As the channel depth becomes shallower, the compressive action causes more frictional heat, which, combined with the conduction supplied by the barrel heaters, causes the plastic to melt. The molten plastic then enters a constant shallow depth section of the screw called the metering section, where the pumping pressure necessary for extrusion through the final shaping die is developed.

The drag flow or volumetric conveying capability Q_d for the plastic melt is dependent only on screw speed N and the geometry A of the screw:

$$Q_d = AN$$

The drag flow is most easily visualized by unwrapping the screw and dragging a flattened barrel surface diagonally across the channel (Fig. 3).

At the discharge end of the metering section, enough pressure must be generated to overcome the resistance of the transfer piping and the shaping die. This same pressure in effect also causes the plastic melt to want to flow back down the channel and possibly also over the flight tips. This pressure flow Q_p, is dependent on the screw geometry B, pressure driving force ΔP, filled length of the screw L, and melt viscosity μ:

$$Q_p = B\Delta P/\mu L$$

The pressure flow is independent of screw speed, except as the latter affects the viscosity of the melt.

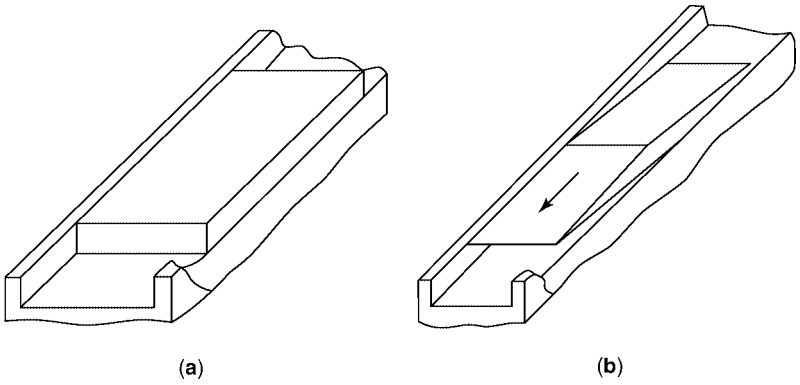

Fig. 3. (**a**) Channel with block of molten plastic; (**b**) channel with moved block of molten plastic; arrow indicates direction of material movement (20).

The net flow Q of an extruder is simply the difference between drag and pressure flows:

$$Q = Q_d - Q_p$$

The pressure and drag flow equations for twin-screw extruders are similar to those expressed above for single-screw extruders but with different geometric constants. The amount being forwarded per revolution (Q_d/N) for fully intermeshing co-rotating twin-screw extruders is one half of the process volume contained in one turn of the screw:

$$Q_d/N = 1.54hDz$$

Where h is the channel depth, D is the screw diameter, and z is the lead length of the screw (23).

Mixing in Extruders. In addition to the conveying and melting steps, extruders perform the vital task of homogenization of additives such as Fillers (qv), stabilizers, and pigments into the base resin (24,25). Incorporation of powdered filters is best accomplished by downstream addition into the barrel after the polymer resin is fully melted. Otherwise, the forces that are generated during melting can cause severe abrasive wear of screws and barrels, and frequently can lead to difficult-to-disperse agglomerates formed by compaction.

If the cross-channel mixing provided by the drag and pressure flows in single-screw extruders is insufficient, various mixing enhancers are available. These generally ensure dispersion by forced passage over a higher shear-restricting slot or an improved distribution by multiple reorientations of flow and sequences of extensional flow.

Mixing in twin-screw extruders benefits from the additional interaction of the two screws with each other as well as with the barrel. Various arrays of kneading paddles are generally used in the most common type, namely the co-rotating, intermeshing, twin-screw extruder. The kneading paddles improve mixing by causing extensive melt reorientation, backmixing, and elongational flow patterns (26).

Further information on extruder operation and plastic processing is available (17,20,27–36). Technology updates and equipment options for specific processing steps are provided annually in publications such as the *Plastics Compounding Redbook* and in *Modern Plastics Encyclopedia*.

Pipe and Tubing. A typical die for extruding tubular products is shown in Figure 4. It is an in-line design, ie, the center of the extruded pipe is concentric with the extruder barrel. The extrudate is formed into a tube by the male and female die parts. The male die part is supported in the center by a spider mandrel. Melt flows around legs of the mandrel and meets on the downstream side. The position of the female die part can be adjusted with bolts; adjustment is required to obtain a tube with a uniform wall thickness.

A vacuum calibrator usually is used for controlled cooling of the tube, as shown in Figure 5. It is a long, closed tank that contains cooling water and uses a vacuum to maintain a constant tube diameter and thickness.

The molten tube enters the tank through a series of cooling rings, and atmospheric pressure inside the tube forces the melt against the rings. The rings

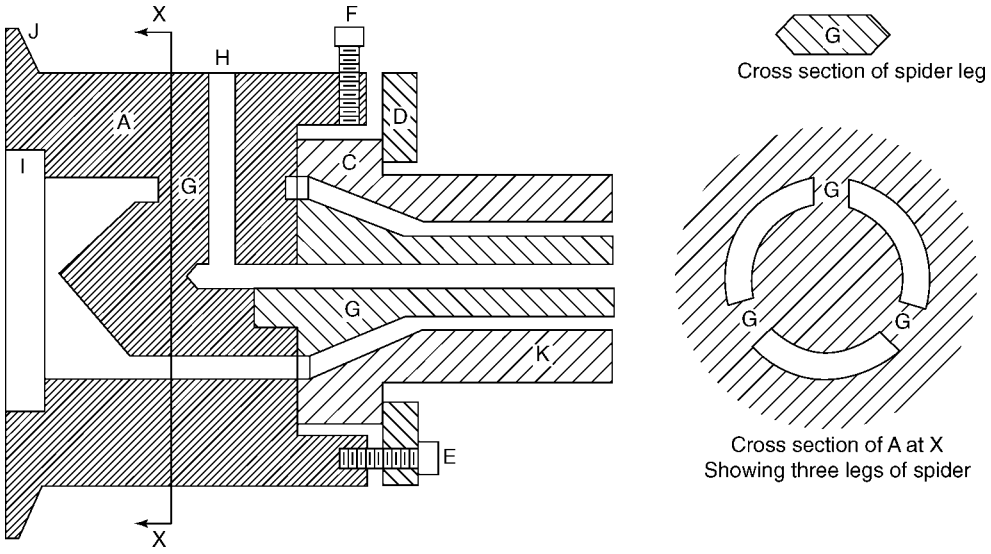

Fig. 4. Pipe or tubing die for in-line extrusion: A, die body; B, mandrel, pin, and male die part; C, die, die bushing, and female part; D, die-retaining ring; E, die-retaining bolt; F, die-centered bolt; G, spider leg; H, air hole; I, seat for breaker plate; J, ring for attachment to extruder; and K, die land (20).

control the expansion of the tube and establish its outside diameters. Water cools the tube and adds strength to it, allowing it to withstand expansion forces. The tube exits the tank through a rubber gasket. A variable-speed takeoff controls the rate at which the tube is pulled through the tank.

Tubing extrusion usually involves drawdown of the resin from the die, ie, the diameter and wall thickness of the tubing are less than that of the die opening. The amount of drawdown is expressed as the ratio of the cross-sectional area of the die opening to the cross-sectional area of the tube wall. Drawdowns in tubing

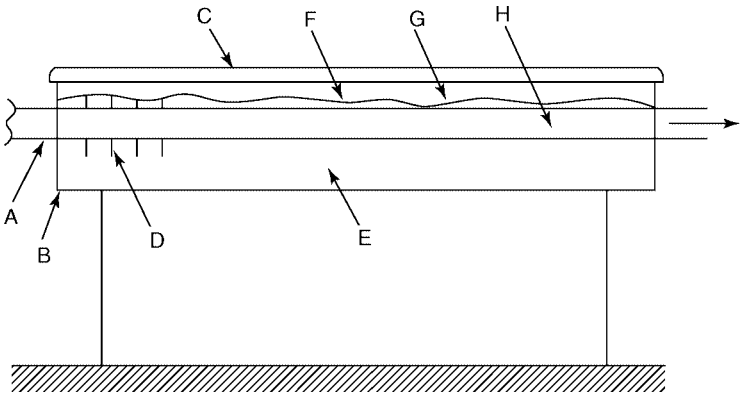

Fig. 5. Vacuum calibrator for pipe and tubing extrusion: A, molten tube from die; B, tank; C, hinged cover with gasket; D, sizing rings; E, circulated and temperature-controlled water; F, water level; G, vacuum; and H, inside of pipe open to atmospheric pressure (20).

extrusion usually range from 2:1 to 8:1. Drawdown in pipe extrusion is often less than 1.1:1. Pipe and tubing may be cut in straight lengths or may be coiled, depending on use and stiffness, eg, polyethylene pipe usually is cut to length, whereas laboratory tubing is coiled. ABS and PVC pipe are made in straight lengths, and soda straws are cut in short lengths.

Pipe extrusion is commonly used in the manufacture of thick-walled products. Die openings are large and resistance to flow is small. Cooling of the pipe is slow because plastics are poor conductors of heat. Long quench tanks and good circulation of cooling water are needed. Low melt temperatures relative to melting or softening points characterize pipe extrusion. Large die openings permit the use of viscous, high molecular weight resins, which yield tougher products.

Profile Extrusion. This method is similar to pipe and tubing extrusion, except that special profile dies are used to produce a variety of asymmetrical products. Typical products include housing siding, window sash molding, decorative trim, plastic lumber, gaskets, and channels. Dies for profile extrusion are designed to allow for shape changes that occur during quenching. Usually, a water trough is used for cooling, but air or cooled metal surfaces are also used. Profile extrusion typically relies on amorphous thermoplastics, such as PVC, ABS, polystyrene, thermoplastic elastomers, etc. The rapid shrinkage accompanying crystallization can result in severe distortion of the profile.

Foam Extrusion. Foamed thermoplastics provide excellent insulating properties because of their very low thermal conductivity, good shape retention, and good resistance to moisture pickup. As such, cylindrical shapes are extruded for pipe insulation, and sheets for building panel insulation. Chemical blowing agents are usually solid powders that can be incorporated into molten plastics without reacting to release their by-product gases until subsequently heated to a higher temperature. Physical blowing agents are dissolved and held in solution by the pressure developed in the extruder (37). As the molten thermoplastic exits the extruder die, the pressure release causes instantaneous foaming. The chlorinated fluorocarbons formerly used as blowing agents have been replaced with more environmentally friendly substitutes, such as hydrochlorofluro carbons (HCFCs) or low molecular weight hydrocarbons such as butane or isopentane. For some thermoplastics, carbon dioxide, nitrogen, or argon can be used (38,39). Critical to the success of most foaming extrusion operations is cooling of the melt just prior to entry to the die. Cooling is most effectively accomplished with a tandem arrangement of two extruders, as shown in Figure 6, wherein the first extruder ensures complete dissolution of the blowing agent, and the second extruder is operated at slow speed for optimum cooling. Additional information on extrusion of foams is contained in References 28,37, and 40 (see CELLULAR MATERIALS).

Film Forming Processes

Blown Film. The blown film process (Fig. 7) uses a tubular die from which the extrudate expands in diameter while traveling upward to a film tower. The top of the tower has a collapsing frame followed by guide and pull rolls to transport the collapsed film to subsequent slitting and windup rolls. The tubular bubble from the die is inflated to the desired diameter by air passing through the center of the

die. Although primary cooling to solidify the melt is supplied by an external air ring, chilled air may also be used internally. Polyethylene is the primary plastic used in most films, especially for packaging and trash bags. Coaxial dies can be used for manufacture of coextruded multilayer films.

The tube is characterized by its blow-up ratio, ie, a larger diameter than the die opening, which is expressed as the ratio of bubble diameter to the die diameter. Typical blow-up ratios range from 2:1 to 4:1. The final film thickness is much thinner than the die gap. Die gaps are slits of ca 0.65 mm. Typical film thicknesses are 0.007–0.125 mm. The process requires a high melt viscosity resin so that the melt can be pulled from the die in an upward direction. Since only air is used for cooling, removal of heat tends to be slow and rate-limiting. Chilled air can also be used internally to improve the efficiency of the air cooling process. The film may be treated for subsequent printing, and it can be slit into various widths and wound onto separate cores.

Cast Film. The cast film process provides a film with gloss and sparkle and can be used with various resins. Figure 8 is an illustration of the essential features of the extrusion equipment. The die opening is a long straight slit with an adjustable gap ca 0.4 mm wide. The die is positioned carefully with respect to the casting roll. The casting or chill roll is highly polished and plated and imparts a smooth and virtually flawless surface to the film. The roll is cooled by rapid circulation of water. Temperature control is critical. A die somewhat longer than the width of the film is needed, because the molten web becomes narrow as it is drawn from the die; this is called neck-in. Edges of the film thicken and are mechanically removed before the film is wound on a roll. The edge trim can be reprocessed.

One of the requirements of this process is that the melt maintain good contact with the chill roll, ie, air must not pass between the film and the roll. Otherwise, air insulates the plastic and causes it to cool at a rate different from the rest of the plastic and this spoils the appearance of an otherwise satisfactory product. The melt should not emit volatiles, which condense on the chill roll, reduce heat

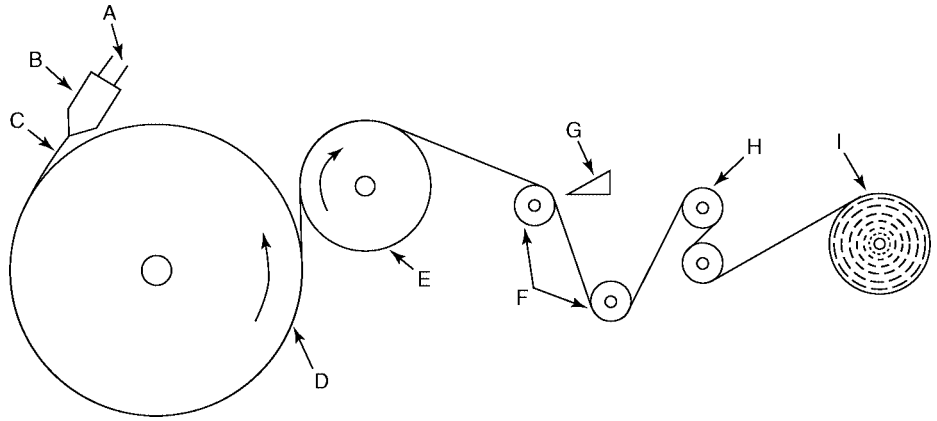

Fig. 8. Extrusion of roll-cast film: A, die inlet; B, cast-film die; C, air gap with molten web; D, casting roll; E, stripping roll; F, idler roll; G, edge-trim slitter; H, pull rolls; and I, windup roll (20).

transfer, and mar the film's appearance. The cast film process allows the use of a higher melt temperature than is characteristic of the blown film process. The higher temperature imparts better optical properties.

Film stretching is a process to impart biaxial orientation in the film by stretching it in two directions simultaneously, the transverse and machine directions, respectively. The process is carried out in a device that grips the edges of the film and extends them to larger widths as the film moves from the inlet to the exit roller. The objective is to increase the modulus and strength of the film uniformly along the entire film plane. Polypropylene and PET have been used successfully in this process (41).

Sheet. The process used to make an extruded plastic sheet is illustrated in Figure 9. Sheeting thicknesses are 0.25–5 mm and widths are as great as 3 m. Heavier gauge sheets are usually cut to a specified length and are stacked. Cooling is controlled by a three-roll stack. The rolls are 25–50 cm in diameter, highly polished, and chrome-plated. They are cored for cooling with circulating water, and the temperature of each roll is controlled by a circulator and temperature control unit. Often the rolls are operated at high temperature to maximize the gloss of the sheeting surface.

A web of molten plastic is pulled from the die into the nip between the top and middle rolls. At the nip, there is a very small rolling bank of melt. Pressure between the rolls is adjusted to produce sheet of the proper thickness and surface appearance. The necessary amount of pressure depends on the viscosity. For a given width, thickness depends on the balance between extruder output rate and the takeoff rate of the pull rolls. A change in either the extruder screw speed or the pull-roll speed affects thickness. A constant thickness across the sheet requires a constant thickness of melt from the die. The die is equipped with bolts for adjusting the die-gap opening and with an adjustable choker bar or dam located inside the die a few centimeters behind the die opening. The choker bar restricts flow in the center of the die, helping to maintain a uniform flow rate across the entire die width.

Drawdown from the die to nip is typically ca 10%. Sheet extrusion requires that the resin be of high melt viscosity to prevent excessive sag of the melt between

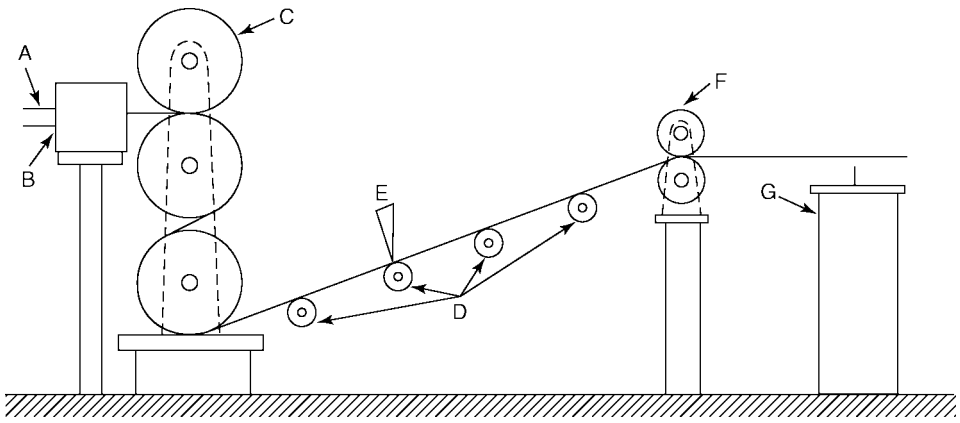

Fig. 9. Sheet extrusion: A, die inlet; B, die; C, three-roll finisher; D, support rollers; E, edge-trim cutter; F, pull rolls; and G, saw or shear (20).

the die and the nip. The melt should reach the nip before touching any other part of the middle roll to prevent uncontrolled cooling of the resin. The appearance of the lower surface of the sheet is determined by the middle roll, ie, its polish, surface temperature, and freedom from condensed materials. The upper surface is cooled by air and has a more glossy appearance. Neither the top roll nor the bottom roll greatly affects the appearance of the top surface of the sheet. Edges of the sheet are trimmed.

Multilayer structures can be formed by simultaneous coextrusion of different layers through a feed block die. The individual layers can be selected for their specific attributes, such as strength, barrier properties, etc, or for incorporation of recycled material. When the basic layers are incompatible, tie layers can also be included to form a cohesive composite structure.

There usually is no need for a high melt temperature to obtain flow through a sheeting die, because die openings are large. Cooling of the sheet is slow because sheeting is thick. Most sheeting is used for thermoforming.

Extrusion Coating. A coating of an appropriate thermoplastic, such as polyethylene, may be applied to a substrate of paper, thin cardboard, or foil to provide a surface property which enables heat sealing or better barrier performance (see BARRIER POLYMERS). Figure 10 is a sketch of the extrusion-coating process. A molten web of resin is extruded downward, and the web and substrate make contact at the nip between a pressure roll and a chill roll. Typical coating thicknesses are 0.005–0.25 mm; the die opening is ca 0.5 mm. The melt web is narrower than the die, which is characteristic of a neck-in, and the edge tends to bead or thicken. Coated substrate is trimmed to the desired width. The highly polished and water-cooled chill roll determines the nature of the surface and removes the heat from the resin. The pressure roll pushes the substrate and the molten resin against the chill roll. Pressure and high melt temperatures are needed for adhesion of resin and substrate.

In contrast to most extrusion processes, extrusion coating involves a hot melt, ca 340°C. The thin web cools rapidly between the die and nip even at high linear rates. Both mechanical and chemical bonding to substrates are involved. Mechanical locking of resin around fibers contributes to the resin's adhesion to paper. Some oxidation of the melt takes place in the air gap, thereby providing

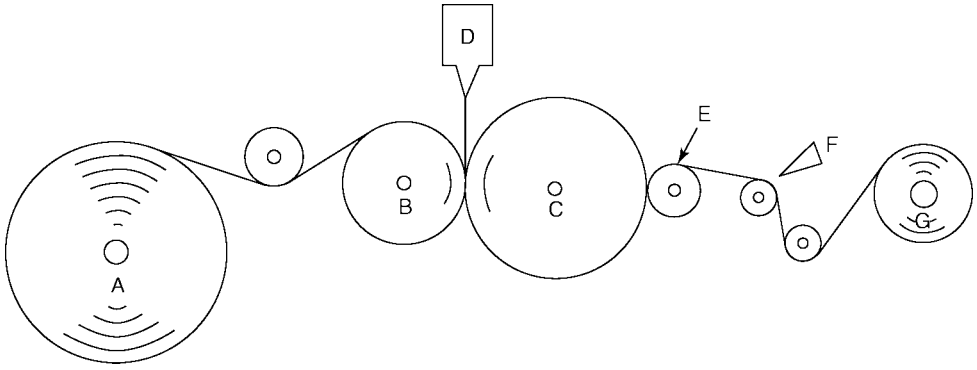

Fig. 10. Extrusion coating: A, unwinding of substrate; B, pressure roll; C, chill roll; D, die; E, stripper roll; F, edge trimmer; and G, windup of coated substrate (20).

sites for chemical bonding to aluminum foil. Excessive oxidation causes poor heat-sealing characteristics.

Wire and Cable Coating. Protective and insulating coatings can be applied continuously to wire as it is drawn through a cross-head die, as shown in Figure 11. A typical wire coating line consists of a wire payoff, wire preheater, extruder, die, cooling trough, capstan, and wire takeup (Fig. 12).

The melt flows from the extruder into the die where it flows around the bend and around the core tube. On the far side of the core tube, it forms a weld. Melt sticks to and is pulled by the moving wire. Details of the sizes and shapes of the die parts in contact with the melt are important in obtaining a smooth coating at high rates. The die exit usually is the same diameter as that of the coated wire and there is little drawdown. Die openings are small and pressures inside the die are high at ca 35 MPa (5000 psi). Wire take-up systems operate as high as 2000 m/min.

Injection Molding

In injection molding a molten thermoplastic is injected under high pressure into a steel mold. After the plastic solidifies, the mold is opened and a part in the shape

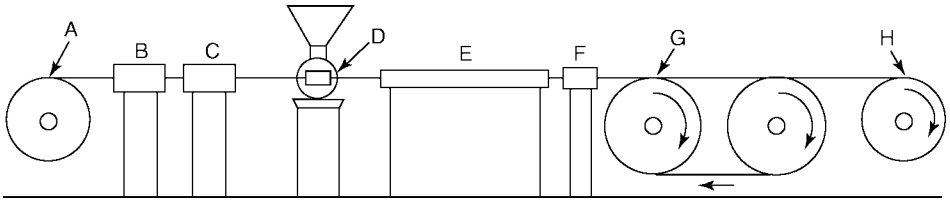

Fig. 12. Wire-coating line: A, unwinding of wire (payoff); B, straightener; C, preheater; D, extruder; E, water trough; F, tester; G, capstan (puller); and H, windup of coated wire (20).

of the mold cavity is removed. General descriptions of the process and related equipment are given in References 2 and 42–45.

Equipment. The machine consists of an injection unit and a clamp unit. The injection unit is usually a reciprocating single-screw extruder that melts the plastic and injects it into the mold or tool. The clamp unit opens, closes, and holds the mold closed against the pressure of injection. The size of an injection molding machine is described by the capacity of its clamping unit, ranging from 50 to 1000 tons. A machine with a given clamp unit can be supplied with a variety of injection units. Injection unit capacity is described by the shot size, which is the maximum volume of melt that can be injected in a single cycle. Shot size is determined by the diameter of the screw and the distance over which it is designed to reciprocate. Shot size is usually expressed as weight or as volume.

An injection molding machine is operated by hydraulic power and equipped with an electric motor and hydraulic pump. The maximum hydraulic oil pressure is ca 14 MPa (2000 psi). A hydraulic cylinder opens and closes the mold and holds the mold closed during injection; another cylinder forces the screw forward, thereby injecting the melt into the mold. A separate hydraulic motor turns the screw to plasticate, homogenize, and pressurize the melt. Control of these movements is a combined function of the hydraulic and electrical systems.

In the injection molding machine shown in Figure 13, the clamp unit is on the left and the injection unit on the right. A mold is shown in position between the platens of the clamp unit with one half of the mold fastened to the fixed platen and the other to the movable platen. When the mold is opened, the movable platen moves away from the fixed platen and the molded part can be removed. After part ejection, the mold is closed in preparation for the next injection cycle. In contrast to extrusion, the screw in the injection unit rotates only during part of molding cycle. When the screw turns, it pumps melt forward. The rearward movement of the screw is controlled by the placement of a limit switch, which stops the hydraulic motor. The maximum length of reciprocation is approximately three screw diameters. The shot size is directly proportional to the amount of screw

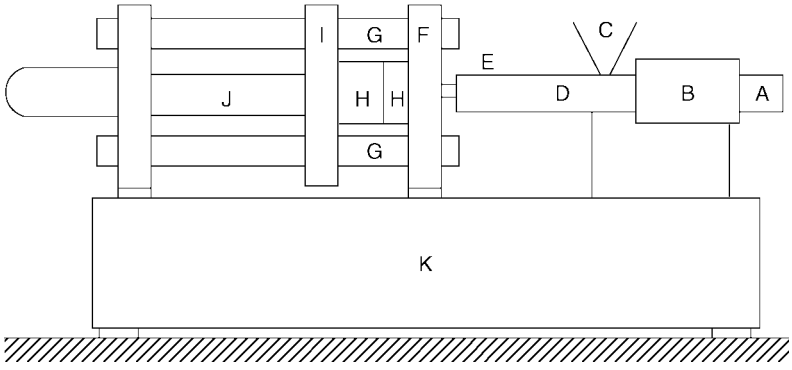

Fig. 13. Injection molding machine: A, hydraulic motor for turning the screw; B, hydraulic cylinder and piston allowing the screw to reciprocate about three diameters; C, hopper; D, injection cylinder (a single-screw extruder); E, nozzle; F, fixed platen; G, tie rods; H, mold; I, movable platen; J, hydraulic cylinder and piston used to move the movable platen and supply the force needed to keep the mold closed; and K, machine base.

reciprocation. The front of the screw is usually equipped with a check valve. While the screw rotates, the melt can move freely forward through the valve. However, the valve closes to prevent any reverse flow. The position of the screw is adjusted in such a way that there is always some melt in front of the screw when the mold is full. This pad or cushion of melt transfers pressure from the screw to the plastic in the mold. After initial filling, some additional melt flows into the mold; this is called packing. The cross section of the hydraulic cylinder, which pushes the screw, is approximately 10 times the cross section of the melt in front of the screw. Thus, 14 MPa (2000 psi) oil pressure corresponds to ca 140 MPa (20,000 psi) melt pressure.

Molding Cycle. The molding cycle begins when the empty mold is closed and full clamp force develops. The screw is then pushed forward in order to inject melt into the mold. The screw holds melt under pressure in the mold for a certain time, often called the injection time, until the gate freezes. When the injection is finished (46,47), the pressure holding the screw forward is reduced to a minimum, the screw starts to rotate, and a mold-closed timer is activated. Before the time expires and the mold opens, the screw stops turning and the next shot is ready for injection. The speed of screw rotation is chosen in such a way that the screw rotation time is less than the mold-closed time. The mold remains open only long enough for the part(s) to be ejected. The length of the molding cycle depends on cooling the part sufficiently so that it may be removed from the mold without distortion. Mold cooling systems are used for cycle reduction. The length of the cycle may also be determined by the appearance of the part; a hotter mold usually imparts a more attractive finish than a cooler mold. Cycle time and quality of moldings are optimized through microprocessor-based controllers that receive inputs from temperature, pressure, and ram position sensors.

Molds and Mold Design. The molds are custom-machined from steel. Cavities must be polished to a very high gloss, since the plastic reproduces the surface in every detail. The cavities are hardened and frequently chrome-plated. Details on mold design are given in References 48–50. A typical shot from a mold, shown in Figure 14, consists of a sprue, runners (43), gates, and two parts. Gate

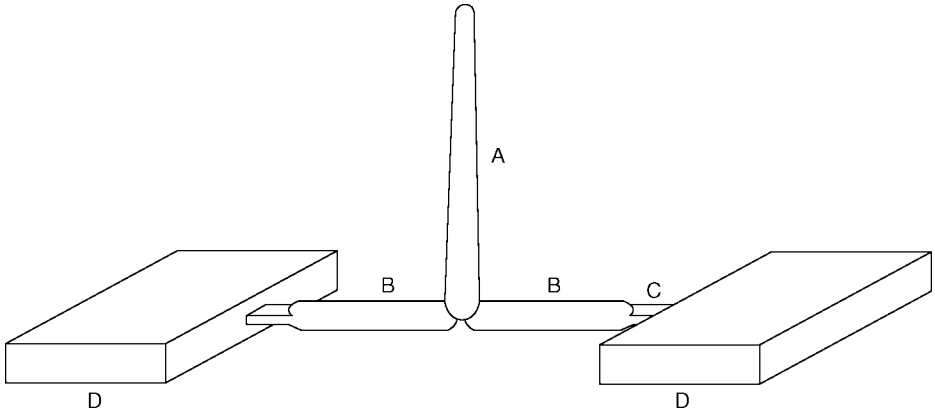

Fig. 14. A full shot: A, sprue; B, runner; C, gate; and D, part.

design is influenced by part geometry, resin type, and processing conditions. Sprue and runners channel the melt into the cavities. After ejection they are separated from the parts, ground, and fed back into the injection unit for reprocessing. Modern mold design tends to reduce or eliminate sprue and runner scrap through a variety of techniques such as hot runners, insulated runners, or by designs that place the nozzle directly against the mold cavity (45,51).

When the mold is opened, the part should be easily removable. Cavities are made with a slight taper to reduce frictional drag of the part on the mold. The half of the mold attached to the movable platen is equipped with ejector pins, which push the part out of the cavity while the mold is being opened. When the mold is closed, the pins are flush with the cavity surface. Release agents or lubricants facilitate ejection and shorten the molding cycle. Some complex parts require that the mold open in several directions in addition to the direction of the platen movement. For a threaded part, eg, a bottle cap, part of the mold must be rotated to remove the article from the mold.

Mold designs must take into account that cooled moldings are always smaller than the cavity, owing to shrinkage. Amorphous plastics shrink less than crystalline plastics (52). In practice, mold shrinkage is expressed as linear shrinkage, rather than volumetric shrinkage. Parts are measured the day after molding and are compared with the size of the mold at room temperature. In actual molding, pressure is maintained to continue packing during cooling to minimize voids and excessive sink marks.

Developments. A variety of process modifications aimed at improving surface finish or weld line integrity, process efficiency, and product costs have been described. They include gas-assisted injection molding developed for the production of hollow plastic parts with separate internal channels, microcellular foam molding that uses supercritical fluids to create microscopic cells throughout the polymer, coinjection, fusible core, multiple live feed, push–pull injection molding, and increasing use of robotic automation for enhanced productivity and part quality (53,57). An important development includes computer-aided design methods, wherein a proposed mold design is simulated by a variety of software packages and the melt flow through it is analyzed (58).

Structural Foam Molding. Structural foam is a modified injection molding process for large articles having a cellular core and an integral solid skin with an overall 20–50% reduction in density, compared to their solid counterparts (40,59,60). It is most frequently used with polyethylene, high impact polystyrene, polypropylene, and several engineering resins. Some modifications to the resin, machine, and mold are required, and a blowing agent must be added to the resin. A chemical blowing agent, which releases gas when heated, is commonly used. The choice of blowing agents depends on the processing temperature required. The most common blowing agent is azodicarbonamide (1,1′-azobisformamide) used at 200–260°C. Upon decomposition, it releases nitrogen, carbon monoxide, and carbon dioxide (qv). Approximately 0.5 wt% of a blowing agent is normally added to the resin pellet as a surface coating or as a pelletized concentrate. Instead of a chemical blowing agent, nitrogen may be mixed with the melt while it is under pressure in an extruder and the mixture maintained under pressure until it is injected into the mold.

The injection molding machine must be equipped with a shutoff nozzle that maintains the melt under pressure while the mold is opened. The screw is retracted only part of the way needed for a full shot, and a short shot is injected into the mold. Without a blowing agent, only a section of a part, ie, a short shot, would be made; the empty space allows the blowing agent to expand the melt, forming the foam structure. Structural foam molding is limited to parts with wall thicknesses of at least 6 mm; below that thickness, reduction in part weight is usually insignificant. Parts, typically, have a dense skin and a foamed interior with various pore sizes. Compared to injection-molded surfaces, the surfaces of structural foam moldings are poor, and are characterized by a rough, swirly finish. Maximum pressure in the mold during foaming is much lower than in injection molding; also, no packing pressure needs to be maintained since the gas keeps the melt front moving. Surface appearance is improved by special techniques.

Because of low injection pressure, some cost savings are possible in mold and press construction. Molding cycles are somewhat longer than for injection molding. The part must be cooled in the mold long enough to be able to resist swelling from internal gas pressure. In structural foam parts there is almost a total absence of sink marks, even in the case of unequal section thickness. Structural foam has replaced wood, concrete, solid plastics, and metals in a variety of applications.

Blow Molding

Blow Molding (qv) is the most common process for making hollow thermoplastic components (61–63). In extrusion blow molding a molten tube of resin called a parison is extruded from a die into an open mold (Fig. 15**a**). In Figure 15**b** the mold is closed around the parison, and the bottom of the parison is pinched together by the mold. Air under pressure is fed through the die into the parison, which expands to fill the mold. The part is cooled as it is held under internal air pressure. Figure 15**c** shows the open mold with the part falling free.

As the parison is extruded, the melt is free to swell and sag. The process requires a viscous resin with consistent swell and sag melt properties. For a large

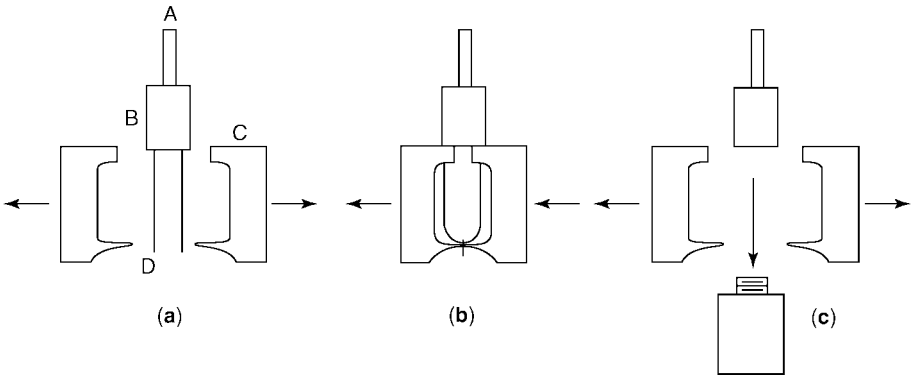

Fig. 15. Three stages of blow molding (**a–c**): A, air line; B, die; C, mold; and D, parison (see text).

container the machine is usually equipped with a cylinder and a piston called an accumulator. The accumulator is filled with melt from the extruder and emptied at a much faster rate to form a large parison; this minimizes the sag of the molten tube.

With a simple parison, the large-diameter sections of the bottle have a thin wall and the small-diameter sections have a thick wall. Certain modifications of the die can control the thickness of the parison wall along its length, which results in a bottle with improved wall thickness distribution and better strength. High density polyethylene (HDPE) is the most common blow-molding resin used to produce containers ranging in size from 30 cm^3 to 200 L.

In injection blow molding, a parison is injection-molded onto a core pin; the parison is then rapidly transferred via the core pin to a blow mold, where it is blown by air into an article. This process is applied to small and intricate bottles.

Soft-drink bottles made from PET are usually made by stretch-blow molding in a two-step process. First, a test-tube-shaped preform is molded, which is then reheated to just above its glass-transition temperature, stretched, and blown. Stretching the PET produces biaxial orientation, which improves transparency, strength, and toughness of the bottle. A one-step process is used for many custom containers that are injection stretch-blow molded.

Development/trends in blow molding focus on the optimization of the viscoelastic properties and improvement in thermal stability of polymers other than HDPE to develop new extrusion/injection blow molding grades; fabrication of small containers by multilayer blow molding for improved barrier properties to water, oxygen, or hydrocarbons; prediction through software packages of wall thickness for parisons and final parts to minimize materials usage.

Other Molding Methods

Rotational Molding. Hollow articles and large, complex shapes are made by rotational molding (qv), usually from polyethylene powder of relatively low viscosity (64–66). The resin is in the form of a fine powder. A measured quantity is placed inside an aluminum mold and the mold is heated in an oven and rotated at low speed. The resin sinters and fuses, coating the inside of the mold. The mold is then cooled by water spray and the part solidifies, duplicating the inside of the mold.

A rotomolding machine has three long arms extending from a central driving mechanism; each arm rotates several molds in two planes. The arms are moved from one process station to the next, ie, from unloading and loading to heating and cooling. Tooling costs are low. The molds are usually made of cast aluminum, but sheet metal is also used. The melt is forced without pressure against the mold surface during heating or cooling, resulting in uniform wall thickness, zero orientation, and high physical properties. Cycle times are long because of the heating and cooling required; they depend on wall thickness and can be as high as 15 min for a 4-mm wall thickness. Common rotomolded products include large tanks and boxes, drums, furniture, and toys. PVC plastisol, a mixture of fine PVC particles and a plasticizer, may also be processed by rotomolding. Plastisols

are liquid at room temperature and are converted to soft solids when heated to ca 180°C. Playballs and toys are made from plastisols.

Among recent trends and developments in rotomolding are the use of microprocessors and temperature sensors for quality assurance, the refinement of methods to produce multiwalled solid or foamed structures all coupled with the continuing availability of new resin grades with suitable viscosities and high thermooxidative stability over the prolonged periods of time in the oven.

Expandable Polystyrene Molding. Molding expandable polystyrene gives foamed products such as insulation board shapes for packaging and disposable food and cup containers. Such processes are also called bead or steam molding (67,68). Expandable polystyrene moldings are manufactured from polystyrene beads 0.25–1.5 mm in diameter containing a blowing agent, such as pentane. These beads, when exposed to heat, expand from 2 to 50 times their original size. The beads are preexpanded by heating with steam or hot air to about the density of the final molded part. After preexpansion, they are stored from 3 to 12 h to let the air diffuse into the cells of the foam. Shaping of the beads is done in special presses and molds, into which the preexpanded beads are transferred by air-conveying systems. Steam causes further expansion and forces the surface fused particles to conform to the shape of the mold. In the manufacture of insulation boards, blocks are molded into cavities up to $5.5 \times 1.2 \times 0.65$ m by injecting steam. After storage and conditioning, the blocks are cut into sheets. Expandable bead molding has been extended to other thermoplastics such as polypropylene.

Thermoforming

Thermoforming (qv) is a process for converting a preform, usually an extruded plastic sheet, into an article such as a thin-wall container or a tray for packaging meat (69–72). Under vacuum the process is called vacuum forming. The sheet is clamped in a frame and exposed to radiant heaters. The sheet softens to a formable condition, is moved over a mold, and sucked against the mold by vacuum. Excess plastic is trimmed and recycled. Timers control the length of the heating and cooling periods, which depend on composition and sheet thickness. Frequently, the process is improved by using mechanical aids (plug-assisted, air-cushioned plug-assisted, drape-assisted). The molds are made of wood, aluminum, steel, or epoxy (73). In some plants the vacuum forming line is run in-line with the sheeting extruder.

Amorphous resins such as styrenics, acrylics, PVC, and some crystalline resins such as polyolefins, PP, and PET are used for thermoforming. Foamed polystyrene sheet is also thermoformed. The polymers must be of fairly high molecular weight because the heated sheet must be form-stable. The significant property is melt elasticity. Sheets of these resins soften but do not sag when heated. Sagging causes thinning; a sagged sheet may have more surface area than the mold, resulting in folds and areas of uneven thickness. Thermoforming is employed for small items such as cups, plates, trays, and larger, deep-drawn moldings such as boats, bath tubs, and freezer liners. Skin packaging, which employs a flexible plastic skin drawn tightly over an article on a card backing, is made by thermoforming.

The process also is used for blister packaging. Thermoforming can be continuous by using rolls of sheet or batch by using precut shapes.

Thermoforming is competing with injection blow molding and rotomolding to prepare hollow parts by refining the twin sheet process by simultaneous or sequential forming of both halves and then compressing at the periphery to effect closure. The growth of thermoforming is also related to the development of software for wall thickness prediction.

Calendering

Calendering is a process uniquely applied to rubbery polymers, mainly semirigid and flexible PVC, for making sheeting of uniform thickness from 0.75–0.05 mm after stretching (74–77). A calender has four heavy, large steel rolls, which are usually assembled in an inverted "L" configuration as shown in Figure 16. This design is preferred for thick sheeting because it gives a long dwell for full heating. The forces generated between the rolls are considerable and sufficient to bend the rolls, resulting in uneven sheet thickness. A common method of compensating for roll bending is by grinding an opposite contour on the roll. A two-roll mill, a Banbury mixer, or an extruder melts the resin, which is subsequently transferred to the calender. Sheet can be made 2.5 m wide and production rates can be as high as 100 m/min. Calendering is often followed by printing, laminating, and embossing. PVC calenders are run at temperatures approaching 200°C to produce highly oriented sheets for items such as shower curtains, rainwear, luggage, and wall paneling.

Casting

Casting refers to the formation of an object in a batch process by pouring a fluid monomer–polymer solution into a mold where it solidifies or by continuously

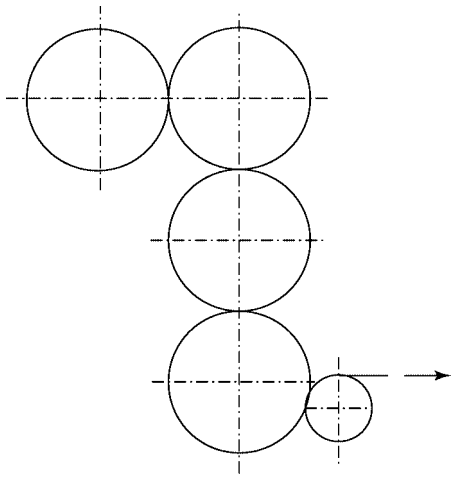

Fig. 16. A four-roll, inverted "L" calender.

pouring the liquid onto a moving belt. The casting process is most frequently used with acrylics. Since the 1950s, cast acrylic sheeting has been made by polymerization of methyl methacrylate in a cell assembled from two glass plates and a flexible gasket. Heating for a few hours until polymerization is complete gives sheets with excellent optical properties. Acrylic sheeting is also made by continuous casting, ie, a monomer–polymer–catalyst mixture is fed onto a stainless steel belt, on which the polymerization is completed. These products are used for glazing and thermoforming. Nylon-6 products with higher molecular weight and crystallinity than extruded or molded resins are also produced by casting in the mold by a process known as *in situ* anionic polymerization.

Thermosetting Resins Processing

Common thermosetting resins are unsaturated polyesters, phenolic resins (qv), amino resins (qv), polyurethanes (qv), epoxy resins (qv), and silicones (qv) (see POLYESTERS, UNSATURATED; URETHANE COATINGS). Less common thermosets (qv) employed in specialized applications are bismaleimides, polyimides (qv), and furan resins. Thermosetting resins are usually low viscosity liquids or low molecular weight solids that are formulated with suitable additives known as cross-linking agents to induce curing; curing involves permanent chemical changes resulting in infusible, insoluble products with excellent thermal and dimensional stability. Thermosetting resins are commonly used in combination with fillers or fibrous reinforcements; as a result, processing methods are often quite different from those employed for thermoplastics (78–80).

Compression, Injection, and Transfer Molding. Compression molding is the oldest process of the plastics industry. General information on the process, which is also applicable to a certain extent to thermoplastics, is found in References 81–85. It is still common, although many thermosetting materials are also injection-molded (86–88). The equipment consists of a vertical hydraulic press with platens for mold attachment. The mold comprises a matched pair of male and female dies. Mold cavities are hardened and highly polished, similar to those of an injection mold. A measured quantity of thermosetting resin compound in granular, sheet, or other form is placed in the hot mold. The mold is closed and the liquified resin through pressure fills the cavity. Continued heating cures the resin within a few minutes, and the part is removed from the mold. Compression molding is commonly employed for phenol–formaldehyde, urea–formaldehyde, melamine–formaldehyde, and polyester molding compounds. To shorten the total cycle, some of these compounds are partially polymerized or preformed into various shapes that are preheated to intermediate temperature before being inserted into the mold. Laminates made of reinforcement layers impregnated with partially polymerized resins are also prepared by compression molding.

Sheet molding compound (SMC) is used in the manufacture of large reinforced compression moldings, which are employed extensively in automotive panels. SMC is prepared as a sandwich, rolled between two polyethylene films; it contains polyester resin, filler (usually calcium carbonate), and 20–30 wt% chopped glass fibers. Other components such as peroxides for cross-linking, thermoplastic additives for shrinkage control, and alkaline-earth oxides and hydroxides to assist maturation are present in smaller amounts. Maturation involves a thickening

chemical reaction that produces within a few days after compounding a tack-free sheet with desirable flow characteristics during molding. The required amount of sheet is then cut to size for placement on the bottom of two matched mold halves to cover at least 70% of the mold area. It is molded at pressures up to 15 MPa (2100 psi) and temperatures in the range 140–180°C. Cure cycles depend on part size and complexity, pressure and heat applied, and formulation characteristics. Cure cycles of 60 s are common. The properties of cured SMC depend on the amount, length, and orientation of the glass fibers.

Bulk molding compound (BMC) is similar to SMC in formulation, but contains shorter glass fibers and higher filler levels (89). The premixed material has the consistency of dough and is supplied in bulk form or as a cylindrical extrudate. BMC is molded by conventional compression or transfer molding; it is also molded in reciprocating screw injection presses equipped with a piston stuffer attached to the barrel to force-feed the material into the screw flights. Other injection-moldable thermoset formulations in granular form (phenolics, amino, epoxy, and diallyl phthalate compounds) are fed through standard gravity hoppers. In thermoset injection molding, screws with low compression ratios are used to convey the material through a short barrel heated typically up to 120°C and decrease its viscosity; this is followed by injection into a hotter mold (typically up to 220°C) where chemical cross-linking takes place. Total cycles may range from 10 to 120 s, depending on part thickness and formulation characteristics.

Transfer molding is a combination of compression molding and injection molding. A measured charge is heated in a reservoir, from which it is injected or transferred through runners to the mold cavity. Forcing the polymer through the entry gate results in a rise in temperature that may promote flow but also accelerates curing. The molten polymer is held at temperature while the cross-linking reaction proceeds to completion.

Open-Mold Processing. Common open-mold processes are hand or mechanized methods such as lay-up and spray-up, that use a single cavity mold and produce one finished surface (90). These techniques are used to produce fiber-reinforced structures containing the reinforcement in the form of cloth, chopped strands, mat, continuous roving, woven roving, etc. Thermosetting resins of choice are liquid unsaturated polyester or epoxy resins. In lay-up, catalyzed resin is used to impregnate the reinforcement that is preplaced on the mold. A spray-up system consists of a resin spray gun, a fiber chopper, and a pumping system; the catalyst is combined with the resin just before deposition with the fibers onto the mold surface. Open-mold processes use little or no pressure during the curing cycle. Cross-linking usually takes place at room or slightly elevated temperature through a proper combination of curing agents. A variety of products such as boat hulls, automotive components, tanks, etc are made by open-mold processing (91). Types of emissions and U.S. environmental regulations for thermoset components and cure reaction by-products are included in Reference 19.

In another open-mold process, filament winding, continuous fibers such as glass, carbon, or aramid are wound on a mandrel surface in a precise geometric pattern (92). Fibers are usually preimpregnated with a low viscosity resin containing a suitable cross-linking agent for room or higher temperature curing. Most common resins are polyesters and epoxies. A tubular component with the fibers in angle-ply arrangement results after curing and the mandrel is withdrawn. The

process, originally developed as a rapid method to manufacture pipes and cylindrical vessels, has expanded to allow more complicated geometries. Products include, among others, helicopter rotor blades, external fuel tanks, pressure bottles, and pipes.

Pultrusion. In pultrusion, reinforcing fibers in a combination of styles are wetted by a resin containing a high temperature cross-linking agent and then pulled through a forming system that positions the fibers into the desired packed structural arrangement; the material then moves through a heated die where curing takes place (93). The process can in principle produce continuous profiles of any length; rods, bars, and other more complex profiles such as I-beams and channels are mostly made from continuous glass fibers and polyester or epoxy resins (94). Glass content can be very high (50–70%) at production rates of about 1.5 m/min (91–93). An analogous method has been used to produce continuous composite lengths by impregnation of fiber bundles with molten thermoplastics which can be chopped to long fiber pellets that are used in injection molding (95).

Reaction Injection Molding. Reaction injection molding (RIM) is used for the production of solid or partially foamed polyurethane moldings by rapid injection of metered streams of polyol and isocyanate into a mold. RIM has been developed around polyurethane and polyurea chemistry; other chemical systems of lesser commercial significance can be processed by RIM (96,97). Articles are produced on a cycle of 3 min or less. The two liquid streams are mixed by impingement before entering the mold. The mold is filled at 0.35–0.70 MPa (50–100 psi), which is a very low pressure compared to that used in standard injection molding. Equipment, and in particular mixing head design, is critical. The cost of the mold and press are less for RIM than for conventional injection molding and the process is particularly suited to the production of large parts.

A wide range of formulations can be used in the RIM process. A typical polyol stream contains 75–80 wt% polyether polyol, 17–20 wt% 1,4-butane-diol, 2–6 wt% blowing agent, and amine and metal catalysts. The most commonly used isocyanates are proprietary products made from 4,4′-methylenedi(phenyl isocyanate). Processing conditions and physical properties depend on the formulation. Often, parts are removed from the mold before curing is complete; then, additional curing is required at elevated temperatures in an oven. Glass fibers and other fillers added for reinforcement and to control shrinkage are dispersed into the polyol component. Another approach is to place continuous fiber mats directly in the mold cavity and inject a low viscosity, reactive mixture through the mat (structural RIM) (98).

Resin Transfer Molding. In resin transfer molding (RTM) a piston-type positive displacement pump injects a premixed resin–catalyst stream into a closed mold thoroughly impregnating a preplaced reinforcement pack. Glass, graphite, or aramid fibers in the form of continuous strand mat, woven rovings, and their combinations are typical reinforcements (99). RTM differs from structural RIM in that it uses slower reacting formulations and injects under lower pressures components that are premixed or homogenized by passing through static mixers. Molds are made of lower cost materials and cycles are longer (10–60 min). RTM machines have been adapted for a variety of resins including polyesters, epoxies, polyurethanes, and isocyanurates (100,101).

Polyurethane Foam Processing.

Flexible Foam. These polyurethane products have varying densities and a relatively low degree of cross-linking (102). They are made from trifunctional polyols (mol wt 3000) and TDI, a mixture of 2,4- and 2,6-toluene diisocyanates, in the presence of tin and amine catalysts, surfactants as foam stabilizers, water, and blowing agents. Physical blowing agents are Freons; CO_2, the reaction product of water and isocyanate, is a chemical blowing agent. Flexible foams are resilient open-cell structures with densities varying from 25 to 650 kg/m^3, depending on the choice of the raw materials. Most flexible foams are produced in the form of a slab or bun in a continuous process in widths up to 2.4 m and thicknesses up to 1.2 m. A liquid foamable mixture is pumped onto a conveyor, which moves through a tunnel where reaction and foaming occur (103). Similar mixtures can be placed in a mold and allowed to foam. This process is used in the manufacture of automobile seats (see Foamed Plastics).

Rigid Foam. These are closed-cell foams with excellent thermal insulation characteristics (104). Most rigid foams are made from a high functionality polyol with ca 500 mol wt and poly(methylene)–poly(phenyl isocyanate), yielding a mixture with a high functionality of 2.7; hence, the foams have a higher degree of cross-linking than the flexible foams. The formulations include blowing agents, catalysts, and foam stabilizers. Rigid foams can be made as continuous slabs that are cut into panels. Other production methods include coating suitable substrates to produce laminated products used for architectural insulation; spraying, as for insulation during construction; and pouring or pumping the foamable mixture into place, as in the manufacture of refrigerators.

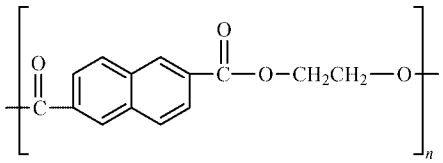
POLY(ETHYLENE NAPHTHALATE) (PEN)

Introduction

Poly(ethylene naphthalate) (PEN) is a thermoplastic polyester consisting of ethylene naphthalate repeat units:



PEN is the polycondensation product of either dimethyl-2,6-naphthalenedicarboxylate (2,6-NDC) or naphthalate dicarboxylic acid (2,6-NDA) with ethylene glycol. To date 2,6-NDC is the preferred feedstock in view of the fact that it can be produced more economically in high purity form relative to purified 2,6-NDA.

Other naphthalate-based polyesters include the butanediol-based analogue, poly(butylene naphthalate) (PBN), as well as copolymers and blends of PET [poly(ethylene terephthalate)] with PEN.

Naphthalate polyesters exhibit physical and mechanical properties generally superior to their terephthalate analogues made from terephthalic acid (TA) or dimethyl terephthalate (DMT), such as PET or poly(butylene terephthalate) (PBT). PEN polymerization was first reported by ICI in 1948 (1). Its superior thermal, mechanical, and physical properties were recognized early on. However, in the 40 years that followed, PEN did not find significant commercialization or application development, due primarily to the lack of commerical availablity of the key monomer, 2,6-NDC. Although studies on PEN film and fiber production and applications were begun by Teijin in the 1960s, it was not until the 1970s that 2,6-NDC became available in sufficient quantities for the first PEN films and fibers to be produced on a semitechnical scale. High value speciality videotapes were found to benefit from the use of PEN film in Japan during the 1980s. In the early 1990s Amoco Chemical Co. announced their plan to invest in a world-scale facility for production of 2,6-NDC in Decatur, Illinois. As a result of the promise of larger scale and more economic raw material supply, plus greater interest from the end market, PEN films were launched commercially in the early 1990s. Since then, the start-up of commercial production at Amoco's (now BP) 30,000 tons/year 2,6-NDC facility has significantly aided the economics of PEN production. This has driven increasing use of PEN in a wide range of applications including films, fibers, and rigid packaging.

An approximate percent breakdown of PEN usage worldwide per end-use segment for the year 2002 is provided in Table 1.

At this time, commercial producers of PEN homopolymer and/or copolymer resins are Teijin Ltd. (Japan), M&G (USA), 3M (USA), KoSa (Europe), Toyobo (Japan), Kolon (Korea), MCC (Japan), Kimex (Mexico), and Shinkong (Taiwan).

Polymer Properties

Naphthalate polyesters, such as PEN and PBN, derive their performance improvement from the double ring structure of the naphthalene group. Incorporation of this double ring structure in the polymer chain increases thermal, chemical, mechanical, and barrier performance versus polymers based on single aromatic rings. Table 2 illustrates the wide variety of property improvements exhibited by PEN versus PET.

Partial substitution of terephthalate-based polymers with the naphthalate group, in a copolymer or blend form, can provide enhanced properties that are

typically intermediate between the respective homopolymers. A description of key thermal, physical, and mechanical properties is provided below.

Thermal Properties of Naphthalate-Containing Polyesters. Naphthalate homopolymers melt at higher temperatures vs terephthalate homopolymers. Table 3 compares the T_m of PEN and PBN vs PET and PBT respectively.

In random copolymers, where both TA and NDC are present, the melting point decreases as NDC partially substitutes TA (eg, starting from PET) or when TA partially substitutes NDC (eg, starting from PEN). This melting point depression effect is caused by a disruption in the regular crystalline pattern by the minor component (Fig. 1).

Figure 1 shows that the melting point of a PEN copolymer modified with 8 mol% DMT (PENT-8) equals the melting point of a PET homopolymer. Use of the lower melting PENT-8 copolymer in preparing PET/PEN blends is preferred over use of a PEN homopolymer. Not only are lower melt temperatures required in the blending process, which reduces the risk of PET degradation, but there is a better viscosity match between the naphthalate and terephthalate polymers which improves mixing and miscibility.

Within the range of approximately 10–90 mol% NDC, PET/PEN random copolymers (PETN) remain essentially amorphous. On the other hand, PET/PEN blends are capable of crystallizing and exhibiting a melting point at any *T*/*N* ratio, which depends not only on this ratio but also on the degree of randomness or

transesterification present. The dotted line in Figure 1 provides a cursory representation of this behavior.

Naphthalate homopolymers have a glass-transition temperature significantly higher than the corresponding terephthalate homopolymers (Table 4).

Unlike T_m, the behavior of T_g vs NDC content is linear and follows the mixing rule (Fig. 2).

This linear relationship offers many opportunities for enhancing the thermal resistance of PET by simply blending-in varying amounts of naphthalate. Practical applications include hot-filled, pasteurized, or washable containers, and outdoor glazing.

An increase in T_g also affords improved long-term aging behavior or reduced embrittlement of amorphous parts. It enables a reduction in cycle time during injection molding (eg, of bottle preforms), since the parts can be released hotter. A 20% faster cycle time has been achieved in the case of PEN preforms vs PET. Finally, the higher T_g of PEN contributes greatly to the reduction of thermal shrinkage, which is of value in tire cord and other industrial fiber applications as well as films (see Table 8).

Crystallization. As in the case of PET, PEN can be quenched to amorphous glass. Its amorphous density, 1.325 g/cm^3 [BP Amoco Chemical Co.], is slightly less than that of PET (1.333) (2). Crystallization from the glass or from the melt at low temperatures (<200°C) leads to a triclinic crystal form labeled α (3), whose unit

cell was determined by Mencik (4). Crystallization from the melt at temperatures above 200°C leads to a more dense crystalline form labeled β (3).

PEN crystallizes in the same crystal pattern as PET, ie, triclinic space group $P\bar{I}$. The unit cell parameters are compared in Table 5.

Gas Permeability. The oxygen, carbon dioxide, and water vapor permeability of polyesters depend not only on composition but also on degree of crystallinity, orientation, and temperature. Regardless of the variable, PEN always exhibits significantly reduced gas permeability relative to PET. Some examples are illustrated in Table 6.

Table 6. Gas Permeability

	PET	PEN	Units and conditions
CO_2 transmission, amorphous sheet	69[a]	15[a]	cc-mil/100 in.^{2}·day·atm @ 23°C and 0% RH

Water vapor transmission, 4 × 4 oriented film (Ref. 6)	1.85[c]	0.52[c]	g-mil/100 in.^{2}·day·atm @ 38°C and 90% RH
Water vapor transmission, commercial biaxially oriented film[d]	0.38[e]	0.09[e]	g·mm/m2·day·atm @ 38°C and 90% RH

[a]For the value with units $\frac{n\ \text{mol}\cdot m}{m^2\cdot s\cdot \text{GPa}}$, multiply by 2.
[b]Data from BP Amoco Chemical Co.
[c]For the value with units $\frac{n\ \text{mol}\cdot m}{m^2\cdot s}$, multiply by 0.253.
[d]*Source*: DuPont Teijin Films (Melinex PET and Kaladex PEN respectively).
[e]For the value with units $\frac{n\ \text{mol}\cdot m}{m^2\cdot s}$, multiply by 0.645.

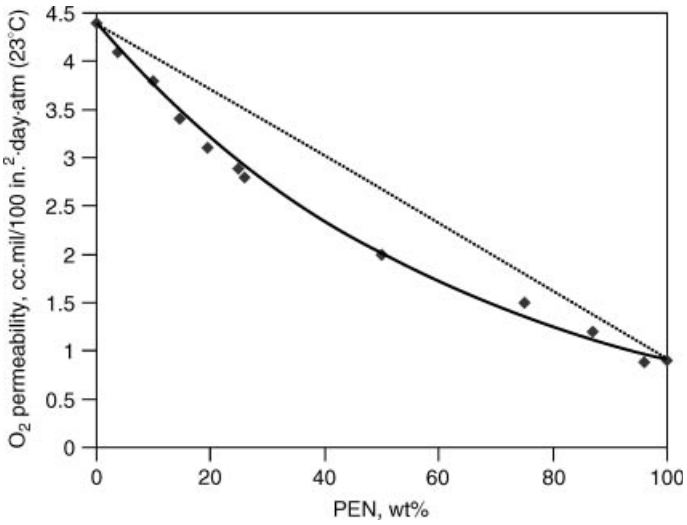

Fig. 3. Oxygen permeability of 4 × 4 biaxially oriented films from PET/PEN blends and copolymers (7). For O_2 permeability values with the units $\frac{n\ \mathrm{mol}\cdot m}{m^2\cdot s\cdot \mathrm{GPa}}$, multiply by 2.

The permeability of PET/PEN copolymers and blends is as good or even lower than that predicted by a linear fit between that of PET homopolymer and PEN homopolymer. For example better-than-linear behavior was reported in the case of O_2 permeability through 4 × 4 biaxially stretched films (Fig. 3).

Chemical Resistance. PEN offers significant improvement in chemical, oxidative, and hydrolytic stability vs PET. This has led to increased use of PEN in demanding engineering resin, fiber, film, and plastics applications and in returnable/refillable, pharmaceutical, and chemical packaging (Table 7).

UV Absorption Characteristics. Naphthalate-containing polyesters demonstrate a dramatically improved barrier to UV radiation. They also exhibit a greater retention of mechanical strength under external exposure or weathering conditions. This behavior is due to the fused aromatic structure of the naphthalate ring of NDC, which absorbs UV light at wavelengths as high as 370 nm. The benzene ring structure of DMT or TA is essentially transparent at wavelengths above 310 nm. This UV absorption behavior is also exhibited in the corresponding polymers (Figs. 4 and 5).

The combination of even very low levels of PEN with PET (by copolymerization or blending) can be a very effective UV barrier. This effectiveness, in the form of transmission versus wavelength through constant thickness (0.33 mm) is illustrated in Figure 6.

Light transmittance T is defined as $T = I/I_0$, where I_0 and I are intensities of incident and transmitted light respectively. The effect of PEN incorporation on light transmission properties at a given wavelength follows the Beer–Lambert Law, $A = \varepsilon CD$, where $A = -\log T$ ("absorbance"), C is PEN concentration, D is light path length, and ε is the naphthalate extinction coefficient at the given wavelength.

[a]From Ref. 8.

Mechanical Properties. Naphthalate presence improves mechanical properties such as modulus and tensile strengths. Like PET, PEN can be oriented uniaxially (fiber) or biaxially (film and bottle) and heat-treated in a variety of ways. Consequently, mechanical properties vary over a wide range depending upon the exact fabrication parameters used. Furthermore, in films, mechanical properties may differ between the machine (MD) and transverse (TD) directions; balanced films have very similar properties between the MD and the TD, whereas in

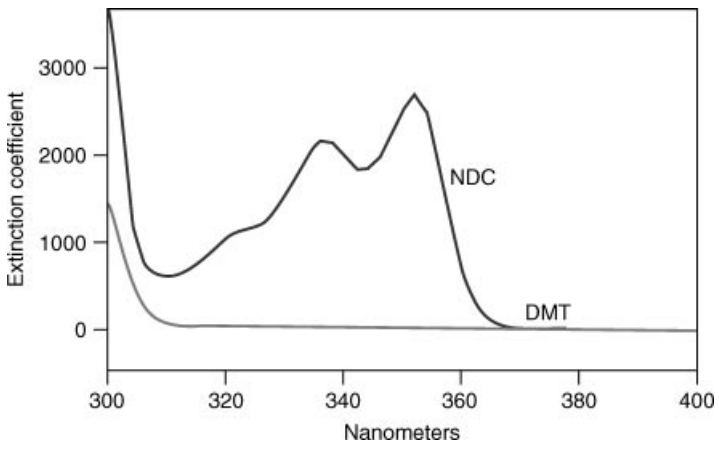

Fig. 4. UV absorption spectrum of NDC vs DMT. Data from BP Amoco Chemical Co.

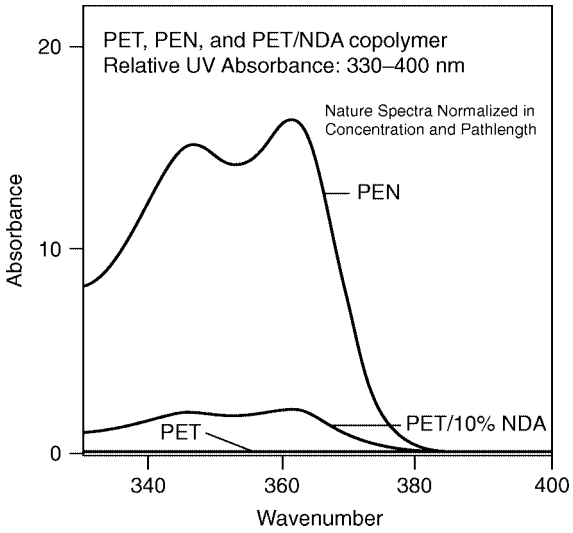

Fig. 5. UV absorption of PEN and PET. Data from BP Amoco Chemical Co.

tensilized films, the properties in MD and TD differ substantially. In general however, PEN bottle sidewalls, fibers, and films are capable of attaining tensile or flex modulus 1.5–3 times higher versus PET. Correspondingly, the elongation at break of PEN is generally lower versus PET.

Table 8 compares mechanical properties of PEN vs PET in typical films and high strength fibers.

PEN Polymerization

Melt-Phase Polymerization. Commercially PEN is produced from 2,6-NDC (abbreviated to "NDC" in the rest of this article) in a process analogous to producing PET from DMT. The reactivity of NDC in a PEN polymerization process is similar to that of DMT in a PET polymerization process and similar catalyst and conditions can be used. Because of this, PEN preparation can be typically accomplished in existing DMT-based polymerization facilities with only minor modification. This modification is generally limited to the NDC feed system and changes required to handle the physical property differences of NDC vs DMT and of PEN vs PET.

Comparative physical properties of DMT and NDC are summarized in Table 9.

The primary differences between PEN and PET polymers from a preparation point of view are the glass-transition temperature and the melt viscosity.

The melt rheology of PEN resin is significantly higher than that of PET even at lower inherent viscosities (IVs) and/or higher temperatures. The rheology of PEN at an IV typically produced in a melt-phase polymerization (0.49–0.53) was

178°C	79.9

[a]Data from PB Amoco Chemical Co.

measured at 295°C and compared to typical PET melt-phase resin. As Figure 7 indicates both PEN IVs had higher viscosities than that of PET.

PEN and copolyesters are readily prepared from NDC and ethylene glycol using either batch or continuous polymerization (12). Solubility data for NDC in ethylene glycol is summarized in Table 10. An example of a typical continuous polymerization process is shown in Figure 8.

NDC, ethylene glycol, and a suitable catalyst are metered into the first of a series of ester-exchange reactors. Normally, several ester exchange reactors provide

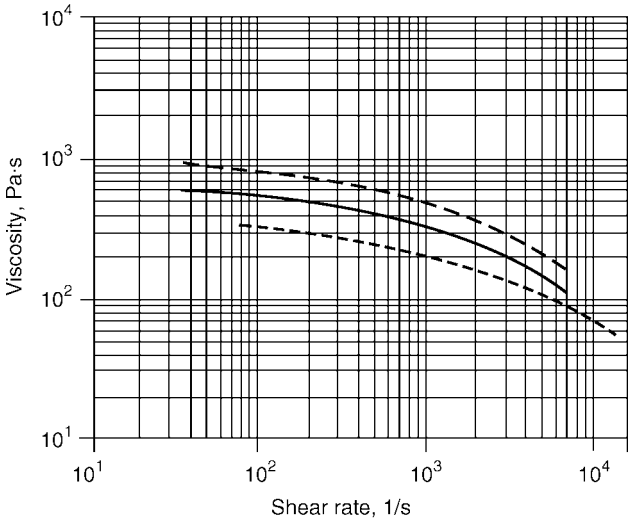

Fig. 7. Viscosity vs shear rate for PEN and PET at 295°C. ——PEN IV = 0.53, — — — PEN IV = 0.49, ▬ ▬ ▬ ▬ PET IV = 0.64. To convert Pa·s to poise, multiply by 10.

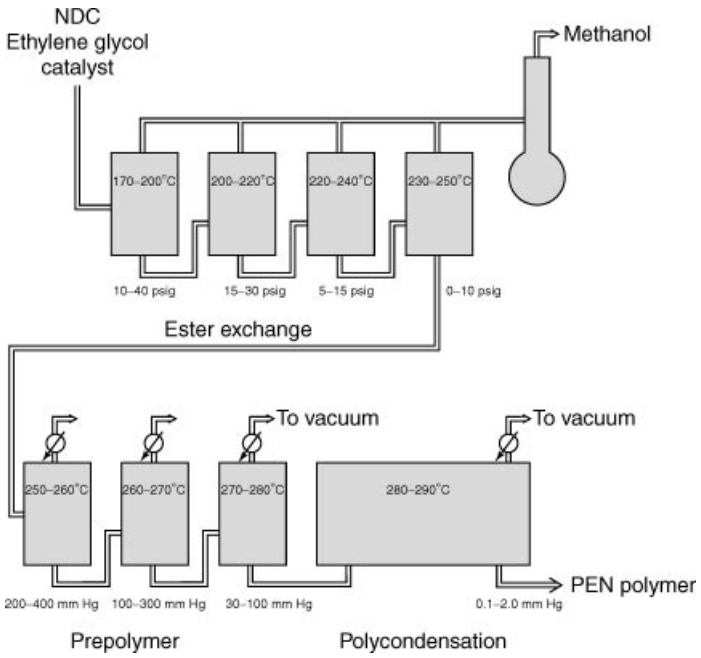

Fig. 8. Continuous PEN polymerization.

control of the temperature profile and conversion to 2-hydroxyethyl terminated oligomers, while the by-product methanol is removed and recovered. Glycol-to-ester feed mole ratios typically range from 1.5 to 3.0, while reactor temperatures range from 170°C in the initial reactor to 250°C in the final reactor. The initial reactor pressure can range from 10 to 40 psig, dropping to 0–10 psig in the final reactor.

The ester-exchange reaction product, a mixture of oligomers, is subsequently metered into the first of a series of prepolymer reactors. Generally, several agitated reactors are used. Operating in a temperature range of 250–280°C, excess ethylene glycol is removed and the resulting prepolymer is metered into a final reactor to complete the polymerization. According to this process, PEN polymer is produced having an IV of 0.4–0.6 dL/g. Examples of suitable final polymerization reactors include the horizontal types supplied by Zimmer AG (Germany) and Hitachi (Japan).

Catalysts, such as manganese, zinc, calcium, cobalt, and titanium, have been widely used as effective ester-exchange catalysts. Polycondensation catalysts, such as antimony, are commonly employed. Phosphorus compounds can be added to increase the thermal stability of the finished resin.

Crystallization/Solid-State Polymerization. As in the case of PET, production of PEN polymer for container or packaging applications will typically include crystallization/solid-state polymerization step. Because PEN has a higher melt viscosity and gas barrier, the volatile byproducts of a solid stating process, such as water, ethylene glycol, or acetaldehyde, are more easily trapped inside the amorphous pellet. This may result in a tendency of the pellets to undergo sudden expansion during crystallization or solid stating.

Several procedures have been described for crystallizing/solid stating PEN. These procedures include adding a devolatilization step (13), or conducting the crystallization under elevated pressure (14) or in the presence of a liquid (15). Because of its higher T_g vs PET, the optimum crystallization temperature range for PEN (180–220 °C) is higher than that of PET (150–190°C). Similarly, because of its higher T_m, the typical SSP temperature of PEN (240–260°C) is higher than that of PET (210–240°C). On the other hand, PEN copolymers with 8–10 mol% TA, which match the PET melting point, should be solid-stated at the same temperature conditions as PET. A typical solid-stated PEN resin has an IV in the range 0.55–0.70 dL/g.

Fiber Applications

The principal applications of PEN and PEN/PET blends and copolymers are as films (see POLYESTER FILMS).

PEN multifilament fibers are commercially available from several polyester fiber producers. These include Teijin in Japan, Honeywell (formally AlliedSignal) in the United States and Europe, Kosa in Europe, and Hyosung in Korea. PEN fibers are produced in a melt spinning/post-drawing process similar to that used in PET fiber manufacture. All production to date is in the form of continuous multifilament yarn, although staple and monofilament fabrication have also been reported.

PEN-based fibers extend the performance of polyesters. PEN fibers have excellent heat resistance, modulus, and dimensional stability relative to PET and demonstrate better retention of mechanical properties in a hot/wet environment and offer improved chemical resistance versus PET fibers (see POLYESTERS, FIBERS). With naphthalate modification, polyester fibers can meet the application requirements, which are currently served by other high performance industrial fibers such as rayon, nylon-6,6, aramids, poly(phenylene sulfide) (PPS), and even steel.

The primary commercial application of PEN fiber today is in rubber reinforcement. Fibers with high molecular weight, crystallinity, and high molecular orientation are required. To produce high orientation PEN fibers requires optimization of both resin design and spinning technology. Typically, high IV (>0.9) solid-stated PEN resin is used. High IV PEN resin is available from suppliers such as M&G and Teijin. In addition to rubber reinforcement (for tires, belts, and hoses) applications for PEN fibers include ropes and cordage, and sailcloth.

Tire Reinforcement. PEN's superior thermal and mechanical properties make it a natural candidate for the reinforcement of radial passenger and light truck tire carcasses. These superior properties are summarized in Table 11.

PEN yarn has higher tenacity and improved modulus vs PET, nylon, and rayon. Its thermal properties, eg, dry heat shrinkage, are also superior. This lower thermal shrinkage is a significant benefit in tire cord manufacture because of the heat-setting treatment and preshrinkage relaxation required to convert yarn to twisted cord. Compared to PET, the lower thermal shrinkage of PEN enables less preshrinkage treatment, which results in a final cord that has improved tenacity and modulus.

There are multiple opportunities for PEN fiber use in tire construction. Figure 9 is a typical tire construction schematic, showing the three different tire cord textile layers, carcass, belt reinforcement, and cap ply, where PEN fiber can be used.

Cap Ply Reinforcement with PEN. The cap ply is wound over the shoulders or the entire body of the belt to provide a compressive force, which resists the centrifugal forces created in the belt at high rpm. Nylon-6,6 has been typically used for cap ply applications because of its high retractive force at elevated temperatures. PEN cord has been demonstrated to offer similar properties to nylon at 177°C and is an excellent replacement material. Honeywell (formally AlliedSignal) has commercialized high tenacity/high modulus PEN fiber under the trade name PENTEX. In January 1999, Italian tire company Pirelli launched a new

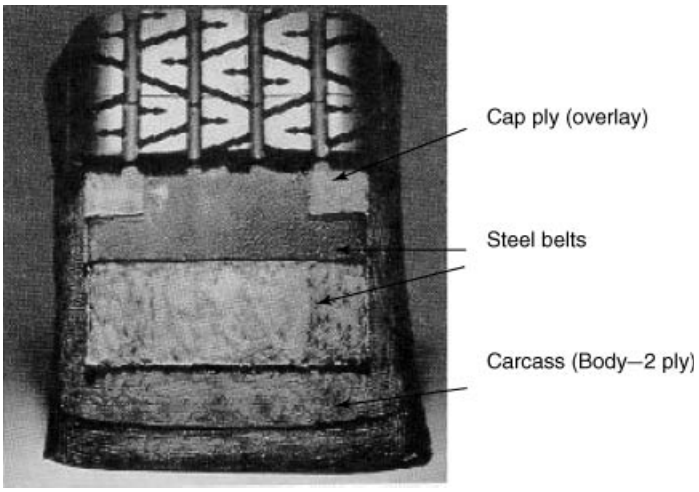

Fig. 9. Radial tire anatomy (19).

tire reinforced with caps made from PENTEX (20). Pirelli uses tire cord made from PENTEX in its Dragon EVO Corsa line of radial motorcycle tires. PEN's significantly higher modulus vs nylon or rayon, 22, 4.4, and 11 N/tex (250, 50, and 125 g/den) respectively, gives it the dimensional stability required for these high performance uses.

Bridgestone, the largest tire company in Japan, is also using PEN cord in nylon cap replacement applications in its Regno GR7000 tire (21). In addition to the dimensional stability improvements, the rigidity that PEN brings to the tire prevents noise generated at the road surface from being transmitted to inside the car. Tests show that these PEN-containing tires reduce road noise by as much as 30%, making the tires ideally suited for high end luxury cars, such as the Lexus.

Carcass Reinforcement. There are several fibers currently used in carcass reinforcement. High modulus/low shrinkage PET is typically used in most radial passenger tires and offers a good mix of properties. Nylon is used extensively in bias ply tires where strength is paramount; this has more value in developing countries with poorly maintained roads and in off-the-road equipment tires. In most of the developed world nylon carcass tires are not longer preferred in passenger cars because of the problem of flat-spotting associated with nylon's high moisture regain. Rayon is the reinforcement cord of choice in Europe for high performance tires, due to its ability to maintain mechanical properties at high temperature.

The performance properties of PEN present opportunities for rayon replacement in carcass construction (22). The use of PEN cord in these applications is currently being evaluated in both Asia and Europe. PEN has a demonstrated acceptable flexural fatigue equivalent to PET and rayon. It has equivalent toughness to rayon, which is important for sidewall impact resistance and curb scuffing resistance. PEN's superior mechanical properties also afford opportunities to use less fiber in carcass construction, enabling production of lighter weight, more fuel-efficient tires.

Steel Belt Replacement with PEN. In radial tires, the carcass provides reinforcement along the radial direction. To provide reinforcement in the rolling direction, belts are necessary. Steel is the traditional material of choice but there has been a drive to replace it with lighter weight synthetic cords. Aramids offer a synthetic alternative but their cost has been prohibitive except for high performance racing tires and luxury cars. PEN has good fatigue at low twist and superior compressive modulus to aramid. This translates into a significant reduction in tire weight and improvement in fuel usage. In addition, use of a polyester fiber-like PEN offers greater opportunity to recycle used tires.

Belts and Hoses. As automotive design trends toward higher engine operating temperatures, the requirements for under the hood reinforcement fibers have changed. Today, fibers not only require good mechanical and thermal properties, but also improved chemical/hydrolytic resistance in a hot-wet environment. PEN fiber meets these more demanding requirements. Performance advantages of PEN include the following:

(1) cost (half compared to aramid)
(2) very low tension decay

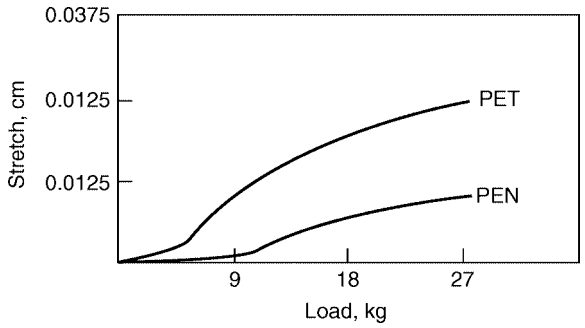

Fig. 10. Stretch at equivalent load of PEN yarn compared to standard polyester (23).

(3) high modulus (two times of PET)
(4) low shrinkage after cure
(5) high adhesion and adhesion retention
(6) improved fatigue resistance

Several types of PEN- or PBN-reinforced belts and hoses, ranging from transmission belts to oil brake hoses, have been produced. Additional applications include timing belts, conveyer belts, high pressure hydraulic, steam, fuel, and coolant hoses, as well as polychain belt cord.

Ropes and Cordage. PEN's high strength, hydrolytic stability, and resistance to UV light degradation create numerous opportunities for its use in rope and cordage applications. The combination of strength and low stretch make PEN cordage the material of choice for rescue rope applications (Fig. 10). For example, Sterling Rope utilized Honeywell's high tenacity PEN yarn, Pentex, in their high performance rescue rope products (24). The dimensional stability of the PEN rescue rope, with less than 1% stretch per 300-lb load, ensures steady support for rescue operations.

Sailcloth. PEN filament yarn has found applications in high performance sailcloth construction. Challenge Sailcloth Inc. has introduced its SuperModulus sailcloth made from Honeywell's high tenacity PEN fiber, Pentex (23). The improved UV resistance of Pentex fibers more than doubles the shelf life of sails in the Caribbean, Mediterranean, and other high UV areas. The low stretch characteristics of PEN also provide a significant advantage in performance and enables production of a much lighter weight sail.

Rigid Packaging Applications

The use of naphthalate-modified polyester resins in packaging applications offers improvement in gas barrier, UV barrier, thermal, and mechanical properties versus PET alone. Naphthalate resins suitable for packaging applications are commercially available in either homopolymer (PEN), PET/PEN copolymers (PETN-x), or PET/PEN blends.

Naphthalate-containing polyester resins at all compositions, from 0 to 100%, are fully regulated for use in food contact applications. Naphthalate polymers are

Table 12. Naphthalate Resin Benefits in Rigid Packaging Applications

Application	Naphthalate Benefit	Typical resin type
Returnable/refillable (Beer, mineral water, water fountain jugs, juice milk)	Improved thermal resistance (washing) Improved chemical resistance (washing) Reduced flavor carryover Reduced adsorption Improve gas barrier (CO_2 loss and O_2 ingress) Increased UV barrier	PEN, copolymers, blends
Beer—one way	Pasteurization capability Increased UV barrier	Copolymers
Small-size carbonated soft drinks (<0.5 L)	Improved barrier against CO_2 loss Increased UV barrier	Copolymers, blends
Hot-fill applications (Foods, sport drinks, fruit juice)	Improved thermal resistance Improved barrier Increased UV barrier	PEN, copolymers, blends
Sterilizable applications (baby bottle)	Improved thermal resistance	PEN, high PEN copolymers
Retort applications (baby food)	Improved thermal resistance	PEN, high PEN copolymers
Pharmaceutical/cosmetic	Improved barrier Improved chemical resistance UV barrier	PEN, copolymers, blends
Industrial and speciality	Improved barrier Improved chemical resistance	PEN, copolymers, blends

permitted for use with all food types and under all conditions of use as defined by the FDA. These include packaging for foods that undergo high temperature sterilization in the container, to frozen foods reheated in the container.

A summary of naphthalate rigid packaging commercial and potential applications is provided in Table 12. Applications of naphthalate-modified polyesters can be segmented by resin type and naphthalate content. This includes PEN homopolymer, medium level PET/PEN blends and PETN-x, or low naphthalate level copolymers. The use of a particular resin type is often dictated by optimization of cost versus the thermal and barrier requirements of the application. Figure 11 summarizes current uses and potential opportunities for naphthalate polyester resins in rigid packaging.

Rigid Packaging Applications for PEN Homopolymer and High PEN Copolymers. PEN homopolymers and high level PEN copolymers are best suited to rigid packaging application requiring the maximum in organoleptics, temperature, and gas barrier improvement. Specific published examples, including market trials and commercial launches, are listed below.

Returnable/Refillable Beer Bottle. In August 1999, Carlsberg A/S launched PEN returnable/refillable bottles for their Carlsberg Lager and Tuborg Green Label brands sold in Denmark (20,25). Danish law requires that all carbonated bottles filled in Denmark are returnable and refillable. Although for one-way

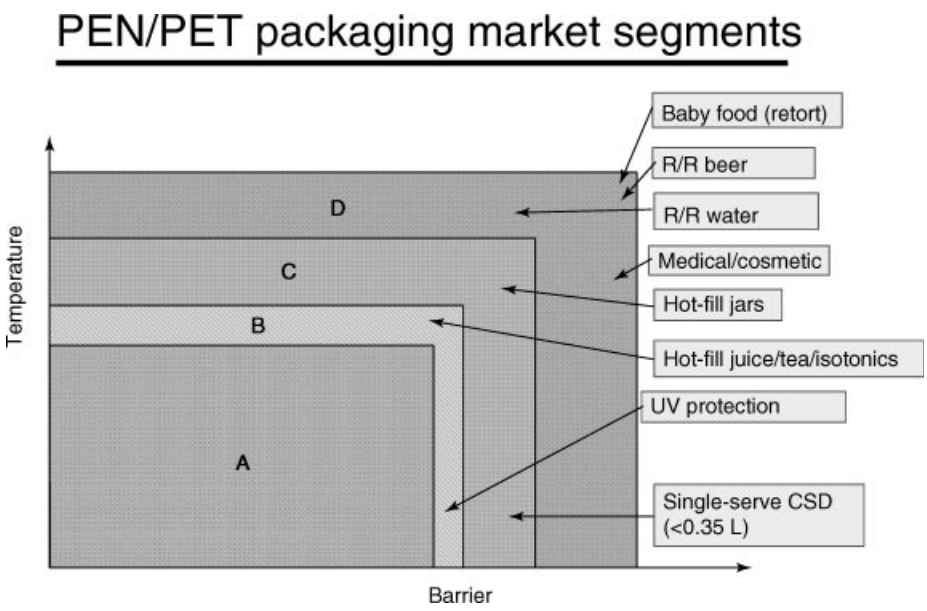

Fig. 11. Opportunities for PEN homopolymers, copolymers, and blends in rigid packaging. A PET, B Low PEN copolymer, C PEN blends, D PEN.

beer coated plastic bottles multilayer PET solutions are available, PEN is the only plastic material that combined the necessary barrier, pasteurization capability and the ability to withstand repeated washings at temperatures used to sterilize glass bottles—up to 85°C. The PEN bottles keep carbon dioxide in and oxygen out, enabling a shelf life of greater than 4 months. The ability to reuse the bottle, an 80% reduction in weight versus glass, makes the PEN return refill package the preferred environmental and total system cost solution. PEN returnable/refillable beer bottles were also launched in Norway and in Brazil (24,25).

PEN Returnable/Refillable Water Bottle. The washing temperature used in returnable/refillable water bottles (up to 90°C in caustic solutions) is higher than the washing temperatures typically used for returnable/refillable carbonated soft drink (CSD) bottles (45–60°C). This is dictated by higher requirements for removal of trace foreign contaminants that might contribute to bad taste. In addition, antiscalping and carbonation retention performance are equally critical. In view of all these factors, PEN, with its high T_g (125°C vs 80°C for PET), high carbonation retention (four times relative to PET) and excellent anti-sorption/desorption characteristics have been an ideal material for packaging returnable/refillable water. In Uruguay, a PEN returnable/refillable bottle was introduced for mineralized water sold under the Bonaqua brand by MONRESA (Montevideos Refrescos, SA), a bottler of The Coca-Cola Co. (26). With PEN bottles, carbonation retention was demonstrated to be four times greater than with PET bottles. The returnable/refillable PEN bottles easily withstand washing with a 2% sodium hydroxide solution at 90°C. No stress cracking and less than 1% dimensional change was shown after 100 washing and refilling cycles.

PEN Cosmetic Bottle. Replacing glass with clear plastic in small bottle applications, like ampules for cosmetics or medicines, requires a polymer that has acceptable resistance against heat distortion, environmental stress cracking, vapor barrier, and creep *in the amorphous state*. This is because the injection blow process used to fabricate clear small containers typically affords an amorphous or low crystalline bottle. PEN homopolymer with its high T_g (125°C) and low gas permeability and chemical resistance is ideal for these applications. One commercial example is a skin care product from Japan's leading mail-order cosmetics company, FANCL (20). Substitution from glass to plastic in this case was driven by two factors: waste disposal in incinerators (glass does not burn) and reduction in total packaging size and cost. With the PEN bottle, FANCL reduced the amount of required protective packing, decreased the size of the box, and substantially reduced the total costs of packaging.

PEN for Medical Applications. Another application for PEN is medical packages, where material selection is driven by chemical resistance, safety, and strength. One example is a package from Abbott Laboratories (24), used for the drug Sevoflurane, a volatile anesthetic used in hospital operating rooms. PEN was chosen to replace glass because of its chemical resistance, low extractables, and strength. The container needs to be able to contain pressure buildup if the contents increase in temperature.

PENT-8 Reusable Baby Milk Bottle. Although polycarbonate (PC) has traditionally been the preferred alternative to glass in reusable baby milk bottles, health concerns with PC usage have been raised in some countries about possible presence of residual bisphenol A. The use of a high PEN-containing copolymer, PENT-8, has been demonstrated to provide a bisphenol A free substitute for PC. In Korea, Kolon has found that PENT-8 has adequate T_g (123°C) to withstand required sterilization in boiling water (20). At the same time, the lower melting point of PENT-8 (250°C) relative to PEN (268°C) makes it processable at PET melt conditions.

PEN School Lunch Tableware. Another example where PEN replaced PC owing to concerns about bisphenol A was in tableware for school cafeterias in Japan (24). The producer, Sanshin, selected PEN homopolymer for its ability to withstand multiple washings and its antiscalping properties.

PEN Bottle Fabrication by Injection Stretch Blow Molding. PEN is semicrystalline polyester-like conventional PET, and those familiar with and skilled in the fabrication of conventional PET should be able to produce good quality bottles from PEN. However, there are some differences between PEN and PET that must be considered when fabricating PEN. The most important of these are the higher glass-transition temperature and melting point of PEN (Tables 2 and 3).

Because of its higher melting point, PEN must be injection-molded at higher temperatures than PET, and because of the higher glass-transition temperature, PEN preforms must be preheated to higher temperature when stretch blow molded.

With respect to preform design, optimization of bottle properties will result from using a slightly higher stretch ratio for PEN than for conventional PET. This is illustrated in Figure 12, which shows stretch ratios of PET and PEN of various IVs. The data were obtained by free blow experiments that were conducted at the

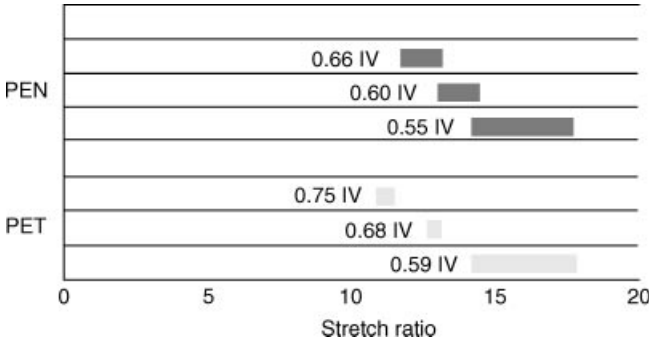

Fig. 12. Stretch ratios of PET and PEN.

optimum stretch temperature range for each resin, which was 105–110°C in the case of PET and 165–170°C in the case of PEN.

The results show that stretch ratio decreases with increasing IV for both PET and PEN but that for a given IV, the stretch ratio of PEN is greater than that of PET. This means that for typical commercial PEN with an IV of about 0.65, one would want to design the preform tooling with a slightly higher stretch ratio than used for typical 0.80 IV commercial PET.

Resin Drying. Like conventional PET, PEN is sensitive to hydrolysis and must be dried prior to melt processing. Recommended drying conditions for PEN are shown in Table 13.

The recommendations are based on a polyester pellet size of 40–50 pellets/g and may need to be adjusted if the pellets are smaller (shorter time) or larger (longer time). The polyester should be dried to a moisture level of 50 ppm or less prior to melt fabrication. Drying temperature greater than 175°C (350°F) should be avoided to prevent discoloration of the polyester.

Preform Injection Molding. PEN homopolymer must be molded at significantly higher temperatures than PET to accommodate the higher melting point and melt viscosity of PEN. In general, for a given injection molding machine, the initial temperature settings should be about 20°C higher for PEN than those typically used for PET. From that starting point, conditions can be adjusted to provide optimum quality preforms. Representative processing conditions for PET and PEN are shown in Table 14 and Figure 13. The data are intended to provide a relative comparison of molding conditions; optimum conditions will depend on the specific resin and injection molding machine used.

Bottle Stretch Blowing. The key difference in stretch blow molding of PEN vs PET is related to the higher glass-transition temperature of PEN. Since the

glass-transition temperature of PEN is approximately 40°C higher than that of standard PET, the PEN preforms must be heated approximately 40°C higher than PET preforms prior to stretch blow molding. This can be accomplished by increasing the infrared lamp power settings. If not enough power is available at a given line speed, the next step is to reduce line speed in order to increase residence time in the infrared oven. Since the preform reheat temperature is significantly above the water boiling temperature, it is recommended that amber-colored preforms are kept dry or dried prior to stretch blowing, since the amber colorant particles might nucleate boiling of moisture present, resulting in blistering. A representative set of stretch blow molding conditions (used in blowing the preforms shown in Fig. 13, made according to Table 14) is shown in Table 15. The resulting bottle is shown in Figure 14.

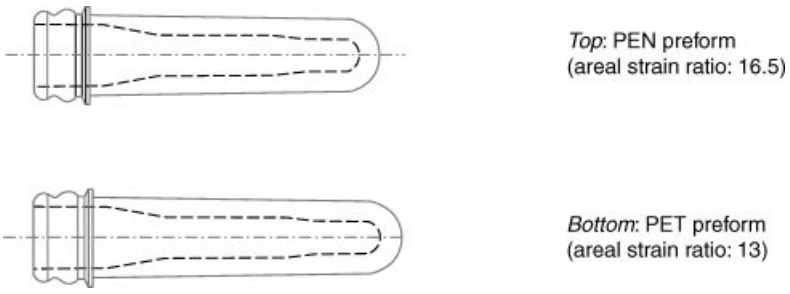

Fig. 13. Difference in preform design for making the same bottle from PEN vs PET (as per Table 14).

Rigid Packaging Applications for PET/PEN Blends. Physical blends of PET with PEN are best suited for rigid packaging applications when performance requirements demand a naphthalate content in a range of 15–90%. Random copolymers within this range lack the ability to develop the strain–induced crystallization needed in most bottle applications. Although PET/PEN blends are initially immiscible, melt-blending PET and PEN under conditions where a limited amount of transesterification takes place enhances miscibility, which results in a single T_g and clear blend. The processing window required to produce an acceptable degree of transesterification is wide enough to produce blends that are clear but still capable of developing strain-induced crystallinity. Several studies have been published describing the necessary blending residence time and temperature conditions (27–29). Aoki has reported barrier properties of containers prepared from blends of PET with PEN (30). The data show that the barrier performance observed for 10, 20, and 40 wt% blends exceed that predicted by extrapolation of simple mixtures (Fig. 15), in agreement with the data shown earlier on films (Fig. 3).

Small Hot-Fillable Wide Mouth Jars. PEN/PET blends have been successfully used in wide mouth, nonheat set hot-fill container applications. Aoki and Guelph Food Technology Center established that the hot-fill performance for wide mouth containers made from PET/PEN blends matched closely the glass-transition temperature of the material (31). As shown in Figure 16, containers from each material were tested under a special protocol for hot-filling performance. The jars were filled at various temperatures. The maximum temperature tried at which a jar gave satisfactory performance is marked as "pass" and the next higher temperature tried is marked as "fail." As seen in all cases the material's T_g lies between the "pass" and "fail" temperature.

The biggest benefit of this performance attribute is in the case of small wide-mouth containers, where development of crystallinity during stretching is minimal and application of heat-setting is not practical. A commercial example was a PET/PEN blend container with 40 wt% PEN introduced under the Aran brand in Scotland (32). The size of the container, made on a one-step Aoki machine, was 28 g and the filling was done at 85°C.

CSD Bottles from PET/PEN Blends. As the container size decreases the need for gas barrier (carbonation retention in the case of CSD) increases. This

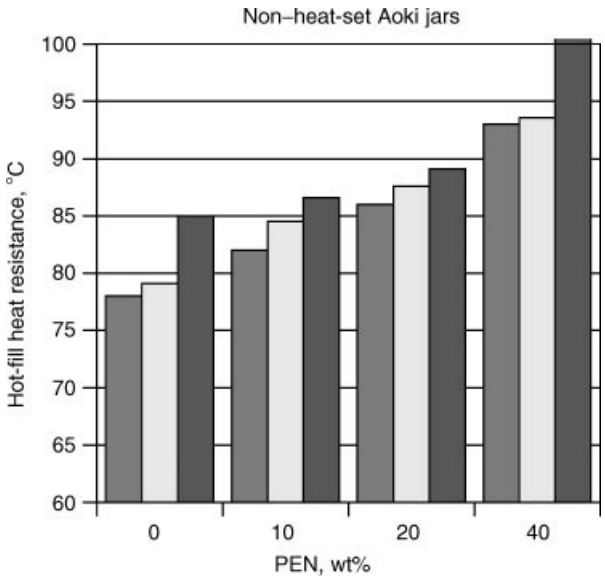

Fig. 16. Hot-fill performance of amorphous jars made from PET/PEN blends. □ Pass ◻ T_g, ■ Fail.

is a direct effect of the increase in specific area or area per unit volume. In general, when considering normal transportation logistics and desired shelf life, the practical CSD bottle size limit attainable with PET is 500 mL. At the same time, market research has shown that smaller single-serve sizes (eg, 350 mL) are desirable in many regions worldwide. The Coca-Cola Co. had demonstrated, through an extended test market introduction in Australia, that a PET/PEN blend is suitable for fabricating a 350-mL bottle that meets the shelf life requirements for Coca-Cola and Diet Coke carbonated beverages (32).

Packaging Applications Using Low PEN Level PET/PEN Copolymers. PETN-x low level copolymers, where $x \leq 1\%$ to typically 10% are used in rigid packaging applications where increased UV barrier resistance or small improvements in thermal performance versus PET are required.

Naphthalate UV Property Benefits in Packaging Applications. As discussed in the Performance Property section, NDC incorporation—even at a low level—into polyesters affords substantial UV-absorber absorption in the 310–370 nm wavelength range. The ability of NDC to function as a UV radiation blocker can be used to protect container contents from the harmful effects of UV light in applications ranging from dairy products to fruit juices and pharmaceuticals. A fundamental advantage offered by NDC-based UV barrier protection in polyester containers is its stability to migration. Unlike many standard UV stabilizers that can leach or migrate out of the polymer matrix, NDC is reacted directly into the polyester backbone and cannot migrate.

Studies completed on model color-sensitive beverages further illustrate the effectiveness of low level naphthalate modification in protecting against UV radiation exposure (33). The model beverage consisted of 20 ppm Yellow #5, 1000 ppm citric acid, 200 ppm sodium benzoate, and 100 ppb iron. This model

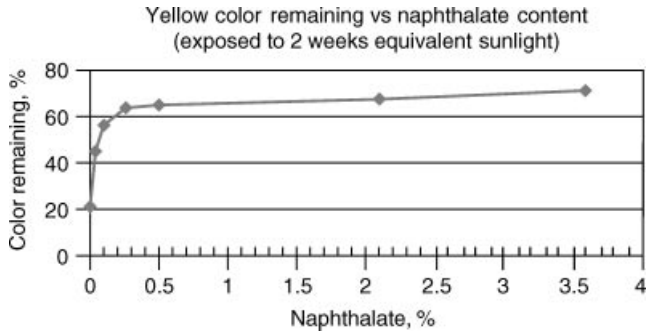

Fig. 17. Color retention of a model beverage in PET and PETN bottles (33).

solution is extremely sensitive to yellow color bleaching upon UV exposure. As Figure 17 illustrates, after accelerated testing in a Xenon weatherometer (corresponding to 2 weeks of equivalent sunlight), substantial protection against color loss occurred even at very low levels of naphthalate content in the PET package. This plot indicates that an NDC level as low as 0.25 mol% should be sufficient for many UV barrier applications.

The same study demonstrated the UV protective capability of PETN copolymers on the color stability of a commercial juice drink containing artificial colorant Blue No. 1. As shown in Figure 18, PET modified with 0.25 mol% NDC offers substantial protection against a dramatic loss in color occurring after only 5 h of sunlight exposure when unmodified PET is used instead.

Low level NDC modification of PET has been used in Japan for Listerine Cool Mint mouthwash, a product of Warner-Lambert Japan. The PETN copolymer in these 80-mL to 700-mL bottles is used to extend shelf life by protection from UV exposure, as well as to prevent absorption of the active ingredients of the mouthwash into the bottle (30). Another commercial packaging application, relying on the UV barrier property of naphthalates, was Fujiya's Lemon Squash (34), packaged in a 1.5-L PETN copolymer bottle. A small amount of naphthalate was incorporated into the PET resin to protect the drink's natural fruit juices and added Vitamin C.

PETN Copolymer Hot-Fill Applications. PETN copolymers at naphthalate modification levels up to 10 mol% are capable of developing strain-induced crystallinity. These copolymers have been used in several bottle geometries and offer both improved thermal resistance and UV barrier versus PET. These advantages derive in part from the increase in T_g (as shown in Fig. 1), and partly from optimizing the bottle stretch blow process and preform design. For example, bottles from PETN that were subjected to a one-stage heat-setting treatment (hot mold) without neck crystallization have been capable of hot-fill temperatures up to 93–95°C. Table 16 shows an example of a hot-fill test comparing a PETN-10 and a PET 500-mL tea-drink bottle.

This increased temperature stability has stimulated several commercial PETN commercial introductions. Examples are illustrated below.

Hero Group, U.K.-based Carters Packaging, had produced a one-way and multitrip container for hot-fill applications (30). Produced on a Sidel standard heat-set, one-wheel blow-molding machine, the package could be hot-filled to 95°C

Table 16. Hot-Water Hot-Fill Test[a,b]

Volume change at:	PET	PETN-10
85°C	−1.0%	−0.2%
90°C	−2.5%	−0.4%
93°C	−2.0%	−0.4%

[a]Data from BP Amoco Chemical Co.
[b]One-step heat-set 500 mL tea-drink bottles, amorphous neck.

after standard aging practices, without having to crystallize the neck to prevent deformation. The one-trip container had a weight of 59 g and a 28-mm neck, while the returnable and rewashable bottle had a weight of 76 g and a 43-mm neck finish. The latter could be washed at 75°C with a 2% caustic solution. For comparison, heat-set PET allows only a washing temperature as high as 59°C.

Säntis Kunstoffe, a Swiss bottle producer, had introduced a 0.5-L PETN-8 container. This bottle contained "Sports + Fit" athletic beverage, which comes in Orange or Citrus Flavor (23). The bottle, which was made on a MAG machine, weighed 40 g and had a filling temperature of 85°C. A similar bottle has been used in Switzerland by the canner Bischofszell AG for its 100% orange juice brand "Sunqueen." which is distributed by the Swiss Migros supermarket chain.

Log Plastics Products Co. of Israel had developed a 1.0-L bottle from PETN copolymer for hot-fill applications (28). The bottle was produced on an Aoki one-step machine. It was used by Gan Schmuel Foods Ltd. for its 100% juices.

Water bottler Powwow has introduced in Europe 5-gallon returnable/refillable containers from PETN copolymers, for use in drinking water fountains, an application typically served by PC (35). Unlike PC containers, which are made by extrusion blow molding, the PETN 5-gallon containers are fabricated by one-step injection/stretch blow molding. Incorporation of PEN repeat units enhances the container's thermal stability against washing with hot caustic solutions, for increased number of trips.

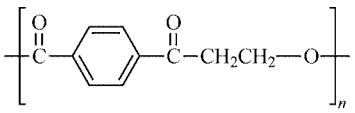
POLYESTER FILMS

Introduction

Biaxially drawn polyester film based on poly(ethylene terephthalate) (PET); **1** ($T_m = 255°C$; $T_g = 78°C$) was developed by ICI (1) in Europe and DuPont (2) in the United States in the 19850s with DuPont introducing the first commercial film line in the late 1950s. There was a slow increase in the number of film manufacturers through the 1960s and 1970s, and production increased in the 1980s and 1990s, but in the late 1990s onwards was a major consolidation in the industry with DuPont buying the ICI Films Business and then forming a joint venture with Teijin, Toray acquiring Rhone Poulenc and Chiel, and joint venturing with Saehan, and Mitsubishi acquiring Hoechst. Global capacity of PET film in 2002 was 1,550,000 ton. There are now over 50 producers of PET film worldwide, many in the rapidly expanding Chinese market. DuPont Teijin Films and Toray Saehan Inc. are the largest, with declared capacities of about 290,000 and 280,000 ton respectively. Mitsubishi and SKC form the "second tier" with approximately half the capacity of the top two. The next is Kolon (Korea) with about half the capacity of Mitsubishi and SKC.



1

The first patent covering poly(ethylene naphthalate) (PEN); **2** ($I_m = 263°C$; $T_g = 120°C$) was filed in 1948 by Cook and co-workers (3) not long after the discovery of PET. However, it was not until the 1970s that the dimethyl ester of 2,6-naphthalene dicarboxylate (2,6-NDC) became available in sufficient quantities for the first PEN films to be produced on a semitechnical scale. Several manufacturers explored this area, with the first PEN film being produced in the early 1970s. However, the raw material continued to be very scarce and costly, and the resulting small scale of film production led to an extremely expensive product compared with PET. This proved to be uneconomic for most applications and there was consequently little commercialization of PEN film until high value speciality videotapes were found to benefit from the use of PEN film in Japan during the 1980s. As a result of the promise of larger scale and more economic raw material supply, plus greater interest from the end market, PEN films were launched commercially in the early 1990s. Since then investment in a world-scale 2,6-NDC production facility by Amoco Chemical Co. (now BP) has significantly aided the economics of PEN film production (see POLY(ETHYLENE NAPHTHALATE) (PEN)). Sales of PEN film are currently of the order of several thousand tonnes and DuPont Teijin Films is the leading producer with its Teonex brand range of films.

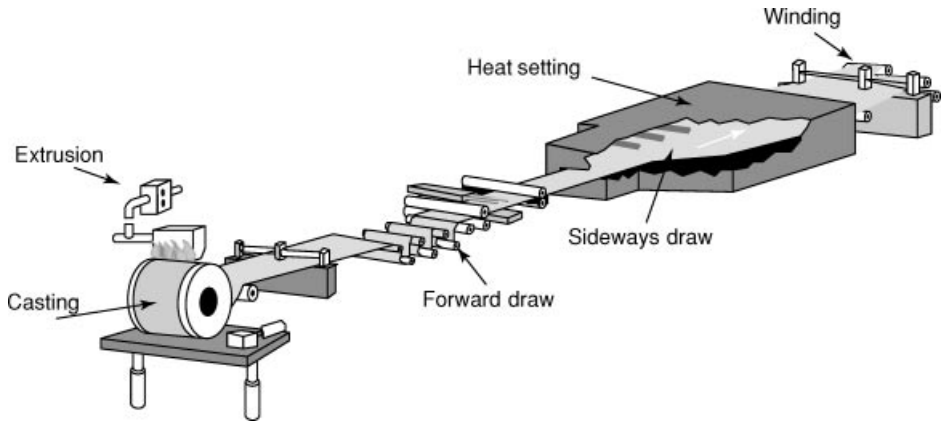

Fig. 1. A Typical film manufacturing process.

The Film Process

Biaxially oriented PET and PEN films are exclusively produced by a stenter process where commonly the amorphous cast film is drawn in the machine direction (MD) by passing it over heated rollers and then fed into a stenter frame to achieve a draw in the transverse direction (TD) (see FILMS, MANUFACTURE; FILMS, ORIENTATION). A schematic of the process is shown in Figure 1.

Normally the sequence of steps is as described above (MD–TD), but the process can be reversed (TD–MD) (4–6); and even a simultaneous stenter process (7) whereby the clips are not interconnected and stretching can therefore be carried out by accelerating the clips in the MD within the diverging TD draw section, has been commercialized. Using this basic process film with thicknesses from 0.6 to 350 μm can be prepared.

The conversion of polymer into film falls into four basic stages:

(1) Polymer preparation and Handling
(2) Extrusion and casting
(3) Drawing and heat setting
(4) Slitting, Winding, and Recovery

The film process and in particular the morphology developed during processing has been described in more detail elsewhere (8,9).

Polymer Preparation and Handling. Polymer can be extruder-fed to the drawing process or it can be directly fed from a continuous polymerizer (CP), but in both cases the virgin polymer tends to be of a number-average molecular weight of about 20,000 although higher and lower molecular weights are filmed. With the extruder-fed film lines the polymer handling involves blending and drying. This is a consequence of the film process never being 100% material efficient and virgin polymer is therefore blended with polymer reclaimed from the film process. Drying is essential in closed (single-screw) extrusion systems as the polyesters are susceptible to hydrolysis, resulting in a reduction in molecular weight, but less commonly, processes have evolved based on vented (twin-screw) extruders where

moisture is removed just after melting. In the drying stage, polymer is crystallized first to avoid the chip sintering during drying and then dried for several hours at 160–180°C to reduce the moisture level to 10–30 ppm. Close-coupled CP film lines do not have this stage and melt is pumped directly through filtration to the die.

Extrusion and Casting. The blended and dried polymer is next melt-extruded through a slot die. There is usually melt filtration before the die to remove degraded polymer, gels, catalyst residues, and pipe deposits. The extrusion system is typically designed to deliver stable output up to about 2.6 ton/h over a wide range of operating conditions and throughputs. Exceptionally, higher outputs are possible, up to about 3.5 ton/h on thick film lines, using complex tandem or parallel extrusion systems (10). More recently twin-screw extruders have been introduced on some film lines to widen the operating window and to provide capital-efficient high throughputs. These are able to cope with a wider range of molecular weights, improve the mixing, and have the advantage of extruding at lower melt temperatures. Other combinations such as tandem single screws with melt pumps are also used to give a stable output. Parallel extrusion systems are also commonly used for high output but these present the problem of ensuring homogeneous melt stream blending. Whichever extrusion system is employed, its purpose is to transport a consistent flow of polymer melt to the flat film die of a stenter process.

The die which can be center- or end-fed converts the melt from a circular cross section to a uniformly thick melt curtain of the required width. The thickness of the film is continuously measured across the web after the stenter process, giving a thickness or gauge profile. This profile data is used to make fine adjustments to flow profile at the die either through thermoviscous heating or by actuation of mechanical bolts (which physically modulate the die gap profile to achieve uniform film thickness profile). Combinations of thermoviscous and mechanical modulation are also employed in some cases.

The purpose of the casting is to produce a continuous uniformly thick film of noncrystalline polymer with no surface blemishes and this is achieved by drawing down the melt curtain onto a casting drum. The polymer melt from the extrusion system will normally be between 280 and 310°C so as to minimize crystallization, which would increase film haze and brittleness and possibly cause a film breakage later in the filming process (9). To ensure this the molten film is cooled as quickly as possible below its glass-transition temperature by cooling the casting drum using recirculated water which passes through a heat exchanger to control its temperature between typically 10 and 15°C. Thin film can be satisfactorily cooled using a single drum, normally of size 600–900 mm in diameter, but for thicker films where the insulating properties of the film prevent cooling through to the air (nondrum) contacting side of the melt, a second drum is used to provide additional cooling.

As the casting drum rotates, air is drawn into the gap between the film of melt and the drum, affecting the contact of the two surfaces and the effectiveness of the cooling. This is avoided by electrostatically charging the film surface by using a pinning wire or blade electrode stretched across the drum just below the die face (11–13). This creates an electrostatic field around the wire or blade which induces a charge on the melt curtain surface. Since the drum is earthed the charge forces the melt curtain onto its surface.

The surface of the casting drum must be of a very high standard so as to avoid imprinting any patterning or "graininess" onto the cast film. The surface must also be hard in order to avoid damage and be resistant to corrosion so that no pitting occurs. Therefore a drum that is hard chrome plated and highly polished is usually favored. During operation the casting drum must be free of vibration and rotate smoothly so as to minimize any source of variation in thickness in the MD of the film.

Drawing and Heat Setting. The cast film initially passes through a preheat zone, where the temperature of the cast film is raised by passage over a series of heated contact rolls until a point, usually about 15°C above its glass transition, T_g, where the material can be readily stretched.

The forward draw stage physically stretches the heated polyester film between two nip roll systems with a surface speed differential and is designed to improve its tensile properties in the MD. Stretch ratios of around 3.5:1 are employed, and the stresses in the structure caused by this step align the molecular chain segments in the direction of the stress and thereby raise its tensile modulus and strength by a factor of about 3.

In the second stage of the stenter oven, the edges of the film web are clipped and led along diverging rails that cause the material to be stretched at temperatures above 100°C (135°C for PEN), for the second occasion, by a factor of between 3 and 4. The object of this step, the sideways draw, is to develop the properties of the film in the TD via orientation at the molecular level, to a point where they balance or approximately balance those measured in the MD (9). The process tends to align molecular chain segments not already aligned in the MD and to realign some MD-oriented crystallites toward the TD. The film at this stage is anisotropic.

The final stage in the stenter oven is designed to develop a crystalline morphology in the film which retains the improved mechanical properties from the drawing stages and which is more stable over time and at elevated temperature.

The heat set or crystallization stage of the process comprises three or more regions of the stenter oven, each with independent temperature control and the capability to adjust the lateral dimension of the web. Thus film can be treated to a range of thermal and strain programs to optimize its final properties. Temperatures of the film can exceed 230°C and although residence time may be only a few seconds this is sufficient for density changes equivalent to a rise of 30–40% in crystallinity to occur. On the same timescale, the noncrystalline regions of the film can exhibit significant molecular relaxation.

Unless all physical anisotropy can be removed from the noncrystalline fraction of biaxial PET film, the product will undergo residual shrinkage at elevated temperature. By managing both the film temperature and a relaxation of strain, achieved by a small convergence of the stenter rails (known as toe-in) during the heat set stage, it is possible to achieve considerable control of this film property (9).

Slitting, Winding, and Recovery. The film in and close to the clips is very thick and cannot be wound into film. This is slit off as the film exits the stenter and reclaimed for reprocessing into film. It is combined with scrap film and is either cut up into flake and compacted into particulate form or is reextruded and formed into pellets. This reclaimed polymer either is fed back in with the virgin polymer at the start of the film process or is fed into the CP process.

The edge trimmed film is then wound up. Rolls of film can be produced either on the stenter, or alternatively they can be slit down off line to the width and lengths required.

Surface and Bulk Properties Control

Film Properties. The film process described produces rolls of PET and PEN films that have the properties required for a standard PET or PEN film, ie high mechanical strength, good flexibility, excellent visual properties, flat and dimensionally stable, and available in a range of thicknesses. The difference in chemical structures of PET and PEN is shown by **1** and **2**. The substitution of the phenyl ring of PET by the naphthalene double ring of PEN has very little effect on the melting point (T_m), which increases by only a few degree Celsius. However, there is a significant effect on the glass-transition temperature (T_g), which increases from 78°C for PET to 120°C for PEN. The result of this is that although the good thermal properties of PET and PEN films enable them to retain physical, chemical, and electrical properties over a wide temperature range, PEN has significantly improved thermal resistance relative to PET. This is particularly noticeable with regard to PEN's higher continuous use temperature (14) Table 1.

The typical properties listed in Tables 1–5 are from DuPont Teijin Films Teonex PEN film datasheet and are for illustrative purposes only and are not intended to be used as design data.

PET and PEN retain their physical properties, including tensile strength, Young's modulus, and tear strength over a wide temperature range (−70 to 150°C) (14) (Table 2). PEN is generally a stiffer film than PET for a given thickness. This has been exploited in the development of the advanced photo system for consumer imaging where it has been possible to downgauge the film, resulting in a smaller, thinner reel of photographic film.

The chemical properties of PET and PEN films include excellent resistance to most chemicals. They retain 100% of tensile strength and modulus after 31 days at 23°C in glacial acetic acid, 10% hydrochloric acid, 10% nitric acid, 30% sulfuric acid, 2% sodium hydroxide, 2% ammonium hydroxide, benzyl alcohol, dioxane(1,4), ethyl acetate, ethyl alcohol, methyl ethyl ketone, toluene, trichloroethylene, tetrahydrofuran, cyclohexane, sulfurhexafluoride, 28% hydrogen peroxide, dimethyl formamide, tricresyl phosphate, and 0.25% detergent. PET film is dissolved by hexafluoro-2-propanol, *m*-cresol, *o*-chlorophenol and is attacked by 35% nitric acid, 10% ammonium hydroxide, and *n*-propylamine (14). PET and PEN films also have very low moisture permeability and overall resistance to staining by various chemicals and food products. PEN film has superior barrier properties relative to PET film (Table 3), and the gas and vapor barrier properties can be significantly improved by coating with a barrier coating such as poly(vinylidene chloride) or by vacuum metallization (15) (see BARRIER POLYMERS).

PET and PEN films have excellent electrical insulating properties as shown in Table 4 (14).

Because of their excellent thermal, insulating, and moisture-resistant properties, they are used in a wide variety of electrical applications, with PEN being the preferred candidate in applications that require higher temperatures and good hydrolysis resistance.

However, for many of the specialty applications that PET and PEN films are used in, further modification of either the surface or bulk properties are required as illustrated below.

Coating. PET and PEN are fairly inert polymers and for many applications the surface of the film is altered by coating or adhesive lamination to other materials, eg film for packaging will be lacquered to accept inks or adhesives, or, for photographic applications, primed to accept photosensitive overcoats. Coatings are also applied to achieve other surface effects, such as antistatic, barrier (water, oxygen, carbon dioxide, flavor), release, and frictional characteristics (8,9).

These coatings are usually acrylic-, vinyl-, polyester-, or polyurethane-based, and PET and PEN films are commonly coated either "in-line" or "off-line". "In-line" coating usually involves aqueous-based materials, and is carried out between the forward draw and before entering the stenter, while "off-line" coating involves unwinding and priming the surface of preformed film reels with aqueous- or solvent-based coatings. In both cases, the coating may be applied to one or both sides, and some products have different coatings applied to either sides of the film. Coatings are mostly applied by offset gravure or by direct gravure coating.

Coextrusion. Coextrusion (qv) is used to produce a film with two or more different polymer layers, so that one or both surfaces of the film have different properties to the "core" polymer. In addition, coextrusion allows manufacture of products with layers thinner than can be made and handled as individual layers. Coextrusion provides a means of flexibly configuring a wide range of film laminate structures which cost-effectively meet product requirements.

The basic coextrusion process consists of the generation of two or more melt streams and their confluence while in the melt phase. The number of separate extrusion systems is determined by the number of polymer types. This is typically 2, but occasionally 3 and exceptionally up to 10. Each polymer type to be incorporated in the structure is separately melted, pressurized, and (optionally) filtered in parallel extrusion systems before flowing into the coextrusion hardware. The optimum method of bringing the separate melts together depends primarily on their respective flow behaviors. The melt layers must remain distinct but well bonded in the process from the point(s) of confluence through to solidification. There are basically two hardware configurations in use for common polymers: the multi-manifold die and the injector block. Combinations of the two are also possible for complex structures (8,9).

Fillers. Fillers (qv) are added to PET for two main reasons: either to modify surface properties, or to modify bulk properties. Particulate fillers such as clays and silica, typically a few micrometers in diameter, are added to create surface roughness during the film drawing process. A primary function of the surface roughness is to reduce the blocking or sticking propensity of the otherwise very smooth film surfaces during winding and reel formation. The roughness also enhances dynamic handling behaviour particularly for high speed transport and winding of thin films through subsequent conversion processes. Surface optical properties can also be regulated via filler-induced surface roughness, for example, to control gloss or eliminate Newton's ring fringes between adjacent film layers (9).

Although mechanical properties such as softness, stiffness, and toughness can be addressed, it is most common for optical properties to be modified via particles. Opacity and whiteness are generated by two discrete mechanisms. Simple pigmentation (light scattering from the particle–polymer interface) can be achieved using similar titanium dioxide technology to that employed in the fibers and coatings industries. It is, however, more common for the anatase crystal form to be employed since this is a less abrasive pigment than the more strongly scattering rutile. The second mechanism involves using the additive to generate microvoiding during the film draw. The additive can be inorganic, for example barium sulfate or calcium carbonate, or polymeric, for example, polypropylene. In this mechanism the opacity is derived from scattering between the polymer and the

void. The use of microvoiding confers the potential advantage of a softer film of reduced density.

Shrinkage. Standard PET and PEN films from the stenter process will shrink between 1 and 3% at temperatures above the T_g. For the high level of accuracy required by some electrical applications shrinkages of below 0.1–0.2% are required. In order to meet this the film is unwound and passed through a carefully temperature-controlled oven, with almost no tension in the film. The amount of residual shrinkage in the film after this process is typically less than 0.1% in the MD and the TD for temperatures up to 150°C for PET and 200°C for PEN.

General Comments on Comparison with Other Films. It is not possible in this article to give a detailed comparison of polyester films compared to other films as each class of film has different strengths and weaknesses and serve different markets. Both PET and PEN films are biaxially oriented crystalline films; this imparts unique properties and differentiates them from amorphous films such as polycarbonate (PC) and polyethersulfone (PES) films. As a generalization PET and PEN films are stiffer films compared to amorphous films (Table 5); they have very good solvent resistance and low moisture absorption, but PES film in particular is a higher T_g and higher temperature performance film and PC film has superior clarity. Compared to crystalline films such as oriented polypropylene (OPP), PET and PEN films are higher temperature performance films. Polyphenylene sulfide (PPS) film is a high performance biaxially oriented crystalline film and has a similar continuous use temperature, but a lower T_g compared to PEN film. PEN has better dimensional stability but PPS offers superior flame retardancy and chemical resistance.

The particular strength of polyester films, however, is the wide range of film effects that can be achieved with fillers, coatings, coextrusion, etc, as outlined in the previous sections—this versatility is unique in the films market.

Application. Typical application areas that exploit the properties of polyester film are illustrated in Table 6. It can be seen that usually a combination of properties are required and these are achieved by a combination of base film properties, fillers, coatings, and coextrusion technologies.

Future Trends

The unique blend of properties of PET and PEN films makes them extremely versatile products and the growth in the films market is predicted to be above 5% per annum. However this masks that some areas such as packaging, industrial, and electrical applications are growing at a greater rate whereas the growth in the more traditional markets such as magnetic media or graphic arts materials is more modest. Advances are continually being made in uprating the film process, but in addition new applications for PET and PEN are continually being developed. The trend will be increasingly toward differentiation through the application of new process technologies and advances in the control of the process coupled with the combinations of base polymer, filler, coating, and coextrusion technologies.

Table 6. Examples of Typical Film Applications and the Key Properties Required

Application	Film properties required
Packaging	Seal (peelable through to permanent) Wide heat seal range Barrier (oxygen and aroma) White, clear Surface roughness Pretreats to allow metal, ink, sealant adhesion Stiffness 12–30 μm
Labels	Clear, white, matte, black Durability Adhesion with inks Silicone adhesion 23–175 μm
Imaging • Montage • Microfilm • Digital technology media • APS (PEN)	High opacity, white through to high clarity, flatness, Antistat Dimensional stability Adhesion with inks 50–175 μm Stiffness
Casting and release	Wider range of surface textures from high gloss to very matte Release coats 12–50 μm
Capacitors	Thin film Low shrinkage Electrical–thermomechanical properties 0.9–23 μm
Electronics • Flexible printed circuits, flat flexible cable • Membrane touch switch • Loudspeakers • RFID tags • Automotive wiring (PEN)	Brilliant clarity-white film Electrical properties Low shrinkage Durability Adhesion with inks 12–175 μm High temperature performance Hydrolysis resistance
Coil coating/fiber-reinforced plastics	Heat bondable UV stable 12–125 μm
Electrical insulation • Motors • Cable	High dielectric strength Thermal endurance at elevated temperatures Dimensional stability Durability Chemical resistance 12–350 μm
Magnetic media • Floppy disks	Tensilized film Surface quality

POLYESTERS, UNSATURATED

Introduction

Low molecular weight polyesters derived from unsaturated dibasic acids (or anhydrides) dissolved in unsaturated vinyl monomers comprise a versatile family of thermosetting materials known generally as *unsaturated polyester resins*. Prototype resins produced in the early 1940s were used in conjunction with glass fiber reinforcements to produce the first composite plastics. The high strength and radiotransparency of this material expanded its role in radome covers employed in large quantities toward the end of World War II.

Markets for the resins have expanded rapidly; the dominant applications are still in conjunction with glass-fiber reinforcement to form laminar composites known generically as *fiber-glass-reinforced plastic* (FRP) in the United States and *glass-fiber-reinforced plastic* (GRP) in Europe and elsewhere. Resins have also evolved for use in casting processes, which usually contain high loadings of fillers or mineral aggregate and are defined as one form of polymer concrete. By 2002, global production of unsaturated polyester resins had exceeded 1,900,000 t, with the United States being the largest market, at over 780,000 t.

Raw Materials

The properties of polymers formed by the step-growth esterification (1) of glycols and dibasic acids can be manipulated widely by the choice of coreactant raw materials (Table 1) (2). The reactivity fundamental to the majority of commercial resins is derived from maleic anhydride [108-31-6] (MAN) as the unsaturated component in the polymer, and styrene as the coreactant monomer. Propylene glycol [57-55-6] (PG) is the principal glycol used in most compositions, and *ortho*-phthalic anhydride (PA) is the principal dibasic acid incorporated to moderate the reactivity and performance of the final resins.

Isophthalic (*m*-phthalic) acid [121-91-5] (IPA) is selected to enhance thermal endurance as well as to produce stronger, more resilient cross-linked plastics that demonstrate improved resistance to chemical attack. Terephthalic (p-phthalic) acid [100-21-0] (TA) provides similar properties as isophthalic acid; it is also used in corrosion resinstance and a wide variety of other applications.

Other glycols can be used to impart selective properties to these simple compositions. Ethylene glycol [107-21-1] (EG) is used to a limited degree to reduce cost, whereas diethylene glycol [111-46-6] (DEG) produces a more flexible polymer that can resist cracking when impacted. Neopentyl glycol [126-30-7] (NPG) is used in most commercial products to improve uv and water resistance. Alkoxylated derivatives of bisphenol A (BPA) not only impart a high degree of resistance

to strong acidic and alkaline environments, but also provide resistance to deformation and creep at elevated temperatures.

Long-chain aliphatic acids such as adipic acid [124-04-9] are generally used to improve flexibility and enhance impact properties, demonstrating subtle improvements over resins modified with the ether glycols (diethylene glycol) and polyether glycols (polypropylene glycol).

Novel polyester compositions have also been derived from dicyclopentadiene [77-73-6] (DCPD), which can enter into two distinct reactions with maleic anhydride to modify properties for lower cost. These compositions have effectively displaced *o*-phthalic resins in marine and bathtub laminating applications.

Recycled poly(ethylene terephthalate) (PET), which offers excellent properties at potentially lower cost, is finding wider use as a raw material component and meeting increasing demands for environmentally compatible resins (see POLYESTERS, THERMOPLASTIC; RECYCLING, PLASTICS).

Other minor raw materials are used for specific needs. Fumaric acid [110-17-8], the geometric isomer of maleic acid, is selected to maximize thermal or corrosion performance and is the sole acid esterified with bisphenol A diol derivatives to obtain optimum polymer performance. Cycloaliphatics such as hydrogenated bisphenol A (HBPA) and cyclohexanedimethanol (CHDM) are used in selective formulations for electrical applications. Tetrahydrophthalic anhydride [85-43-8] (THPA) can be used to improve resilience and impart useful air-drying properties to polyester resins intended for coating or lining applications.

Halogenated intermediates, dibromoneopentyl glycol [3296-90-0] (DBNPG), and alkoxylated derivatives of tetrabromobisphenol A are used extensively in flame-retardant applications. Similar properties can be derived from halogenated

dibasic acids, chlorendic anhydride [115-27-5] (CAN), and tetrabromophthalic anhydride [632-79-1] (TBPA). Processes can be used to produce brominated products by the *in situ* bromination of polymers derived from tetrahydrophthalic anhydride.

Monomers such as methyl methacrylate [80-62-6] are often used in combination with styrene to modify refractive index and improve uv resistance. Vinyltoluene [25013-15-4] and diallyl phthalate [131-17-9] are employed as monomers in selective molding compositions for thermal improvements.

Process Equipment

The polyesterification reaction is normally carried out in stainless steel vessels ranging from 8000–20,000 L, heated and cooled through internal coils (Fig. 1). Blade agitators revolving at 70–200 rpm are effective in stirring the low viscosity mobile reactants, which are maintained under an inert atmosphere of nitrogen or carbon dioxide during the reaction at temperatures up to 240°C.

Weigh tanks or meters measure the liquid glycols into the reactor. Solids are usually added from 25-kg bags or 1000-kg supersacks. Silo and auger are used widely for isophthalic acid, whereas phthalic anhydride [85-44-9] and maleic anhydride are metered in molten form. A packed condenser efficiently separates water from glycol. The glycol is refluxed back into the reactor and the remaining condensate is incinerated on-site using a thermal oxidizer. Once the polymer is formed, it is cooled to below 180°C and drained into a cooled blend tank containing styrene monomer under high agitation.

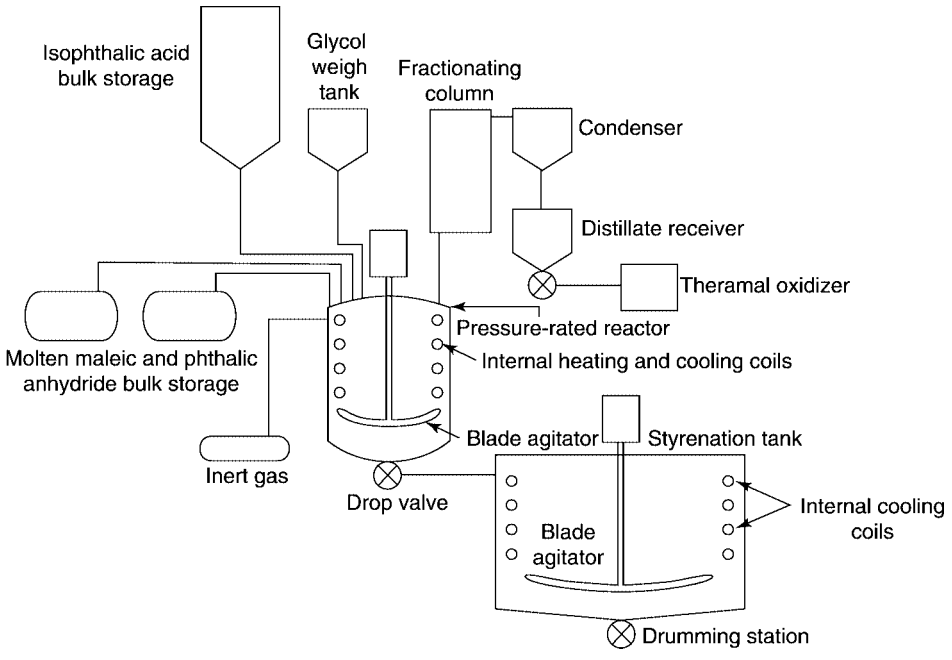

Fig. 1. Reactor system for the manufacture of polyester resins.

Glass-lined reactor systems are used occasionally for halogenated resins to prevent corrosion of the reactor components. Copper and brass fitting should be avoided because of the significant influence on resin cure characteristics.

Polyesterification

The reaction of glycols with dibasic acid anhydrides, such as phthalic and maleic anhydrides, proceeds at above 100°C, ending with the exothermic formation of the acid half-ester produced by the opening of the anhydride ring. The reaction exotherm effectively raises the temperature of the reactants to over 150°C, at which point the half-esters condense into polymers with the evolution of by-product water. As the reaction proceeds, the viscosity of the reactants increases, restricting the release of water, so that the temperatures must be gradually increased to 220°C to maintain a steady evolution of condensate water. Resins normally lose between 8 and 12% of initial charge weight as condensate.

The polyesterification reaction is reversible because it is influenced by the presence of condensate water in equilibrium with the reactants and the polymer. The removal of water in the latter part of the reaction process is essential for the development of optimum molecular weight, on which the ultimate structural performance depends.

The polyesterification reaction is carried out in the presence of an inert gas, such as nitrogen or carbon dioxide, to prevent discoloration. Usually, the sparge rate of the inert gas is increased in the final stages of polyesterification to assist the removal of residual water. Although the removal of water can be facilitated by processing under vacuum, this is rarely used on a commercial scale.

The esterification rate can be accelerated by acid catalysts (3) such as *para*-toluenesulfonic acid and tetrabutyl titanate, but tin salts such as hydrated monobutyl tin oxide are preferred for reasons of product stability during storage. The polyesterification process can be reversed by injecting steam into the reactants; this can be used to control the final molecular weight attained by the polymer. Transesterification during polymer formation also occurs, which leads to changes in the distribution of polymers in the final product. Transesterification is employed on a commercial scale to recycle poly(ethylene terephthalate) waste into useful resins by digesting an equivalent amount of glycol in the presence of catalysts such as tetraisopropyl titanate or zinc acetate. The terephthalate esters subsequently react with maleic anhydride to produce unsaturated terephthalate polymers, which have properties similar to their isophthalic homologues.

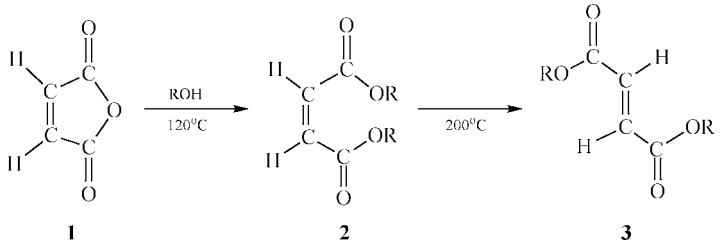
The viscosity of the final polymer melt usually limits the progress of molecular weight development, and number-average values (M_n) between 1800 and 2500 are normally observed. Other side reactions also modify molecular weight growth. Side reactions are influenced by the choice of reactants. Ethylene glycol can form cyclic esters with phthalic anhydride; maleic anhydride can produce addition products (4) with lower glycols, forming trifunctional succinate derivatives that lead to high molecular weight branched polymers and the possibility of gelation during esterification. To maintain maximum unsaturation levels during esterification, fumaric acid is often used in place of maleic anhydride. Fumaric acid

is also used widely in formulations involving alkoxylated bisphenol A to obtain optimum thermal and corrosion performance.

Polyesterification involving insoluble reactants such as isophthalic acid is normally carried out in two-stage reactions, in which isophthalic acid reacts first with the glycol to form a clear melt. The balance of the reactants, including maleic anhydride, is then added to complete the polymer, thus avoiding longer cycle times and some discoloration.

Polyester resins can also be rapidly formed by the reaction of propylene oxide (5) with phthalic and maleic anhydride. The reaction is initiated with a small fraction of glycol initiator containing a basic catalyst such as lithium carbonate. Molecular weight development is controlled by the concentration of initiator, and the highly exothermic reaction proceeds without the evolution of any condensate water. Although this technique provides many process benefits, the low extent of maleate isomerization achieved during the rapid formation of the polymer limits the reactivity and ultimate performance of these resins.

Maleic Isomerization. Polyesters are formulated using maleic anhydride (**1**) as the common unsaturated moiety. During the course of the polyesterification reaction at 220°C, the *cis*-maleate ester (**2**) isomerizes to the *trans*-fumarate (**3**). The fundamental reactivity of the final polyester with styrene is directly proportional to the degree of isomerization and the level of fumarate polymers formed during the course of esterification. Maleate polymers in the cis form create strain across the double bond, causing some displacement from a planar configuration; fumarate polymers in the trans configuration are influenced less by steric effects and the double bond can assume a planar configuration conducive to addition copolymerization with styrene. Branched asymmetric reactants such as propylene glycol and bulky aromatic dibasic acids such as isophthalic acid create sufficient steric interference to promote isomerization to the *trans*-fumarate polymers, whereas linear glycols such as ethylene and diethylene glycol and linear dibasic acids such as adipic acid produce resins that have higher levels of the maleate polymer.



1 **2** **3**

The temperature of esterification has a significant influence on isomerization rate, which does not proceed above 50% at reaction temperatures below 150°C. In resins produced rapidly by using propylene oxide and mixed phthalic and maleic anhydrides at 150°C, the polyester polymers, which can be formed almost exclusively in the maleate conformation, show low cross-linking reaction rates with styrene.

Isomerization is facilitated by esterification at temperatures above 200°C or by using catalysts, such as piperidine and morpholine (6), which are effective

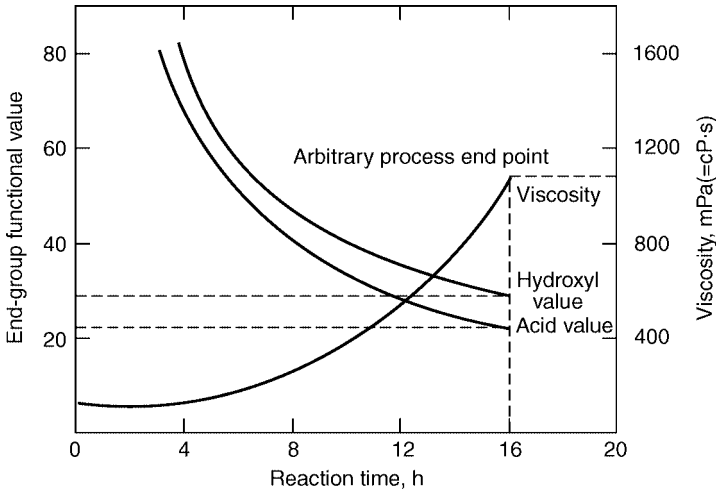


Fig. 2. Functional end groups and solution viscosity during polyester resin manufacture. Acid value is defined as the milligrams of KOH required to neutralize 1 g of polymer; hydroxyl value is defined as the milligrams of acid equivalent required to neutralize 1 g of polymer. Solution viscosities are determined at 60 wt% in styrene.

in raising isomerization of fumarate to 95% completion. Resins made by using fumaric acid are exclusively fumarate polymers, demonstrate higher reactivity rates with styrene, and lead to a complete cross-linking reaction.

End Group Analysis. The reaction of balanced stoichiometric glycol–dibasic acid ingredients theoretically produces polymers with equivalent acid and hydroxyl end groups. Commercial processes, however, normally include an excess of glycol to offset distillation losses. Depending on column efficiency, the polymer can have a higher relative hydroxyl value and a much lower acid value (Fig. 2), and this controls the ultimate molecular size. Most commercial laminating resins have acid values ranging from 25 to 30, whereas higher molecular weight isophthalic resins have values that fall between 10 and 15.

Molecular Weight. Unsaturated polyester resins are relatively low in molecular weight, and are formulated to achieve low working viscosities when dissolved in styrene. The M_n normally falls between 1800 and 2500, although dicyclopentadiene and orthophthalic resins can be useful below this range. The molecular weight follows a Gaussian distribution curve (Fig. 3), the shape of which influences final solution viscosities. In phthalic resins, the presence of a low molecular weight fraction is usually observed, whereas in high maleic resins a high molecular weight shoulder is observed. This indicates significant glycol addition across the double bond to form a trifunctional reactant. Polymers having different chain lengths and compositions exist as a compatible mixture; the ratio of weight-average molecular weight (M_w) and number-average molecular weight (M_n) is defined as the polydispersity D. For o-phthalic and isophthalic resins, D is just over two, but higher molecular weight resins and resins containing high maleic levels are more polydisperse and the distribution curve becomes flatter as the resin viscosity increases.

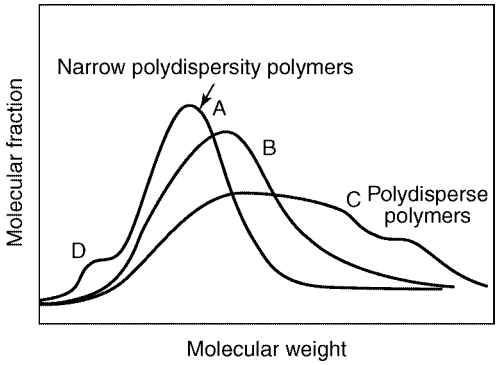

Fig. 3. Molecular weight distribution curves as determined by gel-permeation chromatography. A represents *ortho*-phthalic resins; B, highest molecular weight isophthalic resins; C, high molecular weight polydisperse polymers having high maleic addition reactions; and D, low molecular weight fraction seen in most phthalic resins.

ortho-Phthalic resins consist of chains having an average of 15 ester groups and a narrow distribution curve. The molecular weight development during the manufacturing process is normally followed by using solution viscosity that tends to increase exponentially in the final stages of the reaction. Arbitrary end points are usually established well before this stage to avoid gelation in the reactor (see Fig. 2).

Formulation

***ortho*-Phthalic Resins.** Resins based on *ortho*-phthalic anhydride (Table 2) comprise the largest group of polyester resins and are used in a variety of commercially significant applications, including marine craft, translucent glazing, simulated-marble vanity sets, and buttons. Most laminating and casting processes also rely on both colored and clear gel coats to provide some level of surface protection. The glycol generally controls the required performance; the phthalic–maleic anhydride ratio is adjusted to modify the reactivity according to physical properties required for fabrication needs.

The glycol is charged to the reactor and heated to 50°C under an inert-gas sparge. The lower melting maleic anhydride is metered in, allowing the temperature to rise to 100°C, followed by the phthalic anhydride. A clear solution forms

Table 2. Molar Component Ratio Used in *ortho*-Phthalic Formulations

Button	0.85	0.15		0.60	0.4	1.0

and the temperature is increased to 120°C to initiate the exothermic reaction between the glycol and anhydride forming the half-ester. The temperature increases rapidly to 150°C as the exotherm heat is released, at which point the half-ester begins to condense into low molecular weight polymers. The increasing viscosity of the melt tends to restrict the release of water vapor, and the reactants can foam into the condenser unless the reaction is controlled through cooling. The temperature is gradually increased to 220°C to maintain a constant removal of the condensate, but falls off as the reaction nears completion, usually in 12 h. Solid phthalic anhydride sublimes out in the latter stages of the reaction, requiring close control of the inert-gas flow and temperature. Some processors have used xylene as an azeotropic solvent to assist water removal while suppressing the sublimation of the phthalic anhydride, but this is not widely applied.

Phthalic resins are usually processed to an acid number of 25–35, yielding a polymer with an average M_n of 1800–2000. The solution viscosity of the polymer is usually followed to ascertain the polymer end point. The resin is cooled to 200°C and hydroquinone stabilizer (150 ppm) is added to prevent premature gelation during the subsequent blending process, with styrene at a maximum temperature of 70°C. The final polymer solution is cooled to 25°C before a final quality check and drumming out for shipment.

Isophthalic Resins. Isophthalic acid (IPA) can be substituted for phthalic anhydride to enhance mechanical and thermal performance and improve resistance to corrosive environments. Significant products include underground gasoline storage tanks and large diameter sewer and water pipe. Although phthalic resins find wide application in ambient fabrication processes, isophthalic resins (Table 3) are more widely used in products employing high temperature forming processes such as pultruded profile and electrical-grade laminate.

Isophthalic resins are manufactured by two-stage processing to facilitate the dissolution of the isophthalic acid. In the first stage, the glycol and isophthalic acid react under pressure at temperatures of 235°C under an inert atmosphere to produce a clear melt. High pressure processing [207 kPa (30 psi)] and, optionally, esterification catalysts such as hydrated monobutyl tin oxide are also widely employed to reduce the cycle times of two-stage processing. Maleic anhydride is added in the second stage and the final resin completed at 220°C to control color and molecular weight development. Isophthalic resins intended for corrosion application are processed to an M_n of 2200–2500; the reaction cycle is about 24 h.

The melting flow of the higher molecular weight isophthalic polymer is much higher than *ortho*-phthalic resins, and blending temperatures in styrene must be increased to avoid freezing the polymer out. Stabilizers such as toluhydroquinone

Table 3. Molar Component Ratio Used in Isophthalic Formulations

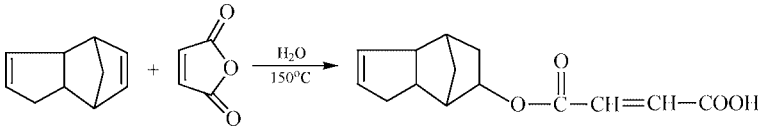
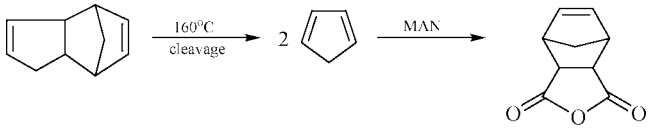
and benzoquinone are more effective gelation inhibitors for the higher styrene-blending temperatures used for these resins.

Dicyclopentadiene Resins. Dicyclopentadiene (DCPD) can be used as a reactive component in polyester resins in two distinct reactions with maleic anhydride (7). The addition reaction of maleic anhydride in the presence of an equimolar amount of water produces a dicyclopentadiene acid maleate that can condense with ethylene or diethylene glycol to form low molecular weight, highly reactive resins. These resins, introduced commercially in 1980, have largely displaced *ortho*-phthalic resins in marine applications because of beneficial shrinkage properties that reduce surface profile. The inherent low viscosity of these polymers also allows for the use of high levels of fillers, such as alumina trihydrate, to extend the resin-enhancing, flame-retardant properties for application in bathtub products (Table 4).



The cleavage of dicyclopentadiene into cyclopentadiene can be accomplished at temperatures above 160°C, producing the heterocyclic Diels–Alder maleic addition product, which opens to the diacid. This product can be esterified with propylene glycol to produce resins that demonstrate enhanced resilience and thermooxidative resistance suitable for molded electrical components.



Flame-Retardant Resins. This type of resins are formulated to conform to fire safety specifications developed for construction as well as marine and electrical applications. Resins produced from halogenated intermediates (Table 5) are usually processed at lower temperatures (180°C) to prevent excessive discoloration. Dibromoneopentyl glycol requires glass-lined equipment because of its corrosive nature due to some elimination of bromine during the process at high tempretaures. Tetrabromophthalic anhydride and chlorendic anhydride (8) are formulated with ethylene glycols to maximize flame-retardant properties; reaction

Table 5. Molar Component Ratio Used in Flame-Retardant Formulations

	Glycol		Acid

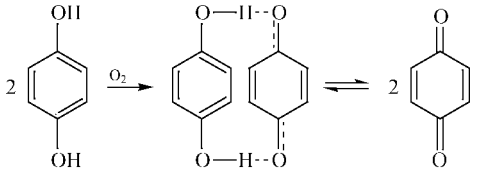
Marine	1.0		0.15	0.35		0.5	1.0

cycle times are about 12 h. Resins are also produced commercially by the *in situ* bromination of polyester resins derived from tetrahydrophthalic anhydride (9).

Methyl methacrylate (MMA) is often used in combination with styrene to improve light transmission and uv stability in flame-retardant glazing applications. Recently, MMA is used to a limited extent because of new environmental regulations. Phosphate ester (triethyl phosphate) additives are also included to supplement flame-retardant efficiency; benzophenone uv stabilizers are required to prevent yellowing of these uv-sensitive resins.

Bisphenol Resins. Ethoxylated and propoxylated derivatives of bisphenol A form the basis for two distinct resin groups that demonstrate superior thermal and corrosion resistance. The addition product of propylene oxide [75-56-9] and bisphenol A, reacted with fumaric acid and dissolved in styrene monomer, has established commercial significance in applications involving extreme corrosive environments. The resins known generically as bisphenol fumarates (10) have been used since 1955 in the fabrication of tanks and piping used in the chloralkali and pulp and papermaking industries. This resin is unique among polyester compositions in resisting strong alkaline solutions that readily decompose *ortho*-phthalic and isophthalic resins.

Stabilizers. Hydroquinone [123-31-9] (**4**) is widely used in commercial resins to provide stability during the dissolution of the hot polyester resin in styrene during the manufacturing process. Incorporation of oxygen (air) into the styrene containing the resin inhibitor is required to activate them, which is converted to an equilibrium mixture of quinone and the quinhydrone (**5**) (11). At levels of 150 ppm, a shelf life of over 6 months can be expected at ambient temperatures.



4 **5**

Toluhydroquinone and methyl *tert*-butylhydroquinone provide improved resin color retention; 2,5-di-t-butylhydroquinone also moderates the cure rate of the resin. Quaternary ammonium compounds, such as alkyl trimethylammonium chloride, are effective stabilizers in combination with hydroquinones and also produce beneficial improvements in color when promoted with cobalt octoate. Copper

naphthenate is an active stabilizer at levels of 10 ppm; at higher levels (150 ppm) it influences the reactivity preventing the resin from curing. Tertiary butylcatechol (TBC) is a popular stabilizer used by fabricators to adjust room temperature gelation characteristics.

Cross-Linking Mechanism

The reaction rate of fumarate polyesters with styrene is 20 times that of similar maleate polymers. Commercial phthalic and isophthalic resins usually have fumarate levels in excess of 95% and demonstrate full hardness and property development when catalyzed and cured. The addition polymerization reaction between the fumarate polyester and styrene monomer is initiated by free-radical polymerization. Commercially, benzoyl peroxide (BPO) and methyl ethyl ketone peroxide (MEKP) are the most common initiators used to cross-link unsaturated polyester and styrene. The initiators can be dissociated by heat or redox metal activators into peroxy and hydroperoxy free radicals.

The free radicals initially formed are neutralized by the quinone stabilizers, temporarily delaying the cross-linking reaction between the styrene and the fumarate sites in the polyester. This temporary induction period between catalysis and the change to a semisolid gelatinous mass is referred to as *gelation time* and can be controlled precisely between 1 and 60 min by varying stabilizer and catalyst levels.

As the quinone stabilizer is consumed, the peroxy radicals initiate the addition chain propagation reactions through the formation of styryl radicals. In dilute solutions, the reaction between styrene and fumarate ester follows an alternating sequence. However, in concentrated resin solutions, the alternating addition reaction is impeded at the onset of the physical gel. The liquid resin forms an intractable gel when only 2% of the fumarate unsaturation is cross-linked with styrene. The gel is initiated through small micelles (12) that form the nuclei for the expansion of the cross-linked network. The free styrene monomer is restrained within the gel and further reaction with fumarate groups is determined by the spacial arrangement; the styrene polymerizes in homopolymer blocks as it intercepts fumarate reaction sites. As individual micelles expand and deplete available fumarate sites in the short polymer chains, the remaining styrene forms homopolymer blocks that terminate at the boundaries between overlapping micelles (Fig. 4). Styryl free radicals simultaneously initiate micelle nuclei at points of high fumarate concentration. The micelles continue to expand, interacting with free styrene until the fumarate groups are depleted. The micelles eventually overlap at the boundaries that contain higher levels of terminal styrene homopolymer blocks.

As the micelles expand, the soft gel is transformed into a hard, rubbery transition stage that demonstrates low physical strength before the onset of the exotherm of polymerization. The temperature increases exponentially as the micelle expands. As the temperature subsides, the resulting cross-linked thermoset solid develops superior properties characteristic of the polymer. Generally, optimum strength characteristics are obtained in resins having a styrene/fumarate molar ratio of 2:1. Most resins are formulated with a styrene content consistent

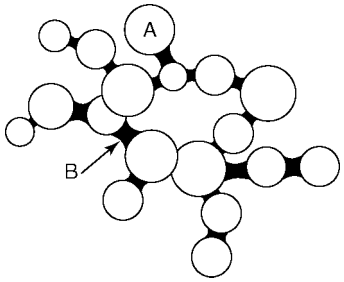


Fig. 4. Micellular gelation mechanism. A shows micelle nuclei, highly cross-linked; B, boundary where micelle growth terminates in styrene block polymers.

with this relationship (Tables 2–5). In resins having equivalent molar ratios of dibasic and unsaturated acid, this equates to resin polymer solutions containing around 40% styrene. However, this imposes some limitation on viscosity and most commercial resins contain between 40 and 45% styrene to achieve lower application viscosities.

In resins having low isomerization levels (80%), the fumarate–styrene reactions run to completion, leaving many unreacted maleate groups within the cross-linked structure. This results in an excess of styrene that inevitably forms larger homopolymer blocks between the intersecting micelles. The performance of such resins is characterized by lower softening temperatures and lower physical properties because of the additional plasticizing effects of the maleate ester group.

The cross-linking reaction mechanism is also influenced by the presence of other monomers. Methyl methacrylate is often used to improve the uv resistance of styrene-based resins. However, the disparate reaction rates of styrene and methacrylate monomer with the fumarate unsaturation not only preclude the use of more than 8% of the methacrylate monomer because of the significant slowing of the cross-linking reaction but also result in undercured products.

Catalyst Selection. The low resin viscosity and ambient temperature cure systems developed from peroxides have facilitated the expansion of polyester resins on a commercial scale, using relatively simple fabrication techniques in open molds at ambient temperatures. The dominant catalyst systems used for ambient fabrication processes are based on metal (redox) promoters used in combination with hydroperoxides and peroxides commonly found in commercial MEKP and related perketones (13). Promoters such as styrene-soluble cobalt octoate undergo controlled reduction–oxidation (redox) reactions with MEKP that generate peroxy free radicals to initiate a controlled cross-linking reaction.

$$\mathrm{ROOH} + \mathrm{Co}^{+2} \rightarrow \mathrm{RO}^{\bullet} + \mathrm{OH}^{-} + \mathrm{Co}^{+3}$$

$$\mathrm{ROOH} + \mathrm{Co}^{+3} \rightarrow \mathrm{ROO}^{\bullet} + \mathrm{Co}^{+2}$$

This catalyst system is temperature-sensitive and does not function effectively at temperatures below 10°C; but at temperatures over 35°C the generation of free radicals can be too prolific, giving rise to incomplete cross-linking

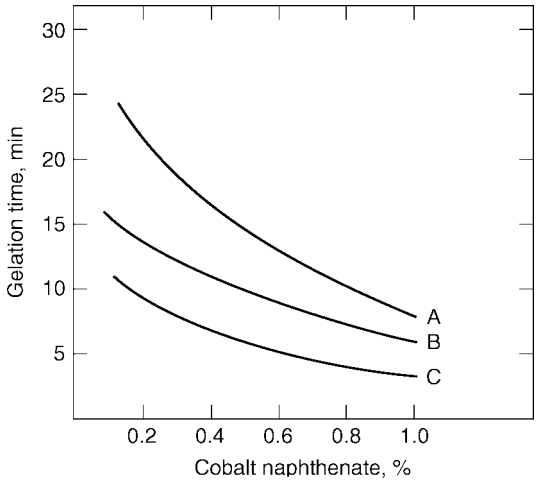

Fig. 5. Influence of catalyst systems on cure rate; gelation time is at 25°C as a function of the initiator concentration. A represents MEKP (1.0%); B, MEKP (1.0%) and dimethylaniline (DMA) (0.05%); and C, MEKP (2.0%).

formation. Redox systems are preferred for fabrication at temperatures ranging from 20 to 30°C (Fig. 5).

Some fabrication processes, such as continuous panel processes, are run at elevated temperatures to improve productivity. Dual-catalyst systems are commonly used to initiate a controlled rapid gel and then a fast cure to complete the cross-linking reaction. Cumene hydroperoxide initiated at 50°C with benzyl trimethylammonium hydroxide and copper naphthenate in combination with *tert*-butyl octoate are preferred for panel products. Other heat-initiated catalysts, such as lauroyl peroxide and *tert*-butyl perbenzoate, are optional systems. For higher temperature molding processes such as pultrusion or matched metal die molding at temperatures of 150°C, dual-catalyst systems are usually employed based on *tert*-butyl perbenzoate and 2,5-dimethyl-2,5-di-2-ethylhexanoylperoxy-hexane (Table 6).

Table 6. Optimal Temperature Range of Conventional Catalyst Systems for Unsaturated Polyesters

Catalyst	CAS registry number	Activator	Processing temperature, °C
Benzoyl peroxide	[94-36-0]	Dimethylaniline	0–25
Methyl ethyl ketone peroxides (MEKP)	[1338-23-4]	Cobalt octoate	20–25
Cumene hydroperoxide	[80-15-9]	Manganese Naphthenate	25–50
Lauroyl peroxide	[105-74-8]	Heat	50–80
tert-Butyl peroctoate	[13467-82-8]	Heat	80-120
Benzoyl peroxide	[94-36-0]	Heat	80–140
2,5-Dimethyl-2,5-di-2-ethyl-hexanoylperoxyhexane	[13052-09-0]	Heat	93–150
tert-Butyl perbenzoate	[614-45-9]	Heat	105–150

The action of redox metal promoters with MEKP appears to be highly specific. Cobalt salts appear to be a unique component of commercial redox systems, although vanadium appears to provide similar activity with MEKP. Cobalt activity can be supplemented by potassium and zinc naphthenates in systems requiring low cured resin color; lithium and lead naphthenates also act in a similar role. Quaternary ammonium salts (14) and tertiary amines accelerate the reaction rate of redox catalyst systems. The tertiary amines form beneficial complexes with the cobalt promoters, facilitating the transition to the lower oxidation state. Copper naphthenate exerts a unique influence over cure rate in redox systems and is widely used to delay cure and reduce exotherm development during the cross-linking reaction.

Another unique redox system used for extending gel times consists of cumene hydroperoxide and manganese naphthenate, which provides consistent gel times of between two and four hours over a temperature range of 25–50°C.

For application temperatures below 10°C or for acceleration of cure rates at room temperature, nonredox systems such as benzoyl peroxide initiated by tertiary amines such as dimethylaniline (DMA) have been applied widely. Even more efficient cures can be achieved using dimethyl-*p*-toluidine (DMPT), whereas moderated cures can be achieved with diethylaniline (DEA).

Tertiary amines are also effective as accelerators in cobalt redox systems to advance the cure rate (Fig. 6). Hardness development measured by Shore D or Barcol D634-1 penetrometer can be used to demonstrate this benefit, which is useful in increasing mold turnover at ambient temperatures.

Cure Exotherm. The cross-linking reaction between the unsaturated polymer and styrene results in a spontaneous change from liquid to a solid state with the onset of the exotherm. The exothermic heat generated is proportional to the fumarate level in the polymer, but increasing styrene levels can enhance

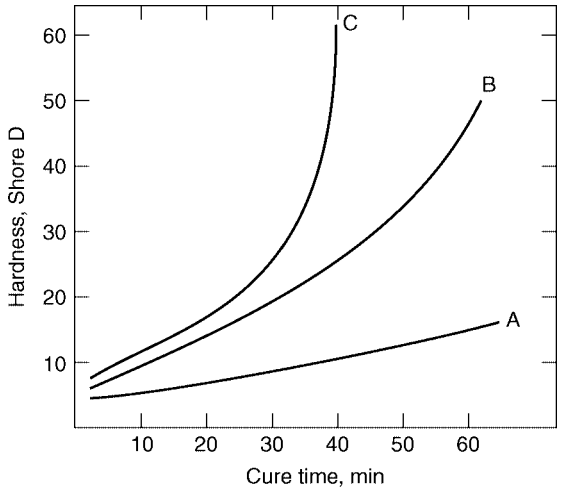

Fig. 6. Influence of catalyst systems on cure rate and effect of dimethylaniline (DMA) on cure rate of cast polymer resin at 25°C. Initiator system contains cobalt naphthenate (0.5%), MEKP (1.0%), and one of the following: A, DMA (0.0%); B, DMA (0.05%); or C, DMA (0.1%).

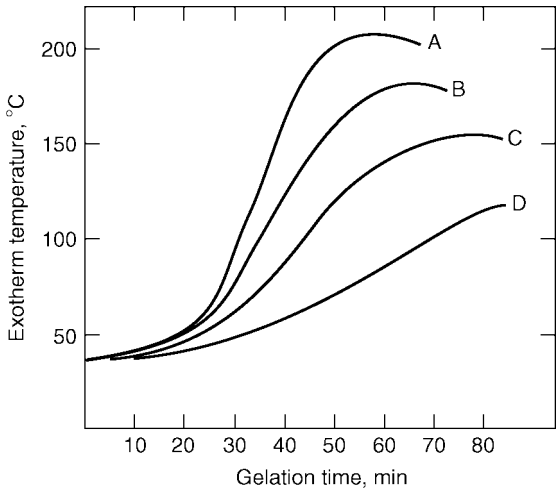

Fig. 7. Influence of copper naphthenate on exotherm temperature. Composition in pph; isophthalic laminating resin is cobalt naphthenate (0.20), dimethylaniline (0.05), and copper naphthenate: A (0.00); B (0.01); C (0.015); or D (0.02).

it further. Although some exotherms can be tolerated in molding processes, these can lead to excessive shrinkage, warpage, and cracking in large moldings or GFR laminations thicker than 9 mm. The cure exotherm can be suppressed in a number of ways to afford a more controllable fabrication system, without adversely affecting the final cure or structural performance.

Copper naphthenate added to the resin at levels between 5 and 20 ppm effectively extends gel and cure characteristics, resulting in a reduction in exothermic heat (Fig. 7). Copper additives are widely used in commercial laminating resins to modify process exothermic effects. α-Methylstyrene [98-83-9] substituted for styrene at levels of 5–8% has also been used effectively in resins cured at above ambient temperatures. The inhibitor 2,5-di-*t*-butylhydroquinone exerts significant exotherm suppression at levels of 200–400 ppm and is useful in high temperature molding processes.

Shrinkage. Polyester resins that undergo cross-linking reactions have as a result a net contraction in volume. Resins dissolved in styrene demonstrate a volumetric shrinkage of 17%. Such high shrinkage can lead to cracking or warping of castings or laminates. Monomers such as vinyltoluene or diallyl phthalate reduce shrinkage; these monomers are often used in high temperature molding compositions to avert warpage or internal voids. With vinyltoluene, volumetric shrinkage during cure is 12.6% and with diallyl phthalate, 11.8%. The effects of shrinkage can also be modified by incorporating soluble poly(vinyl acetate) and related thermoplastic additives into the liquid resins, which phase out during the cross-linking reaction, thus significantly reducing shrinkage. Additional benefits can be obtained by incorporating high filler loadings into resins used in casting or high temperature molding processes.

Air Inhibition. Polyester resins are widely used in open-mold lamination or casting and quite often develop a tacky surface feel after curing. The free-radical polymerization process is sensitive to oxygen, which interferes with the surface

cross-linking mechanism and impedes the cure. Lower molecular weight phthalic resins display a pronounced effect, but higher molecular weight isophthalic resins have less tack. Low molecular weight resins normally produce small fractions of unreactive portions that can migrate to the surface of the resin during the curing process. The lower reactivity of those fractions produce surfaces with high tackiness. Resins based on dicyclopentadiene react with oxygen through an air-drying mechanism and give rise to tack-free surfaces; resins derived from tetrahydrophthalic anhydride have similar air-drying qualities useful for polyester coatings and linings.

Paraffin wax additives are effective in overcoming surface inhibition by forming a monomolecular wax layer at the curing surface. Although effective in excluding oxygen, this waxy layer must be removed for subsequent lamination or bonding processes.

Performance Characteristics. Polyester resins undergo a rapid transformation from a viscous liquid to a solid plastic state that comprises a three-dimensional cross-linked polymer structure. The level of polyester unsaturation determines essential performance characteristics (Table 7), although polymer components can influence subtle features that affect thermal, electrical, and mechanical performance as defined by ASTM procedures.

The cross-linked polymers form a thermoset plastic which cannot be changed or returned to its original condition by heating, as it can with thermoplastics. This thermoset characteristic is beneficial in providing high temperature properties, good solvent and chemical resistance, and high flexural modulus. Cross-linked polyester resins are rigid materials and are highly sensitive to brittle fracture. Reinforcing with glass fiber produces a composite plastic, which has exceptional strength characteristics suitable for replacing conventional fabricating materials such as wood, steel, and concrete. Aggregates and fillers such as ground limestone also improve the strength characteristics of polyester resins and are used widely

in cast objects such as bathroom vanity sets and building components. Polyester resins are used in an unfilled condition in cast objects such as bowling balls and buttons, in thin films for gel coats, and, to a lesser extent, as clear wood coatings.

Mechanical Properties. The performance of various polyester resin compositions can be distinguished by comparing the mechanical properties of thin castings (3 mm) of the neat resin defined in ASTM testing procedures (15). This technique is used widely to characterize subtle changes in flexural, tensile, and compressive properties that are generally overshadowed in highly filled or reinforced laminates.

Resins of higher molecular weight demonstrate higher tensile strength, whereas high fumarate resins have higher flexural modulus. Formulations containing diethylene glycol and adipic acid produce resins that have higher resilience reflected in enhanced tensile and flexural strength but lower flexural modulus. Isophthalic resins provide better mechanical properties than *ortho*-phthalic resins and are consequently preferred in laminate applications requiring higher structural performance. The strength of all polyester resins is enhanced significantly by glass and other fibrous reinforcements. Laminates are usually fabricated from glass fiber mat, having individual fibers 5 cm in length. The structural properties increase in proportion to the glass fiber content, which can be varied from 25 to 40%. Increased reinforcement levels can be achieved by using woven glass roving in alternating plies with chopped strand glass mat. Higher strength can be realized from continuous glass-fiber rovings used in filament-wound structures in the form of pipes or tanks. Helical wind angles are varied to achieve design requirements in hoop or axial directions; a wind angle of 55° can generate twice the strength in the hoop direction. Continuous glass-fiber roving used at reinforcement levels of 65% in pultruded products provides composites that have the highest flexural and tensile properties. Carbon fiber can be useful in developing composites that have higher modulus characteristics, but economics have reduced their wider attractiveness in combinations with polyester resins. Kevlar cloth can be used in combination with unsaturated polyester urethanes to produce light weight, high strength composite plastics for sporting equipment such as kayaks, skis, and bulletproof composites.

Resins filled with ground limestone to levels of 80% by weight are useful in solid-cast products. The fillers reduce sensitivity to brittle fracture and improve modulus, but have little effect on general strength properties (Table 8).

Table 8. Strength Characteristics of Isophthalic Resin and Composite Derivatives

Characteristic	Cast resin	Filled resin	Glass-reinforced laminate	Filament-wound laminate	Pultruded profile
Glass fiber content, %	0	0	30	50	60

[b] To convert GPa to psi, multiply by 145,000.

Thermomechanical Properties. The highly cross-linked structure of cured unsaturated polyester resins produces thermoset characteristics in which the resistance to softening and deformation is greatly enhanced at elevated temperatures. The cross-linked network undergoes a structural transition during heating, in which the rigid crystalline state transforms to a softer amorphous condition at the glass-transition temperature T_g, accompanied by a small expansion in volume, thus facilitating some relaxation along the amorphous micellular boundaries and allowing deformation to take place. Aromatic constituents enhance the T_g, as do high fumarate and high styrene levels, whereas aliphatic derivatives (adipic) and reduced fumarate levels lower T_g values. Resins containing high adipic acid levels display rubbery or elastomeric properties at below ambient temperatures. Glass-reinforced products using these resins have exceptional impact properties and demonstrate high tolerance to low temperature cryogenic applications. Deformation at higher temperatures is moderated by fibrous reinforcements. However, as the temperature exceeds the T_g of the cross-linked polymer, laminate properties fall off considerably (Fig. 8).

Although reinforcements can improve the structural behavior of the composite at elevated temperature, the polymer, irrespective of its composition, begins to disassociate chemically in the presence of oxygen. *ortho*-Phthalic resins having the weaker ester bonds depolymerize readily at temperatures over 200°C and form low molecular weight fractions disintegrating the polymer network. Determination of laminate weight loss or flexural property retention indicates that alicyclic diols, including hydrogenated bisphenol A and cyclohexanedimethanol, perform better than lower glycols such as propylene, and neopentyl glycol imparts exceptional thermal stability at temperatures up to 200°C. However, all resins depolymerize spontaneously at around 300°C as the ester groups disassociates from the polymer

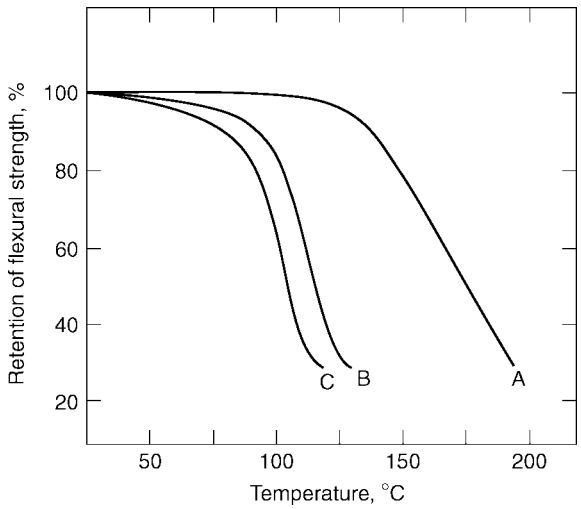

Fig. 8. Flexural properties at elevated temperatures. Laminates constructed from alternating plies of 46.7-g (1.5-az) mat and 746-g/m^2 (24-oz(yd^2) woven roving at a nominal glass content of 45%. A represents bisphenol fumarate (T_g = 130°C); B, isophthalic resin (T_g = 100°C); and C, *ortho*-phthalic resin (T_g = 80°C).

network, producing by-products that include lactones, dimer esters, and glycols. Vinyltoluene provides enhanced thermal performance on account of the increased bond strength resulting from the inductive influence of the methyl group para to the vinyl unsaturation. Oxidative disassociation at elevated temperature can be suppressed with antioxidants, but these eventually interfere with the catalyst's activity, thus reducing cure rate.

Halogenated intermediates based on chlorendic anhydride and alkoxylated brominated bisphenol A are quite stable and are used extensively in flame-retarded high temperature compositions, but brominated alicyclics, such as dibromotetrahydrophthalic resin, are rapidly dehydrohalogenated at lower temperatures.

Cross-linked polyester composites have a relatively low coefficient of thermal conductivity, which can provide beneficial property retention in thick laminates at high temperatures as well as remove the need for secondary insulation. The coefficient of thermal expansion of glass-reinforced composites is similar to aluminum but higher than most common metals.

Dielectric Properties. Polyester resins are nonconductors, have relatively low dipolar characteristics, and provide high dielectric strength and surface resistivity. At high voltage or high current, however, the cross-linked plastics fail due to carbon arcing or tracking caused by the charring of the polymer surface into a conductive carbonaceous residue. Hydrated fillers such as alumina trihydrate (16) suppress surface char formation and are used extensively with glass reinforcement in molding compounds intended for electrical applications. High temperature electrical applications usually specify bisphenol fumarate resins or high molecular weight isophthalic resins having high fumarate reactivity. Dicyclopentadiene resins provide enhanced oxidative resistance, whereas vinyltoluene monomer is used for superior thermal properties. Specialized granulated molding compounds are also formulated by using diallyl phthalate monomers, and are used for injection molding smaller electrical components.

Chemical Properties. The three-dimensional cross-linked network resists penetration and attack by most corrosive chemicals and nonpolar solvents, although weak alkalies and especially polar solvents such as lower ketones, chlorinated aliphatics, and aromatics readily attack *ortho*-phthalic, isophthalic, and dicyclopentadiene resins. Water has wide-ranging effects on different resin compositions as it penetrates into the plastic network. Cross-linking density and the presence of steric constituents local to the ester groups can enhance water resistance. Isophthalic resins have better water absorption characteristics than corresponding *ortho*-phthalic resins. Neopentyl glycol and alkoxylated bisphenol constituents provide maximum performance in aqueous media. Ethylene and diethylene glycols demonstrate high water absorption that leads to the loss of mechanical strength. The presence of glass reinforcements within the cross-linked plastic is also affected by chemical attack. Water absorbed onto surface fibers is carried into the plastic matrix, decoupling the resin–glass fiber interfacial bond in the process. Alkalies compliment this attack on the glass reinforcement and lead to surface blistering and rapid loss of laminate strength. Chemical attack is usually minimized by incorporating surface protection in the form of corrosion-resistant (C glass) surface veils and high surface resin content in laminates intended for chemical service. Reinforced polyester composites or FRPs perform well in

concentrated hydrochloric and phosphoric acids; concentrated sulfuric and nitric acid oxidize and degrade the polymer rapidly. High performance resins based on bisphenol A fumarate and their brominated homologues have featured prominently in FRP piping, tanks, chemical ducting, and scrubbers used to handle corrosive chemicals and emissions in pulp and paper plants, mining and ore classification, and the chloralkali industries. FRP has also emerged as a strategic solution for designing equipment intended for high temperature applications in fossil fuel electric power generating utilities such as chimney stack liners and scrubbers for the control of sulfur dioxide emissions.

Corrosion attack on the polymer is influenced by permeation rate, as well as internal stresses or fatigue, which distorts or fractures the resin glass fiber interface. Localized corrosion failure in large tanks or piping systems can sometimes be explained by stress-induced corrosion failure. FRP composites normally contain air voids that distort into elliptical voids adjacent to the reinforcing fiber. Water and chemicals penetrating these voids set up osmotic cells that plasticize and soften the surrounding polymer, initiating brittle fracture along the fibers and progressively opening up new surface area for corrosion attack in areas under high stress. Nonpolar solvents have little effect on polyester resins and have been used extensively for underground storage of gasoline. However, with the reformulation to unleaded gasoline, the higher aromatic fuels require resins that have higher cross-linking density. This is provided by high fumarate isophthalic or terephthalic derivatives.

Flammability. Polyester resin products ignite and burn by emitting sooty smoke. Flammability can be reduced significantly through halogen-modified components either formulated into the polyester polymer as chlorendic anhydride, tetrabromophthalic anhydride, or dibromoneopentyl glycol, or as part of the monomer system, ie, dibromostyrene. Additives such as phosphate esters are frequently used to enhance flame retardance, whereas antimony trioxide at levels of 5% or less on resin provides optimum retardance in combination with halogenated intermediates. The flame-retardant mechanism depends on the thermal disassociation of the organohalogen component, which, upon exposure to the heat of the flame, releases hydrogen chloride or hydrogen bromide gases that become active as radical transfer agents in suppressing the oxidation–combustion process (17). The activity of the halogen gases is synergized through the formation of antimony oxy halides and trihalides; arsenic and molybdenum salts offer comparable activity. Organophosphorus compounds behave in a supplementary role by forming polyphosphoric acids that induce char at the burning surface. However, phosphates plasticize the polymer and reduce performance at levels exceeding 5%, thus offering marginal benefits. Organoferrous compounds such as ferrocene demonstrate unique synergism with halogenated resins, reducing both flame spread and smoke generation. Also, ferrous oxide (18) is active in chlorendic resins in a similar capacity. The formation of ferric chloride promotes aromatization and enhances char formation and the subsequent reduction of smoke emissions. The exothermic nature of the combustion process can provide sufficient energy for sustained burning, unless halogen modification is used. Nonhalogenated resin systems, based on hydrated fillers such as alumina trihydrate, have emerged. Alumina trihydrate undergoes endothermic disassociation at above 300°C, and can offset the combustion heat and reduce surface temperatures sufficiently to interrupt the high energy oxidation mechanism. Resins incorporating over 40%

by weight of aluminum trihydrate not only qualify for most construction and electrical flammability specifications but also provide significant reduction in smoke emissions. Useful bench-scale tests, such as ASTM E162 and ASTM D2863, have been developed for characterizing flammability and smoke emissions, but the dynamic nature of the combustion process requires large-or full-scale fire testing, such as ASTM E84, to be performed for applications intended for confined areas. Halogenated resins are sensitive to heat and ultraviolet radiation; resins based on tetrabromophthalic anhydride yellow after a few days in direct sunlight. Benzophenone and benzotriazole stabilizers used at levels of 1% are highly effective with chlorendic, dibromoneopentyl, and dibromotetrahydrophthalic derivatives, but resins based on brominated aromatics such as tetrabromophthalic anhydride and tetrabromobisphenol eventually discolor in exterior applications.

Weathering. Polyester resins in the form of laminates, coatings (gel coats), and castings perform well in outdoor exposures; marine craft, tanks, pipes, and architectural facia produced in the 1960s are still in service. Polyesters undergo some change in their surface features in direct sunlight, discoloration or yellowing being most obvious. Dulling and microcrazing occur only in products not appropriately formulated for the exposure. Long-term surface erosion of laminates exposes the glass fibers, which, unless corrected, can lead to rapid loss of structural integrity. Absorption of water influences the interfacial bond between the resin matrix and either the fibrous or aggregate reinforcement, leading to some loss of mechanical properties over 30 years. However, observations indicate that most applications reach this equilibrium after three to five years and do not show much significant change thereafter. Most FRP products are designed with protective and decorative gel coats (19) formulated from neopentyl glycol, which, in combination with some methyl methacrylate monomer and benzophenone uv stabilizers, provides improved weather resistance. Platelet fillers such as talcs and clays, as well as high pigment levels, are incorporated into gel coats to obscure the underlying laminate from the effects of direct sunlight. Surface oxidation and discoloration can also be controlled by using uv-resistant lacquers based on polymethacrylate resins or by cladding with poly(vinyl fluoride) (PVF) or acrylic and poly(ethylene terephthalate) (PET) films.

Application Processes

Open-Mold Process. Polyester resins are fabricated easily in open molds at room temperature. Such processes account for over 80% of production volume, the remaining being fabricated using matched metal dies in high temperature semiautomated processes.

The hand lay-up or spray-up process, used universally for the production of laminar composites incorporating glass-fiber reinforcement, is most efficient for the manufacture of large parts, such as boats, bathtubs, tanks, architectural shapes, and recreational accessories. Resins intended for spray-up processes are usually modified with thixotropic additives, such as fumed silica (1%), to reduce the risk of drainage when applied over large vertical mold surfaces. Molds are also made from FRP for short-run products usually surfaced with a tooling gel coat to provide consistent surface quality and appearance.

Gel coats are pigmented polyester coatings applied to the mold surface and are an integral part of the finished laminate. Gel coats are used widely on hand lay-up and spray-up parts to enhance surface esthetics and coloration, as well as to provide an abrasion-resistant waterproof surface that protects the underlying glass-reinforced structure.

Thermoformed acrylic sheet is displacing gel coats in some bathtub applications; spas have converted almost exclusively to formed acrylic sheet reinforced with glass-reinforced polyester laminations because of higher temperatures and higher structural requirements.

Products of axial symmetry such as pipes and tanks can be produced by filament-winding resin-impregnated glass rovings over a rotating mandrel. This process provides for some versatility in adjusting the winding angle to meet design cost considerations. A winding angle of 55° to the axis produces pipes that have twice the strength in the hoop direction, suitable for conveying high pressure liquids that may be corrosive to metals. Large-diameter piping systems (1–3 m) are also produced by centrifugal casting techniques, by which high levels of silica sand can be used to improve pipe stiffness. FRP pipes have been used extensively as slip linings for deteriorated concrete sewer pipes that avoid costly excavation.

Resins containing fillers and aggregates can be usefully cast into attractive components that simulate marble and granite. Bathroom vanity sets and kitchen countertop components have emerged as a significant commercial outlet for filled resins cast in open molds that often employ gel coats having superior hydrolytic properties to enhance resistance to thermal shock and crazing. Specially formulated isophthalic resins in admixture with sand have been developed for surfacing worn concrete roads and bridges. Polyester resins are also emerging in filled pigmented coatings used as permanent road marking, as some U.S. states displace solvent-based alkyd marking materials. Other products such as buttons and bowling balls are cast from resins containing low filler levels.

Closed-Mold Processes. In an effort to improve the productivity of the hand lay-up process, closed-mold systems containing two mating dies have evolved. In resin-transfer molding (RTM), glass reinforcement is placed in the open mold; once the molds are in place, precatalyzed resin is injected into the cavity under pressure. The process has been further modified to use a vacuum that ensures complete air removal and faster mold filling. The process is adaptable to large components and can be used to encapsulate foam, aluminum, and wood components into the structure. The process is also beneficial in reducing styrene emissions that are regulated under Title III of the U.S. Clean Air Act passed in 1990.

High temperature compression molding has grown rapidly since 1985 as applications for glass-reinforced composites have expanded in the automotive body panel market. Molding compounds incorporating resins, catalysts, fillers, pigments, and glass fiber reinforcements have evolved as bulk molding compounds (BMC) and sheet molding compounds (SMC) to meet requirements in the electrical, business machine, as well as structural automotive markets.

Matched die molding is the most efficient process to produce high volumes of relatively large parts. The mold cycle is under two minutes at 150°C and the process can be incorporated into an automated manufacturing system, reducing labor and scrap while improving quality. Resins have been uniquely formulated to reduce shrinkage and provide composite surfaces that can be primed and coated by using conventional baked enamels. The polyester technology providing these

low profile, low shrink resins is based on the action of thermoplastic additives (20) incorporated into unique polyester resin formulations based on propylene glycol fumarate.

Poly(methyl methacrylate) and poly(vinyl acetate) precipitate from the resin solution as it cures. This mechanism offsets the contraction in volume as the polyester resin cross-links, resulting in a nonshrinking thermoset. Other polymer additives such as poly(butylene adipate) provide similar shrinkage control. The change in volume and compatibility of the polymer produces a whitening of the composite and results in nonuniform coloration in pigmented products. Polystyrene additives used in BMC can be formulated into nonshrinking, pigmentable compounds suitable for colored electrical products and kitchen utensils.

Injection molding of BMC and thick molding compounding (TMC) is expanding to improve the efficiency of the matched die process. TMC is a compound intermediate between BMC and SMC in which the glass-fiber strand integrity is retained in the molded product, thus greatly enhancing strength and impact properties.

High strength composites with linear symmetry can be produced by the pultrusion process (21) using continuous glass-fiber reinforcements in the form of rovings. Special continuous glass mats have also evolved to meet the process requirements of this technology. Glass fiber levels of 65% can be formed into polyester composites that demonstrate exceptional flexural performance characteristics required in such applications as flag poles and automotive springs. The process can also form hollow structures and profiles compatible with extruded aluminum and PVC useful in window and portal construction.

POLYETHERS. See ETHYLENE OXIDE POLYMERS; PROPYLENE OXIDE POLYMERS.

POLYETHERS, AROMATIC

Introduction

Aromatic polyethers are best characterized by their thermal and chemical stabilities and mechanical properties. The aromatic portion of the polyether contributes to the thermal stability and mechanical properties, and the ether functionality facilitates processing but still possesses both oxidative and thermal stability. With these characteristic properties as well as the ability to be processed as molding materials, many of the aromatic polyethers can be classified as engineering thermoplastics (see ENGINEERING THERMOPLASTICS, OVERVIEW).

One class of aromatic polyethers consists of polymers with only aromatic rings and ether linkages in the backbone; poly(phenylene oxide)s are examples and are the principal emphasis of this article. A second type contains a wide variety of other functional groups in the backbone, in addition to the aromatic units and ether linkages. Many of these polymers are covered in other articles, based on the other functionality (see POLYIMIDES; POLYSULFONES).

Poly(phenylene oxide)s, Properties

The poly(phenylene oxide)s are also referred to as polyoxyphenylenes and poly(phenylene ether)s. Variations in the configuration of the ether group, ie, ortho, meta, or para, and in the extent and type of substitution, eg, alkyl, halo, etc, on the aromatic backbone give rise to a large number of possible homo- and copolymers. The polymers with para-oriented ethers have been studied most extensively and several have significant utility. Poly(2,6-dimethyl-1,4-phenylene oxide) [25134-01-4] (DMPPO), prepared by General Electric by the oxidative coupling polymerization of 2,6-dimethylphenol, is marketed as PPO resin. Blends of

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

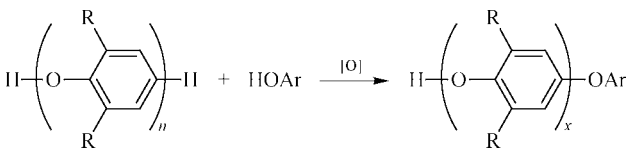
DMPPO with polystyrene and additives is marketed under the trade name of Noryl thermoplastic resin. Blends of DMPPO with nylon plus additives are sold as Noryl GTX resin. Other poly(phenylene oxide)s are also of commercial interest. For example, low molecular weight, unsubstituted poly(phenylene oxide)s are of use as heat-transfer fluids and liquid phases for gas chromatography. Poly(2,6-diphenyl-1,4-phenylene oxide) is sold as a gas absorbent and for gas chromatography.

Many newer poly(phenylene oxide)s were reported in the early 1990s. For example, a number of poly(2,6-diphenyl-1,4-phenylene oxide)s were prepared with substituents in the 4-positions of the pendent phenyl groups. Of particular interest is the 4-fluoro substituent, which imparts a lower melting point, enhanced solubility, and a lesser tendency to crystallize than has been found for the parent material (1).

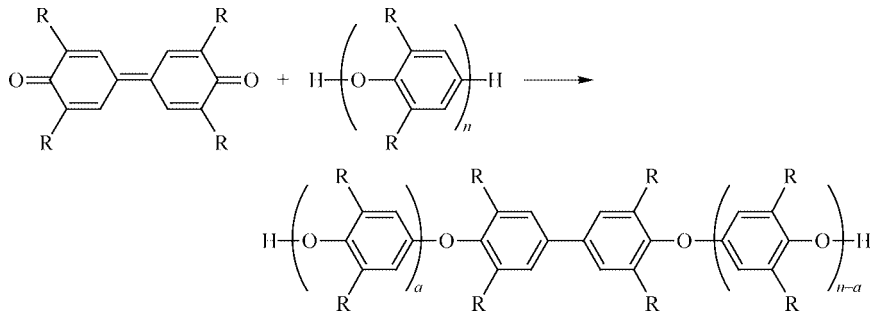
Physical Properties. The glass-transition temperatures and melting points of a variety of poly(1,4-phenylene oxide)s are summarized in Table 1. The very high glass-transition temperatures of DMPPO and poly(2,6-dichloro-1,4-phenylene oxide) relative to their melting points provide polymers with excellent high temperature physical properties. Crystallization of several polymers can be induced with certain liquids, eg, α-pinene, decalin, and toluene for DMPPO, and tetrachloroethane for poly(2,6-diphenyl-1,4-phenylene oxide) (2). Although DMPPO dissolves readily in methylene chloride, a complex of polymer and methylene chloride soon precipitates from the solution (3). Although precipitation of the polymer as the complex can be quantitative, the complex is unstable when separated from the liquid methylene chloride phase and dissociates rapidly to leave the pure polymer. Low molecular weight polymers with very narrow molecular weight distribution ($M_w/M_n = 1.1$) can be prepared by cooling an equilibrating mixture of low molecular weight oligomers in methylene chloride. As the molecular weights of some of the oligomers increase owing to redistribution, these oligomers reach the critical size for complexation and precipitate from solution. The molecular weight at which this occurs is approximately 2000 (4).

Mechanical and electrical properties for DMPPO are given in Table 2.

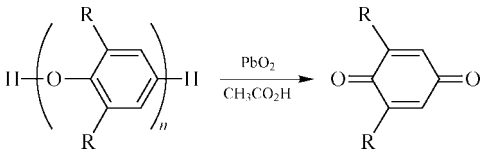
Chemical Properties. The phenolic end groups in poly(phenylene oxides)s react with oxidizing agents in a variety of ways; the type of product depends in part on other reagents that may be present. Thus, in the presence of other phenols, a catalytic amount of oxidizing agent generates aroxy radicals and the ensuing coredistribution produces low molecular weight products (eq. 1, where $x = 1,2,3,\ldots$) (15). In the absence of the phenol HOAr, and with an equivalent of tetrasubstituted diphenoquinone as an oxidizing agent, biphenyl units are introduced into the polymer at the terminal position and then, through redistribution, internally (16,17) (eq. 2, where $a = 0$, 1, 2, 3, etc). Under acidic conditions with excess oxidizing agent, benzoquinones are generated (eq. 3) (18).



(1)



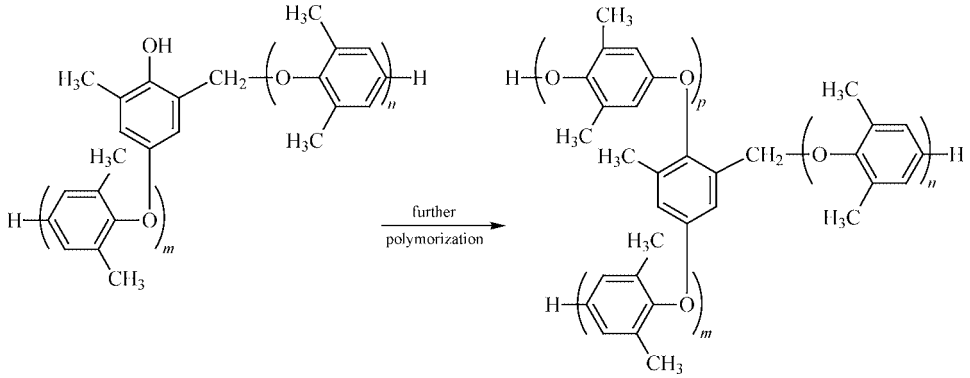
(2)



(3)

The preceding reactions do not occur if the terminal hydroxyl group in the polymer is no longer present, eg, if it has been end-capped by acetylation.

Side reactions during polymerization can lead to abnormal end-group formation and branching. For example, when secondary amines are present during a copper-catalyzed polymerization, they are often covalently bound to the methyl group of a head end group (19). With a manganese catalyst system, secondary amines are bound to the polymer analogously if they are present, but if they are absent polymer chains are bound at this site through the oxygen of a head end group to form a benzyl ether linkage. Additional polymerization attaches more units to produce a branched molecule (20), as follows.



The backbone of poly(phenylene oxide)s is cleaved under certain extreme reaction conditions. Lithium biphenyl reduces DMPPO to low molecular weight products in the dimer and trimer molecular weight range (21) and converts poly(2,6-diphenyl-1,4-phenylene oxide) to 3,5-diphenylphenol in 85% yield (22) (eq. 4).

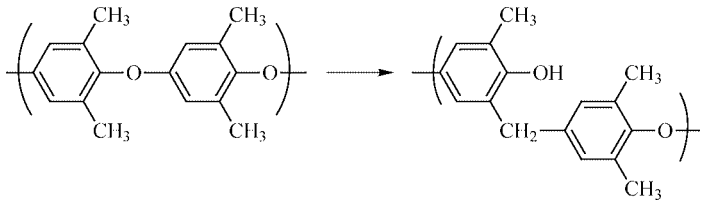
(4)

At temperatures near 370°C, DMPPO undergoes a rearrangement (eq. 5).



(5)

This appears from model studies to be a radical-chain process (23). Abstraction of a hydrogen from a methyl group, followed by migration of the adjacent phenyl group, generates a phenoxy radical that continues the chain process by abstracting a hydrogen from another methyl group.

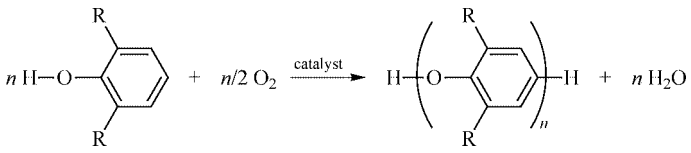
Ultraviolet radiation causes cleavage of the aryl ether linkage (24). DMPPO undergoes oxidation when exposed to ultraviolet light and oxygen by direct attack on the aromatic ring to produce a variety of ring-cleaved and quinoidal structures (25–28).

Poly(phenylene oxide)s undergo many substitution reactions (29). A review of substitution reactions as well as degradation reactions. Reactions involving the aromatic rings and the methyl groups of DMPPO include bromination (30), displacement of the resultant bromine with phosphorus or amines (31), lithiation (32), and maleic anhydride grafting (33). Additional reactions at the open 3-position on the ring include nitration, alkylation (34), and amidation with isocyanates (35).

Health and Safety Factors. Animal-feeding studies of DMPPO itself have shown it to be nontoxic on ingestion. The solvents, catalyst, and monomers that are used to prepare the polymers, however, should be handled with caution. For example, for the preparation of DMPPO, the amines used as part of the catalyst are flammable; toxic on ingestion, absorption, and inhalation; and are also severe skin and respiratory irritants. Toluene, a solvent for DMPPO, is not a highly toxic material in inhalation testing; the TLV (77) is set at 375 mg/m^3, and the lowest toxic concentration is reported to be 100–200 ppm (78). Toxicity of 2,6-dimethylphenol is typical of alkylphenols, eg, for mice, the acute dermal toxicity is LD_{50}, 4000 mg/kg, whereas the acute oral toxicity is LD_{50}, 980 mg/kg (79). The Noryl blends of DMPPO and polystyrene have FDA approval for reuse food applications.

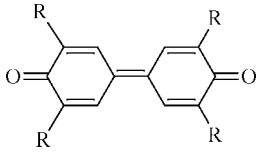
Synthesis of Poly(phenylene oxides)

Oxidative Coupling. Many poly(1,4-phenylene oxide)s have been prepared in a one-step polymerization of 2,6-disubstituted phenols by oxidative coupling (36) (see OXIDATIVE POLYMERIZATION). The scope and mechanism of polymerization has been studied in detail by many investigators (37). For the preparation of DMPPO, oxygen is passed through a vigorously stirred solution of 2,6-dimethylphenol and a catalyst at ca 25–50°C. A typical catalyst is composed of a copper halide and one or more aliphatic amines or pyridine. If the catalyst is susceptible to hydrolysis, a desiccant, eg, anhydrous magnesium sulfate, is added to remove the water coproduct. With an amine such as dibutylamine, the drying agent is not required. The polymerization is exothermic and often requires cooling to maintain catalytic activity and attain a high molecular weight product. Catalysts based on manganese and cobalt salts also are effective (38). Noncatalytic oxidizing agents, eg, silver oxide, lead dioxide, and manganese dioxide, when used in excess of the stoichiometric amount, also polymerize many 2,6-disubstituted phenols (39).



Oxidative coupling polymerizations represent a general reaction for the preparation of high molecular weight linear polymers from many 2,6-di- and 2,3,6-trisubstituted phenols. When the ortho substituents on the phenols are relatively unhindered alkyl or aryl groups, the poly(phenylene oxide) is the chief product (40,41). Bulky ortho substituents, eg, *tert*-butyl, lead to the formation of

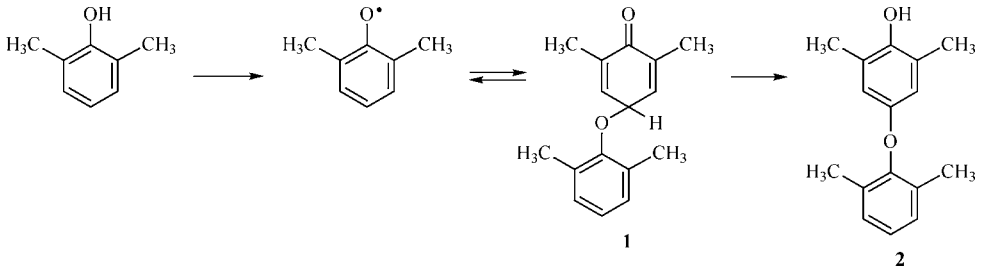
the 3,3′,5,5′-tetrasubstituted 4,4′-diphenoquinone (40).



Significant quantities of the diphenoquinone are also produced if the ortho substituents are methoxy groups (40). Phenols with less than two ortho substituents produce branched and colored products from the reactions that occur at the open ortho sites. It is possible to minimize such side reactions in the case of *o*-cresol oxidation by using a bulky ligand on the copper catalyst to block the open ortho position (42).

The selectivity of the oxidation of 2,6-disubstituted phenols depends on the type of oxidizing agent. For example, with a series of cobalt-containing catalysts of the salcomine type, oxidation of 2,6-dimethylphenol produces three products: the poly(phenylene oxide), the diphenoquinone, and 2,6-dimethylbenzoquinone. The product ratio changes with variation in the nature of the ligands (43). The formation of the benzoquinone suggests that ionic processes as well as free-radical reactions take place. Oxidations with reagents that proceed mainly through ionic pathways produce such nonpolymeric products as benzoquinones and cyclohexadienones. Thus, 2,6-dimethylbenzoquinone and its 3-substituted derivatives form when 2,6-dimethylphenol is oxidized with peracids or metal-catalyzed hydrogen peroxide, whereas dimers of 6-hydroxy-2,6-dimethyl-2,4-cyclohexadien-1-one are produced from periodate oxidations (44).

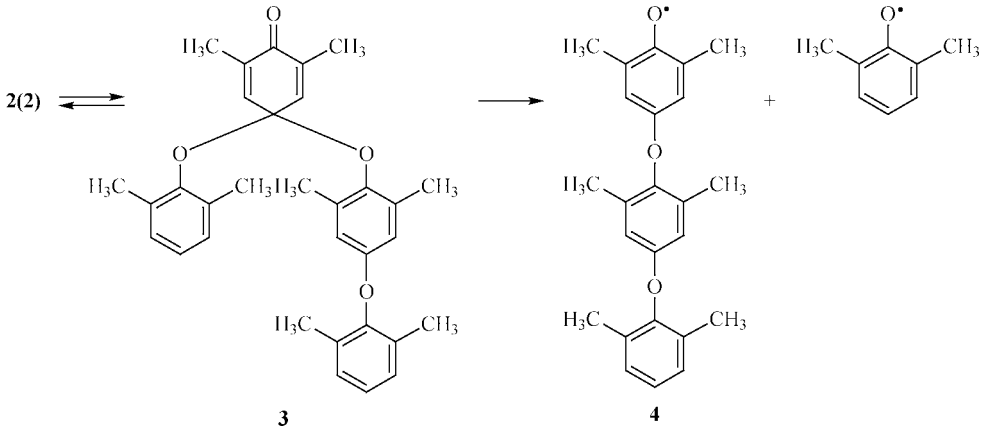
Polymerization Mechanism. The mechanism that accounts for the experimental observations of oxidative coupling of 2,6-disubstituted phenols involves an initial formation of aryloxy radicals from oxidation of the phenol with the oxidized form of the copper–amine complex or other catalytic agent. The aryloxy radicals couple to form cyclohexadienones, which undergo enolization and redistribution steps (36). The initial steps of the polymerization scheme for 2,6-dimethylphenol are as in equation 6.



(6)

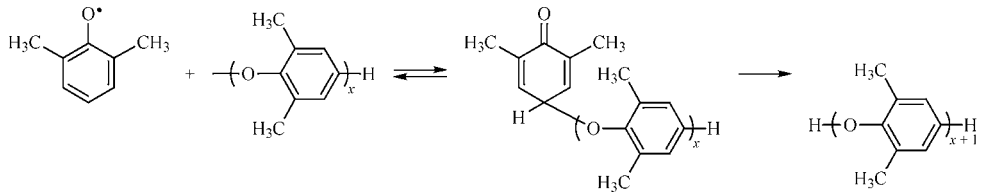
In equation 6, the dimer (**2**) is formed by enolization of the quinol ether (**1**). Oxidation of the dimer produces the dimer radical, which can couple with other radicals that are present. If it couples with a 2,6-dimethylphenoxy radical

to form a quinol ether, enolization can produce the trimer in a reaction analogous to equation 6. Similarly, oxidation of the trimer followed by coupling with a 2,6-dimethylphenoxy radical and enolization produces tetramer. By this process, each oligomeric product can form the next higher oligomer, and eventually high molecular weights are attained. However, the polymerization does not proceed only by addition of one unit at a time to the growing chain, because coupling also can occur between other combinations of oligomers. Thus, this is a step-growth polymerization rather than a chain-growth polymerization. As an example, dimer radical also can couple with another dimer radical to form a quinone ketal (**3**) (eq. 7) or with a larger oligomeric radical to form an analogous ketal. The reaction proceeds further by dissociation of the ketal to form new oligomeric radicals.



(7)

In equation 7, trimer radical (**4**) is produced when (**3**) dissociates. Whenever (**4**) couples with the other product of equation 7, ie, the 2,6-dimethylphenoxy radical, the tetramer is produced as described. These redistribution reactions of oligomers that proceed by ketal formation and subsequent dissociation ultimately generate terminal quinol ethers which enolize to the more stable terminal phenol (eq. 8).

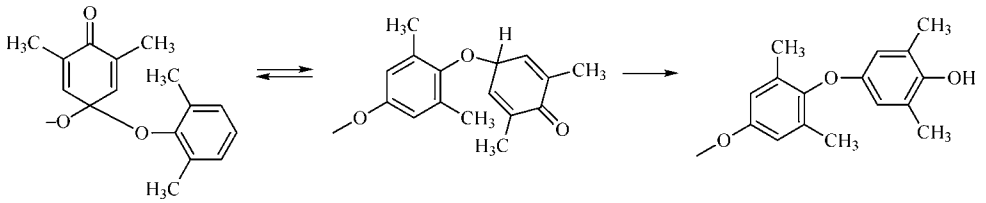


(8)

The enolization aids the attainment of high molecular weights by providing the driving force for the coupling of two oligomeric radicals to form a phenol-terminated oligomer of higher molecular weight, and by generating a phenolic group that can be oxidized to generate a new aryloxy radical which can enter the redistribution–enolization scheme. The overall effect of this combination of

oxidation, radical coupling, dissociation, and enolization is to increase the average molecular weight.

A second process that occurs concurrently with the dissociation–redistribution process is an intermolecular rearrangement by which cyclohexadienone groups move along a polymer chain. The reaction may be represented as two electrocyclic reactions analogous to a double Fries rearrangement. When the cyclohexadienone reaches a terminal position, the intermediate is the same as in equation 8, and enolization converts it to the phenol (eq. 9).

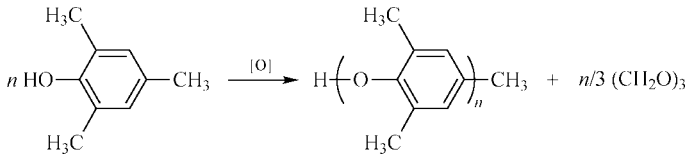


(9)

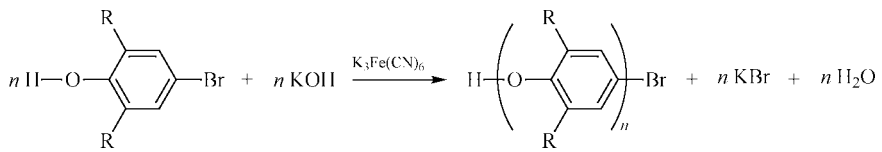
This process, which predominates at low temperatures, causes migration of internal ketal structures along a chain but does not involve the dissociation to separate aryloxy radicals that occurs during the redistribution process.

Considerable evidence supports these routes and rules out several alternative mechanisms (15,45–51) (see also OXIDATIVE POLYMERIZATION).

2,4,6-Trimethylphenol Polymerization. An unusual aspect of the oxidative coupling of substituted phenols is the formation of DMPPO from 2,4,6-trimethylphenol. Oxidative cleavage of the 4-methyl group produces paraformaldehyde and relatively low molecular weight (M_n = 1000–3000) DMPPO with manganese dioxide (60). DMPPO can also be prepared from 2,4,6-trimethylphenol with oxygen as the oxidizing agent and a catalytic amount of copper halide and an amine (61).

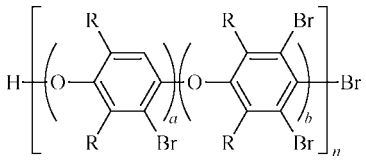


Halogen Displacement. Poly(phenylene oxide)s can also be prepared from 4-halo-2,6-disubstituted phenols by displacement of the halogen to form the ether linkage (52,53). A trace of an oxidizing agent or free radical initiates the displacement reaction. With 4-bromo-2,6-dimethylphenol, the reaction can be represented as in equation 10:

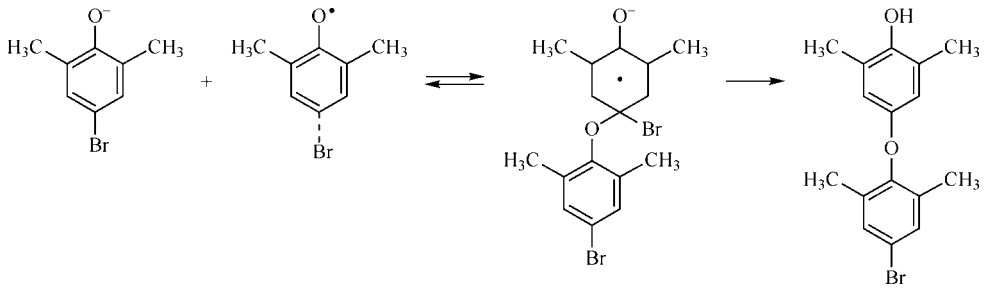


(10)

High molecular weight DMPPO is formed in high yield at room temperature. The reaction is applicable to certain 2,3,5-tri- and 2,3,5,6-tetrasubstituted-4-halophenols. When such compounds have halogens in the 3,4- or 3,4,5-positions only the one in the 4-position is displaced. When a mixture of 3,4-dibromo-2,6-dimethylphenol and 3,4,5-tribromo-2,6-dimethylphenol is polymerized, a random copolymer is formed, where $b = 1$, 2, etc (54,55). The two homopolymers from polymerization of these phenols by themselves are sufficiently insoluble in halogenated and aromatic solvents that they precipitate from the reaction mixture with low molecular weight. The copolymer made from an equimolar mixture of the two monomers is soluble and can be prepared with high molecular weight.



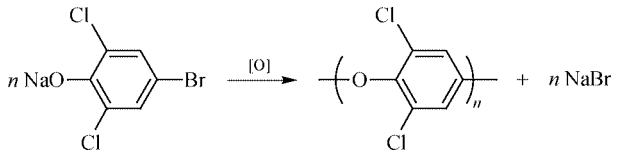
The halogen displacement polymerization proceeds by a combination of the redistribution steps described for oxidative coupling polymerization and a sequence in which a phenoxide ion couples with a phenoxy radical (eq. 11) and then expels a bromide ion. The resultant phenoxy radical can couple with another phenoxide in a manner that is analogous to equation 11 or it can redistribute with other aryloxy radicals in a process analogous to equations 7 and 8.



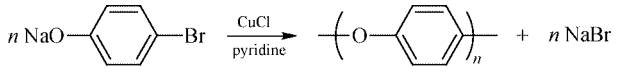
(11)

2,4,6-Trihalophenols can be converted to poly(dihalophenylene oxide)s by a reaction that resembles radical-initiated displacement polymerization. In one procedure, either a copper or silver complex of the phenol is heated to produce a branched product (56). In another procedure, a catalytic quantity of an oxidizing agent and the dry sodium salt in dimethyl sulfoxide produces linear poly(2,6-dichloro-1,4-polyphenylene oxide) (57). The polymer can also be prepared by direct oxidation with a copper–amine catalyst, although branching in the ortho positions

is indicated by chlorine analyses (58).



4-Halophenols without 2,6-disubstitution do not polymerize under oxidative displacement conditions. Oxidative side reactions at the ortho position may consume the initiator or interrupt the propagation step of the chain process. To prepare poly(phenylene oxide)s from unsubstituted 4-halophenols, it is necessary to employ the more drastic conditions of the Ullmann ether synthesis. A cuprous chloride–pyridine complex in 1,4-dimethoxybenzene at 200°C converts the sodium salt of 4-bromophenol to poly(phenylene oxide) (1):



Low molecular weight poly(1,3-phenylene oxide) [25190-64-1] has been prepared from the sodium salt of *m*-chlorophenol with copper as a catalyst (59).

Poly(Phenylene Oxide) Copolymers

Copolymers of poly(phenylene oxide)s can be prepared in several ways. Oxidative coupling of mixtures of phenols, eg, combinations of 2,6-dimethylphenol, and 2-methyl-6-phenylphenol usually provide random copolymers. With a pair of phenols that have different oxidation potentials or that coredistribute at different rates, such as a mixture of 2,6-dimethylphenol and 2,6-diphenylphenol, block copolymers can form (62). Another route is the oxidation of mixed dimers which forms random copolymers (63). Copolymers can also be produced by allowing only some of the rings to undergo reaction in a substitution reaction, eg, bromination of only a fraction of the aromatic rings in DMPPO converts normal units to 3-bromo units (30). Block copolymers have been prepared by condensing the phenolic end groups of DMPPO with other polymers bearing reactive leaving groups on their end groups. For example, block copolymers were formed from aromatic polyesters with α,ω-bis(chloroformyl) end groups by using a phase-transfer catalyst and sodium hydroxide to effect the displacement of the halogen (64). These reactions can be carried out with high yields, thereby enabling the formation of ABA types of block copolymers. In the case of low molecular weight di- or triacyl halides, coupled linear or branched polymers with double or triple the original molecular weight are formed.

Polyether Blends

DMPPO and polystyrene form compatible blends (see POLYMER BLENDS). The two components are miscible in all proportions (65). Reported dynamic–mechanical results that indicate the presence of two phases in some blends apparently are caused by incomplete mixing (66). Transition behavior of thoroughly mixed blends indicates that the polymers are truly compatible on a segmental level (67). Compatibility may be attributed to a π–π interaction between the aromatic rings of the two polymers sufficient to produce a negative heat of mixing. However, the forces are very small, ie, ΔH_{mix} = ca 40 J/mol (9.6 cal/g), and any change in the substitution pattern of either polymer usually makes them incompatible (68). Tensile strength and modulus of blends of DMPPO and crystal polystyrene reach a maximum with a composition containing about 80 wt% DMPPO, but most properties of blends are close to the weighted average for the two polymers (69). Blends with rubber-modified polystyrene, ie, high impact polystyrene (HIPS), also have intermediate property values, but the ductile PPO matrix is toughened more effectively by rubber than is the brittle polystyrene. Therefore, blends of DMPPO with HIPS have much higher impact strength than either material alone (70). This characteristic makes it possible to prepare a family of tough plastics or modified poly(phenylene oxide)s in which some of the high temperature capability of the DMPPO is combined with the easy processibility of polystyrene.

Blends with good mechanical properties can be made from DMPPO and polymers with which DMPPO is incompatible if an appropriate additive, compatibilizing agent, or treatment is used to increase the dispersion of the two phases. Such blends include mixtures of DMPPO with nylon, polycarbonate, polyester, ABS, and poly(phenylene sulfide).

Sulfonation has been used to change some characteristics of blends. Poly(2,6-diphenyl-1,4-phenylene oxide) and polystyrene are immiscible. However, when the polymers were functionalized by sulfonation, even though they remained immiscible when blended, the functionalization increased interfacial interactions and resulted in improved properties (71). In the case of DMPPO and poly(ethyl acrylate), the originally immiscible blends showed increased miscibility with sulfonation (72).

Blends have also been prepared by dissolving DMPPO in a monomer and then polymerizing the monomer. An example is an epoxy–DMPPO blend prepared by curing a solution of DMPPO in Epon 828 at 85°C with an aluminum–tetramethylguanidine catalyst. Some copolymer formation is observed. The solutions can be applied to glass cloth before curing to produce prepregs for composites in applications such as printed circuit boards (73).

Interpenetrating polymer networks (qv) of DMPPO and polymers such as polystyrene, polybutadiene, poly(urethane acrylate), and poly(methyl methacrylate) have been prepared by cross-linking solutions of DMPPO containing bromomethyl groups with ethylenediamine in the presence of the other polymer (74).

Noryl. Noryl engineering thermoplastics are polymer blends formed by melt-blending DMPPO and HIPS or other polymers such as nylon with proprietary stabilizers, flame retardants, impact modifiers, and other additives (75). Because the rubber characteristics that are required for optimum performance in

DMPPO–polystyrene blends are not the same as for polystyrene alone, most of the HIPS that is used in DMPPO blends is designed specifically for this use (76). Noryl is produced as sheet and for vacuum forming, but by far the greatest use is in pellets for injection molding.

Noryl is a rigid dimensionally stable material. Dimensional stability results from a combination of low mold shrinkage, low coefficient of thermal expansion (5.9×10^{-5} per °C), good creep resistance (0.6–0.8% in 300 h at 13.8 MPa (2000 psi)), and the lowest water absorption rate of any of the engineering thermoplastics (0.07% in 24 h at room temperature). Noryl resins are completely stable to hydrolysis. They are not affected by aqueous acids or bases and have good resistance to some organic solvents, but they are attacked by aromatic or chlorinated aliphatic compounds.

Noryl has good impact strength in unfilled grades: Gardner impact strength of 200 to >400 J (150–300 ft·lbf), and notched Izod 0.27–0.53 J/mm (5–10 ft·lb·f/in.) at room temperature and 0.13 J/mm (2.5 ft·lb·f/in.) at 140°C. Other mechanical properties are typical of amorphous engineering thermoplastics: tensile strength 50–70 MPa (8,000–11,000 psi), flexural strength 60–100 MPa (8,000–15,000 psi), and flexural modulus ca 2500 MPa (350,000 psi). Glass- or mineral-filled products have flexural moduli as high as 7600 MPa (1.1×10^6 psi). Dielectric properties are good: dielectric constant is 2.64, dielectric strength is 22 kV/mm at a thickness of 3.18 mm, and it is insensitive to changes in temperature or humidity and to frequencies of 60–10^6 Hz.

DMPPO–polystyrene blends, because of the inherent flame resistance of the DMPPO component (oxygen index ca 29.5), can be made flame retardant without the use of halogenated additives that tend to lower impact strength and melt stability in other polymers. Approximately one-half of total Noryl sales volume is in flame-retarded grades, ie, V0 or V1 in a 1.6-mm section (UL-94).

Properties of DMPPO–polystyrene blends, especially flammability, deflection temperature under load (DTUL) (ASTM D648), and melt viscosity, can be varied over a wide range by changing the ratio of DMPPO to HIPS, the amount and type of additives, and the characteristics of the HIPS. Noryl originally was introduced to fill a price–performance gap between ABS and polycarbonate, but the property range has been extended steadily and 50 standard grades are available with heat-distortion temperatures of 88–150°C; these include products specially designed for foaming, profile extrusion, and electroplating. In addition to the regular grades, approximately equal numbers of special products are available and each is designed primarily for a single application, eg, an easy-flow V0 product for television cabinets, a high heat Noryl for electrical connectors and food packaging for microwave reheating, Noryl GTX blends for automobile parts, etc.

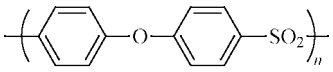
Principal application areas are in water distribution, electrical–electronic applications, business machines, and automobiles. Water distribution applications include pump housings, impellers and filters, shower heads, faucets, valve handles, and other plumbing fixtures. Among the applications in the electrical–electronic areas are cabinets and internal television and radio parts, lighting fixtures, connectors, junction boxes, wiring ducts, cable covers, protective devices, and motor housings. Noryl is used in many small appliances and personal care products, especially those involving exposure to heat and moisture (food processors, hair dryers, steam irons, hot combs, etc) and in console and decorative trim in

dryers, washing machines, and other large appliances. Frames, bases and supports for copiers, display stations, computers, typewriters, printers, and other business machines are commonly made of Noryl. The low temperature impact strength of Noryl and Noryl GTX contribute to its use in a variety of external automotive applications (wheel covers, grilles, fenders, mirror housings steering-column shrouds), instrument panels, electrical connectors, and filler panels.

General Electric is the only U.S. producer of Noryl resin and also has facilities in Japan and Europe. DMPPO is also produced in Japan by Ashahi, Mitsubishi Gas Chemical, and Sumitomo.

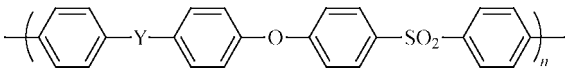
Polyethersulfones

The aromatic sulfone polymers are a group of high performance plastics, many of which have relatively closely related structures and similar properties (see POLYSULFONES). Chemically, all are polyethersulfones, ie, they have both aryl ether (ArOAr) and aryl sulfone ($ArSO_2Ar$) linkages in the polymer backbone. The simplest polyethersulfone (**5**) consists of aromatic rings linked alternately by ether and sulfone groups.



5

Effect of Structure on Properties. The effect of structure on chain flexibility in the series of polymers having the following common structure has been studied by varying the linking group Y (80). The glass-transition temperature changes in a predictable manner with the nature of Y. For example, when Y is a flexible ether, thio, or methylene group, the glass-transition temperature is ca 180°C. Replacement of the hydrogens of the methylene group by alkyl or aryl groups decreases the flexibility and increases the glass-transition temperature; the larger the substituent, the higher the value of T_g. Polar groups, eg, carbonyl and sulfonyl, that are capable of conjugation with the aromatic ring increase the glass-transition temperature, eg, to 245°C for the sulfonyl group, as in (**5**).

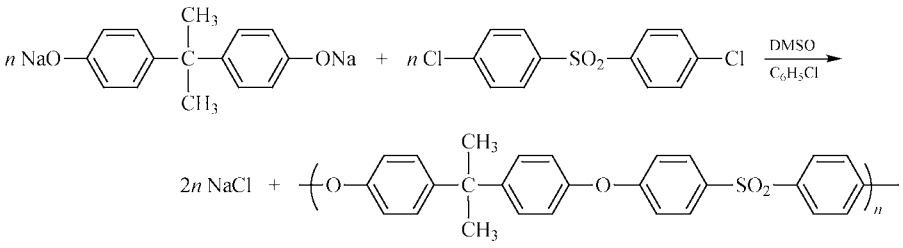


Synthesis. Aromatic polyethersulfones can be prepared by two different routes. In polyetherification, the sulfone group is present in one of the monomers and the ether linkage is formed in the polymerization step. In polysulfonation, the alternative approach is used and the aryl ethers are coupled through a reaction that forms the sulfone linkage. Both processes have been developed commercially. Unlike oxidative coupling polymerization, the mechanisms of both reactions are relatively straightforward, ie, both are polycondensations corresponding to types

of reactions that are well-established in organic chemistry. In general, the two processes are used to produce different types of polymers but some structures, including the basic structure (**5**), are available by either route. Polyetherification and polysulfonation have been reviewed extensively (80–84).

Polyetherification. Aromatic polyethersulfones are formed by reaction of the salts of dihydroxyaromatic compounds with di(haloaryl)sulfones. Reactions of this type, ie, nucleophilic aromatic displacement of halogen in aromatic compounds activated by sulfonyl or other strongly electron-withdrawing groups, are familiar in organic chemistry, but successful application to formation of high molecular weight polymers depends on the accelerating effects of certain dipolar aprotic solvents, which are believed to solvate the cations selectively, thus increasing the reactivity of the phenolate anions. The polar compounds must be stable under the conditions of the reaction and be capable of dissolving both the reactants and the polymer. Dimethyl sulfoxide (DMSO) is commonly employed, and other solvents, eg, tetramethylene sulfone (sulfolane), sometimes are useful when high temperatures are required (80).

The first aromatic sulfone polymer produced commercially was introduced as Bakelite polysulfone but now is sold by Union Carbide under the trade name Udel. It is made by reaction of the disodium salt of bisphenol A (BPA) with 4,4′-dichlorodiphenyl sulfone in a mixed solvent of chlorobenzene and dimethyl sulfoxide (eq. 12).



(12)

Polyetherification is similar to a polycondensation process: formation of high molecular weight polymer requires precise adjustment of composition to approximately 1:1 ratio of bisphenol to dihalosulfone. Trace amounts of water greatly reduce the molecular weight attainable owing to side reactions that unbalance the stoichiometry (84). The reactivity of the halosulfone is in the order expected for two-step nucleophilic aromatic displacement reactions: F > Cl > Br. In addition to being the most reactive of the halides, fluorosulfones are the least affected by traces of water. For economic reasons, only the chlorosulfone is used commercially. The reactivity of bisphenols in polyetherification decreases with increasing acidity of the phenol, but aromatic polyethersulfones can be prepared from almost all dihydric phenols under sufficiently vigorous conditions. The hydroxyl group and the active halogen can be combined in the same molecule; for example, (**5**) is produced by the self-condensation of 4-chlorophenyl-4′-hydroxyphenyl sulfone (85). The dichlorosulfone in equation 12 may be replaced by other dihalogen compounds

having strongly electron-withdrawing groups ortho or para to the halogens, such as carbonyl, azo, sulfamido, and nitro groups (86).

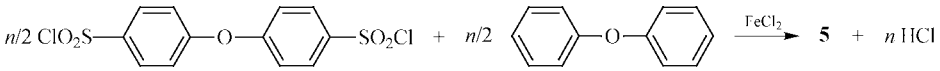
5

Copolymers. Copolymers from mixtures of different bisphenols or from mixtures of dichlorosulfone and dichlorobenzophenone have been reported in the patent literature. Bifunctional hydroxyl-terminated polyethersulfone oligomers are prepared readily by the polyetherification reaction simply by providing a suitable excess of the bisphenol. Block copolymers are obtained by reaction of the oligomers with other polymers having end groups capable of reacting with the phenol. Multiblock copolymers of BPA-polysulfone with polysiloxane have been made in this way by reaction with dimethylamino-terminated polydimethylsiloxane; the products are effective impact modifiers for the polyethersulfone (87). Block copolymers with nylon-6 are obtained when chlorine-terminated oligomers, which are prepared by polyetherification with excess dihalosulfone, are used as initiators for polymerization of caprolactam (88).

Polysulfonylation. The polysulfonylation route to aromatic sulfone polymers was developed independently by Minnesota Mining and Manufacturing (3M) and by Imperial Chemical Industries (ICI) at about the same time (89,90). In the polymerization step, sulfone links are formed by reaction of an aromatic sulfonyl chloride with a second aromatic ring. The reaction is similar to the Friedel–Crafts acylation reaction. The key to development of sulfonylation as a polymerization process was the discovery that, unlike the acylation reaction which requires equimolar amounts of aluminum chloride or other strong Lewis acids, sulfonylation can be accomplished with only catalytic amounts of certain halides, eg, $FeCl_3$, $SbCl_5$, and $InCl_3$. The reaction is a typical electrophilic substitution by an arylsulfonium cation (eq. 13).

(13)

Reaction of bis(sulfonyl chloride)s with diaryl ether produces polyethersulfones. For example, condensation of diphenyl ether with the disulfonylchloride of diphenyl ether yields polyethersulfone (**5**):

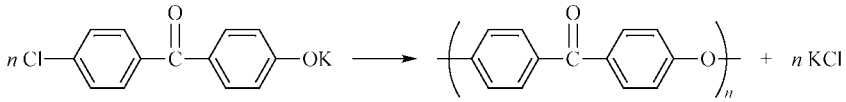


The reaction is carried out either in the melt or in a suitable inert solvent such as acetonitrile; ferric chloride is a preferred catalyst. Successful application of the polysulfonylation reaction to polymer synthesis requires a high degree of para coupling. Chain branching or any substantial degree of ortho coupling without branching results in brittle products. Specificity is improved if the sulfonyl group and the reactive ring are in the same molecule. The process described results in

10–20% of ortho coupling, but self-coupling of the monosulfonyl chloride is without detectable ortho coupling and the product is identical with that obtained by polyetherification. The polysulfonylation reaction is not limited to aryl ethers; it can be applied to most compounds having two or more independent aromatic rings, eg, biphenyl, terphenyl, and naphthalene, but the products are not polyethersulfones unless at least one of the reactants contains the ether linkage. Copolymers of (**5**) in which some of the diphenyl ether units are replaced by other groups are readily available by the sulfonation reaction. Incorporation of rigid biphenyl units by copolymerization of the sulfonyl chlorides of biphenyl and diphenyl ether increases the glass-transition temperature of the polyethersulfones; the Astrel polyethersulfones are of this type (91).

Polyetherketones

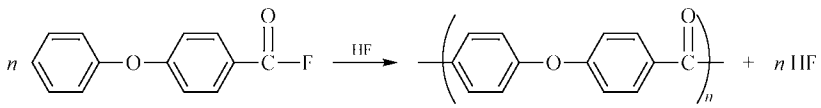
The polyetherification route to polyethersulfones can be adapted to the synthesis of polyethers containing strongly electron-withdrawing groups other than sulfone groups. Poly(1,4-oxyphenylenecarbonyl-1,4-phenylene) [27380-27-4] (**6**) is produced by condensation of 4,4′-dihydroxybenzophenone or by the self-condensation of 4-chloro-4′-hydroxybenzophenone. It has a melting point of 367°C and a glass-transition temperature of 154°C (92).



6

A polyetheretherketone (PEEK) (**7**) was introduced by Imperial Chemical Industries on a developmental scale in 1978. It is crystalline with a melting point of 334°C and a glass-transition temperature of ca 145°C (93,94). PEEK can be molded and is used in applications such as liquid chromatography fittings. It is also used for coatings, in electrical insulation for high temperature service, and in composites. Care must be taken on molding composites since the surface of the mold can affect the surface properties of the composite (95,96). Differential scanning calorimetry and microscopic techniques have been used to determine the morphology of molded PEEK graphite composites (97).

Stilan 1000, introduced by RayChem in 1974 and later withdrawn, is a polyetherketone made by a different route:

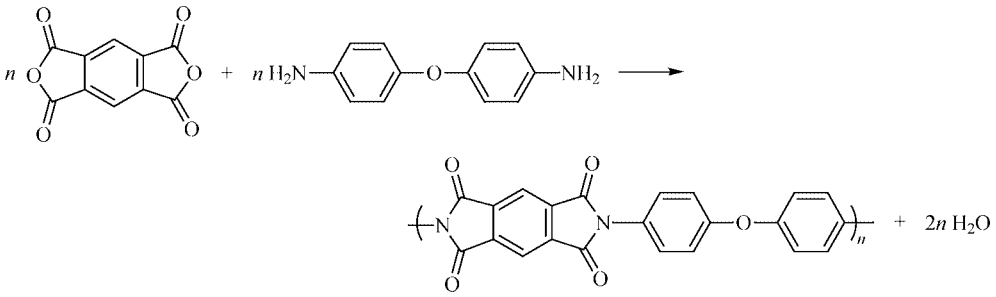


Cyclic aryl ether ketones have been prepared from 1,2-bis(4-fluorobenzoyl)benzene and bisphenols under pseudo high dilution conditions. These materials undergo ring-opening polymerization in the presence of an anionic catalyst (98).

Polyetherimides

A variety of polyetherimides have been described in reviews on polyimides (qv) (99,100). Many more recent materials have additional heterocyclic units such as quinoxaline and benzimidazole units, besides the ether and imide functionalities (101).

An all aromatic polyetherimide is made by DuPont from reaction of pyromellitic dianhydride and 4,4′-oxydianiline and is sold as Kapton. It possesses excellent thermal stability, mechanical characteristics, and electrical properties, as indicated in Table 3. The high heat-deflection temperature of the resin limits its processibility. Kapton is available as general-purpose film and used in applications such as washers and gaskets. Often the resin is not used directly; rather, the more tractable polyamide acid intermediate is applied in solution to a surface and then is thermally imidized as the solvent evaporates.



Not all polyetherimides are limited by their tractability, however. Certain aromatic polyetherimides are characterized by a combination of properties that makes them potential engineering thermoplastics (102,103). One of these polymers contains an isopropylidene unit in the backbone to enhance the solubility. It is a molding material introduced by General Electric in 1981 and sold as Ultem resin. Attractive features include high temperature stability, flame resistance without added halogen or phosphorus, high strength, solvent resistance, hydrolytic stability, and injection moldability.

Table 3. Selected Properties of Kapton[a]

Property	Value
CAS Registry Number	[25036-53-7]
Heat deflection temperature, °C	360
Tensile yield (at 23°C), MPa[b]	86
Tensile modulus, MPa[b]	3110
Flexural strength, MPa[b]	131
Flexural modulus, MPa[b]	3110
Oxygen index	36.5
Density, g/cm^3	1.43
Dielectric strength, V/m	58

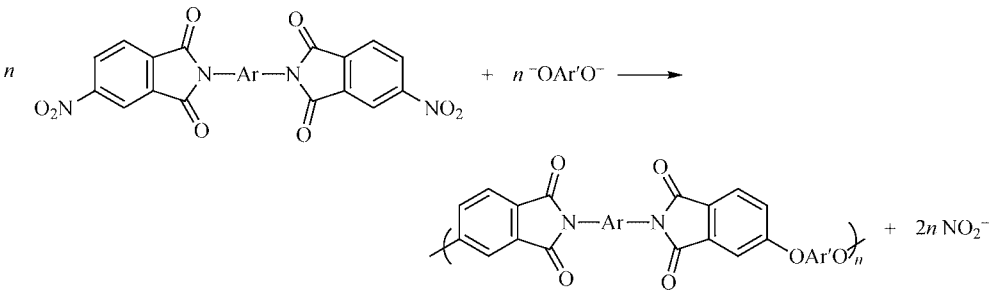
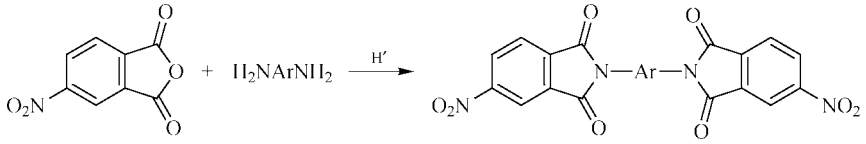
Syntheses. The presence of the ether and imide functionalities provides two general approaches for synthesis. Polyetherimides can be prepared by a nucleophilic displacement polymerization similar to the halide displacement in polysulfone synthesis or by a condensation of dianhydrides and diamines that is similar to normal polyimide synthesis (see POLYIMIDES).

Nitro-Displacement Polymerization. The facile nucleophilic displacement of a nitro group on a phthalimide by an oxyanion has been used to prepare polyetherimides by heating bisphenoxides with bisnitrophthalimides (104). For example with 4,4′-dinitro monomers, a polymer with the Ultem backbone is prepared as follows (105). Because of the high reactivity of the nitro phthalimides, the polymerization can be carried out at temperatures below 75°C. Relative reactivities are nitro compounds over halogens, *N*-aryl imides over *N*-alkyl imides, and 3-substituents over 4-substituents. Solvents are usually dipolar aprotic liquids such as dimethyl sulfoxide, and sometimes an aromatic liquid is used, in addition.

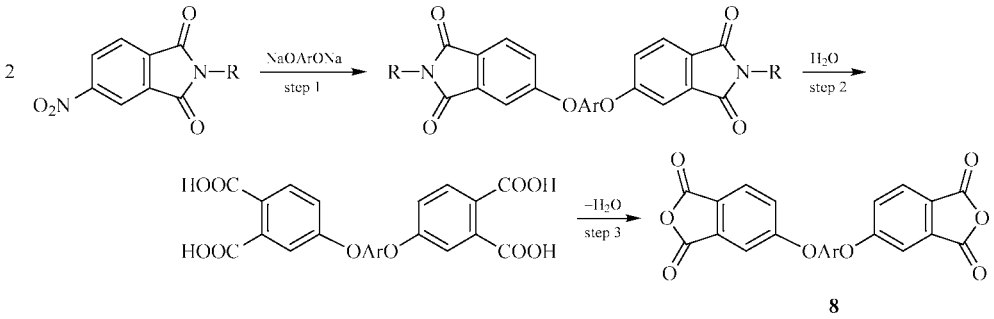


Bisnitrophthalimides can be prepared in high yields and high purity from nitrophthalic anhydrides and diamines under acidic conditions (106).

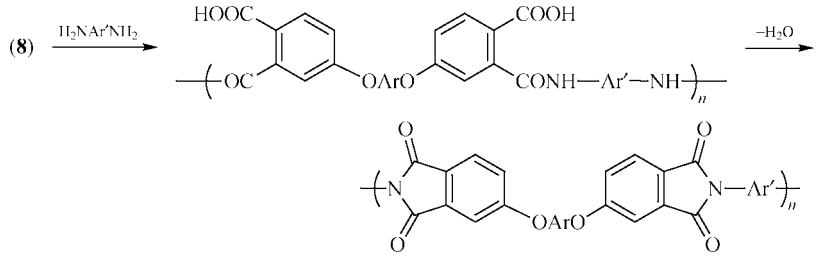


Condensation of Dianhydrides with Diamines. The preparation of polyetherimides by the reaction of a diamine with a dianhydride has advantages over nitro-displacement polymerization: sodium nitrite is not a by-product and thus does not have to be removed from the polymer, and a dipolar aprotic solvent is not required, which makes solvent-free melt polymerization a possibility. Aromatic dianhydride monomers (**8**) can be prepared from *N*-substituted nitrophthalimides by a three-step sequence that utilizes the nitro-displacement reaction in the first step, followed by hydrolysis and then ring closure. For the 4-nitro

compounds, the procedure is as follows.



Polymerization of the dianhydride and diamine proceeds through an intermediate poly(amide acid) stage before ring closure converts the adjacent acid and amide groups to the polyetherimide (107). The polymerization can be carried directly to the polyetherimide as a single-step process, or first to an amide–acid-containing prepolymer, which can be isolated, and then to the polyetherimide.



Properties. The mechanical properties and oxygen index of Ultem polyetherimide are listed in Table 4. In flammability testing, the oxygen index of many polyetherimides is high and they are self-extinguishing (V 0), nondripping, and generate little smoke (108). Many polyetherimides with additional chemical functional groups have been reported. Such materials and a variety of polyether-heterocyclics have received only limited commercial attention.

Table 4. Ultem Polyetherimide Properties

Property	Value
Glass-transition temperature, °C	217
Heat-distortion temperature, °C	ca 200
Tensile yield (at 23°C), MPa[a]	103
Tensile modulus, MPa[a]	3000
Flexural strength, MPa[a]	145
Flexural modulus, MPa[a]	3300
Oxygen index	47
Density, g/cm^3	1.28

[a]To convert MPa to psi, multiply by 145.

Ultem polyetherimides have applications in areas where high strength, dimensional stability, creep resistance, and chemical stability at elevated temperatures are important. Uses include electrical connectors, wave guides and printed circuit boards for electronic equipment, food applications (microwaveable containers, utensils, and films), aircraft interior materials, and sterilizable medical equipment.

A large variety of newer poly(ether imide)s has been described. Included among these are perfluorinated polymers (109), poly(ester ether imide)s (110), poly(ether imide)s derived from *N*,*N*′-diamino-1,4,5,8-naphthalenetetracarboxylic bisimide (111), and poly(arylene ether imide ketone)s (112). In addition, many other heterocylic groups have been introduced into polyether systems, eg, poly(pyrazole ether)s (113) and poly(aryl ether phenylquinoxaline)s (114); poly(aryl ether oxazole)s with trifluoromethyl groups (115); and polyethers with other heterolinkages, eg, poly(arylether azine)s (116).

POLYMER BRUSHES

Introduction

Polymer brushes can be defined as polymer materials prepared and assembled from end-tethered or surface-initiated polymer systems where the average distance between grafting points can be much smaller than the radius of gyration (R_g). This tethering can be of sufficient density such that under equilibrium conditions, these polymer chains stretch along the direction normal to the grafting surface both in the presence or absence of external fields or stimuli (Fig. 1) (1). They can be quite different from that of flexible polymer chains in solutions where the chains are free to adopt a random-walk configuration. In the presence of a good solvent, polymer chains avoid contact with each other in order to maximize polymer–solvent interaction. Also, in the absence of solvent or in melt conditions, polymer chains can stretch away from the interface to avoid overfilling incompressible space (Fig. 2). Moreover, analogous macromolecule systems can be studied and compared to polymer blends (qv), block copolymers (qv), complex polymer architectures, and other functional polymers where confinement in surfaces and interfaces gives unique behavior and properties. In general, the interface to which polymer chains can be tethered may be solid–gas, solid–liquid, liquid–liquid, and liquid–gas. Furthermore, in solid surfaces, polymer chains can be chemically bonded (chemisorption) or may be just physically adsorbed onto the surface (physisorption) of the substrate.

Recently, the investigation of polymer brushes has been focused on the synthesis of new tethered polymer systems primarily through *surface-initiated polymerization* (SIP). Previously, the term polymer brushes has been limited to the investigation of block copolymers (qv) or end-functional linear polymers that have been physically or chemically adsorbed to surfaces, respectively (3,4). Recent synthetic efforts using different polymerization mechanisms have resulted in the discovery of many novel properties of polymer brushes. This has been aided no less than the use of innovative and unique surface-sensitive analysis methods as applied to flat substrates and particles. The study of polymer brushes has benefited from improved dielectric, optical, spectroscopic, and microscopic characterization methods. Understanding the chemistry of these grafting reactions and how

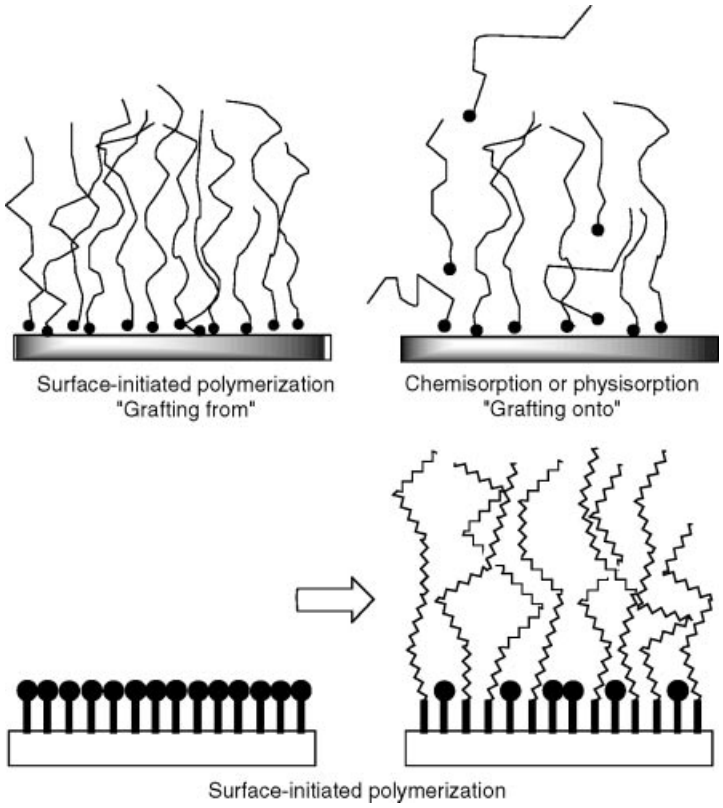

Fig. 1. The polymer brush approach and their classification: grafting to vs grafting from approaches and surface-initiated polymerization (SIP). The influence of grafting density and the enthalphic and entropic factors are clearly present on the "grafting onto" approach. Higher grafting density is expected with the SIP.

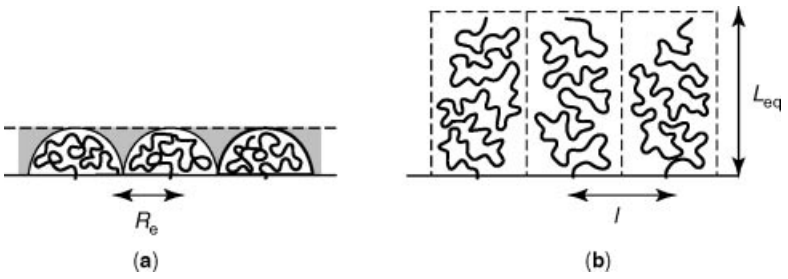

Fig. 2. The two limiting cases of a polymer brush regime, showing (**a**) tethered chains having the critical grafting density $\sigma^* = 1/\pi R_e{}^2$ and (**b**) chains having $\sigma > \sigma^*$ and forming the stretched brush. Other types of brush regime terminologies have been reported in literature. In this case, a characteristic length in the uncompressed brush (**b**) is given by $1 = \sigma^{-1/2}$. From Ref. 2.

changes in monomer type, polymerization conditions, and interfacial properties affect the polymerization kinetics and molecular weight control is essential. It is ideal to have a polymerization technique which affords control over the molecular weight, molecular weight distribution, grafting density, and microstructure of the resulting polymers. In principle, an increase in the molecular weight of polymer chains with monomer conversion and a narrow molecular weight distribution for the grafted chains will give a uniform brush length similar to that observed in living polymerization in solutions. Thus, it is essential to understand the protocols and mechanisms of free-radical, living free radical, anionic, cationic, metathesis polymerizations on surfaces. A number of these polymerization mechanisms have been reviewed in the past by the Tsubokawa and co-workers, including the use of irradiation and plasma ionization techniques to functionalize and polymerize at particle surfaces (5,6). However, of great interest are the recent and current studies on the different polymerization mechanisms on "flat" surfaces and the characterization techniques that can be applied to these systems.

Classification

Grafting onto and Grafting from. The first type of classification that can be used to distinguish polymer brushes is by their source and direction of grafting technique (see GRAFT COPOLYMERS). *Grafting* refers to the tethering or point of anchor for polymer chains. In the case of preformed polymers where an anchoring group was added by design, the polymer is expected to find its way to the surface or interface, where preferential adsorption can take place. This *grafting onto* of preformed functionalized polymers onto the surface could be further divided as a type of *physisorption* or *chemisorption* (another classification). During the grafting procedure, it is expected that the polymer chains will find its way to the surface where enthalpic and entropic considerations will determine the degree of grafting, eg diffusion, steric crowding, solvent quality. On the other hand, in a *grafting from* scheme, the polymer is formed *in situ* from grafting sites (initiators), where the growth of the polymer is limited primarily by reactivity of the active center during propagation, monomer diffusion or availability, and other peculiarities of the interface region, affecting the overall polymerization mechanism. However, to construct a highly dense polymer brush, the *grafting from* technique offers the most promise. This is because the kinetics of adsorption and reactivity is more favorable for smaller molecules, such as the initiator or the monomer (7). Therefore, to achieve a macromolecular design of a dense polymer brush, the SIP technique must be applied.

Physisorption vs Chemisorption. Another important classification involves distinguishing the adsorption process. The *physical adsorption* or *physisorption* of homopolymers or block copolymers have been well reported (4,8). Physical Adsorption (qv) means that noncovalent forces, eg ionic or electrostatic attraction, dipole forces, H-bonding, hydrophobic effect, and van-der Waals forces, are responsible for grafting the polymer to surfaces. A number of macromolecular systems involving the use of linear homopolymers, end-group functional homopolymers, anchor-buoy designated block copolymers, amphiphilic block copolymers, and even star copolymers have been investigated (4). In this case, the polymer is attracted to the surface (both flat or particle) owing to a more

favorable free energy gained by adsorption process (9). However, the problem is that such adsorbed layers are still susceptible to removal, eg by exposure to a thermodynamically good solvent or any subphase conditions that can weaken physical adsorption. Furthermore, it is often difficult to precisely control the physical structure of such adsorbed layers. On the other hand, adhesion between the polymer chains and the substrate may be greatly enhanced if the chains are tethered covalently to organic or inorganic surfaces by *chemical adsorption* or *chemisorption*. This approach involves the reaction of a preformed end-functionalized polymer with appropriate reactive sites on the inorganic surfaces (10). The preformed polymer is synthesized to have a reactive end group that is complementary to another reactive functional group already tethered to a surface (usually by forming self-assembled monolayers or SAM). The polymer end group then finds its way to the surface and a covalent bond is formed between the end-functional polymer and surface-bound complementary functional group. Thus, this method is more thermodynamically favorable than physisorption since the polymer forms a covalent bond anchor, which can only be removed by another chemical reaction. Still, the disadvantage of this method of grafting is that the chains, which are attached at the beginning of the reaction, sterically shields the remaining reactive sites on surfaces (11). Also, not all chemical reactions have the same rates in surfaces as compared to solution and bulk.

Thus, both physisorption and chemisorption have their drawbacks for *grafting onto* surfaces. To this respect, *grafting from* surfaces by SIP has important advantages in terms of polymer brush densities and other physical properties. The rest of this article deals primarily with the subject of polymer brushes prepared by SIP. Other polymer brushes prepared primarily by physisorption or chemisorption is best referred to other review articles and books (12).

Surface-Initiated Polymerization Methods

Polymerization at the interface is governed by thermodynamic and kinetic considerations not necessarily present in bulk or solution. There is a need to understand how these factors affect what is traditionally known about polymerization mechanisms in solution and in bulk. SIP promotes polymerization of monomers directly from initiator sites attached to surfaces, in which case activation of initiator and diffusion of monomers to the reactive sites become primary factors (13). The interface is a highly anisotropic environment where a variety of conditions exists, eg surface energy, polarity, and electrical double layer, not to mention the various geometries, size, shape, and surface properties of the solid-support substrate to which the polymer is bound (14). With the recent popularity of the SIP protocols, unique parameters and conditions toward the various polymerization mechanisms (initiation, propagation, termination, etc) warrant comparison with solution or bulk polymerization methods (15). In terms of chemistries involved at the interface, the homogeneity or heterogeneity of the system and the differences between the bulk phases defines the lifetime of the initiator, the flux of the monomer, and the rate of termination. Because of the high density of grafting sites, it is possible to prepare grafted polymers were the average distance between grafting points is much smaller than R_g. Selective spatial polymer growth is possible by both lithographic and nonlithographic patterning techniques (16). The

behavior of polymer brushes under electric field, temperature gradient, solvent polarity, photochemical effects, and flow gradients can lead to novel types of *field responsive polymers* (17).

Polymer Brushes on Flat Surfaces. By focusing on SIP in flat ideal surfaces, it is possible to take advantage of a wide range of surface-sensitive spectroscopic and microscopic analytical techniques. Flat substrates that have been investigated include glass, quartz, Si wafer, Au-coated glass, and Al-coated glass. There is potential for tailored polymer brush applications via surface modification and patterning (18). Theoretical predictions have been used to calculate molecular weight and polydispersity of polymer brushes grown by SIP on flat surfaces (19). Other theoretical predictions have been made on conformation and dynamic behavior of tethered polymers at flat surfaces (20). For example, it is always interesting to observe theoretical predictions on block copolymer brush behavior with respect to the Flory–Huggins (χ) interaction parameter, Kuhn length, block volume fraction, and substrate surface energies (21).

The number of different polymerization mechanisms reported has increased. Polymer brushes by SIP can be prepared using free-radical (13,22), cationic (23), ring-opening metathesis polymerization (ROMP) (24), atom transfer free-radical polymerization (ATRP) (25), polymerizations using 2,2,6,6-tetramethyl-1-piperidyloxy (TEMPO) (26), and anionic polymerization (27). All these methods are suitable for polymerizing different types of monomers on a variety of flat surfaces, resulting in different polymer growth kinetics and chain densities (Fig. 3). Different polymer brushes by composition (homopolymers, copolymers, mixed polymers) and architecture (block copolymers, hyperbranched, graft, etc) have also been achieved (28). A number of polymers with distinct wetting and polyelectrolyte behavior have been prepared (29).

Since the interface is a highly anisotropic environment, it is typical to use surface-sensitive analytical methods. Innovative use of these analytical tools has allowed elucidation of polymerization mechanisms and physical properties of these tethered polymers *in situ* on flat surfaces. Surface-sensitive spectroscopic and microscopic techniques like atomic force microscopy (AFM), ellipsometry, X-ray reflectometry, etc, have allowed detailed investigations on polymer brush behavior and growth kinetics under glass, melt, or swelling condition. Several articles have focused on reviewing polymer brushes *grafted from* flat surfaces, including SiO_2, Au, and glass (31). It should be emphasized that for each polymerization mechanism, peculiar conditions and parameters have to be optimized for controlled polymer brush growth (length, molecular weight, density, etc). There are parallels or contrasts for the SIP process when applied to flat geometry and particle surfaces.

Polymer Brushes on Particles. SIP from particle surfaces also involves growth of end-tethered polymer brushes under different mechanisms. A variety of initiators, reaction conditions, monomers, and nanoparticles can be employed. Important differences to solution and bulk polymerization can be observed where the nanoparticles with grafted initiators behave as *macroinitiators*. In turn, the development of these materials allow the preparation of thermodynamically and kinetically stable nanocomposites and colloids.

The preparation of polymer brushes grafted on particles and even nanoparticles is by far the more widely studied systems in polymer grafting methods

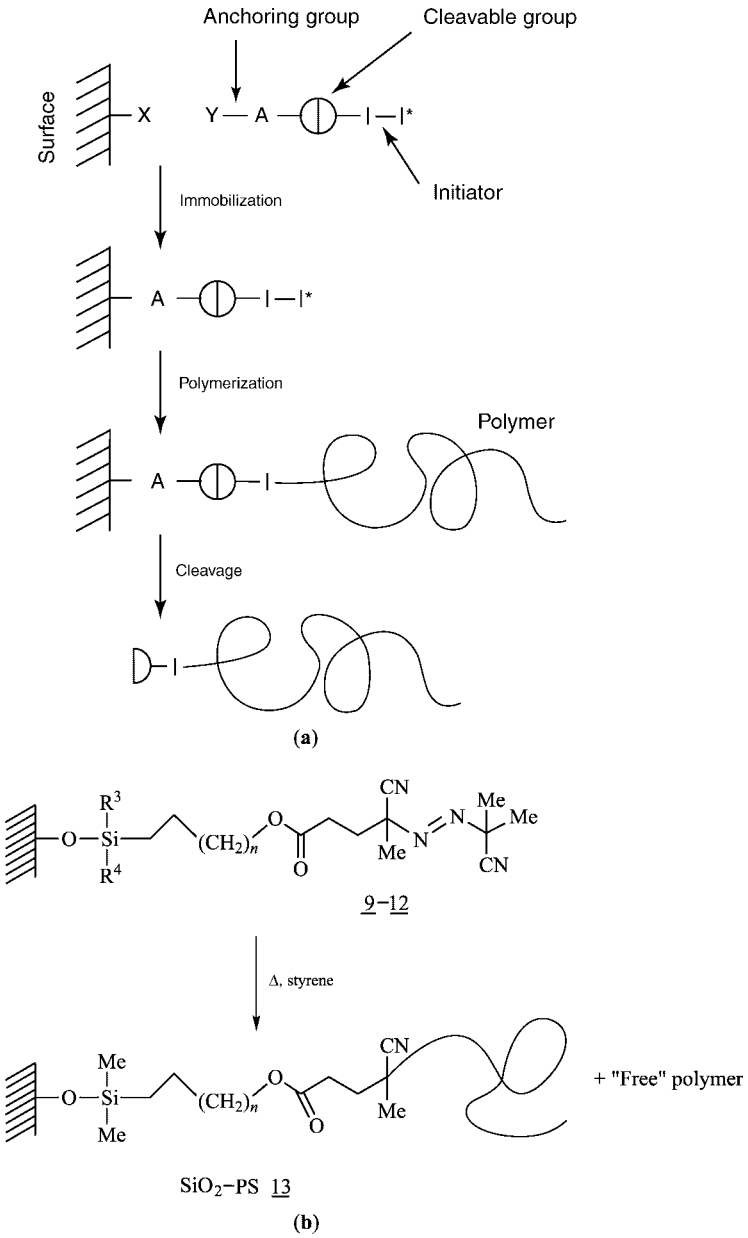

Fig. 3. Protocol for free-radical SIP using AIBN analogue initiators attached to silica nanoparticles. (**a**) general initiator attachment, polymerization, and cleavage scheme; (**b**) AIBN surface initiator. From Ref. 30.

(6). The ease of preparation and analysis of such systems by simple gravimetric methods is one of the most common reasons. Also, particles are readily available and their dispersion properties have been highly studied in industry. In addition, there is great interest in much smaller "nanoparticle" systems as host for the polymerization process (32). The synthesis, characterization, and development of

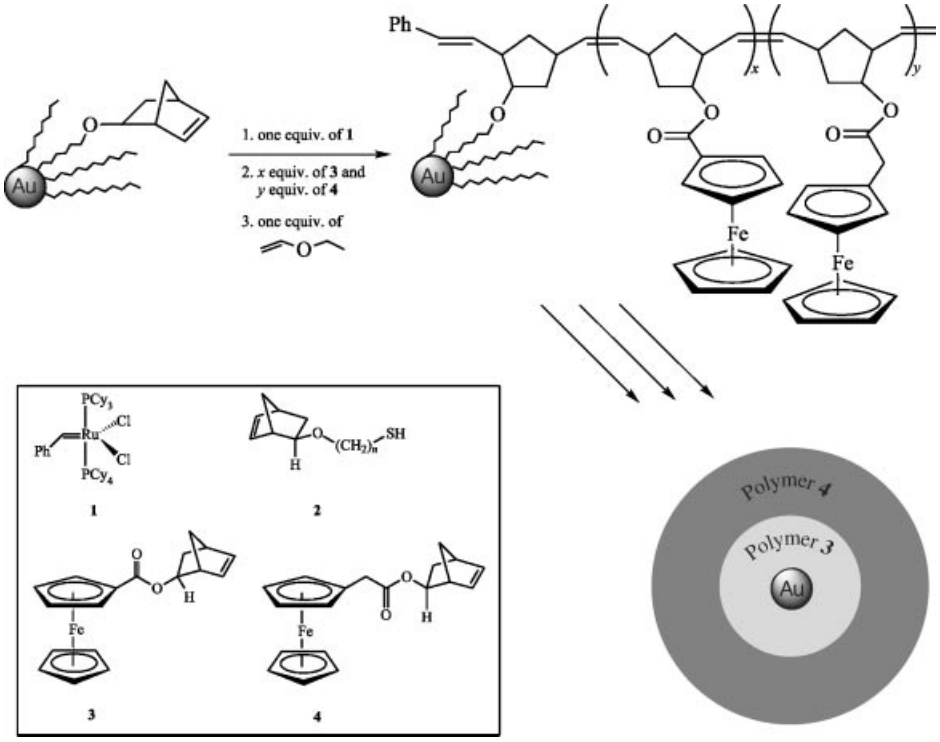

Fig. 4. The protocol for polymer brushes by SIP ring opening metathesis polymerization (ROMP), with initiators attached to Au nanoparticles. From Ref. 39.

new nanoparticle materials have both scientific and technological significance. Primarily through the quantum size effect, a number of these nanoparticle hosts have interesting electrooptical and magnetic properties (33). Different mechanisms are possible on a variety of initiators, reaction conditions, monomers, where a continuum of properties can be possibly observed on going from flat surfaces to high surface-to-volume nanoparticles. A number of polymerization mechanisms for particles have also been reported. This includes free-radical (22), cationic (34), TEMPO (35), anionic (36), ATRP (37), and metathesis (38) (Fig. 4).

Polymerization from particle surfaces is challenging from the perspective of doing surface chemistry with colloids (14). The particle size and geometry vary. Also, the surface energy and solvent polarity changes, which can make a difference in terms of forming stable dispersions in selective solvents at each stage of the polymerization process. There are a number of analytical techniques which have been used to investigate this hybrid systems *in situ*. One of the compelling reasons to do SIP on particles is that it offers the advantage of preparing large quantities of SIP-grown polymers that can be degrafted and extensively analyzed *ex situ*. This is because of the high surface-to-volume ratio afforded by these substrates. However, it is also advantageous to characterize these systems with the polymers still grafted on the particles for the sake of learning more about certain fundamental properties of colloids (14).

Polymerization Mechanisms for Polymer Brushes on Particles

A number of SIP methods on flat surfaces have been the subject of recent reviews (1). More detailed description can be found in this article regarding the various mechanisms used and investigated on flat substrate surfaces. The formation of polymer brushes with various SIP mechanisms on particle systems is the focus of this section. However, as representative polymerization mechanisms, it gives insight into the peculiar aspects for each type of reaction when confined to surfaces.

Surface-Initiated Free-Radical Polymerization. Free-radical SIP of polystyrene from nanoparticle surfaces have been investigated in detail by Ruhe and Prucker (12,32). Using AIBN-type free-radical initiators (qv), they have found that initiation and growth of the polymer at low conversion of a surface-attached initiator are comparable to polymerization in solution. The differences observed were attributed mainly to termination reactions. Another difference between solution polymerization and SIP is that all transfer reactions to either solvent or monomer or transfer agent can lead to termination of growing surface-attached chains via SIP. The consequence is a decrease in the radical efficiency of the initiator in surfaces compared to solution. Similar work on grafting to particles has been reported by Suter and co-workers (40) who tethered azo initiators by ion exchange to mica. A styrene-like initiator has been used to grow polymer brushes from clay surfaces by free-radical SIP (41). Other groups have also reported free radical polymerization (qv) from nanoparticle surfaces (42,43).

Surface-Initiated Atom Transfer Radical Polymerization. Living free radical ATRP show the most promise for polymerization control on surfaces (44,45). It has been shown that typical ATRP conditions proved insufficient for controlled polymerization from flat surfaces (46). The use of a deactivator (Cu(II)) and a "sacrificial" free initiator to the polymerization system afforded molecular weight control. ATRP initiators based on 3-(2-bromopropionyloxy)propyl dimethylethoxysilane have been used to do SIP on surfaces (47). Controlled "living" radical polymerization (qv) was possible through changes in the polymer's grafting density, composition, structure, and molar mass. This was manifested in the linear kinetic plots, linear plots of molecular weight (M_n) versus conversion, increased hydrodynamic diameter with conversion, and narrow molecular weight distributions (M_w/M_n) for the grafted polymer materials. Hybrid nanoparticles possessing well-defined tethered block copolymers are accessible using ATRP (48). Recently, surface-initiated ATRP on silica particles has been demonstrated in aqueous media (49). Other relevant works related to surface-initiated ATRP have been reported (50). Another living free-radical polymerization process called reversible addition-fragmentation chain transfer or RAFT has been applied to surfaces (51). Grafting of polymers to carbon black has been reported using TEMPO (52).

Living Anionic Surface-Initiated Polymerization. Anionic polymerization (qv) is a most versatile method to make well-defined architectures of polymers. It has been employed to grow polymer brushes from various silica gels (53), graphite and carbon black (54), and also flat surfaces (27,55). Results on living anionic polymerization on clay nanoparticles have been reported (56). Special conditions are required since difficulties arise owing to the effects of moisture and other impurities on anionic polymerization. A major limitation of the prior work

by Oosterling and co-workers is that the choice of *tert*-butyllithium (t-C_4H_9Li) as the initiator for styrene polymerization from silica in the presence of toluene is inefficient (54). Yet, despite these difficulties, anionic polymerization remains attractive for the synthesis of complex and well-defined macromolecular architectures (57,58). The Advincula group has recently reported results on living anionic polymerization on clay (59), SiO_2 nanoparticles, and flat surfaces using the initiator precursor 1,1-diphenylethylene (Fig. 5) (27,36,57).

Surface-Initiated Ring-Opening Metathesis Polymerization. Nanoparticles can be coated with alkanethiol-containing and silane-containing initiators for ROMP (39,60). ROMP on surface-functionalized particles makes use of organometallic catalysts to allow metathesis type of polymerization methods. Since this is also a living polymerization process, the advantages of this strategy are numerous, including exceptional control over polymer length and chemical composition as well as particle size, solubility, and shape. Other groups have also reported strategies for ROMP on surfaces (61).

Surface-Initiated Living Cationic Polymerization. Cationic ring-opening surface initiated polymerization reactions can be directed to particle surfaces (34). Using appropriate initiation procedures with 2-oxazoline monomers, a ring-opening cationic polymerization process was observed to proceed in a living manner. Hydroxyundecane-1-thiol-functionalized gold particles were converted to triflate functional groups by exposure to trifluoromethanesulfonic anhydride. Then 2-oxazoline monomer was added and polymerization proceeded under reflux conditions. Termination was done by adding *N*,*N*-di-*n*-octadecylamine. Other groups have reported SIP by living cationic mechanism on a variety of surfaces (62,63).

In summary, different mechanisms are possible and have been successfully demonstrated for grafting polymer brushes. Comparison can be made to their solution or bulk polymerization counterparts. These systems differ in (*1*) rate of polymerization, (*2*) mechanisms and methods of termination, (*3*) consideration of interfacial properties and reaction conditions, and (*4*) methods of analysis and correlation with theoretical trends. Again, different polymerization mechanisms can also be found with polymer brushes on flat surfaces.

Analytical and Characterization Methods

The study of *polymer brushes* has been of great interest not only for their synthesis but also for their unique properties and characterization approaches. The analysis of polymer brushes is a challenge. Because of their reduced dimensionality, assumptions based on analogous solution or bulk systems do not necessarily hold. There is a desire to understand fundamental properties at interfaces and in developing new applications. Since the interface is a highly anisotropic environment, surface energy, polarity, electrical double layer, etc, needs to be taken into account (14). In general, the methods of analysis can be divided into spectroscopic, microscopic, and optical in approach although other classifications can be mentioned. Both *in situ* and *ex situ* methods are possible (see SURFACE ANALYSIS).

Characterization of Polymer Brushes on Flat Substrates. *Ultrathin* organic and polymer films have been the subject of extensive investigations for

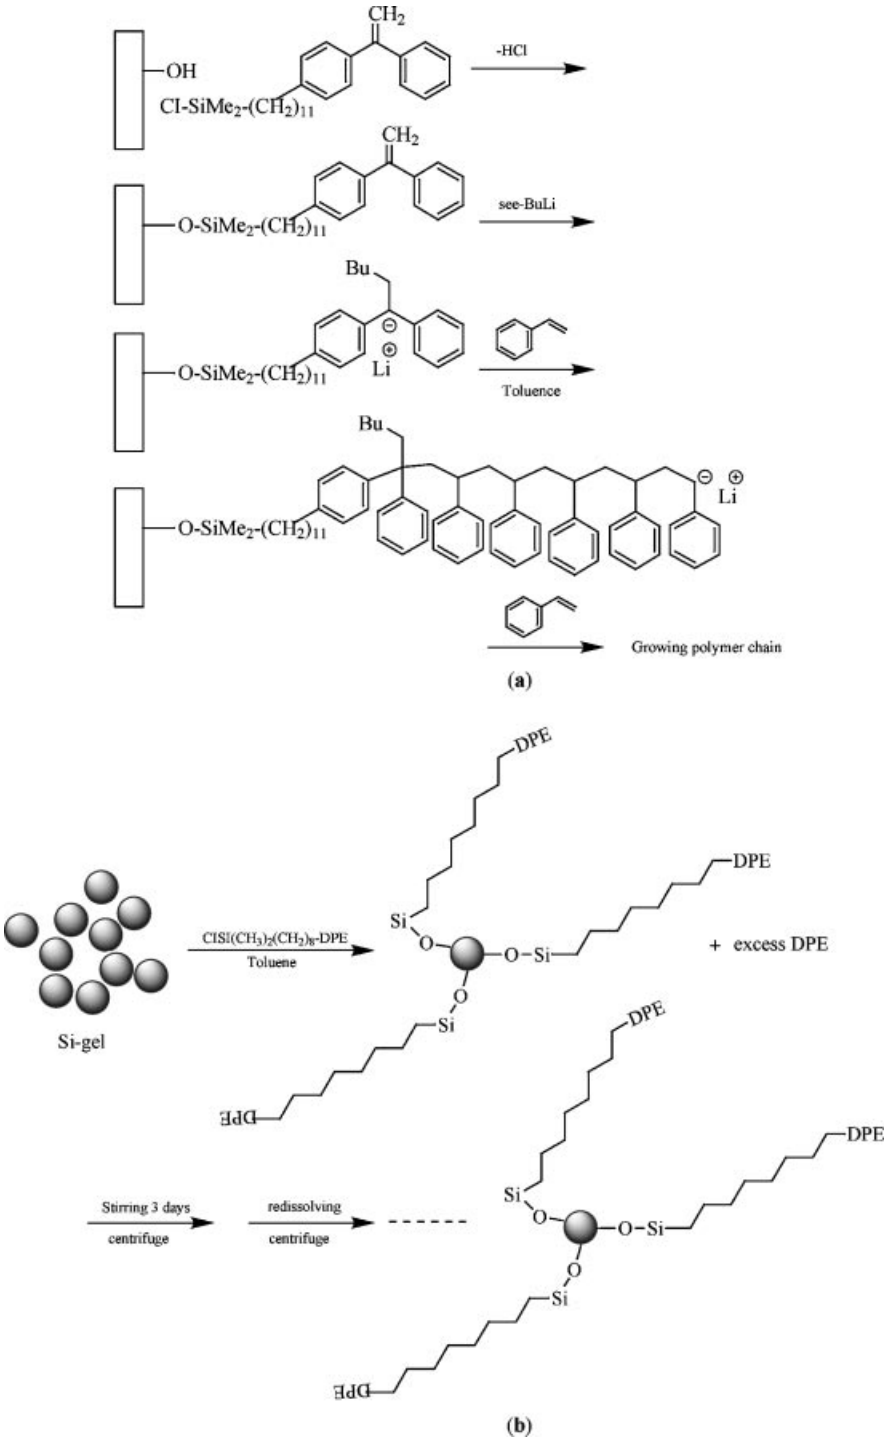

Fig. 5. Protocol for living anionic surface initiated polymerization (LASIP), with initiators attached to silica nanoparticles or clay: (**a**) grafting of initiator and general polymerization scheme; (**b**) nanoparticle grafting procedure. From Ref. 36.

the last few decades (64). They have finite thicknesses of a few to several hundred nanometers, on a variety of solid substrate supported systems. The quasi two-dimensional ordering within layers can be extended into stacked structures perpendicular to the solid substrate. In the investigation of polymer brushes, surface-sensitive spectroscopic and microscopic analytical methods can be applied that have been typically used for investigating other types of organic and polymer ultrathin films which includes spin coating, alternate polyelectrolyte (65), Langmuir–Blodgett technique (66), and self-assembled monolayers (67,68) (see LANGMUIR-BLODGETT FILMS).

Spectroscopic methods such as UV–vis absorbance, fluorescence, and other intensity-sensitive spectroscopic techniques have been used to investigate changes in absorption increase, energy transfer processes, and monitor film growth *in situ* for polymer brushes. The formation of uniform polymer films can also be verified and observed by X-ray reflectivity and other scattering methods (69). Neutron diffraction and reflectometry can be used, relying on deuterated species within layers (70). These techniques are important in probing the mobility of polymer chains, diffusion within layers, and short-range and long-range order parameters that can be correlated with other spectroscopic and microscopic techniques (71).

Techniques for determining the chemical functional group and molecular (elemental) species also include FT-IR and X-ray photoelectron spectroscopy (XPS) (72). XPS in particularly useful for monitoring the presence of different oxidized states of atoms, relative abundance of atomic species, and the presence of the substrate. FT-IR and IR-RAS has been used to monitor specific IR-sensitive functional groups even at monolayer thicknesses (73).

Optical techniques can be used to monitor optical thickness and dielectric constant parameters. This includes ellipsometry, multiple reflection interferometry (74), evanescent wave (75), and surface plasmon resonance spectroscopy techniques (43). Ellipsometry has been used widely and routinely to investigate film thickness of polymer brush films (76). For optical properties of films, it is important that the average film roughness and uniformity is specified. Often, sampling is localized by the "spot" size, such that it is necessary to probe and average different areas of a sample.

Microscopy is very useful especially in monitoring lateral morphologies, layer roughness, domains, or patterns. This includes AFM, scanning electron microscopy (SEM), optical microscopy, and other surface probe microscopy methods (77,78). SEM can be used for relatively thick films combined with microtoming and cryogenic techniques (79). It is very useful for obtaining three-dimensional morphologies and characterization of features of these films. AFM has been used to investigate polymer brushes in a number of ways. This includes (a) general mapping of topology or investigating morphologies (80), (b) identifying features resulting from phase segregations (28), (c) measuring the surface forces involved in different brush geometries (81), (d) estimating the molecular weight of brushes (82), and (e) investigating patterned polymer brushes (Fig. 6) (see ATOMIC FORCE MICROSCOPY).

Other surface-sensitive methods can and have been used

(1) quartz crystal microbalance methods have been used to investigate the deposition process especially *in situ* (84). The value of *in situ*

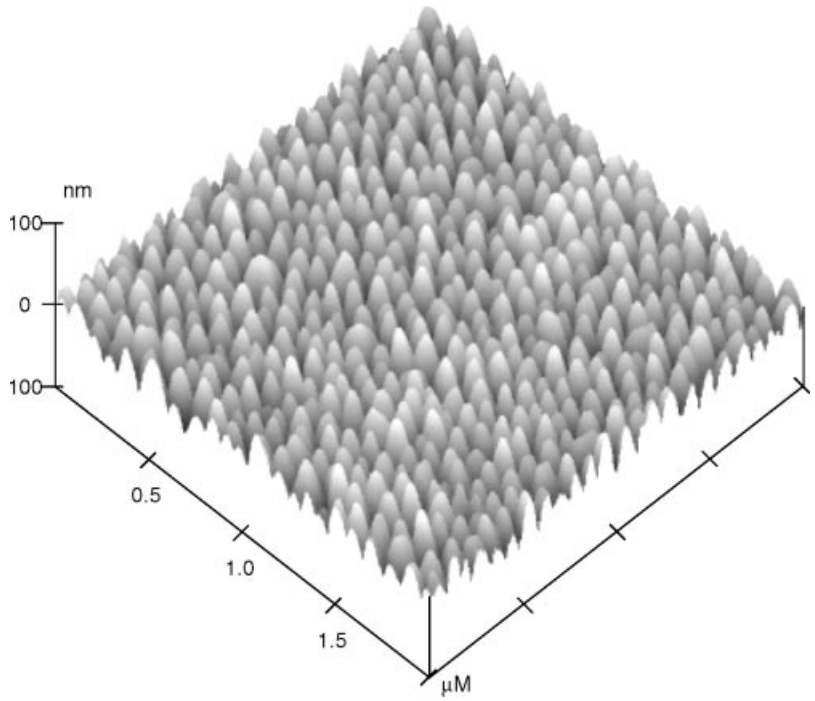

Fig. 6. Formation of a nanopattern from a PS-*b*-PMMA brush with 23-nm PS and 14-nm PMMA as investigated by AFM. From Ref. 83.

monitoring methods is in determining the rate functions of the adsorption process.

(2) Contact angle measurements or surface tensiometry allow determination of surface energy or surface tension on polymer brushes (85). It also gives information on differences in morphology and functional group distribution on surfaces.

(3) Electrochemical methods involve redox behavior of probes or the polymers themselves. It is possible to utilize this technique to investigate permselectivity (86). It can be utilized to probe any redox active species in the polymer films.

(4) Streaming potential measurements with ellipsometry can possibly be applied to polyelectrolyte polymer brushes (87).

(5) A very important technique is the use of a surface force apparatus (SFA) (88). It is capable of measuring the surface forces directly between two molecularly smooth surfaces, eg mica, with a sensitivity of a few millidynes (10 nN) and a distance resolution of about 0.1 nm. These flat smooth surfaces of mica can be covered with polymer brushes to obtain tribological properties between different polymer brush materials. Direct measurement of surface forces is also possible by AFM (89).

Other methods will likely be reported in the future and find unique utility in characterizing and analyzing polymer brushes. It should also be mentioned that

computational and simulation methods are important "tools" for predicting and scaling the observed behavior in polymer brushes and should go hand-in-hand with experimental results (90).

Characterization and Analysis Methods for Polymer Brushes on Particles. There are several important reasons for *in situ* analysis of polymer brushes on particles: (*1*) to monitor grafting of initiator to particle surface, (*2*) to monitor surface functional group conversion, (*3*) to investigate the polymerization mechanism (initiation, propagation, termination), and (*4*) to investigate the properties of a hybrid organic–inorganic particle or nanocomposites. Properties that can be measured include grafting density, polymer shell thickness, swelling and contraction of shell, and polydispersity of polymer brushes. The nature of the particle substrate is important. The analysis of these materials can be further complicated by the fact that different particle and nanoparticle substrates have varying dispersion properties. The particles are governed by size, shape, size distribution, surface charge, hydrophilicity, etc. Each has to be handled properly such that the material is not lost or precipitated with the different polymerization methods.

Direct or *in situ* methods allow monitoring of differences in initiator/monomer composition ratios, time of polymerization, solvent, and temperature conditions. Classical methods for analyzing polymer brush–particle systems include gravimetric (91,92) thermal analysis (93–95) light scattering (96), NMR (97), zeta potential (98,99) and rheology (100). Microscopy methods such as TEM, SEM, and AFM can also be employed, giving direct visualization of core–shell composite architectures (101). An interesting method for investigating polymer–particle dynamics using fluorescence correlation spectroscopy has recently been reported (102). It will be interesting to see in the future how SNOM techniques can be used to probe specific particle–polymer interactions (103). Once polymers have been detached from the substrate, they can be analyzed like any normal polymer product in an *ex situ* manner.

Investigating Polymer Brush Systems on Flat Surface Substrates

Polymer Brush Regimes on Surfaces. In the presence of an interface, the configurational space of polymer chains is limited. The deformation of polymer chains is generally a contribution of both *interaction* and *elastic free energies.* The interplay of these two terms determines the equilibrium thickness and *brush regimes* of tethered polymers. The internal structure and deformation of polymer brushes has also been investigated by numerical and analytical self-consistent field (SCF) calculations, and by computer simulations (104). For example, in densely tethered polymer chains, a strong overlap among the undeformed coils exists at the interface. This increases the polymer-to-polymer contacts and the corresponding interaction energy. The polymer chains are then forced to stretch away along the direction normal to the grafting sites. Stretching lowers the interaction energy per chain, at the price of a high elastic free energy. Thus, different conformational regimes are possible with polymer brushes by the interplay of these two terms. Polymer brushes have equilibrium thicknesses that vary linearly with the degree of polymerization. In contrast, free polymer chains in a theta solvent possess an unperturbed configuration. Research work employing theory, scaling theories, simulation, and surface probe techniques have shown that the

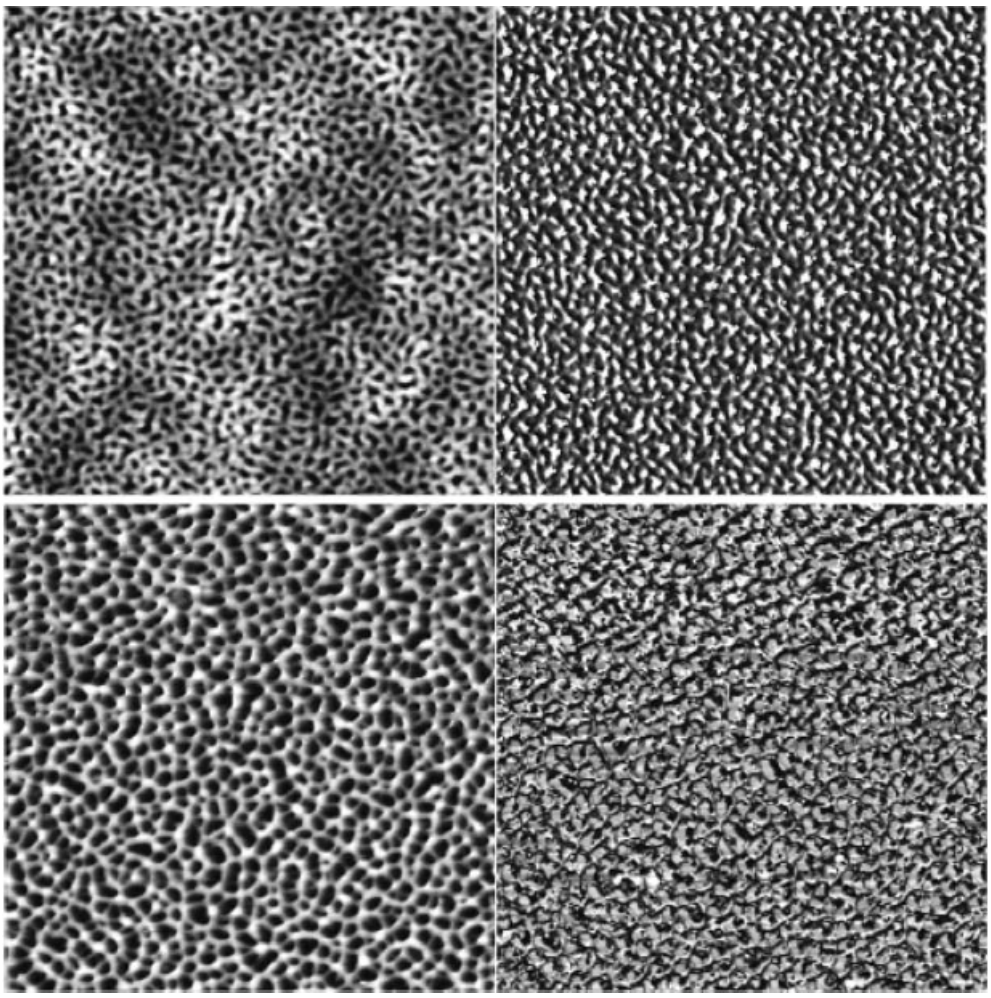

Fig. 7. Investigating phase segregation and formation of patterns in multicomponent polymer brushes as observed by AFM. In this case, glassy and rubbery binary components of grafted polymethacrylate (PMA) and fluorinated polystyrene copolymer (PSF) were sensitively imaged and differentiated between topography (left), phase imaging (right), and glassy (top) and rubbery (bottom) states of the binary brushes. Dimensions at 5×5 μm. From Ref. 107.

different regimes can result from solvent swelling, differences in molecular weight, and differences in grafting density as the tethered polymer chains change their conformation (105). Depending on the equilibrium conditions, densely tethered polymer chains can be deformed and result in a variety of brush regimes which includes "mushroom," "pancakes," "micelle," and "dimples." While such studies have been recently applied to SIP type of polymer brushes, the investigation of brush regimes has long been associated with physisorbed polymers.

Phase Segregation in Multicomponent Polymer Brushes. Phase segregation and ordering in multicomponent polymer brushes have also been extensively studied (Fig. 7) (106,107). In the presence of two tethered immiscible

homopolymers, different ordered phases can be described, similar to lateral microphase separation in bulk (108). The composition varies as a statistical mixture of the two components or as blocks. Theoretical SCF models have been used to examine the equilibrium properties of a binary polymer brush composed of immiscible chains under melt conditions. A number of interesting morphologies and mesophases are possible both by melt and solution conditions (109). By changing the polymer brush architecture, grafting density, chain length, interaction energy between different blocks and interaction energies between blocks and solvents, a variety of novel well-ordered structures have been predicted and observed. Theoretical results indicate that tethered copolymer brushes on a flat substrate are excellent candidates for forming nanopatterned polymer films (110). Recently, this has been a topic of great interest for investigating new morphologies in SIP systems.

Different Stages of the SIP Grafting Technique. SIP on flat substrate surfaces is a step-by-step procedure which begins with the preparation of substrates and ends with characterization of post-polymerized films. Usually the chosen substrate is also dependent on the applicability of various analysis methods. Primarily, the substrate used is determined by the type of SAM technique used to tether initiators on surfaces. In principle, the characterization protocol is typical for investigating SAMs at surfaces but is extended toward macromolecular dimensions once a polymer is attached. The polymerization and post-polymerization characterization is equally important. *However, very few methods are available for in situ characterization during the polymerization itself.* It is difficult to monitor the growth of polymer brushes in real time because the mechanism and kinetics are not necessarily the same as in solution or bulk. The last step, post-polymerization analysis, is a stage where characterization of terminated brushes can be done after several "washing" methods to isolate grafted polymers on surfaces. Any post-polymerization treatments such as cross-linking or functional group conversion of the brush can be examined at this stage. Overall, the step-by-step analysis is useful for characterizing the polymer brush formation and comparing the films "before" and "after" each stage of the grafting or treatment.

Patterning Polymer Brushes. Patterning by both lithographic and nonlithographic technique results in films with features ranging from a few nanometers (nanopatterning) to microns (micropatterning) (111,112). New and simple strategies to fabricate surface-confined patterns with lithographic and nonlithographic methods have been widely reported (113). Nonlithographic methods using microcontact printing (114) and dip-pen nanolithography (DPN) (115) are recently popular. Patterning offers a number of advantages: (*1*) extrinsic, stimuli control of interfacial properties at the micrometer or nanometer scale; (*2*) precisely localized presentation of chemical or topographical features; and (*3*) controlled surface densities, eg required to achieve higher throughput, as in combinatorial methods (116). Various schemes have been reported where microcontact printing and even lithographic methods (18,26) can be used to prepare microscale patterns (Fig. 8). Fabricating nanopatterns by SIP is an interesting goal. One key strategy in the nanopatterning approach is the use of SAM level of initiator self-assembly. In combination with an appropriate nanolithographic technique, such as DPN, interesting future polymeric nanostructures can be prepared.

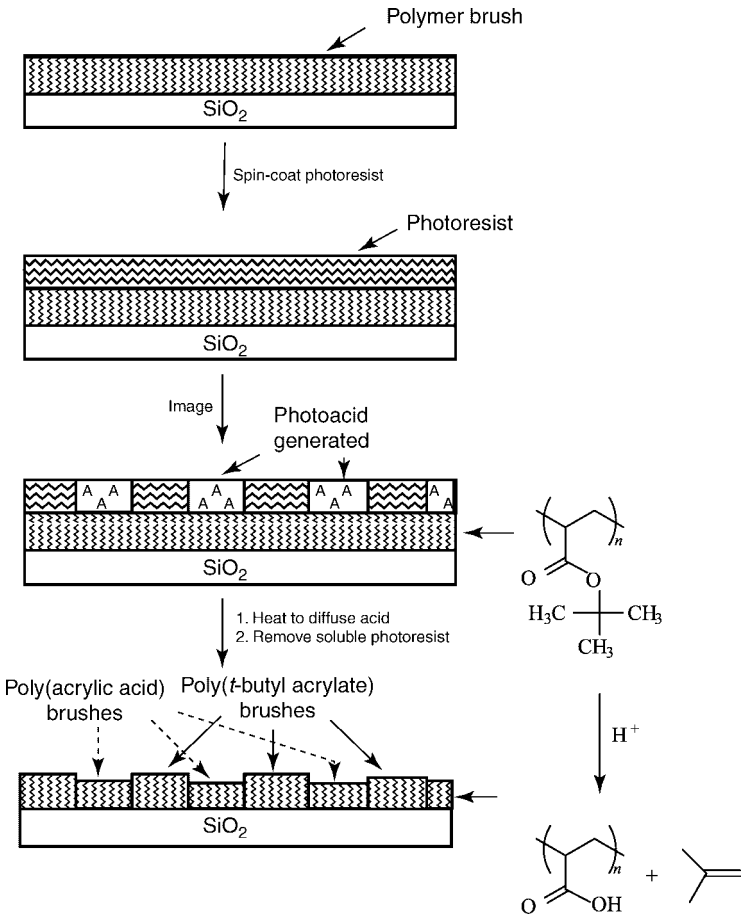

Fig. 8. Scheme for patterning of a polymer brush using a sacrificial photoresist layer and lithographic imaging. From Ref. 18.

Applications

Many applications can be derived from polymer brushes. The most practical use of polymer brushes are modification of surfaces (32), compatible biosurfaces (117), new lubrication materials (118), separations, compatibilizers (119), new adhesives, and polymer composite preparation (120). An interesting application of polymer brushes is in the form of chemical gates (121). Ultrathin and patterned organic films can be prepared which are useful in microelectrics, cell growth control, biomimetic material fabrication, microfluidics, and drug delivery. The versatility of polymer brushes compared to other polymer coating methods is that it allows control of molecular weight, polydispersity, density, composition, block sequencing, and architecture which can be varied for each type of application. Functional polymers observed in solution or in bulk should also have interesting properties when confined to surfaces. This includes liquid crystalline polymers, rigid rods, conjugated polymers, cross-linkable polymers, and polyelectrolytes.

In the area of particles, polymer brushes are of great interest for surface modification and composite material preparation. They have interesting applications in colloidal and interfacial phenomena. In preventing flocculation, the polymer chains, which prefer the solvent to another particle surface, resist overlapping between neighboring particles, resulting in colloidal stabilization. This repulsive force arises from the high osmotic pressure inside these brushes. Strategies have been developed to tailor nanoparticle surfaces by the use of polymer brushes (32). The purpose is to directly tether polymers to nanoparticles, resulting in a *core–shell* type of material architecture. This strategy has lead to the formation of "hairy nanoparticles," which protects the nanoparticle surface and at the same time, increasing the compatibility to polymeric matrices. This is especially important for the preparation of polymer *nanocomposite* materials that can be processed like commercial polymers. A number of inorganic–organic hybrid and nanocomposite materials have been reported (32,118).

POLYMER-SUPPORTED REAGENTS

Introduction

Since the original reports by Merrifield, published some 40 years ago (1), solid supports have been widely used as a synthetic device to avoid expensive and long winded purification processes, principally due to the simplicity of isolating the support and its bound material by direct filtration. There are a number of other advantages when using solid supports; most notably reactions can be driven to completion using high concentrations and mass action of reagents and synthesis can be easily automated (2).

With the introduction of a range of high throughput synthesis methods (3–5), solid supports have become even more indispensable (6), for example, with the use of polymer-supported reagents and catalysts (7), which maintains the target molecules in solution but immobilizes the other component, and renders possible the parallel monitoring of supported reactions but in a solution sense. The most utilized polymer support in solid-phase chemistry is still a copolymer of styrene and divinyl benzene [DVB (2%)], known as a gel-type resin, because of its "gelatinous" and nonmacroporous behavior, originally used by Merrifield for the synthesis of the first tetrapeptide made by solid-phase synthesis (see POLYPEPTIDE SYNTHESIS, SOLID-PHASE METHOD).

Nevertheless, there are some problems correlated with the use of this support, such as its voluminous nature when swollen, its lack of physical stability under harsh handling conditions, and its incompatibility with a number of solvents (8). For this reason, several groups of researchers have investigated a number of alternative solid supports, for solid-phase chemistry, in order to improve resin properties, such as physical robustness, ease of handling, enhancement in loading,

improvement of reaction kinetics, and so forth. This article presents an overview of the materials commonly used in solid-supported chemistry and their evolution.

Styrene–DVB-Based Resins

Polystyrene resins (25–300 μm) are the most commonly used supports in solid-phase chemistry and, in a variety of formats, are extensively used in a wide range of industrial processes (see STYRENE POLYMERS). These basic materials can be easily obtained by radical polymerization of a suspension of an organic phase (the styrene and divinylbenzene monomers in varying proportions) in water, in the presence of a stabilizer (in order to reduce the surface tension of the droplets and to prevent their aggregation) (9). A minimum level (usually at least 0.5%) of DVB is required in order to ensure that the polymer obtained is insoluble in organic solvents. The percentage of DVB (cross-linker), influences the physical and chemical properties of the support. High levels of cross-linking produce more rigid supports; therefore, drastic conditions of reaction such as mechanical stirring and high temperatures are permissible, but on the other hand slower reactions are often observed because of the fact that the reagents cannot easily diffuse within the polymer network (10). On the other hand, low levels of cross-linking produce highly swellable but more fragile beads, which, however, exhibit better reaction kinetics.

In most chemical reactions, the solvent plays a fundamental role and this effect is enhanced in solid-supported chemistry. When in contact with so-called "good" or "poor" solvents, the beads can swell or shrink (this effect depends principally on the level of cross-linking and can be considered akin to the polymer tending to dissolve in the solvent). This phenomenon can increase the ability of reagents to diffuse into the beads, and therefore dramatically influences reaction rates. Reactivity within beads is also highly dependent on resin loading. Loading variations can for example vary, allowing concentrations within beads to range between 50 μM and 0.5 M. As in solution chemistry, such concentration effects can cause huge effects on reaction rates, depending upon the reaction under investigation as a result of electrostatics and/or steric effects of the reagents. To avoid some of these type of issues, spacers are often placed between the polymer and the reactive functionality of the resin (11), but the high concentration of material on a bead is often ignored in solid-phase synthesis.

The reactive functionality (the site of chemistry) on a resin can be added during or after polymerization as shown in Figure 1 (12). Direct functionalization can be performed by including a third monomer into the original monomer mixture, which already bears the desired functional group. Chloromethylstyrene is often used in this regard because it can be easily transformed into a wide range of alternatives (Fig. 2) and is a monomer that incorporates well into styrene/divinyl benzene mixtures (Fig. 1).

Post-functionalization is usually carried out by electrophilic aromatic substitution in the presence of a Lewis acid (27) or by metallation of a brominated resin (Fig. 1) (28).

Good quality polymers are obtained by direct functionalization with the resulting functionality uniformly distributed throughout the bead. However, there are other factors that influence the quality of the polymer. As mentioned by

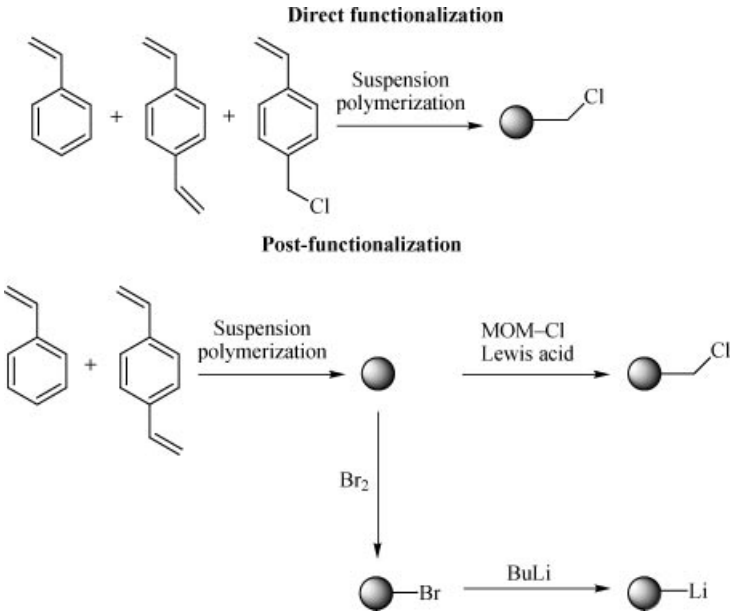

Fig. 1. Functionalization of polystyrene resins.

Czarnik (29), resins from different batches often show different chemical behaviour, as the process of suspension polymerization depends upon many factors such as reactor geometry, agitator design, and agitation rate (30). Uniform, spherical beads are preferred for reproducible chemistry, irregular particles being much more sensitive to mechanical destruction and often falling apart during the reaction. Both 6- and 8-multiparallel polymerization systems have been designed, and these systems show very good reproducibility when used for the synthesis of polymer libraries (Fig. 3) (31), attesting to the parallel advantages of synthesis and maintaining a consistent reaction geometry. A second-generation system allowed 8-multiple polymerizations with the possibility of changing the stirring rate of each reaction vessel.

The level of functional groups or "loading," expressed in mmol/g, can cover a wide range of values (from 0 to virtually 7 mmol/g), but this level varies greatly depending on the application of the support. Generally, the loading and application of polystyrene resins can be grouped as follows:

(1) <0.1 mmol/g, suitable for oligonucleotide synthesis and the synthesis of large peptides/proteins
(2) 0.1–0.7 mmol/g, suitable for supported catalysts (which are added in small amounts)
(3) 0.5–1.5 mmol/g, suitable for solid-phase synthesis (small molecules and peptides) avoiding problems of steric hindrance
(4) >2 mmol/g, preferred for scavenger and reagents based resins, as these types of reagents are added in excess

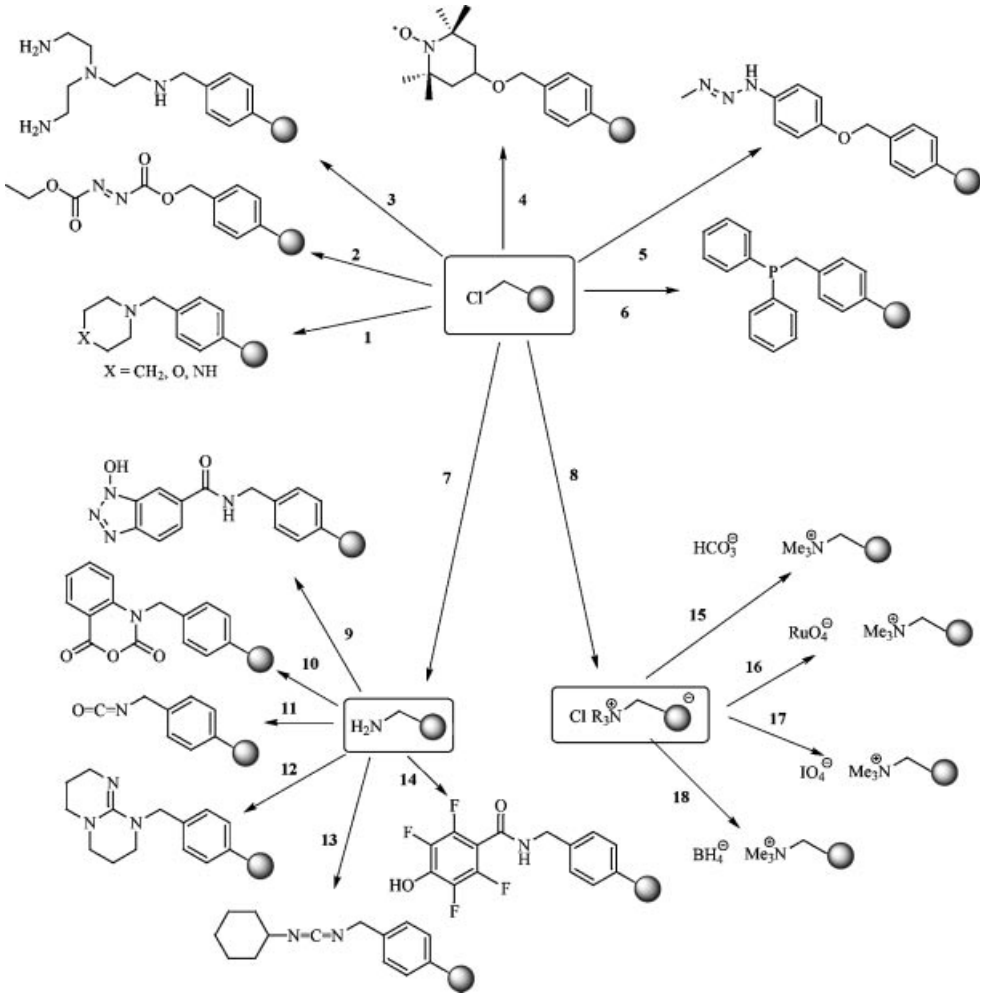

Fig. 2. Preparation of solid-supported reagents and catalysts by derivatization of chloromethyl polystyrene. Resin Types

Gel-Type Polystyrenes. Gel-type polystyrenes can be synthesized by radical suspension polymerization of styrene and DVB as reported in 1946 by Hohenstein and Mark (9,32). When suspended in a solvent with good swelling properties, these "white soft beads" assume a gelatinous state; their volume may increase by 6–8 times and they become optically transparent. This process of swelling, as well as the shrinking, occurs from the outside to the inside of the polymer network and the increment of volume is in correlation with its solvation. This plays an important role in chemistry, because it is through such processes that the reactants diffuse into the polymer network where 99% of the functional sites reside (33).

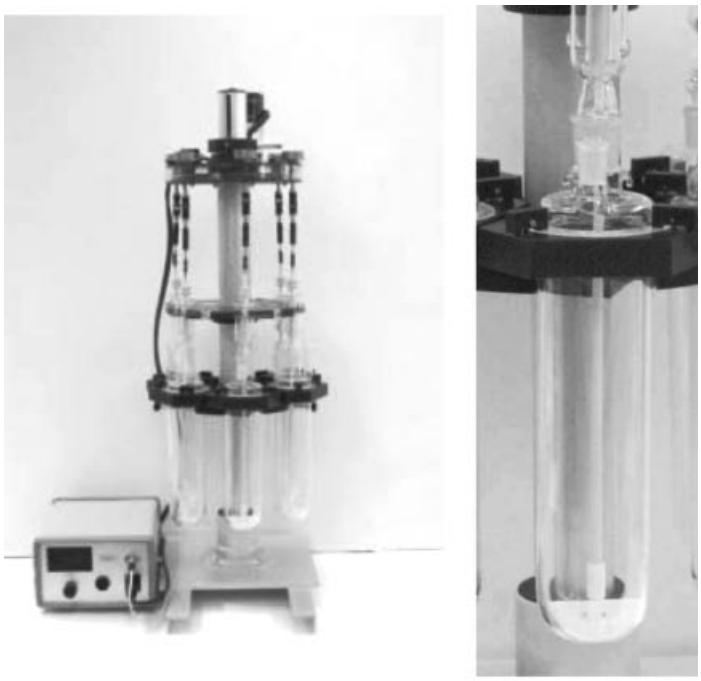

Fig. 3. (**a**) Multiparallel suspension polymerization system; (**b**) close-up of reaction vessel.

As a consequence, the solvent has to be chosen to allow swelling of the resin (34). However, swelling is not the only "solvent dependency", as the type of functionality also affects solvent compatibility. Thus, while Merrifield resins (chloromethyl polystyrene) shrink in highly polar solvents such as water, ion exchange resins show the opposite behavior and do not swell in "good swelling solvents" such as dimethylformamide (DMF). Merrifield observed that the volume of the beads and their behavior with the solvent changed continuously as the supported peptide was grown, attesting to the importance of the resin and the attached molecules, a factor which obviously is influenced by resin loading (35). There are thus a number of other factors which need to be considered when handling and evaluating gel-based supports. If the beads are fully swollen in a "good solvent" and then shrunk rapidly in a bad solvent (eg washing step), "mechanical shock" can take place and the beads may disintegrate, especially with large beads (osmotic shock) (36). To avoid this issue, beads should be washed gradually, starting from a good solvent to a poor solvent, while in the fully swollen state beads should not be agitated with rigid materials, or they may become damaged.

Although a number of issues are correlated with the use of this material, gel-type polystyrene resins are the most used supports in solid-phase chemistry, because of their acceptable loading capacity and relative good kinetics when fully swollen in good solvents.

Macroporous-Type Resins. Macroporous resins were prepared as long ago as 1962 by Millar (37). Macroporous resins have been used for many years

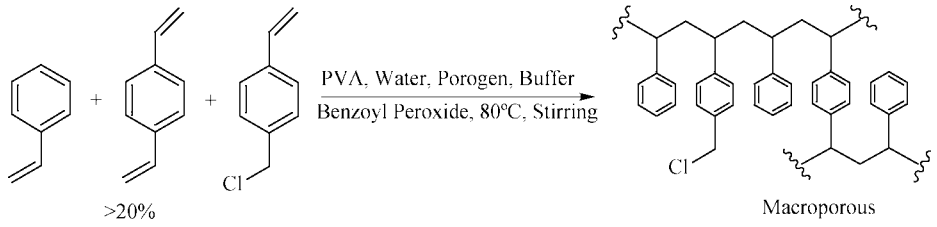

Fig. 4. Synthesis of macroporous polystyrene chloromethyl resin.

as ion-exchange materials, polymeric adsorbents (38), and preparative reverse phases for purification of biomolecules (39), but there are also several examples of this type of support in organic synthesis as carriers for reagents and catalysts (40,41).

Even although the IUPAC definition for macroporous refers to materials that have pores with a diameter greater or equal to 50 nm, the term has been generalized in the resin area to include resins that present a porous structure in the dry state (36).

The formation of the pores occurs when an inert solvent, or porogen, is added to a polymerization mixture containing relatively high levels of cross-linker (Fig. 4). After polymerization, removal of the solvent from the beads leaves intact pores that do not collapse because of the high level of cross-linker used (>20%).

The morphology of the pores (surface area, total pore volume, and average pore diameters) can be adjusted and controlled by an appropriate choice of the type and amount of porogen and the level of cross-linker used (42).

Several porogens (also called diluents) have been used to prepare macroporous resins (43), and they can be divided in three main classes:

(1) Solvating (SOL), such as toluene or dichloroethane (small pore)
(2) Nonsolvating (NONSOL), such as *n*-heptane or alcohols (large pores)
(3) Polymeric (POLY), such as linear polystyrene (very large pores) (44)

Pore formation and their different morphologies have been explained in a recent review (Fig. 5) (36).

When polymerization begins, droplets are formed by the suspension process. The monomer droplets start forming small spherical, so-called microgel, particles.

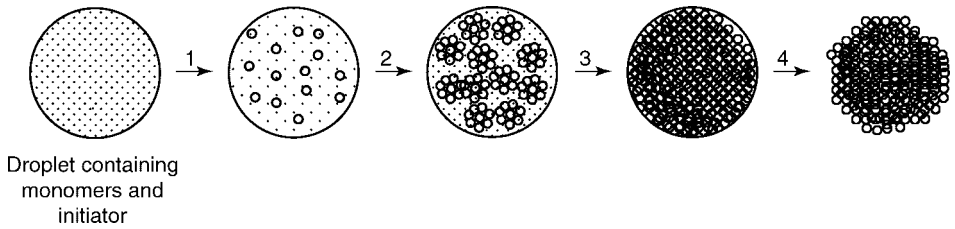

Fig. 5. Pore formation in macroporous resins. (1) Highly solvated swollen microgels, (2) aggregation of swollen microgels, (3) phase separation, (4) solvent removal.

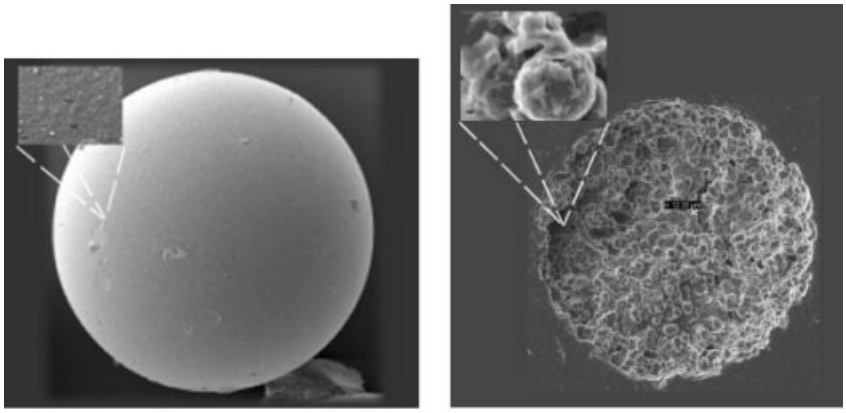

Fig. 6. SEM micrograph of macroporous resins synthesized using (**a**) toluene (solvating) and (**b**) heptane (nonsolvating) porogen.

If these contain a good solvent for the monomers, such as toluene, these particles are fully solvated until there is a high conversion to polymer. Thus, when phase separation takes place (ie, the polymer is no longer soluble in the solvent), the environment within the particle contains only a small amount of unreacted monomer. These particles, therefore, retain their identity and the network of small pores already generated between them is essentially retained. When a nonsolvating porogen, such as heptane, is used, the microgel particles are poorly swollen and phase separation takes place early (low conversion to polymer). In this case the droplet contains a high level of unreacted monomers and these have the effect not only of fusing the microgel particles together, but also of causing significant filling of small pores between the microgel particles. The results of two extreme cases are shown in the Figure 6. Smooth beads polymerized with 200% vol/vol of toluene showed a rough surface only when magnified, whereas beads obtained from heptane (150% vol/vol) gave an irregular morphology.

To improve the benefits of solid-supported reagents and scavengers, macroporous beads need to have a large surface area and large pores. While a high surface area provides more sites for functionalization, large pores provide efficient transport of reagents through the beads. However, as suggested by Sherrington, these two parameters are obviously related (12). If a resin bead has a large surface area and a large number of pores, then each pore is likely to have a small diameter and vice versa. Experimentally, these parameters are measured by nitrogen adsorption/desorption (BET) (45), mercury intrusion porosimetry (46), and electron microscope techniques.

Another consequence of the fixed pores and the rigid structure (high DVB levels) is that macroporous resins have limited swelling. Thus a wide range of solvents commonly used in organic synthesis can be used in solid-phase "macroporous resin assisted chemistry" (even water), without modification of the reaction conditions as required for the use of gel-type resins. Moreover, the rigid structure makes these supports very resistant to mechanical agitation and easy to handle (macroporous resins do not stick like gel type resins).

A comparison between macroporous and 2% gel-based Merrifield resins was performed by Janda (47) who demonstrated the efficiency of washing a dye from pretreated resins was better with a macroporous resin than a gel-type resin. Comparison of a palladium catalyst, for Wacker olefin oxidation, supported on gel-type and macroporous resins gave better results on the macroporous support. Contributions in this area have also been made by Labadie who demonstrated good results using tailored macroporous resins, commonly known as ArgoPore (these resins had surface area, pore volume, and loading well defined for optimal performance in solid-phase chemistry), for example, reactions in water such as the $TiCl_3$-mediated reduction of nitro compounds, periodate-mediated olefin oxidations (48), Suzuki reactions on polymer-supported iodides and bromides (49), and alkylation of supported acids via enolate formation at low temperature (50). Nowadays, it is possible to find a wide range of macroporous polymer-supported reagents and catalysts commercially available. In conclusion, well-designed macroporous resins exhibit better efficiency and kinetics than gel-type resins in highly polar solvents and have become a valid alternative for solid-phase chemistry, without significant swelling and washing issues, although maximum available loadings cannot be as high as the gel-type counterpart (commercially available macroporous resins for solid-phase chemistry have a loading that depends on the manufacturer (ie, Argonaut Technologies: 0.2–1.8 mmol/g; Polymer Labs: 3.0 mmol/g).

Microgel Polystyrenes. Microgels are soluble polymers with a certain degree of cross-linking, but can be precipitated using an appropriate solvent (51). Beads with a diameter of 5–25 μm can be prepared by radical dispersion polymerization in the presence of a surfactant.

It is imperative to use low levels of monomers during preparation to avoid macrogelation due to the aggregation of the microgels to form large-size particles. One of the main characteristics reported for microgels are their ease of handling when solubilized. A consequence of their solubility is that reactions can be easily monitored by classical solution-phase techniques (eg NMR) but that materials can then be readily recovered in a solid-phase manner.

Janda reported a detailed investigation of polymerization parameters such as the type of solvent, percentage of monomer, and level and different type of cross-linker and showed that polymers with good characteristics could be obtained using 5 wt% monomer solution in tetrahydrofuran (THF) (52). Good polymers were achieved using 10% of DVB or 5% of alternative cross-linkers (Fig. 7). Precipitation of the soluble polymers was achieved by addition of cold methanol and filtration through a glass frit.

Becuse of their recent deployment there are only a few examples in literature on the use of this material in solid-phase chemistry. Wulff (53) used microgel

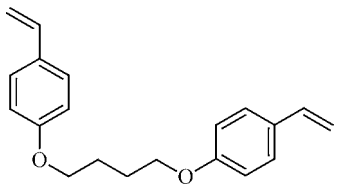

Fig. 7. Cross-linker used in the preparation of microgels.

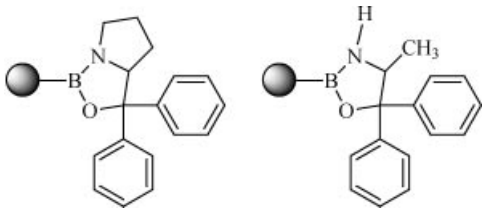

Fig. 8. Microgel-supported oxazaborolidines catalysts.

polymers for the preparation of supported oxazaborolidines as catalysts for asymmetric reduction of ketones (Fig. 8).

This type of catalyst, supported on polystyrene gel type resins, gave results comparable to the homogeneous counterpart. However, because of the poor mechanical properties of the resin under the reaction conditions, a more suitable polymer support was needed. Unfortunately, highly cross-linked resins, with their poor kinetics, decreased the overall selectivity of the catalyst. Although linear polymers were used (54), microgels offered advantages because of their ease of handling. Janda used these supports to perform the solid-phase synthesis of oxazoles (55) and later produced a combinatorial library of phthalimides in good purities and yields using these supports. In addition, microgels were used for the preparation of supported tris(2-aminomethyl)amine and borohydrides to remove isocyanates and to reduce aldehydes respectively.

Polystyrene Nanoparticles. Polymer-based nanoparticles are used in several areas of life science, for example drug delivery (56), and one such polymer matrix commonly used is poly(L-lactic acid) (57). However, nanoparticles with a polystyrene–DVB matrix have been also synthetized (58,59) and used as novel solid supports for organic synthesis (60). The method commonly used to generate these monodisperse particles is Microemulsion Polymerization (qv) (58). However, nanoparticles have also been prepared by precipitation polymerization (61). A microemulsion of styrene and DVB, with an amphiphilic comonomer, in water (three component oil-in-water) (62) allows the preparation of nanobeads with a hard core of polystyrene and the amphiphilic comonomer dispersed on the surface with diameters around 50 and 300 nm that can be precipitated by the addition of methanol. Functionalization of the nanoparticles surface, can be easily achieved using the functionalized amphiphilic comonomer (Fig. 9) (60).

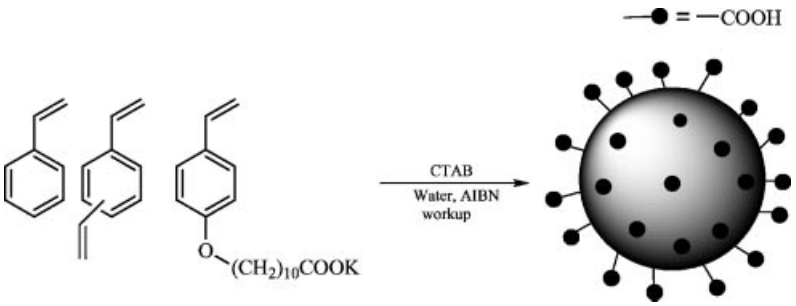

Fig. 9. Synthesis of functionalized polystyrene nanobeads.

These types of beads were used by Cammidge (60) to perform a solid-phase synthesis of porphyrin derivatives following the method described by Leznoff and co-workers (63). Although the final yield of the product was not brilliant (4 and 8% for both the isomers), they were higher than that achieved using "conventional polystyrene resin."

PEG-Grafted Resins

Although gel-type resins are the most widely used supports in solid-phase chemistry, it has been found that such supports are not always the most suitable for peptide synthesis. This is due to two main factors: polystyrene chains are hydrophobic and are not completely compatible with peptides and, furthermore, bulky peptides can adopt unfavorable conformations within the polystyrene cross-linked matrix.

These issues can be avoided by performing the synthesis on linear polymers such as poly(ethylene glycol) (PEG) (64,65), as PEG is soluble in a wide range of organic solvents and, when linked to polypeptides, enhances solubilization. Furthermore, Bayer demonstrated that during coupling reactions, PEG-linked amino acids had the same kinetic properties as amino acid esters (66). However, the main problem in liquid-phase peptide synthesis is the separation of linear PEG from the final polypeptide after cleavage.

Because of its compatibility with peptide chemistry, several authors began to solve the issue of PEG isolation by grafting it onto polystyrene–DVB resin.

As reported by Bayer, polymer grafting by simple reaction with oligomeric PEG and Merrifield resin did not give good results (68), because of the fact that the hydroxylic PEG functionalities could react with two adjacent chloromethyl PS groups, giving an additional degree of cross-linking and reducing the final loading of the resin. However, Barany demonstrated that the grafting of PEG could be achieved by the use of a bifunctional amino-PEG acid (Table 1, entry 2) (69,70). Unfortunately, this support has not found wide use, probably because of its amide linkage.

Bayer described grafting of PEG onto PS resin, by direct anionic polymerization of ethylene oxide onto poly(styryl-methyltetraethylene glycol ether) (68).

The "tentacle polymer" so obtained is commercialized by Rapp Polymere under the name of TentaGel and it is the second most used support for solid-phase organic synthesis after polystyrene resin (Table 1, entry 1) (67). The main characteristic of these resins is their greater swelling in polar solvents such as water, methanol, ethanol, etc, compared to PS resins. As shown in Table 2, entry 2, the swelling of TentaGel is uniform in high to medium polarity solvents. This behavior allows the packing of resins into columns for continuous flow peptide syntheses (68).

Moreover, because of the fact that molecules bound to the highly solvated PEG chains are in a "solution-like" environment and the interactions with the hydrophobic polystyrene backbone are reduced, reaction rates in solid-phase peptide synthesis on TentaGel are greater than on the equivalent Merrifield resins (74,75). Because of the high mobility of PEG chains, gel-phase and MAS NMR result in narrow lines (76). Kinetic comparisons between TentaGel and other supports have been carried out (77,78), and there are several examples of "nonpeptide"

chemistry where the rates are faster on TentaGel than PS resins (ie, Suzuki reactions using supported boronic acids (79), or Sm(II) mediated radical cyclizations (80), or Sharpless asymmetric dihydroxylations) (81). Yan, however, demonstrated that this rule was not always true (82), and found that some reactions, for example terminal modification of aspartic acid or the synthesis of dansyl hydrazones, were faster on PS resins. There are several drawbacks that limit the use of TentaGel resin as a universal support for solid-phase chemistry. The substitutions of TentaGel resins are lower than PS resins although loading can be increased by decreasing the grafting level. However, Lee has demonstrated recently that the swelling of these types of resins depends on the level of grafted PEG (83). When the solvent used was water, there was a direct relationship between PEG level and swelling, but in other solvent systems such as THF or DMF there was a discontinuous trend until the level of PEG was greater than 72% by weight.

A method to increase loading was demonstrated by Bradley by dendrimerization. In this way, TentaGel bead loading was amplified about 10 times (Fig. 10) (84,85).

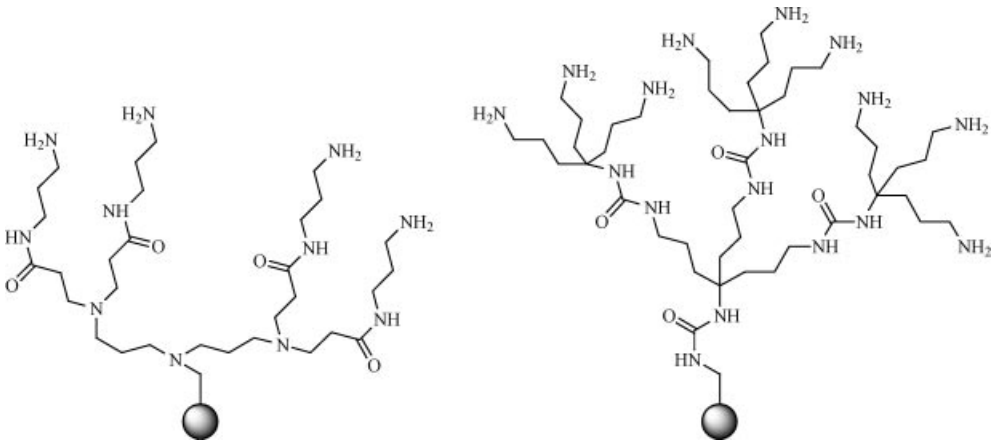

Fig. 10. Dendrimeris for loading improvement.

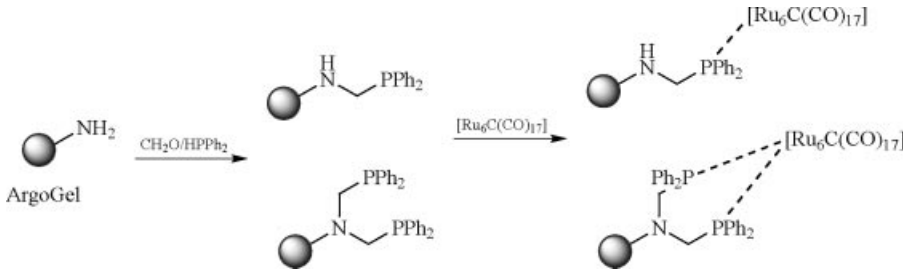

Fig. 11. Preparation of ruthenium-supported catalysts.

There is at least one other main issue that has to be cited. It has been observed that traces of linear PEG are found in final products after cleavage because of the weak benzyl ether bond that links the PEG to the polystyrene backbone.

For this reason, Gooding prepared a PEG-grafted polystyrene resin using a polystyrene diol as a scaffold for the PEG grafting (Table 1, entry 3) (71) [Rapp also used hydroxyethyl PS in the new generation of TentaGel resins (TentaGel S)]. In this way, the chemical stability as well as the loading (0.4–0.5 mmol/g) of such resins was improved. The higher stability of this support was proved by repeated amide cleavages under acidic conditions, where no impurities of linear PEG were found even after long treatments (86). This resin is commercially available from Argonaut Technologies under the name of ArgoGel, and it has been used as a support in the preparation of substituted imidazoles, *N*-alkyl sulfonamides, acylamines, benzofurans, etc (71). De Miguel demonstrated the use of such flexible supports for the immobilization of a highly selective ruthenium cluster catalyst for hydrogenation of olefins and ketones (Fig. 11) (87). Recently, the same group reported the use of such supported catalysts in applications such as gas sensors for H_2S, CO, and SO_2 by color changing of the resin (88).

During his research to improve PEG-grafted resins, Hudson, following the example of Barany, by linking oligomeric PEG chains to aminomethylated resins by a urethane linkage (Table 1, entry 4) (72). These "NovaGel" resins have been commercialized by Novabiochem. The main difference between these supports and the others previously described is that the reactive functionality is still bound to the polystyrene backbone and not to the PEG chains. The effect of the PEG grafting in this case improves swelling as shown in Table 2, entry 4.

However, even if the urethane linkage is more stable than the benzyl ether linkage, leaching of linear PEG can contaminate the final product. Recently, Bradley reported the preparation of novel supports using a principle similar to NovaGel resin, where short PEG chains were linked in the polymer by a phenyl ether and the functionality copolymerized into the beads backbone (Table 1, entry 5). Polystyrene–MPEG nongrafted resins were prepared by adding a new PEG derivative comonomer during polymerization as shown in Table 1, entry 5 (73). Such resins exhibit higher loading capacities (0.63–0.77 mmol/g) compared to PEG-grafted resins and at the same time showed broad solvent compatibility (Table 2, entry 5) and improved resistance to acidic and basic conditions. In addition, during their synthetic evaluations, such supports showed similar, if not better, results compared to grafted polymers without detection of PEG impurities in the final products.

Alternative Cross-Linkers for Polystyrene-Based Resins

To overcome the incompatibility of the hydrophobic polystryrene–DVB matrix with highly polar solvents (aqueous), alternative types of cross-linkers have been utilized over the last few years. Polyethers have been extensively used for this purpose and properties such as swelling and mechanical stability have been improved compared to gel-type resins. The cross-linking agents described herein are (*1*) PEG and (*2*) (poly)tetrahydrofuran based.

Copoly(styrene–PEG). As explained above, PEG grafted onto polystyrene improves its swelling properties in polar solvents (89). One of the major drawbacks of this type of supports is their inherent low loading (0.2–0.6 mmol/g) because a large part of the polymer mass is PEG (∼70%) (48). An alternative to this method is to include PEG in the polymer matrix during polymerization as a cross-linker. Vinyl PEG derivatives have been used to replace DVB as a cross-linker in the synthesis of a polymer matrix (TTEDA–PS: tetraethyleneglycol diacrylate cross-linker–polystyrene) (90). Although this resin showed comparable mechanical properties to gel-type resins, it showed much more effective swelling and solvatation than PS–DVB in polar and nonpolar solvents. The synthesis of an 18-residue peptide on such a chloromethylated resin afforded better yield and purity than PS–DVB. Later bis-styrene–PEG monomers were synthesized, copolymerized with styrene, and used in supporting catalyst in Diels–Alder reactions (91). Oligo(ethylene glycol) styrene derivatives have also been synthesized and copolymerized with styrene by Meldal to prepare polymers used for peptide synthesis (92). Kurth reported an interesting evaluation of the swelling and diffusion properties for these polymers compared to 2% DVB polystyrene (93). In this study several PEG-based cross-linkers, linking two styrene monomers (with different polyether chain lengths, $n = 1, 2, 4, 6$; see Fig. 12), were prepared and used to prepare a library of PEG-based resins using different proportions of PEG cross-linking (2%, 10%, 20%).

As expected, the swelling of these beads in all solvents was much better than their 2% PS–DVB counterpart. At low levels of PEG cross-linking (2%) the swelling was independent of the PEG tether length, but at high levels (20%) better swelling was observed when $n = 6$. In conclusion, the swelling and at the same time the physical stability of the beads were improved. The diffusion of the reagents within these resins was measured by the inclusion of a vinyl dye derivative (dansyl derivative) in the monomer mixture, and the fluorescence quenching of the resulting polymer bound dye was measured by adding triethyloxonium tetrafluoroborate

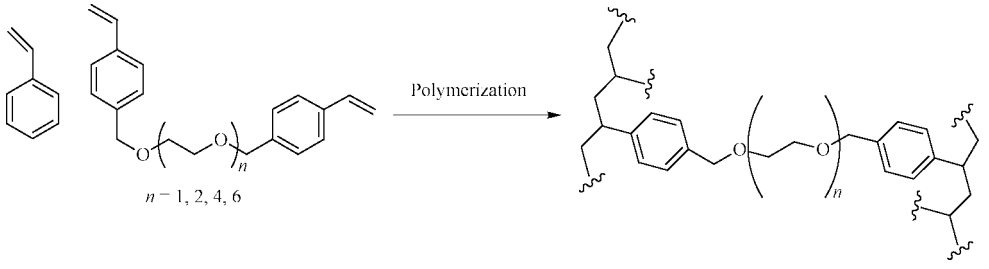

Fig. 12. Synthesis of PEG cross-linked PS resin.

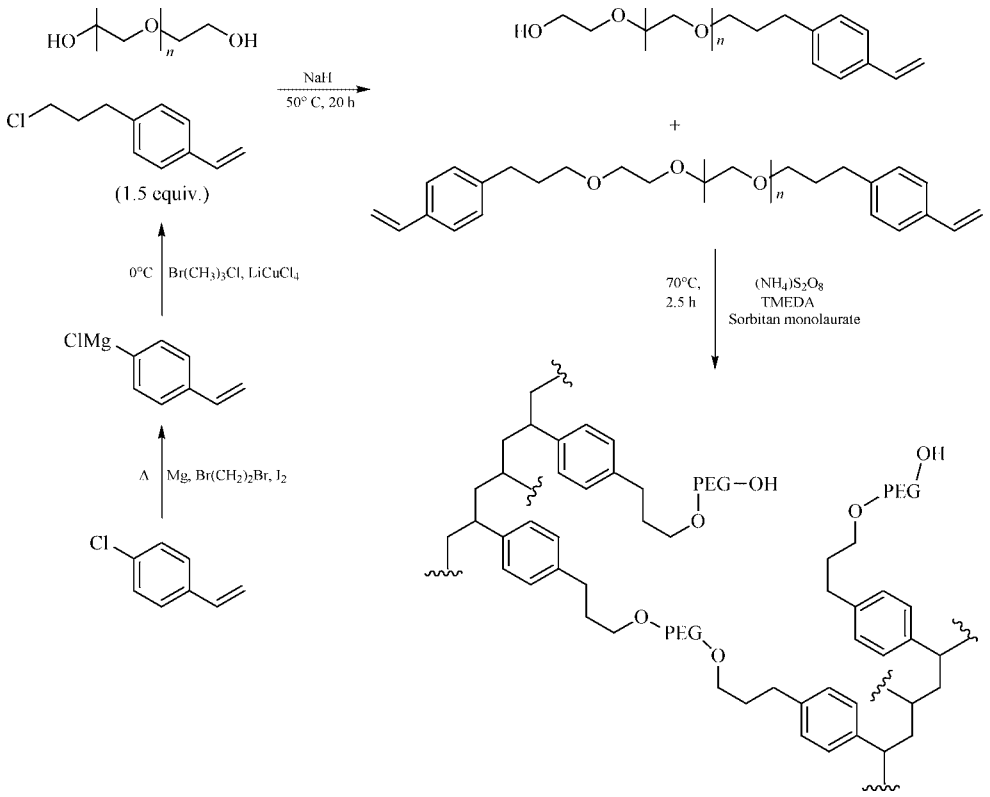

Fig. 13. Synthesis of POEPS-3.

in accordance with the method of Shea (94). These studies showed only a slight difference between conventional PS resins and that modified with PEG cross-linker when the reactions were performed in a good swelling solvent (toluene); however, in poor solvents the PEG-based cross-linked resins showed the best kinetics.

However, one of the drawbacks of using this type of cross-linker is that PEG is connected to the polystyrene backbone by a benzyl ether bond that could be cleaved by the use of Lewis or protic acids. Meldal reported the synthesis and the use of an alternative cross-linker containing a three-carbon spacer between the PEG chain and the polystyrene backbone (85) (Fig. 13).

Properties such as swelling, loading, diffusion, and ability to furnish high quality MAS-NMR have been investigated and compared to commercial counterparts such as TentaGel, ArgoGel, 2% PS-DVB, and macroporous PS (96). The results of this study showed that POEPS-3 was comparable to TentaGel and ArgoPore, in terms of swelling, NMR quality, and diffusion. Moreover, these supports showed better swelling in the range of solvents tested.

Copoly(styrene-butylene glycol). Because of the favorable properties shown by the PEG-based cross-linkers, Janda investigated other types of cross-linkers (97). Because of the tendency of PEG to complex organometallic compounds and its high hydrophilicity, new types of polystyrene resin containing "polytetrahydrofuran"–styrene derivatives as cross-linkers were prepared to allow

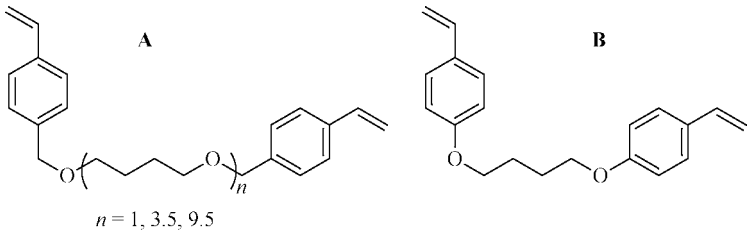

Fig. 14. Cross-linker used in the synthesis of copoly(styrene-tetrahydrofuran) resins.

better solvation of the resin and its functionality that might show reactivity close to homogeneous-phase conditions.

Resins with 1–2% of cross-linker (Fig. 14, **A**) degraded in the presence of strong Lewis acids (TMSOTf) or strong bases (BuLi). However, increasing the cross-linking level (5–10%) gave resins that were unaffected by these conditions. Resins with 1–2% of cross-linker (Fig. 14, **B**) showed good stability under the conditions reported above. The resin synthesized with 2% of cross-linker (Fig. 14, **B**) is commercialized under the name of JandaJel.

The main characteristic of these resins was their incredible swelling in organic solvents, almost doubled compared to conventional gel-type 1% polystyrene resin with 1% DVB (Table 3).

JandaJel was used to prepare a small library of phthalides where the key step of the synthesis was the ortho-lithiation of the supported benzamide (98). The same research group investigated several applications of these resins: Jacobson asymmetric epoxidation with a supported catalyst (99); synthesis of tertiary amines using the REM linker (100); solid-phase synthesis of oligoesters (101); solid-phase peptide synthesis using a routine Boc Protocol (102). Other benefits were reported by Shibasaki during the development of new supported catalysts for Reisser- and Strecker-type reactions (103,104). In a recent publication (105), atom transfer radical polymerization ligands on JandaJel were used to remove a copper catalyst, because of its better solvent compatibility compared to PS–DVB. However, although JandaJel showed less efficiency compared to low molecoular polyethylene capped with appropriate ligands previously developed (106), the reaction times were shorter. In conclusion, JandaJel is more "organic solvent-like" than PS–DVB. However, although its excessive swelling might improve reaction kinetics and yields, it can be a drawback because of the difficulty of handling the support during library synthesis.

Alternative Formats for Polystyrene Supports

The synthesis of combinatorial libraries by the split and mix method allows thousands of compounds to be obtained in just a few synthetic steps. In accordance with the original concept, each resin bead bears one single compound, and identification of biologically active compounds can be achieved directly on the beads. The drawback of this process is that the amount of compound that each bead can carry is limited (a few hundreds of picomoles), which is not enough for chemical identifications. To resolve this issue several approaches have been developed. The original method by Bradley was the enhancement of loading by "dendrimerization" (107). Bigger beads can be used, but such supports suffer from poor reaction kinetics and a propensity to disintegrate. Several authors have proposed different formats for solid-supported chemistry for split and mix as well as parallel synthesis applications to improve the issues described above and to improve the ease of handling.

Monoliths and Discs. Fréchet and co-workers introduced the monolith format in the 1990s for applications in chromatography (108) and solid-supported catalysts (109). In 1999, Sherrington described the preparation of polymer discs, cut from monoliths, for synthetic purposes (110). Among the cross-linkers used, PEG_{1000} diacrylates showed better resistance to mechanical stirring and osmotic shock than PS–DVB. After chloromethylations, the discs were coupled with 5-bromosalicylic acid and treated with phenylboronic acid in the presence of $Pd(PPh_3)_4$. Unfortunately, the Suzuki products were not obtained in good yields. In the same year, Fréchet demonstrated the use of their porous-grafted macroporous polystyrene–DVB monolith-disc in so-called "reactive filtration" with good results (111). For the preparation of the monoliths, the monomer mixtures and the porogen were placed into a shrinkable polyethylene tube that acted as a mould inside a glass tube. After polymerization, the glass tube was broken, leaving the monolith tightly trapped in the polyethylene tube which could be cut into 5-mm disc shapes (Fig. 15) (112). The resulting PE-encircled discs showed good mechanical stability and also ease of handling.

To increase the accessibility of the inner reactive groups and also the number of functionalities, the monolith surface was grafted as showed in Figure 16. The chloromethyl polystyrene discs (Fig. 16, **A**) reacted with azobis(4-cyanovaleric acid) (ACVA), a symmetrical azo initiator, to give the polymer-supported acid (Fig. 16, **B** and **C**). The pores were then filled with an appropriate monomer and polymerized to afford the final products (Fig. 16, **D**). The initiator could also react with two chloromethyl groups (Fig. 16, **C**) and this was indeed preferred to obtain

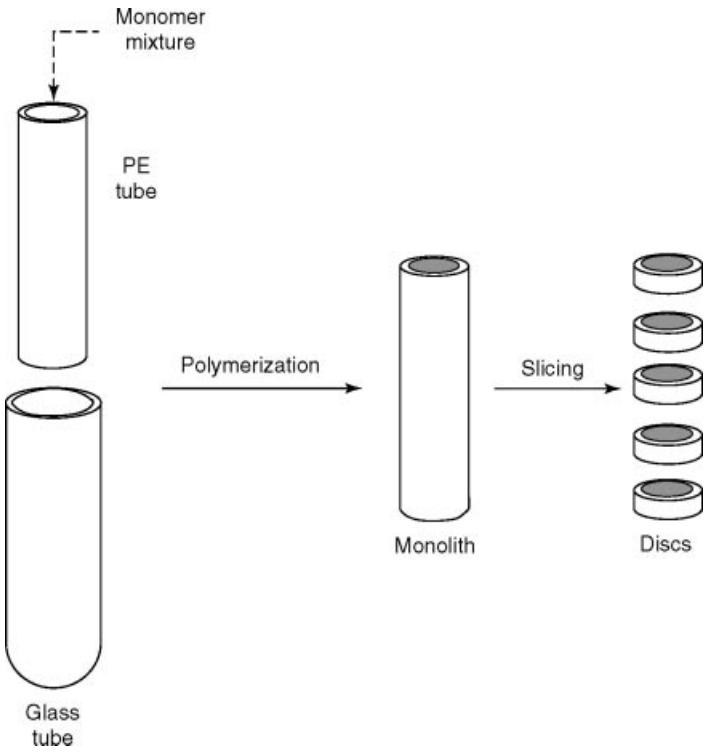

Fig. 15. Preparation of monolithic discs using the method of Fréchet (112).

better grafting as propagation could occur from both the sides of the initiator and, therefore, maximize grafting efficiencies.

Supported disc-reagents were prepared for acylation of several amines in a flow system (113), affording very good conversions into the corresponding amides (114).

The major advantage of this format is that the polymer could be fitted into a cartridge, allowing easy interchangeability during automatic synthesis. Moreover, they could be used to perform synthesis and purification in a flow system (114).

One other application of such monoliths, for the synthesis of a split and mix library, was presented by Janda (115). The preparation of "euclidean-shape" monoliths was performed using a monomer mixture of styrene, chlroromethylstyrene, and 1,4- bis(vinylphenoxy)butane as cross-linker. Dodecanol was used as inert diluent and benzoyl peroxide as initiator.

Films. PS-based films were introduced by Sherrington to be used as an easy device for FTIR *in situ* monitoring (116). Thin films (76mm $\times$ 14mm $\times$ 60–120μm) were obtained by polymerization of monomers in presence of porogen (for macroporous films), and a UV-sensitive initiatior, inserted between two microsocpe slides (Fig. 17). The microscope slides were filled by capillarity, and polymerization initiated by UV irradiation.

Gel-type films were produced using different cross-linkers coupled with styrene and chloromethylstyrene (CMS). The best films were obtained using a

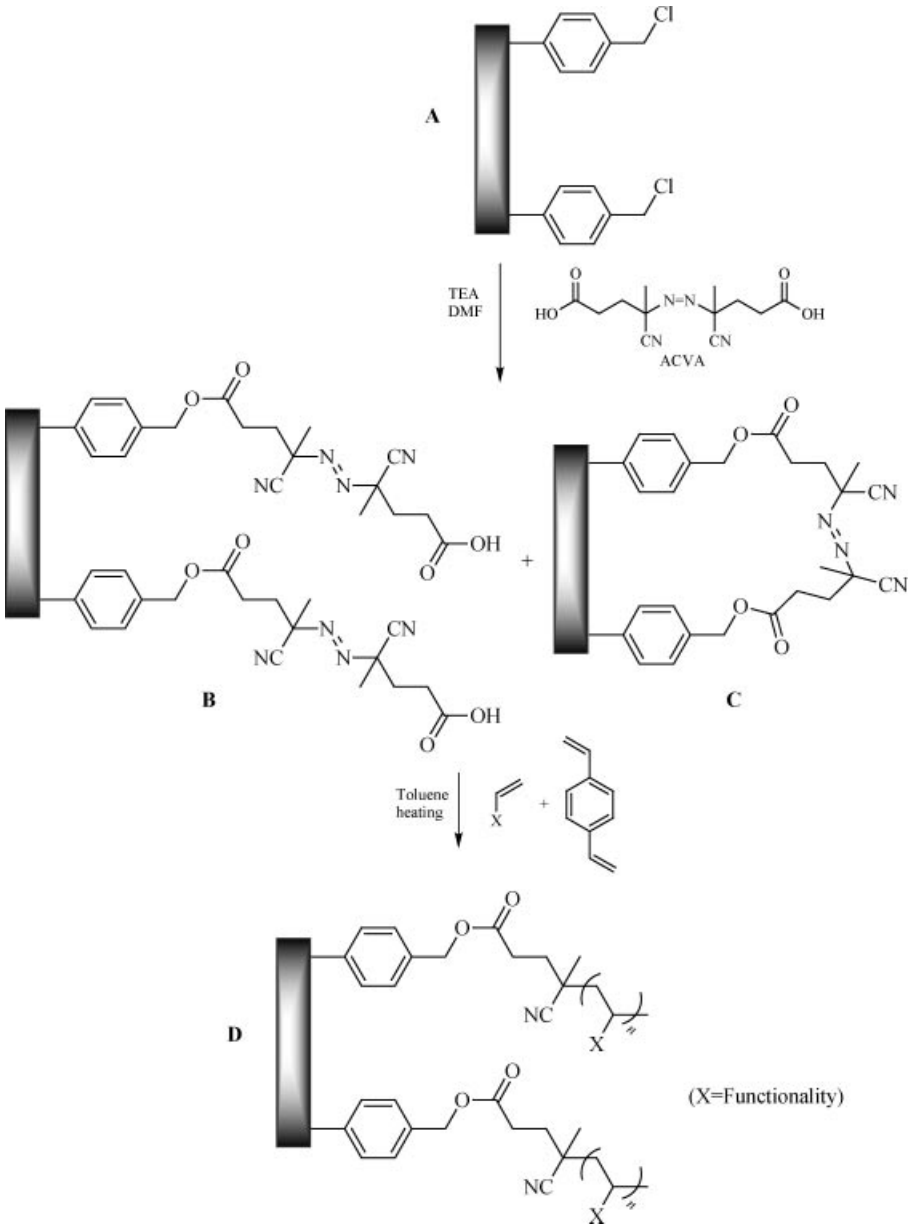

Fig. 16. Grafting of polymer discs.

$PEG_{1000/1500}$-DVB cross-linker, but the PS–DVB films resulting were fragile. The chemistry of these gel-type films was evaluated by nucleophilic displacement of the chlorine with 5-bromosalicylic ester. Macroporous films were also produced using styrene, DVB, and 4-vinylpyridine. Flexible and resistant films were obtained using long-chain alcohols as porogens. To evaluate diffusion through the macroporous films, the pyridine functionality was methylated with methyliodide

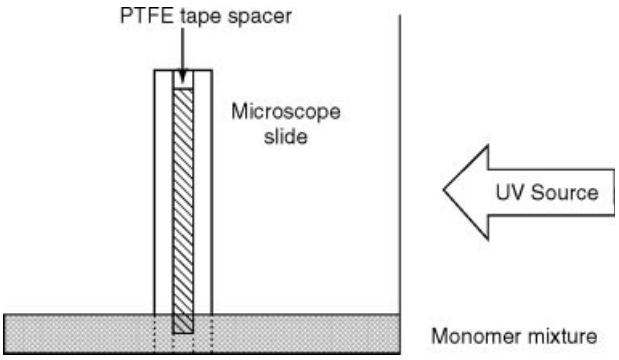

Fig. 17. Preparation of polymeric films (116).

in acetone and the yellow color of the film examined due to the pyridinium iodide charge transfer absorption band. Treatment of the supported pyridinium salt with $KMnO_4$ allowed the film to change color to purple because of the exchange of the iodide with the permanganate. Treating the supported pyridinium salt with $CuSO_4$ caused the film to turn blue because of coordination of the pyridine with Cu(II). The supported-pyridinium salts were also used for the preparation of immobilized rhodium complexes and for mechanistic studies on the carbonylation of olefins by FTIR (117).

Plugs and Tablets. In 2001, Bradley introduced resin plugs as a method to handle polymer supports (118). Plugs were achieved by sintering resin beads with an inert polymer matrix (ultrahigh molecular weight PE). The plugs were obtained in cylindrical forms (9.9-mm length × 7.5-mm diameter) and had loadings between 50 and 150 μmol). Although both PS- and PEG- grafted resins were used for the preparation of the plugs, they are now prepared using StratoSphere resins and commercialized by Polymer Laboratories with the name of StratoSphere Plugs (Fig. 18).

During their evaluations, plugs were used as supports for solid-phase synthesis of small libraries of biaryl compounds, sulfonamides, tertiary amines, ureas, and amides. Although yields and purities were similar to the loose beads counterpart, the reaction times were slightly increased. Because of their mechanical stability and limited swelling, plugs are much easier to handle than the corresponding

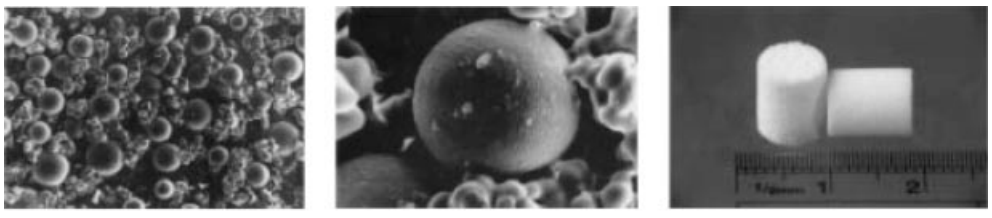

Fig. 18. (**a**) Cross-section of a resin plug (100 × magnification); (**b**) single bead within the matrix of the resin plugs (270 × magnification); (**c**) illustration of the dimension of the resins plugs.

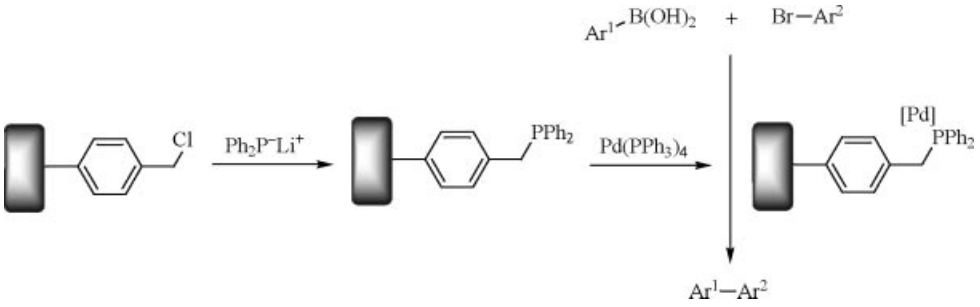

Fig. 19. Preparation and use of palladium plug-supported catalyst.

loose beads. In solution-phase synthesis, plugs have been employed as supports for immobilized palladium catalysts to prepare libraries of biaryl compounds (Fig. 19) with yields comparable to $Pd(PPh_3)_4$ (119).

In conclusion, plug-supported palladium maintained comparable catalytic activities, but were much easier to handle than the homogeneous analogue $Pd(PPh_3)_4$.

An alternative to improve resin handling was introduced by Ruhland, who described the preparation of tablets obtained from the compression of a blend of resin with solid reagents or catalysts (120). The preparation of such tablets involved three steps: swelling of the beads (and the solid reagent or catalyst) in a good solvent; sieving; and compression. The first step was essential for the preparation of mechanically stable tablets. The effect of swelling and drying resulted in agglomerations caused by bead–bead interactions as observed by SEM. Observation of the tablet structure showed that the beads were distorted after compression but not destroyed. The disintegration time of the tablets, measured by gentle shaking, was very solvent-depending and implicated that the swelling of the beads caused disintegration. As a consequence, good solvents such as THF or DCM gave shorter times of disruption (7–16 min) than DMSO or ethanol (>30 min). Functionalized tablets were employed to carry out Mitsunobu reactions and amine acylations, giving results comparable to the corresponding loose resins. During syntheses, tablets were loaded in 48-well plates in only 3 min, whereas the same procedure applied to resin beads took much longer. Moreover, preparation of tablets allowed the protection of sensitive functional groups from moisture or oxygen, and also a drastic reduction in the time of exposure to toxic hazardous and dusty materials in the working environment.

Nonpolystyrene Polymer Matrices

All the polymer supports described so far for solid-phase chemistry have a common factor: the main presence of a polystyrene backbone. Although this polymer matrix has good characteristics, such as chemical and mechanical stability (depending on the type and amount of cross-linker) and favorable loadings in solvent, its compatibility with polar solvents and large biomolecules, such as enzymes and receptors, is quite poor (121). In order to resolve these problems, several authors have replaced hydrophobic polystyrene with a more amphiphilic backbone. In the

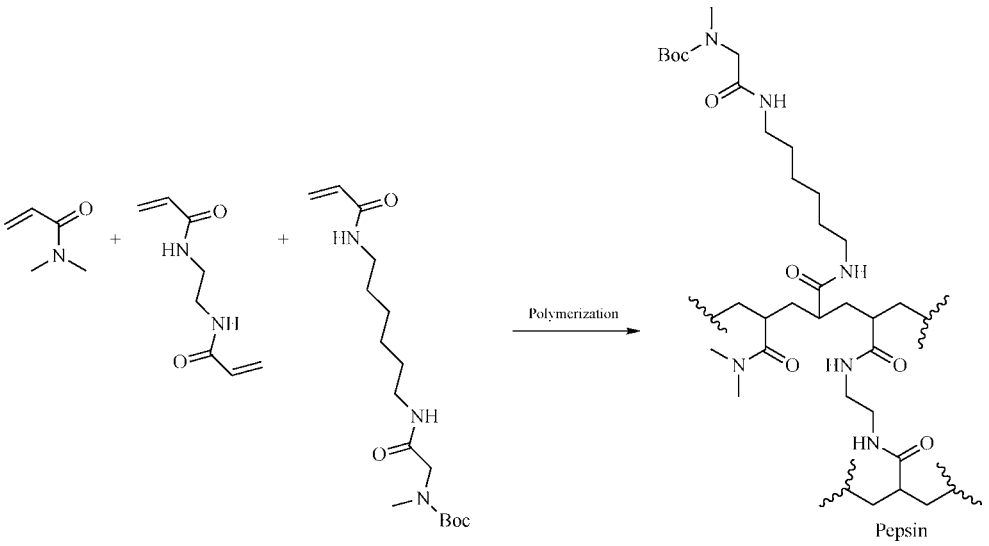

Fig. 20. Preparation of polyamide resins (Pepsin)

early 1970s, Sheppard introduced polyacrylamide supports, prepared by emulsion polymerization (Fig. 20), as an alternative to polystyrene gel-type resin for polypeptide synthesis (122). Such resins showed good swelling in highly polar solvents (see ACRYLAMIDE POLYMERS). Moreover, polypeptides were obtained in higher yields and purities and their syntheses were faster than with traditional polystyrene gel-type resin. These commercialized resins are still in use for large-scale preparation (33).

However, such supports, being very soft and fragile, are difficult to work with (123). Pepsin K was prepared by polymerization of pepsin monomers within rigid macroporous particles to help solve this problem (124).

In the 1990s, Meldal, following the work of Sheppard, developed an improved support which was named PEGA (PEG–polyacrylamide) (125), obtained by inverse suspension polymerization (126) of *N*,*N*-dimethylacrylamide cross-linked with different bis-acrylic-PEG derivatives (Fig. 21, **A**).

Functionalization was introduced by inclusion of acryloyl-PEG-NH_2 monomers (Fig. 21, **C**; loading = 0.08–0.13 mmol/g) or acryloyl-sarcosine

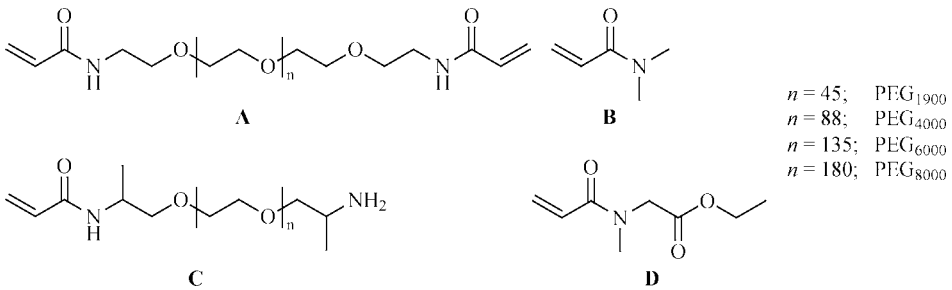

Fig. 21. Monomers used for the preparation of PEGA.

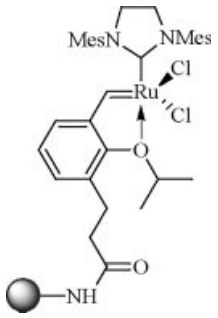

Fig. 22. PEGA supported ruthenium catalyst.

methylester monomer (Fig. 21, **D**; loading = 0.22–1.0 mmol/g) (127). The first version of such resins (PEG_{1900}) allowed the diffusion of biomolecules with a mass of ∼32 kDa into the beads. Although monomer A (Fig. 21), prepared using $PEG_{4000,6000,8000}$, improved the limit (>120 kDa), handling and loadings were poor. Recently, Gardossi observed that the introduction of a positive charge by trialkylammonium species in $PEGA_{1900}$ allowed better swelling than neutral PEGA and consequent inclusion of large proteins (128) although favorable charge–charge interactions are perhaps a more reasonable explanation (but also see Section 3.1). Although the main area of use of PEGA remains for biological based chemistry, because of size accetability (129–131), it has also been used with water-insoluble ruthenium catalysts for metathesis reactions in aqueous and protic solvents (in such conditions the nonsupported catalyst does not work) (Fig. 22) (132).

This catalyst not only showed good activity in metathesis reactions but also did not need to be used in degassed solution, as required by conventional Grubbs catalysts (133). However, the main problem of PEGA is its difficulty of handling: having to be handled in a solvated state as it may disintegrate when dry. A more robust cross-linked ethoxylate acrylate resin (CLEAR) was presented in 1996 by Kempe and Barrany (134). The main component of such supports is a branched PEG-acrylate derivative used in ∼50 mol% (Fig. 23), which gave good swelling in a range of solvents.

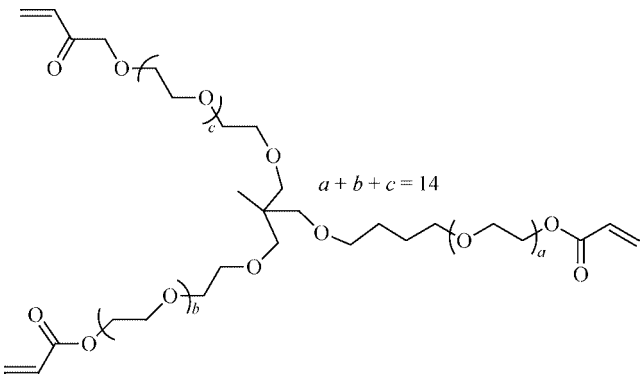

Fig. 23. Trimethylopropane ethoxylate (14/3 EO/OH) triacrylate.

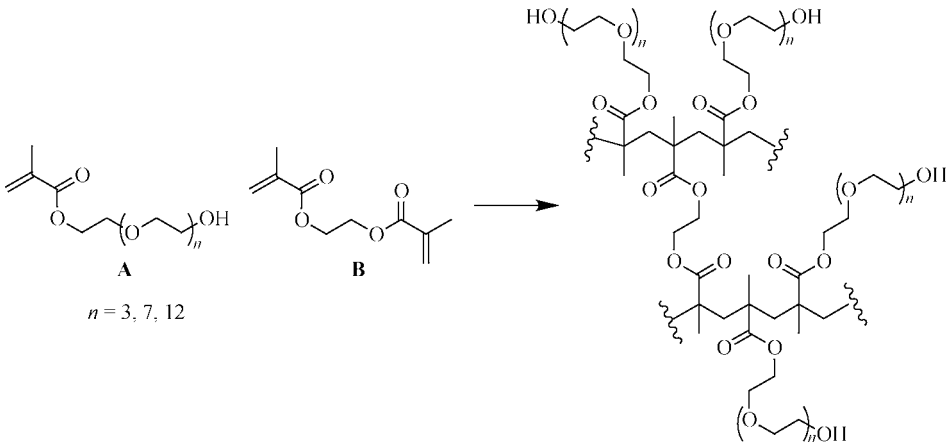

Fig. 24. Preparation of PEG-MA.

Unfortunately, CLEAR is vulnerable to strong bases (such as NaOH or NH_3), although complete polymer dissolution occurs only after long reaction times.

In 2001, Fréchet introduced PEG-MA (PEG methacrylate) (135). The monomers are PEG methacrylate derivatives (Fig. 24, **A**) and ethylene dimethacrylate is used at 2 mol% as a cross-linker (Fig. 24, **B**). Although such monomers are soluble in aqueous media, the preparation of PEG-MA was conducted by a "modified suspension polymerization."

As expected for resins that contained poly(ethylene glycol), PEG-MA was compatible with a broad range of polar and nonpolar solvents. Swelling depended on the chain length of the PEG incorporated in the monomer (Fig. 24, **A**), longer chains giving better swelling. Although loadings calculated were much lower (51–67%) than the ones expected, such values were still much higher than commercial PEG-grafted resins (1.2–1.8 mmol/g). The PEG-MAs were used for the preparation of a small library of hydantoins. The advantages of using PEG clearly reside in the improved property of the tailored polymer matrix. Loading, solvent compatibility (and so, swelling), and mechanical resistance depend on the level of this polymeric monomer. In 2002, Meldal prepared a new class of polymers named SPOCC (superpermeable organic combinatorial chemistry) resins (136). The main characteristic of these polymers was that the backbones and cross-linker both contained PEG. The second generation of such polymers ($SPOCC_{194}$) was prepared by cationic polymerization of the two monomers shown in Figure 25.

Novel SPOCCs exhibit great chemical resistance under various reaction conditions, because there are no benzyl ether, ester, and amide linkages. The use of shorter PEG chains in $SPOCC_{194}$ allowed higher loading compared to the previous generation resins (longer PEG chains), although swelling decreased. Although mainly used in peptide chemistry, SPOCC resins have seen successfully tested in a variety of different organic transformations (136,137). Direct comparison of this support, PS resin, and TentaGel showed comparable if not better kinetics in peptide synthesis.

Cellulose: From Paper to Beads. The first use of cellulose (qv) as a solid support for peptide chemistry can be attributed to Merrifield. Unfortunately, at

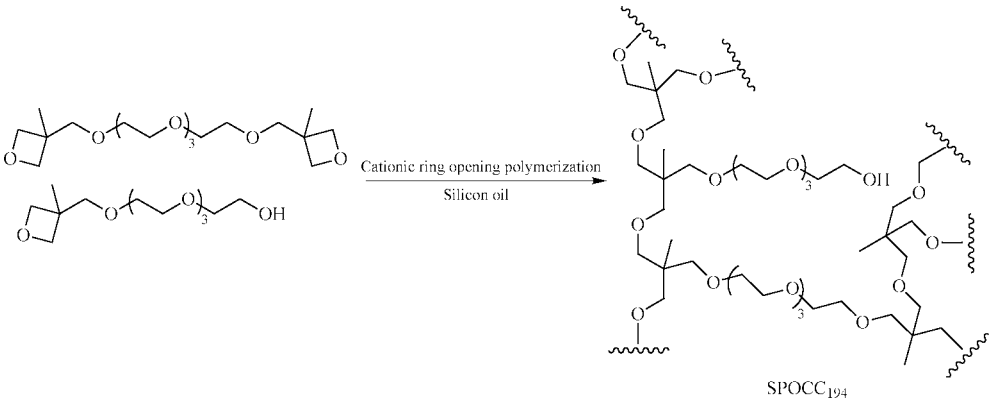

Fig. 25. Preparation of $SPOCC_{194}$.

that time, only a dipeptide was obtained in unsatisfactory yield. Moreover, cellulose was not chemically stable to the conditions used in the synthesis. Merrifield decided to abandon this support and to search for others with better properties (138). Peptides and oligonucleotides have been synthesized on paper and cotton (139,140), and Frank demonstrated, in 1992, the flexibility of cellulose for the preparations of large arrays of peptides on membranes by Spot synthesis (141). At the end of the synthesis, biological assays could be performed directly on each spot on the filter disk, as cellulose is compatible with many binding, enzymatic, and cellular essays (142). However, paper membranes are not suitable for scavenger or supported reagents, because of difficulties in their handling and their limited loading. In 1977, Stamberg found a method to prepare spherical cellulose particles with a certain degree of porosity by heating a viscose suspension (an aqueous solution of sodium cellulose xanthate) in a water-immiscible solvent under stirring (143). Such beads became commercially available under the name of Perloza. Because of the availability of three hydroxyl groups for each glucopyranose monomer, such supports provided very high loadings. Functionalized cellulose beads (0.37–0.65 mmol/g) were used for the synthesis of peptides (5–34 amino acids). The analysis of crude peptides (20 amino acids length) showed better purity when assembled on Perloza than polystyrene (144). The application of cellulose beads in solution-phase chemistry was demonstrated by Chesney and Steel (145). In their procedure, the pendant hydroxyl groups first reacted with allyl bromide; addition of bromine in water was followed by treatment with excess of tris(2-aminoethyl)amine and led to supported branched amino resins (2.2 mmol/g, 4 mmol/g). Such amino resins exhibited good and uniform swelling properties in polar and nonpolar solvents (between 8 and 10 mL/g in all solvents). Moreover, they allowed the synthesis of small libraries of amides and ureas in quite good purities and yields by the scavenging of excess acid chloride and isocyanate derivatives (Fig. 26, **B**). Treatment of Perloza with the enzyme cellulase allowed the complete biodegradation of the beads to glucose that, after treatment with brewers' yeast, led to ethanol, CO_2, and H_2O.

The supported allyl beads were also reactive enough to permit their application as a scavenger of bromine (Fig. 26, **A**) (146). Recently, Perloza aniline

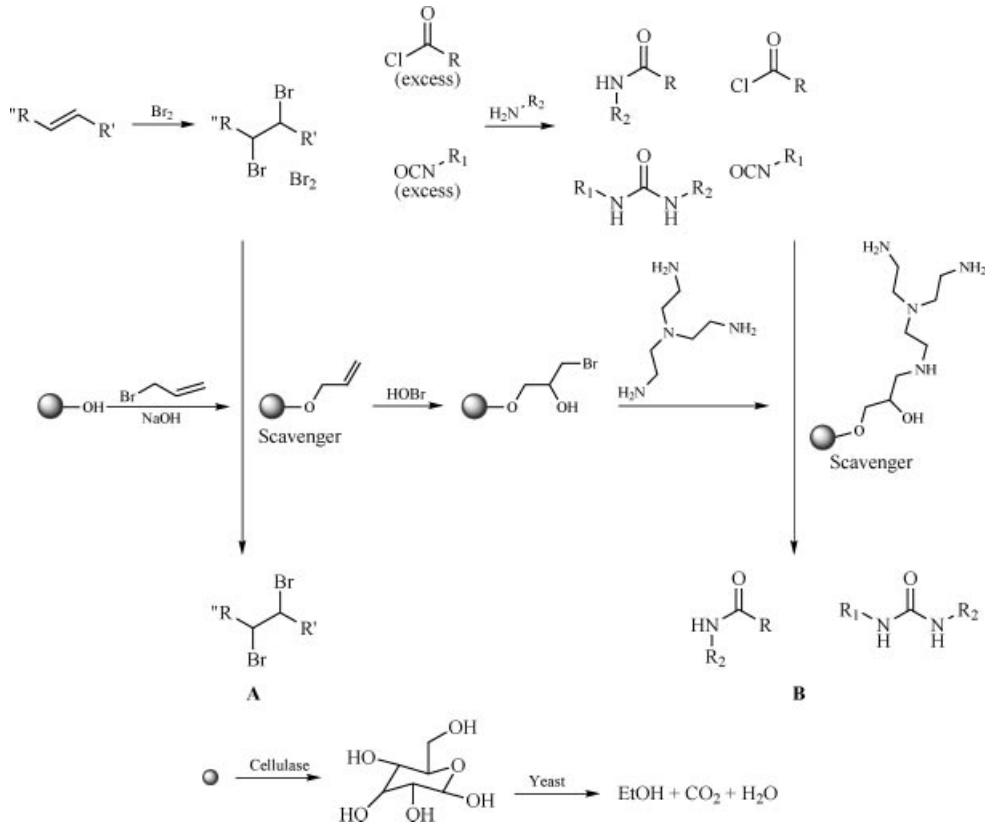

Fig. 26. Scavenger uses of biodegradable cellulose beads.

functionalized beads were used for a synthesis of a library of pyrazoles. Once the reaction conditions were established, the "catch and release" method was adopted and allowed the continuous recycling of the beads without decreasing yields and purities (147).

In conclusion, cellulose beads have interesting properties, such as relatively high loading, cheapness, chemical and mechanical stability, and recycling and easy disposal, factors that could be of use in large-scale industrial processes.

As can be seen, over the years there has been huge development in supports for synthetic applications, with variation of improvement in loading, morphologies, and polymer type.

Gel-type polystyrene resins are still the most widespread supports in solid-phase organic chemistry, exhibiting good characteristics of loading, swelling, and handling. However, they are not universal. Although an ideal support should be inert to reactions conditions, it does not mean that it does not have to interact with the reagents. "Resin beads are like solvents," suggested Czarnic (29), and this concept could be expanded by saying that "different polymer supports are like different solvents." As the choice of a particular solvent can change the course of a reaction, a polymer support has to be considered in the same way. For this reason, research groups continue the early work of Merrifield (139) in order to screen

and synthesize new and enhanced polymer supports for a range of chemical and biological applications.

POLYPEPTIDE SYNTHESIS, SOLID-PHASE METHOD

Introduction

Peptides play key structural and functional roles in biochemistry, pharmacology, and neurobiology, and are important probes for research in enzymology, immunology, and molecular biology. A *peptide* is a chain of 3–50 amino acid building blocks, taken from among the 20 genetically encoded L-residues, or unusual ones. The sequences can be linear, cyclic, or branched. A rapid, efficient, and reliable method for the chemical synthesis of peptides is of utmost importance. Synthesis can confirm structures of naturally occurring substances and make them available in greater quantities for further investigations, can delineate antigenic determinants

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

to allow preparations of artificial vaccines, and can lead to potent new drugs by judicious chemical substitutions that change functional groups and/or conformations of the parent peptide. These synthetic methods can also be extended to the study of *proteins*, which are defined as polypeptide chains of 50 or more residues.

The last century has witnessed the development of an extraordinary array of techniques for the chemical assembly of amino acids to form peptides. They can be subdivided into solution and solid–phase methods. The former have evolved since the beginning of the twentieth century (1–3); although quite powerful, they also require considerable labor, time, and skill because of the unpredictable solubility characteristics of intermediates and because of the lack of a method for automation. Recognizing the mechanical and physical limitations of the earlier chemical precedents, but retaining their strengths, in 1959 R. B. Merrifield of the Rockefeller University conceived the method of solid–phase peptide synthesis (SPPS). The solid–phase method has since been expanded to include other oligomeric systems, including DNA and polysaccharides, and to include combinatorial libraries. In recognition of the maturation and impact of this body of work, Merrifield was honored with the 1984 Nobel Prize in Chemistry (4). Many comprehensive reviews of SPPS have been written over the years (5–20).

Solid-phase synthesis is based on the covalent attachment (anchoring) of the growing peptide chain to an insoluble polymeric support or resin carrier, so that unreacted soluble reagents can be removed by filtration and washing without loss of the peptide–resin. Subsequently, the insoluble peptide–resin is extended by a series of addition cycles, which are required to proceed with high yields and fidelities. Excess soluble reagents drive the reactions to completion. Because of the speed and simplicity of the repetitive steps, the solid-phase procedure is amenable to automation. After the chain has been established, it is necessary to release (cleave) the crude peptide from the support under conditions that do not affect sensitive residues in the sequence. Purification and characterization follow to ensure and verify that the desired structure has been obtained.

Strategy and Tactics

A general strategy for stepwise solid-phase synthesis of linear polypeptides is shown in Figure 1. An insoluble polymeric support (Resin) is functionalized with a reactive group, typically an aminomethyl moiety. The first amino acid is attached to this functional group through a linker, usually a handle. A handle is defined as a bifunctional spacer that on one end typically contains a carboxyl group for coupling to an aminomethyl group on the polymeric support. The other end attaches to the first amino acid and acts as a permanent protecting group during chain assembly (7). The first amino acid is then attached to the handle by the C^{α}-carboxyl group as either an ester or amide linkage depending on whether the desired peptide will contain a C-terminal acid or amide group, respectively. Each amino acid contains a temporary protecting group (**T**, Fig. 1) on the N^{α}-amino group and a permanent protecting group (**P**, Fig. 1) on a reactive side-chain functional group if necessary. The peptide chain is then elaborated in the C $\rightarrow$ N direction by repeated cycles of deprotection of the temporary N^{α}-protecting group followed by coupling of the next protected amino acid. This deprotection/coupling cycle is repeated until all amino

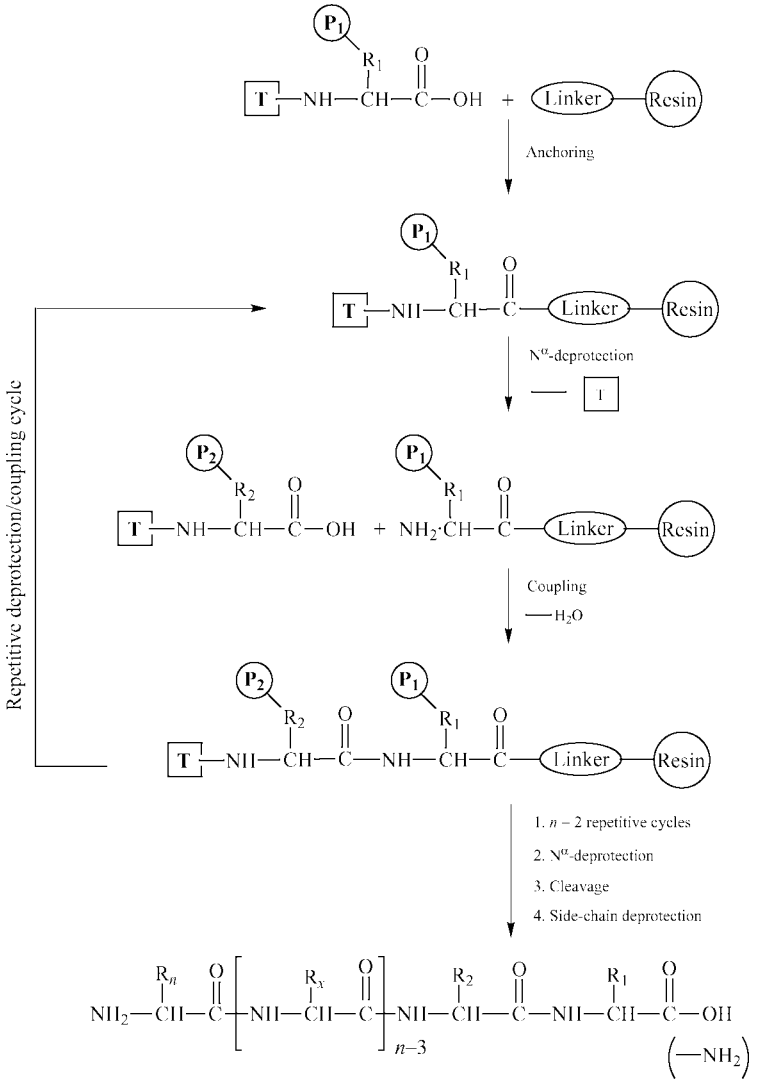

Fig. 1. Generic stepwise solid-phase synthesis of linear polypeptides. **T**, temporary protection; $\mathbf{P}_x$, permanent side-chain protection; $\mathbf{R}_x$, amino acid side chain.

acids of the peptide have been introduced. The peptide is then cleaved from the polymeric support, and the permanent protecting groups are removed; these last two steps are often combined in a single procedure. This strategy with C → N chain assembly offers the advantage that racemization is negligible. Variations on this general scheme exist that allow other C-terminal modifications such as thioesters, esters, or hydrazides to be synthesized. The chain may also be attached to the resin via either a side-chain functional group or the peptide backbone to allow elongation in the N → C direction as well as C → N (bidirectional synthesis) and to allow on-resin cyclization between the termini and/or a side chain for the synthesis

Table 1. Statistics of Chain Assembly in SPPS[a]

Average % yield of repetitive deprotection/coupling cycles	Total number of residues				
	5	10	25	50	100
80.0	32.8	10.7	0.4	0.0	0.0
90.0	59.0	34.9	7.2	0.5	0.0
95.0	77.4	59.9	27.7	7.7	0.6
99.0	95.1	90.4	77.8	60.5	36.6
99.5	97.5	95.1	88.2	77.8	60.6
99.9	99.5	99.0	97.5	95.1	90.5

[a] One can select a sequence length from the column headings and an average percent yield over all deprotection/coupling cycles from the left-most column of numbers. The number at the intersection of the selected column and row represents the theoretical percentage of peptide chains on resin that will contain the correct sequence after linear assembly has been completed. This theoretical percentage yield does not include side reactions and manipulative losses that will result from the cleavage and the purification steps that follow chain assembly in a synthesis.

of lactams, see References 3,5,7,8,10,12, and 16–20 for further information on C-terminal modifications.

Because the growing peptide is not isolated and purified after each repetitive deprotection/coupling cycle (Fig. 1), the fidelity of each step must proceed in near quantitative fashion. Table 1 contains the percent of correct peptide sequence that will be found on the resin at the end of a synthesis as a function of the average percent yield over all deprotection/coupling cycles and as a function of the total number of residues in the sequence. Yields of 95% per cycle, what would be considered fantastic in a solution synthesis, are unacceptably low for even peptides as short as 10 amino acids, as only 59.9% of the correct sequence would be assembled on the resin. Yields must be greater than 99% for each repetitive deprotection/coupling cycle to have any hope of isolating the desired product. The data of Table 1 also show that for sequences of greater than 25 amino acids, increasing the yield of each cycle by a few tenths of a percent makes a substantial difference in the overall yield. Thus, double coupling of each amino acid is routinely done on longer syntheses. Fortunately, the art of peptide synthesis has progressed to the level that yields greater than 99.5% for each repetitive cycle can generally be achieved. The impurities are often deletion peptides that differ from the desired sequence by only one or two amino acids and that may be hard if not impossible to remove during purification. Thus, for longer sequences many peptide chemists routinely include a capping step with acetic anhydride, after double coupling and before deprotection, to terminate the chain before the next cycle is begun. The termination peptides will then differ in length from the desired product by many amino acids and will be easier to remove from the desired product during purification.

In the repetitive deprotection/coupling cycle of Figure 1 are three classes of protecting groups. The first is the temporary N^{α}-protection. The remaining two classes contain permanent groups, the side-chain-protection and the peptide-linker bond, that remain intact during chain assembly. Implicit in this repetitive cycle is that the two permanent classes are stable to the conditions used to remove

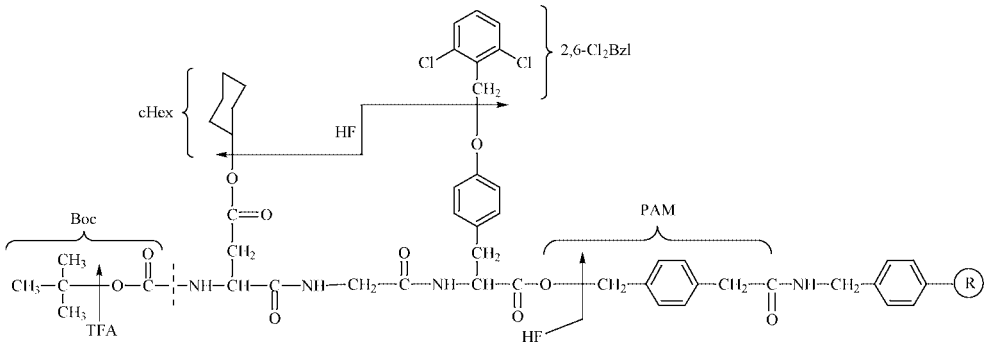

Fig. 2. Commonly used protection scheme based on graduated acidolysis. Temporary N^{α}-amino protection is provided by the *tert*–butyloxycarbonyl (Boc) group, removed at each step by the moderately strong trifluoroacetic acid (TFA). Permanent benyzl- and cyclohexyl-based side-chain–protecting groups and the phenylacetamidomethyl (PAM) ester handle linkage are cleaved simultaneously at the end of the synthesis by HF to yield the free peptide acid.

the temporary N^{α}-protection. If all classes are removed by the same chemical mechanism, for example acidolysis, differential stability between classes can only be achieved by designing protecting groups that are cleaved at different kinetic rates. This often necessitates very harsh conditions for final removal of the two classes of permanent protection. The alternative is to design protecting groups for each class that are cleaved by different or orthogonal mechanisms (7,21). Ideally, a fully orthogonal protection scheme would allow each class of protecting group to be cleaved in any order without removing the other two classes (22). Orthogonal protection schemes allow milder overall conditions, because deprotection strategies are based upon mechanism rather than kinetics.

Many combinations of temporary and permanent protecting groups have been developed over the years. Only two have survived the test of time and are routinely used today. The first is an improved version of the original Merrifield system. This system is a non-orthogonal scheme based on graduated acid lability to differentiate temporary from permanent protecting groups (Fig. 2). The N^{α}-*tert*-butyloxycarbonyl (Boc) group (23–25) is used for temporary protection. The Boc group is stable to alkali and nucleophiles but is rapidly removed by organic and inorganic acids (7). The Boc group is usually removed by trifluoroacetic acid (TFA) (20–50%) in dichloromethane (DCM) or HCl (4N) in dioxane. Permanent side-chain–protecting groups are ether, ester, and urethane derivatives based on benzyl alcohol "fine-tuned" with electron-donating methoxy or methyl groups or electron-withdrawing halogens to achieve the proper level of stability to acid. Alternatively, ether and ester derivatives based on cyclopentyl or cyclohexyl alcohol are sometimes used to mitigate certain side reactions. These permanent side-chain–protecting groups and the peptide-handle linkage are cleaved by the strong Lewis acid anhydrous HF. In neat anhydrous HF, cleaved protecting groups exist as carbocations that may alkylate sensitive side chains of residues such as tryptophan. Thus, acid cleavages are always carried out in the presence of carbocation scavengers such as anisole. Scavengers such as dimethyl sulfide, *p*-cresol,

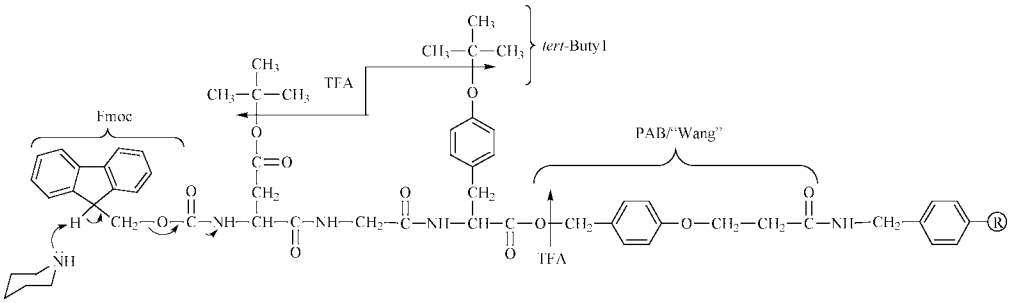

Fig. 3. A mild two-dimensional orthogonal protection scheme for solid-phase synthesis. Temporary N^{α}-amino protection is provided by the 9-fluorenylmethyloxycarbonyl (Fmoc) group, removed by a base-catalyzed elimination mechanism, typically with piperidine. Permanent *tert*-butyl-based side-chain-protecting groups and the *p*-alkoxybenzyl (PAB) ester handle linkage are both cleaved by treatment with TFA to yield the free peptide acid at the end of the synthesis. Details in text.

and *p*-thiocresol have been recommended in conjunction with a two-stage, low–high HF cleavage method that is said to provide extra control and higher purities (see section 3.4, Cleavage).

The Merrifield system is still popular today and up until the mid-1980s was the most commonly used synthetic strategy. In the last 15 years a two-dimensional orthogonal strategy based on the N^{α}-9-fluorenylmethyloxycarbonyl (Fmoc) group (26) has emerged as the method of choice for the synthesis of most research peptides (Fig. 3). The temporary Fmoc group is removed by a β-elimination mechanism with piperidine (20–50%) in *N,N*-dimethylformamide (DMF) or *N*-methylpyrollidinone (NMP) (27–30). Permanent protection is now provided by ether, ester, and urethane derivatives based on *t*-butyl alcohol, triphenylmethanol, or 9-hydroxyxanthene, which are cleaved by TFA at the same time the peptide is released from the resin. Whereas the anhydrous HF used in the final deprotection step in Boc chemistry requires a special apparatus made of all fluorocarbon (Kel F) lines and trained operators to safely cleave and isolate the peptide, the milder conditions for final cleavage in Fmoc strategies, TFA (90%), have allowed a wide variety of scientists of diverse training to now synthesize peptides by the solid-phase method. Once again, scavengers are necessary to remove reactive carbocations during final TFA cleavage. The scavenger cocktails are covered in the section on cleavage.

A three-dimensional orthogonal protecting scheme for the synthesis of lactams is illustrated in Figure 4. The side chains of aspartic acid and lysine are protected with ester and urethane derivatives, respectively, of allyl alcohol. The allyl-based protecting groups may be cleaved under neutral conditions mediated by Pd(0) while the fully protected peptide is still attached to the resin. The lactam ring may then be formed taking advantage of the psuedo-dilution effect of the peptide–resin. Fmoc removal followed by final TFA cleavage from the 5-(4-aminomethyl-3,5-dimethoxyphenoxy)valeric acid (PAL) handle results in the side chain-to-side chain cyclic peptide with a C-terminal amide.

Side-chain–protecting groups keep reactive side chains from coupling with the next incoming activated amino acid and thus forming a branch point in the

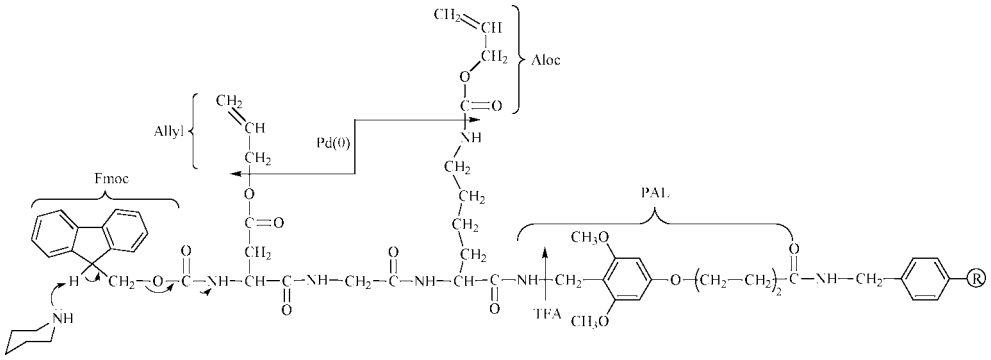

Fig. 4. A mild three-dimensional orthogonal protection scheme for side chain-to-side chain cyclization strategies. The allyl alcohol based side-chain protection of Asp and Lys are removed with Pd(0) without affecting the temporary Fmoc protection or the permanent peptide–PAL handle linkage. The lactam bond between Asp and Lys can now be formed on resin, followed by sequential treatment with piperidine to remove the Fmoc group and TFA to cleave the peptide from the PAL handle to yield the side chain-to-side chain cyclic C-terminal amide peptide.

peptide, they protect sensitive residues from degradation during synthesis, and they can greatly increase the solubility of certain residues in the common solvents used in peptide synthesis. Because the occurrence of many of the degradation side reactions are sequence-dependent, for the synthesis of research peptides in which process development is often not an option, a maximal protecting group strategy is recommended in which all trifunctional amino acids are protected. The recommended protecting groups for each trifunctional amino acid that are commercially available and compatible with either Boc or Fmoc chemistries are listed in Tables 2 and 3, respectively. These permanent side-chain–protecting groups are cleaved at the same time as the peptide–resin linkage is cleaved.

For the synthesis of cyclic peptides, either lactams (58,59) (Fig. 4) or multiple disulfide-containing (60) peptides, and for the synthesis of protected fragments, permanent protecting groups must be selected whose cleavage mechanism is orthogonal to that used to remove the N^{α}-protecting group and to that used to cleave the peptide–resin linker. If on-resin cyclization is to be attempted, the orthogonal protecting group does not have to be stable to the final cleavage/deprotection conditions. All that is necessary is that the orthogonal side chain group can be removed without affecting the N^{α}-protection, the other permanent side-chain–protected amino acids, and the peptide-linker bond. Table 4 summarizes the commercially available amino acid derivatives for both Boc and Fmoc chemistries with side-chain protection that is cleavable by mechanisms orthogonal to either acidolysis and/or piperidine treatment.

The standard methodology of SPPS involves attachment of the first amino acid to the resin via the C^{α}-carboxyl. Synthesis then proceeds in the C → N direction. The majority of anchoring linkages have been designed to provide C-terminal ester or amide linkages to provide upon cleavage, respectively, peptide acids or amides (Table 5). The original linker used by Merrifield was a benzyl ester formed by the reaction between the first protected amino acid and chloromethyl groups on

5-(9-Aminoxanthen-3-oxy)valeric acid (XAL)	Dilute TFA	Amide	13,102, 103	3-Nitro-4-aminomethylbenzoic acid (Nonb)	$h\nu$ (350 nm)	Amide	104	4-(4-Fmoc–aminomethyl-3,5-diethoxy–phenoxy)butyric acid (BAL)	TFA	Amide	105	4-(α-Mercaptobenzyl)phenylacetic acid	HF	Thioester	106–108	
[a] Structural diagrams are oriented so that the resin or point of attachment to support is on the far right, and the site for anchoring the C-terminal amino acid residue is on the far left. Benzyl ester linkages may also be cleaved by a range of nucleophiles to create acids, esters, or other derivatives. Consult References 7,9, and 20 for further examples.

[b] Cleavage by aminolysis results in 0.6–2% racemization (79).

polystyrene resin (Table 5). The simple benzyl ester linkage was found to be slowly cleaved by TFA and has now been replaced by the phenylacetamidomethyl (PAM) ester handle (Fig. 2) which is stable to TFA but readily cleaved by HF. The preferred loading technique for ester linkages is to attach the first amino-acid to the handle in solution forming a "preformed handle." The preformed handle may be purified in solution before coupling to an amino-functionalized resin. The preformed handle strategy gives one greater control over the loading in that the formation of the amide bond between the handle and the resin can easily be driven to completion (75,76). For synthesizing peptide acids by Fmoc chemistries, *p*-alkoxybenzyl esters (PAB), "Wang resins" (Fig. 3, Table 5), are the preferred handles. Both PAM and Wang resins preloaded with the first amino acid are now commercially available at low cost and high purity from a variety of vendors (see Appendix). Finally, for a detailed discussion of side reactions that can occur when forming the ester bond between the first amino acid and either a handle- or a resin-bound hydroxyl group, see Reference. 20 (pp. 129–132).

The recommended linker for synthesizing C-terminal amides compatible with Boc chemistries is the MBHA linker (Table 5). For Fmoc chemistries either the PAL (Fig. 4) or the Rink handles are recommended (Table 5).

Many other handles exist that are cleavable by orthogonal mechanisms for the synthesis of protected peptide fragments; these are also summarized in Table 5. A novel strategy for the synthesis of cyclic peptides on resin is to attach the peptide to the resin by a backbone nitrogen rather that the C^{α}-carboxyl. The N- and C-termini then remain free for further functionalization such as cyclization, esterification, or thioester formation. This backbone amide linker (BAL) is listed in Table 5. Other strategies such as attaching the peptide to the resin via the side chain of trifunctional amino acids and more comprehensive listings of linkers and handles are covered in References 9,12, and 109–111.

Procedures

Deprotection/Coupling Cycle. Tables 6 and 7 show representative deprotection/coupling cycles for Boc- and Fmoc-based syntheses, respectively. When

Table 6. General Boc Chemistry SPPS[a]

Step	Description	Solvents/chemicals	Time[b], min
1.	Deprotection	20–50% TFA in DCM or NMP	1 + 30
2.	Wash	DCM or NMP	4 × 2
3.	Neutralization	5% DIEA in DMF or NMP	2 × 2
4.	Wash	DMF or NMP	4 × 2
5.	Activation and coupling[c,d,e]	Selection from Table 8	
6.	Wash	DMF or NMP	4 × 2

[a] Boc–Asn and Boc–Gln are side-chain–protected.
[b] Times are for batchwise synthesis. If a flow apparatus is used, the time is the combined times of a step, eg, 2 × 2 min = 4 min of flow.
[c] When double coupling, steps 1 through 4 are omitted between couplings.
[d] When capping, the coupling reagents of Table 8 are replaced with acetic anhydride/DIEA (10 equiv each), and steps 1 through 4 are omitted as when double coupling.
[e] Steps 3 and 5, neutralization and coupling, may be combined into one step (112–116).

Table 7. General Fmoc Chemistry SPPS[a]

Step	Description	Solvents/chemicals	Time[b], min
1.	Wash	DMF or NMP	3 × 1
2.	Deprotection	Piperidine/DMF or NMP (1:4)	1 + 20
3.	Wash	DMF or NMP	3 × 1
4.	Activation and coupling[c,d]	Selection from Table 8	
5.	Wash	DMF or NMP	3 × 1

[a] Fmoc–Asn and Fmoc–Gln are side-chain–protected.
[b] Times are for batchwise synthesis. If a flow apparatus is used, the time is the combined times of a step, eg, 3 × 1 min = 3 min of flow.
[c] When double coupling, steps 1 through 3 are omitted between couplings.
[d] When capping, the coupling reagents of Table 8 are replaced with acetic anhydride/DIEA (10 equiv each), and steps 1 through 3 are omitted as when double coupling.

double coupling or capping, the deprotection step is skipped and the protocol is repeated, starting at the wash step before the activation and coupling steps.

The recommended coupling reagents and their respective protocols are listed in Table 8. The structures of the coupling reagents are shown in Figure 5. Each lab has a preference for coupling reagent, reaction time of each step, and solvents (DCM, DMF, or NMP) used. Each coupling reagent has certain limitations. *N,N′*-Diisopropylcarbodiimide (DIPCDI) activation in DMF or NMP is a slow process that takes about 1 h to reach completion. In DCM the reaction is instantaneous (117). Thus, preactivation in a separate vessel while deprotection is occurring is often done with carbodiimide activation in DMF or NMP. Activated arginine derivatives undergo a slow side reaction, where the guanido group attacks the activated C^{α}-carboxyl to form a six-membered ring. The amino acid is then no longer able to couple. This side reaction does not affect the purity of the peptide, it only nonproductively consumes the activated arginine residue. Thus, long preactivation of arginine by carbodiimides is not recommended to avoid the loss of the activated amino acid before it can couple to the free amino group of the peptide–resin. The reagents benzotriazol-1-yl-oxy-tris(dimethylamino)phosphonium hexafluorophosphate (BOP), 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), and *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU) must contain excess *N*-methylmorpholine (NMM) or *N,N*-diisopropylethylamine (DIEA) for efficient coupling (118–124). The excess tertiary amines present in these coupling cocktails (Table 8, entries 2–4) will racemize cysteine (125). Either the DIPCDI or the pentafluorophenyl active ester protocols are recommended for coupling this amino acid. The BOP reagent releases the carcinogen hexamethylphosphoramide, so the waste stream from this reagent must be handled with care. Excess unreacted HBTU and HATU can cap unreacted amino groups (126,127); preactivation should always be done in a separate vessel and the amino acid derivative should always be present in slight excess to these two coupling reagents. Because of this side reaction, HBTU and HATU are not recommended as reagents for on-resin cyclizations. Pentafluorophenyl esters (*O*Pfp) couple slowly as compared to the other methods, addition of HOBt can increase the reaction rate (128,129).

The coupling times listed in Table 8 are only approximate, and for manual syntheses the actual length of the coupling step is determined by monitoring for unreacted amino groups by the sensitive ninhydrin test.

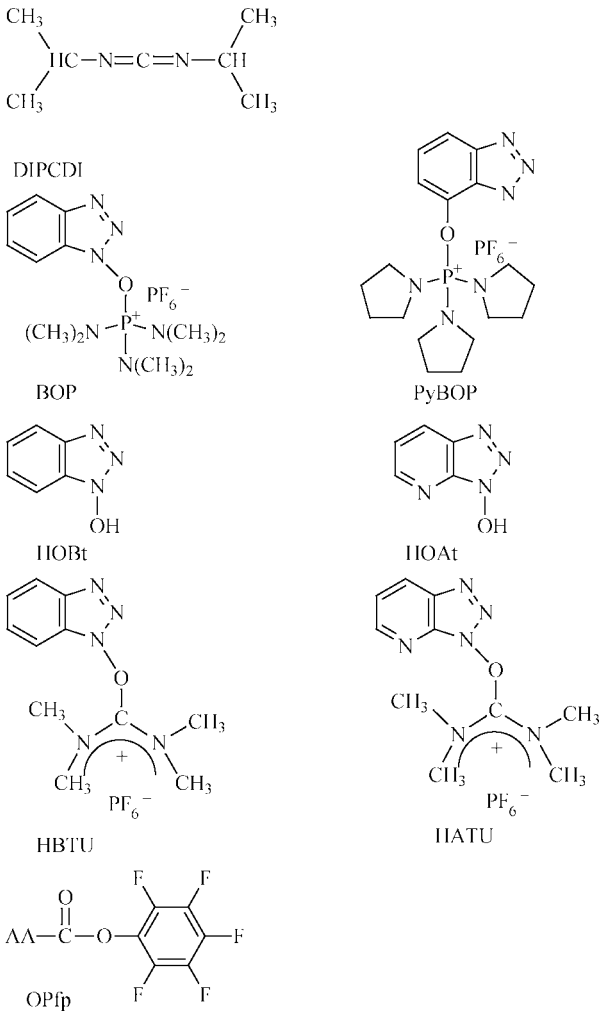

Fig. 5. Structures of coupling reagents of Table 8.

Many other side reactions that can occur during coupling have been documented and are listed in the more comprehensive reviews (5–8, 10–20). However, if one uses the protected amino acids listed in Tables 2–4 and the deprotection/coupling protocols of Tables 6–8, these other side reactions generally are not a problem during chain elongation.

Monitoring. A key assumption in solid-phase procedures is that coupling reactions can be made to go to completion (Table 1). A number of qualitative and quantitative methods of monitoring these steps exist, including some with a possibility of "real-time" feedback based on the kinetics of appearance or disappearance of soluble chromophores measured in a flow-through system. Most accurate and meaningful are qualitative and quantitative tests for the presence of unreacted amines after a coupling step. Such tests should ideally be negative before proceeding to the next deprotection/coupling cycle.

The most widely used qualitative test for monitoring unreacted amines is the ninhydrin test (130). For monitoring imines (secondary amines) such as proline,

Table 8. Coupling Protocols for SPPS

Entry	Solvents/chemicals	Time[a], min
1.	Protected amino acid (4 equiv) in DMF or NMP	5
	DIPCDI (4 equiv)/HOBt (4 equiv) in DMF[b,c]	60
2.	Protected-amino acid (4 equiv) in DMF or NMP	5
	BOP or PyBOP (3 equiv)/NMM (4.5 equiv)/HOBt (3 equiv) in DMF or NMP[b]	20
3.	Protected amino acid (4 equiv) in DMF or NMP	5
	HBTU (3.6 equiv)/DIEA (7.2 equiv)/HOBt (4 equiv) in DMF[d]	20
4.	Protected amino acid (4 equiv) in DMF or NMP	5
	HATU (3.6 equiv)/DIEA (7.2 equiv)/HOAt (4 equiv) in DMF[d]	20[e]
5.	Protected amino acid pentafluorophenyl ester (4 equiv) in DMF or NMP	60

[a]The first line in the second column is the preactivation time, and the second line is the coupling time. Entry 5 is the coupling time only.

[b]The reagents can be added directly to the reaction vessel without preactivation, eg, during on-resin cyclizations to form a lactam.

[c]Earlier references on the carbodiimide method of activation use *N,N′*-dicyclohexylcarbodiimide (DCC) as the coupling reagent. DCC can cause severe dermatitis when handled, and the urea by-product is prone to precipitate in the lines of automated synthesizers. DCC is no longer recommended for use in solid-phase synthesis.

[d]Preactivation in a separate vessel is required to avoid capping the N^{α}-amino group.

[e]Coupling times as short as 1 min have been recommended with the reagents of entry 4 (115,116).

the isatin test is used (131). These tests, which are carried out on an aliquot of peptide–resin, are easy, reliable, and require only a few minutes to run, making it possible to make a quick decision on how to proceed. A highly accurate quantitative version of the ninhydrin test has been described (132). The ninhydrin test is not amenable to automation, however. Other monitoring techniques exist that are nondestructive and may be carried out on the whole batch of resin. These tests are time consuming and not widely used.

As an alternative to monitoring unreacted N^{α}-amino groups, soluble reactants and coproducts can be analyzed. Continuous measurement of electrical conductivity can be used to evaluate Fmoc coupling and Fmoc deprotection efficiencies (133–135). The progress of Fmoc chemistry can be evaluated by observing the decrease of absorbance at 300 nm when Fmoc amino acids are taken up during coupling, and by the increase in absorbance at 300 nm when the Fmoc group is released with piperidine (136). Software on modern peptide synthesizers can evaluate the kinetics of these deprotection/coupling steps and lengthen reaction times if necessary.

Continuous flow monitoring is inherently insensitive for direct judgment of reaction end points. In a typical coupling procedure with a fourfold excess of amino acid, absorbance drops from 4.00 to 3.05 or 3.01 units with 95 or 99% coupling, respectively. It is difficult to distinguish the approximate 1% difference between 3.05 and 3.01 accurately. In contrast, the 400% difference between 0.05 and 0.01 is easily measured when monitoring unreacted N^{α}-amino groups.

An essential, although time-consuming, way to monitor the course of solid-phase synthesis is total hydrolysis of aliquots of the peptide–resin removed after

Table 9. Preview in the Sequential Degradation of a Hypothetical Peptide Made by Solid-Phase Synthesis[a]

	Edman cycle	%	1	2	3	4
Correct	A-B-C-D-E-F-resin	90	A	B	C	D

[b] With respect to expected residue.

certain synthetic steps. The technique of internal reference amino acids (IRAA) is often used to measure yields and chain retention accurately (11,101,137).

Invasive monitoring of both synthetic efficiency and amino acid composition of peptide–resins can be achieved by a powerful quantitative variation of the Edman sequential degradation, called "preview analysis" (138–140). To illustrate preview analysis (Table 9), assume that the desired sequence A-B-C-D-E has been assembled on 90% of the peptide–resins, that deletions of A, B, and C have occurred at 0.4, 0.4, and 0.2%, respectively, and that due to a significant error at the step to incorporate D, 9% of the chains lack this latter residue. After one cycle of Edman degradation, the residue B is quantitatively determined by sensitive analytical techniques at 0.4% of the expected A, even though B should only be viewed in the second cycle. Thus the 0.4% preview of B reflects that amount of deletion of A. The second cycle of Edman degradation in Table 9 shows the amplification effect inherent in the method, because now 0.8% preview of C is noted. It is difficult to ascribe a low degree of deletion to specific positions in the chain, but an average deletion can be assumed because the precision increases with each Edman step. In fact, the average level of deletions in a typical synthesis is $<0.3\%$ per step. The fourth degradation of the example (Table 9) illustrates the dramatic jump in preview reflecting a failure in the corresponding stage of the synthesis. Because this level is large, the specific location of the deletion can be identified.

Recently, on-resin mass spectrometry (MS) via the MALDI (matrix-assisted laser desorption/ionization) technique has been developed. This method can be used as a semi-on-line monitoring technique during SPPS (141). An especially elegant approach for on-resin MS is to use the photolabile α-methylphenacyl ester linker (Table 5, α-bromophenacyl entry), which is cleaved directly upon laser photolysis and MALDI ionization (142,143).

Resins. The solid-phase support (Resin, Fig. 1) is a well-solvated polymeric matrix in which the peptide chains are attached throughout a resin bead. The polymeric backbone is a flexible superstructure through which reagents and solvents can easily flow and once swollen has the physical properties of a gel (144,145). This is in contrast to the common perception that solid-phase chemistry only occurs on the surface of each polymer bead. Because of the permeable nature of the polymers, reaction rates approach but are slightly slower than that found in solution. Commercially available polymers have functional group loadings typically in the 0.2–1.0 mmol/g range. As an example of the distribution

of peptide chains within a polymer, polystyrene contains approximately 10 mmol/g phenyl groups. Thus, a polystyrene resin with an aminomethyl substitution of 0.5 mmol/g contains a functional group on about every 20th phenyl ring. By the end of the synthesis a resin may easily double in mass and volume but will remain a well-solvated gel in the common solvents used in SPPS. This increase in size does not appreciably affect reaction rates, and couplings generally continue to proceed to completion (144).

Polymeric supports must be compatible with either of the two modes of SPPS. The first is the batchwise method, where the reactions are agitated by mechanical means such as shaking, vortexing, or bubbling with an inert gas such as nitrogen. Reagents are removed by filtration either with suction or with nitrogen pressure. The second mode is the continuous-flow method. In this mode reagents and solvents are pumped through columns packed with resins. Resins for use in continuous-flow SPPS must have sufficient mechanical stability to be stable to the back pressures that develop during synthesis.

Two polymeric supports have classically been used in batchwise SPPS. The first is polystyrene polymer cross–linked with 1% of 1,3-divinyl benzene. A typical dry bead has a diameter of 50 μm that swells five- to sixfold in DCM or DMF (144). The second was developed on the basis of the idea that the polymeric backbone should be of similar chemical composition, a polyamide, as the peptide backbone (11). Thus, copolymerized dimethylacrylamide, *N,N*'-bisacryloylethylenediamine, and acryloylsarcosine methyl ester, or polyamide resin, was developed (146). Polyamide supports are commercially known as Pepsyn resin. Many other supports have been developed that are compatible with batchwise SPPS and are summarized in the more comprehensive reviews (7,10–20,109).

The original supports designed to withstand the high flow rates and resulting back pressures of continuous-flow SPPS are low density, highly permeable inorganic matrices that have polyamide embedded within. These matrices include polyamide–kieselguhr (Pepsyn K) (147) and polyamide–Polyhipe (148). These polyamide-embedded resins have now been largely replaced by polyethylene glycol–polystyrene graft supports that have superior swelling properties in a range of solvents and have excellent physical and mechanical properties for both batchwise and continuous-flow SPPS (13,149–154). These graft polymers are commercially available as PEG-PS, TentaGel (Rapp Polymere GmbH, Tübingen, Germany), and ArgoGel (Argonant, Foster City, Calif.)

Other resins compatible with both batchwise and continuous-flow SPPS are poly(*N*-[2-(4-hydroxyphenyl)ethyl]acrylamide) (core Q) (155), polyethylene glycol dimethylacrylamide (PEGA) resins (156,157), and cross–linked ethoxylate acrylate resin (CLEAR). CLEAR has excellent swelling properties in a wide range of polar and nonpolar solvents ranging from water to DCM (158).

Cleavage. Upon completion of chain assembly the peptide must be cleaved from the resin. In standard Boc and Fmoc chemistries cleavages simultaneously remove side-chain–protecting groups as the peptide is liberated from the resin by acidolytic conditions. A variety of unwanted side reactions can occur during cleavage, so careful attention to detail is necessary to successfully complete this step in a synthesis. Detailed discussions of the fine points of cleavage are covered in the reviews (5–8,10–20).

Fmoc chemistries utilize the moderate-strength acid TFA to cleave the PAB ester and either Rink or PAL amide linkages. TFA simultaneously cleaves the

Table 10. Recommended Cocktails for Final Cleavage of the Peptide–Resin Linker and the Permanent Side-Chain–Protecting Groups Used in Fmoc-Based Synthesis[a]

Cocktail	Ratio of ingredients, v/v	Reference
Reagent K	TFA/phenol/thioanisole/ethanedithiol/water, 82.5:5:5:2.5:5	165,166
Reagent R	TFA/thioanisole/ethanedithiol/anisole, 90:5:3:2	101
Reagent B	TFA/phenol/water/triisopropylsilane, 88:5:5:2	166,167

[a]The peptide–resin is swollen in the cocktail, approximately 5 mL/g resin, for 1–2 h. The cleavage solution is then added to 10 volumes of ice-cold diethyl ether to precipitate the peptide. The crude peptide is then isolated by centrifugation to form a pellet that is washed with cold ether. After washing, the pellet may be dissolved, and the peptide purified by preparative reversed–phase HPLC.

side-chain–protecting groups listed in Table 3. In TFA the cleaved *tert*-butyl groups exist either as cations or *tert*-butyl trifluoroacetate (159–162). The trityl, 9-xanthenyl, and Pbf groups also exist as cations. Alkylation of Trp, Met, and to a lesser degree Cys and Tyr by these reactive species is prevented by including scavengers in the reaction mixture (47,163,164). Table 10 contains three cocktails that effectively scavenge reactive intermediates and also help prevent oxidation of Met to Met(O) and oxidation of Trp by ozone generated in the reaction mixture from dissolved oxygen (165,168). Once again the choice of cocktail is a preference of each lab.

Final cleavage in Boc-based syntheses is usually achieved with anhydrous HF. HF cleaves both the PAM and MBHA handles along with the side-chain–protecting groups listed in Table 2 (31). HF cleavage procedures require an all-fluorocarbon apparatus, since this strong acid will dissolve glassware. Just as in the Fmoc TFA procedure, HF cleavages must contain carbonium ion scavengers. The standard cleavage conditions are HF-anisole (9:1) at 0°C for 1 h (8). To deprotect Trp(CHO) and Met(O), a two-stage "low–high HF" procedure is used in which low HF concentrations of 20–25% in the presence of 4-thiocresol and dimethyl sulfide first deprotect these two residues and others as well. Final cleavage from the resin is then achieved by increasing the HF concentration to near that found in the standard procedure. This low–high procedure is said to give better control and better product purities than the standard procedure (31).

Purification. Reversed phase HPLC is the standard method for purification of synthetic peptides. This technique can generally remove the accumulated low level systematic by-products present in the crude peptide isolated after cleavage. The homogeneity of purified peptides should be checked by at least two orthogonal techniques, either, analytical reversed-phase or ion-exchange HPLC, or capillary zone electrophoresis (169). Mass spectrometry must also be used to confirm that the molecular ion of the isolated product has the correct mass. Amino acid analysis is used to confirm the correct amino acid composition. Sequencing information either by automated Edman degradation or by mass spectrometry techniques may also be done, although sequence analysis is not routinely required.

Side Reactions.

Solvents and Reagents. To assure that each deprotection/coupling cycle is completed with the necessary high fidelities illustrated in Table 1, all solvents and reagents must be of the highest grade available. In Fmoc-based syntheses,

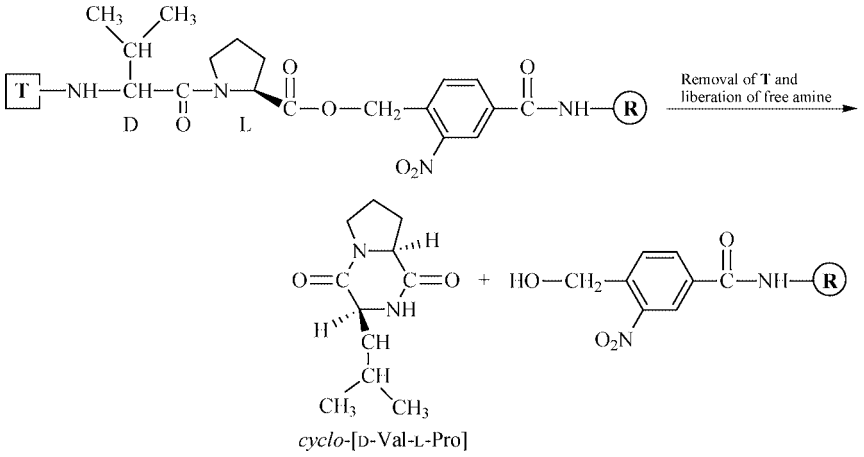

Fig. 6. Formation of a diketopiperazine from a D-valyl-L-proline sequence anchored as an *o*-nitrobenzyl ester. The example shown is designed to accentuate the potential problem, in that susceptible amino acid residues and a very good leaving group toward intramolecular aminolysis were both chosen. In this example, the level of diketopiperazine formation depended significantly on the N^{α}-amino-protecting group used, with >75% side reaction occurring in 2 min under Fmoc removal conditions and ~40% shortly after neutralizataion following Boc removal (22). See References 7,170, and 171 for additional information on mechanistic details regarding diketopiperazine formation, and References 105,112, and 171–173 for coupling protocols that mitigate the problem.

low levels of contaminating secondary amines found either in the DMF (dimethylamine) or in the DIEA used during an activation/coupling step can prematurely deprotect the Fmoc group. The highest purity, "peptide synthesis grade," of these reagents should always be purchased; old reagents should not be used in syntheses. Secondary amines can be detected with the ninhydrin test.

Diketopiperazine Formation during Attempted Incorporation of Third Amino Acid. The free N^{α}-amino group of an anchored dipeptide is poised for acid- or base-catalyzed intramolecular attack upon the C-terminal carbonyl (Fig. 6). The formation and release of the six-membered-ring diketopiperazine from the resin is kinetically favorable for residues that can form *cis*-peptide bonds, for example, Gly, Pro, *N*-methylamino acids, and D-amino acids in either of the dipeptide residues. A hydroxymethyl group remains on the resin. Diketopiperazine formation is also a problem when the third amino acid is added to a BAL-anchored (Table 5) sequence (105) or to an activated leaving group such as the *O*-nitrobenzyloxy handle (22). However, for most syntheses this problem can be adequately handled.

Succinimide Formation and $\alpha \rightarrow \beta$ Rearrangement, Particularly at Asn–Gly Sequences. Asn- and to a lesser extent Asp-containing peptides can cyclize to form a succinimide derivative (Fig. 7). The formation of the five-membered succinimide ring is kinetically favorable. The ring can open to yield either α- or β-Asp peptides. The Asn–Gly sequence has the greatest tendency to rearrange (174). This rearrangement can be a significant problem, especially if a peptide is left to stand for too long in dilute acid solutions, such as the aqueous

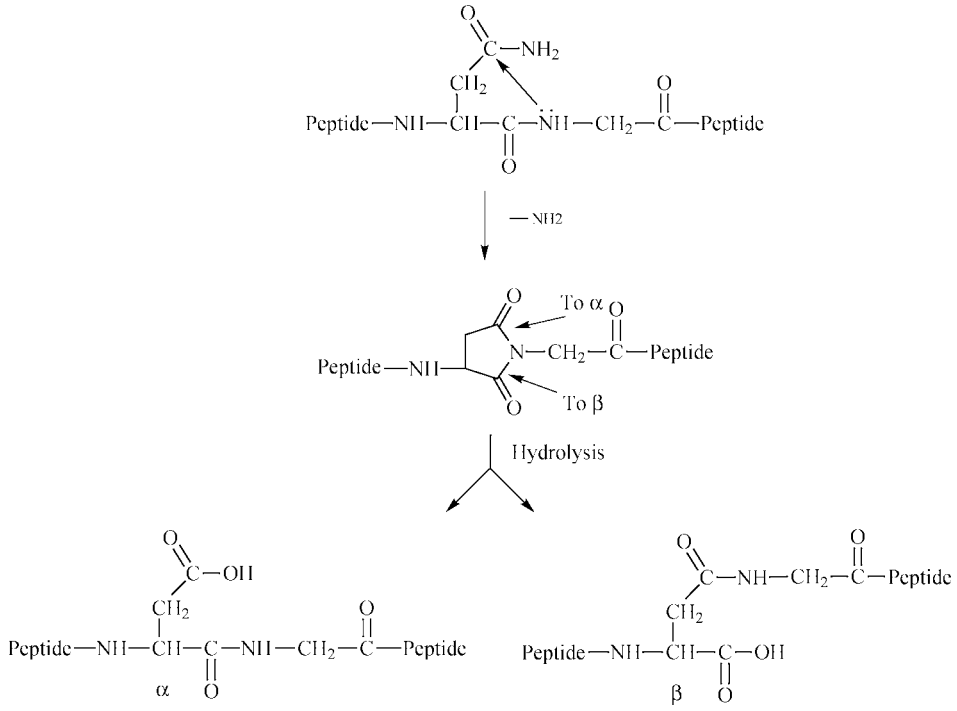

Fig. 7. Succinimide formation at the Asn–Gly sequence. The ultimate ratio of α/β peptides is determined by the thermodynamic stability of each sequence.

0.1% TFA commonly used for purification by preparative reversed-phase HPLC (174–176), or even if stored with residual acid in the solid state (177).

Acid-Sensitive Side Chains and Bonds. Trp is very sensitive to acidic conditions and to a lesser extent so is Tyr. Both can easily react with carbocations and activated molecular oxygen species. To avoid repeated exposure to acid, multiple-Trp–containing peptides are best synthesized by Fmoc strategies. Use of one of the cleavage cocktails listed in Table 10 during final cleavage is essential to avoid degradation of Trp and Tyr residues. Finally, the Asp—Pro bond is acid-labile, and Fmoc chemistries are recommended for peptides that contain this sequence (178).

Problems with Methionine and Cysteine. Sulfur-containing amino acids are susceptible to oxidation and alkylation. The cocktails of Table 10 will protect these residues during cleavage. Met is very susceptible to oxidation to methionine sulfoxide, Met(O), while standing in acidic solutions that contain dissolved oxygen. Low levels of this side reaction are very hard to avoid during HPLC purification of peptides that contain this residue. C-terminal-esterified Cys residues can be racemized by repeated piperidine deprotection treatments during Fmoc SPPS (179,180). This side reaction is manageable if the protecting groups of Table 3 are used. Alternatively, attachment of C-terminal Cys residues to the XAL handle (Table 5) via the side chain followed by chain elongation has been shown to prevent racemization (181). The use of either Trt or Xan side-chain protection also diminishes the formation of 3-(1-piperidinyl)alanine by-products (Fig. 8) that can be a serious side reaction with C-terminal Cys during Fmoc SPPS (181,182).

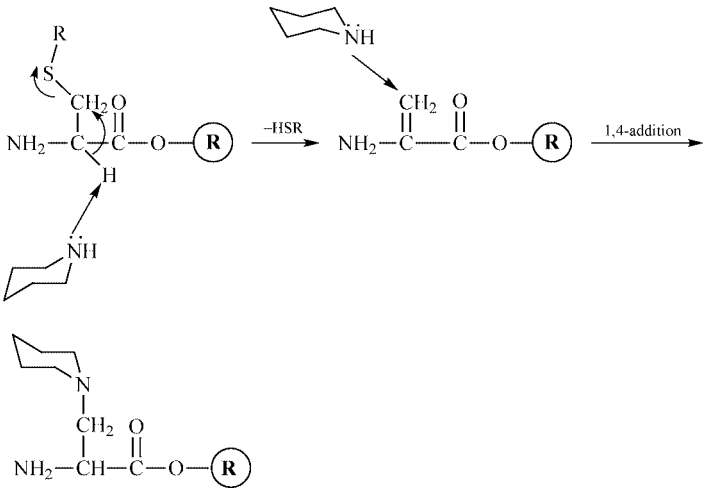

Fig. 8. Base–catalyzed elimination of C-terminal Cys residues attached to the resin via an ester linkage. 1,4-Addition of piperidine results in the formation of a 3-piperidinylalanine derivative, which can undergo chain elongation in subsequent cycles.

Prognosis

Solid-phase synthesis has evolved to where even the nonspecialist can easily make peptides of 50 amino acids or more in length. It is important to remember that each synthetic procedure has limitations, and that even in the hands of highly experienced workers, sequences will arise that defy facile preparation.

This article has touched on the key issues of chain assembly, cleavage, and purification. More challenging issues such as modification by phosphorylation (183–185), glycosylation, prenylation, and sulfation, are covered in References 20 and 186. The appendix contains strategies for finding synthesis apparatus, amino acid derivatives, resins, handles, and chemical reagents on the Internet. Research continues in other challenging areas such as disulfide bond formation, lactam cyclization, combinatorial methods, and improved reagents, handles, and resins. Finally, there is the exciting area of chemical ligation, where peptide fragments synthesized by the solid-phase method are chemoselectively condensed together to form proteins, of both natural and designed sequences (187–190). With the increasing number of peptide and protein targets identified by genomic sequencing, improvements in synthesis, and especially purification and isolation are needed to accelerate research in the field of proteomics (191–193). Thus, even now 45 years after the introduction of SPPS by Merrifield, much challenging and exciting work remains to be done.

Appendix

Solid-phase Peptide Synthesis and the Internet. The Internet contains many sites of interest for the peptide chemist. Since Internet addresses tend to regularly change, we have chosen to list terms that one can use in a search

engine rather than addresses. One should search the term contained in the quotation marks to find the specific site or topic of interest. Combining various parts of the terms in quotations while searching can make a search more accurate.

Peptide Societies. The first three societies have sites in English. The last three are in the native language of the respective country.

(1) "American Peptide Society"
(2) "Australian Peptide Society"
(3) "European Peptide Society"—The European Peptide Society Web site contains the best links to manufacturers of automated synthesizers and reagents for SPPS at the time of publication of this review
(4) "Chinese Peptide Society"
(5) "Japanese Peptide Society"
(6) "Korean Peptide Society"

General SPPS Information.

(1) "ABRF Peptide Synthesis Research Group"—This Association of Biomolecular Resource Facilities (ABRF) Web site contains summaries of difficult peptide syntheses attempted by its members. This is a good resource to see how various procedures actually work when used by practicing peptide chemists.
(2) "NRC peptide synthesis database"—This database, run by the National Research Council of Canada, contains a wealth of information about amino acid derivatives.

Consumables and Automated/Manual Synthesizers. Many manufactures of protected amino acids, resins, coupling agents, and automated/manual synthesizers exist.

(1) "Fmoc amino acids," "Boc amino acids," or "protected amino acids"—Trying either of these phrases will lead to the majority of the commercial amino acid vendors. Many of these vendors also sell resins and coupling reagents.
(2) "Solid-phase resins"—To find manufactures of resins for solid-phase synthesis
(3) "Solid-phase coupling reagents" or "peptide coupling reagents"—To find commercial sources for the coupling reagents of Figure 5
(4) "Solid-phase synthesis vessels," "Solid-phase synthesis glassware," "peptide synthesis vessels," or "combinatorial chemistry glassware"—To find reaction vessels for manual SPPS
(5) "Peptide synthesizers" or "Solid-phase synthesizers"—To find automated SPPS machines
(6) "HF apparatus"—This term will find the special all-fluoropolymer apparatus necessary for final cleavage with HF.

POLYSACCHARIDES

Introduction

Polysaccharides are naturally occurring polymers in which the repeat unit consists of monosaccharides linked through glycosidic linkages by a condensation type reaction; the example of cellulose is given in Figure 1. They exist in plants, animals, or microbial worlds where their roles as energy storage or structural materials or as source of biological activity are recognized. Many general books published can be taken into consideration (1–13).

Monosaccharides are most readily obtained from natural sources; in that respect D-glucose plays a central role in the biochemistry of carbohydrates.

In addition, because of the presence of —OH groups, natural polysaccharides may be modified by controlled chemical reaction to give derivatives with new specific properties; industrial derivatives are mainly obtained from cellulose (qv), starch (qv), and chitin and chitosan (qv). The presence of these —OH functional groups is also the origin of interaction with water molecules (hydrophilic character of oligo- and polysaccharides) and intra- and interchain H-bond network formation playing a role in reactivity control, swelling, or dissolution rate.

This article describes the structure of the principal polysaccharides from natural sources, some methods for their characterization, and some physical properties. Few derivatives are described and this article is extended to synthetic polymers having a sugar entity in the basic structure.

Carbohydrate Nomenclature

The international rules of carbohydrate nomenclature adopted by the International Union of Pure and Applied Chemistry and the International Union of Biochemistry have been published (14). A brief summary of the structural basis for naming oligo- and polysaccharides is given in the following.

Structure of Monosaccharides. Monosaccharides (general formula $C_n(H_2O)_n$) are the basic constitutional units of oligo- or polysaccharides. A monosaccharide is a polyhydroxycarbonyl compound classified as tetrose, pentose, hexose, etc, according to the number of carbon atoms in the molecule; a prefix indicates the nature of the carbonyl group which is an aldehyde or a ketone. Thus, aldohexose has six carbons and one end of the molecule (position 1) has an aldehydic group with a reducing character. If the reducing group is a ketone in the second position, a six-carbon chain is called a ketohexose (Table 1) (9,10).

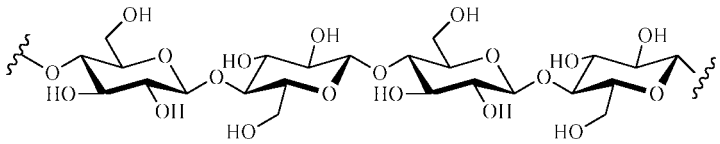

Fig. 1. Cellulosic chain formed from condensed D-glucose.

Fig. 2. The two tetrahedral representations of glyceraldehydes.

Configuration of Monosaccharides. Different representations were proposed to show the structure of the monosaccharide. The original Fischer representation allows description of different structures and especially demonstrates the chiral relation between monosaccharides, eg, that D-galactose is the C-4 epimer of D-glucose.

The chirality of monosaccharides is related to the presence of asymmetric carbon in the molecule; aldohexose contains four asymmetric carbons (see Table 1) and consequently 16 stereoisomers can be described.

The first member of the polyhydroxycarbonyl series is the aldotriose glyceraldehyde which contains one asymmetric carbon, and thus two stereoisomers. Figure 2 shows the two different molecules, which are mirror images of each other, in the tetrahedral representation with the asymmetric carbon in the center. The projection on a plane of these molecules corresponds to the Fischer representations (Fig. 3). Initially, one of the forms was found to be dextrorotary (+) and was named

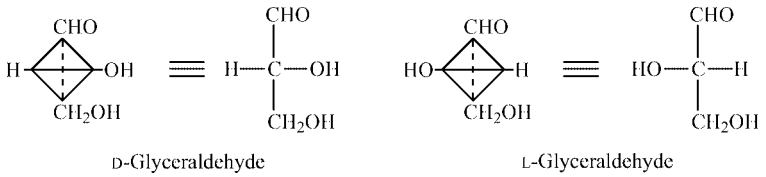

Fig. 3. Fisher projection of D- and L-glyceraldehyde.

D-glyceraldehyde; the other one was levorotary (−) and called L-glyceraldehyde. From the triose, in the Fischer representation, a series of stereoisomers are generated as indicated in Figure 4. The D-series refers to molecules in which the —OH on the last asymmetric carbon is on the right. The D- or L-identification does not mean that it is dextro (+) or levo (−) (Rosanoff convention). Physical investigation, later after Fischer, concluded that the D- and L-attribution represents the absolute configuration as demonstrated for (+)-D-glyceraldehyde. The majority of natural monosaccharides involved in polymeric systems belongs to the D-series.

Cyclic Conformation of Monosaccharides. The crystalline form of glucose was shown as cyclic (six-membered, oxygen-containing ring) from X-ray diffraction (15); infrared spectroscopy detects no carbonyl group, confirming a

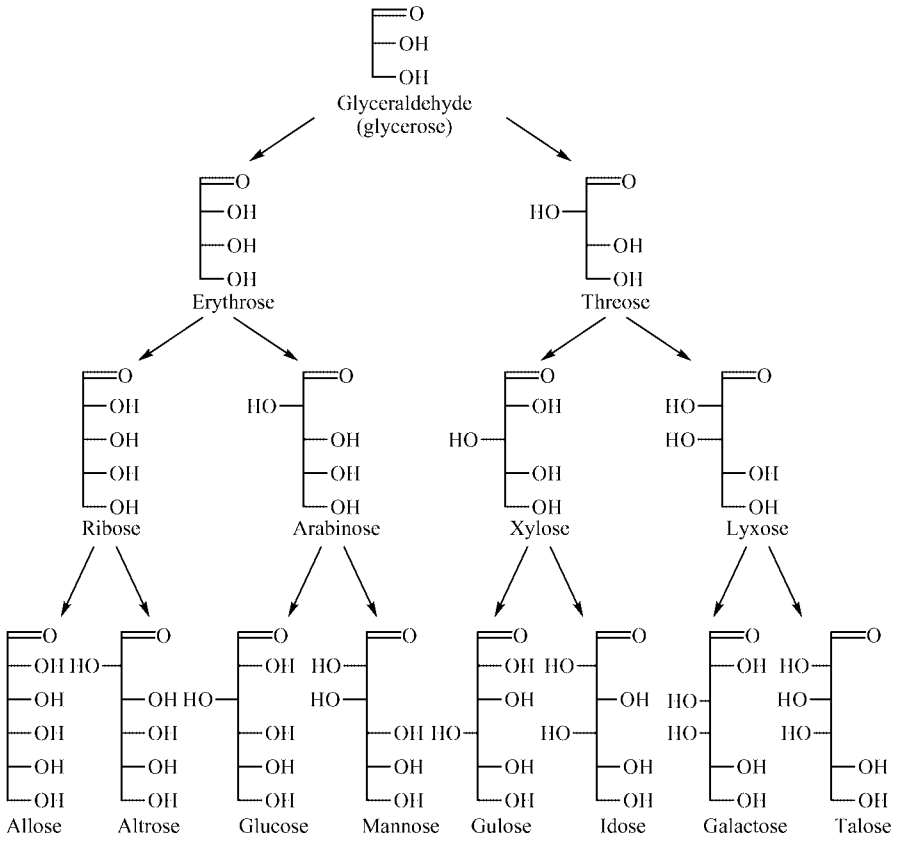

Fig. 4. Acyclic forms of D-aldoses in their Fischer projections.

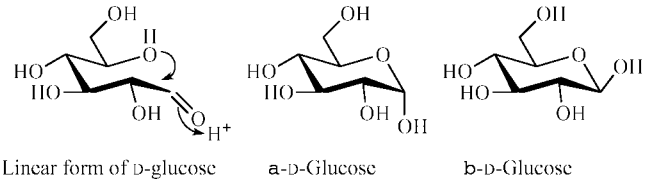

Fig. 5. Representation of the α- and β-cyclic anomers of D-glucopyranose.

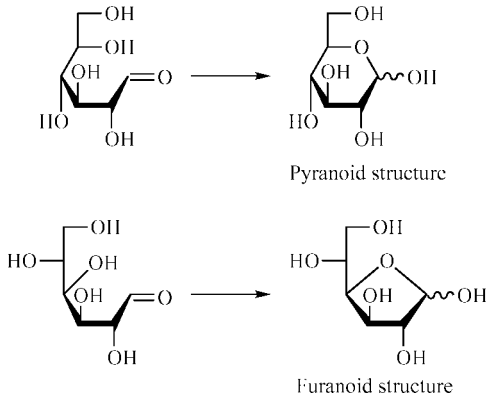

Fig. 6. Haworth representation of the cyclic forms (pyranoid and furanoid) of D-glucose.

cyclic hemiacetal structure. In the hemiacetalic form, the carbonyl carbon changes from sp^2 to sp^3 hybridization and thus becomes chiral with two anomeric forms (α and β) on carbon C-1 as shown in Figure 5. Among common hexoses, six-membered (pyranose) and/or five-membered (furanose) rings can be formed. Haworth introduced more realistic pictures of the cyclic forms (Fig. 6). The representation ~OH means that the two configurations α and β exist in equilibrium. For the D-series, the α-anomer has the hydroxyl at the anomeric center (position 1) downwards in the Haworth representation; the β-anomer is upwards.

Considering the six-membered ring, different conformations can be distinguished, taking as reference the cyclohexane. The favored conformations are chairs in the $^4C_1$ and $^1C_4$ conformations. The representation of α-D-glucose is

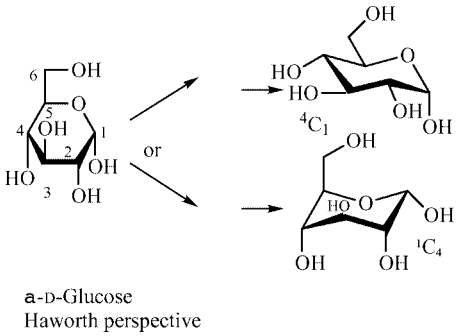

Fig. 7. Two chair conformations for α-D-glucose.

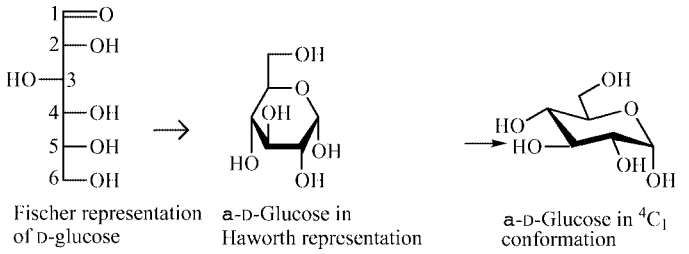

Fig. 8. The different representations for D- glucose in the α conformation for the cyclic form: (**a**) Fischer, (**b**) Haworth, (**c**) $^4C_1$ chair corresponding to the energy minimum.

given in Figure 7; the $^4C_1$ conformation, with all but the OH at C-1 in the equatorial orientation, is preferred compared with the $^1C_4$ conformation. In the α-D geometry, the anomeric hydroxyl (on C-1) is axial but it is equatorial in the β-D conformer.

For D-aldopyranose in general, the conformation $^4C_1$ is usually preferred. A summary of the different representations of D-glucose and the most probable conformation of α-D-glucose are given in Figure 8.

Mutarotation in Solution. In solution, equilibrium exists between the linear conformation and the two anomeric forms of pyranose and furanose cyclic hemiacetal forms (Fig. 9); the percentage of each form as well as the ratio α/β is characteristic of the monosaccharide considered.

A few values of the percentage at equilibrium are given in Table 2. Because of this equilibrium the reducing nature of the sugar is maintained.

^1H NMR in D_2O allows characterization of the anomeric contents in equilibrium after a short time at 25°C; an example is given in Figure 10: the H-1

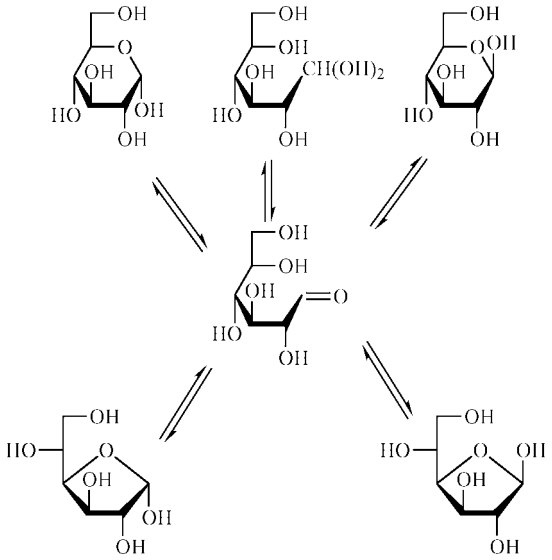

Fig. 9. Mutarotation in solution: representation of the different species in equilibrium for D-glucose (see Table 2).

Table 2. Conformation Equilibrium for Some Monosaccharides[a]

Sugar	$T_{°C}$	α-Pyran, %	β-Pyran, %	α-Furan, %	β-Furan, %	Acyclic, %
Arabinose	31	60	35.5	2.5	2	0.03
Glucose	31	38	62	—	0.14	0.02
Galactose	31	30	64	2.5	3.5	0.02

[a]Reference 10.

signal corresponding to the α-anomer is located at 5.12 ppm with a narrow doublet ($J = 3.7$ Hz) but the signal for the β-anomer is located 0.6 ppm upfield with a coupling constant $J = 7.9$ Hz. ^{13}C NMR also allows identification of the equilibrium in solution; in addition, no C=O signal is seen, confirming the cyclic configuration. The NMR characteristics given for D-glucose in water are recalled in Table 3 (16,17).

From this example, it is shown that the coupling constants and the location of the signals allow identification of the nature of the sugar and its configuration (16–19). The NMR technique is one of the most powerful tools for characterizing monosaccharides but also for establishing the structure of polysaccharides. The anomeric equilibrium only affects the reducing end of the chain; for a high molar mass, the spectrum is not perturbed by this effect and only one series of signals appears.

Uronic Acid and Other Monosaccharides. Formation of a uronoside requires the oxidation of the primary hydroxyl group of a hexopyranoside. This type of unit is very important in many natural polysaccharides such as alginates, pectins, or some hemicelluloses. Some important monosaccharides are represented in Figure 11.

Some chemical or enzymic methods are recognized to allow the specific oxidation of primary hydroxyls in the C-6 position. The TEMPO method applied to polysaccharides was used to oxidize the *N*-acetylglucoamine unit in hyaluronan (20); galactose oxidase was used to modify the galactose side groups in galactomannan (21,22).

Table 3. NMR Spectrum Characteristics of D-Glucose in D_2O

	H-1	H-2	H-3	H-4	H-5	H-6	H-6′

(**b**)

Fig. 10. ^{1}H and ^{13}C NMR spectra for D-glucose after a short time in D_2O at 25°C at 400 and 100 MHz respectively (low content of β-form).

Important monosaccharides are the amino sugars which have an amino group at any position other than anomeric carbon: 2-amino-2-deoxy-D-glucose or D-glucosamine also called chitosamine is the monomeric unit constitutive of chitosan, the polymer obtained by deacetylation of chitin which is based on the *N*-acetyl derivative of D-glucosamine (see Fig. 11). The sugar 2-amino-2-deoxy-D-galactose is found in dermatan and chondroïtin sulfate, constituents of mammalian tissues and cartilage.

Oligosaccharides. These oligomers result from partial acid or enzymatic hydrolysis of polysaccharides and they are prepared for structural analysis of polysaccharides. Few disaccharides exist naturally, or are produced by enzymes;

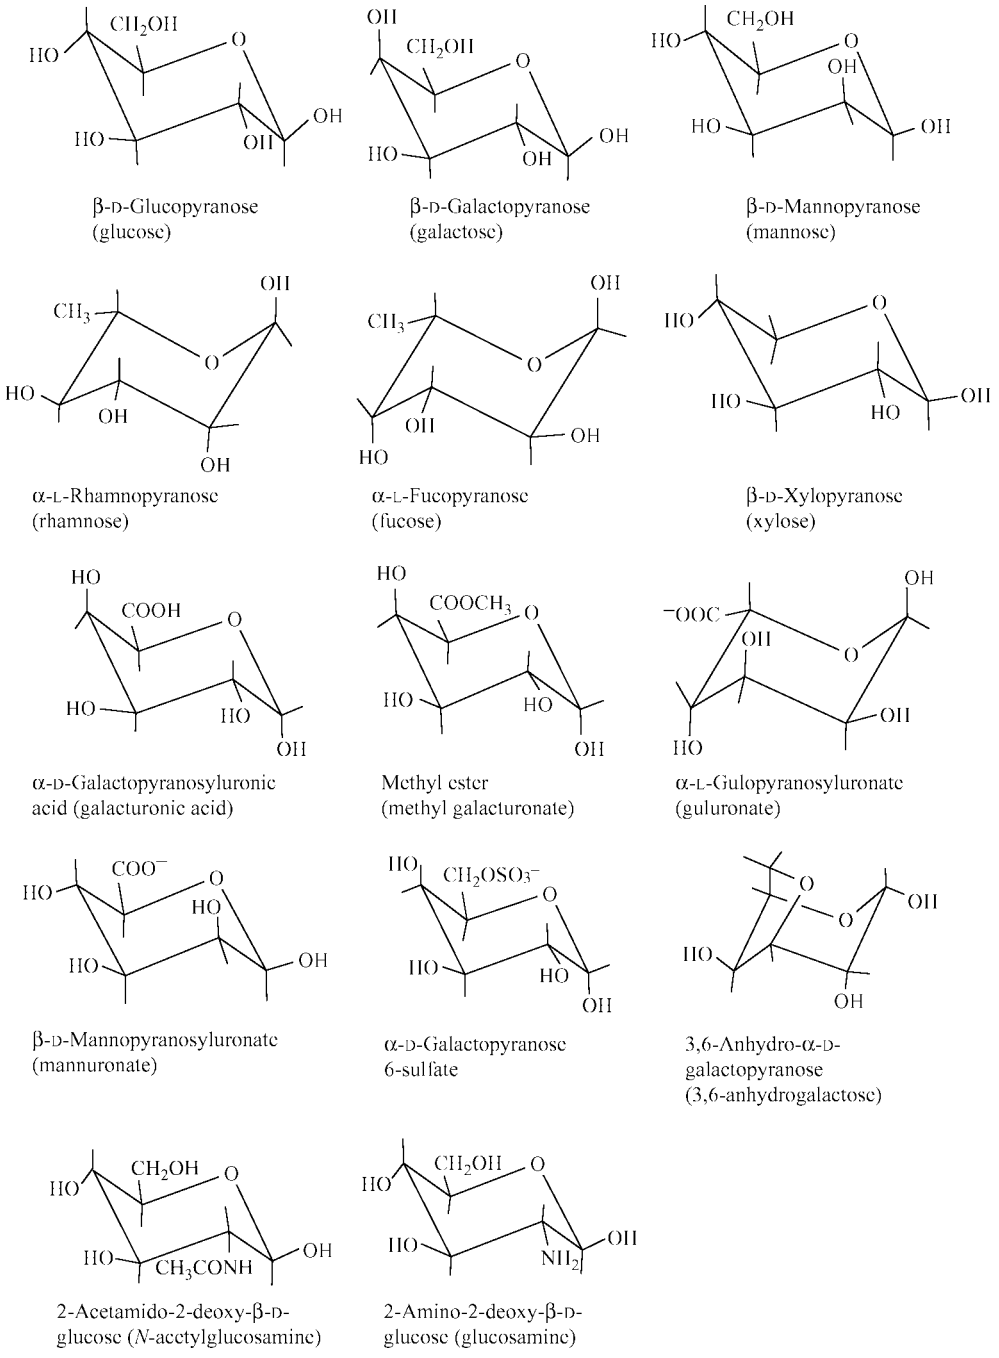

Fig. 11. Representation of some monosaccharides involved in most of the polysaccharides.

the linkage between two monosaccharides is an acetal bond also called an osidic bond. The acetal bond imparts a nonreducing character to the anomeric carbon. For common di- or trisaccharides, trivial names are normally used instead of systematic names. The nonreducing elements of an oligosaccharide are designated by the suffix -yl. In the case of nonreducing disaccharides the monomers are listed in alphabetical order.

Examples of reducing disaccharides are such as lactose and maltose. Lactose occurs in milk of mammals and is named systematically as β-D-galactopyranosyl-(1→4)-D-glucopyranose or 4-*O*-β-D-galactopyranosyl-D-glucopyranose and abbreviated Gal*p*-β-(1→4)-Glc (the italic *p* indicates the pyranoid form). Maltose, obtained by hydrolysis of amylose, is named (4-*O*-α-D-glucopyranosyl-D-glucose or α-D-glucopyranose-(1→4)-D-glucose). The -ose suffix in the systematic name denotes a reducing disaccharide, eg, one with one anomeric carbon in a hemiacetal form. Sucrose or saccharose is a nonreducing disaccharide. It is extracted from sugarbeet or sugar cane, is named β-D-fructofuranosyl-α-D-glucopyranoside, and abbreviated as β-D-Fru*f*-(2↔1)-α-D-Glc*p*. The biosynthesis and structure of disaccharides are developed in Reference 11. The -ide suffix denotes a nonreducing disaccharide wherein both anomeric carbons are in the acetal linkage.

In Figure 13, the ^{13}C NMR spectra of cellobiose (β-D-Glc*p*-(1→4)-D-Glc) (Fig. 12**a**) and maltose (α-D-Glc*p*-(1→4)-D-Glc) (Fig. 12**b**) are given; the anomeric equilibrium of D-glucose at the reducing end is demonstrated (23); the signals corresponding to the C-1 of the nonreducing D-glucose (indicated as ′) are located at a different chemical shift depending on the anomeric configuration: C-1′β is at 105.3 ppm (cellobiose) but C-1′α is at 102.5 ppm (maltose) (in D_2O at 60°C). NMR spectroscopy data are given in the literature for mono- and oligosaccharides (16–19).

Cyclodextrins (qv) represents a series of cyclic α-(1→4)-linked D-glucopyranose oligomers obtained by enzymic degradation of starch using a cyclodextrin glucotransferase (11). The most common cyclodextrins are called α, β, γ cyclodextrins with 6, 7, 8 sugars respectively resulting in intrasaccharide α-1,4-glycosidic bonds.

They have a toroïdal structure with hydrophilic exteriors and a hydrophobic cavity in which hydrophobic organic compounds can be trapped.

They are used to stabilize vitamins against temperature or increase solubility of pharmaceutical products. They also show an interesting selectivity in relation with the dimensions of the cavities (Fig. 13).

Fructosans are oligomers or polymers of β-D-fructofuranose and belong to the inulin-type ((2→1)-β-linked) or to the phlein-type (2→6 linked); inulin oligomers are found in Jerusalem artichoke or dahlia tubers where they are carbohydrate reserves. They are usually low molecular weight polymers (degree of polymerization, DP $\leq$ 50). The high yield in fructosans in Jerusalem artichoke may be considered as a source of fructose for the food industry. The juice extracted from grounded tubers was isolated and studied by liquid chromatography (HPLC). The oligosaccharide distribution was obtained by size exclusion chromatography (SEC) and by normal-phase HPLC (24–29). After separation of the different constituents and NMR analysis, it is concluded that the juice consists of an oligomer series formed of oligo-β-fructofuranosyl units (2→1) ended by one α-D-glucopyranosyl unit (Fig. 14).

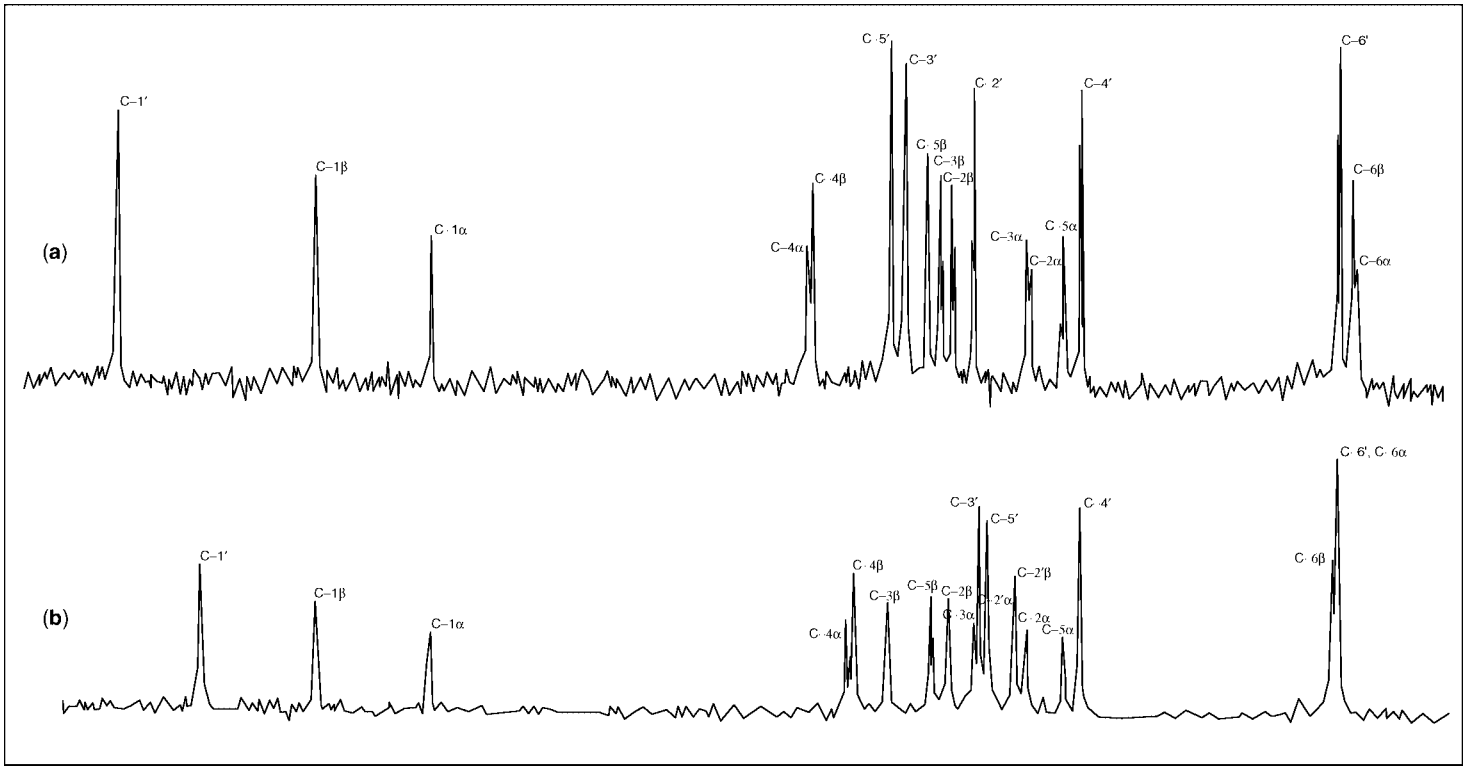

Fig. 12. ^{13}C NMR of (**a**) cellobiose and (**b**) maltose at 60°C in D_2O at 62.86 MHz. The anomeric equilibrium is clearly observed on the C-1 position. Reproduced from Ref. 23, with the permission of John Wiley & Sons (Copyright 2003).

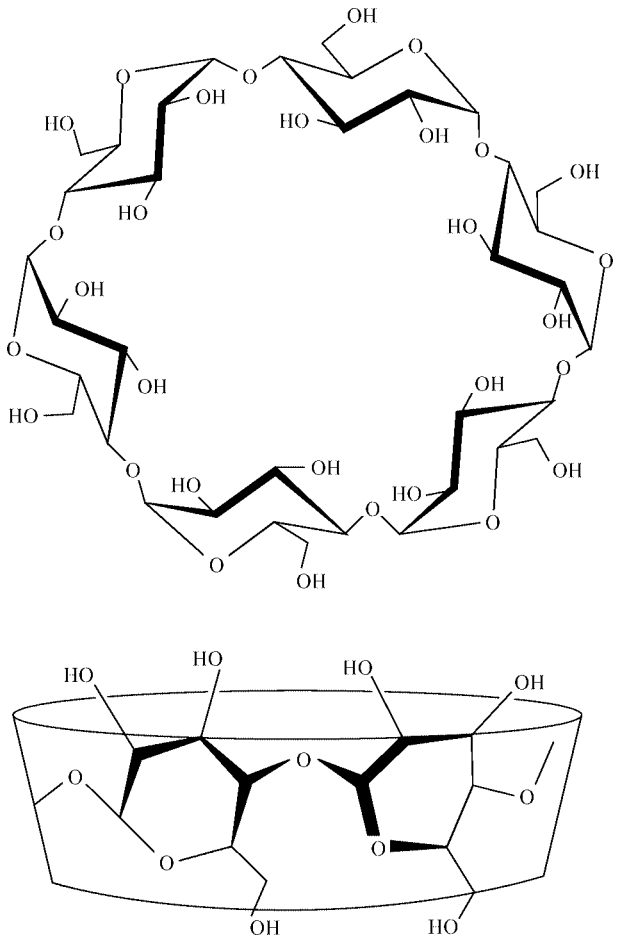

Fig. 13. Representation of the α-cyclodextrin (six glucose units) in the cyclic and toroidal forms showing the hydrophobic cavity and the hydrophilic faces.

Oligosaccharins. It has been demonstrated that specific oligosaccharides are used to control biological processes in plant. Albersheim who was a pioneer in this work recognized that specific oligosaccharide components of plant cell walls (named oligosaccharins) can have biochemical activity which results in regulatory response (30). α-(1→4)-linked D-galacturonic acid oligosaccharides obtained from pectins have regulatory effects on plant growth and development.

In connection with the biological activity of mono- and oligosaccharides, it is important to mention plant lectins: lectins are proteins possessing at least one noncatalytic domain which binds reversibly to specific mono- and oligosaccharides (31,32); lectins are carbohydrate-binding (glyco)proteins of nonimmune origin capable of specific recognition of carbohydrates and reversible binding to them, without altering their covalent structure. Many of plant-based food ingredients contain lectins, some with striking biological activities.

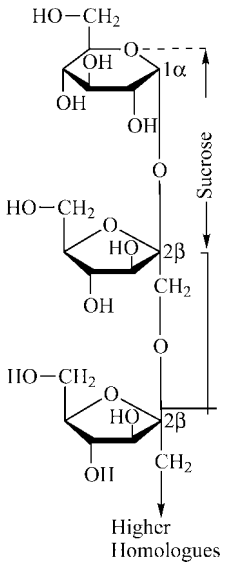

Fig. 14. Fructans, as reserve polysaccharides, from the inulin-type like in Jerusalem artichoke.

Glycans. The generic name for polysaccharides is glycan using the suffix "an." The names of polysaccharides should be D-glucan, or D-mannan for homopolymers constituted of D-glucose or D-mannose respectively. Certain historic names have been retained such as cellulose (β-(1→4)-D-glucan) or amylose (α-(1→4)-D-glucan). The homopolymers are also named homoglycans, whereas polysaccharides composed of two or more monosaccharides are named heteroglycans. An example is given with the bacterial polysaccharide called Fucogel® based on a trisaccharide repeating unit:

$$3)\alpha\text{−L−Fuc}p\text{−}(1\rightarrow3)\text{−}\alpha\text{−D−Gal}p\text{−}(1\rightarrow3)\text{−}\alpha\text{−D−Gal}p\text{A−}(1\rightarrow$$

in which the sequence, the name of the constitutive sugars, the type of bonds, and the configuration are all given (33). A labile acetyl substituent was located on the Gal*p*A unit.

Single words such as xylans or mannans may also be used to refer to related groups of polysaccharides without implying that they are homopolymers. The name xylan is used for arabinoxylan and glucuronoarabinoxylan, heterogeneous polysaccharides found in plants. The term mannan is used for glucomannan, galactomannan, and galactoglucomannan.

The extract from a natural source is often a mixture of different polymers, especially from plant sources; the extract must be fractionated but each fraction still contains molecules with minor structural features (partial acetylation or length of side chains). The fraction is polydisperse in molecular structure; the difference in local structure is also termed the microstructure.

Bacterial polysaccharides produced by a specific strain are usually perfectly homogeneous; the only difference between molecules being in the DP (or the

molecular weight); the sample is characterized by the *polydispersity index*, which is defined as the ratio between the mass-average molar mass (M_w) and the number-average molar mass (M_n) (34) (see MOLECULAR WEIGHT DETERMINATION).

Molecular Modeling

The physical and biological properties of macromolecules depend on their three-dimensional structures. Knowledge of the different stable conformations is required to better understand and to predict their behavior in different environments. This knowledge is also important to control and modify the role played by these macromolecules in recognition and interaction processes. Conformational data can be obtained by both experimental and computational methods. Experimental studies give data that are often incomplete, dependant on conformational equilibra or specific for a frozen state. An alternative method is molecular modeling where results depend unfortunately on human decisions. However, conjunction, these two approaches lead to a good understanding of the three-dimensional arrangements of the studied molecule.

Monosaccharides. Most of the monosaccharides exist as pyranose rings. The most stable conformation of such six-membered ring systems is usually one of the chair forms (C). In principle the pyranoid ring can also adopt energetically less favorable conformations. Six different skew conformers (S) separated by six different boat conformers can be identified on the pseudorotational itinerary (35). Three puckering parameters define unambiguously the position of the individual forms of the pyranoid ring on the conformational sphere (Fig. 15), Q is the maximum puckering amplitude, the parameters θ and ϕ are angles in the range $0^\circ < \theta < 180^\circ$ and $0^\circ < \phi < 360^\circ$, and can be thought as polar and azimutal angles for a sphere of radius Q. The two poles $\phi = 0^\circ$ and 180° represent the energy wheels of the chair conformations; $^1C_4$ and $^4C_1$.

All 12 flexible forms are located at the equator. In unsubstituted cyclohexane, the two chair forms are the prominent species. Substitution of heteroatom in the ring and addition of hydroxyls or other exocyclic substituents further stabilize or destabilize ring conformers in reference to cyclohexane. As a general rule, the equatorial position of bulky substituents would be preferred because of 1, 3 *syn–diaxial* interaction that causes steric clashes. The $^4C_1$ of glucopyranose having all ring substituents in the equatorial position is preferred to the $^1C_4$ conformer in which all the substituents are in axial orientation. However, at high temperature conformational transition to this form can arise spontaneously as demonstrated by the formation of levoglucosan (1,6-anhydro-β-D-glucopyranose). Besides, the α-L-iduronate ring, which is a constituent of the glycosaminoglycans (heparin, heparan sulfate, and dermatan sulfate), shows conformational mobility. Three forms, namely $^1C_4$, $^2S_0$, and $^4C_1$, of this ring have been suggested to be responsible for the biological activities of these compounds.

Very important furanose molecules (five-membered rings) are commonly found in nature. For example, D-ribose and D-deoxyribose are found as the building units of nucleic acids, and fructose is a constituent of sucrose. These rings are not planar, either one (envelope form) or two (twist form) atoms are out of the plane containing the others. The different envelope and twist conformations

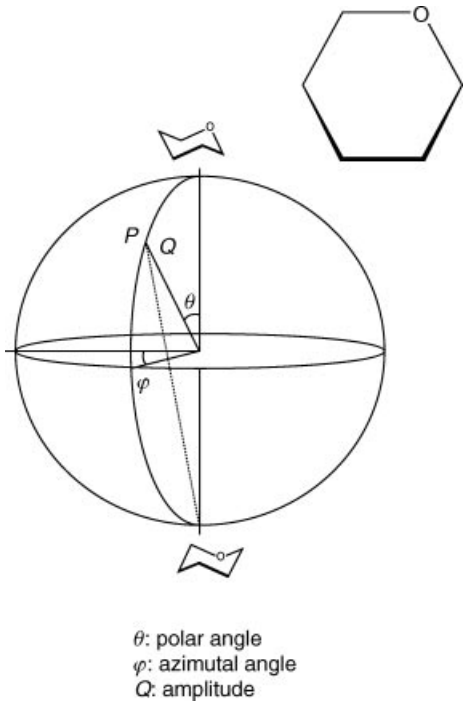

Fig. 15. Pseudorotation sphere of pyranoid rings.

are of similar energy, and the barrier to their interconversion is small, therefore mixtures of different conformations are expected in solution. The different conformations of the furanoid ring are described by a pseudorotation circle (Fig. 16). Two puckering parameters are needed to define a conformation for those rings, the puckering amplitude ν and the phase angle P (35).

Several low energy conformations are accessible for the primary hydroxyl exocyclic groups. The energies of the different ring conformations are affected by the orientations of the hydroxymethyl group. This group usually exists in three staggered positions called *gauche–gauche*, *gauche–trans*, and *trans–gauche* (Fig. 17).

In this terminology, the torsion angle ω(O-5—C-5—C-6—O-6) is stated first, followed by the torsion angle ω'(C-4—C-5—C-6—O-6). It is known from crystallographic studies, NMR measurements, and theoretical calculations that the conformational equilibrium around the C-5—C-6 bond in aldopyranoses depends significantly upon the configuration at C-4. For the "gluco" configuration (O-4 equatorial) the *trans–gauche* is high in energy and the remaining two conformations are almost equally populated, while the *trans–gauche* and *gauche–trans* positions are preferred for those having a "galacto" configuration (36).

The secondary hydroxyl groups undergo almost free rotational transitions. All these hydroxyl groups can participate in the creation of hydrogen bonds. As a result of the many possible orientations of such groups, prediction of the hydrogen bonding network is a difficult task. Most carbohydrates offer an exceptionally

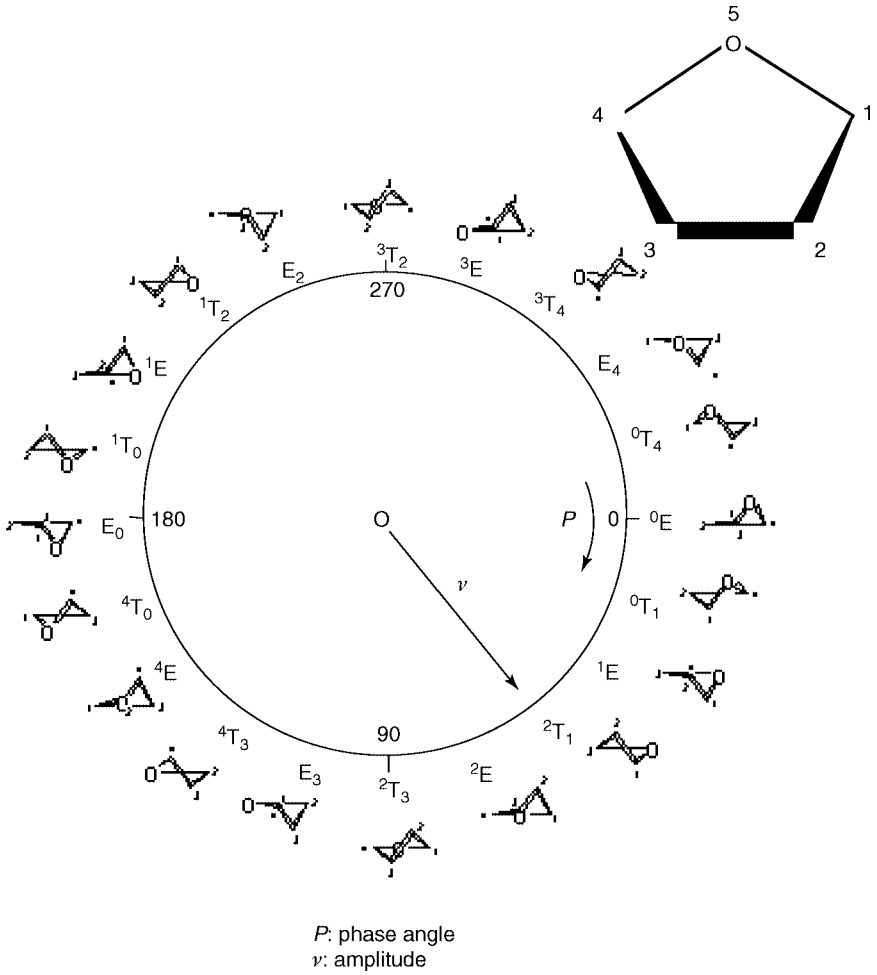

Fig. 16. Pseudorotation wheel of furanoid rings.

high ratio of hydroxyl groups per saccharide residue. Such a hydrogen-bonding potential is satisfied by association with neighboring carbohydrate molecules, glycoproteins, or surrounding water molecules.

Anomeric Effect. The anomeric effect describes the axial preference for an electronegative substituent of the pyranose ring adjacent to the ring oxygen, whereas the exo-anomeric effect describes the rotational preference of the glycosidic C-1—O bonds (37). These stereoelectronic effects are of general importance for all molecules having two heteroatoms linked to a tetrahedral center. Survey of X-ray crystallographic data reveals that these effects have geometrical consequences. The most obvious feature of the experimental data on both the α and β configuration is a marked difference in the molecular geometry around the acetal group. By way of example, in the axial configuration one observes a general shortening of the C-1—O-5 bond, a lengthening of the C—O-*X* bond (for a 1→*X* linkage), and an increase in the O-5—C-1—O-*X* bond angle value. Molecular orbital

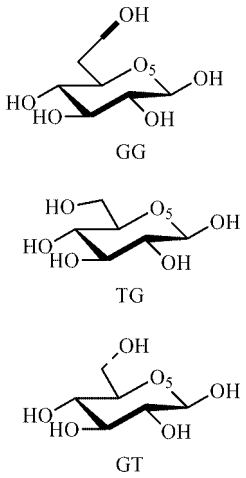

Fig. 17. The staggered orientations of the hydroxymethyl group. GG = *gauche–gauche*; GT = *gauche–trans*; TG = *trans–gauche*.

theory accounts for these observations. The magnitude of the anomeric effect varies with the nature of the electronegative group, the polarity of the solvent, and the location of the other substituents in the molecule.

The exo-anomeric effect influences the rotations around the glycosidic C-1—O bond and is therefore important in determining the relative orientations of saccharide units in carbohydrate chains. The exo-anomeric effect is a balance between electronic and steric effects. The three staggered orientations for rotation about the glycosidic bond are not equivalent; the exo-anomeric effect causes preference for the +*synclinal* orientation of the aglycone group in the α series and −*synclinal* for the β series (see Fig. 18 for the definition of the torsion angle domains).

Disaccharides. Monosaccharides can be condensed to produce oligomeric structures through glycosidic bond formation. Water is eliminated between the anomeric hydroxyl and any one of the hydroxyls of a second monosaccharide or oligosaccharide. The glycosidic linkage is constituted by two bonds, the glycosidic C-1—O-*X* and the aglycone O-*X*—C-*X*. In the case of (1→6) linkages between two pyranosic units, three bonds connect the successive sugar rings.

The low energy conformers of a disaccharide can be estimated using molecular mechanics. The conformational parameters that occur for a simple disaccharide are as follows:

OH rotation	7 torsion angles
CH_2 OH rotation	2 torsions
Aglycone rotation	1 torsion
Glycosidic bond	2 torsions
Puckering	6 variables

If we assume three minima that should be explored for each variable, there are 3^{18} combinations to consider, far beyond the available computer resources.

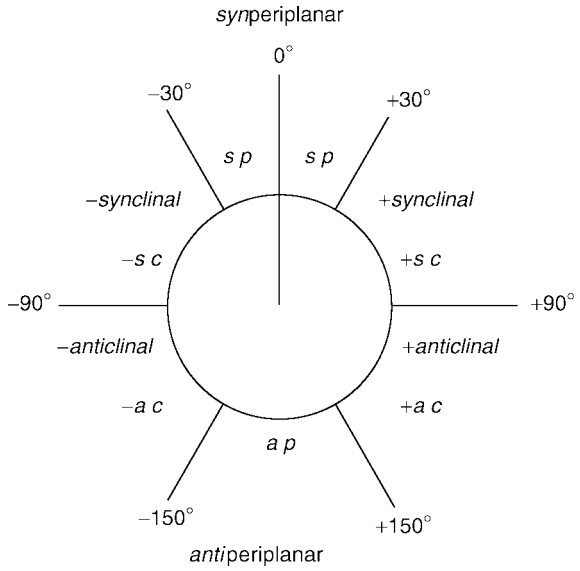

Fig. 18. Definition of angle domains.

It is therefore important to recognize that the global shape of a disaccharide depends mainly on rotations around the glycosidic linkages, because the flexibility of the pyranose ring is rather limited and the different orientations of the pendant groups do not participate in the description of the backbone trajectories. The relative orientations of saccharide units are therefore expressed in terms of the glycosidic linkage torsional angles Φ and Ψ which have the definition $\Phi =$ O-5—C-1—O-X—C′-X and $\Psi =$ C-1—O-X—C′-X—C′-$(X + 1)$ for a $(1\rightarrow X)$ linkage. The Φ,Ψ space is then explored in a systematic fashion. Both torsions are sequentially rotated in small increments over the full 360° range. At each point on the grid, energy contributions calculated from the force field in use are evaluated. It is then possible to represent the energies of all the conformations available as a contour map in the Φ,Ψ space. These contour maps enable graphical description of energy change as related to the relative orientation of the monosaccharides; this is a three-dimensional cross section of the complex conformational space of disaccharides. They indicate the shape and position of minima, the routes for interconversion between conformers, and the heights of the transitional barriers. Among the many different methodologies for calculating contour maps, adiabatic procedures are now widely accepted. In such procedures, the strain produced by steric interactions inherent from rotation of monosaccharide residues is relieved by the inclusion of bond length and angle adjustment in the form of minimization, with respect to all degrees of freedom of the system (except Φ,Ψ), at each point of the space. However, as minimization will only lead to conformations "downhill" from the starting structure, the torsional dimension where most conformational variation occurs is limited to only one orientational well. It is possible that rotation of pendant groups over torsional barriers could produce lower energy conformations at that point in Φ,Ψ space. Ideally at each point in Φ,Ψ space investigation of all possible combinations of pendant group orientations is required. Adiabatic

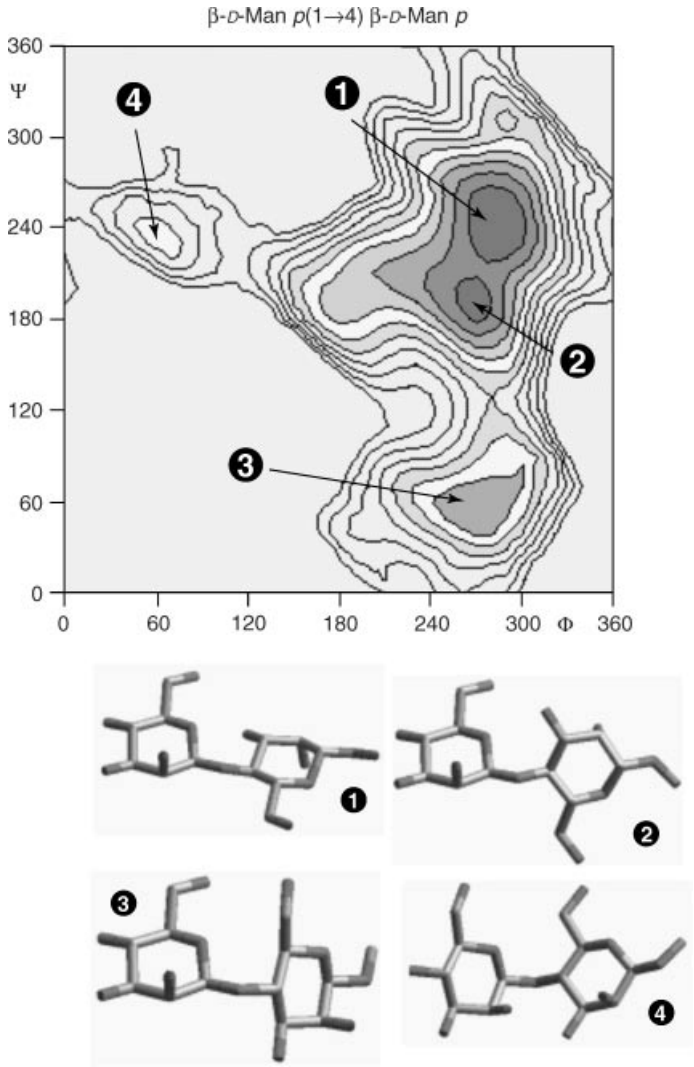

Fig. 19. The potential energy surface of mannobiose.

maps attempt to represent the lowest energy of all possible pendant group orientations at each point in the Φ,Ψ space. An example of an adiabatic map is given in Figure 19.

Solvation. It is important to recognize that most procedures are designed to treat molecules in the isolated state. Omission of the effect of the environment from the calculation results in a neglect of the fraction of the energy contribution that arises from these interactions.

Several different approaches have been proposed to treat solvation effects (38). In the simplest one, the effect of the solvent is achieved by increasing the dielectric constant for calculations of electrostatic interactions or by the use of a distance-dependant dielectric constant. Another possible way is to explicitly

include a limited number of solvent molecules in the calculation. By way of example, in aqueous solution the potential importance of hydrogen bonding and the great strength and directionality of hydrogen bonds requires explicit consideration of the water molecules surrounding the solute. An example obtained on maltose–water interaction is given in Reference 39. To account for such a solvent effect, molecular dynamics with the inclusion of explicit water molecules around the carbohydrate can be used. An alternative approach is to treat the solvent as a dielectric continuum. The conformational free energy of a given conformer in a particular solvent may be described as arising from the contribution of the energy of the isolated state and the solvation free energy. The latter is evaluated from the continuum model and is partitioned into cavity, electrostatic, and dispersion contributions.

Probing Potential Energy Surfaces. The accuracy of the predicted potential energy surfaces has to be evaluated. Indeed, many observable properties of oligosaccharides can be calculated and have been shown to be sensitive to the details of the conformational energy surface. Many crystal structure determinations of carbohydrates, nucleosides, and nucleotides are available in the Cambridge Crystallographic Database. X-ray analysis gives the best data for the conformation of an oligosaccharide. Precise atomic coordinates are provided, along with an explicitly defined environment. Comparisons with crystal structures are among the most precise test of modeling available for carbohydrate molecules, provided that packing forces are taken into account. These surveys of crystalline conformations are indicative of the structural variations and the conformational flexibility that the glycosidic linkages exhibit in the solid state.

In solution, the method of choice to study the three-dimensional structure of saccharides is NMR, through the parameters represented by chemical shifts, coupling constants, nuclear Overhauser effects (nOe), and also relaxation time measurements. Although the conformational dependence of the carbon chemical shifts is far from understood, coupling constants can be used to evaluate the magnitude of the torsion angles, and nOe measurements can provide estimations of distances between protons located in rather close proximity. In addition, relaxation time measurements give information on the mobility and the behavior of molecules in solution.

Three bond coupling constants provide a source of information with regards to torsional angles about the bonds. They can be interpreted by trigonometric formulas with suitable parameters derived from empirical studies on model compounds. $^{3}J_{\mathrm{H-H}}$ coupling constants allow the extraction of information about the sugar ring pucker. For the exocyclic group of pyranose, the vicinal coupling constants between H-5 and H-6 define the torsional angle about C-5—C-6, provided that the stereospecific assignment of the two H-6 protons is possible. The relative magnitudes of the coupling constants, $^{3}J_{\mathrm{H5-H6}}$ and $^{3}J_{\mathrm{H5-H6'}}$ can be used to determine the distribution of conformers about the ω angle in the case of (1→6)-linked pyranoses. As for the torsional angles Φ and Ψ about the glycosidic linkage, only heteronuclear coupling constants $^{3}J_{\mathrm{C-H}}$ and $^{1}J_{\mathrm{C-H}}$ can be used, and empirical trigonometric formulas relating $^{3}J_{\mathrm{C-H}}$ to torsional angles have been proposed. The angular dependence that incorporates the solvent effects of $^{1}J_{\mathrm{C-H}}$ have been established in α- and β-oligosaccharides (40,41).

The nOe data may be obtained by either one- or two-dimensional methods. These through-space effects may be used to estimate internuclear distances. However, nOe cross-peak volumes are inversely proportional to the sixth power of the distance between the correlated protons only in the case of rigid spherical molecules whose tumbling is isotropic. The simplest method that has been proposed for the interpretation of nOe-derived distance data is the "isolated spin pair approximation." The matrix treatment is more rigorous, although relying also on several approximations. A set of equations describing the cross-relaxation pathways of all the protons in the molecule is cast into a matrix form and solved.

All these NMR parameters represent average values, because of the acknowledged flexibility of carbohydrates and of all the rapidly interconverting conformations accessible to the molecule on the NMR time scale. This means that a straightforward interpretation of experimental data leads only to the definition of a "virtual conformation" without real physical meaning. Conformational averaging based on the abundances of the predicted structures gives averaged values which can be compared safely to the experimental ones.

The Disordered State of Polysaccharides. The polysaccharide chains in solution tend to adopt a more or less coiled structure. Such a dissolved coil would fluctuate between local and overall conformations. Polysaccharides are able to assume an enormous variety of spatial arrangements around the glycosidic linkages because these molecules have extensive conformational freedom; they may sample a large part of the space around the glycosidic and aglycone bonds. Theoretical polysaccharide models are based on studies of the relative abundance of the various conformations, of a given polysaccharide, in conjunction with the statistical theory of polymer chain conformation (42). Possible interactions between residues of the polysaccharide chain that are not nearest neighbors in the primary sequence of the polymer are ignored.

The Monte Carlo sample then reflects the number of conformations of polymer molecules. This means that observable parameters describing the solution behavior of polysaccharides are averages of the properties of individual conformations. This approach yields properties corresponding to the equilibrium state of the chain. Results refer to a model for an unperturbed chain that ignores the consequences of the long range excluded volume effect, because only nearest-neighbor interactions are accounted for in the computation of the Φ,Ψ surfaces.

Given a sufficient Monte Carlo sample of unperturbed polysaccharide chains, it is possible to assess many mean properties of the polymer in question simply by computing unweighted arithmetic averages over the chains of the sample. For example, the mean-square end-to-end distance, the average square radius of gyration, the mean persistence length, and dipole moment, are all average geometric properties readily computed from a knowledge of the coordinates of the atoms or atomic groups making up the Monte Carlo sample.

Models of polymer chain extension were first used to compare the effect of the glycosidic linkage geometry of simple polysaccharide chains, eg cellulose and amylose (43). Both polymers are 1,4-linked glucans; the only difference is in the anomeric configuration on the C-1 atom of the monomeric unit, α for amylose and β for cellulose. The calculated data show a remarkable pseudohelical chain

trajectory of the amylosic chains, the characteristic ratio of 5 denotes a moderately compact chain configuration. This behavior seems to be the consequence of the glycosidic bond geometry because changing this geometry from the α to the β configuration has a dramatic effect on the character of the chain trajectory. Relative to amylose, the cellulosic characteristic ratio of 100 is an increase of a factor of 20. This reflects the extended character of the cellulosic chains. Investigation of the solvent effects on those two representative polysaccharides has also been carried out (44). In good concordance with the experimentally observed solvent dependence, significant changes in the unperturbed chain dimensions were found; the characteristic ratio is larger in water than in vacuum for amylose, whereas for cellulose it is smaller.

The answer to the question of how reliable is the predicted conformational behavior of the polysaccharide chains lies again in the comparison of theoretically and experimentally measured properties. A few examples were analyzed (chitin, chitosan, hyaluronan, galactomannan) and the local stiffness of the chain reflected by the persistence length L_p has been compared with the value obtained experimentally using multidetection SEC (45–47).

Molecular Structure

The polymer may be linear (such as hyaluronan) (Fig. 20**a**) or branched with a long side chain (as in xanthan) (Fig. 20**b**) or with many short chains or monosaccharide side groups (as in galactomannan) (Fig. 20**c**) or branched with side chains themselves branched giving rise to a tree-like structure (as in amylopectin) (Fig. 20**d**).

The determination of the structure is a very difficult task especially in heteroglycans. The structure must be established on a pure sample isolated from its natural source with a minimum degradation.

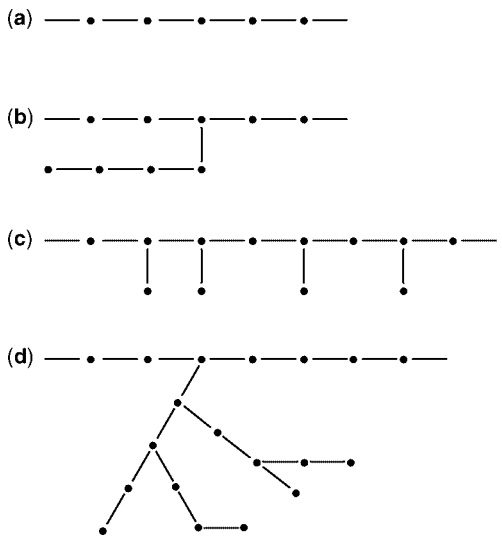

Fig. 20. Structural patterns of polymer chains.

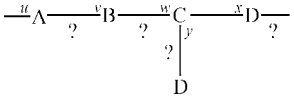
Considering the repeat unit of a polysaccharide represented by the scheme,



the answers to the different following questions are required:

(1) What is the nature and relative proportion of the A, B, C, D monosaccharides involved in this oligomer, including ring size and their configuration (D- or L-)?
(2) At which positions (u, v, x) are A, B, D engaged in the osidic linkage and what is the anomeric geometry (α or β) of each glycosidic linkage ?
(3) Unit C is substituted at w and y positions but which position corresponds to the attachment of the side chain and which to the main chain linkage?
(4) Which is the exact sequence of the four sugars in the repeat unit?

The general methods are reviewed in many books (3) and in this article only general overview will be given.

If there are any substituents on the rings as is frequent in plant or bacterial polysaccharides (acetyl, pyruvyl, succinyl groups), they must be located on a specific position, but often they are labile in acidic or mainly basic conditions and the structure determination becomes even more difficult.

Extraction–Purification. Purification of polymeric molecules is often easier than for small molecules. It is relatively easy to separate small (impurities) from large molecules on solubility criteria, gel filtration, or by dialysis.

If the polymer is water soluble as in exocellular bacterial polysaccharides, it is often a polyelectrolyte (containing uronic acid); it can be precipitated using a nonsolvent such as ethanol or 2-propanol (in a ratio around 1:1 water/alcohol) after clarification of the extract by filtration and addition of monovalent salt excess to exchange the multivalent counterions. The presence of bivalent counterions left in the sample will prevent resolubilization after drying. For a strongly interacting polymer with calcium (such as pectin) the use of oxalate as chelating agent is useful.

Before extraction of polysaccharides from plants or woods, it is recommended

(1) to extract these materials with organic solvents (toluene, chloroform, methanol, etc) to remove pigments, waxes, or oils;
(2) then, to eliminate Lignin (qv), a highly cross-lilnked polyaromatic compound, by chemical treatment (chlorite, ozone, sulfite, etc).

For neutral polymers (cellulose being excluded), extraction can be performed using DMSO (48), *N*-methylmorpholine *N*-oxide (49), NaOH, or KOH at different concentrations. Over pH 12, alcoholate is formed on the —OH groups, increasing the solubility of polysaccharides. When hemicelluloses have to be extracted from a plant source, KOH 24% or NaOH 18% are often used; these hydroxides produce

swelling of the cellulosic matrix by rupturing hydrogen-bonding associations, allowing better diffusion of other polymers (50).

The extract may contain different polysaccharides and it is useful to resolubilize this material after first purification and to perform SEC in addition to ion-exchange chromatography before establishment of the structure. This allows separation of fractions with different average molecular weights and different average charge densities.

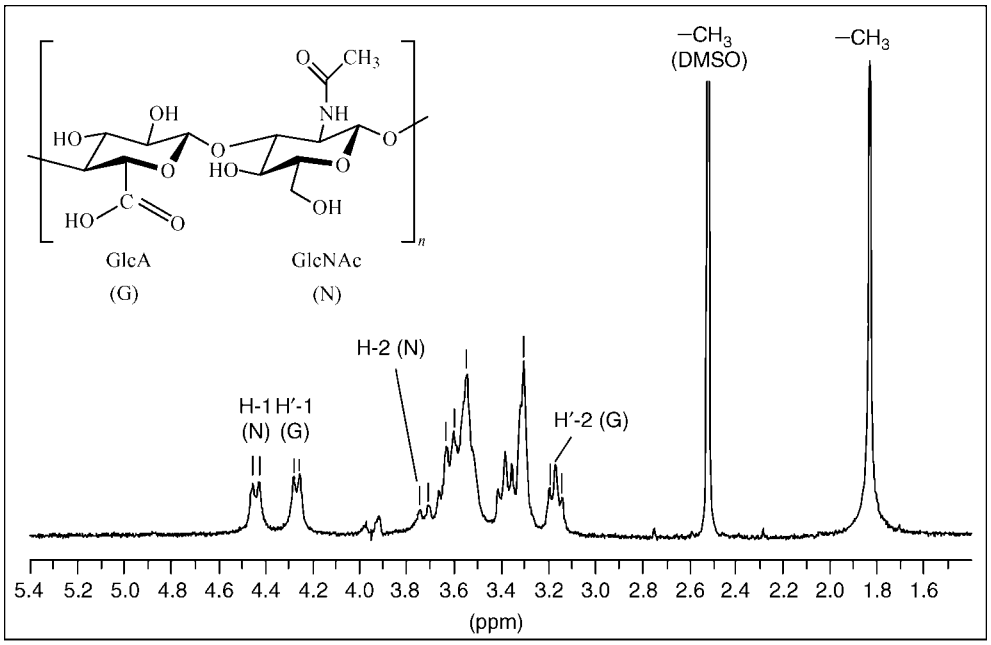
NMR Spectroscopy. The structure can be established as mentioned before using ^{1}H and ^{13}C NMR; many examples are given in the literature. NMR is very useful especially for analyzing polysaccharides with a regular structure. Figure 21 shows the NMR analysis of a bacterial polysaccharide (hyaluronan) based on a 2 sugars repeat unit. On the ^{1}H NMR spectrum, the two anomeric C-1 are identified as well as the acetyl of the *N*-acetyl-D-glucosamine unit. On the ^{13}C NMR spectrum, two different C=O appear in the range of 175 ppm due to the carboxylic group and to the acetyl group. The attribution of all the signals was given by Haxaire (51). NMR is also useful for estimating the population of substituents, the number of sugars in the repeat units, and to determining the anomery as well as the position of linkage and the sequence.

Composition. The most usual method to determine the composition of a polysaccharide (nature of the sugar units) is the complete hydrolysis by heating in acidic conditions (1 *M* H_2SO_4 followed by neutralization with barium carbonate, or with 2 *M* trifluoroacetic acid, which is volatile and easily eliminated after reaction) (52,53). Nevertheless, no recommendation can be proposed a priori; especially, for heteropolysaccharides, the rate of hydrolysis of the osidic linkage depends on the sugars involved: glycosidic bonds of deoxysugars and furanose sugars (like arabinose and fructose) are more labile whereas the glycosidic bond of the uronic moiety is more stable. In the latter case, it is better to reduce the polymer before hydrolysis (54,55). Methanolysis is sometimes preferred to simple acid hydrolysis, leading to methyl-glycoside derivatives (56).

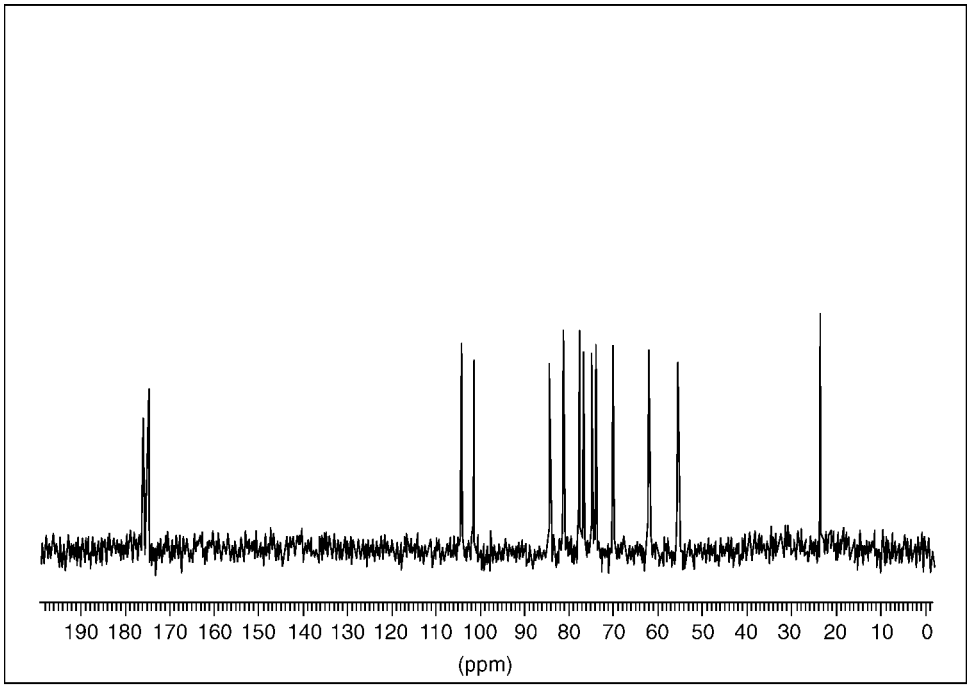
Quantitative determinations of sugars are achieved by liquid chromatography (HPLC) or gas chromatography (GC). HPLC has the advantage of utilizing sugars directly but each sugar can give two or more peaks corresponding to the anomeric equilibrium; an example of HPLC chromatogram obtained on C18-μ Bondapak on maltodextrins is given in Figure 22. The peaks corresponding to DP = 4–6 show the anomeric equilibrium (26).

Reduction of the saccharide gives alditols and only one peak per sugar. The same occurs in GC; but, in addition, as sugars are not volatile, they must be transformed into alditol acetates by reduction and peracetylation to get a single peak per sugar in GC (57).

Methylation. Methylation involves the complete conversion of all free hydroxyl groups in a polysaccharide into methoxyl groups ($-OH \rightarrow -OCH_3$). The most used method is the Hakomori procedure using DMSO, sodium hydride, and methyl iodide (58). To give significant results, methylation must be perfectly completed; then, total hydrolysis yields monomeric units with different degrees of methylation. The position of nonetherified —OH indicates the position of the glycosidic bond. Thus, a tetra-*O*-methylhexose is representative of a terminal unit (nonreducing end). In a linear oligo- or polysaccharide, the fraction of these units can be used to estimate the number-average degree of polymerization.



(**a**)



(**b**)

Fig. 21. (**a**) ^{1}H and (**b**) ^{13}C NMR spectra for hyaluronan in D_2O at 85°C in the presence of DMSO as standard at 300 and 75 MHz respectively (51).

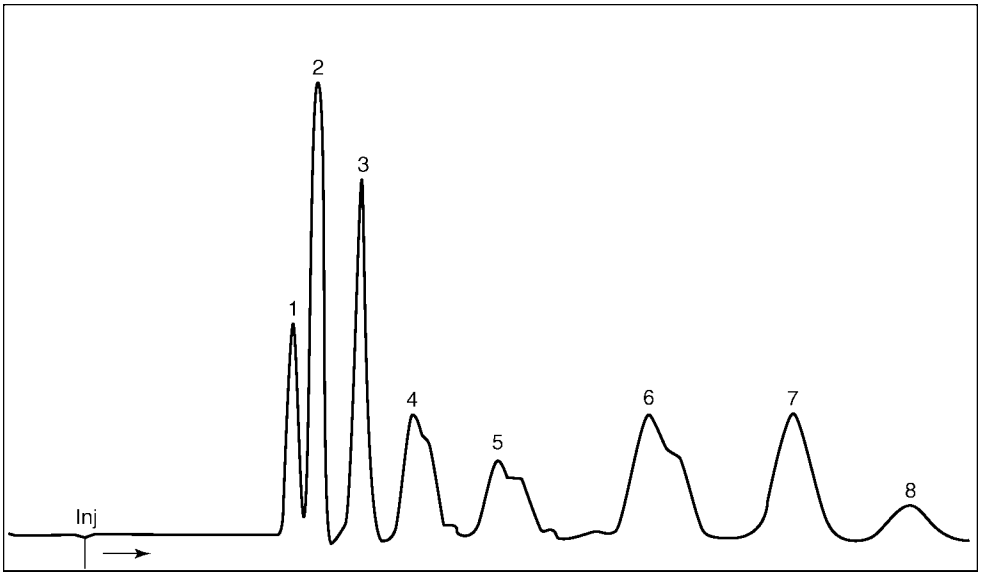


Fig. 22. Separation of maltodextrins (the degree of polymerization is indicated by the number over the peaks) by gel permeation chromatography on Biogel P-2 ($T = 15°C$; eluent: water). Anomeric equilibrium is shown under peaks 4–6. Reproduced from Ref. 26, by courtesy of Marcel Dekker, Inc. (Copyright 2003).

A tri-*O*-methylhexose is an in-chain unit; di-*O*-methylhexose indicates the existence of a branched point. The partially methylated sugars can be fractionated by HPLC. This technique allowed determination of the distribution of methyl substituents in methylcellulose (59); Figure 23 shows the chromatogram obtained for partially methylated glucose after total hydrolysis of the methylcellulose. Eight modified D-glucose derivatives are obtained including unsubstituted glucose.

Usually, the methylated sugars are derivatized to alditol acetates and separated by GC combined with mass spectroscopy (60–63).

Partial Acid and Enzymic Hydrolysis. Partial hydrolysis with acid under mild conditions gives a mixture of oligosaccharides. Homoglycan gives a series of homologous oligomers, whereas heteroglycan gives a series of products depending on the relative acid labilities of the different glycosidic bonds. The fragments permit the sequencing of the monosaccharide residues in the polysaccharides.

Establishment of the polysaccharide structure can be obtained by the use of specific enzymes. The most developed studies concern the amylopectin molecular structure using α- and β-amylase and debranching enzymes (isoamylase, pullulanase, glucoamylase). These enzymes hydrolyze specifically the $\alpha(1\rightarrow6)$ and/or $\alpha(1\rightarrow4)$ linkages, allowing separation of the side chains. The different sizes of side chains in amylopectins were separated by SEC (64,65). Endo- and exoglycanases specific for the cellulose ($\beta(1\rightarrow4)$ linkage) were also investigated; a cocktail of these types of enzymes is also used to disrupt the plant cell walls. Bacteriophages possess a highly specific endoglycanase for a single glycosidic bond in each repeat unit of the corresponding bacterial polysaccharide, thus giving a single oligosaccharide motive in good yield, identified as the repeat unit, easier to characterize (66).

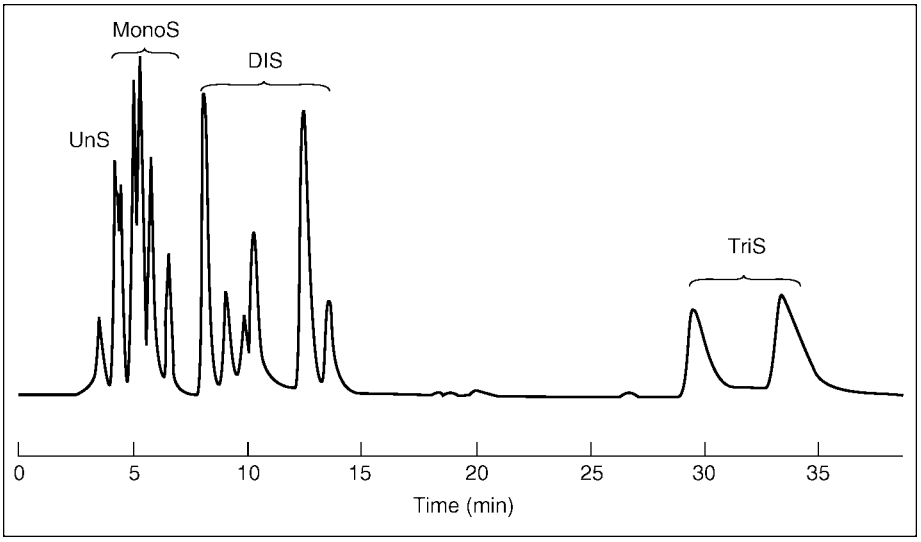

Fig. 23. HPLC analysis of methycellulose (DS = 1.7) after total hydrolysis on a Nucleosil C18 reverse-phase column. Eluent: water; ambient temperature. Reproduced from Ref. 59, with permission from Elsevier (Copyright 2003).

Molecular Weight Determination. Whenever the polysaccharide is perfectly water soluble it is easy to perform SEC; but the polyhydroxyl nature of polysaccharides causes specific problems: owing to the large number of —OH groups in the molecules, cooperative interaction may form aggregates; the associated molecules are connected by a network of H-bonds, often created by the conditions of isolation and drying of the pure polysaccharide. The presence of aggregates disturbs the chromatogram which becomes difficult to interpret.

In addition, when uronic acid or pyruvic acid substituents are present, the polysaccharide becomes a polyelectrolyte (see POLYELECTROLYTES). It is necessary to shield the polymer from electrostatic interactions; this implies that the polymer has to be solubilized in the presence of an external 1–1 electrolyte (67–70). A multidetection experimental device in which a complete molecular weight distribution can be obtained without any calibration has been developed (71).

Another important parameter is the intrinsic viscosity $[\eta]$ (expressed in mL/g). It is obtained by extrapolation to zero polymer concentration of the reduced viscosity (η_{red}) of the polymeric solution plotted as a function of the polymer concentration C (g/mL) in accordance with the Huggins relation:

$$\eta_{red} = (\eta - \eta_0)/\eta_0 C = [\eta] + k'[\eta]^2 C \quad (1)$$

in which η is the viscosity of the polymer solution, η_0 is the viscosity of the solvent, and k' is the Huggins constant. There is a relative relation between the intrinsic viscosity and the molecular weight of the polymer following the Mark–Houwink relationship:

$$[\eta] = K M_v^a \quad (2)$$

Table 4. Mark–Houwink Parameters for Cellulose and Some Cellulosic Derivatives and for Starch and Starch Derivatives

Polymer	Solvent	T, °C	K, 10^{-3} mL/g	a	Reference
Cellulose	Cupriethylenediamine	25	10.1	0.9	92
Cellulose	Cupriethylenediamine	25	7.62	0.936	72
Cellulose nitrate	Tetrahydrofuran	25	1.32	1.01	73
Cellulose acetate	acetone	30	16.0	0.82	74
Cellulose acetate butyrate	acetone	25	13.7	0.85	75
Cellulose triacetate	acetone	25	14.9	0.82	76
Sodium carboxymethylcellulose	Aqueous NaCl (0.1 M)	25	12.3	0.91	77
Methylcellulose	Water	25	316	0.55	78
Methylcellulose	Water	20	280	0.55	79
Amylose	Dimethyl sulfoxide	25	15.1	0.70	80
Amylose	Dimethyl sulfoxide	25	30.6	0.64	81
Amylose	Water	20	13.2	0.68	82
Amylose	Aqueous KOH (0.15 M)	25	8.36	0.77	80
Amylose triacetate	Chloroform	30	1.06	0.92	83

in which M_v is the viscometric average molecular weight; K and a are two parameters depending on the polymer, the solvent, and the temperature. Some values are given in Table 4.

Plant Polysaccharides

Polysaccharides from the biomass consist largely of renewable polymers which have been used for a long time in many industrial applications. The main polysaccharides concerned are cellulose (qv) and starch (qv) (84).

Cellulose is the main structural polymer in wood (representing around 50% of the dried matter) or agricultural resources (normally between 35 and 75% of the dried matter depending on the source; in the case of cotton (qv), values are between 90 and 99%) (85–88). Cellulose is found in a very organized fibrous structure. In contrast, starch constitutes the reserve polysaccharide organized in a granular structure. Both of these polymers are semicrystalline polymers (qv) based respectively on β-(1→4)-D-glucose and α-(1→4), α-(1→6)-D-glucose (89,90).

Derivatization may be used to extend the domains of application for these natural polymers; nevertheless, their relative lack of solubility and their high degree of organization lead usually to heterogeneous chemical modifications. Heterogeneity of the substitution gives bad reproducibility of the samples, depending also on the sources of polymers. Because of this problem, a large variety of parameters relating the degree of substitution and molecular weight to the physical properties can be found in the literature.

The supramolecular structure of the initial materials is a very important point. The swelling and/or dissolution in different conditions depend on the morphology of the native substrate. Cellulose in cellulosic fibers and

amylose/amylopectin in starch granules are tightly packed in a more or less regular organization, depending on their source but also on the presence of other additional components. Thus, the accessibility of the reactive groups (—OH) depends on this supramolecular structure in addition to the degree of crystallinity (diffusion control of the reactants) and on the intra- or interchain H-bonds modulating the —OH reactivity. This is why cellulose and starch are not thermoplastic materials but in presence of water playing the role of plasticizer; especially starch becomes thermoplastic. Only a complete destructuration passing through a solution state avoids a memory effect of the original state of organization and attainment of regular chemical modification.

The two main characteristics of cellulose and starch derivatives are the distribution in molecular weight (the weight average DP_w or M_w) in addition to the degree of substitution represented by DS (DS is the average number of substituents per glucose unit; $0 < DS < 3$).

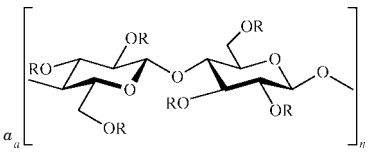
Cellulose and Cellulose Derivatives. The solubilization of cellulose to determine its molecular weight is delicate; one of the most powerful solvents is cupriethylenediamine for which the Mark–Houwink parameters relating the intrinsic viscosity to the molecular weight ($[\eta] = KM^a$) have been determined (see Table 4). Some authors previously prepared cellulose derivatives (nitrocellulose or cellulose tricarbanilate) to determine the molecular weight and molecular weight distribution, assuming no polymer degradation (72–83,91,92).

Cellulose derivatives are the most important derivatives obtained from natural sources. Chemical modifications of cellulose are very useful to enhance solubility in organic or aqueous solvents or to obtain new thermoplastic materials. The main derivatives are described in Table 5.

In designing derivatives for various properties and applications the degree of substitution is a very important parameter, as well as the chemical structure of the substituent. Recent studies have been done in selective cellulose functionalization obtaining regioselectively substituted esters and ethers (93–97).

Table 5. Main Substituents in Cellulose Derivatives

Product	Functional group (R=)[a]	DS[b]	MS[c]
Cellulose nitrate	—NO_2	1.8–2.8	
Cellulose acetate	—$C(O)CH_3$	0.6–3.0	
Carboxymethylcellulose	—CH_2COONa	0.5–2.9	
Methylcellulose	—CH_3	0.4–3.0	
Hydroxyethycellulose	—$[CH_2CH_2O]_x$ H ($x = 1, 2, 3, \ldots$)	0.8–1.2	1.7–3.0
Hydroxypropylcellulose	—$[CH_2CH(CH_3)O]_x$H ($x = 1, 2, \ldots$)		<4.6
Ethylcellulose	—CH_2CH_3	0.5–4.6	



[b] $0 < DS < 3$ is the degree of substitution.

[c] MS is the molar substitution (gives the average number of monomoles of reactant added to one anhydroglucose unit).

Among the large variety of cellulose derivatives, two main groups of products are prepared: cellulose esters and cellulose ethers. Worldwide, around 1.4×10^6 t/year of cellulosic dissolving pulp is used in the production of cellulose esters, whereas 5.4×10^5 t/year is used in the production of cellulose ethers (98).

Cellulose ethers (qv) are obtained by substitution of hydroxyl groups by ether groups, and depending on the substituent they can be soluble in water or organic solvents. Carboxymethylcellulose (CMC) is the ether of cellulose of largest production. Approximately 300,000 t/year is produced each year. It is a water-soluble polymer in the sodium salt form and when DS is larger than 0.5. It is produced by reaction of the alkalicellulose with sodium chloroacetate or reaction with sodium in liquid nitrogen in the presence of chloroacetic acid (99–101). On a laboratory scale, soluble CMC with DS varying from 0.5 up to 3 has been produced. Typical raw materials for cellulose-ether production are wood pulp or cotton linters. Cotton linters are used for the production of high viscosity ethers because of their higher DP. CMC sodium salt is a white, odorless, and nontoxic solid. Viscosities range in aqueous solution from 10 to over 50,000 mPa·s (=cP) for 2% aqueous solutions. The DS of commercial samples may be between 0.3 and 1.2 although clear and fiber-free CMC solutions require a minimum DS value of about 0.5. The majority of commercial products have a DS between 0.65 and 0.85. Most CMC solutions are highly pseudoplastic (102,103).

Methylcellulose (MC) is produced, as in the case of CMC, by the Williamson synthesis, ie, by reaction of alkali cellulose with methyl chloride. World annual production is around 80,000 t/year (98). Other hydroxyalkyl derivatives or mixed ethers such as hydroxyethylmethylcellulose, hydroxypropylmethylcellulose, hydroxybutylmethylcellulose, ethylmethylcellulose, and carboxymethylmethylcellulose have similar properties to MC.

MC is a white to slightly off-white, essentially odorless and tasteless powder. The solubility of MC varies as a function of DS. In fact, commercial MC is divided into two types of products according to DS. MC with a degree of substitution between 1.4 and 2.0 are soluble in cold water, whereas lower substituted materials are soluble in dilute alkali. MC is also soluble in ethanol, acetone, ethyl acetate, benzene, and toluene for higher DS. Just as in the case of CMC, viscosity values of MC vary as a function of (average) molecular weight. Apparent viscosity at 2% and 20°C can vary between 10 and 19,000 mPa·s (=cP) in a range of average molar mass between 13,000 and 140,000. MC and its derivatives form gels at specific temperatures when heated (104).

The mechanism of gelation is related to the distribution of substituents along the chain; two steps in the gelation mechanism have been demonstrated. The first step of gelation is the formation of a clear gel related to the existence of blocks of highly substituted glucose units (105–108). The second step is the phase separation giving a turbid gel when temperature is larger than 60°C. Below their gel point, solutions of MCs exhibit pseudoplastic rheology, but appear to be Newtonian at low shear rates. MCs have excellent water retention properties.

The two main types of commercial hydroxyalkylcelluloses are hydroxyethylcellulose (HEC) and hydroxypropylcellulose (HPC). HEC is produced in larger amount with around 60,000 t/year, but investments are planned in order to increase the capacities of HPC, in future years. HEC and HPC are synthesized by reaction of alkali cellulose with ethylene oxide or propylene oxide respectively in a

slurry process in an organic medium. In the case of HPC it is possible to use liquid propylene oxide as a medium of reaction; after etherification the crude product is purified by washing with hot water (109–111).

HEC is available in a wide range of viscosities (from 10 to 100,000 mPa·s (=cP) in 2% aqueous solution at ambient temperature). It is soluble in cold and hot water or some mixtures of water and water-miscible organic solvents. The nonionic chemical structure and its solubility in both cold and hot water are the main advantages for the utilization of HEC. HPC has a thermal gel point like MC and it is thermoplastic. Because of its high level of substitution (molar substitution about 4) and its remarkable hydrophobic character it is soluble in a number of organic solvents as well as water.

Many general books develop the structure and reactivity of cellulosic materials and the preparation of their derivatives (112–115).

Starch and Starch Derivatives. The starch granule dimensions depend on the sources as well as the composition and degree of crystallinity. The molecular structure of the principal component in the starch granules consists of a linear (1→4)-D-glucose chain, amylose. Amylose is a flexible polymer having a relatively low thickening power; its molecular weight seems to remain relatively low (less than 1 million). The second major component is a highly grafted polymer, amylopectin. It is a very compact molecule with a very high molecular weight (10–100 millions have been cited in the literature). Also, in some materials a third component is a slightly grafted amylose called the intermediate material (116,117).

The main techniques to characterize starch molecules consist of iodine or butanol complex formation to estimate the fraction of linear amylose (118). A colored complex is formed with iodine; its wavelength of absorption is characteristic of the length of the helicoïdal segments involved in the complex formed with iodine. This technique has been examined by Salemis (119). The second important characteristic is the molecular weight or better, the molecular weight distribution. It is often difficult to solubilize starch in aqueous solution. In one SEC investigation of starch in aqueous systems containing KOH (120), it was shown that amylopectin has a low solubility. SEC studies were also done in DMSO (121,122). The determination of the molecular weights can be performed using the empirical relation relating the intrinsic viscosity to the viscometric average molecular weight. Some parameters are given in Table 4.

Nowadays, starch is used in industry as native starch (world production: (10–12) $\times$ 10^6 t/year), gelatinized starch, modified starch (7 $\times$ 10^6 t/year), or as partially or totally degraded starch ((16,17) $\times$ 10^6 t/year), (98). First, the characteristics of the products depend on the parent starch sample.

The hydroxyl groups of starch can be derivatized as esters or ethers, as in the case of cellulose. Table 6 gives the main substituents for starch.

Starch esters are synthesized by reaction of a carboxylic acid or an acyl chloride or an acid anhydride with the hydroxyl groups of amylose or amylopectin chains. As in the case of cellulose derivatives, there are organic and inorganic esters depending on the origin of the substituent.

Acetate of starch is the most important ester of starch industrially produced. Commercial products are traditionally low substituted derivatives (DS $<$ 0.3) (123–125). In this range of DS it is possible to derivatize preserving the granule

Table 6. Main Substitutents in Starch Derivatives

Product	Functional group	DS	MS
Starch acetate	$-C(O)CH_3$	0.04–3.0	
Starch phosphate	$-OPO_3HNa$	0.02–0.25	
Hydroxyethylated starch	$-[CH_2CH_2O]_xH$ ($x = 1, 2, 3, \ldots$)		0.05–1.25
Hydroxypropylated starch	$-[CH_2CH(CH_3)O]_xH$ ($x = 1, 2, \ldots$)		0.1–1.0
Quaternary ammonium starch esters	$-OCH_2CH(OH)CH_2N(CH_3)_3Cl$ and others	0.1–0.7	
Starch alkenylsuccinates	$-OC(O)CH_2CH_2C(O)ONa$	0.02	

structure, to purify by washing with water, and to recover by centrifugation or filtration. The acetylating agent is commonly acetic anhydride in aqueous medium in the presence of dilute sodium hydroxide. Derivatization eases the formation and stability of colloidal dispersions of starch and the adjustment of the colloidal properties to the requirements of the application. Products obtained have high purity and low ash content. The principal uses are in food (paste clarity and viscosity stability) and the pharmaceutical and textile industry (warp sizing, finishing operations). Other higher acetylated starches are those obtained with a DS of 2–3 (126,127). Their characteristics of solubility and thermoplasticity permit their utilization as materials. Nevertheless, this type of material has not been developed commercially because they could not compete with similar cellulose derivatives in terms of strength and cost. The glass transition (T_g) stabilizes around 150°C. These polymers have been proposed to prepare hydrophobic thermoplastic materials or to coat hydrophilic films (128–130). Even up to DS $\sim$ 3, the polymers remain biodegradable (129).

Syntheses of longer chain organic esters (C_3–C_{18}) have been carried out on a laboratory scale, but have not yet been industrially produced because at present they are not profitable (125,130–133).

Starch can be etherified by reaction of an alkyl halide or an epoxy in alkaline medium. Depending on the substituent it is possible to obtain anionic, hydroxyalkyl, and cationic products.

The two main types of hydroxyalkyl ethers industrially produced are hydroxyethyl starch and hydroxypropyl starch. These compounds are synthesized by reaction of ethylene oxide or propylene oxide respectively with starch under alkaline conditions (134).

Low MS hydroxyalkyl starch products (MS < 0.1) are prepared by reaction of the epoxy in an aqueous and alkaline starch slurry. A salt such as sodium sulfate is often added to protect the starch from swelling so that relatively high levels of caustic can be added to increase the reaction efficiency. In this case usual temperatures are between 25 and 50°C. If the temperature is increased and the salt eliminated, it is possible to do the reaction in a starch solution and obtain higher molar substitutions.

High MS hydroxyalkyl products are prepared by reaction of the epoxy in alcohol slurry and alkaline conditions. The alcohols typically used are methanol, ethanol, and 2-propanol. Another possibility is to combine starch with a low level

of moisture (5–15%) with ethylene or propylene oxide under pressure in presence of an alkaline catalyst. In this process the starch retains its granular form.

Low MS hydroxyalkyl starches are very similar in appearance to unmodified starch. Nevertheless, there are two main differences in their properties owing to the presence of hydroxyalkyl groups. On one hand, these groups weaken the hydrogen bonding between starch molecules and facilitate the reduction of pasting temperature. On the other hand, when the product is solubilized, retrogradation of the starch chains is inhibited, resulting in a more fluid paste with improved clarity, viscosity stability, freeze–thaw stability, and cohesiveness. Although the substituted starch paste thickens when it cools, reheating will return it to its original hot viscosity and clarity.

When the MS increases the pasting temperature decreases, until the product is soluble in cold water. These products have excellent viscosity stability over a wide range of conditions. The viscosity of high MS hydroethyl starch solution is quite stable to shear changes, changes in pH, and enzymatic attack. Salts have little effect on these products.

Hydroxyethyl starch is used in papermaking, textile manufacturing, medical and pharmaceutical industries. Hydroxypropyl starch is used in the food industry, textile and paper products, building materials, cosmetics, and pharmaceuticals (134).

Cationic starches are obtained by reaction of starch with reagents containing amino, imino, ammonium, sulfonium groups. The two main types of commercial products are the tertiary amino and quaternary ammonium starch ethers (135).

Quaternary Ammonium Starch Ethers. Among the reagents that can add quaternary ammonium groups to starch probably the most popular is 2,3-epoxypropyltrimethylammonium chloride. Ethers of this type with different DS have been prepared and tested for their role in adsorption on calcium carbonate in relation with the mechanisms of dispersion and flocculation of small particles (136).

Cross-linking. Starch polymer chains can be cross-linked with difunctional reagents to form diethers or diesters. These derivatives are distinguished from starch ethers and starch esters because the properties obtained by the cross-linking of starch are specific. In general terms cross-linking reinforces granule integrity, modifies the water retention capacity, and provides higher mechanical resistance and improves film properties.

Cross-linking is employed when a stable, high viscosity starch paste is needed, and particularly when the dispersion is to be subjected to high temperature, high shear, and/or low pH (137).

Hemicelluloses. Hemicelluloses constitute a series of polysaccharides associated with cellulose in plants. In wood, in addition to lignin and cellulose, hemicelluloses represent around 25% by weight (138). Some structures are given in Figure 24. The composition of hemicelluloses depends on the source: deciduous trees (hardwoods) have mainly glucuronoxylan; coniferous trees (softwoods) yield more glucomannans, *O*-acetylgalactoglucomannans, and xylans having both arabinofuranosyl and 4-*O*-CH_3-galacturonic side chains. Some softwoods also have significant amounts of arabinogalactan (eg in larch wood) (138).

Hemicelluloses from annual plants (cereals crops) are mainly of the xylan type; mixed-linked β-1,3-1,4 glucans are also found. The structure has been

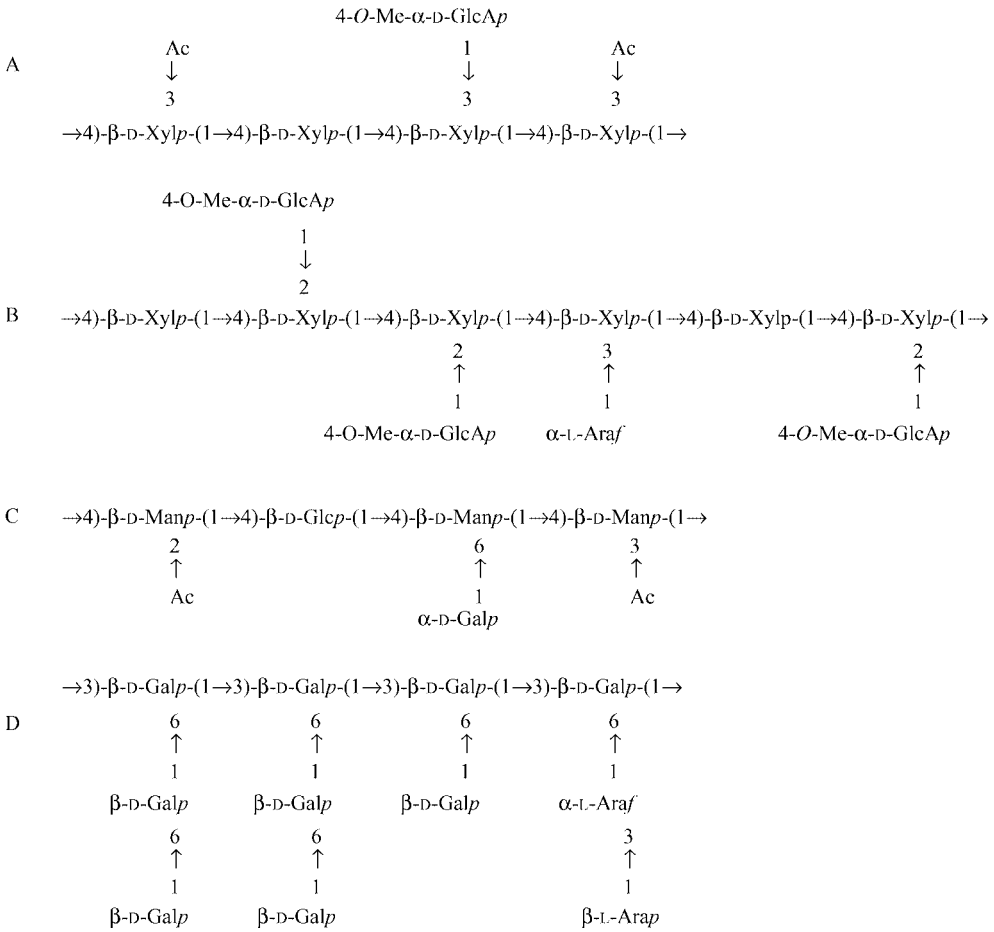


Fig. 24. Partial chemical structure of some hemicelluloses: **A** = *O*-acetyl-(4-*O*-methylglucurono)xylan from hardwood; **B** = arabino-(4-*O*-methylglucurono)xylan from softwood; **C** = *O*-acetyl-galactoglucomannan; **D** = arabinogalactan from larch wood (138).

reviewed (138) and it is clear that they represent a large variety of molecules. There are no important applications for hemicelluloses extracted from plants.

Galactomannans and Glucomannans. Galactomannans are neutral polysaccharides isolated from seeds (carob, guar, locust bean, tara, etc) (140). The main chain is made of →4-β-D-Man-(1 (M) with different degrees of substitution on *O*-6 with α-D-galactopyranosyl units (G) (Fig. 25). The structure is easily determined by ^{1}H NMR.

The solubility of the galactomannan depends on the ratio M/G and on the distribution of galactose units along the mannan chain; the larger the galactose content, the higher the solubility in water. The ratio M/G varies from 1:1 to 1:5 in *Mimosa scrabella* to locust bean gum respectively. In addition, the rheological properties of solutions depend on M/G because of an increase of loose interchain interactions when G content increases (141–144).

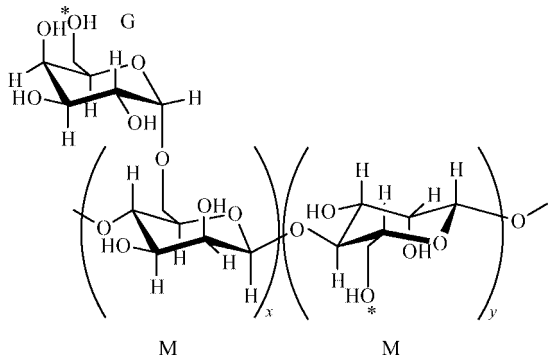

Fig. 25. Representation of the galactomannan structure. ∗ represents the C-6 position where —OH can be specifically modified.

Cooperative interactions may be stabilized between xanthan and galactomannan depending on the conformation of xanthan (helical or coiled). Two types of gels can be identified: one around 20°C involving disordered xanthan and galactomannan whatever its content in galactose; the second one, around 60°C, engages helical xanthan and it is the usual gel identified when these two polymers are mixed (145–152). Molecular modeling was applied for the determination of the persistence length of a galactomannan model for which M/G $\approx$ 1 (47); the value predicted as a function of the DP is given in Figure 26. The role of the microstructure of the polymer (random or blockwise distribution of galactose, content of galactose) was also analzsed by molecular modeling (153).

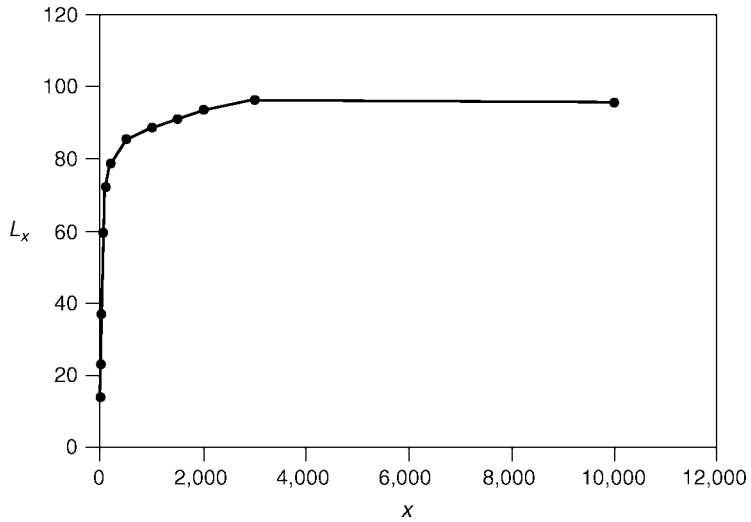

Fig. 26. Persistence length of galactomannan (for G/M = 1) as a function of the degree of polymerization x. L_∞ is equal to 9.6 nm. Reproduced from Ref. 47, with permission from Elsevier (Copyright 2003).

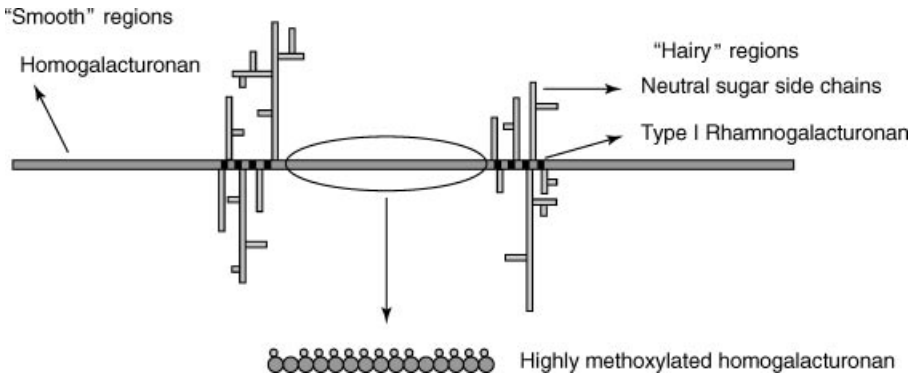

Fig. 27. Schematic representation of the pectin structure. Reproduced from Ref. 157 with the permission from American Chemical Society. (Copyright 2003).

Glucomannans are also obtained from seeds or roots; the structure is a random arrangement of $\rightarrow$4)-β-Glc-(1 and $\rightarrow$4)-β-Man-(1. The ratio Glc/Man depends on the source and varies from 1:1 in Iris bulbs to 1:5 in certain gymnosperms. Konjac glucomannan has been developed mainly in Japan for food applications (154,155).

Pectins. Pectins are located in the middle lamella and primary cell walls of plant tissues. They are extracted from apple skins and citrus peels. Pectins consist primarily of 1,4-linked α-D-galacturonic units or their methyl esters with some interruption by a rhamnogalacturonan region kinking the linear polygalacturonic backbone (156). They also contain branched chains composed of neutral sugars such as galactose or arabinose. These neutral sugars amount to 10–15% of the pectic dried weight and are concentrated in blocks (called the hairy region; Fig. 27) (157).

In nature, they occur often with different degrees of esterification (DE) around 70%. Because of enzymic degradation, they can have a lower DE; in that case (if DE $<$ 50%), they are insolubilized by calcium cross-linkage. Extraction requires the use of chelating agent.

The interaction between calcium ions and carboxyl groups of the pectins forms gels; the interaction with calcium is very cooperative owing to the stereochemistry of the 1,4-linked monomeric units, leading to the formation of a polar cavity that can be occupied by calcium or related cations. The mechanism of interaction is described by the egg-box model. A series of galacturonic acid oligomers was investigated to test the minimum carboxylic group necessary to get a stable junction (158–160). A two-step process leads to gelation: first dimer formation followed by aggregation forming junction zones (161–163).

The ability to gel can be determined from the dependence of viscosity as a function of counterions added (164). At a given concentration, the critical amount of cations at the gel point is directly related to the distribution of carboxyl groups along the chain (Fig. 28).

It is shown that the divalent counterions form gels with a sequence of affinity Ba $>$ Sr $>$ Ca, but Mg does not form gels nor dimers. The interaction with counterions as well as change in conformation have been identified by X rays (165) and by circular dichroism (162).

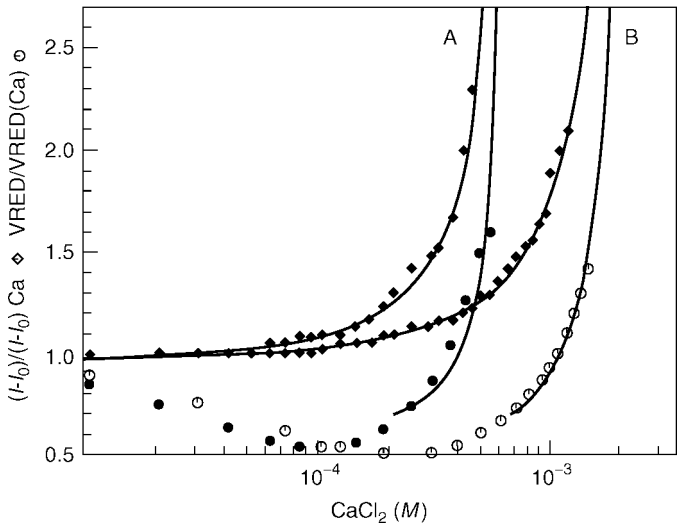

Fig. 28. Change in reduced viscosity and scattered light during addition of $CaCl_2$ to pectins (polymer concentration: 0.2 g/L; 5×10^{-3} *M* $CaCl_2$). Role of the carboxyl groups distribution: (**a**) DE = 30% blockwise distribution obtained by pectinesterase hydrolysis; (**b**) DE = 30% random distribution obtained by alkaline hydrolysis. Reproduced from Ref. 164, with permission from John Wiley & Sons, Inc., on behalf of the Society of Chemical Industry (Copyright SCI 2003).

There are different categories of pectins: HM pectins (high methoxyl; DE > 50%) form gels in acid conditions and in the presence of sucrose to decrease the water activity. The gelation is based on H-bond association and is thermoreversible. Only, LM pectins (low methoxyl; DE < 50%) form gels in presence of calcium.

HM pectins can be extracted by water, mineral acids, or bases. LM pectins immobilized *in situ* via metallic ions need a sequestering agent to displace the counterions. Alkaline treatment also has a role in the deesterification. Different treatments were compared on sugar beet and potato pulps. HM pectins are naturally occurring in sugar beet pulp; they were extracted in alkaline conditions (50 m*M* NaOH, pH 12) and precipitated with ethanol after neutralization to pH 6.5–7. A pretreatment of the plant material is necessary to inactivate enzymes (water at 85°C, 20 min). On the contrary, for potato pulp containing an LM pectin the extraction is performed in acid conditions (pH 3.5 in presence of 0.75% hexametaphosphate, 75°C, 1 h). The pectins are precipitated at pH 2 with HCl. The precipitate is redispersed in water with NaOH up to pH 6.5–7 and reprecipitated by ethanol. Potato pulp was also extracted in alkaline conditions with hexametaphosphate, precipitated at pH 2, redispersed in water to pH 6.5–7, and precipitated by ethanol as previously. The LM pectins obtained in alkaline conditions have a higher gelling ability due to deesterification and partial deacetylation (166,167).

Seaweed Polysaccharides

Algae are an important sources of polysaccharides with different structures. Among the different groups of algae, green algae (Chlorophycea), red algae

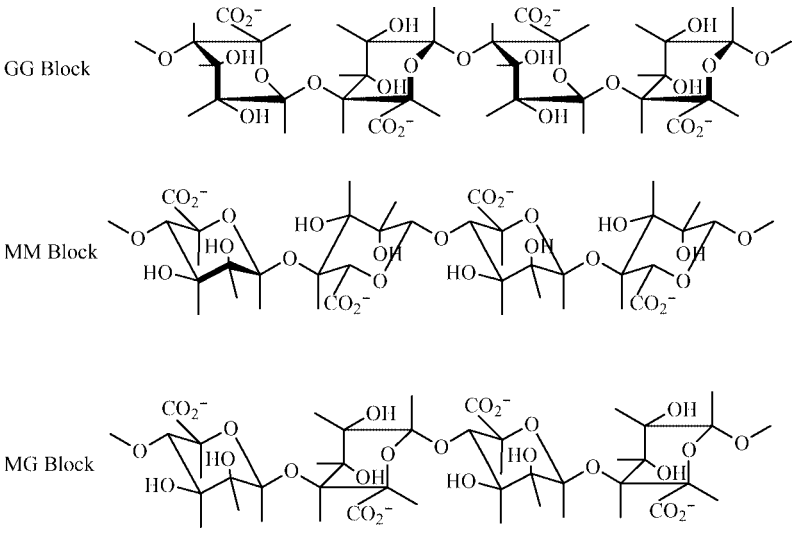

Fig. 29. Structure of alginate consisting of guluronic (G) and mannuronic (M) blocks or MG blocks.

(Rhodophycea), and brown algae (Phaeophycea), only the last two series are used on an industrial scale (168). Many different polysaccharides may be extracted but alginates and carrageenans are the more developed especially as physical gel formers (169). Fucoidans also are now under investigation because of the importance of sulfated polysaccharides for biological applications (170,171).

Alginates. Alginates are linear copolymers of α-L-guluronate (G) and α-D-mannuronate (M) (Fig. 29). They are also called polyuronides and are extracted from brown algae. Their gelling properties derive from the cooperative binding of divalent cations on the G blocks in the egg-box model (similar to that proposed in LM pectins).

Alginates behave as polyelectrolytes in the presence of monovalent counterions, and in 0.1 *M* NaCl, the intrinsic viscosity allows determination of the average molar mass (172).

Mechanical properties of calcium alginate gels are related to the ratio M/G and also to the distribution of the G units along the chain and to the molar mass of the polymer (173). Alginate is often used for encapsulation of pharmaceuticals, bacteria, or yeasts in biotechnological processes. The beads of gel are formed by a dripping technique; drops of alginate solution falling in 1 *N* $CaCl_2$ solution form beads which are washed in water after a few hours maturation. Smaller and more regular particles can be obtained by emulsification (174,175); the porosity of these gels is smaller than for that obtained by the dripping method.

Agarose and Carrageenans. These polysaccharides represented a family of alternating (AB) type copolymers with different degrees of sulfation; agarose is the neutral polymer form. They are extracted from red algae. Their structures are given in Figure 30. They consist of alternating (1→3)-β-D-galactose and (1→4)-α-(3,6)anhydro-D-galactose or (1→4)-α-(3,6)anhydro-L-galactose (in agarose).

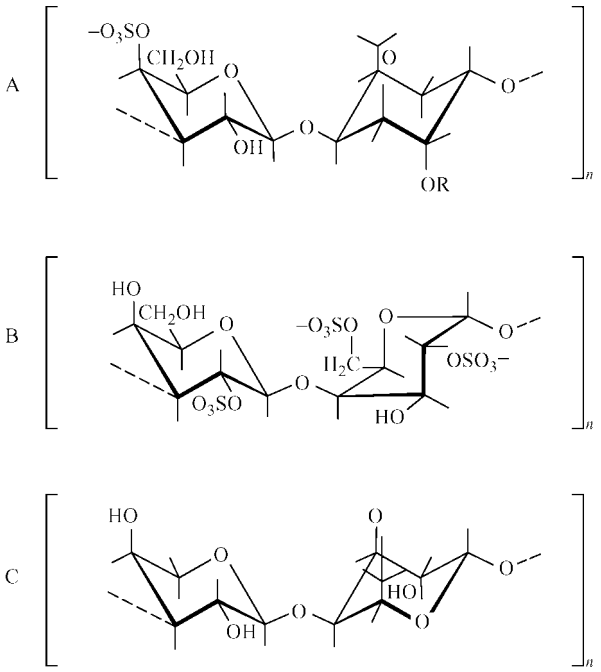

Fig. 30. Structure of red algae polysaccharides. (**A**) R = H in κ-carrageenan; R = SO_3^- in ι-carrageenan; (**B**) λcarrageenan; (**C**) agarose.

Agarose, κ-carrageenans, and ι-carrageenans are recognized as gelling polymers; the conditions of gelation as well as the mechanism of gelation have been abundantly discussed in the literature. The gels are thermoreversible based on H-bond stabilized conformations. Gelation is based on the formation of double helices which associate forming an aggregate or a junction zone which is the basis of the network formation; a two-step gelation process has been demonstrated clearly. Gelation and melting of the gel present a hysteresis in temperature directly related with the degree of aggregation of double helices and to the charge density of the polymers (176–178). The rigidity of the gels follows the same trend. A sequence of solubility has been established : Agarose $<$ κ-carrageenan $<$ ι-carrageenan $<$ λ-carrageenan following the order of sulfate density: No sulfate $<$ 1 sulfate $<$ 2 sulfates $<$ 3 sulfates The stiffness of the gels formed in presence of K^+ counterions varies in the following order: Agarose $>$ κ-carrageenan $>$ ι-carrageenan The polymer λ-carrageenan never forms gels or helical conformation.

For charged polysaccharides, the formation of double helices and gelation depends on the ionic concentration, nature of electrolyte, and temperature. A phase diagram relating the total ionic concentration and the inverse of the temperature for conformational change ($T_m{}^{-1}$) has been established for each of them. For κ-carrageenan, the ionic selectivity among monovalent cations is very important (179,180); the sequence is as follows:

$$Rb^+ > K^+, Cs^+ > Na^+ > Li^+, NH_4^+ > R_4N^+$$

The mechanical properties of the gels formed in the presence of different counterions follow the same order: Rb-carrageenan gel has a higher modulus and a higher melting temperature than those of Na-carrageenan gel. The molecular weight also plays a role on the elastic modulus which increases up to a limit around $M \sim 250{,}000$ (181). The mechanism of gelation in two steps is described in Reference 182.

In the series of anions, a characteristic behavior was observed with I^-; it stabilizes the double helix but prevents gelation (180).

Microbial Polysaccharides

Fungi and bacteria are sources of polysaccharides and especially of exopolysaccharides which can be produced in culture media on an industrial scale. They are a source of new additives for cosmetic or food applications but also for biological activity. Many of them are now in development; a review will be published in the second edition of Reference 12. Many of these polysaccharides are water soluble and able to compete with natural polysaccharides as described before (alginates, carrageenans, galacto- and glucomannans, chitosans, pectins, etc) especially in the domain of food additives. Many books discuss their applications (183–187).

The best examples of fungal polysaccharides are the $\beta(1\rightarrow3)$ glucans with a few $\beta(1\rightarrow6)$ glucose units as side groups. They often form a triple helical conformation with a tendency to give physical gel. There have been studies on scleroglucan, lentinan, schizophillan, etc (139,188,189). Because they are neutral, solubility depends on the fraction of side glucose units and their distribution.

Bacterial polysaccharides represent a large variety of polymers biosynthesized by bacteria. Their chemical structures and also their physical properties in solution or in the solid state may vary widely. They often contain uronic acid and then become polyelectrolytes (190). Many new polysaccharides have been developed from bacteria for industrial purposes. Exocellular polysaccharides are produced on a large scale by the usual techniques of microbiology and fermentation. This procedure allows good control of the characteristics of the polymers and allows purification of the polysaccharides more easily than from other natural sources (191–194). Extension of such production also allows reducing the price and extends the range of applications. A good example remains the hyaluronan previously produced by extraction from animal sources but in which some fraction of proteins remained. Bacterial hyaluronan can be prepared in a very pure form (195).

In general, polysaccharides are especially important in the domain of water-soluble polymers; they play an important role as thickening, gelling, emulsifying, hydrating, film forming, and suspending polymers. Especially important is the fact that some polysaccharides give physical gels in well-defined thermodynamic conditions. They constitute a very important class of materials in food, cosmetics, or pharmaceutical applications.

Specific methods for the purification of the polysaccharides have been developed. They are usually isolated in their sodium salt forms by precipitation from aqueous solution with ethanol or 2-propanol. This step is the most important one to get reproducible experimental characteristics. In fact, because of the presence

of many —OH groups in the molecule, the polysaccharides have a tendency to form cooperative intra- and interchain H-bonds, causing some insolubility or at least the presence of aggregates when solutions are prepared. Because of their stereoregularity, they are often able to form helical conformations in solution. Their ordered conformation has a semirigid character and its stability depends on temperature and ionic concentration if the polysaccharide structure contains uronic acid unit or ionic substituents; an example is given for succinoglycan (196,197).

Details of the chemical structure of bacterial polysaccharides have been given previously (198,199). In the following, the main industrial bacterial polysaccharides (xanthan, succinoglycan, gellan) are described briefly.

Succinoglycans are produced by many soil bacteria of the species *Pseudomonas*, *Rhizobium*, *Agrobacterium*, and *Alcaligenes*. These polysaccharides have a general chemical structure based on an height sugar repeat unit (D-glucode/D-galactose ratio equals 7:1); this structure is given in Figure 31.

Different substituents are also present in the molecule such as acetyl, succinyl, and pyruvyl groups, depending on the strain and on the conditions of fermentation and/or isolation (200–203). The content in substituents is easily determined by ^{1}H NMR in the presence of an internal standard to calibrate the signals and get a quantitative determination.

Succinoglycan, whatever its origin, is water soluble and, being stereoregular, it adopts a single-chain helical conformation at least in dilute solution. As shown by different techniques, the conformational transition is reversible and very cooperative at least in the presence of some salt excess. The stability of the ordered conformation depends on the salt concentration in solution as is usual for charged polysaccharides. On the two sides of the transition, the stiffness is completely different. In the helical conformation, the chain behaves as a semirigid chain having an intrinsic persistence length (L_p) estimated to be 35 nm and becoming more flexible at higher temperature in the coiled conformation with $L_p \sim 5$ nm. The persistence length in the helical conformation has been confirmed by AFM from the analysis of chain curvature (204).

The rheological behavior in dilute and semidilute solution is quite usual and typical of viscoelastic systems (197).

Xanthan was the first bacterial polysaccharide produced by the strain *Xanthomonas campestris* and developed on a large scale. The chemical structure of xanthan is recalled in Figure 31; it was confirmed by NMR. The ^{13}C spectrum allows identification of the different sugar units as well as the substituents (205). ^{1}H allows quantification of the yield in substituents. Xanthan is a semirigid polymer for which, in the native conformation, a persistence length around 40 nm was found (206–208). It has been demonstrated that when the native form is heated to coil conformation (with a much lower stiffness) and renatured by cooling, the conformation is changed. Xanthan has many industrial applications due to its suspending character (stabilizer of solid suspensions or foams), its pseudoplastic and thickening properties, good stability of the rheological properties as a function of pH, temperature, and salt concentration, and also its ability to be cross-linked and gelled. It is used in paints and coatings, cosmetics, ceramics, etc. In Figure 32 the rheological behavior characteristic for these semirigid polysaccharides is shown. The dependence of the viscosity as a function of shear rate and polymer concentration demonstrates the existence of a Newtonian plateau for low shear

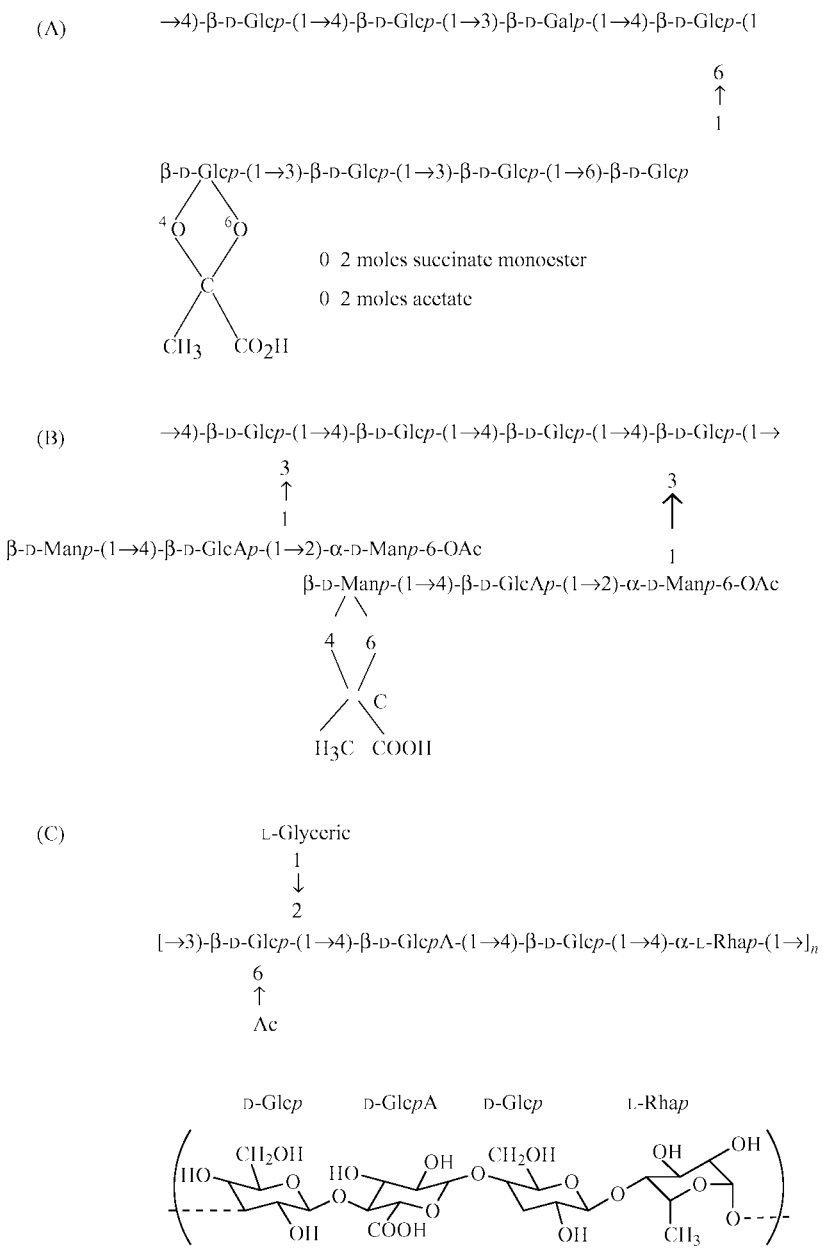

Fig. 31. Examples of some bacterial polysaccharide structures: (**A**) succinoglycan; (**B**) xanthan; (**C**) gellan in the native form and after deacylation.

rate followed by a decrease of the viscosity due to the viscoelastic character of the solution (209).

Gellan is produced by the bacteria *Sphingomonas elodea* (210). The native gellan as produced by the bacteria contains two additional substituents (acetyl and L-glyceryl) compared to the commercial polymer named Gelrite® (Fig. 31).

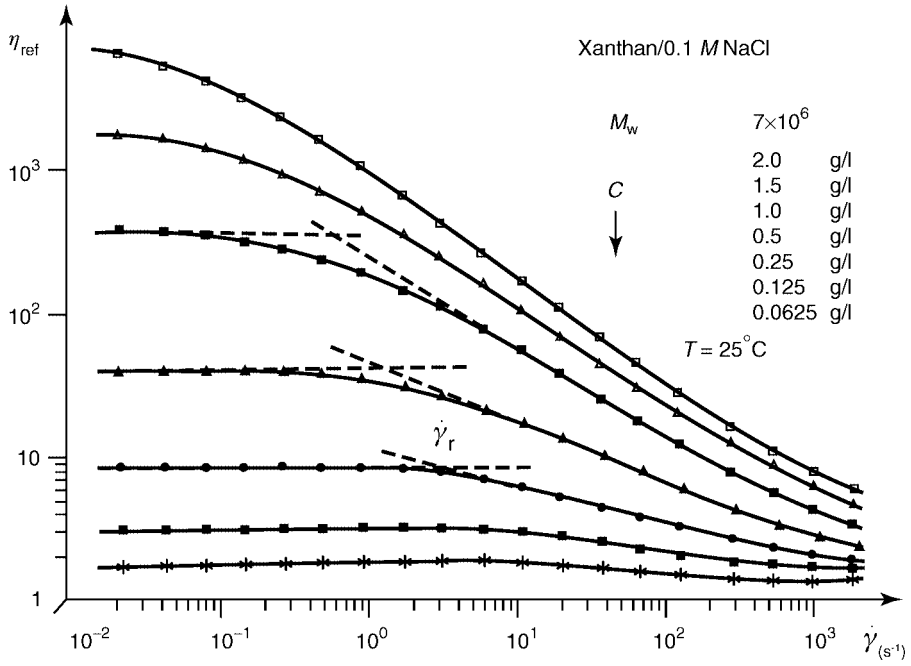

Fig. 32. Relative viscosity–shear rate curves for xanthan at different polymer concentration. Solvent: 0.1 *M* NaCl; $T = 25^\circ C$; $M_w = 7 \times 10^6$. Reproduced from Ref. 209, with the permission from Springer-Verlag GmBh & Co. (Copyright 2003).

The native gellan gives highly viscous solutions with a loose gel-like behavior. After deacylation, gellan gives a strong and rigid gel; a comparison between the native and deacylated gellan has been done (211,212). The chemical structures of the repeat units of the native and deacylated gellans are easily controlled by ^1H NMR.

The mechanism of gelation of deacylated gellan was examined and shown as a two-step process similar to the mechanism proposed for κ-carrageenan (182,213). Deacylated gellan adopts an ordered double-helix conformation in salt excess and the temperature for conformational change T_m increases when the salt concentration increases as is usual for stereoregular Polyelectrolytes (qv). The helical conformation is more stable in the presence of divalent counterions but no ionic selectivity appears among monovalent counterions (Li, Na, K, TMA) on one side and among divalent counterions (Ca, Mg) on the other side (212). When the salt and polysaccharide concentrations increase, the double helices interact to give a physical gel with strong ionic selectivity. The sequence of selectivity is

$$K^+ > Na^+ > Li^+$$

K^+ promotes gel formation and gives the higher elastic modulus.

Many new bacterial polysaccharides are now under development when they have specific physical behavior.

Mammalian Polysaccharides

Two homopolysaccharides are found in animals: glycogen and chitin. The others are heteroglycans based on disaccharide repeat units (they are also named glycosaminoglycans).

Glycogen. It is a storage polysaccharide able to produce D-glucose depending on the nutritional level. It is a highly branched neutral polysaccharide, analogue to amylopectin but more highly branched; thus, its solubility in water is larger.

Chitin. It is found in bacteria, fungi (such as *Aspergillus niger*), and crustaceans but only crustaceans are important commercial sources (see CHITIN AND CHITOSAN). Especially crab or shrimp shells are the main sources of chitin; *in situ* chitin is embedded in calcium carbonate and proteins. Chitin is a linear polymer made of $\rightarrow$4(β-D-*N*-acetyl-D-glucosamine)-1. Treatment of shells with acid and alkali allows isolation of chitin partially deacetylated. When chitan in decetylated to about 50% of the free amine form it is refered to as chitosan. Chitin is the renewable polysaccharide of most importance in quantity produced per year after cellulose. It has found many applications, at least on laboratory scale in food, medical, cosmetic applications in which their original structure is appreciated. After partial deacetylation, the polymer becomes soluble in acidic conditions by protonation of the amino group in C-2 position; the intrinsic pK of the $-NH_2$ groups is around 6 (214,215). Methods for characterizing chitosans with different degrees of acetylation (DA) have been re-examined using infrared spectroscopy and NMR (216–218). The molar mass distribution was examined by SEC (219). This polymer is the only natural water soluble polycation; it may be used for flocculation in water purification. It is recognized for its mucoadhesive properties. Unlike cellulose or starch, chitosan is able to be chemically modified on the specific C-2 position of the glucosamine unit. Several derivatives have been prepared. Alkylation gives alkylchitosans (220,221), amphiphilic polymers which are good thickeners. Carboxymethylation gives an anionic polymer (222) and quaternization of $-NH_2$ gives a cationic polymer (223,224). Grafted cyclodextrin–chitosan has also been prepared (225,226). Another original property of chitosan is its chelating properties; a specific complex is formed with Cu^{2+} and its structure has been proposed (227,228). The applications and biochemical properties of chitosan have been reviewed in two books (229,230).

Proteoglycans. They are carbohydrate–protein polymers in which many long polysaccharide chains are covalently linked to the protein core. The percentage of protein is low. They are also classified as glycoproteins, but the name proteoglycan is now preferred to the historical term mucopolysaccharide. These polymers are widely distributed in connective tissue, cartilage, tendon, or synovial fluid. Carbohydrate components (with an alternating structure $(AB)_n$ divided into six groups) based on disaccharide repeat units (Table 7) are joined to the protein core in different ways by a N- or O-glycosidic linkage. Depending on their composition, glycoaminoglycans are known as hyaluronan, chondroïtin sulfate (in 4- or 6-position), dermatan sulfate, heparin, heparan sulfate, and keratan sulfate. Much research is in progress on these biopolymers; a review on the structure, properties, medical and biological applications of hyaluronan has been published (231).

Table 7. Disaccharide Units Constitutive of Proteoglycans

Basic disaccharide unit	Common names
GlcNAcβ1,4-GlcAβ1,3	Hyaluronic acid
GalNAc(6 or 4-SO_3^-)β1,4-GlcAβ1,3	Chondroitin sulfate
GalNAc(4-SO_3^-)β1,4-L-IduAα1,3	Dermatan sulfate
GlcNSO$_3$(6-So_3^-)α1,4-L-IduAα1,4	Heparin
GlcNSO$_3\beta$1,4-L-IduAα1,4	Heparan sulfate
GlcNAc(6-SO_3^-)β1,3Gal(6-SO_3^-)β1,4	Keratan sulfate

Glycoconjugates

Glycoconjugates, eg glycoproteins and glycolipids, are biopolymers; the name indicates that the carbohydrate is the minor component. In the glycoconjugates, oligosaccharide moieties consist of up to 20 monomers. They are basic components of all the cell membranes. Thus, certain oligosaccharides can be associated with degenerative cell growth and can be used in cancer diagnostics as so-called tumor-associated antigens.

Glycoproteins. They are proteins containing one or several oligosaccharide side chains. The linkages are N- or O-glycosidic linkages or by ethanolamine phosphate. The *O*-glycoproteins seem to be more involved in the stabilization and protection of protein structures rather than as signaling molecules in cell communication.

Glycolipids. They are amphiphilic molecules of low molecular weight. The lipophilic part consists of 1,2-di-*O*-diacylglycerol or *N*-acylsphingosin; the hydrophilic part is a phosphate group and/or a carbohydrate moiety. There are many glycolipids with different covalent structures with specific biological roles.

Another series of glycoconjugates (but usually not joined in this classification) is represented by natural plant gums such as Arabic gum which is recognized as very specific to stabilize emulsion. In these polymers, the glycosidic part is the most important in weight fraction compared to the protein fraction.

Glycopolymers

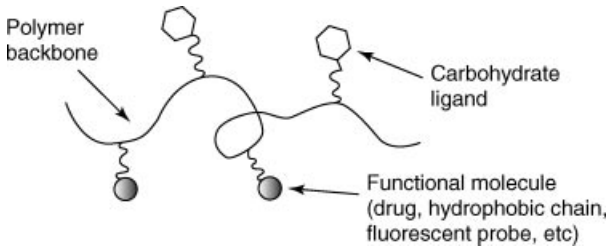
Under this term we refer to synthetic polymers in which at least one of the monomers engaged contains a saccharidic unit.

The extensive participation of saccharides in recognition processes has sparked the synthesis of new polymeric materials expected to have sophisticated functions similar to or even superior to natural glycoconjugates. Numerous synthetic polymers carrying various kinds of saccharide residues as information elements have therefore been developed. It has been shown that such glycoconjugates may have enhanced binding capacity with lectins based on a polymer sugar-cluster effect whereas the monomeric carbohydrate derivatives exhibit only weak affinity to the same lectins (232–235). These “glycopolymers” have thus diverse potential uses, such as multivalent inhibitors of cell or virus binding, cell-specific culture substrata, artificial antigens, targeted drug delivery systems. The

term "glycopolymers" was first introduced by Roy and co-workers (236) as a replacement for "pseudo-polysaccharide" previously used, to designate water-soluble as well as insoluble polymers bearing covalently bound carbohydrates. In the following, the term *glycopolymer* refers to synthetic (or natural) linear polymers possessing sugar moieties as pendant or terminal groups irrespective of whether they are water soluble or not. Glycopolymers can be obtained by polymerization of sugar-carrying monomers. An alternative synthetic method consists of the chemical modification of preformed polymers using carbohydrate-containing agents. Nevertheless, both strategies generally rely on the same carbohydrate precursors.

In accordance with the great attention that these glycoconjugates have attracted for the last 10 years, several reviews on the synthesis and biological functions of these macromolecules have been published (237–243). In fact, the selection and design of a glycopolymer for a given application is a challenging task because of the inherent diversity of structures and to the impact of the latter and solution conformation of the sugar-containing polymers on their biorecognition. Here in is considered glycopolymers with an emphasis on their structures, their physicochemical and biological properties, and their applications.

Synthesis Strategy. Polymer chemistry offers the possibility to prepare glycopolymers with custom-designed properties since several groups with specific properties can be easily introduced along the polymer chain, as shown in the scheme:



Indeed, besides the saccharide moieties which are expected to act, in most cases, as recognition signals, various molecules such as hydrophobic chains, fluorescent probes, and drugs can be used to modulate the solution properties of the polymer, label the cells, or deliver a given drug on site. In addition, the polymer backbone can be adjusted to confer desired physical or biological properties.

The most commonly used strategies for the syntheses of such glycopolymers involve direct homopolymerization of sugar-bearing monomers or copolymerization of the latter with one or two other monomers. The next most used strategy involves chemical modification of preformed polymers with suitably functionalized carbohydrate residues. Generally, both methodologies require the same glycosynthons and several methods leading to activated carbohydrate derivatives suitable to be covalently linked to either a preformed polymer or a polymerizable anchor have been described. These methods belong to five main categories, discussed below and depicted in Figures 33–37.

The first one relies on standard glycosylation chemistry, providing *O*-, *C*-, or S-glycosides having, for example, alkene, styrene or amine groups in the aglycon portion (Fig. 33) (236,244–255) The intermediate amine-containing glycoside can be used in graft copolymerizations or acryloylated to give a monomer precursor.

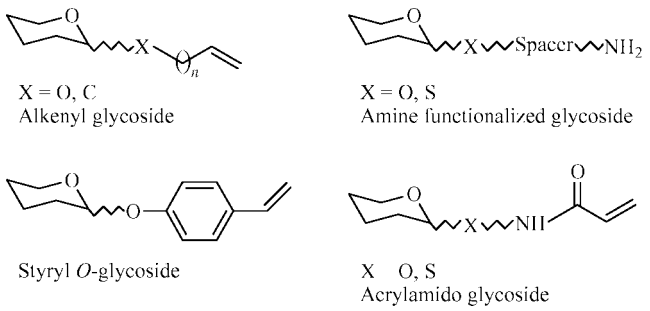


Fig. 33. Examples of glycosynthons obtained by standard glycosylation reactions.

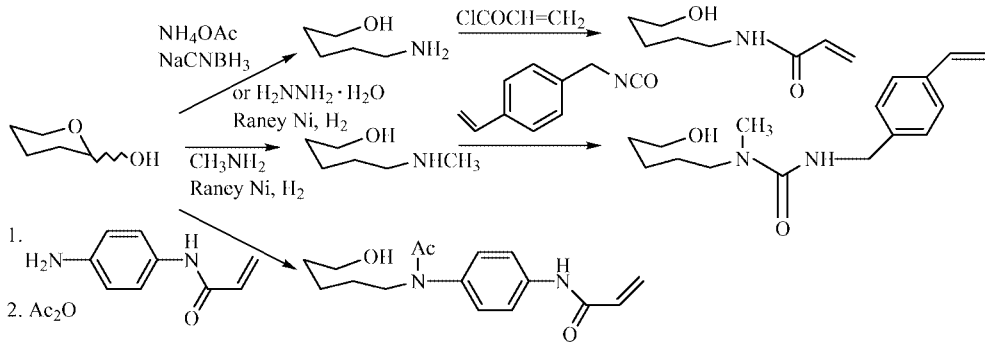

Fig. 34. Synthetic routes to carbohydrate monomers based on the reductive amination reaction.

The second approach is based on the reductive amination of the saccharide (lactose, maltose, *N*-acetylchitooligosaccharides, etc) by ammonium acetate, hydrazine, *N*-methylamine, or 4-acrylamidobenzylamine, followed by N-acryloylation (256,257), addition of 4-vinylbenzyl isocyanate (258) or N-acetylation (259,260) (Fig. 34).

This method is quite easy and rapid; however, it leads to an altered saccharide, the reducing sugar being transformed into a linear polyol amine derivative. Therefore, it is rather applied to oligosaccharides since at least, the terminal sugar is preserved.

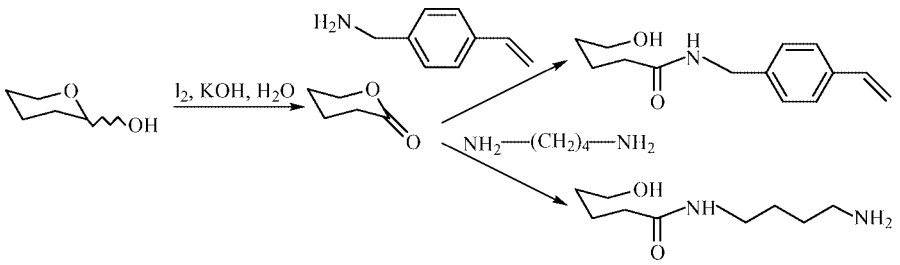

Fig. 35. Preparation of suitable glycosynthons for polymer synthesis from carbohydrate lactones.

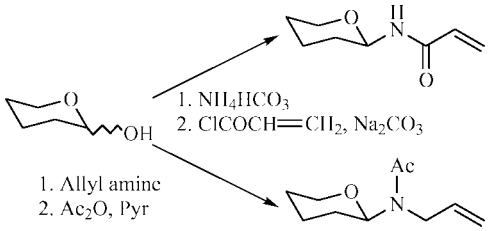

Fig. 36. Synthetic routes to polymerizable glycosylamides.

In the third approach, the reducing end of the carbohydrate (maltose, lactose, maltotriose, etc) is oxidized by hypoiodite and then, the resulting lactone can be condensed with *p*-vinylbenzylamine (261) or 1,4-diaminobutane (262) (Fig. 35). For the same reasons as those described above, this reaction is rather applied to oligosaccharides.

In the fourth approach, the carbohydrate can be reversibly converted into a glycosylamine by treatment with an ammonium salt (263,264) or an aliphatic amine (265,266). However, these derivatives are quite unstable in slightly acidic medium or neutral medium. They are further stabilized by acylation with, for example, anhydride acetic (265), *p*-vinylbenzoyl chloride (267), acryloyl chloride (263), or chloroacetic anhydride, followed by ammonolysis (268) (Fig. 36). The N-linked structure of these glycosynthons is distinct from the open chain structure of the carbohydrate derivatives described above. This method may be useful to introduce complex oligosaccharides.

These different methodologies generally provide unprotected activated glycosynthons. Carbohydrate hydroxyl or amine residues at positions other than the anomeric center can also be used to introduce functional groups for direct or graft polymerization. These carbohydrate precursors can be fully protected or unprotected. However, in the former case, the resulting glycopolymers must undergo a final deprotection step of the carbohydrate moieties under the usual conditions. Some examples of these glycosynthons such as *N*-methacryloylglycylglycylgalactosamine (MA-GG-GalN) (269,270), diacetone glucofuranose acrylate (271), *p*-vinylbenzylether (272) are given in Figure 37.

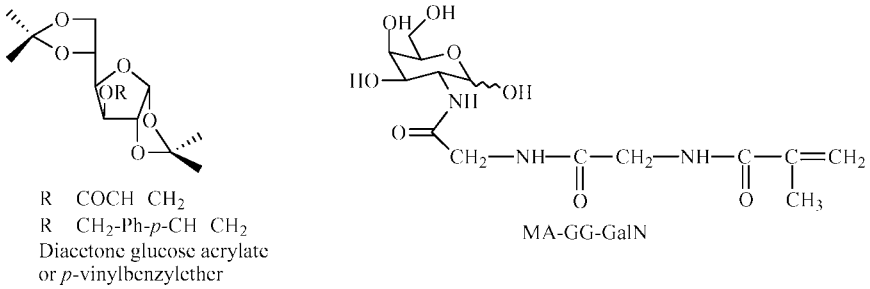

Fig. 37. Examples of carbohydrates monomers bearing a polymerizable group at a position other than the anomeric center.

In this last approach, although it has been shown in some cases that the carbohydrate–protein interaction remains efficient (269,270), the carbohydrate modification at a position other than the anomeric center may decrease its affinity toward the protein.

Glycopolymer Syntheses by Homo- or Copolymerization. The radical polymerization of *N*-acryloylated carbohydrate precursors with acrylamide and/or acrylamide derivatives with specific properties is likely one of the most commonly used strategies for the syntheses of glycopolymers. Indeed, this is a versatile method which can be easily and efficiently performed in aqueous solution from unprotected sugar-carrying monomers. Moreover, it generally leads to water-soluble derivatives. This method has been extensively used for the preparation of sialic acid bearing polyacrylamides as inhibitors of influenza virus adhesion (251–253,273). Several custom-designed glycopolymers made of two or more components were also synthesized according to this methodology. Various applications of such copolymers have been envisaged as discussed in the following section.

Numerous carbohydrate styrene monomers such as (*p*-vinylbenzamido)-β-lactose and *N*-(*p*-vinylbenzyl)-4-*O*-β-D-galactopyranosyl-D-gluconamide have been homopolymerized (or copolymerized) in an organic solvent (dimethyl sulfoxide) using 2,2′-azobisisobutyronitrile (261,267). The resulting polystyrenes, having amphiphilic structures, were shown to have strong affinity toward specific lectins. Moreover, the hydrophobic effect of the styrene moiety allowed preparation of polymeric nanospheres with a polystyrene core and a glycopolymer corona. These nanospheres were synthesized by free radical copolymerization in a polar solvent (ethanol/water mixture) of styrene with a hydrophilic carbohydrate macromonomer such as the glucosyloxyethyl methacrylate macromonomer (Fig. 38) (274). The concanvalin A lectin recognized the glucose on the nanospheres with a better binding activity than with the monomeric glucose.

Living polymerization techniques have been successfully used for the synthesis of glycopolymers with controlled molecular weights and molecular weight

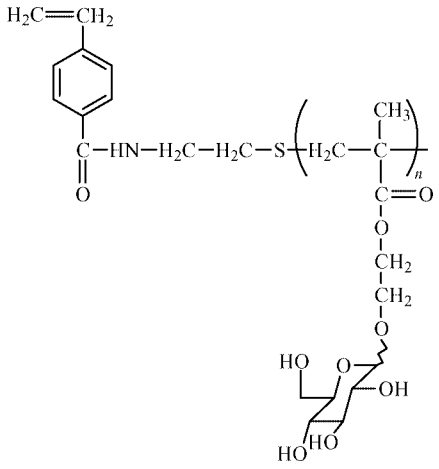

Fig. 38. Structure of the glucosyloxyethyl methacrylate (GEMA) macromonomer.

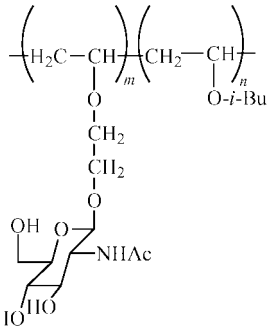

Fig. 39. Example of an amphiphilic block copolymer obtained by living cationic polymerization.

distributions. They have also served for the preparation of well-defined block copolymers. These methods are based on "living" radical polymerizations such as nitroxide-controlled polymerization (271,275) and atom transfer radical polymerization (276), living cationic (277–279) or anionic (280) polymeriation (see LIVING POLYMERIZATION, CATIONIC; ANIONIC POLYMERIZATION; CARBOCATIONIC POLYMERIZATION). Thus these polymerization strategies allowed preparation of new amphiphilic block copolymers, the hydrophilic segment having pendant sugar moieties (see Fig. 39). However, one of the drawbacks of the approach is that it involves protected carbohydrate monomers and thus, a final deprotection step of the glycopolymer is necessary.

An alternative method developed by Kiessling and co-workers is ring-opening metathesis polymerization (ROMP) (281–285). A significant advantage of this strategy is that living polymerization can be performed from unprotected carbohydrate monomers including, for example, sulfated sugar-carrying monomers. Moreover, besides the possibility of preparing block copolymers, specific endlabels can be introduced. However, although the molecular weight distribution of glycopolymers obtained by the ROMP strategy is narrower than polymers prepared through classical radical polymerization approaches, the control of molecular weights remains difficult.

Glycopolymer Syntheses by Reactions on Preformed Polymers. Compared to the methodologies based on polymerizations of sugar-carrying monomers, the chemical modification of preformed polymers using carbohydrate-containing reagents is generally advantageous as it requires fewer reaction steps and it allows easy control of the number of sugars along the polymeric chain. Moreover, large quantities of preformed polymers can be synthesized with the desired molecular weight. Therefore, the same polymer backbone can be used to prepare glycopolymers with different carbohydrate contents and/or carbohydrate residues. Of course, the preformed polymers must have reactive functionalities such as amine, carboxylic acid, or alcohol groups. These polymers may be activated or not. For instance, polyacrylates with *p*-nitrophenyl (249,268) or succinimidyl esters (252,255) react at room temperature with carbohydrate amines in aprotic polar solvents (DMSO or DMF) to give glycopolymers after the quenching of excess active esters with sodium hydroxide, ammonia, or ethanolamine.

Carbohydrate amines also react with polymers possessing pendant hydroxyl groups partially functionalized with *p*-nitrophenyl carbonate groups (286). Maleic anhydride copolymers have the advantage of being directly modified by carbohydrate amines under mild conditions. This method allowed efficient preparation of various glycopolymers useful for solid-phase assays or new drug delivery systems (262,287–289). Various carbohydrate derivatives have also been grafted to natural polymers such as chitosan. The free amine group at the C-2 position of the glucosamine unit can easily react with aldehydes which allows preparation of a wide variety of compounds such as L-fucose-, D-fucose-, D-mannose-branched chitosan (290), cyclodextrin-grafted chitosans (225,291,292), and a sialic acid dendron-grafted chitosan (293).

Moreover, the pendant carbohydrate chains of synthetic glycopolymers have been shown to be further elongated by enzymatic reactions. Thus, by this approach, Nishimura and co-workers have been able to prepare a glycopolymer having a sialyloligosaccharide using glycosyl transferases and transglycosidases (294). More recently, this strategy allowed the selective modification of a glycopolymer possessing both lactose and mannose residues (254). Indeed, using a galactosyl transferase, a galactose unit could be introduced specifically on the pendant lactose moieties.

Role of Glycopolymer Structure. The properties of glycopolymers of course depend on the nature of the pendant saccharide chain as a biorecognizable element, but also on the whole chemical structure. Indeed, the latter influences conformation, charge, biodegradability, etc, which are important parameters for the glycopolymer functions. For example, glycosylated polystyrenes have been shown to exhibit strong binding affinities to lectins, viruses, and cells (267,295,296) The strong binding affinity has been attributed to the characteristic conformations based on the amphiphilic structure of glycopolystyrenes. Indeed, the hydrophobic main chain tends to form a hydrophobic core that is sheltered from water, and hence the saccharide chains gather on the outside of the polymer in water. In addition, as mentioned above, the hydrophobic effect of the styrene moiety allowed preparation of original polymeric nanospheres having a polystyrene core and a glycopolymer corona. Furthermore, the significant enhancement of protein–carbohydrate interactions due to hydrophobic associations in water has been well evidenced by Kopecek and co-workers (269) who have synthesized glycopolymers with photoresponsive benzospiropyran side chains. Upon irradiation by UV light, benzospiropyrans change to a red colored polar (zwitterionic) merocyanine form. On exposure to visible light, merocyanine converts back to the nonpolar (hydrophobic) spiro form. Thus, under visible light, the photoresponsive glycopolymers show a high lectin binding due to contraction of the polymer chains, which tends to increase the probability of formation of clustered saccharide chains. After irradiation, the binding decreases as a result of the expansion of polymer chains.

The flexibility of glycopolymers may also have a large influence on their biorecognition. In the case of flexible glycopolymers, the increased content of carbohydrate side chains generally increases biorecognition. This is not confirmed at all in the case of rigid ones. Indeed, rigid cylindrical phenyl isocyanide (PPI) glycopolymers have been shown to exhibit little specific interactions with lectins (297). In these systems, the saccharide arrays are crowded too thickly to be accessible or to be induced-fit to the binding sites. The decrease of saccharide density

by insertion of comonomer units into the rigid PPI glycopolymer backbone was found to increase the binding affinity to the lectin.

Applications of Glycopolymers. Most applications of glycopolymers arise from the specific molecular and cell recognition of saccharides. Therefore, many bio- and immunochemical properties have been demonstrated for a large number of glycopolymers. The synthesis of sugar-based hydrogels from carbohydrate monomers and cross-linking agents or by covalent attachment of carbohydrates to commercially available affinity supports made of agarose, cellulose, or polyacrylamide allowed preparation of new bioaffinity supports (298–300). The latter have been used for the purification of antibodies, enzymes, lectins, and myeloma proteins. Sugar-based hydrogels also show potential as substrates for cell growth. Indeed, the replacement of agar, used in culture plates, by hydrogels containing specific sugars may enhance the adhesion of cells. Such properties have also been evidenced by a lactose-carrying styrene homopolymer (301,302). The latter has been shown to be adsorbed on the surface of glass culture dishes and the resulting polymer-coated dishes have been found to be useful for hepatic cell cultures.

Moreover, glycopolymers have been shown to constitute very sensitive coating antigens in solid-phase enzyme-linked immunosorbent assays (ELISA). In comparison to protein glycoconjugates, glycopolymers offer several advantages such as lower cost productions and improved thermal and biological stabilities. Therefore, many examples of applications of glycopolymers in the detection of carbohydrate-binding proteins including serodiagnosis of bacterial antigens have been reported. These have been summarized in several reviews (240–242).

Glycopolymers can also be advantageously used to inhibit cell adhesion. Typical examples are polymers bearing pendant α-sialoside groups which show potent anti-influenza activity (249,251–253,268,273,303). Indeed, it is now well established that human infections by influenza viruses are mediated by the binding of the viral membrane protein hemagglutinin (hyaluronan) to sialosides on cell surface glycolipids and glycoproteins. The inhibitory properties of such glycopolymers illustrate the value of cooperative polyvalent interaction in the design of potent inhibitors of viral adherence to the host cell.

Glycopolymers also show promising properties as drug-targeting delivery agents. One of the most successful polymer–drug–saccharide conjugate systems reported are the *N*-(2-hydroxypropyl)methacrylamide (HMPA) copolymer–adriamycin (ADR)–sugar conjugates, in which both ADR and sugar were attached to a polymer backbone via lysosomally cleavable oligopeptide spacers (304). The conjugates containing galactosamine moieties were reported to accumulate in the liver selectively (305). Other glycopolymers such as lactose-carrying styrene polymers were also found to be very efficient liver-specific targeting materials (306).

Besides these fields of applications, Wulff and co-workers (307,308) investigated the potential ability of glycopolymers to modify surface properties. Thus, they copolymerized several isopropylidene-protected vinyl sugars with styrene, methyl methacrylate, and acrylonitrile. After eliminating the isopropylidene protecting groups from the copolymer surfaces by acid hydrolysis, these surfaces were shown to become hydrophilic with improved dyeability and surface conductivity.

Synthesis of Oligo- and Polysaccharides

The chemical synthesis of oligosaccharides or their analogues is well developed now; nevertheless, it is a difficult task. Protection of labile groups of the —OH position which are not engaged in an osidic linkage is needed. Then, reaction with specific groups of the anomeric and nonanomeric position must be done with a control of the stereochemistry of the anomeric position. Oligosaccharides in which glycosidic oxygen atoms are replaced by sulfur atoms can be routinely synthesized by iterative or convergent approaches (309,310) and these nonnatural compounds are not hydrolyzed by various glycosidases (311,312).

Polysaccharides having a regular structure were first obtained by polymerization of anhydrosugars or step-by-step elongation. For synthesis of irregular structures, a step-by-step elongation by polycondensation is the usual method at least to produce the repeating unit which is then polymerized. These routes have been discussed previously in the review of Kochetkov (313).

A different but interesting approach comes from the enzymatic polymerization of the corresponding mono- or disaccharide precursors with controlled structure.

Synthesis of Regular Polysaccharides. The first attempt at such synthesis appears with the work of Haq and Whelan in 1956 (314); they proposed, without success, the polycondensation of 2,3,4,-ti-*O*-acetyl-α-D-glucosyl bromide in the presence of Ag_2O and $CaSO_4$ to get a (1–6)-β-D-glucan. Other negative attempts have been published (313).

The most fruitful results came with the synthesis of polysaccharides by polymerization of anhydrosugars. Schuerch (315–317) investigated the mechanism of cationic polymerization in solution of 1,6-anhydro-hexopyranoses wherein the 2,3,4 positions were protected by benzyl groups. He got high molecular weight (1,6)-α-D-glucan and the benzyl groups were easily removed at the end of polymerization. The 1,4; 1,3; 1,2 anhydrosugar polymerizations were also performed with less success. However, (1–3)-α-D-glucopyranans and (1–3)-α-D-mannopyranans were obtained with high stereoregularity. These results are discussed in the review by Kochetkov (313).

Chemoenzymatic Synthesis. Original oligosaccharides bifunctionalized with fluorescent entities were synthetized in the presence of a mutant of *Humicola insolens* endoglucanase (318). Hemithiocellodextrins with degree of polymerization from 4 to 14 were synthetized in the presence of a cellulase in buffer/organic solvent (319).

Homopolymers were also obtained with mutant of Barley (1,3)-β-D-glucan endohydrolase producing (1,3)-β-D-glucan and with mutant of cellulase producing β-(1$\rightarrow$4)-oligo- and polysaccharides (320,321).

A very active research is lead by the Kobayashi group in Japan; in a recent review, cellulose, chitin, and xylan syntheses were described using Enzymatic Polymerization (qv) (322).

Hydrolases were most often used as catalyst forming the glycosidic bonds *in vitro*. Recently, synthetic polysaccharides were synthetized using other enzymes such as glycosyltransferase, phosphorylases, oxidoreductases, and lipases (323).

Copolymers may also be produced using combinations of chemically modified mono- or disaccharides and enzymatic condensation. Such a route has been proposed to prepare an artificial hyaluronan, GlucA-β-(1→3) GlucNAc oxazoline monomer reacting with hyaluronidase (324).

PROCESSING, MODELING

Introduction

A *model* is a quantitative abstraction of a physical process, in which the description of the process is represented by the solution to a set of mathematical equations (1,2). The model equations represent the behavior of the real process to the extent that the equations embody an accurate description of the underlying physical and physicochemical phenomena. The mathematical formulation enables the model to be used for a variety of purposes, including design, control, and exploration of operating strategies; the effects of changes in process variables and material properties can be inferred from the model without extensive experimentation. Mathematical models have long been used for these purposes in the chemical and petrochemical industries, and computer-aided design and computer-aided manufacturing (CAD/CAM) have been taking on growing importance in some polymer processing operations.

The essential elements of any model of a physical process are threefold: the geometry, the relevant laws of physical conservation (mass, momentum, and energy), and the specific constitutive relations. In polymer processing applications, the last of these could include the stress-deformation equations for the material being processed (the material rheology) and the kinetic equations for phase change. The mathematical complexity of a model depends on the process and the type of information required. Qualitative information can often be obtained from a model that greatly simplifies the physical phenomena to obtain mathematical simplicity and consists only of one or more algebraic equations, for example, whereas structural predictions typically require the consideration of details of stress and flow fields and hence the solution of nonlinear partial differential or integral equations. Advances in computing technology have made the latter goal possible for some processing applications (3,4).

The term *computer model* is often employed as a consequence of the extensive use of computing technology in conjunction with mathematical models. This terminology is unfortunate, because it confuses modeling and simulation. The equations describing the physical phenomenon make up the model and incorporate the full understanding of the process. The model is independent of the means that are used to solve the equations, which might be analytical or numerical, with or without the use of computers. Application of the model to simulate some specific situation requires the choice of a solution technique; numerical artifacts associated with the solution method could introduce errors that are not inherent in the physical assumptions on which the model is based. Comparison of the predictions of a model with experiments requires careful separation of the effects of modeling assumptions and numerical techniques.

Polymer processing operations include polymerization reactors; devices for mixing, conveying, and extruding molten polymer or polymer solutions; and devices for forming shaped objects in the liquid state and post-forming solid-state operations. The modeling of chemical reactors to predict conversions and product distributions is a mature art (5). Efforts in this field have focused on process control and the conditions leading to instabilities and "runaway" reactions.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Polymerization reactors form a subset of the subject of reaction engineering, distinguished only by the need to know the details of the specific reaction pathways and kinetics, and perhaps the dependence of viscosity on conversion. Polymerization reactions and reactors, including reaction injection molding, are treated elsewhere, and this article is concerned only with the modeling of the mechanics and structure development in mixing, conveying, extrusion, and forming processes.

Rheology

Models of the mechanics of polymer processing operations can be categorized by the rheological description used. Low molecular weight liquids are Newtonian, which means that the stress at any point in a deformation field is a linear function of the instantaneous rate of strain and is independent of any prior history; the stress in an incompressible Newtonian liquid is characterized by a single material parameter, the viscosity (η), which can be temperature- and pressure-dependent but is independent of the deformation rate:

$$\boldsymbol{\sigma} = -p\boldsymbol{I} + \boldsymbol{\tau} \tag{1}$$

$$\boldsymbol{\tau} = \eta[\nabla v + (\nabla v)^{\mathrm{T}}] \tag{2}$$

Here, $\boldsymbol{\sigma}$ is the total stress, p the isotropic pressure, $\boldsymbol{I}$ the identity (unit) tensor, and $\boldsymbol{\tau}$ the extra stress (ie, the stress in excess of the isotropic pressure). ∇ is the gradient differential operator, and v is the velocity vector; $^{\mathrm{T}}$ denotes the transpose of a tensor. For a one-dimensional flow with a single velocity component v, in which v varies in a single spatial direction y that is transverse to the flow direction, equation 2 simplifies to the familiar form

$$\tau = \eta \, \mathrm{d}v/\mathrm{d}y \tag{3}$$

When the flow is isothermal and the liquid has a viscosity that can be taken to be independent of pressure (ie, η is constant over the entire flow field), substitution of equations 1 and 2 into the balance of linear momentum leads to the Navier–Stokes equations, which have been the subject of intense study in classical fluid mechanics for more than a century.

In contrast, the stress in a macromolecular liquid depends in a nonlinear manner on the entire history of deformation. The nonlinearity is manifested by phenomena such as the strain-rate dependence of the shear viscosity, strain hardening in extension, and the transverse normal stresses in shear flow that cause extrudate swell. The dependence on history is demonstrated by the transient buildup and relaxation of stresses following changes in flow variables, and by the existence of the dynamic storage modulus (G') in oscillatory shearing. There have been many routes to the development of appropriate stress constitutive equations for use in processing flows of polymeric liquids (6–8), including general continuum mechanics formulations and molecular and quasi-molecular theories. No constitutive theory developed to date is adequate for quantitative predictions in all processing flows, in some cases because the complexity of the equation prevents

efficient calculation in complex flow geometries, but some stress equations have been useful in particular classes of flows.

Purely viscous constitutive equations, which account for some of the nonlinearity in shear but not for any of the history dependence, are commonly used in process models when the deformation is such that the history dependence is expected to be unimportant. The stress in an incompressible, purely viscous liquid is of the form given in equation 2, but the viscosity is a function of one or more invariant measures of the strength of the deformation rate tensor, $[\nabla v + (\nabla v)^{\mathrm{T}}]$. [An invariant of a tensor is a quantity that has the same value regardless of the coordinate system that is used. The second invariant of the deformation rate tensor, often denoted II_{D}, is a three-dimensional generalization of $2(\mathrm{d}v/\mathrm{d}y)^2$, where $\mathrm{d}v/\mathrm{d}y$ is the strain rate in a one-dimensional shear flow, and so the viscosity is often taken to be a specific function–a power law, for example–of $(\frac{1}{2}\mathrm{II}_{\mathrm{D}})^{\frac{1}{2}}$.]

The dependence of the stress on the strain-deformation history of macromolecular liquids can be incorporated in two ways. The stress constitutive equation can be formulated as a differential equation, in which the extra stress $\boldsymbol{\tau}$ is the solution of an equation that is typically of the general form

$$\mathbf{A}(\boldsymbol{\tau}/G)\cdot\frac{\boldsymbol{\tau}}{G}+\lambda\frac{\mathcal{D}(\boldsymbol{\tau}/G)}{\mathcal{D}t}=\lambda[\nabla v+(\nabla v)^{T}] \tag{4}$$

Here, $\mathbf{A}(\boldsymbol{\tau}/G)$ is a nonlinear tensor function of the extra stress; the simplest such form is a Maxwell liquid, in which $\mathbf{A}$ is equal to the unit tensor and the first term in equation 4 simply becomes $\boldsymbol{\tau}/G$. λ is the time constant for stress relaxation, and G is the shear modulus, which is a material property; the shear viscosity η is equal to the product λG. $\mathcal{D}/\mathcal{D}t$ denotes a nonlinear time derivative that accounts for the invariance of the physical quantities under changes of the frame of reference of the observer; $\mathcal{D}/\mathcal{D}t$ contains terms of the form $\boldsymbol{\tau}\cdot\nabla\boldsymbol{v}$, but the precise form depends on the particular constitutive theory. Equations of this type follow from transient-network theories, which are based in part on concepts embedded in the theory of rubber-like elasticity. Equations of this type also follow from "tube" or "reptation" theories, in which the chain in an entangled melt or concentrated solution is envisioned as being restricted to an imaginary tube made up of the constraints imposed by the surrounding chains, which restrict chain motion that is transverse to the molecular backbone. (Differential equation forms for tube models usually require mathematical approximations that are not contained in the basic model.) The relaxation time and shear modulus depend on the deformation rate or stress in some theories, whereas in others they depend on a dynamical scalar or tensor variable characterizing the structural state of the melt or solution. If the spectrum of relaxation modes characterizing the linear viscoelastic response is to be included, the stress is comprised of a sum of terms,

$$\boldsymbol{\tau}=\sum\boldsymbol{\tau}_i \tag{5}$$

where each term in the sum satisfies an equation of the form of equation 4, with a spectrum of material parameters $\{\lambda_i, G_i\}$. The values of the spectral parameters in the limit of vanishingly small deformations are obtained from classical linear viscoelastic experiments.

The stress constitutive equation can also be formulated as an integral over the history of the deformation. The most common form used for simulations is

$$\tau(t) = \int_{-\infty}^{t} m(t-t')\, h(\mathrm{I_C}, \mathrm{II_C})\, \mathbf{C}^{-1}(t,t')\, dt' \tag{6}$$

Here, $\mathbf{C}^{-1}$ is the Finger measure of strain and $m(t)$ is a memory function that can be determined from the linear viscoelastic response; $m(t)$ can be expressed in terms of the spectral parameters $\{\lambda_i, G_i\}$ and is usually taken to be a sum of exponentials. $h(\mathrm{I_C}, \mathrm{II_C})$ is a nonlinear "damping" function that depends on the first and second invariants of the Finger strain. Other strain measures may also be used, and the popular K-BKZ model includes a small second term proportional to the Cauchy strain measure **C**. The time–strain separability indicated by the product of the functions m and h fails experimentally at very short times (9). As with the differential equation forms, constitutive models of the general form of equation 6 follow from general continuum mechanics formulations, from transient-network formulations, and from tube theories. There is sometimes a one-to-one equivalence between a differential and integral equation formulation, but in general only approximate equivalences can be developed. Most tube models are naturally formulated as integral equations.

There are advantages and disadvantages to both differential and integral constitutive equations. Differential equations adapt naturally to the numerical methods commonly used for the solution of the momentum and energy equations, which are in differential form, and most process modeling has been carried out using differential stress constitutive equations. It is often important to include the relaxation spectrum in process calculations, however, and each term in the spectrum (eq. 5) requires an additional nonlinear partial differential equation in the solution set, which greatly increases the magnitude of the computational problem. The entire spectrum enters naturally in the integral formulation through the memory function $m(t)$, but it now becomes necessary to track the history of the strain with great accuracy along material element paths on a computational grid that cannot be laid out to ensure that particle paths pass through the spatial nodes.

Finally, there are some constitutive models that cannot be expressed in closed form as differential or integral equations, but require the solution of a Fokker–Plank equation (or an equivalent set of stochastic differential equations) for the orientation distribution of chain segments in order to compute the stress (Reference 4, pp. 338 ff; Reference 10 and references therein). This technique may become more useful as computing power increases, but to date it has been used only for viscometric flows and a few very simple non-viscometric geometries.

Classification

Classifications of viscoelastic flows are useful for analysis, mainly in determining conditions under which a viscoelastic constitutive equation that accounts for fluid memory can be replaced by a much simpler purely viscous equation.

The broadest classification scheme that has been found to be useful in modeling is based on the Deborah number (11–13), which is loosely defined as the ratio of the fluid time scale to the time scale of the process. Small Deborah numbers correspond to situations in which stress transients occur rapidly compared to the total processing time; hence the "memory" of the fluid is short and can be neglected. Large Deborah number flows take place over a time scale in which stress transients cannot be neglected, and a viscoelastic description like that in equation 4 or 6 is essential. The significance of this classification is apparent in a linear viscoelastic frequency sweep, where the Deborah number is the product of the relaxation time λ and the frequency ω; for $\lambda\omega \ll 1$ the loss modulus G'' dominates and the response is that of a viscous liquid, whereas for $\lambda\omega \gg 1$ the storage modulus G' dominates and the response is closer to that of an elastic solid. The fluid time scale is unambiguous for polymeric liquids described by constitutive equations such as equation 4; if the spectrum of relaxation times is required, as with equation 5 or 6, an average or maximum relaxation time would be used, and there is some ambiguity in the choice. There is frequently ambiguity in the choice of the process time scale; the residence time is the obvious choice in a unidirectional flow, but the selection is not clear in more complex flow fields.

The concept of strong and weak flows (14) is one attempt to quantify the Deborah number concept unambiguously. This classification is based on the notion that shearing flows are an ineffective (weak) means of stretching polymer molecules, whereas extensional flows can be effective (strong) in elongating molecules. The physical basis for the concept is rooted in the coil-stretch transition; a macromolecule modeled by a Rouse chain with a maximum relaxation time λ_m will be stretched out in an elongational flow with stretch rate Γ when $\lambda_m\Gamma > \frac{1}{2}$. (The "upper convected" Maxwell model is the continuum equivalent of a fluid made up of Rouse chains, and the stresses in an elongational flow for this fluid model become unbounded when $\lambda_m\Gamma > \frac{1}{2}$.) Let $\boldsymbol{L}$ be the velocity gradient, $\boldsymbol{L} = \nabla v$, and α an eigenvalue of the matrix $\lambda_m\boldsymbol{L} - \frac{1}{2}\boldsymbol{I}$. A flow is strong if any eigenvalue α has a positive real part, in which case a Rouse chain will become fully extended if the time in the flow is large relative to a relaxation time; this is equivalent to the condition $\lambda_m\Gamma > \frac{1}{2}$ for pure extension. A processing flow can be strong in some regions and weak in others according to this classification.

Classification in terms of stress level has not been widely used, but stress level is an important factor in process modeling. It is well known that process behavior in confined flows changes dramatically when the wall stress in highly entangled melts or concentrated solutions is comparable in magnitude to the shear modulus, which is essentially equal to the plateau value of the storage modulus. Flow instabilities like melt fracture (15) are observed, for example, and there is an apparent failure of adhesion between the melt and the metal surface (15). Low stresses are those for which $\|\tau\|/G_p' \leq 1$, where $\|\tau\|$ denotes the magnitude of the stress tensor and G_p' is the plateau modulus. This ratio is equivalent to what is often called the recoverable shear and is proportional in channel flow to a dimensionless group known as the Weissenberg number, $We = \lambda v/d$, where λ is a characteristic relaxation time, v is the average velocity, and d is the diameter or thickness of the channel. As discussed subsequently, the appropriate formulation of wall boundary conditions for model equations is uncertain outside the low stress regime.

Flows must also be classified on the basis of whether the melt is isotropic or anisotropic at rest, and whether the material is homogeneous or heterogeneous. Liquid crystalline polymers are anisotropic at rest and heterogeneous in the melt, containing highly oriented "domains" over micrometer-length scales. Even elementary flows of liquid crystalline polymers have not been successfully modeled, because the continuum rheology is incompletely understood. Highly filled fiber composites are heterogeneous and usually anisotropic in the melt even at rest because of the absence of Brownian restoring forces. Modeling of shaping flows for these systems is primitive, except in some idealized situations, because of the need to account for nonlocal interactions in the rheology. The only well-developed art is for homogeneous polymers that are isotropic at rest.

Numerical Methods

The equations describing polymer processing operations are usually coupled, nonlinear partial-differential or partial-differential-integral equations in which two or three spatial directions and perhaps time appear as independent variables. Fully three-dimensional problems can usually be solved only for purely viscous liquids, and substantial simplification is usually required even for two-dimensional problems of viscoelastic liquids because of limitations of computer speed and memory. In some situations the geometry provides simplifications that lead to closed-form analytical solutions, but these are rare, and numerical methods are usually required in order to obtain process information. Numerical methods relevant to polymer processing flows are discussed in (3,4,16,17). The following three broad classes of numerical methods are in common use:

Finite difference methods are the traditional approach to the numerical solution of partial differential equations. The spatial regime is divided into a grid, as shown in Figure 1. Partial derivatives are approximated by differences; the derivative $\partial u/\partial x$ at grid point (i,j) might be approximated as $[u_{i,j} - u_{i-1,j}]/h$, for example. The partial differential equations are thus reduced to a set of algebraic equations for the values of the dependent variables at the grid points. Iterative

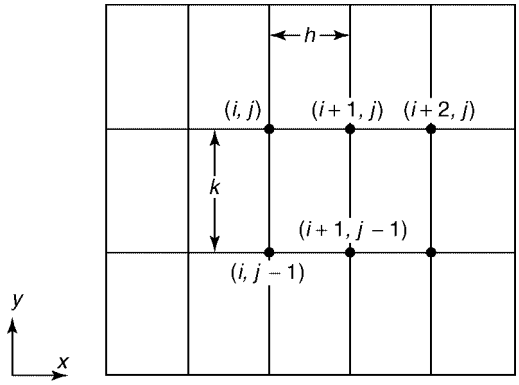

Fig. 1. Finite difference grid.

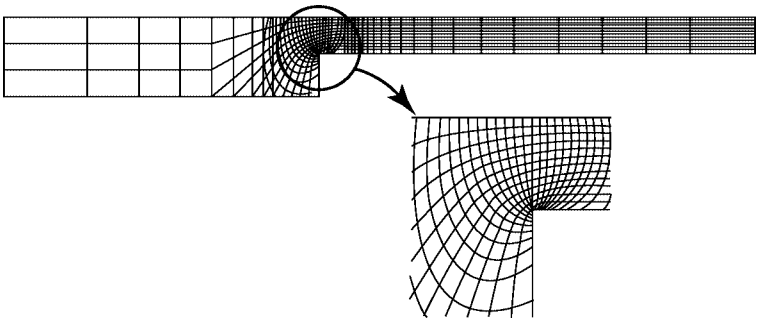

Fig. 2. Finite element grid.

methods are usually required, because the equations are generally nonlinear. Finite difference methods are used infrequently for numerical simulation of viscoelastic flows because of a perceived lack of versatility. Programming is difficult unless the grid spacing is uniform, but accurate approximation of derivatives requires closer spacing of grid points in regions of rapid change of the dependent variables than in regions of little change; nonuniform spacing can be introduced, usually through coordinate transformations, but the techniques for doing so have not been widely adopted for viscoelastic simulation. Finite difference methods are difficult to apply to complex shapes, especially with curved boundaries, although this limitation too can be overcome. Finite difference is the approach of choice for flow problems when inertial effects are significant, but this is rarely the case in polymer processing.

Finite element methods are used in most commercial simulation programs for polymer processing. In this approach the spatial regime is broken up into small elements, usually of triangular or quadrilateral shape, as shown in Figure 2. The solution is approximated over each element in terms of simple functions, usually linear or quadratic, with unknown coefficients that must then be evaluated. The Galerkin method of weighted residuals is the most common method for evaluating the unknown coefficients; in this method, weighted averages of the equations, using the approximating functions themselves as weighting functions, are required to be zero. The approximation leads to a set of algebraic equations for the coefficients that are usually nonlinear and must be solved iteratively. The finite element method is adaptable to complex shapes, and the element size can be easily changed throughout the regime to account for different rates of change of dependent variables.

The Galerkin finite element method has a rigorous foundation for the type of equation set that usually arises in creeping isothermal flow of Newtonian fluids and in steady heat conduction, where the differential operator is elliptic and "self-adjoint," but the method is commonly used for other flows as well. Inertial terms in the momentum equation, and the convective flow terms in the energy equation, which are important even in the absence of inertia, cause the system to be non-self-adjoint, however, whereas the equations describing viscoelastic flow are non–self-adjoint even for creeping flow; the operator for viscoelastic flow can sometimes change from elliptic to hyperbolic in a part of the flow domain. Hence, the standard tools may sometimes fail. "Streamline upwinding" and "discrete Galerkin"

methods are sometimes used for the convective terms. Some codes, particularly those that include heat transfer in the metallic surfaces, use hybrid methods in which some parts of the problem are solved using finite elements and others using finite differences.

Boundary element methods can be applied to a limited class of problems in which Green's theorem equating volume and surface integrals can be exploited; this usually requires that the differential operator in the equations be the Laplacian. The differential equations can be partially integrated and converted to a set of equations in which the dependent variables enter only through integrals along the boundary. In such a case the computational problem is substantially reduced; instead of approximations over a two-dimensional area, for example, approximation is required only along a one-dimensional boundary curve. The method of approximation along the boundary is usually similar to that used in finite element methods, hence the name boundary element. The boundary element method has been adapted to the solution of several transient and free-surface processing problems, as well as to the calculation of the orientation of rodlike suspensions in Newtonian fluids, but general-purpose codes are not widely available.

Continuous Low Deborah Number Processes

The most successful process modeling has been carried out on continuous low Deborah number processes (18–20). This category includes calendaring, the metering region in melt extrusion, and many coating operations. The fluid deformation in these flow fields is closely approximated by combined drag- and pressure-driven flow between nearly parallel surfaces, and the lubrication approximation (21,22), developed by Reynolds for the analysis of lubrication flows, is applicable as a first approximation. The lubrication approximation is broadly based on the assumption that the flow between nearly parallel surfaces is locally the same as the fully developed flow between parallel walls, for which exact solutions to flow problems exist. (The isothermal lubrication flow of a Newtonian fluid would have a locally parabolic velocity profile, for example, but with the length scale defining the parabola changing slowly with position in the flow.) The lubrication equations are sometimes integrated across the gap in flows in which there are two primary flow directions and a narrow gap in the transverse direction, leading to a set of equations for local gap-averaged velocities and the pressure distribution; this averaged formulation is sometimes referred to as the Hele–Shaw approximation.

The flow of a viscoelastic liquid between infinite parallel walls is a viscometric flow, or a flow with constant stretch history. The velocity profile for a fluid that is isotropic at rest is determined in such a flow only by the shear viscosity, although the stress distribution depends on the viscoelastic parameters. A nearly parallel flow for which the Deborah number is low, and stress growth and relaxation is not important, can be treated as though the local flow were that between infinite parallel walls; in that case the viscoelasticity is not important for determining the flow field and the process can be analyzed with the lubrication or Hele-Shaw equations as though the polymer were purely viscous. Effects attributable to the viscoelastic parameters (eg, interface movement in co-extrusion)

can then be determined using the computed flow field. The main complicating factors in such a calculation are the correct incorporation of the energy balance equation, since the temperature field is generally developing throughout the flow, and the pressure dependence of the viscosity. Calculation of velocity and temperature distributions, residence times, and pressure drops is straightforward; some closed-form analytical solutions are available for simple processing geometries, and some commercially available computer codes can routinely handle two- and three-dimensional nonisothermal creeping flows of inelastic liquids. Good heat transfer coefficient data are limited, however, and little attention has been paid to the effect of high pressure on physical properties (22).

The procedure outlined above has long been the standard approach. The simulation of coating thickness in blade coating, for which experimental data are available for a range of liquids of increasing viscoelasticity, is a good example of the application and limitation of these approximations. The process geometry is shown schematically in Figure 3, together with a finite element mesh used for computation. Data for the coating thickness as a function of gap spacing are

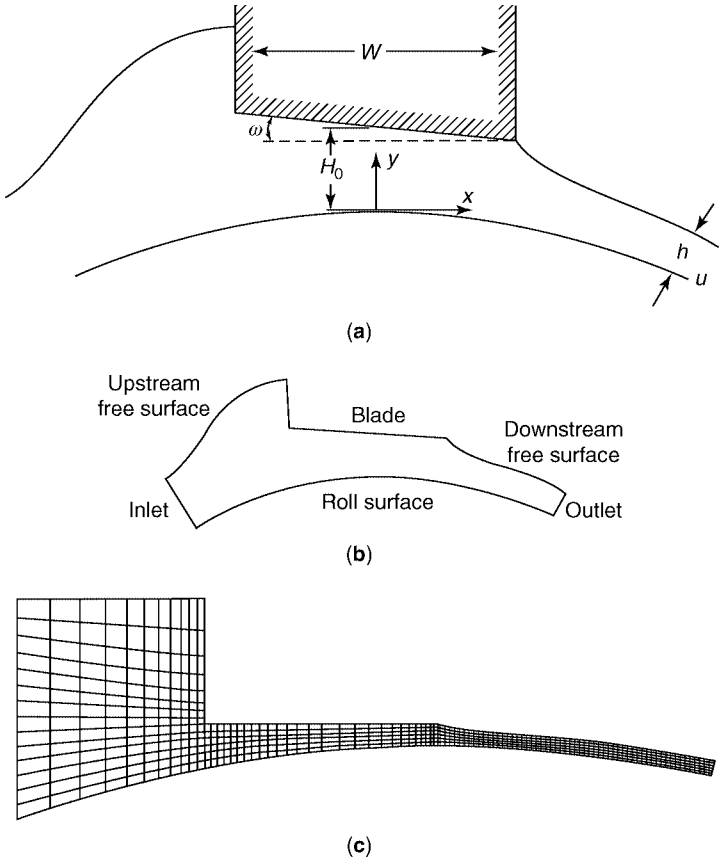

Fig. 3. (**a**) Blade coating; (**b**) surfaces requiring boundary conditions; and (**c**) finite-element mesh used in calculations. From Ref. 23. Courtesy of the American Institute of Chemical Engineers.

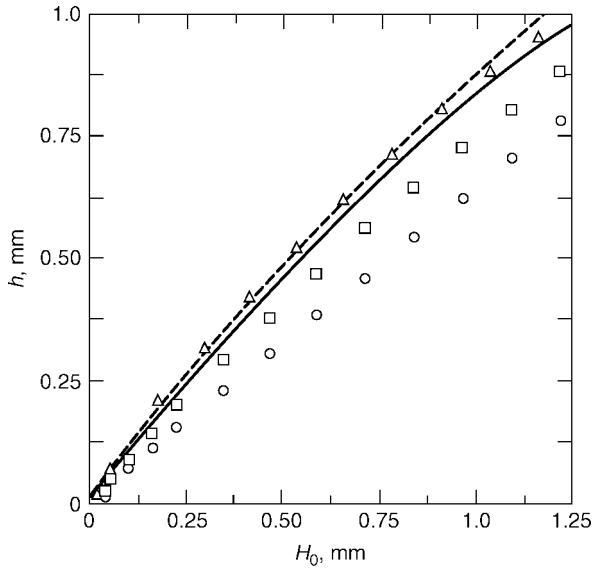

Fig. 4. Coating thickness as a function of gap thickness for a blade angle of 10°, showing agreement between lubrication theory (——), finite element calculations (– – –), and experimental data for aqueous solutions of 1.25% carboxymethylcellulose and (△, 0%; □, 0.005%; ○, 0.020%) polyacrylamide. shown in Figure 4 for three shear-thinning polymer solutions: an aqueous solution of 1.25% carboxymethylcellulose, and the same solution with an additional 0.005% and 0.02% of a high molecular weight polyacrylamide; all three liquids have nearly the same shear viscosity functions, with a power-law index of 0.6 in the power-law region, but the polyacrylamide solutions are more viscoelastic. The solid line is the lubrication approximation to the flow. The dashed line is a finite-element numerical solution of the full two-dimensional purely viscous equations without the nearly parallel approximation. The lubrication approximation is acceptable for small gap spacings but deviates systematically from the numerical solution of the full equation set for larger spacings. The solution to the purely viscous equations agrees well with the data for the least elastic solution, but deviates substantially for the most elastic liquid; the coating flow with the latter is clearly not a low Deborah number process.

Periodic Low Deborah Number Processes

Mold filling, which is a repetitive transient process, can often be treated as a low Deborah number process when the fill time is long relative to a characteristic time for stress relaxation, so that only purely viscous rheology need be considered. The fluids are usually of very high viscosity, and the characteristic gap size is usually small; inertial effects are thus usually negligible compared with viscous stresses. The transient terms in the momentum balance are inertial, so the

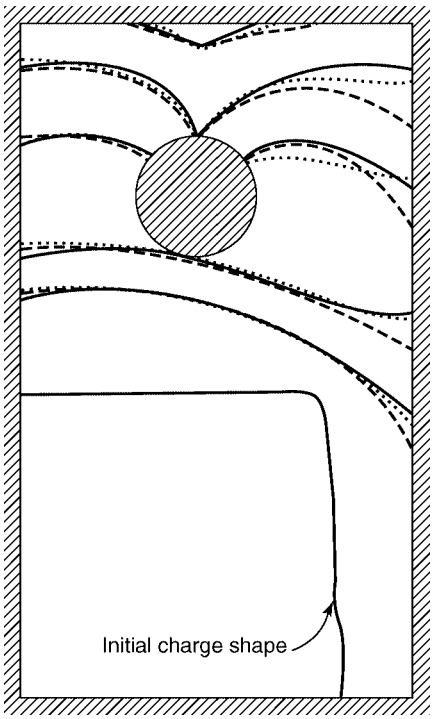

Fig. 5. Experimental and computed front movement during filling of a compression mold with a silicone liquid. (——) experimental; (– – –) predicted (FEM); (-----) predicted (BEM). Reproduced from Ref. 27. Courtesy of the Society of Plastics Engineers.

momentum equation becomes quasi-static if inertial effects can be neglected. Mold filling under these conditions is simulated by solving the steady-state momentum equation for an inelastic liquid, with the front movement calculated at each time step from the normal velocity at the front. The numerical methods used for continuous processes can thus be applied, with (conceptually) minor modification to follow the moving front (24–26). Special techniques must be implemented to follow temperature transients and any solidified regions.

Fill rates and front movements are usually well described by Hele-Shaw calculations for purely viscous fluids. Simulations of isothermal mold filling of a silicone oil in a compression mold using both finite element (FEM) and boundary element (BEM) methods are shown in Figure 5, together with experimental front locations. Simulation of front movement in the injection molding of polypropylene with a series of short shots, including the development of the weld line, is shown in Figure 6. The polypropylene was treated as a purely viscous power-law fluid with temperature-dependent physical properties, using a hybrid finite element-finite difference technique to solve the Hele-Shaw equations.

Details of the kinematics within the mold, which would be required for the computation of stress distributions, require solution of the full (quasi-static) momentum equation with an appropriate stress constitutive equation. This can be done routinely for purely viscous fluids for flows with two velocity components

(two-dimensional or axisymmetrical) and for three-dimensional flows in relatively simple mold geometries. Complex geometries can be addressed by linking together Hele-Shaw solutions in regimes where the transverse velocity component can be neglected with full three-dimensional calculations in other portions of the mold. The three-dimensional flow near a moving front is rarely treated, although the "fountain flow" near the front can be approximated by neglecting the larger of the two radii of curvature of the front. A typical calculation of the flow near the front is shown in Figure 7; numerous studies modeling these kinematics indicate that the agreement with experiments on front movement is very good, and that the computed flow field is insensitive to the particular choice of constitutive equation, although the stress field is not. The implication of this observation for mold filling is quite important, since low Deborah number computations, in which viscoelasticity can be neglected, are much simpler than computations with viscoelastic constitutive equations. In many mold filling applications the flow field can be computed first, treating the melt as purely viscous, and the viscoelastic stress computed afterward. Since stress and orientation are linked in noncrystalline polymers through the stress-optical law, such a decoupled approximation is efficient in computing molecular orientation distributions.

The computational problem is considerably more difficult if solidification is to be taken into account. The assumption is often made that solidification is instantaneous at a specified temperature. Some modeling studies have been carried

out in which crystallization kinetics are included in the mass and energy balances in order to estimate the degree of crystallization and the morphology when the motion is frozen. Most such studies have used quiescent crystallization data. A reliable theory of crystallization rates during deformation at very high stress levels is still a subject of research (30,31), as is a complete theory of the rheology of the crystal/melt mixture, and commercial codes do not address this issue. The ultimate goal is the prediction of stress and morphology following molding (32).

Free-Surface Processes

The modeling of polyester fiber spinning from the melt is well developed for take-up speeds below about 4,000 m/min, where crystallinity is low (33); commercial and in-house computer codes have long been available for the prediction of temperature and diameter profiles along the spinline and the radial birefringence distribution (through a stress-optical coefficient) at take-up, and they have been used widely to analyze process performance and to evaluate modifications. The major challenge has been the incorporation of crystallization, which is an important factor in the spinning of nylon at all take-up speeds and of polyesters at high speeds. Spinline models that account for stress-induced crystallization and the effect of the crystalline phase on the rheology (34) are now available .

Most spinline models are based on thin-filament equations, in which the essentially elongational character of the deformation is exploited and the conservation and constitutive equations are averaged over the diameter or, in a mathematically equivalent process, expanded in a small scaling parameter. The thin-filament approximation is similar in approach to the lubrication approximation for confined flows, but the low Deborah number assumption need not be made. It is straightforward to include a solution of the energy equation that incorporates the radial dependence of temperature in this formalism. (There is a region near the point of extrusion where the melt undergoes a transition from the shear flow in the spinnerette to the extensional flow on the spinline, and the thin-filament approximation cannot apply in this region. Finite-element solutions of the flow

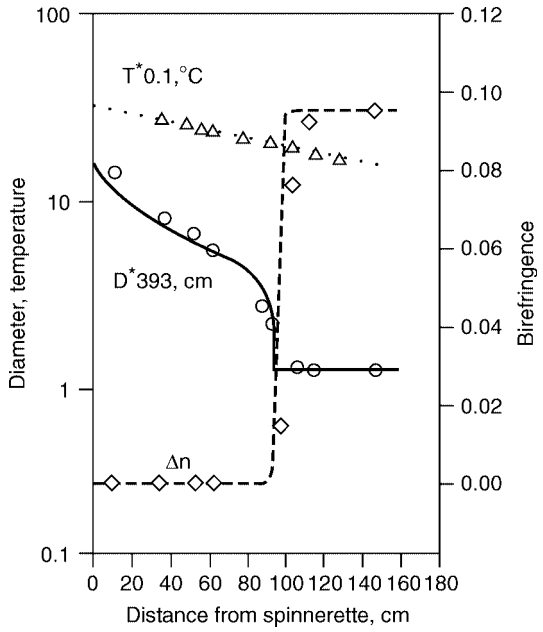

Fig. 8. Comparison of model calculations of diameter attentuation, birefringence, and temperature profiles with pilot plant data for melt spinning of 0.65 IV poly(ethylene terphthalate) at a take-up speed of 5947 m/min. Reproduced from Ref. 33. Courtesy of the Society of Rheology.

in the transition region indicate that the thin-filament equations become valid within a few spinneret diameters.) Full two-dimensional axisymmetric models are available but add little additional physical understanding. Most spinline models assume that the polymer is a Newtonian fluid, but differential viscoelastic models are easily incorporated and there is no reason to use the Newtonian approximation when rheological data are available. A comparison of the prediction of diameter attenuation, birefringence, and mean temperature profiles for high-speed spinning of poly(ethylene terephthalate) with pilot plant spinning data is shown in Figure 8. The viscoelastic model incorporates stress-induced crystallization and successfully captures the rapid diameter attenuation and increase in birefringence at the onset of crystallization. Predictions of the temperature profile and the final stress level tend to be insensitive to stress constitutive assumptions, despite the sensitivity of the diameter attenuation profile to the constitutive assumptions. Limited dynamic simulations to study disturbance propagation through spinlines have been less successful, probably because of inadequate treatment of the solidification process (35).

The proper representation of macroscopic transport properties, particularly the heat transfer coefficient, is a major problem in the predictive modeling of spinning and other free-surface processing flows. Heat transfer coefficients are typically obtained from experiments on nondeforming wires, and the extension to a deforming surface with a variable cross section is not obvious. Data obtained on real spinlines require either infrared or intrusive contact temperature

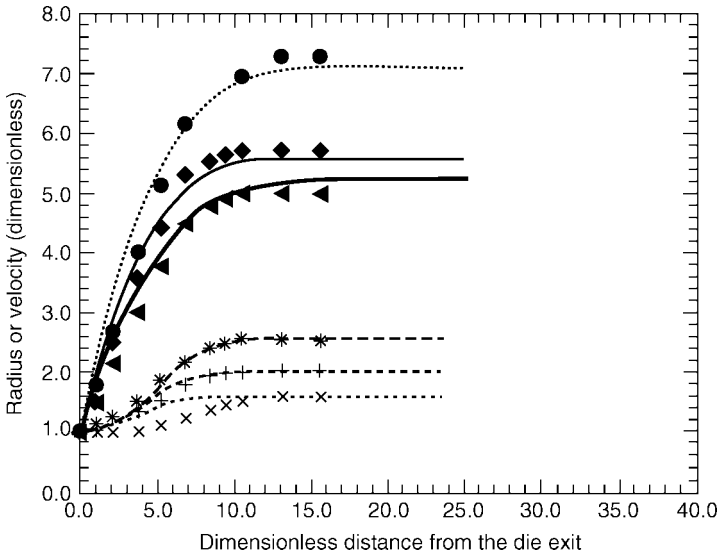

Fig. 9. Comparison of model calculations of bubble radius and film velocity with blown film data for a low density polyethylene, 3.84-cm radius × 0.8-mm thickness die, 4.1-kg/hr throughput. measurements, neither of which is reliable for the accurate determination of a heat transfer coefficient. Model calculations indicate that the diameter attenuation is highly sensitive to the heat transfer coefficient; small uncertainties can mask other factors and make extrapolation to new processing conditions questionable.

The blown film process is kinematically similar to fiber spinning, and thin-sheet equations analogous to the thin-filament equations have been employed in process modeling (36–38). As with the thin-filament equations, temperature variation in the film thickness direction can be incorporated in a straightforward way. Figure 9 compares bubble radius and velocity profile data from three experiments on a blown film line with a thin-sheet calculation that incorporates a viscoelastic constitutive equation, a transverse temperature variation, and a crystallization model (38). The calculation was based on an empirical heat transfer coefficient that is not formulated in terms of scalable dimensionless groups. The operating characteristics of film lines depend on details of the placement of cooling air, but this feature cannot be incorporated into existing blown film models without a better understanding of the heat transfer.

Modeling of the blown film process illustrates characteristics that are very different from those of fiber spinning, even with primitive representations of the heat transfer (37). These differences are a consequence of the hoop stress in the bubble. Multiple steady states are computed for fixed operating conditions, for example, and steady axisymmetric bubbles can vanish suddenly following small changes in operating parameters; both phenomena are seen in practice. The

models also show important differences in the stability characteristics of the two processes.

Numerics

The numerical realization of a model requires the availability of algorithms that can solve the model equations accurately. Modeling of the detailed flow and stress fields in confined geometries has been limited historically by the fact that iterative numerical algorithms for solving the momentum and continuity equations together with the nonlinear constitutive equations typically fail to converge to a solution above a critical value of the recoverable shear or Weissenberg number. This convergence failure, which is often called the "high Weissenberg number problem," appears to be a numerical artifact of the techniques in use, which propagate the large stresses generated near corners, lips, and other areas of stress concentration into the bulk and degenerate the solution quality; precise identification of the cause is difficult, because the strength of the stress singularity near a corner is an outstanding mathematical problem for the flow of most viscoelastic fluids, for which only partial solutions have been obtained (Reference 4, pp. 68 ff).

Stress constitutive equations with the structure of equation 4 are hyperbolic when the flow field is specified. Experience in areas where hyperbolic equations commonly arise, such as compressible gas dynamics, has guided the development of special techniques, including operator decompositions and "upwinding," that are implemented in some available computer codes. Use of these methods has extended the range over which convergence can be obtained to the lower end of practical processing conditions. Reviews can be found in References 4,16, and 17. A simulation that is representative of the state of the art of computations for highly viscoelastic melts is shown in Figure 10. Calculated isochromatic fringes, which are contours of the principal stress $[(\tau_{xx} - \tau_{yy})^2 + {\tau_{xy}}^2]^{\frac{1}{2}}$, are superposed on the

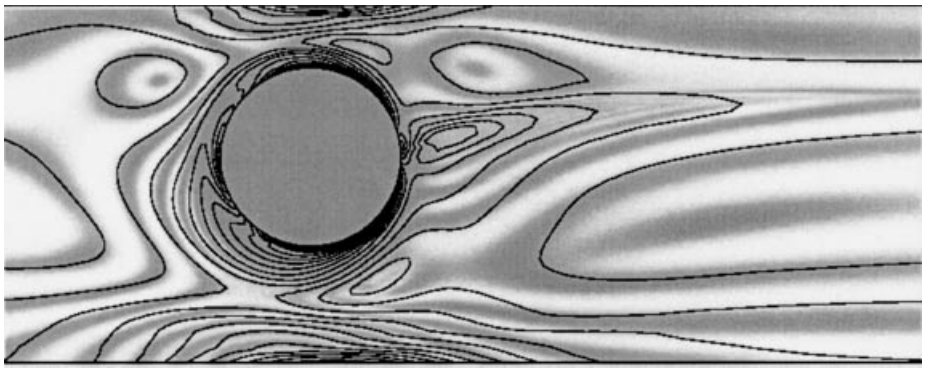

Fig. 10. Isochromatic fringe patterns for flow of a low density polyethylene ($M_w = 1.55 \times 10^5$, $M_w/M_n = 11.9$) past an offset cylinder of diameter 2.5 mm in a plane channel at 190°C with a mean upstream velocity of 8.53 mm/s. The mean relaxation time of the melt is 1.5 s. From Ref. 39. Courtesy of Elsevier Science Publishers.

experimental fringes at 190°C for the flow of a low density polyethylene through a planar region containing an offset cylindrical insert. Characteristic Deborah numbers based on mean residence times for flow in the small and large gaps were, respectively, 0.7 and 11.5, indicating the likelihood of strong elastic effects. The constitutive equation, which was fit to linear viscoelastic and steady shear data, is a special form of equations 4 and 5 often used for simulations known as the Phan–Thien/Tanner equation, with four terms in the linear viscoelastic spectrum. The computations are in qualitative agreement with the experiments and show the development of an asymmetric wake in which the stresses are very high downstream of the aft stagnation point. The experimental wake extends farther in the downstream direction than the calculated wake. The fringes appear to be more densely packed in the lower upstream region close to the cylinder in the experiments than in the calculations, indicating that the experimental stress gradients were stronger than the computed gradients.

Boundaries

The tradition in fluid mechanics, dating to the mid-nineteenth century, has been that a fluid adheres to a solid boundary during flow, and that the fluid at the boundary therefore takes on the velocity of the solid. This "no-slip" condition has been used routinely in the modeling of polymer flows, despite occasional hints in the processing literature as early as the 1960s that there might be "slip" at the wall. It is now generally accepted that the composition and state of the boundary affect the flow (15); the properties of a polymer extrudate can be controlled by changing the materials of construction of the metal die-face, for example, thus establishing that the boundary is not simply a passive element in the flow field. Figure 11 shows flow curves for a linear low density polyethylene extruded through two

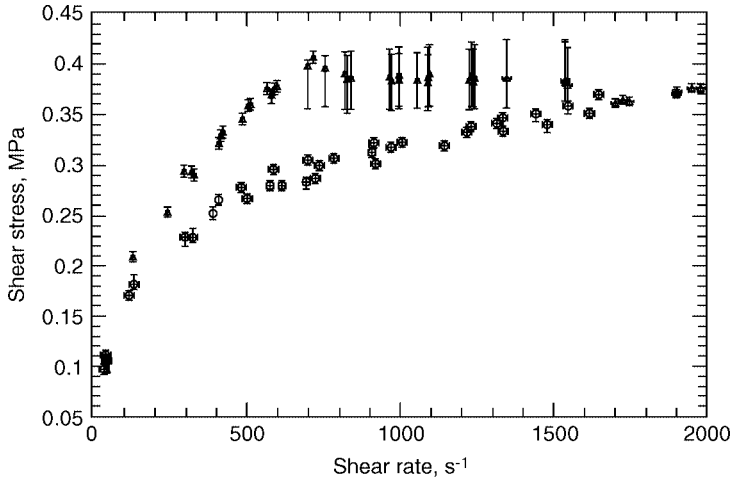

Fig. 11. Flow curves for a linear low density polyethylene ($M_w = 114{,}000$, $M_n/M_w = 3.9$) at 200°C in identical 1 × 20 mm 304 stainless steel (△) and CDA-464 naval brass (○) capillaries. Reproduced from Ref. 40. Courtesy of the Society of Rheology.

geometrically identical capillaries, one constructed of 304 stainless steel and the other of CDA-464 naval brass (40). The data for the steel capillary show the range of pressure fluctuations in the "spurt" regime. The polymer extruded through the brass capillary experienced significantly lower stresses at the same throughput ("apparent slip") and was free of surface defects that appeared on the extrudate from the steel die at a stress just above 0.17 MPa.

Most experimental evidence indicates that deviations from the no-slip condition are unimportant up to a wall stress of the order of 0.2 MPa (29 psi). Since the plateau modulus of most polymers at processing conditions is of the same order, this observation suggests that no-slip can be used with confidence under conditions where $\|\tau\|/G_p' < 1$. The appropriate boundary condition at higher stresses is not known, although some data indicate that the tangential velocity at the wall is proportional to a power of the wall shear stress; the slip law proposed by Navier in the early nineteenth century assumes a power of unity. It is not straightforward to impose a slip boundary condition in a numerical code and simultaneously satisfy mass conservation at a sharp corner, however. Slip conditions have therefore been implemented only sparingly. The range of convergence of numerical schemes is extended when a slip condition is used, since the high stresses that degenerate the solution are moderated. The effect of wall slip in complex geometries is relatively unexplored. Analytical solutions for flow of shear-thinning inelastic liquids between converging planes using a Navier slip law indicate substantial departure from the expected radial streamline pattern (41), which, as discussed subsequently, could have a large impact on the stability of die entry flows.

Mixing

Mixing in polymer melt processing takes place in the laminar regime. Laminar mixing, which is related to the theory of chaotic dynamical systems, has been intensely studied since the late 1980s (42), and techniques have been developed for visualizing the evolution of apparent disorder in strictly deterministic systems. Application to the simulation of continuous mixers for immiscible materials with viscosities of comparable magnitude requires the use of an efficient mapping procedure for tracking fluid elements as they progress through the three-dimensional flow (43), where the local kinematics and pressure profile are calculated with a finite-element solution. A simulation of a cross section of identical black-and-white inelastic shear-thinning Carreau-Yasuda fluids with a power-law exponent of 0.1 following laminar flow through a static mixer is shown in Figure 12. Simulations of this type can be used in principle to optimize mixer design, but they have been limited to inelastic fluids with identical viscosity functions and no interfacial tension.

Droplet breakup and coalescence are the primary physical processes in the mixing of liquids with very different viscosities. Computational tools for the breakup of individual Newtonian droplets are well developed; Figure 13 shows a boundary element calculation of the sequence of shapes of a polydimethylsiloxane droplet in a polyisobutylene of nearly the same viscosity, together with experimental data. Computational tools for breakup with viscoelastic constitutive

Fig. 12. Simulation of the mixing pattern for two identical shear-thinning inelastic liquids in a static mixer after passing six blades oriented at 140°. Reproduced from Ref. 44. Similar images for Newtonian liquids may be found in Ref. 45.

equations are not well developed. Emulsion models for the rheology of immiscible blends with a dispersed droplet phase do an excellent job of describing the linear viscoelasticity, and models for nonlinear deformations of blends based on an understanding of droplet dynamics are under development (47).

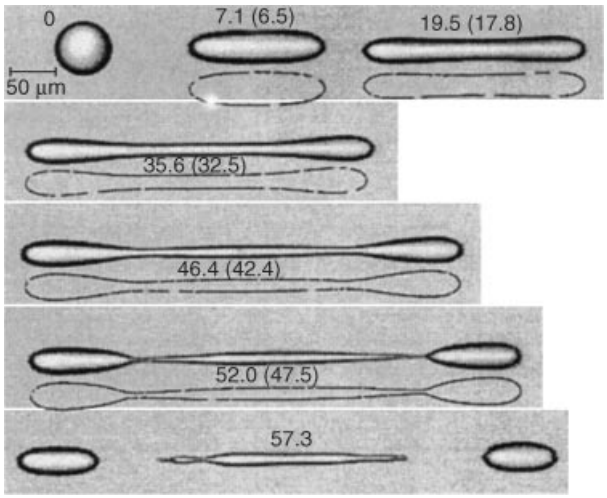

Fig. 13. Deformation and breakup of a polydimethylsiloxane droplet in a polyisobutylene of nearly the same viscosity; viscosity $\approx$ 100 Pa · s, interfacial tension $\approx$ 2.4 mN/m. Images are experimental data and profiles are simulations using slightly adjusted parameters to ensure a good fit at pinch-off. Numbers are experimental total strain (time multiplied by shear rate), whereas numbers in parentheses are computed total strain for the same droplet shape. Reproduced from Ref. 46. Courtesy of the Society of Rheology.

Stability and Sensitivity

Polymer processes are subject to a variety of instabilities that limit throughput or degrade product quality. Dynamic models are routinely used in engineering applications to study conditions under which stable operation cannot be maintained, and idealized models of some polymer process have been employed to gain insight into operability. The most common technique for studying process stability is linear stability theory (48), in which the dynamical response to infinitesimal disturbances is obtained by solution of a set of approximate linear equations through an eigenvalue analysis. Complex flows can be analyzed through the eigenvalues of a matrix that arises in the course of a finite element solution. If infinitesimal disturbances die out, the steady mode of operation is stable; if infinitesimal disturbances grow, the steady mode of operation cannot be maintained (since no process can be kept free of infinitesimal disturbances), and the system is unstable. Linear stability theory establishes absolute instability but only relative stability; a process that is unstable to infinitesimal disturbances is unstable to all disturbances, but a process that is stable to infinitesimal disturbances might still be unstable to some finite disturbances.

Dynamic modeling has been quite successful in describing the onset of a flow instability known as draw resonance, which occurs in fiber spinning and extrusion coating (1,19,33). Draw resonance is characterized by regular oscillations in the fiber diameter or coating thickness, with a period that is slightly greater than the residence time in the melt zone. Some subtleties associated with the role of heat-transfer mechanisms remain, and the effect of the spinneret flow (as transmitted through the initial conditions used in the thin-filament equations) has not been completely quantified, but the mechanism is well understood and the models have been very useful in discriminating between the effects of rheology, cooling, gravitational forces, and inertia. Dynamic modeling to describe the propagation of disturbances through a melt spinline under stable spinning conditions is much less well developed (35).

Spinline failure appears to occur through a cohesive mechanism, which has received little theoretical attention (49,50). A simple scaling model that predicts a critical value of the recoverable strain as a function of stretch rate captures the qualitative features of the limited data on melt failure in extension (50,51).

The blown film process undergoes a variety of processing instabilities. Modeling of these is less advanced than for fiber spinning, in large measure because of the sensitivity to details of the heat-transfer mechanisms and the treatment of the solidification region. A draw resonance-like instability is predicted to occur under some conditions (37). One striking result predicted by the dynamic model is that the process stability is highly sensitive to the manner in which process control is effected; under some conditions, a bubble controlled by air-flow adjustment to maintain a constant diameter is predicted to be stable, whereas the same bubble controlled by a feedback system utilizing the internal pressure is predicted to be unstable.

Melt extrusion is characterized by at least two distinct instabilities that cause surface defects, generally known as melt fracture, or gross melt fracture, and sharkskin, or sharkskin melt fracture (15). Sharkskin, a high frequency,

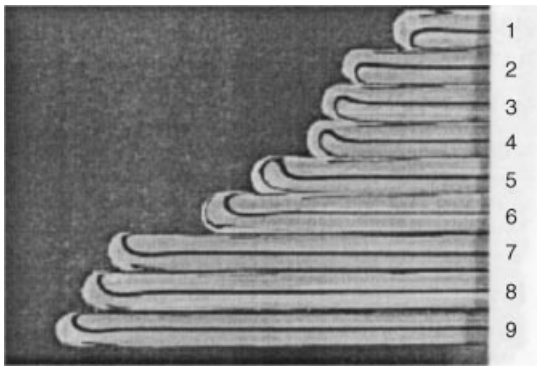

Fig. 14. Short shots with two-color injection molding of a filled polypropylene compound. Reproduced from Ref. 55. Courtesy of the Society of Rheology.

small-amplitude surface distortion, appears to occur only in highly entangled linear polymers and is believed to be associated with a material failure resulting from the stress concentration at the die exit. Melt fracture, in which the distortions may be regular or irregular, typically occurs when the wall shear stress is comparable to the plateau modulus (recoverable shear of order unity) and appears to originate in the die land or at the die entry. There have been numerous linear stability analyses of fully developed pressure-driven viscoelastic flow in long slits and capillaries; the general conclusion has been that the flow is stable to infinitesimal disturbances in the absence of inertia, but a linear instability may exist for some constitutive equations (52). A weakly nonlinear ("subcritical") instability has been reported (53,54). Whether model calculations can predict the instability that is observed in the actual process remains an open question.

Flow mark surface defects on injection-molded parts were first reported in the early 1960s and have been considered by some authors to be an indication of wall slip in the neighborhood of the advancing front (15). Figure 14 shows a series of short shots of injection molding of a filled polypropylene compound in which a thin strip of black polymer was placed along the centerline. With stable fountain flow, as shown in Figure 7, the black polymer will coat both mold surfaces. Instead, the black strip is first carried to the bottom of the mold, then to the top. A swirling flow near the melt front is predicted by linear stability theory combined with a finite element analysis for one of two constitutive equations studied (55). It thus remains an open question as to whether an instability in the neighborhood of the front is the cause of the flow marks, although this is the likely mechanism.

Interface stability in co-extrusion has been the subject of extensive analysis. There is an elastic driving force for encapsulation caused by the second normal stress difference (56), but this is probably not an important mechanism in most coprocessing instabilities. Linear growth of interfacial disturbances followed by dramatic "breaking wave" patterns is observed experimentally. Interfacial instabilities in creeping multilayer flows have been studied for several simple constitutive equations (57–59). Instability modes can be traced to differences in viscosity and normal stresses across the interface, and relative layer thickness is important.

Aside from the examples cited here, the experimental literature on viscoelastic flow instabilities in the absence of inertia has emphasized dilute polymer solutions. These stability studies include the flow between rotating concentric cylinders, torsional cone-and-plate flow, flow in a "lid-driven" cavity, stagnation flow, and flow past a cylinder in a channel, all of which have been analyzed for simple constitutive equations (60). It is likely that these phenomena have relevance to polymer melt processing, but direct connections have not been made. The common feature of these inertialess "elastic" instabilities seems to be the coexistence of normal stresses and curved streamlines, and the experimental and theoretical onsets of instabilities for this class of flows correlate with a criterion of the form $\lambda U/(\Re H)^{\frac{1}{2}} > M_{\text{crit}}$ (61,62). λ is a mean relaxation time, U the characteristic velocity, H the length scale defining the shear rate, and $\Re$ the length scale defining the curvature of the streamlines. M_{crit} is a constant characteristic of the specific flow. The critical value can be interpreted as the geometric mean of the Deborah and Weissenberg numbers. Substantial streamline curvature predicted in converging flow of shear-thinning fluids with wall slip (41) suggests a possible die entry mechanism for melt fracture.

Anisotropic Materials

Anisotropic materials, such as liquid crystalline polymers and fiber-filled melts, present special difficulties because of the incomplete state of development of constitutive models that account for the spatial distribution of the orientation and stress fields. In nearly all cases the constitutive equations are derived from microscopic theories of the orientation of rodlike elements, and the statistical mechanics requires a closure approximation that expresses the fourth moment of the orientation distribution in terms of the second moment (63,64). The closure approximation can affect the details of the evolution of the orientation distribution. The models for both types of anisotropic liquids are very similar in structure, differing in the way in which structural interactions are incorporated. Liquid crystalline polymer models incorporate interaction potentials between neighboring rigid molecules and include Brownian forces. Simulations using continuum models of liquid crystalline polymers in simple geometries show orientational structures and layering in rectilinear shear flows, but they are unable to replicate the complex defect-driven textures characteristic of real nematic polymers, where the correlation lengths for nematic order are independent of the geometric scale of the system (63,65,66). Models for fiber-filled systems are based on theories for noninteracting and slightly interacting non-Brownian rods, and they do not rigorously account for coordinated fiber motions; the latter are dealt with empirically by introducing an apparent diffusion term with a coupling coefficient that correlates with the product of fiber aspect ratio and volume fraction (67). Simulations of both liquid crystalline polymer and fiber-filled systems often assume that the flow field can be calculated independently of the orientation distribution, but full coupling is usually required to obtain even qualitatively correct flow and orientation field solutions to the constitutive and field equations (63,64,68,69).

PROPYLENE POLYMERS

Introduction

The stereospecific polymerization of propylene by Giulio Natta in 1954 is one of the most commercially significant scientific breakthroughs in polymer chemistry. Natta's discovery that a Ziegler catalyst could be used to produce highly isotactic polypropylene led to the first commercial processes for the production of this polymer by Montecatini in Italy and Hercules in the United States in 1957. The attractive properties and relatively low cost of polypropylene produced using this technology led to its rapid commercial acceptance. Consequently, Karl Ziegler and Giulio Natta were awarded the Nobel Prize in Chemistry in 1963. The commercial potential of olefin polymerization was recognized by many of the leading companies, leading to a tremendous amount of activity and the invention of a number of competing technologies in the early 1950s. These technologies were not economically competitive with those based on Ziegler–Natta catalysts. However, the competing claims of a number of companies led to a massive patent interference in the United States that continued for almost 30 years, eventually resulting in the award of a U.S. patent for the composition of matter of crystalline polypropylene to Hogan and Banks of Phillips Petroleum in 1983. Continued interest in olefin polymerization led to the invention of the supported high yield, high stereoregularity catalyst systems by Montedison and Mitsui Petrochemical. This led to the development of a number of low cost polymerization processes, spurring a dramatic increase in production capacity. Today, these catalyst systems are used to produce polypropylene in every major region of the world. The use of homogeneous organometallic (metallocene) olefin polymerization catalysts has led to the development of a number of unique propylene polymers. Currently, these polymers are produced in relatively limited amounts for a number of specialty applications.

Polypropylene is one of the most widely used polymers in the world because of the widespread availability and low cost of monomer, low manufacturing cost, and attractive polymer properties. These properties can be modified to be suitable for a wide variety of applications. Polypropylene can be processed by almost all commercial fabrication techniques. Approximately 30,000,000 ton was consumed worldwide in 2001.

Table 1. Physical Properties of Propylene

Property	Value	Reference
Molecular weight	42.078	1
Boiling point at 101.3 kPa[a], °C	−47.7	3
Melting point, °C	−185.3	3
Critical temperature, °C	92	1
Critical pressure, MPa[b]	4.65	1
Critical density, g/mL	0.233	2
Critical compressibility	0.275	3
Dipole moment, 10^{-30} C·m[c]	1.3	3
Refractive index, n_D	1.3567	3
Explosion limit, % by volume in air		
Lower	2.4	1
Upper	11.1	1
Autoignition temperature, °C	224	1
Solubility in water (at 20°C, 101.3 kPa[a]), mL gas/100 mL	44.6	3

[a] To convert kPa to mm Hg, multiply by 7.5.
[b] To convert MPa to atm, multiply by 9.87.
[c] To convert C·m to D, divide by 3.336 x 10^{-30}.

Monomer

Properties. Propylene is an olefin hydrocarbon that is a gas under ambient conditions but is normally stored as a liquid under pressure. The physical properties of propylene are given in Table 1. Thermodynamic properties are widely reported in the literature. Vapor–liquid equilibria of mixtures of propylene with other hydrocarbons and hydrogen are accurately represented by correlations for hydrocarbon mixtures, such as the Chao–Seader correlation.

The reactivity of propylene is a result of the olefinic double bond in $H_2C{=}CHCH_2$, which gives rise to addition reactions. Consequently, propylene is used in the synthesis of many industrially important compounds, including propylene oxide, acrylonitrile, cumene, and isopropyl alcohol. The consumption of propylene in the production of polymers, however, is greater than the total for all other chemicals. Propylene is also used in alkylating feedstocks for gasoline.

Manufacture. The major commercial sources of propylene are processes for the cracking of hydrocarbons. Initially, these processes were designed for the manufacture of other products, and propylene was considered an undesirable by-product. Now, propylene is often an equally desirable co-product. Ethylene is produced by the steam cracking of hydrocarbons at high temperatures and very short residence times. The two most common feedstocks are naphtha and ethane. This process produces a variety of by-products; the ratio of ethylene to by-products is dependent on the type hydrocarbon feedstock and the reaction conditions. Propylene production is higher when naphtha is used as a feedstock rather than ethane. Catalytic cracking of hydrocarbons is often used to increase the production of gasoline in oil refining. Increasing consumption of gasoline in the United States has led refiners to increase the severity of the cracking process, resulting in an increase of the production of propylene as a by-product. Consequently, the ratio of

propylene isolated from refineries to propylene from steam cracking is greater in the United States than in Western Europe and other parts of the world. The propylene isolated from the cracking processes is purified by distillation to remove propane and other impurities. Propylene is commercially available as chemical grade (approximately 95% propylene) and polymerization grade (>99.5% propylene) where propane is the major impurity. However, the suitability of propylene as polymerization monomer is dependent on the levels of trace impurities rather than on the propane content. Commonly occurring impurities are acetylenes, dienes, CO, COS, water, and alcohols. These impurities affect the activity and stereospecificity of propylene polymerization catalysts. Typical limits for the level of impurities acceptable in polymerization grade propylene are given in Table 2.

Propylene is also produced by the metathesis of butene and ethylene. Usually, this process is installed as an addition in a refinery or steam cracking facility to increase the production of propylene. The first commercial metathesis process for the production of propylene was developed by Phillips, and is now licensed by ABB Lummus.

The relative abundance of propane and other light hydrocarbons in certain locations has increased interest in the production of propylene by the catalytic dehydrogenation of propane. Currently only a few propane dehydrogenation plants are operating, producing a small fraction of the world supply of propylene; however, it is anticipated that propane dehydrogenation will be the major source of propylene in the Middle East. The two major processes available are the Catofin process originally developed by Houdry and now licensed by ABB Lummus and the Oleflex process licensed by UOP. Natural gas can be used as the feedstock for the production of propylene by adding a Lurgi MTP process facility to a conventional methanol plant.

Transportation, Storage, and Handling. Propylene is stored and transported as a liquid under pressure The preferred method of transporting propylene is through pipelines. Commercial quantities of propylene are also shipped by tanker and rail. The most extensive pipeline system for the transportation of propylene is in the Gulf Coast region of the United States. This pipeline system is also connected to a series of underground brine caverns used for propylene storage. Pressure vessels are also used for the storage of propylene.

Propylene is a flammable gas under normal ambient conditions and is not hazardous at low concentrations, but is an asphyxiant, which is a concern in closed environments. Direct contact with liquid propylene can cause skin burns from freezing. Fire or explosion is the greatest potential hazard associated with the storage and handling of propylene. Care must be exercised to avoid creating an explosive atmosphere when disconnecting lines and unloading vessels containing propylene. Explosions of vapor clouds formed from large leaks of liquid or gaseous propylene are the greatest potential hazard. The fire and explosion hazards associated with propylene are similar to those of propane and liquified petroleum gas (LPG).

Molecular Structure

The unique feature of propylene polymerization, versus ethylene polymerization, is the symmetry of the monomer insertion into the growing polymer chain. It is the presence of the methyl group in the propylene monomer that is responsible for this difference. This gives the monomer insertion an orientation (the monomer has a "head" and a "tail") and a stereochemical configuration with respect to the other units in the chain backbone. Regularity with respect to monomer orientation is termed the *regiospecificity* of the polymerization. Regularity of the methyl group placement relative to the other methyl groups along the chain backbone is termed the *stereospecificity* of the polymerization. The three limiting classifications of stereospecificity in polypropylene (PP) are illustrated in Figure 1. In isotactic polypropylene (iPP), all of the methyl groups have the same configuration with respect to the polymer backbone. In syndiotactic polypropylene (sPP), the methyl groups have an alternating configuration. Atactic polypropylene (aPP) has a random configuration. An additional configuration, hemi-isotactic polypropylene, is discussed elsewhere (4). iPP is overwhelmingly the most commercially significant form of PP. In practice, the degree of stereoregularity (and tacticity microstructure) can vary considerably within these general classifications. For the specific case of isotactic polymerization, Figure 2 shows three idealized limiting sample microstructures. Figure 2**a** shows a case where an isolated stereo error is immediately corrected along the growing chain. Figure 2**b** shows a case where a stereo error is propagated along the growing chain, and Figure 2**c** shows an iPP/aPP multiblock structure (5–7). Figure 2**a** is most common. Further discussions of stereo defects are available in the literature (4–22). In general terms, stereoregularity (or stereospecificity) refers to the content of defects that disrupt the regular placement of methyl groups. The intrachain defect content can also vary widely between chains (interchain distribution) (23) for different catalyst systems. The

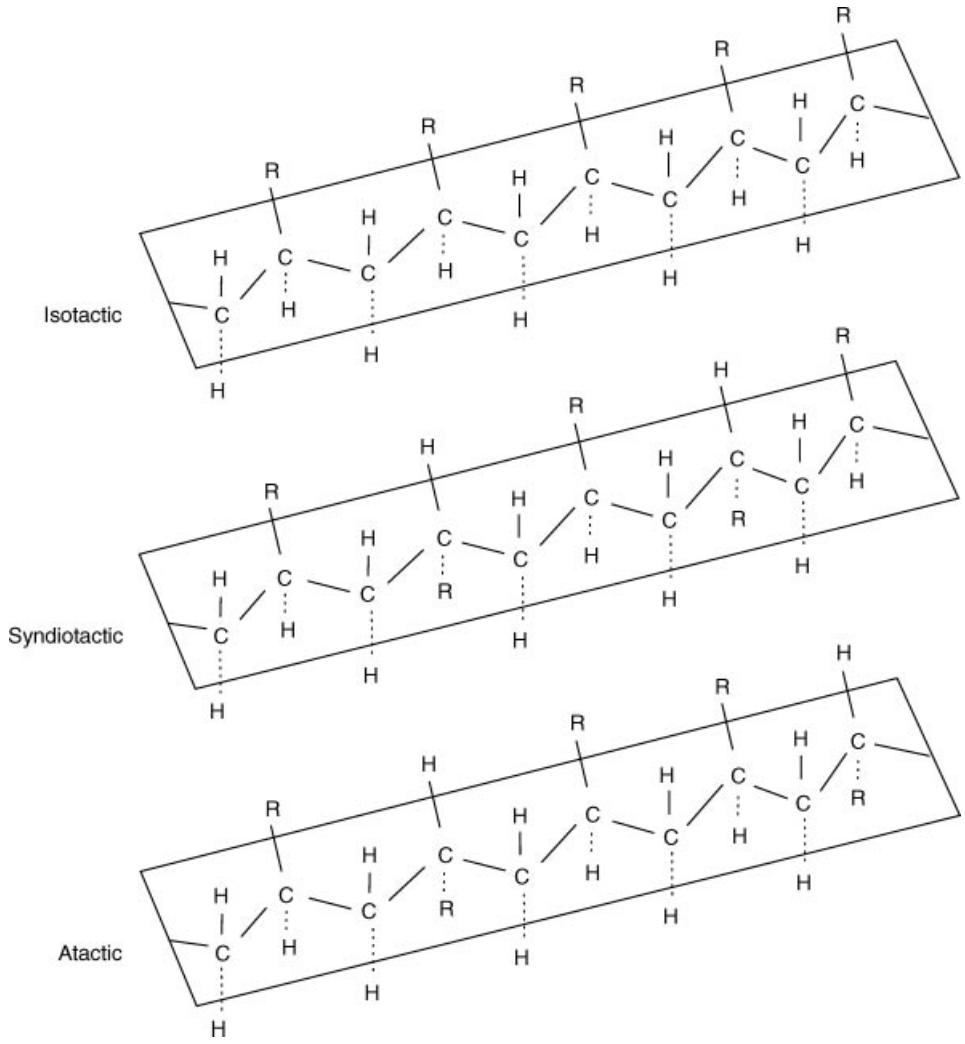

Fig. 1. Polypropylene stereochemical configurations: (**a**) isotactic; (**b**) syndiotactic; (**c**) atactic.

control of stereoregularity by catalyst and polymerization process is a critical determinant of PP properties.

Kinetic arguments suggest that iPP polymerization shows a strong preference for primary "head-to-tail" insertion of monomer into the growing chain (24–26). Regioirregular insertion of monomer renders the active site kinetically dormant (24–30), and its incorporation in the growing polymer chain occurs infrequently. With Ziegler–Natta polymerization catalysts, regio misinsertion errors are generally not present in the isotactic fraction (30). Metallocene polymerization catalysts can show appreciable levels of regio misinsertion errors in chains of high stereospecificity (4,27,31–41) (see METALLOCENES; SINGLE-SITE CATALYSTS).

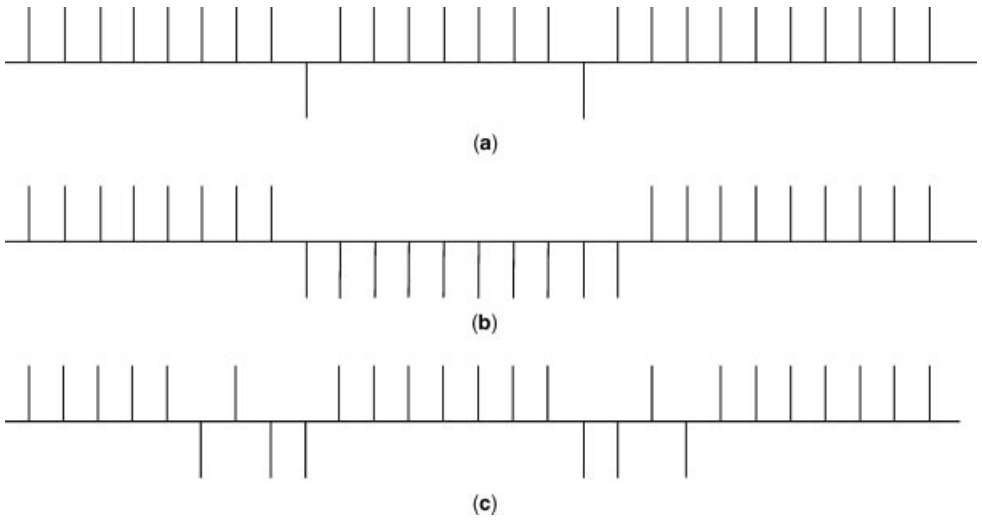

Fig. 2. Sample tacticity microstructures in isotactic polymerization: (**a**) isolated stereo error is corrected in growing chain; (**b**) stereo error is propagated in growing chain; (**c**) an iPP/aPP multi-block structure.

The stereo- and regioregularity of PP is best characterized by solution ^{13}C NMR spectra (42). These spectra can also provide information on the polymerization mechanism (4,7,9,11,12,14–22,30), and have been modeled in terms of the interchain tacticity distribution (14,43–45). Infrared spectroscopy (IR) has also been used to characterize the stereospecificity of iPP. Commonly the ratio of the 998 and 973 cm^{-1} band absorbance is used (46,47). The result is sensitive to thermal history (46). Solvent fractionation techniques are commonly used in industrial practice. These methods are based on the fact that chains with varying stereospecificity have different crystallinity and solubility in hydrocarbon solvents. In nominally isotactic PP, the atactic fractions of the interchain tacticity distribution are soluble, whereas the isotactic fractions are not. The isotactic index suggested by Natta represents the percentage of polymer insoluble in boiling *n*-heptane (48). Other procedures require preliminary total dissolution of the polymer in high boiling hydrocarbons such as xylene, and subsequent cooling in order to separate the precipitated crystalline portion (an example is ASTM D5492-94). The insoluble fraction is a measure of the stereospecificity. Often the term *stereoblock* is used to refer to fractions of the interchain distribution of intermediate solubility. Related solvent fractionation techniques include preparative and analytical temperature rising elution fractionation (TREF) (49). The use of pulsed proton solid-state NMR has been demonstrated as an alternative to solubility measurements of stereoregularity (50). Other secondary measurements which probe melting and/or crystallinity behavior can also be applied.

In addition to tacticity, important additional parameters of the PP chain which influence properties include the molecular weight, polydispersity, and composition and comonomer distribution in blends and copolymers. PP, like all synthetic and most natural polymers, consists of a distribution of macromolecules of different lengths. Therefore, the polymers exhibit a molecular weight

distribution. The number-average molecular weight (M_n) is determined by gel-permeation chromatography (GPC), more generally referred to as size-exclusion chromatography (51). Because of the strength of the GPC technique, the older techniques of osmometry (52,53), cryoscopy (54), and ebulliometry (54) are less commonly used today. For PP, the GPC method typically utilizes high temperatures (135–145°C) in solvents such as *o*-dichlorobenzene and trichlorobenzene. The weight-average molecular weight (M_w) can be obtained by light scattering (55) and GPC. Higher moments of the molecular weight distribution can also be obtained by GPC. The viscosity-average molecular weight M_v can be obtained by measurement of the solution intrinsic viscosity $[\eta]_0$ (52). M_v and $[\eta]_0$ are related by the Mark–Houwink equation:

$$[\eta]_0 = K \cdot (\mathrm{M}_v)^a$$

Generally, values of M_v lie between M_n and M_w values. Values of the constant K and exponent a are determined by calibration with homogeneous fractions of known molecular weight for specific solvent/temperature conditions. In practice, for polypropylene, homogeneous fractions are not available and values for some moment of the molecular weight distribution (M_n or M_w) are used in equation 1 on an empirical basis to determine K and a. This allows for the correlation of viscosity to molecular weight, though corrections need to be applied for samples with polydispersity much different from the correlation standards (56). Representative values using M_w from relatively narrow polydispersity fractions in decalin at 135°C are $K = 2.38 \times 10^{-4}$, $a = 0.725$ (57) and $K = 1.0$–1.10×10^{-4}, $a = 0.80$ (58,59), and in tetralin at 135°C are $\mathrm{K} = 9.42 \times 10^{-5}$, $a = 0.784$ (60). A common industrial measure of molecular weight is the melt-flow rate (MFR) (ASTM D1238), which is related to the melt viscosity. The MFR technique measures the amount of molten polymer extruded by a standardized apparatus in 10 min. Higher MFR values are obtained for lower molecular weight polymer. The breadth of the molecular weight distribution (polydispersity) has a large effect on polymer properties. The polydispersity is commonly characterized by the ratio M_w/M_n as measured by GPC or by semiempirical correlation of the dynamic melt oscillitory shear behavior of the polymer (61). This ratio has a value of 1 for macromolecules of equal molecular weight (monodisperse) and increases with increasing polydispersity. Rheological measurements, including the steady-state compliance, can be very sensitive to higher moment components (62) important in flow processes.

The molecular structure of PP can be further modified by the introduction of comonomers during the polymerization process, most commonly ethylene or butene. This comonomer incorporation greatly expands the property range of PP. Table 3 illustrates the broad range of copolymer microstructures possible for the specific case of propylene–ethylene copolymerization. Similar to the case of stereoregular defects in PP homopolymer, comonomer defects introduced into "random" PP copolymers (PP-RACO) can show an interchain composition distribution depending on the catalyst and process. In some cases it can be advantageous, in terms of quality and the process conditions, to achieve a homogeneous distribution of the comonomer molecules. Metallocene catalysts show a greater tendency for homogeneous comonomer incorporation (4). In this case, each chain, regardless of length, contains the same percentage of comonomer. Impact-modified

[a] P= propylene, E= ethylene.

"copolymers" (PP-EPR) are better described as polymer blends or alloys. The composition of the PP-EPR formulations varies over a wide range in industrial practice. However, a typical formulation would contain 60–90% homopolymer (or PP-RACO) and 10–40% ethylene–propylene copolymer rubber (EPR) with ethylene concentration of 30–60%. The EPR component has a lower glass-transition temperature (T_g), lower crystallinity, and typically exists as a separate phase. PP-EPR formulations were first produced by mechanical blending of two components. Today they are commonly synthesized directly in a multistage process to obtain better economics, and often better distribution of the elastomeric phase in the polypropylene matrix and thus better quality. In some cases polyethylene is present as a third phase. The characterization of PP copolymers is often complicated by the multiplicity of structural species present. An in-depth characterization requires knowledge of the distributions of molecular weight and composition. Different solvent fractionation techniques are combined, and each fraction is analyzed. Composition is most frequently determined by solution ^{13}C NMR, by IR, or inferred from secondary measurements which probe melting behavior, crystallinity, or glass-transition temperature.

Morphology

Crystallography and Polymorphism. The stereochemistry of PP plays a critical role governing the packing of chains in the crystalline regions of the morphology (qv). Figure 3 shows the wide-angle X-ray scattering (WAXS) patterns of iPP, sPP, and aPP (23). The regular molecular structure of iPP and sPP readily enables crystallization of the chains, leading to well-defined crystalline reflections differing in unit cell symmetry. aPP lacks a regular molecular structure, and does not crystallize. This leads to a very broad and diffuse scattering from X-rays. The iPP chain adopts a helical conformation in the crystalline unit cell, as shown in Figure 4 (63). The helix repeats itself after three monomeric units, with an identity period of 0.65 nm. Four helical arrangements are possible by right- or left-handed rotation about the central axis with unique (non-identical) "up" and "down" inclinations independent of the handedness (23,64,65). The dominant

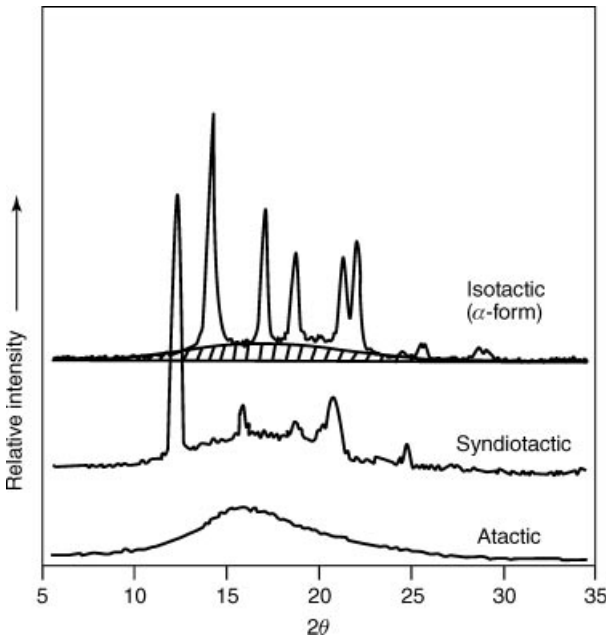

Fig. 3. Wide-angle X-ray scattering (WAXS) patterns of iPP, sPP, and aPP. The shaded region illustrates the separation of crystalline and amorphous scattering contributions. Adapted from Ref. 23.

crystallographic form for iPP is the α-form. The elementary unit cell of α-form iPP is monoclinic, containing 4 chains and 12 monomeric units with specific packing of helical arrangements. Crystallographic densities are generally in the range of 0.936–0.946 gm/cm^3. Representative cell constants are given in Table 4, and have been reviewed elsewhere (23). The helical conformation of sPP differs from that of iPP, and has an identity period of 0.74 nm. The elementary unit cell of the most stable crystallographic form of sPP is orthorhombic, containing 4 chains and 16 monomeric units with specific packing of helical arrangements (23,64,66–69). The crystallographic density is 0.930 gm/cm^3. Representative cell constants are given in Table 4 (69).

Table 4. Unit Cell Constants of Polypropylene

Cell constants	Isotactic[a]	Syndiotactic[b]
Unit cell	monoclinic	orthorhombic

[a]Averages from literature compilation of $P2_1/c$ space group symmetry refinements (23).
[b]From Ref. 69.

Both iPP and sPP exhibit polymorphism, which is the tendency to crystallize into different crystallographic forms depending on crystallization conditions. In iPP, the dominant form is the α-form. Other forms include the β-, γ-, and mesomorphic (smectic) forms. All of these crystalline forms maintain the same helical conformation with 0.65 nm repeat distance, but differ in unit cell symmetry, interchain packing, and structural disorder. The mesomorphic form is formed by rapid quenching conditions, and has important property implications, particularly in film and fiber applications. Crystallographically, the mesomorphic form has disordered interchain packing relative to the other polymorphic unit cell symmetries (65,70,71). The mesomorphic form converts rapidly to the α-form on heating (23). Formation of the β-form results from the addition of specific nucleators and additives, specific crystallization conditions, crystallization under controlled temperature gradients, and in some cases crystallization under shear (20). The β-form has lower unit cell density, higher rate of crystallization, and lower apparent melting point relative to the α-form which

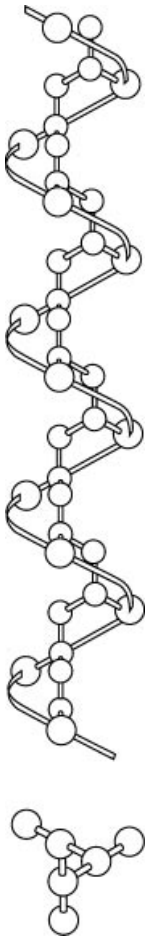

Fig. 4. Chain conformation of isotactic polypropylene (iPP).

is due, in-part, to its unique crystallography (64,72,73). The γ-form is rarely observed in pure form in commercially significant homopolymer from Ziegler–Natta catalysts under typical processing conditions. A variety of conditions for γ-form formation are outlined below (23). The γ-form occurs in low molecular weight fractions, homopolymer from some homogeneous (metallocene) catalysts (74–76), random copolymers, random copolymer and metallocene homopolymer at high crystallization temperature (76), samples with high stereoblock content, and homopolymer crystallized at high pressure (77). Crystal structure refinements suggest that γ-form iPP has nonparallel chains (64,65,78–81), a conclusion not previously cited in polymeric crystal structure. Because of its importance, further discussion of iPP morphology is restricted to the α-form of iPP.

sPP also exhibits polymorphism (23,64,66–69,82,83). Polymorphism is related to both the intrachain conformation and interchain packing. Crystallization at lower temperature can lead to defect structures relative to the unit cell symmetry of the dominant form (66–68,84–86). Other unit cell variations are formed from sPP with low syndiospecificity (87,88), as-polymerized sPP (89–92), sPP copolymers (92), oriented sPP (23,87,93), sPP crystallized at low temperature (94,95), and nonhelical structures associated with cold drawing (87,96) and exposure of cold drawn samples to solvent vapor (97).

Crystallinity. The degree of crystallininity varies between 0 for a completely amorphous material (such as aPP) and 1 for a completely crystalline material. As with most semicrystalline polymers (qv), the degree of crystallinity plays a critical role in determining properties of PP. Commonly measured properties such as modulus, yield stress, oxygen and moisture barrier resistance, and hardness, to name a few, all increase with increasing crystallinity. In iPP (and sPP) tacticity is a critical factor influencing the crystallinity (23,47,98). This is due to the role of stereo defects in disrupting the length of the crystallizable isotactic sequences. Details of the interchain tacticity distribution affect not only the crystallinity at room temperature, but also the partial melting behavior (and hence crystallinity) at elevated temperature, influencing hot drawing characteristics. Solvent fractionation techniques, which separate the interchain tacticity distribution of the whole iPP homopolymer into fractions of varying tacticity, show that the lower tacticity fractions have lower crystallinity (47). With metallocene catalysts (4,18,30), PP chain microstructure can now be varied continuously with decreasing isospecific sequencing from iPP (stiff thermoplastic) to aPP (very low modulus lacking dimensional integrity) to sPP (stiff thermoplastic) correlating to changes of either isotactic or syndiotactic crystallinity. The crystallinity of sPP is less than that of iPP with currently available catalysts. In addition to tacticity, crystallinity generally increases with decreasing molecular weight (increased chain mobility), and is promoted by slower cooling rates from the melt. It should be emphasized that the crystalline fraction of perfectly isotactic PP is still much less than unity because of the long-chain nature. Copolymerization (PP-RACO in Table 3) is also used to modify the polymer crystallinity in a controlled manner. In this case, the comonomer is the source of irregularity in the polypropylene chain. The introduction of comonomer decreases crystallinity, reduces stiffness and melting temperature, and increases impact resistance (99).

The degree of crystallinity is determined by a number of analytical techniques based on different criteria (see CRYSTALLINITY DETERMINATION). The most widely used are fractional solubilization (previously discussed), density determination, X-ray diffraction, and thermal analysis. The density of iPP in the α-form varies between the limit of 100% amorphous (ρ_a=0.850 to 0.855 g/cm^3) and 100% crystalline (ρ_c=0.936 to 0.946 g/cm^3) (20). In this way, the measured mass density ρ gives a measure of the crystallinity. Values of ρ are most often measured by the density gradient technique (ASTM D1505-85). Similarly, dilatometric methods are used to measure variations of density as a function of temperature (100). X-ray diffraction (101) is also widely used to determine PP crystallinity. Figure 3 shows the contributions of the crystalline scattering and amorphous scattering in the unoriented pattern of the α-form of iPP. The shaded region represents the area attributable to the noncrystalline fraction. From the relationship of the peak area to the total area, crystallinity can be evaluated by a number of numerical means (101). Orientation complicates the analysis (101). Differential scanning calorimetry (DSC) provides useful information on PP structure by the determination of related parameters, such as transition temperature, heat of fusion, crystallization temperature, and others. The crystalline fraction is given by the ratio of the measured heat of fusion to the value for 100% crystalline material (see THERMODYNAMIC PROPERTIES OF POLYMERS). The shape of the melting curve gives information on the melting distribution.

Lamellar and Spherulitic Morphology. The crystal habit of iPP quiescently crystallized from the melt, like other semicrystalline homopolymers, is that of folded chain lamellae (Fig. 5). The lamellar thickness ($\langle l_c \rangle$) increases with increasing crystallization temperature, and is generally in the range of 5–20 nm for iPP. iPP in the α-form exhibits a tendency, unique among semicrystalline polymers, to form a "cross-hatched" pattern (23,64). Radial lathlike lamellae coexist with "cross-hatched" tangential lamellae oriented nearly orthogonal to the radial direction. This homoepitaxy (102–107) is related to the relatively modest mismatch between the c- and a-axis unit cell parameters (Table 4), and the detailed molecular aspects have been reviewed (64). Spherulites are larger scale aggregates made up of the smaller scale lamellar building blocks. Depending on the

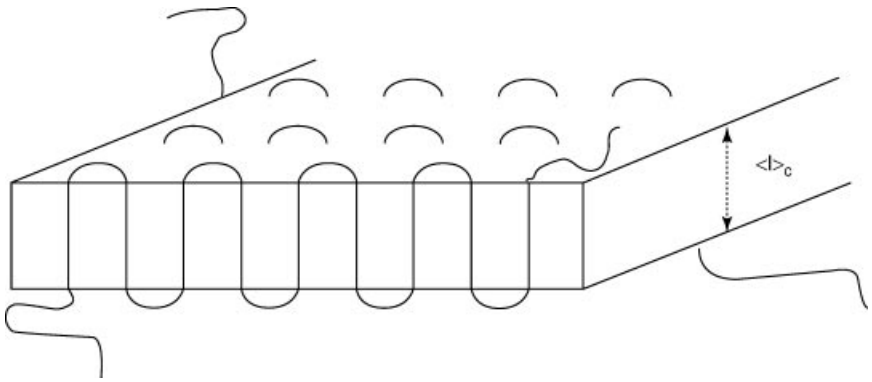

Fig. 5. Schematic of chain-folded lamellar structure in semicrystalline polymers.

crystallization conditions, the dimensions of spherulites can vary from a few micrometers to 100 μm, or larger. In the α-form of iPP, there is a strong link between lamellar and spherulitic morphologies. The α-form iPP spherulites have been classified according to different optical characteristics in cross-polarized light (106,108,109). The optical characteristic is highly sensitive to crystallization temperature and resin type, and has been linked to the lamellar morphology through the balance of cross-hatched radial and tangential lamellae (23,103,104,106,109,110). Optical and mechanical properties depend on the dimension and number of spherulites, which can be modified with nucleating agents that act as crystallization centers. Optical properties (such as clarity) improve with decreasing spherulite size. The borders among spherulites can represent weak zones (111), with large spherulites adversely affecting properties such as impact. Unlike iPP, pronounced cross-hatched lamellar morphologies in bulk crystallized material appears limited in sPP (112,113). As with iPP, well-developed small-angle X-ray (SAXS) long spacings, characteristic of well-developed lamellar morphologies, are observed for sPP of high syndiospecificity (113–116). In general terms, spherulite formation in as-polymerized metallocene based sPP tends to be more restricted than in iPP (117–119), and the spherulite-scale morphologies are generally smaller than in iPP in bulk-crystallized specimens. Spherulitic growth rate measurements have been summarized (120), with rates lower than those of Ziegler–Natta iPP (113). Unique morphologies (relative to iPP) are observed in sPP with special preparation procedures, including a transition from single-crystal like entities to spherulitic structures on cooling (68,117–119).

Macromorphology and Processing Relationships. Other morphologies in iPP include the macroscopic phase morphologies in multiphase structures such as rubber-modified iPP (an example being PP-EPR in Table 3), and additional morphologies associated with the specific method of polymer processing. Unique morphologies and structure/processing relationships are associated with fiber, film, and injection molding processes to name a few. In parts formed by the injection molding process, pronounced morphological gradients exist in a processed part which can be crudely partitioned into highly oriented skin layers (near the mold surface) and less oriented core layers (near the part center). These layers can approach macroscopic dimensions ($\sim$mm) depending on the part geometry, resin, and molding conditions. The properties of moldings can often be correlated to the orientation and crystallinity of the part (23,121). A literature review of more detailed aspects of the morphology of iPP injection moldings is available (23). In mixtures of iPP homopolymer and EPR (PP-EPR in Table 3), the two components are generally immiscible in the melt. In the solid state, the rubber has low glass-transition temperature (T_g) and imparts impact resistance to the blend. The effectiveness of the rubber phase as an impact modifier depends critically on the dispersion (particle size). The dispersion is a complex function of (*1*) matrix and rubber phase composition, (*2*) viscosity ratio of matrix and dispersed phases, (*3*) compounding history, and (*4*) melt deformation history during fabrication of the final processed part (23). In impact-modified copolymers for injection molding applications, the dimension of the dispersed rubber phase in the core (reduced melt deformation) is typically on the order of 0.5–2 μm in formulations with optimal impact performance. Near the surface of moldings (high melt deformation), highly anisotropic dispersed phase morphologies can be observed

depending on blend composition. Generally rubber phase dispersion worsens (increased phase size) with increasing melt temperature and melt time prior to molding due to coalescence.

High speed melt spinning of fibers represents another of the most common processing methods for iPP. The final morphology results from the complex interrelationships of polymer structure (polydispersity, molecular weight, tacticity) and processing conditions (melt temperature, melt throughput, spinnerette design, spin speed, cooling rate). For high spinning speeds, the orientation of melt-spun fibers greatly exceeds that of injection-molded parts. The orientation of crystalline regions is greater than the non crystalline regions (122). As the spinning speed increases, orientation increases. The orientation can be further increased with post-spinning drawing operations (122). As with unoriented material, the as-spun fiber shows alternating crystalline and amorphous regions on lamellar size scales (10–30 nm), but generally smaller than hot-drawn articles. This periodicity is highly oriented along the fiber axis, and characterized by a high fraction of tie molecules (the same chain passing through several crystalline regions).

Drawn film, and more specifically biaxially oriented polypropylene (BOPP) film, is another of the most common fabrication methods (see FILMS, MANUFACTURE; FILMS, ORIENTATION). During BOPP film formation, a cast sheet of iPP is drawn below the melting point in two directions. This drawing process creates a film of useful dimension while imparting desired properties such as barrier and stiffness. These properties are related to the imposed orientation during drawing. During unidirectional drawing of semicrystalline polymers at elevated temperature, the initial spherulitic morphology of the cast sheet is transformed to an oriented fibrillar morphology (122–125). The yielding process, during which the lamellar crystallites are disrupted, is strongly correlated to the crystallinity at the draw temperature. As with melt-spun fibers, the orientation of the crystalline regions is greater than that of the noncrystalline regions (122). Orientation is generally much higher than in injection moldings. For BOPP, the molecular orientation is dominated by the transverse orientation stage for sequentially oriented film (126), and tends to be planar (126,127) for both sequential and simultaneous oriented film. Generally, the lamellar crystals in the initial as-cast sheet are highly disrupted in the final BOPP film.

Polymerization Particle Morphology. Morphological control of as-polymerized polymer particles influences the polymerization process. Aspects of the particle morphology include the shape, size, size distribution, and porosity. Control of particle morphology is also a critical concern to technologies which utilize the as-polymerized particle in subsequent polymerization processes (128). Because of the replication phenomenon (129–137), the morphological characteristics are strictly dependent on the catalyst. The catalyst reproduces its shape in the polymer on an obviously greater scale according to its activity. The activity is the quantity of polymer produced by a unit of catalyst.

The replication phenomenon of iPP polymerization from magnesium chloride supported Ziegler–Natta catalysts is illustrated in Figure 6. The polymer particle has the same shape as the catalyst particle, although its diameter is approximately 20–100 times larger. The growth of the polymer particle during polymerization has been extensively modeled (129–137). In the multigrain model (131–135,137), the

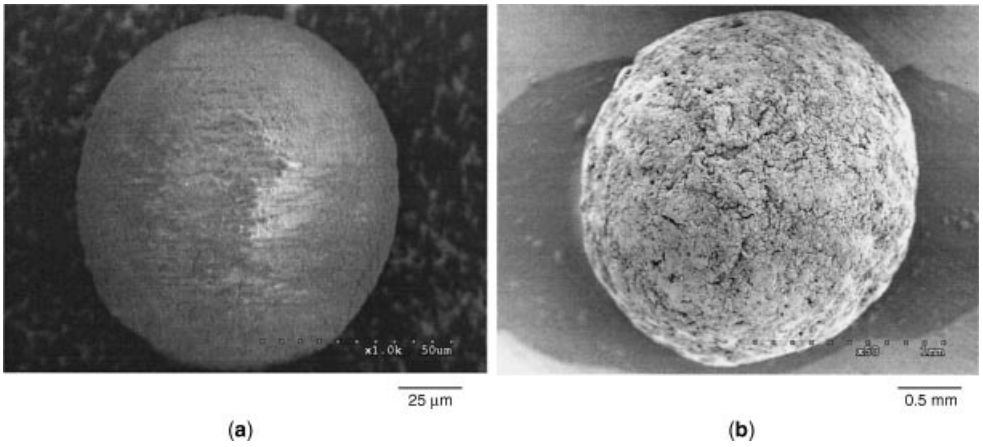

Fig. 6. Ziegler–Natta catalyst particle (**a**) and corresponding polymer particle (**b**).

catalyst undergoes fragmentation into microparticles evenly distributed within the macroscopic particle due to forces exerted by the growing polymer layers. In Ziegler–Natta catalysts, fragmentation occurs at very low polymer yields (137–139), which provides a large active surface from the beginning of polymerization. The growth of the macroparticle results from the cumulative uniform expansion of microparticle layers. Although the actual morphology of Ziegler–Natta polymerized particles shows a more complicated hierarchy than the "two-level" approach of the multigrain model, a key feature is the replication of the porous spherical catalyst morphology into a porous spherical polymer particle during polymerization. In practice, a careful morphological analysis of the polymerization particle requires, beyond microscopic investigations, analyses of particle size distribution (ASTM D1921-96), poured bulk density (ASTM D1895-96, Method A), and pourability (ASTM D1895-96, Method A).

Thermodynamic Properties

Melting. The melting point of α-form iPP is strongly influenced by the stereoregularity (19,23,47,99,140–144) and regioregularity (4,33,34,145,146). Melting point increases with improved regularity. T_m^0 is the theoretical equilibrium melting point of a perfect and infinitely large crystal. This value exceeds experimentally observed melting points because of kinetic effects leading to small crystal size (23) (Fig. 5). The value of T_m^0 is sensitive to stereoregularity. However, the value for 100% isotactic material is not expected to differ significantly from that of highly isotactic commercial materials (23). For highly regular materials, literature summaries of T_m^0 suggest that values of 185–188°C seem reasonable (23), though there remains disagreement in the literature (147). Melting points in the 160–168°C range are typical for commercial homopolymer samples under normal analysis conditions. Introduction of comonomer (ethylene, butene, and higher α-olefins) reduces the melting point, and can vanish at intermediate compositions

as the material approaches an amorphous rubber (Table 3). Literature summaries of the heat of fusion of 100% crystalline material, ΔH^0, generally lie in the range of 148–209 J/g (23). The most often applied values are clustered around 165 J/g (77,140,148,149) and 209 J/g (150,151).

As with iPP, the melting point of sPP is highly sensitive to stereoregularity. While comparison of T_m^0 for 100% syndiotactic sPP is ambigous, with current catalysts and in current commercial sPP materials, the observed melting point is generally less than that of Ziegler–Natta iPP under practical crystallization conditions when compared at comparable stereospecificity (23). This difference is often of the order of 10–15°C. Introduction of comonomer also reduces the melting point of sPP. Syndiospecific copolymerization with butene has the unique feature of being crystalline at all compositions because of the similarity of crystal structures of sPP and syndiotactic polybutene (152). Literature summaries of ΔH^0 lie in the range of 105–190 J/gm (23). Values in the lower end of this range agree with extrapolated heats of fusion versus density (23) and X-ray crystallinity (116).

Glass-Transition Temperature. The value of the glass transition (qv) temperature (T_g) is dependent on the crystallinity of the polymer, the molecular weight, and the measurement techniques used. DSC measurements of T_g for high molecular weight aPP and sPP are generally similar and usually close to 0°C. The DSC glass-transition temperature in highly stereospecific iPP is often difficult to distinguish because of the high crystallinity. Transition temperatures are generally in the range of −13 to 0°C. Other techniques, such as dynamic mechanical analysis, are often more sensitive to the T_g of iPP. Copolymerization with ethylene reduces the glass-transition temperature. Figure 7 shows DSC measured T_g values of propylene/ethylene copolymers prepared with an aspecific catalyst. In this case, all samples are noncrystalline and not affected by crystallinity. A similar trend is generally observed for isospecific and syndiospecific catalysts as well. Copolymerization with butene is less effective at lowering the T_g.

Heat Capacity and Thermal Expansion. Extensive tabulations of the extrapolated heat capacities of crystalline and amorphous iPP as a function of temperature are available (147). The specific volume (153) and heat capacity (154) of iPP in the melt as a function of temperature and pressure, and typical thermal expansion coefficients in the solid state as a function of temperature (151) are also reported.

Chemical Properties

iPP is soluble in high boiling aliphatic and aromatic hydrocarbons at high temperature. sPP shows solubility at lower temperature and in lower boiling hydrocarbons. aPP shows the highest solubility of the three forms. Extensive chemical resistance data is available for iPP (155). The high chemical resistance of iPP results in exceptional stain resistance, and has led to the use of iPP in automobile batteries (156). iPP has outstanding resistance to water and other inorganic environments (155). iPP resists most strong mineral acids and bases, but like other polyolefins is subject to attack by oxidizing agents including 98% sulfuric acid and 30% hydrochloric acid at high temperature (∼100°C), and fuming nitric acid (ambient temperature) (155). Inorganic chemicals produce little or no effect over

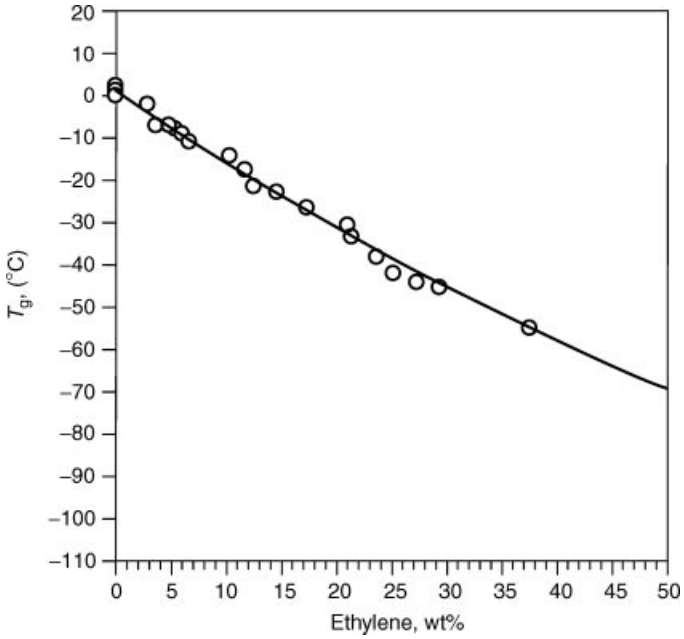

Fig. 7. Glass-transition temperature (T_g) versus ethylene concentration in propylene–ethylene random copolymer using aspecific catalyst (no crystallinity). Values were determined by differential scanning calorimetry (DSC).

a period of 6 months at temperatures up to 120°C (155). For organic media, absorption is greater for higher temperatures and decreased polarity, and is higher in copolymers than in homopolymer.

PP reacts with oxygen in several ways, causing chain scission and brittleness that is associated with the loss in molecular weight. This action is promoted by high temperatures, light, or mechanical stress. A wide variety of stabilization packages are added for protection, depending on the application (157).

The reactivity of iPP can also be usefully exploited. For example, treatment with peroxides has led to controlled rheology resins (61,158,159) with reduced molecular weight and narrow polydispersity relative to as-polymerized product from Ziegler–Natta catalysts. For a fixed final melt-flow rate (MFR), lower precursor MFR gives narrower polydispersity. These resins are used in some fiber-spinning and injection-molding applications. The creation of radical sites along the polymer backbone, most often through peroxide-based initiation, is also an essential condition for many functionalization/grafting chemistries. The functionalization chemistry of post-polymerized iPP has been extensively reviewed (160). The focus has been on the incorporation of polar functional groups into the polymer chain and/or the graft polymerization of monomers which are generally incompatible with Ziegler–Natta catalysts. The incorporation of polar functionality has been sought to improve paintability, printability, and metal adhesion characteristics (important to coatings); to act as coupling agents in composites such as glass-reinforced iPP; to improve oxygen barrier resistance; and to act as compatibilizers in polymer alloys. Recent advancements in metallocene and

related transition metal catalysts are showing promise for the direct copolymerization of polar monomers with ethylene and propylene (161). Other chemical modifications include plasma and acid treatment technologies.

Radiation chemistry of PP has been extensively reviewed (162). Under suitable conditions, radiation treatment can lead to desirable branching reactions (163) with rheological characteristics favorable for thermoforming, foaming, blow molding, and extrusion coating. Resistance to radiation sterilization is an important requirement in some medical applications, and requires specialized formulation and stabilization packages.

Physical Properties

A vast number of PP grades are sold in the United States, including homopolymers with varying molecular weight (melt-flow rate) and tacticity, filled grades, grades with varying stabilization packages, and grades which incorporate comonomers with varying architecture (Table 3). The basic categories of iPP polymers are homopolymers, random copolymers, impact or heterophasic copolymers, and filled polymers. A number of grades are approved for food contact (164). Many polymers carry a UL94 flammability class HB rating (164), and some specialized formulations have improved ratings. Additional specialty grades include nucleated polymers for improved clarity and mechanical properties, radiation-resistant formulations, chemically visbroken "controlled rheology" grades (61,158,159), high melt strength grades, and a large number of formulations with specialized additive functions including slip agents, antiblocking agents, antistats, and pigments to name a few (157). Standardized test methods such as ASTM or ISO are used in commercial specifications. The properties that distinguish iPP from high density polyethylene are high heat distortion temperature, stiffness, hardness, and lower density.

Properties of various homopolymer grades are given in Table 5. In this table, polymer molecular weight and polydispersity is tailored to give the best processing characteristics for each fabrication process. The polymers shown in Table 5 are produced by direct polymerization. Higher melt flow grades, and "controlled rheology" grades with narrow polydispersity, can be important in other applications, including fibers. Narrow polydispersity resins can also be produced by metallocene catalysts (4). These catalysts can also produce iPP with a narrow interchain tacticity distribution and low levels of extractables. High crystallinity (tacticity) grades, and high polydispersity grades, provide additional stiffness and higher heat distortion temperature in injection molding applications (23,120,166,167). Properties of selected random copolymer grades are given in Table 6. These copolymers have ethylene as the comonomer, although butene copolymerization is also possible. The stiffness of these polymers is lower than that of homopolymers. The impact resistance is improved, particularly at refrigeration temperatures. Clarity is also enhanced. The low melting point allows the use of some copolymer grades as sealant layers in PP films. Properties of impact-resistant, or heterophasic, copolymers are given in Table 7. Much of this class of material is used in injection-molding applications,

providing impact resistance well below 0°C. Copolymers containing high flexible product. Mineral fillers, such as talc or calcium carbonate, and other reinforcements such as glass fiber or mica, increase the stiffness and heat-distortion temperature. Some properties of mineral-filled iPP are given in Table 8. Filled formulations based on impact copolymers (PP-EPR) are also common.

Catalysts for Polymerization

$TiCl_3$-Based Catalyst. Isotactic polypropylene was first synthesized by Natta in 1954 by employing a system consisting of $TiCl_4$ and $Al(C_2H_5)_3$ activator (169–174). It was based on Ziegler's catalyst system (175), which was used for the polymerization of ethylene. Only 30–40% of the polypropylene produced by Natta's catalyst had the typical characteristics of isotactic polypropylene; for example, it was insoluble in boiling heptane and had a melting point of about 165°C. The remaining product was atactic with poor structural uniformity and a rubbery consistency. Natta quickly realized that the polymer isotacticity was directly connected to the uniformity of the catalyst surface. Thus for the polymerization of propylene, he employed solid crystalline $TiCl_3$ (obtained by the reduction of $TiCl_4$) (176) with $Al(C_2H_5)_2Cl$ or $Al(C_2H_5)_3$ and obtained a higher percentage of isotactic product (see ZIEGLER-NATTA CATALYSTS).

The various $TiCl_3$ structural forms, α, β, γ, and δ, were identified in subsequent studies (177); the δ-form, in combination with $Al(C_2H_5)_2Cl$, gave the best results. The high polymer isotacticity (ca 90%) permitted a scaled-up industrial process by Montecatini, which had supported Natta's research at the Politechnic in Milan. This first plant (and subsequent others) contained a large section for the separation of the undesirable atactic fraction from the isotactic fraction and a section for the removal of catalyst residues that affected product quality. Substantial progress was achieved in a short time (178,179).

Hercules discovered the role of hydrogen as a molecular weight regulator (180). Esso improved performance by using $AlCl_3$ in $TiCl_3$ solid solution instead of pure $TiCl_3$ (181). Mitsubishi increased isotacticity to 92–94% by adding an electron donor, such as carboxylic acid ester, to the $TiCl_3$ (182).

The treatment of the $TiCl_3$ produced from the reaction between $TiCl_4$ and $Al(C_2H_5)_2Cl$, first with the electron donor, diisoamyl ether, and then with $TiCl_4$, gave a highly stereospecific catalyst. This catalyst system was four to five times more active than δ-$TiCl_3$ (183) and capable of producing a polymer with narrow particle size distribution. This system can be referred to as the second-generation catalyst (Table 9). However, the catalyst yield was still insufficient to reduce catalyst residues enough to eliminate the deashing step in the production process.

In the meantime it was established that only a small percentage of the titanium on the catalyst was actually active. The active titanium was located on the lateral faces and edges, and along the crystal defects (184). This led to the realization that much of the catalyst mass acted as the support (185). Decisive progress could be achieved by depositing the active Ti on a support whose residues, unlike those of $TiCl_3$ would not be detrimental to polymer properties.

$MgCl_2$-Supported Catalysts. Magnesium chloride, in the active form as a support (186,187), increases catalyst yield and allows for the simplification of the

polymerization process in hydrocarbon slurry with the elimination of the costly deashing step. This discovery and further improvements led to the development of the superactive, third-generation catalysts (188–193) (Table 9). Better yield, higher stereospecificity, and morphology control resulted in simplified processes in which the monomer is the polymerization medium.

Other catalyst systems that are usually soluble in the reaction medium are of high scientific importance but not used industrially. Among these is the system consisting of the product of the reaction of AlR_2Cl and $Al_2R_2Cl_4$ with vanadium compounds. This system is utilized in the production of syndiotactic polypropylene at very low temperature (194,195).

Isotactic polypropylene has been obtained, although with very low yields, from Ti and Zr benzyl compounds (196) and allylic derivatives (197).

Other highly active catalyst systems are based on single-site catalyst, for example (η-$^5C_5H_5)_2M(CH_3)_2$; (M = Ti, Zr). These systems will be discussed in more detail in the Homogeneous Catalyst section.

Heterogeneous Catalyst Preparation.

$TiCl_3$-Based Catalysts. First-generation catalysts are prepared by the reduction of $TiCl_4$ with metallic aluminum in aromatic solvent between 100 and 200°C (198,199). A solid solution with the composition of $AlCl_3 \cdot 3TiCl_3$ (200) is formed. Milling converts the crystalline $TiCl_3$ from the α- to the δ-form, increasing its surface area and radically improving its performance (201); $Al(C_2H_5)_2Cl$ is the best activator. Hydrogen and $Zn(C_2H_5)_2$ are the molecular weight regulators, but diethyl zinc is rarely used. Typical performance for this type of catalyst is reported in Table 9. Milling produces a catalyst, and thus a polymer, with broad particle size distribution.

A second-generation catalyst (183) is prepared by reducing $TiCl_4$ with $Al(C_2H_5)_2Cl$ in a hydrocarbon at 0°C. The $3TiCl_3 \cdot AlCl_3$ product with surface area

around 1 m^2/g thus obtained is washed at 35°C with diisoamyl ether to remove most of the $AlCl_3$. The product is then treated with $TiCl_4$ at 65°C and washed with hydrocarbons. The catalyst has a high surface area (up to 150 m^2/g). In polymerization with $Al(C_2H_5)_2Cl$ and hydrogen, it gives the average performance shown in Table 9. The polymer has regular shaped, compact particles and narrow particle size distribution, with an average diameter around 300–400 μm. Catalyst activity is maintained by storage under refrigeration.

$MgCl_2$-Supported Catalysts. The scientific and patent literature reports several methods for the preparation of the $MgCl_2$-supported catalysts of third and superactive third generations. They can be classified as follows:

(1) Catalysts obtained by milling mixtures of anhydrous $MgCl_2$ with an electron donor and a titanium compound (186,187)
(2) Catalysts obtained by milling anhydrous $MgCl_2$ with an electron donor and treated with a titanium compound ($TiCl_4$) above 80°C, followed by washing with hydrocarbons (188–192)
(3) Catalysts obtained by treatment of "active" $MgCl_2$ with an electron donor and a titanium compound ($TiCl_4$) under conditions similar to those of the previous case (202)

The second method gives the average results reported in Table 9 with regard to third-generation catalysts. In practice, anhydrous $MgCl_2$ and an aromatic ester, usually ethyl benzoate (EB) in molar ratios between 2 and 15, are shaken in a vibrating mill containing steel spheres for 20–100 h. The $MgCl_2$ is activated; that is, it is converted from the crystalline ordered form to the disordered δ-form while the crystallite size is reduced.

The product is treated twice with an excess of $TiCl_4$ between 80 and 130°C, washed repeatedly with hydrocarbons, and dried. During the treatment with $TiCl_4$, the base is partially extracted, and $TiCl_4$ enters the support. The final composition of the solid includes 0.5–3.0 wt% Ti and 5–15% EB; the remainder is $MgCl_2$. The surface area is in excess of 100 m^2/g. The active or δ-form of $MgCl_2$ resembles the δ-form of $TiCl_3$ (203). It can also be obtained by direct contact of anhydrous $MgCl_2$ with Lewis base or by chlorination of magnesium organic compounds (188–192). The degree of activation can be determined by X-ray diffraction (203), where the passage from α to δ gives rise to a widening and lowering of the diffraction peaks. The active form, because of the corners, edges, and surface defects of the crystallites, binds the titanium compound strongly, and repeated washing or treatment under vacuum cannot remove it. This strong binding is attributed to the closeness of the Mg and Ti ionic radii (204) and to the similarity among the crystallographic forms of their halogens. The Ti atoms located in exposed sites give rise to polymerization active centers (205–208). Magnesium chloride may easily interact with electron donors, probably affecting the stereospecificity of the active site. It can be easily transformed into particles with controlled morphology because of the low melting point of its adducts with alcohols or water. These catalysts are used with aluminum trialkyl alone or in blends with chlorinated aluminum alkyls and with a second electron donor, which can be equal to or different from that contained in the solid catalyst.

Heterogeneous Catalyst Evaluation. To evaluate a catalyst system, the following characteristics must be known: yield or productivity, which is the amount of polymer produced per unit of total catalyst or single component; the polymerization kinetics, or yield development with time; stereospecificity; sensitivity to the molecular weight regulator; the molecular weight distribution of the polymer produced; the microtacticity of the resulting polymer; ability to copolymerize; and the final polymer morphology.

To forecast the behavior of a catalyst system in an industrial continuous polymerization, these characteristics should be determined within a wide range of conditions; eg, temperature, concentration, and ratios of the various components (activator, external donor, solid catalyst, etc). A laboratory batch-scale test can provide most of this information. A small, simple reactor suitable for these studies is shown in Figure 8. The polymerization can be carried out in a hydrocarbon or liquid propylene. In some cases the polymerization test can be performed in the gas phase, provided the reactor is prepared with a suitable heat transfer and catalyst dispersing bed (eg, a salt bed).

The stainless steel reactor is provided with a jacket for temperature control in the range $\pm 0.5^{\circ}C$ using a steam and chilled water mixture. The reactor contents are agitated by a magnetic stirrer (500–900 rpm). The consumption of the propylene is followed by weighing the vessel from time to time or through gas flow meters.

A test using hexane as diluent is the simplest to perform because it does not require the safety measures required for tests in liquid propylene. It can be carried out as follows.

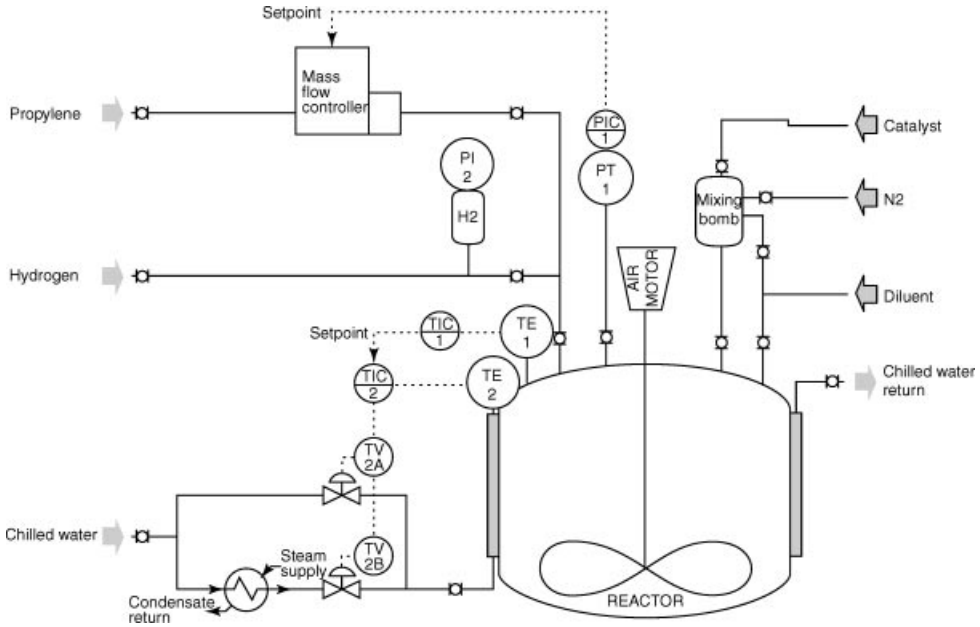

Fig. 8. Lab-scale polymerization reactor.

The reactor is kept under nitrogen at 40–50°C to exclude oxygen and moisture. Anhydrous, deaerated hexane is introduced followed by a fixed amount of catalyst. The reactor is closed and heated to 60–70°C, and hydrogen and propylene are fed at the desired concentrations. These feeds are maintained for a certain time. Data on the polymerization kinetics are obtained from the mass of propylene fed over time. At the end of the test the temperature is reduced, the reactor degassed, and the slurry (hexane/polypropylene) discharged from the reactor (either through a dip tube or a bottom valve). The polymer is separated from the hexane by filtration or by evaporation. The polymer is dried at 60°C under nitrogen, weighed, and analyzed.

Typical graphs follow which represent the performance of a superactive, third-generation catalyst system as a function of processing variables. The activity is expressed as kilograms polymer per gram catalyst, and the isotacticity as polymer percentage residue from a boiling heptane extraction in a modified Soxhlet extractor for 12 h.

Figure 9 shows the trend of activity for polymerizations in hexane with a propylene concentration of 14% at 70°C; Figure 10 shows the isotactic index.

Polymerization temperature, as reported in Figure 11, influences performance; an increase from 50 to 80°C increases both activity and isotacticity.

Isotacticity should be between 94 and 98% to meet various application requirements. The ratio between aluminum and electron donor controls stereospecificity. At very high levels of electron donor the activity will be reduced, as shown in Figure 12 (209).

The aluminum compound alkylates the transition metal and can act as a transfer agent. It also removes impurities from the reaction medium (eg, water, CO_2, alcohols), thereby avoiding catalyst poisoning. In addition, aluminum alkyl reduces the transition metal to lower valence, thus affecting its activity (210). In the case of supported catalysts, aluminum alkyl plays a fundamental role by complexing the electron donors (204).

Polymerization Reaction Mechanisms

The rate R_p of the primary propagation step of monomer to polymer in Ziegler–Natta catalysis is represented by

$$R_p = k_p[C^*][M]$$

where k_p is the propagation constant, [C*] the concentration of active sites, and [M] the monomer concentration.

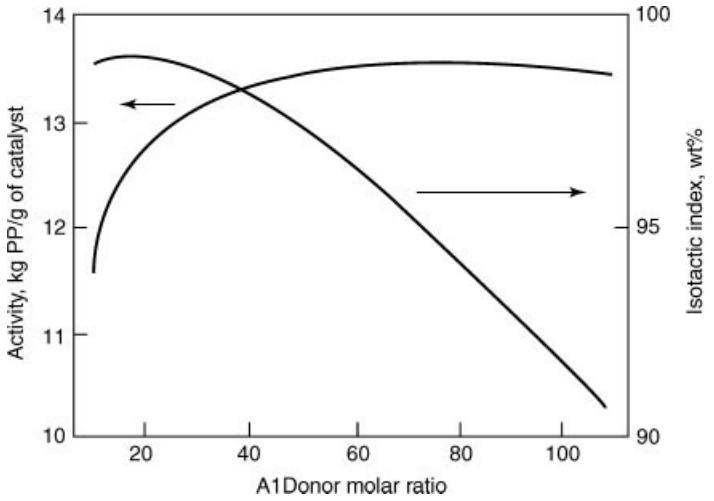

Fig. 12. Activity and isotactic index vs Al:donor ratio.

The global polymerization rate changes with time. A period of increasing rate is usually followed by a decline and eventually by a stationary state. The rate decay is often attributed to the change in concentration of active sites in the context of the above noted expression. The initial increase may be due to the progressive activation of new active centers. The deactivation, particularly evident in supported catalysts (211,212), is attributed to variations in both number and chemical nature of the centers (213).

Global polymerization rate and rate of primary propagation are affected by the catalyst system and polymerization conditions (203,214). Effects are due to the chemical and physical structure of the catalyst as well as to the nature of the activator. Important parameters include the ratio between catalyst and activator, and their concentrations, hydrogen concentration, temperature, stirring rate, and type and amount of Lewis base. The effects vary with the polymerization medium; ie, diluent or the monomer in liquid or gas phase (215–218).

The complexity of the catalyst systems and their heterogeneous nature make an accurate analysis of the parameters associated with the primary propagation step difficult. This is one reason why literature analyses are rarely in agreement; also, the data are obtained by methods and under conditions that are rarely comparable. A typical example is the determination of the concentration of the active sites and the propagation constant, which can be carried out by various methods (chemical, radiochemical) that are not completely reliable. Nonetheless the parameters are valuable in determining catalyst potential and performance.

The same uncertainty is involved in the determination of the activation energy of the propagation reaction and the average lifetime of the polymer chain. A value of 23 kJ/mol (5.5 kcal/mol) for $TiCl_3$-based catalysts is reported for the former (219). For the latter, values of 360–600 s (220) and 160 s (219) for $TiCl_3$-based catalysts are reported at 70°C and 5 s (221) for $MgCl_2$-supported catalysts at 45°C.

A short time after the discovery of Ziegler–Natta catalysts, it was suggested (222,223) that chain propagation occurred by monomer insertion into a Ti–carbon

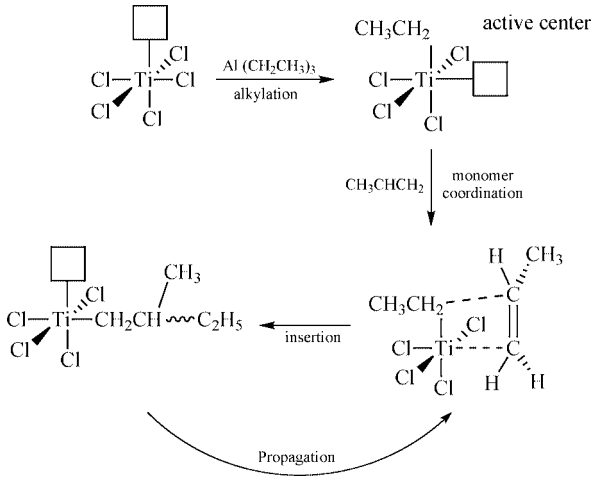
bond of the catalyst. This bond was considered to be polarized, with a weak negative charge on the carbon atom; this hypothesis is still widely supported today. It was confirmed by IR analysis of chain terminal groups (224) as well as by ^{13}C enriched aluminum alkyls (225).

In an attempt to provide a model to explain the growth of the polymer chain satisfactorily, several hypotheses have been suggested. In Boor's book on Ziegler–Natta catalysis (179), he exhaustively reviewed the literature and addressed four mechanisms for chain growth. The four mechanisms are based on the description of the center where chain growth takes place:

(1) transition metal–carbon bond,
(2) activator metal–carbon bond,
(3) bound radical center, and
(4) bound anion center.

Of these four, the majority of the research tends to support the transition metal–carbon center model, as the mechanistic scheme of choice. Using a homogeneous catalyst (Cp_2TiEt_2) as a model, Breslow and Newburg proposed that polymerization growth occurred at the Ti—C center. Somewhat later, Cossee extended this concept into a more elaborate mechanism for supported catalysts, which he substantiated with molecular orbital calculations (see Ref. 179, Chapt. 13).

According to this widely accepted model (226–230) for the surface site and surface coordination environment, the active site is a titanium atom with octahedral shape and a vacant position (the other positions being occupied by an alkyl group derived from the alkylation by the aluminum alkyl and the remaining chloride atoms). In total the active site is made up of four ligands, which, in the case of $TiCl_3$, are chlorine atoms, the alkyl group, and the vacant site.



Monomer insertion occurs through a first step of monomer coordination to the transition metal, with formation of a π-complex, subsequent weakening of

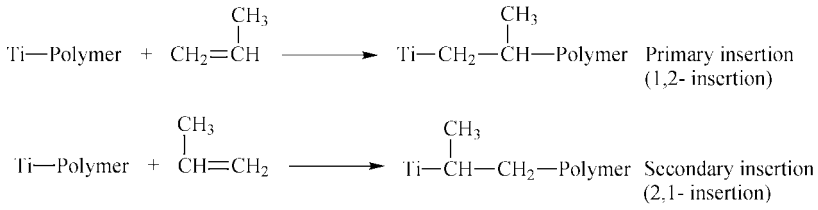
the Ti—C bond, and finally insertion of the monomer coordinated between the transition metal and the C atom. Because the two positions are not equivalent in the crystal lattice of the catalyst, the vacancy and the growing chain exchange positions. These phases are repeated at the insertion of each monomer unit. On the basis of molecular orbital theory, a semiquantitative interpretation of the mechanism was provided by assuming weakening of the metal–carbon bond during olefin complexation in the case of metal ions with 0–3 d-electrons (as in Ti, V, Cr), and with more difficulty when the number of d-electrons is greater. This mechanism is called monometallic; it requires only the participation of the transition metal, attributing to the aluminum compound the role of forming the active center by alkylating the titanium atom. The aluminum compound is also involved, as demonstrated by the different effects that various aluminum alkyls have on the performance of these catalyst systems.

Some researchers believe that the active metal (aluminum) directly participates in directing of the incoming monomer, in which case this system would be considered a bi metallic site. However, Boor makes a convincing argument that because of the size of the polypropylene helix, there is no room at the active site for the aluminum to participate. The titanium site occupies roughly 0.16 nm^2 (diameter $\sim$0.45 nm) and the cross-sectional area of a polypropylene helix is about 0.35 nm^2 (diameter $\sim$0.7 nm). This would eliminate the titanium and aluminum from sharing a common chloride bridge and thus preclude aluminum from directly participating in directing the incoming monomer (179). It has been suggested that the effect the different aluminum alkyls have on polymer microstructure and molecular weight is due to the way in which the alkyl aluminum sets up the titanium chloride surface. These differences in polymer microtacticity and molecular weight could be due to the fact that the activator may be generating different isotactic sites.

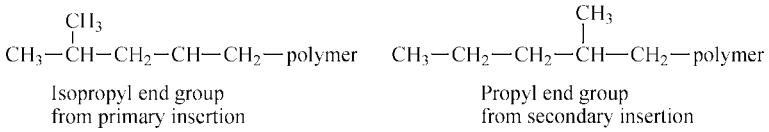
The basic concept of monomer insertion has now been discussed and for the polymerization of ethylene this simple description of a monometallic, transition metal–carbon centered active site would be sufficient to describe the polymerization. However, with α-olefins the matter of stereo- and regio-chemistry must be addressed and will be done in the next section.

Stereo- and Regiochemistry of Monomer Insertion. For substituted α-olefins a number of issues concerning monomer coordination/insertion must be considered. The way in which the monomer inserts itself into the polymer chain determines the microstructure of the polymer and subsequently the properties. Does the methyl group on the propylene end up towards the chain or away? What is the position of the methyl group on the propylene molecule with respect to coordination site of the metal and the polymer chain, cis versus trans? The way in which the propylene molecule may be inserted in the polymer chain by various mechanisms can give rise to complex phenomena of structural and steric isomerism.

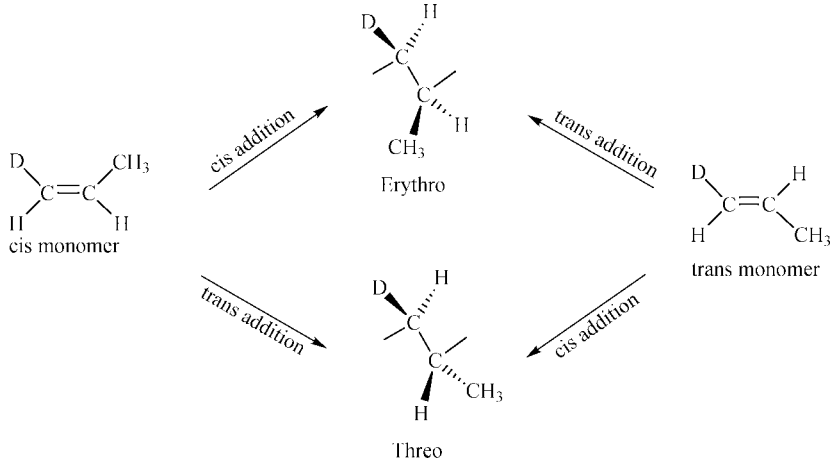
Two possible regio-insertion mechanisms for α-olefins exist—primary and secondary. In a primary insertion the unsubstituted end (methylene group) of the monomer attaches to titanium center. This is also known as a 1,2-insertion. In a secondary insertion the substituted end of the monomer attaches the titanium. This is also called a 2,1-insertion.



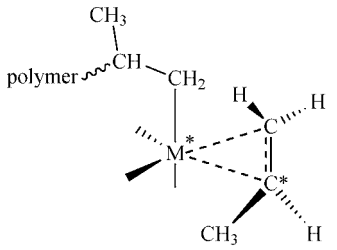
The experimental evidence indicates that for the production of isotactic polypropylene the primary insertion mechanism is predominant. This is substantiated via end group analysis by the presence of isopropyl groups as the end groups after chain transfer by hydrogen. The regioselectivity of Ziegler–Natta catalysts is very high as have been proved by NMR analyses (231,232). Syndiotactic polypropylene can be prepared by the low temperature polymerization of propylene using a vanadium catalyst. In this case the secondary insertion mechanism is operative (233,234).



For stereoregular insertion there are two modes to consider—cis insertion and trans insertion. For both isotactic and syndiotactic production, the cis mechanism has been determined to be in operation. This was established by polymerizing with *cis*-, and *trans*-1-deuteriopropylene or related monomers. The expected stereochemistry was demonstrated when deuteriopropylene was polymerized. The cis monomers produce *erythro* monomer units whereas the trans monomer yields the *threo* units when *cis*- and *trans*-1-d-propylene is polymerized. In some cases the nomenclature appearing in the literature can be confusing and contradictory, but all indicate cis insertion. To be specific, as defined below, stereochemical structures from cis and trans addition to the double bond of *cis*-(1-d_1) and *trans*-(1-d_1)-propylene to isotactic polypropylene are as follows (229):

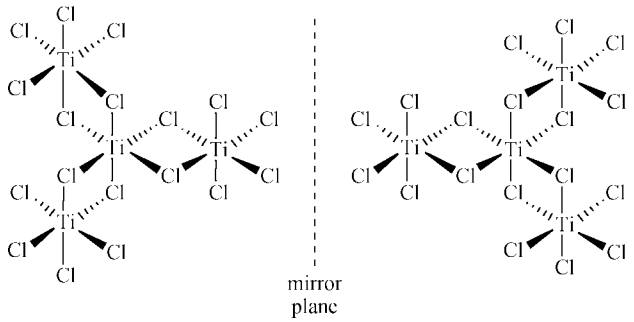


Two potential mechanisms have been proposed as governing factors regulating the stereochemistry of the isotactic insertion, the first being the asymmetric structure of the active site (enantiomeric site control) and the second being the asymmetric carbon atom of the last chain-inserted monomer unit (chain end control). It has been proved experimentally that the regulating factor is the active center (enantiomeric site control) because the steric order is transferred also through ethylene units and because an occasional error is not perpetuated in the chains (231,232). This mechanism is valid for Ziegler–Natta catalysts and many (if not most) homogeneous metallocene catalysts. In addition it has been shown (235–240) how, in the polymerization of racemic α-olefins, a mixture of optically active polymer can be obtained with an asymmetric catalyst.



Chiral centers in the propagation step

Examination of the crystalline structure of the catalyst components reveals the asymmetric structure of the active center. In $TiCl_3$ six chlorine atoms at the vertices of an octahedron surround each titanium atom. These six chlorine atoms are then chelated, by pairs, to three other titanium atoms. This creates two enantiomorphic structures.



The next section will discuss some of the concepts associated with models for the catalytic sites.

Ziegler–Natta Active Site Models

An important characteristic of a polymerization catalyst is its morphology or structural architecture. Titanium chloride exhibits four different crystalline modifications: α, β, γ and δ forms depending upon the method of preparation. In each

case the titanium atom is octahedrally coordinated, except at various defects and edges. The violet α-form, and the γ and δ forms consist of regular stacking of Cl—Ti—Cl layers containing titanium atoms between two layers of chloride ions. The α-$TiCl_3$ form, which will be discussed, is hexagonally close packed.

Stereospecific behavior of the catalyst site is related to the chirality of the surface sites of the solid $TiCl_3$. Models by Corradini can explain a number of observations—the type of tacticity errors along a predominantly isotactic chain, stereospecificity of the initiation reaction, and the maintenance of isotacticity after the insertion of ethylene monomer in the chain (241). Furthermore, since violet $TiCl_3$ and $MgCl_2$ solid-state crystal structures are similar, Corradini's model relates well to both $TiCl_3$ and $MgCl_2$-supported catalysts.

The structure of titanium trichloride and other Ziegler–Natta catalysts consisting of transition metal halides (VCl_3, $CrCl_3$, etc) is comprised of layers of close-packed chlorine atoms. The crystalline modifications are based on the different ways in which the layers are stacked on top of one another. Within each layer the metal atoms reside in an ordered arrangement. The metal atoms occupy two thirds of the octahedral positions. The adjacent metal atoms, which are bridged by two chlorine atoms, have opposite chirality. The chirality of these metal atoms is designated Λ and Δ according to the International Union of Pure and Applied Chemistry (IUPAC) nomenclature (242). In the $MgCl_2$ structure there are no vacancies in the lattice and every octahedral position is occupied by a magnesium atom; however, it can be seen that the gross structures of $TiCl_3$ and $MgCl_2$ are similar. This similarity in structure between $TiCl_3$ and $MgCl_2$ is what makes magnesium chloride a suitable substrate for the deposition of titanium chloride to form active sites. It was determined early on that only a small portion of the titanium on $TiCl_3$ catalysts was active; the rest was essentially acting as a support. The bulk of the titanium chloride was the culprit in causing polymer instability and degradation problems. When using $MgCl_2$ as a support the yield of polymer per weight of catalyst is much greater. Along with the fact that the magnesium chloride is practically inert, this produced a polymer that was inherently more stable.

A diagram of the $TiCl_3$ structure of the (110) cut and the (100) cut of $MgCl_2$ is shown in Figure 13; the chloride atoms are omitted for clarity.

Magnesium chloride can be treated either chemically or physically (ball milling) to achieve activation. Activated $MgCl_2$ has a very disordered structure, which consists of very small lamellae. In the bulk, magnesium atoms are coordinated to six chlorine atoms, but at the lateral edges or cleaved surfaces the coordination is with 4 or 5 chorine atoms. These lateral cuts correspond to the (110) and (100) faces respectively for magnesium chloride. Upon treatment of activated $MgCl_2$ with $TiCl_4$, the bridged dinuclear Ti_2Cl_8 species coordinate on the (100) surface while the single $TiCl_4$ species usually prefer the (110) faces. Treatment of the catalyst by aluminum alkyls will reduce the Ti_2Cl_8 to Ti_2Cl_6 species and alkylate the titanium. This will generate both $TiCl_3$ and Ti_2Cl_6 species on the $MgCl_2$ support. The placement of these Ti_2Cl_6 units on the (100) lateral surface of $MgCl_2$ produces sites very similar to those on the (110) surface of $TiCl_3$ catalysts. These Ti_2Cl_6 sites are chiral and stereospecific. Coordination of the $TiCl_4$ species on the (110) faces and reduction by aluminum alkyls produce $TiCl_3$ sites, which lack chirality and are nonstereospecific producing sites for propylene polymerization. In Figure 14, is shown both the $TiCl_3$ catalyst and $MgCl_2/TiCl_4$ catalyst after

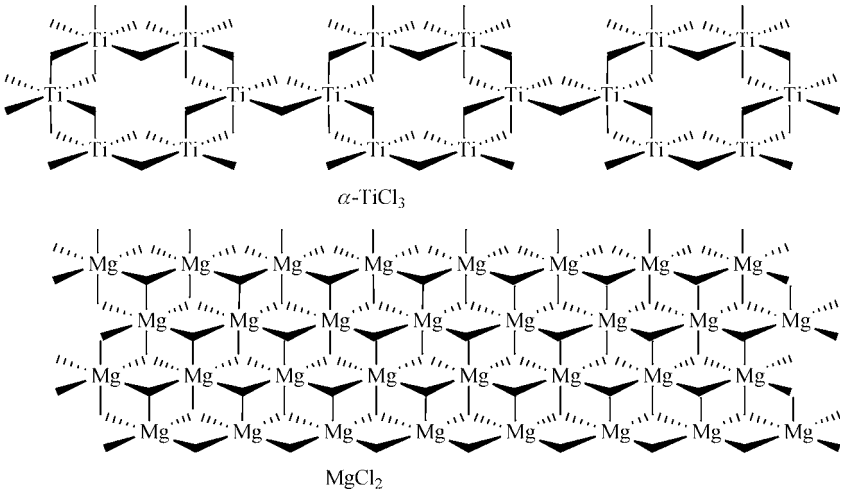


Fig. 13. Comparison of the structures of α-$TiCl_3$ and $MgCl_2$.

reduction with AlR_3. Now with the basics of the active centers and structures described, the details of the polymerization mechanism can be discussed.

As mentioned previously, a two-stage reaction mechanism for the polymerization of propylene was proposed which consists of a coordination stage of the olefin then followed by an insertion step of the monomer into the Ti–polymer bond. Although this picture (Fig. 15) reveals the basic mechanism of monomer coordination and then insertion, it does not provide any insight into the mechanism for stereocontrol of the propylene monomer. This is addressed by chirality considerations.

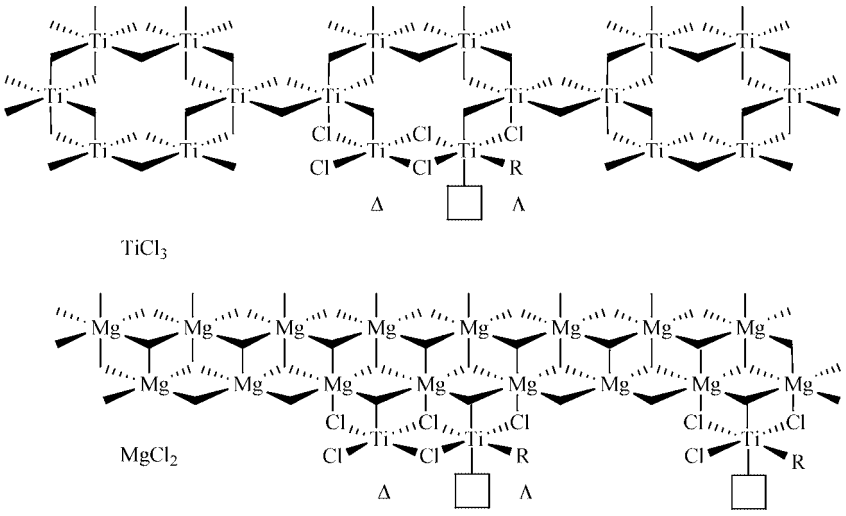

Fig. 14. Crystal structures of α-$TiCl_3$ and $MgCl_2$ with Ti_2Cl_6 clusters. Chlorine atoms are shown at the catalyst sites, and substrate chlorine atoms are omitted for clarity.

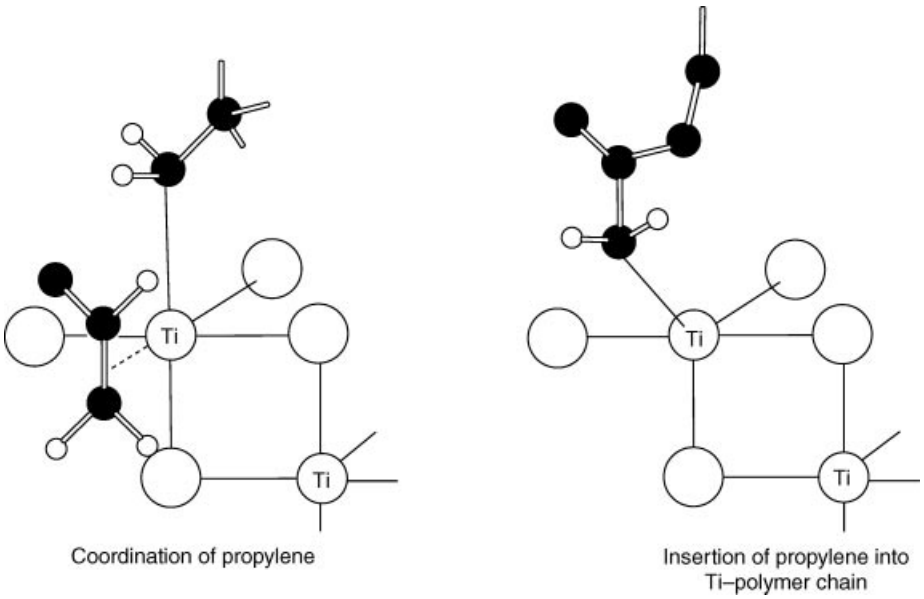

Fig. 15. Propylene coordination to titanium and then insertion of propylene into the Ti–polymer bond.

As discussed previously the active sites on $TiCl_3$-based catalysts or $MgCl_2$-supported catalysts are chiral. In all, there are three elements of chirality that are considered with respect to the polymerization of α-olefins and stereospecificity of the polymer:

(1) α or δ chirality of the titanium atoms
(2) The *si* or *re* chirality of the coordinated propylene monomer
(3) The chirality of the tertiary carbon atoms of the growing polymer chain

For this discussion the bridged dimers of Ti_2Cl_6 on the lateral face of a $MgCl_2$ crystal will be considered. If Figure 16 (below) is studied in detail, it can be seen that at one of titanium atoms of the Ti_2Cl_6 cluster there are two positions that are available to the growing polymer chain and the coordinating monomer. One position can be considered outside or away from the bulk of the crystal and the other can be considered inside, or towards the bulk of the crystal lattice. These two positions are not sterically equivalent. Through computer modeling calculations, Corradini and co-workers demonstrated that the most favorable energy position for the growing chain was at the inside position (241).

If the most favorable energetic position for the chain is at the inward position, then the monomer must occupy the outside location. For the Λ titanium site, the *si* outward coordination of propylene is favored (*re* for the outward Δ titanium site). In this model the production of stereospecific polypropylene can be explained.

For syndiotactic propagation it was proved that the steric control of the insertion comes from the last inserted monomer unit, whose hindrance affects the

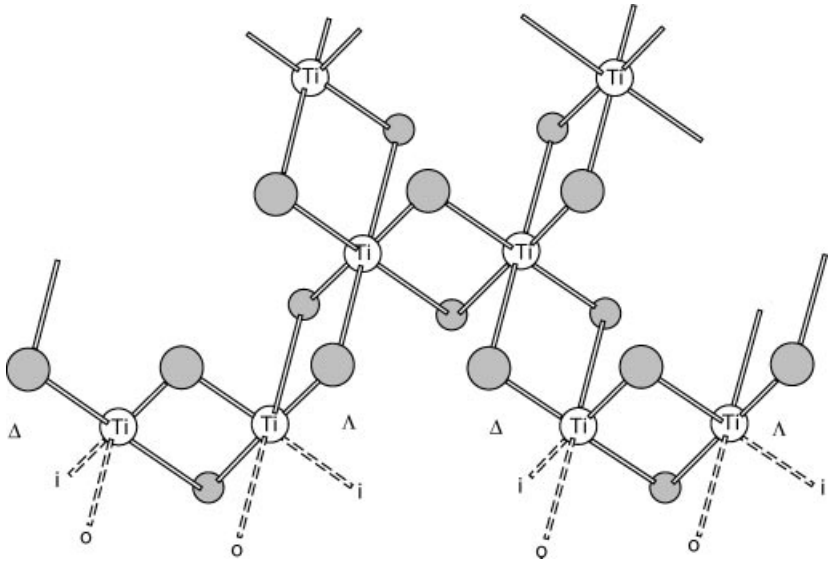

Fig. 16. Inward and outward positions available for occupation by the monomer and polymer chain.

insertion of the subsequent unit in such a way as to prevent a monomer molecule with the same configuration of the previous molecule from entering (243,244). Recall that syndiotactic polymerization from Ziegler–Natta vanadium catalysts differs from this isotactic polymerization monomer insertion. For the vanadium syndiotactic catalysts secondary or 2,1-insertion is operative (233,234). More recently developed homogeneous syndiotactic catalysts follow 1,2-insertion.

Summarizing, isotactic and syndiotactic propagation highlights the catalyst site as the entity controlling stereoregularity for iPP and the last monomer unit of growing chain for syndiotactic propagation with vanadium catalysts. The monomer insertion type is primary (1,2) for isotactic and secondary (2,1) for this latter syndiotactic catalyst.

Electron Donors

There are two classifications of electron donors, internal and external. Electron donors are thus named for their ability to act as Lewis bases and donate electrons to Lewis acid sites. For the $TiCl_3$ type catalyst, the electron donors are traditionally referred to as just donors and are generally amines, esters, ethers, alcohols, etc. Their roles range from modifying the catalyst site and structure of the $TiCl_3$ substrate to complexing with the alkyl aluminum either during catalyst preparation or catalyst activation.

For $MgCl_2$-supported catalysts (the third- and fourth-generation types; see Table 9 the electron donors are classified as internal and external based on their sequence of addition during catalyst preparation or during activation, respectively. For the preparation of the $MgCl_2$-supported catalyst an electron donor is added

during the process of adding the $TiCl_4$ (titanation of the support) to the activated $MgCl_2$-support; this is referred to as the *internal donor*. At the stage of activation of the $MgCl_2$-supported catalyst, another donor is added during the addition of the alkyl aluminum; this donor is referred to as the *external donor*. For the third-generation $MgCl_2$-supported catalyst, the internal donors are usually phthalates and the external donors are alkyl alkoxy silanes. For the fifth-generation type catalysts, the internal donors are diethers and the external donor (alkyl alkoxy silane) may or may not be used. In most cases electron donors are used to increase the activity and stereospecificity of the catalyst system.

Donors work in a variety of ways and the roles of both internal and external donors as they relate to the $MgCl_2$-supported catalysts will be discussed in this section. As mentioned previously, $MgCl_2$ can be activated through mechanical or chemical means. The process of activating magnesium chloride through mechanical means can be achieved by ball milling. This process usually involves co-milling the magnesium chloride with a Lewis base (233). The preparation of the catalyst is followed by treatment of the activated magnesium chloride with $TiCl_4$ and heat. The subsequent treatment of the $MgCl_2$/internal donor support with $TiCl_4$ usually removes some to the internal donor. In other cases the activated $MgCl_2$-support can be treated with $TiCl_4$ and the Lewis base at the same time, and then given a heat treatment. The internal donor helps structurally stabilize the activated magnesium chloride, prepare sites for the $TiCl_4$, and possibly block certain sites on the $MgCl_2$ surface, thus making them unavailable for titanium chloride.

Whereas third-generation Ziegler–Natta catalysts use an ester (ethyl benzoate, EB) as internal donors and another ester as the external donor (methyl *para*-toluate, MPT), the fourth-generation catalysts use a phthalate (usually di-iso-butylphthalate, DIBP) as the internal donor and an alkyl alkoxy silane (eg phenyl triethoxy silane, PES) as an external donor (233). In both cases the internal and external donors play similar roles. The internal donors stabilize the $MgCl_2$ support and set up positions for the $TiCl_4$ complex. The purpose of employing an external donor in both the third- and fourth-generation catalyst systems is that without them, the stereospecificity of the catalyst would be very poor for the polymerization of propylene. This is due to the fact that activation of the catalyst with the alkyl aluminum extracts a portion of the internal donor out of the catalyst. The external donor is added during the activation of the catalyst for the purpose of occupying the site left vacant by the extracted internal donor (233).

From the discovery of the high yield $MgCl_2$-supported catalysts it was apparent that the presence of both an internal and external donor was a necessary condition for a highly active, highly stereospecific catalyst. Soon after, it was learned that an interrelationship existed between the two donors and, furthermore, specific donor pairs gave optimum results. However, with the advent of the fifth-generation catalysts, those employing diethers, there was no need for the addition of an external silane donor (234). These catalysts, $MgCl_2/TiCl_4$/diether, did not lose the internal donor during activation with the alkyl aluminum and consequently maintained relatively good stereocontrol and excellent activities (2 to 3 times that of the conventional $MgCl_2$-supported/phthalate catalysts) (245,246) (see Table 9). Interestingly enough, these diether donors can also be used as external donors in the more traditional $MgCl_2$-supported/phthalate/$TiCl_4$ catalyst systems and they produce the same type of homopolymer. This supports the theory that there is a phthalate/external donor exchange during activation where

the external donor (diether) occupies the site left vacant by the phthalate, very similar to the phthalate/alkoxy silane exchange. In general the following model best describes the interactions between the internal and external donors with the catalyst and activator (246,247):

(1)

(2)

(3)

(4)

(5)

As previously mentioned, the alkyl activator will extract internal donor from the catalyst; therefore equilibrium 1 is always present even in the absence of an external donor. Depending upon the location of the titanium site on the magnesium chloride support, the free site (Cat-□) could be isospecific or aspecific. Equilibrium 2 is also present because of the propensity of the external donor and AlR_3 to form acid/base adducts. These $ED{\cdot}AlR_3$ adducts may also form exchange products (248). In fact, these exchange products are important because they reduce the concentration of free external donor present in the system, which also acts as a poison. In the presence of excess aluminum, there should be very little free external donor present in the system; therefore equilibrium 3, (the interaction of catalyst with free external donor) can be neglected. For the external donor to interact with the free titanium site there are two possibilities—through the $ED{\cdot}AlR_3$ complex (equilibrium 4) and through the $ED{\cdot}AlR_3$ complex initially as a carrier for the ED (equilibrium 5). In equilibrium 5, the $ED{\cdot}AlR_3$ complex releases the ED to the vacant titanium site. Experimental results indicate equilibrium 5 as the most likely case. The alkyl aluminum activates the titanium and removes the internal donor but does not participate in the actual stereochemical regulation of the polymerization of propylene (246).

To recap, there are two types of donors, internal and external. For the third-generation catalysts the internal/external pair is an ester/ester pair, while for the fourth-generation it is the phthalate/alkoxy silane pair. The fifth-generation Ziegler–Natta catalysts are comprised of an internal donor, which is a diether compound and may be used with or without the additional external donor (see Table 9).

There has been a large effort towards elucidating the roles of the external donor in the polymerization of propylene. Some of this work has centered on the

structural considerations of the external donor. Since the $MgCl_2/TiCl_4$/phthalate–alkoxy silane/AlR_3 catalyst system is the most widely used commercial catalyst system for polymerization of propylene, the focus in the next section will be on the alkoxy silane as the external donor.

Structural Considerations of Electron Donors. The most effective alkoxy silanes used in the polymerization of propylene give the greatest activity along with the highest selectivity. These types of silanes are of the general formula $R^1R^2Si(OR)_2$ and $R^1Si(OR)_3$, with R = methoxy or ethoxy (any larger alkoxy group is ineffective). Early on, $PhSi(OEt)_3$ was used; however, the more effective silanes for catalyst performance are those that contain methoxy groups (R = OMe). Interestingly enough, silanes with only one alkoxy group were poor performers, producing polypropylene with low isotacticity. The best activity/selectivity balance was found for silanes having two methoxy groups and two alkyl groups (R^1 and R^2) that are relatively large—in other words, sterically bulky. The importance of steric volume was investigated by Okano and co-workers (249). They correlated silane molecular volume and electron density (calculated by molecular modeling) with polymerization performance (activity) and stereocontrol (isotactic index). In their study they found a straight-line correlation with silane volume and isotacticity. Both Okano's group and Härkönen (250) found a decrease in atactic polymer formation with an increase in electron density.

In addition to affecting polymer stereoregularity and catalyst activity, silane donors influence other aspects of propylene polymerization. It was also found that external silane donors influenced molecular weight of the polymer via the use of hydrogen as a chain-transfer agent. When using hydrogen to decrease the molecular weight of the polymer, there was also an increase in activity when using an external alkoxy silane with the $MgCl_2/TiCl_4$/phthalate ester catalyst system (251–254). While hydrogen is used as a molecular weight control agent, this level of control varies from external donor to external donor. In some cases, under the same hydrogen charge, two different donors will give polypropylene with two very different molecular weights (255). These differences between donors in molecular weight control are not unlike the differences observed in stereocontrol. Some donors are better at stereocontrol than others. The general observation is that donors with good stereocontrol or high selectivity (usually those containing bulky hydrocarbon groups) are usually poor at effectively using hydrogen to lower the molecular weight of the polymer. Donors with poor regio- or stereocontrol exhibit good hydrogen response. Chadwick and co-workers have explained this phenomenon by the process of chain transfer after a regioirregular insertion of propylene (256). With a 2,1-insertion it is harder for the next propylene unit to insert into the $Ti{-}CH(CH_3)CH_2$–polymer bond; however, there is a probability of hydrogen inserting to affect a chain transfer. Therefore those donors with low regio-control permit more 2,1-insertions, thus making chain transfer with hydrogen easier. Donors with good regio- control make far fewer 2,1-insertions, thus denying an easy path and an opportunity towards chain transfer with hydrogen.

Molecular Weight and Molecular Weight Distribution Effects of Electron Donors. The production of broad molecular weight distributed polypropylene is a function of the multiplicity of active centers, which differ in stereo- and regiospecificity, and the propagation rate. Lewis bases in general, and external alkoxy silane donors in particular can influence the molecular weight

distribution of polypropylene by associating with these multiple active centers (245,257,258). The regio- and stereoselectivity of the external donors affects the molecular weight distribution of the polymer indirectly. Normally the atactic fraction of polypropylene has a lower molecular weight. This is in part due to regioirregular insertions of the monomer, which in turn leads to the easier pathway of hydrogen complexation and subsequent chain transfer (259). It has been shown that the different fractions of homopolypropylene separated by temperature rising elution fractionation (TREF) not only differ in microtacticity but also by molecular weight (245). For the $MgCl_2/TiCl_4$/diether based catalyst, Chadwick and co-workers found that the higher temperature eluting fractions also had higher molecular weights. Not unexpectedly, each fraction from TREF exhibited a narrow molecular weight distribution (259).

Microtacticity Considerations. In the early days of Ziegler–Natta polymerization of propylene, two concerns were activity of the catalyst and the stereospecificity of the polymer. Stereospecificity or stereoregularity of the polymer was measured by the amount of insolubles produced versus the amount of solubles. However, another important feature affecting the performance of polypropylene is the microtacticity of the polymer chain. Nowadays, with the aid of TREF and ^{13}C NMR spectroscopy, the overall stereospecificity of polypropylene can be further defined by observing stereoirregular and regioirregular insertions. The type and quantity of these disruptions in the chain lead to differences in the physical properties and processing performances.

Chadwick and co-workers demonstrated that the quantities of the three major fractions derived from TREF vary with different donors (256). The fraction of polymer that elutes from 26 to 95°C, normally referred to as the *stereoblock fraction*, can vary from as little as 4% up to 21% by weight of the total polypropylene sample (260). The differences in homopolymer made with two different donors can be seen by looking at the *mmmm* pentads, via ^{13}C NMR spectroscopy, of the TREF fraction eluting from 96 to 125°C.

In summary, donors, both internal and external (alkoxy silanes and diethers), affect catalyst performance and polypropylene properties in the following ways:

(1) The internal donors restrict the placement of titanium on the (110) face of $MgCl_2$.
(2) The internal donors shift the equilibrium between the aspecific monomeric species ($TiCl_3$) to the stereospecific dimeric species (Ti_2Cl_6) on the (100) face of the $MgCl_2$.
(3) The external donors transform nonstereospecific sites into isospecific sites by blocking open coordination sites near the titanium active centers.
(4) External donors control the path of the incoming monomer to varying degrees:
    a. Little control produces stereo- and regioirregularities that result in microtacticity changes; this in turn affects crystallinity and thus the solubles levels.
    b. Lack of monomer insertion control also affects regioirregular insertions (2,1-insertions), which leads to chain transfer by hydrogen and lower molecular weight.

Metallocenes

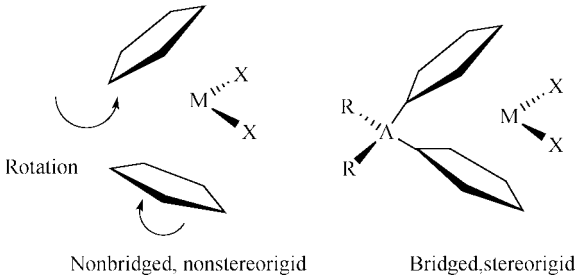
Metallocene catalysts for the polymerizations of olefins have been known since early 1957 when Natta and co-workers first reacted triethyl aluminum ($AlEt_3$) and bis(cyclopentadienyl) titanium dichloride $(\eta^5\text{-}C_5H_5)_2TiCl_2$ to form a complex that polymerized ethylene. The structure of this complex was described and the polymerization results reported. With ethylene they reported to have made 7 g of crystalline polyethylene in about 8 h at 95°C with 40 atm ethylene pressure in *n*-heptane. Later in the same year, Breslow and co-workers repeated Natta's experiments. They found that the blue complex described by Natta was a somewhat poor catalyst (in agreement with Natta's findings), but discovered that small amounts of oxygen in the ethylene boosted polymerization activity. When compared to the heterogeneous Ziegler–Natta catalyst system, these metallocene catalysts were poor with respect to polymerization activity. They were used essentially for mechanistic studies because of their simplicity and ease of structure elucidation.

In 1975 Kaminsky found that a slight amount of water added to a mixture of biscyclopentadienyl titanium dimethyl and trimethyl aluminum rapidly polymerized ethylene. Eventually it was determined that the addition of water produced methylaluminoxane (MAO), which was responsible for the boost in activity (261). Although these Cp_2MX_2/MAO catalyst systems rapidly polymerized ethylene and copolymerized other monomers with ethylene, they were less effective for the polymerization of propylene. There were several critical shortcomings with these early metallocene catalysts toward the polymerization of propylene: low activity, poor stereospecificity, and low molecular weight polypropylene production.

Because these metallocene catalysts are discrete, single molecules, their structures can easily be determined by X-ray crystallography. This allows the catalyst chemist to begin the process of relating the structure of the metallocene catalyst to polymer properties (molecular weight, stereoregularity, stereospecificity, etc) and polymerization activity. This ability to relate catalyst structure to polymer properties allows the process of elucidating polymerization mechanisms and designing catalysts to tailor make polymers and copolymers. This is a big advantage over the traditional Ziegler–Natta catalysts, which contain multiple sites (see METALLOCENES; SINGLE-SITE CATALYSTS).

General Description of Structures. A brief description of metallocene catalyst structures is necessary before going any further in discussions concerning these systems. In their most basic form these metallocenes consist of a Group IV metal (M= Ti, Zr, Hf), two π-bonded cyclopentadienyl rings, and two sigma-bonded groups (these rings are also referred to as carbocyclic π-ligands while all the groups attached to the metal are generally referred to as ligands). Because of the nature of the π-bonding between the metal atom and the carbocyclic π-ligands, there is free rotation of these ring groups about their metal-to-ring centroid axes. This free rotation makes these metallocenes nonstereorigid and produces atactic polypropylene.

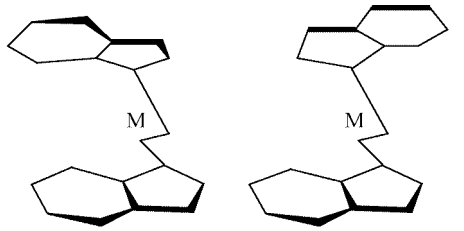
A bridged metallocene contains a linking unit (usually CH_2, $-CH_2CH_2-$, or SiR_2) between the two carbocyclic ligands. These bridged metallocenes are stereorigid, but will not necessarily produce stereospecific polypropylene.



Nonbridged, nonstereorigid Bridged,stereorigid

Furthermore, these bridged metallocenes can become more complicated structurally with more substitutions on the carbocyclic π-ligands. In fact, the more complicated bridged metallocenes are of commercial interest because they provide for the production of isotactic and syndiotactic forms of polypropylene at high molecular weights. Because of the carbocyclic π-ligand's complexity, catalyst stereochemistry will be addressed in the next few paragraphs.

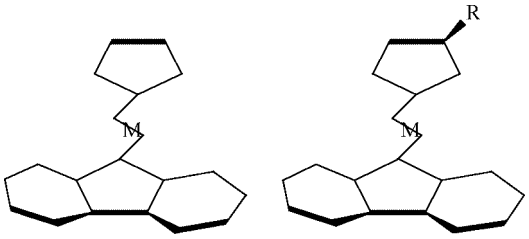
Bridged metallocenes can be further classified based on their stereochemistry. Using an ethylene-bridged bis-indenyl metallocene ($CH_2CH_2[Ind]_2MX_2$) as an example, one can follow the spatial relationships between the ligands and their effects on monomer insertion mechanisms and polymer properties. The $CH_2CH_2[Ind]_2MX_2$ metallocene can exist in two forms, *mesomeric* and *racemic* (*meso* and *rac*). The *meso*-$CH_2CH_2[Ind]_2MX_2$ catalyst has a mirror plane and is nonstereospecific in the polymerization of propylene; it is designated as C_s-symmetric. The *rac*-$CH_2CH_2[Ind]_2MX_2$ catalyst has a nonsuperimposable mirror image and, to a certain degree, each enantiomer is a stereospecific catalyst site; it is labeled as C_2-symmetric.



meso-$CH_2CH_2[Ind]MX_2$ C_s-symmetric *rac*-$CH_2CH_2[Ind]MX_2$ C_2-symmetric

Finally, two other structural types of metallocenes need to be mentioned. One type consists of carbocyclic π-ligands, which are not identical but each possessing a plane of symmetry (orthogonal to the ring plane). These types of metallocenes are labeled as C_s-symmetric. The other type of metallocene contains two nonidentical carbocyclic ligands, one symmetrical and one asymmetrical. These types of

metallocenes are labeled as C_1-symmetric.



C_s-symmetric C_1-symmetric

Implications of Metallocene Catalyst Structure on Polypropylene Structure. The previous section gave a brief description of the various types of metallocenes. In this section a general relationship between metallocene structure and type of polypropylene produced will be made. It is important to note that these are generalizations. While the stereochemistry of the metallocene plays an important role in mechanism of monomer insertion and ultimately the stereo- and regiospecificity of the polymer, the substituents and location of the substituents on the carbocyclic π-ligands also effect the microstructure of the polymer.

In general, metallocenes that are either bridged or nonbridged *and* posses C_{2v} symmetry (eg, Cp_2TiCl_2 or $Me_2Si[fluorenyl]_2ZrCl_2$) will produce atactic polypropylene. This is because these types of catalysts have low stereocontrol. The only stereocontrol mechanism operating in these systems is chain end control from the polymer. Consequently the polymer is predominately atactic at normal polymerization temperatures. In fact, these metallocenes are the best source for producing high molecular weight, high atactic polypropylene (very low to almost zero crystalline polymer).

To produce highly isotactic polypropylene the metallocene catalyst should be a bridged chiral metallocene (preferably containing zirconium) having C_2 symmetry with some alkyl substitution in the ring (262). However, with the right substitution others have shown that a C_1-symmetric metallocene can also produce highly isotactic polypropylene with high T_m (161°C) (263).

Early metallocenes were less than desirable polypropylene catalysts because they produced polymer with low stereocontrol and low molecular weight. Recently there has been much progress in making high molecular weight, high stereo- and regioregular polypropylene with relatively high melting points. In general, all these metallocenes are structurally complicated and the reader should refer to references cited.

Advantages of Metallocenes. Because they are discreet molecules, one of the important features of metallocenes is that their structures are easily deduced. This allows almost direct correlation between the catalyst's structure and the microstructure of the polymer produced. This fact allows for a rather rapid evolution of focused catalyst design to tailor polymer properties to specific needs. For example, one of the early successful metallocenes used in the isospecific polymerization of propylene was $[Et(Ind)_2]ZrCl_2$. By structurally characterizing this compound and making some changes in the bridging group, a new metallocene was prepared $[Me_2Si(Ind)_2ZrCl_2]$ which produced a higher molecular

Table 10. Evolution of the Carbocyclic π-ligands and the Effect on Polypropylene Properties[a]

Metallocene	kg PP/mmol Zr·hr	MW, g/mol	Melting point, °C	Isotacticity,% mmmm pentads
$[Et(Ind)_2]ZrCl_2$	188	24,000	132	78.5
$[MeSi_2(Ind)_2]ZrCl_2$	190	36,000	137	81.7
$[MeSi_2(2\text{-}Me\text{-}4,6\text{-}iPr_2(Ind)_2]ZrCl_2$	245	213,000	150	88.6
$[MeSi_2(2\text{-}Me\text{-}4\text{-}PhInd)_2]ZrCl_2$	755	729,000	157	95.2

[a]Bulk polymerization in 1 L of liquid propylene at 70°C, Al/Zr = 15,000 using MAO as activator.

weight polypropylene with high isotacticity and, consequently, a higher melting point. The evolution of the carbocyclic ligand and subsequent improvement in isotactic polypropylene properties can be seen in Table 10.

From the standpoint of monomer insertion control, judicious choice of groups and location on the carbocyclic π-ligand produce polypropylene with higher isotacticity, greater molecular weight, and higher melting points.

Polymer Property Advantages. Metallocene catalysts, through variation of catalyst structure, can produce a broad spectrum of polymer microstructures leading to a very wide property envelope which is potentially accessible. Because of the defined molecular structure of the catalyst, once a catalyst is chosen for a given application, the properties can be precisely controlled.

Some of the property advantages and types of polypropylene and copolymers of propylene that can be realized with metallocenes are as follows:

(1) Highly tunable tacticity microstructure (isotactic, syndiotactic, atactic, isoblock/stereoblock, regiospecific microstructures)
(2) Narrow molecular weight distribution
(3) Absence of oligomers and extractables
(4) Improved melting point/extractable balance
(5) Narrow interchain composition distribution in copolymers
(6) Polypropylene with vinyl end groups
(7) Polymerization of expanded comonomer types (including dienes and cycloolefins)

Activators/Cocatalysts. As in conventional Ziegler–Natta catalysts, metallocene catalysts must be activated before polymerization of olefins can proceed. Methyl aluminoxane (MAO) has been the activator of choice since its discovery by Kaminsky in 1975 (261). MAO is prepared by the controlled hydrolysis of trimethyl aluminum. The product is a relatively difficult species to characterize. It consists of oligomers, both linear and cyclic. The composition of the numerous oligomer structures varies depending upon the preparation methods, concentration of the reactants, temperature, and time. The two simplified linear and cyclic oligomeric alumoxane structures (with a general alleyl group) are shown in Figure 17.

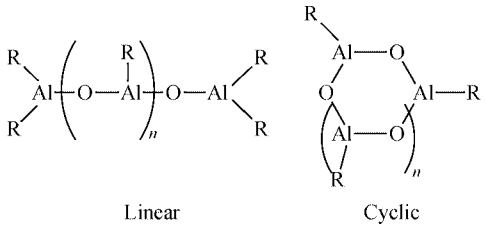


Fig. 17. Aluminoxane oligomer structures, linear and cyclic.

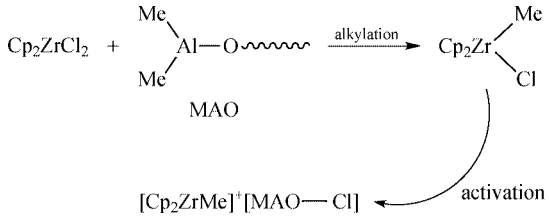

Fig. 18. Aluminoxane activating Cp_2ZrCl_2.

The role of MAO in the activation of a metallocene is essentially the same as in the traditional Ziegler–Natta catalyst that is to alkylate the halogenated metal center. The MAO forms a cationic complex with the metallocene and a dispersed anionic charge on the aluminoxane. An excess of MAO will lead to dialkylation of the metallocene metal center. One of the main disadvantages of aluminoxane activators is the high aluminum concentration level needed; typical AlZr ratios are over 1000:1. The basic mechanism for the alkylation and activation of a Cp_2ZrCl_2 is shown in Figure 18.

Other cocatalysts can be used to activate single-site catalysts. Some other typical activators, in addition to other alumoxanes, include tetraphenylborate $[(C_6H_5)_4B^-]$, tetra(perfluorophenyl)borate $[(C_6F_5)_4B^-]$, and carborane $(C_2B_9H_{12}^-)$.

Supportation of Single-Site Catalysts. Without the ability to support single-site catalysts, the commercial use of these systems would be eliminated in the numerous bulk and gas-phase polymerization facilities used today. In essence, they would be restricted to a limited number of slurry processes. The strategy of supporting a single-site catalyst for an industrial process is much the same as that for the heterogeneous Ziegler–Natta catalysts. The target is a morphologically uniform catalyst particle that is easy to feed into a slurry, bulk-monomer, or gas-phase process, which produces a polymer that is roughly the same shape as the catalyst particle but that is 20 to 200 times in volume. In addition the catalyst particle should be robust and not easily fractured during polymerization. Fracturing of the polymer particle during polymerization produces fines that foul the process.

There are a number of materials suitable for supporting single-site or metallocene catalysts. These are inorganic oxides, metal halides, and polymers. Among the inorganic oxides, silica or silica gels have been the supports most widely used because of their wide range of particle sizes, porosities, etc. More about

silica supports will be discussed later. Other types of supports, which will not be discussed in detail, are the other types of inorganic oxides such as aluminas (zeolites type materials), MgO, etc. However, it should be noted that zeolites have shown some promise as supports because of their ordered structures and precisely known pore sizes. Other support materials are polymers which include polystyrene, derivatized polystyrenes, polysiloxanes, and various polyolefins (porous types of polyethylene and polypropylene) and copolymers. The following discussions will be predominately focused on silica gel since it is the most widely used support for metallocenes.

There are essentially three methods in which to make a supported-metallocene catalyst:

(1) Supporting the metallocene, then treating with an activator
(2) Supporting the activator, then treating with the metallocene
(3) Preparing the metallocene/activator complex in solution, then treating the support with the complex

Supporting the Metallocene, then Treating with the Activator. Because of their method of preparation, silicas have a high concentration of surface hydroxyl groups and complexed water. Normally both hydroxyl groups and water will promote decomposition of a metallocene or metallocene/activator complex. Therefore it is necessary to remove the water either by thermal or chemical dehydration. Full dehydration of silica can occur at 150°C. At this point the silica gel will have a surface that is fully hydroxylated. Even these hydroxyl groups can decompose some types of metallocenes. In most cases the silica gel can be further dehydrated at 400°C (see Fig. 19).

Much work has been reported in the literature on the preparation of silica at various temperatures and under various conditions. Needless to say, the calcination conditions play a large part in preparing the silica support for the metallocene.

As far as the actual mechanism of how the metallocene is supported, various theories abound. However, the metallocene can be "connected" in two ways to

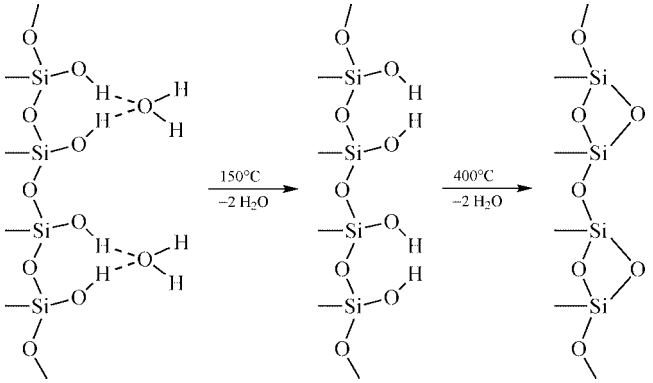

Fig. 19. The steps to the dehydration of silica gel.

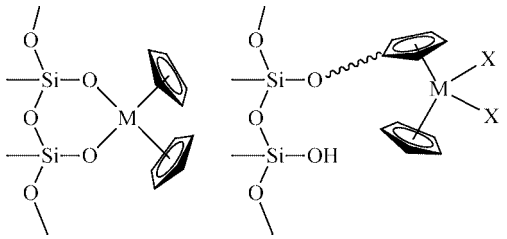

Fig. 20. Methods of attachment of a metallocene to silica.

the support: (*1*) through bonding to the metal and the oxygen of the Si—O to create the Si—O—Metal complex, or (*2*) by connection of the metallocene to the support via a linkage through the carbocyclic ligand moiety (Fig. 20). Tethering the metallocene to the support through the ring system is the method of choice, but requires preparing specialized carbocyclic ligands, which have spacers with groups that are able to react with residual OH groups on the silica. In this case it is necessary to have some remaining hydroxyl groups on the silica.

Supporting the Activator, then treating with the Metallocene. Supporting the alumoxane on the silica support first and then treating with the metallocene was one of the first methods used for supporting metallocenes. Many methods of silica treatment, prior to contacting with the MAO, have been reported. In addition, treatment of the silica gel with solutions of MAO at various temperatures and pressures, heating with dry MAO, etc, have been reported. All of these methods have advantages and disadvantages depending on the metallocene, monomers polymerized, and polymerization conditions used.

Supporting the Metallocene/Activator Complex. The last method to discuss is the supportation of the Metallocene/MAO complex. In this method the metallocene and the MAO are reacted in solution to form a complex. The silica is then treated with the metallocene/MAO solution. The solvent is then evaporated from the silica support to leave a dry, free-flowing catalyst. In some cases the support is held under low pressure while treated with the metallocene/MAO solution to assist in the impregnation of the catalyst complex into the pores of the silica. Other methods have been developed which improve the impregnation of the metallocene/MAO complex into the interstitial pores of the support. Concentrating the catalytic complex into the interior of the support rather than on the surface improves flowability of the supported catalyst system, decreases fouling, and improves the final polymer morphology. While much is known about the structure of the single-site catalyst and the properties of the resulting polymers, much of this changes upon supportation.

Commercialization Aspects of Metallocene/Single-Site Catalysts. While metallocenes have been known to polymerize olefins since the 1950s, only in the last 10 years have they been introduced commercially. Exxon introduced its first generation metallocene in 1989 for the limited production of polyethylene. This was a homogeneous catalyst used in solution. Other companies have followed with their own metallocene catalyst technologies, which are supported and are used in solution, gas phase, and supercondensed phases and processes.

Table 11. Metallocene/Single–Site Technologies

Company	Technology Name	Type of Polymer
Exxon/Mobil	Univation (Exxpol/Unipol)	iPP, impact co-PP (commercial)
Basell	Metocene	iPP, impact co-PP (in development)
Dow	INSPiRE	iPP (in development)
Borealis	Borecene	iPP, impact co-PP (commercial)
JPC/Mitsubishi	Proprietary use[a]	iPP, impact co-PP (in development)
TotalFina	Proprietary use[a]	iPP (commercial)
Mitsui	Proprietary use[a]	sPP (in development)
Chisso	Proprietary use[a]	iPP, sPP (in development)
BP Amoco	Proprietary use[a]	EPP (in development)

[a]Implies that technology is not commercially available, but the polymer may be commercially available.

The nonsupported metallocenes are used only in solution processes. The strategies for market penetration run from targeting commodities to specialty grades.

In the infancy of metallocene catalysis, many companies spent considerable research dollars on metallocene preparations and understanding the structure of the metallocene in relation to the polymer properties. In addition to these research dollars, large expenditures were also made to establish strong patent positions. In an effort to recoup these expenses for this budding technology, to be competitive, and to fill voids in their technology portfolios, many have established cooperative alliances or have consolidated.

At the time of this writing a number of metallocene/single-site catalyst technologies are available with which to produce polypropylene (see Table 11). Metallocene-based polypropylenes are commercially available and even catalyst licenses are available (264).

Manufacturing Processes

The first commercial processes for the production of polypropylene were batch polymerization processes using $TiCl_3$ catalysts activated by $Al(C_2H_5)_2Cl$ in a hydrocarbon medium. The hydrocarbon, usually hexane or kerosene, maintained the isotactic polypropylene in suspension and dissolved the undesirable atactic fraction. After polymerization, the suspension is treated with alcohol to deactivate and solubilize the catalyst residues, and filtered to separate the residues and atactic fraction from the desirable polymer, which is then dried. The alcohol and diluent are recovered by multiple distillations, and the atactic fraction is sold as a by-product. As the demand for polypropylene increased, these batch polymerization processes were rapidly replaced by continuous ones, such as the Hercules process shown in Figure 21. In this process, typical of those used throughout the 1960s and 1970s, a suspension of $TiCl_3$ catalyst in $Al(C_2H_5)_2Cl$ and kerosene diluent is continuously fed to the first of a series of continuous stirred overflow reactors. Monomer is fed to the first reactors and allowed to react out in the later ones, obviating the requirement for monomer recycle. Typical polymerization temperatures were in the range of 55–70°C and maximum pressures as high as 0.5 MPa (75 psig).

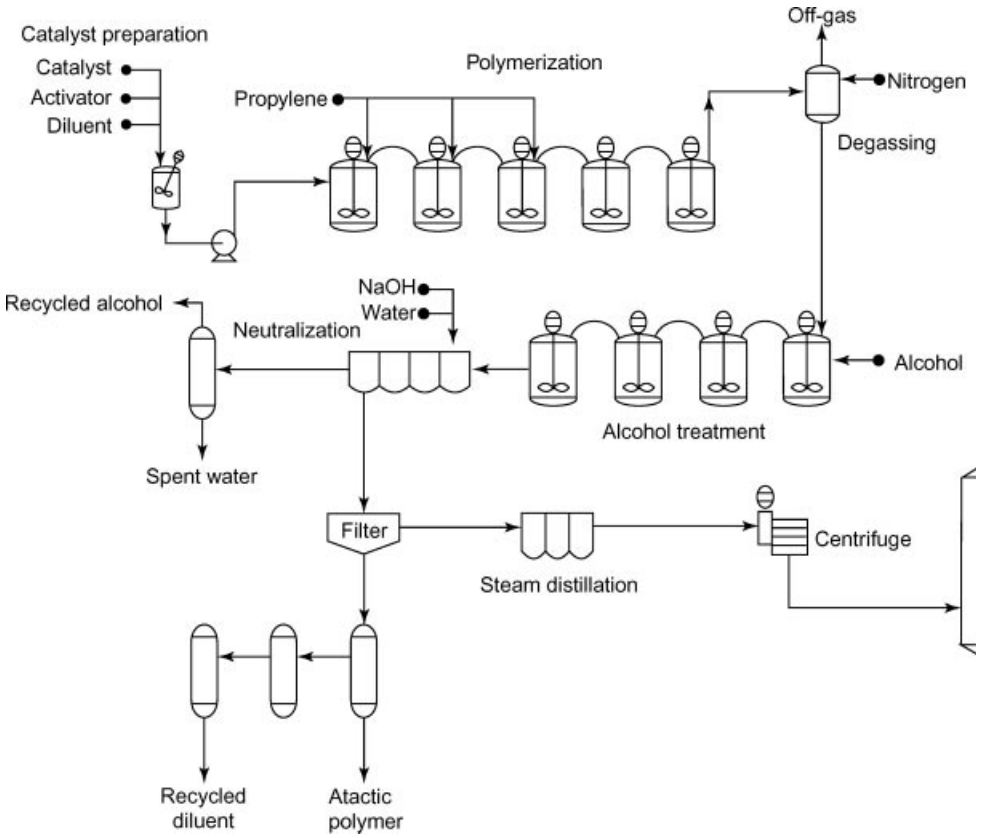

Fig. 21. Hercules slurry process for polypropylene.

Other similar processes, such as Montedison's, operated at pressures as high as 1.3 MPa (200 psig) with monomer recycle (265). Hydrogen is added to the reactors as required to achieve the desired polymer molecular weight (266). Following polymerization, the slurry is contacted with isopropyl alcohol, then aqueous caustic to decompose and neutralize catalyst residues. The aqueous phase containing the alcohol and catalyst residues is separated from hydrocarbon, polymer slurry phase. The suspended isotactic polymer is separated from the diluent containing the atactic polymer by continuous filtration or centrifugation, then dried. The alcohol and kerosene are each purified by a series of distillations, then recycled. Atactic polymer is dried using a thin-film evaporator and sold as by-product. The aqueous stream containing catalyst residues is treated prior to disposal of wastewater and inorganic solids. The products available from this technology were limited to homopolymers with relatively high molecular weights (MFR$<$ 15 dg/min), random copolymers containing low amounts of ethylene, and impact-resistant copolymers of high molecular weight and low rubber content. Excessive production of soluble polymer causing fouling of heat-transfer surfaces, was the primary cause of this limitation, more so than the loss of monomer to the production of less valuable by products. This limitation, and the high energy cost of recycling

diluent and alcohol, led to the development of processes that eliminated the need for diluent.

Polymerization in liquid monomer was pioneered by Rexall Drug and Chemical and Phillips Petroleum. In the Rexall process, liquid propylene is polymerized in a stirred reactor to form a polymer slurry. This suspension is transferred to a cyclone to separate the polymer from gaseous monomer under atmospheric pressure. The gaseous monomer is then compressed, condensed and recycled to the polymerizer (267). In the Phillips process, polymerization occurs in loop reactors, increasing the ratio of available heat-transfer surface to reactor volume (268). In both of these processes, high catalyst residues necessitate post-reactor treatment of the polymer.

Gas-phase polymerization of propylene was pioneered by BASF, who developed the Novolen process, using stirred-bed reactors (269). Unreacted monomer is condensed and recycled to the polymerizer, providing effective removal of the heat of reaction. As in the early liquid-phase systems, post-reactor treatment of the polymer is required to remove catalyst residues (270). The high content of atactic polymer in the final product limits its usefulness in many markets.

In the 1970s, Solvay introduced an advanced $TiCl_3$ catalyst with high activity and stereoregularity (271). The level of atactic polymer was sufficiently low so that its removal from the product was not required. When this catalyst was used in liquid monomer processes, residues were sufficiently reduced so that simplified systems for post-reactor treatment were acceptable. Montedison and Mitsui Petrochemical introduced $MgCl_2$-supported high yield catalysts in 1975 (272). Use of these catalyst systems reduced the level of corrosive catalyst residues to the extent that neutralization or removal from the polymer was not required. Stereospecificity, however, was insufficient to eliminate the requirement for removal of the atactic polymer fraction. These catalysts were used in the Montedison high yield slurry process, which does not contain the sections required for alcohol treatment, neutralization, and diluent purification in older slurry processes (265).

Current Processes. Introduction of high yield, high stereoregularity catalysts by Montedison and Mitsui in 1983 enabled the development of processes in which removal of catalyst and atactic polymer is unnecessary. This enabled the widespread use of processes in which monomer is the polymerization medium replacing slurry processes using an inert diluent. Investment and operating costs were dramatically reduced because of the elimination of the sections of the plant required for handling and purifying diluent and alcohol, removing catalyst and separating atactic polymer. Consequently, many companies invested in new plants either increasing capacity or replacing plants using the older, now obsolete processes. Almost all of the plants built in the past 15 years use one of the simplified processes. Moreover, the production capacity of a newer plant using these processes is often many times greater than those of earlier plants. Single line production capacities of 250 kt/y are no longer unusual, and plants with higher production capacities have been announced. The most widely used processes are Spheripol, licensed by Basell; Unipol, licensed by Univation; and Novolen, licensed by Novolen Gmbh.

The Spheripol process consists of one or more loop reactors for production of homopolymer and random copolymer, and one or more fluid bed gas-phase reactors for the production of the rubber phase for impact-resistant copolymers (Fig. 22).

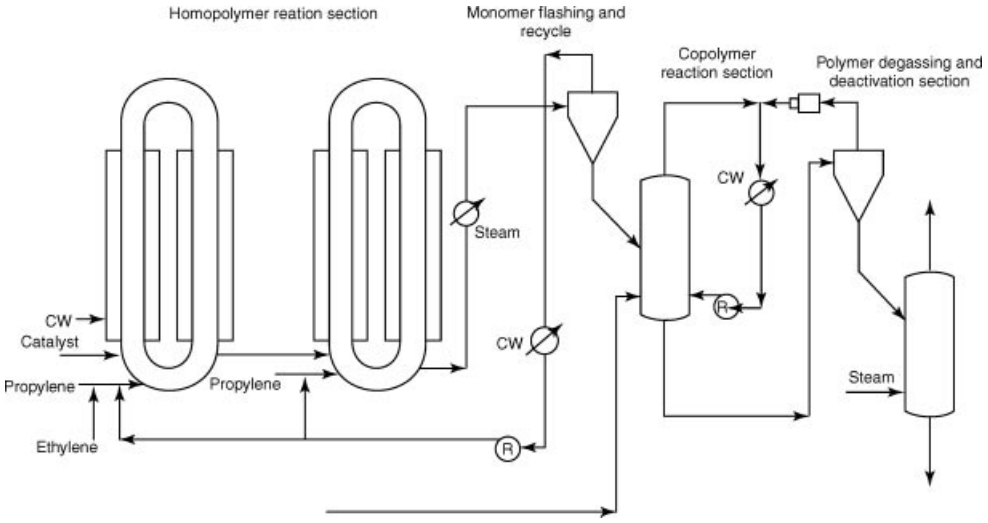

Fig. 22. Spheripol process

When producing impact-resistant copolymers, monomer and catalyst components are fed to the loop reactor for homopolymerization. The use of spherical form catalyst, with a narrow particle size distribution, coupled with high liquid velocities, minimizes reactor fouling maintaining effective heat transfer and enabling specific outputs in excess of 400 kg PP/h·m^3. After polymerization in the loop reactors, the polymer is separated from the liquid monomer by flashing at a pressure sufficient to allow condensation and recycle of the liquid monomer without recompression. The polymer is then transferred to the gas-phase reactors for the production of the rubber phase of impact-resistant copolymers. Ethylene and propylene are fed to the fluid bed reactor to produce ethylene–propylene rubber of the desired composition. Unreacted monomer is recycled and cooled using an external heat exchanger. The polymer is then separated from the unreacted monomer at a pressure slightly above 1 atm, and then contacted with steam for complete removal of residual monomer and termination of polymerization (273).

Liquid monomer is polymerized in continuous stirred tank reactors in a number of processes. The Hypol process, developed by Mitsui Petrochemical, uses a cascaded series of stirred reactors for homopolymerization, followed by fluidized bed gas-phase reactors for copolymerization (274). El Paso (now Huntsman) converted the Rexall liquid monomer process to use high yield catalysts eliminating the sections required for deashing and removal of atactic material (275). Shell (now Basell) developed the LIPP process to produce homopolymers and random copolymers, using their high yield catalysts.

The Unipol PP process developed by Union Carbide (now Dow) and licensed by Univation, uses a large gas phase fluidized bed reactor for the production of homopolymer and random copolymer. A second, smaller fluidized bed reactor is used in series to produce the rubber required for impact copolymers. The heat of reaction is removed by cooling the monomer through an external heat exchanger (Fig. 23). The heat removal capacity of this heat exchanger and, consequently, the

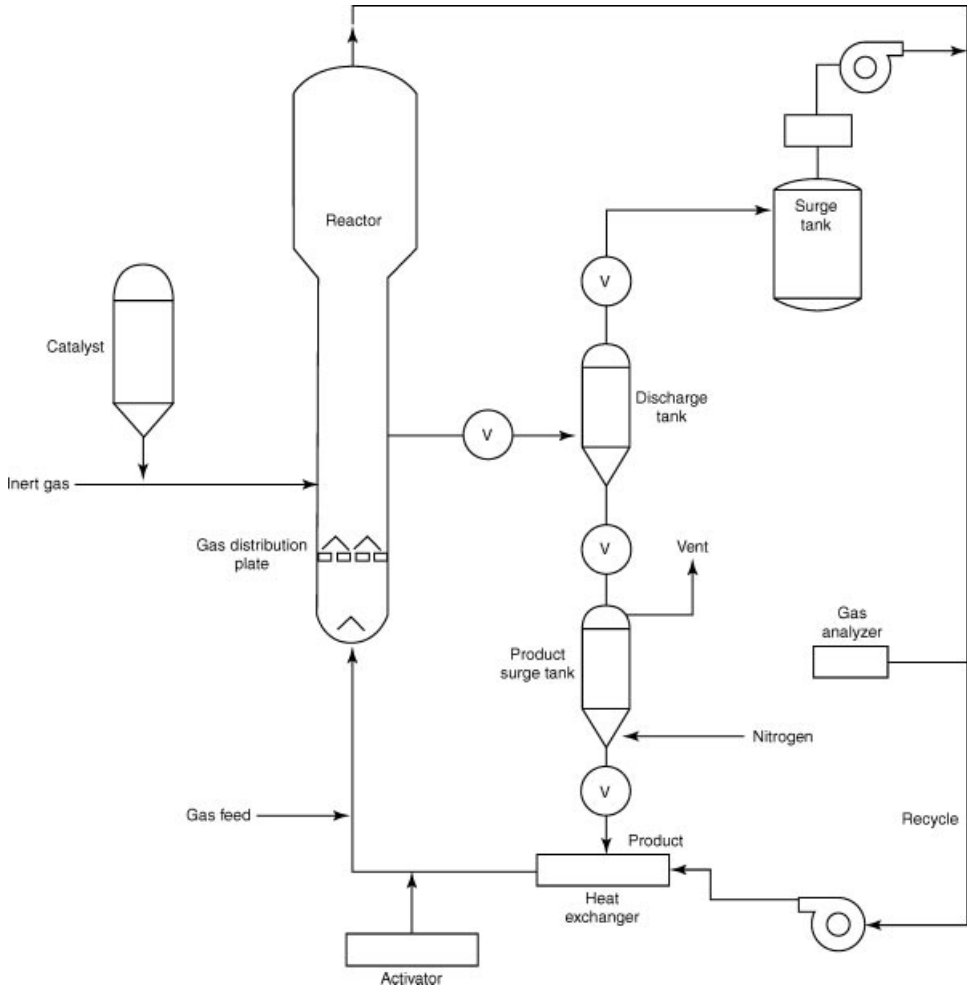

Fig. 23. The Unipol process.

production capacity of the plant is increased by facilitating condensation of hydrocarbon. This "condensing mode" technology has enabled this process to be used in very large single line polymerization plants (patent). Use of high yield catalysts in the Novolen process (Fig. 24), developed by BASF and licensed by Novolen Gmbh, has eliminated the problems associated with the use of first-generation catalysts. These catalysts enable the plants to achieve high capacity and improve product quality by minimizing catalyst residues and atactic polymer. This process uses a single vertical stirred bed reactor for the production of homopolymer and random copolymer and a second, similar reactor for the production of impact copolymers. Amoco (now BP) developed a horizontal stirred bed gas-phase reactor that acts as a series of polymerization stages in a single reactor vessel. This facilitates the production of homopolymers with broad molecular weight distribution. As in other processes, a second reactor can be used in series for the production of impact

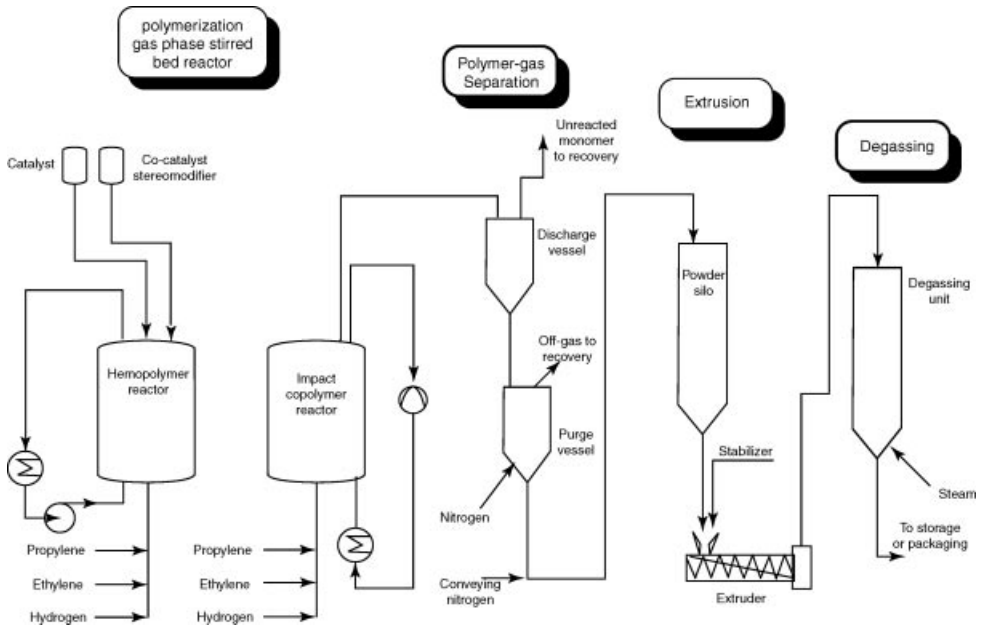

Fig. 24. The Novolen process.

copolymers. Basell produces specialty propylene copolymers in the multistage gas-phase Catalloy process (276).

The Borstar PP process developed by Borealis can operate at temperatures above the critical temperature of the reaction medium. This process uses a loop reactor and gas-phase reactor in series for the production of homopolymer. Additional gas-phase reactors are required for the production of impact copolymers. The first commercial scale plant using this process started in 2000. Basell has announced the development of the Spherizone process using a recirculating gas-phase reactor (Covezzi paper). The reactor contains two zones that can be operated under different conditions, enabling the production of multiphase specialty copolymers in a single reactor. This reactor was first used in a commercial scale plant in 2002.

Processing

PP structure can be tailored for use in most polymer processing technologies. The physical and mechanical properties of PP in the end use product are a function of both the molecular structure and the processing conditions. The most commonly used processes for iPP are discussed in the following.

Injection Molding. In the injection molding (qv) process, molten polymer is injected into a cold mold cavity. During mold filling, the melt is oriented by a combination of shear and elongational flow (277). Crystallization partially freezes in this orientation history. Injection-molded iPP articles are made from homopolymers, random and impact copolymers, and filled polymers. Melt flow rates lower

than 4 dg/min and as high as 100 dg/min in some impact copolymers can be used, depending on the mold geometry, part thickness, and cycle time desired. Processing conditions vary over a wide range because of the differences in polymer types. Since iPP melts exhibit shear-thinning properties, high injection pressures and high shear rates are used to promote the filling of the mold. Higher melt flow (lower molecular weight) polymers provide more uniform flow and low cycle times in parts with thin sections. Lower melt flow (higher molecular weight) polymers are employed when toughness is required, and can be used in parts that have thicker cross sections. Melt temperature varies with the melt-flow rate of the polymer and the mold shape. Higher temperatures reduce the melt viscosity and facilitate mold filling; however, the cycle time is increased. Melt temperatures as low as 200°C can be used with high melt-flow polymers; higher melt temperatures are required with low melt-flow polymers. Mold temperatures typically range from 20 to 50°C. Lower mold temperatures reduce the cycle time, but may produce a rough or low gloss surface. Orientation is an important determinant of properties and related to the skin layer thickness (see MORPHOLOGY). Melt temperature, melt-flow rate (MFR), polydispersity, and proximity to the mold gate influence skin thickness (120,278–286). Lower values result from higher melt temperature and MFR, and lower polydispersity. Regions far from the gate also have lower values. Molds should be designed to minimize localized stresses and ensure mold filling. When nonuniform wall thickness is required, it should decrease gradually in the flow direction. Like all crystalline thermoplastics, iPP is sensitive to failure at notches, and smooth radii are recommended at all sharp angles, corners, or ribs. Mold shrinkage varies with thickness from 1 to 2.5%. Thicker sections shrink more than thinner sections.

Fiber.

Melt Spinning. Melt spinning produces a broad range of iPP fibers, ranging from short staple fiber to continuous filament (CF) or bulked/textured continuous filaments (BCF) (see OLEFIN FIBERS). The tex per filament of the as-spun filaments, where tex is the mass of fiber (g) per 1000 m of length, is typically in the range of 0.14–7.78 tex (1.3–70 dpf). The lower end of this range corresponds to fine filaments of ∼15-μm diameter. Noncircular cross sections can be used to modify fiber appearance.

Melt spinning of iPP typically involves forcing molten polymer through a spinnerette (a collection of small-diameter orifices) and collecting it, typically on a take-up reel, some distance from the spinnerette at a velocity exceeding the orifice velocity. The tension provided by the take-up reel (melt drawing) provides partial orientation which greatly influences the final properties of the fiber. Yarns are collections of individual filaments, and can range from monofilaments to several thousand filaments depending on the process. Spinning speeds can approach 3000 m/min or higher in some cases. The iPP melt expands upon exiting the holes, a phenomenon known as *extrudate die swell* (287). The diameter of the extruded filament just after the die plate can typically increase on the order of 30–100% relative to the spinnerette hole depending on resin structure (melt flow rate, polydispersity). The swelling increases as the size of the die holes is reduced. This factor, and most often more importantly the maximum sustainable spin speed, determines the minimum diameter of melt-spun iPP fibers. During the spinning process, a fluid element experiences an acceleration (increase of velocity), decreasing temperature

due to a high rate of cooling, and decreasing diameter with increasing distance along the spin line (288). Large vertical air-cooling chambers, or chimneys, as high as 15 m can be required to cool the molten filament and allow adequate time for crystallization under the applied extensional force. Short spin processes generally use low spinning speeds to minimize the space required for quenching.

Fiber properties depend on the complex interrelationship of polymer structure (polydispersity, molecular weight, tacticity), processing conditions (melt temperature, melt throughput, spinnerette design, spin speed, cooling rate), and equipment design. Both material and processing variables influence the die swell, extensional melt rheology, maximum spin speed, crystallization/nucleation characteristics along the spin-line, and fiber orientation. Controlled rheology resins with narrow polydispersity are often used to improve the balance of spinning performance and fiber properties. Metallocene iPP resins have been introduced as an alternative technology (289,290). The tenacity (ultimate stress) of individual as-spun filaments is generally in the range of 0.088–0.353 N/tex (1–4 g/den). Break elongation decreases and tenacity increases with increasing spin speed due to increasing orientation. Post-drawing of filaments in the solid state below the polymer melting point, either via in-line continuous or off-line batch processes, further increases the tenacity of the fibers by improving fiber orientation. Drawing is generally carried out at temperatures exceeding 70°C, with draw ratios in the 2–10 range. The drawability is a function of the starting morphology, polymer structure, draw rate, and draw temperature. The ultimate tenacity of perfectly oriented iPP fibers has been estimated to be 1.32 N/tex (15 g/den) (121), though most commercial drawn fibers have tenacities of 0.353–0.794 N/tex (4–9 g/den). A heat setting, or annealing process below the polymer melting point, can minimize fiber shrinkage.

Melt Blowing. The melt-blowing process uses very high melt-flow rate (low molecular weight) iPP, sometimes in excess of 400–1500 dg/min. These melt-flow rates are much higher than for melt-spinning operations. The flow of molten, low viscosity polymer, extruded through a small die is disrupted by high velocity hot air. A large volume of cooling air fed near the die exit quenches the fibers and deposits them on a collecting screen as a mat of entangled fibers. Processing conditions and polymer structure can be varied to alter the filament diameter, characteristics of the collected mat, and undesirable large "shots," or polymer particles. Very fine fibers, less than 5 μm in diameter, can be produced. The fiber entanglement is sufficient to maintain the integrity of the web, and thermal bonding is not necessary. Fabrics produced by this process are very soft because of the small fiber diameter. Because the fibers are not highly oriented or bonded, meltblown fabrics usually have low tensile strength. Meltblown fabrics have improved barrier properties to aqueous liquids relative to spun-bonded fabrics.

Spun Bonded Fabrics. Spun bonded fabrics are produced by depositing extruded, spun filaments onto a collecting belt in a uniform randomized manner, followed by thermal bonding of the filaments. Polymers with melt-flow rates above 20 dg/min and narrow polydispersity improve stability during fiber formation and adequate melt throughput. The fibers are separated during the web-laying process by air jets and the collecting belt is usually perforated to prevent the air stream from deflecting and carrying the fibers in an uncontrolled manner. Thermal bonding, using heated embossing rolls or hot needles, imparts strength to the web

by fusing some of the fibers. This process can be combined with the melt-blowing process to produce soft, multilayer fabrics with good tensile properties. In these multilayer structures the meltblown fabric provides barrier resistance and the spun bonded fabric imparts strength.

Slit and Split Films. Thick industrial-grade yarns are often produced by slitting films, providing a less expensive alternative to direct extrusion. Cast film is slit in the machine direction by parallel rotary knives. The resulting tape can then be cold drawn in an oven below the polymer melting point, in a manner similar to drawn melt spun fibers, to produce the final fiber. Draw ratios of 4–11 are common. Higher draw ratios produce higher tenacity. The width of the slit tapes depends on the spacing between knives and the draw ratio. Knife spacings as low as 1 mm are sometimes used to produce textile fibers, although spacings of 10–35 mm are more common. Tapes produced by slitting a fully drawn film are wider than those oriented after slitting because of the physical limitations on minimum knife spacing. An alternative approach is to directly extrude the tapes prior to drawing. The tapes are annealed to minimize shrinkage. Fibers from split or fibrillated films are formed by the drawing of polypropylene film to the degree that it splits into numerous fiber-like interconnected tapes. In some processes the draw-induced splitting is mechanically augmented by gears, rollers, or gas jets (291).

Film.

Cast Film. The first commercial iPP films were produced by extrusion casting. Polymer is extruded through a slit or a tubular die and quenched by cooling on chill rolls or in a water bath. Cast film is not highly oriented and consequently does not have the stiffness of oriented films. Resins are typical iPP homopolymer or random copolymers. Random copolymers have improved clarity, and somewhat improved impact resistance. Rapid quenching often results in conversion to the mesomorphic form, which can be advantageous for film clarity. This tendency is greater in random copolymers than in homopolymer. High chill roll temperatures can result in hazy films, while chill roll temperatures which are too low (below the dew point of the ambient air) can result in water condensation on the film. Additives such as antiblock and slip agents are often added for improved handling of the film rolls.

Biaxially Oriented Polypropylene. Orientation improves the strength of iPP films. Biaxially oriented polypropylene (BOPP) films have higher strength and stiffness than cast films and consequently can often be used in much thinner gauges. Homopolymers are used almost exclusively to provide maximum stiffness and water-vapor barrier. Oriented films are produced by the tenter frame and tubular blown or double bubble methods. Most of the newly installed capacity has utilized the tenter frame process, taking advantage of the economics of the large, high capacity units available. The trend is to ever increasing line speeds, with 300 m/min not uncommon. In the tenter frame process, iPP is melt extruded through a slot die to form a sheet after quenching onto a cast roll. The cast sheet is heated to a temperature below the melting point, and drawn. In the case of sequential orientation, the softened cast sheet is drawn by a series of rolls to the desired draw ratio in the machine (longitudinal) direction, and subsequently clamped by a series of clips and conveyed into a tenter oven where it is subsequently drawn in the transverse direction to the desired draw ratio by the divergent chain clips. In the bubble process, a tube is extruded, quenched, and radially expanded by

inflation with air to provide transverse orientation. Axial orientation is provided by extension in the machine direction through a series of nip rolls. The tube is then flattened and slit into flat film. Orientation in both processes is provided by stretching below the melting point. The drawing process is strongly correlated to the crystallinity at the draw temperature which is closely related to the stereoregularity of the resin. Generally there is a trade-off between processability and final film mechanical and barrier properties. Heat aging under slight tension at a temperature above the orientation temperature but below the melting point minimizes subsequent shrinkage. Opaque films are produced by introducing microvoids into the film during the orientation by introducing small particles during extrustion. During orientation, microvoids are created as the polymer expands from the inelastic solid. Untreated oriented iPP films are not easily heat sealed. Consequently, lower melting random copolymers and terpolymers are often coextruded with the homopolymer to form a heat sealing layer.

Blow Molding. Low melt flow polymers are used in blow molding (qv) to provide the melt strength required to maintain stability of the parison, ie, a molten, thick-walled tube of melt. High density polyethylene has been more commonly used to form large parts because of its greater stability; however, a number of improved polypropylene grades are suitable for these applications (292). In extrusion blow molding, the extruded parison hangs freely before entering the mold, and low melt temperatures (between 205 and 215°C) are preferred. In injection blow molding, a preform is injection-molded on a steel rod, transferred to a blow molding mold, and blown. Consequently, the melt strength requirements of extrusion molding is alleviated to some extent, and higher melt temperatures can be used. Injection stretch blow molding produces a biaxially oriented part with higher stiffness, lower temperature impact strength, and greater clarity. The parison is cooled after it is formed by extrusion or injection molding, reheated to the desired orientation temperature, mechanically stretched, and then formed into the desired shape by blowing. Random copolymers of intermediate melt-flow rate (~10 MFR) have improved processing characteristics.

Extrusion and Thermoforming. iPP is extruded into sheet, usually for subsequent stamping or thermoforming (qv), or into pipes and profiles (see EXTRUSION). Low melt flow rate resins are used to provide the melt strength required to maintain uniformity. The choice of resin can often be dictated by subsequent forming operations. High melt strength polymers, produced by post-polymerization modification of conventional iPP, improve uniformity. Care must be taken for profiles of complicated geometry due to dimensional changes on crystallization, and variable cooling rate for regions differing in thickness. Good mixing of the melt during the extrusion process is important. Melt temperatures which are too high can promote degradation, leading to loss of properties, discoloration, and *plate out* which is the migration of additives and/or low molecular weight polymer to the surface of the sheet or profile. Lower temperatures reduce throughput and uniformity and lead to higher levels of orientation detrimental to subsequent forming.

In the thermoforming process, the sheet is extruded either in-line or off-line and formed, either in melt phase or solid phase, into a part of desired shape. Sheet uniformity is important. Historically, iPP has not been used in conventional melt-phase thermoforming equipment because of its narrow forming temperature range and the tendency of the melt to sag. Controlling the sag is particularly important

for large parts or multiple cavities. The introduction of newer iPP grades with higher melt strength and improved sag resistance has increased the use of iPP in conventional melt-phase thermoforming equipment (293). Processes such as Shell's solid-phase pressure forming (294) were developed to overcome problems associated with melt forming. The iPP article is formed at temperatures close to but below the crystalline melting point, by stretching the sheet into the mold cavity with a shaped plug. The part is forced against the mold surface by cold air to obtain the desired shape. Manufacturers of thermoforming equipment have also modified their processes to effectively utilize iPP (295).

Stabilization. Polypropylene is subject to attack by oxygen, radiation, and excessive heat causing a loss of molecular weight and physical properties. Stabilizers are added to the polymer to minimize these effects. Small quantities of hindered phenolic antioxidants (qv) are added in the polymerization plant, usually in the drying section, to protect the polymer against degradation (qv) during short-term storage. Typically 2,6-di-*tert*-butyl-*p*-cresol (BHT) and octadecyl 3,5-di(*tert*-butyl-4-hydroxy)hydrocinnamate (Irganox 1076) are used. The bulk of the stabilizer is added during pelletization or fabrication to protect the polymer during processing or in the final application. Typical stabilization formulations include a hindered phenolic antioxidant, possibly with a thiodipropionate synergist, a phosphite to provide high temperature melt stabilization, and an acid scavenger such as calcium stearate or dihydrotalcite (296). Hindered phenols limit the propagation of alkyl radicals and the resulting chain scission. Thiodipropionic acid esters act to decompose peroxides formed by polypropylene oxidation. More importantly, the sulfonic acid intermediate of thiodipropionate oxidation acts as a scavenger for the free radicals formed by the decompositon of phenols, increasing the effectiveness of the phenolic antioxidant (297). Phosphites also act to decompose peroxides and are most effective at the temperatures usually encountered in processing. The acid scavenger acts to prevent the reactions between hindered phenols and metal chlorides that can form colored titanium phenolates, as well as minimize equipment corrosion. Protection against ultraviolet radiation is usually provided by a hindered amine light stabilizer (HALS), such as Tinuvin 770 (see UV STABILIZERS). Stabilization (qv) of polypropylene has been reviewed (157).

Economic Aspects

Polypropylene consumption continues to increase more rapidly than the economy and most other thermoplastics. Although the comparative growth in polypropylene consumption has slowed from that in the 1970s and 1980s, the relative share of polypropylene use in North America has increased from 17% to 20% of all thermoplastics during the 1990s (298). The annual increase in consumption of polypropylene in North America averaged about 7% through the same period (299). Consumption in Western Europe has also increased at a similar rate. Growth in Japan has been much slower than in other countries, in part because of the protracted Japanese recession in the late 1990s, but also because of competition from the emerging economies in East Asia. The rapid growth of the Asia/Pacific region has been the major economic story of the past decade, and the growth in polypropylene consumption and production has been phenomenal. This region is

[a] Ref. 300.
[b] U.S. consumption in 2002 was 7748×10^3 t (301).

now the world's largest market for polypropylene, accounting for almost 40% of supply and demand (302). China has developed as one the world's major markets for polypropylene and other thermoplastics, and is the leading importer of plastics, despite a significant increase in its production capacity. World consumption data for polypropylene are listed in Table 12. Malaysia, South Korea, India, and Thailand have joined Taiwan as significant producers, with the construction of modern, world-scale manufacturing plants. Brazil, the largest market in Latin America, has also grown at a rapid pace.

This increase in consumption has, however, been more than matched by a larger increase in production capacity, fostering a situation of oversupply and low capacity utilization. New plants often have production capacities of 250 kt/y to capitalize on the economy of large-scale facilities. In North America, where refinery propylene is the source for most monomer, the decision to invest in polypropylene capacity is often related to the need to market propylene. Arco Products (now part of BP) and Tosco (now owned by Phillips) both decided to produce polypropylene as the most cost-effective way to eliminate regulatory problems caused by excess propylene production at their refineries. Arco/Tosco capacity increased by 23% from 1998 to 2001; however, consumption only increased by 17% over the same period. Capacity utilization dropped to the lowest levels since 1989. Producers' profit margins have decreased dramatically as the polymer prices have fallen relative to the cost of production. These profit margins are highly dependent upon the difference between the price of polymer and the price of propylene monomer. Monomer prices are related to oil prices; however, polymer prices are related to supply and demand. This difference has decreased consistently through the past decade, as some producers have been willing to supply at the lower prices. It has been estimated that a significant number of producers have been operating at a loss (303). Consequently, producers reduced capacity by closing or idling plants. Table 13 gives world production data, and Table 14 gives world capacity information and Table 15 gives U.S. production and capacity for the years 2000–2002. The 4% decrease in polypropylene capacity in 2002 is unprecedented in North America. Excess capacity and low profit margins characterize the polypropylene industry throughout the world, not just in North America, as the industry has become globalized. The market situation in Asia can dramatically affect prices in North America and Europe as imports into that region increase or decrease.

To combat the decrease in profitability major producers have chosen to reduce costs through mergers. Royal Dutch/Shell and BASF have merged their polyolefin activities, formerly Montell, Elenac and Targor, to form Basell, which is the world's largest producer of polypropylene. This company contains facilities that were once part of BASF, Hercules, Hoechst, ICI, Montedison, and Shell. Borealis, one of the largest European producers and the result of a merger between the polyolefin businesses of Statoil and Neste, acquired PCD and OMV, two smaller producers. Major mergers of large petroleum companies, such as Exxon and Mobil (ExxonMobil), BP, Amoco and ARCO (BP), and Total, Elf Aquitane and Fina (TotalFina) have also resulted in the combination of their polymer operations. The Dow Chemical Co. purchased Union Carbide, combining the polypropylene businesses of the two companies. Japanese producers affiliated with Mitsui have

merged operations to form Grand Polymers and those affiliated with Mitsubishi have formed Japan Polychem. Mitsui and Sumituomo have announced a merger of their chemicals businesses, and included polypropylene. At the end of 2001, the largest producers of polypropylene in order of capacity are Basell, BP, Atofina, ExxonMobil, and Dow Chemical (305). In Europe, the largest producers are Basell, Borealis, Atofina, Sabic, and BP, respectively.

The principal market applications of polypropylene in North America are shown in Table 16. The use of polypropylene in packaging has grown more rapidly than other areas because of its increased use in injection-molded containers and packaging films. The consumer and institutional products sector is the largest market for polypropylene. This sector is the most diverse and includes nonwoven polypropylene fabrics in baby diapers as well as injection-molded toys and houseware. This market has also grown considerably in the past decade. The consumption of polypropylene in furniture and furnishings, which includes carpet fiber, continues to be one of the major applications, but is growing more slowly than overall consumption. The use of polypropylene in transportation, primarily automobiles, is not growing as fast as other areas. Consumption of polypropylene in injection-molded transportation applications has declined in recent years, as shown in Table 17. Polypropylene is most commonly extruded into fibers or films, or injection molded. Other fabrication processes are not used as frequently.

RADICAL POLYMERIZATION

Introduction

Free radical polymerization is one of the most studied chemical processes. This is not surprising, because free radical polymerization is carried out on a large industrial scale; the world production of polymers by this method is in the range of 100 million tons per year. This enormous production corresponds to nearly 50% of all synthetic polymers. The importance of free radical polymerization is likely to increase in the coming years as new controlled/living radical polymerization techniques find industrial applications. Free radical polymerization has been known for more than 60 years. As far back as the 1950s, the basic theory and comprehension of radical polymerization was established (1–5). It included the thorough understanding of the mechanism of the process, encompassing the chemistry and kinetics of the elementary reactions involved, with the determination of the corresponding absolute rate constants, the structure, and concentrations of the growing species, as well as a correlation of the structure of the involved reagents and their reactivities. Similar to other chain reactions, the radical polymerization process may be subdivided into initiation, propagation, transfer, and termination steps as depicted in Scheme 1. The radicals necessary to initiate the chain process have to be generated *in situ* in most cases.

A multitude of monomers can be used in radical polymerization and it is impossible to list them all. The fundamental feature of the vast majority of monomers in question is the vinylic double bond. Thus the simplest monomer is ethylene, which, however, can only be polymerized under high pressure and high temperature to the commercially very important low density polyethylene. Common monomers are monosubstituted or unsymmetrically (1,1-) disubstituted ethylenes, $CH_2{=}CHR$ or $CH_2{=}CRR'$. The substituents R and R′ determine the properties of resulting polymers and also the kinetic and thermodynamic

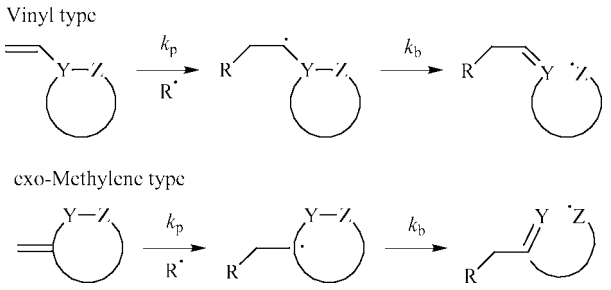
Scheme 1.

polymerizability of monomers. Polymerizable monomers under radical conditions include styrene and its substitution products, dienes, mono- and disubstituted ethylene derivatives, such as vinyl acetate, acrylonitrile, (meth)acrylates, (meth)acrylamides, and vinyl chloride, and a variety of halogenated alkenes. Carbon–heteroatom (N,O) double bonds only rarely polymerize via radical polymerization (eg, CF_3—CHO (6)).

The essential polymerization step is a repetitive free radical addition to the monomer double bonds, forming chains of carbon atoms constructed of units —(—CH_2—CHR—)— or —(—CH_2—CRR′—)— linked together predominantly head-to-tail (the substituted carbon atom is denoted as the head). Since the free radical is essentially sp^2 hybridized, very limited control of tacticity is observed, with many monosubstituted monomers providing atactic polymers and disubstituted like methacrylates showing (thermodynamic) preference for syndiotacticity.

Monomers with exocyclic double bond can polymerize via ring-opening polymerization and incorporate heteroatoms to the backbone. The systematic study of ring-opening polymerization started in the 1950s (7). Ring-opening polymerization has several characteristic features, and it can produce a wide variety of polymers, many of which have found important industrial applications (8,9). A characteristic feature of ring-opening polymerization is the smaller volume shrinkage of cyclic monomers during polymerization in comparison with vinyl monomers (10). Consequently, cyclic monomers are better as adhesives, curing resins, and molding and filling materials. Vinyl monomers show volume shrinkage about two times larger than the shrinkage of cyclic monomers of identical molecular weight. This is due to the compact structures of cyclic monomers and the compensation of the closeness of monomer molecules by ring opening during polymerization.

Most cyclic monomers polymerize ionically, but there are several monomers undergoing radical ring-opening polymerization (RROP). The copolymerization of radically polymerizable cyclic monomers with common vinyl monomers can add functions to common vinyl polymers. Scheme 2 illustrates the typical patterns of RROP, depicting vinyl-substituted cyclic and *exo*-methylene-substituted monomers. The radical species formed by the radical addition to the double bond undergoes ring opening to form a propagating radical species. RROP is commonly



Scheme 2.

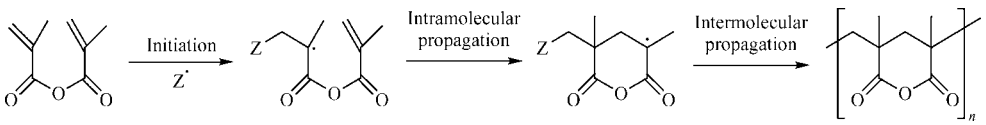
accompanied by so-called vinyl polymerization without ring opening of the cyclic structure.

Although fewer monomers undergo RROP than cationic, anionic, and coordination ring-opening polymerizations, novel monomers undergoing RROP are steadily being developed, some of which were recently examined as monomers for living radical polymerization (11). RROP can provide a wide variety of functional polymers with industrially promising radical polymerization.

1,6-Dienes having vinylic double bonds that are not polymerizable can form polymers consisting of repeat units made up of five- or six-membered rings. Such processes are called cyclopolymerization (qv), and typically the intramolecular cyclization followed by intermolecular addition of the cyclized radicals (see Scheme 3) is orders of magnitudes faster than individual propagation via the carbon–carbon double bonds (12–15).

Typical cyclopolymerizable monomers include N-substituted dimethylacrylamides where the nonpolymerizability of the N,N-disubstituted methylacrylamido group results in the generation of five-membered cyclic structures involving head–head linkages. In cases where one of the carbon–carbon double bonds is severely sterically hindered, cyclopolymerization (qv) may not occur and a linear polymer with pendant double bonds is formed (16). Other examples of monomers that undergo cyclopolymerization are 4-(*N,N*-diallylamino)pyridine, 5,6-di-*O*-isopropylidene-D-mannitol, 1,5-hexadiene, *N*-methyl-*N*-methallyl-2-(methoxycarbonyl)-allyl amine, and dipropargyl compounds (13). One of the most efficient ways to achieve structural control in radical polymerization is via cyclopolymerization. For example, the free radical cyclopolymerization of a diacryloyl monomer involving a chiral template results in the generation of stereogenic centers and four different stereoisomers (17).

Another essential component of free radical polymerization systems are initiators which should provide initiating free radicals via homolytic cleavage of covalent bonds, redox reaction, photochemical or other stimuli. In addition, various



Scheme 3.

compounds which can regulate molecular weights (transfer agents) or rates (retarders/inhibitors) can be used. Free radical polymerizations tolerate many protic impurities such as water or alcohols but require absence of oxygen, which act as a powerful inhibitor. Various solvents can be used which should not (unless desired) participate in transfer.

Initiation

The initiation process constitutes the first reaction step in free radical polymerization, leading to the generation of (primary) radicals. The kinetics of the initiation process, ie its rate and effectiveness, are of fundamental importance in both theoretical studies and commercial applications. Commercial procedures mainly rely on the formation of primary radicals via thermal decomposition processes using azo- and peroxy-type compounds. Investigative kinetic studies are—to a large extent—carried out using photoinitiators, which decompose upon irradiation with UV or visible light. The main reason for this choice is the possibility to define exact start and end times of the initiation and subsequently the polymerization process.

The decomposition scheme (eq. 1) describing the generation of radicals is common to both thermal and photoinitiators.

$$\text{Initiator} \xrightarrow[h\nu,\,\Delta]{k_d} I_1^{\cdot} + I_2^{\cdot} \tag{1}$$

The measurable decrease of the initiator concentration [I] in a polymerizing systems with time is given by

$$-\frac{d[I]}{dt} = k_d[I] \tag{2}$$

Integration of equation 2 leads to equation 3, an expression which describes the decreasing initiator concentration as a function of time.

$$[I] = [I]_0\, e^{-k_d t} \tag{3}$$

However, the rate of the formation of initiating primary radicals is of greater interest in kinetic studies. The rate of generation of radicals that are capable of initiating the polymerization process, R_d, is described via the following general first-order rate law:

$$R_d = \frac{d[I^{\bullet}]}{dt} = -2f\frac{d[I]}{dt} = 2fk_d[I] \tag{4}$$

where k_d corresponds to the rate coefficient of initiator decomposition and f denotes the initiator efficiency (see below). It should be noted that in the case of photoinitiation, k_d is a composite of various variables.

In order to initiate the polymerization process via reaction with a monomer unit, the generated primary radicals, $I_1^{\bullet}$ and $I_2^{\bullet}$, have to leave the solvent cage that surrounds them. The ability of the primary radicals to leave the solvent cage

unreacted and to start the polymerization process is quantified by the initiator efficiency f, with theoretical values between zero and unity. Not all generated primary free radicals initiate polymer growth. Shortly after decomposition, the free radicals are very close to each other and recombination can occur. In addition, they can also react in alternative ways before they can react with a monomer unit. An efficiency of zero corresponds to no initiation taking place, whereas $f = 1$ indicates that every generated primary radical escapes the solvent cage and subsequently initiates polymerization. Typical values of f are between 0.5 and 0.8, depending on the viscosity of the reaction medium, indicating that the escaping process is diffusion controlled. It should be noted that in the case of an unsymmetrical initiator molecule, $I_1^\bullet$ and $I_2^\bullet$ do not necessarily display the same reactivity toward the monomer unit (18–20). Hence, the initiation process may be described by equations 5 and 6:

$$I_1^\bullet + M \xrightarrow{k_i^{(1)}} R_1^\bullet \tag{5}$$

$$I_2^\bullet + M \xrightarrow{k_i^{(2)}} R_1^\bullet \tag{6}$$

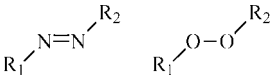
where $I_1^\bullet$ and $I_2^\bullet$ represent initiator fragment 1 and 2, respectively, M indicates a monomer unit, $R_1^\bullet$ corresponds to a macroradical of chain length 1, and $k_i^{(1)}$ and $k_i^{(2)}$ refer to the individual initiation rate coefficient of the respective fragments. The rate of initiation, R_i, is given by equation 7:

$$R_i = \frac{d[R_1^\bullet]}{dt} = -\frac{d[I_1^\bullet]}{dt} - \frac{d[I_2^\bullet]}{dt} = k_i^{(1)}[M][I_1^\bullet] + k_i^{(2)}[M][I_2^\bullet] \tag{7}$$

Because $[I_1^\bullet] = [I_2^\bullet] = [I^\bullet]/2$, the rate coefficient of initiation, k_i, is a composite of the individual rate coefficients of initiation for the initiator fragments $I_1^\bullet$ and $I_2^\bullet$.

$$R_i = k_i[M][I^\bullet] \quad \text{with} \quad k_i = \frac{k_i^{(1)} + k_i^{(2)}}{2} \tag{8}$$

Thermal Initiation. Thermally decomposing initiators (mainly) fall into two classes: azo- and peroxy-type molecules. The general structures of azo- and peroxy-initiators are represented by **1** and **2** respectively.



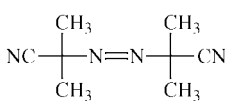
1 **2**

An important quantity of a thermal initiator is its *half-life* $t_{1/2}$ (at a certain temperature), given by equation 9. The half-life is the time period during which half of the initiator molecules initially present is decomposed.

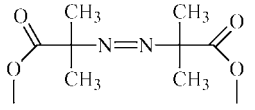
$$t_{1/2} = \frac{\ln 2}{k_d} \tag{9}$$

There are initiators available for virtually any desired decomposition rate in a given solvent (or monomer) at a given temperature. Initiators are often characterized by the temperature at which their half-life is 10 h. These temperatures range from 20 to 120°C, depending on the structure of the initiator. Extensive data on initiator decomposition rates and their activation parameters can be found in the *Polymer Handbook* (21). In the following, the basic features of thermal initiation systems are discussed.

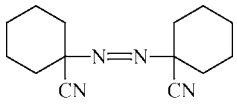
Azoinitiators. This widely used class of thermally decomposing initiators generates both carbon- and oxygen-centered radicals by either C—N (dialkyl diazenes) or O—N (dialkyl hyponitrites) bond scission driven by the expulsion of a stable nitrogen molecule (22–25). Dialkyl diazenes are generally used at higher temperatures than dialkyl hyponitrites. Most of the azoinitiators generate two identical radical species upon fragmentation. The most common azoinitiators are 2,2′-azobisisobutyronitrile (AIBN, **3**), dimethyl 2,2′-azobisisobutyrate (**4**), 1,1′-azobis(1-cyclohexanecarbonitrile) (**5**), and 2,2′-azobis-2,4-dimethylvaleronitrile (**6**). Both the delocalization of the free electron in the generated radical (22,23) and the steric demand of the leaving radical (24) significantly affect the decomposition rate coefficient k_d: The more the free electron in the resulting radical is delocalized and the bulkier the leaving radical, the larger is k_d. The choice of the solvent, however, has comparatively little effect on the rate of azoinitiator decomposition (26).



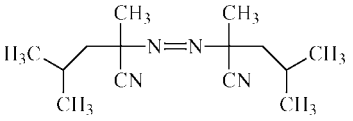
3



4



5

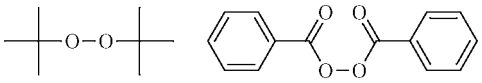


6

The concept of azoinitiators has been extended toward the generation of macroazo-initiators for the synthesis of block copolymers. The development of techniques for block copolymer preparation was especially important before the advent of living free radical polymerization processes such as reversible addition–fragmentation chain transfer (RAFT) polymerization or atom transfer radical polymerization (ATRP). Macroazoinitiators are low molecular weight polymers containing one or more —N=N— units (27–32). Usually, the macroazo-initiator is prepared by a technique other than free radical polymerization, ie polycondensation of low molecular weight azoinitiators with suitable end groups. A typical example of such a strategy is the polycondensation of 2,2-azobis(2-cyanopropanol) with isocyanate functionalized prepolymer. The generated polymer can subsequently be used to initiate the free-radical polymerization of styrene. The rate of macroazo-initiator decomposition may be different from the parent initiator, but still follows first-order kinetics (32). Macroazo-initiators have also been used in conjunction with (NMP) (nitroxide-mediated polymerization) and ATRP for the

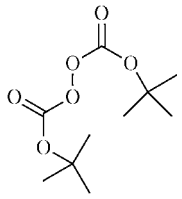
synthesis of block copolymers (29,33). It is interesting to note that polymers containing azo-moieties along the backbone have been reported to be biodegradable (34).

Peroxide-Based Initiators. The use of peroxides as thermally decomposing initiators is—especially in an industrial context—more widely spread than the use of azoinitiators (35,36). Peroxy compounds range from alkyl, acyl, and peresters to inorganic peroxides (26,37). The most employed peroxides are di-*tert*-butyl peroxide (**7**), benzoyl peroxide (**8**), di-*tert*-butyl peroxalate (**9**), cumene hydroperoxide (**10**), and di-*n*-propyl peroxydicarbonate (**11**). The primary—oxygen-centered—radicals that are generated by organic peroxide decay may undergo further reactions such as β-scission, which leads to the formation of secondary radicals. A common reaction pathway is the expulsion of carbon dioxide from the generated primary radicals originating from acyl peroxides. For example, the decomposition of benzoyl peroxide leads to the formation of benzoyloxy and phenyl radicals. The mechanism of peroxide decomposition is still under investigation, especially in the case of alkyl peroxyesters. Peresters may decompose—depending on their structure—by either a concerted two-bond scission or a one-bond homolysis of the oxygen–oxygen bond (38). The one-bond homolysis results in the formation of acyloxy and alkoxy radicals, whereas the concerted two-bond fragmentation generates alkyl and alkoxy radicals plus carbon dioxide.

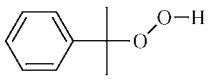


7

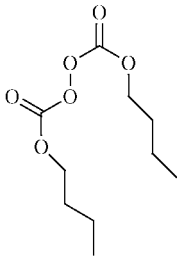
8



9



10



11

The rate of peroxide decomposition is strongly dependent on the structure of the molecule in question. The rate of decomposition for diacyl peroxides and peresters increases when going from aryl to primary alkyl to secondary alkyl to tertiary alkyl substituents (39). In the case of peresters, the structure of the molecule governs both the rate of fragmentation and the above mentioned mode

of fragmentation (ie one-bond homolysis vs concerted two-bond cleavage). Experimental data indicate that the rate of decomposition increases when going from primary to secondary to tertiary carbons connected to the $(CO)O_2$ moiety in the perester. The concerted mechanism is favored in the case of secondary and tertiary carbons (38,40,41). Because of the strong dependence of the rate of decomposition on the peroxide structure, a wide variety of decomposition rates exists for a given temperature. The general guideline is that dialkyl peroxides and hydroperoxides are mostly used at elevated temperatures, whereas dialkyl peroxydicarbonates are best suited for lower temperatures. The solvent in which the decomposition is carried out affects the rate to much larger extent than for azoinitiators. For example, the decomposition rate coefficient for the diacyl peroxide bis(3,5,5-trimethylhexanoyl)peroxide increases by a factor of 7 when going from pentadecane to acetonitrile (at 150 MPa and 80°C) (42). The rate of diacyl peroxide and peroxy ester decomposition has also been studied in supercritical CO_2 and—contrary to the above—no significant change in decomposition rate compared to *n*-heptane as solvent has been observed (43).

Photoinitiation. An attractive alternative to thermally decomposing initiators are photoinitiators that decay upon irradiation with UV or visible light (44–48). The use of photoinitiators is (in most cases) restricted to applications involving accurate kinetic measurements, whereas their usage in industrial processes is very limited because of the technical problems associated with the uniform irradiation of large reaction volumes. Some exceptions are applications involving coatings and surface polymerizations. The main advantage of photoinitiators used in polymerizing systems is the possibility to define exact start and end points of the polymerization process via the duration of the irradiation period. In addition, the rate of (most) photoinitiator decomposition is almost independent of the reaction temperature, but depends strongly on the (UV) light intensity. However, weak temperature dependencies of the primary quantum yield (see below) have long been known for the photoinduced decomposition of azoalkanes (23). The weak dependence of the rate of decomposition on the reaction medium temperature is due to the large amount of energy which is deposited into the initiator molecules via the light source. This energy exceeds the thermal energy of the surrounding medium by orders of magnitude. An ideal photoinitiator for a specific polymerization may be defined via the following criteria:

(1) The photoinitiator should decompose upon irradiation with the (UV) light source; eg, an absorption should coincide with the radiation wavelength. The monomer(s) used in the specific polymerization process should not absorb light at the selected wavelength.
(2) The efficiency of the initiator should be high, preferably close to one; ie, all radicals generated should start growing chains.
(3) At best, there should be only one type of free radical species that is formed upon laser irradiation.

On the basis of the mechanism by which initiating radicals are formed, photoinitiators are generally divided into two classes: Type I photoinitiators undergo a unimolecular bond cleavage upon irradiation to yield free radicals. Type II

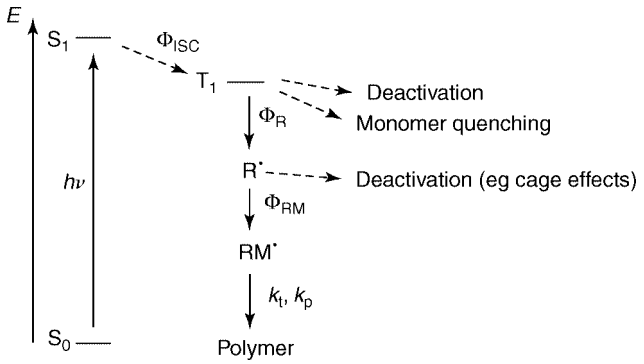


Fig. 1. Simplified Jablonski diagram of the photochemically initiated acetophenone type initiator decomposition.

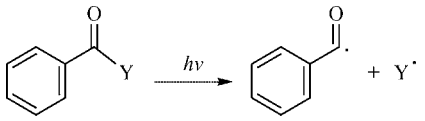
photoinitiators undergo a bimolecular reaction where the excited state of the photoinitiator interacts with a second molecule (a co-initiator) to generate free radicals. However, visible light photoinitiators belong almost exclusively to the Type II class of photoinitiators. Within the Type I initiator class, there are several structural variations. The most widely used class are photoinitiators containing a benzoyl group as the effective initiating moiety (acetophenone type). Their general formula and primary decomposition products are given in equation 10.

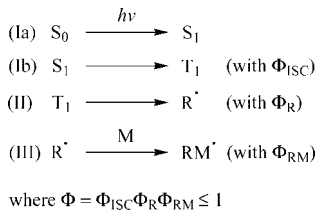


(10)

It is a standard practice to show the processes that can take place upon irradiation (ie assuming that each photoinitiator molecule absorbs a certain dose of energy) in a so-called Jablonski diagram. Such a diagram is a simplified illustration of the relative positions of the electronic energy levels of a molecule.

Upon (UV) irradiation, the molecule is converted from its (singlet) ground state to its first excited state. The Jablonski diagram given in Fig. 1 shows that there is more than one possibility to deactivate an excited initiator molecule. This multitude of deactivation modes is quantified in the quantum yield for the primary free radical production, Φ. Φ is composed of three parts, which can be assigned to the reactions shown in Scheme 4.

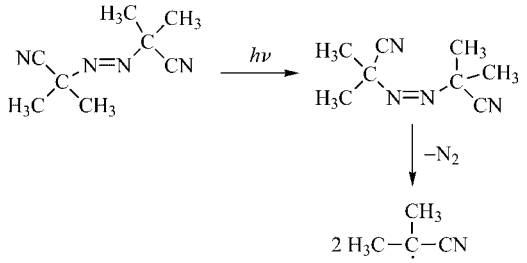
The quantum yield for intersystem crossing (Ib) is rather high for ketones (49), so that to a good approximation Φ_{ISC} can be set to one. Thus, the overall



Scheme 4.

quantum yield of the initiation process depends only on Φ_R and Φ_{RM}. From the T_1 triplet state, parallel reactions can lead to a decrease in the quantum yield Φ_R. In free radical polymerizations these reactions are deactivation by molecular oxygen and deactivation by the monomer (50). This is one of the reasons why the monomer mixture should be thoroughly degassed prior to the polymerization process. The longer the lifetime of the triplet state, the higher the chances that deactivation processes can reduce the quantum yield. For example, 2,2-dimethyl-2-phenylacetophenone (DMPA) has a rather short-lived T_1 state [$\tau < 0.1$ ns (51), whereas the respective value for 1,1-dimethoxy-1-hydroxyacetophenone (Darocur 1173) is close to 20 ns (52)], which results in a high Φ_R value. The quantum yield of the third reaction, which leads to the formation of macroradicals, has been termed *initiator efficiency*, $f \equiv \Phi_{RM}$. The initiator efficiency is influenced by the ability of the radicals formed by the laser pulse to diffuse from the solvent cage to the reaction site and its definition is analogous to the definition of the efficiency factor for thermally decomposing initiators. This process has been termed *cage effect*. The initiator efficiency of the typical acetophenone initiator DMPA (at 30°C and ambient pressure) is close to 0.4 (53). However, the situation for most acetophenone-type initiators is more complex than for a photoinitiator which yields only a single type of free radical, $R^\bullet$, upon irradiation. It is generally accepted that most acetophenone-type initiators (eg, DMPA, Darocur 1173, or benzoin) decompose into two radical species, $R_1^\bullet$ and $R_2^\bullet$, as detailed in equation 10. Generally, both species are distinctly different in their character. The carbonyl radical is very efficient in terms of starting macromolecular growth, whereas the second radical is often not [for the example of DMPA, the methoxy-type radical is only involved in termination steps (54)]. Initial radicals that come from a common initiator molecule, but have clearly different efficiencies, may be termed "effective" and "ineffective" (primary) initial radicals, respectively. The sum of both radical concentrations is termed "overall" radical concentration and is two times ρ, with ρ being the concentration of primary radicals that are capable of starting macromolecular growth. The concentration of effective and ineffective initial radicals is the same and equal to ρ. The occurrence of primary radicals with markedly different reactivities may have serious consequences for the polymerization kinetics.

Another widely used structural variation of class I photoinitiators are azoinitiators, which are also employed as thermal initiators. However, their mechanism of photodecomposition is markedly different from acetophenone-type initiators. Equation 11 shows the UV-induced decomposition of the widely used azoinitiator 2,2′-azobisisobutyronitrile (AIBN).



(11)

Upon irradiation by laser light, the initiator molecule changes its stereochemical configuration from the trans to the cis isomer. This cis/trans isomerism becomes of importance if azoinitiators are employed in pulsed laser experiments: The time at which the laser pulse hits the reaction mixture is no longer identical with the generation of the primary radicals. The time delay is usually in the order of microseconds and may be observed in time-resolved pulsed laser experiments.

It is possible to calculate the effective primary free radical concentration ρ generated by monochromatic irradiation of a reaction mixture containing a photoinitiator. The radical concentration ρ, which is generated by a specific number of absorbed photons, is given by equation 12:

$$\rho = 2\Phi \frac{n_{\text{abs}}}{V} \tag{12}$$

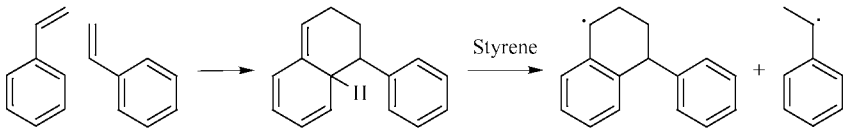
where Φ is the primary quantum yield (see above), n_{abs} is the number of absorbed photons, and V is the irradiated volume. According to Beer–Lambert's law, the number of absorbed photons may be calculated by equation 13:

$$n_{\text{abs}} = \frac{E_{\text{p}}}{E_{\lambda}}(1 - 10^{-\varepsilon c d}) \tag{13}$$

where E_{p} is the energy deposited, E_{λ} is the energy of 1 mole of photons at the irradiation wavelength λ, ε is the molar absorption coefficient of the initiator molecule at the laser wavelength λ, c is the photoinitiator concentration, and d is the optical path length.

The rate of photochemical initiation is given by the product of the intensity of absorbed light (in moles of light quanta per liter and second) and the primary quantum yield. A good survey on different photoinitiators and their photodecomposition by UV light was given by Gruber (55).

Self-Initiated Polymerization. Free radical polymerizations can also be initiated by the monomer itself or peroxy compounds that are formed via exposure of the reaction mixture to molecular oxygen. The processes (mainly) take place at high temperatures. However, under very pure conditions in exhaustively purified reaction vessels, most monomers do not tend to polymerize spontaneously by increasing the temperature. Styrene is one of the rare monomers that—also in its purest state—does exhibit initiation processes without additionally added initiator. The self-initiation of styrene has been studied in great detail with respect to its kinetics and mechanism (56–58). The underlying reaction is a self-Diels–Alder cycloaddition of two styrene moieties as shown in equation 14:



(14)

The self-initiated bulk polymerization of styrene has a substantial activation energy: a 50% monomer conversion needs 400 days at 29°C, but only 4 h at 127°C. However, the produced polystyrene is very pure because of the absence of

initiators and other additives. Methyl methacrylate was also thought to undergo self-initiated polymerization, but increasing evidence indicates that this may not be the case (59–64). It should be noted that certain pairs of monomers undergo spontaneous copolymerization without the addition of a thermal initiator. Examples include maleic anhydride/styrene (65) and acrylonitrile/styrene (66,67). The mechanism of initiation of such copolymerization is still unclear, but pathways analogous to that operative in styrene homopolymerizations but with acrylonitrile acting as the dienophile in the formation of the Diels–Alder adduct is debated. Other postulated mechanisms for spontaneous initiation include hydrogen atom transfer between the solvent and charge-transfer complex (68) and electron transfer followed by proton transfer to yield macroradicals (69).

Redox-Initiated Polymerization. Redox-initiating systems are very often used, especially in aqueous media. However, the redox initiation can also be carried out in organic media. These systems consist of a reducing and oxidizing agent (70,71). Redox initiators very often form only one radical (eg, classic Fenton system of ferrous salts and hydrogen peroxide or other peroxides) which, by eliminating cage termination, increases initiation efficiency:

$$Fe^{2+} + RO{-}OR \rightarrow Fe^{3+} + RO^- + RO^{\bullet} \quad (15)$$

Commercially important is also the use of ceric salts, which can reduce alcohols to alkoxy radicals and enable grafting from cellulose and other surfaces with OH groups.

Some redox systems provide two radicals such as persulfates with thiosulfates and metabisulfates:

$$S_2O_8^{2-} + S_2O_3^{2-} \longrightarrow SO_4^{\bullet -} + SO_4^{2-} + S_2O_3^{\bullet -} \quad (16)$$

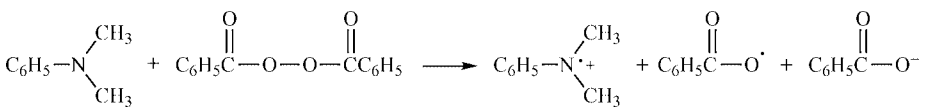
$$S_2O_8^{2-} + S_2O_5^{2-} \longrightarrow SO_4^{\bullet -} + SO_4^{2-} + S_2O_5^{\bullet -} \quad (17)$$

The electrostatic repulsion between radical anions also reduces the probability of cage termination.

Transition metals in redox initiation usually act as reducing agents but may also act as oxidants:

$$Co^{3+} + {}^-OH \rightarrow Co^{2+} + {}^{\bullet}OH \quad (18)$$

There are also several nonaqueous redox systems which proceed by either outer- or inner-sphere electron transfer (OSET or ISET). As already stated before, aromatic amines accelerate decomposition of peroxides by electron transfer and formation of peroxide radical anions as depicted in equation 19:



(19)

Trialkylboron derivatives are also powerful reducing agents and their interaction with benzoyl peroxide allows to initiate radical polymerization at very low temperatures, approximately −50°C. A similar low temperature redox-initiating system consists of trialkylboron derivatives and oxygen.

Another class of redox-initiating systems involves transition metal complexes which either alone provide radicals by homolytic cleavage or react with organic halides. The latter system applied under reversible conditions forms the basis of ATRP, one of the most powerful controlled/living radical polymerization systems (*vide infra*).

Some transition metal chelates, such as Mn(II), Co(II), Ce(IV), Fe(III), or Cu(II) acetylacetonates, initiate polymerization of alkenes at wide temperature range 25–100°C, depending on monomer and solvent, which both can affect the stability of the complexes.

The reaction of transition metal complexes with alkyl halides may occur via OSET or ISET, depending on the redox potential of the components and also on the coordination sphere of the transition metal compound. The saturated coordination sphere favors OSET or requires ligand dissociation. The open coordination sphere enables ISET process, as in ATRP. The most common alkyl halides used in this process are polyhalogenated methanes (CBr_4, CCl_4, $HCCl_3$) and also halogenated esters (CCl_3CO_2R, $ClCH_2CO_2R$), sulfonyl halides, *N*-haloamines, or *N*-haloureas.

$$Mt^0 + Cl{-}CCl_3 \rightarrow Mt^{I}Cl^- + {}^{\bullet}CCl_3 \qquad (20)$$

Low oxidation state transition metal complexes include $Mo(CO)_6$, and $Ni(P(OR)_3)_4$, and $Ni(CO)_4$; more recently many Cu(I) complexes with bi-, tri-, and tetradentate N-ligands and Fe(II), Ni(II), and Ru(II) complexes with phosphine ligand as well as CO, Cp, and other ligands have been reported.

Other Methods of Initiation. Apart from the above-mentioned methods of initiating free radical polymerizations, there are several more alternatives which can be selected from, if required for the specific application. These techniques include (*1*) ionizing irradiation, (*2*) plasma initiation, (*3*) electroinitiation, and (*4*) ultrasonic initiation.

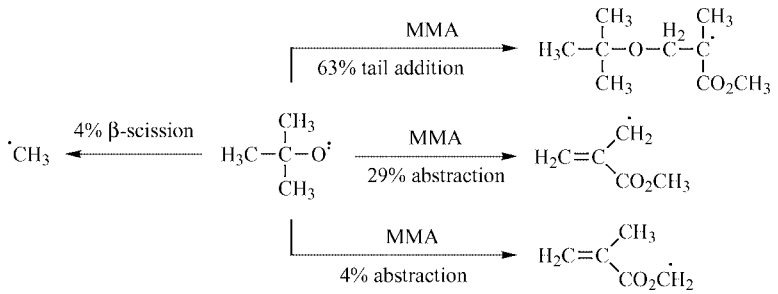
(1) Radioactive sources and ionizing particles (such as γ-irradiation (72), electrons (73), neutrons, and α-particles) are used to initiate free radical polymerization processes. The interaction of these radiations with matter are—compared to the interactions of less energetic irradiation (such as UV or visible light)—much more complex. High energy radiation applied to vinylic monomers usually results in the formation of anions, cations, and primary free radicals. These species may then initiate chain growth. Whether this growth is of the free radical type depends largely on the reaction conditions. Ionic chain initiation is predominant at low reaction temperatures, because the formed ions tend to dissociate into free radicals at higher reaction temperatures. High-energy-radiation-initiated free radical polymerizations are less applied in scientific and commercial applications, which is mainly due to the complex initiation mechanism and the safety issues associated with the usage of this type of irradiation.

(2) When a gaseous monomer under low pressure is exposed to a high voltage electric discharge, plasma polymerization may occur (74). The plasma consists of ionized molecules. A large number of monomers undergo plasma polymerization and form high molecular weight products. The polymerization process appears to be rather complicated but seems to involve both ionic and free radical species. Plasma polymerization is especially attractive for the generation of thin polymer films for a variety of applications (75).

(3) Electroinitiation—which is not to be confused with initiation by an electron beam—is done by direct electrolysis of the reaction mixture. The reaction mixture usually contains an organic solvent, the monomer, and an inorganic compound that allows to conduct the current or participates in the ionization process itself (76). The polymerization proceeds via either free radicals or ions, depending on the reaction conditions and the substances present in the reaction mixture.

(4) Sonication—the application of high intensity ultrasound—produces high concentrations of $H^{\bullet}$ and $OH^{\bullet}$ radicals in water, which can lead to polymerization of aqueous monomer solutions. Free radicals are also produced in organic solvents and vinyl monomers, however, to a lesser extent than in water. Most of the physical and chemical effects caused by ultrasound are due to the process of cavitation, or the formation and collapse of microscopic bubbles as the sound wave passes through the liquid. Although the origin of chemical effects has been attributed to electrical discharge processes, the most widely accepted theory assumes the generation of very large temperatures and pressures during an adiabatic bubble collapse (77–79).

Initiator-Derived Radical/Monomer Reactions. An initiator-derived radical (also called a primary radical) can undergo a multitude of reactions including hydrogen abstraction (from the solvent, the monomer, or already present polymer), tail/head addition to the monomer, fragmentation, and/or primary radical termination. Which of these reactions primarily occurs depends on the structure of the generated radicals, the monomer, and to some extent the solvent and the general reaction conditions (ie pressure and temperature). The reaction pathways of the primary radicals may be studied via the nitroxide trapping technique and for some initiator/monomer systems these have been successfully mapped out (80–82). For example, the specificity of reaction with styrene monomer is found to decrease in the series cyanoisopropyl ~ methyl ~ *tert*-butoxy > phenyl > benzoyloxy. While cyanoisopropyl (83), *tert*-butoxy, and methyl radicals almost exclusively afford tail addition, (84), phenyl radicals give tail addition and 1% aromatic substitution (84). Benzoyloxy radicals have been reported to undergo head addition, tail addition, and aromatic substitution (84,85). Interestingly, in methyl methacrylate free radical polymerizations, the same radicals display a very different order of reactivity. Here, the regiospecificity decreases in the order cyanoisopropyl ~ methyl > phenyl > benzoyloxy > *tert*-butoxy. Methyl and cyanoisopropyl radicals almost exclusively yield tail addition. Phenyl and benzoyloxy radicals also tend to react with the double bond, whereas hydrogen abstraction is very minor (86,87). *tert*-Butoxy radicals react with methyl methacrylate via 63% tail addition



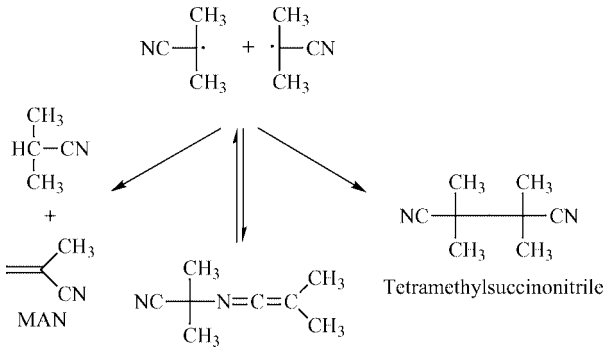
Scheme 5.

(88) and hydrogen abstraction mainly from the α-methyl group or the ester methyl group (see Scheme 5) (88,89).

Inspection of Scheme 5 indicates that a significant proportion of the poly(methyl methacrylate) chains will have an olefinic end group, when *tert*-butyl peroxide is employed as free radical initiator. Such chains may themselves undergo reaction in the polymerization, leading to a variation in the desired product properties. It is thus mandatory to carefully match the monomer with the initiator to achieve the required end group functionalities.

Some initiators generate two types of radicals upon fragmentation, which greatly differ in their reactivity and/or reactions toward the monomer units. Such initiators include the above-discussed photoinitiators, such as DMPA or benzoin, but also encompass acyl phosphine oxides and the thermal iniferter phenylazotriphenylmethane. The reactivity differences between the individual radicals can be quite dramatic. It has been proposed that the acetal-type radical generated by DMPA decomposition is not involved in initiation reactions at all, while its counter benzoyl radical is very effective in initiating macromolecular growth (18). Similarly, the addition rates to vinyl monomers of (2,4,6-trimethyl benzoyl)diphenylphosphine oxide derived radicals have been found to differ greatly (90–92). The carbon-centered radicals add to vinyl monomers about 2 orders of magnitude slower than the phosphorus-centered ones.

Initiator Efficiency. A prerequisite for primary radical/monomer reactions is the successful escape of the generated radicals from their "solvent cage". If the formed radicals remain inside the cage, they may undergo reactions with themselves. Potential 'in-cage' reactions are the main reason for initiator efficiencies, f, being below unity ($0.3 < f < 0.8$, typically) (93). In-cage reactions include radical recombination or disproportionation. If the initiator is regenerated by an in-cage reaction, the initiator efficiency is not affected, but the rate of initiator decomposition is reduced. The importance of reactions within the solvent cage strongly depends on the rate of diffusion of the generated radicals away from each other. Therefore, both the size and the reactivity of the primary radicals as well as the medium's microviscosity determine the initiator efficiency. As increasing monomer-to-polymer conversion goes hand in hand with a large increase in system viscosity, the likelihood of in-cage reaction will increase with monomer conversion (94,95). The species generated by reactions within the solvent cage can be reactive under the polymerization conditions or they may have detrimental effects on the polymer properties. For example, cyanoisopropyl radicals formed by



Scheme 6.

the fragmentation of AIBN can react to yield methacrylonitrile, which undergoes copolymerization and will be incorporated in the final polymer (83,96). In addition, the toxic tetramethylsuccinonitrile is generated (97). The in-cage reaction pathways of primary cyanoisopropyl radicals generated from AIBN are depicted in Scheme 6.

These reactions are almost exclusively taking place within the solvent cage when styrene monomer is present. In the absence of monomer, however, with only a solvent present (eg, benzene), close to half of the products are formed outside the solvent cage, indicating that the addition of the cyanoisopropyl radicals to the monomer units is effectively competing with self-reactions of the primary radicals (94).

The efficiency of peroxide initiators is affected by the mode of their fragmentation. Concerted decomposition results in an alkoxy and in an acyloxy radical, whose recombination will not affect the initiator efficiency (38). Such processes have also been termed 'cage-return' reactions. However, concerted two-bond scission yields alkyl and alkoxy radicals, which—when coupled inside the cage—lead to a lower f value. Experimental investigations into the initiator efficiency can be carried out via radical trapping techniques (98), infrared spectroscopy (99), and product or polymer-end-group analysis via NMR (94). Measurements of the temperature dependency of the initiator efficiency are extremely scarce; however, it has been found that in the AIBN-initiated bulk free radical polymerization of styrene at 100 MPa, f increases by approximately a factor of 1.5 when going from 40 to 80°C (99). The same study indicated that the initiator efficiency decreases when the reaction pressure is increased (f decreases by close to one third when going from ambient pressure to 200 MPa bar at 70°C).

As mentioned earlier, initiation efficiency is much higher in the redox process since in many systems only one radical is generated. However, with transition metals, the radicals may be formed reversibly either by abstracting back halogen or by formation of organometallic species.

Propagation

The propagation step in free radical polymerization has been in the center of scientific interest within the last decade, because of the advent of novel methods for the

accurate determination of propagation rate coefficients. The addition of a macroradical to a monomer unit can be described via the following rate law expression:

$$-\frac{\mathrm{d[M]}}{\mathrm{d}t} = \sum_i k_\mathrm{p}^i[\mathrm{R}_i^\bullet][\mathrm{M}] \tag{21}$$

with $k_\mathrm{p}{}^i$ being the propagation rate coefficient of a macroradical with chain length i, R_i, [M] the monomer concentration, and [R_i] the free radical concentration. It is generally accepted that the propagation reaction is chemically controlled up to high monomer conversions, ie high viscosities of the reaction medium. This implies that the propagation rate coefficient is independent of monomer conversions up to 80%. The chemical control of the propagation step is impressively demonstrated when comparing the average collision frequency of 10^{12} s^{-1} in the liquid phase at room temperature (100) to the frequency of successful propagation reactions (typically close to 10^3 s^{-1}). These numbers indicate that (approximately) only every 10^9th collision leads to a successful addition of a monomer unit to a macroradical. The propagation rate coefficient given in equation 21 carries the index i (representing the chain length of the growing chain), because it is beyond doubt that k_p is a chain-length-dependent rate coefficient. This is especially true for the first few addition steps, which proceed at a markedly increased rate compared to long-chain propagation. In the case of methyl methacrylate, for example, the first propagation step at 60°C is approximately 16 times faster than the long-chain propagation (101–106). The difference in the polymerization of monosubstituted monomers may be smaller (107). Nevertheless, recent evidence points toward a chain length dependence of the product of k_p and the monomer concentration [M], up to chain lengths of hundreds of monomer units (108–111). Unfortunately, to this date, there is no method to determine k_p independently of the monomer concentration. It is thus quite possible that the apparent chain length dependence of k_p reflects a structuring of the monomer concentration at the propagating chain end.

For most free radical polymerizations, the propagation step is fast (see below) and exothermic. The thermodynamics of free radical polymerization propagation have been reviewed by a few authors including Busfield (112), Sawada (113), and Allen and Patrick (114). Heats of free radical polymerization have been commonly determined from calorimetric data using standard thermochemical techniques. Entropies of polymerization are more scarce. It should be noted that the addition of radicals to vinyl monomers is—at least in principle—a reversible process. Depropagation is favored entropically and its importance increases with increasing temperature. Details about depropagation reactions can be found in the relevant subsection.

The propagating radical has been studied in great detail via electron spin resonance (ESR) spectroscopy. The monomers under ESR investigation include styrene and substituted styrenes (115–117), acrylic esters (118,119), methacrylic esters (120–124), vinyl chloride (125), α-substituted acrylic esters, and other monomers (115,121). In the overwhelming majority of cases, free radical propagation proceeds in a regioselective way to afford a polymer chain almost exclusively consisting of head–tail linkages. For mono- and 1,1-substituted monomers, it is usual to call the less substituted side the 'tail' and the more substituted side the

'head.' For more complex monomer substitution patterns (such as 1,2-di-, tri-, and tetrasubstituted monomers), the above definition is less stringent and the terms 'head' and 'tail' are used more arbitrarily. A terminology has been suggested for polymerization *regioselectivity*, where head–tail linkages are called *isoregic*, head–head linkages *syndioregic*, and tail–tail linkages *aregic* (126). Despite the high regiospecificity of the propagation step, it is in general not stereospecific, because of an addition of the very shallow pyramidal propagating radical center to an almost planar vinyl double bond.

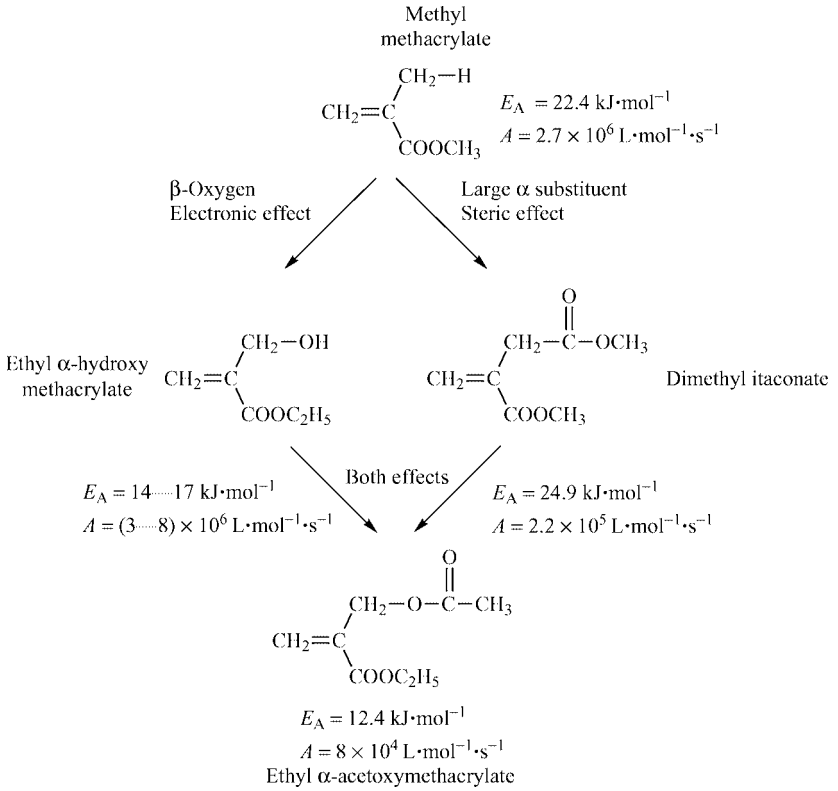
For the formation of high molecular weight polymer, the propagation step must be sufficiently fast to compete with other elemental reactions such as transfer and termination. In fact, range of factors may prevent fast propagation, as discussed below.

Free radical propagation is poorly stereocontrolled, with nearly equal proportion of meso and racemic dyads in polymerization of monosubstituted alkenes and a preference for syndiotactic placement for disubstituted monomers such as methacrylates ($rr = 0.62$, $mm = 0.04$). The sequence distribution follows a first-order Markov model with a slight deviation from Bernoulian statistics. However, for very bulky substituents, as in polymerization of triphenylmethyl methacrylate, the preference for isotacticity was observed ($mm = 0.64$, $rr = 0.12$). Recently, complexation with Lewis acids and acidic solvents enabled to enhance stereocontrol in polymerization of vinyl esters and acrylamides, and to a smaller degree in polymerization of methacrylates (127–129).

Complexation with Lewis acids has also been used to alter sequences in copolymerization and prepare alternating copolymers in systems which usually provide very small tendency for alternation like styrene/methyl methacrylate ($r_S \sim r_{MMA} \sim 0.5$) (130,131).

Monomer Structure and Reactivity: Electronic and Entropic Effects. The absolute value of the propagation rate coefficient is governed by the nature of the monomer unit and the reactivity of the propagating radical. Both entropic and electronic factors influence the absolute value of the propagation rate coefficient and its activation parameters, E_A and A. It is important to note that the reactivity of the propagating radical and the reactivity of the monomer units correlate reciprocally. For example, methacrylates are several times more reactive then acrylates but polyacrylate radicals are significantly more reactive than poly(methacrylate) radicals. For polymerization and chain growth to take place, it is mandatory that the free macroradical lives long enough to survive the above-mentioned 10^9 ineffective collisions. The addition of the monomer in a propagation reaction has to take place before any possible decomposition reaction or other side reaction. For example, acetone cannot be polymerized at ambient reaction conditions—besides thermodynamic reasons, which make the polymerization unfavorable, because the associated free radicals quickly decompose into methyl free radicals and a ketone.

The substituent that is introduced into the ethene molecule to facilitate polymerization via activation of the double bond and stabilization of the propagating radical, respectively, has also the effect of adding steric hindrance to the propagation step. A mechanistic model has been proposed for the propagation of sterically hindered monomers (132). In such a model the propagating radical and the monomer attain the maximum overlap of the π-electrons and the unpaired electron at a certain angle between the C_α—C_β bonds of the monomer and the



Scheme 7.

propagating radical. If the propagation reaction is sterically hindered, the bond formation is energetically not suppressed, but the probability that the radical and the monomer approach each other such that bond formation can occur is decreased. It is thus evident that it is close to impossible to completely separate enthalpic from entropic effects.

An attempt to separate individual contributions using different monomers is illustrated in Scheme 7. While electronic effects should be reflected in the activation energy E_A, steric effects are associated with the preexponential factor A. When going from methyl methacrylate to dimethyl itaconate (133), a substantial decrease in the preexponential factor of about one order of magnitude is observed (r.h.s. of Scheme 7). This decrease is due to the sterically more demanding nature of the propagating dimethyl itaconate radical. When going from methyl methacrylate to ethyl α-hydroxy methacrylate (EHMA), the preexponential factor remains unchanged, but the activation energy is reduced due to the electronic effect of the additional β-oxygen atom (l.h.s. of Scheme 7). Both effects may be combined in one monomer (ethyl α-acetoxymethacrylate, EAMA, bottom of Scheme 7), with a resulting decrease in the activation energy and the preexponential factor.

This illustrates the effect of different contributions (ie steric and electronic) to the activation parameters using different monomers.

Table 1. Activation Parameters for the Propagation Step for Various Monomers, Obtained via PLP–SEC[a]

Monomer	E_A, kJ · mol^{-1}	A, L · mol^{-1} · s^{-1}	k_p at 60°C, L · mol^{-1} · s^{-1}
Methyl methacrylate	22.3	2.65×10^6	833
Ethyl methacrylate	23.4	4.07×10^6	873
Butyl methacrylate	22.9	3.80×10^6	976
Isodecyl methacrylate	20.8	2.19×10^6	1,590
Dodecyl methacrylate	21.0	2.51×10^6	1,280
2-Ethylhexyl methacrylate	20.4	1.87×10^6	1,190
Cyclohexyl methacrylate	22.3	4.88×10^6	1,560
Glycidyl methacrylate	21.9	4.41×10^6	1,620
Hydroxyethyl methacrylate	21.9	8.89×10^6	3,270
Hydroxypropyl methacrylate	20.8	3.51×10^6	1,900
Isobornyl methacrylate	22.5	4.28×10^6	1,290
3-[Tris(trimethylsilyloxy)silyl]propyl methacrylate[b]	19.9	1.44×10^6	1,092
Dimethyl itaconate[c]	24.9	2.20×10^5	27
Dicyclohexyl itaconate[d]	22.0	1.74×10^4	6
Methyl acrylate[e]	13.9	3.61×10^6	24,000
Butyl acrylate	17.4	1.8×10^7	33,700
Dodecyl acrylate[e]	15.8	1.09×10^7	36,400
Styrene	32.5	4.27×10^7	341
p-CH_3-Styrene	32.4	2.84×10^7	236
p-Cl-Styrene	32.1	4.48×10^7	415
p-F-Styrene	32.0	3.50×10^7	336
Vinyl acetate	20.4	1.49×10^7	9,460

[e] Experiments carried out at 10 MPa (100 bar).

The propagation rate coefficients of similar monomers are also similar, which allows them to be arranged in groups or families. This is the case for structurally similar monomers such as acrylates or methacrylates. The homologous series of acrylates with increasing ester groups, such as methyl, ethyl, butyl, and dodecyl acrylate, have approximately the same k_p value as do the corresponding methacrylate systems. The propagation rate coefficients and Arrhenius parameters [determined via the pulsed laser polymerization–size exclusion chromatography (PLP–SEC) method] for these and additional monomers are given in Table 1 (data taken from References 134 and 137).

The propagation rate coefficient for most monomers is pressure dependent with negative activation volumes; ie, an increase in pressure leads to an increased k_p value. Typical activation volumes $\Delta V^{\#}$ (cm^3 · mol^{-1}) for the propagation step for some common monomers are as follows: −11.7 (methyl acrylate) (138), −11.7 (dodecyl acrylate) (138), −16.7 (methyl methacrylate) (139), −16.0 (butyl methacrylate) (140), and −16.5 (dodecyl methacrylate) (140).

It should be noted that the termination rate coefficient is unexpectedly decreasing with increasing pressure, owing to viscosity effects. The opposite behavior of k_p and k_t with respect to an increase in pressure results in markedly increased overall polymerization rates at higher reaction pressures.

Effect of the Reaction Medium. Since the transition state in propagation is relatively nonpolar and the propagation reaction is chemically controlled (up to high monomer conversions of ~80%), there is weak solvent influence on the propagation rate coefficients. Extensive studies have been carried out, which mainly confirm this small influence of the solvent on the propagation rate coefficient (141–143). Larger effects in solvents have only been observed for specific monomers, eg, EHMA (144), vinyl acetate (145), vinyl benzoate (146), or specific solvents like supercritical CO_2 (147–151). Furthermore, the k_p values for the polymerizations of methacrylic acid and acrylic acid in water are significantly affected by the monomer concentrations (152–154). In the case of the solvent effects on EHMA, where k_p falls between 580 $L \cdot mol^{-1} \cdot s^{-1}$ (tetrahydrofuran) and 1860 $L \cdot mol^{-1} \cdot s^{-1}$ (xylene), it was proposed that the solvent is playing a specific role in the transition state of the reaction by possibly affecting the geometry of the transition state via specific interactions. This suspicion is underpinned by the observation that the solvent also affects both the activation energy and the preexponential factor. However, it should always be kept in mind that any existing technique to assess the propagation rate coefficient is only capable of measuring the product of k_p and the monomer concentration. Results obtained from free radical polymerizations carried out in supercritical CO_2 suggest that the actual monomer concentration at the reaction site is somewhat different from the solution concentration; ie, a structuring of the solution occurs. Since at present there is no methodology to separate the propagation rate coefficient from the monomer concentration, these interpretations are somewhat speculative.

Effects of solvents on the tacticity of the generated polymeric material have been reported (155). When fluoroalcohols were used as solvents, the stereochemistry of the polymerizations of some vinyl esters was affected to varying extents, depending on the structure of the acyl group of the monomer (156–159).

It has been shown that for conversion exceeding 80%, the propagation reaction becomes diffusion controlled, which leads to a marked decrease of k_p. For example, in the case of the bulk free radical polymerization of methyl methacrylate, both the propagation rate coefficient and the initiator efficiency decrease significantly at high monomer conversion in a highly viscous regime (160–162). However, exact measurements in this highly viscous reaction regime are extremely difficult to carry out and thus reliable data are scarce.

Transfer

The measured average molecular weights, eg, obtained from molecular weight distributions, of macromolecules generated by free radical polymerization processes are often lower than those predicted by accounting for initiation, propagation, and termination processes. This experimental observation can be attributed to chain stopping events via chain transfer reactions (163,164). The transfer reaction can be described via equations 22 and 23.

$$R_i^{\bullet} + T{-}X \xrightarrow{k_{tr}} P_i{-}X + T^{\bullet} \quad (22)$$

$$T^{\bullet} + M \xrightarrow{k_i} R_1^{\bullet} \quad (23)$$

The propagating macroradical of chain length i, R_i, abstracts a weakly bonded atom X (eg, a hydrogen or halogen atom) from the transfer agent TX. A dead polymer chain with X attached to the end group is generated, as well as a new small free radical ($T^{\bullet}$), which can in turn react with a monomer unit. The transfer agent may be the monomer itself, the initiator, the solvent, or any other deliberately added transfer agent. The transfer reaction does not change the free radical concentration—at least in its ideal form—but transfers the radical center from one end of the growing polymer chain to another molecule. The overall rate of polymerization hence remains unchanged. The kinetic chain length, which describes the amount of monomer units that are polymerized by one radical during its lifetime between initiation and termination, remains unaltered. However, the transfer process relocates the radical center from one molecule to another and enables the radical site to polymerize more than one molecule to completion. Hence, the actual physical chain length, ie the degree of polymerization, of the produced polymer is reduced and concomitantly the number of polymer molecules increases (see Figure 2).

The decrease in the degree of polymerization should not be confused with the effect of a decrease of monomer concentrations and increase of initiator concentration, which also leads to an effective reduction of the kinetic chain length. It should be noted that an increase in the initiator concentration is always associated with a considerable increase in the rate of polymerization according to equation 56, which may lead to a loss over the control of the polymerization.

The fragments of the chain transfer agent (T and X) are incorporated into the polymer chain as end groups instead of the end groups otherwise resulting from the initiation and termination process. A transfer reaction can therefore be used to introduce specific end groups into the polymeric material. This technique is however limited by the fact that the degree of polymerization is strongly decreased

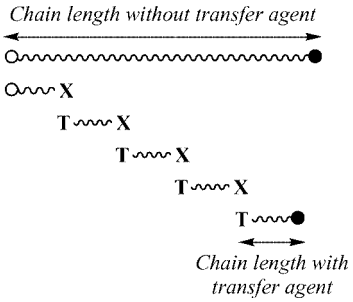

Fig. 2. Schematic description of chain transfer: ○ denotes the initiator-derived end group, ● denotes the end group generated by the termination process. Additional transfer-agent-derived end groups (T and X) are incorporated into the polymeric material by the transfer mechanism and the chain length of the polymer is reduced.

when using a transfer agent and that an efficiency of 100% regarding the end group introduction can never be achieved—even with very effectively transferring compounds—because the bimolecular termination reaction is always present in free radical polymerization.

The chain transfer reaction is mainly used in industrial processes to effectively reduce the molecular weight of the generated polymer. This procedure prevents the significant increase of the viscosity, which is related to the weight-average degree of polymerization. This facilitates the heat transfer inside the reactor and the processing of the final polymeric material. It should be kept in mind that conventional chain transfer agents are consumed according to equations 22 and 23 during the reaction. However, there are catalytic chain transfer agents based on transition metal complexes [eg, Co(II)] that are capable of effectively transferring the radical center without being consumed. Such agents were discovered in the late 1970s and are now commonly used in industrial applications (see below).

The rate of the transfer reaction is described by the consumption of the transfer agent TX, expressed by the following equation:

$$-\frac{\mathrm{d[TX]}}{\mathrm{d}t} = k_{\mathrm{tr}}[\mathrm{R}^{\bullet}][\mathrm{TX}] \tag{24}$$

where k_{tr} is the transfer rate coefficient, [TX] is the concentration of the transfer agent, and [$\mathrm{R}^{\bullet}$] is the free radical concentration. The transfer rate coefficient is often reported as a ratio with the propagation rate coefficient k_{p}. The resulting quantity is called the transfer coefficient, C:

$$C = \frac{k_{\mathrm{tr}}}{k_{\mathrm{p}}} \tag{25}$$

The transfer coefficient C is, in principle, not constant, since it is dependent on the same external parameters as the propagation rate coefficient (ie chain length, temperature, pressure, etc). However, C is also often denoted the chain transfer constant. The chain transfer coefficient C describes the effectiveness of the transferring compound to reduce the degree of polymerization. Its value depends on structural features of the attacking radical and the transfer agent. A chain transfer coefficient of one has been called optimal, because the transfer agent/monomer ratio will remain constant throughout the polymerization (165). The degree of polymerization therefore stays constant up to high conversions and the polydispersity of the product remains at the theoretical value of close to 2. If $C \gg 1$, the transfer agent will be consumed rapidly during the polymerization and the molecular weight will increase with conversion. A small value of the transfer coefficient ($C \ll 1$), on the other hand, will lead to a decrease of the molecular weight, accordingly. In both cases, a broadening of the molecular weight distribution with conversion occurs.

The ideal chain transfer reaction does not alter the overall rate of polymerization, R_{p}. However, if the chain transfer reaction has a measurable effect on R_{p}, this rate depends on the size of the propagation, reinitiation, and transfer rate coefficients. That is, the free radical which is newly formed by the transfer

step is not always of the equal activity to that which is lost. Four cases can be distinguished:

(1) $k_p \gg k_{tr}$ and $k_{ri} \approx k_p$ leads to 'ideal' chain transfer, decreasing molecular weights, and no measurable effect on R_p.
(2) $k_p \ll k_{tr}$ and $k_{ri} \approx k_p$ leads to telomerization (166), a large decreasing effect on molecular weights, and no measurable effect on R_p.
(3) $k_p \gg k_{tr}$ and $k_{ri} < k_p$ leads to retardation (167), a decrease in molecular weights, and a decrease in R_p.
(4) Finally, $k_p \ll k_{tr}$ and $k_{ri} < k_p$ results in degradative chain transfer (168), a large decrease in molecular weights, and a large decrease in R_p.

It can thus be easily inferred that chain transfer may alter the properties of the polymeric product in an undesirable way, or—in contrast—may be used advantageously to specifically reduce the molecular weights obtained in a specific polymerization process or to introduce specific end groups. The first case discussed above (which refers to the kinetic concept of chain transfer) is assumed for the derivation of the Mayo equation, which is frequently used to derive chain transfer rate coefficients. This specific case does not alter the overall rate of the polymerization system, because it does not change the overall free radical concentration, but rather influences the molecular weight distribution.

There are at least two basic mechanisms for chain transfer: (*1*) atom or group transfer and (*2*) addition–fragmentation (169). The two mechanisms differ mainly in the nature of the intermediate that is formed by the two participating molecules. The atom transfer mechanism—the most common mechanism—proceeds via an S–2 mechanism (substitution, homolytic, bimolecular) as depicted in equation 26.

$$R_i^{\cdot} + X{-}Y \longrightarrow \left[R_i \cdots X \cdots Y\right]^{\cdot \ddagger} \longrightarrow R_i{-}X + Y^{\cdot} \tag{26}$$

The intermediate of this reaction is identical with the activated complex at the transition state (170), and hence is destabilized and immediately decomposes into the final products (see Figure 3**a**).

Tedder (171) suggested guidelines to predict qualitatively the rate and outcome of radical transfer processes:

(1) When there is little polarity in the transition state, the relative rates of the atom transfer by a specific radical will correlate with the strengths of the bonds being broken.
(2) The strength of the bond being formed is important for the absolute rate of the transfer event.
(3) The steric strain released or incurred when going from the reactants to the products is especially important for endothermic or thermoneutral reactions.
(4) Nucleophilic radicals will preferably attack electron-rich sites, and electrophilic radicals will attack electron-poor sites. For example, transfer coefficient for nucleophilic trialkylamine with partially positively charged

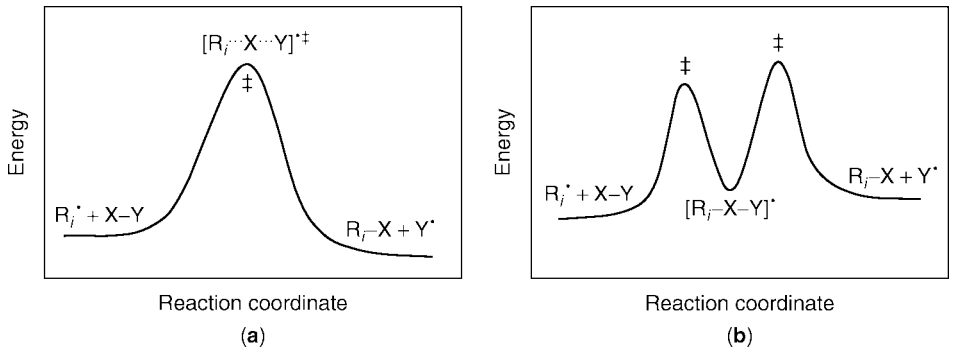

Fig. 3. Schematic representations of the energy profile along the reaction coordinate for (**a**), atom or group transfer and (**b**) addition–fragmentation transfer.

β-hydrogens is over 1000 times higher with electrophilic polyacrylonitrile and polyacrylate radicals rather than with polystyrene radicals. On the other hand, in dimethyl formamide, the electrophilic $FeCl_3$ with partially negatively charged Cl atoms transfers 15 times faster with nucleophilic polystyrene radicals than with polyacrylonitrile radicals (172).

The addition–fragmentation mechanism, on the other hand, proceeds via the formation of a relatively stable intermediate, as depicted in equations 27 and 28, with k_β being the rate coefficient of the addition reaction and $k_{-\beta}$ the rate coefficient of the fragmentation. The corresponding energy profile along the reaction coordinate is outlined in Figure 3**b**. The absolute depth of the sink may vary according to the stability of the intermediate. The reactivity of the transfer agent, toward the propagating species and the properties of the intermediate radical—especially its stability—are both important to characterize the overall transfer reaction. If the fragmentation rate coefficient is small, ie the intermediate exhibits a significant lifetime, it is possible that it reacts via different pathway other than fragmentation. Depending on the structure of the intermediate radical, reversible and irreversible bimolecular termination reactions may occur, leading to inhibition and/or retardation. If the intermediate radical adds on to monomer, ie initiates polymerization, the compound is not a transfer agent, but rather a comonomer and a branching agent.

$$R_i^{\bullet} + X{-}Y \xrightarrow{k_\beta} [R_i{-}X{-}Y]^{\bullet} \tag{27}$$

$$[R_i{-}X{-}Y]^{\bullet} \xrightarrow{k_{-\beta}} R_i{-}X + Y^{\bullet} \tag{28}$$

Transfer to Monomer. The only transfer reaction that cannot be avoided is transfer to monomer. Thus, the maximum molecular weight that can be reached under a given set of reaction conditions is limited by the transfer-to-monomer reaction, assuming the absence of all other transfer events. Fortunately, the transfer-to-monomer rate coefficients in free radical polymerization are usually

rather low, approximately between 3×10^{-5} and 20×10^{-5} $L \cdot mol^{-1} \cdot s^{-1}$. It is important to be aware that the transfer-to-monomer reaction cannot be suppressed by a decrease in monomer concentration, because the number-average degree of polymerization is independent of the monomer concentration for the transfer-to-monomer step. This is, because the transfer-to-monomer effect is governed by the ratio of the transfer rate to propagation rate and both the denominator and numerator of this ratio contain the monomer concentration, which consequently cancels out. (This is illustrated in eq. 91). However, the activation energies for propagation and transfer to monomer differ for most of the common monomers. Thus, a decrease in the temperature normally lowers the monomer transfer coefficient C_M. Table 2 gives the transfer-to-monomer constants C_M for some common monomers.

Table 2. Transfer Coefficients to-Monomers, C_M, at 60°C[a]

Monomer	T,°C	C_M (10^{-5})
Acrylamide	60	6.0[b]
Acrylonitrile	60	3.3–10.2[c]
1-Butene	60	73

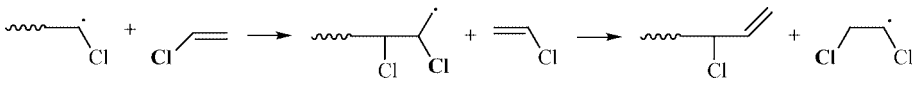
The transfer-to-monomer reaction mostly proceeds via an abstraction of a hydrogen atom; however, it is often not clear which hydrogen is involved. This abstraction mechanism is reasonable for monomers with aliphatic hydrogens (eg, methyl methacrylate, vinyl acetate), but different mechanisms seem to be operational when only vinylic and/or aromatic hydrogens are present. The transfer to monomer in the free radical ethylene polymerization, for instance, also involves hydrogen atom transfer from the radical to the monomer (182). Although this hydrogen transfer (see eq. 29), is thermoneutral—reactants and products are the same—it is disfavored—due to the high strength of the vinylic hydrogen–carbon bond that has to be broken—over the endothermic hydrogen abstraction reaction depicted in equation 30.

$$CH_3{-}CH_2^{\bullet} + CH_2{=}CH_2 \rightarrow CH_2{=}CH_2 + CH_3{-}CH_2^{\bullet} \quad (29)$$

$$CH_3{-}CH_2^{\bullet} + CH_2{=}CH_2 \rightarrow CH_3{-}CH_3 + CH_2{=}CH^{\bullet} \quad (30)$$

The transfer to styrene monomer is unlikely to proceed via a direct hydrogen abstraction, because the chain transfer coefficient is higher than that of ethylbenzene with its weaker bound hydrogen atoms. The transfer step rather involves the abstraction of a weakly bound hydrogen of the Diels–Alder adduct (see eq. 14), formed by two styrene molecules (183).

The chain transfer to vinyl chloride monomer involves a chlorine atom transfer reaction, following a head-to-head addition of a monomer molecule to the growing macroradical (184–186). The head-to-head addition leads to a highly unstable radical that stabilizes itself via a chlorine abstraction. This reaction pathway (eq. 31) accounts for C_M being much greater than for other commercially important monomers.



(31)

Allylic compounds ($CH_2{=}CHCH_2X$) are usually reluctant to undergo homopolymerization, because of the activation of the allylic hydrogen atom toward abstraction. The generated allylic radical is highly stabilized both by the substituent X and by delocalization of the free electrons into the double bond. These radicals add to monomer very slowly and perform side reactions that in turn lead to retardation.

Transfer to Initiator. In most polymerization systems the transfer reaction to the initiator is also unavoidable. However, this form of chain transfer is to some extent controllable via the choice of the employed initiator. In addition, the effects on the overall polymerization kinetics and on the molecular weight distribution are small if low concentrations of initiator are employed. Typical transfer-to-initiator constants C_I are presented in Table 3.

A special case of chain transfer to initiator is the reaction involving thiurams. The photosensitizers tetraalkylthiuram disulfides can either be cleaved

Table 3. Transfer Coefficients to Initiators, C_I, at 60°C[a]

	C_I

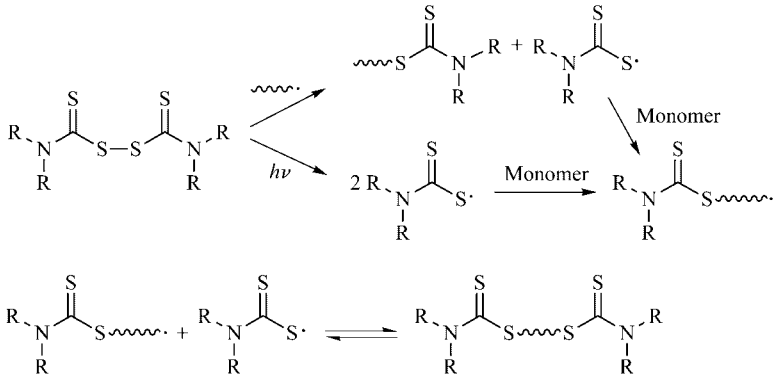
photochemically to initiate polymerization or exhibit a transfer reaction via group abstraction with another macroradical, as depicted in Scheme 8. The resulting thiyl radical can either initiate macromolecular growth or terminate a growing chain to give a polymer chain with $R_2NC(S)S-$ groups at both ends (193,194). Under the photoirradiating conditions this termination reaction is reversible, leading to an equilibrium of propagating and dormant radicals. This equilibrium can effectively reduce the free radical concentration and hence bimolecular termination reactions. The tetraalkylthiuram disulfides are known as *iniferters* (195,196) and they function as initiator, transfer agent, and terminator simultaneously.

Transfer to Transfer Agents and Solvents. In contrast to transfer to monomer and initiator, the transfer to a solvent molecule is of considerable importance, because solvents are used in high concentrations in most industrial



Scheme 8.

polymerization processes. Many organic solvents exhibit transfer coefficients similar to those found for common monomers and their significant transfer effect can be largely attributed to their usage in high concentrations. There are a few solvents that show significantly higher transfer coefficients, such as carbon tetrachloride. In the case when the transfer coefficient of a solvent is too high, it may not be used as a solvent but rather as a modifier, ie a 'conventional' chain transfer agent. Chain transfer agents with chain transfer coefficients greater than one are very useful, as they can be employed in low concentrations. Every solvent that contains abstractable hydrogen atoms is capable of acting as a chain transfer agent. However, most of the common solvents show only minor transfer activity as can be seen in Table 4. The transfer reaction is strongly dependent on the nature of the propagating radical. The very reactive vinyl acetate radical, for example, has a much higher tendency to transfer than the relatively low reactive methyl methacrylate radical. However, many transfer agents exhibit significant retardation when used in vinyl acetate polymerization (203). The factors influencing the reactivity in hydrogen atom abstraction reactions are discussed above in general terms. The transfer of aromatic compounds may involve the addition of the growing radical to the aromatic system, generating a cyclohexadienyl radical adduct, which in turn may restore its aromaticity via the transfer of a hydrogen to another macroradical. A solvent can also be deliberately used to introduce specific end groups into the polymeric chain if its transfer coefficient for the specific system is moderate. The compound then serves as both solvent and transfer agent, and side reactions may hence be suppressed (204).

Thiols. There are various thiols (R—SH) that are used as chain transfer agents and they are employed in many different free radical polymerization processes (205). A considerable disadvantage of these transfer agents is their often very unpleasant odor. The general transfer process of these compounds is depicted in equations 32 and 33.

(32)

(33)

The vast majority of the generated polymeric material possesses a thioether end group. The chain transfer coefficients of some thiols in styrene and methyl methacrylate polymerizations are given in Table 4. It should be noted that the value of the chain transfer coefficient is dependent on the polymerization system, ie monomer, temperature, pressure, etc. However, the tabulated values are guidelines for the transfer ability of the transfer agents in other monomer systems. A number of functional thiols have been used to prepare end-functional polymeric material. These were used as starting materials for block (206,207) and graft (208) copolymers for the application as emulsifier, thermoplastic elastomers, compatibilizer, and adhesives. Thiols react more rapidly with nucleophilic than electrophilic radicals. Hence, thiols have a greater transfer coefficient with styrene and vinyl esters than with acrylates and methacrylates. Aromatic thiols have a higher transfer ability; however, they exhibit more retardation. The thiyl

radical produced by the transfer reaction of a thiol is electrophilic and, when used in copolymerizations, will more likely react with electron-rich monomers.

A wide range of functional thiols, eg, mercaptoethanol ($OHCH_2CH_2SH$) and thioglycolic acid ($OH(CO)CH_2SH$), have been used to produce monofunctional polymers (165,209,210).

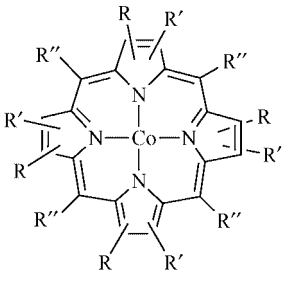
Sulfides. A wide range of various disulfides have been employed as chain transfer agents: dialkyl disulfides (211), diaryl disulfides (212,213), diaroyl disulfides (214), and xanthogens (215). The reaction of these compounds leads to the incorporation of sulfur-containing end groups at both ends of the polymer, as shown in equations 34 and 35. They therefore have found some applications in the preparation of telechelic polymers.

(34)

(35)

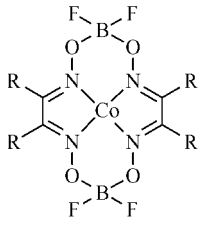
The transfer coefficients of disulfides are extremely low for styrene and methyl methacrylate (see Table 4), but are close to one for the vinyl acetate polymerization. In general the xanthogens and thiurams have higher chain transfer ability, which has been attributed to the iniferter mechanism described above. Monosulfides have lower transfer coefficients in comparison to disulfides. This may reflect steric factors and the relative strength of the C—S bond, which is significantly stronger than the S—S bond.

Catalytic Chain Transfer. A highly useful variant of chain transfer was discovered in the 1970–1980s in the Soviet Union (216). A number of reviews have been published in recent years (217–221) on this synthetic method which has acquired the nomenclature of either catalytic chain transfer (CCT) or special chain transfer (SCT). The most commonly adopted catalysts are based on low spin cobalt macrocycles, although other metal-containing complexes have also been suggested in the patent and scientific literature. Some typical catalyst structures are shown as **12** and **13**.



Cobalt(II)Porphyrins

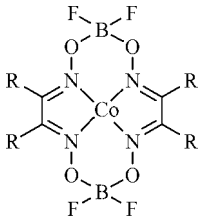
12



Cobaloximes

13

Some of the highest chain transfer constants ever measured have been reported for COBF (**14**), as shown below:

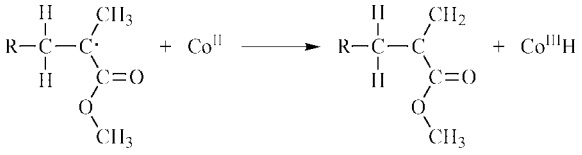


COBF: R = Methyl
COPhBF: R = Phenyl

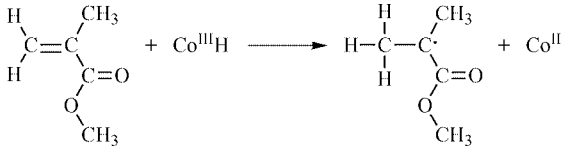
14

Monomer	C_s (10^{-3}) at 60°C
Methyl methacrylate	28.1 (222)
tert-Butyl methacrylate	15.1 (222)
Dimethyl itaconate	9.5 (222)
Styrene	9.0 (223)

These high transfer values would only be of curiosity value for synthetic purposes if a conventional chain transfer mechanism was operative. However, these cobalt complexes appear to catalyze transfer to monomer and they do not get incorporated into the polymer chains, nor do they get consumed in the transfer reaction. A catalytic cycle involving methyl methacrylate as the monomer is thought to be a good representation of the mechanism. The cobalt complex abstracts a β-hydrogen from a growing radical (creating terminal unsaturation) and a cobalt hydride, which then reinitiates a monomer unit via hydrogen-atom addition or insertion into the double bond (eqs. 36 and 37).



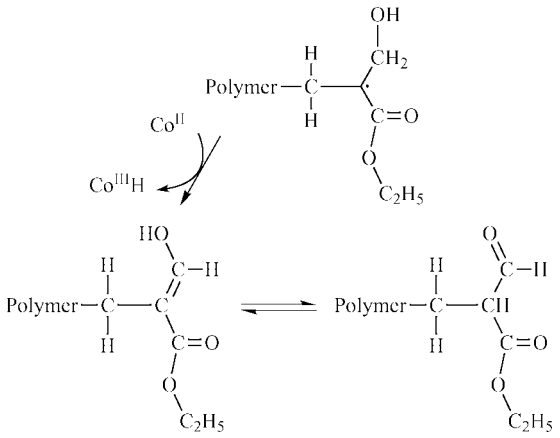
(36)



(37)

An interesting variation of this reaction (224,225), termed *catalytic chain transfer isomerization*, has been described whereby transfer occurs from a radical with a β-CH_2OH group, as shown in Scheme 9. A keto–enol isomerization occurs and an aldehyde end group results.

Catalytic chain transfer is most efficient for tertiary propagating radicals such as methyl methacrylate. When secondary radicals are involved, such as



Scheme 9.

acrylates or styrene, the efficiency of the reaction is diminished. It is now thought that this is primarily caused by cobalt–carbon bonding acting as a significant side-reaction, effectively removing some active catalyst from the reacting system (226). This cobalt–carbon bonding has been observed directly in methyl acrylate polymerization using MALDI (227) (see MASS SPECTROMETRY).

There remains some minor unsolved mechanistic mysteries in the CCT reaction. The rate constant for transfer in methacrylates is similar to those for radical–radical termination reactions; these are known to be diffusion controlled. This has lead to speculation that the CCT reaction is also diffusion controlled (229) and there is some evidence to support this. However, this evidence is not absolute and the most prudent analysis is that the CCT reaction of methacrylates falls in a regime where both features of diffusion and chemical control can be observed dependent on the reaction conditions. Hopefully further experimental work will allow clarification of this situation.

The CCT reaction has attained commercial utility as it is ideal for synthesizing low molecular weight polymers with terminal unsaturation. The resultant macromonomers can be used as either chain transfer agents (useful for making block structures) or polymerizable monomers, useful in the synthesis of comb- and star-type molecules. The reaction is tolerant of many functionalities and of water, making it amenable to emulsion reactions.

Alkyl Halides. Transfer to alkyl halides depends on structures of both alkyl group and halogen, but also on the polymeric radicals. Thus, nucleophilic radicals (styrene) react faster with alkyl halides than electrophilic radicals (acrylates). Hence, the C values with styrene and vinyl acetate are higher than those with acrylic monomers.

The halogen abstraction ability decreases according to I > Br > Cl. For example, in styrene polymerization, transfer coefficient for iodoacetates is $C = 0.8$, for bromoacetates $C = 0.043$, but only $C = 0.0001$ for chloroacetates. The C value increases with number of halogens, for example for dibromoacetates $C = 0.27$ and $C > 10$ for tribromoacetates. Among the most often use alkyl halides are halomethanes and aforementioned halogenated esters. Both of them—including

chloroform, carbon tetrachloride, carbon tetrabromide, bromotrichloromethane—have widely been used in the preparation of telomers. The application of effective transfer agents in very high concentrations leads to so-called telomerization, ie the exclusive formation of oligomeric (dimeric, trimeric, etc) species. The kinetics of such telomerization is far from simple, because of the disparate radical reactivities displayed by the very short—halogen-substituted—radicals involved: The shorter radicals show a smaller reactivity toward propagation and transfer reactions than do the longer ones. In the case of carbon tetrachloride mediated polymerizations, this has been attributed to the stabilizing effect of the CCl_3 end group (229–231). The chain length dependence of the chain transfer coefficient most likely reflects a variation of both k_p and k_{tr} with the length of the macroradical. However, common techniques for the determination of C do not allow for the separation of such effects.

The perhalomethanes react in the chain transfer process (as shown in eq. 38) to give a perhaloalkyl radical, which in turn is capable of initiating the polymerization.

(38)

With hydrohalomethanes, two pathways for the transfer step may be envisaged: halogen- or hydrogen-atom abstraction. For chloroform the hydrogen transfer is favored because of the relative bond strengths, especially for electrophilic radicals.

Very fast transfer which results in the inhibition occurs with transition metal halides such as $FeCl_3$ and $CuCl_2$. In dimethyl formamide at 60°C transfer coefficients for $CuCl_2$ decrease in the order, styrene ($C = 10{,}000$) > MMA ($C = 2000$) > acrylonitrile ($C = 100$). $FeCl_3$ is less efficient transfer agent and C values decrease in the following order: vinyl acetate ($C = 626$) > styrene ($C = 536$) > vinyl chloride ($C = 85$) > MMA ($C = 4$) and acrylonitrile ($C = 2$) (232). Ligands which solubilize transition metal halides provide additional possibility for tuning transfer coefficients. Moreover, the resulting lower oxidation state transition metal compounds can activate the alkyl halides, resulting from the transfer process. Such a reversible activation/deactivation is used for ATRP.

Atom Transfer Radical Polymerization. ATRP is one of the most successful controlled/living radical polymerization (CRP) systems, in addition to NMP and degenerative transfer processes, such as RAFT (5,233,234). The key feature of all of them is the dynamic equilibration between the active radicals and various types of dormant species (see LIVING RADICAL POLYMERIZATION).

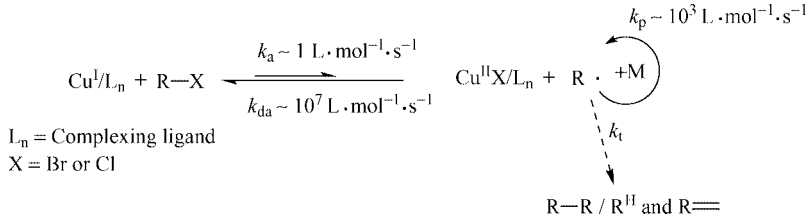
Mechanistically, these systems are quite similar to conventional radical polymerizations. Polymeric radicals grow and terminate with similar rate constants. The main difference is how the radicals are generated. They are generated slowly and irreversibly in the conventional processes through dissociation of peroxides or diazo compounds which typically have a half-life in the range of 10 h. Propagation is rapid with an approximate frequency of monomer addition of ∼1 ms. This means that within 1 s, a polymer chain with the chain length P ∼ 1000 is typically formed. Within approximately the same time, chains terminate by either

coupling or disproportionation. During such a short time, it is not possible to perform any kind of macromolecular engineering by adding another monomer, functionalizing reagent, etc. In controlled/living reactions, however, the radical formation is reversible. Similar values for the equilibrium constants during initiation and propagation ensure that the initiator is consumed at the early stages of the polymerization, generating chains which slowly and continuously grow, as in a living process. Perhaps the most important difference between the two approaches is the lifetime of the propagating chains, which is extended from ~1 s to more than 1 h. The second major difference is the dramatic increase in the initiation rate, which enables simultaneous growth of all the polymer, chains. Both parameters allow various macromolecular engineering techniques to be applied, such as making well-defined star polymers, block and grafts, end functional polymers, and many other well-defined, materials.

Termination processes cannot be avoided in CRPs. Since termination is a bimolecular process, increasing the polymerization rate increases the concentration of radicals and enhances the termination process. Termination also becomes more significant for longer chains and at higher conversion. However, this process is somehow self-tuned, since termination is chain length dependent. Polymers prepared by CRPs will never have 100% functionality and 100% blocking efficiency. For monomers with low values of rate constants of radical propagation (k_p), such as dienes, styrenes, and methacrylates, it is necessary to slow down the polymerization rate to avoid excessive termination; for those with high k_p value, such as acrylates, this is less important. Since propagating species are free radicals, chemo-, regio-, and stereoselectivities are similar to those found in conventional radical polymerizations. This means that similar reactivity ratios, similar sensitivity to transfer reagents, and similar tacticities are observed.

Each of the controlled/living radical polymerization systems has some limitations and some special advantages, and it is expected that each technique may find special areas where it would be best suited synthetically. For example, NMP carried out in the presence of bulky nitroxides cannot be applied to the polymerization of methacrylates owing to fast β-hydrogen abstraction. ATRP cannot yet be used for the polymerization of acidic monomers, which can protonate the ligands and complex with copper. RAFT is very slow for the synthesis of low molecular weight polymers because of retardation effects, and may provide branching owing to trapping of growing radicals by the intermediate radicals. At the same time, each technique has some special advantages. Terminal alkoxyamines may act as additional stabilizers for some polymers. ATRP enables the synthesis of special block copolymers by utilizing a halogen exchange and has an inexpensive halogen at the chain end. RAFT can be applied to the polymerization of some less reactive monomers, such as vinyl acetate.

A successful ATRP (and any controlled/living radical polymerization process) should meet three requirements: initiator should be consumed at the early stages of polymerization to form polymers with degrees of polymerization predetermined by the ratio of the concentrations of converted monomer to the introduced initiator ($DP = \Delta[M]/[I]_0$); the number of monomer molecules added during one activation step should be small, resulting in polymers with low polydispersities; the contribution of chain breaking reactions (transfer and termination) should be negligible to yield polymers with high degrees of end functionalities, and allow the synthesis



Scheme 10.

of block copolymers. In order to reach these three goals, it is necessary to select appropriate reagents and appropriate reaction conditions.

ATRP is based on the reversible transfer of an atom or group from a dormant polymer chain (R-X) to a transition metal (M_t^n/Ligand) to form a radical ($R^\bullet$), which can initiate the polymerization, and a metal halide whose oxidation state has increased by one (X—M_t^{n+1}/Ligand); the transferred atom or group is covalently bound to the transition metal. A catalytic system employing copper(I) halides (M_t^n/Ligand) complexed with substituted 2,2′-bipyridines (bpy) was successful for polymerization of styrenes, various (meth)acrylates, acrylamides, acrylonitrile, and other monomers (235–238). Other metal centers have been used, such as ruthenium, nickel, iron, and other transition-metal-based systems. Copper salts with various anions and polydentate complexing ligands were used, such as substituted bpys, pyridines, and linear polyamines. The rate constants of the exchange process, propagation and termination shown in Scheme 10 relate to styrene polymerization catalyzed by CuBr/2bpy and initiated by 1-phenylethyl bromide at 110°C.

According to this general ATRP scheme (Scheme 10), the rate of polymerization is given by the following equation:

$$R_p = k_p[M][RX]_0 k_a[Cu^I]/(k_{da}[X—Cu^{II}]) \quad (39)$$

Thus, the rate of polymerization is internally first order in monomer, externally first order with respect to initiator and activator, Cu(I), and negative first order with respect to deactivator, XCu^{II}. However, the kinetics may be more complex because of the formation of XCu^{II} species via the persistent radical effect. The actual kinetics depend on many factors, including the solubility of activator and deactivator, their possible interactions, and variations of their structures and reactivities with concentrations and composition of the reaction medium. It should also be noted that the contribution of persistent radical effect at the initial stages might be affected by the mixing method, solubility of the metal compound and ligand, etc (239–242).

One of the most important parameters in ATRP is the dynamics of exchange, and especially the relative rate of deactivation. If the deactivation process is slow in comparison with propagation, then a classic redox initiation process operates, leading to conventional, and not controlled, radical polymerization. Polydispersities in ATRP are defined by the following equation, when the contribution of chain

breaking reactions is small and initiation is complete:

$$M_w/M_n = 1 + \{(k_p[RX]_0)/(k_{da}[X - Cu^{II}])\}(2/p - 1) \quad (40)$$

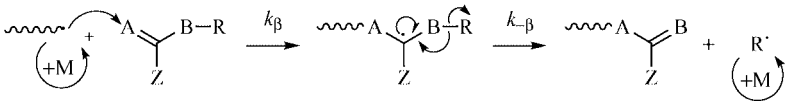
Thus, polydispersities decrease with conversion, p, the rate constant of deactivation, k_{da}, and also the concentration of deactivator, $[XCu^{II}]$. They, however, increase with the propagation rate constant k_p and the concentration of initiator, $[RX]_0$. This means that more uniform polymers are obtained at higher conversions, when the concentration of deactivator in solution is high and the concentration of initiator is low. Also, more uniform polymers are formed when the deactivator is very reactive and monomer propagates slowly (styrene rather than acrylate). Polydispersities can also be expressed as a function of the reaction time t (243):

$$M_w/M_n = 1 + 1/(2k_a[Cu^I]t) \quad (41)$$

The most important benefit of living polymerizations is that they allow preparation of new macromolecules with precisely designed and controlled compositions (homopolymers, random, periodic, block, graft, and gradient copolymers), topologies (linear, star, comb, (hyper)branched, networks, etc), and functionalities placed at different parts of macromolecules or various combinations of these. Some of the possibilities are outlined below (244,245).

The advent of controlled/living radical polymerization enables preparation of many new materials such as well-defined components of coatings (with narrow molecular weight distribution, precisely controlled functionalities, and reduced volatile organic compounds), nonionic surfactants, polar thermoplastic elastomers, entirely water-soluble block copolymers (potentially for crystal engineering), gels and hydrogels, lubricants and additives, surface modifiers, hybrids with natural and inorganic polymers, various biomaterials and electronic materials. Extensive discussion of more detailed aspects, such as the monomers, initiators, catalysts, and media, can be found in Reference 5.

Addition–Fragmentation Chain Transfer. The addition–fragmentation chain transfer process is induced by the addition of a growing radical to a simple organic compound with a reactive double bond. The general structure of the addition–fragmentation chain transfer agents and the transfer process is depicted in equation 42: A is part of the activated double bond, Z is both the activating group for the double bond and the stabilizing group for the intermediate radical, and B and the leaving group R are connected to each other by a weak single bond. The propagating radical adds to the activated double bond with the rate coefficient k_β, and an intermediate radical is formed. This intermediate radical in turn fragments with the rate coefficient $k_{-\beta}$ via generation of a new double bond and a small radical. The success of the transfer process is dependent on three factors: (*1*) the reactivity of the double bond toward radical addition must be similar or higher to that of the polymerizing monomer double bond, (*2*) the leaving ability of the released moiety R must be substantial, and (*3*) the reactivity of the expelled radical $R^\bullet$ toward reinitiation of the polymerization process has to be high (246,247).

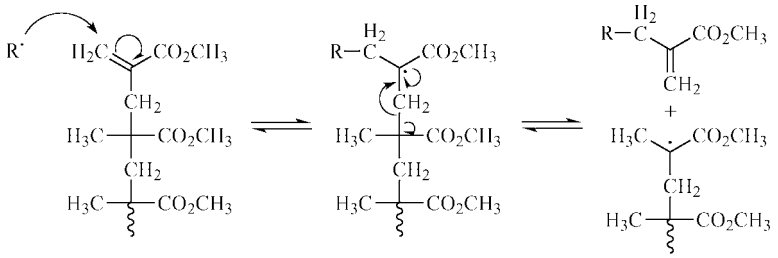


(42)

Several different types of addition–fragmentation chain transfer agents may be envisaged, when considering different types of atoms and/or groups for A, B, Z, and R in the general structure given in equation 42. The first class (A = B = CH_2) represents the allylic compounds, which include the allylic sulfides (R = SR) (248–250), allylic peroxides (R = OOR) (251,252), allylic bromides (R = Br) (248,253,254), allylic sulfones (R = S(O)R) (248,253), allylic phosphonates (R = $P(O)(OR)_2$) (248,253), and allylic stannanes (R = SnR) (248,253). The other two classes are the vinyl ethers (A = CH_2 and B = O) (248,255) and the thiocarbonyl compounds (A = S and B = O) (256,257). R is any good homolytic leaving group and *Z* can be varied to give optimum transfer coefficients. The addition–fragmentation chain transfer coefficients of the various compounds are very high compared to common transfer agents with *C* values in the order of one and above (0.2–20) (246) depending on the structure of the transferring compound and the reacting radical.

The addition–fragmentation chain transfer is a versatile process being applicable to a wide range of monomers (styrene, acrylates, methacrylates) to introduce functionalized end groups (246,258). End functional polymers—the type of end group may be governed by the chosen transfer agent and its different A, B, Z, and R groups—are very useful for building block, graft, and network polymer structures (259–261).

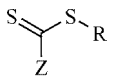
Methyl methacrylate macromonomers act as a chain transfer agent by an addition–fragmentation mechanism as depicted in equation 43. By that, an olefinic group is installed at the end of the polymer chain. These products are themselves macromonomers that can react in the same way during the polymerization. In the acrylate polymerizations these macromonomers are readily copolymerized, hence leading to branching (262). The polymerization of methacrylates in the presence of methacrylate macromonomers will produce new macromonomers, which are in turn participating in the described addition–fragmentation mechanism. This reversible addition–fragmentation process gives rise to living behavior, as described in the next section.



(43)

Reversible Addition–Fragmentation Chain Transfer. The RAFT represents a process for performing living free radical polymerization. Many simple organic compounds possessing a thiocarbonylthio (S=C–S) moiety are employed

as mediating agents which exhibit a great effectiveness and versatility toward controlling the free radical polymerization. The general scheme of these dithio-compounds is depicted as structure **15**. The ability of a RAFT agent to control the polymerization activity is governed by two characteristic groups, the Z and R groups, also denoted as the 'stabilizing' and the 'leaving' group.

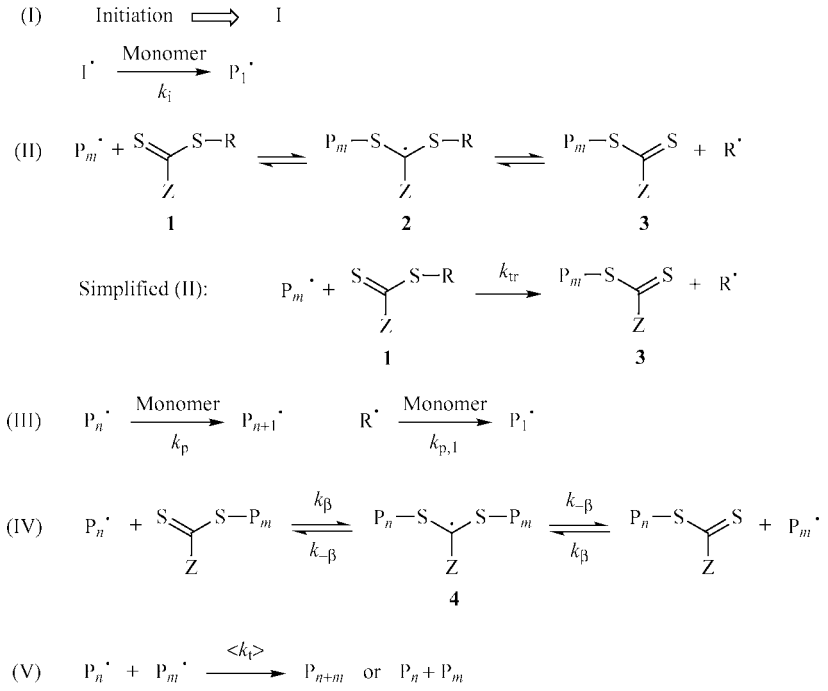


15

Different substituents as Z and R groups lead to a wide array of different RAFT agents: (*1*) dithioesters (Z = phenyl, methyl, etc), (*2*) trithiocarbonates (Z = S—R), (*3*) xanthates (Z = O—R), and (*4*) dithiocarbamates (Z = NR_2). A controlled polymerization involving xanthates is referred to as MADIX (263,264). The RAFT polymerization is performed by adding a chosen quantity of an appropriate RAFT agent to a conventional free radical polymerization mixture. The process yields polymers of predetermined chain length and narrow polydispersity. Polydispersities indices of less than 1.1 can be usually achieved under optimal conditions. The RAFT process generates polymeric material with active thiocarbonylthio end groups, which can be used for chain extensions and/or further chemical reactions, to yield complex polymeric architectures. Polymeric structures ranging from star and comb polymers to block copolymers can be prepared with relative ease for a variety of monomers (265–272).

The mechanism of the living free radical RAFT polymerization with dithio compounds involves two important equilibrium reactions that are superimposed on a conventional free radical polymerization (see Scheme 11). As in conventional free radical polymerization, initiation leads to the formation of propagating chains. In the early stages of the polymerization the macroradicals react with the initial RAFT agent (species 1 in Scheme 11), generating the intermediate radical (species 2 in Scheme 11), followed by the decomposition of these species by formation of polymeric RAFT agent (species 3 in Scheme 11) and the leaving group radical. The first equilibrium reaction may be simplified by an overall transfer step involving the initial RAFT agent as transfer agent. The leaving group radical $R^{\bullet}$ initiates in turn a new polymeric chain with the rate coefficient $k_{p,1}$ by reaction with monomer and leads to macromolecular chain growth of the free radicals with the propagation rate coefficient k_p. The reaction step (IV) constitutes the core of the RAFT process and has been termed the main or core equilibrium. The addition reaction proceeds with a rate coefficient k_β, whereas the formed intermediate—the macro-RAFT radical (species 4 in Scheme 11)—fragments proceed with the rate coefficient $k_{-\beta}$. Finally, the reaction step (V) considers the termination reactions of the linear macroradicals, which proceed with a chain-length-averaged termination rate coefficient $\langle k_t \rangle$.

The equilibrium between the active propagating species ($P_n^{\bullet}$ and $P_m^{\bullet}$) and the dormant polymeric RAFT agent (species 3 in Scheme 11) provides an equal probability for all chains to grow. Because of the reversible nature of the transfer reaction, the transfer agent (ie the polymeric RAFT agent) is not consumed and the active dithio groups are incorporated into the final polymeric material (273). Each



Scheme 11.

RAFT agent molecule is transformed into the end group of one polymer chain. Hence, the final chain lengths of the polymeric material can easily be controlled via varying the ratio of RAFT agent concentration to conversion. It should be noted that the free radical concentration—at least in principle—is not reduced in the RAFT process. Hence, the overall rate of polymerization is unchanged in an ideal RAFT polymerization compared to a conventional free radical polymerization.

A successful RAFT process is, on the one hand, dependent on the effective addition of the growing radical to the RAFT agent compound. On the other hand, the leaving and reinitiating ability of the leaving group also governs the effectiveness of the transfer step. This very effective transfer reaction—which has to be competitive with the propagation step—is illustrated by the large transfer coefficients for the simplified preequilibrium: transfer coefficients of more than 5000 in styrene polymerization can be observed for some dithiobenzoates (274). The transfer step is strongly enhanced when the RAFT agent possesses a well-stabilizing Z group (eg, phenyl). The stabilizing ability of the Z group, however, leads to relatively stable RAFT intermediate radicals, causing rate retardation, that is, a decrease in the overall rate of polymerization up to high conversions with increasing initial RAFT agent concentration. This kinetic phenomenon may be explained either by intermediate radicals with very long lifetimes (275) or by reversible (276–278) and/or irreversible (279) termination of this species. The different leaving abilities of various R groups sometimes affect the preequilibrium and leads to inhibition phenomenon, that is, a time period without any polymerization activity at early

Table 5. Transfer-to-Polymer Constants, C_P[a]

Polymer	T,°C	C_P (10^{-4})
Poly-1,3-butadiene	50	11

Poly(vinyl acetate)	50	0.06–10.2

[a]Data from Ref. 173.

reactions times, dependent in extent on the initial RAFT agent concentration (280).

Transfer to Polymer. At higher monomer conversion, transfer processes to the formed polymer are becoming significant. Interestingly, the transfer-to-polymer rate constants are considerably higher (approximately by a factor of 10) than those observed for the corresponding monomer. Transfer to polymer is resulting in so-called long-chain branching if the reaction takes place intermolecularly (281). In the case of intramolecular transfer to polymer, the reaction is described as 'backbiting,' leading to short-chain branching, as observed in ethylene polymerizations. The length of the branched side chains generated via backbiting is usually smaller than five carbons. Typical values for the transfer-to-polymer constants C_P of some common monomers are collected in Table 5.

Transfer coefficients to polymers are not as readily determined as other transfer coefficients because the process does not necessarily lead to a reduction of the molecular weight. Polymerization in the presence of polymer yields a mixture of the polymer initially present and the new polymer formed, and thus the decrease in the molecular weight cannot be accurately evaluated. However, chain transfer coefficients to polymers are accessible via the structural investigations of the generated branched macromolecules, eg, via NMR (282,283). As NMR measurements of branching rely on the determination of the branching points on the polymeric backbone, a quantitative distinction between long- and short-chain branching is a major analytical problem. The determination of the number of end groups per polymeric chain is another viable technique to quantify the branching of macromolecules (284). For some polymers, the value of C_P depends on the polymer molecular weight. This may account for the wide range of values for C_P in the literature.

Detailed structural analysis of poly(vinyl acetate) has revealed that hydrogen abstraction from the acetyl group is the predominant chain transfer mechanism (285). Abstraction from the methine hydrogen of the main chain leads to a small amount of branching (286,287).

Mid-chain radicals may be formed by intermolecular abstraction of a tertiary hydrogen atom from the polyacrylate main chain. This pathway is favored under the conditions of low monomer and high polymer concentration such as during emulsion polymerization, where the particles consist of large amount of polymer and small amount of polymer (288–290) and at high conversion during solution/bulk polymerization (281). It has been proposed that this process and

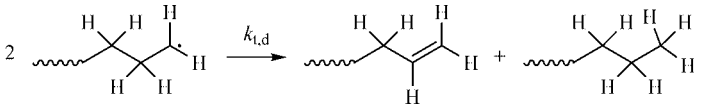
the consequent formation of branches may contribute to the early onset of the gel effect in the polymerization of acrylates.

The presence of long-chain branches in low density polyethylene accounts for the difference in properties (eg, better melt strength, greater toughness) when compared to completely linear polyethylene chains. The long-chain branching can be routinely detected by determining the end group—ie methyl—content of the polyethylene via infrared spectroscopy (291,292). Other studies involve NMR (293–295) and SEC (size exclusion chromatography) (296,297). The extent of long-chain branching is known to be strongly dependent on the reactor design and the reaction conditions employed.

Termination

The radical–radical termination reaction in free radical polymerization is the most complex reaction in the polymerization process (298,299). Its termination rate coefficient k_t is influenced by a multitude of different factors, which are not easily separated. Only within the last 15 years new methods have become available that allow for an accurate measurement of this rate coefficient. The scatter of the termination rate coefficients given in the *Polymer Handbook* (173) reported for the same monomer at the same reaction temperature is a direct manifestation of the influence of these various parameters on k_t. This appreciable disagreement is partly explainable by the frequent use of incorrect values for the propagation rate coefficient k_p, which is always needed to determine k_t from the coupled form of the two coefficients. However, the situation has improved greatly with the invention of the PLP–SEC method.

Combination vs Disproportionation. There are two modes of termination: one is the direct coupling (combination) of two free macroradicals to give a dead polymer chain of chain length $i + j$, with the rate coefficient $k_{t,c}$. The other mode is the so-called disproportionation, where a hydrogen atom is transferred from one of the radical chain ends to another radical, yielding two stabilized polymer chains, of which one carries a double bond. This reaction is associated with the rate coefficient $k_{t,d}$. The process is illustrated in equation 44 using polyethylene macroradicals as the example. It is important to notice that—in the case of macroradicals derived from other monomers—in principle any β-hydrogen may be abstracted.



(44)

The reactions between carbon-centered radicals generally give a mixture of disproportionation and combination. Which termination mode dominates depends largely on the structure of the monomer unit, and to a lesser extent on the reaction temperature, pressure, and solvent (300). Disproportionation is (slightly) favored at higher reaction temperatures. The reasons for this behavior have yet

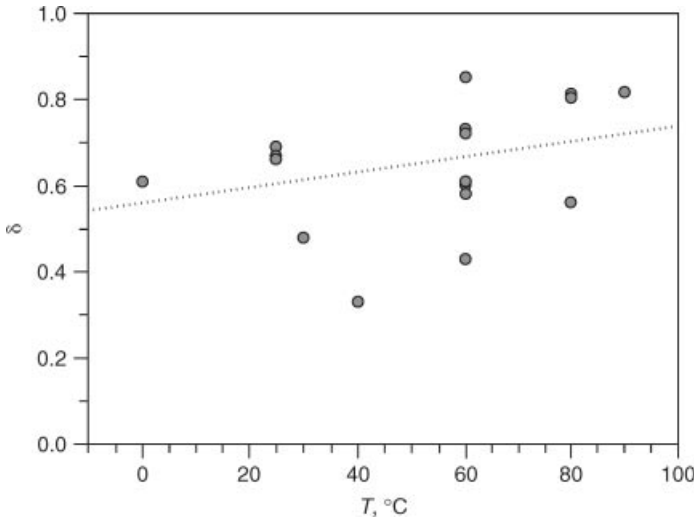


Fig. 4. Temperature dependence of the contribution of disproportionation to the overall termination process, δ, for a methyl methacrylate polymerization at ambient pressure (selected references: Refs. 305–308).

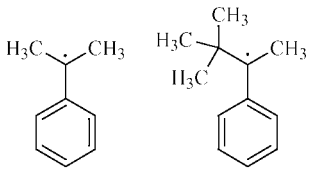
to be clarified, but there is some evidence pointing toward a different temperature dependence of the corresponding preexponential factors in the Arrhenius expression for $k_{t,c}$ and $k_{t,d}$. Combination and disproportionation should be considered as two different reactions with two distinct transition states; this is supported by theoretical studies (301–304). However, the observed effects are small and associated with a large experimental scatter, as indicated in Figure 4, showing the temperature dependence of the contribution of disproportionation to the overall termination process, δ, defined according to equation 45, for a methyl methacrylate polymerization at ambient pressure.

$$\delta = \frac{k_{t,d}}{k_{t,d} + k_{t,c}} \tag{45}$$

For a given series of radicals, δ increases with the number of β-hydrogen atoms. However, there is no direct relationship and it is clear that a number of other factors are involved (300,309). In addition, it is generally observed that the importance of disproportionation increases with increasing substitution at the radical center. Steric effects play a very important role as demonstrated by the self-reaction of cumyl radicals **16** and of the *tert*-butyl-substituted equivalent **17**. The termination reaction of radical **16** shows predominantly combination, whereas radical **17** gives predominantly disproportionation, although there are less β-hydrogen atoms. This finding may imply that the combination reaction is more suppressed by the steric hindrance than the disproportionation reaction. The statistical effect that favors disproportionation when more β-hydrogen atoms are available is hence to be considered less pronounced than the steric effect (310). The steric crowding can lead in extreme cases to persistent radicals

(eg, di-*tert*-butyl methyl radical (311) and triisopropylmethyl radical (312)) that are relatively reluctant to undergo radical–radical reactions.



16 17

The increase of δ with polar solvents is attributed to the fact that the transition state of disproportionation has polar character while that for combination is neutral (304).

It should be noted that the mode of termination has no influence on the kinetics of the free radical polymerization process. However, the generated molecular weight distributions are strongly influenced by the termination mode and it is hence vital to the understanding of structure–property relationships. Since some methods for the determination of the termination rate coefficient rely on the analysis of the full molecular weight distributions, it is mandatory to have reliable data on the termination mode of a specific monomer. In addition, the termination mode governs the end groups of the generated polymer (one initiator derived end group with disproportionation and two with combination). Table 6 gives data on combination–disproportionation modes for various monomers at ambient pressure and various temperatures.

The dead polymer chains generated via disproportionation carry an unsaturated end group which may be reactive during polymerization. Copolymerization of these macromonomers is a possible mechanism for the formation of long-chain

Table 6. Contribution of Disproportionation to the Overall Termination, δ, for Different Monomers

Monomer	T,°C	δ	Reference
Acrylonitirile	10–90	0	313–315
Butyl methacrylate	80	0.54	316

branches (316,324). A comprehensive review of the literature known data on combination vs termination modes for various monomers and model systems can be found in Reference 325. However, unequivocal numbers for α are not yet available for most of the polymerization systems and in most cases there is only a qualitative agreement between different literature values. Despite these discrepancies four different generalizations can be made:

(1) Termination of polymerizations involving vinyl monomers involves predominantly combination.
(2) Termination of polymerizations involving α-methylvinyl monomers always exhibit a significant contribution of disproportionation.
(3) The hydrogen atoms of the α-methyl group are much more prone to abstraction during the disproportionation reaction than the methylene hydrogens.
(4) Within a series of vinyl or α-methylvinyl monomers, δ apparently decreases according to the radical-stabilizing ability of the substituent.

Kinetic Aspects of the Termination Reaction. It is generally accepted that the termination rate coefficient depends on the following factors and experimental parameters: (*1*) the system viscosity, (*2*) the chain length of the terminating free macroradicals, (*3*) the temperature, (*4*) the pressure, and (*5*) the monomer-to-polymer conversion.

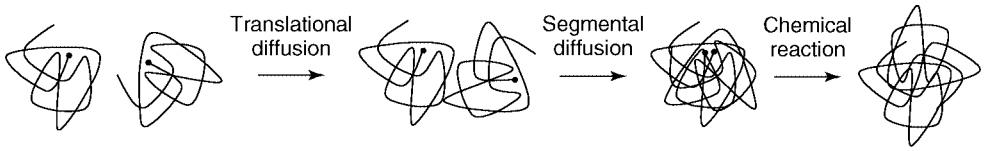
The rate law expression for the termination step that describes the variation of the free radical concentration with time reads (326)

$$-\frac{\mathrm{d}[\mathrm{R}^\bullet]}{\mathrm{d}t} = \sum_i \sum_j 2k_\mathrm{t}^{i,j}[\mathrm{R}_i^\bullet][\mathrm{R}_j^\bullet] \tag{46}$$

The indices i and j indicate the individual chain lengths of the terminating macroradicals. There has been considerable confusion in the past on whether to incorporate the factor 2 from the rate law expression into the termination rate coefficient. The factor 2 is necessary if the rate law describes the rate of the loss of macroradicals; however, it is unnecessary if only termination events are considered. Nevertheless, the IUPAC ruling on this is clear; termination rate coefficients are to be reported without the incorporated factor 2. All termination rate coefficients given in this article are in accordance with the IUPAC guideline.

Because of the above-mentioned chain length dependence of the termination rate coefficient (327) and its strong dependence on the monomer conversion, it is rather difficult to report tabulated values for k_t. However, it is possible to give a chain-length-averaged k_t value for a specific monomer conversion, $\langle k_\mathrm{t} \rangle$. It is important to note that for many of the reported chain-length-averaged k_t values, it is unclear to which chain length region they correspond. Since most measurements of the termination rate coefficient have been carried out at low monomer conversion, it is sensible to report k_t values for the low conversion regime (see below for a discussion of high conversion k_t data).

Average termination rate coefficients have been reported over several orders of magnitude, ranging from approximately 50 to 10^9 L $\cdot$ mol^{-1} $\cdot$ s^{-1} (173). This impressive range may be explained by a shift in the rate-determining step when



Scheme 12.

going from one monomer to another. The termination reaction can be broken down into a three-stage process (328–330), as can be seen in Scheme 12:

(1) The translational (ie center of mass) diffusion of the individual macroradical coils toward each other through the reaction medium.
(2) The so-called segmental diffusion of the radical chain ends toward each other. This segmental diffusion process brings the chain ends into a position that enables them to react.
(3) The chemical reaction of the two radicals which yields the polymeric product(s).

The slowest reaction step—in a sequence of reaction steps—will always determine the rate of the overall reaction according to equation 47, which describes the inverse overall termination rate coefficient as the sum of the inverse rate coefficients of the individual reaction steps:

$$\frac{1}{k_t} = \frac{1}{k_{TD}} + \frac{1}{k_{SD}} + \frac{1}{k_R} \tag{47}$$

with k_{TD} being the rate coefficient for the translational diffusion, k_{SD} the rate coefficient for the segmental diffusion, and k_R the rate coefficient for the chemical reaction of radical–radical recombination. Because of the extremely fast reaction rate of the radical combination/disproportionation reaction (ie strictly speaking the termination itself) with k_R being in the order of 10^{10} L · mol^{-1} · s^{-1}, the center of mass and segmental diffusion steps are (in almost all the cases) the rate-determining steps. At low monomer conversions, the rate-determining step for reasonably high molecular weight macroradicals (of length 50 or above) is believed to be almost exclusively segmental diffusion. Typical examples for high k_t monomers are methyl methacrylate and styrene, ie, $\langle k_t \rangle \approx 10^8$ L · mol^{-1} · s^{-1}. Differences in the (average) termination rate coefficients that can be observed when comparing different monomers are most likely due to differences in segmental diffusion coefficients. However, lower values of k_t, as observed for example for dodecyl methacrylate, ie $\langle k_t \rangle \approx 10^6$ L · mol^{-1} · s^{-1}, have been attributed to the sterically demanding substituents, leading to a (partly) chemically controlled termination process (331). For reported ultralow k_t monomers, such as the fumarates (332,333) or itaconates (135,334) with $\langle k_t \rangle < 500$ L · mol^{-1} · s^{-1}, a chemically controlled termination process may also be envisaged, but evidence for this hypothesis is nonexistent and other explanations can by no means be ruled out.

As indicated above, the termination reaction for most common monomers is believed to be segmental diffusion controlled at low and intermediate monomer

conversions and center of mass diffusion controlled at high conversion. If the diffusion controlled nature of the termination reaction is accepted, this has the immediate consequence that the termination rate coefficient should be chain length dependent. However, the chain length dependence of k_t is markedly different for the two diffusion mechanisms.

The chain length dependence of k_t is normally quantified by the following equations: A macroscopic—ie experimental—k_t value may be obtained by the following averaging procedure (335):

$$\langle k_t \rangle = \frac{\sum_i \sum_j k_t^{i,j} [R_i^\bullet][R_j^\bullet]}{\left(\sum_i [R_i^\bullet]\right)^2} \tag{48}$$

The microscopic k_t value $k_t{}^{i,j}$ corresponds to the individual termination rate coefficient involving two free macroradicals with the chain length i and j. The averaging procedure is advantageous because the chain length distribution of the macroradicals in free radical polymerization is normally highly disperse. The individual termination rate coefficient $k_t{}^{i,j}$ may be described via the following equation:

$$k_t^{i,j} = k_t^0 (\bar{i,j})^{-\alpha} \tag{49}$$

with $\bar{i,j}$ denoting some average [eg, the harmonic (336) or the geometric (337) mean] of the two chain lengths i and j involved and α being a positive constant. As a consequence, the problem of determining k_t is not solved by the evaluation of one specific value but comprises the evaluation of an entire functional dependence. The chain length dependence of the macroscopic $\langle k_t \rangle$ is consequently often expressed via the following power law:

$$\langle k_t \rangle = k_t^0 \bar{P}_n^{-\alpha} \tag{50}$$

This power law correlates the average value of the termination rate coefficient $\langle k_t \rangle$ with the number-average degree of polymerization, $\bar{P}_n$. The chain length dependence of k_t is now easily described and quantified by the exponent α in equation 50.

If center of mass diffusion is the rate-determining step in the termination reaction, an exponent of 0.5–0.6 results, depending on the thermodynamic quality of the solvent. This result can be explained by considering the translational diffusion properties of the polymer coil. The diffusion coefficient D of the polymer coil is inversely proportional to its hydrodynamic radius. If the hydrodynamic radius is equated with the radius of gyration $\langle s^2 \rangle^{0.5}$, it can be inferred that for a theta solution $\langle s^2 \rangle \propto i$ and for an athermic solution $\langle s^2 \rangle \propto i^{1.176}$ (338). This leads directly to the chain length dependence of the diffusion coefficient of $D \propto i^{-0.5}$ for theta solutions and $D \propto i^{-0.59}$ for athermic solutions. According to various theories for diffusion controlled reactions, the diffusion coefficient is directly proportional to the termination rate coefficient. The majority of these models is based on the work by Smoluchowski (339), which describes the rate coefficient for a diffusion

controlled reaction (see eq. 51):

$$k_t^{i,j} = 2p\pi(D_i + D_j)\sigma N_A \tag{51}$$

in which p is the spin multiplicity, σ is the capture radius of the reaction, and N_A is the Avogadro's number.

The segmental diffusion coefficient is generally chain length independent. However, a slight chain length dependence of the termination rate coefficient of close to $\alpha = 0.16$ is predicted for athermic solvents, owing to thermodynamic shielding effects of the chain. The chain shields its own reactive center owing to its size from the second chain, which displays a similar shielding effect. The exponent of -0.167 has been confirmed in various theoretical studies applying the scaling theory (336,340), as well as in chain statistical simulations (341). The chain length dependence of k_t is almost negligible in theta solvents for the segmental diffusion controlled regime, with α being close to 0.05.

Experimentally, evidence has been gathered for both exponents, ie 0.1–0.2 for segmental diffusion and 0.5–0.6 for center of mass diffusion, depending on the size of the macroradicals undergoing termination. Consequently, the chain length dependence of the termination rate coefficient is best described by a step function featuring two (main) domains of different chain length dependencies, as depicted in Figure 5.

Domain A is associated with center of mass diffusion controlled termination, owing to the small size of the macroradicals (ie, $\alpha \approx 0.5$–0.6), whereas domain B is controlled by segmental diffusion processes (ie, $\alpha \approx 0.05$–0.16). Domain C represents an intermediate region associated with the change in mechanism. These numbers have been confirmed experimentally by various research groups in the past (18,342–347) and the general shape of the curve could be confirmed in recent work (348,349). Styrene and methyl methacrylate have been studied particularly extensively with respect to the chain length dependence of the termination rate coefficient in the segmental diffusion region. These chain length dependencies

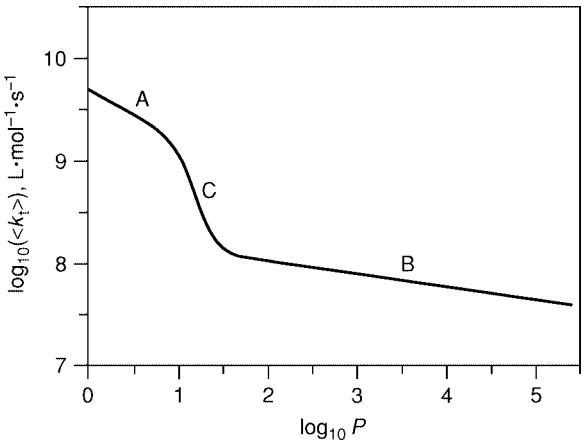


Fig. 5. General step function for the termination rate coefficient as a function of the chain length of terminating macroradicals. For details see text.

Table 7. Activation Parameters of the Termination Step for Various Acrylates and Methacrylates

Monomer	E_A, kJ · mol^{-1}	$\Delta V^{\#}$, cm^3 · mol^{-1}	log(k_t), L · mol^{-1} · s^{-1}	Reference
Methyl acrylate	8.0 (100 MPa)	16.0 (30°C)	8.13	350
Butyl acrylate	6.0 (100 MPa)	16.0 (40°C)	7.55	351
Dodecyl acrylate	3.0 (100 MPa)	20.0 (40°C)	6.38	350
Methyl methacrylate	6.0 (100 MPa)	15.0[a] (40°C)	7.39	352,353
Butyl methacrylate	—	—	6.70	352,353
Dodecyl methacrylate	—	10.8 (30°C)	6.22	

[a]This activation volume is pressure dependent; the value is valid for the pressure range from 100 to 150 MPa. To convert MPa to bar, multiply by 10.

may be described by the following (345):

$$\text{MMA } (25^\circ\text{C}): \langle k_t \rangle_i = 7.56 \times 10^7 \times i^{-0.18} \quad \text{Styrene } (25^\circ\text{C}): \langle k_t \rangle_i = 1.21 \times 10^8 \times i^{-0.16}$$

where $\langle k_t \rangle_i$ denotes the average experimental termination rate coefficient for a mean chain length i.

Although the termination rate coefficient of a particular monomer is influenced by the system viscosity and the chain lengths of the terminating free macroradicals, it is important to notice that the pressure and, to a lesser extent, the reaction temperature have a significant effect on its value. Especially the reaction pressure influences the absolute value of the termination rate to a far greater extent than the change in k_t associated with its chain length dependence. Table 7 gives activation energies and activation volumes for selected acrylate and methacrylate termination rate coefficients along with its value at 100 MPa and 40°C at low monomer conversions. The numbers given in Table 7 were mainly derived from single pluse–pulsed laser polymerization (SP–PLP) experiments.

Inspection of Table 7 shows that the activation energies are rather low and between 3 and 8 kJ · mol^{-1}. This observation is consistent with the diffusion (either segmental or translational) controlled nature of the termination reaction. Strictly speaking, these activation energies correspond to the temperature dependence of the inverse system viscosity. Up to this date, there is no data on the activation energy of the actual termination reaction itself. However, it is very likely that the termination reaction itself has a close to zero activation energy. This conclusion may be deduced from the activation parameters observed for small radical termination (354,355). It is interesting to note that the activation volume of the termination reaction is positive, ie the value of k_t is reduced at higher reaction pressures. The activation volumes of a given reaction is defined by

$$\frac{\mathrm{d}\ \ln k}{\mathrm{d}p} = -\frac{\Delta V^{\#}}{RT} \tag{52}$$

where $\Delta V^{\#}$ is the activation volume and p is the pressure.

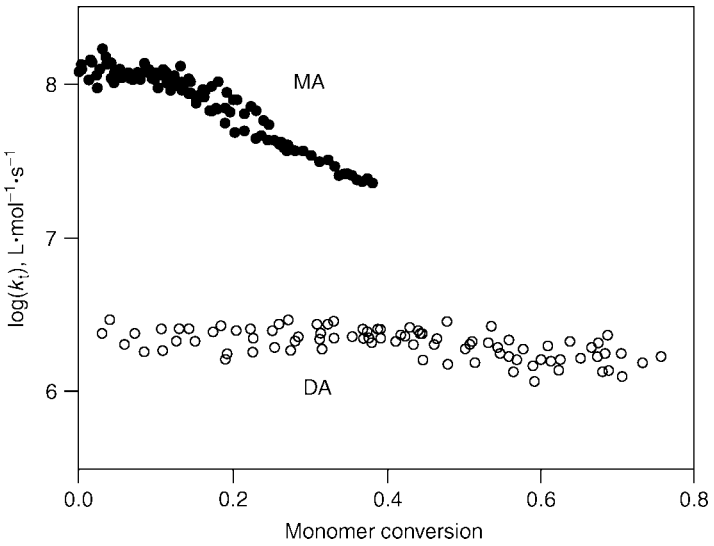

Fig. 6. Termination rate coefficients in bulk methyl acrylate (MA) and dodecyl acrylate (DA) homopolymerizations as a function of monomer conversion. The reaction conditions were 40°C and 100 MPa.

This experimental observation can also be correlated with the pressure dependency of the viscosity. The reaction medium tends to be more viscous at higher reaction pressures, thus slowing the rate of termination; ie, the activation volume of the termination rate coefficient is very close to the corresponding activation volume that characterizes the pressure dependence of the inverse of the monomer viscosity (356). It is important to note that the pressure dependencies of the termination and propagation rate coefficients display opposite behavior, ie allowing for increased rates of polymerization at elevated pressures.

As has been indicated above, the termination rate coefficient is—depending on the monomer in question—strongly dependent on the overall monomer conversion. The conversion dependencies of the (average) termination rate coefficient have been reported for several monomers, with most measurements being done via the SP–PLP technique, which allows to point-wise probe the kinetics of the polymerization reaction up to high overall monomer conversions. A typical k_t vs monomer conversion dependence is given in Figure 6 for the example of methyl acrylate and dodecyl acrylate. The data are taken from Reference 331.

Inspection of Figure 6 shows that both monomers behave very differently. While in the case of methyl acrylate different regions for the change of the termination rate coefficient with conversion can be identified, dodecyl acrylate exhibits a constant (average) k_t value up to high conversions. The different regions in the methyl acrylate k_t vs conversion dependence may be attributed to segmental diffusion (0 to ∼15%), followed by translational diffusion and the onset of the so-called gel effect, which is characterized by a strong autoacceleration of the reaction (see below). At very high monomer conversions, the reaction medium is highly viscous and the macroradicals are no longer capable of movement via translational diffusion. Instead, the addition of new monomer units to the chain end results in

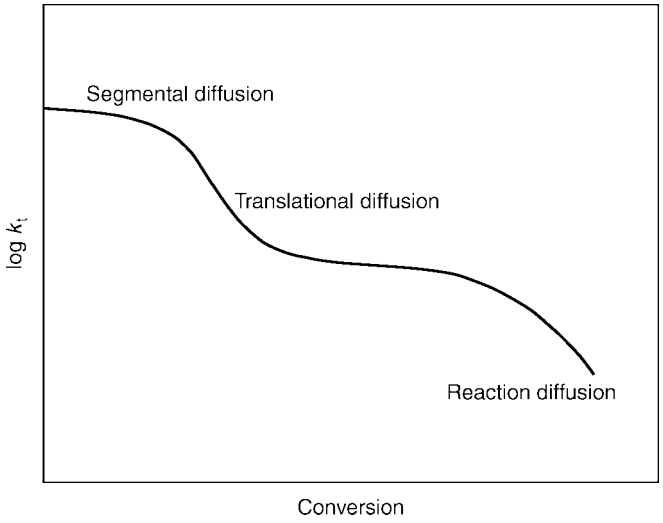

Fig. 7. Schematic dependence of the (average) termination rate coefficient on the overall monomer conversion, indicating different regimes of reaction control.

a change in the position of the radical chain end. This process has been termed reaction diffusion or propagation diffusion. Buback has introduced a model for the above-described dependence of the termination rate on the monomer conversion, which considers segmental, translational, and reaction diffusion processes (357). This model has been extremely successful in describing a large set of data up to high monomer conversions (358–360). In the case of dodecyl acrylate, the segmental diffusion region seems to extend to high monomer conversions, although the system viscosity changes by orders of magnitude when going from 0 to 80% conversion. However, in a monomer behaving like dodecyl acrylate, it has not been conclusively clarified up to this point (*1*) whether the entire conversion range is in the segmental or translational diffusion controlled regime and (*2*) what the exact cause for a nonchanging (average) termination rate coefficient is.

Figure 7 shows the three different regimes of the termination rate coefficient in general, which can be described as follows:

(1) Low conversion: this regime—prior to the onset of the gel effect—is characterized by highly mobile propagating species. Segmental diffusion is the rate-determining step for the termination reaction.
(2) Medium-to-high conversion: The diffusion mechanism of the propagating radicals becomes complex after the onset of the gel effect. Large chains become immobile; however, the chain ends may move by reptation or reaction diffusion. Monomer and short species may still be highly mobile in the polymerizing system. Translational center-of-mass diffusion may become the rate-determining step for radical–radical termination.
(3) Very high conversion: The polymerizing system becomes a glassy matrix. Reaction diffusion is the only remaining pathway for radical movement.

The precise conversion ranges are determined by the nature of the monomer, the molecular weight of the polymer that is produced, and the solvent. For bulk polymerizations, these regimes are (a) typically <10–20%, (b) between 15 and 90%, and (c) >90%. When using a solvent and/or chain transfer agents to reduce the molecular weight of the polymer, the initial regime (a) can be extended and (c) may not even occur.

It has been observed that the average k_t value slightly increases up to 5–10% of conversion and then starts to decrease (361–364). An explanation for such behavior was first offered by North and Reed who assumed faster segmental diffusion to be responsible (328). The initial increase of k_t with increasing monomer conversion has also been associated with a change in solvent quality: k_t increases when going from a good to a poor solvent, because of either diminishing coil sizes (which increases the segmental diffusion coefficient) or decreasing repulsions between macroradicals. This behavior of k_t has not only been observed experimentally, but is also predicted theoretically (365,366).

The conversion dependence of the termination rate coefficient is linked to the above-mentioned autoacceleration effect of the polymerization (367,368), which can be observed with some monomers at increased conversion, eg, methyl methacrylate (369), styrene (370), vinyl acetate (371), and methyl acrylate (372). Also known as the 'Trommsdorff,' 'Norrish–Smith,' or 'Norrish-Trommsdorff' effect, this effect can cause problems within both an industrial and scientific context ranging from a product mixture to reactor explosion, owing to its exothermic nature (373,374). It is important not to confuse the gel effect with the autoacceleration that is observed when a polymerization is carried out under nonisothermal conditions, so that the reaction temperature increases with increasing monomer conversion, owing to the exothermic nature of the polymerization reaction. The gel effect is observed under isothermal reaction conditions. The cause of the gel effect has been debated over 50 years and various theories have emerged which can explain all or part of the experimental data (excellent reviews on the topic can be found in References 375 and 376). In theory, any given model that links the termination rate coefficient to the increasingly difficult diffusion of macroradicals through the reaction mixture as the monomer conversion increases and thus accounts for a decrease in the termination rate, is capable of explaining the gel effect, without introducing a drastic change in the physical chemistry of the polymerizing system. The debate does not so much focus on the fact that the termination reaction becomes increasingly hindered as the mobility of the polymer chains decreases, than on the details of exactly what type of mobility is important. The main explanation for the gel effect that is offered concentrates on the formation of chain entanglements that hinders the diffusion of the macroradicals, thus causing a decrease in the rate of termination.

Primary Radical Termination. Primary radical termination refers to the bimolecular reaction between a propagating radical and a primary, initiator-derived radical. This process leads to lower rates of initiation and propagation, thus causing a deviation from the predictions of classical kinetics (377). In analogy with the termination reactions between propagating radicals, primary radical termination can also occur by either combination or disproportionation. It has been shown that primary radical termination between cyanoisopropyl radicals and polystyryl radicals occurs mainly via combination at 98°C with extremely

high AIBN concentrations, generating polymeric material with degree of polymerizations of 10 and below (378). Primary radical termination in conventional AIBN- or benzoyl peroxide-initiated polymerizations occurs only to a significant extent when high initiator or low monomer concentrations are used. Hence, the effect of primary radical termination becomes more pronounced at high conversions and high dilutions (319,379–381). Even under experimental conditions that would favor the primary radical termination reaction, more than 85% of the termination events occur between two macroradicals in AIBN-initiated styrene polymerization at 100°C (83). In conventional bulk polymerizations of the same system under conventional conditions (ie initiator concentration in the order of 10^{-2} mol · L^{-1}) less than 2% of the end groups in the generated polymeric material are due to primary radical termination events. When using BPO as initiator, approximately 8% of the end groups have been formed through transfer or termination with primary radicals (85).

Many industrial photopolymerization processes exploit unusually high initiation rates in order to achieve a rapid cure and a high final degree of conversion. These conditions favor primary radical termination reactions (380,382). Certain primary radical fragments derived from photoinitiators exhibit a relatively high stability and show reluctance to initiate polymerization. This is often observed with benzoin and benzoin ethers that fragment upon UV irradiation into an initiating species (the benzoyl fragment) and an inhibiting species (the benzyl alcohol fragment in the case of benzoin, and the acetal fragment in the case of benzoin ethers) (19,20,54,383). A manifestation of such a photoinitiator nonideality has been reported for 2,2-dimethoxy-2-phenylacetophenone- (DMPA-) and benzoin-initiated SP–PLPs of various monomers (18). A decrease in monomer conversion per single laser pulse with increasing photoinitiator concentrations was observed. MALDI-TOF investigations of benzoin and DMPA photoinitiated polymer show that the two radical fragments generated upon pulsed laser irradiation show markedly different reactivity toward methyl methacrylate: whereas the benzoyl fragment—common to both DMPA and benzoin—clearly participates in the initiation process, the acetal and benzyl alcohol fragments cannot be identified as end groups in the polymer (384). Another example of how comparatively low rates of addition of primary radicals to monomer may lead to higher rates of primary radical termination is the polymerization of hindered monomers, eg, fumarates and itaconates, initiated by AIBN (379,385).

Rate of Polymerization

Stationary Polymerization. A stationary polymerization system is characterized by a constant free radical concentration as given by equation 53:

$$\frac{d[R^{\bullet}]}{dt} = 0 \tag{53}$$

In the past it has been a standard practice to derive a simple but general expression for the rate of polymerization, R_p. This expression correlates the rate of polymerization with the initiator and monomer concentrations on one side and the

kinetic rate coefficients k_d, k_p, and k_t on the other side. Although this expression contains many approximations, it is surprisingly successful in describing the experimental reality. Detailed kinetic studies have revealed the shortcomings of this equation. However, it remains the basis of standard free radical polymerization kinetics. The approximations that are made in its derivation are

(1) chain length and conversion independent rate coefficients k_t and k_p;
(2) instantaneous establishment of a steady-state free radical concentration;
(3) assumption that monomer is only consumed by chain propagation and not via the initiation process or chain transfer. This assumption allows to equate the rate of the loss of monomer with the rate of polymerization;
(4) all reactions are irreversible;
(5) the effective concentration of initiator-derived free radicals is constant throughout the polymerization.

The core of the derivation for the rate of polymerization expression is the assumption that the rate of initiation equals the rate of termination, equation 46 in its simplified form. This assumption is mandatory for the establishment of a constant free radical concentration (eq. 54).

$$2fk_d[\mathrm{I}] = 2k_t[\mathrm{R}^\bullet][\mathrm{R}^\bullet] \tag{54}$$

Rearrangement of equation 54 and insertion into the simplified form of equation 21

$$R_p = -\frac{d[\mathrm{M}]}{dt} = k_p[\mathrm{M}][\mathrm{R}^\bullet] \tag{55}$$

yields the final expression for the rate of polymerization, R_p:

$$R_p = -\frac{d[\mathrm{M}]}{dt} = k_p\left(f\frac{k_d}{k_t}\right)^{0.5}[\mathrm{M}][\mathrm{I}]^{0.5} \tag{56}$$

Equation 56 indicates a first-order dependence of the rate of polymerization on the monomer concentration and a square-root dependence on the concentration of the initiator. These dependencies have been confirmed for the example of many polymerizing systems. It should be pointed out that deviations from equation 56 (such as chain-length-dependent rate coefficients or primary radical termination) are manifest in a change in the exponents associated with the initiator and monomer concentrations (386,387). The rate of polymerization will scale with a weaker than square-root dependence on [I] and a stronger than linear dependence on [M]. Extreme dilution of monomer can also change the exponents of monomer and initiator concentration. Equation 56 is easily integrated to yield an expression which directly correlates the monomer conversion with the observed kinetic rate coefficient k_{obs}.

$$\ln\left(\frac{1}{1-p}\right) = k_{obs}t \quad \text{where} \quad k_{obs} = k_p\left(f\frac{k_d}{k_t}[I]\right)^{0.5} \tag{57}$$

where p is the conversion of monomer to polymer. The temperature dependence of the polymerization rate is given by the temperature dependencies of the individual rate coefficients. Each rate coefficient follows its own Arrhenius law, $k = A\ \exp(-E_A/RT)$, where A is the preexponential factor and E_A denotes the activation energy. The overall activation energy of the rate of polymerization, $E_A^{R_p}$, equals the sum of the weighted activation energies of the elementary reactions, propagation (E_A^p), initiation (E_A^i), and termination (E_A^t).

$$E_A^{R_p} = E_A^p + \frac{1}{2}E_A^i - \frac{1}{2}E_A^t \tag{58}$$

Activation energies for commonly used thermal decomposing initiators, E_A^i, are in the order of 120–150 kJ · mol^{-1}. The E_A^p values for most common monomers lie within the range of 20–40 kJ · mol^{-1}, and E_A^t is generally in the range of 4–10 kJ · mol^{-1}. Hence, typical values for overall activation energies for the rate of polymerization initiated by a thermally decomposing initiator are close to 80 kJ · mol^{-1}. This corresponds to a two- or threefold increase in rate for a 10°C temperature increase. Photochemical polymerization rates have a much lower activation energy of about 20 kJ · mol^{-1}, according to close to zero activation energy of the photoinitiation process.

Dead-End Polymerization. To reach a steady state in free radical polymerization it is important that the initiator concentration is constant over a significant time span to ensure a constant rate of initiation. However, the initiator decomposes according to equation 3 and its concentration unavoidably decreases. This can often be neglected when the decomposition rate of the initiator is very small in comparison with the rate of polymerization. To perform a steady-state experiment an appropriate initiator should be chosen with a rate coefficient of decomposition, k_d (at the given temperature), that ensures a maximum decrease in initiator concentration of no more than 10% over the entire reaction time. Especially for fast decomposing initiators or very long reaction times the decreasing initiator concentration has to be accounted for. If all initiator molecules are decomposed before the end of polymerization, the reaction ceases. This experimental conditions are referred to as *dead-end polymerization* (388–391). However, the polymerization can be reinitiated by adding new initiator. Insertion of equation 3 in equation 56, separation of the variables, and integration from $[M]_0$ to [M] and from $t = 0$ to $t = t$ yields

$$-\ln\frac{[M]}{[M]_0} = -\ln(1-p) = 2k_p\left(\frac{f[I]_0}{k_d k_t}\right)^{0.5}(1-e^{-k_d t/2}) \tag{59}$$

where p is the monomer-to-polymer conversion and is defined by $p = ([M]_0-[M])/[M]_0$. At long reaction times ($t \to \infty$), the monomer concentration and conversion reach the limiting values of $[M]_\infty$ and p_∞.

$$-\ln\frac{[M]_\infty}{[M]_0} = -\ln(1-p_\infty) = 2k_p\left(\frac{f[I]_0}{k_d k_t}\right)^{0.5} \quad (60)$$

The example for polymerizations of styrene using AIBN at 60°C shows how the maximum conversion depends on the concentration of the initiator (k_p = 341 $L\cdot mol^{-1}\cdot s^{-1}$, $k_t = 5\times10^7$ $L\cdot mol^{-1}\cdot s^{-1}$, $k_d = 1.35\cdot10^{-5}$ s^{-1}, $f = 0.5$):

$[AIBN] = 0.001$ mol $\cdot$ L^{-1}	$p_\infty = 44.4\%$
$[AIBN] = 0.01$ mol $\cdot$ L^{-1}	$p_\infty = 84.4\%$
$[AIBN] = 0.1$ mol $\cdot$ L^{-1}	$p_\infty = 99.7\%$

A higher initiator concentration results in a higher polymer yield. However, the molecular weight of the polymer produced decreases at the same time.

Nonstationary (Instationary) Polymerization. Especially at the beginning and at the end of the polymerization process the steady-state principle does not hold. The generation of new free radicals by the initiator decay exceeds their consumption via termination events at early reaction times (preeffect) (392). After the initiation process ceases, the free radical concentration decreases according to the termination rate law expression (aftereffect) (393). Consequently, the rate of polymerization is not constant over the entire time period of the polymerization (394–396). Measurement of the polymerization rate in the pre- and aftereffect regions allows for the determination of the coupled form of termination and propagation rate coefficients, k_p/k_t, whereas in the steady-state region, they can only be accessed as the ratio k_p^2/k_t. The individual propagation and termination rate coefficients can be calculated by combining the above two ratios. The determination of k_p/k_t and k_p^2/k_t via the pre- and aftereffects and stationary polymerization experiments, respectively, has long been the only possibility to determine propagation and termination rate coefficients. However, recent studies reveal that serious problems were associated with this approach, owing to the chain length dependence of k_t, (397), which was not accounted for. This may be the reason for the large discrepancies observed when comparing values for k_p and k_t from different sources. The situation has improved drastically by the invention of the pulsed laser polymerization (PLP) method, which has been introduced in the late 1980s. This improvement is impressively demonstrated when comparing recent data for the propagation rate coefficient in styrene homopolymerizations with earlier data (see Figure 8).

Although the steady state is reached within a couple of seconds after starting the initiation process, the generation of free radicals exceeds their loss by termination (ie the preeffect) in this period. Therefore, the concentration of free radicals $[R^\bullet]$ is not constant but a function of time. The rate of free radical production is the rate of initiation minus the rate of termination, as given by equation 61:

$$\frac{d[R^\bullet]}{dt} = R_i - 2k_t[R^\bullet]^2 \quad (61)$$

Assuming a constant rate of initiation, integration leads to

$$[R^\bullet] = [R^\bullet]_S \tanh\left[(2k_t R_i)^{0.5} t\right] \quad (62)$$

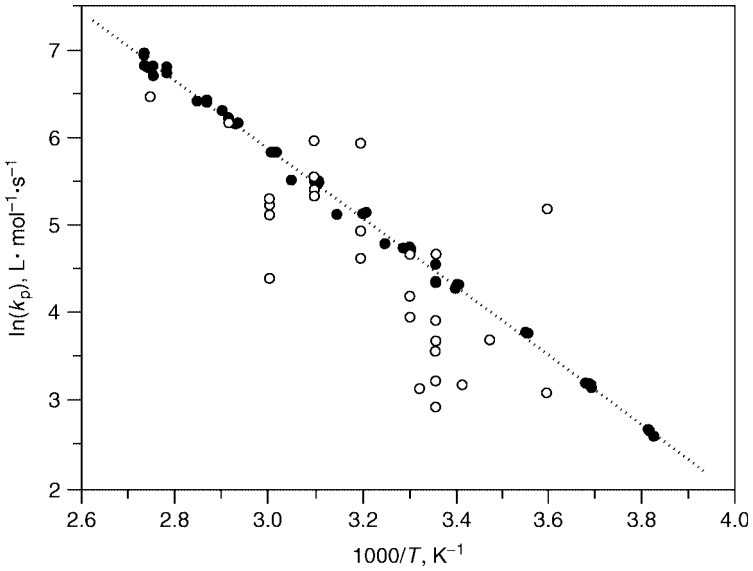

Fig. 8. Comparison of propagation rate coefficients for bulk styrene homopolymerizations from two generations: PLP–SEC data from an IUPAC benchmark publication (Ref. 398 (●), and data compiled from Ref. 399 (○).

where $[R^{\bullet}]_S$ represents the steady-state free radical concentration. The example for polymerizations of styrene using 10^{-3} mol · L^{-1} AIBN at 60°C shows how fast the steady state is reached: $k_p = 341$ L · mol^{-1} · s^{-1}, $k_t = 5 \cdot 10^7$ L · mol^{-1} · s^{-1}, $k_d = 1.35 \cdot 10^{-5}$ s^{-1}, $f = 0.5$ (see Figure 9). The polymerization can be considered to proceed in a steady state after approximately 3 s.

After stopping the initiation process no new free radicals are available and the concentration decreases according to a second-order rate law. Integration of

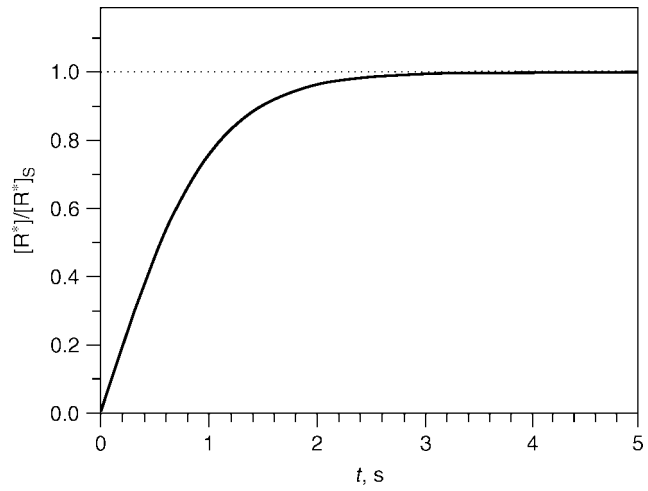

Fig. 9. Increase of the radical concentration in a conventional AIBN-initiated bulk polymerization of styrene. For kinetic parameters see text.

equation 61 with $R_i = 0$ yields the concentration of free radicals as a function of time in the so-called aftereffect region:

$$[R^\bullet]^{-1} - [R^\bullet]_S^{-1} = 2k_t t \tag{63}$$

Insertion into the rate law of propagation (eq. 54)—assuming that the rate of loss of monomer equals the rate of polymerization, R_p—gives

$$R_p = \frac{k_p[M]}{2k_t t + [R^\bullet]_S^{-1}} \tag{64}$$

which contains the individual rate coefficients k_p and k_t in a combination different from that obtained via steady-state experiments. Thus, the ratio k_p/k_t is accessible by equation 64 via the measurement of the polymerization rate in the aftereffect region.

Pseudostationary Polymerization. Conversions in the pre- and after–effect regions are rather low, making it experimentally challenging to determine them accurately. To overcome this problem a structured continuous initiation profile is chosen by which the system is facing pre- and aftereffects in sequences. This can be achieved by using a photo-polymerizable system, which is exposed to a succession of light and dark periods, leading to a *pseudostationary* state, which provides a continuous polymerization of a system being in a non-steady state (400,401). It is characterized by a constant mean free radical concentration, averaged over one cycle period, but a permanently changing actual concentration of the reactive intermediates. While the technique was introduced by using a rotating sector (402–404)—where light periods are considerably long, ie about 1/4 of the whole cycle time t_0—the technique improved by using a pulsed laser as light source (51,405–407). The extremely short duration of the laser flash—in the order of nanoseconds—allows to assume an instantaneous formation of free radicals. Strictly speaking, instantaneous radical generation is equivalent to neglecting the preeffect and termination during the laser pulse, respectively. Figure 10 shows a typical time profile of the free radical concentration in a pulsed laser experiment.

The maximum free radical concentration $[R_+^\bullet]$ is reached immediately after the laser pulse has been applied. It is the sum of the radical concentration formed at each laser flash, ρ, and the amount of free radicals still in the system, which are produced by former pulses, $[R_-^\bullet]$. This value is identical to the minimum free radical concentration in the polymerizing system. Radical formation during the dark time is neglected. Assuming that termination is not dependent on the chain length, the rate law for termination can be written as

$$-\frac{d[R^\bullet]}{dt} = 2k_t[R^\bullet]^2 \tag{65}$$

Integration of equation 65 over the whole pulse period t_0 yields

$$[R_-^\bullet]^{-1} - [R_+^\bullet]^{-1} = 2k_t t_0 \tag{66}$$

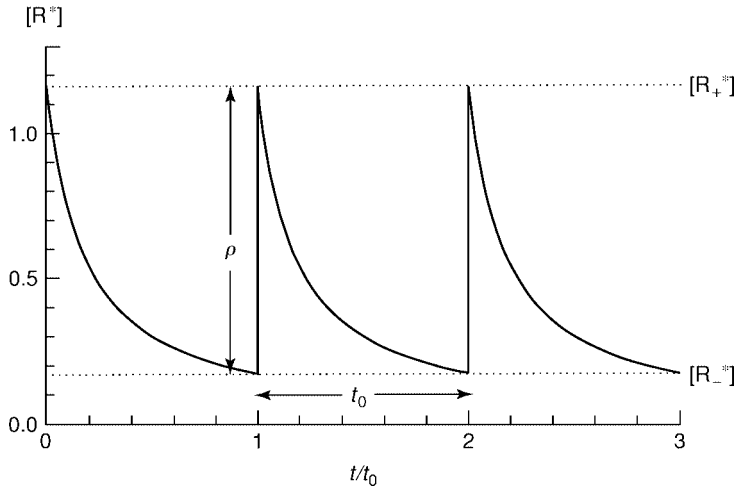

Fig. 10. Typical radical concentration profile generated by the pulsing action of laser on a reaction mixture of photoinitiator and monomer. The maximum free radical concentration $[R_+^\bullet]$ is reached immediately after the laser pulse has been applied. It is the sum of the radical concentration formed at each laser flash, ρ, and the amount of free radicals still in the system produced by former pulses, $[R_-^\bullet]$.

The pseudostationary state is defined by the exact compensation of the loss of free radicals during the dark period via termination by the radical formation of the laser pulse.

$$\rho = [R_+^\bullet] - [R_-^\bullet] \tag{67}$$

Combination of equations 66 and 67 leads to

$$[R_+^\bullet] = \rho\left[\frac{1}{2} \pm \left(\frac{1}{4} + \frac{1}{2\rho k_t t_0}\right)^{0.5}\right] \tag{68}$$

The free radical concentration at any moment during the pulse period is

$$[R^\bullet] = \left(\frac{1}{[R_+^\bullet]} + 2k_t t\right)^{-1} = \frac{[R_+^\bullet]}{1 + 2[R_+^\bullet]k_t t} \tag{69}$$

Averaging over the whole pulse period leads to a mean value for the free radical concentration

$$[\bar{R}^\bullet] = \frac{1}{t_0}\int_0^{t_0} \frac{[R_+^\bullet]}{1 + 2[R_+^\bullet]k_t t}\, dt = \frac{1}{2k_t t_0}\ln(1 + 2[R_+^\bullet]k_t t_0) \tag{70}$$

By insertion of equations 68 and 70 in equation 55, the expression for the polymerization rate in pseudostationary PLPs is obtained.

$$R_p = \frac{k_p[M]}{2k_t t_0} \ln \left\{ 1 + \rho k_t t_0 \left[1 + \left(1 + \frac{2}{\rho k_t t_0} \right)^{0.5} \right] \right\} \quad (71)$$

This expression contains the ratio of k_p/k_t, which is typically derived from nonstationary polymerizations. The measurement of the rate of polymerization under pseudostationary conditions may hence allow for the determination of the ratio of k_p/k_t (408). However, the major advantage of pseudostationary polymerization does not lie within the possibility to separate the ratio of k_p^2/k_t into its individual components, but to generate structured chain length distributions. These structured distributions allow for the accurate determination of the propagation and termination rate coefficients.

A special case of the PLP is the SP–PLP technique (409,410). The equations needed to analyze the monomer conversion vs time traces obtained from SP–PLP experiments are easily derived. Integration of the rate law expression for termination, assuming a chain length independent, average termination rate coefficient k_t (eq. 65), yields

$$[R^\bullet] = \left(2k_t t + \frac{1}{[R_+^\bullet]} \right)^{-1} \quad (72)$$

Substitution of equation 72 into the rate law expression for the propagation step (eq. 55) and subsequent integration yields the change in relative monomer concentration after a single laser pulse:

$$\frac{[M]}{[M]_0} = (2k_t[R_+^\bullet]t + 1)^{-k_p/2k_t} \quad (73)$$

Expression 73 can be fitted to time-resolved monomer conversion vs time traces obtained from SP–PLP experiments (see below), with the two fit variables being $k_t[R_+^\bullet]$ and k_p/k_t. With knowledge of the primary free radical concentration $[R_+^\bullet]$, it is possible to determine k_t and k_p from a single conversion vs time trace. Unfortunately, in reality, $[R_+^\bullet]$ is often not known (because of insufficient knowledge about initiator efficiencies) and k_t can only be assessed via knowledge of the propagation rate coefficient from independent experiments (eg, PLP–SEC). However, in recent studies the accurate determination of primary radical concentrations produced by a laser flash have been reported in nonpolymerizing systems (411,412), giving promising results for future work.

The Chain Length Distribution

The kinetic rate coefficients of the various steps involved in the polymerization reaction are controlling the rate of polymerization, R_p, and the overall free radical concentration. Keeping in mind that the polymerization is a chain mechanism leading to macromolecules, it is self-evident that the same kinetic parameters may be employed to calculate the sizes of polymeric intermediates and the polymer generated. For this purpose it is necessary to solve the complete set of

coupled differential equations, one equation for each chain length plus one for the initiation step.

The rate law for the concentration change of a macroradical with chain length i can be written as

$$\frac{\mathrm{d}[\mathrm{R}_i^\bullet]}{\mathrm{d}t} = k_\mathrm{p}^{i-1}[\mathrm{M}][\mathrm{R}_{i-1}^\bullet] - \left(k_\mathrm{p}^i[\mathrm{M}] + k_\mathrm{tr}^\mathrm{M}[\mathrm{M}] + \sum_k k_\mathrm{tr}^{\mathrm{T}_k}[\mathrm{T}_k] + 2\sum_{j=1}^{\infty} k_\mathrm{t}^{i,j}[\mathrm{R}_j^\bullet] \right)[\mathrm{R}_i^\bullet] \tag{74}$$

This rate law reflects a polymerization process during which a free radical with chain length i is solely formed by a propagation step from the free radical with chain length $i - 1$. The free macroradical has then the possibility to grow either by reaction with a monomer molecule M, giving a chain length of $i + 1$, or it can undergo a transfer reaction with the monomer or any other transferring molecule T_k (eg, transfer agent, solvent, initiator, polymer). Alternatively, it may be terminated by another free radical. The analytical solution of this problem is obviously very difficult. However, numerical solutions of this set of equations became possible because the rapid increase in computer power and simulations of chain length distributions of polymers are of increasing importance for academic and industrial applications (413).

The chain length distribution of a polymer is defined as the fraction of molecules x_P that contains P basic monomer units. It should be noted that the degree of polymerization P is equivalent to the chain length i. The living macroradicals by which the dead polymer is generated through any chain-stopping event show a chain length distribution, too. Both distributions are closely related to each other and the chain length distribution of the dead polymer can be calculated via the derivative of the distribution of the living macroradicals.

Like any other distribution function, the chain length distribution is described by its statistical moments, which are defined as

$$m^{(k)} = \sum_{P=1}^{\infty} P^k x_P \tag{75}$$

By combination of such moments one can easily calculate mean values for the degree of polymerization, $\bar{P}$, which characterize the chain length distribution. The distribution is only fully described if all moments are known. However, in practice there are two mean values calculated by the first three statistical moments, which are extensively used: the number-average degree of polymerization, $\bar{P}_\mathrm{n}$, and the weight-average degree of polymerization, $\bar{P}_\mathrm{w}$.

$$\bar{P}_\mathrm{n} = \frac{m^{(1)}}{m^{(0)}} = \frac{\sum_{P=1}^{\infty} P x_P}{\sum_{P=1}^{\infty} x_P} \quad \bar{P}_\mathrm{w} = \frac{m^{(2)}}{m^{(1)}} = \frac{\sum_{P=1}^{\infty} P^2 x_P}{\sum_{P=1}^{\infty} P x_P} \tag{76}$$

Stationary Polymerization.

Average Degree of Polymerization. To calculate the number-average degree of polymerization, $\bar{P}_\mathrm{n}$, of a polymer produced by a steady-state polymerization,

it is mandatory to know how many propagation steps occur before the chain reaction is stopped. A distinction has to be made between the term 'chain' used in a molecular sense and 'chain' used as a kinetic concept. The kinetic chain length ν, assuming that every radical $I^{\bullet}$ initiates polymerization, is defined as

$$\nu = \frac{\text{Total number of polymerized monomer unit}}{\text{Total number of initiation step}} = \int_0^t \frac{d[M]}{dt} dt \Big/ \int_0^t \frac{d[M]}{dt} dt \tag{77}$$

In a system that has reached the steady state, the integrands of equation 77 may be constant over a significant time span. By substituting equations 4 and 21—with the assumption of chain-length-independent rate coefficients—equation 77 can therefore be rewritten as

$$\nu = \frac{R_p}{R_d} = \frac{k_p[R^{\bullet}][M]}{2fk_d[I]} \tag{78}$$

Elimination of $[R^{\bullet}]$ by means of equation 54 leads to an expression for the kinetic chain length ν that shows the dependence of the different kinetic parameters. One important characteristic of the free radical polymerization is hereby well illustrated: The sizes of the macromolecules produced are inversely proportional to the square root of initiator concentration. Increasing the initiator concentration leads to smaller size polymer molecules.

$$\nu = \frac{k_p[M]}{2\left(fk_dk_t[I]\right)^{0.5}} \tag{79}$$

Disregarding any transfer effect as a first approximation correlates the kinetic chain length with the number-average degree of polymerization, $\bar{P}_n$. In the case of termination by disproportionation one polymer molecule is produced per every kinetic chain

$$\bar{P}_n = \nu \tag{80}$$

Termination by combination leads to one polymer molecule per two kinetic chains, reflecting the combination mechanism.

$$\bar{P}_n = 2\nu \tag{81}$$

Any mixture of both mechanisms can be described by using the value δ (see eq. 45), the contribution of disproportionation to the overall termination process.

$$\bar{P}_n = \frac{2}{1+\delta}\nu \tag{82}$$

The mean kinetic chain length can be experimentally determined by using marked initiator molecules, eg, ^{14}C radiolabeled (414). By these means the number

of initiator fragments per weight of polymer can be measured, and therefore the number of monomer units polymerized by each initiator step may be calculated. This represents one method to determine the mode of termination. With the values for the AIBN-initiated styrene polymerization (10^{-3} mol · L^{-1} AIBN at 60°C, k_p = 341 L · mol^{-1} · s^{-1}, $k_t = 5 \times 10^7$ L · mol^{-1} · s^{-1}, $k_d = 1.35 \times 10^{-5}$ s^{-1}, $f = 0.5$) the average kinetic chain length is about 3500 and it will take approximately 1.2 s to be finished.

Without changing the free radical concentration, 'normal' chain transfer processes remain hidden in any experiment measuring the rate of polymerization alone. The kinetic chain length is also unaffected by the transfer process, because the growing free radical center generated by the initiation step stays alive after any chain transfer event, although more than one polymer chain is produced. For this reason, equation 82 does not hold true any longer if chain transfer reactions are taken into account. In many kinetic measurements based on the analysis of the molecular weight distributions, transfer processes are neglected and are seen as disturbing factors. However, determination of the chain length distribution of a polymer remains the only possibility to measure the rate coefficients for transfer processes.

Taking chain transfer into account, the number-average degree of polymerization, $\bar{P}_n$, can be described as

$$\bar{P}_n = \frac{\text{Total number of polymerized monomer units}}{\text{Half the number of formed end groups}} \tag{83}$$

The various reactions within the polymerization process generate different amounts of end groups per initiation step:

Initiation	1 end group
Propagation	0 end groups
Transfer	2 end groups
Termination by disproportionation	1 end group
Termination by combination	0 end groups

Again the steady state with its general approximations is assumed in which the concentrations of the reactants, such as the monomer, free radicals, and transfer agent, do not vary with time. Hence, in equation 83 the number of polymerized monomer units can be substituted with the rate of polymerization and the numbers of end groups by the rate of their formation.

$$\bar{P}_n = \frac{R_p}{(1/2)(R_i + R_{t,d} + 2R_{tr})} \tag{84}$$

Insertion of the simplified rate laws of the different processes

$$\textit{Initiation} \quad R_i = 2fk_d[I] = 2(k_{t,d} + k_{t,c})[R^\bullet]^2 \tag{85}$$

$$Propagation \quad R_p = k_p[M][R^\bullet] \tag{86}$$

$$Termination \ (disproportionation) \quad R_{t,d} = 2k_{t,d}[R^\bullet]^2 \tag{87}$$

$$Chain\ transfer \quad R_{tr} = \sum_k k_{tr}^{T_k}[T_k][R^\bullet] + k_{tr}^{M}[M][R^\bullet] \tag{88}$$

and subsequent inversion leads to

$$\frac{1}{\bar{P}_n} = \frac{2k_{t,d} + k_{t,c}}{k_p^2[M]^2}R_p + \frac{k_{tr}^{M}}{k_p} + \sum_k \frac{k_{tr}^{T_k}}{k_p}\frac{[T_k]}{[M]} \tag{89}$$

$[T_k]$ is the concentration of any molecule that is capable of taking part in a chain transfer reaction, including solvent S, initiator I, polymer P, and added chain transfer agent T. It is usual to define chain transfer coefficients C for the different molecules:

$$C_M = \frac{k_{tr}^{M}}{k_p}\ C_S = \frac{k_{tr}^{S}}{k_p}\ C_I = \frac{k_{tr}^{I}}{k_p}\ C_P = \frac{k_{tr}^{P}}{k_p}\ C_T = \frac{k_{tr}^{T}}{k_p} \tag{90}$$

Thus, equation 89 becomes

$$\frac{1}{\bar{P}_n} = \frac{2k_{t,d} + k_{t,c}}{k_p^2[M]^2}R_p + C_M + C_S\frac{[S]}{[M]} + C_I\frac{[I]}{[M]} + C_P\frac{[P]}{[M]} + C_T\frac{[T]}{[M]} \tag{91}$$

This equation gives the fundamental correlation of the number-average degree of polymerization with the rate of polymerization and the various chain transfer coefficients. Equation 91 constitutes the basis for determining the various chain transfer coefficients.

Performing a polymerization experiment with only low conversion of monomer to polymer, the concentration of polymer is often too low to show significant chain transfer. The same holds true for the initiator, which is mainly used in the range of low concentrations. Without addition of solvent and additional chain transfer agent, equation 91 reads after introduction of equation 45

$$\frac{1}{\bar{P}_n} = \frac{(1+\delta)k_t}{k_p^2[M]^2}R_p + C_M \tag{92}$$

Hence, a plot of the inverse number-average degree of polymerization, $\bar{P}_n$ against the rate of polymerization, R_p, (the rate of polymerization can easily be varied by the concentration of the initiator) yields the monomer chain transfer coefficient C_M as intercept and the ratio $(1+\delta)k_t/(k_p^2[M]^2)$ as slope of a linear plot. The value of C_M entails an inevitable limit for the maximum number-average degree of polymerization, $\bar{P}_n^{max}$. The value for $\bar{P}_n$ is increased by lowering the rate of polymerization R_p according to equation 92. The limit is reached when R_p becomes zero.

$$\lim_{R_p \to 0} \left(\frac{1}{\bar{P}_n} \right) = C_M \tag{93}$$

Hence, the maximum number-average degree of polymerization, $\bar{P}_n^{max}$, which is feasible is given by

$$\bar{P}_n^{max} = C_M^{-1} \tag{94}$$

Methyl methacrylate, for instance, has a monomer chain transfer coefficient of about $C_M = 5 \times 10^{-5}$ at 60°C, leading to a maximal mean chain length of about 20,000, whereas in a free radical polymerization of vinyl acetate with a monomer chain transfer coefficient of $C_M = 2 \times 10^{-4}$ at 60°C, the limit is already reached at a number-average degree of polymerization of 5000.

The Full Chain Length Distribution. So far, only the average degree of polymerization has been considered. To calculate the distribution function itself for a steady-state polymerization it is convenient to choose a statistical approach based on kinetic parameters. A probability factor α of propagation is defined as the probability that a radical will propagate rather than terminate. The factor α is the ratio of the rate of propagation over the sum of the rates of all possible reactions the macroradical can undergo.

$$\alpha = \frac{R_p}{R_p + R_{tr} + R_t} \tag{95}$$

Firstly, we assume that termination is solely by disproportionation and that the propagation probability factor is equal for each chain length. The probability for the occurrence of a polymer chain—hence its distribution function—with the length P is given by the probability of $P - 1$ propagation steps and the probability of one chain-stopping event (termination *or* transfer).

$$x_{P,d} = \alpha^{P-1}(1 - \alpha) \tag{96}$$

The molecular weight averages can be evaluated by calculating the moments of this distribution function by insertion of equation 96 into equation 75,

$$m^{(0)} = \sum_{P=1}^{\infty} x_{P,d} = 1 \tag{97}$$

$$m^{(1)} = \sum_{P=1}^{\infty} P x_{P,d} = (1 - \alpha)^{-1} \tag{98}$$

$$m^{(2)} = \sum_{P=1}^{\infty} P^2 x_{P,d} = (1 + \alpha)(1 - \alpha)^{-2} \tag{99}$$

and subsequent insertion into equation 76.

$$\bar{P}_{n,d} = m^{(1)}/m^{(0)} = (1-\alpha)^{-1} \quad \bar{P}_{w,d} = m^{(2)}/m^{(1)} = (1+\alpha)(1-\alpha)^{-1} \tag{100}$$

The ratio of the weight-average and the number-average degree of polymerization, $\bar{P}_w/\bar{P}_n$, describes the polydispersity of a chain length distribution. It becomes unity if all chains have the same length—called a monodisperse distribution—and values greater than one, if the distribution exhibits a broader shape.

$$\frac{\bar{P}_{w,d}}{\bar{P}_{n,d}} = \frac{m^{(2)}m^{(0)}}{m^{(1)}m^{(1)}} = 1+\alpha \tag{101}$$

It should be noted that the propagation step must be highly favored over chain-stopping events to produce polymer with a significant chain length and the value of α must be near to one. Hence, equation 101 shows that for a chain length distribution of a polymer produced in a stationary experiment, where chain-stopping events are termination by disproportionation or transfer, the polydispersity becomes nearly 2. This holds true for chain length distributions which are controlled by termination via disproportionation and also for distributions where chain transfer is the dominant chain-stopping event. It should be kept in mind that this theoretical value for the polydispersity is valid for an instantaneous chain length distribution. The polydispersities in real polymerizing systems are always higher than the theoretical value, because of changes in the concentration of the participating compounds (ie initiator, monomer, transfer agent), which lead to an overlay of a multitude of different chain length distributions.

Expressions may also be derived for the chain length distribution produced, when the termination process is by combination. The expression for the probability of the occurrence of a chain with the chain length P is now given by the contributions of two chains with the chain length n and m, which form the desired molecule by combination. Hence, the auxiliary condition $n + m = P$ must be valid:

$$x_{P,c} = \sum_{n=1}^{P-1} \alpha^{n-1}(1-\alpha)\alpha^{m-1}(1-\alpha) = (P-1)\alpha^{P-2}(1-\alpha)^2 \tag{102}$$

Evaluating the moments of this distribution function by insertion of equation 102 into equation 75 as above

$$m^{(0)} = \sum_{P=1}^{\infty} x_{P,c} = 1 \tag{103}$$

$$m^{(1)} = \sum_{P=1}^{\infty} P x_{P,c} = 2(1-\alpha)^{-1} \tag{104}$$

$$m^{(2)} = \sum_{P=1}^{\infty} P^2 x_{P,c} = (4+2\alpha)(1-\alpha)^{-2} \tag{105}$$

leads to

$$\bar{P}_{n,c} = m^{(1)}/m^{(0)} = 2(1-\alpha)^{-1}\ \bar{P}_{w,c} = m^{(2)}/m^{(1)} = (2+\alpha)(1-\alpha)^{-1} \tag{106}$$

The breadth of the distribution is therefore given by

$$\frac{\bar{P}_{w,c}}{\bar{P}_{n,c}} = \frac{m^{(2)}m^{(0)}}{m^{(1)}m^{(1)}} = 1 + \frac{\alpha}{2} \tag{107}$$

Keeping in mind that α has a value close to one, equation 107 leads to a polydispersity of 1.5 for a polymer produced in a polymerization process where termination is by combination. The corresponding chain length distribution is somewhat narrower than that generated by disproportionation, because of the statistical coupling of two chains with different sizes.

Almost every polymerization system shows both disproportionation and combination modes. In order to combine the two modes the general expression for the polydispersity of any given termination-controlled chain length distributions reads

$$\frac{\bar{P}_w}{\bar{P}_n} = \frac{1}{2}(3-\delta)(1+\delta) \tag{108}$$

Because the value of α is close two one, the expression $\ln(\alpha) \approx \alpha - 1$ does hold true, leading to $\alpha \approx \exp[-(1-\alpha)]$. With this correlation in mind the combination of equation 96 with the l.h.s of equation 100 gives

$$x_P = \frac{1}{\bar{P}_n}\alpha^{P-1} \approx \frac{1}{\bar{P}_n}\exp\left[-\frac{(P-1)}{\bar{P}_n}\right] \approx \frac{1}{\bar{P}_n}\exp\left(-\frac{P}{\bar{P}_n}\right) \tag{109}$$

with the factor $(P-1)$ substituted by P, because the chain length P is assumed to be much larger than 1, ie $P \gg 1$. Equation 109 demonstrates that the chain length distribution of the polymer formed by disproportionation or chain transfer follows an exponential function in the limit of infinite chain length.

The same calculation procedure, starting with equation 102, also leads to an exponential expression for the chain length distribution for termination by combination.

$$x_P = \frac{4P}{\bar{P}_n^2}\exp\left(-\frac{2P}{\bar{P}_n}\right) \tag{110}$$

However, equation 110 has the independent variable, the chain length P, in the preexponential factor, giving the chain length distribution of the polymer formed by combination a different shape.

Evaluation of equation 95 immediately leads to

$$\alpha = \frac{k_p[M]}{k_p[M] + 2(fk_dk_t[I])^{0.5} + k_{tr}[T]} \tag{111}$$

All derived distribution functions and average degrees of polymerization may now be expressed via the kinetic coefficients.

Nonstationary (Instationary) Polymerization. Calculation of chain length distributions of a polymer formed via a nonstationary polymerization (also sometimes denoted as instationary polymerization) is reasonable only if the nonstationary process is not linked to another polymerization process, eg, the pre- and aftereffect of a steady-state polymerization. One possibility to perform such an uncoupled nonstationary polymerization is the so-called single pulse experiment. A single laser pulse produces a free radical concentration ρ; the polymerization process is started, and no new free radicals are generated. The kinetic equations for such an experiment can be solved analytically, even if a chain-length-dependent termination rate coefficient is assumed. This is the case, because in such an experiment all macroradicals have the same chain length—within a narrow Poisson distribution and neglecting chain transfer—at any given time.

The free radical concentration formed by the laser pulse, ρ, decays according to the termination rate law expression.

$$-\frac{\mathrm{d}[\mathrm{R}^\bullet]}{\mathrm{d}t} = 2k_\mathrm{t}[\mathrm{R}^\bullet]^2 \tag{112}$$

Assuming a perfect correlation of time and the degree of polymerization, $P = k_\mathrm{p}[\mathrm{M}]t$, the average frequency of the propagation steps, and the postulated law for the chain length dependence of k_t, $k_\mathrm{t} = k_\mathrm{t}^0 P^{-\alpha}$, equation 112 can be written as

$$-\frac{\mathrm{d}[\mathrm{R}^\bullet]}{\mathrm{d}t} = 2k_\mathrm{t}^0(k_\mathrm{p}[\mathrm{M}])^{-\alpha}t^{-\alpha}[\mathrm{R}^\bullet]^2 \tag{113}$$

Solving this differential equation yields the concentration of free radicals as function of time, where ρ is the free radical concentration at $t = 0$:

$$[\mathrm{R}^\bullet]_\mathrm{t} = \left\{\frac{1}{\rho} + \frac{2k_\mathrm{t}^0(k_\mathrm{p}[\mathrm{M}])^{-\alpha}}{1-\alpha}t^{1-\alpha}\right\}^{-1} \tag{114}$$

The termination process by disproportionation transforms the living macroradicals into dead polymer chains with exactly the same chain length. This transformation process can be written as

$$-\frac{\mathrm{d}[\mathrm{R}^\bullet]_\mathrm{t}}{\mathrm{d}t} = [\mathrm{P}_P]k_\mathrm{p}[\mathrm{M}] \tag{115}$$

because the loss of free radicals must equal the generation of dead polymer. The factor $k_\mathrm{p}[\mathrm{M}]$ allows for the transformation of time to chain length. The concentration of dead polymer with chain length P, $[\mathrm{P}_P]$, is the chain length distribution in terms of concentrations. Division of $[\mathrm{P}_P]$ by the free radical concentration at the beginning, ρ, according to $x_{P,\mathrm{d}} = [\mathrm{P}_P]/\rho$ with $\sum[\mathrm{P}_P] = \rho$), insertion of equations 113, 114, and 115, and rearrangement yields the number chain length distribution for a single pulse experiment with termination by disproportionation.

$$x_{P,\mathrm{d}} = \frac{2k_\mathrm{t}^0\rho}{k_\mathrm{p}[\mathrm{M}]}P^{-\alpha}\left\{1+\frac{2k_\mathrm{t}^0\rho}{(1-\alpha)k_\mathrm{p}[\mathrm{M}]}P^{1-\alpha}\right\}^{-2} \tag{116}$$

The combination process gives a dead polymer chain with exactly double the chain length of the living macroradical, because all macroradicals have the same size at any given time. The transformation process from time to chain length therefore reads

$$-\frac{\mathrm{d}[\mathrm{R}^\bullet]_t}{\mathrm{d}t} = 4[\mathrm{P}_{2P}]k_\mathrm{p}[\mathrm{M}] \tag{117}$$

Because two free radicals are leading to one dead polymer, $\sum[\mathrm{P}_{2P}] = \rho/2$ must hold true. With this in mind and insertion of equations 113, 114, and 117 and subsequent rearrangement gives the number chain length distribution for a single pulse experiment with termination by combination.

$$x_{P,c} = \frac{2k_\mathrm{t}^0\rho}{4k_\mathrm{p}[\mathrm{M}]}\left(\frac{P}{2}\right)^{-\alpha}\left\{1+\frac{2k_\mathrm{t}^0\rho}{(1-\alpha)k_\mathrm{p}[\mathrm{M}]}\left(\frac{P}{2}\right)^{1-\alpha}\right\}^{-2} \tag{118}$$

According to the different termination modes the overall number chain length distribution can be calculated via

$$x_P = \frac{2}{1+\delta}[\delta x_{P,\mathrm{d}} + (1-\delta)x_{P,\mathrm{c}}] \tag{119}$$

with δ being the contribution of disproportionation to the overall termination process.

Pseudostationary Polymerization. Throughout many decades the pseudostationary polymerization was carried out—mainly with a rotating sector—to measure a different ratio of the individual rate coefficients k_p and k_t as that obtained from steady-state experiments. The rate of polymerization was the only measured value, and the chain length distribution of the polymer produced during such an experiment was not evaluated, mainly because of the lack of suitable analytical techniques. The invention and improvement of SEC paved the way for detailed investigations of the chain length distribution formed throughout a pseudostationary polymerization experiment (415). This improvement eventually lead to the invention of the PLP–SEC method (416), which turned out to be the best improvement in polymerization kinetic measurements long since. This technique allows for the direct measurement of the individual propagation rate coefficient k_p (133,417).

The principle of the pulsed laser technique is simple but ingenious. A monomer/photoinitiator mixture is irradiated by a pulsed laser beam. Each laser flash generates free radicals which initiate a polymerization process. No new free radicals are formed during the dark time periods. All growing macroradicals formed by one specific laser pulse have the same chain length within a narrow Poisson distribution. As the free radical concentration decreases owing to termination processes, the rate of termination decreases according to equation 46, too.

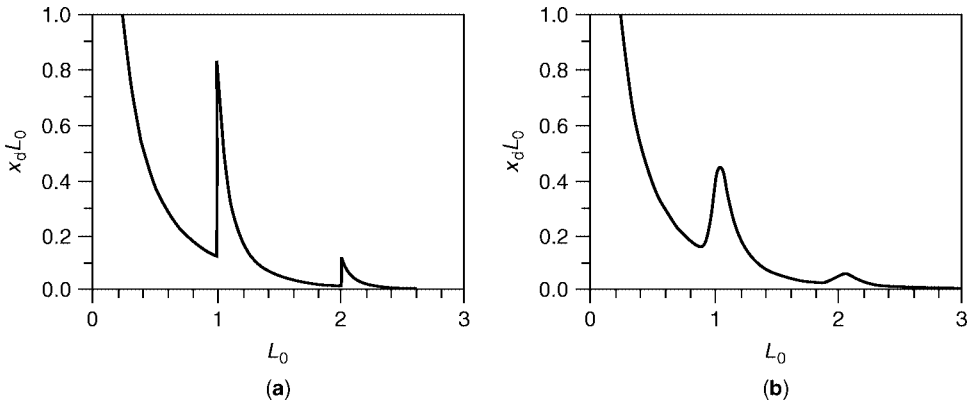

Fig. 11. Simulated and normalized number distribution for a pulsed laser experiment, with termination exclusively via disproportionation (**a**) without and (**b**) with Poisson broadening.

After the dark period, t_0, the next laser flash irradiates the system and instantaneously increases the free radical concentration. Hence, the termination rate is suddenly highly increased, too, leading to a significant amount of dead polymer with the chain length L_0 being the chain length of a macroradical that grew for one dark time period, t_0. Taking into account that the radicals have a certain probability to survive the laser flash and to terminate at any later pulse, the relative concentration of polymer with the chain length $2L_0$, $3L_0$, and so on, is increased, too. The described polymerization conditions therefore produce a well-structured chain length distribution with additional peaks at the chain length of L_0 and its multiples (see Figure 11). The radicals which are formed at the laser pulse are very small. The mode of termination is therefore not overly important for the formation of the additional peaks of the chain length distribution.

Assuming a low conversion of monomer to polymer, the monomer concentration can be expected to be constant. The propagation rate coefficient and the monomer concentration can therefore be combined into a new rate coefficient, $\tilde{k_p} = k_p[M]$, which is associated with the following first-order rate law:

$$R_p = \tilde{k}_p[R^\bullet] \quad \text{with} \quad \tilde{k}_p = k_p[M] \tag{120}$$

The average time span between two first-order reaction steps, τ, is given by

$$\tau = k^{-1} \tag{121}$$

with k being the first-order rate coefficient. Insertion of equation 120 into equation 121 yields the time of an average propagation step τ_p, assuming the monomer concentration is constant.

$$\tau_p = \frac{1}{\tilde{k}_p} = \frac{1}{k_p[M]} \tag{122}$$

The chain length $L_{0,n}$ of a macroradical that grows n laser periods, nt_0, is now easily correlated with the propagation rate coefficient k_p.

$$L_{0,n} = nk_p[M]t_0 \tag{123}$$

The evaluation of the additional peaks occurring in the chain length distribution of a PLP experiment and the corresponding values of $L_{0,n}$ by means of SEC enables the calculation of k_p, because the monomer concentration and the laser frequency are known.

Because of the statistical process of the chain growth, the macroradicals produced by the same laser pulse do not exhibit the same chain length at any given time, but rather show a narrow Poisson distribution with L being the mean value.

$$x_P = e^{-L}\frac{L^P}{P!} \tag{124}$$

The theoretical chain length distribution is therefore subject to a broadening, losing its discontinuities (see Figure 11**b**). It turned out that the inflection point on the low molecular weight side of the additional peak is in most cases the best measure for the real value of L_0 (418). Only at the so-called high termination limit, where the free radical concentration produced by each laser pulse is extremely high, the maximum of the additional peak may be a better choice (419). However, second or higher points of inflection can often be evaluated, even when there is no peak maximum visible. In addition, because of being a point of second order, the inflection point is less affected by baseline errors occurring during the SEC.

Analytical solutions for the chain length distribution generated by PLP (415, 416,420,421) are very complex, even in their simplest form, assuming no Poisson distribution, no transfer, and no initiation process during the dark time period. The chain length distribution for assuming a strict coupling of time and degree of polymerization for termination by disproportionation can be written as

$$x_{P,d}^{(n)} = \rho\left\{\frac{\tilde{C}}{L_0}\left[1+\frac{\tilde{C}}{L_0}(P-nL_0)\right]^{-2}(1+\tilde{C})^{-n}\right\} \tag{125}$$

where

$$0 \le P \le L_0 \quad \text{for} \quad n = 0$$

$$nL_0 < P \le (n+1)L_0 \quad \text{for} \quad n = 1,\ 2,\ 3\ldots$$

with the definitions

$$\tilde{C} = C\frac{[R_+{}^\bullet]}{\rho} \tag{126}$$

$$C = 2\rho k_t t_0 \tag{127}$$

$$L_0 = k_p[M]t_0 \tag{128}$$

Especially the value C is of importance, because it governs the overall shape of the chain length distribution. A typical value of C is 0.5–10, whereas higher values of C yield more pronounced first additional peaks (high termination limit). The shape of a PLP distribution can be (in principle) held constant by balancing the product of the laser period t_0 and the free radical concentration produced by each laser pulse, ρ, to give constant values of C. It should be noted that the extra peaks are sharper greater the value for L_0.

The expression for the chain length distribution for termination by combination reads

$$x_{P,\mathrm{c}}^{(n)} = \rho\left[n(1+\tilde{C})^{-n+1}\frac{\hat{x}_{P-(n-1)L_0,\mathrm{c}}}{\rho} + (n+1)(1+\tilde{C})^{-n}\frac{\hat{x}_{P-nL_0,\mathrm{c}}}{\rho}\right] \tag{129}$$

with

$$\hat{x}_{P,\mathrm{c}} = \frac{\rho}{2}\frac{C}{2L_0}\left(1+\tilde{C}\frac{P}{2L_0}\right)^{-2} \tag{130}$$

The statistical moments of the chain length distribution in the long-chain limit can be calculated by insertion of equations 125 and 129 into equation 75.

For termination by disproportionation,

$$m_{\mathrm{d}}^{(0)} = \rho \tag{131}$$

$$m_{\mathrm{d}}^{(1)} = \rho\left[L_0\frac{\ln(1+\tilde{C})}{C}\right] \tag{132}$$

$$m_{\mathrm{d}}^{(2)} = \rho\left(2L_0\frac{L_0}{C}\right) \tag{133}$$

For termination by combination,

$$m_{\mathrm{c}}^{(0)} = \frac{\rho}{2} \tag{134}$$

$$m_{\mathrm{c}}^{(1)} = \rho\left[L_0\frac{\ln(1+\tilde{C})}{C}\right] \tag{135}$$

$$m_{\mathrm{c}}^{(2)} = \rho\left(3L_0\frac{L_0}{C}\right) \tag{136}$$

The number- and weight-average degrees of polymerization can be calculated via combination of these moments according to equation 76. For termination by disproportionation,

$$\bar{P}_{\mathrm{n,d}} = L_0\frac{\ln(1+\tilde{C})}{C} \tag{137}$$

$$\bar{P}_{\mathrm{w,d}} = 2L_0\frac{1}{\ln(1+\tilde{C})} \tag{138}$$

For termination by combination,

$$\bar{P}_{n,c} = 2L_0 \frac{\ln(1+\tilde{C})}{C} \tag{139}$$

$$\bar{P}_{w,d} = 3L_0 \frac{1}{\ln(1+\tilde{C})} \tag{140}$$

The polydispersity of the chain length distribution of a polymer produced via a pulsed laser experiment for disproportionation reads

$$\frac{\bar{P}_{w,d}}{\bar{P}_{n,d}} = 2\frac{C}{[\ln(1+\tilde{C})]^2} \tag{141}$$

and for combination

$$\frac{\bar{P}_{w,c}}{\bar{P}_{n,c}} = \frac{3}{2}\frac{C}{[\ln(1+\tilde{C})]^2} \tag{142}$$

As can be easily seen, the breadth of the PLP distribution is not only dependent on the termination mode, as this is the case for steady-state experiments. The polydispersity is additionally controlled by the polymerization conditions like initiator concentration and laser intensity, which both influence the value of the free radical concentration which is produced at each laser flash, ρ. The polydispersity is also different for different pulse periods, t_0.

Thermodynamics

Especially at elevated temperatures the propagation step can no longer be considered irreversible. The propagation step is in fact reversible, leading to a thermodynamic equilibrium. This equilibrium can be described by the magnitude of the free energy difference ΔG_p between the polymer and the monomer. The polymerization process is thermodynamically favored if ΔG_p is negative. The value of the free energy difference is given by the fundamental equation

$$\Delta G_p = \Delta H_p - T\Delta S_p \tag{143}$$

For long polymer chains the enthalpy and entropy changes in the propagation reaction are effectively those of the overall polymerization reaction (113,422). The polymerization enthalpies ΔH_p of most free radical polymerizations are negative, with typical values of -30 to -100 kJ $\cdot$ mol^{-1} as can be seen in Table 8.

The values for the polymerization entropies are negative, too, reflecting the loss of degrees of freedom of the monomer becoming a part of the polymer chain. Typical values for the polymerization entropies are -100 to -120 J $\cdot$ K^{-1} $\cdot$ mol^{-1} (see Table 8). Hence, the two terms on the r.h.s. of equation 143 are antagonistic. Under normal temperature conditions, the exothermicity of the reaction exceeds the entropic term and ΔG_p becomes negative. However, at elevated temperatures

Table 8. Standard Polymerization Enthalpies ΔH_p^0 and Polymerization Entropies ΔS_p^0 of Various Monomers for the Reaction of Liquid Monomers to Condensed Polymers[a]

Monomer	$-\Delta H_p^0$, kJ · mol^{-1}	$-\Delta S_p^0$, J · K^{-1} · mol^{-1}

Vinylidene chloride	60	106

[a] Data from Ref. 173.

the entropic term becomes significantly larger and finally equals the enthalpic term at the so-called ceiling temperature T_c.

$$T_c = \frac{\Delta H_p}{\Delta S_p} \tag{144}$$

At this temperature the free energy difference is zero and no polymerization process occurs—the system is in equilibrium (423). A few systems are known in which both the enthalpy and the entropy changes of the polymerization reaction are positive. The polymerization of sulfur of the eight-membered ring conformation is one example (424–426): the entropy increases because the S_8 ring is rigid and the ring-opening reaction makes additional conformations available. It follows from equation 143 that in such cases there exists a floor temperature with polymerization possible only above a certain temperature.

The kinetic interpretation of the thermodynamic effects describes the propagation reaction as reversible with a propagation and depropagation step (113,427):

$$R_i^{\cdot} + M \xrightarrow{k_p} R_{i+1}^{\cdot} \tag{145}$$

$$R_{i+1}^{\cdot} \xrightarrow{k_{dp}} R_i^{\cdot} + M \tag{146}$$

The rate coefficient of depropagation is written as k_{dp}. The activation energy of the depropagation reaction, $E_{A,dp}$, is generally much higher than that of the propagation reaction, $E_{A,p}$, the difference being equal to the enthalpy change of

the polymerization reaction:

$$E_{A,p} - E_{A,dp} = \Delta H_p \tag{147}$$

For many typical free radical polymerization systems and conditions, depropagation does not occur to any appreciable extent. However, for some 1,1-disubstituted ethylene monomers, it is possible to polymerize at conditions where the effects of the reverse reaction cannot be neglected. The classical example of such a monomer is α-methylstyrene, with a low ceiling temperature of around 60°C for bulk polymerization, arising from its relatively low heat of polymerization (Table 8), and the equilibrium monomer concentrations are correspondingly high (0.76 mol $\cdot$ L^{-1} at 0°C) (427). Methacrylate and styrene monomers also exhibit depropagation, although at much higher temperatures (220 and 310°C, respectively, for bulk polymerizations). The depropagation process lowers the rate of polymerization according to

$$R_p = k_p[M][R^\bullet] - k_{dp}[R^\bullet] = \left(k_p - \frac{k_{dp}}{[M]}\right)[M][R^\bullet] = k_p^{eff}[M][R^\bullet] \tag{148}$$

The effective rate coefficient of propagation is therefore defined as

$$k_p^{eff} = k_p - \frac{k_{dp}}{[M]} \tag{149}$$

The depropagation effect is inversely proportional to the monomer concentration, because it is part of the thermodynamic equilibrium. The effective propagation rate coefficient can be determined via the PLP–SEC method. Figure 12

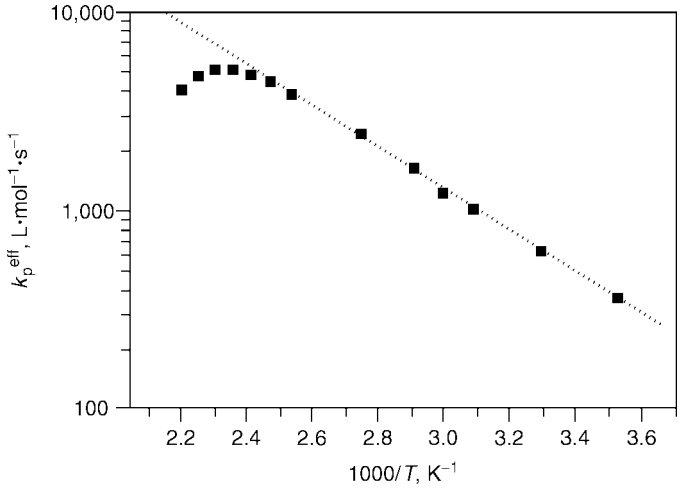

Fig. 12. Temperature dependence of the effective propagation rate coefficient k_p^{eff} observed in the bulk polymerization of dodecyl methacrylate. The data are taken from Ref. 429.

shows the deviation of k_p^{eff} from the linear slope of an Arrhenius plot at higher temperatures, where depropagation becomes important (429).

At the ceiling temperature, the effective rate coefficient becomes zero, that is, k_{dp} equals $k_p[M]$. Using this and equation 147 leads to

$$T_c = \frac{\Delta H_p}{R \ln(A_p/A_{dp}) + R \ln[M]} \tag{150}$$

when introducing Arrhenius relations for k_p and k_{dp} with A_p and A_{dp} being the frequency factors for the propagation and depropagation reactions. Comparison of equations 144 and 150 shows that

$$\Delta S_p = R \ln(A_p/A_{dp}) + R \ln[M] = \Delta S_p^0 + R \ln[M] \tag{151}$$

where ΔS_0^p is the standard entropy change for $[M] = 1 \text{ mol} \cdot L^{-1}$, so that

$$T_c = \frac{\Delta H_p}{\Delta S_p^0 + R \ln[M]} \tag{152}$$

The considerations leading to equation 152 enable the *ceiling temperature* to be defined as the temperature above which no polymerization to high polymers can occur, with monomer at the specified concentration [M]. It should therefore be kept in mind that the ceiling temperature is a function of the monomer concentration. It is determined by thermodynamic parameters and is independent of the mechanism, eg, whether ionic or free-radical. The applicability of the above relations depends on depropagation being the exact reverse of propagation. Hence, the observation of a ceiling temperature requires the presence of active centers. In their absence polymers can exist without change at temperatures well above their ceiling temperatures. When active centers are present there exists an equilibrium concentration of monomer given by equation 152. The introduction of active centers, eg, via UV radiation and/or high temperatures, and subsequent depropagation is one pathway for the degradation of polymers. By adding stabilizers these radicals can be trapped and the depropagation may hence be suppressed.

With many monomers the equilibrium monomer concentrations at ambient temperatures are too small to be measured directly since the ceiling temperatures are relatively high. However, they may be obtained via extrapolation (430). Some of the deviations from simple kinetic behavior at high temperatures recorded in the older literature can be explained by the occurrence of depropagation. Use of the effective monomer concentration, defined as the total concentration minus the equilibrium concentration, removes the discrepancies.

The thermodynamic definition of the equilibrium constant K reads

$$\Delta G_p = -RT \ln K \tag{153}$$

whereas the kinetic expression for K is the ratio of the rate coefficients of the forward reaction to the rate coefficient of the backward reaction. This can be set equal to the thermodynamically definition of K (eq. 153). If the degree of polymerization

is very large, the concentrations of growing chains i and $i + 1$ can be considered nearly identical, which leads to

$$K = \frac{\overrightarrow{k}}{\overleftarrow{k}} = \frac{k_p}{k_{dp}} = \frac{[R_{i+1}^{\bullet}]}{[R_i^{\bullet}][M]_e} \approx \frac{1}{[M]_e} \tag{154}$$

where $[M]_e$ is the equilibrium monomer concentration (eg, 10^{-6} mol$^{-1} \cdot$ L^{-1} for styrene at 25°C). By combining equations 149 and 154 it can be seen that when the monomer concentration equals the equilibrium monomer concentration, the effective propagation rate coefficient k_p^{eff} becomes zero, which is the definition for the ceiling temperature. This implies that there exists a specific ceiling temperature for every given monomer concentration. The maximum ceiling temperature is reached for the bulk polymerization system. It has been recently demonstrated that effective molecular weight control in copolymerizations may be achieved by the judicious selection of monomers which display a low ceiling temperature (431).

Equilibrium concentrations and ceiling temperatures are additionally influenced by the pressure. According to the Clausius–Clapeyron equation, a change in the molar volume change $\Delta V_c = V_p - V_m$ at the ceiling temperature generally leads to

$$\frac{dT_c}{dp} = T_c \frac{\Delta V_c}{\Delta H_p} \tag{155}$$

The polymer usually has the smaller molar volume with respect to monomer units, ΔV being therefore negative, eg, -14.7 cm$^3 \cdot$ mol^{-1} for α-methylstyrene (432). This leads, together with a negative reaction enthalpy, to a positive pressure dependence of the ceiling temperature. The T_c value, for instance, of α-methylstyrene rises from 60°C at 0.1 MPa (1 bar) over 131°C at 421 MPa to 171°C at 648 MPa. With increasing pressure, however, the melting points of the monomers are also raised, and polymerizations of crystalline monomers are far from being easy.

Inhibition and Retardation

Since the polymerization reaction should proceed under controlled reaction conditions it is undesirable that polymerization activity is induced during the monomer preparation, storage, or purification. However, premature radical formation from the pure monomer and from impurities or contaminants can easily lead to unwanted polymerization. If a substance can quantitatively scavenge these initiating radicals the propagation reaction is effectively suppressed (167,433). When this scavenger compound is consumed by reaction with the generated radicals, the polymerization proceeds with the same rate as without any additives. These additives are consequently denoted as *inhibitors*. The *inhibition period*, ie the time span that is necessary for the complete consumption of the scavenger molecules, is often measured to calculate the initiation rate (see Figure 13**b**). A *retarder* is a substance that

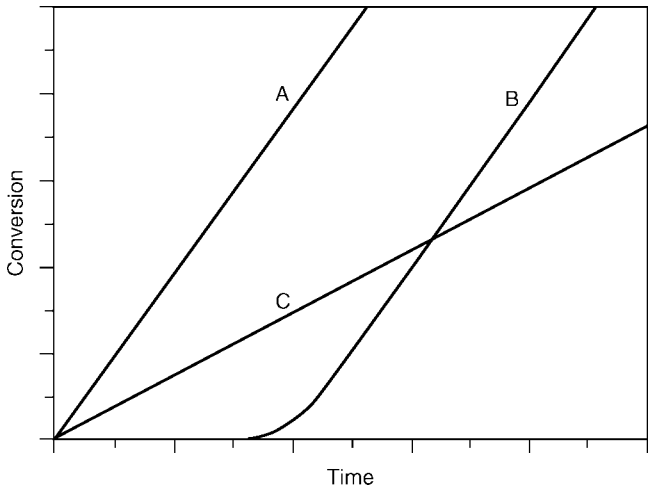

Fig. 13. Typical conversion versus time profiles for conventional free radical polymerization (A) with addition of inhibitor (B) and retarder (C).

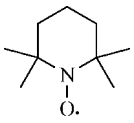
decreases the overall polymerization rate without any induction period, and is not completely consumed throughout the polymerization (see Figure 13**c**). The distinction between inhibition and retardation is not always clear. However, both effects are based on the concept of effectively preventing the generated radicals from initiating polymerization. Two general cases can be identified:

(1) The scavenger molecule reacts with the initiator-derived—or very small polymeric—radical to form a relatively stable radical that by itself is not capable of initiating polymerization. However, this radical may be active toward other radicals in the system and may hence terminate irreversibly or reversibly via radical–radical reactions.
(2) The scavenger molecule is by itself a radical and reacts with any other radicals in the system to generate nonreactive products. Because of the stability of the radical compounds employed for such inhibition/retardation reactions, the generated bond is very weak and may homolytically cleave at elevated temperatures to give back the radical reactants. This reaction behavior is exploited in the living free radical polymerization technique using nitroxides as mediators (434,435).

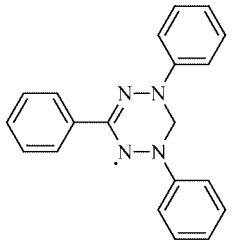
Stable free radicals are frequently employed as inhibitors (436,437). The most commonly used species are nitroxides, eg, 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) **18**. They are far too stable to be able to initiate polymerization, but they are reactive enough to undergo reaction with other free radicals (438). Nitroxides are very efficient inhibitors, being capable of producing induction periods when present in concentrations of less than 10^{-4} mol $\cdot$ L^{-1}. Nitroxides, such as TEMPO, react with carbon-centered radicals at close to diffusion controlled reaction rates (439–441). The stoichiometry between the number of the chains

terminated and the number of the nitroxide molecules consumed is 1:1, making these compounds very useful for quantitative measurements of free radical concentrations (81,82,442). The coupling process of the nitroxide with the propagating radical is reversible, especially at elevated temperatures. This equilibrium enables a living free radical polymerization by capping the reactive chain ends. The free radical concentration is therefore extremely decreased, suppressing the termination process. Temporarily uncapped free radicals are adding monomers, leading to a very slow, but controlled polymerization process (435,443,444). Recent review articles on nitroxide-mediated living free radical polymerization are References 434 and 445.

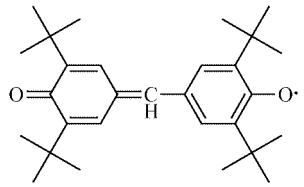


18

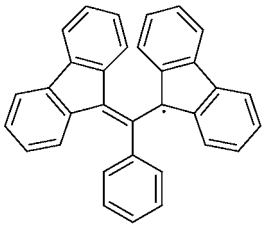
Another commonly used stable radical is 1,3,5-triphenylverdazyl **19** (446, 447). It is less thermally stable than TEMPO. Both TEMPO and the verdazyl radical do not react with oxygen-centered radicals or oxygen. If an initiator generates an oxygen-centered radical the nitroxide will capture the carbon-centered radical that is generated via the first addition step involving a monomer. Galvinoxyl **20** and 1,3-bisdiphenylene-2-phenylallyl (or Koelsch's) radical **21** can also be used as inhibitors. Diphenylpicrylhydrazyl **22** is used much less frequently because of its complicated reaction mode of inhibition (448).



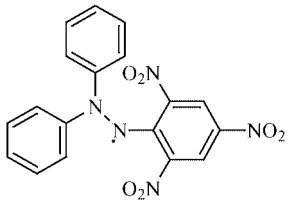
19



20



21



22

The overall polymerization rate decreases with increasing concentration of retarder. An induction period as with inhibitors is not observed. The rate retarding

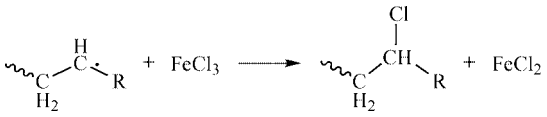
reactions can be considered very similar to the inhibition reactions; however, the reactivity of retarding agents toward radicals present in the polymerization mixture is smaller than that of inhibitors, and the compounds are therefore consumed slower, not depleting during the polymerization. Some retarder-derived radicals may even reinitiate the polymerization slowly—therefore constituting a comonomer—again leading to decreased polymerization rates. This slow reinitiation rate of the retarder-derived radicals effectively increases their concentration in the polymerization mixture, hence leading to an increased probability of termination reactions and other side reactions. In some cases it is very difficult to completely identify the real reason for rate retardation, because of the coupled nature of all the different reactions involved.

The most common retarders—denoted as *stabilizers*, because of their application in stabilizing monomers during their storage—are substituted phenols (eg, *p*-methoxyphenol, 2,6-di-*tert*-butyl-4-methyl phenol, used as stabilizer for styrene) (449). They readily undergo subtraction of the weakly bonded phenolic hydrogen to yield low reactive phenoxy radicals. The retardation ability of these compounds is strongly dependent on the type of monomers, since the phenoxy radicals may add on to monomer molecules with very different rates, hence acting as a transfer agent with a slow reinitiation rate. Phenols react slowly with electrophilic radicals and essentially do not inhibit polymerization of acrylates and methacrylates in the absence of oxygen (450,451).

Benzoquinone, which also may be employed as retarder (used as stabilizer for methyl methacrylate), gives a phenoxy radical as a result of a rapid addition of the radicals present in the system to the C=O double bond. The addition is facilitated by aromatic stabilization (452–454). The relative reactivities of alkyl- and methoxy-substituted benzoquinones have been correlated to their redox potentials and steric factors of the substituents (455,456). Industrially, hydroquinone is often added to monomers, although hydroquinone itself acts neither as an inhibitor nor as a retarding agent. However, if oxygen or peroxides are present in the system, the hydroquinone will be oxidized to quinone. Hydoquinone therefore acts in two ways: it reduces the peroxides that may initiate the polymerization and acts as an inhibitor in its oxidized quinone form.

A further important class of retarders, generally less effective than quinones, are the aromatic nitro compounds. They show very different effectiveness toward the retardation of different monomer types: the polymerization of vinyl acetate is inhibited, the styrene polymerization is retarded, but there is nearly no influence on the polymerization rate of acrylates and methacrylates. The effectiveness, however, increases with the number of nitro groups per molecule.

Transition metal [eg, Fe(III), Cu(II), Ce(IV), Hg(II), and Ag(I)] salts such as halides or pseudohalides are also employed as inhibitors (457). The reaction mechanism involves the effective electron transfer (redox process) or a ligand transfer mechanism. The carbon carrying the unpaired electron is converted to a σ-bonded carbon or ionic species. In nonaqueous systems the most used retarder is iron(III) chloride which shows no reinitiation abilities, hence being considered as an ideal inhibitor or retarder (205). The Fe(III) is reduced to Fe(II) during the reaction. This Fe(II) formation can be monitored by UV/vis spectroscopy to investigate the reaction rate. Equation 156 shows the reaction scheme for the retarding reaction involving ferric chloride.



(156)

$CuCl_2$ is an even more powerful inhibitor/transfer agent than $FeCl_3$. It reacts with growing polystyrene radicals 20 times faster ($C = 10{,}000$ vs 500) and with poly(methyl methacrylate) radicals 50 times faster ($C = 2000$ vs 4) (458). In the presence of a suitable ligand the resulting alkyl halides can react reversibly with Cu(I) species and establish an atom transfer equilibrium, which is at the essence of ATRP.

One of the most well-known retarders of free radical polymerization is molecular oxygen (459,460). Because of the diradical character of oxygen it reacts readily with carbon-centered radicals present in the polymerization system via an addition process to yield peroxy radicals. These peroxy radicals may reinitiate the polymerization, effectively incorporating the molecular oxygen into the polymeric chain, so that oxygen is a potential comonomer. In many cases the reinitiation reaction is slower than the propagation and oxygen acts as a retarder. The generated polyperoxides may act subsequently as initiator (461–463). Consequently, the kinetics of polymerizations performed in presence of oxygen may be complex.

Interestingly, the polymerization rates of vinyl esters are remarkably retarded by small amounts of styrene. The highly reactive vinyl ester radicals readily react with the activated styrene monomer, which results in a relatively stable benzyl-type styrene radical. The vinyl ester monomer molecule is not activated enough for the addition of the styrene radicals and the reaction ceases (464).

Buckminsterfullerene (C_{60}) has attracted much interest, not only because of its structure and physical properties, but also because of its reaction behavior in radical polymerization systems. C_{60} reacts rapidly with radicals to yield ESR-detectable radical species $C_{60}^{\bullet}$ (465). C_{60} was found to act as an effective inhibitor in vinyl acetate polymerization and all consumed C_{60} molecules were incorporated into the polymeric chains during the polymerization. The relation between the induction period and the initiation rate revealed that one C_{60} molecule can trap 15 radicals (466). The rate of polymerization of styrene and methyl methacrylate is also significantly retarded in the presence of C_{60} (467–471). The average number of C_{60} molecules incorporated in the polymer chains increases when increasing the C_{60} concentration, maybe because of coupling of polymer–$C_{60}^{\bullet}$ to give polymer–C_{60}–C_{60}–polymer (472).

The kinetics of the retardation effect for a stationary polymerization can be analyzed by adding an additional reaction to the basic scheme of polymerization, including initiation, propagation, and termination (473,474).

$$R_i^{\cdot} + Q \xrightarrow{k_Q} P_i + Q^{\cdot} \tag{157}$$

where Q is the retarder or inhibitor and k_Q is the rate coefficient of the retardation reaction.

The kinetics is simplified by assuming that the generated radical $Q^{\bullet}$ does neither reinitiate nor show any transfer behavior. The steady-state assumption—which is only a very rough approximation until all inhibitor is consumed (475)—can now be written as

$$-\frac{d[R^{\bullet}]}{dt} = R_i - 2k_t[R^{\bullet}]^2 - k_Q[R^{\bullet}][Q] = 0 \tag{158}$$

which yields in combination with equation 55 (again assuming that the rate of the loss of monomer, $-d[M]/dt$, equals the rate of polymerization, R_p)

$$R_i - \frac{2k_t R_p^2}{k_p^2[M]^2} - \frac{k_Q R_p[Q]}{k_p[M]} = 0 \tag{159}$$

The ratio of the rate coefficients for retardation, k_Q, and propagation, k_p, is often referred to as the inhibition constant, $z = k_Q/k_p$, which reflects the ability of a molecule to cause inhibition. Table 9 gives selected values for the inhibitor constants of some inhibitors in conjunction with a specific monomer.

If the inhibition constant is large ($z \gg 1$), the second term of the l.h.s. of equation 159 will become much smaller than the third one. In this case, the rate of inhibition is much larger than the rate of termination. Equation 159 then reads

$$R_p = \frac{k_p[M]R_i}{k_Q[Q]} \tag{160}$$

Table 9. Inhibition Constants *z* of Various Inhibitors to Selected Monomers at 50°C[a]

Inhibitor	Monomer	*z*
Nitrobenzene	Methyl acrylate	0.00464
	Styrene	0.326
	Vinyl acetate	11.2
1,3,5-Trinitrobenzene	Methyl acrylate	0.204
	Styrene	64.2
	Vinyl acetate	404
Chloranil	Methyl methacrylate (44°C)	0.26
	Styrene	2,040
Oxygen	Methyl methacrylate	33,000
	Styrene	14,600
Phenol	Methyl acrylate	0.0002
	Vinyl acetate	0.012
TEMPO	Styrene	335,712
$CuCl_2$	Styrene	10,000
	Methyl methacrylate	2,000
$FeCl_3$	Styrene	536
	Methyl methacrylate	4

[a] Data from Ref. 173.

Equation 160 shows that the polymerization rate is inversely proportional to the inhibitor concentration. It should be kept in mind that the inhibitor concentration will decrease during the reaction. Each free radical generated by the initiation process will consume one inhibitor molecule. If the inhibitor concentration finally becomes sufficiently low, propagation can become competitive with the inhibition reaction.

Dividing the rate law for the loss of inhibitor, $-\mathrm{d[Q]}/\mathrm{d}t, = k_\mathrm{Q}[\mathrm{R}^\bullet][\mathrm{Q}]$, by the rate law of propagation, $-\mathrm{d[M]}/\mathrm{d}t, = k_\mathrm{p}[\mathrm{R}^\bullet][\mathrm{M}]$, leads to

$$\frac{\mathrm{d[Q]}}{\mathrm{d[M]}} = \frac{z[\mathrm{Q}]}{[\mathrm{M}]} \tag{161}$$

and subsequent integration with $[\mathrm{Q}]_0$ and $[\mathrm{M}]_0$ being the concentration of inhibitor and monomer at the beginning of the reaction.

$$\ln\left(\frac{[\mathrm{Q}]}{[\mathrm{Q}]_0}\right) = z \ln\left(\frac{[\mathrm{M}]}{[\mathrm{M}]_0}\right) \tag{162}$$

It is apparent from equation 162 that if z is large, the monomer conversion remains nearly zero until the inhibitor is consumed.

Experimental Methods

The aim of most kinetic experimental methods has always been to determine accurate values for the individual rate coefficients that govern the free radical polymerization process, especially k_t, k_p, and k_tr. Up to the late 1980s termination and propagation rate coefficients were accessible only in their coupled form, $k_\mathrm{p}/k_\mathrm{t}^{0.5}$, or individually via combination with pseudo flickering techniques like the rotating sector or spatially intermittent polymerization methods in combination with stationary polymerization measurements. The only exception has been the direct determination of the propagation rate coefficient via the measurement of the steady-state free radical concentration by ESR experiments in combination with rate measurements. However, the detection of such low free radical concentrations (typically close to 10^{-8} mol $\cdot$ L^{-1}) has always been subject to large uncertainties, leading to a large scatter in the values for the rate coefficients. The situation has dramatically improved with the invention of the PLP technique in the late 1980s. Since then, this technique (and its spin-offs like SP–PLP) has been extensively used to collate propagation and termination rate coefficients for various homo- and copolymerizations. Today, the PLP method is almost exclusively used to determine propagation and termination rate coefficients and has been recommended by the IUPAC for the measurement of propagation rate coefficients. In contrast, the methods available for the determination of the chain transfer rate coefficient have not changed significantly over the last decades. It should, however, be mentioned that the interpretation of the transfer controlled molecular weight distributions generated in stationary free radical polymerizations has been somewhat refined with the introduction of the Clay–Gilbert method.

Methods for the Measurement of k_d.

Direct Measurement of the Initiator Concentration as a Function of Time. The rate coefficients of initiator decomposition, k_d, can be assessed by various methods. A straightforward approach is to directly assess the thermal decay of the initiator via the measurement of its concentration as a function of the reaction time by equation 3. The concentration can be measured via any quantity it is directly proportional to, eg, a spectroscopic infrared absorption that can be easily followed with reaction time. The connectivity of the initiator concentration and the intensity of the absorption (at a specific wavelength) is given by Beer–Lambert's law. Infrared spectroscopy has been used extensively in the past to study the decay of organic peroxides in various reaction media (including supercritical CO_2). Organic peroxides are widely used to initiate polymerizations, and knowledge about their rate of decomposition at various temperatures and their mechanism of decomposition are vital for optimizing polymerization processes (476,477).

Dead-End Polymerization. *Dead-end polymerization* refers to a polymerization process where the initiator concentration significantly decreases to a very low value during the polymerization. The measurement of the conversion of monomer to polymer, p, according to such an experiment, allows to determine the rate coefficient of initiator decomposition, k_d, and the calculation of the efficiency factor f.

Dividing equation 59 by equation 60, rearranging, and subsequently taking the logarithms of both sides yields

$$-\ln\left[1-\frac{\ln(1-p)}{\ln(1-p_\infty)}\right]=\frac{k_d t}{2} \tag{163}$$

The value of k_d can now easily be evaluated from a slope of a plot of the l.h.s. of equation 163 against the polymerization time t. If the ratio of $k_p{}^2/k_t$ is known by other studies, a value for the frequency factor f can be estimated by insertion into equation 56 or equation 60.

Methods for the Measurement of k_p.

Pulsed Laser Polymerization–Size Exclusion Chromatography. The careful determination of the chain length distribution of the polymer produced via a pseudostationary pulsed laser experiment allows to obtain accurate values for the propagation rate coefficient k_p. The polymerizable system—containing monomer and photoinitiator, occasionally solvent and transfer agents—is irradiated by a pulsed laser beam and the chain length distribution formed is subsequently analyzed by SEC. The determination of the additional peaks and its points of inflection on the low molecular side, respectively, gives a value for $L_{0,n}$ which can easily be inserted into equation 123.

$$L_{0,n}=nk_p[\mathrm{M}]t_0 \tag{123}$$

The propagation rate coefficient k_p is now available because the monomer concentration [M] and the time interval between laser pulses, t_0, are known. This method has developed into the IUPAC recommended method for k_p determination (398,478,479).

Prior to the PLP experiment the monomer should be purified to remove the stabilizer, which is added to most of the commercially available monomers. This can be achieved by either distillation or column chromatography. Both methods have different advantages: distillation removes small amounts of polymer dissolved in the monomer, but many inhibitors are very volatile and distillation does not completely remove them. However, PLP experiments without cleaning the monomer were reported and have shown the robustness of this method. Photoinitiators are added in typical concentrations of millimoles per liter. Degassing the samples by a number of freeze–pump–thaw cycles on a high vacuum line or purging with inert gases like nitrogen or argon makes sure that the dissolved oxygen, which disturbs the kinetic measurements by an inhibition effect, is removed.

For a successful PLP experiment, care must be taken to ensure a homogeneous intensity profile over the whole optical cross section of the reaction cell so as to produce homogenous reaction conditions. In addition, absorption of the laser light by initiator and monomer molecules should be accounted for. Accurate temperature control is necessary to dissipate the heat of reaction and any possible temperature increase induced by absorbed laser energy. Typical laser sources are pulsed Nd/YAG solid-state lasers (355 or 532 nm) or XeF excimer lasers (351 nm) with a pulse energy up to 80 mJ per pulse and a pulse width of 5–20 ns. Laser repetition rates between 100 and 0.1 Hz have been used in the past. The value of ρ (ie the free radical concentration generated by each laser pulse) can be varied by the initiator concentration and the laser pulse energy. Samples are exposed to pulsed laser irradiation to allow for a maximum conversion of monomer to polymer of about 1–3%, with typical pulsing times between 1 min and 5 h.

It should be noted that a pulsed lamp or even a rotating sector in combination with a continuous lamp as a pulsed radiation source leads to well-structured molecular weight distributions, allowing for the determination of k_p. However, optimum results are obtained by the use of a pulsed laser.

After the monomer solution has been irradiated, the produced polymer is analyzed by a SEC system, which is calibrated by narrow polymer standards or by absolute molecular weight detection methods. The values of $L_{0,n}$ can easily be determined by differentiating the chain length distribution. The use of different types of distributions (size exclusion, mass, or number distribution) leads to slightly different values for k_p. Figure 14 shows a typically data sheet for styrene bulk polymerization. It should be noted that the obtained k_p value is slightly dependent on the type of molecular weight distribution (ie size exclusions, weight, or number distribution) that is used for the data analysis (480).

Electron Spin Resonance Spectroscopy—Stationary Polymerization. The experimental determination of k_p data usually proceeds via the IUPAC recommended PLP–SEC procedure (see above). However, under certain circumstances, k_p data are also available by direct determination of the concentration of propagating free radicals via ESR spectroscopy, accompanied by the measurement of the overall polymerization rate (481) (see ELECTRON SPIN RESONANCE). The calculation of k_p then proceeds via either the differential (eq. 55) or the integrated form of the propagation rate law expression:

$$\ln\frac{[M]_1}{[M]_2} = k_p[R^\bullet](t_1 - t_2) \tag{164}$$

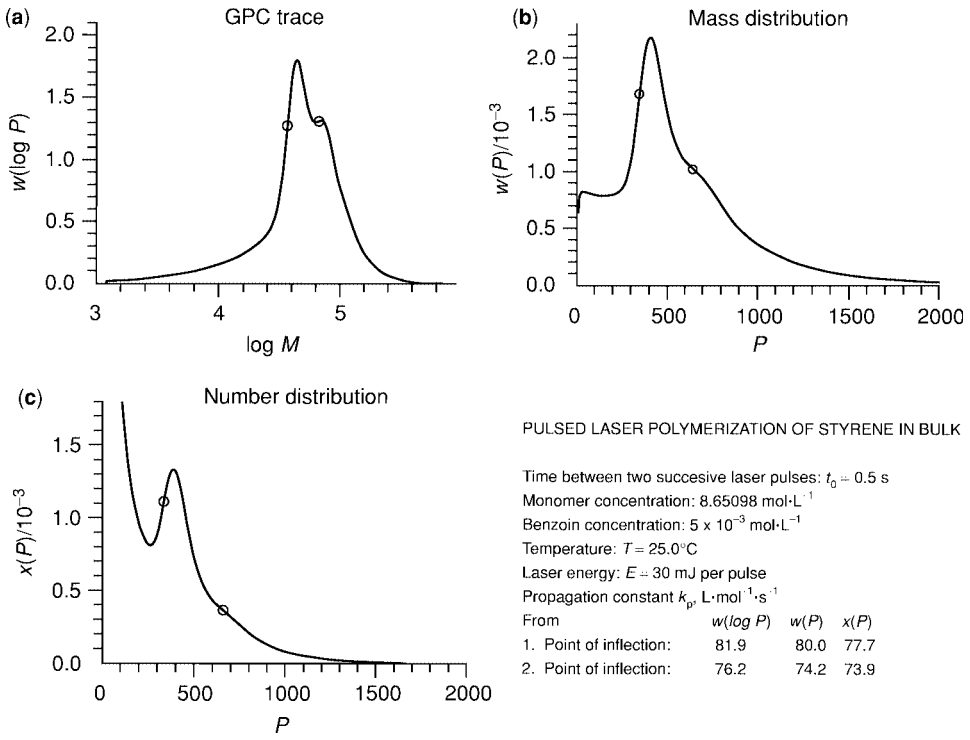


Fig. 14. Typical data sheet detailing the outcome of a successful PLP–SEC experiment for a styrene bulk polymerization at 25°C.

where $[M]_1$ and $[M]_2$ are the monomer concentrations at the reaction times t_1 and t_2, respectively. The determination of the monomer conversion at various reaction times can proceed via independent experiments (under the same experimental conditions as the ESR measurements) using, eg, NMR spectroscopy, infrared spectroscopy, gravimetry, or chromatographic methods.

Inspection of the existing literature indicates that k_p values derived from ESR are in poor agreement with k_p data from PLP–SEC measurement (482–485). Only a few recent studies indicate a somewhat better agreement (117,120), which is partly due to a significant increase in the quality of the ESR signals by using optimized ESR cavities and spectrometers (482). The studies indicating better agreement seem to have been carried out under specific experimental conditions, allowing for a reliable measurement of the long chain limit of the propagation rate coefficient. These studies indicate that particular attention needs to be paid to the size of the steady-state free radical concentration, which should be in an intermediate range. The type of initiator also seems to be important as is the fact that the only free radical in the system is the propagating species. This point is of special importance in photochemically induced polymerizations where, in addition to the photoinitiator, the monomer may also be excited. Additionally, the experimental conditions must be such that the majority of propagating radicals are of sufficiently large size to avoid determination of untypically high propagation rate coefficients,

which are known to occur with free radicals of short chain length. Because of this limitation, studies into higher k_p monomers may be advantageous (unless polymerization rates become too fast to precisely determine monomer conversion vs time profiles). Moreover, it should be checked that high molecular weight material is indeed produced. A specific problem of ESR spectroscopy is the calibration of the spectrometer. Usually, calibration proceeds via the measurement of the signal of a known concentration of a stable radical (eg TEMPO) in the same medium as the polymerization is carried out. The calibration may be the most serious drawback of the ESR method for k_p determination, since (*1*) it is very likely that the two different radicals, ie the radical used for calibration purposes and the propagating radical, are not comparable in terms of their detector signal, and (*2*) the calibration is—strictly speaking—only valid for the hypothetical case of 0% conversion and is immediately invalidated as the polymerization process changes the bulk viscosity of the reaction medium. It should also be noted that—similar to the PLP–SEC technique—only the product of the propagation rate coefficient and the monomer concentration is the measured quantity. Up to this date, no technique exists that allows the direct measurement of k_p.

Because these problems, the ESR technique remains problematic for the reliable determination of propagation rate coefficients and may only be applicable in very specific cases. However, the ESR technique also has the indisputable advantage of actually probing the propagating radicals directly and—in contrast to the PLP–SEC method—does not rely on the interpretation of secondary data material such as a molecular weight distribution. Valuable insight into the polymerization process, particularly at high conversions, has been deduced from ESR spectra recorded at different monomer conversions.

It should be briefly mentioned that the ESR technique may (via equation 65) also be applied toward the measurement of termination rate coefficients. There are several publications reporting on the k_t measurements via ESR. However, these measurements are associated with same problems as the k_p determinations (see for example References 161,486,487).

Quenched Instationary Polymerization Systems. Quenched instationary polymerization systems (QUIPS) (488,489) are characterized by the complete deactivation of all radicals by reaction with an inhibitor after a certain time. A photopolymerizable mixture passes through a capillary system, is irradiated at a specific location, and polymerizes in the capillary during a well-defined dark period until it drops into a quenching bath. The parameters determining the type of QUIPS are the duration of the initiation period (t_L) and an eventual following dark period (t_D). The method is based on the intentional limitation of the maximum active chain length $L_{act,max}$ the radicals can achieve. For this purpose all radicals present at a certain time in the system are deactivated by reaction with an inhibitor. Therefore, the kinetic scheme for the free radical polymerization is extended by the quench reaction with the rate constant k_q. A number of stable free radicals are known which fulfill the conditions of an extremely fast and efficient quench reaction (for instance nitroxyl radicals below 100°C). It is essential that the products of the quench reaction are stable and are not mediators for consecutive reactions. Experimental conditions can be chosen to ensure that the quench reaction is complete within the time span necessary for an ordinary propagation step, namely $1/(k_p[M])$. Under these conditions the radical spectrum present at

the beginning of (the short) quench period is immediately converted into inactive products.

Measuring the chain length distribution by SEC reveals a structured shape which allows to determine k_p in accordance to the same equation 123 used in PLP–SEC, which relates the active lifetime of a growing macroradical with its maximum active chain length. Recently, Vana and co-workers (135) modified the QUIPS technique in an attempt to make it applicable to hindered monomer systems. The original QUIPS method was changed into a batch operation; ie, a multipulse sequence of laser pulses was applied to the reaction mixture to effect a high primary radical concentration. Subsequently, the reaction mixture was quenched after a quenching time, t_q, by rapid mixing with an inhibitor containing solution. The propagation rate coefficient (at varying temperatures) can be assessed via the maximum of the formed polymer distribution, L_{max}. In addition, the multipulse quenched instationary polymerization also allows for easy access to termination rate coefficients k_t. The novel strategy has so far been successfully applied to the hindered monomer dicyclohexyl itaconate.

Methods for the Measurement of k_{tr}. The evaluation procedures and theoretical basis for the determination of transfer coefficients C have been extended and perfected over the past decade and a great number of transfer coefficients have been determined by various research groups [see for example References 490 and 491 or the multiple entries in the *Polymer Handbook* (492)]. The transfer coefficient is defined by equation 90 as the ratio of the transfer rate coefficient k_{tr} to the propagation rate coefficient k_p.

$$C = \frac{k_{tr}}{k_p} \tag{165}$$

The classical procedure for transfer coefficient measurement (to the monomer itself, any other added substance, or deliberately added transfer agent, such as a thiol or a catalytic chain transfer agent) has always been the Mayo method (493). However, Gilbert and co-workers recently introduced the chain length distribution (CLD) method (494) as an alternative way to determine transfer coefficients. The Mayo and CLD methods in themselves also provide different choices of data analysis. Both methods have been carefully compared and thoroughly discussed with the conclusion that both are theoretically equivalent (201).

In terms of applied experimental procedures, there are only two conceptually different methods available. The first one is the conventional or classical polymerization via thermal polymerization experiments, with specific amounts of thermally decaying initiator being present in the reaction mixture. Various groups have used this technique to determine transfer coefficients, as the impressive collection of data in Reference 492 indicates. Kukulj and co-workers (178), for example, investigated the transfer-to-monomer constant of methyl methacrylate, styrene, and α-methylstyrene at 50°C using thermal polymerization. To generate a sufficiently low radical flux to achieve transfer-dominated reaction conditions, the stock solution of the initiator in monomer is successively diluted. This gives a series of solutions with decreasing initiator concentrations, yielding increasing molecular weights upon polymerization. In many cases and when the initiator

concentrations are chosen correctly, a limiting molecular weight is reached which may then be used to determine the transfer to monomer constant via either the Mayo or the CLD method.

A second and more recent experimental technique became possible with the advent of pulsed laser systems: PLP in combination with subsequent SEC of the resulting polymer is the standard and IUPAC recommended technique for the determination of propagation rate coefficients k_p (398). However, several research groups have used PLP to determine transfer rate constants to a range of chain-transfer agents. For example, Hutchinson and co-workers (495) determined the transfer coefficients for transfer to *n*-dodecyl mercaptan in methyl methacrylate, styrene, ethyl methacrylate, and butyl methacrylate homopolymerizations in the temperature range between 20 and 80°C. By adding sufficient transfer agent, these authors were able to generate transfer-dominated conditions, as seen by the loss of the PLP characteristics in the molecular weight distributions obtained by SEC analysis of the polymers. In addition, Buback and co-workers (496) designed a method to determine the value of the propagation rate coefficient k_p and the transfer-to-monomer rate coefficient k_{tr}^M from a single PLP experiment. Packages of high frequency pulses separated with long dark time intervals give rise to two polymer distributions. This procedure has been termed the 'rail-road' experiment, because of the characteristic pulse profile of the light source that resembles the sound patterns generated by a moving train. The polymer produced during the high frequency pulse packages may be used to determine k_p, while the polymer produced in the longer dark time may be used to determine C_M (413,496).

PLP, however, is normally not the method of choice for measuring transfer-to-monomer rate coefficients via the CLD method, because the CLD method requires termination to be an unimportant or even absent route of radical chain stoppage as compared to transfer to monomer. In addition, the CLD method is, like the Mayo method, derived for steady-state polymerizations. Moreover, the radical flux must be low enough so that transfer, rather than termination, is the main chain-stopping event, so that the polymerization is truly transfer dominated. PLP is essentially used as a flickering termination rate technique, ie as a technique that makes essential use of effective termination. PLP, can however, be made applicable for studying even transfer to monomer, if combined with a rotating reactor/cuvette assembly (179). This assembly permits time efficient experiments with very long pulse periods and thus enables high molecular weight material to be produced at very low radical concentrations or termination rates, respectively. The rotating reactor/cuvette allows for acceptable polymerization rates even for slowly propagating monomers such as styrene.

The mathematical methods used to analyze molecular weight distributions generated in transfer-controlled free radical polymerization experiments, ie the Mayo and CLD methods, are discussed below.

The Mayo Method. The overall chain transfer coefficient C is defined as the ratio of the chain transfer and propagation rate coefficients, k_{tr}/k_p. For example, C_T is the ratio of the rate coefficient for chain transfer to the chain transfer agent T, and the rate coefficient for propagation. It is a measure for the reactivity of a chain transfer agent. The higher the value of C_T, the lower the concentration of the chain transfer agent required for a particular molecular weight reduction. This effect on the molecular weight of the polymer is quantitatively described by

the Mayo equation 91, which expresses the reciprocal of $\bar{P}_n$, the number-average degree of polymerization, as a function of the rates of chain growths and chain-stopping events. Neglecting chain transfer to solvent, initiator, and polymer—this assumption is nearly fulfilled in bulk polymerizations at low overall monomer conversions—equation 91 reads after insertion of equation 45.

$$\frac{1}{\bar{P}_n} = \frac{(1+\delta)k_t}{k_p^2[M]^2}R_p + C_M + C_T\frac{[T]}{[M]} \tag{166}$$

The usual procedure for measuring the chain transfer coefficient C_T—henceforth referred to as the Mayo procedure—involves the determination of the average degree of polymerization for a range of [T]/[M] values and plotting the data as $(\bar{P}_n)^{-1}$ vs [T]/[M], ie, a so-called Mayo plot. The value of C_T is then determined as the straight-line slope of this plot. This procedure assumes that the intercept is independent of the variation of [T]/[M]. However, the chain-length-dependent termination rate coefficient implies that the first term on the r.h.s. of equation 166 is in general not a constant, and therefore a Mayo plot is not necessarily linear. This is a principal weakness of the Mayo method. However, in practice, this effect does not seem to be significant, which suggests that in systems with added chain transfer agent, the first term on the r.h.s. of equation 166 generally makes a negligible contribution to $(\bar{P}_n)^{-1}$.

CLD Method. The transfer process shifts the chain length distribution generated by the polymerization process to lower molecular weights. The Mayo method, described above, relies on the accurate determination of the number-average degree of polymerization, $\bar{P}_n$. Especially if the chain length distribution shows considerable amounts of low molecular weight material, the application of the Mayo method is problematic. In the cases when SEC is chosen to measure the number-average degree of polymerization, $\bar{P}_n$, baseline errors in the low molecular weight region show a significant influence on its value.

To overcome this problem, Gilbert and co-workers introduced a method which puts more emphasis on the high molecular weight region of the polymer chain length distribution (497).

The general rate law for the polymerization process reads

$$\frac{d[R_i^\bullet]}{dt} = k_p[M][R_{i-1}^\bullet] - \left(k_p[M] + k_{tr}^M[M] + k_{tr}^T[T] + 2\sum_{j=1}^{\infty}k_t^{i,j}[R_j^\bullet]\right)[R_i^\bullet] \tag{167}$$

Introducing the steady-state principle, $d[R^\bullet]/dt = 0$, yields an recursive expression for the concentration of macroradicals with chain length i.

$$[R_i^\bullet] = \left(1 + \frac{k_{tr}^M[M] + k_{tr}^T[T] + 2\sum_{j=1}^{\infty}k_t^{i,j}[R_j^\bullet]}{k_p[M]}\right)^{-1}[R_{i-1}^\bullet] \tag{168}$$

A repeated substitution leads to an expression of this free radical concentration as a function of the concentration of radicals being composed of one monomeric unit, $[R_1^\bullet]$.

$$[R_i^\bullet] = \left(1 + \frac{k_{tr}^M[M] + k_{tr}^T[T] + 2\sum_{j=1}^{\infty} k_t^{i,j}[R_j^\bullet]}{k_p[M]}\right)^{1-i} [R_1^\bullet] \tag{169}$$

The rate law for radicals of chain length one, $[R_1^\bullet]$, combines the rate of formation of these radicals via the initiation process, R_i, the rate of their formation by transfer, and the rate of their loss by propagation, transfer, and termination events.

$$\frac{d[R_1^\bullet]}{dt} = R_i + \left(k_{tr}^M[M] + k_{tr}^T[T]\right)\mu_0 - \left(k_p[M] + k_{tr}^T[T] + 2\sum_{j=1}^{\infty} k_t^{i,j}[R_j^\bullet]\right)[R_1^\bullet] \tag{170}$$

where $\mu_0 \equiv \sum_{i=1}^{\infty} [R_i^\bullet]$ is the overall free radical concentration.

Introducing the steady-state assumption and inserting equation 170 into equation 169 leads to

$$[R_i^\bullet] = \left(\frac{R_i + k_{tr}^M[M]\mu_0 + k_{tr}^T[T]\mu_0}{k_p[M]}\right)\left(1 + \frac{k_{tr}^M[M] + k_{tr}^T[T] + 2\sum_{j=1}^{\infty} k_t^{i,j}[R_j^\bullet]}{k_p[M]}\right)^{-i} \tag{171}$$

If transfer and termination events are much less probable than propagation, ie $k_{tr} \ll k_p$, and $2\sum_{j=1}^{\infty} k_t^{i,j}[R_j^\bullet] \ll k_p[M]$, the r.h.s. of equation 171 can be rewritten as a progression with only two terms, using $e^x \cong 1 + x$,

$$[R_i^\bullet] \propto \exp\left(-\frac{k_{tr}^M[M] + k_{tr}^T[T] + 2\sum_{j=1}^{\infty} k_t^{i,j}[R_i^\bullet]}{k_p[M]} i\right) \tag{172}$$

For transfer-dominated systems the shape of the polymer distribution is the same as that of the free radical distribution, $[R_i^\bullet] \sim [P_P]$, keeping in mind that the chain length i equals the degree of polymerization, P. It turns out that this situation is in fact more general: Clay and Gilbert (497) have shown that for partly termination controlled distributions also, the following equation holds true, in which the slope of the logarithmic number distribution ($x_p \equiv [P_p]/\sum_{P=0}^{\infty}[P_P]$) is correlated with the kinetic parameters:

$$\frac{d\ \ln x_P}{dP} = -\frac{k_{tr}^M[M] + k_{tr}^T[T] + 2\sum_{j=1}^{\infty} k_t^{i,j}[R_j^\bullet]}{k_p[M]} \tag{173}$$

Equation 173 indicates that a semilogarithmic number distribution should be linear, as can be seen in Figure 15.

A plot of the slopes of semilogarithmic number distributions, $d\ \ln\ x_P/dP$, against the ratio of the transfer agent-to-monomer concentration, [T]/[M], allows

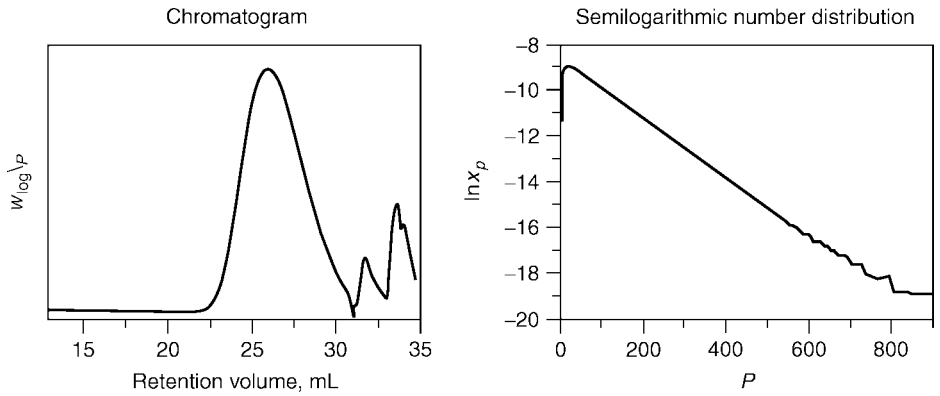

Fig. 15. Transformation of a gel permeation chromatography (GPC) trace of a stationary styrene bulk polymerization at 25°C with carbon tetrachloride as transfer agent, into a semilogarithmic number distribution according to equation 173.

to calculate the transfer coefficient $C = k_{tr}/k_p$. It should be kept in mind that because of the chain length dependent termination process, equation 173 is only valid in the long chain limit. However, reasonable results are achieved at lower molecular weights as well. This method has been studied extensively in the last few years (201) and is now frequently used as an alternative to the classical Mayo method. Although it was recently shown that both methods are in essence the same (498), there may be situations which makes the CLD method preferable over the Mayo method.

As mentioned earlier, the number-average degree of polymerization, $\bar{P}_n$, is associated with a certain degree of error. This is a difficulty of the Mayo method, which therefore encounters problems with low molecular weight polymers. Another situation when the CLD procedure is more advantageous than the Mayo method, is when one must analyze a contaminated polymer sample. A contamination (of an arbitrary nature) may alter the molecular weight distribution and will therefore significantly change the molecular weight averages, rendering the Mayo procedure useless. However, if a region in the molecular weight distribution can be identified in which the distribution is less affected by the contaminant, this region can still be used in the CLD procedure. The CLD procedure is also expected to be more robust when one has systematic errors in the SEC calibration, because then the obtained molecular weight averages will not be accurate, but the systematic error in values of x_P can be expected to cancel out to some extent when the slope of a ln x_P plot is taken.

Methods for the Measurement of k_t.

Single Pulse–Pulsed Laser Polymerization. Applying PLP in conjunction with infrared or near-infrared spectroscopic measurement of monomer conversion induced by a single laser pulse (SP–PLP) allows for the determination of the ratio of termination to propagation rate coefficients, k_t/k_p, in wide ranges of temperature, T, pressure, p, and monomer conversion. The SP–PLP technique was pioneered in the 1980s by Buback and co-workers (409). The monomer conversion induced by a single laser pulse, typically of 20 ns width, is measured by on-line

IR/NIR spectroscopy, with a time resolution of microseconds. The distribution, of free radical chain lengths after a single laser pulse is close with a Poisson distribution, with chain length being linearly correlated with time, unless chain transfer interferes. As a consequence, SP–PLP experiments may provide access to investigations into the chain length dependence of k_t. SP–PLP has first been used for studies into ethene kinetics and subsequently to measure free radical termination of methyl acrylate, butyl acrylate, and dodecyl acrylate (350,351). Because of the high academic and technical interest in detailed k_t studies on slowly propagating monomers, the technique has also been applied to methyl methacrylate (353), butyl methacrylate, and dodecyl methacrylate and various acrylate/methacrylate binary and ternary comonomer systems (499). Figure 16 shows the spectroscopically measured relative monomer concentration vs time profile of a methyl acrylate/dodecyl acrylate copolymerization at equimolar amounts of both monomers in the reaction mixture. The relative change in overall monomer concentration induced by the single laser pulse in this particular experiment is 1% after about 600 ms. Equation 73 has been used to evaluate the kinetic trace. The difference between measured and fitted data is illustrated by plotting the residuals (*res*) in the lower part of the figure, indicating the excellent applicability of equation 73 to represent the kinetic data.

The majority of SP–PLP experiments reported in the literature have been carried out under high pressure to increase the conversion per single pulse. 'True' single pulse experiments can readily be carried out for the acrylates (eg, methyl acrylate, butyl acrylate, or dodecyl acrylate). However, for slowly propagating monomers like methyl methacrylate and styrene, the signal-to-noise ratio of a 'true' single pulse experiment is too poor to allow a meaningful kinetic analysis of the monomer conversion vs time trace. Nevertheless, slowly propagating monomers may be studied by enhancing the signal-to-noise ratio by co-adding a larger number of individual SP–PLP signals recorded under virtually the same conditions, with only a minor decrease in both monomer and photoinitiator concentration between 'true' single pulse experiments. As the concentration of free radicals originating from the previous pulse decays to a very low level and as small primary radicals are generated by each pulse, the range of chain length covered during successively recorded individual concentration vs time traces is identical. The number of co-added signals is limited by the requirement of deriving k_t/k_p for a small range of monomer conversion extending over no more than about 2% to stay close to the intention of 'pointwise' probing the kinetics. To effectively probe the kinetics of a given monomer, a minimum of 0.001% monomer conversion per single laser pulse is required for a sufficient signal-to-noise ratio after approximately 100 co-additions of single pulse signals. A particular strength of the SP–PLP technique is that it offers the possibility to probe the conversion dependence of the termination rate coefficient. At present, the technique is limited to studying monomers with a $\ln(k_t/k_p)$ of less or close to approximately 10, otherwise the resulting conversion per single pulse is insufficient to be detected even with co-addition of true single pulses. In the past and again recently, the SP–PLP technique has been used for investigations into the chain length dependence of the termination rate coefficient. Since all chains grow linearly with time upon initiation with a laser pulse, the time-resolved monomer conversion vs time signal contains information about the chain length dependence of k_t. The linear

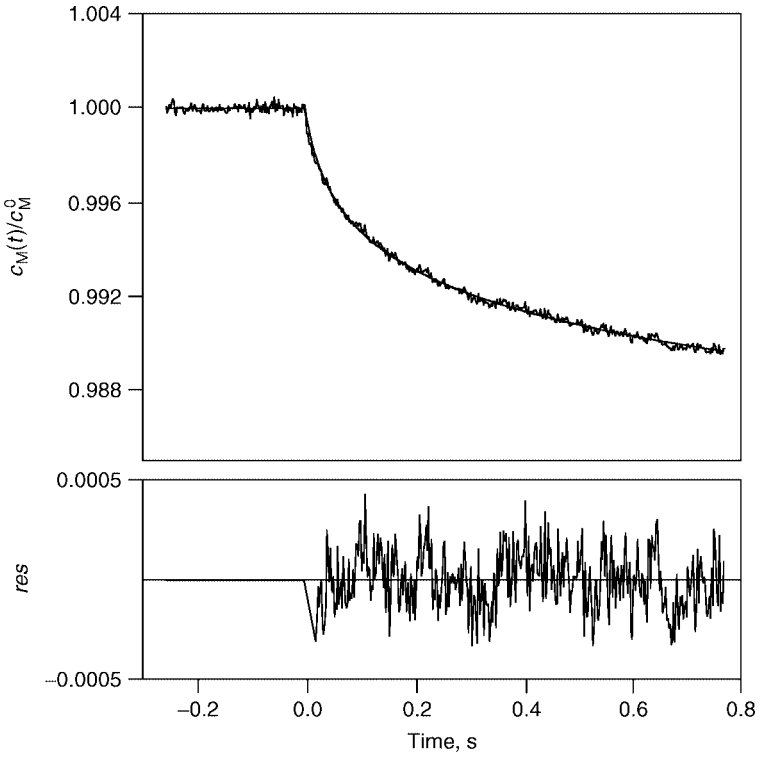

Fig. 16. Monomer concentration vs time trace of a methyl methacrylate/dodecyl acrylate copolymerization at equimolar amounts of both monomers measured in a reaction mixture at 40°C, 100 MPa, and 5 wt% polymer concentration. The difference between measured and fitted data (eq. 73) is illustrated by plotting the residuals (*res*) in the lower part of the figure. Reprinted with friendly permission by the American Chemical Society.

chain growth–time relation is, however, valid only if chain transfer, does not interfere. Early investigations into $k_t^{i,i}$ using the SP–PLP technique were carried out on ethylene (500,501), whereas more recent data are available for styrene, methyl acrylate, butyl acrylate, and dodecyl acrylate (18). It should be mentioned that the SP–PLP equipment requires a relatively high level of technical expertise to be successfully operated. Furthermore, the related equipment costs are high. However, to this date it probably remains the most powerful tool for detailed investigations into the termination rate coefficient.

The CLD Method. The shape of the chain length distribution of a polymer is directly governed by the kinetic parameters of the polymerization process by which the distribution is generated. It is therefore self-evident to try to extract these parameters from such a distribution, which is convincingly realized by measuring k_p by PLP or determining the chain transfer coefficient C via the Mayo or CLD method. Determining the rate coefficient of termination, k_t, via the evaluation of the chain length distributions is possible only in combination with polymerization rate measurements. However, these methods also allow for the determination of the chain length dependence of k_t. The chain length dependence of the termination

rate coefficient should always be taken into account if reasonable results are to be achieved.

The termination rate coefficient is strictly speaking not a constant, but is proven to vary with the chain length of the two radicals involved in the termination process (342).

$$k_t^{i,j} \propto F(i,j) \tag{174}$$

where $k_t{}^{i,j}$ is the rate constant of termination between radical chains of length i and j. $F(i,j)$ is usually represented by a power law of the type

$$F(i,j) = (\bar{i,j})^{-\alpha} \tag{175}$$

with $\bar{i,j}$ denoting some average [eg, the harmonic (336) or the geometric (337) mean] of the two chain lengths i and j involved and α a positive constant. As a consequence, the problem of determining k_t is not solved by the evaluation of one specific value but rather comprises the evaluation of an entire functional dependence.

Most of the methods employed to deduce k_t and k_p are based on the assumption of a chain-length-independent termination rate coefficient and yield k_p and k_t in some combination (k_p/k_t or $k_p{}^2/k_t$, respectively). In the past, before k_p could be determined directly, the usual procedure was to use two different ratios of k_p and k_t and to split them into their individual components via combination. In view of the chain length dependence of k_t it is clear that any (single) experiment aiming at the determination of k_t will render only an average value $\bar{k_t}$, which is defined by the method used and the experimental conditions chosen (eg, monomer and initiator concentration, type of initiation). Combination of k_p/k_t and $k_p{}^2/k_t$ ratios, which are invariably taken from different experiments, therefore always involves averages of k_t, which are not consistent with each other.

Any serious approach aimed at the determination of k_t should therefore avoid the shortcomings outlined above. This implies that one should (*1*) preferentially refer to single point measurements, (*2*) avoid combinations of two different ratios of k_p and k_t, (*3*) take advantage of the possibility of determining k_p directly (eg by PLP–SEC), and (*4*) make sure that the average of k_t is a fair replicate of the true average of k_t, $\langle k_t \rangle$ (see eq. 48), which is operative in the respective experiment.

With these premises fulfilled it is possible to treat a k_t value originating from an experiment dealing with reactions between radicals of different chain lengths, as an average $\bar{k_t}$ specific for the experimental conditions chosen. Assuming this average $\bar{k_t}$ to be physically correct, a power law of the form

$$\bar{k_t} = k_t^0 \nu'^{-\alpha} \tag{176}$$

with the same exponent α as in equation 175 will be obtained. In order to establish the correct chain length dependence of k_t, the averages of k_t have to be correlated with a quantity characteristic of the population of terminating radicals in each experiment. The best solution to this problem appeared to chose a quantity ν' which marks the number-average chain length of the radicals at the moment

of their termination. ν', which is proportional to the number-average degree of polymerization, $\bar{P}_n$, of the polymer formed

$$\nu' = \bar{P}_n(1+\delta)/2 \tag{177}$$

thus in itself is independent of the mode of termination (combination or disproportionation). The preexponential factor in equation 176, k_t^0, is not to be confused with the termination rate coefficient of two radicals of chain length one, but is rather a proportionality factor with no physical meaning associated with it.

Two successful approaches, designed for systems with negligible chain-transfer, are (*1*) the analysis of the second moment of the chain length distribution, represented by the product of the rate of polymerization, R_p, and the weight-average degree of polymerization, $\bar{P}_w$, and (*2*) the formal solution for $\bar{k}_t$ of the rate equation for polymerization with periodic laser pulses. Both methods were originally derived for chain-length-independent termination (502,503). In both cases additional quantities have to be known: Apart from k_p, the quantity δ (contribution of disproportionation to overall termination) must be available in the first case and the quantity ρ (the concentration of new radicals formed in each laser pulse) in the second (implicitly the knowledge of δ is necessary, too).

The two averages of k_t, $\bar{k}_t^m$ and $\bar{k}_t*$, are calculated as follows:

(1) $\bar{k}_t^m$ from the product of rate of polymerization, R_p, and weight-average degree of polymerization, $\bar{P}_w$ (which represents the second moment of the chain length distribution per time)

$$\bar{P}_w R_p = \frac{k_p^2}{2\bar{k}_t^m}[M]^2(3-\delta) \tag{178}$$

(2) $\bar{k}_t*$ from the rate of polymerization under the same conditions given by

$$R_p = \frac{k_p[M]}{2\bar{k}_t^* t_0} \ln\left\{1+\rho\bar{k}_t^* t_0\left[1+\left(1+\frac{2}{\rho\bar{k}_t^* t_0}\right)^{0.5}\right]\right\} \tag{179}$$

As indicated above, both equations were originally developed for chain-length-independent termination; their use in the context of chain length dependence, however, is permissible only if the k_t data obtained are explicitly treated as averages.

The quantity ρ can be determined as follows. In systems with negligible chain transfer the following relation holds:

$$\rho = \frac{2R_p t_0}{\bar{P}_n(1+\delta)} \tag{180}$$

Once $\bar{P}_n$ is known, ρ can be calculated for a given δ. A reasonable estimate of δ is sufficient because δ never appears as an isolated factor in the calculation [either as $(3-\delta)$ or as $(1+\delta)$]. However, errors in δ do not significantly influence

absolute values of k_t. The values for α, representing the chain length dependence of k_t, remain nearly unchanged.

The polymerization is performed via a PLP–SEC experiment, which allows to control the number-average degree of polymerization easily by choosing different laser frequencies and gives the exact chain length distribution of the produced polymer. The value of the propagation rate coefficient k_p can be obtained by the same experiment. Measuring the rate of polymerization, R_p, by determining the conversion of the polymer produced per time, and the number- and weight-average degrees of polymerization, $\bar{P}_n$ and $\bar{P}_w$, allow to calculate the absolute values of average k_t according to equations 178 and 179. Insertion into equation 176 gives values of α, which is a measure for the chain length dependence of the termination rate coefficient for macroradicals of sufficiently large size [according to region B in Figure 5].

Another method to measure the chain length dependence of k_t via evaluation of the chain length distribution of the polymer formed in a single pulse experiment uses equation 181 to measure model independent values of the termination rate coefficient k_t at any given chain length (504,505).

$$k_t^{i,i} = \frac{V k_p [M] x_{2P}}{\left(\int_0^\infty x_{2P}\, dP - \int_0^P x_{2P}\, dP\right)^2} = \frac{V k_p [M] x_{2P}}{\left(\int_P^\infty x_{2P}\, dP\right)^2} \tag{181}$$

where x_{2P} is the differential number distribution for termination by combination and V is an arbitrary volume.

There are two uncertainties in this development which prevent a direct application of equation 181. The first one is the quantity V, which plays the role of a scaling factor, and the second refers to the fact that the integration of x_{2P} cannot be carried out to infinity in practice, because of the effect of chain transfer in the high molecular weight region. This implies that some maximal chain length, P_{max}, has to be introduced which corresponds to a specific residual radical concentration $[R^\bullet]_{res}$ present at the moment at which integration is stopped. The calibration problem as a whole might be solved by estimating values for $[R^\bullet]_0$ as well as for $[R^\bullet]_{res}$. They may be calculated via $k_t^{1,1}$ from the Smoluchowski equation or from literature data and by combination with average $\bar{k}_t$ data linking $[R^\bullet]_0$ and $[R^\bullet]_0$ or alternatively from SP–PLP traces.

The chain length dependence of k_t can also be assessed by fitting a chain length distribution obtained from a single pulse experiment to the theoretical distribution given by equation 119 (506). However, with this method it is also not possible to measure absolute termination rate coefficients, because of unknown absolute scaling factors.

Stationary Polymerization Methods. The determination of the kinetic rate coefficients k_t and k_p in their coupled form k_p^2/k_t has long proceeded via measurement of the rate of polymerization and the calculation of the k_p^2/k_t via equation 56. With the advent of pulsed laser techniques that allow to obtain much more accurate and detailed information about the kinetic rate coefficients (such as chain length dependencies), these techniques became less important. Nevertheless, measurements of the rate of polymerization are still widely performed and are

especially used for systems where the novel techniques are not applicable. This is especially true for measurements of the termination rate coefficient k_t, where rate of polymerization measurements, in combination with independent experiments for the k_p determination, are sometimes the only possibility to get an estimate for k_t. However, it should always be kept in mind that the determination of termination rate coefficients from stationary polymerization experiments yields only an average and approximate value for k_t, as has been outlined above. The polymerization rate can be measured via any quantity that it is directly proportional to. Possible quantities are the density (dilatometry), the refractive index (refractrometry), the heat of polymerization (calorimetry), the polymer mass (gravimetry), or a spectral absorption (IR/NIR and NMR spectroscopy).

The two most common methods are dilatometry and spectroscopic methods. Dilatometry has the advantages of being easy to perform and having low equipment costs. This technique utilizes the volume change that occurs upon polymerization to follow monomer conversion vs time. It is well applicable to free radical polymerization, because of the large difference in the densities of polymer and monomer. For example, the density of methyl methacrylate changes by approximately 22% when going from its monomeric to its polymeric form. The density changes in other polymerizing systems are of the same order of magnitude. The density change is followed in a volume calibrated dilatometer. In modern dilatometers the volume change is followed via the computer controlled observation of the meniscus of a solvent in a capillary on top of the reaction mixture. It is important that the solvent does not mix with the reaction mixture.

The spectroscopic measurement of the rate of polymerization is inherently more elegant than any other of the above-mentioned methods, since it directly probes the reaction mixture on a molecular level and does not rely on the interpretation of a secondary quantity. In addition to providing the rate of polymerization, spectroscopic methods provide real-time insight into the reaction process. The major disadvantage of spectroscopic methods is the relatively large price of, eg, NMR or FTIR spectrometers. Kinetic spectroscopic measurements normally proceed via the recording of a part of the spectrum where a spectroscopic absorption is directly associated with the monomer in the reaction mixture. Care has to be taken that during the course of the reaction no formed product displays an absorption in the same frequency region as the monomeric species. This requirement is met for most monomers in kinetic ^{1}H NMR spectroscopic investigations, where the vinylic absorption(s) can be easily used to probe the progress of the reaction (507). However, NMR spectroscopic investigations are limited in their time resolution. For faster proceeding reactions, NIR/FTIR spectroscopy has been successfully performed to follow free radical acrylate and methacrylate polymerizations, using the first overtone of the C—H stretching vibration on the double bond at roughly 6200 cm^{-1} (351).

Using Living Free Radical Polymerization for k_t Determination. Living free radical polymerization presents—at least in theory—an ideal tool for investigations into chain-length-dependent termination rate coefficients, since in living systems the monomer conversion and the molecular weight, ie the chain length of the growing polymer, are closely interlinked. With increasing reaction time, ie monomer conversion, the terminating polymer chains increase linearly in length. If termination events are occurring, it should be possible to extract information

about the chain length dependence of the termination rate coefficients from rate of polymerization measurements. Thus, the use of a living free radical polymerization system is similar to the time-resolved SP–PLPs described above. In some living free radical polymerization systems, however, the concentration of propagating radicals is greatly reduced, thus almost completely suppressing termination events from occurring. A typical example of such systems are NMP (434) and ATRP (508,509). The RAFT process (268,269), however, makes use of repeated reversible transfer events during the polymerization without, changing, at least in principle the free radical concentration so as to induce an equilibrium of dormant and living chains. In such an 'ideal' living RAFT system—in which no rate retardation effects and other kinetic phenomena occur that may alter the radical concentration, the overall rate of polymerization, R_p, and the rate of the individual reaction steps remain unaltered. The specific characteristics of the RAFT process thus allow for undisturbed investigations into the termination reaction of free radical polymerizations. Because the termination reaction is present throughout the polymerization, RAFT is a suitable tool to study radical–radical termination events. A study of the chain length dependence of an average termination rate coefficient for the termination reaction of two radicals with (approximately) the same chain length i, $\bar{k}_t^{i,i}$, is therefore possible.

The basis of the RAFT k_t method (as mentioned above) is the direct determination of R_p as a function of time throughout a free radical polymerization.

$$\bar{k}_t(t) = \frac{k_p^2}{[R_p(t)]^2}(2fk_d)[I]_0 e^{-k_d t}\left[[M]_0 - \int_0^t R_p(t)\,dt\right]^2 \tag{182}$$

Equation 182 gives $\bar{k}_t$ as a function of time during a free radical polymerization when considering the concentration changes of the participating reagents. It should be noted that this expression assumes steady-state conditions.

When using a RAFT polymerization, the terminating radicals are considered to be approximately of the same chain length—ideally Poisson-distributed—at every single instant in time. The time axis may hence easily be converted to a chain length axis following the simple procedure of calculating the conversion vs time data from the measured polymerization rate and assuming that the chain length of the polymer chains increases linearly with conversion. The chain length P may therefore be calculated as a function of time by

$$P(t) = \frac{\int_0^t R_p(t)\,dt}{[RAFT]_0} \tag{183}$$

with the initial RAFT agent concentration $[RAFT]_0$. The termination rate coefficient is now accessible by measuring the polymerization rate as a function of time in a RAFT-agent-mediated polymerization to ensure that all terminating chains have the same chain length. This task may be carried out by isothermal differential scanning calorimetry, which directly determines the polymerization rate by monitoring the reaction heat. The chain length dependence *and* the absolute value of k_t are therefore accessed via *one* experiment. This very novel procedure has to

this date been used to successfully determine chain-length-dependent termination rate coefficient of styrene (510). The main advantage of this novel RAFT-based technique for k_t determination is its simplicity in combination with the enormous amount of information that is obtained: A single polymerization rate measurement yields the conversion dependence, the chain length dependence, and the absolute value of k_t. It should be noted that it is very important to choose the RAFT agent carefully and the selected RAFT agent/monomer system must not show any retardation and inhibition phenomena. In addition, the technique is suited only for monomers that polymerize fairly rapidly in order to allow for a precise measurement of the polymerization rate.

Determining the Mode of Termination: Disproportionation vs Combination. Several experimental approaches have been taken to determine the mode of chain termination in free radical polymerization. These have been extensively reviewed by Moad and Solomon (511,512). In the case of termination by disproportionation, a chain is generated with one initiator fragment, whereas in the case of combination, a chain with two initiator fragments is formed. The determination of the ratio of number of end groups to the number of monomer units consumed by the polymerization process allows for the calculation of δ, via the additional knowledge of the number-average degree of polymerization, $\bar{P}_n$. Unfortunately, identification and quantification of chain ends are not simple as they give only small signals (relative to the rest of the polymer chain) in a spectroscopic analysis. This can be overcome to some extent by isotopic labeling of the initiator end groups by ^{14}C or by using initiator fragments containing fluorine or phosphorus as NMR-sensitive molecules. Other complications in the analysis include isolating the long-chain termination process from other chain-stopping mechanisms such as chain transfer and primary radical termination. Because of these experimental difficulties, there remains considerable uncertainty in existing termination mode measurements and there is a large scatter in the obtained results. The application of soft ionizing mass spectrometry techniques, such as the matrix-assisted laser desorption ionization time-of-flight mass spectroscopy and electrospray ionizaton, to the problem of end group analysis of polymers brought some promising results to this field of polymerization kinetics (317,319).

RHEOLOGICAL MEASUREMENTS

Rheology is the science of the deformation and flow of matter. It is concerned with the response of materials to applied stress. That response may be irreversible viscous flow, reversible elastic deformation, or a combination of the two. Control of rheology is essential for the manufacture and handling of numerous materials and products, eg, foods, cosmetics, rubber, plastics, paints, inks, and drilling muds. Before control can be achieved, there must be an understanding of rheology and an ability to measure rheological properties.

Deformation is the relative displacement of points of a body. It can be divided into two types: flow and elasticity. Flow is irreversible deformation; when the stress is removed, the material does not revert to its original form. This means that work is converted to heat. Elasticity is reversible deformation; the deformed body recovers its original shape, and the applied work is largely recoverable. Viscoelastic materials show both flow and elasticity.

This article is concerned with rheological measurements on both liquids and solids and the principles on which they are based. The flow properties of a liquid are defined by its resistance to flow, ie, viscosity, and may be measured by determining the rate of flow through a capillary, the resistance to flow when the fluid is sheared between two surfaces, or the rate of motion of an object or ball moving through the fluid. The mechanical properties of an elastic solid may be studied by applying a stress and measuring the deformation or strain. Many solids, such as polymers, undergo flow in addition to recoverable elastic deformation. Furthermore, a number of liquids show elastic as well as flow behavior. These materials are viscoelastic, and additional techniques beyond those indicated for solids and liquids are needed for complete characterization. Examples of such methods are the measurement of response to sinusoidal oscillatory motion; the measurement of flow with time after application of stress, ie, creep; and the measurement

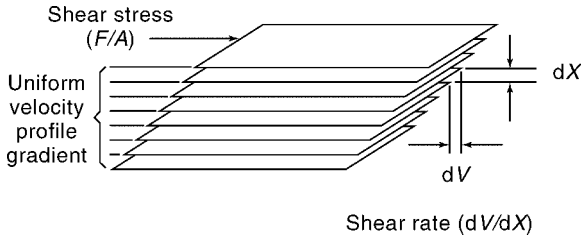

Fig. 1. Laminar flow in simple shear. $F/A = \eta\ \mathrm{d}V/\mathrm{d}X$, where F is the force acting on area A, V the velocity and X the thickness of the layer, and η the coefficient of viscosity or the Newtonian viscosity.

of the rate and degree of recovery after removal of stress, ie, creep recovery or recoil.

In addition to viscometers, optical devices such as microscopes and cameras can be used for defining and solving flow problems as well as characterizing materials (1–3). Optical techniques allow the investigator to determine the physical structure of the material and visualize its flow processes.

Viscosity

A liquid is a material that continues to deform as long as it is subjected to a tensile and/or shear stress. The latter is a force applied tangentially to the material. In a liquid, shear stress produces a sliding of one infinitesimal layer over another, resulting in a stack-of-cards type of flow (Fig. 1).

For a liquid under shear, the rate of deformation or shear rate is a function of the shearing stress. The original exposition of this relationship is Newton's law, which states that the ratio of the stress to the shear rate is a constant, ie, the viscosity. Under Newton's law, viscosity is independent of shear rate. This is true for ideal or Newtonian liquids, but the viscosities of many liquids, particularly a number of those of interest to industry, are not independent of shear rate. These non-Newtonian liquids may be classified according to their viscosity behavior as a function of shear rate. Many exhibit shear thinning, whereas others give shear thickening. Some liquids at rest appear to behave like solids until the shear stress exceeds a certain value, called the yield stress, after which they flow readily.

Some commonly observed types of flow behavior are shown in Figure 2, in which the shear stress is plotted against shear rate. These plots are called flow curves and are frequently used to express the rheological behavior of liquids. Newtonian flow is shown by a straight line, and shear thinning and thickening by curves. Yield stresses, τ_0, are shown by intercepts on the stress (y) axis. It should be pointed out that the existence of yield stresses is controversial; they may be artifacts resulting from high Newtonian viscosity at low shear rates (4). However, in many dispersed systems, particularly where severe flocculation occurs, this viscosity is so high that the material would take years to flow. Therefore, in practice, there are true yield stresses. This parameter can be quite useful in characterizing materials. Additional information on yield is available (5–8).

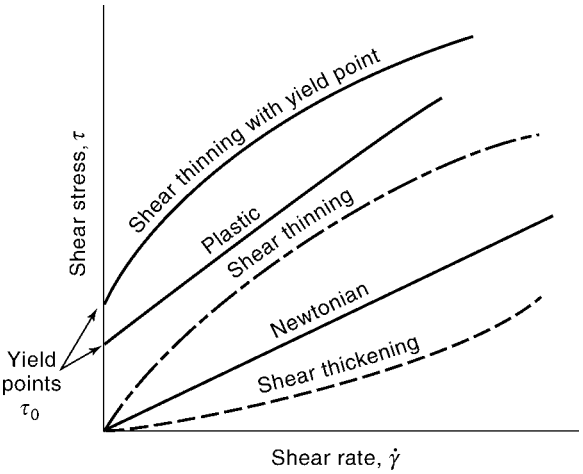

Fig. 2. Flow curves (shear stress vs shear rate) for different types of flow behavior.

Viscosity is equal to the slope of the flow curve, $\eta = d\tau/d\dot{\gamma}$. The quantity $\tau/\dot{\gamma}$ is the viscosity η for a Newtonian liquid and the apparent viscosity η_a for a non-Newtonian liquid. The kinematic viscosity is the viscosity coefficient divided by the density, $\nu = \eta/\rho$. The fluidity is the reciprocal of the viscosity, $\phi = 1/\eta$. The common units for viscosity, dyne seconds per square centimeter ((dyn·s)/cm^2) or grams per centimeter second ((g/(cm·s)), called poise, which is usually expressed as centipoise (cP), have been replaced by the SI units of pascal seconds, ie, Pa·s and mPa·s, where 1 mPa = 1 cP. In the same manner the shear stress units of dynes per square centimeter, dyn/cm^2, have been replaced by Pascals, where 10 dyn/cm^2 = 1 Pa, and newtons per square meter, where 1 N/m^2 = 1 Pa. Shear rate is $\Delta V/\Delta X$, or length/time/length, so that values are given as per second (s^{-1}) in both systems. The SI units for kinematic viscosity are square centimeters per second (cm^2/s), ie, Stokes (St), and square millimeters per second (mm^2/s), ie, centistokes (cSt). Information is available for the official Society of Rheology nomenclature and units for a wide range of rheological parameters (9).

Flow Models. Many flow models have been proposed (8,10), which are useful for the treatment of experimental data or for describing flow behavior (Table 1). However, it is likely that no given model fits the rheological behavior of a material over an extended shear rate range. Nevertheless, these models are useful for summarizing rheological data and are frequently encountered in the literature.

Of the models listed in Table 1, the Newtonian is the simplest. It fits water, solvents, and many polymer solutions over a wide strain rate range. The plastic or Bingham body model predicts constant plastic viscosity above a yield stress. This model works for a number of dispersions, including some pigment pastes. Yield stress, τ_0, and plastic (Bingham) viscosity, $\eta_p = (\tau - \tau_0)\dot{\gamma}$, may be determined from the intercept and the slope beyond the intercept, respectively, of a shear stress vs shear rate plot.

The other models can be applied to non-Newtonian materials where time-dependent effects are absent. This situation encompasses many technically important materials from polymer solutions to lattices, pigment slurries, and polymer

Table 1. Flow Equations for Flow Models

Flow model	Flow equation
Newtonian	$\tau = \eta\dot{\gamma}$
Plastic (Bingham) body	$\tau - \tau_0 = \eta\dot{\gamma}$
Power law	$\tau = k\lvert\dot{\gamma}\rvert^n$
Power law with yield value	$\tau - \tau_0 = k\lvert\dot{\gamma}\rvert^n$
Casson fluid	$\tau^{1/2} - {\tau_0}^{1/2} = {\eta_\infty}^{1/2}\ \dot{\gamma}\rvert^{1/2}$
Williamson	$\eta = \eta_\infty + \frac{(\eta_0 - \eta_\infty)}{1 + \frac{[r]}{r_m}}$
Cross	$\eta = \eta_\infty + \frac{(\eta_0 - \eta_\infty)}{1 + \alpha\dot{\gamma}^n}$

melts. At high shear rates most of these materials tend to a Newtonian viscosity limit. At low shear rates they tend either to a yield point or to a low shear Newtonian limiting viscosity. At intermediate shear rates, the power law or the Casson model is a useful approximation.

The power law, $\tau = k\dot{\gamma}^n$, is widely used as a model for non-Newtonian fluids. It holds for many solutions and can describe Newtonian, shear-thinning, and shear-thickening behavior, depending on the power factor, n, also called the flow behavior index. For a Newtonian fluid, $n = 1$ and the equation reduces to the Newtonian model. If n is less than 1, the fluid is shear thinning; if it is greater than 1, the fluid is shear thickening. A test of whether the power law applies and a means of determining n is to plot the log shear stress vs the log shear rate. If the plot is linear, the power law applies. The value of n, which is the reciprocal of the slope of the line, can be used as a measure of the degree of shear thinning or shear thickening. Dividing the power law equation through by $\dot{\gamma}$ gives an expression in terms of viscosity, $\eta = k'\dot{\gamma}^{n-1}$.

The power law model can be extended by including the yield value $\tau - \tau_0 = k\dot{\gamma}^n$, which is called the Herschel–Bulkley model, or by adding the Newtonian limiting viscosity η_∞. The latter is done in the Sisko model, $\eta_\infty + k\dot{\gamma}^{n-1}$. These two models, along with the Newtonian, Bingham, and Casson models, are often included in data-fitting software supplied for the newer computer-driven viscometers.

Another model is the Casson equation (11), which is useful in establishing the flow characteristics of inks, paints, and other dispersions. An early form of this expression (eq. 1) was modified (12) to give equation 2.

$$\tau^{1/2} = k_0 + k_1\dot{\gamma}^{1/2} \tag{1}$$

$$\eta^{1/2} = \eta_\infty^{1/2} + \tau_0^{1/2}\dot{\gamma}^{-1/2} \tag{2}$$

The square root of viscosity is plotted against the reciprocal of the square root of shear rate (Fig. 3). The square of the slope is τ_0, the yield stress; the square of the intercept is η_∞, the viscosity at infinite shear rate. No material actually experiences an infinite shear rate, but η_∞ is a good representation of the condition

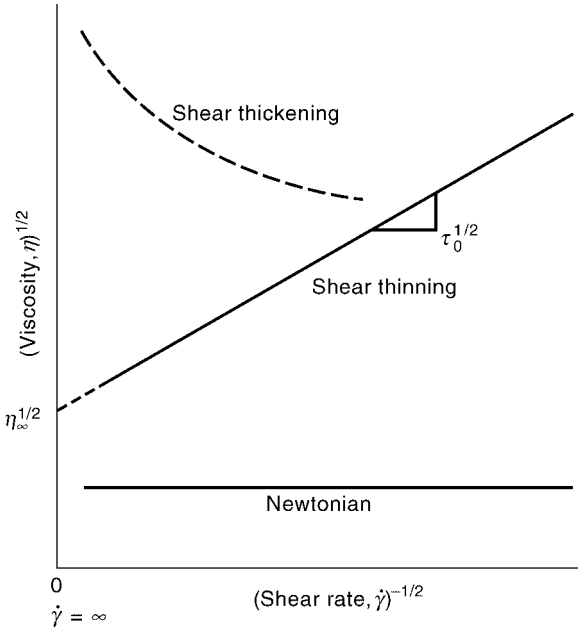

Fig. 3. Examples of Casson plots: (viscosity)$^{1/2}$ vs (shear rate)$^{-1/2}$. The Casson equation is $\eta^{1/2} = {\eta_\infty}^{1/2} + {\tau_0}^{1/2}\dot{\gamma}^{-1/2}$.

where all rheological structure has been broken down. The Casson yield stress τ_0 is somewhat different from the yield stress discussed earlier in that there may or may not be an intercept on the shear stress–shear rate curve for the material. If there is an intercept, then the Casson yield stress is quite close to that value. If there is no intercept, but the material is shear thinning, a Casson plot gives a value for τ_0 that is indicative of the degree of shear thinning.

The Williamson equation is useful for modeling shear-thinning fluids over a wide range of shear rates (13). It makes provision for limiting low and high shear Newtonian viscosity behavior (eq. 3), where τ is the absolute value of the shear stress and τ_m is the shear stress at which the viscosity is the mean of the viscosity limits η_0 and η_∞, ie, at $\eta = (\eta_0 + \eta)_\infty/2$.

$$\eta = \eta_\infty + \frac{\eta_0 - \eta_\infty}{1 + (|\tau|/\tau_m)} \tag{3}$$

The Cross equation assumes that a shear-thinning fluid has high and low shear-limiting viscosity (14) (eq. 4), where α and n are constants.

$$\eta = \eta_\infty + \frac{\eta_0 - \eta_\infty}{1 + \alpha\dot{\gamma}^n} \tag{4}$$

The value for n is often given as 2/3, but polymer melts have shown a wide range of values. The constant α is associated with rupture of the linkages in the structure

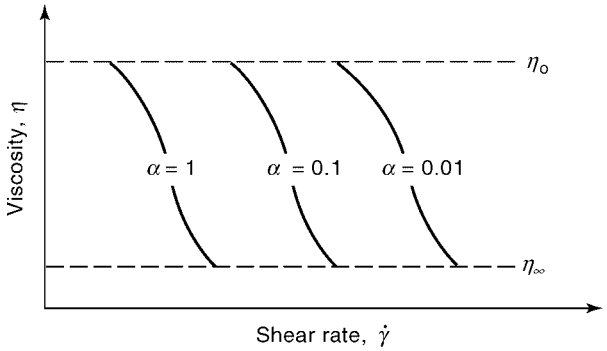

Fig. 4. Graphic representations (viscosity vs shear rate) of Cross model with different values for α.

of the fluid. The effect of different values of α, ie, at the same values of η_0 and η_∞, is shown in Figure 4. As α increases, breakdown occurs at lower and lower shear rates.

Thixotropy and Other Time Effects. In addition to the nonideal behavior described, many fluids exhibit time-dependent effects. Some fluids increase in viscosity (*rheopexy*) or decrease in viscosity (*thixotropy*) with time when sheared at a constant shear rate. These effects can occur in fluids with or without yield values. Rheopexy is a rare phenomenon, but thixotropic fluids are common. Examples of thixotropic materials are starch pastes, gelatin, mayonnaise, drilling muds, and latex paints. The thixotropic effect is shown in Figure 5, where the curves are for a specimen exposed first to increasing and then to decreasing shear rates. Because of the decrease in viscosity with time as well as shear rate, the up-and-down flow curves do not superimpose. Instead, they form a hysteresis loop, often called a thixotropic loop. Because flow curves for thixotropic or rheopectic liquids depend on the shear history of the sample, different curves for the same material can be obtained, depending on the experimental procedure.

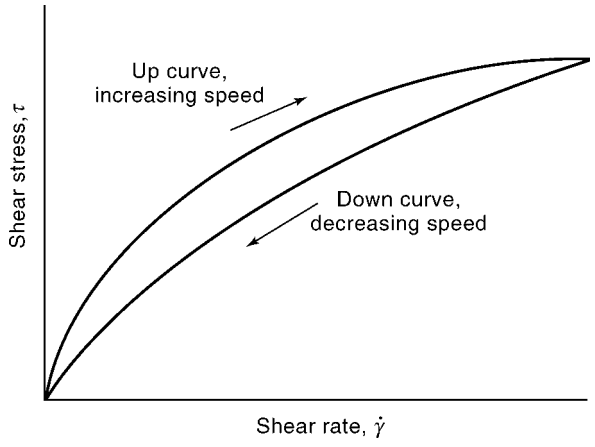

Fig. 5. Flow curves (up and down) for a thixotropic material: hysteresis loop.

Experimentally, it is sometimes difficult to detect differences between a shear-thinning liquid in which the viscosity decreases with increasing shear, and a thixotropic material in which the viscosity decreases with time, because of the combined shear and time effects that occur during a series of measurements. This is especially true if only a few data points are collected. In addition, most materials that are thixotropic are also shear thinning. In fact, one definition of a thixotropic fluid limits it to materials whose viscosity is a function of both shear rate and time (8).

Viscosity–time measurements during or after shearing can be used to show time-dependent effects. The plots in Figure 6 (15) are representative of the results of such measurements on a thixotropic material. On shearing at a given shear rate, the viscosity drops sharply at first, but the rate of change continually decreases until a constant or nearly constant level is reached. This is sometimes referred to as the sheared state. Changing to a higher shear rate causes a a further drop in viscosity. When the shear rate is reduced, the viscosity increases quickly at first, and then increases more slowly. A good example of this is the behavior of latex house paint. The shearing plot represents the brushing action, whereas the recovery plot shows what happens when the brushing stops. The thixotropic behavior allows the paint to be easily brushed to a thin film and gives a short period of time for the brush marks to level; then the viscosity increase prevents running and sagging.

Causes of time-dependent behavior include irreversible changes such as cross-linking, coagulation, degradation, and mechanical instability, and reversible changes involving the breaking and re-forming of colloidal aggregations and networks. Models of time-dependent behavior are less satisfactory and more controversial than those of shear-dependent behavior. Few comprehensive investigations of the viscosity–shear–time profiles of thixotropic and rheopectic materials have

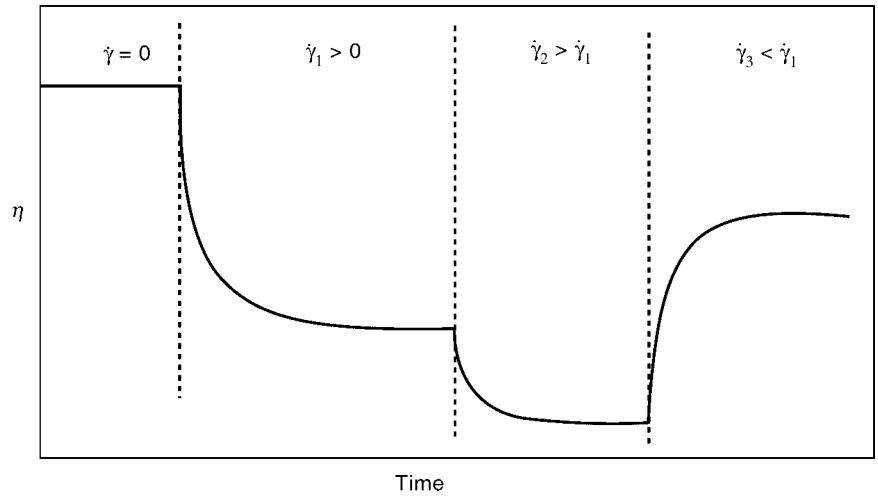

Fig. 6. Viscosity–time effects for a thixotropic material at rest ($\dot{\gamma} = 0$), at some shear rate, $\dot{\gamma}$, at an increased shear rate, and then at a lower shear rate.

been published, but there are sources that contain good discussions of thixotropy (15–17). Rheopexy has also been described (18,19).

Time-dependent effects are measured by determining the decay of shear stress as a function of time at one or more constant shear rates (20). Sequential increases in shear rate followed by equilibration allows the shear stress to reach a maximum value and then decrease exponentially toward an equilibrium level. The peak shear stress, which is obtained by extrapolating the curve to zero time, and the equilibrium shear stress are indicative of the viscosity–shear behavior of unsheared and sheared material, respectively. The stress–decay curves are indicative of the time-dependent behavior. A rate constant for the relaxation process can be determined at each shear rate. In addition, zero-time and equilibrium shear stress values can be used to construct a hysteresis loop that is similar to that shown in Figure 5, but unlike that plot, is independent of acceleration and time of shear.

Another method is the step-shear test (15), which uses controlled shearing and the recovery behavior shown in Figure 6 to characterize the material. In this method, a high shear rate ($\sim 10^4$ s^{-1}) is applied to the specimen until the viscosity falls to an equilibrium value. The shear rate then is reduced to a low value (~ 1 s^{-1}), allowing the structure to re-form and the viscosity to recover. The data can be analyzed in a number of ways. The time it takes to achieve 50% viscosity recovery or some other fraction of the original value can be used to indicate the rate of recovery. Comparisons can be made based on these times or on the time needed to reach a given viscosity. Equation 5 has been fit to the recovery curve, where $\eta\,(t)$ is the viscosity as a function of time, t; $\eta_{t=0}$, the sheared-out viscosity at recovery time zero; $\eta_{t=\infty}$, the infinite time recovered viscosity; and τ, a time constant describing the recovery rate.

$$\eta(t) = \eta_{t=0} + (\eta_{t=\infty} - \eta_{t=0})(1 - e^{-t/\tau}) \tag{5}$$

Another method for estimating thixotropy involves the hysteresis of the thixotropic loop. The area of the thixotropic loop is calculated or measured, which works well with printing inks (1). In a variation of this method, the up curve on an undisturbed sample is determined. The sample is then sheared at high shear (>2000 s^{-1}) for 30–60 s, followed by determination of the down curve (21). The data are plotted as Casson–Asbeck plots, $\eta^{1/2}$ vs $\dot{\gamma}^{-1/2}$ (12), as shown in Figure 7. Such plots are best used for comparison and ranking, but a measure of the degree of thixotropy can be gained by determining the angle formed by the two lines or the area of the triangle formed by the lines and a vertical line through a given value for $\dot{\gamma}^{-1/2}$. Additional methods for determining the degree of thixotropy have been described (7).

Results from measurements of time-dependent effects depend on the sample history and experimental conditions and should be considered approximate. For example, the state of an unsheared or undisturbed sample is a function of its previous shear history and the length of time since it underwent shear. The area of a thixotropic loop depends on the shear range covered, the rate of shear acceleration, and the length of time at the highest shear rate. However, measurements of

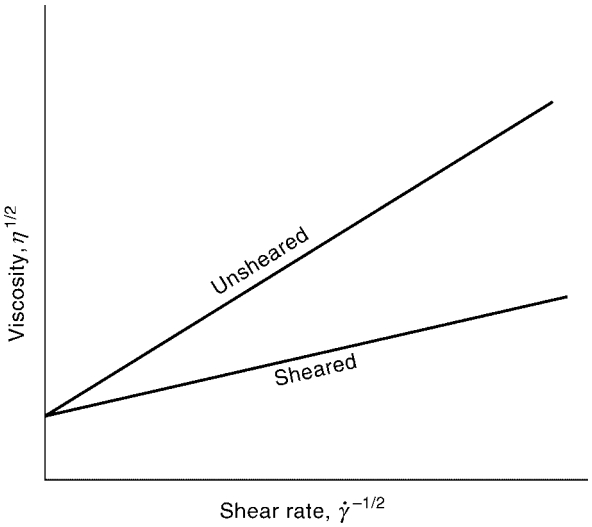

Fig. 7. Casson plots of sheared and unsheared paints. The degree of divergence of the lines is used to estimate thixotropy.

time-dependent behavior can be useful in evaluating and comparing a number of industrial products and in solving flow problems.

Effect of Temperature. In addition to being often dependent on parameters such as shear stress, shear rate, and time, viscosity is highly sensitive to changes in temperature. Most materials decrease in viscosity as temperature increases. The dependence is logarithmic and can be substantial, up to 10% change/°C. This has important implications for processing and handling of materials and for viscosity measurement.

A common expression relating viscosity to temperature is the Arrhenius equation, $\eta = A \times e^{B/T}$ or $\eta = A \times 10^{B/T}$, where A and B are constants characteristic of the polymer or other material, and T is the absolute temperature. Estimation of the viscosity of a polymer at a given temperature requires a knowledge of the viscosity at two other temperatures. This knowledge allows calculation of the constants A and B and subsequent determination of viscosities at other, intermediate temperatures.

The Arrhenius equation may also be expressed in logarithmic form (eq. 6):

$$\log \eta = \log A + B/T \tag{6}$$

For two temperatures (viscosity known at one), this expression may be written as follows (eq. 7):

$$\log(\eta_1/\eta_2) = B\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \tag{7}$$

In practice, plots of $\log \eta$ vs $1/T$ tend to be straight lines over a considerable range of values. Such plots may be used to predict viscosity at one temperature

from viscosities at other temperatures. Likewise, previously measured viscosity–temperature curves for commerical products are often used to ensure meaningful viscosity data for quality assurance even where temperature control is not possilbe.

The Arrhenius equation holds for many solutions and for polymer melts well above their glass-transition temperatures. For polymers closer to their T_g and for concentrated polymer and oligomer solutions, the Williams–Landel–Ferry (WLF) equation (22) works better (23,24). With a proper choice of reference temperature T_s, the ratio of the viscosity to the viscosity at the reference temperature can be expressed as a single universal equation (eq. 8):

$$\log(\eta/\eta_s) = \frac{-8.86(T - T_s)}{101.6 + (T - T_s)} \tag{8}$$

Because T_s is often defined as $T_g + 50$ K, the equation thus becomes

$$\log(\eta/\eta T_g) = \frac{-17.4(T - T_g)}{51.6 + (T - T_g)}$$

In general, the WLF equation holds over the temperature range T_g to $(T_g + 100^\circ\text{C})$.

Dilute Polymer Solutions. The measurement of dilute solution viscosities of polymers is widely used for polymer characterization. Very low concentrations reduce intermolecular interactions and allow measurement of polymer–solvent interactions. These measurements are usually made in capillary viscometers, some of which have provisions for direct dilution of the polymer solution. The key viscosity parameter for polymer characterization is the limiting viscosity number or intrinsic viscosity, $[\eta]$. It is calculated by extrapolation of the viscosity number (reduced viscosity) or the logarithmic viscosity number (inherent viscosity) to zero concentration.

The *viscosity ratio* or *relative viscosity*, η_{rel}, is the ratio of the viscosity of the polymer solution to the viscosity of the pure solvent. In capillary viscometer measurements, the relative viscosity (dimensionless) is the ratio of the flow time for the solution t to the flow time for the solvent t_0 (Table 2). The specific (sp) viscosity (dimensionless) is also defined in Table 2, as is the viscosity number or reduced (red) viscosity, which has the units of cubic meters per kilogram (m^3/kg) or deciliters per gram (dL/g). The logarithmic viscosity number or inherent (inh) viscosity likewise has the units m^3/kg or dL/g. For η_{red} and η_{inh}, c, the concentration of polymer, is expressed in convenient units, traditionally g/100 cm^3 but kg/m^3 in SI units. The viscosity number and logarithmic viscosity number vary with concentration, but each can be extrapolated (Fig. 8) to zero concentration to give the limiting viscosity number (intrinsic viscosity) (Table 2). Usually, measurements at four or five concentrations are needed.

The specific viscosity can also be represented by (25)

$$\eta_{sp} = [\eta]c + k_1[\eta]^2 c^3$$

Table 2. Viscosity Expressions

Common name	Recommended name	Definition	Common units
Relative viscosity	Viscosity ratio	$\eta_{rel} = t/t_0 = \eta/\eta_0$	None
Specific viscosity		$\eta_{sp} = (\eta - \eta_0)/\eta_0 = \eta_{rel}^{-1}$	None
Reduced viscosity	Viscosity number	$\eta_{red} = \eta_{sp}/c = \left(\eta_{rel}^{-1}\right)\Big/c$	dL/g
Inherent viscosity	Logarithmic viscosity number	$\eta_{inh} = (\ln \eta_{rel})/c$	dL/g
Intrinsic viscosity	Limiting viscosity number	$[\eta] = \text{limit}_{c\to 0} \frac{\eta_{rel}}{c} = \text{limit}_{c\to 0} \frac{\ln \eta_{rel}}{c}$	dL/g

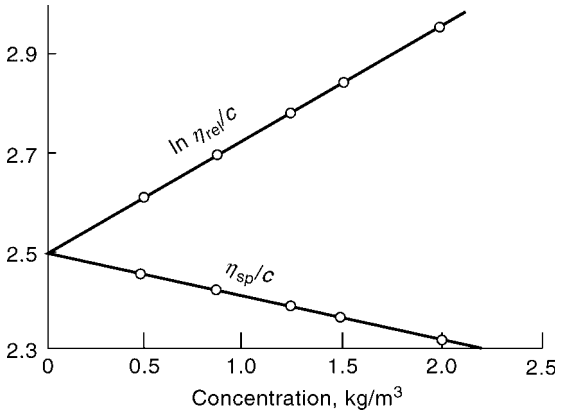

Fig. 8. Plots of viscosity number ($\eta_{rel} = \eta_{sp}/c$) and the logarithmic viscosity number ($\eta_{inh} = \eta_{rel}/c$) vs concentration. Extrapolations to zero concentration give the limiting viscosity number $[\eta]$.

which becomes the Huggins equation (26)

$$\eta_{sp}/c = [\eta](1 - k_h[\eta]c)$$

where k_h is the Huggins viscosity constant, the most commonly used dilute solution viscosity number or index. It is easily determined from the slope of a plot of η_{sp}/c vs c such as the lower plot in Figure 8. The Huggins constant can be thought of as a measure of the "goodness" of the solvent for the polymer with values around 0.3 in good solvents and 0.5–1 in theta solvents. A large number of Huggins constants can be found in Reference 25 along with constants for another semiempirical equation relating viscosity and concentration, that of Schulz and Blaschke (27).

The Huggins equation and Huggins constants can be used to determine values for $[\eta]$ (28,29). The latter gives an equation

$$[\eta] = (1 + 4k_h\eta_{sp})^{1/2} - 1/2k_hc$$

that can be used for single-point determinations (calculations from a single viscosity measurement at a known concentration). The general validity of single-point methods has been questioned, however (30). An even simpler but equally useful method is to approximate $[\eta]$ by the logarithmic viscosity number of a single sufficiently dilute solution: $[\eta]\eta_{inh} = (\ln \eta_{rel})/c$, where c = 1–2 kg/m^3 or 0.1–0.2 g/100 cm^3.

The limiting viscosity number depends on the polymer, solvent, and temperature, but under a given set of conditions it is related to the molecular weight by the Mark–Houwink relation, $[\eta] = KM^a$, where K and a are constants and M is the molecular weight of the polymer. Tables of K and a are available for a large number of polymers and solvents (31,32). Excellent summaries of equations, techniques, and references relating to the viscosity of dilute polymer solutions are also available (33,34), as is information on dilute polymer solutions that are shear thinning (35).

Concentrated Polymer Solutions. Knowledge of the viscosity behavior of concentrated solutions (36–38) is important to the manufacture and application of caulks, adhesives, inks, paints, and varnishes. It is also useful for designing and controlling polymer manufacturing processes, fiber spinning, and film casting. Viscosity behavior can be investigated by a variety of methods, including the use of simple capillary viscometers, extrusion rheometers, and rotational viscometers. Unlike dilute solutions, concentrated polymer solutions show a vast amount of interaction between the macromolecules. The degree of interaction is governed by the concentration, the characteristics of the chains, and the nature of the solvent. A convenient measure of concentration is the dimensionless reduced concentration $\tilde{c}$, which is the product of the concentration and the limiting viscosity number (intrinsic viscosity) $[\eta]$ (36). The transition from dilute to concentrated solutions occurs at a critical concentration c_c and corresponds to c values of several units. In addition, at a critical molecular weight, where $M > M_c$ and $c > c_c$, a fluctuating entanglement network forms. For a concentrated solution, properties above and below M_c may be quite different. For example, the dependence of viscosity on molecular weight, which is much greater in concentrated than in dilute solutions, changes from a value on the order of unity below M_c to one of 3.4–3.5 above M_c (37,39,40). That is, $\eta = KM$ below M_c and $\eta = KM^{3.4-3.5}$ above M_c. Viscosity in these expressions should be the zero-shear viscosity η_0, but because the relationships hold for low shear measurements in many cases, the notation remains in the more general form η.

The break point above which entanglement occurs varies widely with molecular structure; a range of 3,800–36,000 molecular weight has been shown (41). In highly concentrated oligomeric solutions such as high solids organic coatings (volume fraction > 0.7), high dependencies of viscosity on molecular weight occur even at low molecular weights (42–44). This is probably on account of hydrogen bonding that causes the stringing together of short chains or the formation of a loose network, thereby increasing the effective chain length. Something similar to

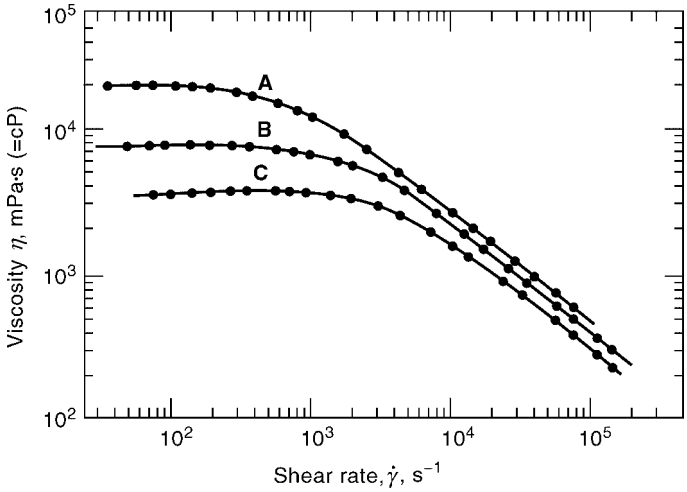

Fig. 9. Viscosity vs shear rate for solutions of a styrene–butadiene–styrene block copolymer (46). (**A**) Cyclohexanone, where $c = 0.248$ g/cm^3; (**B**) *o*-xylene, where $c = 0.246$ g/cm^3; (**C**) toluene, where $c = 0.248$ g/cm^3. Courtesy of the Society of Plastics Engineers, Inc.

this has been seen with the formation of viscosity-building needle-like structures by low molecular weight materials (45).

Depending on the concentration, the solvent, and the shear rate of measurement, concentrated polymer solutions may give wide ranges of viscosity and appear to be Newtonian or non-Newtonian. This is illustrated in Figure 9, where solutions of a styrene–butadiene–styrene block copolymer are Newtonian and viscous at low shear rates, but become shear thinning at high shear rates, dropping to relatively low viscosities beyond 10^5 s^{-1} (46). The shear rate at which the break in behavior occurs depends on the concentration and on the solvent.

Melt Viscosity. The study of the viscosity of polymer melts (47–62) is important for the manufacturer who must supply suitable materials and for the fabrication engineer who must select polymers and fabrication methods. Thus, melt viscosity as a function of temperature, pressure, rate of flow, and polymer molecular weight and structure is of considerable practical importance. Polymer melts exhibit elastic as well as viscous properties. This is evident in the swell of the polymer melt upon emergence from an extrusion die, a behavior that results from the recovery of stored elastic energy plus normal stress effects. Theoretical developments include a constitutive equation that correctly captures nonlinear behavior in both elongation and shear (63,64).

A number of experimental methods have been applied to measure the melt viscosity of polymers (53–55,65), but capillary extrusion techniques probably are generally preferred. Rotational methods are also used, and some permit the measurement of normal stress effects resulting from elasticity as well as of viscosity. Slit rheometers can also be used to measure normal stress (66). Oscillatory shear measurements are useful for measuring the elasticity of polymer melts (57,58). Controlled stress methods have also been applied (59). Squeeze film flow has also been proposed as a geometry suitable for processibility testing of polymer melts

(60). Nonlinear viscoelastic behavior is found in many molten plastics. Theoretical (67) as well as practical approaches address this issue, including a sliding plate normal-thrust rheometer (68,69).

Polymer melts show a low shear rate Newtonian limit and a region of diminishing viscosity with increasing shear rate. Although it is likely that a high shear rate Newtonian region exists, this has generally not been observed experimentally because of the effects of heat generation and polymer degradation at high shear rates.

The limiting low shear or zero-shear viscosity η_0 of the molten polymer can be related to its weight-average molecular weight M_w by the same relations noted for concentrated solutions: $\eta_0 = KM_w$ for low molecular weight and $\eta_0 = KM_w^{3.5}$ for high molecular weight.

The transition between two forms of behavior occurs at a critical molecular weight M_c, which corresponds to a critical chain length, Z_c. The transition is clearly shown in Figure 10, which is a plot of Newtonian viscosity vs chain length in terms of carbon atoms for a series of molten polyethylenes (34). This transition is thought to be related to chain fluctuations in the polymer melt in such a way that the motion changes from displacement of whole chains to restricted motion called *reptation*, ie, wiggly, snake-like motion within the tight tube formed by the matrix of neighboring chains (70–73). Polymer entanglement and reptation

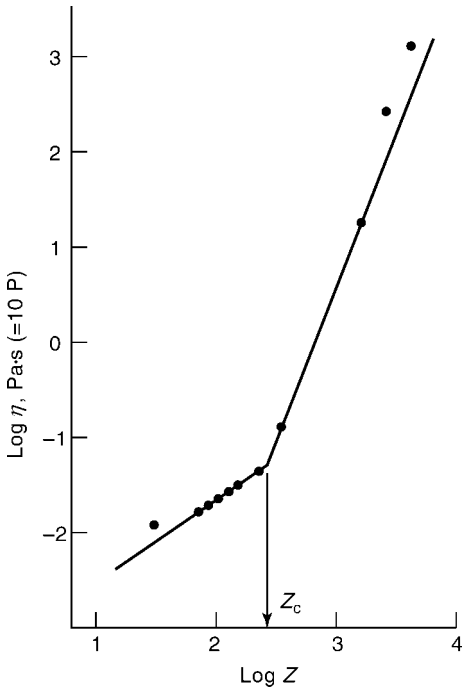

Fig. 10. Newtonian viscosity vs chain length in terms of the number of carbon atoms for a series of molten polyethylenes. To convert Pa·s to P, multiply by 10. Courtesy of Springer Verlag.

have considerable influences on melt rheology, particularly on viscoelasticity, with many consequences for the molding and extrusion of plastics.

The viscosity–molecular weight relationships noted above hold for narrow molecular weight distribution polymers. For polymers having broad molecular weight distributions, viscosity depends on a molecular weight average between M_w and the next higher average M_z (z average), approaching M_z as the distribution broadens. Branching can have a considerable effect, reducing or increasing the viscosity depending on the ratio of the length of the branch to the entanglement length (74). The flow curve for a polymer melt can be predicted from the molecular weight distribution (75) and, under some circumstances, a molecular weight distribution can be determined from the flow curve (76,77). As might be expected, fillers also have an effect on melt viscosity (78).

The dependence of viscosity on temperature is critical to the handling of molten polymers in molding, extrusion, and other manufacturing processes. In fact, the drop in viscosity with increasing temperature makes these operations possible. Therefore, viscosity–temperature relationships are important. Data for many polymers can be found in the literature (47–56). The behavior of others can be determined by viscosity measurements over a range of temperatures. Viscosity–stress master curves are useful in the prediction of viscosity at a given temperature (79). The viscosity–stress curves shown in Figure 11 (47) are approximately superimposable by shifting at constant stress.

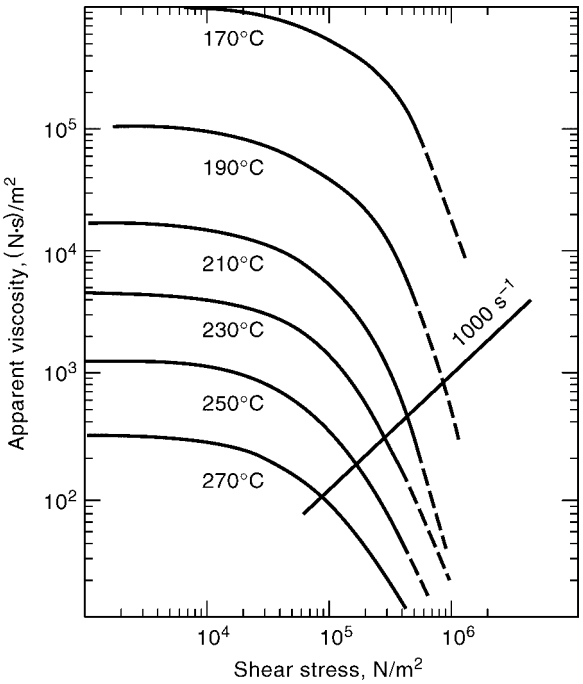

Fig. 11. Viscosity at different temperatures measured by a capillary viscometer: injection-molding grade of poly(methyl methacrylate) (47). To convert N/m^2 to psi, multiply by 145; to convert $(N \cdot s)/m^2$ to $(dyn \cdot s)/cm^2$(P), multiply by 10.

The temperature dependence of melt viscosity at temperatures considerably above T_g approximates an exponential function of the Arrhenius type. However, near the glass transition the viscosity temperature relationship for many polymers is in better agreement with the WLF treatment (22).

Melt viscosity is also affected by pressure (47,80,81). The compression of a melt reduces the free volume and therefore raises the viscosity. For example, the viscosity of low density polyethylene increases by a factor of roughly 10 over a static pressure range of 34–170 MPa (5,000–25,000 psi).

Dispersed Systems. Many fluids of commercial and biological importance are dispersed systems, such as solids suspended in liquids (dispersions) and liquid–liquid suspensions (emulsions). Examples of the former include inks, paints, pigment slurries, and concrete; examples of the latter include mayonnaise, butter, margarine, oil-and-vinegar salad dressing, and milk. Dispersion of a solid or liquid in a liquid affects the viscosity. In many cases Newtonian flow behavior is transformed into non-Newtonian flow behavior. Shear thinning results from the ability of the solid particles or liquid droplets to come together to form network structures when at rest or under low shear. With increasing shear the interlinked structure gradually breaks down, and the resistance to flow decreases. The viscosity of a dispersed system depends on hydrodynamic interactions between particles or droplets and the liquid, particle–particle interactions (bumping), and interparticle attractions that promote the formation of aggregates, flocs, and networks.

Emulsions have not been studied as thoroughly as dispersions, probably because of the greater complexity of the former. Emulsions tend to be unstable, and frequently droplets begin to coalesce soon after the emulsion forms. Thus the emulsion is continually changing. In addition, droplets may change shape under shear or when packed tightly together. This makes it difficult to apply theories developed for solid spheres or other well-defined geometries of shape.

Detailed treatments of the rheology of various dispersed systems are available (82–88), as are reviews of the viscous, elastic, and yield behavior of dispersions (89–92), of the flow properties of concentrated suspensions (90,93–99), and of viscoelastic properties (100–102).

The viscosities of dilute dispersions have received considerable theoretical and experimental treatment, partly because of the similarity between polymer solutions and small particle dispersions at low concentration. Nondeformable spherical particles are usually assumed in the cases of molecules and particles. The key viscosity quantity for dispersions is the relative viscosity or viscosity ratio, η_{rel}.

$$\eta_{rel} = \frac{\eta}{\eta_0} = \frac{\text{Dispersion viscosity}}{\text{Viscosity of liquid}} \tag{9}$$

This is because the effect of the dispersed solid, rather than the dispersing medium, is usually more significant. However, the latter should not be ignored. Many industrial problems involving unacceptably high viscosities in dispersed systems are solved by substituting solvents of lower viscosity.

The relative viscosity of a dilute dispersion of rigid spherical particles is given by $\eta_{rel} = 1 + a\phi$, where a is equal to $[\eta]$, the limiting viscosity number (intrinsic viscosity) in terms of volume concentration, and ϕ is the volume fraction. Einstein has shown that, provided that the particle concentration is low enough and certain

other conditions are met, $[\eta] = 2.5$, and the viscosity equation is then $\eta_{rel} = 1 + 2.5\phi$. This expression is usually called the Einstein equation.

For higher ($\phi > 0.05$) concentrations where particle–particle interactions are noticeable, the viscosity is higher than that predicted by the Einstein equation. The viscosity–concentration equation becomes equation 10, where b and c are additional constants (103).

$$\eta_{rel} = 1 + 2.5\phi + b\phi^2 + c\phi^3 + \cdots \tag{10}$$

The deviation from the Einstein equation at higher concentrations is represented in Figure 12, which is typical of many systems (104,105). The relative viscosity tends to infinity as the concentration approaches the limiting volume fraction of close packing ϕ_m ($\phi = \sim 0.7$). Equation 10 has been modified (106,107) to take this into account, and the expression for η_{rel} becomes (eq. 11)

$$\eta_{rel} = \frac{1 + 2.5\phi + b\phi^2 + c\phi^3 + \cdots}{1 - (\phi_m/\phi)} \tag{11}$$

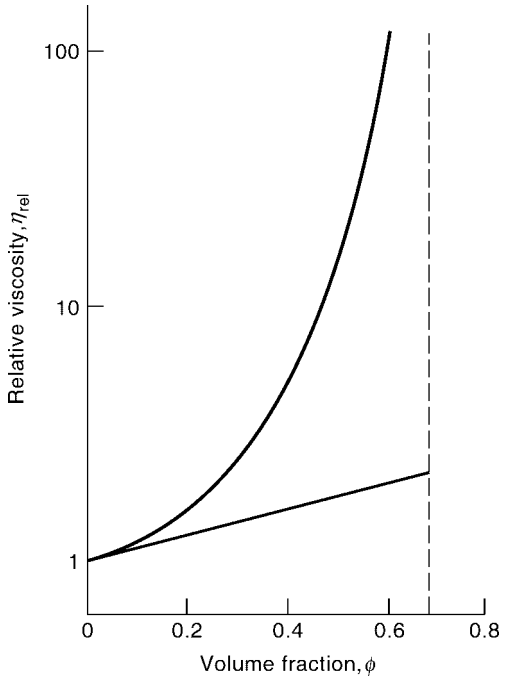

Fig. 12. Relative viscosity vs volume fraction for a typical dispersion (curved line), where the solid straight line represents the Einstein relationship $[\eta] = 2.5$, and the dashed line is an approximate value for the limiting volume fraction ϕ_m.

Another model that has been successful in fitting much data is the Krieger–Dougherty equation (eq. 12) (8,108):

$$\eta_{\mathrm{rel}} = \left(1 - \frac{\phi}{\phi_{\mathrm{m}}}\right)^{-[\eta]\phi_{\mathrm{m}}} \tag{12}$$

Factors other than concentration affect the viscosity of dispersions. A dispersion of nonspherical particles tends to be more viscous than predicted if the Brownian motion is great enough to maintain a random orientation of the particles. However, at low temperatures or high solvent viscosities, the Brownian motion is small and the particle alignment in flow (streamlining) results in unexpectedly lower viscosities. This is a form of shear thinning.

If the dispersion particles are attracted to each other, they tend to flocculate and form a structure. At low concentrations the particles form open aggregates, which give a fractal structure (109,110). At higher concentrations a network structure results, which can be so pronounced that the mixture has a yield point and behaves like a solid when at rest. Shearing breaks up this structure, and viscosity decreases.

If the volume concentration of the solid in the dispersion is high enough, shearing may produce an increase rather than a decrease in viscosity. Such behavior, called *shear thickening* (8,16,111–114) or *dilatancy*, is common in dispersions of certain pigments and other powders. These dispersions are closely packed, but are usually shear thinning up to moderate shear rates, ie, a few hundred to a few thousand per second. Higher shear introduces irregularities in the packing, with bridging effects occurring between the particles. The overall packing loosens, which implies that the total space between particles increases. The liquid is not able to fill this space and can no longer wet all the particles. Much of the lubricating effect of the liquid is therefore lost, and internal friction rises, producing a high viscosity. This is true dilatancy, and the volume actually increases. Shear thickening can also occur in dilute suspensions (115). In such cases there is no volume expansion; instead there is buildup of particle aggregates which ultimately produces a network that behaves like a gel.

Because emulsions are different from dispersions, different viscosity–concentration relationships must be used (82,103). In an emulsion the droplets are not rigid, and viscosity can vary over a wide range. Several equations have been proposed to account for this. An extension of the Einstein equation includes a factor that allows for the effect of variations in fluid circulation within the droplets and subsequent distortion of flow patterns (116,117).

Extensional Viscosity. In addition to the shear viscosity η, two other rheological constants can be defined for fluids: the bulk viscosity, K, and the extensional or elongational viscosity, η_{e} (36,52,53,118–125). The bulk viscosity relates the hydrostatic pressure to the rate of deformation of volume, whereas the extensional viscosity relates the tensile stress to the rate of extensional deformation of the fluid. Extensional viscosity is important in a number of industrial processes and problems (36,118,126–128). Shear properties alone are insufficient for the characterization of many fluids, particularly polymer melts (119,125,129,130).

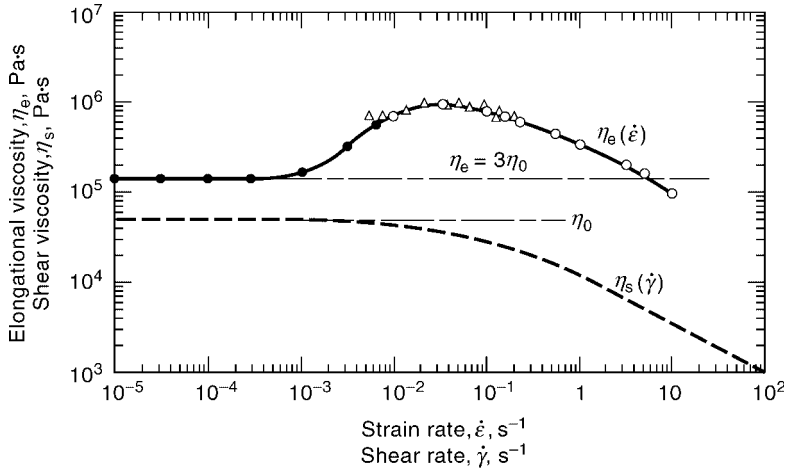

Fig. 13. Shear viscosity, η_s, and extensional viscosity, η_e, as a function of deformation rate of a low density polyethylene (LDPE) at 150°C (129). To convert Pa·s to P, multiply by 10. Courtesy of *Rheologica Acta*.

Extensional flows occur when fluid deformation is the result of a stretching motion. Extensional viscosity is related to the stress required for the stretching. This stress is necessary to increase the normalized distance between two material entities in the same plane when the separation is s and the relative velocity is ds/dt. The deformation rate is the extensional strain rate, which is given by equation 13 (126):

$$\dot{\varepsilon} = \frac{1}{s}\frac{ds}{dt} \tag{13}$$

Unlike shear viscosity, extensional viscosity has no meaning unless the type of deformation is specified. The three types of extensional viscosity identified and measured are uniaxial or simple, biaxial, and pure shear. Uniaxial viscosity is the only one used to characterize fluids. It has been employed mainly in the study of polymer melts, but also for other fluids. For a Newtonian fluid, the uniaxial extensional viscosity is three times the shear viscosity: $(\eta_e)_{uni} = 3\eta$. This is confirmed at very low shear rates in Figure 13, which provides a typical example of the extensional viscosity behavior of a polymer (129). The two other extensional viscosities are used to study elastomers in the form of films or sheets. Uniaxial and biaxial extensions are important in industry (118,125–128,130,132), the former for the spinning of textile fibers and roller spattering of paints, and the latter for blow molding, vacuum forming, film blowing, and foam processes.

Electrorheological Behavior. Electrorheological (ER) fluids are colloidal suspensions whose properties change strongly and reversibly upon application of an electric field. When an electric field is applied to an ER fluid, it responds by forming fibrous or chain structures parallel to the applied field. These structures greatly increase the viscosity of the fluid, by a factor of 10^5 in some cases. At low

shear stress the material behaves like a solid. The material has a yield stress, above which it will flow, but with a high viscosity.

A parameter used to characterize ER fluids is the Mason number, M_a, which describes the ratio of viscous to electrical forces, and is given by equation 14, where ε is the solvent dielectric constant; η_0, the solvent viscosity; $\dot{\gamma}$, the strain or shear rate; β, the effective polarizability of the particles; and E, the electric field (133).

$$M_a = \frac{24\pi\varepsilon\eta_0\dot{\gamma}}{(\beta E)^2} \tag{14}$$

A considerable literature on ER fluids and their measurement has developed: a selection of reviews and papers is given in References 134–163. There is an analogous magnetorheological (MR) effect where suspensions filled with magnetic particles show reversible changes in their rheological behavior when subjected to a magnetic field (163–168). Measurements on ER and MR fluids are made with viscometers modified to allow the the application of electric or magnetic fields.

Elasticity and Viscoelasticity

Elastic deformation is a function of stress and is expressed in terms of relative displacement or strain. Strain may be expressed in terms of relative change in volume, length, or other measurement, depending on the nature of the stress. An ideal elastic body (169,170) is a material for which the strain is proportional to the stress (Hooke's law) with immediate recovery to the original volume and shape when the stress is released. The relationship between the stress σ and strain ε may be written as $\sigma = K\varepsilon$, where K is a proportionality constant called the modulus of elasticity. For a homogeneous, isotropic, Hookean solid, three moduli may be defined. Young's modulus, E, relates tensile stress to tensile strain. The shear modulus, G, relates shear stress to shear strain, ie, $G = \tau/\gamma$. The bulk modulus B relates hydrostatic pressure to the change in volume. Another elastic constant needed for complete specification of behavior in tension is Poisson's ratio, μ, which relates change in volume to change in shape. Incompressible solids and polymer melts have $\mu = 0.5$, but for most solid materials, $\mu < 0.5$. For isotropic, Hookean materials, Young's modulus is related to the shear modulus by $E = 2G(1 + \mu)$. If μ is 0.5, Young's modulus is three times the shear modulus. Values for the various moduli and Poisson's ratio for some representative materials are given in Table 3.

Materials such as metals are nearly elastic and show almost no flow or viscous component. Polymers and many of their solutions are both viscous and elastic, and both types of deformation must be taken into account to explain their behavior (see VISCOELASTICITY).

Mechanical Behavior of Materials. Different kinds of materials respond differently when they undergo mechanical stress. For purely viscous behavior, stress is relieved by viscous flow and is independent of strain. For purely elastic behavior, there is a direct dependence of stress on strain and the ratio of the two is the modulus E (or G).

Table 3. Measured Values of Elastic Constants at Small Extensions and 25°C[a]

Material	Young's modulus, E, GPa[b]	Proportionality limit[c] % extension	Shear modulus, G, GPa[b]	Poisson's ratio, μ	Bulk modulus, B, GPa[b]
Vitreous silica	70.0	3	30.5	0.14	37.4

The response of different materials to a constant stress applied at time $t = t_0$ followed by removal of that stress at $t = t_1$, ie, creep and recovery, is shown in Figure 14 (171). For an elastic material (Fig. 14**a**), the resulting strain is instantaneous and constant until the stress is removed, at which time the material recovers and the strain immediately drops back to zero. In the case of the viscous fluid (Fig. 14**b**), the strain increases linearly with time. When the load is removed, the strain does not recover but remains constant. Deformation is permanent. The

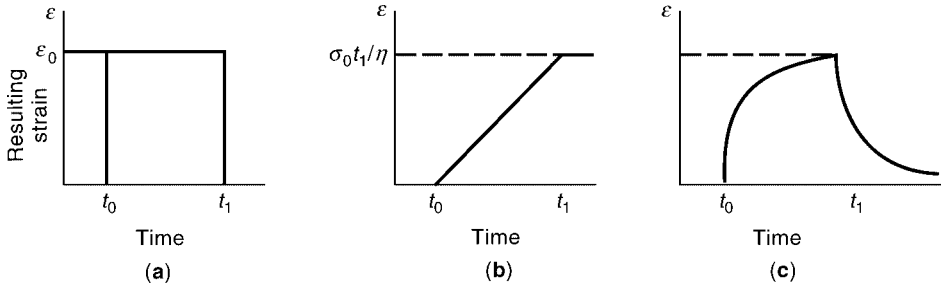

Fig. 14. Response (strain) of different idealized materials to an instantaneous application of a stress at time $t = t_0$: (**a**) elastic, (**b**) viscous, and (**c**) viscoelastic.

response of the viscoelastic material (Fig. 14**c**) draws from both kinds of behavior. An initial instantaneous (elastic) strain is followed by a time-dependent strain. When the stress is removed, the initial strain recovery is elastic, but full recovery is delayed to longer times by the viscous component.

Mechanical Models. Because the complex rheological behavior of viscoelastic bodies is difficult to visualize, mechanical models are often used. In these models the viscous response to applied stress is assumed to be that of a Newtonian fluid and is represented by a dashpot, ie, a piston operating in a cylinder of Newtonian fluid. The elastic response is idealized as an ideal elastic (Hookean) solid and is represented by a spring. The dashpot represents the dissipation of energy in the form of heat, whereas the spring represents a system that stores energy. Mechanical behavior of materials may be approximated by combinations of springs and dashpots. These models, which are largely being replaced by mathematical (integral and differential) models, have been covered in detail elsewhere (8,10,20,103,171,172).

Whether a viscoelastic material behaves as a viscous liquid or an elastic solid depends on the relation between the time scale of the experiment and the time required for the system to respond to stress or deformation. Although the concept of a single relaxation time is generally inapplicable to real materials, a *mean characteristic time* can be defined as the time required for a stress to decay to 1/*e* of its elastic response to a step change in strain. The ratio of this characteristic time to the time scale of the experiment, t_e, is called the Deborah number. A material at a high Deborah number responds elastically, whereas that at a low Deborah number exhibits viscous behavior: at $t_e \ll \lambda$, it behaves like an elastic solid; at 0 $t_e > \lambda$, like a viscous liquid. These effects can be seen in geological strata, where rock has flowed to relieve the stresses imposed by geological events. The time scale is long, and the material appears to be viscous.

Dynamic Behavior. Knowledge of the response of materials to stress–strain, creep, and stress–relaxation measurements are useful to define material properties. The dynamic response of viscoelastic materials to cyclic stresses or strains is also important, partly because cyclic motion occurs in many processing operations and applications, and partly because so much rheological information can be gained from dynamic measurements. By subjecting a specimen to oscillatory stress and determining the response, both the elastic and viscous or damping characteristics can be obtained. Elastic materials store energy, whereas liquids dissipate it as heat. This dissipation results in highly damped motion. Viscoelastic materials exhibit both elastic and damping behavior. The latter causes the deformation to be out of phase with the stress applied in the dynamic measurement.

A sinusoidal stress applied to an ideal elastic material produces a sinusoidal strain proportional to the stress amplitude and in phase with it. For ideal viscous materials the stress and strain are out of phase by 90°. Figure 15 gives an example of a stress–strain diagram for a sinusoidal stress applied to a real material. The amplitude of the deformation (strain) in response to the stress is proportional to that of the stress, but lags behind the strain curve by some angle δ between 0 and 90°, depending on the elastic/viscous characteristic of the material. This behavior is usually analyzed by the use of complex variables to represent stress and strain. These variables, complex stress and complex strain, ie, τ^* and γ^*, respectively, are

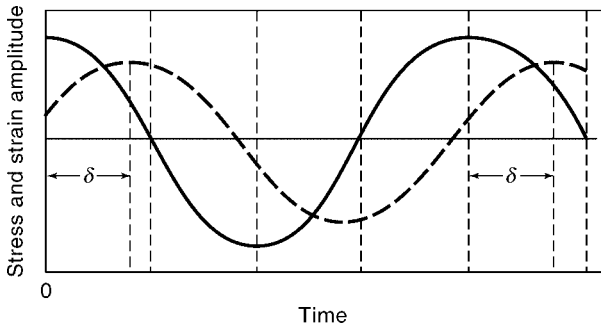

Fig. 15. Viscoelastic material: stress (—) and strain (---) amplitudes vs time where δ is the phase angle that defines the lag of the strain behind the stress.

vectors in complex planes. They can be resolved into real (in phase) and imaginary (90° out of phase) components.

The complex stress is $\tau^* = \tau' + i\tau''$, which is the sum of a real part of the stress and an imaginary part; the complex strain is $\gamma^* = \gamma' + i\gamma''$, where i is the operator $\sqrt{-1}$ that signifies the rotation of 90° between τ' and τ' and γ' and γ''. The shear modulus can also be represented by a complex variable, ie, the complex dynamic modulus G^*, which is the ratio of the complex stress and complex strain: $G^* = \tau^*/\gamma^*$. The dynamic modulus can also be resolved into two components or vectors (G' and G'): $G^* = G' + iG''$, where equation 15 holds, and where $G' = G^* \cos\delta$ and $G' = G^* \sin\delta$.

$$G^* = [(G')^2 + (G'')^2]^{-1} \tag{15}$$

The parameter G' is called the storage modulus. It is in phase with the real components of γ^* and τ^* and is a measure of elasticity. It is associated with the energy stored in elastic deformation and is approximately equal to the elastic modulus determined in creep and stress–relaxation experiments when measured at appropriate timescales, ie, $G'(\omega)G(t)$ when $t = 1/\omega$. The value of G' is high when a polymer is in its glassy state, but drops with increasing temperature as the polymer goes through the glass transition and becomes soft and rubbery (Fig. 16). If the polymer is cross-linked, the storage modulus does not drop so far after the glass transition. The exact level depends on the degree of cross-linking. For viscoelastic melts it is common practice to associate G' with the ability of a melt to recover from a deformation. However, this has been shown to be invalid in some cases, and an association with the stiffness of the melt is preferred (173).

G' is called the loss modulus. It arises from the out-of-phase components of γ^* and τ^* and is associated with viscous energy dissipation, ie, damping. The ratio of G'' and G' gives another measure of damping, the dissipation factor or loss tangent (often just called tan δ), which is the ratio of energy dissipated to energy stored (eq. 16).

$$\tan\delta = G''/G' \tag{16}$$

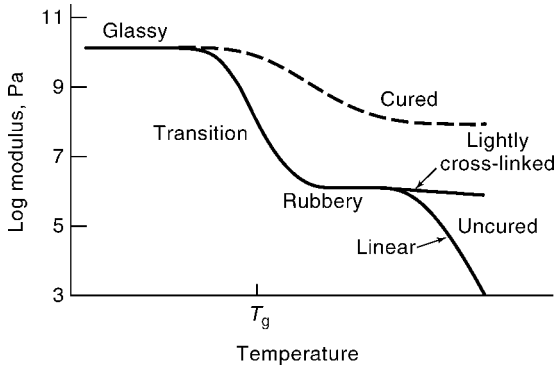

Fig. 16. Generalized modulus–temperature curves for polymeric materials, showing the high modulus glassy state, glass-transition regions for cured and uncured polymers, plateau regions for cross-linked polymers, and the drop-off in modulus for a linear polymer.

Plots of loss modulus or tan δ vs temperature for polymers give peaks at energy absorbing transitions, such as the glass transition and low temperature secondary transitions (Fig. 17). Such plots are useful for characterizing polymers and products made from them.

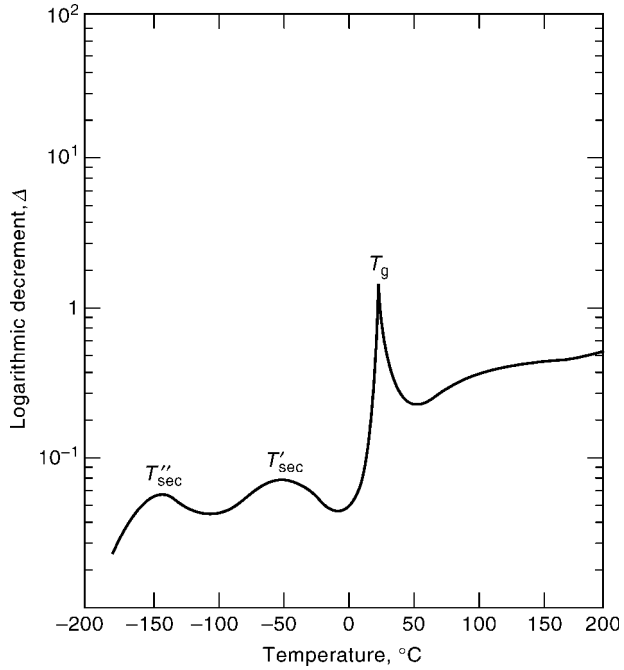

Fig. 17. Logarithmic decrement (related to tan δ and loss modulus) vs temperature for a fluorocarbon dibenzoxazole (174). After drying up to 200°C, the experiment was conducted at 200 → −180 → 200°C: $\Delta T/\Delta t = \pm 1.5$°C/min in a helium atmosphere. The T_g gives a sharp damping peak, whereas the secondary glassy state transitions, T_{sec}, are very broad.

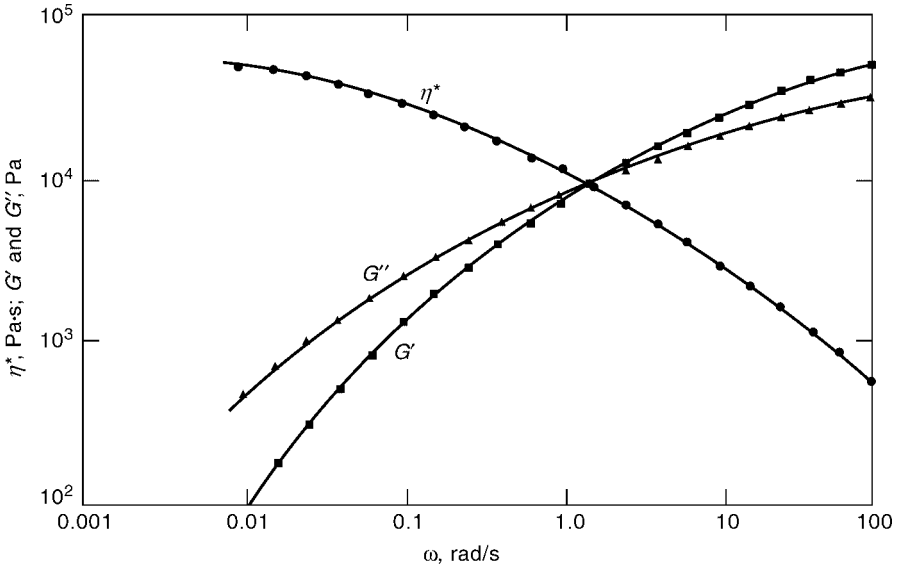

Fig. 18. Dynamic viscoelastic properties of a low density polyethylene (LDPE) at 150°C: complex dynamic viscosity η^*, storage modulus G', and loss modulus G' vs angular velocity, ω. To convert Pa·s to P, multiply by 10; to convert Pa to dyn/cm^2, multiply by 10. Courtesy of Rheometric Scientific.

A viscoelastic material also possesses a complex dynamic viscosity, $\eta^* = \eta' + i\eta''$, and it can be shown that $\eta^* = G^*/i\omega$; $\eta' = G'/\omega$; and $\eta'' = G'/\omega$, where ω is the angular frequency. The parameter η^* is useful for many viscoelastic fluids in that a plot of its absolute value η^* vs angular frequency in rad/s is often numerically similar to a plot of shear viscosity η vs shear rate. This correspondence is known as the Cox–Merz empirical relationship (175,176). The parameter η' is called the dynamic viscosity and is related to G', the loss modulus; the parameter η'' does not deal with viscosity, but is a measure of elasticity.

The significance of G', G', tan δ, η', and η'' is that they can be determined experimentally and used to characterize real materials. These parameters depend on frequency and temperature, and this dependence can be used to define behavior. For example, viscoelastic fluids are often characterized by log–log plots of one or more of these quantities vs the angular frequency ω, as shown in Figure 18, which illustrates the behavior of a polymer melt (177,178).

Normal Stress (Weissenberg Effect). Many viscoelastic fluids flow in a direction normal (perpendicular) to the direction of shear stress in steady-state shear (20,106). Examples of the effect include flour dough climbing up a beater, polymer solutions climbing up the inner cylinder in a concentric cylinder viscometer, and paints forcing apart the cone and plate of a cone–plate viscometer. The normal stress effect has been put to practical use in certain screwless extruders designed in a cone–plate or plate–plate configuration, where the polymer enters at the periphery and exits at the axis.

The two normal stress functions, $N_1(\dot{\gamma})$ and $N_2(\dot{\gamma})$, are referred to as the first and second normal stress differences, respectively. The former is positive

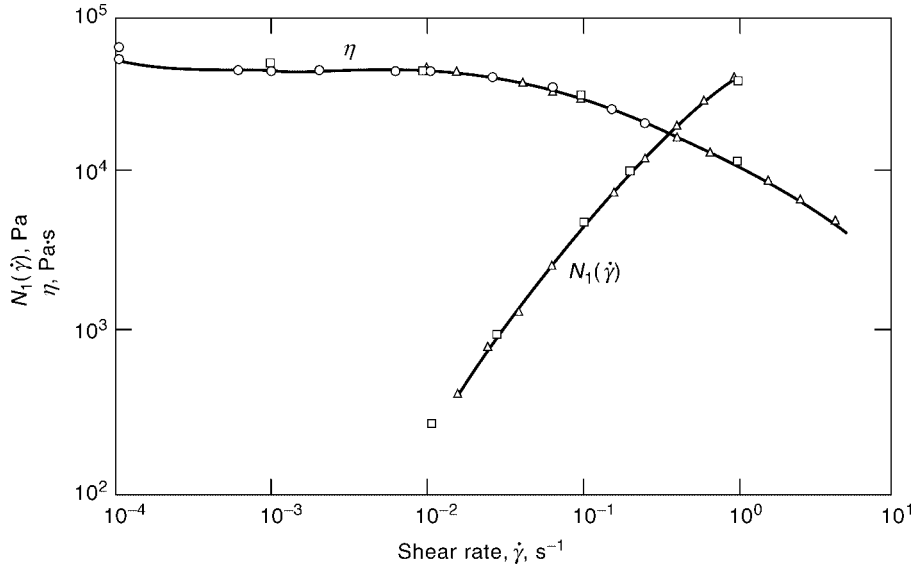

Fig. 19. Shear viscosity η and first normal stress difference $N_1(\dot{\gamma})$ vs shear rate $\dot{\gamma}$ for a low density polyethylene at 150°C (177,178), where ○ parallel plate; Δ cone and plate; and □: Weissenberg rheogoniometer. To convert Pa to dyn/cm^2, multiply by 10; to convert Pa·s to P, multiply by 10. Courtesy of *Rheometric Scientific*.

and increases with increasing shear rate, as shown in Figure 19 (177,178), which describes the steady-shear behavior of the polymer melt in Figure 18. The stress function $N_2(\dot{\gamma})$ is smaller in absolute value than $N_1(\dot{\gamma})$ and is sometimes negative. The first normal stress difference is a useful quantity, as it often gives a good quantitative measure of viscoelasticity. It can be determined from the normal force, which is measurable with several commercial rotational viscometers. In highly elastic liquids it is common for $N_1(\dot{\gamma})$ to be considerably larger than the shear stress.

Description of normal stress measurements on a practical but complex material, paint, is available (179). Other publications (180–183) give the results of investigations of normal stress differences for a variety of materials. These papers and their references form a useful introduction to the measurement of normal stress differences.

Viscometers

To solve a flow problem or characterize a given fluid, an instrument must be carefully selected. Many commercial viscometers are available with a variety of geometries for wide viscosity ranges and shear rates (8,20,53,54). Rarely is it necessary to construct an instrument. However, in choosing a commercial viscometer a number of criteria must be considered. Of great importance is the nature of the material to be tested, its viscosity, its elasticity, the temperature dependence of its viscosity, and other variables. The degree of accuracy and precision required, and

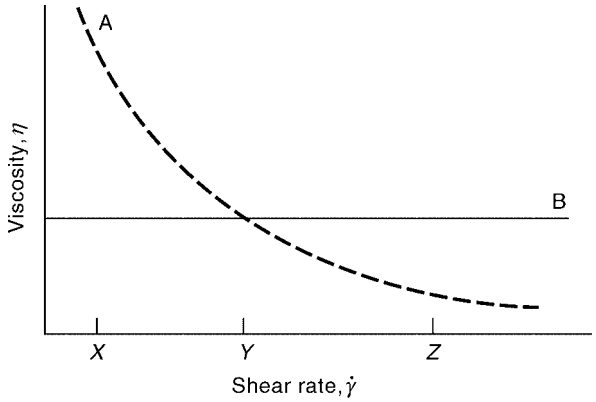

Fig. 20. Viscosity vs shear rate curves for two fluids, showing the fallacy of a single-point measurement. Fluid A would appear to be more viscous than fluid B if measured only at point X, of the same viscosity if measured at point Y, and less viscous if measured only at point Z.

whether the measurements are for quality control or research, must be considered. The viscometer must be matched to the materials and processes of interest; otherwise, the results may be misleading.

Most early viscometers, many of which have been incorporated into standard industrial tests, give single-point measurements. Instead of describing viscosity or shear stress over a range of shear rates, only a single point on the flow curve is produced; the rest of the curve is unknown. This is not a problem with Newtonian liquids because viscosity is independent of shear rate, but it can be misleading in the case of non-Newtonian materials, as shown in Figure 20, where the viscosity profiles of two fluids cross each other. Measurements carried out at the shear rate corresponding to the intersection would indicate that the two materials are identical, even though a simple examination, such as shaking or pouring, would show that they are not. A non-Newtonian fluid cannot be adequately characterized by a single-point measurement, and multipoint measurement techniques are strongly recommended.

Temperature control is also important. Viscosity is highly dependent on temperature; accurate, precise measurements can be made only if the temperature is carefully controlled. More errors are made and more disagreements over viscosity results arise because of incorrect or drifting temperature than for any other reason. Good temperature control can be achieved with commercial baths or circulators equipped with thermostats. Unfortunately, this is impossible with some viscometers. Others lose temperature control because of heat generation at high shear rates, especially with high viscosity materials. Such a temperature increase causes an apparent loss of viscosity under shear. A natural but erroneous conclusion would be that the material is thixotropic or shear thinning.

Viscometers may be separated into three main types: capillary, rotational, and moving body. There are other kinds, usually designed for special applications. For example, it has been reported that the viscosity of volumes of liquid in the nanoliter range can be measured by monitoring the shape of a droplet while it is

suspended in a medium with an extensional or shear field (184). For any given type of viscometer there is usually a choice of several different instruments. The choice depends on the particular requirements of the investigator and the price range.

Capillary Viscometers. Capillary flow measurement is a popular method for measuring viscosity (20,171,172); it is also the oldest. A liquid drains or is forced through a fine-bore tube, and the viscosity is determined from the measured flow, applied pressure, and tube dimensions. The basic equation is the Hagen–Poiseuille expression (eq. 17), where η is the viscosity, r the radius of the capillary, Δp the pressure drop through the capillary, V the volume of liquid that flows in time t, and L the length of the capillary.

$$\eta = \frac{\pi r^4 \Delta p t}{8VL} \tag{17}$$

Steady-state, laminar, isothermal flow is assumed. For a given viscometer with similar fluids and a constant pressure drop, the equation reduces to $\eta = Kt$ or, more commonly, $\nu = \eta/\rho = Ct$, where ρ is the density, ν the kinematic viscosity, and C a constant. Therefore, viscosity can be determined by multiplying the efflux time by a suitable constant.

Capillary viscometers are useful for measuring precise viscosities of a large number of fluids, ranging from dilute polymer solutions to polymer melts. Shear rates vary widely and depend on the instruments and the liquid being studied. The shear rate at the capillary wall for a Newtonian fluid may be calculated from equation 18, where Q is the volumetric flow rate and r the radius of the capillary; the shear stress at the wall is $\tau_w = r\Delta p/2L$.

$$\dot{\gamma}_w = \frac{4Q\pi}{r^3} \tag{18}$$

Absolute viscosities are difficult to measure with capillary viscometers, but viscosities relative to some standard fluid of known viscosity, such as water, are readily determined. The viscometer is calibrated with the reference fluid, and viscosities of other fluids relative to the reference sample are determined from their flow times.

For highly accurate work, corrections must be made for kinetic energy losses, incomplete drainage, turbulence, and possible surface tension and heat effects (20). The largest correction for liquids is that resulting from loss of effective pressure because of the appreciable kinetic energy of the issuing stream. The next most important correction for liquids and the largest for polymer melts is that for energy loss resulting from end effects, ie, viscous resistance caused by velocity gradients as the liquid enters and leaves the capillary (171,172,185). When the terms for these two correction factors are incorporated into the viscosity equation, it is changed to equation 19, where t is the time of flow and B and C are instrument constants generated from measurements of fluids of known viscosity.

$$\nu = \eta/\rho = Ct - B/t \tag{19}$$

These corrections are rarely used in industrial applications because the Poiseuille equation adequately expresses the flow. However, corrections are absolutely necessary for determining even approximate viscosities when using short capillary devices, such as orifice viscometers. Use of a long capillary (>10 dia) and long efflux times (>300 s) minimizes the need for corrections. The ASTM standards D3835 and D5099 describe experimental procedures for using capillary rheometers to measure rheological properties of polymers and rubbers under process conditions.

The glass capillary viscometer is widely used to measure the viscosity of Newtonian fluids. The driving force is usually the hydrostatic head of the test liquid. Kinematic viscosity is measured directly, and most of the viscometers are limited to low viscosity fluids, approx 0.4–16,000 mm^2/s. However, external pressure can be applied to many glass viscometers to increase the range of measurement and enable the study of non-Newtonian behavior. Glass capillary viscometers are low shear stress instruments: 1–15 Pa or 10–150 dyn/cm^2 if operated by gravity only. The rate of shear can be as high as 20,000 s^{-1} based on a 200–800 s efflux time.

The basic design is that of the Ostwald viscometer: a U-tube with two reservoir bulbs separated by a capillary, as shown in Figure 21**a**. The liquid is added to the viscometer, pulled into the upper reservoir by suction, and then allowed to drain by gravity back into the lower reservoir. The time that it takes for the liquid to pass between two etched marks, one above and one below the upper reservoir, is a measure of the viscosity. In U-tube viscometers, the effective pressure head and therefore the flow time depend on the volume of liquid in the instrument. Hence, the conditions must be the same for each measurement.

The original Ostwald viscometer has been modified in many ways, and a number of different versions are on the market (Table 4) (20). Most are available with a wide choice of capillary diameters and therefore a number of viscosity ranges. A number of viscometers are described in ASTM D445, which also lists detailed recommendations on dimensions and methods of use.

[c] Standard Inspection Laboratories.

The Cannon–Fenske viscometer (Fig. 21**b**) is excellent for general use. A long capillary and small upper reservoir result in a small kinetic energy correction; the large diameter of the lower reservoir minimizes head errors. Because the upper and lower bulbs lie on the same vertical axis, variations in the head are minimal even if the viscometer is used in positions that are not perfectly vertical. A reverse-flow Cannon–Fenske viscometer is used for opaque liquids. In this type of viscometer the liquid flows upward past the timing marks, rather than downward as in the normal direct-flow instrument. Thus the position of the meniscus is not obscured by the film of liquid on the glass wall.

The Ubbelohde viscometer is shown in Figure 21**c**. It is particularly useful for measurements at several different concentrations, as flow times are not a function of volume, and therefore dilutions can be made in the viscometer. Modifications include the Cannon-Ubbelohde, semi-micro, and dilution viscometers. The Ubbelohde viscometer is also called a suspended-level viscometer because the liquid emerging from the lower end of the capillary flows down only the walls of the reservoir directly below it. Therefore, the lower liquid level always coincides with the lower end of the capillary, and the volume initially added to the instrument need not be precisely measured. This also eliminates the temperature correction for glass expansion necessary for Cannon–Fenske viscometers.

For accurate and precise measurement the glass capillary must be clean. The viscometer must be cleaned thoroughly after each series of operations. Samples being tested and cleaning solvents should be filtered to remove particles that can clog the capillary.

All glass capillary viscometers should be calibrated carefully (20). The standard method is to determine the efflux time of distilled water at 20°C. Unfortunately, because of its low viscosity, water can be used only to standardize small capillary instruments. However, a calibrated viscometer can be used to determine the viscosity of a higher viscosity liquid, such as a mineral oil. This oil can then be used to calibrate a viscometer with a larger capillary. Another method is to calibrate directly with two or more certified standard oils differing in viscosity by a factor of approximately 5. Such oils are useful for calibrating virtually all types of viscometers. Because viscosity is temperature-dependent, particularly in the case of standard oils, temperature control must be extremely good for accurate calibration.

In recent years several commercial capillary viscometers that allow automation have been developed. For example, the time of flow is measured by the interruption of a light beam focused on a photoelectric cell. Such a device can be attached to an existing viscometer to facilitate measurements and improve precision. Some completely automatic instruments control the temperature, fill the viscometer, take several readings (sometimes with dilutions), as well as clean, rinse, and dry the viscometer before the next filling. The instrument prints efflux times and in some cases can be programmed to print viscosities. Manufacturers of automated viscosity systems include Cannon, Schott, Design Scientific, and Lauda; Wescan supplies timer and photocell combinations. An inexpensive timer is based on light pipes and an electronic stopwatch (186). Cannon Instrument Co. supplies a wide range of glass capillary viscometers, temperature baths, viscosity standards, and related equipment.

Orifice viscometers, also called efflux or cup viscometers, are commonly used to measure and control flow properties in the manufacture, processing, and application of inks, paints, adhesives, and lubricating oils. Their design answered the need for simple, easy-to-operate viscometers in areas where precision and accuracy are not particularly important. In these situations knowledge of a true viscosity is unnecessary, and the efflux time of a fixed volume of liquid is a sufficient indication of the fluidity of the material. Examples of orifice viscometers include the Ford, Zahn, and Shell cups used for paints and inks and the Saybolt Universal and Furol instruments used for oils (Table 5).

Orifice viscometers usually have extremely short capillaries. The typical orifice viscometer is a cup with a hole in the bottom. The cup is filled, and the time required for the liquid to flow out is measured. The hydrostatic head decreases as the liquid flows, and there is a large kinetic energy effect. Flow analysis shows that the flow does not follow the Hagen–Poiseuille law, and efflux times are not related to viscosities in any simple manner. Therefore, it is better not to convert efflux times to viscosities except during calibration with standard oils. Efflux times should be accepted as arbitrary measures of viscosity and noted in terms of the viscometer being used, ie, Saybolt seconds, Ford seconds, etc. The precision of orifice viscometers is poor because of the lack of temperature control, wear during use, and variations in manufacture. However, they are widely used in industry because they are inexpensive, robust, and easy to use. Some of these instruments have the added convenience of being capable of dipping into or remaining in the material to be tested. Dip cups determine approximate or relative viscosities in resin reactors, ink reservoirs, paint dip tanks, adhesive mixing tanks, etc. These are applications where the limitations of orifice cups are unimportant.

Orifice viscometers should not be used for setting product specifications, for which better precision is required. Because they are designed for Newtonian and near-Newtonian fluids, they should not be used with thixotropic or highly shear-thinning materials; such fluids should be characterized by using multispeed rotational viscometers.

Some orifice viscometers, such as the Shell dip cup and the European ISO cup, which resembles a Ford cup with a capillary, have long capillaries. These cups need smaller kinetic energy corrections and give better precision than the corresponding short-capillary viscometers. However, they are still not precision instruments, and should be used only for control purposes.

If it is necessary to calculate kinematic viscosities from efflux times, such as in a calibration procedure, equation 20 should be used, where t is the efflux time and k and K are constants characteristic of the particular viscosity cup (see Table 5) (187–189,192).

$$\nu = kt - K/t \tag{20}$$

In most cases it is sufficient to be able to convert from one viscometer value to another or to approximate kinematic viscosities with the help of charts or tables; literature from manufacturers is useful.

Linear equations of the type $\nu = ct–C$, where c and C are constants, relate kinematic viscosity to efflux time over limited time ranges. This is based on the fact that, for many viscometers, portions of the viscosity–time curves can be taken

as straight lines over moderate time ranges. Linear equations, which are simpler to use in determining and applying correction factors after calibration, must be applied carefully as they do not represent the true viscosity–time relation. Linear equation constants have been given (187) and are used in ASTM D4212.

Pressure-driven piston cylinder capillary viscometers, ie, extrusion rheometers (Fig. 22), are used primarily to measure the melt viscosity of polymers and other viscous materials (20,51,53–55). A reservoir is connected to a capillary tube, and molten polymer or another material is extruded through the capillary by means of a piston to which a constant force is applied. Viscosity can be determined from the volumetric flow rate and the pressure drop along the capillary. The basic method and test conditions for a number of thermoplastics are described in ASTM D1238. Melt viscoelasticity can influence the results (190).

Polymer melts are frequently non-Newtonian. In this case the earlier expression given for the shear rate at the capillary wall does not hold. A correction factor $(3n + 1)/4n$, called the Rabinowitsch correction, must be applied in such a way that equation 21 applies, where $\dot{\gamma}_{\mathrm{tw}}$ is the true shear rate at the wall and n is a power law factor (eq. 22) determined from the slope of a log–log plot of the true shear stress at the wall, τ_{tw}, vs $\dot{\gamma}_{\mathrm{w}}$. For a Newtonian liquid, $n = 1$. A true apparent viscosity, η_{t}, can be calculated from equation 23.

$$\dot{\gamma}_{\mathrm{tw}} = \frac{(3n+1)\dot{\gamma}_{\mathrm{w}}}{4n} \tag{21}$$

$$n = \frac{\mathrm{d}\log \tau_{\mathrm{tw}}}{\mathrm{d}\log \dot{\gamma}_{\mathrm{w}}} \tag{22}$$

$$\eta_t = \frac{\tau_{\mathrm{tw}}}{\dot{\gamma}_{\mathrm{tw}}} \tag{23}$$

An even more important correction for polymer melts is that for end effects. Entrance and exit effects cause pressure drops that interfere with an accurate determination of the pressure gradient, $\Delta p/L$, needed for viscosity determination

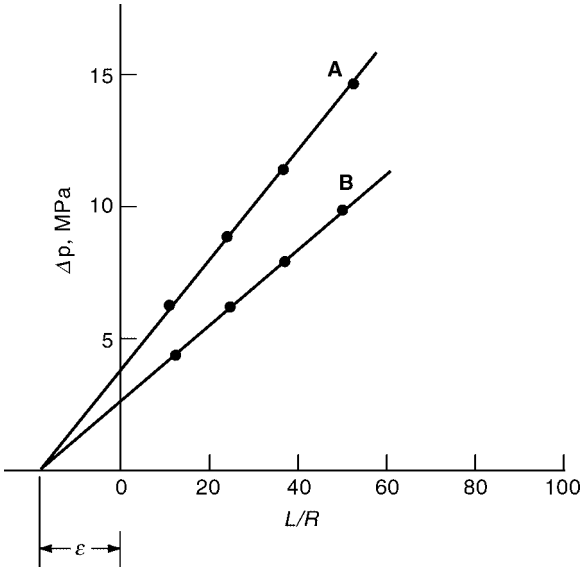

Fig. 23. Bagley plot of pressure, p, drop along a capillary versus capillary aspect ratio, L/R, at (**A**), $\dot{\gamma} = 590\ s^{-1}$ and (**B**), $\dot{\gamma} = 295\ s^{-1}$. To convert MPa to psi, multiply by 145.

using the Hagen–Poiseuille equation. It has been assumed (185) that the effective length of the capillary is greater than the actual length, and the shear stress at the wall has been corrected as equation 24, where R is the capillary radius, L is the actual length, and E is an empirical parameter obtained by extrapolating a plot of Δp versus the capillary aspect ratio, L/R, to zero pressure drop at constant shear rate, $\dot{\gamma}$, for capillaries of different length, as shown in Figure 23 (171).

$$\tau_w^c = \frac{R\Delta\,p}{2(L+ER)} \tag{24}$$

A number of instruments are based on the extrusion principle, including slit flow and normal capillary flow (Table 6). These instruments are useful when large numbers of quality control or other melt viscosity test measurements are needed for batches of a single material or similar materials. When melt viscosities of a wide range of materials must be measured, rotational viscometers are preferable. Extrusion rheometers have been applied to other materials with some success with adhesives and coatings (8,191).

Rotational Viscometers. Rotational viscometers consist of two basic parts separated by the fluid being tested (20,171,172,187,192–197). The parts may be concentric cylinders (cup and bob), plates, a low angle cone and a plate, or a disk, paddle, or rotor in a cylinder. Rotation of one part against the other produces a shearing action on the fluid. The torque required to produce a given angular velocity or the angular velocity resulting from a given torque is a measure of the viscosity. Rotational viscometers are more versatile than capillary viscometers. They can be used with a wide range of materials because opacity, settling, and non-Newtonian behavior do not cause difficulties. Viscosities over a range of

shear rates and as a function of time can be measured. Therefore, they are useful for characterizing shear thinning and time-dependent behavior.

Since the 1990s rotational viscometers have been developed that have integrated computers for operation and control of the instrument as well as for data collection, reduction, and storage. The combination of a computer, modern electronics, and feedback loops provides great flexibility and control. For example, pulses from the computer coupled with feedback from the viscometer can give precise oscillatory motion as well as shear viscosity measurement at constant stress or speed; only simple hardware is involved. Such instruments are useful for rheological measurements and studying the structure of dispersions and formulated products. These new instruments are versatile, easy to use, and allow the collection, analysis, and comparison of large amounts of data in a short time.

The mechanical parts of computer-controlled viscometers can be simple and should not become obsolete for many years. The complexity is in the software, and this is where changes will have to be made to keep the instrument up to date. Some manufacturers are offering new, updated software free for a period of several years after the instrument is purchased.

Rotational viscometers often were not considered for highly accurate measurements because of problems with gap and end effects. However, corrections can be made, and very accurate measurements are possible. Operating under steady-state conditions, they can closely approximate industrial process conditions such as stirring, dispersing, pumping, and metering. They are widely used for routine evaluations and quality control measurements. The commercial instruments are effective over a wide range of viscosities and shear rates (Table 7).

The equations and methods for determining viscosity vary greatly with the type of instrument, but in many cases calculations may be greatly simplified by calibration of the viscometer with a standard fluid, the viscosity of which is known for the conditions involved. General procedures for calibration measurement are given in ASTM D2196. The constant thus obtained is used with stress and shear rate terms to determine viscosity by equation 25, where the stress term may be torque, load, or deflection, and the shear rate may be in rpm, revolutions per second (rps), or s^{-1}.

$$\eta = K(\text{stress term}/\text{shear rate term}) \tag{25}$$

Constants and factors are often supplied by the manufacturer. Separate constants may be given for converting the stress and shear rate terms to the correct quantities and units.

A constant is often determined from measurements with a Newtonian oil, particularly when the calibrations are supplied by the manufacturer. This constant is valid only for Newtonian specimens; if used with non-Newtonian fluids, it gives a viscosity based on an inaccurate shear rate. However, for relative measurements this value can be useful. Employment of an instrument constant can save a great deal of time and effort and increase accuracy because end and edge effects, slippage, turbulent interferences, etc, are included.

The earliest and probably the most common type of rotational viscometer is the coaxial or concentric cylinder instrument. It consists of two cylinders, one within the other (cup and bob), keeping the specimen between them, as shown in Figure 24. The first practical rotational viscometer consisted of a rotating cup with an inner cylinder supported by a torsion wire. In variations of this design the inner cylinder rotates. Instruments of both types are useful for a variety of applications.

The relationship between viscosity, angular velocity, and torque for a Newtonian fluid in a concentric cylinder viscometer is given by the Margules equation (eq. 26) (20,172), where M is the torque on the inner cylinder, h the length of the inner cylinder, Ω the relative angular velocity of the cylinder in radians per second, R_i the radius of the inner cylinder wall, R_o the radius of the outer cylinder wall, and k an instrument constant.

$$\eta = \left(\frac{M}{\Omega 4\pi h}\right)\left(\frac{1}{R_i^2} - \frac{1}{R_o^2}\right) = \frac{kM}{\Omega} \tag{26}$$

Therefore, the viscosity can be determined from the torque and angular velocity. However, the viscosity is usually calculated from the shear rate and shear stress, which can be obtained from the Margules equation. The shear rate is given by equation 27, where r is any given radius.

$$\dot{\gamma} = \frac{(2\Omega/r^2)\left(R_i^2 R_o^2\right)}{R_o^2 - R_i^2} \tag{27}$$

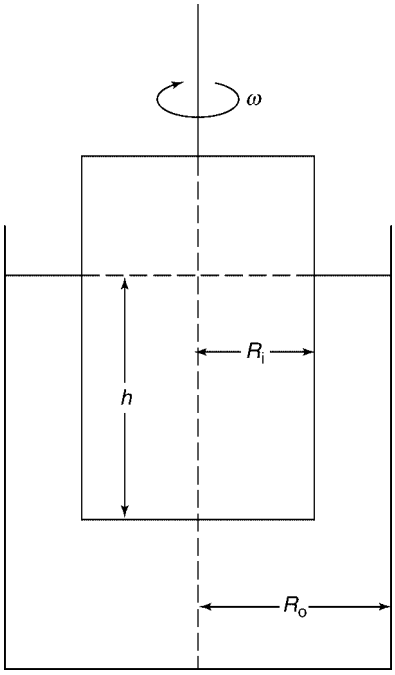

Fig. 24. Concentric cylinder viscometer. R_i and R_o are the radii of the inner and outer cylinder, respectively, and ω is the relative angular velocity.

The shear stress is given by equation 28:

$$\tau = \frac{M}{2\pi r^2 h} \tag{28}$$

The shear rate and shear stress can be calculated for any radius r from these equations. In most cases the radius used is R_i because the shear stress and shear rate of interest are at the inner, torque-sensing cylinder. Thus equations 27 and 28 become

$$\dot{\gamma} = \frac{2\Omega R_o^2}{R_o^2 - R_i^2} \text{ and } \tau = \frac{\mathrm{M}}{2\pi R_i^2 h}$$

The viscosity of a Newtonian fluid may be determined from the Margules equation or from the slope of a shear stress–shear rate plot. Non-Newtonian fluids give intercepts and curves with such plots. Viscosities can be calculated, but accurate values depend on including correction factors for yield points and shear thinning, ie, shear rate corrections, in the above equations (20). The shear rate correction may be minimized by using a very small gap size; in other words, the ratio of the inner to outer radius should be as close to unity as possible. In practical terms this means maintaining a ratio of 0.95, which is impossible with many sensors used with commercial rotational viscometers. With highly shear thinning materials even this is insufficient, and corrections must be made regardless of the

gap size. However, with viscosity–shear rate curves, although correction shifts each point by a rather large amount, the corrected curve itself is only slightly different from the uncorrected curve (198).

In addition to non-Newtonian flow, the main correction necessary for concentric cylinder measurements is that on account of end effects. Because the inner cylinder is not infinitely long, there is drag on the ends as well as on the face of the cylinder. The correction appears as an addition, h_0, to the length, h. The correction is best determined by measuring the angular velocity and torque at several values of h, that is, at various depths of immersion. The data are plotted as M/Ω vs h, and extrapolation is made to a value of h_0 at $M/\Omega = 0$. The quantity $(h + h_0)$ is substituted for h in the various equations.

In a cone–plate viscometer (Fig. 25), a low angle ($\leq 3^\circ$) cone rotates against a flat plate with the fluid sample between them. The cone–plate instrument is a simple, straightforward device that is easy to use and extremely easy to clean. It is well-suited to routine work because measurements are rapid and no tedious calculations are necessary. With careful calibration and good temperature control it can be a very effective research and problem-solving tool. Heated instruments can be used for melt viscosity measurements.

In most rotational viscometers the rate of shear varies with the distance from a wall or the axis of rotation. However, in a cone–plate viscometer the rate of shear across the conical gap is essentially constant because the linear velocity and the gap between the cone and the plate both increase with increasing distance from the axis. No tedious correction calculations are required for non-Newtonian fluids. The relevant equations for viscosity, shear stress, and shear rate at small angles α of Newtonian fluids are equations 29, 30, and 31, respectively, where M is the torque, R_c the radius of the cone, v the linear velocity, and r the distance from the axis.

$$\eta = \frac{3\alpha M}{2R_c^3} \tag{29}$$

$$\tau = \frac{3M}{2\pi R_c^3} \tag{30}$$

$$\dot{\gamma} = \frac{\mathrm{d}\,v}{\mathrm{d}\,r} = \frac{\Omega}{\alpha} \tag{31}$$

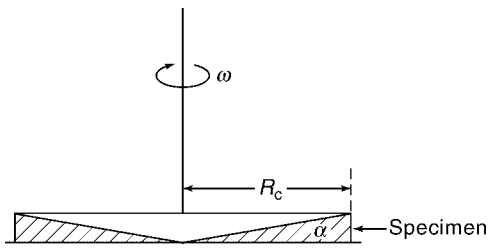

Fig. 25. Cone–plate viscometer. R_c is the radius of the cone, α is the angle between cone and plate, and ω is the relative angular velocity.

Cone–plate geometry has several advantages over concentric cylinder geometry, including a smaller sample size, a homogeneous shear rate, and easy conversion of data. Disadvantages include the need for precise adjustment of the gap (done automatically in many viscometers), including resetting when the temperature is changed, specimen drying, solvent evaporation, slinging of material from the gap, and the possibility of viscous heating, particularly at high shear rates. The last problem is compounded by the fact that temperature control with commercial instruments is not always as good as it should be.

In parallel plate viscometers (195) the gap width is usually larger and can be varied freely. This is an advantage when measuring suspensions or dispersions with large particles or with a tendency to fly out of the gap. The wide gap means that there is less sensitivity to temperature changes. Therefore, resetting is usually not necessary and temperature scans are much easier to run than with a cone–plate viscometer. However, with the plate–plate instrument, the velocity, and therefore the shear rate, varies with the distance from the center of the plate. This makes viscosity data more difficult to evaluate.

The maximum shear rate (at the plate rim) is given by equation 32, where R_p is the radius of the plate and h the distance between the two plates.

$$\dot{\gamma}_\mathrm{m} = \frac{\Omega R_\mathrm{p}}{h} \tag{32}$$

The viscosity is given by equation 33, where M is the torque.

$$\eta = \frac{3M}{2\pi R_p^3 \dot{\gamma}_\mathrm{m}} \left(1 + 3\frac{\mathrm{d}\ln M}{\mathrm{d}\ln\dot{\gamma}}\right) \tag{33}$$

A dynamic viscometer is a special type of rotational viscometer used for characterizing viscoelastic fluids. It measures elastic as well as viscous behavior by determining the response to both steady-state and oscillatory shear. The geometry may be cone–plate, parallel plates, or concentric cylinders; parallel plates have several advantages, as noted above.

Many rotational viscometers operate by controlling the rotational speed and, therefore, the shear rate. The shear stress varies uncontrollably as the viscosity changes. Often, before the structure is determined by viscosity measurement, it is destroyed by the shearing action. Yield behavior is difficult to measure. In addition, many flow processes, such as flow under gravity, settling, and film leveling, are stress-driven rather than rate-driven.

An instrument where the shear stress and rate of stress change, rather than the rotational speed, are controlled offers advantages. A few such instruments have existed for many years, eg, the Stormer; others have been developed more recently (199–205). A typical instrument consists of a drag cup motor, a frictionless air-bearing torque shaft, sensors for measuring angular deflection and velocity, and a rotating bob and fixed cup or parallel plates (201–204). The rotating shaft must be suspended in a frictionless manner to permit measurements at very low stresses.

Controlled stress viscometers are useful for determining the presence and the value of a yield stress. The structure can be established from creep measurements, and the elasticity from the amount of recovery after creep. The viscosity can be determined at very low shear rates, often in a Newtonian region. This zero-shear viscosity, η_0, is related directly to the molecular weight of polymer melts and concentrated polymer solutions.

Yield stresses are determined with the help of a vaned cylinder acting as sensor (206), which is attached to a stress rheometer (207). The sensor has four to eight thin blades centered around the cylindrical shaft. The instrument is immersed in the material, and a stress is applied. If the stress is below the yield stress, the material deforms elastically (small strain), but does not yield. When the applied stress exceeds the yield stress, the material flows and the sensor rotates continuously. Usually, a series of measurements are carried out at successively higher stresses, as shown in Figure 26 (207). The yield behavior is seen as a large strain over a short period of time. The torque for yielding is between the last nonyield torque value and the one that produced continuous rotation. Subsequent tests are performed with smaller torque increments to narrow the range for the yield stress. Details of the method and the equation relating yield stress to torque are available (207). Controlled stress techniques are used to determine yield stresses and other flow properties for polymer melts (59) as well as for solutions and dispersions.

Some rotational viscometers employ a disk as the inner member or bob, eg, the Brookfield and Mooney viscometers; others use paddles (a geometry of the Stormer). These nonstandard geometries are difficult to analyze, particularly for an infinite bath, as is usually employed with the Brookfield and the Stormer. The Brookfield disk has been analyzed for Newtonian and non-Newtonian fluids and shear rate corrections have been developed (21). Other nonstandard geometries are best handled by determining instrument constants by calibration with standard fluids.

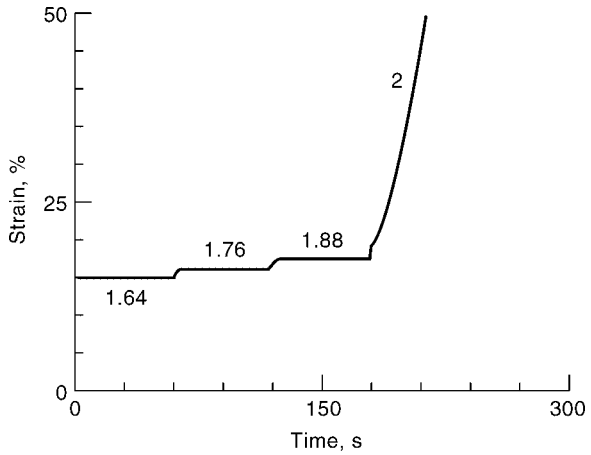

Fig. 26. Measurements of yield stress with a vane device and Rheometrics controlled stress rheometer. The torque required to cause yielding is between 1.88 and 2 mN·m as indicated on the curve. To convert mN·m to dyn·cm, multiply by 10^4. Courtesy of the Society of Rheology.

Information on selected commercial rotational viscometers can be found in Table 7. Pictures and more detailed descriptions are available on the relevant Web sites. Great changes have been made in commercial instruments, particularly in their integration with computers, but a recent paper may point to even greater changes in the future (208). Rheometers generally require actuators to stress specimens and sensors to record the response. However, sensors contribute considerably to the cost and complexity of instruments. A possible alternative to sensors is self-sensing, a technique that involves using knowledge of the actuator's behavior to estimate force or position. Torque or force is self-sensed in some commercial rheometers, but they still need position sensors to measure motion. Since it is possible to self-sense motion of electromagnetic actuators, it should be possible to construct a rheometer having no sensors. Such a rheometer could be small, simple, and inexpensive. To prove their point the authors built a rheometer that fit that description.

Moving Body Viscometers. In moving body viscometers, the motion of a ball, bubble, plate, needle, or rod through a material is monitored. A number of commercial moving body viscometers are listed in Table 8.

Falling ball viscometers are based on Stokes' law, which relates the viscosity of a Newtonian fluid to the velocity of the falling sphere. If a sphere is allowed to fall freely through a fluid, it accelerates until the viscous force is exactly the same as the gravitational force. The Stokes' equation relating viscosity to the fall of a solid body through a liquid may be written as equation 34, where r is the radius of the sphere; d_s and d_l are the density of the sphere and the liquid, respectively; g is the gravitational force; and v is the velocity of the sphere.

$$\eta = \frac{2r^2 g(\mathrm{d_s} - \mathrm{d_l})}{9v} \tag{34}$$

Viscometers of the falling ball type can be used over an extremely wide viscosity range, but are usually employed for fairly viscous materials because small balls and small differences in density are needed to obtain a suitably slow rate of fall in a low viscosity fluid. The devices are limited to measurements of Newtonian fluids because no practical formula has been developed for non-Newtonian materials. They had been considered as instruments for routine viscosity measurements rather than highly accurate work, but more recent designs (209–211) have changed this. The technique has proved to be useful in the study of suspensions, including those that are opaque and concentrated. The cylinder is jacketed for temperature control to within 0.1°C. Optical techniques are used for clear solutions and X-rays for opaque suspensions. A high speed video system is used for recording data.

The speed at which a sphere rolls down a cylindrical tube filled with a fluid or down an angled plate covered with a film of the fluid also gives a measure of viscosity. For the cylindrical tube geometry, equation 35 a generalized form of the Stokes' equation, is used for any given instrument, where v is the translational velocity of the rolling sphere and k is the instrument constant determined by calibration with standard fluids.

The technique of determining viscosity from the velocity of a rolling ball on an inclined plate or panel has been used largely for following the flow, drying, and curing of paints and other coatings (212–215), but can also be used for other materials. The system can be calibrated with standard oils or other fluids of known

viscosity. The geometry is ill-defined because the ball often slides and rolls, but the technique is useful. Rolling ball methods based on an inclined plane or an inclined path leading to a horizontal test specimen have been employed to determine the tack of pressure-sensitive adhesives (ASTM D3121) (216–218). The reciprocal of the distance rolled by the ball is considered to be proportional to the tackiness of the adhesive.

Under a broad definition of a moving body, certain other viscometers can be considered to be of this type, including the band, falling rod, falling needle, sliding plate, and bubble tube viscometers. The band viscometer includes an arrangement of parallel plates, the basic geometry used to define shear viscosity. The band, which is a strip of Mylar film, is sandwiched between two fixed plates. The fluid is placed between the band and the plates, and the band is pulled through the fluid. For a given gap and force on the band, the speed of the band is a measure of viscosity.

The falling rod viscometer, though similar to the band viscometer, is based on the movement of a rod rather than a plate through the fluid (219–222). It is a form of a falling coaxial cylinder viscometer. Initially, this device was used for semiempirical studies of materials such as bitumens and rosins. In the 1990s, the Laray falling rod viscometer became a standard test instrument in the ink industry (ASTM D4040), and more recent versions of the falling rod viscometer are capable of precise measurements of polymer melts and solutions (223). In the falling needle viscometer (224,225) (ASTM D5478), the moving body is a glass or stainless steel needle that falls vertically through the fluid. The viscous properties and density of the fluid are derived from the velocity of the needle.

The sliding plate rheometer has been in use for some time, but new types were developed in the 1990s (226–230). The well-defined simple shear deformation generated by this technique is useful for the characterization of polymer melts and concentrated solutions. Of particular interest is the fact that it can cause a high degree of molecular stretching. The sliding plate rheometer is useful for the characterization of polymer slip at solid boundaries and the determination of the effectiveness of processing aids (231,232).

Viscosity can also be determined from the rising rate of an air bubble through a liquid. This simple technique is widely used for routine viscosity measurements of Newtonian polymer solutions. A bubble tube vicometer consists of a glass tube of a certain size to which liquid is added until a small air space remains at the top. The tube is then capped. When it is inverted, the air bubble rises through the liquid. The rise time may be taken as a measure of viscosity or matched to that of a member of a series of standards (ASTM D1545).

Other Viscometers. A number of other viscometers are built for specific research or product applications. In one type of design, vibrational techniques are used to measure viscosity. The A&D Weighing SV-10 (233), the Automation Products Dynatrol (234), and the Nametre (235) are all based on this principle. The SV-10 and the Nametre measure viscosity by monitoring the power required to maintain torsional vibrations in their sensors, two small, thin circular plates for the SV-10 and a small stainless steel rod with a bulb at the end for the Nametre. The Dynatrol determines viscosity by measuring the amplitude of vibration of an immersed flexural member. Because the rate of shear is not easily determined or changed, these instruments are best used for controlling or studying

processes in which viscosity changes with time or temperature. In such cases they can be useful because wide ranges of viscosity can be measured without changing sensors (for example, 10^{-1}–10^{6} mPa·s for the Nametre). Special versions of the Dynatrol and Nametre devices are employed for in-line process control for many polymeric solution-based products because of their insensitivity to stirring and flow, wide viscosity ranges, simplicity of design, and ability to be controlled from and transmit data to a remote point.

The Vilastic VE system (236) is based on controlled oscillatory flow in a cylindrical tube. Measurements are performed using oscillatory flow generated at a selected frequency in a precision measurement tube. Viscosity, elasticity, and storage and loss moduli are calculated from data obtained from sensors that monitor the pressure drop across the tube and volume through the tube.

Extensional Viscosity Measurement Techniques

All three types of extensional viscosity can be measured (119,121): uniaxial, biaxial, and pure shear. Only a few commercial instruments are available, however, and most measurements are made with improvised equipment. Extensional viscosity of polymer melts can be estimated from converging flow (entrance pressure) or from a melt strength drawdown test (237) as well as measured with techniques described below.

Most uniaxial measurement techniques involve extending a strand or cylindrical rod of the material and measuring the force required. To measure fluids, the fluid is extruded from a spinnerette nozzle and allowed to fall under gravity. It is then extended by being rolled up on a rotating drum (119,127,238–241). The generated force is measured by the deflection of the nozzle or tube as the latter is pulled by the filament of fluid or at the take-up roller. This method has been the basis for home-built viscometers and a commercial instrument (238,241).

Another type of experiment involves a fluid filament being drawn upward against gravity from a reservoir of the fluid (119,242,243), a phenomenon often called the tubeless siphon. The maximum height of the siphon is a measure of the spinnability and extensional viscosity of the fluid. More quantitative measures of stress, strain, and strain rate can be determined from the pressure difference and filament diameter. A more recent technique involves monitoring the stretching of a fluid filament as it is extended (244–251). The basic design is called a filament stretching rheometer (FSR). With a commercial version, the CaBER (Capillary Breakup Extensional Rheometer (252), a specimen is placed between two parallel plates, and then the upper plate is raised to form a filament. A laser micrometer measures the midpoint diameter of the filament as it thins. The filament breakup time, deformation rate, and extensional viscosity can be calculated from the decrease in diameter with time. All of these methods are limited to spinnable fluids under small total strains and strain rates. High strain rates tend to break the column or filament.

There is another technique that can be used with low viscosity (100 mPa·s) nonspinnable fluids and which allows high strain rates ($>10^{3}$ s^{-1}). A modified opposing jets device (253) is employed that consists of opposing nozzles through which the fluid is sucked or blown out. Extensional viscosity is determined from

the force required to keep the nozzles at a fixed distance apart as a function of flow rate. A wide range of fluids can be investigated, and the high strain rates obtainable make it possible to study industrial processes and the effects of low concentrations of additives. A commercial instrument based on this device was on the market for a few years and has been used for some interesting research (254–258).

A sliding plate rheometer (simple shear) can be used to study the response of polymeric liquids to extension-like deformations involving larger strains and strain rates than can be employed in most uniaxial extensional measurements (68,226,230). The technique requires knowledge of both shear stress and the first normal stress difference, $N_1(\dot{\gamma})$, but has considerable potential for characterizing extensional behavior under conditions closely related to those in industrial processes.

Flow entering an orifice from a larger tube produces both shear and extensional deformation of the fluid (259). Although both shear and extensional effects are present, the pressure across the orifice is often dominated by extensional effects. This has been used as the basis for an extensional viscosity attachment for the Vilastic VE tube viscometer (236,260).

A method for measuring the uniaxial extensional viscosity of polymer solids and melts uses a tensile tester in a liquid oil bath to remove effects of gravity and provide temperature control; cylindrical rods are used as specimens (261,262). The rod extruder may be part of the apparatus and may be combined with a device for clamping the extruded material (263). However, most of the more recent versions use prepared rods, which are placed in the apparatus and heated to soften or melt the polymer (121,129,264–266). A constant stress or a constant strain rate is applied, and the resultant extensional strain rate or stress, respectively, is measured. Similar techniques are used to study biaxial extension (119).

In another elongational rheometer (264), the specimen is suspended on the end of a flexible tape, which is wound onto a wheel turned by a servo-controlled torque motor. This design is the basis for the Göttfert Rheostrain instrument. One device for melts and solids is an add-on fixture for rotational rheometers. The SER testing platform (267) incorporates dual wind-up drums and can be used for tensile, tear, peel, and friction testing as well as for elongational viscosity measurements.

The Rheometric Melt Elongational Rheometer (RME) (Fig. 27) is designed for high elongations of polymer melts (268–270). It uses a small ($\sim$1 g) compression-molded specimen which it supports on a stream of inert gas and holds in place with a rotary clamping device. The specimen is heated to the test temperature (up to 350°C) by electric heaters and extended by the motion of metal belts. Three sets of belts are available to provide different ranges of extensional strain rates: 10^{-3}–10^{-1} s^{-1}, $3 \times 10^{-3} - 3 \times 10^{-1}$ s^{-1}, and $10^{-2} - 1$ s^{-1}. The force generated by the specimen is measured by a spring-type transducer.

An FSR similar to those becoming popular for measuring the extensional viscosity of fluids has been constructed and applied to polymer melts (271). The FSR results were compared to those obtained from RMEs and agreement was good. Advantages of the FSR include the ability to make measurements on less viscous fluids than with the RME and the use of a smaller size specimen. In addition, the FSR measures all parameters online and very little post-processing of data is

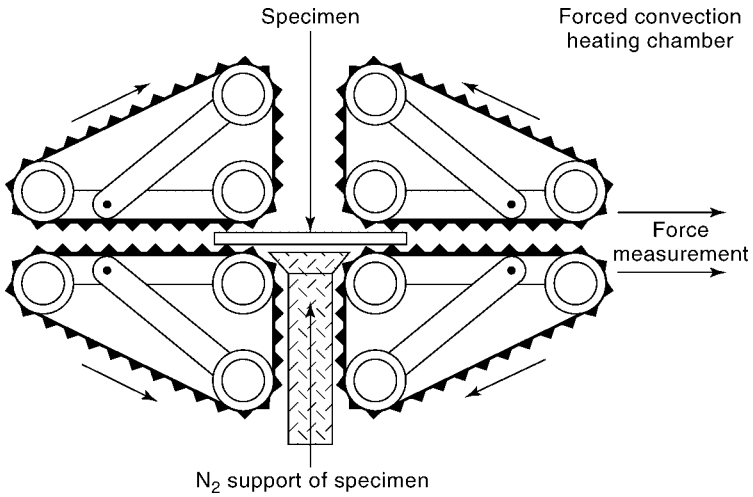

Fig. 27. Diagram of the Rheometric Melt Elongational Rheometer for elongational viscosity measurements on polymer melts. Courtesy of Rheometric Scientific.

necessary. In the RME, a measure of strain during an experiment usually requires observation from a videotape or similar (270).

Biaxial extensional viscosity can be measured by several methods. The most common is bubble inflation, in which a thin polymer sheet is inflated with an inert gas or liquid (272–274). Another method involves stretching a polymer sheet using eight rotating clamps placed in an octagonal pattern (275). A complex servo control system is required to coordinate the motion of the clamps. In a newer technique, displacement is measured as the material is squeezed between two disks having lubricated surfaces (lubricated squeezing flow) (276–285). A commercial instrument based on this technique, the MARS-III Multifunction Axial Rheometer System, has been developed (280). The specimen is a disk 1–4 cm in diameter and 1–2 cm in thickness. A variety of deformation modes that emulate industrial processes are provided: deformation under constant load, constant strain rate, or constant velocity, or in a step mode for stress relaxation. After deformation the specimen can be monitored for elastic recovery. The temperature ranges are 20–250°C in oil and 20–400°C in air. The viscosity range is $10^4 - 10^{10}$ Pa·s, with strain rates of $2 \times 10^{-5} - 20\ s^{-1}$. The instrument is computer controlled and data collection is as automatic as the operator wishes.

Extensional viscosity that results purely from shear deformation seems to be of less interest, but has been measured (126). The rheology of several different polymer melts in terms of shear viscosity and uniaxial and biaxial extensional viscosity has been compared (279). Additional information on the measurement of extensional viscosity is also available (123,286–289).

Viscoelastic Measurement. A number of methods measure the various quantities that describe viscoelastic behavior. Some require expensive commercial rheometers, others depend on custom-made research instruments, and a few require only simple devices. Even qualitative observations can be useful in the case of polymer melts, paints, and resins, where elasticity may indicate an inferior batch

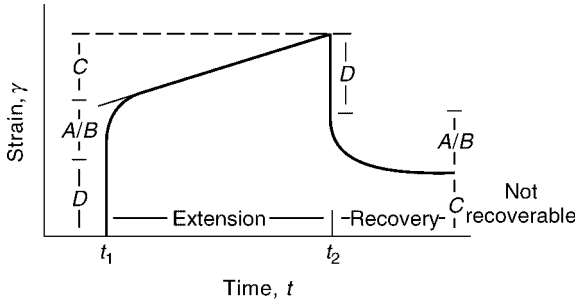

Fig. 28. Typical creep curve for a viscoelastic material. Stress applied at time t_1 and removed at t_2.

or unusable formulation. For example, the extrusion swell of a material from a syringe can be observed with a microscope. The Weissenberg effect is seen in the separation of a cone and plate during viscosity measurements or the climbing of a resin up the stirrer shaft during polymerization or mixing.

Creep experiments are among the simplest for describing viscoelastic behavior. They involve the measurement of deformation as a function of time after a given load has been applied. Such measurements may be made on specimens in tension, compression, or shear. Many more sophisticated devices exist, including tensile testers. The data are usually presented in the form of a strain–time curve (Figs. 14 and 28). Most materials undergo initial elastic deformation followed by a slow increase in strain with time. After the stress is removed, elastic deformation is recovered, but viscous deformation is not. Creep measurements are useful for evaluating the behavior of structural materials, fasteners, gaskets, pipe, and other articles that are subject to loading while in use. Creep measurements can also be carried out on fluids and are useful for measuring low shear viscosity and elasticity and for estimating and comparing structures, particularly in dispersions such as paints and inks.

Figure 28 is representative of creep and recovery curves for viscoelastic fluids. Such a curve is obtained when a stress is placed on the specimen and the deformation is monitored as a function of time. During the experiment the stress is removed, and the specimen, if it can, is free to recover. The slope of the linear portion of the creep curve gives the shear rate, and the viscosity is the applied stress divided by the slope. A steep slope indicates a low viscosity, and a gradual slope a high viscosity. The recovery part of Figure 28 shows that the specimen was viscoelastic because relaxation took place and some of the strain was recovered. A purely viscous material would not have shown any recovery, as shown in Figure 14**b**.

In a stress–relaxation test the deformation is held constant, and the resulting stress is measured as a function of time. Deformation produces an initial stress that decays with time in the case of viscoelastic materials. In an experiment the sample is rapidly deformed, and the resulting force measured as a function of time. The data may be plotted as stress, stress/initial stress, or modulus. A stress–relaxation curve for a lightly cross-linked rubber is shown in Figure 29 (290).

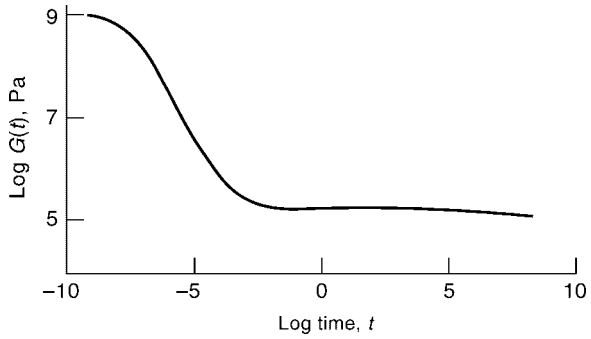

Fig. 29. Stress–relaxation curve for a lightly vulcanized rubber (290). To convert Pa to dyn/cm^2, multiply by 10.

The stress–relaxation process is governed by a number of different molecular motions. To resolve them, the thermally stimulated creep (TSCr) method was developed, which consists of the following steps:

(1) The specimen is subjected to a given stress at a temperature T for a time t, both chosen to allow complete orientation of the mobile units that one wishes to consider.
(2) The temperature is then lowered to $T_0 \ll T$, where any molecular motion is completely hindered; then the stress is removed.
(3) The specimen is subsequently heated at a controlled rate. The mobile units reorient according to the available relaxation modes. The strain, its time derivative, and the temperature are recorded versus time. By running a series of experiments at different orientation temperatures and plotting the time derivative of the strain rate observed on heating versus the temperature, various relaxational processes are revealed as peaks (291).

In a similar fashion, thermally stimulated current spectrometry (TSC) makes use of an applied d-c potential that acts as the stress to orient dipoles. The temperature is then lowered to trap these dipoles, and small electrical currents are measured during heating as the dipoles relax. The resulting relaxation maps have been related to G' and G' curves obtained by dynamic mechanical analysis (292–294). This technique, long carried out only in laboratory-built instruments, is available as a commercial TSC spectrometer from Thermold Partners LP, formerly Solomat Instruments (295).

Penetration and indentation tests have long been used to characterize viscoelastic materials such as asphalt, rubber, plastics, and coatings. The basic test consists of pressing an indentor of prescribed geometry against the test surface. Most instruments have an indenting tip, eg, cone, needle, or hemisphere, attached to a short rod that is held vertically. The load is controlled at some constant value, and the time of indentation is specified; the size or depth of the indentation is measured. Most instruments make use of a probe geometry which gives an increasing area of contact as penetration proceeds. In this way, at some depth of penetration, the resisting force can become sufficient to balance the applied force on the

indentor. Unfortunately, many geometries, eg, diamonds, pyramids, and cones, do not permit the calculation of basic viscoelastic quantities from the results. Penetrometers of this type include the Pfund, Rockwell, Tukon, and Buchholz testers, used to measure indentation hardness which is dependent on modulus.

The Rheo-Tex rheometer is an inexpensive, automated instrument using load cell technology to measure indentation and creep. Available software calculates hardness/softness, brittleness, plasticity, and tensile strength. This instrument is particularly valuable for measurements on foods and personal care products.

Other penetrometer–indentometers include transducers to sense the position and movement of the probe and microprocessors for temperature control and data collection and reduction. These instruments are used mainly to measure softening points, which are not glass transitions but are usually close to those values. Because a softening point is indicative of behavior under load, it is often more useful for predicting performance than the T_g. Penetrometer–indentometers can also be used to measure indentation hardness, creep, creep recovery, and modulus. Examples of such instruments include the TA Instruments, Mettler, Perkin-Elmer, Seiko, and Shimadzu thermomechanical analyzers (TMAs). They can be used to generate modulus and modulus–temperature data from indentation–time plots by applying the Hertz equation (eq. 36) (170,296), where E is the elastic or Young's modulus, μ the Poisson's ratio, r the radius of the hemispherical indentor, P the force on the indentor (mass load $\times$ g), h the indentation, and H_k the indentation hardness.

$$\frac{E}{1-\mu^2} = \frac{3}{4r^{1/2}} \frac{P}{h^{3/2}} = H_k \tag{36}$$

Because the indentation varies with time, the modulus must be specified for a certain indentation time, eg, a 10-s modulus. The Hertz equation holds only for purely elastic materials. However, it has been applied to viscoelastic materials, including polymers and coatings, with excellent results (296–303). Indentation hardness vs temperature curves are shown in Figure 30 (296–298).

A fully automated microscale indentor known as the Nano Indentor is available from Nano Instruments (304–306). Used with the Berkovich diamond indentor, this system has load and displacement resolutions of 0.3 N and 0.16 nm, respectively. Multiple indentations can be made on one specimen with spatial accuracy of better than $\pm$200 nm using a computer-controlled sample manipulation table. This allows spatial mapping of mechanical properties. Hardness and elastic modulus are typically measured (306,307) but time-dependent phenomena such as creep and adhesive strength can also be monitored.

Indentation is not usually thought of as a method for measuring viscoelastic properties, but the technique can be useful particularly for measurements of coatings on rigid substrates. Modern instrumentation, as described above, allows for precise, computer-controlled loading and unloading of force. The Mettler TMA, Perkin-Elmer's DMA, and the Nano Indentor have modes by which periodic and very short indentation creep measurements can be made while the specimen is being heated, thereby allowing estimates of the changes in modulus with temperature. A more quantitative technique is called modulus profiling, which uses a modified TMA instrument to measure tensile compliance, a measurement closely

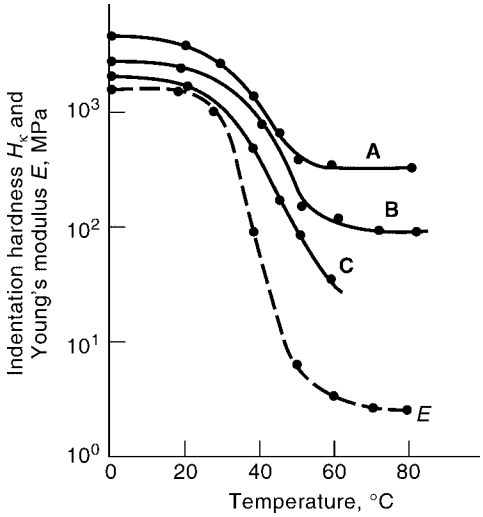

Fig. 30. Indentation hardness H_k at (**A**) 19 μm; (**B**) 47 μm; and (**C**) 108 μm thickness, and Young's modulus, E, of a free film (as functions of temperature) of an acrylic coating (296). These results show the dependence of thickness that occurs with thin films. To convert MPa to psi, multiply by 145. Courtesy of *Farbe & Lack*.

related to the inverse of the tensile modulus (308). The instrument can be used to profile or map tensile properties of a polymer specimen to show spatial variations resulting from processing inhomogeneities or aging phenomena such as oxidation.

The most widely used instrument for measuring the viscoelastic properties of solids is the tensile tester or stress–strain instrument, which extends a sample at constant rate and records the stress. Creep and stress–relaxation can also be measured. Numerous commercial instruments of various sizes and capacities are available. They vary greatly in terms of automation, from manually operated to completely computer controlled. Some have temperature chambers, which allow measurements over a range of temperatures. Manufacturers include Applied Test Systems, Benz, Com-Ten Industries, Custom Scientific, Detroit Testing Machine, Dillon Force Measuremet, Dynatek, GRC Instruments, Instron, MTS, Monsanto,, SATEC Systems, Inc., Shimadzu, Thwing-Albert, and Tinius Olsen.

A typical stress–strain curve generated by a tensile tester is shown in Figure 31. Creep and stress–relaxation results are essentially the same as those described above. Regarding stress–strain diagrams and from the standpoint of measuring viscoelastic properties, the early part of the curve, ie, the region of small deformations, is usually of the most interest. At small strains, stress is proportional to strain; therefore, the modulus is constant. At higher stresses and corresponding strains, a point is reached where the modulus depends on strain. Eventually, irreversible changes take place, resulting in rupture. These forms of behavior are shown in Figure 31. The linear relationship between stress and strain is shown in the region between the start of the experiment and point A. The latter is the yield point common to many materials, in which the specimen yields with no increase or with a decrease in stress. At higher levels the sample breaks at break point B. The tensile strength b and elongation at break d are important

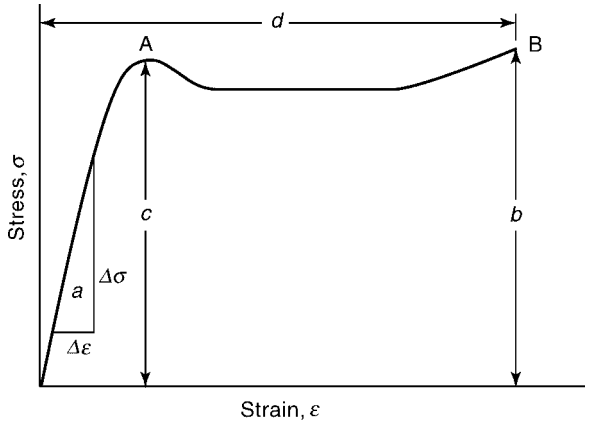

Fig. 31. Typical stress–strain curve. Point A is the yield point of the material; the sample breaks at point B. Mechanical properties are identified as follows: $a = \Delta\sigma/\Delta\varepsilon$, modulus; $b =$ tensile strength; $c =$ yield strength; $d =$ elongation at break. The toughness or work to break is the area under the curve.

mechanical properties, used to characterize plastics, paint films, and many other materials. For more information on tensile testing, consult ASTM methods D2370, D638M, and D882 as well as more recent literature (309–313).

Measurement of the propagation of ultrasonic acoustic waves has been found useful for determining the viscoelastic properties of thin films of adhesives. In this method, the specimen is clamped between transmitting and receiving transducers. The change in pulse shape between successive reverberation of the pulse is dependent on the viscoelastic properties of the transmitting material. Modulus values can be calculated (314,315).

Dynamic Measurements. Dynamic methods are required for investigating the response of a material to rapid processes, studying fluids, or examining a solid as it passes through a transition region. Such techniques impart cyclic motion to a specimen and measure the resultant response. Dynamic techniques are used to determine storage and loss moduli, G' and G', respectively, and the loss tangent, tan δ. In addition, the frequency dependence of these moduli can provide insight into polymer architecture (316,317). Some instruments are sensitive enough for the study of liquids and can be used to measure the dynamic viscosity η'. Measurements are made as a function of temperature, time, or frequency, and results can be used to determine transitions and chemical reactions as well as the properties noted above. Dynamic mechanical techniques for solids can be grouped into free vibrations and forced vibrations. Dynamic techniques have been described in detail (290,298,302,313,318–328). A number of instruments are listed in Table 9. Related ASTM standards are listed in Table 10.

Free-vibration instruments subject a specimen to a displacement and allow it to vibrate freely. The oscillations are monitored for frequency and damping characteristics as they disappear. The displacement is repeated again and again as the specimen is heated or cooled. The results are used to calculate storage and loss modulus data. The torsional pendulum and torsional braid analyzer (TBA) are examples of free-vibration instruments.

D6382-99	Standard Practice for Dynamic Mechanical Analysis and Thermogravimetry of Roofing and Waterproofing Membrane Material

The torsional pendulum is a simple apparatus for making dynamic tests in the frequency range of 0.1–10 Hz. The specimen is rigidly clamped at its lower end, and the upper end is clamped to an inertia bar or disk that is free to rotate. The suspension wire supporting the system is passed over a pulley, and the weight is counterbalanced to prevent tensile stresses on the specimen. The experiment is begun by setting the inertia member into free oscillation, and the natural frequency and decay of these oscillations are measured. The storage modulus, G', is calculated from the square of the frequency, and the loss tangent, tan δ, from the logarithmic decrement of the sample. The logarithmic decrement is the natural logarithm of the ratio of two successive amplitudes.

A TBA is a torsional pendulum with which a composite specimen instead of a free film is used (318,322,323). The specimen is prepared by soaking a multifilamented glass braid in a polymer solution and, after mounting the specimen in the apparatus, removing the solvent by heating. Measurements are similar to those with the torsional pendulum. Rigidity and damping values are calculated. The former is proportional to G'; the latter, to tan δ.

With both instruments, data can be plotted as a function of time or temperature to give dynamic mechanical spectra. An example is shown in Figure 32, where rigidity and damping from TBA experiments are shown as functions of temperature for a styrene–butadiene–styrene radial block copolymer (329). Such spectra are particularly useful for the study of polymers, including the identification of physical transitions and the onset and kinetics of cross-linking (323,330) or embrittlement (329), as well as for measuring various viscoelastic parameters. The

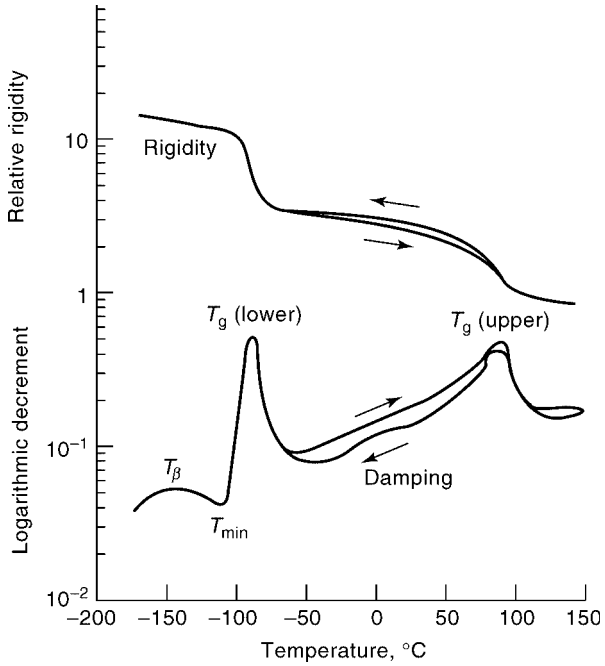

Fig. 32. Thermal mechanical behavior of a styrene–butadiene–styrene block copolymer in nitrogen at −180 to 150°C (329). Courtesy of the Federation of Societies for Coatings Technology.

curves in Figure 32 show that the material has two glass-transition temperatures, each indicated by a downturn in the rigidity curve and a damping peak. The material is glassy (high modulus) below the lower T_g, rubbery or leathery (moderate modulus) between the two transitions, and almost fluid (low modulus) above the upper T_g. Knowledge of such characteristics is important for predicting behavior under processing or use conditions.

Forced-vibration instruments drive specimens at specific frequencies and determine the response, usually over a range of temperatures. Storage and loss moduli or related parameters are determined. Series of modulus–temperature curves can be generated by making measurements at several different frequencies. Because thermal and mechanical transitions are functions of frequency as well as temperature, data from such curves can be used to calculate activation energies of transitions. In addition, frequencies can be chosen to represent or approximate polymer processing effects and use conditions.

Probably the most common modes of operation are the double cantilever and the tensile mode. In double cantilever, the specimen is held at its ends and driven by a vibrating drive shaft which is clamped to the center of the specimen. In tensile mode the specimen is also clamped at both ends but is driven along the axis between the clamps as one of them is part of the vibrating shaft. With most instruments, several frequencies can be monitored at the same time, as shown in the modulus and tan δ plots of Figure 33. A typical modulus range is $10^3 - 10^{11}$ N/m^2 ($10^4 - 10^{12}$ dyn/cm^2).

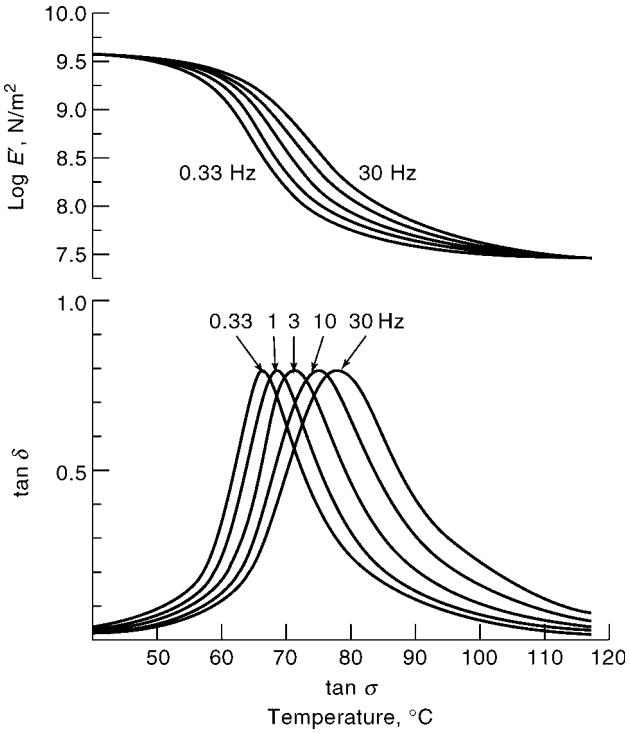

Fig. 33. Multifrequency modulus and tan δ vs temperature plots. To convert N/m^2 to psi, multiply by 1.45×10^4.

Fluids. The methods described above were designed for solid specimens, although some can be used for fluids if a solid support or carrier is used. The fluid must be highly viscoelastic for data to register, and absolute modulus values are difficult to determine because of the presence of the support. Different instrumentation is needed for the determination of meaningful modulus values over wide viscosity and elasticity ranges. Viscoelastic fluids can be characterized with a number of the rotational viscometers described previously. However, instead of constant rotational motion in one direction, a sinusoidal oscillatory motion must be used. Some oscillatory instruments can act as both dynamic viscometers and dynamic mechanical testing devices. They are capable of making measurements on solids, melts, and relatively concentrated solutions and dispersions. Viscoelasticity can also be determined by a controlled stress rheometer. The shape of a creep curve can show that a fluid is viscoelastic, and the amount of recovery after the stress is removed gives a measure of elasticity.

Time–Temperature Superposition and Master Curves. Because the modulus of a viscoelastic material varies with time and temperature, measurements must be made over wide ranges of these variables for full characterization. This is often impossible, particularly for very long and very short times. Even if it were possible, the amount of experimental work involved would be prohibitive. Therefore, techniques have been developed to determine modulus values

and curves at times or temperatures not attainable experimentally. A series of stress–relaxation, indentation, or modulus curves measured at different temperatures can be shifted on a log time axis to give a single modulus time master curve that covers a wide time range. A creep–compliance–time master curve can be constructed in the same fashion, as can a similar curve by using the families of modulus curves at different frequencies, such as those in Figure 33, generated by dynamic mechanical instruments with multiplexing capabilities. These curves can be shifted to a single modulus–frequency master curve because time and temperature have equivalent effects on modulus and other viscoelastic quantities (171,319,320,325–328).

The shift factor required to superimpose a set of data for an amorphous polymer is described mathematically by the WLF equation (eq. 8) (22), which becomes

$$\log a_T = \frac{-17.4(T - T_g)}{51.6 + (T - T_g)}$$

where a_T is the shift factor, the amount of horizontal shift of the timescale. Figure 34 shows the preparation of a modulus master curve from experimentally measured stress–relaxation curves at various temperatures (331).

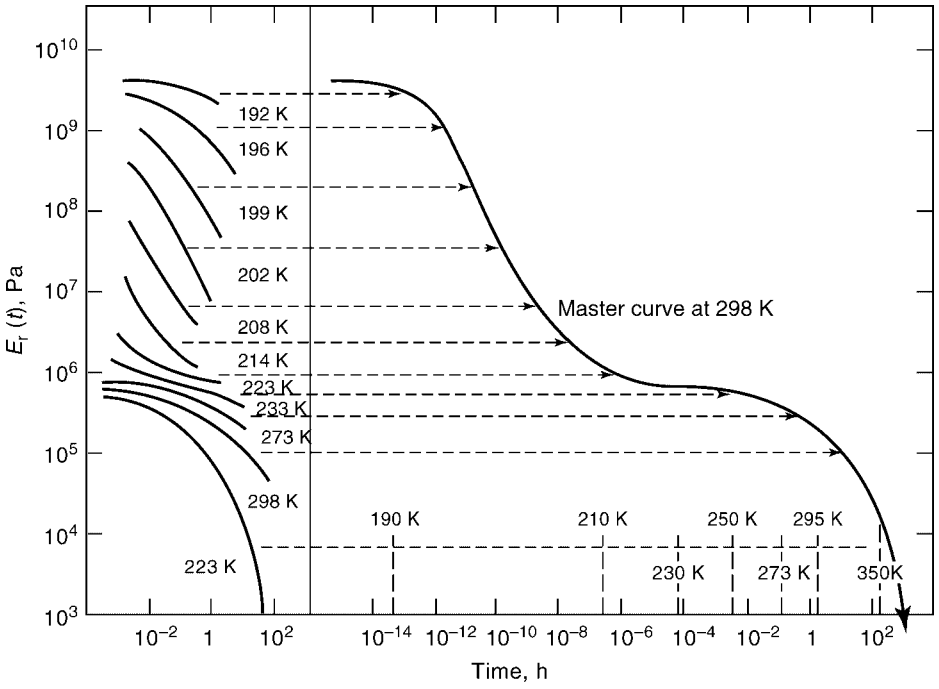

Fig. 34. Illustration of the time–temperature superposition principle as based on stress–relaxation data for polyisobutylene (331,332). To convert Pa to dyn/cm^2, multiply by 10. Courtesy of International Textbook Co., Ltd.

Master curves can also be constructed for crystalline polymers, but the shift factor is usually not the same as the one calculated from the WLF equation. An additional vertical shift factor is usually required. This factor is a function of temperature, partly because the modulus changes as the degree of crystallinity changes with temperature. Because crystallinity is dependent on aging and thermal history, vertical factors and crystalline polymer master curves tend to have poor reproducibility.

Master curves can be used to predict creep resistance, embrittlement, and other property changes over time at a given temperature, or the time it takes for the modulus or some other parameter to reach a critical value. For example, a rubber hose may burst or crack if its modulus exceeds a certain level, or an elastomeric mount may fail if creep is excessive. The time it takes to reach the critical value at a given temperature can be deduced from the master curve. Frequency-based master curves can be used to predict impact behavior or the damping ability of materials being considered for sound or vibration deadening. The theory, construction, and use of master curves have been discussed (171,290,320,326,327,331,332).

There also is interest in applying the principle of superposition to and developing master curves for polymer solutions. A recent paper (333) describes success in doing so. Measurements of shear viscosity, viscoelasticity, and extensional viscosity were carried out on solutions of polyisobutylene in a solvent consisting of a mixture of polybutene oil and dekalin. Eight solutions were tested, ranging in concentration from 0 to 2.5%. The results showed that both time–temperature and time–concentration superposition held for shear flows. By means of time–concentration superposition, a single master curve could be generated from the various flow curves. A single master curve was not possible for extension dominated flows. Instead, three curves were found, one for each of three concentration regimes, 0–0.1%, 0.25–1.5%, and 2.5%.

Practical Rheology

A common problem in rheology is that technologists in charge of research and development, quality control, and problem-solving are rarely trained in rheology, and rheologists are rarely trained in the technology of the product or process. The technologist may use flow to describe effects that are not connected with rheology in the way that a trained rheologist would interpret them. For example, a paint technologist may describe a paint as having poor flow, meaning that the surface has imperfections or defects. However, the same sample may flow easily in a rheological sense during application and cure. The solution of the problem may not involve a change in viscosity, and a small amount of a surfactant may improve the surface appearance of the paint film.

A good working rule in the correlation of viscosity measurements with processing conditions is to select and compare viscosities of materials at the shear rate that corresponds to the process in question. However, problems are encountered with high shear processes. For example, a viscometer with a sufficiently high shear rate may not be available. High shear rates can give heating effects, slip, and erroneous viscosity values. These difficulties can be solved by careful

extrapolation from lower shear measurements; Casson plots and other viscosity models can be useful.

Often, a simple ordering of good and poor materials can provide insight into the desired range of viscosity required for satisfactory processing. This strategy assumes that the viscosity of the material is the significant controlling parameter in the process, an assumption that should always be tested. Often, other factors have an equal or even greater influence on the system. For example, in the case of thin films and surfaces, the surface tension and physics of wetting can play a role equal to that of viscosity.

Few processes involve a single shear rate or set of mechanical conditions. Typical processes involve low, intermediate, and high shear regions or sections or stages. For example, a paint or coating may be pumped (intermediate shear rate), be sprayed (high shear rate), coalesce, and flow to form a uniform film (intermediate to low shear rate) and sag or run under gravity (low shear rate) during application. Thus a complete rheological evaluation of a material to determine its processing characteristics requires consideration of the viscosity of the material over an extended shear rate range. A given material may process well at low or intermediate shear rates, but fail completely at higher shear rates.

Additional complications can occur if the mode of deformation of the material in the process differs from that of the measurement method. Most fluid rheology measurements are made under shear. If the material is extended, broken into droplets, or drawn into filaments, the extensional viscosity may be a more appropriate quantity for correlation with performance. This is the case in the parting nip of a roller in which filamenting paint can cause roller spatter if the extensional viscosity exceeds certain limits (127). In many cases shear stress is the key factor rather than shear rate, and controlled stress measurements are necessary.

These examples indicate that the correlation of rheological measurements with product and process performance requires study, knowledge, and hard work (3,8,103,172,187,193,194,334). Extensive applications of rheological measurements have been made to food products (19,103,282,284,335–340), lubricants (341–344), adhesives (216–218,345–349), paints (8,17,21,42–45,127,128, 179,188–190,195,214,215,324,350–359), printing inks (1,190,219,222,360–362), rubber (334,363–366), polymers and plastics (47,171,226–232,289,314–323,325–328,367–370), sealants (371), foams (372–376), slurry fuels (377) and other slurries (378,379), cosmetics (103,380), concentrated suspensions (381–389), crude oil (390,391), and powders and granular material (392–395). Careful rheological measurements and a thorough knowledge of the literature should enable the investigator to meet most rheological challenges.

RING OPENING POLYMERIZATION

Introduction

Poly(ε-caprolactone) and polylactides are synthetic polymers with quite unusual properties of biodegradability and biocompatibility. They have thus great potential as biomaterials and environmentally friendly thermoplastics. This explains why attention was paid quite early to the macromolecular engineering of these aliphatic polyesters (1). For this purpose, living, or at least controlled, polymerization is a prerequisite, which nowadays is met whenever the ring opening polymerization (ROP) of lactones, lactides, and glycolide (Fig. 1) proceeds through a coordination–insertion mechanism. Then, aliphatic polyesters can be prepared with a predictable degree of polymerization, a narrow molecular weight

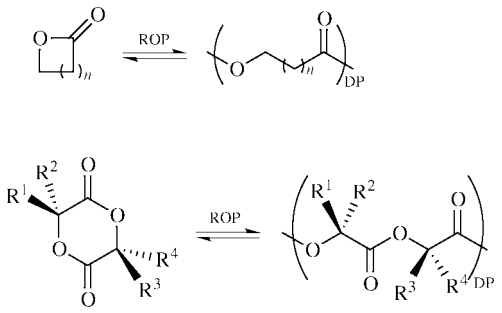

Fig. 1. Ring opening polymerization of unsubstituted lactones, lactides, and glycolide. $n = 1$: β-propionolactone (β-PL); $n = 2$: γ-butyrolactone (γ-BL); $n = 3$: δ-valerolactone (δ-VL); $n = 4$: ε-caprolactone (ε-CL); DP = degree of polymerization. $R^1 = R^2 = R^3 = R^4 = H$: glycolide; $R^1 = R^4 = CH_3$ and $R^2 = R^3 = H$: L-lactide (L-LA); $R^1 = R^4 = H$ and $R^2 = R^3 = CH_3$: D-lactide (D-LA); $R^1 = R^3 = CH_3$ and $R^2 = R^4 = H$: *meso*-lactide (*meso*-LA); D-LA/L-LA = 50/50: *racemic*-lactide (D,L-LA).

distribution, and well-defined end groups at one or both ends. Synthesis of block and graft copolymers of lactones and lactides has also been reported. In all these instances, lactones of different ring sizes, substituted or not by functional groups, have been involved (2).

The first reports on ROP mainly dealt with anionic and cationic polymerization of lactones, with formation of aliphatic polyesters of low molecular weight as a result of detrimental side reactions. Indeed, anionic propagating species are known for their propensity for transesterification reactions (Fig. 2). Whenever intramolecular, these reactions decrease the molecular weight and form low molecular weight cyclics. Intermolecular reactions are responsible for a Poisson distribution of the chain length. Moreover, the basicity of anionic species can account for proton transfer reactions, such as epimerization of the chiral center of poly(LA) units. A first strategy proposed to suppress, or at least reduce, the extent of the side reactions is the use of bulky ligands able to protect the ester groups in the chains against nucleophilic attack by the propagating species. For example, Lin and co-workers reported on the controlled ROP of L-LA by a mixed-ligand lithium aggregate prepared by reaction of 2,2′-ethylidene-bis(4,6-di-*tert*-butylphenol) and *n*-butyl lithium. The lithium alkoxide which is formed

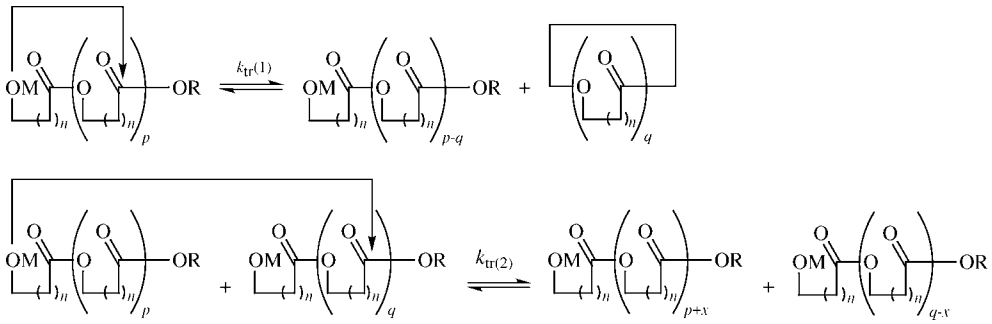

Fig. 2. Intramolecular and intermolecular transesterification reactions.

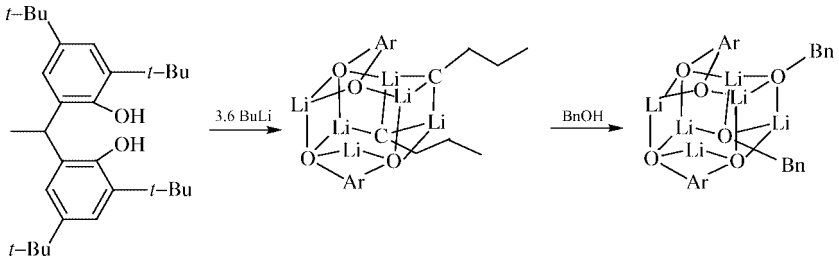

Fig. 3. Synthesis of mixed lithium–ligand aggregate, for the controlled ROP of L-LA.

further reacts with benzyl alcohol (Fig. 3) (3). Polydispersity of poly(L-LA) is then low (∼1.1) and M_n is predetermined by the monomer/initiator molar ratio. Nevertheless, the more general and powerful strategy consists in using active species of lower basicity and nucleophilicity, ie, organometallics derived from metals with d orbitals of favorable energy such as Al, Sn, Y, Nd, Yb, Sm, La, Fe, Zn, Zr, Ti, and Mg. Kricheldorf and co-workers studied the kinetics of the intramolecular transesterification reactions when poly(ε-CL) is exposed to a series of metal alkoxides. $(C_4H_9)_3SnOR$ and $(C_4H_9)_2Sn(OCH_3)_2$ turned out to be very active transesterification reagents. In contrast, no cyclic was formed at 150°C within 4 days, when $Al(O\text{-}i\text{-}C_3H_7)_3$ was the initiator (4). An intermediate behavior was reported for $Ti(O\text{-}i\text{-}C_3H_7)_4$ and $Zr(O\text{-}n\text{-}C_3H_7)_4$. Penczek and co-workers determined experimentally two selectivity factors, $\beta = k_p/k_{tr(1)}$ and $\gamma = k_p/k_{tr(2)}$, where $k_{tr(1)}$ and $k_{tr(2)}$ stand for the rate constant for the unimolecular and bimolecular transfer reactions, respectively, and k_p is the propagation rate constant (5). The most crowded and least reactive species expectedly shows a higher selectivity, as illustrated by this order of reactivity: $Al(O\text{-}i\text{-}C_3H_7)_3 < Ti(O\text{-}i\text{-}C_3H_7)_4 < Fe(OR)_3 < (C_2H_2)_5AlOR < La(OR)_3 < (C_4H_9)_3SnOR < (C_4H_9)_2Sn(OCH_3)_2 < Sm(OR)_3 < K^+ {}^- OR$.

Living/Controlled ROP Initiated or Catalyzed by Organometallics

Alkoxides of some metals with d-orbitals, including Al and Sn, are efficient initiators for ROP of ε-CL and LA, which proceeds according to a *coordination–insertion* mechanism (Fig. 4). The very first step is the coordination of the alkoxide (ROM) to the carbonyl of the monomer. As a result of this nucleophilic attack, the acyl–oxygen bond of the monomer is cleaved with the simultaneous insertion into the metal–alkoxide bond. This mechanism is supported by ^1H NMR analysis of oligomer end groups, ie, an OR-containing ester as the α end group and a hydroxyl ω end group that results from the hydrolysis of the propagating alkoxide. The energy of each transition state, TS1 and TS2 (Fig. 4), and thus the electronic and steric properties of the monomer, decides which step is rate-determining (6). The reactivity of the initiator also depends on how electronic and steric effects are combined (6). For instance, a lower energy for the LUMO orbital of the alkoxide results in a more electrophilic initiator and a faster ROP. Instead of being preformed, the alkoxide can be formed *in situ* by the reaction of a metal derivative, eg, tin octanoate and alkyl Al, with an alcohol. Whenever the alcohol is used in

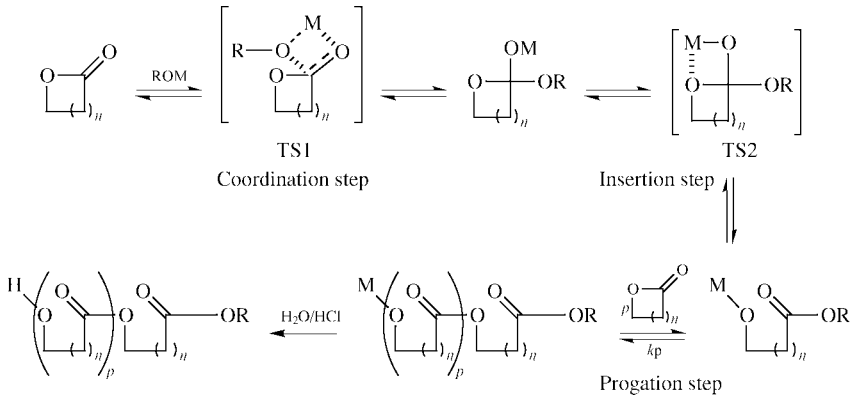

Fig. 4. The coordination–insertion mechanism for ROP of lactones and lactides.

excess and it participates in a fast exchange with the *in situ*–formed alkoxide, the metal derivative is rather a catalyst than the actual initiator. This "catalytic" system has the advantage of decreasing the extent of the polyester contamination by metal residues. The structure of the α end group is then dictated by the alcohol.

Aluminum Alkoxides. Aluminum alkoxides [$R_{3-n}Al(OR)_n$] are widely used as initiators for the macromolecular engineering of polylactones and polylactides (1,5), particularly Al trialkoxides [$Al(OR)_3$] and dialkyl Al alkoxides [R'_2AlOR]. Transesterification reactions are minimized and a good control is imparted to ROP, as assessed by a high γ value (for instance, 100 for ROP of L-LA in THF at 80°C) (7). Many experimental data reported in the literature confirm indeed that the molecular weight can be predicted from the monomer/initiator molar ratio and that the molecular weight distribution is narrow, in line with a fast initiation compared with propagation.

Except for γ-BL (8), high molecular weight polyesters can be prepared in the presence of Al alkoxides (9). This type of initiator can also polymerize other cyclic monomers, such as adipic anhydride and trimethylene carbonate, reviewing which is however beyond the scope of this review (9).

Because aluminum alkoxides can be prepared by reaction of trialkyl aluminum with an alcohol, the large variety of alcohols available offers a large choice for the structure of the α end group, including polymerizable end groups of the methacrylate and the norbornenyl types (10–13). These hydrophobic macromonomers can be copolymerized with hydrophilic comonomers, such as 2-hydroxyethylmethacrylate (HEMA), with formation of amphiphilic diblock copolymers (14). In case of α,ω-acrylate PCL (or PLA), formation of amphiphilic polymer network can be envisioned. In apolar solvents, aluminum alkoxides tend to self-associate (5), which may influence the polymerization course. For instance, $Al(O\text{-}i\text{-}C_3H_7)_3$ exists in toluene and benzene as a mixture of tetrameric (A_4) and trimeric (A_3) species in equilibrium (Fig. 5) (15,16). Only the trimers are active in ROP of ε-CL in toluene at 0°C (17), which explains that the average number of alkoxides active per Al is not 3.0 but rather close to 1.0 (16). This average number actually depends on the position of the A4 <=> A3 equilibrium in relation to the experimental conditions (solvent, temperature, and monomer).

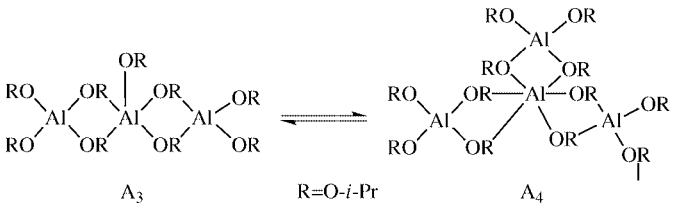

Fig. 5. Equilibrium between tetramers and trimers of $Al(O\text{-}i\text{-}C_3H_7)_3$.

Additives that coordinate to Al perturb the polymerization kinetics in toluene. For instance, THF and cyclohexanone compete ε-CL for coordination to aluminum (18), which decreases the propagation rate and may even inhibit polymerization. In contrast, kinetics is faster upon addition of a Lewis base, such as 4-picoline (19), because the coordination of this Lewis base onto the Al atom polarizes the metal–alkoxide bond and facilitates the monomer insertion. Although the reactivity of the active sites is increased, the extent of transesterification reactions is reduced, more likely for steric reasons.

Preparation of polyester free from toxic metallic residues is a prerequisite for biomedical applications. Because the metal extraction is time-consuming, it is worth decreasing the amount of initiator by using an alcohol as co-initiator. The molecular weight is then predetermined by the monomer/(alcohol + alkoxide) molar ratio. The apparent propagation rate increases first with the excess of alcohol up to a certain value, beyond which the kinetics becomes slower (20).

ROP has been initiated by well-defined single-site aluminum alkoxides modified by bulky ligands (21), eg, tetraphenylporphyrin (22), 2-2′-ethylidenebis(4,6-di-*tert*-butylphenol) (23,24), SALEN (25), and SALBINAP (26) (Fig. 6). The 5-Cl-SALEN (27,28) and HAPENOMe (28,29), ligands are efficient to promote ROP of LA at room temperature in dichloromethane. Interestingly enough, chiral ligands can induce stereoselective ROP of LA. Spassky and co-workers reported that (*R*)-(SalBinap)AlOMe polymerizes D-LA 20 times faster than L-LA (26). Similarly, the bulk poylmerization of L-LA is 14 times faster than that of D-LA when initiated by (*R*,*R*)-(SALEN)AlO-*i*-C_3H_7 (30). Long isotactic sequences are shown by ^{13}C NMR analysis of poly(LA), which then exhibits a tapered stereoblock microstructure. This stereocontrol is important because it directly influences the thermal properties of poly(LA). As an example, ROP of *rac*-LA initiated by (*rac*)-SALENAlO-*i*-C_3H_7 (30) or by achiral complexes (31) results in a polymer with a high melting temperature ($\sim$185°C) owing to the cocrystallization of poly(L-LA) and poly(D-LA) sequences. ROP of *meso*-LA initiated by (*R*)-(SALBINAP)AlO-*i*-C_3H_7 results in syndiotactic PLA (32), whereas *rac*-(SALBINAP)AlOR polymerizes *meso*- and *rac*-LA into heterotactic poly(LA) (33) and formation of isotactic stereoblocks (34), respectively. An exchange mechanism has been proposed to account for the poly(LA) microstructure prepared from *meso*-LA (33).

Tin. Tin octoate, $Sn(O(O)CCH(C_2H_5)C_4H_9)_2$, abbreviated further as $Sn(Oct)_2$, is one of the more widely used promoter of the ROP of lactones and lactides, owing to its acceptance as a food additive by the American Food and Drug Administration (FDA). $Sn(Oct)_2$ is used at the industrial scale for the

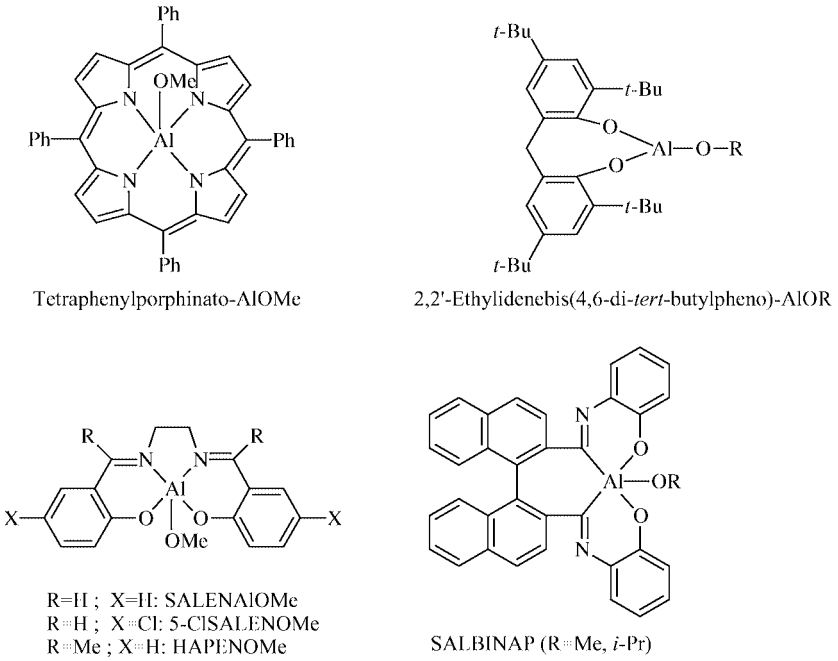

Fig. 6. Single-site aluminum alkoxides.

polymerization of LA by Cargill. Its activity depends on the availability of a protic co-initiator, either contaminating water and/or octanoic acid (35), or an alcohol added on purpose. Molecular weight in the 10^2–10^4 range is easily controlled by the monomer/alcohol molar ratio (35).

Although different mechanisms were proposed in the past in order to account for the role of $Sn(Oct)_2$ (36), it is now accepted that the active species are tin(II) alkoxides formed *in situ* by reaction of $Sn(Oct)_2$ with either adventitious water and hydroxy acids, or with an alcohol co-initiator as schematized by equations 1 and/or 2. The classical coordination–insertion mechanism shown in Figure 4 would thus be operative. Kricheldorf and co-workers pointed out that $Sn(Oct)_2$ initiators is a complex dynamic system that responds to changes of the reaction conditions (37). When the bulk polymerization of ε-CL is carried out at high temperature (180°C), the reaction of $Sn(Oct)_2$ with an alcohol is more complex and leads to a variety of compounds that contain tin–oxygen bonds (eg, tin hydroxides, stannoxanes, lactate complexes) and are liable to initiate the polymerization (37).

$$Sn(Oct)_2 + ROH \rightleftharpoons OCT\text{—}Sn\text{—}OR + Oct\text{—}H \quad (1)$$

$$Oct\text{—}Sn\text{—}OR + ROH \rightleftharpoons Sn(OR)_2 + Oct\text{—}H \quad (2)$$

Whenever water coexists with the $ROH/Sn(Oct)_2$ initiating system, it converts propagating tin(II) alkoxides into dormant hydroxyl end-capped chains and stannous hydroxide, which is less reactive than stannous alkoxide. The accordingly decreased concentration in the active propagating species accounts for a

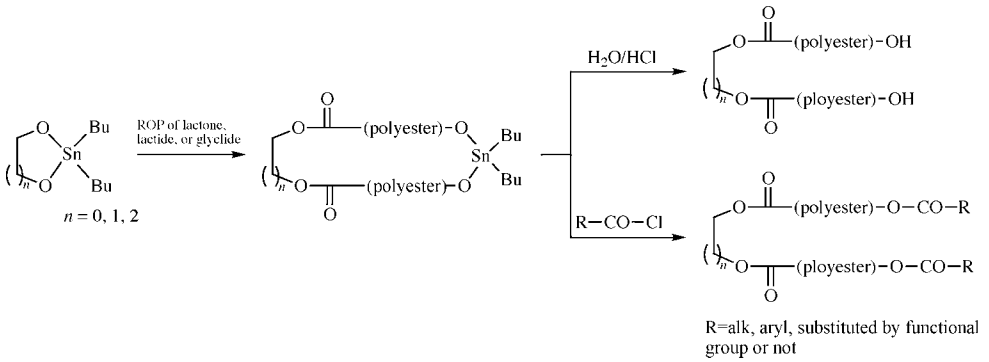

Fig. 7. ROP initiated by cyclic tin(IV) alkoxides.

slower polymerization. Because reaction is equilibrated, the molecular weight is not affected by water (38). The same general mechanism holds for dibutyltin dicarboxylates (39). The use of stannous(II) trifluoromethane sulfonate has also been reported for the ROP of ε-CL at low temperature (0°C) (40,41).

Tin alkoxides have also been preformed and used as ROP initiators. Alkyl-substituted tin(IV) alkoxides are more commonly used than the tin(II) counterparts. Compared with tin monoalkoxide (R'_3SnOR), tin(IV) dialkoxides (R'_2SnOR_2) are preferred because of a higher reactivity (42). Cyclic tin(II) alkoxides deserve interest because they form macrocyclic polyesters, which are precursors of telechelics, upon ring opening by acidic hydrolysis or reaction with acid chlorides (Fig. 7).

One drawback of tin(IV) alkoxides compared with aluminum alkoxides, is the broader molecular weight distribution of the formed polyesters. For instance, polydispersity of PCL is in the range of 1.4 and higher. Several phenomena contribute to this effect depending on the structure of the alkoxide, the monomer and the experimental conditions: (43) (*1*) slow initiation, (*2*) slow equilibrium between differently aggregated species, and (*3*) transesterification reactions (44). As a rule, tin alkoxides, are efficient transesterification catalysts and they are less selective in ROP than aluminum alkoxides, in agreement with the lower γ values (43). Nevertheless, the molecular weight is still predetermined by the monomer/initiator molar ratio. The control of ROP mediated by tin(IV) alkoxides is maintained in environmentally friendly supercritical carbon dioxide (45). The extraction of monomer and tin residues by this supercritical fluid is a further advantage, particularly for the production of biomedical-grade aliphatic polyesters.

ROP of ε-CL or LA initiated by tin(II) butoxide is living and proceeds through the previously mentioned coordination–insertion mechanism (35,43). This very good control results from the very low extent of intermolecular transesterification reactions, as witnessed by the very high value of γ (125 for ROP of L-LA in THF at 80°C). The higher reactivity of tin(II) alkoxides ($Sn(OR)_2$) compared with tin(IV) alkoxides ($((C_4H_9)_2Sn(OR)_2$) is consistent with the lower steric hindrance of tin at the benefit of the monomer coordination and with the positive induction effect of the R (butyl) groups, which decreases reactivity toward nucleophiles. The higher reactivity of tin(II) dialkoxides compared with aluminum trialkoxides results from

the difference in the ionic radii of the two metals and the accordingly stronger polarization of the tin–oxygen bond.

Rare Earth Metals. A large variety of rare earth derivatives have been used to initiate ROP of lactones and lactides (46). Their usually high reactivity must be emphasized, as exemplified by the polymerization of a low-strained lactone, ω-pentadecalactone, by $Y(O\text{-}i\text{-}C_3H_7)_3$ (47) Similarly, β-BL is polymerized by $Y(OCH_2CH_2OMe)$ at room temperature (48), in contrast to the long reaction time and high temperature required when aluminum-based initiators are used.

Several divalent lanthanide derivatives, eg, SmI_2, SmI_2/Sm (48), $SmCp_2$ (49), $Sm(OAr)_2(THF)_3$, $[(C_6H_5)Sm(\mu\text{-}OAr)]_2$, $(C_5H_9C_9H_6)_2Yb(THF)_2$(II) (50), promote ROP with a poor control. Trivalent lanthanide halides (LnX_3) are not very active initiators (51). For instance, ROP of ε-CL requires long reaction times (16–40 h) and temperature higher than 100°C. LnX_3 is actually a catalyst, which activates lactones by coordination to the carbonyl group, ROP being then initiated by traces of water or nucleophilic impurities. $LnCpX_2$ and $LnCp_2X$, are more active, such that the polymerization temperature can be decreased to 50-60°C. It is worth noting that a mixture of propylene oxide and LnX_3 initiates ROP at 30°C, as result of the *in situ* formation of a lanthanide alkoxide by ring opening of propylene oxide by LnX_3 (51). Halo-bridges/Sm(III) complexes ($[Sm(\mu\text{-}X)(N(SiMe_3)_2)_2(THF)]_2$) and non-halo-bridged Sm(III) complexes ($SmCp_3$, $Sm(N(C_6H_5)_3)_3$, $Sm(N(SiMe_3)_2)_3$) promote ROP at room temperature in less than 1 h without the assistance of a cocatalyst. The polydispersity index is rather high (~2.0 and higher) even though "livingness" has been supported by synthesis of block copolymer) (48). Recently, Greiner and co-workers have shown that bimetallic $[Sm_2I(NP(C_6H_5)_3)_5(DME)]$ is an effective initiator for ROP of ε-CL and δ-VL in toluene (52). At 0°C, the molecular weight distribution is narrow (PDI ~ 1.2), which indicates a fast initiation compared with propagation and transesterification reactions if any. The experimental molecular weight agrees with the theoretical value on the assumption that two chains are initiated per complex molecule. From the analysis of the chain end groups by ^{1}H NMR, the *in situ* formation of samarium alkoxides is supposed to result from the addition of the bridged nitrogen atom to the carbonyl group of the lactone, followed by the cleavage of the endocyclic acyl–oxygen bond (Fig. 8) (52).

$Y(CF_3CO_2)_3/Al(O\text{-}i\text{-}Bu)_3$ also leads to the formation of poly(ε-CL), poly(DL-LA) (53), and block copolymers (54) with a rather good control of the molecular parameters. The mechanism remains however an open question.

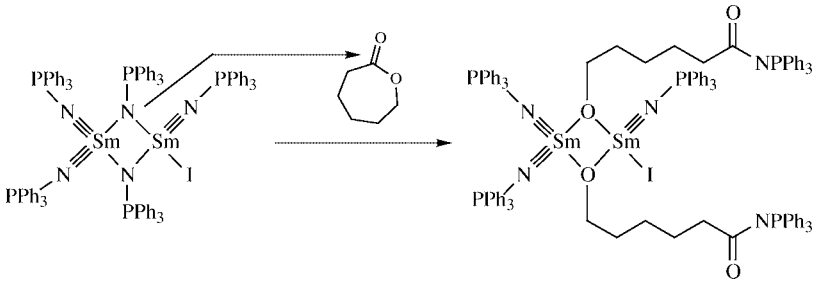

Fig. 8. Mechanism of ROP initiated by $Sm_2I(NP(C_6H_5)_3)_5(DME)$.

Yasuda and co-workers have reported on ROP of ε-CL and δ-VL initiated $Cp_2SmMe(THF)$ and $[SmHCp_2]_2$ with an efficiency of ~60%. Very high molecular weight polyester with very low polydispersity ($M_n > 75000$ and $M_w/M_n < 1.08$) is accordingly formed (55). Reaction of $Cp_2SmMe(THF)$ with the lactone would form *in situ* the actual initiator, ie, $Cp_2SmO(CH_2)_x{-}C(=O)Me$ (x = 4, 5). A difunctional initiator, $Cp_2SmO(CH_2)_xOSm_2Cp$, is proposed to be formed as result of the reaction of $[SmHCp_2]_2$ with the monomer, including β-PL (55).

Monomeric lanthanide alkoxides are generally unstable, unless they are stabilized by bulky substituents (20). Spassky and co-workers have shown that clustered lanthanide alkoxides $Ln_5(\mu\text{-}O)(O\text{-}i\text{-}C_3H_7)_{13}$ can initiate ROP of DL-lactide in dichloromethane (56). The following order of reactivity (La ≫ Sm ≫ Yb) has been reported. Low polydispersity is seen even at high conversion and long reaction time, except in case of lanthane because of exceedingly high reactivity and low selectivity. ROP of ε-CL is more complex, and transesterification reactions can occur before the monomer conversion is complete.

Samarium, neodynium, and yttrium isopropoxide have been used in combination with benzyl alcohol, which is a transfer agent, for the ε-CL polymerization. The catalytic activity is higher compared with aluminum and zirconium counterparts. The apparent propagation rate constant first increases with the alcohol/metal molar ratio up to an optimum value, and then decreases according to an egg-shaped curve (20,57). Once again, the use of a catalytic amount of lanthanide alkoxides is a valuable strategy to decrease the polyester contamination by metallic residues.

Soum and co-workers reported on experimental conditions such that $La(O\text{-}i\text{-}C_3H_7)_3$ is a dimer or a trimer or a mixture of both, in equilibrium with nonassociated species. The number of active isopropoxy per La however depends on the monomer and the $[monomer]_0/[initiator]_0$ molar ratio (58). Propagating poly(δ-valerolactone) chains are aggregated in contrast to the poly(ε-caprolactone) active ones.

In order to overcome the drawbacks associated to the clustering of Y isopropoxide. Feijen and co-workers initiated ROP of ε-CL and LA by converting *in situ* the inactive tris(2,6-di-*tert*-butylphenoxy) yttrium precursor into the active monomolecular Y alkoxide by reaction with 3 equivalents of 2-propanol (Fig. 9) (59). A well-defined kinetics is then observed, being first-order in both the monomer and the initiator (60). The propagation rate constant for LA in dichloromethane at 22°C is $1.92 \times 10^3\ L \cdot mol^{-1} \cdot min^{-1}$, which is an exceptionally high activity. This strategy was improved further by Jérôme and co-workers, who substituted the commercially available tris(bis(trimethylsilyl)amido) yttrium ($Y[N(SiMe_3)_2]_3$) for the Y phenoxide, whose synthesis is time consuming (61).

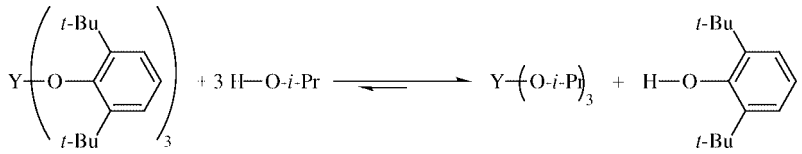

Fig. 9. *In situ* formation of $Y(O\text{-}i\text{-}C_3H_7)_3$ from Y triphenoxide.

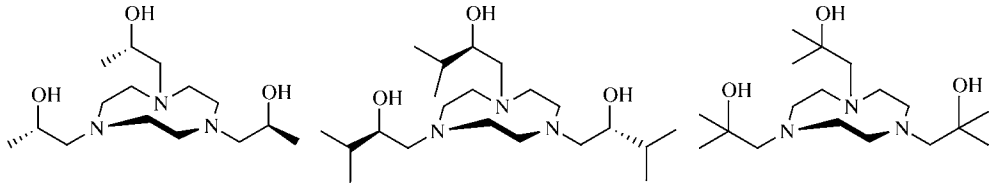

Fig. 10. Multidentate amines used by Hillmyer and co-workers as yttrium ligands.

The rapid exchange between the *in situ*–formed yttrium alkoxide and the alcohol allows the average number of the initiated chains to be controlled by the excess of alcohol with respect to Y. At a molar excess of 50, all the alcohol molecules participate to the exchange and thus to the initiation of ε-CL polymerization at 20°C. In addition to M_n, which can be predicted from the monomer/alcohol molar ratio, the molecular weight distribution is narrow even at high monomer conversion. The same strategy has been extended to the preparation of neodynium alkoxides from tris(bis(trimethylsilyl)amido) neodynium ($Nd[N(SiMe_3)_2]_3$) (62).

Multinuclear complexes of Y alkoxide have been synthesized with multidentate amines and they have shown high activity in ROP (Fig. 10) (63,64). Although the polymerization of ε-CL can be controlled, the polydispersity is rather high ($1.5 < PDI < 1.7$), and parasitic aggregation and clustering can be the source of complexity.

Mononuclear complexes have also been considered as controllable single-site catalysts, as illustrated in Figure 11 (21). In contrast to the poor efficiency of an arylimidinate ligand (65), $(EA)_2YO\text{-}i\text{-}C_3H_7$ and $(EA)_2NdO\text{-}i\text{-}C_3H_7$ (where EA stands for ethylacetoacetate) are more promising initiators of ROP of ε-CL and DL-LA (66). The polydispersity index is then rather low ($1.1 < M_w/M_n < 1.5$), and the polymerization kinetics is first order in monomer and in initiator, thus not perturbed by aggregation. An interesting alternative may be found in the addition of $Nd(O\text{-}i\text{-}C_3H_7)_3$ by a donor adduct, ie, 1,10-phenanthroline, 2,2′-bipyridyl, and 18-crown-6, because then M_w/M_n of PCL is as low as 1.05–1.10 (66).

Titanium. $Ti(O\text{-}n\text{-}C_4H_9)_4$ was tested as an initiator by Kricheldorf and co-workers (4). In order to restrict transesterification reactions, bulky ligands were associated to titanium, as illustrated by mono(cyclopentadienyl)titanium

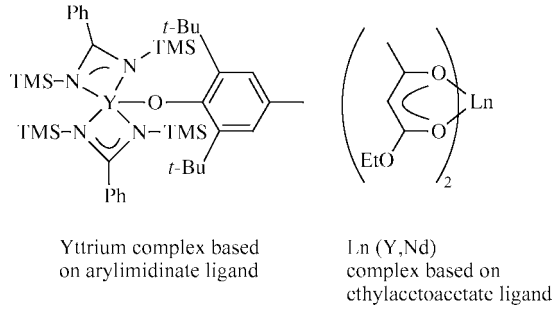

Fig. 11. Well-defined mononuclear lanthanide complexes used in ROP of ε-CL and LA.

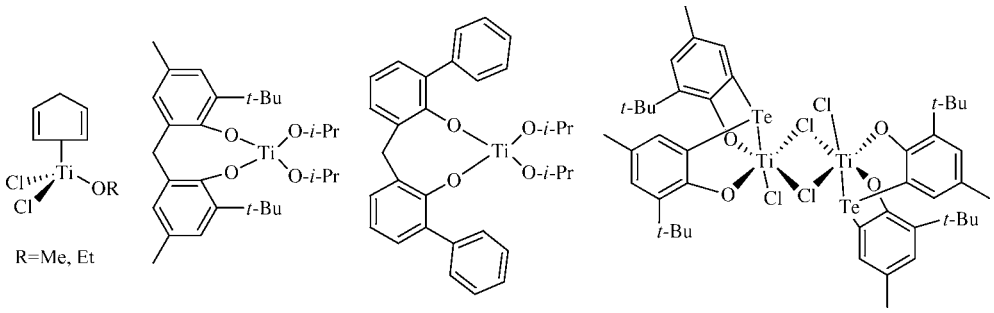

Fig. 12. Examples of titanium alkoxide complexes used as ROP initiators.

complexes (67), titanium dialkoxides ligated by bulky bis(phenoxides) (68), and titanium complexes with chalcogen-bridged chelating diaryloxo ligands (69) (Fig. 12).

Miscellaneous Metals. With the purpose of producing aliphatic polyesters free from toxic metallic residues, Kricheldorf and co-workers screened a large series of bioresorbable salts that could be active in the ROP of LA at 180°C (70,71). Na^+, K^+, Mg^{2+}, Ca^{2+}, Zn^{2+}, and Fe^{2+} were considered as cations, andchloride, iodide, oxide, hydroxide, carbonate, acetate and higher fatty acids, lactate, tartrate, citrate, α-amino acids and peptides as anions. Zinc lactate gave the best results (70,71).

Although strong Lewis acid metal halogenides are known catalysts for cationic ROP, zinc dichloride can initiate ROP of ε-CL, according to a coordination–insertion mechanism in which the alkyl–oxygen bond of the monomer is cleaved (Fig. 13) (72). The mechanism was assessed by computational calculations, analysis of the two chain-ends by ^{1}H NMR, and agreement between M_n and the monomer/zinc dichloride molar ratio. Zinc carboxylates are ROP promoters in the presence of alcohols (71,73). Similarly to tin octanoate, zinc alkoxide is formed, which is the real initiator (72,74). Side formation of octanoate ester end groups is kinetically less favorable compared with the tin counterpart (73).

Zinc alkoxides have also been prepared by reaction of diethylzinc with alcohols. $Zn(O\text{-}n\text{-}C_4H_9)_2$ was studied by Kricheldorf (4). $C_2H_5ZnO(CH_2)_2Br$ and $Zn(O(CH_2)_2Br)_2$ were used by Jérôme and co-workers for the controlled ROP of ε-CL (75). Well-defined single-site zinc-based catalysts, $[(BDI\text{-}1)ZnO\text{-}i\text{-}C_3H_7)]_2$ (Fig. 14), convert β-BL and β-VL into high molecular weight poly(3-hydroxyalkanoates) (76). Moreover, ROP of (*S*,*S*-LA, *rac*-LA, and *meso*-LA leads to isotactic, heterotactic, and syndiotactic PLAs, respectively (77–79).

Only few reports deal with iron-containing catalysts/initiators (80–84). Iron monocarboxylate derivatives mediate bulk polymerization of L-LA at high temperature (170–200°C) with formation of high molecular PLLA (~150,000). An iron alkoxide is proposed to be formed by ring opening of one monomer and to initiate ROP (84). Recently, Hillmyer and co-workers have shown that the structure of $Fe_5(\mu_5\text{-}O)(OC_2H_5)_{13}$ is similar to that of clustered yttrium alkoxide and that ROP of LA can be controlled in toluene at 70°C (85). $Fe_2(OCH(C_6H_5)_2)_6$ initiates ROP of LA and ε-CL and imparts a good control to the polymerization (86). A first order in both the monomer and the initiator is the rule. The mononuclear

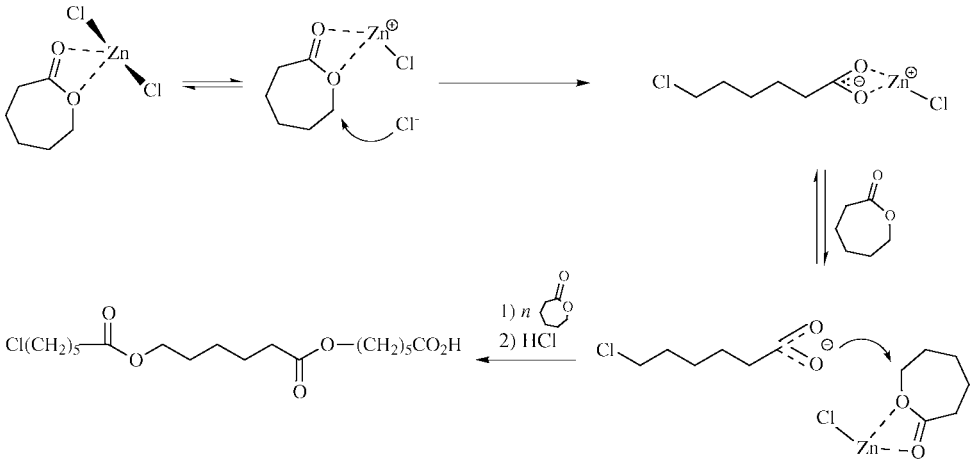

Fig. 13. Initiation of ROP of ε-CL by zinc dichloride.

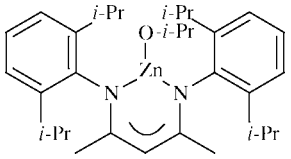

Fig. 14. Single-site zinc-based alkoxide.

$L_2Fe(OCHC_6H_5)_2$ (L stands for *N*,*N*-bis(trimethylsilyl)benzamidinate) (Fig. 15) is also an effective initiator. The polydispersity of poly(ε-CL) and poly(LA) is however rather high ($1.5 < M_w/M_n < 1.9$), and the order in iron alkoxide is fractional (0.5), which points to an aggregation phenomenon. In this case, the bulky ligand makes the kinetics more complex and 50 times slower (86).

Although commercially available and highly active in ROP of ε-CL and L-LA, calcium methoxide is of limited interest because of its low solubility and aggregation (87). Feijen and co-workers used however successfully the strategy implemented for lanthanide alkoxides. The $(THF)_2Ca[N(SiMe_3)_2]_2$ precursor was indeed reacted with isopropanol with *in situ* formation of Ca isopropoxide. ROP of ε-CL and L-LA is then controlled at room temperature as testified by the agreement between theoretical and experimental M_n and low M_w/M_n(<1.3). Poly(ε-CL)-*b*-poly(L-LA) was also synthesized with success, racemization was not observed during ROP of L-LA, and the kinetics was second order in monomer (88).

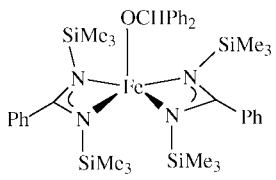

Fig. 15. Structure of $L_2Fe(OCH(C_6H_5))_2$, where L = bis(trimethylsilyl)benzamidinate.

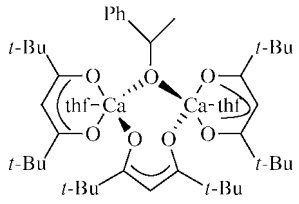

Fig. 16. Structure of $[(THF)Ca(tmhd)]_2[\mu\text{-}OCH(Me)Ph](\mu\text{-}thmd)$.

A bimetallic catalyst $[(THF)Ca(tmhd)]_2[\mu\text{-}OCH(CH_3)C_6H_5](\mu\text{-}thmd)$ (where thmd stands for 2,2,6,6-tetramethylheptane-3,5-dione) (Fig. 16), was prepared by the same authors who observed an induction period of time for ROP of ε-CL and LA and a first order in LA up to high conversion. Added with isopropanol, $[(THF)Ca(tmhd)]_2[\mu\text{-}N(Si(Me)_3)_2Ph](\mu\text{-}thmd)$ releases the parent alkoxide which initiates the controlled ROP of ε-CL and LA, no induction period is observed and the apparent propagation rate of ROP of LA ($0.125\ min^{-1}$) is 4.4 times higher compared with the preformed compound. Remarkably, ROP is much faster when initiated by β-diketonate calcium alkoxides than by aluminum, yttrium and tin alkoxides.

Zirconium derivatives are 10 times less toxic than tin counterparts. Zr-containing drugs and cosmetics are accepted by the Food and Drug Administration (89). Kasperczyk and co-workers (co)polymerized LA and CL by $Zr(acac)_4$ in the 100–150°C range (89,90). Because Zr complexes usually aggregate (coordination number = 6) (20), Hamaide and co-workers added benzyl alcohol to $Zr(O\text{-}n\text{-}C_3H_7)_4$ (20,57). M_n was determined by the monomer/alcohol molar ratio, M_w/M_n was low and, in contrast to aluminum alkoxides, the propagation rate decreased regularly with increasing benzyl alcohol/Zr molar ratio.

Kricheldorf and co-workers paid attention to germanium alkoxides because of less toxicity and higher reactivity in transesterification than tin alkoxides (91). However, ROP of ε-CL required higher temperature [140°C for $Ge(OC_2H_5)_4$], the content of cyclics was low (less than 1 mol% at 120°C), and the molecular weight distribution broad. It must be pointed out that spirocyclic germanium-based alkoxides are soluble and can initiate ROP of ε-CL at 140°C, which is not the case for tin, zirconium, and titanium analogues. The use of magnesium alkoxides as initiators or catalysts was scarcely reported (77,92,93). Initiation by $Mg(OC_2H_5)_2$ was briefly discussed by Kricheldorf and co-workers.

Heterogeneous ROP. Grafting of metal alkoxides onto solid supports is a valuable strategy to produce polyesters free from metallic residues. These heterogeneous initiators/catalysts can be used in batch production and their easy recycling/reactivation is promising for continuous processes (57).

Hamaide and co-workers grafted metal alkoxides (eg Al, Nd, Y, Sm, Zr) onto silica and alumina (57,94). Nevertheless, the alcohol that is released in the reaction medium can react with the silanol groups of silica and form water. Therefore, part of the active species can be lost by hydrolysis. In case of alumina, Al—O—R species can be additionnally formed and participate in the polymerization.

Jérôme and co-workers tackled this problem by using an Y alkoxide precursor, ie $Y[N(SiMe_3)_2]_3$ (95). The Y triamide was first reacted with one or two equivalent(s) of isopropanol with formation of mixed yttrium alkoxide/amide. The

unreacted amide functions were then used to graft the Y alkoxide to the support. This method is free from side reactions, quite reproducible, and allows to vary the average number of alkoxides per Y (1 or 2). The grafted alkoxide can participate in a fast exchange with an alcohol added on purpose in the polymerization medium, at 40°C. Chains are detached from the support by methanolysis, which restores the Y alkoxides at the surface of the support. Starting with Y amide, rather than with preformed Y alkoxide known for fast association in solution, has the advantage of grafting, well-defined monomolecular species to the support.

Enzymatic Ring Opening Polymerization

Enzymatic Polymerization (qv) is an alternative technique for producing metal-free polyesters. Some lipases are known to catalyze (trans)esterification reactions. A first report on the enzymatic bulk ROP of ε-CL in organic solvents was published in 1993 (96,97). At the time being, many lactones with the ring size from 4 up to 17 have been polymerized by lipases (98), either in organic solvents or in more environmentally friendly supercritical carbon dioxide (99). ROP of γ-BL, which is usually a problem by traditional techniques, is oligomerized in the presence of porcine pancreas and *Pseudomonas capacia* (100). As a rule, large-size lactones react faster than the smaller ones (73), which is the reverse of what is observed for chemical ROP. Actually, the rate-determining step in enzymatic polymerization is the formation of a lactone–lipase complex (Fig. 17), which is more favorable for more hydrophobic large-size lactones (73). The catalytic site of lipases is a hydroxyl-containing serine residue (73). ROP takes place according to an "activated monomer" mechanism (Fig. 17) (73). The key step is the reaction of lipase with the lactone with formation of an acyl–enzyme intermediate, which further reacts with water, alcohols, or hydroxyl end-capped chains during either the initiation or the propagation step. Moreover, a second mechanism, which should also be taken into account, relies on the activation of the polyester chain-end either by direct activation of carboxylic acid end groups by lipase (Fig. 18) (101) or by transesterification of an inner ester group by lipase (Fig. 19) (102).

By tuning the monomer/initiator molar ratio, M_n ranging from 10^3 up to 10^5 can be prepared (98,103), Unfortunately, the control imparted to ROP in not as

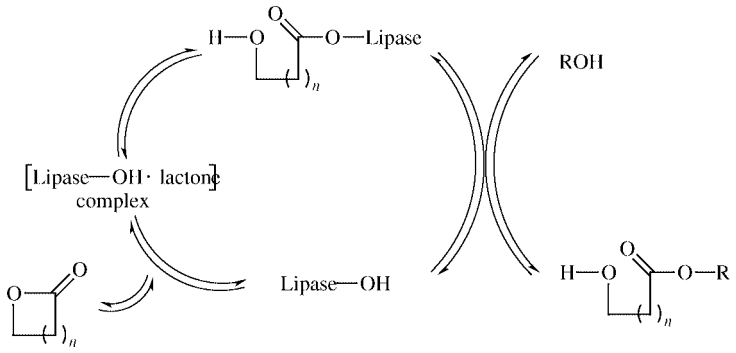

Fig. 17. Mechanism of enzymatic ROP catalyzed by lipases.

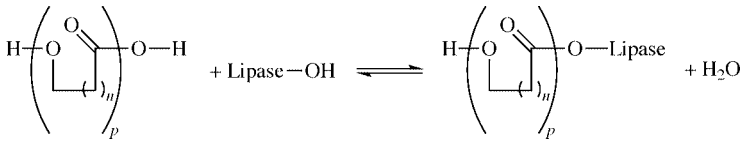

Fig. 18. Activation of polyester chain-ends by lipases.

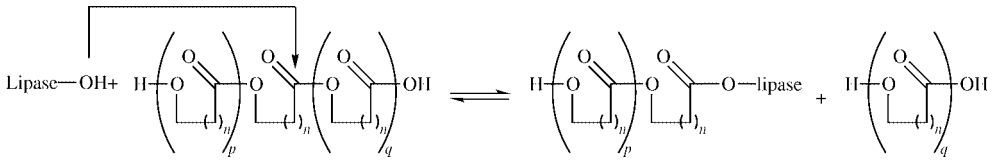

Fig. 19. Intra-chain activation of polyesters by lipases.

good as the one obtained by chemical ROP, with M_w/M_n higher than 2 (98). One advantage of the enzymatic route is to be found in the optical activity of lipases, which opens up a new route to stereoselective ROP. For example, the enantioselective ROP of racemic α-methyl-β-propiolactone by *Pseudonomas capacia* lipase produces an (*S*)-enriched polyester with an enantiomeric excess of 50% (103). More recently, isotactic (*S*)-enriched poly(4-methyl-ε-CL) and poly(4-ethyl-ε-CL) with an enantiomeric purity higher than 95% have been prepared by enantioselective ROP of the racemic mixture, in the presence of lipase Novozym-435. Optically active (*R*)-4-methyl-ε-CL and (*R*)-4-ethyl-ε-CL, which remain unreacted after ROP completion, have been isolated and further polymerized by tin octoate into isotactic (*S*)-enriched poly(4-methyl-ε-CL) and poly(4-ethyl-ε-CL), respectively (104).

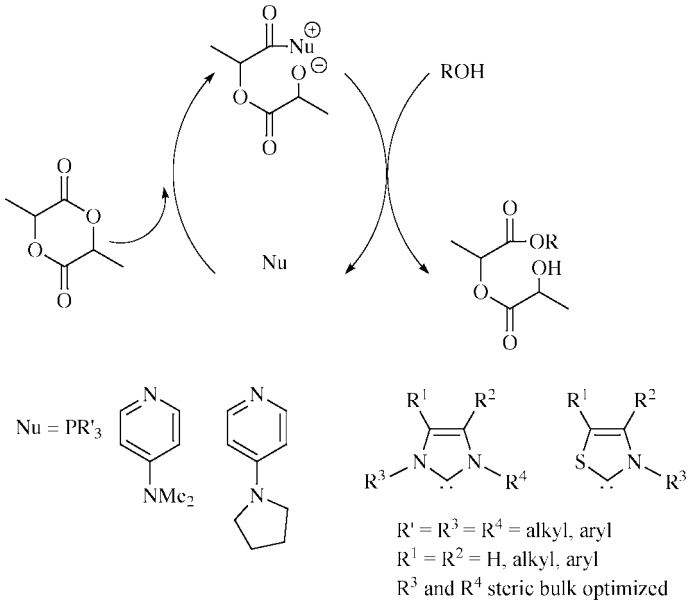

Fig. 20. Mechanism of all-organic ROP promoted by nucleophilic catalysts.

"All Organic" Ring Opening Polymerization

Last but not least, metal-free polyesters can be prepared by using all-organic initiators. Endo showed that a mixture of alcohol and $HCl \cdot C_2H_5O$ is a cationic catalyst for the controlled ROP of ε-CL and δ-VL (105). One limitation of this system is that low M_n chains are usually prepared, ie, M_n lower than 15,000 for poly(ε-CL) (106). Poly(δ-VL) is an exception, with M_n up to 50,000.

The use of nucleophilic catalyst is also promising (Fig. 20). Indeed, ROP of LA initiated by alcohols is catalyzed by phosphines (107), tertiary amines (eg, 4-dimethylaminopyridine, 4-pyrrolidinopyridine) (108), *N*-imidazolium (109) and thiazaolium (110) carbenes. The mechanism would be similar to the one reported for biocatalysis: activation of the monomer by the nucleophilic attack of the carbonyl by the catalyst, with formation of an intermediate that reacts further with an alcohol, polymeric or not. *N*-heterocyclic carbenes can be generated *in situ* from the corresponding imidazolium and thiazolium salts (110), whereas changing the substituents of these compounds is a tool for tuning their reactivity (110). This promising process could be more widely used in the future.

ROTATIONAL MOLDING

Introduction

Rotational molding (also referred to as *rotomolding* or *rotational casting*) is a unique molding process. The heating, shaping, and cooling of the plastic all takes place inside the mold, with no application of pressure. This method dates back to the early 1900s. Today the rotational molding industry is one of the fastest growing segments of the plastics industry, with an annual growth of 10%. This is largely due to the efforts of the Association of Rotational Molders (ARM), an international organization that includes molders, equipment suppliers, professional consultants, and design firms, and the Society of Plastics Engineers (SPE), who have recently formed a rotomolding division.

Initially only vinyl plastisols were used for rotational molding; however, in the early 1960s, polyethylenes, the first polyolefin powders, were employed (1). This created the opportunity for molders to enter markets where vinyl products could not compete. In the early 1970s cross-linkable and modified polyethylenes opened up more new areas, especially in the large-tank market. In the mid-1970s, linear low density polyethylene, a major development in resins, was formulated. In the 1980s nylon, polypropylene, and polycarbonate were introduced for rotational molding applications. The 1990s saw rotolining resins, materials that bonded to metal, and one-step foam resin systems that provided for a finished part with a rotomolded outer skin and a foam-filled core. The year 2000 ushered in single-site catalyst resins, some known as metallocenes as well as numerous compounders providing blends of resins for very specific end use requirements. Most resin is used as a ground powder, ranging in particle size from 20 to 120 mesh (125–840 μm). Liquids and small-diameter micropellets can also be rotomolded. Rotational molding provides a more uniform wall thickness, for both single- and double-wall construction, than other methods. Thick corners impart strength. Inserts, ribs, and undercuts are easily included (2,3).

The range of designs is limitless. The ARM organization has published a design manual for rotational molding (4). This was the first publication to address the design guidelines required in the rotational molding industry. Since that time, numerous books have been published on rotomolding (5).

Molds and tooling costs are lower than those of other processing methods, since channels for cooling water and resistance to a clamping force are not required. Different articles and colors may be molded on the same machine and in the same cycle. Quick mold changes are possible when several short production runs are required. Large, hollow products are conveniently made by rotomolding. The largest article molded to date is an 85-m^3 tank. Trimming can be eliminated since very little flash is produced. Rotomolded parts are comparatively stress-free. Corner sections are thicker than with other processes, which increases strength.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Undercuts, intricate contours, molded-in inserts, and double-wall construction are routinely included; wall thicknesses are uniform.

Process

In most rotomolding operations the molds or cavities are filled with a certain amount of powder or liquid (charging the molds); the mold halves are pressed together by bolts or clamps, placed in a heated oven, and rotated biaxially. During heating the resin melts, fuses, and densifies into the shape of the mold. The molds are moved into a cooling chamber, where they are slowly cooled by air and water. After removal from the cooling chamber, the molds are opened and the finished articles are released.

Many rotomolded parts are produced in the color of the plastic. For colored parts, suppliers provide a compounded colored resin; however, many molders blend a dry color into the resin—for this operation, addition and dispersion are critical. New developments in liquid colors allow for use at both the compounder and rotomolder. Nylon and polycarbonate may require drying before molding. Although scrap or regrind is not produced in large quantities, only a small percentage of regrind should be used with the virgin resin.

The particle size of the resin is extremely important; 500-μm (35-mesh) powder is the standard of the industry, although coarser or finer grinds may be employed.

Wall distribution is determined by the rotation ratio. The fewer rpms in a certain ratio, the more uniform the wall thickness. Resin, molds, and final application must be taken into consideration to establish the most efficient cycle.

Equipment. The equipment used in rotational molding is simple; many variations are available. The most common type is the so-called carousel type (Fig. 1). This machine consists of a heating station or oven, a cooling station (frequently an enclosed chamber), and a loading and unloading station. A carousel has three to six spindles or arms where the mold or molds are mounted. Most carousels have the freedom to revolve in a complete circle. The spindles are mounted on a central hub and driven by variable motor drives. New control systems allow each arm to operate independently in movement and control of oven temperature and time. Microprocessors are incorporated in the control system. Computer simulation software can be utilized in prototyping and manufacturing.

The ovens are usually fired with natural gas and equipped with blowers to distribute the heat throughout the chamber. Some ovens can be heated by oil or propane gas, but natural gas is preferred. A new composite mold technology is also available to produce rotomolded parts. This is done without an oven as heating and cooling takes place inside the mold.

A fan provides forced air to the cooling station for the initial cooling, whereas a water system cools the molds and products. A spray mist is used for even cooling. The cooling station may or may not be enclosed.

In an open-flame machine a mold is rotated on a single axis over an open flame. After the article is formed, the excess resin is discarded and the flame is turned off to allow for air-cooling. This process requires a longer cycle time, but the equipment is less expensive.

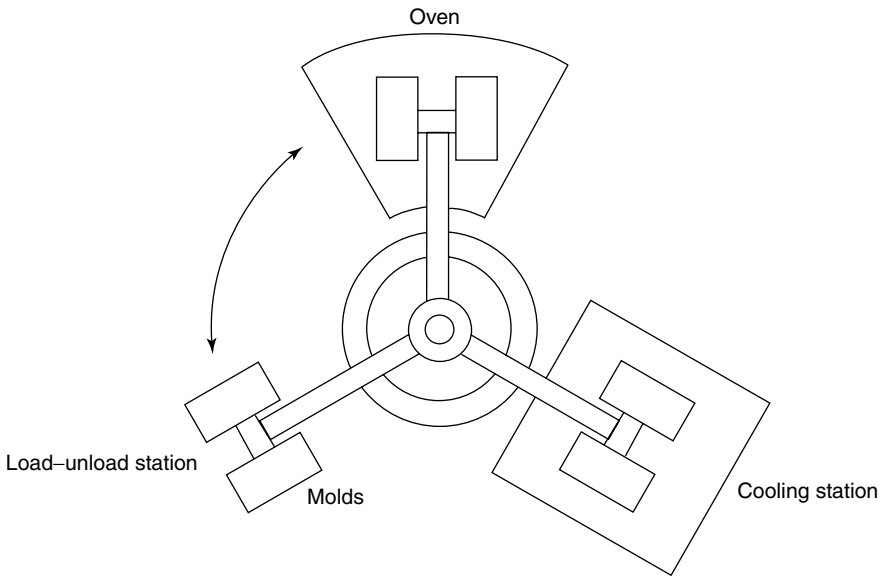

Fig. 1. Carousel-type machine.

The shuttle-type machine (Fig. 2) is used for large products, such as tanks. A frame for holding a mold is mounted on a movable bed. The drive motors for turning the mold biaxially are incorporated in the bed, which is on a track that allows the mold and bed to move into and out of the oven. After the heating cycle is completed, the mold is moved into the cooling station, which is not enclosed, Another bed with a mold is moved into the oven from the opposite end. (Some shuttle machines will use a movable oven.)

The clamshell type of rotational molder utilizes an enclosed area that serves as both the oven and the cooling station (Fig. 3). This machine employs only one arm; heating, cooling, and loading–unloading stations are all in the same location.

Rock and roll machines are commonly used for kayaks and canoes. These machines do not rotate biaxially but will rock back and forth while spinning on

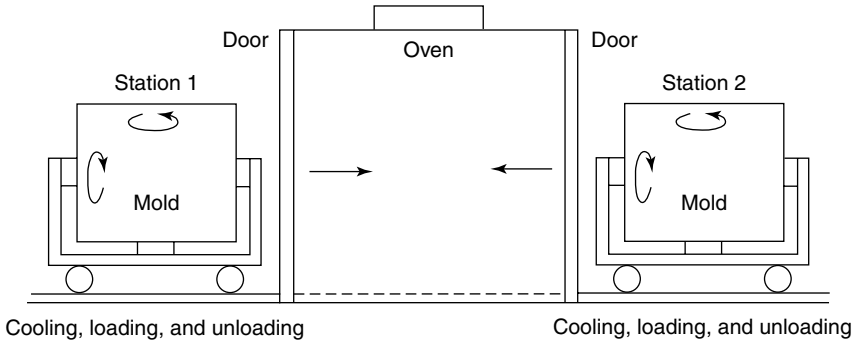

Fig. 2. Shuttle-type machine.

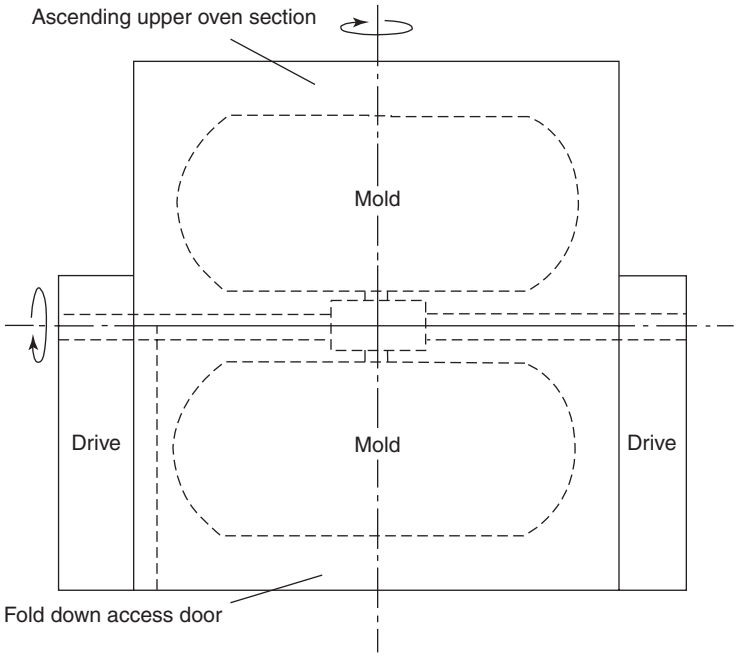

Fig. 3. Clamshell-type machine.

the longest axis. This can be accomplished over an open flame or a variation, which uses a rocking oven.

Machine maintenance is of extreme importance. A weekly inspection, as well as a good inventory of spare parts, is necessary in case of breakdowns. Filling devices can be automated but are usually manually operated. This requires an accurate weighing device and a container for each of the resins. Robotic systems for loading/unloading of powder and parts are now making their way into this industry. Some resins, such as nylons, require a nitrogen atmosphere. The nitrogen is introduced through a channel in the spindle and connected to the mold with rotary hoses.

Molds. The molds used in rotational molding are among the easiest and least expensive to fabricate; two-piece molds are standard, but three-piece molds are sometimes required to remove the finished products. Molds can be as simple as a sphere, or complex, with undercuts, ribs, and tapers. Design considerations include heat transfer, mounting, parting lines, clamping mechanisms, venting, and material stability. Mold makers commonly use 2-D and 3-D electronic files to design new molds.

Cast aluminum is the most widely used mold material. Small to medium articles are molded with a cast mold. Cast aluminum has good heat transfer, and is cost-effective when several moldings of the same article are required. Cast molds can be porous, however, and are easily damaged. Sheet-metal molds are normally used for larger parts. They are easy to fabricate; frequently the sections of the molds only have to be welded together. Sheet-metal molds are cost-effective for large articles. Other molds, such as electroformed nickel molds, give a product

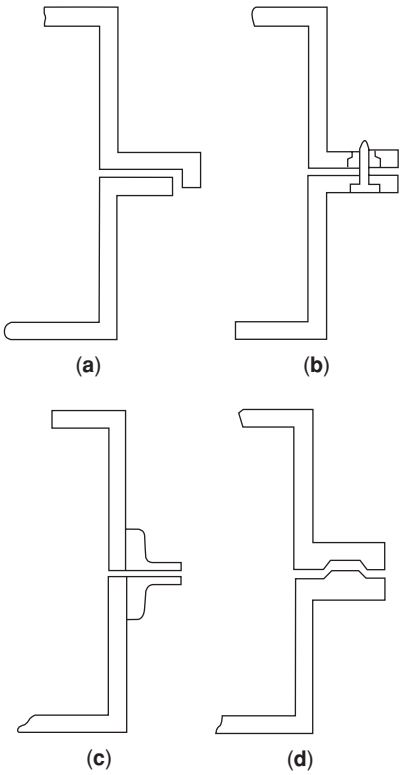

Fig. 4. Parting lines (**a**) stepped, (**b**) pin and bushing, (**c**) fabricated, and (**d**) tongue and groove.

with very fine detail. Vapor-formed nickel molds also give good detail but are more expensive.

Parting Lines. Each mold must have two or more sections, requiring good parting lines (Fig. 4) for a close fit and minimum flash.

Mounting. The molds are mounted on the spindle or the arm of a rotational molding machine. Large sheet-metal molds are easily mounted by bolts or simple clamping systems. Several small to medium aluminum molds can be mounted on spindle or arm. A part commonly known as a spider is used to mount several cast aluminum molds. The spider consists of several arms or mounting legs where each mold is attached, normally by bolts. A central mounting location is attached to the spindle by bolts. The spider allows two or three dozen cast molds to be mounted on one central structure. The entire spider, or just one or two cast molds, can be removed or mounted efficiently. The spider or a single, large sheet-metal mold may be removed easily with a forklift or crane. This is important, since the rotomolding industry normally requires short production runs of a variety of parts. Figure 5 shows molds mounted on a straight arm and an offset arm.

Clamping Systems. The most common clamping system for small to medium molds is that of spring-loaded clamps, which are welded onto the sections of a mold. As the molds get larger, nuts and threaded bolts are normally used; they are installed and removed with an air gun (impact wrench).

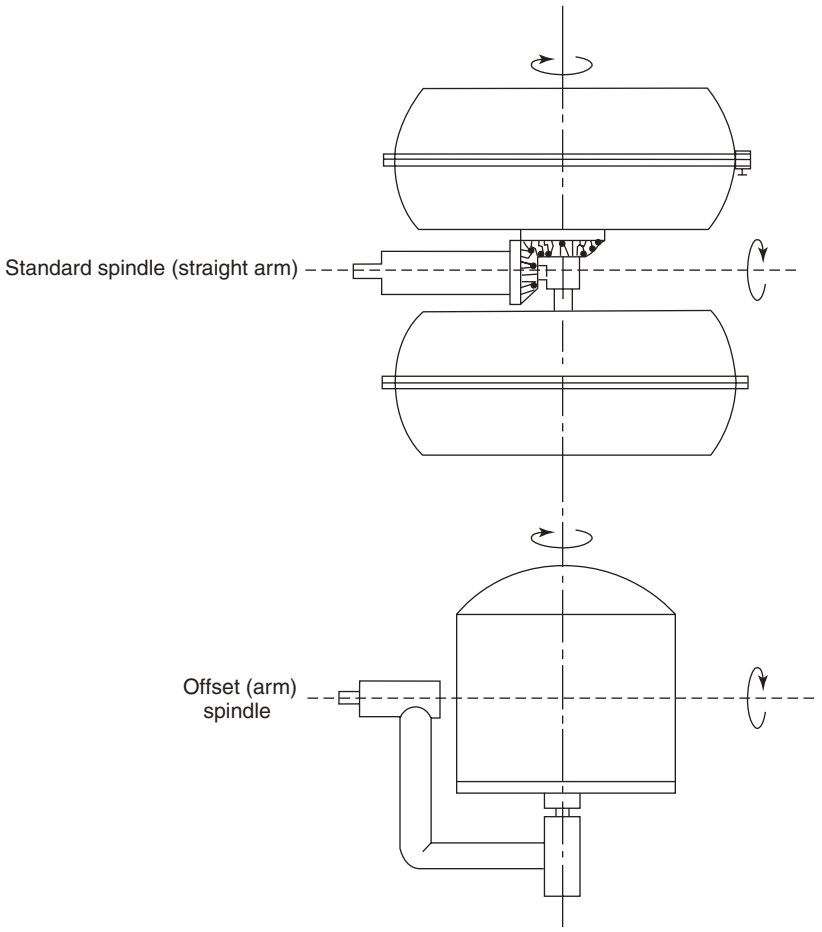

Fig. 5. Mold mountings.

Venting System. Most rotational molds require a venting system to remove the gas that develops in the heating cycle. Depending on the mold size, vents range from 3 to 50 mm in diameter. A 12.5-mm-i.d. tube is used for an article of 0.76-m^3 volume.

Since vents leave a hole in the molded parts, correct placement is essential. They should be located in an area that may be cut out of the finished product or where a patch does not impair appearance. Vents must also be so located as to prevent water from entering the product while it is in the cooling cycle, because this may leave a water-track mark on the inside of the hot article. Improper venting can cause problems, such as blow holes in the parting line.

Mold Release. Since most rotational molds are designed with little or no draft angle, they must be treated with a release agent. Molds are usually cleaned with a solvent and a lightly abrasive cloth to remove foreign particles from the surface. A light coating of release agent is applied and baked on to ensure adhesion. The amount of release agent required depends on the resins to

be used. After the initial application, several hundred articles can be molded before the mold is stripped and another coating is applied; during this time touch-up may be required. Sandblasting is also used to remove resin buildup before reapplying the mold release. A more effective release agent is usually applied to the parting line to facilitate demolding. Teflon provides for a permanent-release coating but care must be taken not to damage it, as it is normally very thin.

Special Molds. Some molds may require a complicated design, inserts, and special machining. Alignment pins may be used to ensure a perfect fit. If a rotomolded article contains a large section where no resin buildup is desired, the mold can be shielded with an insulating material such as Teflon.

Regular maintenance prolongs the useful life of the mold. For cleaning, nonabrasive tools should be used. Steel molds should be oiled to prevent rusting.

Secondary Operations. Secondary operations may be required, such as automatic or manual drilling. Additional fittings can be added by spin welding. Sections may be joined by hot-bar, hot-gas, or ultrasonic welding. Flame treatment before painting provides a surface for adhesion. As in all plastic processing methods, secondary operations are time-consuming and should be kept to a minimum. Automatic computer-driven 3–5-axis routers are now commonplace for secondary operations. Decorating, labeling, and graphics have become an important area for parts that are rotomolded. Graphics, labels, and colors can be molded in or applied afterwards.

Resins

In the early days of rotational molding only vinyl plastisols were used. The first polyethylene for rotomolding was produced in the 1960s. Today polyethylene is the principal material for the industry. The distribution of resin use in rotational molding is indicated below (6).

85%	Polyethylene
10%	Fluorocarbons
	Polycarbonate
	Nylon
	Poly(vinyl chloride)
	Polypropylenes
5%	ABS
	Acetals
	Acrylics
	Cellulosics
	Epoxies
	Phenolics
	Polybutylenes
	Polyesters
	Polystyrenes
	Polyurethanes
	Silicones

A rotomolding resin requires good flow, which is measured by the melt index. The higher the melt index, the better the flow. Most rotomolding resins have melt indexes between 3 and 20. The melt index is also an approximate measure of molecular weight or chain length. A resin with a high index has shorter chains and a lower molecular weight; a low index indicates longer chains and a higher molecular weight. Molecular weight distribution is also important. The narrower the distribution, the more uniform the melt properties.

Polyethylene. Linear low density polyethylenes (LLDPE) are the most widely used materials for rotational molding. Large pellets cannot be used and must be reduced to a smaller particle size to promote heat transfer from the mold to the powder. This also improves the flow of the particles during melting to prevent the deleterious effect of oxidation. This size reduction is done by the resin supplier, a custom grinder compounder, or the molder on mechanical grinding mills. Some resins, such as nylon, are supplied as small pellets and can be molded without grinding (see ETHYLENE POLYMERS, LLDPE).

The molecular weight distribution of a polyethylene for rotational molding should be very narrow, allowing for uniform melting of the particles during the molding cycle. Polyethylenes are easily ground to 500 μm (35 mesh) at high rates, yielding acceptable powder at nominal upcharge. They are thermally stable, and with stabilization can be molded in high temperature, high speed rotational-molding equipment without oxidation. Excellent low temperature physical properties, such as impact strength, allow use in a broad temperature range.

Polyethylenes are inexpensive and available in a wide range of densities and melt indexes for a wide variety of applications. Ultraviolet stability or outdoor life is significantly improved by the addition of pigment or UV stabilizer. Most polyethylene resins meet FDA food additive regulations, except for some specialized cross-linkable polyethylenes and some resins with certain UV stabilizers. The high dielectric strength of polyethylenes makes them suitable for electrical applications. Density and melt indexes (2.0–20 g/10 min) are the main criteria for selecting a polyethylene for a particular application (Table 1).

Polyethylene is classified by density. Type I has a density of up to 0.925 and is called low density (LDPE). Type II has a density range from 0.926 to 0.940 and is called medium density (LMDPE); most LLDPEs fall into this range. Type III has a range from 0.941 to 0.969 and is classified as high density copolymer (HDPE). Type IV is above 0.960 and is classified as high density homopolymer; it is not used in rotational molding.

LDPE is flexible and tough, easy to process, and has excellent chemical resistance. LLDPE and LMDPE have better mechanical properties than LDPE, higher stiffness, excellent low temperature impact strength, and excellent environmental stress crack resistance. HDPE is the stiffest polyethylene, with excellent chemical resistance and good processability. XLPE contains a cross-linking agent that reacts with the resin during the molding cycle, similar to a thermoset. This reaction improves the toughness and stress-crack resistance of the rotomolded product.

Ethylene vinyl acetate copolymer (EVA) is a low density polyethylene copolymer with excellent low temperature impact properties. The higher the level of vinyl acetate, the greater the flexibility of the material. Colorants, flame retardants, and foaming and antistatic agents may be added to polyethylene for specialty applications. Comparisons with other resins are given in Table 2.

Table 1. Molding Properties of Polyethylenes

Resin	Advantages	Disadvantages
LDPE	Flexibility	No stiffness
	Excellent warp resistance	No ESCR[a]
	Uniform shrinkage	
	FDA accepted	
BVA	Flexibility	No stiffness
	Excellent cold temp. impact	No ESCR[a]
	Uniform shrinkage	
	FDA accepted	
LLDPE–LHDPE	Excellent ESCR[a]	Less stiff than HDPE
	Good warp resistance	Lower heat deflection
	More stiffness than LDPE	
	FDA accepted	
HDPE	Excellent stiffness	Low ESCR[a]
	FDA accepted	Warpage and shrinkage are not consistent
	Good impart strength	
	Higher heat deflection	
XLPE	Excellent impact	Not accepted by FDA
	Excellent ESCR[a]	Longer molding cycle

[a]Environmental stress-crack resistance.

Table 2. Resins Used for Rotomolding

Resin	Advantages	Disadvantages
Polyethylene	Low cost, ease of moldability	Lower impact strength than other types
Polycarbonate	Clarity, toughness	Tendency to absorb moisture, harder to mold than PE
Nylon	Excellent impact strength	High cost, harder to mold than PE
	High heat resistance	
Poly(vinyl chloride)	Flexibility, paintability	Greater cost than PE, stiffness

Poly(vinyl chloride). Poly(vinyl chloride) can be molded in liquid or powdered form. The liquid plastisols are fluid suspensions of fine particle-sized resins in a plasticizing liquid. PVC compounds are easily processed. They can be formulated to produce articles ranging from flexible to semirigid, with durometer hardness of 60 Shore A to 65 Shore D (see VINYL CHLORIDE POLYMERS).

Molded plastisols possess outstanding chemical resistance. Plastisol systems for rotational molding are usually formulated to a Brookfield viscosity of 1000–4000 mPa·s (=cP) to provide high mold detail reproduction. Plastisols have excellent fluorescent pigment retention, which eliminates pigment bleeding. This can be an advantage in rotomolding when bright colors are required.

Nylon. Nylon has excellent tensile strength, stiffness, impact strength, and high heat resistance, and properties are maintained at elevated temperatures; chemical resistance is excellent (see POLYAMIDES, PLASTICS).

Table 3. Less Important Resins Used in Rotomolding

Resin	Advantages	Disadvantages
ABS	Good dimensional stability, low temp. impact strength	Hard to mold
Acetals	Very rigid, good chemical resistance	Hard to mold, high cost
Acrylics	Good clarity	Low impact strength
Cellulosics	Good chemical resistance, impact strength, and clarity	Hard to mold
Epoxies	Good electrical properties and chemical resistance	Hard to mold
Fluorocarbons	Good thermal properties, excellent chemical resistance	Hard to mold
Phenolics	Good at high temp.	Hard to mold, low impact strength
Polybutylenes	Good abrasion properties, long-term water resistance	Hard to mold
Polypropylene	Good chemical resistance	Low impact strength
Polystyrenes	Good electrical properties and clarity	Low impact strength
Polyurethanes	Good insulating properties and abrasinn resistance	Hard to mold
Styrene acrylonitrile (SAN)	Good chemical resistance and clarity	Hard to mold
Silicones	Good moisture resistance, excellent, chemical resistance	Hard to mold, high cost

Polycarbonate. Polycarbonates (qv) provide resins with excellent mechanical properties, including stiffness, tensile strength, creep resistance, and the highest heat resistance of all rigid plastics.

Other Resins. Many other resins have been processed by rotational molding. In most cases their disadvantages outweigh their advantages. Disadvantages include high cost, poor impact strength, and low flowability (Table 3).

Applications

Almost any type of part or product can be produced by rotational molding. Rotomolding has fewer limitations than any other plastic processing method. It is used for tanks, ranging in size from 19 L to 88 m^3. Rotomolded tanks are utilized in the agricultural, chemical, and recreational vehicle industries. Rotomolded containers are used for packaging and material handling. Rotational molding is used for portable toilets, battery cases, light globes, vacuum cleaner and scrubber housings, toys, and garbage containers. Rotomolded kayaks, canoes, boats, and playground equipment are commonplace.

Economic Aspects

Compared with blow molding, rotational molding offers lower equipment and mold costs and broad design parameters. Blow molding, however, provides a quicker

Table 4. Plastics Processing[a]

	Rotomolding	Blow Molding	Thermoforming
Equipment cost	2	3	1
Mold cost	1	3	2
Cycle time	3	1	2
Design limits	1	3	2
Materials available	1	3	2

[a] 1 = lowest costs; 3 = highest costs.

cycle and can be used with more resins. Compared with thermoforming, rotational molding offers cheaper mold cost and more design freedom. Thermoforming equipment is cheaper, cycles are shorter, and the resin selection is wider. Table 4 compares these processes. Rotomolding resins are priced slightly higher than most other resins because of higher stabilizer requirements. Grinding costs are 11–15 cents/kg. Rotomolding machine prices range from $80,000 for a small machine up to $800,000. Grinding systems are $50,000 to $100,000.

Safety

Rotational molding is a reasonably safe industry. Most resins used are nonhazardous. Some resins may cause mild irritation; suppliers provide safety information on their handling and use. Most resins used for rotational molding are ground to 500 μm (35 mesh), and appropriate procedures should be followed to prevent a dust explosion and fire. A rotomolder is a relatively safe piece of processing equipment; fans are enclosed with guards; spindles and arms operate at a low speed. The oven is equipped with a temperature control.

RUBBER CHEMICALS

Introduction

Rubber processing chemicals are used extensively to impart performance and processability to rubber and the products made thereof. These chemicals are typically organic compounds but several inorganic materials are also included under the umbrella of rubber chemicals. The rubber compound is described as a mixture of one or more rubber polymers (elastomers) with a combination of one or more of fillers, oils, and rubber chemicals (see RUBBER COMPOUNDING). The compound, once vulcanized, provides technologically useful properties, such as may be applied to tires, hoses, belts, tracks, and a variety of mechanical goods.

Vulcanization systems and antidegradants are the two dominant classes of rubber chemicals, given that the largest class of rubbers used in industry (the so-called general-purpose rubbers) require cross-linking by sulfur or other curative to provide meaningful performance, and require protection from oxygen and ozone to provide meaningful service lifetimes (see ANTIOXIDANTS).

The present article reviews several recent developments in the field of rubber chemicals of particular interest to practitioners. These topics include

(1) non-nitrosamine curatives as a response to health concerns and legislation
(2) reversion-resistance curatives to enhance product durability and support higher temperature cures
(3) silica-to-rubber coupling agents to support expanded use of silica filler
(4) nonstaining and persistent antidegradants for enhanced performance

Non-Nitrosamine Curatives

General-purpose rubbers are those made from the monomers isoprene, 1,4-butadiene, and styrene. Each isoprene and butadiene unit contributes one

carbon–carbon double bond to the final structure, plus a number of allylic hydrogen sites, which are the reactive centers for sulfur vulcanization. In sulfur vulcanization, polymer chains are connected by covalent bonds (cross-linked) of sulfur atoms or chains of sulfur atoms attached to the allylic positions of individual chains. The chemical components necessary for this process include the polymer(s) with allylic hydrogens, elemental sulfur or a source of sulfur, plus chemical promoters called accelerators and activators. In current practice, the curative promoter package typically employs a primary accelerator, one or more secondary accelerators, and zinc oxide and fatty acid (or a zinc fatty acid salt) activator. Several excellent reviews have been written detailing the chemistry involved between these ingredients and the influence they have on the development of final vulcanizate properties (1–9).

The benefits of an optimized sulfur vulcanization system are several: economical, good kinetics, and good performance. *Economical* in that sulfur is very inexpensive, and typical accelerators and activators are also low cost commodity chemicals. *Good kinetics* in that rapid cross-linking is achievable in a matter of a few minutes at usual curing temperatures of 130–180°C but that the rubber compound can withstand many minutes at processing temperatures often in the range of curing temperatures (ie, 100–140°C) before the onset of cross-linking.

The undesirable premature cross-linking of polymer chains in the processing step is called scorch; the ability of the vulcanization system to withstand the heat of processing without premature cross-linking is called scorch safety. This attribute of delayed action (scorch safety) with fast cure is unique to accelerated sulfur vulcanization, and allows for safe and rapid mixing and fabrication of rubber compounds and parts coupled with rapid cure.

Good performance derives from the structure of the cross-links as a blend of sulfur chain lengths, from one sulfur atom (monosulfidic) to two (disulfidic) to three or more, up to eight and more (polysulfidic). The differing chain lengths impart differing physical characteristics: shorter chain impart heat stability and resistance to permanent set, longer chain lengths impart tear resistance. The ratio of sulfur to primary accelerator controls cross-link length distribution, and thus can be used to tailor physical properties, even as the concentration of curatives controls cross-link density, itself a dominant contributor to compound properties such as modulus, strength, hardness, and abrasion resistance.

Figure 1 illustrates the curing process as measured by a rheometer. The rheometer follows the development of cure state as a function of time. Vulcanization characteristics such as minimum torque M_L (a measure of compound green viscosity), onset of cure (T1 pt rise), M_H (a measure of maximum cure state reached), and T90% cure (time required to reach 90% cure state) are valuable properties defining cure behavior. Likewise the rheometer cure profile can be broken into three regions of interest, an estimate of scorch safety, an idea of what the cure state development looks like during the cross-linking phase, and how the cross-linked vulcanizate network matures with additional heat.

Primary Accelerators. The primary accelerator of choice is a mercaptobenzothiazole sulfenamide of general chemical structure (**1**). Specific examples of this class are listed in Tables 1 and 2.

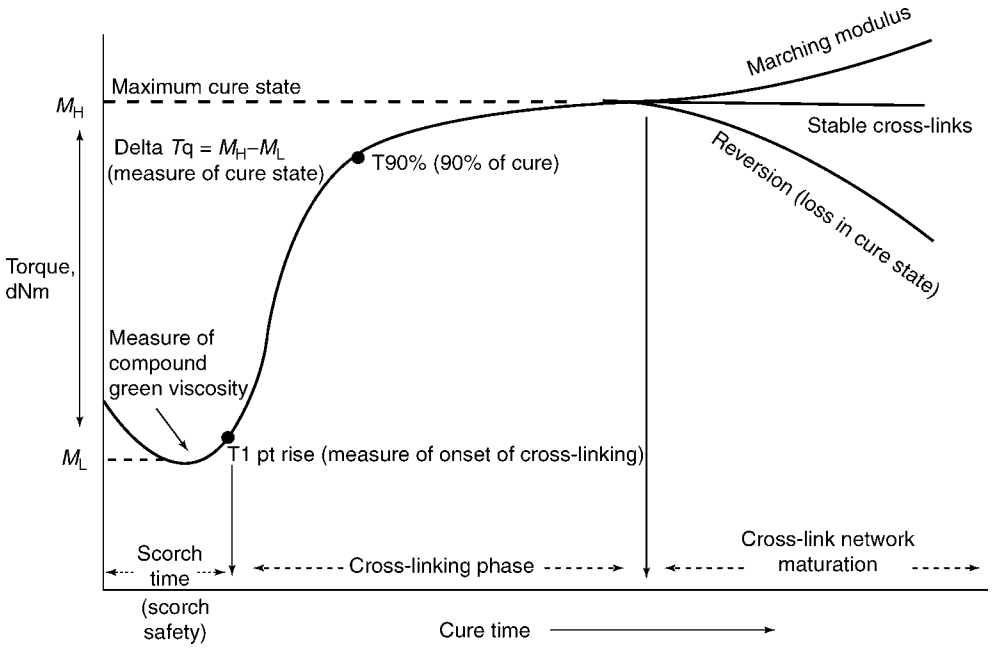

Fig. 1. Example of rheometer cure curve illustrating major cure attributes. To convert dNm to in lb, multiply by 0.885.

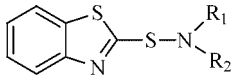

1

The sulfenamide S—N bond strength controls the scorch safety and cure rate. The more labile this bond, the more readily the active cure promoter mercaptobenzothiazole is released at the onset of the cross-linking process. A family of sulfenamides has been developed to span a range of cure rates. Common historical members of this class are shown in Table 3, arranged from fast curing to

Table 1. Nitrosamine-Generating Sulfenamides

slow, based on primary amines of weakening base strength (ie, a to b to c) and/or increasing steric hindrance (ie, c to d to e) (10).

German legislation targeting elimination of stable and volatile nitrosamines as by-products of vulcanization became effective in September 1988 as the "Technical Rules for Hazardous Materials TRGS 552" (11,12). It recognized 11 nitrosamines as carcinogenic and set industry limits to exposure. Nitrosamines are potent carcinogens in laboratory animal testing, and are suspect human carcinogens. The amines released from sulfenamide accelerators in the necessary early step of vulcanization can combine with nitrogen oxides (NO_x) in the atmosphere to produce nitrosamines. Primary amines form unstable nitrosamines that immediately decompose and do not constitute a health risk, whereas secondary amines produce stable nitrosamines by this process, $(R\text{-})_2\text{—N—N=O}$). The

Table 3. Sulfenamide Structure Influence or Cure Rate and Scorch Safety

MBS	100	100
MBSS	27% shorter	45% shorter
DIBS	7% longer	10% longer
Non-nitrosamine alternatives		
CBS	27% shorter	29% shorter
TBBS	15% shorter	22% shorter
DCBS	31% longer	30% longer

[a]Base compound: SBR, 50; polyisoprene, 50; N299 carbon black, 50; naphthenic oil, 28; stearic acid, 1; ZnO, 3; antioxidant, 1; sulfur, 1.75; sulfenamides at an equal molar level (4.74 mmol).
[b]Samples tested at 150°C.

immediate effect of the legislation was thus to target for elimination from vulcanization systems of all sulfenamides made from secondary amines able to form 1 of the 11 listed nitrosamines. The accelerators given in Table 1, MBS and MBSS (derived from morpholine) and DIBS (derived from diisopropyl amine), had to be replaced at least for European markets.

Compromise cure systems based on the faster and slower curing "non-nitrosamine" sulfenamides listed in Table 2 have been recommended as alternatives (12–14). The sulfenimide variant *N-tert*-butyl-2-benzothiazole sulfenimide (TBSI) was also produced to satisfy this need (15). As with DCBS the large steric hindrance associated with the sulfenimide slowed the reaction kinetics, resulting in slower cures and extended scorch safety.

Table 4 (16) makes a comparison of cure properties for the sulfenamides listed in Tables 1 and 2 relative to MBS. No exact replacements are available for MBS, MBSS, and DIBS, but DCBS can serve as an alternative for MBS and DIBS and CBS and TBBS can serve as alternatives for MBSS. Proper adjustments in sulfur and sulfenamide levels can provide similar cure performance. CBS and TBBS also satisfy the need in providing rapid curing kinetics where required. Additional scorch protection, if needed, can be obtained by application of the widely used scorch inhibitor *N*-(cyclohexylthio)phthalimide (17).

Secondary Accelerators. Even bigger changes have come to the secondary curative segment. Three classes of chemicals served historically as secondary accelerators, useful in low levels to speed up sulfenamide cures: the thiuram (**2**) and dithiocarbamate (**3**) types, and the guanidine type (**4**). Specific examples for these classes are listed in Tables 5 and 6.

Table 5. Nitrosamine-Generating Thiurams

Chemical name	Abbreviation	Chemical structure
Tetramethylthiuram disulfide	TMTD	Tetramethylthiuram monosulfide	TMTM	
Two workhorse members of the thiuram class, particularly active in cure rate as well as economical, are TMTD and TMTM (R= methyl, $x = 2$ and 1, respectively, in **2**). Both TMTD and TMTM are stable nitrosamine generators, as they liberate the secondary amine, dimethyl amine, during vulcanization (12,13). Replacements for these rubber chemicals has been a target of considerable technical effort in the rubber industry. Several candidates have emerged, each with its own attributes. None is a direct substitute for either TMTD or TMTM but several have proven

Table 6. Low or Non-Nitrosamine-Generating Thiurams, Dithiocarbamates, and Guanidines

[b] Base compound: SBR, 50; Polyisoprene, 50; N299 carbon black, 50; naphthenic oil, 28; stearic acid, 1; ZnO, 3; antioxidant, 1; sulfur, 1.75; sulfenamides at an equal molar level (4.74 mmol).
[c] Samples tested at 150°C.

useful in non-nitrosamine cure packages. Cure properties of likely replacements are compared to TMTD in Table 7 (16).

As secondary curatives, both TBzTD and IBT provide slightly longer cure times but have the advantage of prolonging scorch safety. A much closer match to TMTD is ZBzDC in both cure time and scorch time. When used at equal molar concentrations, significantly more weight of the non-nitrosamine replacements are required versus TMTD.

TBzTD and ZBzTD do, in fact, generate stable nitrosamines from the secondary amine dibenzyl amine; however, this nitrosamine is nonvolatile and is not readily released from the vulcanized product into the atmosphere. It is also considered noncarcinogenic (18). Therefore, these materials are considered non-nitrosamine in usage. IBT likewise generates a stable nitrosamine but its level has been claimed to be 100 times less than TMTD (19).

Sulfur Donors. A fourth class of sulfur vulcanization chemicals has been affected by the move to non-nitrosamine generators: the sulfur donors. These are organic chemicals which have a relatively high level by weight of sulfur atoms that are able to be donated in the vulcanization process to create sulfur cross-links. Elemental sulfur is the material of choice as a source of the sulfur atoms which create these cross-links, but some articles cannot tolerate free sulfur for requirements of color, solubility, or performance.

With regard to solubility, compounds which require a very high cure state may require more sulfur than can be supplied as elemental sulfur. Sulfur has a solubility limit of about 1 part per hundred rubber at room temperature (20) and at higher levels will "bloom," that is, crystallize out of solution onto the rubber compound surface, where it can be detrimental to processing, particularly to "tack," the ability of rubber to stick to itself or other rubber component in the building of a composite product. So-called insoluble sulfur has been developed as an alternative form of elemental sulfur: it has a polymerized long-chain structure ($-S_x-$) as opposed to crystalline sulfur (S_8 rings) (21,22). Insoluble sulfur can be substituted for crystalline sulfur and can be used at levels well above the solubility limits without bloom, in theory. In practice, however, insoluble sulfur will revert to soluble sulfur at the temperatures often attained in mixing and shaping rubber components, and thus can result in bloom in processing (23). Suffice it to say that some alternative forms for sulfur are sometimes needed for processing.

Table 8. Nitrosamine-Generating Sulfur Donors

Chemical name	Abbreviation	Chemical structure
4,4′-Dithiodimorpholine	DTDM	4-Morpholinyl-2-benzothiazole disulfide	MBSS	N-Oxydiethylenethiocarbamoyl-*N*′-oxydiethylenesulfenamide	OTOS	Tetramethylthiuram disulfide	TMTD	
Likewise, for performance, sometimes a sulfur donor is needed as well. Elemental sulfur gives rise to variable cross-link lengths, regulated to some extent by sulfur-to-accelerator ratio. In some applications, particularly those which require very high temperature and or oxidative stability, one may need a preponderance of cross-links of very low rank, mostly monosulfidic. For this purpose, organic sulfur donors may be useful (24).

Four conventional sulfur donor curatives employed historically are all nitrosamine generators, derived from either morpholine or dimethylamine, as shown in Table 8. The industry has developed non-nitrosamine substitutes, as shown in Table 9. As discussed earlier, TBzTD is used primarily as a secondary accelerator to further accelerate cure while offering good scorch protection. Similarly, IBT performs like TBzTD. CLD appears to be as active as DTDM in donating sulfur evidenced by its ability to generate the same cure state as DTDM when used at equal available sulfur levels. CLD however can introduce more scorch. These attributes are illustrated in Table 10 (16). TESPT has found value as a sulfur donor in what has been described as an equilibrium cure, or EC for short (25). The concept relies on the slow release of sulfur from TESPT during the curing process to control the reversion process illustrated in the rheometer chart of Figure 1. Rhenocure® SDT/S is a thiophosphite and thus not amine-based. It can be used where high levels of short cross-links of the mono- and di-type are desirable for long-term heat age stability (26). The Vultac® class of Table 9 has found uses in diene rubbers as partial or total replacement for sulfur (27). Benefits claimed include improvements in aging properties and promoting covulcanization of blends. Table 10 illustrates the sulfur-donating ability of the Vultac® class by showing Vultac® 7 provides a similar cure state as sulfur when used as a total replacement. One drawback is the introduction of scorch.

The rubber chemist has reacted vigorously to the challenge of eliminating volatile nitrosamine-generating chemicals in the workplace, even though many had been fixtures of the sulfur vulcanization process. Non-nitrosamine primary and secondary accelerators and sulfur donors are now available and used extensively.

Reversion-Resistance Curatives

Concomitant with the several benefits of sulfur vulcanization described above are certain deficiencies owing to the complexity of the formation of, and instability of, the sulfur cross-link system. Reversion is defined as the anaerobic (nonoxidative) degradation of sulfur-cured vulcanizates which results in a loss of compound performance. This phenomenon is generally associated with loss in cross-link density via thermal degradation of sulfur cross-links caused by heat and/or extraneous accelerator fragments (28,29). It occurs during overcure conditions, elevated cure temperatures (30), and severe service conditions (31). Reversion is most pronounced for natural rubber, which tend to lose cross-links and soften with heat and aging, whereas synthetics (polybutadiene, styrene-butadiene copolymers (qv)) tend to add cross-links and harden with heat and aging (see BUTADIENE POLYMERS).

Overcure, elevated cure temperatures, and severe service are all growing trends industrially, particularly for large tires as are used in over-the-highway trucks, off-the -road equipment, and aircraft tires, all of which also use a lot of natural rubber. Manufacturing efficiencies promote higher temperature cure conditions for better throughput. Tires are cured from heat applied at the outside (mold) and inside (bladder) surfaces. For tires with thick rubber cross sections, and given the poor thermal conductivity of rubber, a temperature gradient is produced from surfaces to interior. The surfaces may see significantly more total heat history than the interior. This may be so even allowing for slow cooling of the interior and continued cure of the inside after the tire is removed from the mold. Cure systems are tailored for individual components to try to balance the cure profile across the cross section, but a given thick tread may still be subjected to a broad range of heat inputs, so that only a portion of that one component will be optimally cured while a portion will be overcured. (No portion can be undercured without generating a useable product. Indeed, cure conditions are set so as to require all portions of the tire to achieve a minimum acceptable level of cure.) Tires, like other rubber goods, perform to ever higher levels: mileage, service life, and service conditions. Still, high operating temperatures and loads may impart reversion. Thus, there has been a growing interest in chemicals which inhibit the tendency to reversion of sulfur-cured natural rubber.

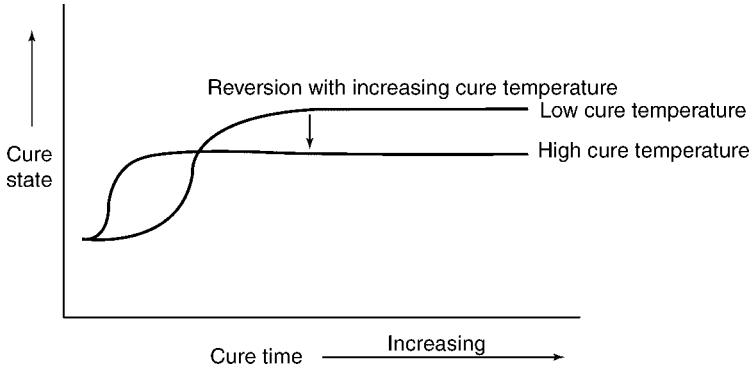

Fig. 2. Reversion during cross-link formation.

Reversion can occur during cross-link formation (high temperature cure) and after cross-link formation (overcure or in service). These are shown pictorially in Figures 2 and 3.

For processes which contribute to reversion seen during cross-link formation, several pathways can be envisioned contributing to loss in ultimate cure state development. As Figure 4 shows, these pathways most likely involve desulfuration or decomposition of intermediate polythio-sulfurating species or the polythio-benzothiazole cross-link precursor formed by the heat of the curing process. This decomposition pathway effectively reduces the concentration of active cross-linking agents resulting in lower cross-link density. Also at very high temperatures as cross-links are forming, they may, in a similar manner, be immediately desulfurated and decomposed.

In the development of maximum cure state, the initial cross-link structure, which may be high in polysulfides, goes through a rearrangement process in which the Zn-accelerator complexes, which promote curing, extrude sulfur from the initial cross-links and reutilize the extruded sulfur to form additional cross-links (29). After the maximum cure state is established with a desired proportion of polysulfide, disulfide, and monosulfide cross-links for compound performance, the network cross-link structures will continue to evolve with additional heat introduced

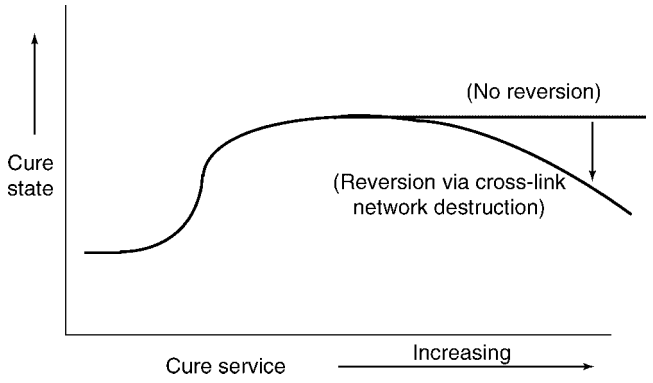

Fig. 3. Reversion after cross-link formation.

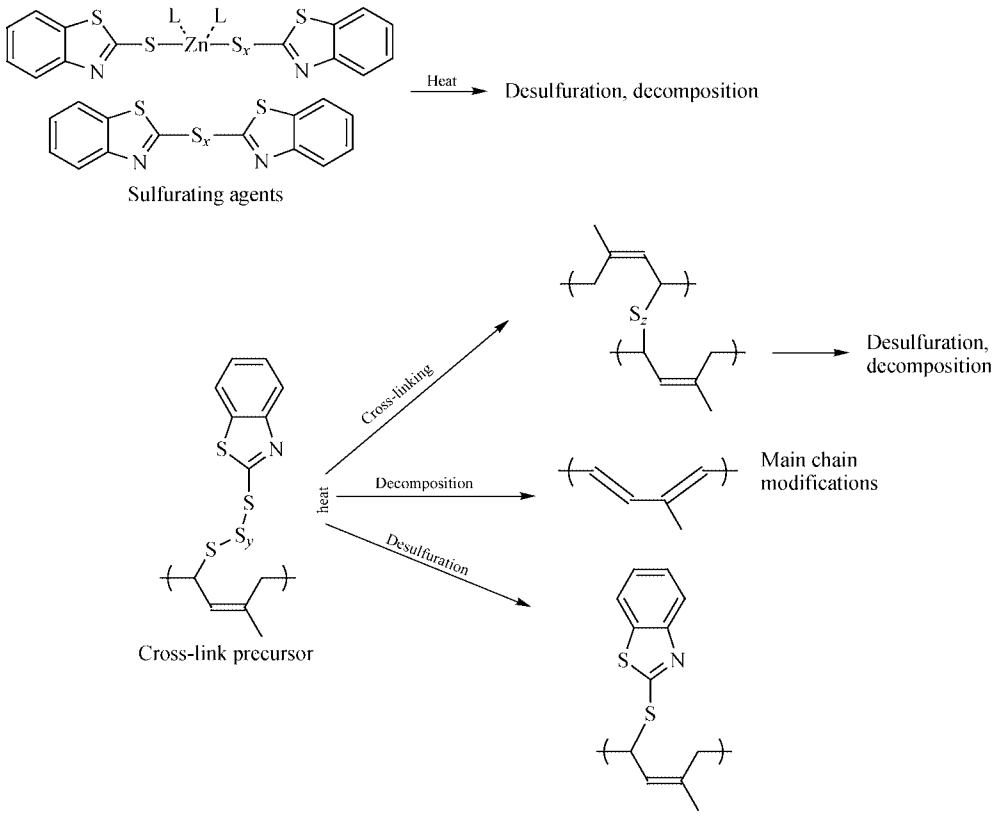

Fig. 4. Reversion pathways during cross-link Formation.

during an overcure situation (30) or during the service life of the compound (31). Figure 5 shows that this reversion process involves loss of polysulfide cross-links with the formation of more mono and disulfide types and finally decomposition of the mono and disulfidic types yielding modifications in the polymer backbone. Modifications would include carbon–carbon double bond rearrangement, growth of diene and triene structures, and isomerization of existing double bonds. For

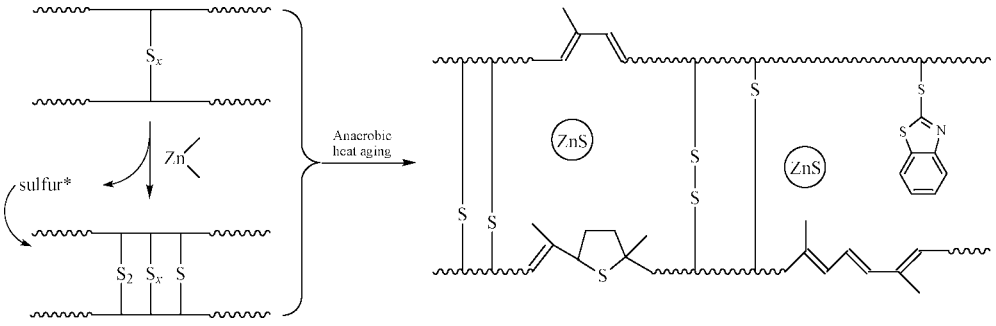

Fig. 5. Cross-link network maturation and reversion with heat from curing or high temperature service.

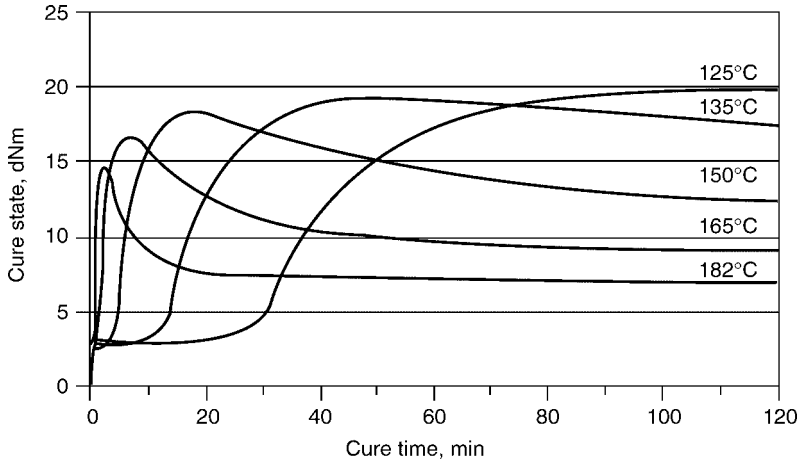

Fig. 6. Effect of temperature on cure rate and cure state. Base compound: NR, 100; N347 carbon black, 50; naphthenic oil, 8; stearic acid, 1; ZnO, 3; antioxidant, 0.75; sulfur, 3; TBBS, 0.75. To convert dNm to in lb, multiply by 0.885.

natural rubber, this results in creation of some trans double bonds in the otherwise all-cis structure. Additionally, unproductive (nonload bearing) cyclic sulfides increase in number in reversion: sulfur attached by both of its valences to neighboring segments of the same polymer chain. Zinc sulfide is produced as a stable but inactive by-product of both vulcanization and reversion. All these changes are followed by a drop in cross-link density (32–35).

The effect of cure temperature on the cure kinetics and cure state profile of a simple carbon black filled, sulfenamide/sulfur cured natural rubber compound is shown in Figure 6 (16). As shown in the growth of the cure state, an article which would require 110 min to cure to its maximum cure state at 125°C can be cured at 135°C in 50 min, at 150°C in 18 min, at 165°C in about 7 min, and at 182°C in about 3 min. However, the maximum state of cure achieved keeps dropping as cure temperature increases.

The same process continues beyond "optimum" or maximum cure state if cure is allowed to continue ("overcure"). Again, as seen in Figure 6, the cure state now drops from the maximum to attain a lower plateau. This decline is faster and more pronounced as cure temperature increases. The window of time for near-optimum cure narrows, and the regime of overcure grows.

Physical manifestations of reversion, beyond loss in cure state, include

(1) loss in resilience
(2) greater heat buildup
(3) loss in abrasion resistanec
(4) loss in wire adhesion
(5) initial increase then large loss in tear and fatigue resistance
(6) loss in modulus and hardness
(7) loss in tensile strength

How much of the decay in properties is due to cis–trans isomerization, cyclic sulfides, growth of dienes, reduction in sulfur rank, and reduction in total cross-link density is a subject of ongoing research, but all processes likely contribute.

Because of the large demands put on rubber compounds to address issues of increased productivity via high cure temperatures or increased service temperatures brought about by overloads and high speeds, reversion-resistance chemicals are now becoming part of the compounder's arsenal to combat reversion issues.

Reversion-resistance chemicals operate by one of two mechanisms:

(1) Relink polymer chains to maintain cross-link density. These may be via sulfur or non-sulfur covalent bonding.
(2) Form heat stable cross-links that are more resistant to scission than conventional sulfur cross-links. These may or may not contain sulfur.

Several rubber chemicals have been developed to inhibit or compensate for sulfur cross-link reversion. Several of these are shown in Table 11.

MPBM operates under the mechanism of forming heat-stable cross-links. It has been reported that the network structures formed with MPBM are not prone to revert (36,37) and offer heat resistance during high temperature curing and overcure. Detailed mechanistic studies have found the major reactions occurring during vulcanization in sulfur-containing systems to be 1,2-cross-linking of the imide double bond across polymer chains generating a heat-stable carbon–carbon cross-link. Additional reactions included homopolymerization, copolymerization giving multiple cross-links, and Michael addition reactions with 2-mercaptobenzothiazole and amines derived from sulfenamide curatives as well as other extraneous sulfur species formed during cure (38).

BCI-MX also provides its heat-resistant performance by the formation of carbon–carbon cross-links but does it by the mechanism of relinking polymer chains to maintain cross-link density (38,39). The relinking mechanism takes place only during reversion when sulfur cross-links are broken and in their place cyclic sulfides, dienes, and trienes are formed along the polymer backbone (16,35). The structural differences of BCI-MX from MPBM prevent it from undergoing the reactions discussed about MPBM. Instead, the citraconimide group undergoes a Diels–Alder addition reaction with these chain modifications to relink polymer chains and compensate for the lost, reverted, sulfur cross-links (39–41). For BCI-MX to be effective, some initial reversion must take place. This is nicely illustrated in Figure 7 (16) which shows the reversion characteristics of BCI-MX versus the same compound with no BCI-MX added.

As discussed earlier, TESPT functions as a reversion-resistant chemical by the slow release of sulfur to compensate for cross-links lost (25). It has also been found that TESPT leads to higher levels of monosulfidic cross-links (42), which yields improved reversion (thermal aging) resistance (43,44).

Both HTS and BDTCH can be classified as proceeding through the mechanism, which forms heat-stable cross-links that are more resistant to scission. The cross-link has been referred to as a hybrid cross-link in which a hexylmethylene dithio group $-S_n-[(CH_2)_6-S_x]_k-$ is the bridging group between two polymer chains (45–49). In this scheme, k is presumed to be small. At high sulfur

Table 11. Anti-Reversion Agents

Chemical name	Abbreviation	Chemical structure
N-*N*′-*m*-phenylenedimaleimide	MPBM	1,3-Bis(citraconimidomethyl) benzene	BCI-MX	Bis(3-triethoxysilylpropyl)tetrasulfane	TESPT	Hexamethylene bis-thiosulfate disodium salt dihydrate	HTS	$NaO_3SS(CH_2)_6SSO_3Na\ 2\ H_2O$
Mixture of zinc salts of aliphatic and aromatic carboxylic acids	Activator® 73	 R = aliphatic–aromatic mix
1,6-Bis(*N*,*N*-dibenzylthiocarbamyldithio)hexane	BDTCH	Trifunctional acrylate coagent	Sartomer SR534	

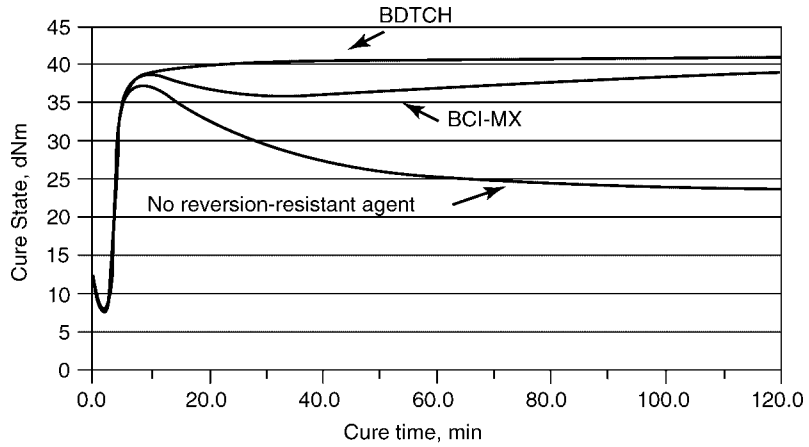

Fig. 7. Example of reversion-resistant agent effect on reversion (cure temperature 165°C). Base compound: NR, 100; N347 carbon black, 50; naphthenic oil, 8; stearic acid, 1; ZnO, 3; antioxidant, 0.75; sulfur, 3; TBBS, 0.75. To convert dNm to in lb, multiply by 0.885.

levels both n and x would be greater than 1. As reversion proceeds, the number of n and x sulfur atoms would be reduced to one resulting in a hybrid cross-link with monosulfide linkages for thermal stability and the hexylmethylene bridge to add flexibility to the cross-link for improved tear and fatigue properties. Figure 7 illustrates the reversion-resistant capabilities the hybrid cross-link can offer.

Since Activator 73 A is a mixture of zinc salts of linear aliphatic and aromatic carboxylic acids (50), it would be expected that the mechanism of action would be similar to zinc stearate, which can extract sulfur from polysulfidic cross-links and reuse that sulfur to generate more cross-links (51). Ultimately this would result in a network structure high in monosulfidic content (42).

Trifunctional acrylates, such as Sartomer SR534, have been found to provide reversion-resistant protection (52). Test results of the three trifunctional acrylate and methacrylate monomers, pentaerythritol triacrylate, trimethylolpropane trimethacrylate, and trimethylolpropane triacrylate, versus BCI-MX prove interesting (53). Rheometer traces of cure development and reversion characteristics with these trifunctional monomers duplicated BCI-MX behavior even to the point of having initial reversion chemistry occurring before they became active. This would suggest these materials operate by the same mechanism as BCI-MX.

To conclude this section, the rubber chemist has vigorously pursued materials and means to inhibit and counteract the tendency to reversion, so as to permit higher temperature cures, buttress rubber goods against overcure, and permit increasingly greater operating conditions and service lifetimes.

Silica-to-Rubber Coupling Agents

Rubber must be cross-linked to be technologically useful, hence the emphasis historically and in the two sections above, on chemicals to facilitate and optimize this process. However, even cured rubber is practically of little value unless the rubber

is reinforced by a particulate filler (see FILLERS). Cured, unfilled ("gum") rubber has very low tensile strength, and poor tear and abrasion resistance. Contrast a pencil eraser or a rubber band to a tire tread or transmission belt, for example. The early tires and rubber goods were "filled" with inert fillers such as zinc oxide. The discovery about a century ago that carbon black (qv) greatly enhanced rubber performance began the evolution of tough durable goods made from rubber. It turns out that very few other substances reinforce rubber as does carbon black. None do at the same cost. Hence, even today, carbon black is the dominant reinforcing filler for rubber, even as talc, calcium carbonate, kaolin clay, and other lower cost, nonreinforcing fillers retain uses in selected nontire applications.

The characteristics shared by reinforcing fillers are few but vital:

(1) Small hard particles, with diameters upon ultimate dispersion below micron size
(2) Ability of said particles to disperse in the rubber medium
(3) Ability of said particles to interact with themselves, so as to produce an independent filler network, which interpenetrates with and synergistically supports the polymer network. This attribute is called "filler/filler interaction."
(4) Ability of said particles to interact with the polymer matrix. This attribute is called "polymer/filler interaction."

Carbon Black. Carbon black (qv) has all of these characteristics. Carbon black is amorphous elemental carbon with a graphitic-like microcrystalline substructure (54). The furnace process rubber grades come in a range of particle and aggregate sizes and shapes, with reinforcing grades in the 10–100 nm ultimate particle diameters. Carbon black disperses very well in general-purpose rubbers, with which it shares an organic chemical nature. It has a strong self-affinity; once a sufficient loading is achieved in a rubber matrix, it imparts electrical conductivity to the composite via the filler network, for example. This filler network is also responsible for the enhanced low strain dynamic stiffness of filled rubber, and the loss (recoverable upon relaxation) of this stiffness with strain. This phenomenon is called the Payne effect (55). Finally, and most importantly, carbon black has a strong affinity to general-purpose rubbers, as a function of attributes built into the carbon black in its manufacture ("surface activity") and the unsaturated organic structures of the polymers, such as carbon–carbon double bonds, and styrene units.

Much has been written on the nature of the carbon black/rubber interaction, which is still not fully understood (selected references include References 56–59). One thing is clear: carbon black has a strong affinity to general-purpose rubbers. It is manifest in the simple experiment called "bound rubber" or "insoluble polymer" measurement. A sample of uncured rubber, which may or may not be devoid of rubber chemical additives, is admixed with an amount of reinforcing carbon black. The composite is then immersed in a solvent in which the polymer is soluble. Whereas all, or all save any gelled portion, of the unfilled rubber dissolves in the solvent, the same polymer, as a carbon black filled composition, produces only a portion of soluble polymer. For a typical recipe containing 30–50 parts by weight

of carbon black per hundred parts rubber, a typical value for the nondissolved or bound polymer might be 20–40%. Empirically, the quantity of bound rubber correlates with abrasion resistance, or tread wear for a (subsequently cured) tire tread compound (60). Bound rubber cannot be measured on cured rubber, of course; all but a fraction of a percent will be bound in that case, regardless of the type or amount of filler. But the phenomenon of polymer/filler interaction, measured in the uncured state, carries forward to the cured compound and product, in many toughness and resilience related properties.

The search for alternative reinforcing fillers to carbon black has continued for decades, and has recently produced one material which offers in selected applications, even greater performance: precipitated silica.

Silica. Silica (a mineral with a repeat unit of SiO_2) is, in its crystalline form, as quartz and sand/sandstone, the most abundant compound on the earth's crust. Synthetic silica can be produced by a fumed process via silicon tetrachloride, $SiCl_4$, or aqueous process, via sodium silicate, itself made from natural silica. The product of the aqueous process is precipitated in an amorphous form, which provides two of the attributes of a reinforcing filler: small particle size and high degree of self-affinity or networking. The self-affinity is due to hydrogen bonding between surface silanol groups (Si—OH), which are present in large amount (5–7 per nm^2) on the surface. Fumed silica has much fewer surface silanol groups. A representation of the silica surface is given in Figure 8.

In the early 1990s, a new generation of precipitated silicas was developed: the so-called highly dispersable silicas (HDS) (61–65). This class provides another vital attribute of a reinforcing filler for rubber: easy dispersability at high loadings to submicron sizes.

The remaining attribute, polymer/filler interaction, is inherently missing from silica but can be provided by the use of a specific class of rubber chemicals, the silica-to-rubber coupling agents. Silica-to-rubber coupling agents have been known since the 1960s, and had permitted limited use of silica filler, much of this in nonblack mechanical goods and shoe soles. Use in tires was restricted to low levels in skim compounds for wire adhesion and treads for cut resistance. A good review of the state of the technology in the mid-1970s is given by Wagner (66).

With the advent of HDS, the ability to disperse silica to levels equal to that of carbon black is now possible for the creation of highly silica-filled rubber compounds. Thus, there has been a revolution in growing use of silica in place of carbon black in tires since the early 1990s, requiring growing use of specific coupling agents, whose number and chemistries have also expanded in this time period. A description of this class of rubber chemicals follows.

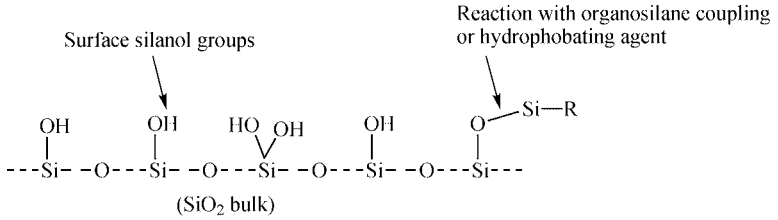

Fig. 8. Silica surface chemistry.

The predominant chemical class of silica-to-rubber coupling agents are the functionalized silane esters of general structure **5** (where typically R = Me, Et, $n = 3$; R″ = propylene [—$(CH_2)_3$—]; and X is a variable function). Many of these were developed in the mid-1970s (67).

$$(RO)_n(R,)3-n—Si—R"—X$$

5

The most commonly used silane coupling agents (qv) for rubber are shown in Table 12.

All Silane Coupling Agents (qv) work by a twofold bonding mechanism (68–70):

(1) The silane ester moiety hydrolyzes because of heat and moisture present on the surface of the silica (RO—Si → HO—Si) and the then-formed silanol condenses with a silanol group on the silica surface to produce a siloxane bond linking coupling agent to silica (—Si—O—Si—).

(2) The functional group (X above) on the other end of the coupling agent reacts directly either with the polymer chain or with the vulcanization system so as to provide a covalent bond between the coupling agent (already attached to silica) and the polymer.

Step 1, reaction with silica, occurs in the mixing (with heat) of the silica, rubber, and coupling agent. The polymer is as yet uncured and not bonded to the filler. This step is called *hydrophobation*: the hydrophilic silanol containing surface is converted to a hydrophobic organic modified surface. The silica loses much of its self-affinity by this process, rendering it more compatible with rubber. The Payne effect is reduced and may be nearly eliminated if hydrophobation is thorough.

Step 2, reaction with polymer, occurs in the vulcanization step (with heat, after curatives have been added in a *lower* temperature stage addition). Figure 9 shows the two-step coupling mechanism in the general case.

A subclass of silane rubber chemicals exists in which the "X" function of structure **5** is replaced by an inert alkyl group, creating a silica-reactive but non-coupling process aid, of the general formula **6** (where R′ = C1—C18 *n*-alkyl). These materials can be very effective in reducing compound viscosity and the Payne effect (71) but do not themselves provide cured compound reinforcement. A selected series of alkyl silanes is shown in Table 13. Alkyl silanes may be used in conjunction with coupling agent silanes to balance processability and cured performance.

$$(RO)_3\text{-Si-R'}$$

6

The nature of function "X" is dependent on the nature of the cure system. Historically, the methacrylate function was used for peroxide-cured rubber and the mercapto function was first used for sulfur-cured rubber (see *a* and *b* in Table 12). Definitive studies of the role of coupling bonds on physical properties

and tire performance of silica-filled tire rubber compounds was done by Wagner using these two coupling agents (72).

Several other silanes were originally used to adhere rubber to glass substrates as well as applied to various rubbers with mineral fillers such as clays. Some of these are given in Table 12 as well.

Despite the performance benefits of mercaptosilane, serious drawbacks limited its use in tires: a strong and bad odor, plus a large reduction in scorch safety, resulting in inability to process the rubber. The mercapto group was simply too reactive to the rubber, when combined with sulfur and curatives. Cross-linking would initiate in mixing or extrusion.

In the 1970s, the first step change improvement in coupling agents for sulfur-cured rubber, as used in tires, came with the development of the tetrasulfide silane, TESPT (see *c* in Table 12) (67,68). Now, the mercaptan function was protected in the form of a polysulfide. To generate the active mercaptan, a sulfur–sulfur bond cleavage was needed. By analogy to the generation with scorch safety of mercaptobenzothiazole (MBT) by the cleavage of the disulfide MBTS, the tetrasulfide silane imparted scorch safety yet retained polymer reactivity of the mercaptosilane.

TESPT remained the industry standard coupling agent for sulfur cured rubber into the 1990s. With the development of HDS came expanded applications for silica-based compounds, particularly in high performance passenger tire treads which needed a combination of tread wear, low rolling resistance, and good wet traction (73). This combination of performance attributes can be simultaneously optimized to unique levels with silica. Recipes with 50–100 phr silica were now permissible and desirable.

As silica technology expanded to meet market performance targets, certain processing deficiencies grew in importance, and remedies through materials development emerged and continue to do so presently.

First, it became apparent that highly silica-filled compounds, even using HDS, required longer mixing times and processed worse than their carbon black counterparts (extrusion, tire building). It became clear that TESPT itself did not have sufficient scorch safety for all operating conditions; the middle sulfur–sulfur bonds in the polysulfide bridge are relatively weak and can be broken, liberating elemental sulfur to impart scorch. TESPT is a known sulfur donor curative, after all. So, the market for TESPD expanded (see *c* and *d* in Table 12). The stronger sulfur–sulfur bonds in TESPD provided extra processability in production while retaining necessary polymer reactivity.

The newest sulfur silane coupling agent, NXT (see *e* in Table 12) (74,75) carries this approach even further. A substituted carbonyl group is used to protect a mercaptosilane during processing and reaction at the silanol end with the silica (**7**), deprotection occurs during cure, catalyzed by curatives, to release active mercaptan function (**8**), which, through reactions with the vulcanization system, bonds to polymer (**9**), as shown below.

7

8

9

The rubber chemist has recognized and reacted to the growing trend to employ silica as reinforcing filler for rubber with development of multiple silane ester coupling agents and alkyl silane process aids for improved processability and performance.

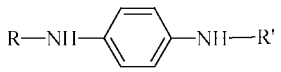
Nonstaining and Persistent Antidegradants

General-purpose rubbers are susceptible to degradation by atmospheric oxygen (O_2) and ozone (O_3).

Chemical antioxidants (qv) act to preserve rubber from degradation by molecular oxygen. This degradation is manifest in hardening (cross-linking) for polybutadiene and SBR and initial softening (chain scission) than hardening for polyisoprene rubber (natural or synthetic). All rubbers lose tensile strength and cut and tear resistance due to oxidation as well. Antioxidants inhibit the free-radical autoxidation cyclic chain reaction process via several mechanistic pathways. The primary antioxidants scavenge polymer carbon and hydroperoxy radicals by donation of an active hydrogen. Secondary antioxidants decompose hydroperoxides. A review is available, with attendant references to the historical development of antidegradants and their mechanisms of action in rubber (76). Autoxidation and antioxidant mechanisms have also been reviewed (77,78).

The hydrogen-bonded intermediate complex of a hindered phenolic antioxidant with a stable aminoxyl radical (TEMPO), used as a model for a hydrocarbon oxidant, has been isolated and its structure determined, as confirmation of the radical scavenging mechanism (79).

The principal classes of primary antioxidants for rubber remain the phenolics (nonblack articles) and amines (black-filled articles). Among the amine types are the substituted diphenylamines, *para*-phenylenediamines (PPD, (**10**), where R,R′ = alkyl or aryl), and polymeric trimethyl-dihydroquinoline (TMQ). Representative phenolic antioxidants are given in Table 14, and selected amine antidegradants are given in Table 15. The majority of tire and mechanical goods made from general-purpose rubbers are protected by the phenolic and amine antioxidants.



10

Macroscopically, ozonation leads to cracking of the rubber surface and ultimate product failure. A polar mechanism was proposed by Criegee for ozonation of unsaturated hydrocarbon rubbers, with addition of ozone to the carbon–carbon double bond followed by decomposition of the intermediate ozonide leading to cleavage of the polymer chain (80). Polymers without carbon bond unsaturation in the backbone do not crack in the presence of ozone. Zhang recently proposed a free-radical mechanism and attributed PPD antiozonant activity to its low ionization potential and ability to quench polymer radicals (81).

The PPD class of antidegradants provides by far the best antiozonant protection (for a review of antiozonants, see Reference 82). PPDs inhibit ozone degradation of rubber by multiple mechanisms (76,83–85):

(1) Migration to the surface of the rubber article
(2) Competitive reaction with and scavenging of ozone at the surface

(3) Formation, through its reaction products with ozone, of a protective film at the rubber surface

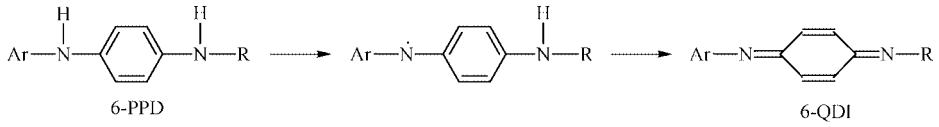
(4) Increase in the critical stress of the rubber article. The critical stress is the applied static stress at which ozone cracking appears on the surface of a rubber article exposed to ozone.

N-(1,3-dimethylbutyl)-*N*′-phenyl-*p*-phenylenediamine; abbreviated 6-PPD, is a particularly versatile chemical offering a blend of antioxidant and antiozonant behavior combined with good rubber solubility and modest volatility, although other PPDs have applications as well. The diaryl PPDs have limited rubber solubility but lower volatility than 6-PPD. They provide excellent antioxidant protection and decent persistence with diminished antiozonant protection.

All PPDs are highly staining and discoloring. This behavior is not necessarily a problem in carbon black filled articles, but restricts usage in colored goods—or even tires with colored components.

Two long-standing deficiencies with the PPD antidegradants, lack of persistence and discoloration/staining, have been addressed, respectively, in recent additions to the field: 6-QDI, a dehydrogenated PPD, and TAPDT, a trimeric, high MW form of PPD.

6-QDI (*N*-(1,3-dimethylbutyl)-*N*′-phenyl-*p*-quinonediimine, Table 15) offers improved persistence because of its partial immobilization and binding to the polymer matrix during mixing (86,87). As an efficient radical trap, 6-QDI acts as a chemical peptizer to reduce natural rubber chain length and viscosity in mixing by capping cleaved polymer chain end radicals. 6-QDI still provides chemical antidegradant protection similarly to its hydrogenated parent, 6-PPD, and is considered to be produced *in situ* from 6-PPD as part of the latter's mechanism of action in the cured rubber compound, as shown in equation 1 (88,89). 6-QDI is also reported to preserve sulfur network rank stability better than 6-PPD and impart improved abrasion resistance to a natural rubber tread compound relative to PPD and TMQ antidegradants (90).



(1)

TAPDT [2,4,6-tris-(*N*-1,4-dimethylpentyl-*p*-phenylenediamino)-1,3,5-triazine, Table 15 provides reduced discoloration as a result of its increased molecular size which imparts reduced mobility in the rubber matrix (91). Discoloration results from bloom of ozonation by-products of the antidegradant to the rubber surface. PPD containing compounds will stain adjacent compounds in a composite structure because of migration of the PPD. An example is a black sidewall protected by PPD staining the white sidewall of a tire. TAPDT does not

migrate like the monomeric PPDs. TAPDT gives excellent static ozone protection, flex resistance, as well as antioxidant behavior, but does not provide the same level of dynamic ozone protection (protection to product under stress, such as in cyclic flexing) as the monomeric PPDs (91). Blends of TAPDT and 6-PPD have been shown to give excellent overall protection and durability (91).

A new partially graftable, aminic PPD of unspecified structure was recently presented as another means to nonstaining antidegradant protection for rubber (92).

In summary, the field of rubber chemicals is both mature and ever evolving. Recent advances and changes have been prompted by environmental concerns, the move to higher efficiency cures and processing, the pursuit of more durable rubber products, and the growth of silica as a reinforcing filler.

RUBBER COMPOUNDING

Introduction

Rubber compounding is the complex, multidisiplinary science of selecting and blending the appropriate combination of elastomers and other ingredients to meet the performance, manufacturing, environmental, and cost requirements for rubber goods made and used in commerce. There is a wide variety of elastomers and ingredients that are available in making rubber goods, which include all of the following types of products: tires, innertubes, retreaded tires, footwear, rubber rolls, hoses, belts, weatherstripping, O-rings, seals, diaphragms, tubing, rubber and latex gloves, ball bladders, medical devices, bumpers, and numerous other products. This is a review of the basic materials used in designing many common types of rubber products. The development of the combination of materials contained in a usable rubber compound involve many disciplines that include chemistry, physics, mathematics, and polymer science. In many cases, classical scientific methods can predict the interaction effects and estimate the properties expected from rubber compounds. However, discovery and development of new materials that modify the rubber compound to produce new, useful, and beneficial properties are appearing regularly. Also, environmental concerns are creating an interest in utilizing recycled rubber products into new rubber compounds.

Compounding Hierarchy

Compounding is a term that has evolved within the plastics and rubber industry and in many respects is a misnomer for the material science of modifying a polymer or polymer blend through addition of other materials to achieve a set of mechanical properties for a specific service application. Compounding is therefore a highly

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

complex science involving many traditional disiplines such as organic chemistry, polymer chemistry, materials physics, mathematics, and engineering mechanics.

There are some excellent reviews and discussion papers on the science of rubber compounding (1–8). The purpose of this discussion is to provide an introductory overview of the range of materials used by the materials scientist in compounding elastomers. In designing or making the selection of ingredients for use in a rubber article, the technologist relies upon published literature, experimental work, competitive benchmark information, and various information sources such as raw material supplier data, technical documents, and reports. Raw materials for a compound are generally selected in the following order:

(1) polymer (natural or synthetic rubber)
(2) fillers or reinforcing agent
(3) antioxidants and antiozonants
(4) plasticizers or oils
(5) bonding agent or adhesive (if needed)
(6) tackifer (if needed)
(7) vulcanization system [curing agent, accelerator(s), or coagent]

Performance requirements of the final product often dictate which specific type of elastomer can be used. The expected usable life for the product is controlled by many factors such as end-customer needs, competitive situation in the marketplace, safety, and reliability. Rubber products are almost always used as a functional part of another system. For example, tires, hoses, belts, O-rings, and numerous rubber components are used in manufacturing automobiles and trucks. The overall life of the vehicle as well as its performance level often relates to the service life or quality level of the rubber parts.

Elastomers Used in Rubber Compounding

Elastomers can be divided into two general categories, natural rubber and synthetic rubbers. Synthetic elastomers in turn are either termed *general purpose rubbers* (GPR) or *special purpose rubbers*. Natural rubber is generally obtained from southeast Asia or Africa. Synthetic rubbers are produced from monomers obtained from the cracking and refining of petroleum. The most common monomers are styrene, butadiene, isoprene, isobutylene, ethylene, propylene, and acrylonitrile. There are monomers for specialty elastomers which include acrylics, chlorosulfonated polyethylene, chlorinated polyethylene, epichlorohydrin, ethylene–acrylic, ethylene–octene rubber, ethylene–propylene rubber, fluoroelastomers, polynorbornene, polysulfides, silicone rubber, thermoplastic elastomers, urethanes, and ethylene–vinyl acetate.

Elastomers can be classified by their heat resistance and resistance to swelling (Fig. 1). The Society of Automotive Engineers (SAE) has developed a specification, SAE J200 (9), for classifying special-purpose elastomers by swelling in a special oil denoted IRM 903, which replaced ASTM (American Society for Testing and Materials) Number 3 (10). Properties for evaluating elastomers include

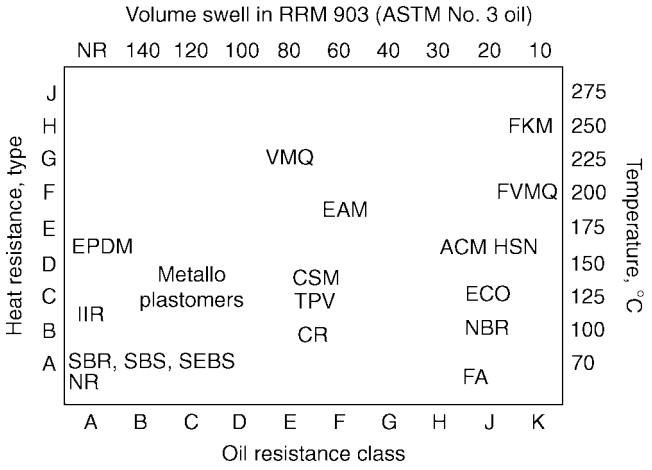

Fig. 1. SAE J200 classification systems for IRM 903 (ASTM No. 3) oil, where, for volume swell, NR = no requirement. Polymer abbreviations are defined in Table 1 (9,10).

hardness, tensile strength, change in tensile strength, elongation, and change in volume, tensile strength, and hardness after exposure to IRM 903 oil. However, probably the most effective classification system has been published by the International Standards Organization in specification ISO 1629 (11). Polymers containing residual unsaturation such as polybutadiene have abbreviations ending in —R (eg, BR), methylene containing polymers ending in —M (eg, ethylene propylene diene monomer, EPDM), silicone rubbers ending in —Q, oxygenates ending in —O, and urethanes ending in —U. A list of International Institute of Synthetic Rubber Producers (IISRP) abbreviations are shown in Table 1 (12). Table 2 displays typical general physical properties for a selection of the different types of elastomers including specifc gravity, hardness, tensile strength, and ratings for resilience, compression set, and permeability.

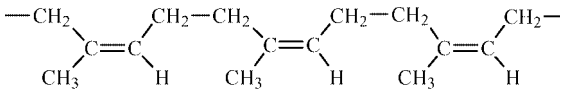
Natural Rubber. Natural Rubber is a biological homopolymer of isoprene and has the general structure illustrated in equation 1. The principal producing countries are Malaysia, Indonesia, Thailand, India, China, and Sri Lanka (see RUBBER, NATURAL). New sources are also being developed. To obtain natural rubber (NR), the Hevea brasiliensis tree is tapped for its sap. An off-white sap is collected and is coagulated by the addition of a strong acid such as sulfuric acid. The tapped latex consists of between 30% and 35% rubber, 60% aqueous serum, and 5 to 10% of other constituents such as fatty acids, amino acids and proteins, starches, sterols, esters, and salts. Some of the nonrubber substances, such as lipids, carotenoid pigments, sterols, triglycerides, glygolipids, and phospholipids, can influence the final properties of rubber such as compounded vulcanization characteristics and classical mechanical properties. Natural rubber is predominantly of the cis structure though the trans isomer, or *Gutta Percha*, can be found in latex tapped from the trees of the genus *Dichopsis*.

There are several systems that define the quality and uniformity of natural rubber. One system of grading natural rubber is based on form and visual observation of color and cleanliness. This is known as the International Natural Rubber Specification. The principal types and grades presented in Table 3 (13).

Table 1. IUPAC Nomenclature for Selected Elastomers[a]

AU	Polyester urethane
BR	Polybutadiene
BIIR	Brominated isobutylene–isoprene (bromobutyl)
CIIR	Chlorinated isobutylene–isoprene (chlorobutyl)
CPE	Chlorinated polyethylene
CR	Chloroprene rubber
CSM	Chlorosulfonyl polyethylene
EAM	Ethylene–vinyl acetate coploymer
EPDM	Terpolymer of ethylene, propylene, and a diene with a residual unsaturated portion in the chain
EPM	Ethylene–propylene copolymer
EU	Polyether urethane
HNBR	Hydrogenated acrylonitrile–butadiene rubber (highly saturated nitrile rubber)
IIR	Isobutylene–isoprene rubber
IR	Synthetic polyisoprene
NBR	Acrylonitrile–butadiene rubber
SBR	Styrene–butadiene rubber
E-SBR	Emulsion styrene–butadiene rubber
S-SBR	Solution styrene–butadiene rubber
X-NBR	Carboxylated nitrile–butadiene rubber
X-SBR	Carboxylated styrene–butadiene rubber
YSBR	Block copolymers of styrene and butadiene

[a] From Ref. 12.



cis-Polyisoprene (1)

Malaysian and Indonesian natural rubber growers have established a system based on technical characteristics. A summary of the standard technical specification scheme shown in Table 4 for natural rubber can be found in ISO 2000 (14,15). In addition to the solid form of natural rubber, it is available as a suspension in water and is known as latex. Synthetic rubbers are also available in latex form. Latex has become an important commodity used in the manufacture of dipped goods for pharmaceutical applications. The principal uses of natural rubber are as follows: tires and tire retreading, 70%; latex (eg, gloves), 12%; mechanical goods, 9%; load-bearing components, 4%; and other, 5%.

Styrene–Butadiene Rubber. Styrene–butadiene rubber (SBR) is made by either an emulsion or solution process (eq. 2). The classification systems for emulsion SBR is shown in Table 5. In the emulsion process, it is more difficult to control polymer microstructure and the final product is not as pure as the solution form. However it tends to show a higher tensile strength and tear strength, and is easier to process. It is used in applications such as tire treads, sidewalls, bead

Table 2. Physical Properties of Elastomers[a]

Elastomer[b]	Specific gravity	Hardness Shore A	Tensile strength,[c] MPa[d]	Elongation,[c] %	Resilience[e]	Compression set[e]	Impermeability to gases[e]
NR	0.93	30–100	27.6	750	E	G	F

[e] E = excellent; G = good; F = fair, and P = poor.

Table 3. Selected Categories of Visually Inspected Natural Rubber[a]

Type	Grade	Description
1	Ribbed smoked sheet	Coagulated sheets, dried and smoked latex. Five grades are available
2	White and pale crepe	Coagulated natural rubber latex milled to produce a crepe
3	Estate brown crepe	Fresh lump and other high quality scrap generated on the plantation
4	Compo crepe	Lump, tree scrapes, and smoked sheet cuttings milled to a crepe
5	Thin brown crepe	Unsmoked sheet, wet slab, lump, and other scrap from estates and small holdings
6	Thick blanket crepe	Wet slab, lump, and unsmoked sheets milled to give a crepe
7	Flat bark crepe	All types of scrap natural rubber including earth scrap
8	Pure smoked blanket crepe	Milled smoked rubber derived exclusively from ribbed smoked sheet

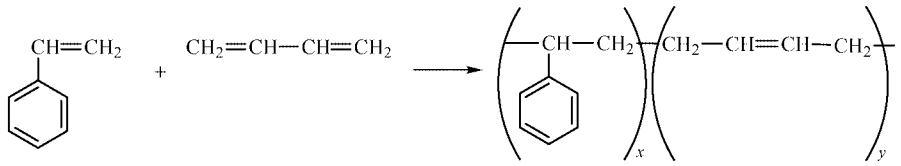
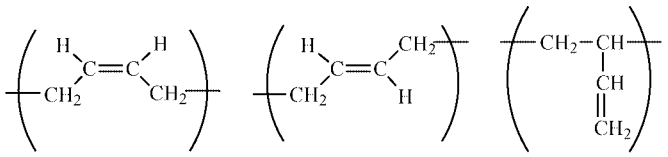
wire insulation, ply and breaker compounds of bias tires, conveyor belt covers, and other industrial products not requiring oil resistance.



Styrene Butadiene (2)

Solution SBR is classified as shown in Table 6. The principal use of solution polymerized SBR is in the tire industry as a major component of passenger and light truck tire treads (see STYRENE-BUTADIENE COPOLYMERS). It is also finding application in radial medium truck tire drive axle tire tread, aircraft, farm tire treads, and large, off-the-road tires. It can replace emulsion SBR in ply compounds and even in sidewalls where a lower modulus is required. SBR uses in North America are tires, 75%; automotive mechanical goods, 8%; and other, 17% (14). Important properties of SBR are relatively low cost, good physical properties with the proper reinforcing agent, good abrasion, and skid resistance. A deficiency of SBR is its tendency to have fairly high heat generation (hysteresis).

Polybutadiene. The many forms that can result from the polymerization of butadiene, depending on the catalysts used, include high cis, medium cis, low cis, trans, and high vinyl polybutadiene (BR) as illustrated in equation 3 (see BUTADIENE POLYMERS). The property of polybutadiene of most interest to the rubber compounder is abrasion resistance coupled with good resilience (14). The polymer has very high rebound and low heat-generation values. With a few exceptions, such as the core of solid golf balls, the polymer is blended with other polymers to take advantage of its excellent abrasion resistance and hysteretic properties. Table 7 illustrates the effect the cataysts system has on polymer microstructure.



cis-1,4-Polybutadiene *trans*-1,4-Polybutadiene Vinyl-1,2-polybutadiene (3)

Table 7. Microstructure of Commercially Available Polybutadiene

	Typical expected microstructure		
Catalyst	Cis, %	Trans, %	Vinyl, %
	(levels to ± 1%)

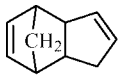
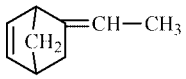
Co	96	2	2
Nd	98	1	1
Ni	96–98	0–1	2–4

Ethylene–Propylene Rubber. Ethylene and propylene can be copolymerized to produce a wide range of elastomeric and thermoplastic polymers. Often a third monomer such as dicyclopentadiene, hexadiene, or ethylidene norbornene, illustrated in equation 4, is incorporated at between 2 and 12% into the polymer backbone, and therefore leads to the designation ethylene–propylene–diene monomer (EPDM) rubber (see ETHYLENE-PROPYLENE ELASTOMERS). The diene monomer introduces sites of unsaturation in the polymer that allow vulcanization by conventional sulfur curatives (16). At high levels of a third monomer, it is possible to achieve cure rates that are equivalent to conventional rubbers such as



Dicyclopentadiene (DCPD)



Ethylidene norbornene (ENB)

$H_2C{=}CH{-}CH_2{-}CH{=}CH{-}CH_3$ 1,4 -Hexadiene (1,4 -HD) (4)

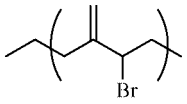
SBR and BR. Ethylene–propylene rubber (EPR) is typically vulcanized using a peroxide-based cure system.

Variation of the ethylene–propylene ratio changes the viscoelastic properties of the rubber. The hardness can be varied widely by the filler and plasticizer level. In addition, EPDM can be highly extended with black and nonblack fillers, and oils. At high levels of fillers, EPDM can display very good resistance to swelling by the IRM 903 oil. The principal properties of EPR and EPDM are excellent weathering, good heat and water resistance, electrical insulation, and low temperature brittleness. As a result, EPDM is used in a wide variety of rubber goods. EPR elastomers are used in applications such as roofing, 20%; plastic modification, thermoplastic olefins (TPOs) and thermoplastic vulcanizates (TPVs), 17%; weather stripping, 15%; hoses and belts, 14%; oil viscosity modification, 10%; wire and cable, 6%; molded goods, 5%; tires, 3%; carpet backing, 2%; and other, 9% (14). EPR and EPDM have been made by either solution or emulsion polymerization processes and by gas-phase polymerization using metallocene catalysts.

Butyl and Halobutyl Rubber. Butyl rubber is made by the copolymerization of isobutylene with 1–3% isoprene (eq. 5), which is added to provide sites for curing. It is designated IIR because of these monomers. Halogenation of butyl rubber with bromine or chlorine increases the reaction rate for vulcanization (eq. 6). It is estimated that of the 200,000 kt of butyl (IIR) and halobutyl (HIIR) rubber manufactured in North America, over 90% is used in tire applications. The halogenated polymer is used in the innerliner of tubeless tires.

Isobutylene Isoprene Butyl (5)

Butyl rubber is used to make innertubes and curing bladders (see BUTYL RUBBER). Butyl polymers are about eight times more resistant to air permeability compared to natural rubber and have excellent resistance to heat, steam, and water. This accounts for its use in gaskets and diaphragms for hot water and steam services. In addition, butyl rubber can be compounded to have low resilience properties and has found use in high damping mounts for engines, motors, and similar devices (6,17,18).



Most common isomer of bromobutyl (or chlorobutyl) rubber (6)

Special-Purpose Elastomers. Polychloroprene and polysulfide rubber were the first synthetic specialty elastomers discovered. Since their invention in the 1930s the total number of classes of synthetic rubbers has grown to almost 30. Table 1 has listed standard acronyms by the International Institute of Synthetic Rubber Producers (12).

Chloroprene Elastomers. Polychloroprene is made by polymerizing 2-chloro-1,3-butadiene (eq. 7). The elastomer is largely composed of the trans isomer. There are three major polymer types: the G-type, the W-type, and the T-type.

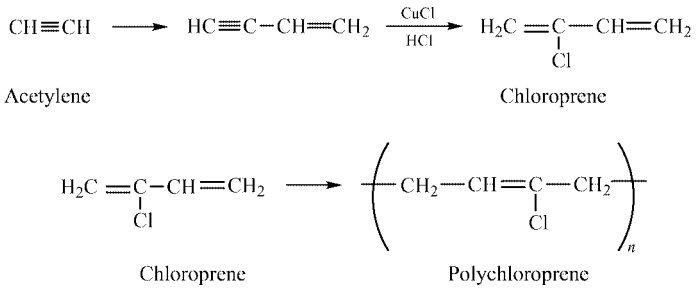
(1) G-types are made by using a sulfur-modified process. G-type polymers possess excellent processing and dynamic properties, and are thus used in applications such as V-belts. However, they have poorer aging properties than W-types. They contain sulfur and tetramethylthiaram disulfide (TMTD) and they can be cured with only a metal oxide.

(2) W-types use no sulfur modification. The W-type polymers tend to be used in applications requiring better aging, such as rolls and mechanical goods (see CHLOROPRENE POLYMERS). W-type polychloroprenes require an organic accelerator.

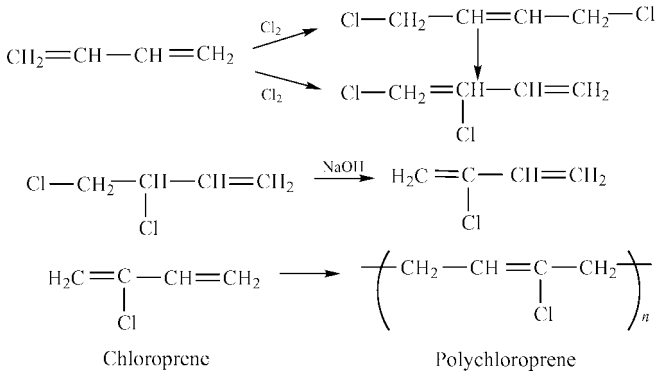
(3) T-types are similar to W-type polychloroprenes but contain a high level of gel, which in this instance offers improvements in processing. They find use where fast, uniform extrusions and calendering is required.

Polychloroprene is made from one of two starting materials, acetylene or butadiene. Acetylene can be dimerized and then chloronated to form chloroprene. Alternatively, when adequate butadiene is available, this can be directly halogenated (eqs. 7 and 8). In either case, the chloroprene product can then be polymerized to polychloroprene. Essentially a butadiene elastomer with chlorine present in the backbone,the polymer exhibits excellent tensile strength and low hysteresis, much like natural rubber. Tensile strength properties up to 28 MPa are possible with the proper reinforcing system (see FILLERS). The polarity imparted by the chlorine atom improves the oil and solvent resistance approaching those of nitrile polymers. The polymer can be protected with *para*-phenylenediamine antiozonants to give ozone resistance, and heat aging is also good. As a result, chloroprene elastomers are used in a wide variety of applications needing a balance of such properties.

Principal uses include automotive V-belts, industrial and hydraulic hoses, specialty roofing, heels and soles in footwear, wire covering, and a wide variety of coated fabric uses, eg, rafts. Polychloroprene elastomers are also used extensively in adhesives. It is estimated that about 77,000 ton of polychloroprene are used each year in the United States (4,7,19).

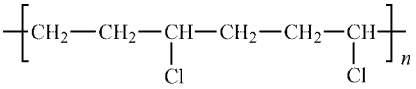


(7)



(8)

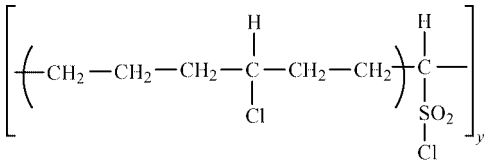
Chlorinated Polyethylene. Under pressure, polyethylene can be chlorinated to produce a polymer having a halogenated monomer content varying from 25 to 42%. The polymer requires the incorporation of carbon black and minerals for achieving good physical properties. The polymers handle like conventional polymers and can be mixed and processed on conventional rubber equipment. Chlorinated polyethylene (CPE) has excellent ozone, oil, and heat resistance, and as a result chlorinated polyethylene has replaced chloroprene elastomers. CPE has a lower specific gravity than chloroprene compounds and produces compounds that are similar to CR in properties but with lower costs. Also, because of high levels of chlorine, the flame resistance of compounds of CPE are high.



Chlorinated polyethylene (9)

An estimated 18 kt of these elastomers is used per year. The main uses of CPE are in construction, automotive, and electrical applications. These include power steering hose, electrical cords used in low voltage applications (extension cords, ignition wire), pond liners, and as a plastic modifier to improve impact modification.

Chlorosulfonated Polyethylene. This elastomer is made by the simultaneous chlorination and chlorosulfonation of polyethylene in an inert solvent. The resulting polymer is an odorless, colorless chip that is mixed and processed on conventional rubber equipment (2). The polymer (eq. 10) typically contains between 20 and 40% chlorine and 1% sulfur (see ETHYLENE POLYMERS, CHLOROSULFONATED). The polymer requires compounding with normal fillers to produce useful properties. Chlorosulfonated polyethylene (CSM) excels in resistance to attack by oxygen, ozone, corrosive chemicals, and oil, and in addition has very good electrical properties. The physical properties and abrasion resistance are also good. Light-colored articles made from CSM have excellent color-fastness. Because of the presence of chlorine atoms, this elastomer also shows good flame resistance.



Chlorosulphonated polyethylene (10)

CSM is extensively used in construction and electrical applications. This includes roofing membranes, automotive ignition boots and wires, roll compounds, and some automotive hoses requiring good heat and oil resistance, eg, air conditioning and power steering hoses. It is also used in nuclear power plants because of its excellent resistance to radiation degradation. Chlorosulfonated polyethylene is sold under the trade name Hypalon.

Fluoroelastomers. Fluoroelastomers were introduced to the rubber industry in the late 1950s. They were made by modification of Teflon polymers and designed to have excellent heat and chemical resistance, but remain elastomeric in nature. With the increasing demand in the automotive and industrial market for improved reliability and longer in-service life, fluoroelastomers have made significant inroads into these applications (see FLUOROCARBON ELASTOMERS). Compared to all other elastomers, fluoroelastomers excel in heat, chemical, flame, weathering, fuel, and ozone resistance. In addition, oil, oxygen, and water resistance are very good. Fluoroelastomers, however, are attacked by amines and some highly polar solvents. Abrasion resistance and low temperature properties are adequate for most applications.

Seals and gaskets in the marine, oilfield, and chemical processing industries employ fluoroelastomers. In addition, many hoses in the automotive and chemical industry are made entirely of fluoroelastomer compounds or have a veneer of the fluoroelastomer as a barrier exposed to the harsh environment.

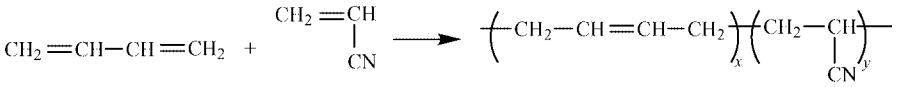
Epichlorohydrin. Commercial polyester elastomers include both the homopolymer and the copolymer of epichlorohydrin with ethylene oxide. The very polar chloromethyl group creates basic resistance to oil for these polymers, and they have been extensively used in fuel lines; however, the desire for lower fuel permeation is causing a search to be made for other polymers (20). Epichlorohydrin (ECO) has excellent resistance to fuel and oil swell. The ECOs show a volume swell of 35% at room temperature compared to 70% for a medium ACN–nitrile rubber in ASTM Reference Fuel C. The copolymer has a low temperature brittle point of −40°C; and the homopolymer, −15°C. An interesting property of these elastomers is a stable dynamic performance over a wide temperature range; however, the electrical properties are only average.

The principal uses of ECO are in automotive applications; eg, for fuel line and fuel vapor recirculation. There are also some downhole seal applications where ECO is used.

Nitrile and Acrylic Rubber. Nitrile rubbers are made by the emulsion copolymerization of acrylonitrile (9–50%) and butadiene (21) and are abbreviated NBR (eq. 11). The ratio of acrylonitrile (ACN) to butadiene has a direct effect on the properties and the nature of the polymers. As the ACN content increases, the oil resistance of the polymer increases (14). As the butadiene content increases, the low temperature properties of the polymer are improved. Nitrile rubber is much like SBR in its physical properties. It can be compounded for physical strength and abrasion resistance using traditional fillers such as carbon black, silica, and reinforcing clays. The primary benefit of the polymer is its oil and solvent resistance. At a medium ACN content of 34% the volume swell in IRM 903 oil at 70°C is typically 25–30%. Nitrile rubber can be processed on conventional rubber equipment and can be compression, transfer, or injection molded. It can also be extruded easily. Nitrile rubber compounds have good abrasion and water resistance. They can have compression set properties as low as 25% with the selection of a proper cure system. The temperature range for the elastomers is from −30 to 125°C. The compounds are also plasticized using polar ester plasticizers.

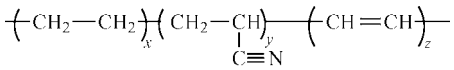
Applications requiring good oil resistance and moderate heat aging are the principal uses of nitrile rubber compounds. The automotive industry has been the primary consumer of nitrile rubber based products with hoses, fuel lines, and

numerous O-rings and seals representing typical applications. In addition many rolls in the printing industry are made from nitrile rubber. However, fluoroelastomers, silicone, epichlorohydrin, and acrylic elastomers have been replacing nitrile rubber for better durability and longer service life.



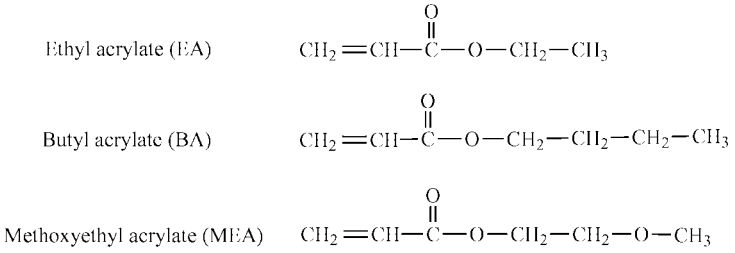
Nitrile elastomers (11)

For compounding of nitrile elastomers, reference should be made to model formulations for a range of applications where such polymers are used (22). Hydrogenation of nitrile rubber improves the aging properties of the oil-resistant backbone. The polymers are available with acrylonitrile contents from 17 to 50% and residual double-bond unsaturation from 2 to 20% (eq. 12). In addition to outstanding oil resistance and improved aging properties, the abrasion resistance of the polymers is very good. The basic polymer is quite polar, giving inherent resistance to swelling in oils or gasoline, but can be affected by ketones, halogenated solvents and oils, and oxygenated solvents. They have a service range from −45 to 149°C. Hydrogenated nitrile rubber (HSN or HNBR) compounds compete with FKM, FVMQ, ECO, ACM, and high ACN content nitrile rubbers. Major applications include automotive timing belts, blow-out preventors, drill pipe protectors, and numerous oil and fuel pump components.



Hydrogenated NBR
y 17–50%
z = 1–15% (12)

Acrylic elastomers possess good oil and heat resistance. They are made by polymerizing monomeric acid esters of ethyl or butyl acrylate and methoxyethyl acrylate or ethoxyethyl acrylate. They can be polymerized in emulsion, suspension, or solution systems (8). The polyacrylates are inherently tacky and soft. They require compounding with carbon black or mineral fillers for achieving useful properties. Their main properties are a temperature performance range of −40 to 175°C. They have good resistance to oils, oxidation, ozone, aliphatic solvents, sunlight, and weathering, and exhibit low permeability to gases. The tensile strength is usually 7 to 14 MPa (1000–2000 psi). Compounds can be fabricated with Shore A hardness values ranging from 40 to 90.



(13)

The major monomers used in in polyacrylates are shown in equation 13. It is estimated that 9000 ton of these elastomers are used annually in the United States, principally in automotive applications requiring both oil and heat resistance. These include transmission, valve stem, crankshaft, pinion, and oilpan gaskets and seals. In addition, hoses, tubing, rolls, and belts are made from acrylic polymers (2,7).

Other Special Polymers. There are a variety of other polymers which, though when compared to the general-purpose polymers such as SBR, are used in low quantities but still merit discussion. These include elastomers such as polysulfides, silicone rubbers, and polyurethanes. Each are considered in turn.

Polysulfides. Polysulfides are also called Thiokol's (T) after the company that originally made them. They were discovered in 1927 (see POLYSULFIDES). Thiokol elastomers have low tensile strength and tear strength properties. However, they have good resistance to both aliphatic and aromatic solvents at room temperature and at slightly elevated temperatures. It is estimated that 1.4 to1.6 kt are used annually in the United States. The primary use of polysulfide elastomers are in seals, gaskets, rolls, and diaphragms where solvent resistance and low permeability are required.

Silicones. Silicone elastomers have a siloxane (—Si—O—Si—) backbone with methyl, vinyl, or phenyl groups attached. The elastomers are designated by their chemical composition as follows: methyl silicone (MQ), methyl vinyl silicone (VMQ), methyl phenyl silicone (PMQ), methyl phenyl vinyl silicone (PVMQ), and fluorovinyl methyl silicone (FVMQ). Silicone elastomers possess good resistance to heat aging. The siloxane backbone imparts resistance to oxygen, ozone, UV light, and to some polar fluids. However, the tensile strength of these elastomers is usually low. They also have low abrasion resistance and tear strength (see SILICONES). By fluorinating the silicone polymer it is possible to improve the solvent, fuel, and oil resistance of this already heat-resistant class of elastomers. The resulting polymers are especially useful in select automotive seals and gaskets, military, and oilfield equipment parts. Fluorosilicones (FVMQ) have excellent low temperature flexibility properties coupled with good oil, fuel, and solvent resistance and excellent aging properties. The materials are compounded and reinforced with fine particle fillers such as silica. The materials are mixed and processed on especially clean equipment and are peroxide-cured. The primary uses of these elastomers are in O-rings, shaft seals, wire and cable, and electrical connectors.

Urethanes. Urethane elastomers are prepared by the reaction of an isocyanate molecule with a high molecular weight ester or ether molecule. The result

is either an elastomeric rubber form or a liquid prepolymer that can be vulcanized with an amine or a hydroxyl molecule (see POLYURETHANES). Urethanes are processed as rubber-like elastomers, cast systems, or thermoplastic elastomers. The elastomer form is mixed and processed on conventional rubber mills and internal mixers, and can be compression, transfer, or injection molded. The liquid prepolymers are cast using automatic metered casting machines, and the thermoplastic pellets are processed like all thermoplastic materials on traditional plastic equipment. The unique property of polyurethane is high abrasion resistance and moderately high Shore A (75–95) hardness. In addition, tear strength, tensile strength, and resistance to swelling by many oils is very high. The main deficiencies of the urethanes are their resistance to heat over 100°C and that shear and sliding abrasion tend to make the polymers soft and gummy. It is estimated that close to 68,000 ton of these rubbers are used per year in the United States if all forms are included. Uses include sport wheels (roller blades, ski wheels); printing, paper, and steel processing rolls; gears; pump liners; appliance components; and solid industrial tires.

Vinyl Acetate–Ethylene Copolymers. Vinyl Acetate–Ethylene copolymers would also fall into this category. In these random copolymers, the ratio of ethylene to vinyl acetate (EVA) is varied from 30 to 60%. As the vinyl acetate content increases, the oil and heat resistance increases. With higher ethylene content the physical strength, tensile, and tear increases. The polymers are cured with peroxides. The main properties of these elastomers include heat resistance, moderate oil and solvent resistance, low compression set, good weather resistance, high damping, and excellent ozone resistance, and they can be easily colored (see VINYL ACETATE POLYMERS). Applications include automotive electrical system components, eg, ignition cable, footwear, weather stripping, and miscellaneous O-rings and seals for industrial applications.

Fillers for Rubber

Fillers (qv) are particulate materials added to improve the physical properties and optimize the cost of the rubber compound (see FILLERS). All particulate fillers increase the hardness and stiffness of rubber compounds. The chemical composition and its effect on rubber compound physical properties typically classify fillers into three broad categories: nonreinforcing, semireinforcing or extending, and reinforcing fillers. Reinforcing fillers improve the physical properties of the rubber vulcanizate, while some fillers simply act as diluents or extenders. Improvements in rubber compound physical properties are directly related to the filler particle size, whereby the smaller particulate fillers impart greater reinforcement. Particle-size distribution and particle shape also have significant effects on composite reinforcement. Filler structure ranges from precise geometrical forms, such as spheres or hexagonal plates, to irregular masses. A particle with a high aspect ratio has higher reinforcement than a more spherical one. Fillers having a broad particle-size distribution have better packing in the rubber matrix and provide lower viscosity than that provided by an equal volume of the filler with a narrow particle-size distribution. The properties of particulate-filled elastomers are determined by the properties of the components, by the shape of the filler phase, by the morphology of the system, and by the polymer-filler interfacial interactions.

A wide variety of particulate fillers are used in the rubber industry. Carbon black is the filler of choice. All grades, with the exceptions of N880 and N990 thermal blacks, reinforce rubber with the finest particle-size carbon blacks imparting the highest degree of reinforcement based upon improved abrasion resistance, tear strength, tensile strength, and stiffness. A number of mineral fillers are used in the rubber industry to extend and/or reinforce elastomers. They include carbonates, clays, silicas, silicates, and talc. However, when compared to carbon black, the use of nonblack fillers by the tire and rubber industry is limited.

Carbon Black. This is the primary reinforcing filler used in the rubber industry. Carbon black can be made by three processes: the furnace process, the thermal process, and the channel process. Over 97% of black is made by the furnace process (see CARBON BLACK).

The furnace process involves spray injection of a low end fraction of crude oil into a heated chamber. The temperature, shape of the injectors of the oil, rate of injection, shape of the reactor, and other factors are controlled to produce carbon black fillers of different particle sizes and structures. The particle size and structure control and the reinforcing character of carbon black are the bases of their classification system (Table 8). There are approximately 30 common grades of carbon black used in the rubber industry. There are also numerous specialty grades produced for use in plastics, conductive applications, and proprietary grades produced for use in tires and other special-purpose products (14).

Carbon black primarily owes its reinforcing character to the size and shape of the aggregate structure; for example see Figure 2. An aggregate consists of primary particles essentially spherical in shape that are chemically bonded (fused) to one another. The two most important properties of carbon black are surface area and structure. Surface area depends inversely upon the size of the primary particles, and is one measure of the area available for physical interaction with an elastomer. The structure of carbon black depends upon the size and grouping of these primary particles in the aggregate. The more the primary particles in the aggregate, the higher is the structure of the carbon black due to the more complex shape and void volume (porosity). Surface activity refers to the strength of the carbon black/rubber interaction either from nonbonded physical interactions or chemisorption. The small (2–3%) but significant amount of noncarbon atoms, such as hydrogen, oxygen, and sulfur, that are present on the carbon black surface results in surface activity differences. During mechanical mixing with polymers, it is desirable to minimize the presence of agglomerates, which are physically

Table 8. Tire and Industrial Products Carbon Black Categories[a]

Type	ASTM designation	Particle size, nm	Application
SAF	N110	11–19	Tires

associated aggregates. Aggregate structures are not thought to be broken down into primary particles by simple mechanical processes such as mixing, milling, etc.

The structure of the carbon black is determined by dibutyl phthalate (DBP) absorption and the surface area is estimated by nitrogen or CTAB absorption (Table 9).

Table 9. Common Commercial Grades of Carbon Black[a]

ASTM Designation	Iodine number	DBP	Compressed DBP	CTAB	Nitrogen absorption	Tint strength

Carbon blacks are also classified into reinforcing, semireinforcing, and extender blacks. The furnace blacks from N100 through N300 are considered reinforcing blacks based on the increase in tensile strength observed when they are incorporated into rubber. They are sometimes referred to as *hard blacks*, and are used in treads, black sidewalls, casings, and breaker compounds of radial passenger and truck tires. In addition, they are commonly used in the covers of belts, a few select hose compounds, and other rubber goods requiring high tensile strength, tear strength, modulus, and good abrasion resistance.

The N500 through N700 series carbon blacks are considered semi-reinforcing blacks. These are used widely in bias and radial tire casings, innerliners, beads, squeeges, and other tire components not requiring the ultimate in strength and abrasion. They are also used in matting, roofing, curing bladders, and innertubes.The N900 series thermal blacks are viewed as extender blacks because of the limited reinforcement they provide for the rubber compound. All semi-reinforcing carbon blacks are often referred to as *soft blacks*.

Mineral Fillers. Mineral fillers are naturally occurring materials that are mined and are ground to a specified particle size (24,25). Grinding may be done dry using mechanical mills. For a finer product the ore is ground wet. Wet grinding may be autogenous where the ore grinds by attrition with itself or a grinding media may be employed. Additional processing may include a combination of steps. They include (*1*) separation of fine and coarse particles by use of screens, by air or water flotation, or by centrifugal filtration (*2*) removal of impurities by washing,

heat treatment, magnetic separation, or chemical treatment and/or (*3*) surface treatment with a variety of chemicals to improve the compatibility with the rubber matrix.

Calcium carbonate is usually derived from a naturally occurring source, such as calcite or whiting, by wet grinding. Precipitated and synthetic calcium carbonates are available in high purity; typically have a higher surface area, finer particle size, and narrower particle-size distribution; and thus a higher degree of reinforcement. Kaolin clay, a hydrated aluminum silicate, is one of the most abundant silicate minerals. Depending upon the type of processing, kaolin can be categorized as air-floated, water-washed, calcined, or surface-treated. Kaolin has the finest particle-size range of any naturally occurring mineral. Silicas are categorized as naturally occurring such as crystalline and diatomaceous earth, or as synthetic silicas which include precipitated silica, pyrogenic (fumed) silica, and silica gel. Crystalline silica is an inert, abrasive, large particle obtained from grinding sand or quartz. Diatomaceous earth or dolomite is obtained from sedimentary rocks and often contains up to 30% organic matter and inorganic impurities such as sand, clay, and soluble salts. Precipitated and pyrogenic silicas are high surface areas, fine-particle reinforcing fillers (see Fig. 3). Talc is a hydrated magnesium silicate with a morphology and purity varying according to the mining location.

Among the nonblack fillers, the highest hardness is provided by rod-shaped or plate-like particles, which can orient parallel during processing, compared to spherical particles of similar diameter. Uses of clay in rubber produces compounds with high hardness values. Clay is further classified as a hard clay if it reinforces rubber also imparting high modulus, tensile strength, and resistance to abrasion, or as a soft clay if it produces a compound with lower physical properties. Of the spherical particulate fillers, precipitated silicas, surface-treated clays, and calcium silicates also produce high hardness and high modulus compounds (see Fig. 4). The highest tensile strengths are produced in rubber compounds by using precipitated silicas. Calcium silicate and surface-modified clay also afford high tensile strength compounds, followed by use of zinc oxide, carbonates, and hard

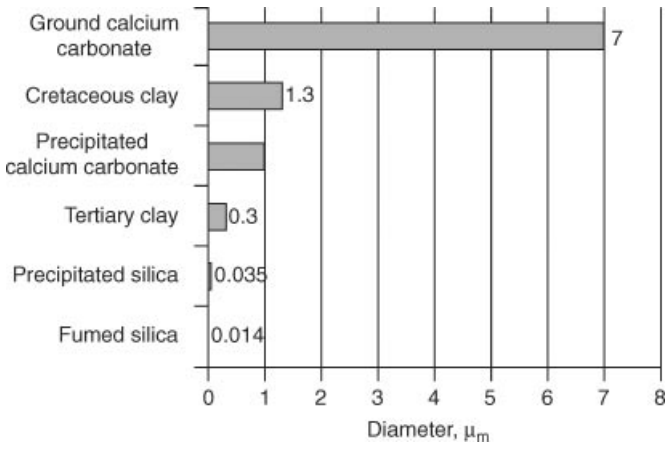

Fig. 3. Median particle diameters of nonblack fillers.

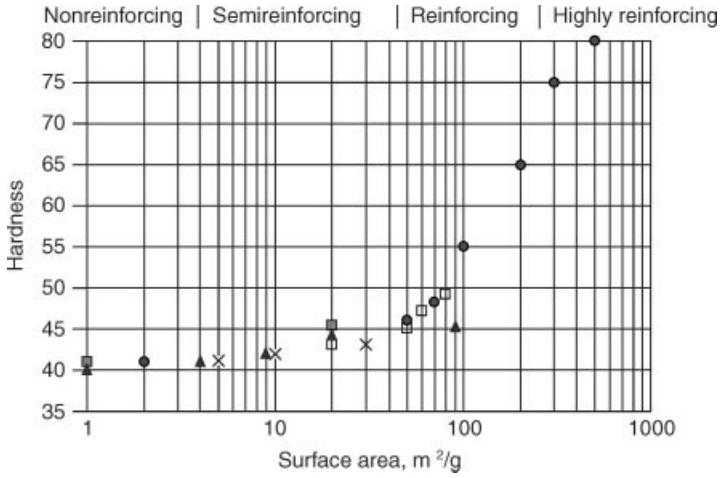

Fig. 4. Reinforcing effect on hardness of nonblack fillers with different surface areas. ● Silica, ■ talc, ▲ calcium carbonate, × soft clay, □ hard clay.

clay. No other nonblack filler approaches the precipitated silicas for imparting abrasion resistance.

Calcium Carbonate. Calcium carbonate ($CaCO_3$) is also known as whiting, limestone, marble, chalk, or calcite. It has been ground and added to rubber compounds to reduce cost and to impart hardness and opacity to rubber articles. Particle sizes range from 2 to 80 μm for dry-ground product and from 0.5 to 11 μm for wet-ground product. The chemical composition and crystalline nature depend on the limestone deposit that is mined, for example chalk or marble, and the color of the deposit.

Important applications of calcium carbonate in the rubber industry include use in electrical wire and cable insulation where the low moisture content and natural insulating properties make it a preferred filler, in the production of articles where low cost and smooth surface appearance are desired, such as footwear, and in extruded hoses and automotive sealing parts.

Clay. Kaolin clay, also called kaolinite or China clay, is hydrous aluminum silicate [$Al_2Si_2O_5(OH)_4$] consisting of platelets with alternating layers of silica and alumina in the structure. The weathering of granite forms fine particles of clay. Clay deposits are classified as primary, secondary, and tertiary. Primary deposits are mixtures of clay and granite found where they were originally weathered, and contain only 40 to 50% particles less than 2 μm in diameter. Secondary deposits form when fine particles from primary deposits flow and are deposited in a new location. Tertiary deposits are the most important commercial deposits because of their fine particle size, with >80% of the particles being less than 2 μm in diameter. Their high purity results when water carries the fine particles of a secondary deposit to a new location.

Clay can be generally divided into soft and hard clays on the basis of their producing softer and harder rubber compounds at a given loading level. There are several processes for producing clay for rubber reinforcement from the mined form: (*1*) Air-floated clay, in which the ore is milled to break up lumps and air

classified, is the least expensive form of clay and imparts moderate reinforcement. (*2*) Water-washed clay involves gravity separation of impurities, bleaching, magnetic separation to improve color properties, and centrifuging to produce the desired particle size range to impart higher reinforcement by the control of pH, color, and particle size. (*3*) Delaminated kaolin uses chemical and/or mechanical means to break apart the platelet structure of the clay, which further increases the available surface area and reinforcement properties. (*4*) Metakaolin is partially calcined by heat treating to 600°C. (*5*) Calcined clay is formed by heating to 1000°C, which produces a very white, high surface area mineral with an inert surface.

Clays are used as a filler for many rubber goods. The natural air-floated and water-washed clays are considered semi-reinforcing fillers for most rubber compounds. They are used in large volumes by the footwear, mat, industrial tire, and mechanical goods manufacturers. In addition, a small amount of clay is used by the tire industry in innerliners and white sidewalls, using the clay as an extender filler in low to medium dynamic stress applications. Clays are also used as partitioning agents in slab dips and antitacks. Clays were formerly used as fillers for bias tire carcasses; however, radial tires require better flex fatigue resistance than clay can impart.

Talc. Talc [$Mg_3Si_4O_{10}(OH)_2$] is a platelet form of magnesium silicate with a high aspect ratio. Platelets can orient in the extrusion process, thus providing rubber extrudates with smooth surfaces that can be extruded at high rates. It is commonly used in compounds, which have critical surface appearance such as exterior automotive components or consumer goods.

Talc is used in tires in white sidewall compounds to provide a smooth appearance to the buffed sidewall. The large platelets of talc provide a barrier to gas and moisture permeability in compounds, which allows talc to be used in applications such as hydraulic and automotive hoses, barrier films, and tire innerliners.

Synthetic Fillers. Synthetic fillers are generally manufactured by precipitation of soluble materials under carefully controlled conditions to provide tailored properties. They may be found as colloidal particles which may be spherical, ellipsoid, rod, or tube shaped; as aggregates which are covalently bonded groupings of individual particles, or as agglomerates that are loosely held associations of aggregates physically interacting. Reinforcement properties are a function of the colloidal particle size and shape, the aggregate dimensions and morphology, and the ability of agglomerates to break down during mixing. Additionally, the composition and surface chemistry of the filler plays a significant role.

Precipitated Calcium Carbonate. Precipitated calcium carbonate is formed by dissolving limestone and precipitating $CaCO_3$ as very fine particles using carbon dioxide (Aroganite Process) or sodium carbonate (Solvay Process). Typical particle sizes range from 0.02 to 2 μm. Most commercially available precipitated calcium carbonate is spherical colloidal particles or aggregates consisting of a few spherical particles. Additional shapes and aggregates of varying morphology are possible and provide increased reinforcement. Precipitated calcium carbonate is used as a semi-reinforcing filler in shoe products and industrial rubber goods, particularly when resistance to alkali solutions is needed. The low moisture content and good reinforcement allow precipitated calcium carbonate to be used in wire and cable insulation applications.

Metal Oxides. Zinc oxide, which is formed from the burning of zinc metal, was the first nonblack filler used for reinforcement of rubber compounds. Although zinc oxide and magnesium oxide are still used as a reinforcing filler in some specialty compounds, particularly those that require heat resistance, their role in rubber compounding in the last several decades is that of an activator for the sulfur cure system or as curatives for chloroprene rubber compounds.

The rutile form of titanium dioxide (TiO_2) is an important filler for white and colored rubber articles. The ability of the titanium dioxide particle to scatter light provides high whiteness and opacity to rubber, which gives the filler particle the ability to cover background colors. The anatase crystalline form of titanium dioxide is also used.

Silicates. Amorphous silicates are precipitated from aqueous blends of soluble silicate, typically sodium silicate, and soluble salts of other metals. The most important types for reinforcement of elastomers are aluminosilicates with mixed Al_2O_3 and SiO_2 structures, magnesium aluminosilicates, and calcium silicates. The silicates have surface areas and resultant reinforcement which span the range from the highest surface area clays (ca 30 m^2/g) to the lower end of the precipitated silicas (ca 100 m^2/g).

Silica. Because of its small particle size and complex aggregate structure (see Fig. 5), precipitated silica imparts the highest degree of reinforcement to rubber among all of the nonblack particulate fillers. The main uses of silica are in the treads of passenger and truck tires for traction and low rolling resistance, in the treads of off-the-road tires for improved chunking and tear resistance, and as a component of the bonding system for adhering brass and zinc-plated steel cord to rubber. Silica is used in shoe soles for its resistance to wear and tearing, its nonscuffing characteristics, and to obtain compounds with light color. It is used to improve the tear strength and resistance to flex fatigue (cracking, cut-growth) and heat aging in a wide variety of manufactured rubber goods including conveyor and power transmission belts, hoses, motor and dock mounts, bumper pads, and rubber rolls. For comparative purposes, some properties of silica and their applications are illustrated in Tables 10 and 11.

The reaction of a bifunctional organosilane with precipitated silica involves the hydrophobation of the alkoxy group of the silane with a surface silanol group of the silica, followed by reaction of the sulfur-containing function of the silane with an olefin group of the elastomer to afford a covalently bonded structure. This silane-coupled silica is useful in improving the abrasion resistance of silicas to levels of carbon blacks, and promoted their use in the treads of radial passenger tires.

For comparative purposes, the effects of nonblack fillers, both natural rubber and SBR compounds, are shown in Tables (12) and (13). For example it illustates

Highly dispersible	Tire casings; tire treads	Tire treads	High performance tire treads

how tensile can vary from 11 MPa for ground whiting or calcium carbonate filled NR to 25 MPa for HiSil 233 or silica-filled compounds.

Surface Treatment. Carbon black remains the particulate filler of choice for rubber articles since the inherent reinforcing effect of the nonblack fillers in hydrocarbon elastomers is not comparable. This is primarily due to the nonbonded interactions established between the particulate filler and polymer functionality (28). Surface chemistry plays an important role in the interaction of the nonblack fillers and the polymer with contributions ranging from electrostatic interactions to covalent bonding to the polymer backbone. However, surface chemistry also strongly affects the interaction of the nonblack filler with other chemicals in the rubber compound, particularly active metal oxides, curatives, and antidegradants.

Both surface morphology and surface chemistry play an important role in the interaction of a filler with coupling agents. For example, the dipole-induced dipole interactions between the polar groups such as siloxane and silanol on the surface of silicas to the nonpolar groups (methyl, alkenyl, aryl) of hydrocarbon elastomers are weak compared to the dipole–dipole interactions resulting from hydrogen bonding between surface silanol groups in silica aggregates. In addition, the dispersive forces between a nonpolar molecule and silica are low, while those between a nonpolar molecule and carbon black are high. Thus, materials to improve the compatibility between hydrocarbon elastomers and mineral fillers are of considerable interest. Organosilane coupling agents have been successfully utilized to further increase the physical properties of a number of nonblack fillers including calcium silicate, clays, mica, silica, and talc. Clays pretreated with an amino-functional or mercapto-functional silanes, and silicas pretreated with the mercapto-functional or tetrasulfide-containing silanes are commercially available. A manual of commercial coupling agents to promote adhesion between polymers and various substrates is available (29). The reaction of a bifunctional organosilane with a silica or silicate particulate filler involves the hydrophobation of the alkoxy group of the silane with a surface silanol group of the silica or silicate, followed by reaction of the sulfur-containing function of the silane with an olefin group of the elastomer to afford a covalently bonded structure (see Fig. 6).

[d]Silene EF stocks contain 2.4, 3.8, and 5.0 parts of diethylene glycol, respectively.

[e]The HiSil 233 stocks contain 2.3, 3.5, and 4.8 parts of diethylene glycol, respectively. The 30 vol stock contains 1.2 parts MBTS and 0.15 parts TMTD instead of the combination in the recipe; the 20 and 40 vol stocks contain 1.5 parts MBTS and 0.1 parts TMTD.

Silane-modified clays have found broad acceptance in a wide variety of rubber goods. The silane serves as a bridge between the organic rubber molecule and the inorganic filler particle. The result is a filler with higher reinforcing properties than regular clay. However, the dynamic properties and the degree of reinforcing improvement usually does not permit their use as a carbon black substitute or replacement.

Silane-modified silicas are used in tire tread compounds to reduce rolling resistance, increase wear resistance, and improve wet and snow traction properties.

Reclaim Rubber. Reclaimed and recycled rubber is considered as a filler in this discussion. The process of reclaiming rubber by chemical digestion has been in use since the late 1800s. Early processes involved the treatment of the rubber cord mix with acid. Acids attack cotton, rayon, and nylon. The acid treatment was used to remove the reinforcing components. The rubber was ground and treated. It was then washed, steam devulcanized, and shaped so it could then be reincorporated into new rubber compounds. An improvement on this technique was the use of alkali digestion. The principal benefit of using reclaim is its lower cost compared to new polymers. Reclaim typically sells for 20–30% of the cost of its nonreclaimed counterparts. Reclaimed rubber also imparts some desirable improvements in processing such as lower nerve, seen when milled or extruded components tend to snap back or develop distortions, than new polymers. As a result, compounds containing reclaim have a much lower die swell and faster extrusion rates. It also increases calendering rates and improves flow and mold filling. One of the shortcomings of reclaim is that it lowers the green strength and tensile strength of the compounds in which it is used. Reclaim is in fact a mixture of rubber, carbon black, oil, zinc oxide, stearic acid, and other compounding ingredients used in the original compounds. The levels of reclaim used are generally 15 to 25 phr, about half of which is rubber and the other half compounding ingredients. In some low performance requirement rubber products, such as mats, much higher levels can be used.

Reclaim can be used in many tire applications such as internal casings components and innerliner compounds, sidewalls, chafers, and rubber used in bead components. The introduction of radial tires changed the property needs for compounds used in tire manufacturing and reduced the volume of reclaim. Butyl reclaim made from tubes is used in the innerliner of both bias and radial tire compounds and some reclaim is used in low speed bias tires. There is a fairly large volume of some high quality rubbers such as natural rubber and butyl being reclaimed and used in some solid tires and other mechanical goods to extend the compound without having too adverse of an effect on the product. Ground rubber has replaced reclaim in many tire applications including treads, innerliners, subtreads, and bead components. It is also used in mechanical goods, footwear, solid tires, mats, and retreads. Cryogenic and wet-ground rubbers which are of smaller particle size can be used at moderately high levels and still allow compounds to be processible. A comprehensive discussion on reclaim and recycled elestomers is available (31).

Steam digestion of silicone rubber produces a silicone reclaim, used to reduce the cost of silicone compounds. It has been widely used by silicone automobile ignition systems. The resulting compounds have excellent aging characteristics and still possess outstanding electrical properties.

Antidegradants

Good aging properties of rubber compounds are essential for providing required service life of rubber products. The type of elastomer used is the principal factor in considering aging properties. In general, the more saturated the backbone of the elastomer, the better is the aging properties. For example, EPDM and butyl rubbers are quite stable when compared to more unsaturated polymers such as polyisoprene, sytrene-butadiene rubber, and polybutadiene. Unsaturated polymers are susceptible to oxidation thermally or by reaction with ozone; thus antioxidants and antiozonants are needed to extend the useful service lives of products made with these elastomers. The factors affecting the aging of general-purpose rubber having conventional sulfur and accelerator systems are as follows (6,32,33).

Oxygen. Addition of only 1 to 2% of oxygen is sufficient to cause deterioration of properties for most general-purpose elastomers. Oxidation proceeds by free-radical mechanisms and leads to chain scissioning and cross-linking (34). In the chain scission reaction, free radicals attack the unsaturated polymer backbone causing chain breaking, which results in softening and weakening. This is the primary effect observed for oxidation of natural rubber and butyl rubber. Brittle stocks result from attack at cross-links, resulting in formation of new cross-links. This is a predominant reaction with SBR, neoprene, nitrile, and EPDM rubbers. A drop in ultimate elongation is the most sensitive physical criterion for the aging measurement regardless of mechanism, and is a favored method compared to measurement of tensile loss for cured compounds. In synthetic rubber production (SBR, in particular), viscosity increases with aging and can affect processing if not prevented.

Heat. As expected, heat accelerates oxidation. Therefore, the effects described previously are observed earlier in product use and are more severe as the service temperature of the product is increased. Because oxidation is a chemical reaction, a temperature increase of 10°C almost doubles the rate of oxidation.

Flexing. Flex cracking is a common mode of fatigue failure in rubber compounds. Flex cracking involves not only a mechanical fatigue but also oxidation that is accelerated by heat generated during the flexing cycle. The higher the rate of flexing, the greater is the heat generation, and the worse is the fatigue life of the compound or product.

Ozone. Although ozone concentration in the atmosphere is only a few parts per hundred million (pphm), it rapidly reacts with an elastomer's carbon–carbon double bonds, particularly the backbone unsaturations, causing cracking of the rubber products. This reaction is especially accelerated by stress (stretching and bending) of the elastomer. For every rubber compound, there is a critical elongation below which cracks do not form. Usually, this is in the range of 5–10% elongation. Ozone reacts with double bonds so rapidly that it cannot diffuse into the rubber and therefore all action is at the surface. Thus, surface-protective agents are most useful against ozone attack. For example, waxes that bloom to the surface of rubber to form an inert film are used effectively for static protection (34). Effective antiozonants protect rubber surfaces initially by a sacrificial reaction with ozone, and then by the formation of a protective surface layer on the ruber surface by the reaction products called ozonides (7,14) which are formed in reaction with ozone, but which can also further react to protect the rubber. Certain polymers

also provide good ozone protection. The use of 40–50 parts of a low diene rubber, such as brominated isobutylene-*co*-*p*-methylstyrene, chlorobutyl, or EPDM, in natural rubber, polybutadiene or SBR compounds significantly increases ozone resistance.

Light. Ultraviolet (UV) light promotes free-radical oxidation at the rubber surface causing discoloration and formation of a brittle film of oxidized rubber. This skin cracks in random directions to form a pattern called crazing but can be minimized by the addition of carbon black fillers or UV stabilizers. Carbon black filled rubber compounds are more resistant to UV light than are gum (unfilled) or light-colored stocks containing mineral fillers. Nonblack compounds require use of larger quantities of nonstaining antioxidants which should continually bloom to the product surface as the UV stabilizers on the surface are depleted.

Sulfur. Low sulfur compounds and *efficient vulcanized* (EV) sulfur-accelerated systems have better aging resistance. Normally, the oxidation rate increases with the amount of sulfur used in the cure. The increased rate may be due to activation of adjacent C—H groups by high levels of combined sulfur. Saturated sulfides are more inert to oxidation than allylic sulfides. Polysulfidic cross-links impart excessive hardening of SBR as compared to more stable monosulfidic cross-links.

Metals. Transition-metal ions, such as iron, copper, manganese, and cobalt, when present even in small amounts, catalyze rubber oxidative reactions by affecting the breakdown of peroxides in such a way as to accelerate further attack by oxygen. Natural rubber vulcanizates are especially affected. Therefore, these metals and their soluble salts, such as oleates and stearates, should be avoided.

Selection of Proper Antidegradant. Because the various antioxidants function by different mechanisms, an antioxidant under one condition may become an oxidation promoter in a different condition. Therefore, an antioxidant should be carefully selected depending on service requirements. Most antioxidants are either amines, phenols, or phosphates. The following are some important properties in the selection of proper antidegradant that should be considered.

Persistence in Service (Volatility, Leachability, etc). Volatility is related to molecular weight, and type of antioxidant molecule. In general, the higher the molecular weight, the less the volatility (37). The type of molecule also has an effect. For example, hindered phenols have higher volatility than amine types of the same molecular weight. Volatility is also important from the standpoint of loss of antioxidant during service and depends on surface exposed, temperature of service, flexing, etc. Comparative loss studies for amine and phenolic-type antioxidants have been done (17). Rubber testing is affected by the volatility of antidegradants and widely varying results are obtained depending on whether open or closed aging chambers are used.

Solubility. Another desirable property of an antidegradant is its high solubility in rubber, but poor solubility in water and solvents that come in contact with rubber. Poor solubility in the rubber means that only small quantities of antioxidants can be dissolved without producing a bloom, a migration to the surface. As an example, *N*-isopropy-*N*′-phenyl-*p*-phenylenediamine (IPPD) has limited use because of its poor solubility in, for example, natural rubber (less than 2.0 phr). On the other hand, phenolic and phosphite antioxidants have high solubility and

bloom is not a concern. Solubility of antiozonants in rubber is especially important because their effectiveness depends on the use of small amounts, ie 2 to 5 phr, which must be soluble in the rubber but which also must migrate to the rubber surface in sufficient concentrations to establish a protective layer.

Protection Against Flex Cracking. Most antioxidants including waxes provide oxidation protection under static conditions. However, most of them are not effective in rubber products subjected to dynamic flexing, such as sidewall compounds in tires. The best dynamic protection is provided by *N*-alkyl-*N*′-phenyl-*p*-phenylenediamines.

Stability. In order to have maximum effectiveness over long periods of time, an antioxidant should be stable upon exposure to heat, light, oxygen, water, etc. Many antioxidants, especially in the presence of an impurity when exposed to light and oxygen, are subject to oxidation reactions with the development of colored species. Alkylated diphenylamines are least susceptible and the *p*-phenylenediamine derivatives the most susceptible to direct oxidation.

Physical Form. Physical form is an important characteristic. Compounders prefer solid, free-flowing, nondusty materials, whereas polymer manufacturers prefer materials that are liquid. Less desirable forms are semicrystalline materials which may stratify during storage. Also, substances to be avoided are highly viscous liquids and low melting resins which may solidify upon storage.

Staining Properties. For rubbers containing carbon black, discoloration is not generally a problem and the more potent staining amine antioxidants are used. For white or light-colored rubber products, nonstaining antidegradants are required. Functional classes of nonstaining antioxidants include substituted monophenols, hindered bisphenols and thiobisphenols, substituted hydroquinones, organic phosphites, and thioesters. Triphenyl phosphine, substituted thioureas and isothioureas, thiosemicarbazides, esters of dithiocarbamates, lactams, and olefinic and enamine compounds are reported to be nonstaining antiozonants. Approaches to completely replace the para-phenylenediamine antiozonants with a non-discoloring antiozonant have had only limited success leading to the development of new classes of nonstaining antiozonants (30).

Metal Deactivation. Compounds capable of forming coordination complexes with metal ions are needed for this purpose. A chelating agent such as ethylene–diaminetetraacetic acid (EDTA) is a good example.

Condition of Use. The selection of suitable antioxidants is highly dependent on the conditions under which the rubber product is to be used. It is difficult to find a single material that meets all requirements of a product. Consequently, quite often, blends of antioxidants are used. Table 14 provides a summary of characteristics of commercially important antidegradants (7).

Antioxidant Types. Commercially available antioxidants may be divided into three general classes: secondary amines, phenolics, and phosphites. In general, the amines are more active than the phenolics which in turn are more active than the phosphites. Amine antioxidants, however, often cause staining problems and are therefore used mainly in black-colored compounds. The phenolics and phosphites are relatively nonstaining and are normally used in light-colored elastomer formulas. Many antioxidants in these classes are volatile to some extent at elevated temperatures and almost all antioxidants are readily extracted from their vulcanizates by the proper solvent. These disadvantages have become more

Table 14. Antidegradants[a]

Type	Example (trade name)	Staining	Resistance[b] to				
			Oxygen	Heat	Flexing	Metal catalysis	Ozone
Hindered phenols	2,6-Di-*t*-butyl-*p*-cresol (CAO-1)	None to slight	F	F	F–P	P	P
Hindered bisphenols	2,2′-Methylenebis-(4-methyl-6-*t*-butylphenol) (Antioxidant 2246)	None to slight	G–F	G–F	F–P	G	P
Hindered thiobisphenols	4,4′-Thiobis(6-*tert*-butyl-*m*-cresol) (Santowhite Crystals)	Slight	G–F	G–F	F–P	F	P
Hydroquinones	2,5-Di(*tert*-amyl)hydroquinone (Santovar A)	None to slight	G–F	F	F–P	P	P
Phosphites	Tri(mixed mono- and dinonylphenyl)-phosphite (Polygard)	None to slight	G–F	F	F–P	P	P
Diphenylamines	Octylated diphenylamine (Cyanox 8)	Slight to moderate	G–F	G–F	F	P	P
Naphthylamines	Phenyl-α-naphthylamine (Akrochem PANA)	Moderate	G	G	G–F	F	P
Quinolines	Polymerized 2,2,4-trimethyl-1,2-dihydroquinoline (AgeRite Resin D)	Slight to moderate	G	E	F	P	F–P
Carbonylamines condensation products	Reaction product of diphenyl-amine/acetone (BLE-25)	Considerable	G	E	E–G	P	F–P
para-Phenylene-diamines	Mixed diaryl-*p*-phenylenediamines (Wingstay 100)	Considerable to severe	E–G	E–G	E–G	E	E–G

[a] Ref. 7.
[b] E = excellent, G = good, F = fair, and P = poor.

pronounced as performance requirements for rubber products have been increased. Higher operating temperatures and the need for improved oxidation resistance under conditions of repeated extraction have accelerated the search for new techniques for polymer stabilization. Seals, gaskets, and hoses are some examples where high temperatures and solvent extraction can combine to deplete a rubber product of its antioxidant and thus lead to its oxidative deterioration faster (38,39).

Techniques for providing increased protection against oxidation under severe temperature and solvent extraction conditions include the use of polymer-bound antioxidants. Chemical attachment of the antioxidant molecule to the polymer backbone eliminates volatility and extraction by making the antioxidant essentially infinite in molecular weight after curing. Two general methods of accomplishing this attachment have been used:

(1) functionalized macromolecules react with antioxidant molecules to provide the bound antioxidant, and
(2) antioxidant molecules containing polymerizable functional groups may be copolymerized with conventional monomers during polymer production.

Test Methods. The most common methods used for determining the efficiency of antioxidants in vulcanized elastomers involve accelerated aging tests rather than oxygen absorption experiments. The standard tests involve aging dumbbell specimens cut from tensile strength test sheets under varying conditions of time, temperature, and oxygen content. They are as follows:

(1) air oven (ASTM D573) at 70°C for 1, 3, 5, 7, and 14 days, or in a test tube (ASTM D865) to eliminate cross-contamination (40,41);
(2) oxygen pressure (oxygen bomb, ASTM D572) of 2 MPa (300 psi) at 70°C for 2, 48, 72, and 96 h (42); and
(3) air pressure heat test (air bomb, ASTM D454) at 126°C, and at 80 psi of air for 3, 5, 8, 12, 20, and 30 h (43).

Because of the simplicity of the first test method, most of the comparisons are made using this technique. The effects of the aging process are usually measured on tensile properties such as breaking strength, elongation, and stress (modulus) at 300% elongation. In general, one day of oven aging at 70°C corresponds to one year of shelf aging (a minimum requirement for rubber products), whereas the oxygen and air bomb methods are more drastic. By varying the amounts, types, or combinations of antioxidants, the relative effectiveness of these materials against oxygen deterioration can be determined.

Processing Agents

To improve processing and to plasticize the rubber compound, numerous processing agents have been used over the years, such as petroleum and ester plasticizers, resins and tars, liquid rubber peptizers, peptizers, fatty acids and derivatives from

Table 15. Benefits Through Use of Processing Aids[a]

Operation	Benefit of processing aids	Controlling materials parameters
Mixing	Faster filler incorporation	Reduced viscosity
	Better dispersion	Hydrophobation reaction in silica compounds
	Reduced viscosity	
	Improved release	Homogenization
	Lower dump temperature	
	Reduce mix times	
Processing	Faster and easier calendering and extrusion	Rheological properties
	Improved release	Viscosity
	Less energy consumption	Green strength
		Tack, bloom
Curing and molding	Faster cavity fill at lower operating pressure	Scorch resistance
	Reduced stress in molded parts through easy cavity fill	Rheological properties
	Shorter cycle times	Clean
	Improved release	Mold

[a]Refs. 6,7 and 44.

vegetable oils, and polyethylene and hydrocarbon waxes. Benefits from the use of plasticizers are illustrated in Table 15 (6).

Petroleum plasticizers are the most universally used plasticizers for all rubber compounds. They improve flow and processing properties and also reduce the cost of the final compound. Aromatic process oils are the most common plasticizer for general-purpose rubbers. Naphthenic process oils are used where a minimum of discoloring or staining is required. Paraffinic process oils are used in the low polarity rubbers where high loadings and good solubility are required to avoid bleeding and maximize the plasticizing action.

Ester plasticizers are used in highly polar elastomers, such as neoprene and nitrile rubber, to improve low or high temperature performance or impart particular oil or solvent resistance to a compound. From 5 to 40 phr are commonly used (see PLASTICIZERS). Resins and tars are added to impart tack, soften the compound, improve flow, and in some cases improve filler dispersion, as is the case with organic resins in mineral-filled SBR. Resinous substances are also used as processing agents for homogenizing elastomer blends.

Stearic acid is used in many compounds as a cure activator and in addition may serve as a processing agent to improve mill and processing equipment release properties. Thus stearic acid may be the most widely used processing agent in the rubber industry. Stearic acid is typically used at 1 to 3 phr, and may also be added as a zinc salt (ie, zinc stearate). Because of its low molecular weight it has limited solubility in many elastomers. The term *stearate* often refers to a fatty acid mixture containing palmitates and small quantities of other fatty acids such as oleic acid and linoleaic acid.

Processing agents can be prepared by blending fatty acids, zinc, and calcium soaps into waxes, such as myricyl palmitate, to overcome solubility limitations of individual products. The result is a blend of organic fatty acids, usually in paste form, which serves to improve processing. In some cases, processing agents contain blends of fatty-acid chemicals and an ester-type plasticizer. This makes the processing agent more effective in highly polar elastomers such as nitrile rubber.

Table 16 illustrates how specific classes of processing aids may be used depending on the need. For example, should the rubber technologist encounter difficulties in the product-building operation, tackifiers can be used to assist in ensuring that the respective components in the product will come together in an efficient manner. Further upstream in mixing, peptizers, dispersion aids, or homogenizing agents can be varied to give the desired throughput and compound quality at the mixers. A comphensive review of processing aids has been prepared (44).

Vulcanization

Vulcanization is a chemical process where sulfur or other materials form cross-links in the elastomer and thereby improve the polymer's mechanical properties. In many instances, not all of the desired properties reach an optimum level simultaneously. The task is to achieve a balance of the most important property requirements through design of the cure system and time–temperature cure cycle so as to attain the necessary compound mechanical properties. Frequently, the curing equipment available, such as presses or autoclaves, do not allow the curing conditions to be varied as desired, and so a cure system compatible with the existing equipment must be designed and also meet the compound performance requirements.

Measuring Vulcanization. The formation of a three-dimensional cross-linked structure during vulcanization increases the stiffness (modulus) of the compound. Therefore, following the modulus increase versus cure time provides a continuous picture of the vulcanization process. Oscillating disk rheometers (ODR) and moving die rheometers (MDR) provide useful methods (45,46). In these tests, a preweighed sample of uncured rubber is placed into a preheated cavity containing a conical rotor. The cavity is closed and the rotor is set to oscillate within the rubber sample. As vulcanization proceeds, the compound's resistance to rotor movement increases and this resistance is followed as a function of time, thereby generating a continuous profile of cure behavior. A cure curve, shown in Figure 7, provides information on scorch safety or cure induction time, cure rate, state of cure or stiffness developed, optimum cure time or time when modulus no longer increases significantly, and reversion or the tendency of the compound to degrade upon overcure.

Sulfur vulcanization is a complex reaction during which both the number (density) and type (structure) of cross-links are continuously evolving as the reaction proceeds. The chemical structures formed at any given time during cure may favor one set of properties such as tear strength while not being optimum for others such as hysteresis and compression set. A cure system designed to minimize these trade-offs is always an objective of the rubber technologist (47).

For example, modulus or stiffness increase as the number of cross-links increase because the three-dimensional structure which forms becomes more

Table 16. Operations Using Processing Aid, Types, Examples, and Function[a]

Processing operation	Processing aid	Examples	Function
Mixing	Chemical peptizer	2,2′-Dibenzamididiphenyl-disulfide	Reduces polymer viscosity by chain scission; reduces molecular weight
		Pentachlorothiophenol	
	Physical peptizer	Zinc soaps	Reduces polymer viscosity by internal chain lubrication
	Dispersing agent	Mineral oils	Improves filler dispersion; reduces mixing time; reduces mixing energy
		Fatty acid esters	
		Metal soaps	
		Fatty alcohols	
	Homogenizing agent	Resin blends	Improves polymer blend compatibility; improves compound uniformity
Mixing extruding	Lubrication agent	Mineral oils	Improves compound flow and release
		Metal soaps	
		Fatty acid esters	
		Fatty acid amides	
	Fatty acids		
	Softening agent	Mineral oils	Lower hardness
	Plasticizer	Aromatic di and tri esters	Improves product performance at low and high temperatures
		Aliphatic di esters	
		Alkyl and alkylether monoesters	
Building product assembly	Tackifier	Hydrocarbon resins	Improves green tack; use hydrocarbon resins in summer, phenolics in winter, or as temperature varies
		Phenolic resins	
Curing	Stiffening agent	High styrene resin—rubber	Increased hardness
		Masterbatches	
		Phenolic resins	
		trans-polyoctenamer	
	Mold release agent	Organosilicones	Easier product release from mold; decreased mold contamination
		Fatty acid esters	
		Metal soaps	
		Fatty acid amides

resistant to deformation under load, thereby requiring greater force to reach a given elongation. With overcure, cross-link structure either degrades and modulus drops as in the case of natural rubber, or it continues to build, resulting in a *marching modulus* as in the case of SBR.

Tensile strength, tear strength, and fatigue resistance frequently pass through a maximum as cure state or cross-link network evolution progresses. These ultimate properties are highly dependent on the presence of flaws in the material. As cross-linking proceeds and modulus builds, any applied load acting on a flaw (from poor dispersion, small nicks or tears, localized overcure due to inhomogeneity, etc) concentrates the stresses at the flaw and provides a mechanism for tensile failure and tear propagation or poor fatigue life (Fig. 8). Permanent set and low hysteresis properties depend on minimizing the viscous or plastic component of modulus. Because cross-linking increases elasticity, a high state of cure typically provides the best compression set and heat buildup properties.

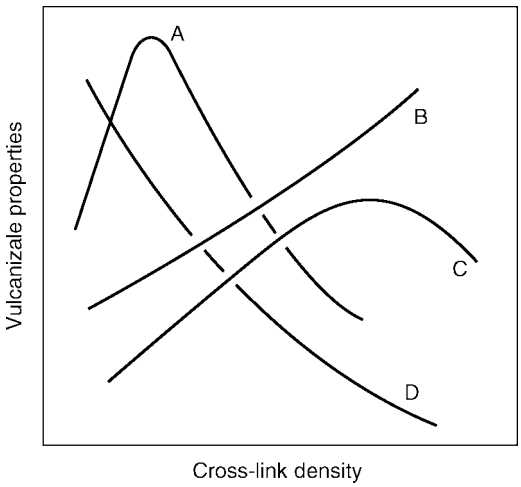

Fig. 8. Effect of cross-link density where **A** represents tear strength, fatigue life, and toughness; **B**, elastic recovery and stiffness; **C**, tensile strength; and **D**, hysteresis, permanent set, and friction coefficient.

Heat resistance is influenced by both the type and extent of cure. The greater the strength of the chemical bonds in the cross-link, the better is the compound's heat resistance. Peroxide cure systems, which result in carbon–carbon bonds, show good heat resistance because of more thermally stable, short, cross-links. This is an important factor in designing the desired cure system.

Cross-link density has only a minor effect on some compound properties such as thermal conductivity, electrical properties, and low temperature brittleness. Another cure system consideration is the compound scorch behavior. Prior to vulcanization, rubber is plastic-like and can be processed into desired shapes such as tires, hoses, belts, or other articles. The time available to accomplish this processing depends largely on the cure system and is referred to as the scorch time. If a compound cures prematurely during the processing step, it is usually scraped. Therefore, a key requirement of the vulcanization step is to minimize premature vulcanization or scorch (Fig. 7).

Vulcanizing Agents. Sulfur is the most common vulcanizing agent for the widely used diene-containing elastomers, such as natural rubber, SBR, and polybutadiene. Rubbermakers' sulfur is a rhombic form existing as a cyclic or eight-member ring structure. Insoluble sulfur is an amorphous polymeric form with molecular weights of 100,000–300,000. Because this material is insoluble in rubber, it resists migration to the surface prior to cure and this bloom-free attribute contributes to maintaining better building tack and better component-to-component adhesion (48,49). Sulfur-containing chemicals such as dimorpholinyl disulfide (DTDM) and tetramethylthiuram disulfide (TMTD) are not only effective accelerators, but they can also be used as sulfur donors. As such, they are effective in controlling sulfur cross-link length to form primarily mono- and disulfide cross-links. These short cross-links are more thermally stable than conventional sulfur curing and thereby provide better heat and set resistance. However, these accelerators are potentially nitrosamine-generating species, and research continues to replace them.

Peroxides are probably the most common materials used after sulfur because of their ability to cross-link a variety of diene- and nondiene-containing elastomers, and their ability to produce thermally stable carbon–carbon cross-links. Carbon–carbon bonds are inherently stronger than the carbon–sulfur bonds developed with sulfur vulcanization (49). Peroxides decompose when heated to produce active free radicals, which in turn react with the rubber to produce cross-links. The rate of peroxide cure is controlled by temperature and selection of the specific peroxide, based on half-life considerations (see INITIATORS, FREE-RADICAL). Although some chemicals, such as bismaleimides, triallyl isocyanurate, and diallyl phthalate, act as coagents in peroxide cures, they are not vulcanization accelerators. Instead, they act to improve cross-link efficiency (cross-linking vs scission), but not rate of cross-link formation.

Halogen-containing elastomers such as polychloroprene, chlorosulfonated polyethylene, and brominated isobutylene-*co*-*p*-methylstyrene are cross-linked by their reaction with metal oxides, typically zinc oxide. The metal oxide reacts with halogen groups in the polymer to produce an active intermediate which then reacts further to produce carbon–carbon bonds. Zinc chloride is liberated as a by-product and it serves as an autocatalyst for this reaction. Magnesium oxide is typically used with zinc oxide to control the cure rate and minimize premature cross-linking (scorch).

Two commercially important, high performance elastomers which are not normally sulfur-cured are the fluoroelastomers (FKM) and the polyacrylates (ACM). Polyacrylates typically contain a small percent of a reactive monomer designed to react with amine curatives such as hexamethylene–diamine carbamate (Diak #1). Because the type and level of reactive monomer varies with ACM type, it is important to match the curative type to the particular ACM in question. Sulfur and sulfur-bearing materials can be used as cure retarders; they also serve as age resistors (50). Fluoroelastomer cure systems typically utilize amines as the primary cross-linking agent and metal oxides as acid acceptors.

Other examples of difunctional compounds used for curing are epoxy resins for nitrile rubber, quinone dioximes for butyl rubber, and phenolic resins for butyl rubber, EPDM, and some EPDM-based thermoplastic elastomers (TPEs). The cross-linking mechanism involves a condensation reaction between each of the two curative difunctional groups with the polymer chain to form a three-dimensional network. Because only carbon–carbon linkages result, thermal stability and permanent set resistance are excellent, often approaching those of peroxide curing. A summary of the advantages and disadvantages of each of the various cross-linking agents appears in Table 17.

Rubber Vulcanization Chemicals. The vulcanization systems consist of the following components; the vulcanizing agent such as sulfur, the accelerator to activate the sulfur, a retarder to help control the rate of vulcanization, and an activator such as zinc oxide and stearic acid.

Accelerators. During sulfur vulcanization of rubber, accelerators serve to control time to onset of vulcanization, rate of vulcanization, and number and type of sulfur cross-links that form. These factors in turn play a significant role in determining the performance properties of the vulcanizate.There are seven principal classes of accelerators which include thiazoles, sulfenamides, guanidines, carbamates, thiurams, xanthates, and phosphates (Fig. 9). There are also miscellaneous accelerators that do not fit into these categories. In addition, blends of several accelerators are prepared which are designed as cure packages for a specific applications. Choosing the best cure system requires extensive knowledge of each accelerator type and its applicability in each elastomer. Table 18 shows a simplified comparison of the scorch and cure rate attributes for the five most widely used classes of accelerators used in the high volume diene-based elastomers.

Table 17. Vulcanization Agents

Accelerator Class	Elastomer	Advantages	Disadvantages
Sulfur	Dienes	Versatile	Heat and compression set resistance
Sulfur donors			
Peroxides	Saturated polymers	Heat and compression set resistance	Cure rate control
	Dienes		
Resins	Primarily butyl-based polymers	Heat resistance	Slow cure rate
Metal oxides	Halogenated polymers	Preferred for CR, CSM	Water resistance

Table 18. Accelerated Sulfur Vulcanization

Accelerator class	Example	Abbreviation	Scorch safety	Cure rate	Expected sulfur cross-link length
None present	Sulfur only	—	—	Slow	S4–S8
Guanidines	Diphenyl guanidine	DPG	Moderate	Moderate	S2–S4
Mercapto-benzothioazoles	Mercaoptobenzothiazole	MBT	Moderate	Moderate	S2–S4
	Mercaptobenzothiazole Disulfide	MBTS	Moderate	Moderate	S2–S4
Sulfenamides	Cyclohexyl-2-benzothiazole-sulfenamide	CBS	Long	Fast	S2–S4
	tert-Butyl-2-benzothiazole-sulfenamide	TBBS	Long	Fast	S2–S4
Thiurams	Tetramethylthiuram disulfide	TMTD	Short	Very fast	S2
Dithiocarbamates	Zinc dimethyldithiocarbamate	ZDMC	Very short	Very fast	S2

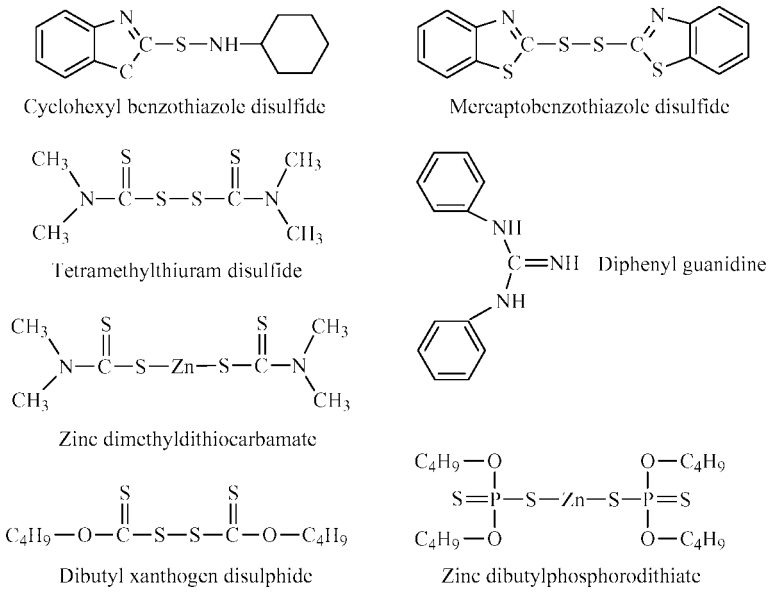

Fig. 9. Structure of a selection of accelerators.

Although differences in accelerator response do occur from one rubber type to another because of inherent differences in their molecular structures, the guidelines in Figure 10 serve as an overview of the principal accelerators and their performance (see RUBBER CHEMICALS).

It is common practice in the rubber industry for a compounder to use combinations of several accelerators in developing a cure system. Typically, these cure systems comprise a primary accelerator and one or more secondary types. Primary accelerators are generally the thiazole and sulfenamide classes; the secondary accelerators are the thiurams, dithiocarbamates, guanidines, and to a much lesser extent, certain amines and the dialkylphosphorodithioates (32). Typically, secondary accelerators are more basic than the primary or major accelerator.

The role of activators in the mechanism of vulcanization is as follows. The soluble zinc salt forms a complex with the accelerator and sulfur termed the

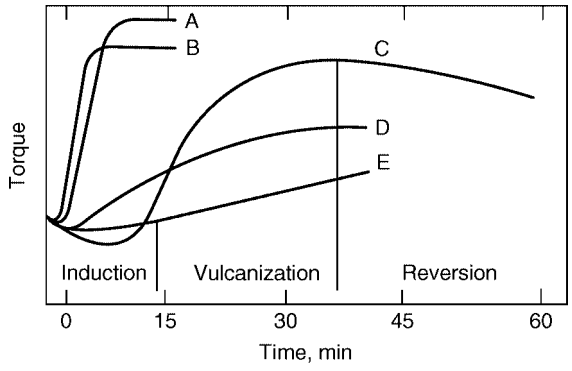

Fig. 10. Cure characteristics of accelerators: **A**, thiurams; **B**, dithiocarbamates; **C**, sulfenamides; **D**, thiazoles; **E**, guanidines. The induction period represents scorch time.

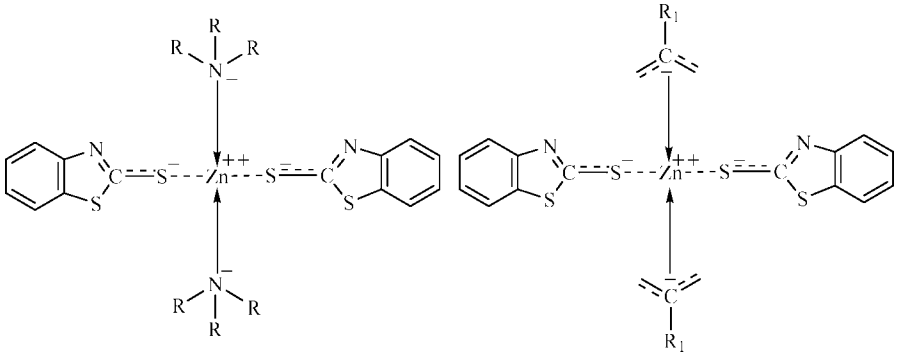
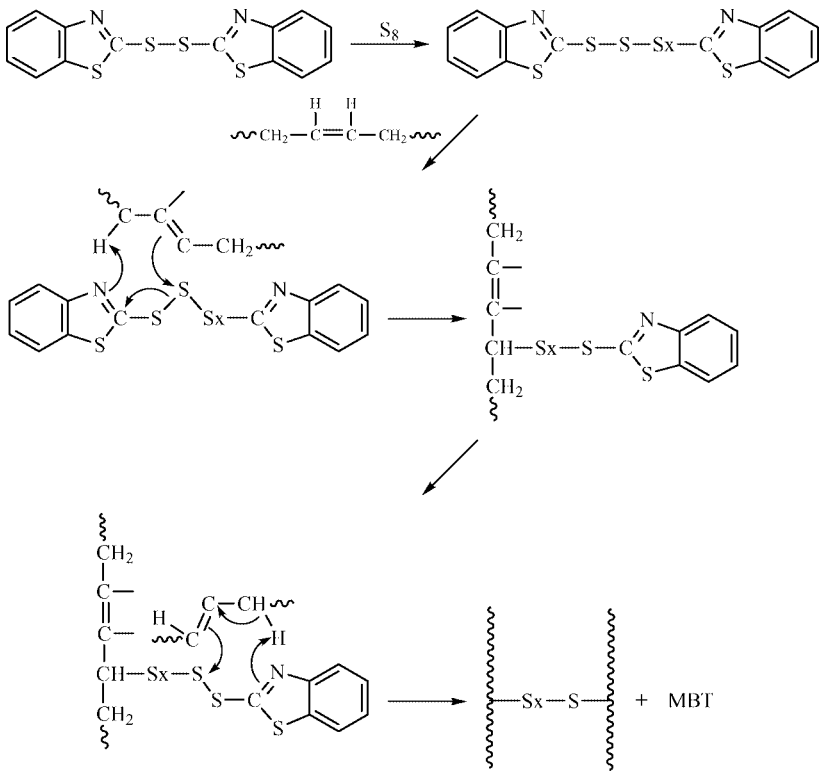
sulfurating agent (eq. 14). The sulfurating agent



(14)

is stabilized by amine from the accelerator or COO— ligands. This complex then reacts with a diene elastomer to form a rubber–sulfur–accelerator cross-link cursor while also liberating the zinc ion. For simplicity the vulcanization mechanism leading to completion of the sulfur cross-link to another rubber diene segment can be illustrated in the schematic in equation (15) (50). As a general rule the sulfenamides exhibit faster cure rate than the thiazoles. If secondary accelerators are used, dithiocarbamates give the fastest cure followed by the thiurams, then the guanidines.



(15)

Comprehensive reviews on the mechanism of vulcanization, roll of the sulfurating complex, metal oxide vulcanization, etc, are available (50,51).

Activators. *Activators* are chemicals that increase the rate of vulcanization by reacting first with the accelerators to form rubber-soluble complexes. These complexes then react with the sulfur to form sulfurating agents (eqs. 14,15). The most common activators are combinations of zinc oxide and stearic acid. Other fatty acids used include lauric, and oleic, acids. Soluble zinc salts of fatty acid such as zinc 2-ethylhexanoate are also used, and these rubber-soluble activators are effective in natural rubber to produce low set, low creep compounds used in load-bearing applications. Weak amines and amino alcohols have also been used as activators in combination with the metal oxides. Natural rubber usually contains sufficient levels of naturally occurring fatty acids to solubilize the zinc salt. However, if these fatty acids are first extracted by acetone, the resultant "clean" natural rubber exhibits a much lower state of cure. Therefore, to ensure consistent cure rate, fatty acids are usually added. Synthetic rubbers, especially the solution polymerized elastomers, do not contain fatty acids and require their addition to the cure system.

Sulfenamide accelerators generally require lower levels of fatty acid because they release an amine during the vulcanization process which acts to solubilize the zinc. Guanidines and similar amine accelerators also serve to both activate and accelerate vulcanization. A study of the effect of stearic acid and zinc oxide on a sulfenamide-accelerated, sulfur-cured natural rubber compound showed the need for both zinc and fatty acid activators is presented in Figure 11 (52).

Retarders. The purpose of vulcanization retarders is to delay the initial onset of cure in order to allow sufficient time to process the unvulcanized rubber. Several main classes of materials are used commercially such as organic acids and anhydrides, cyclohexylthiophthalimide (Santogard PVI), and a sulfenamide

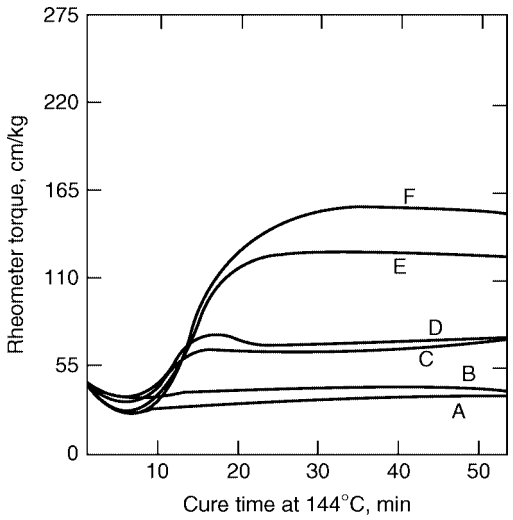


Fig. 11. Effect of activators on cure rate, where **A** is 2.5 phr sulfur, **B** sulfur plus stearic acid (2 phr) plus zinc oxide (5 phr), **C** sulfur plus TBBS (0.6 phr), **D** sulfur plus stearic acid, **E** sulfur plus TBBS plus ZnO, **F** sulfur plus TBBS plus stearic acid plus ZnO.

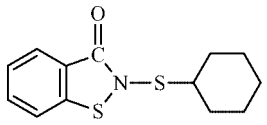
(Vulkalent E). Examples of organic acid retarders include phthalic anhydride, benzoic acid, and salicylic acids. These materials are thought to function by reaction with basic components present as accelerator fragments, from other basic compounding ingredients, and from impurities. These basic moieties, which would normally serve to accelerate vulcanization and produce a higher state of cure, are neutralized by the acid retarders. Therefore, they are effective in delaying the initial onset of cure. However, some retarders also lower the rate of vulcanization and in many cases detract from the final mechanical properties (22).



N -(cyclohexylthio) phthalimide (16)

The thiophthalimide (CTP) and sulfenamide classes of retarders differ from the organic acid types by their ability to retard scorch (onset of vulcanization) without significantly affecting cure rate or performance properties. Much has been published on the mechanism of CTP retardation. It functions particularly well with sulfenamide-accelerated diene polymers, typically those used in the tire industry. During the initial stages of vulcanization, sulfenamides decompose to form mercaptobenzothiazole (MBT) and an amine. The MBT that is formed reacts with additional sulfenamide to complete the vulcanization process. If the MBT initially formed is removed as soon as it forms, vulcanization does not occur. It is the role of CTP to *temporarily* remove MBT as it is formed. The retardation effect is linear with CTP concentration and allows for excellent control of scorch behavior.

Cure System Design. There are three generally recognized classifications for sulfur vulcanization: conventional, efficient (EV) cures, and semiefficient (semi-EV) cures. These differ primarily in the type of sulfur cross-links that form as shown in Figure 12, which in turn significantly influences the vulcanizate properties (33). The term *efficient* refers to the number of sulfur atoms per cross-link (32).

Conventional cure systems use relatively high levels (2.5 phr and higher) of sulfur combined with lower levels of accelerator(s). These typically provide high initial physical properties, tensile strength, tear strength, and good initial fatigue resistance, but with a greater tendency to lose these properties after heat aging.

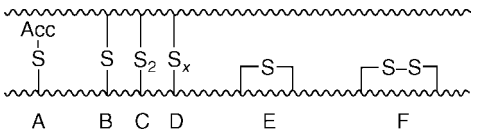


Fig. 12. Sulfur-based cure system designs where conventional systems are polysulfidic, EV systems are mono- to disulfidic, and semi-EV are di- to polysulfidic. **A** is pendent sulfide group terminated with accelerator residue, **B** monosulfidic cross-link, **C** disulfidic cross-link, **D** polysulfidic cross-link ($x > 20$), **E** cyclic monosulfidic cross-link, **F** cyclic polysulfidic cross-link, and Acc accelerator residue.

In contrast, EV cure systems employ much lower levels of free sulfur (0.1 to 1.0 phr) or they use sulfur donors such as TMTD or DTDM combined with higher accelerator levels. The short mono- and disulfide cross-links that form often do not exhibit the physical properties afforded by the conventional systems, but they better retain properties after aging. Semi-EV cures represent a compromise between conventional and EV cures. Although semi-EV cures do yield polysulfide cross-links, they tend to minimize formation of inefficient moieties such as sulfur bridging with itself, accelerator-terminated sulfur linkages, etc. This cleaner usage of sulfur is the reason for their affording a compromise properties between conventional and EV cures.

The reason for the greater loss in properties with conventional cure systems can be understood by examining cross-link bond strengths. Polysulfide bond strengths are significantly lower than are the bond strengths from the shorter cross-links obtained with EV cure systems. The relatively unstable S_x bonds break and rearrange to form mono- and disulfide linkages plus non-cross-linking cyclic and accelerator-terminated fragments. These reactions are observed as changes in properties with increased aging severity. However, conventional systems in natural rubber do provide better flex life than EV cures, and this is one of the limitations of EV curing. The short monosulfide bonds are less able to rearrange to relieve localized stresses which can build during flexing, whereas the longer S_x bonds can rearrange. This ability for stress relief is thought to be one mechanism for the superior flex life of conventional cures. If natural rubber compounds are subjected to thermal aging plus fatigue, the conventional systems perform no better than EV systems. The compromise obtained by using semi-EV systems involves the balance between heat aging and flex life.

Table 19 illustrates formulas for conventional, semi-EV, and EV cure systems in a simple, carbon black-filled natural rubber compound cured to optimum cure (t90).

All three systems give similar tensile strength, elongation, and hardness properties. Conventional and semi-EV systems tend to display better hysteresis (heat buildup) as measured by tangent delta and unaged fatigue resistance.

Table 19. Cure System Classification

Material	Conventional cure system, phr	Semi-EV (semiefficient vulcanization system, phr	EV (efficient vulcanization system), phr

[b] CBS = Cyclohexyl-2-benzothiazole-sulfenamide.
[c] TMTD = Tetramethylthiuram disulfide.

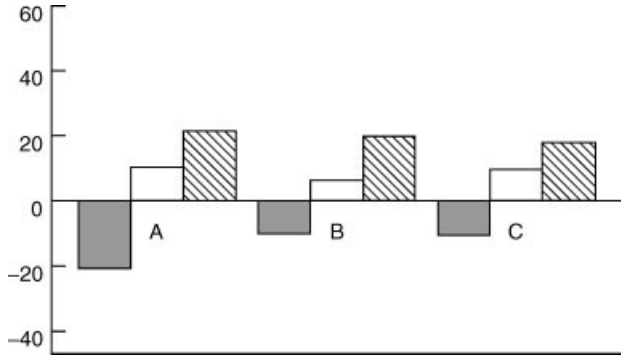

Fig. 13. Aging properties of cured natural rubber. **A** conventional cure system, **B** semi-EV, **C** EV system, ■ tensile strength loss (%), □ fatigue life, and ◥ hardness change.

Figure 13 summarizes properties obtained after heat aging these compounds at 70°C. Both EV and semi-EV systems are superior in tensile strength and hardness retention. Loss of fatigue resistance is greatest for the conventional cure. These observations illustrate the importance of achieving the necessary cross-link structures for an optimum balance of properties. These illustrations are for compounds subjected to ideal or t90 cure conditions at a relatively mild temperature of 140°C. Extremely high cure temperatures, such as those used in injection molding, can be expected to alter these results, but not the overall trends.

In a study of how cross-link structure of a conventionally cured compound changes as a function of cure time, it was observed that total cross-links decrease rapidly past optimum cure (reversion) and that most of the cross-links lost are the S_x types as cure progresses (7). Cure temperature affects cross-link density; there is a dramatic decrease in cross-link density as cure temperature increases. This is a serious concern for the compounder charged with increasing productivity by going to higher temperature, shorter cure cycles. Although plant efficiencies might improve, compound performance is likely to deteriorate.

Cure Systems of Butyl Rubber and EPDM. Regular (nonhalogenated) butyl rubber is a copolymer of isobutylene with a small percentage of isoprene which provides cross-linking sites. Because the level of unsaturation is low relative to that of natural rubber BR, or SBR, cure system design generally requires higher levels of fast accelerators such as the dithiocarbamates and thiurams. Examples of typical butyl rubber cure systems, their attributes, and principal applications have been reviewed (18). Use of conventional and semi-EV techniques can be used in butyl rubber as shown in Table 20 (4).

EPDM is a terpolymer of ethylene, propylene, and a small amount of an unsaturated diene as a third monomer to provide a cure site. Unlike the elastomers previously discussed, the unsaturation in EPDM is not in the main chain, but it is pendent to the chain. Peroxide-based cure systems afford better aging resistance and low compression set. A comparison of a sulfur-based cure to two different peroxides in EPDM is shown in Table 21 (4). Initial properties for these three compounds are reasonably close. However, after air aging, the advantages of peroxide curing are apparent. Most dramatic is the improved compression set

Table 20. Conventional and Semi-EV Cure Systems for Butyl Rubber (in PHR)[a,b]

Ingredient	Semi-EV	Conventional
Sulfur	0.5	2.0

obtained by the highly stable C—C cross-links developed with peroxides. Other advantages include ability to achieve high transparency or nondiscoloring and very low creep or stress relaxation. Disadvantages limiting the use of peroxides include poor hot tensile and tear strengths, slow cure rate, a tendency for scorch problems, and somewhat more difficult storage and handling problems in the factory.

Effect of Other Compounding Ingredients on Vulcanization. Other ingredients besides the elastomer and the cure system itself influence cure and scorch behavior. Usually the effect of a material on compound vulcanization is dependent upon the pH of the material. Ingredients which are basic in nature tend to accelerate the rate of both scorch and cure, whereas acidic materials exhibit the opposite effect. Reviews of the effect of antidegradants, fillers, process oils, and plasticizers are available (6,14,32,33).

Amine-type antioxidants or antiozonants such as the *p*-phenylenediamines (PPD) can decrease scorch time. As the PPD degrades and liberates free amine, scorch time decreases and cure rate is increased.

Nonblack fillers such as the precipitated silicas can reduce both rate and state of cure because of their strong physical interactions with the polar activator and accelerator chemicals. Neutral fillers such as calcium carbonate (whiting) and clays have little or no effect on the cure properties. Carbon black effects are small.

General Strategy (Statistical Techniques). Often statistically designed experiments are used to optimize curative levels (53). By using properly designed experiments, ie, balanced and/or orthogonal arrays of curative levels, regression analyses can be performed which quantify the effect of each ingredient, and combination of ingredients (interactions), on the properties of interest. From this, an optimum balance of properties is obtained much more efficiently than via the traditional approach of linearly varying one ingredient at a time. It is encouraged

that this technique be used for solving problems in cure system design or any problem involving optimizing combinations of materials and identifying interactions between materials.

Tire Compounding

The pneumatic tire consists of two basic areas: the tread area which is responsible for ground contact, and the casing which is responsible for supporting load and transmitting power to the tread area. Each of these areas has several components with different properties which serve specific and unique functions, and all of which must interact for maximum performance (8,54). The role of the rubber compounds which are used in these basic components is threefold: (*1*) to provide the contact area between the vehicle and the surface; (*2*) to provide the cohesive

material that holds the tire together such that it acts as an integral unit; and, (*3*) to provide protection for the ultimate strength bearing components, ie, the textile, steel beads, and steel or fabric breakers or belts in radial tires.

Tire Component Parts. Desired properties in the components of a radial steel belted passenger car (PC) tire are as follows. The tread is designed and compounded for abrasion resistance, traction, low rolling resistance, vehicle handling characteristics, and protection of the casing from road hazards and obstacles. Often it is divided into two subcomponents to maximize performance: the outer tread for surface contact and the undertread for tying into the casing while reducing tire rolling resistance through decreased hysteresis.

The steel belt, which provides strength and protection for the ply or plies, is encased in a compound that must possess adhesion to the steel which provides stress transfer from the very rigid steel to the considerably more flexible tread, sidewall, and textile carcass components. The wedge compound is formulated to reduce belt-edge sheer stresses while tying the belt to the carcass and reducing hysteresis.

The casing ply coat compound functions are similar to the steel breaker compound. Normally in the steel belted passenger car tire, the ply is a textile cord of polyester or nylon fabrics which are soft and flexible. The truck radial steel tire normally uses a steel cord ply. Earthmover tires are of two basic constructions, ie, radial using steel and bias using textiles. The sidewall compound is formulated to protect the ply and must possess resistance to weathering, ozone, abrasion, and tearing while providing excellent flex fatigue resistance. The innerliner compound must provide good air-permeation resistance and resist moist, hot-air aging.

The apex (often referred to as bead filler) compound must be formulated for dynamic stiffness to facilitate stress distribution and provide good car-handling properties. The bead insulation compound must possess good adhesion to this most important component for enclosing the plies of the tire and holding the tire to the rim. The chafer or rim strip compound protects the plies from rim abrasion and seals the tire to the rim.

There are many ways to measure these properties, some of which are proprietary. However, most laboratory tests are standardized by the American Society for Testing Materials (ASTM). Many of them are interactive to various degrees. The rate and state of vulcanization is especially important to consider for components of heavier and thicker tires. The heat used to vulcanize the tire in a mold under pressure requires time to penetrate from both sides, of the larger tire to the innermost portions. Securing a balanced state of cure, ie, the maximizing of physical properties in all the components, results in the innermost components having a faster rate of cure. The peripheral compounds should have a cure system which holds its physical properties well when overcured. Most tire companies utilize their own physical and chemical laboratories in addition to extensive tire-testing facilities which include laboratory and field vehicle tests. These facilities are augmented by the availability of private commercial companies which operate worldwide.

Materials. Tire compounds contain the following generalized ingredients in the approximate proportions noted. Industry practice is to formulate starting with 100 parts per hundred weight of the rubber (phr). Table 22 offers examples for various treads.

Table 22. General Composition of Tire Tread Compounds by Application[a]

Compound	Material	Standard, phr	High performance, phr	Low rolling resistance, phr	Radial medium truck, phr
Polymer	NR			0–40	60–100

[a]Ref. 7.

There may be as many as 15 different compounds in a single tire. Each compound typically uses between 8 and 12 ingredients. There are approximately 1000 different chemicals or materials used in the tire compounding field. Thus, the potential combinations are extremely high. In addition, interactions between materials are encountered and must be controlled. For example, premixing of certain vulcanization ingredients must be avoided because of their reactions with each other and formation of end products that do not give the desired rate and state (number of elastomer cross-links) of cure in the finished tire. Interactions are not limited to the 8 to 12 ingredients within a single formula, but may also occur between the compounds of adjacent components, in preassembly of components for tire building, in storage of green (uncured) tires, in vulcanization of the tire, in warehousing, and during operation of the tire through its service life.

Migration of chemicals from adjoining compounds, in addition to preferential absorption of various materials into each other, makes knowledge of the chemistry and physics of materials most important in realizing specific, highly varying properties in the different compounds and components necessary to maximize tire performance and optimize cost. Some interactions of materials are desired. For example, without migration of resins at compound component interfaces, adhesion of one component to another is significantly weakened and intercomponent separation is enhanced. Solubility parameters of materials are important in processing of compounds and components. A material used in excess of this parameter can bloom (diffuse to the surface of the component) and render it difficult in final tire assembly or inhibit the desired migration of other ingredients and weaken component interfacial adhesion.

Tire Elastomers. For the mechanical strength requirements of tires, NR is better than SBR or BR and offers excellent tread chipping/chunking resistance with low tire running temperatures and improved rolling resistance. Although more difficult to mix and process, it is very good in downstream processes such as extruding, calendering, and tire building. Although good in chip/chunk-type wear and in severe stress wear, it is usually faster wearing in nominal passenger and truck over-the-road tires. It offers better ice traction and excellent flexibility in extreme low temperature service (ie, less than 40°C). It is by far the preferred rubber for wire belt and textile ply/breaker coat compounds.

SBR is by far the preferred polymer for passenger car tire treads, mainly owing to its good wear and traction. It is also the least expensive polymer when produced by the emulsion (water-based) process which is the most commonly used. In the 1980s, specialty solution polymerized SBRs (SSBR) were introduced. These rubbers, using hydrocarbon solvent such as hexane as media and special catalytic systems, were found to offer increased capabilities for compounders to improve rolling resistance for decreased fuel consumption while maintaining high levels of wear and traction. The specialty SSBRs accomplish this through control of the styrene–butadiene polymer backbone structure, coupling of polymers, and addition of reactive chemical units at the polymer ends. Not all of these changes are used in the same specialty polymer, but coupled polymers are common and can significantly affect polymer molecular weights; ie, larger (higher molecular weights) branched polymers which are more difficult to produce, are more expensive, and have some deficiencies in processing. Many of these polymers are available in the

oil/black master batch (premixed blends) as is the emulsion SBR. SBR, whether emulsion or solution, is still not as resilient as NR or BR which limits applications in tires.

BR can be produced in both emulsion and hydrocarbon solution processes. It is the butadiene part of SBR that is controlled in specialty SSBRs. Originally polybutadiene found its niche in tires by offering excellent over-the-road wear characteristics because of its high cis, high linearity structure. This offers resilience (low hysteresis) and excellent flex fatigue resistance along with excellent wear and could only be achieved in the more expensive solvent process. BR is more difficult to process in the factory, particularly in milling operations. It does not possess the excellent tack of NR and makes tire building more difficult. BR is also very low in resistance to tearing.

Halobutyl rubber (HIIR) is used in innerliner and white sidewalls, and sometimes in treads to improve winter traction properties. This class of polymer offers marked improvements in tire-air retention owing to lower air permeability as well as excellent age resistance and flex fatigue life. Both the chlorine and bromine versions of isobutylene isoprene rubber (IIR) are used to improve co-vulcanization with the other commodity tire rubbers. It is an almost saturated polymer with few sites (1–2%) available for conventional sulfur curing. IIR offers high hysteresis at nominal tire operating temperatures and thus acts as a superior cushioning rubber. It is the preferred rubber for tire curing press bladders. A new isobutylene polymer modified with *p*-methylstyrene and subsequently brominated is available which offers a fully saturated backbone to resist aging while improving compatibility with tire commodity rubbers. Use of such polymers may allow improvement in a broad range of tire performance parameters.

EPR has a fully saturated backbone and has only unsaturation points available for vulcanization cross-linking in very small percentages of the pendent diene modifier (EPDM). It is an excellent aging compound with high flex fatigue life even when heavily loaded with fillers and is utilized in PC tire white sidewalls.

It is common to use more than one type of rubber within a given compound. An example of this is the truck tire sidewall which must not only possess high strength but must also have excellent aging and flex fatigue life in order to survive multiple retreading, ie, vulcanizing a new tread to the worn original tire casing. The original casing of a radial truck tire, if properly maintained, can last for a million miles, while the original tread on this casing can deliver 100,000 to 300,000 miles. In passenger car tires, as many as four different polymers may be used for the tread compound totaling 100 phr; eg, 25 phr emulsion SBR, 25 phr SSBR, 30 phr BR, and 20 phr NR. If solution polymerized SBR categories can be considered as falling with a 10°C T_g range increments, there are at least nine groups of specialty SSBRs that are commercially available. In addition some large vertically interated, tire companies are producing for their own captive use. Natural rubber can be purchased in several grades. SBR also comes in different grades and is available in oil and oil/carbon black master batches (oil and/or carbon black added to the rubber at the rubber producers) which may use a different SBR (usually higher molecular weight) than if it were produced without master batching. The use of different materials within a single grouping is commonly encountered, ie, the use of two or more elastomers making up the 100 parts total as mentioned above.

Table 23. Carbon Blacks and Their Applications in Tires

		Tire components						
Series	Tire types	Tread	Sidewall	Ply breaker	Apex	Chafer	Bead	Liner

N200	Most	+				+		
N300	Most	+	+	+	+	+	+	
N500	Most			+			+	+
N600	Most			+			+	+
N700	Most			+				

Tire Compound Filler Reinforcement. The popular carbon blacks for tires and their application patterns are shown in Table 23. In tires, carbon black is important because of the high flex fatigue and tear strength requirements of this product. Poor dispersion may result in premature cracking in both treads and sidewalls. In off-the-road tires, poor dispersion could result in excessive chipping, chunk-outs, and cutting of tread material, causing a significant loss in treadwear in addition to tread "base-of-lug" cracking which can lead to loss of an entire lug. Because of demands for improved fuel consumption through reduced rolling resistance, a new series of carbon blacks referred to as low hysteresis or LH, which are N220 or N300 series, have emerged. Basically these series of carbon blacks have a wider size range in both the primary particles and primary aggregates in addition to a more chemically active surface area.

Second in tonnage for tire use, silica's utilization has been increasing in spite of higher per kilogram cost because of increased compound tear strength and contribution to improvement in tire traction performance, and lower rolling resistance. Silica as a tire reinforcing filler was first introduced in earthmover tire treads owing to its ability to improve tear resistance and lower tire operating temperatures. These properties are of utmost importance in off-the-road tires, which function at high operating temperatures and encounter rocks that may cut and tear out large chunks of tread under high traction and torque conditions. With demand for improved rolling resistance, silica usage has expanded into other tire lines. This expansion has also been boosted by the introduction of a silane coupling agent, which forms a chemical bond between the silica and the rubber resulting in improved treadwear. With the use of the bifunctional silane coupling agent silica treads are equal in wear to some carbon blacks while still offering an improvement in rolling resistance. Silane use slightly reduces tear, but this is acceptable in most applications. Silica has also found applications in wire breaker coat compounds, where it stabilizes the copper sulfide bonding layer to the brass-coated steel cable, thus improving adhesion.

Reinforcement and stiffness of a compound can also be achieved with the use of reactive resins. Resins consisting of two-component systems of resorcinol or resorcinol condensation products and a methylene donor, such as hexamethoxymethylmelamine (HMMM) or hexamethyltetramine (HMT), are the most popular in tires. These materials can be prereacted and added to the formula, or for more effective results they can react *in situ*; ie, they can be added separately into the formula and react when the tire is vulcanized.

Softeners, Extenders, and Plasticizers. Other materials can affect the properties of rubber such as softeners, extenders, and Plasticizers (qv). In tires the most popular of these are petroleum oils. They are utilized for controlling green compound viscosity and vulcanized compound hardness. The term *extender* is used to denote their use to allow for increased use of reinforcing fillers as the oils are significantly less expensive than are the rubbers. These materials also act as processing aids. The term *plasticizer* is used to denote their ability to act as an internal lubricant for processing purposes as well as for improving low temperature flexibility in the vulcanized product. The synthetic phthalates are the most effective in meeting low temperature flexibility while also serving as softeners. Cost limits their application.

The petroleum oils are of three basic types: aromatic, naphthenic, and paraffinic. Naphthenic oil does not contain high levels of polynuclear aromatics and is therefore less hysteretic. Because of these considerations the naphthenic oil is gaining in usage at the expense of aromatics. Paraffinic oil is only used in very limited quantities in tire compounds. The petroleum oils are more specific to certain rubbers and therefore require compounding considerations for full optimized usage. All three softeners migrate from one compound to another, and this must be considered when compounding for a set range of stiffness (modulus) gradiations in the tire components designed to alleviate stress.

(1) *Processing aids*. Petroleum oils are processing aids as well as functioning as softeners, extenders, and plasticizers.

(2) *Peptizers* are materials used rather extensively in natural rubber (NR) compounds. When added to NR in premastication, they cleave or break the molecular backbone resulting in lower molecular weights which allows for easier processing. However, there has been a move to reduce usage in order to maximize strength. Some tire companies have gone to mixing variations which are more expensive to preserve molecular weight.

(3) *Other processing aids* utilized in tires are vegetable oils (fatty acids, fatty acid esters, alcohols, and metal salts of these oils), naturally occurring resins such as pine tar, and hydrocarbon resins.

The main benefits of processing aids are as follows: (*1*) improving incorporation of fillers; (*2*) reducing mixing energies; (*3*) reducing internal friction for ease of milling, extruding, and calendering; (*4*) compatibilizing the different rubbers for improved processing as well as for better adhesion of one compound to a different compound in the vulcanized tire (compatibilizers have gained markedly in usage because of polarity differences of blended polymers); and (*5*) providing improved green tack (tackifiers) for better tire building.There is a definite trend in the industry to develop multifunctional materials with value-added properties.

Vulcanization System Components. Tire compounds are almost exclusively cured (cross-linked) with sulfur. Sulfenamides, thiazoles, thiurams, guanidine, and carbamates are the most popular choices to accelerate curing. Efficient vulcanization (EV), semiefficient (semi-EV), and the conventional curing systems

are all used, sometimes in the same tire for different compounds and components. They are also varied depending on the elastomer or elastomer blend used within a given compound, such as a compound using a blend of NR and SBR which uses a more efficient cure system than NR alone may require.

Zinc oxide and stearic acid are used to activate the curing system as well as to preserve cured properties when overcuring, which is curing beyond the point of time and temperature at which maximum properties are obtained.

Overcuring is encountered to some degree in all compounds of any thickness because of the slow conduction of heat through rubber. Earthmover tires may have tire shoulder gauges in excess of 0.3 m (12 in.). The outside and inside of the tire are overcured to obtain a satisfactory state-of-cure in internal components. Even though heat is being conducted to the midpoint of the tire shoulder from both sides it can take many hours to reach the same temperature as the plies and that portion of rubber next to the mold. Although the earthmover tire epitomizes this phenomena, it is an excellent example of the problem of maximizing cured properties which change rather dramatically with state-of-cure. The properties of tear strength, resilience, modulus, tensile strength, elongation, and cut growth (fatigue) are significantly affected by state-of-cure. Of course many factors are involved in effecting the desired end goal of an optimized state-of-cure: the mold, the temperatures and media to effect the temperatures, the pressures, etc. Thus knowledge and understanding of engineering and physics, particularly thermodynamics, in addition to the chemistry of rubber and material reactions, are required.

An important consideration of any vulcanization system is scorch resistance. Scorch time is that period after heat has been applied until a significant change in compound stiffness occurs indicating that cross-linking of the polymer has initiated. As the rubber compound is hot when the accelerators and sulfur are added, it appears that the scorch period starts immediately. As the compound is processed through the factory to form tire components, it is heated and is subject to premature vulcanization (scarch) if heat is excessive (scorch). Scorched compounds are more difficult to process to their finished component.

To assist in control of the onset of vulcanization, a retarder or prevulcanization inhibiter (PVI) is used. Retardation of the onset of cure does not mean that the rate of cure is slowed; in fact, cure rate may actually be increased. Rather, there is an extension to the induction period prior to cure.

Compound Formulating. Generally two basic approaches are used to formulate for achieving desired tire performance: the use of known relationships of materials used in a given compound to a specific performance parameter, and computing relationships of materials to physical properties and in turn estimating the effect on a given performance parameter. Using physical properties relating to performance parameters facilitates development of regression equations to predict performance for laboratory screening of potential improvements. Many of these relationships are well established. The two main categories of measurement criteria are either classical mechanical or dynamic mechanical properties.

Mechanical Strength. Strength is measured in the laboratory with tests of stretch, compression, and torque in both uncured and cured compounds. Uncured or so-called green compounds are measured to assess processing

characteristics. An example is plasticity of the green compound at a given temperature and torque to predict the ease or difficulty of milling, extruding, and calendering to secure a given profile and, or gauge of a component for subsequent tire building. Cured compounds are tested for mechanical or physical properties to relate them to a specific tire parameter. Both green and cured properties are run after mixing of a formula to assure its correctness before subsequent processing for given components. Testing is also conducted on the final component before tire building in some cases.

Some tests, while undergoing deformation, are usually referred to as static, in that they are performed at slow speeds or low cycles. Examples of these tests are stretch modulus, ultimate tensile strength, and elongation to break, ie, a measure of total energy capabilities or rupture phenomena. Dynamic properties are measured by continuous cycles of varying deformation (tension, compression, or shear), at varying frequencies which can be set close to that which a component would experience in a tire. These properties are more correlative to many tire performance parameters.

Aged and Fatigued Properties. Tire compounds are subjected to static and dynamic aging throughout their entire life cycle. Static aging begins even in the green (uncured) state with exposure to oxygen, ozone, light, heat, and humidity. In the tire factory, these effects can be minimized to the point where they barely exist. Factory tire compounders are assigned to tire plants to assure the integrity of their compounds throughout the production cycle. Even as tires are warehoused they are protected by regulations and procedures followed by the material's technologist or compounders. It is when tires are applied to the vehicle that this natural phenomenon of aging becomes most important.

Heat has a detrimental effect on rubber compounds. For example, the tensile strength of a tire compound at 150°C may only be 50% of its room temperature maximum. Furthermore, most of the strength properties, such as tear strength and modulus, are similarly affected. When a tire is heated up through use and allowed to cool again to ambient temperature, it loses some of its original strength and is subject to attack by ozone. This can sever molecular chains and leads to cracking at points of deflection. Finally, flex fatigue resistance diminishes markedly upon aging and repeated cycling because of chemical changes in the compound when heated by rolling and working. Low tire inflation means more work and more heat adding to degradation by a power factor.

Wire cords are particularly subject to degradation of their adhesion values by moisture. To combat this, halogenated butyl (HIIR) use is essential in tire innerliners because of its property of low air and water vapor diffusion rates. Moisture is present in most air pumps and many tires are mounted with water left in the tire on mounting. For these reasons, tires and tire compounds are tested extensively at simulated aging conditions in the laboratory and on test vehicles before they are sold to the customer.

Test Methods

Because of the long-range elasticity of soft rubber vulcanizates and the various special conditions under which they are degraded in use, special test methods

have been developed which in many respects are unlike those used for wood, metals, and hard plastics. The American Society for Testing and Materials (ASTM), through its Committee D11 on Rubber and Rubber-like Materials, is constantly developing and promulgating new and improved methods for testing rubber and rubber products.

Test methods to characterize rubber compounds fall into four general catagories.

(1) Rheological characterization, which would include measurement of compound viscosity using a Mooney Viscometer, indicating ease of processing, vulcanization and curing kinetics, and rheological information obtained from a capillary rheometer.
(2) Classical mechanical properties such as tensile strength, tear strength, peel adhesion, hardness, and aged properties.
(3) Dyanamic mechanical properties such as storage modulus and loss modulus obtained in tension, compression, and shear. A range of associated terms may be calculated from this data which in turn can be used to estimate final product performance parameters.
(4) Secondary properties which might include properties such as permeability, fatigue resistance, rebound, and heat buildup.

The test protocol followed in a development program will depend on the nature of the final product under development. However, as a minimum, based curing properties, processing properties, and basic mechanical properties are required for decisions regarding selection of a compound formula to be used in a product such as a hose or belt.

Summary

The science of rubber compounding is among the most complex disiplines in industrial chemistry. The role of the modern materials scientist in the tire and rubber industry is to use materials to improve current products and develop new technology products. Four major factors govern this development process:

(1) *Quality*. The product must meet the design expectations and be trouble-free.
(2) *Performance*. The product must meet the customer's expectations.
(3) *Environmental*. Products must be in compliance with regulatory requirements and present minimum concern with regard to disposal.
(4) *Cost*. The product or system of which the rubber part is a component must provide value to the customer.

In meeting these objectives, the disipline of rubber compounding has evolved from an "art" 50 years ago to a highly complex science.

RUBBER, GUAYULE

Introduction

Natural rubber (*cis*-1,4-polyisoprene [9003-31-0]) is a vital, strategic, and irreplaceable raw material used in enormous quantities by the commercial, medical, transportation, and defense industries (1) (see RUBBER, NATURAL). At least 40,000 different products and over 400 medical devices contain natural rubber (2). Primarily due to its molecular structure and high molecular weight (>1 million g/mol), natural rubber has excellent performance properties, such as elasticity, resilience, heat dispersion, abrasion resistance and cold-malleability, which cannot easily be mimicked by artificially produced polymers derived from petroleum. Demand for natural rubber has increased throughout the last century, despite competition from synthetic rubber, and currently constitutes 40–45% of the total amount of natural and synthetic rubber used (1,3,4). Temperate-zone regions, including the United States and Europe are wholly dependent upon imports from tropical countries. At present, almost all commercial natural rubber comes from a single tropical plant, *Hevea brasiliensis* Müll. Arg. [the Brazilian rubber tree (5) referred to as "Hevea" in this article], mostly from plantation-grown, clonal trees, made by grafting clonal buds onto seedling rootstocks. Global dependence on this single species for natural rubber is risky because *H. brasiliensis* cultivars have very little genetic variability. This lack of genetic diversity leaves the crop susceptible to pathogenic attack and failure (6,7). Disease is the primary cause of the current dearth of production in South America, and global rubber production could essentially be destroyed by the introduction of South American leaf blight into southeast Asia. Asia currently supplies over 90% of the world demand for Hevea natural rubber (1). Despite steadily increasing demand, largely fueled by the developing automotive industry in China, Hevea acreage has diminished in recent years as growers change to palm oil and other higher value crops, and a shortage of natural rubber is expected in the near future. Moreover, Hevea has strict climatic requirements, limiting its cultivation to specific tropical regions. Natural rubber prices are directly tied to labor costs which increase as the rubber-producing countries develop; latex production is labor-intensive since it is tapped by hand following incisions in the bark of the trees (5,8). In addition, in 2002, the

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

three principal rubber-producing countries, Thailand, Malaysia, and Indonesia, formed an (Organization of Petroleum Exporting Countries) OPEC-like rubber triumvirate. The immediate goal of the triumvirate, which controls 70% of global production, is to reduce rubber production by 4% and exports by 10%, and drive up natural rubber prices.

The United States is the largest single natural rubber consumer in the world, using about 18% of the global supply of 6.8 million metric tons for its commercial, medical, transportation, and defense industries (1,2,9,10). The United States imports, at a cost approaching $2 billion, about 1.2 million metric tons of raw natural rubber for manufacturing products worth billions of dollars, in addition to its enormous finished goods imports (over $8 billion, containing 349,000 metric tons of rubber) (1,2,9,11). Unlike fossil fuel, the United States has no domestic source of natural rubber to buffer or ameliorate the effects of the triumvirate's decisions, and prices are expected to increase in double digits for several years to come.

Quite apart from the issue of security of supply, another fundamental problem with Hevea rubber concerns the worldwide occurrence of life-threatening, IgE-mediated, latex allergy caused by the proteins in Hevea latex and latex products. Complete protein removal cannot be easily or cheaply achieved, or proven, and, when attempted, negatively impacts latex product performance (3,12). This has led to the ongoing effort to commercially produce hypoallergenic latex from domestically-grown guayule employing the best lines from the U.S. Department of Agriculture (USDA) and university plant-breeding programs.

Although over 2500 plants are known to produce natural rubber, few synthesize commercial quality or quantities (13,14). A notable exception is guayule (*Parthenium argentatum* Gray), a species classified in the Class Angiospermae, the Subclass Dicotyledonae, the Superorder Asteridae, the Order Asterales, the Family Asteraceae (Compositae), the Subfamily Asteroidae, and the Tribe Helianthae. Guayule is a woody shrub native to the Chihuahuan Desert of northern Mexico and the Big Bend region of Texas. Guayule produces linear, high molecular weight natural rubber that can have physical properties and applications equivalent to those of Hevea rubber (15,16). Guayule rubber can be extracted as a solid bulk polymer (17) or as a latex (18–21). Guayule also is one of very few rubber-producing plants to have ever been used commercially for rubber production (22,23). Although guayule rubber was commercially produced in the early part of the last century (22,23), more recent efforts to reinstate production have not led to commercial success because the production costs of bulk rubber were too high to permit direct competition with Hevea rubber (24). Guayule commercialization has been revitalized in recent years by use of the plant to produce hypoallergenic latex, a higher value rubber raw material (25–30).

Biology and Biosynthesis

Natural rubber is a secondary product, compartmentalized in cytosolic rubber particles, which is not recatabolized during the life of the plant. Rubber particles are often made in laticifers, as in Hevea (5,8), but guayule produces them in generalized bark parenchyma cells (31,32). The rubber particles probably originate

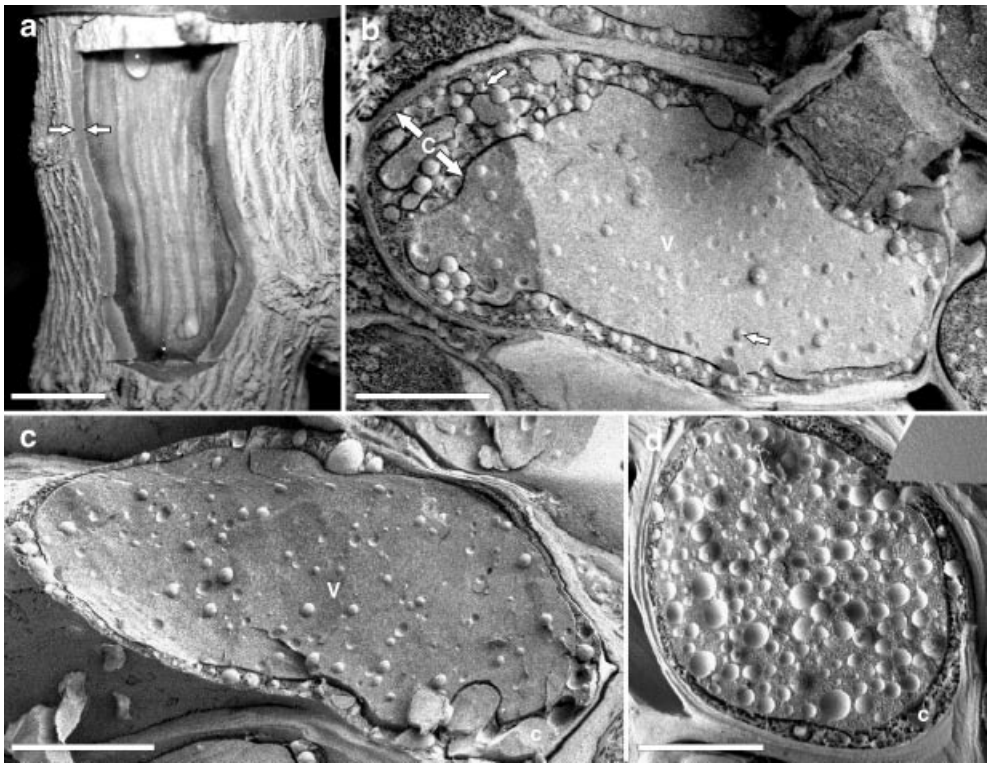

Fig. 1. (**a**) Guayule stem segment (line O-16-1, large, older stem) showing the region where the excised tissue piece for SEM study was taken. The cells containing the rubber particles are located in the tissue indicated between the two arrows, just beneath the bark. (**b–d**) Cryo scanning electron micrographs of rubber-containing cells showing cells from (**b**) young tissue containing rubber particles in the cytosol as well as in the vacuoles, (**c**) maturing cells from medium-sized stems showing an increasing accumulation of rubber particles in the large central vacuole and rubber particles compressed into a single layer in the much-diminished, surrounding cytosol, and (**d**) mature cells from large-sized stems showing a central vacuole filled with rubber particles, and a single layer of rubber particles in the remaining cytosol. Cells are from the following lines: O16-1 (**b**); AZ101 (**c**); N9-5 (**d**). C, cytosol; cw, cell wall(s); V, vacuole. Magnification bars: (**a**) 5 mm; (**b–d**) 10 μm. Photograph from Ref. 33.

in the rough endoplasmic reticulum, but little is known about ontogeny or development. In guayule, as tissues age and the cytosol fills with particles, the rubber particles also move from the cytosolic compartment to fill the vacuole (Fig. 1). As in all rubber-producing plant species investigated to date, rubber is synthesized in guayule by an enzyme called rubber transferase (*cis*-prenyl transferase, EC 2.5.1.20). Although soluble rubber transferases have been reported (34; and see literature reviews in References 35 and 36), rubber polymerization is catalyzed by a rubber particle-bound enzyme (35–41); the earlier reports can be explained by the role of the soluble enzymes in the synthesis of allylic pyrophosphate (allylic-PP) initiator molecules. The membrane-bound rubber transferase is associated with the monolayer biomembrane surrounding the rubber

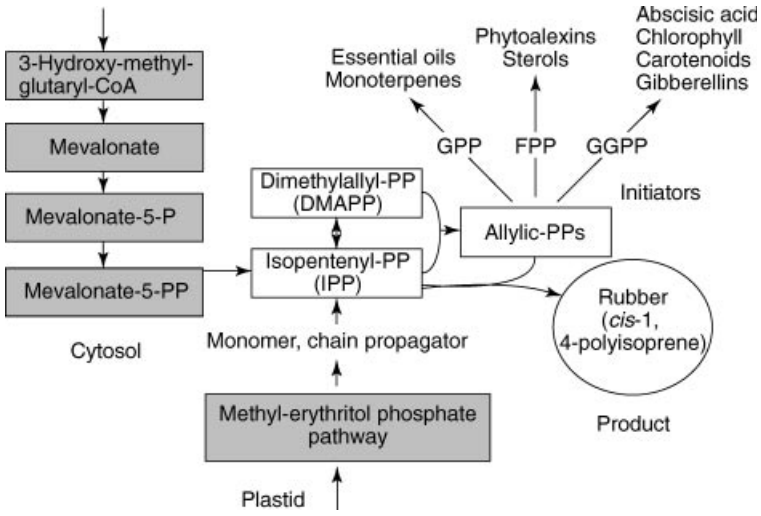

Fig. 2. A section of the isoprenoid pathway illustrating the branch to rubber biosynthesis. Rubber (the product) is synthesized in the cytosol from one molecule of allylic pyrophosphate (the initiator) and many molecules of isopentenyl pyrophosphate (the monomer). Isopentenyl pyrophosphate is produced by the cytosolic mevalonate pathway and by the plastidic methyl-erythritol pathway, as indicated by the shaded boxes. GPP, geranyl pyrophosphate; FPP, farnesyl pyrophosphate; GGPP, geranylgeranyl pyrophosphate.

particles (32,35–44). Rubber transferase produces the rubber polymer (*cis*-1,4-polyisoprene) from isoprene monomers, which it links, chain-like, to an allylic-PP initiator molecule. The rubber polymer grows as more isoprene units are added to the chain. Each rubber transferase is capable of producing many rubber polymers in series, but the eventual polymer molecular weight may vary depending upon substrate concentration, and also varies considerably among species (2,9,45–47). In all rubber-producing species so far investigated, including guayule, rubber transferase requires an allylic-PP substrate (produced by soluble *trans* prenyl transferases) to initiate polymer formation, and a divalent cation, such as Mg^{2+} or Mn^{2+}, as cofactor (35,39–41,48,49). The initiator normally used *in vivo* by rubber transferase appears to be the C_{15} farnesyl pyrophosphate (FPP) (48), although rubber transferases are able to accept a wide range of allylic-PP's as initiating substrate (38,39,45,50), and Mg^{2+} is the *in vivo* cofactor (49). The substrates for rubber biosynthesis, isopentenyl pyrophosphate (IPP) (the monomer) and its allylic pyrophosphate (APP) catabolites (the initiators), are synthesized from carbohydrates via acetyl-coenzyme A, 3-hydroxy-3-methylglutaryl-coenzyme A reductase, and mevalonate (Fig. 2) (51). The plastid-localized deoxy-xylulose/methyl-erythritol phosphate pathway also produces IPP (52,53), but it is not yet known if this contributes to the cytosolic IPP pool from which the rubber polymers are synthesized.

Rubber biosynthesis is an unusual enzymological reaction in that the rubber transferase can accept any one of a number of APPs as the initiating molecule (38,39,45,50). However, the identity of the initiating molecule affects the IPP condensation reaction rate as the rubber molecule polymerizes (Fig. 3). In nonlimiting

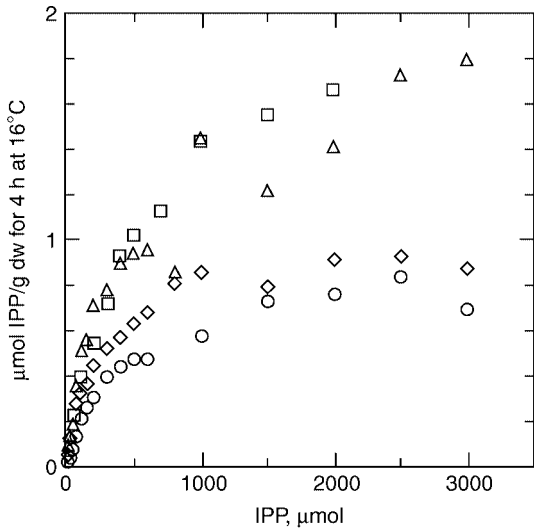

Fig. 3. Dependence of IPP incorporation rate by rubber transferase on IPP concentration in 20 μM allylic pyrophosphate initiator: ○ DMAPP, △ GPP, □ FPP, ◇ GGPP. Data from Ref. 54.

APP concentrations, the longer the initiator, up to the FPP, the higher the rate of IPP incorporation into rubber by the guayule rubber transferase (45,54). In this species, the C_{20} initiator geranylgeranyl pyrophosphate (GGPP) leads to a slower IPP polymerization rate with only the C_5 dimethyl allyl pyrophosphate (DMAPP) giving a slower rate. It is noteworthy that the lower IPP incorporation rate in the presence of GGPP as the initiator is not due to a decrease in the affinity of the rubber transferase for IPP as compared to the affinity in the presence of GGPP or FPP. In fact the IPP affinity is actually greatest in GGPP (Table 1).

Kinetic analysis of the dependence of IPP incorporation on APP concentration (Fig. 4, Table 1) has indicated that multiple binding constants are involved in the reaction, and led to the interpretation that the rubber transferase active site contains a nonspecific hydrophobic binding region which traverses the particle monolayer membrane and with which the growing rubber molecule interacts

Table 1. Substrate Binding Constants for IPP in the Presence of Different APP-Initiating Substrates and the Different APPs[a,b]

Initiator	Size (Number of Carbons)	K_m^{IPP}, μM	K_m^{APP}, μM
DMAPP	5	400	3.52
GPP	10	400	0.50
FPP	15	370	0.02
GGPP	20	240	0.02

[a] Reactions were performed for IPP (isopentenyl pyrophosphate) in the presence of 20 μM APP (allylic pyrophosphate) initiator and for the APPs in the presence of 1 mM IPP.
[b] Apparent K_m's were calculated from log plots of $v/(V_{max} - v)$ against substnrate concentration [S].

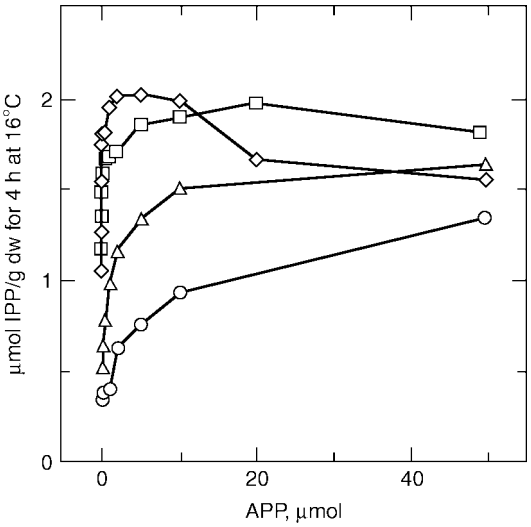

Fig. 4. Dependence of IPP incorporation rate on allylic pyrophosphate initiator concentration in 1 m*M* IPP: ○ DMAPP, △ GPP, □ FPP, ◇ GGPP. Data from Ref. 54.

until the rubber core is reached (2,9). Because DMAPP is an effective initiator of rubber biosynthesis, the specific allylic pyrophosphate binding site probably recognizes the allylic carbon and pyrophosphate and specifically binds via an amino acid/magnesium ion/pyrophosphate bridge in a manner comparable to other prenyl transferases [aspartate being the amino acid employed there (55–57)]. The rubber transferase presumably binds the same small portion of the larger allylic pyrophosphate molecules. A nonspecific hydrophobic binding region may account for the higher binding affinity of the larger allylic pyrophosphate initiators, and the greater this hydrophobic interaction between the allylic pyrophosphate and the binding site, the higher the overall affinity of the enzyme for the substrate.

The binding affinity of the guayule rubber transferase for the different APPs varies considerably. The K_m^{FPP} and K_m^{GGPP} are much lower than the K_m^{GPP} or K_m^{DMAPP} (Table 1). The guayule rubber transferase also exhibits strong negative cooperativity for the FPP and GGPP (Fig. 5). Thus, when a new rubber molecule is initiated by FPP (or GGPP) it becomes much more difficult for another initiator to bind. This directly inhibits the chain transfer reaction and allows the rubber molecule to continue to grow. This property of the guayule rubber transferase may be why the rubber produced during the summertime still appears to be of high molecular weight even though the overall rate of synthesis is slow at that time of year. Of course, *in vivo* it is unlikely that the plastid-produced GGPP initiates rubber biosynthesis, whereas FPP is produced in the cytosol and shares this compartment with the rubber particle-bound rubber transferase.

Rubber biosynthesis in guayule is under strong environmental control, the rubber transferase being induced at the onset of winter (Fig. 6) (40,58–67). The substrate synthesis pathway also appears to be induced at this time (65). In the wintertime, the guayule plant is essentially dormant and can afford to use

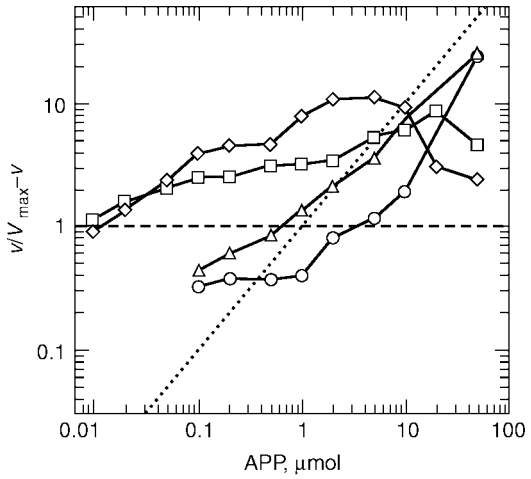

Fig. 5. Hill plot of IPP incorporation rate as a function of allylic pyrophosphate initiator concentration in 1 m*M* IPP: ◯ DMAPP, △ GPP, □ FPP, ◇ GGPP. The diagonal dashed line indicates a gradient of 1. The intercept of the data lines with the horizontal dashed line indicates K_m^{APP}. Data from Ref. 54.

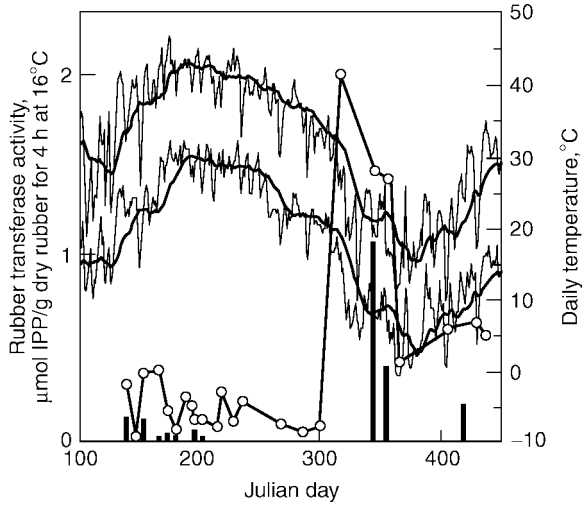

Fig. 6. Rubber transferase activity in rubber particles purified from two lines of field-grown, five-year-old guayule throughout one year. The activity for line 11591 (open circles) and line 593 (filled bars) was determined in 80 μM IPP in rubber particles purified from whole branches. The maximum and minimum daily temperatures also are plotted (light lines), as well as moving averages of both temperature sets (dark lines, data smoothed over 21 days). Data from Ref. 58.

large quantities of photoassimilate to make a compartmentalized secondary product, which it cannot recatabolize. During the summertime, when guayule is rapidly growing and is dependent on the isoprenoid pathway to fuel developmental processes (Fig. 2), the unique kinetic properties of the guayule rubber transferase

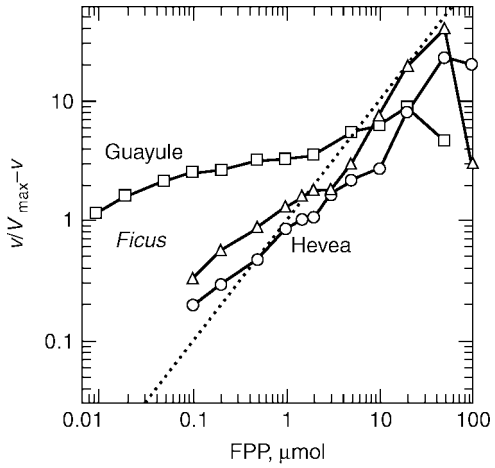

Fig. 7. Hill plot of IPP incorporation rate (5 mM IPP) as a function of FPP concentration for guayule (□), *Ficus* (△) and Hevea (◯). Data from Ref. 47.

appear to allow rubber production without adversely affecting plant growth and development. The high rubber transferase K_m^{IPP}, which is at least 10-fold greater than known competing enzymes in the cytosol, ensures that rubber can only be made when IPP is not required for vital reactions (40,000 isoprenoid metabolites have been identified in higher plants as a group). However, the K_m^{FPP} is smaller than reported K_m^{FPP}'s for other FPP-utilizing enzymes, meaning that rubber transferase can compete successfully for FPP in the presence of cytosolic FPP-requiring enzymes. Substrate deficits are avoided, in this case, because FPP negative cooperativity ensures that rubber biosynthesis does not deplete the FPP pool to the detriment of plant growth and development. It is interesting that the rubber transferases from two laticiferous rubber-producing species (Hevea and *Ficus elastica*) evince much less FPP negative cooperativity than the guayule transferase (Fig. 7) (47,54). This may reflect the disparate location of rubber production in the three species. *F. elastica* and Hevea both synthesize rubber in laticifers; multinucleate systems anatomically separate from the rest of the plant. Thus, production in laticifers depends on a flow of photoassimilate to the laticifer, which then regulates the rate of rubber biosynthesis. If something goes amiss with regulation, rubber biosynthesis may cease but the tree lives on (eg, tapping panel dryness) (68,69). In contrast, guayule makes its rubber in generalized bark parenchyma cells, which may make the process of rubber biosynthesis more dependent on developmental processes.

Even though FPP negative cooperativity plays a role in the regulation of rubber molecular weight in guayule (47,54), outside the concentration range through which the negative cooperativity operates (0.1 to 2.0 μM FPP) rubber molecular weight *in vivo* is highly dependent upon the concentration and ratio of IPP and FPP (2,9,45–47). The initiator concentration seems to be the critical parameter and, as substrate concentrations increase, while maintaining a constant IPP:FPP substrate ratio, the rubber molecular weight produced by the guayule rubber transferase decreases (47,54). Increasing IPP concentrations will increase the

molecular weight of the polymer, but only if FPP is limiting or at a concentration at which negative cooperativity is operating.

Production

Cultivation. Guayule agronomy is well understood (70–74), and so will not be covered in this article. In general terms, guayule likes alkaline, well-drained soil, hot summers, and cold winters without snow cover or serious frosts. Stands can be established using transplants or by direct seeding (75–78). As a crop, guayule has many environmental advantages, requiring relatively little water and fertilizer, and no pesticide. Major advances have been made within the last five years in the development of new, improved germplasm. The time to harvest was generally considered to be from 3 to 5 years, but with the latest germplasm releases this time has been reduced to harvesting in 2 to 3 years (79).

Harvesting. The guayule research carried out in the 1980s demonstrated that guayule can be harvested effectively by pollarding as well as by digging the entire shrub (80). The advanced lines from the plant breeding programs have been selected for their ability to regrow after pollarding, in addition to high rubber yield and biomass (79). Thus, the current commercialization effort is based on farming guayule as a perennial crop harvested biennially using pollarding (cutting the shrub about 10 cm above the soil). The plants regrow rubber-containing branches and can be harvested again in two years, avoiding costs associated with crop replacement. However, once a stand begins to decline, or when new, improved lines warrant its replacement, the entire stand would be dug so that the rubber latex could be extracted from the roots as well as from the above-ground branches.

Processing. Guayule produces its rubber in the form of membrane-bound rubber particles suspended in the aqueous cytosol and vacuole of the bark parenchyma cells (Fig. 1). There is no laticifer system that would allow tapping, as with Hevea, even if this were a cost-effective procedure. Whether processing guayule for latex or dry rubber, it is necessary to rupture the latex-bearing cells.

Latex. To produce guayule latex, the rubber particles must be removed intact from the parenchyma cells while maintaining an aqueous suspension (18,19,21,81,82). Thus, the shrub must remain in a hydrated condition through harvest, shipping, and storage until homogenized in an alkaline aqueous extraction medium. The rubber particles, which have a specific gravity of slightly less than 1, can then be purified from the homogenate using a series of centrifugation steps and/or flotation with alginate creaming agents (82). This process results in an artificially-produced natural rubber latex from which the cytoplasmic components have been removed. Throughout this process it is important to prevent coagulation or degradation of the rubber particles. Coagulation within the plant is highly tied to tissue hydration level (83), beginning after 10% of the defoliated branch water is lost, leading to almost complete coagulation after 50% water loss. Rubber particle coagulation is distinct from degradation, a temperature dependent process that can destroy the latex fraction in hydrated and dehydrated shrub

as well as in shrub homogenate. At high temperatures (40°C) commonly experienced in the southwestern United States during the summer, the extractable latex rapidly declines, in this case primarily through degradation. This effect is clearly demonstrated by a large increase in polydispersity of the rubber in the extractable latex, especially in the smallest and youngest branches, with values as high as 4 being reached (12) (a value of 1 indicates a monodispersed sample). This is probably caused by some cells in the harvested branches dying before others allowing some rubber particle membrane damage, which in turn allows access to, and degradation of, the rubber polymers. Severely damaged or destroyed rubber particles would not show up in this analysis because they would no longer be extractable in the latex fraction. The rubber particle size distribution appears unaltered during the degradative process although the number of particles declines.

These parameters still leave reasonable windows of operation for farmers and processors. Losses in baled and tarped shrub brought out of the direct summer heat are much less, and the latex content is quite stable over two weeks (12,83).

The guayule shrub must be wet-ground in an aqueous, alkaline medium to extract the latex. Grinding protocols must be optimized for each grinding system, with the goal of disrupting every rubber-containing cell without damaging the rubber particles themselves. Inefficient grinding and extraction will greatly impact profitability (19,81,82). Woody material can then be filtered away from the homogenate. The filtered homogenate is then clarified to reduce the substantial component of fine solids that cannot be filtered away from the rubber particles because of their similar size.

Ammoniated homogenate appears to provide a stable environment for latex, without refrigeration, provided that the pH is kept basic (eg, pH 10) and the concentration of rubber particles is at least 5 mg/ml (84). The latex concentration and polymer molecular weight remains stable for 20 weeks before significant degradation occurs. Interestingly, the polymer polydispersity varies little even while the polymers are being degraded after 20 weeks of storage, indicating a uniform degradation process throughout the homogenate. Degradation does not appear to generate the mixture of small and large polymers seen in harvested branches over time.

The latex can be separated from the clarified homogenate and purified and concentrated using continuous flow centrifugation, and/or creaming agents (82), purified and concentrated. Purified latex (in 0.2% NH_4OH, 0.1% Na_2SO_3, and 0.05% ammonium alginate) appears to be stable for months.

In summary, guayule latex is stable within the living plant, the ammoniated homogenate, and in purified form, and is unstable in harvested shrub. This means that, as in the dairy and fresh vegetable industries, harvesting must be coordinated with processing, to minimize the delay between shrub harvest and homogenization. Unavoidable post-grinding delays in a latex extraction and purification process are unlikely to cause serious latex losses.

Dry Rubber. Typically, the plant material is coarsely ground and then subject to compression and shear forces (17,85,86). Dry bulk guayule rubber has been produced by two basic methods: flotation (87,88) and solvent extraction (17,88). Flotation processing was in common use during the early part of the 20th century.

Ground shrub was mixed with a dilute caustic solution that coagulated the rubber and resin (extractable low molecular weight secondary metabolites) as solid particles called "worms". The worms were skimmed from the surface, deresinated with an acetone wash, dried, and compressed into bales. Alternatively, the deresinated rubber was dissolved in a nonpolar solvent such as hexane. Antioxidant was added to the hexane cement prior to filtration and desolventization. The weaknesses of flotation processing included the rate-limiting nature of the deresination step and the need to dispose of large volumes of caustic flotation medium.

Solvent extraction addresses the need to remove nonrubber resinous components from the rubber product. Evaluated at the USDA Northern Regional Research Center (89), sequential extraction involves deresination with a polar organic solvent, followed by rubber removal with a nonpolar hydrocarbon solvent. In the USDA study, defoliated ground shrub was extracted with acetone to remove resin. The deresinated shrub was then extracted with hexane at 60°C in a semibatch continuous countercurrent operation. An oilseed extractor was used at a shrub feed rate of 12 kg/h. Rubber recoveries were as high as 88%. The performance properties of the rubber product were not determined, however.

Sequential extraction does not accommodate an important constraint on the quality of the rubber product: unlike Hevea, cultivated guayule does not produce rubber that meets established product specifications (17,90). The process would have to incorporate an additional operation for the selective recovery of the high molecular weight fraction of the rubber polymer.

In simultaneous extraction, the grounded shrub is initially extracted with a rubber solvent to produce a dilute solution, or miscella, of rubber and resin. The rubber solvent may have a single component such as xylene, or it may be a mixed system such as the acetone–pentane azeotrope. A polar solvent such as methanol or acetone is then added to the miscella to coagulate the high molecular weight rubber fraction. At Texas A&M University, a continuous countercurrent extractor with a nameplate capacity of 900 kg of shrub per 24 hours yielded 270 kg of rubber product (91). The majority of the rubber was extracted with xylene or toluene at 100–125°C. Methanol was the precipitating medium. Under these conditions, rubber recovery was 92% based on whole shrub analysis. Between 1988 and 1990, the Bridgestone/Firestone prototype processing facility in Sacaton, Ariz, produced a total of 8.8 ton of rubber product, of which 5.4 ton met the release specifications described below in Table 2 (92). The Bridgestone/Firestone process employed simultaneous extraction using either the acetone–pentane azeotrope or an equivalent mixture of acetone and hexane, although the primary extraction medium was actually recycled rubber-resin miscella. Extraction was carried out at 50°C. Acetone was the precipitating/fractionating medium. The processing facility had a feed rate capacity of 990 kg fresh weight per hour. Table 3 summarizes the composition and plasticity properties of several batches from a typical production lot.

of which is species-specific (43). As can be seen (Fig. 8) guayule rubber particles contain relatively few different proteins compared with Hevea. The figure indicates that latices from *F. elastica*, guayule, and *Helianthus annuus* (sunflower) contain far fewer potential allergy-causing epitopes than either Hevea or *Taraxacum kok-saghyz* (Russian dandelion).

Guayule latex not only contains few proteins compared with Hevea but also contains very little protein, ranging from 0.2 to 4% of the amount in Hevea latex (Table 4) (3,12,93). Animal and human trials, including western blot analysis, ELISA (enzyme-linked immunosorbent assay), skin-prick tests, and *in vivo* RAST (radioallergosorbent) assays demonstrated that guayule proteins do not cross-react with anti-Hevea latex protein antibodies at concentrations of up to 1000× the amount of protein sufficient to cause a response with Hevea proteins (94–96). Reciprocal tests in mice showed that guayule latex antibodies do not cross-react with Hevea latex proteins (96). Thus, Hevea latex allergy can be circumvented using rubber products made from guayule latex. The low protein content of guayule latex, and the hydrophobic nature of these proteins, makes it unlikely that large-scale use of guayule latex products will induce a widespread guayule latex allergy in its turn.

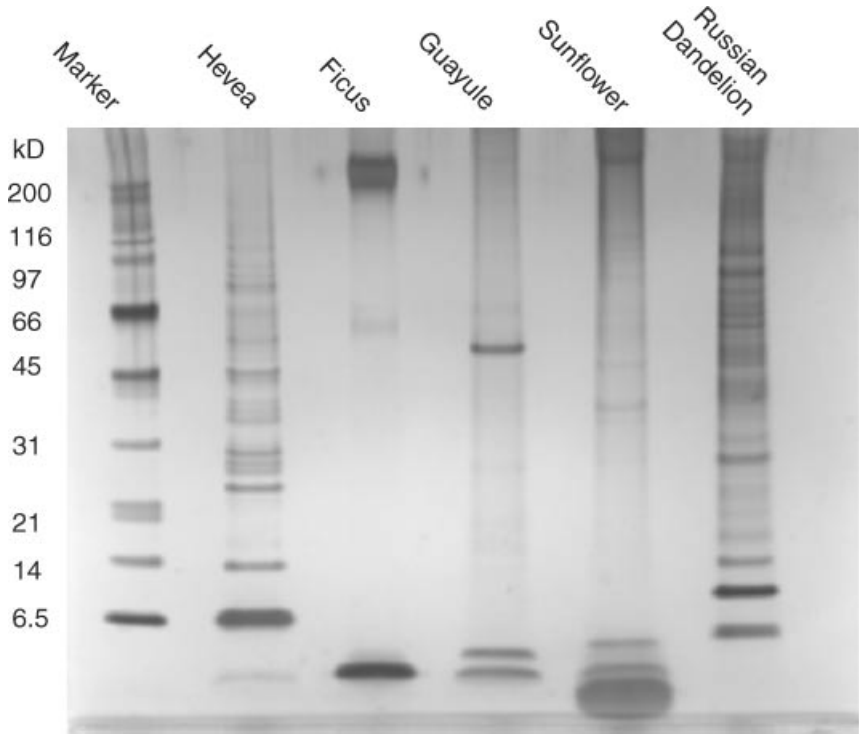

Fig. 8. The protein profiles of washed rubber particles from several different rubber-producing species, separated on a 4–12% SDS PAGE gel. From Ref. 12.

The lipid composition of rubber particles also differs among species (43). Guayule particles contain a rather ordinary complement of fatty acids in contrast to the unusual, but disparate, membrane compositions in Hevea (high in furanoid fatty acid) and *Ficus elastica* (high in long-chain fatty acids). The guayule particle composition may reflect their origin in bark parenchyma cells—a much less specialized cell type than the laticifers producing the rubber particles in Hevea and *F. elastica*.

Rubber Particle Size. The guayule rubber particle mean diameter (1.4 μm) is larger than that of *Hevea* (1.0 μm), and the distribution is broader (Fig. 9) (12,42,97). The absence of a well-known minor subset of *Hevea* particles of 0.1–0.2 μm may reflect their resistance to creaming in the ammonium alginate used to purify the latex tested here.

Rheology. Latex purified from guayule and Hevea was concentrated to the maximum possible degree using ammonium alginate creaming agent and centrifugation. The maximum rubber particle concentration approximated 550–600 mg/ml dry rubber content (DRC) for Hevea and 400–450 mg/ml for guayule. These numbers reflect the concentration at which the latex undergoes a phase shift and gels to a reversibly aggregated semisolid (similar to whipped cream). The Hevea and guayule gelled latices have to be thoroughly remixed in additional suspension medium before the latex particles will fully resuspend. Viscosity of the two

[a]From Ref. 17.
[b]The guayule latex value is a mean of 20 latex samples prepared throughout a year from bimonthly harvests of different lines. Each value in the mean was itself a mean of four protein determinations. All Hevea latex determinations are the mean of 4 assays $\pm$ s.e. Hevea latex samples were obtained from CentroTrade, Virginia Beach, Va, although the enzymatically deproteinized material is Allotex from Tillotson Rubber Co.

latices was investigated using flow temperature ramps, over a temperature range in which the particular latex did not coagulate (97). At any particular temperature and concentration, guayule latex was more viscous than Hevea latex. In addition, the tendency for the latex to coagulate increased with increasing temperature and with increasing particle concentration. Guayule latex also was more sensitive to temperature than Hevea latex, with respect to coagulation (97). In both latices, latex viscosity increased with increasing rubber particle concentration, but declined with increasing temperature at all concentrations. This effect was fully reversible over all the experimental temperature ranges used (97). The difference between the two species was dramatically illustrated when the viscosity of their latices was plotted as a function of rubber particle concentration, at several selected temperatures (Fig. 10). Intrinsic latex differences clearly override the concentration effects. Temperature effects are large only at the highest concentration of Hevea latex.

The underlying causes of these differences in latex rheology are not clear but may partially relate to the particle size, the particle size distribution, and/or to the considerable differences in the biochemical components of the monolayer biomembrane that surrounds the different rubber particles (43).

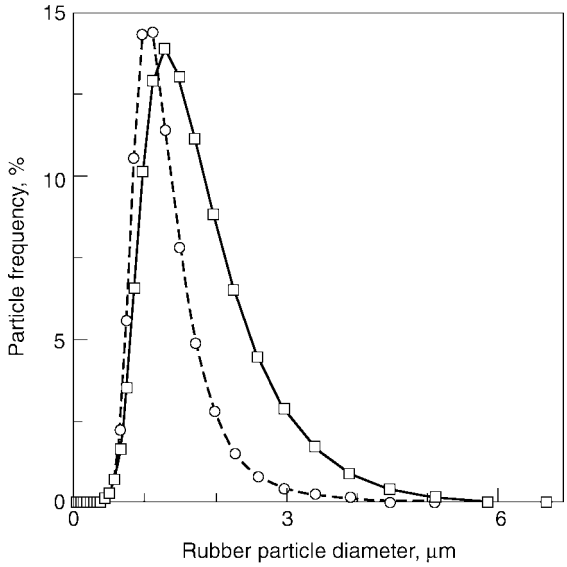

Fig. 9. Particle size distribution of rubber particles purified from guayule stem bark and Hevea latex. Measurements were made on rubber particles in aqueous suspension using a Horiba LA-900 Laser Light Scattering Particle Size Distribution Analyzer. —○—, Hevea; —□—, Guayule. Data from Ref. 12.

For example, the rubber particles are not of a single size, but are a distribution of particle sizes existing in both latices (Fig. 9). The smaller particles mixed with the larger ones would have a large effect on viscosity by impeding the flow of the larger particles and leading to gel formation at a lower concentration. The differing viscosities and packing densities of the two latices suggest that smaller particles play a pronounced role in the low gel point and high viscosity of the guayule latex.

Differences in the molecular weight of the rubber contained within the rubber particles (see References 12, 14, and 42, and Table 5) seem less likely to play a role since the particles were intact in this study.

Rubber Polymer Molecular Weight

When molecular characteristics of THF-dissolved purified rubber particles were determined, the 18-angle light-scattering analysis indicated a single peak for both Hevea and guayule rubber (Fig. 11) although the change in amplitude as the angle increased indicated some interspecific differences. The molecular weight distribution derived from the light-scattering data coupled with refractive index data indicate that guayule latex contains uniformly high molecular weight rubber (Fig. 12). This appears, at first sight, to conflict with published reports of a broad bimodal distribution in this species (98). However, these bimodal rubber peaks were found in rubber solvent extracted from guayule shrub. Rubber from purified rubber particles that coagulated during particle purification (suggesting

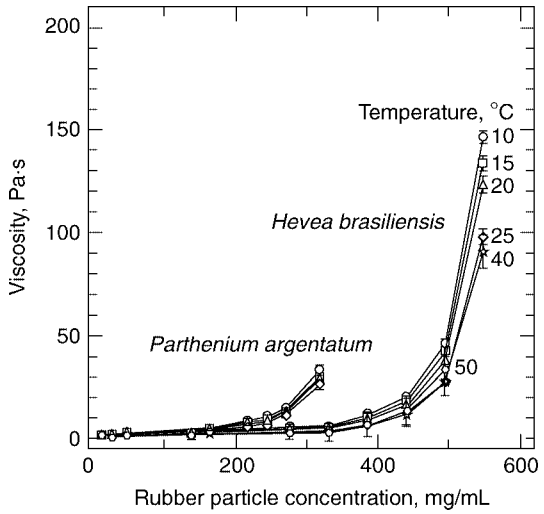

Fig. 10. Viscosity of purified latex from guayule and Hevea, as a function of rubber particle concentration. To convert Pa · s to P, multiply by 10.

that the particle membranes had been damaged prior to separation) was of a substantially lower molecular weight (M_p) of about 87,000. This suggests that the polymer in these damaged rubber particles had been degraded in the plant. Thus, it seems that healthy, intact rubber particles consistently contain high molecular weight rubber, but the entire plant also contains degraded rubber in dying and

dead cells. Solvent extraction removes all of the rubber in the plant, not just the rubber from the healthy particles obtained through latex extraction. Solvent extraction of fresh, healthy, shrub, under conditions designed to minimize thermal and oxidative degradation, yielded high molecular weight rubber with a unimodal distribution (99), suggesting that intact healthy shrub contains very little low molecular weight rubber. Thus, reported broad bimodal distributions probably reflect a combination of polymer degradation during processing and extraction, and poor quality shrub.

In data generated from purified latex (Table 5), the molecular weight of the guayule latex rubber is consistent over season. Also, rubber molecular weight was not affected by the presence of leaves during extraction (84). The sample of Hevea rubber measured appears to be of a higher molecular weight than the guayule samples. However, the guayule stem latex is of a sufficiently high molecular weight to consistently generate high quality products (3,100).

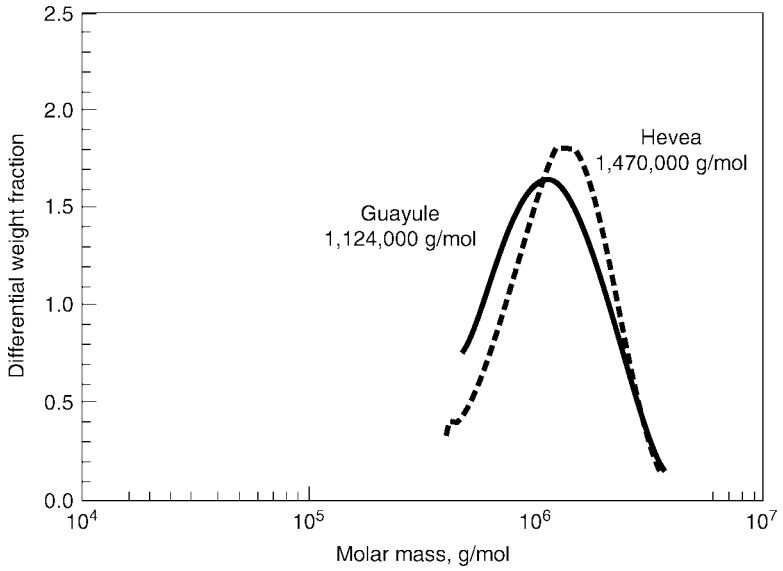

Fig. 12. Molecular weight distributions of rubber from purified latex of guayule and Hevea, determined using an Agilent Technologies HP 1100 HPLC, 2 P-gel columns in series, with an HP1047 RI Detector, and a Wyatt Technology Corporation DAWN DSP Laser Photometer.

Modern guayule is farmed as a biennial crop with repeated harvests of the same plants. The high molecular weight rubber present in the root and stem base latex sample [Table 5 (12)] indicates that the high yielding, last harvest of shrub, when a stand is dug in order to replant a new line, also will be of high quality. Film tests of latex purified from stems and roots confirmed high performance characteristics (unpublished data).

The RMS (root mean square measurement of the molecular radius) versus the molar mass gives an indication of polymer molecular shape and branching, where a value of 1 indicates an unbranched, rod shaped molecule; 0.5 a random coil; 0.3 a spherical structure; and 0.1 a highly branched molecule. Guayule stem rubber seems to form a random coil with few branch points, whereas Hevea rubber appears to be a more compact and branched polymer [Table 5 (12)]. Guayule latex rubber from the roots and stem bases seems more like the Hevea rubber in shape than the stem latex rubber, but it is not known whether this is a reflection of its location or of its greater age.

Dry Rubber. The microstructure of the guayule rubber polymer has been studied in detail (100). Although similar to Hevea rubber in many respects, guayule rubber has lower green strength and an enhanced crystallizability. The higher green strength of Hevea rubber has been ascribed to the formation of cross-linked polymer gel (101) through reactive substituents such as epoxides, amines, and carbonyl groups naturally present in the polymer (102–104). Guayule rubber contains few such reactive substituents. As a result, guayule rubber has a lower viscosity and a shorter stress relaxation time (105). Mixing operations produce a more rapid dispersion of fillers and compounding ingredients in guayule rubber

(106). Compared with higher purity or deproteinized Hevea rubber, guayule rubber has a higher propensity for strain-induced crystallization (107,108). This behavior is ascribed to the presence of higher levels of nonrubber impurities in guayule rubber.

Among these nonrubber impurities, those extractable with polar organic solvents such as acetone are collectively known as resin. Guayule resin is a complex mixture of low molecular weight secondary metabolites such as terpenes, sesquiterpenes, and fatty acid triglycerides (109). It is these latter components that have been implicated as contributors to the degradative effect that resin has on guayule rubber (110). As a consequence, reducing the resin content of bulk guayule rubber has been an important goal of process development efforts.

The sulfur vulcanization properties of guayule rubber reflect the low level of reactive substituents. Because of natural vulcanization activators not present in guayule rubber, Hevea rubber has a higher cure rate and attains a higher level of cross-linking (111,112). However, adjusting the cure system can reduce these performance differences (112).

Technical Specifications. The guayule rubber produced by Bridgestone/Firestone, Inc., and accepted for testing by the Department of Defense met either one of two specifications (Table 2) (113). These were derived from the ASTM specification for grade 20 natural rubber (114) or a modified Federal Emergency Management Agency (FEMA) specification (115) established for guayule rubber itself.

Applications

Latex. The physical properties of guayule latex differ from those of Hevea latex, and a Hevea compounding recipe will generate a guayule latex film with poor performance characteristics (116). However, successful compounding formulations, with excellent physical properties, were developed by the Akron Rubber Development Laboratory, Akron, Ohio (Harry Bader, unpublished results). Guayule latex prototype medical products were then manufactured (Akron Rubber Development Laboratory, Akron, Ohio), including surgical gloves, examination gloves, household gloves, industrial gloves, miniature gloves, surgical tubing, assorted surgical balloons, condoms, and children's balloons. Even after four years of storage, films from condoms and examination gloves were proved to provide an effective barrier to the transmission of human viruses (100). No signs of film deterioration have yet been observed (now seven years post-manufacture). Also, when stabbed with an 18 gauge hypodermic needle against a styrofoam backing, a smaller hole was left in guayule latex glove films than in unchlorinated, powdered Hevea or nitrile films (3). For the new Hevea glove film and the nitrile films, the holes on the inner glove surface were only slightly smaller than the needle diameter. However, it was interesting to note that almost all films were left with holes considerably smaller than the needle diameter when the narrower 25 gauge needle was used. The relatively large holes in the thinnest nitrile gloves indicate that this film lacked sufficient strength to stretch around the needle as it penetrated the film. The old Hevea glove films used in this study were of a similar age as that of the guayule gloves but, unlike the guayule gloves, had noticeably deteriorated.

Research by Apex Medical Technologies, San Diego, Calif, in collaboration with Yulex Corp, has led to a report that a novel cure process creates even better performance properties in guayule latex films than synthetic polyisoprene films (3,117). The guayule latex films have essentially the same tensile strength as those obtained from Hevea latex under similar processing conditions. Guayule latex films exceed ASTM standards for surgical gloves and are 33% stronger than synthetic polyisoprene latex films produced under similar conditions. They are considerably stronger than enzymatically deproteinized Hevea latex films made from enzyme-treated but unwashed latex (see Table 4). Also, the deproteinized latex was unstable and, especially when purified, prone to coagulation. Synthetic polyisoprene and deproteinized Hevea latex films are generally expected to become more common in the nonallergenic latex medical products market. The films were cured via an organic peroxide post-vulcanization system, where anaerobic conditions are used to affect a total cure without concurrent polymer degradation. The prevulcanization step normally used with traditional sulfur-cured Hevea materials is not necessary, which represents a considerable cost savings in manufacturing. Total curing can now be accomplished in less than five minutes (3).

The organic peroxide curing system was used to cure films made from latex extracted from different guayule lines and plant parts as well as from Hevea samples. Performance parameters (Table 6) indicate that good quality films can be made from different guayule lines, and from stem latex and latex extracted from the roots and stem bases.

Nonetheless, it is clear that guayule latex rubber differs from Hevea latex rubber. It seems possible to compensate for undesirable differences by the astute application of rubber chemistry and judicious selection of compounding methods and ingredients. However, some of these unique differences may prove advantageous. For example, of potential product relevance, the rubber particle cores of raw guayule latex retain malleability at $-196^{\circ}C$, independent of purification procedure and line or tissue age (33). Raw latex from Hevea is brittle at this temperature and currently available Hevea latex products are considered malleable only to about $-50^{\circ}C$. Low temperature malleable polymeric materials are especially desired by the aerospace industry, for high value gaskets, seals, tires, bags, tubing, and numerous other products, and many other applications await the development of such materials. Although the underlying causes of the low temperature malleability are not yet understood, compounded guayule latex may be able to serve such applications.

Dry Rubber. Because of its enhanced crystallizability, guayule rubber can exhibit superior failure properties in unfilled rubber compositions. As a double network, an elastomer cured a second time while in a deformed state guayule rubber exhibits substantially better fatigue resistance than deproteinized Hevea rubber (118). When compounded with carbon black, guayule rubber and Hevea rubber behave similarly (119). In tread and wire skim stocks, the compounding and performance behavior of guayule rubber was comparable to that of Hevea rubber (Tables 7, 8) (120).

Recent evaluations of guayule rubber in finished rubber goods have focused on military applications. Guayule rubber has been evaluated in tank track pads (121,122), in aircraft tires (123–125), and in light truck tires (126). The performance of rebuilt aircraft tires built with guayule rubber was comparable to the

Table 6. Some Performance Characteristics of Latex Films Cured With an Organic Peroxide Post-Vulcanization System

Plant	Sample[a]	500% Modulus, MPa	% Elongation at break	% Swell

[a] All samples were adjusted to 0.05% ammonium alginate before making the films. The soluble proteins were removed from a sample of high protein Hevea (normal) latex by several cycles of creaming to generate the low protein Hevea sample. The guayule latex samples also contain no soluble protein.

performance of those containing Hevea rubber (123,124). However, new aircraft tires fabricated either from 100% guayule rubber or from a 50:50 blend of guayule rubber and NR did not pass all dynamic testing requirements. Guayule rubber was not a direct drop-in replacement for NR in this application (125). Comparative performance tests have been run on light truck tires containing 100% guayule rubber or a 50–50 blend of guayule and Hevea rubbers, with guayule rubber or the guayule–Hevea rubber blend being substituted in all component stocks normally containing Hevea rubber. Commercial tires served as controls. Overall, the performance of the tires containing guayule rubber was comparable to that of the controls (126).

Commercialization Update. High quality guayule latex rubber and bulk rubber can both be produced from guayule, but the economics of latex production

Table 7. Guayule Rubber (GR) Performance in a Steel Belt Skim Compound Relative to a Hevea Rubber (NR) Control (NR Performance = 100)

Property	NR	GR[a]
Cure time	100	85
Maximum rheometer torque	100	107
50% Modulus	100	119
Tensile strength	100	102
Aged retention, %	40	46
Elongation, %	100	108
Aged retention, %	32	35
Tear strength 23°C	100	100
100°C	100	133
Steel cord adhesion	100	95
Rubber coverage, %	95	95
Aged retention, %	67	69
Aged coverage, %	40	50
Stock–stock adhesion	100	82
Aged retention, %	45	56

[a] Plasticity = 29, PRI = 73, volatiles = 0.33%, ash = 0.38%.

Table 8. Guayule Rubber (GR) Performance in a Tread Compound Relative to a Hevea Rubber (NR) Control (NR Performance = 100)

Property	NR	GR[a]
Cure time	100	98
Maximum rheometer torque	100	108
50% Modulus	100	118
Tensile strength	100	113
Aged retention, %	77	96
Elongation, %	100	98
Aged retention, %	76	86
Tear strength 23°C	100	92
100°C	100	100
Pico abrasion	100	109
Rebound, % 23°C	100	109
100°C	100	104
Aged coverage, %	40	50
Stock-stock adhesion	100	100
Aged retention, %	61	53

[a]Plasticity = 29, PRI = 73, volatiles = 0.33%, ash = 0.38%.

favor commercialization based upon hypoallergenic latex as the primary product. The solvent-based extraction process proved too expensive to produce guayule rubber commercially competitive with the low cost of Hevea bulk rubber. The water-based latex extraction process not only is cheaper than the solvent-based process but produces guayule rubber in the higher value latex form. In addition, the low protein, hypoallergenic properties of the guayule latex allow market entry into the hypoallergenic medical products market where high priced synthetic polymers are the principal competitors, and Hevea latex products are less usable because of Type I latex allergy. The exclusive licenses to the USDA's guayule latex process (19) and product patents (21) were awarded to Yulex Corp in 1997. Yulex has identified over 75 commercial farms in southern Arizona and the desert southwest United States with the interest and established infrastructure to grow guayule. The company has developed large-scale commercial processes for producing, harvesting, cleaning, and conditioning guayule seed for transplant operations, and currently maintains seed banks for the advanced lines (from the plant breeding programs) to plant several thousand hectares. Yulex Corp began operation of their first commercial pilot latex bioprocessing facility (750 ton shrub per year) in 2003, and moved guayule farming from an experimental industrial crop into main-stream agriculture. In addition, Yulex has entered into product development agreements with several major medical device manufacturers. Yulex may be reached at www.yulex.com for additional information.

Implications of Commercial Guayule Production. Domestic rubber production will safeguard natural rubber supplies to the United States and provide hypoallergenic latex products safe for use by patients suffering from Type I latex allergy. Economic value to rural America is harder to assess, but domestic guayule farmland is rapidly expanding. Much of the acreage will be on currently retired farmlands, enhancing its impact on rural economies. Ten-fold increases

in production capacity are planned in 2004 (7500 ton/y) and 2005 (75,000 ton/y). These production facilities will be located in the guayule-growing region enhancing the positive impact on rural development. Improved guayule lines will enhance profitability for the farmers and processors.

As the guayule crop expands, a vast quantity of bagasse will be generated as a by-product of latex production. The United States already produces large agricultural surpluses and large volumes of agricultural wastes, which has led to extensive research into biobased products and biofuels to profitably consume these resources, and supplement and eventually supplant synthetic petroleum-derived products and fuels (127,128). A harvest of 1,000,000 acres of guayule would generate approximately 5,000,000 t of biomass composed of 500,000 ton of rubber, 500,000 ton of resin, and 4,000,000 ton of lignocellulosic bagasse.

The natural resins present in native guayule have been extensively studied and include mono-, sesqui-, di-, and triterpene groups, as well as other secondary metabolites (108). Unfractionated guayule resin has shown considerable promise in the areas of wood preservation (in marine and terrestrial environments) (129) and insect antifeedents (termite resistance) (130–132). These resins also show promise as a biobased renewable replacement for petroleum-based monomers and oligomers in adhesives and coatings. Additional profitable uses for the resins include a natural, low toxicity replacement for creosote in wood treatment and for prevention of termite attack. Resin/lignin products, such as additives for phenol formaldehyde resins, may also prove possible.

Guayule bagasse has shown promise in the manufacture of particleboard and ceiling tiles, especially because it contains sufficient low molecular weight rubber and resin components to provide a natural adhesive. Additional potential uses for guayule bagasse and fiber, before or after resin extraction, include their use in building materials (108,133,134).

Residual guayule bagasse also shows promise as a feedstock for the production of biofuels. The energy content of the bagasse from the latex extraction process is equivalent to 5×10^{12} Btu or 62,500,000 gallons of ethanol. California currently uses 2 billion gallons of gasohol per annum containing 200 million gallons of ethanol. The bagasse from 10 million acres of guayule processed per year, if all converted to ethanol through fractionation and fermentation, could meet projected western annual needs for 600 million gallons ethanol (135), while greatly reducing transportation costs of corn ethanol from the mid-western states. The bagasse could also be used to generate energy via gasification or the production of pyrolysate oils, or through combustion.

Conclusions

New rubber-producing crops face substantial barriers they must overcome before they can successfully enter the commercial arena (133–143). Decades of guayule research have allowed guayule to overcome these barriers and reenter the commercial arena. Researchers have investigated a plethora of approaches seeking ways

to best exploit and consume the crop (144), and research into new applications and uses for the latex and the resins and lignocellulosic coproducts is continuing. Guayule latex can be used to make high quality medical products (3,98) and substitute for latex from *H. brasiliensis*. However, latex characterization has also revealed novel properties that affect manufacturing processes and product quality (3,96,99,117,144). Some of these properties may lead to natural rubber products superior to those currently available. Continuing research on novel polymers and properties, and on utilization of the coproducts and bagasse, will not only increase the profitability but will allow conversion of the entire guayule crop to a plethora of products, while essentially eliminating the negative environmental impact of agricultural waste. Thus, guayule is positioned as a model industrial crop feeding a new generation of biorefineries capable of producing a wide range of bioproducts and biofuels.

SCANNING FORCE MICROSCOPY

Introduction

Synthetic polymers, as well as biopolymers, exhibit a rich and very complex structural and morphological hierarchy on multiple length scales, spanning the size range from monomer residue units comprising the polymer chains to higher order micro- or macroscale structures, such as fibers or spherulites. Since the performance of polymeric materials is intimately related to this hierarchy, the structural and morphological analysis of polymers has played a central role in polymer science and technology. With the continual striving toward the mesoscopic and nanoscopic size regime in modern technology, high resolution analysis tools gain increasing importance.

Following the Nobel prize winning invention of the scanning tunneling microscope (STM) (1,2), the well-developed and established family of microscopy techniques in the field of polymer science, such as polarized optical microscopy (OM) (3) and various electron microscopies (4), was enriched by a range of newly developed scanning proximity probe microscopy techniques in the late 1980s (5). Among these techniques, scanning force microscopy (SFM) in particular has successfully complemented the traditional techniques for studying simultaneously polymer morphology *and* surface properties.

Compared to STM, which is inherently limited to conducting samples or ultrathin samples on conducting substrates, SFM is generally applicable to a much broader range of materials, including insulators, such as polymers. SFM, which includes the originally developed atomic force microscopy (AFM) (5), can be considered to be a unique technique in the sense that it yields topographical information in 3-D with, in the optimized case, (sub-)nanometer spatial resolution over lateral length scales of >100 μm to nanometers. In addition, material-specific

contrast can also be obtained based on, eg, adhesion, friction, or elasticity differences, thus enabling high resolution mapping of composition in heterogeneous systems.

It is clear that SFM has been quickly established as an important research tool in academia in the field of polymers; at the same time its huge potential has been realized in industry, where it finds increasing application in research and development laboratories. The range of applications reaches from unraveling structure–property relationships, as well as long-standing, unresolved issues, such as polymer crystallization, polymer morphology and its relation to processing and mechanical properties, to the analysis of novel polymer architectures and substrate-supported assemblies. It includes studies of the behavior of macromolecules in confinement, compositional mapping for applications in the biomedical sector, as well as in polymer surface modification and elucidation of failure mechanisms, and more recently real-time studies of *dynamic* processes at the relevant length scale. In addition to a still needed standardization and definition of protocols in the industrial environment, the development and improvement of new SFM modes, in particular local thermal analysis (6) and chemically sensitive imaging (7), pose challenges for the near future. The impact of SFM can undoubtedly be expected to further grow for polymer science and technology.

Considering the rapid increase in the number of SFM-related publications in the field of polymers, it is necessary to focus on key areas and make a narrow selection of the discussed material. The author would like to offer his apologies to those authors who consider possible omissions as negligence by the author. Whenever possible and appropriate, references to the many excellent reviews on particular topics have been included.

In this contribution, the basic concepts and modes of SFM, as well as some rudimentary theory, are introduced and only briefly reviewed in order to provide a self-supporting basis for the discussion of selected areas of application of SFM on polymers. The study of the morphology and hierarchical ordering of polymers by SFM is reviewed, starting from the visualization of single macromolecules, chain packing, and surface crystal structures. The imaging of lamellar crystals, hedrites, and spherulites by SFM approaches is discussed, followed by investigations on effects of deformation and processing, as well as studies on morphology of latex particles and fibers. A second central section is devoted to the mapping of surface properties and composition via the spatially resolved measurement of forces and surface mechanical properties. Finally, structure development and dynamic processes, including polymer crystallization, followed in real-time by SFM are discussed.

Within the numerous proximal probe techniques developed in the years following the breakthrough inventions of the STM (1) and AFM (5), scanning force microscopy (8) represents a family of scanning probe techniques that rely in their contrast mechanism on various forces between probe tip and sample (9–12) (see ATOMIC FORCE MICROSCOPY). In order to provide a basis for an understanding and appreciation of the SFM work on polymers (13–18), as presented in this review, the basic principles of SFM, as well as selected imaging modes, are briefly discussed.

SFM and Its Imaging Modes

In scanning probe microscopy (SPM), a scanned probe is utilized to collect highly localized information of sample surface properties via the corresponding physical quantities. Typically, the proximal probe and the sample specimen are in (near) contact and the corresponding information is collected, while probe and sample are mutually displaced laterally by suitable transducers (Fig. 1). The probe microscopy techniques belonging to the family of SFM discussed below comprise, among others, contact, intermittent contact, and force modulation modes. These modes are of central importance to provide information on, eg, topography (quantitative surface profile), composition in heterogeneous systems, elasticity, and other mechanical properties of polymeric materials on length scales between $\sim$100 μm and the mesoscopic and nanoscopic size regime. In most of the SFM modes, topography and additional properties can be probed simultaneously, which allows one to make important correlations of structure and local physical properties. Complicated sample preparation, such as replication techniques needed for transmission electron microscopy (TEM), can often be circumvented and experiments can be carried out in a wide range of media (gas, vacuum, liquids) and experimental conditions. For other specialized SFM techniques the reader is referred to the corresponding literature (8–20).

Contact Mode SFM. The different SFM techniques have many basic features in common, which will be introduced in this first section on contact mode SFM. In *contact mode* SFM a sharp probe tip, which is attached to a cantilever

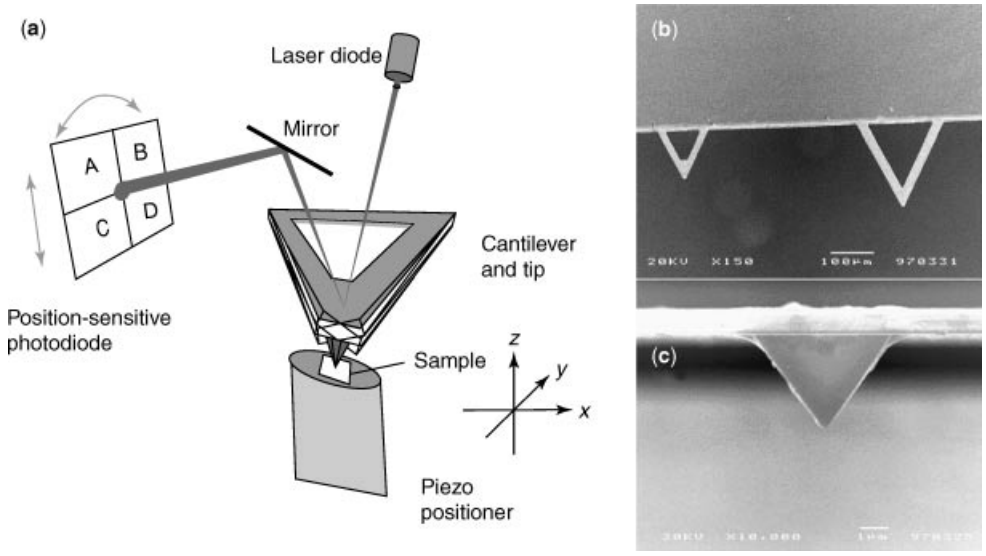

Fig. 1. (**a**) Schematic diagram of contact mode SFM and SEM images of (**b**) V-shaped SFM cantilevers and (**c**) tip. The basic elements of transducer (piezo positioner), cantilever and tip assembly, and ultra-sensitive force detection system (optical beam deflection/photodiode detector) are common for all SFM techniques, while details may differ. Adapted with permission from Ref. 21.

(typical spring constant k of 1.0–0.1 N/m), is brought into contact with the sample surface (Fig. 1) (21). While the probe is scanned across the sample surface, or likewise the sample is scanned under this probe, the deflection of the cantilever is measured.

SFM cantilevers and tips are often made of silicon or silicon nitride; SFM tips possess radii of curvature at the apex between few and several tens to hundreds of nanometers (Fig. 1). A piezoelectric transducer is used in order to position the sample accurately. Depending on the scanner type (piezo tube length and design) the maximum scan sizes vary between ca 1 μm and several hundred micrometers, with an accuracy of positioning in the best cases of $\sim$0.01 nm. The cantilever deflection is typically monitored by an optical beam deflection technique (Fig. 1**a**). Other possibilities to measure the deflection include STM, piezoresistive, capacitance, or interferrometric detection schemes (22). In the optical beam deflection setup, laser light is reflected off the end of the cantilever and is collected by a position-sensitive photodiode. For instance, a 4-quadrant photodiode can simultaneously measure deflections in vertical (surface normal) and horizontal (lateral) direction (Fig. 1**a**).

In the so-called constant height mode the deflection of the cantilever is measured in order to obtain the surface profile or topography of the specimen. The deflection of the cantilever is a result of the repulsive and attractive interactions between the atoms of the tip and the atoms of the sample surface. In the more commonly used constant force mode, a feedback loop holds a preset deflection of the cantilever constant by adjusting the sample height (z). A graphic representation of the adjustment of specimen height z yields an isoforce surface, which represents the sample topography. These data correspond to the true profile *only* if variations in local sample compliance are negligible (23,24). On the basis of an accurate calibration, SFM thus becomes an instrument for metrology, which includes the quantitative determination of surface roughness as well (25).

SFM experiments are often performed in ambient conditions, although the presence of a contamination layer (typically water) gives rise to sometimes significant capillary forces (26). In addition to measurements in air, experiments can be performed in other gases, in liquids, or under (high) vacuum. The problem of capillary forces can be easily eliminated by performing measurements in liquids utilizing a liquid cell (27). Contact mode SFM imaging is typically difficult or impossible on very rough samples, samples with high adhesion, such as adhesives, as well as most types of liquids (28). Highly viscous liquids, such as polymer melts, can be imaged in some cases even with *contact mode* SFM (see section Structure Development and Dynamic Processes in Real Time). In addition, the lateral forces between tip and sample may lead to modification or destruction of delicate polymer specimens (29,30).

The true lateral resolution for imaging is limited by the shape (aspect ratio) and the radius of curvature of the tip (31–34). Imaging artifacts, which are inherent to microscopic techniques, are well known and can be identified as such by systematic variations of relative scan angles, scan velocities (comprising scan rate and scan size), respective imaging forces, and a thorough tip shape analysis (35).

The data, in imaging applications most importantly the surface profile or topography (height), can be displayed graphically using a color scale to indicate the

height of each point observed. A significant difference between SFM and scanning electron microscopy (SEM) for imaging surface topography is that SFM provides a *quantitative* surface profile with excellent lateral and vertical resolution. In addition, contact mode SFM has been used to measure both repulsive and attractive forces between sample and surface with a high accuracy (force spectroscopy), as well as (lateral) friction forces, as will be discussed in the sections under Normal Forces and Lateral Forces, respectively.

Intermittent Contact Mode SFM. Intermittent contact mode SFM, also called tapping mode SFM, has been developed to reduce shear forces (36), which can cause sample deformation or even destruction of soft samples in contact mode SFM (for a recent review see Ref. 19). In addition, this mode can be useful to probe adhesive or surface mechanical properties, and thus achieve contrast between different materials. Intermittent contact mode SFM uses an oscillating cantilever/tip assembly to minimize contact time and contact forces, and to especially eliminate shear forces between tip and sample surface. This mode relies on a similar setup as contact mode SFM. However, in intermittent contact mode (in air) a stiffer cantilever is used (k = 20–80 N/m). This cantilever is excited to vibrate near its resonance frequency by an excitation piezo. Close to a sample surface, the vibration is damped as a result of tip sample interactions. The original amplitude A_0 is hence reduced to A, depending sharply on the distance to the surface (Fig. 2**c**). The

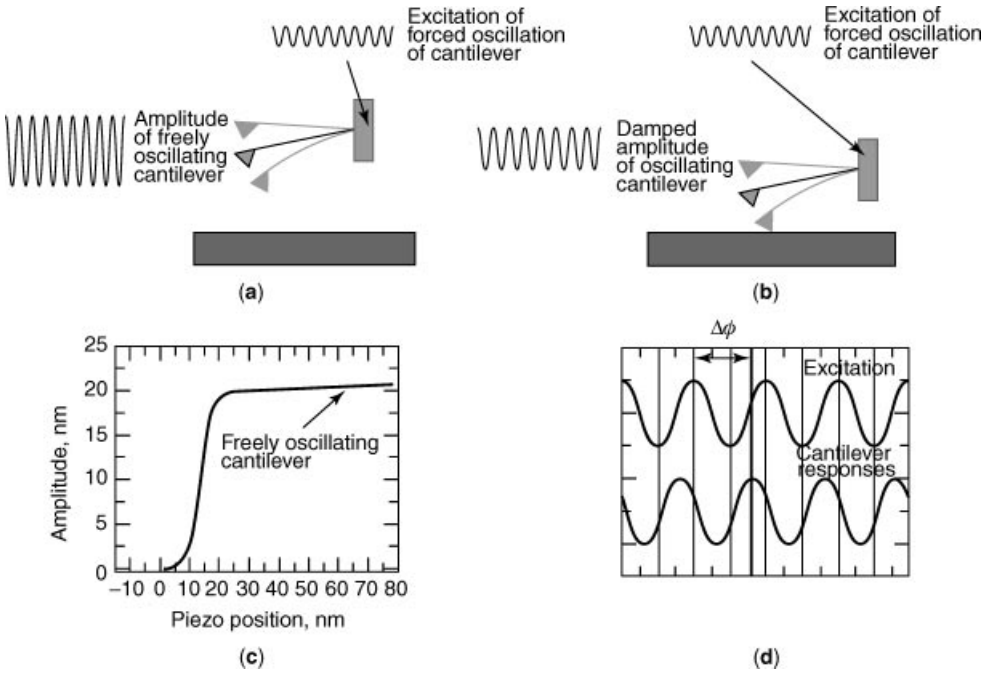

Fig. 2. Schematic of intermittent contact mode SFM: (**a**) cantilever vibrating freely in air vs (**b**) damped oscillation due to interactions with the surface; (**c**) amplitude vs displacement dependence showing the steep decrease of the amplitude as function of distance; (**d**) phase angle shift $\Delta\phi$ between excitation signal and cantilever response owing to interactions of the tip with the surface.

feedback loop uses the amplitude as control variable and holds a certain amplitude damping constant, while the sample is raster-scanned. Typically, high A/A_0 ratios are chosen in order to keep the contact time and peak forces during one cycle of oscillation to a minimum (intermittent contact) (37–41).

Anomalous height data may be observed in intermittent contact mode SFM owing to various reasons. Reduced heights may be observed because of flattening of soft matter as a result of forces exerted by the probe tip (42), as well as owing to the effect of attractive forces (43–45). The corresponding force gradient near the imaged surface changes the effective spring constant of the oscillating cantilever, and this change in effective spring constant causes a shift of the amplitude vs frequency curve of the cantilever and thus a change in the acquired amplitude. As the tip is scanned over a heterogeneous surface, the induced force is dynamically changing owing to perturbations from the different phases present (46,47). Anomalously increased heights can also be observed when certain surface areas damp the oscillation of the probe tip much stronger than other areas. Since the feedback loop holds a predefined amplitude constant by adjusting the sample position in z direction, this leads to an often significant overestimate of the "true" height (48).

The phase relation of the excitation piezo and the vibration of the cantilever in time yields often highly useful information on the interaction of tip and sample surface (Fig. 2**d**) (49). The phase angle shift $\Delta\phi$ between excitation oscillation and forced oscillation of the cantilever can be described by a simple harmonic (50–52), but also more complicated anharmonic (19), treatment of a forced oscillator. The phase angle shift can be used to obtain contrast due to different surface characteristics related to materials properties (intermittent contact mode SFM *phase* imaging) (49). These properties include, depending on the operation conditions, differences in adhesion (53) or differences in Young's modulus (50–52,54,55). Hence the amorphous and crystalline phases in semicrystalline polymers can be clearly differentiated, as well as different phases in polymer blends or filled systems.

Force Modulation Mode SFM. Force modulation mode (FMM) SFM is a contact mode technique that allows one to resolve lateral differences in modulus (56,57). In FMM SFM, the cantilever is excited by a bimorph to oscillate at a frequency of tens of kilohertz, while it scans the surface in contact mode. By monitoring the oscillation amplitude, the elastic modulus of the surface can be mapped with high resolution. Depending on the corresponding moduli, the contrast in the amplitude image reveals high modulus (ie, large amplitude) and low modulus (ie, lower amplitude) areas (Fig. 3) (58).

Recently, the use of frequency-dependent FMM SFM has been described, where selective contrast can be achieved in heterogeneous systems (59,60). A practical limitation for the approach in the field of polymers is the fact that shear forces, similar to contact mode, may cause severe sample damage or distortion of the underlying morphology.

Further Relevant Modes of SFM. In addition to the standard modes of SFM, there exists a plethora of different modes, which found their niche applications. Instead of treating all these modes in detail, the most relevant modes in light of the work reviewed in the following sections will be very briefly mentioned.

Laterally resolved imaging of adhesion and modulus in contact mode SFM is becoming increasingly important, for instance, in the current strive for mesoscale

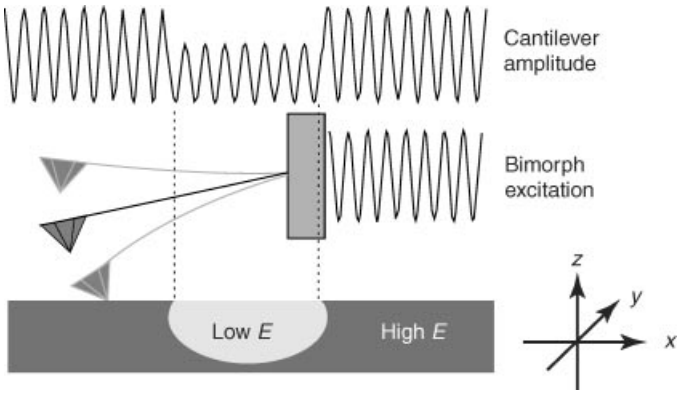

Fig. 3. Schematic of FMM SFM. The cantilever is excited by a bimorph during a contact mode SFM scan. The cantilever amplitude depends on the local modulus of the underlying material.

and nanometer-scale structured or patterned polymers, as well as for biopolymers and polymers in biomedical applications. In these techniques (61–63), described first by Mizes and co-workers for polymers (64), force–displacement (f-d) curves (see section under Normal Forces) are recorded for each pixel and the pull-off force, as a measure for adhesion, and the indentation part of the loading curve, to extract/fit the elastic modulus, are evaluated for each pixel. In particular for adhesion mapping, the use of chemically functionalized SFM probe tips (7,65) has been shown to be a suitable approach to map chemical composition and functional group distributions down to the sub-50-nm scale (see section Mapping of Surface Properties and Composition) (66).

The slow data acquisition rates of this useful approach have been overcome in the so-called pulsed force mode SFM technique developed by Marti and co-workers (67). In this mode, the sample is modulated sinusoidally ($\sim$1 kHz) during a conventional contact mode SFM scan with an amplitude, which is just large enough to overcome the adhesive interactions. Hence the tip contacts, indents, and breaks free from the surface with a frequency of $\sim$1 kHz during scanning. Instead of recording the complete f-d curve, only the four points are captured, ie, the baseline, the maximum repulsive force, the maximum adhesion force, and a point that can be used with the maximum repulsive force to define the slope in the loading regime as a measure of stiffness, respectively. Thus, the simultaneous mapping of sample topography, pull-off forces, *and* stiffness at useful scan rates becomes possible.

Other SFM methods, including scanning thermal imaging (68), electrochemical (69), and noncontact mode SFM (19) have been recently reviewed.

Force Measurements

The basis for the SFM methodologies are by definition forces between the probe tip and the sample surface of interest. Consequently, SFM techniques can be directly used to qualitatively and quantitatively measure these forces, often with high precision and, depending on the range of the corresponding forces (70), with high

lateral resolution. The discussion of the measurement of these forces and some rudimentary theory has been divided into two sections dealing with forces in the surface normal direction and lateral forces, respectively.

Normal Forces. In the treatment of normal forces, a differentiation into the measurement of adhesive forces, related to, eg, surface chemistry, quantification of entropic and enthalpic forces, dealing with single polymer chain properties, and finally indentation measurements, yielding surface mechanical properties, has been made.

Adhesive Forces. Forces that give rise to adhesion (qv) at polymer surfaces include, depending on the material and medium, electrostatic forces, electrostatic double layer forces, hydrogen bonding, dipolar interactions, van der Waals interactions, as well as steric forces and bridging forces (70). In suitable experimental setups, all these interactions can be probed, often down to a molecular level. In a typical *force spectroscopy* experiment, the force between (modified) probe tip and polymer is measured by monitoring the deflection of the cantilever as a function of sample/piezo position, while the tip is brought periodically in and out of contact with the sample surface. The measured cantilever deflection Δz can be converted to the corresponding force F, by applying Hooke's law, if the spring constant of the lever k is known.

$$F = k\Delta z \tag{1}$$

In Figure 4 the corresponding movements of piezo (sample) and cantilever deflection are schematically depicted. The resulting f-d plot (force curve) is shown in Figure 5. The interpretation of force curves has been discussed in detail by Burnham and co-workers (71) and by Cappella and Dietler (72).

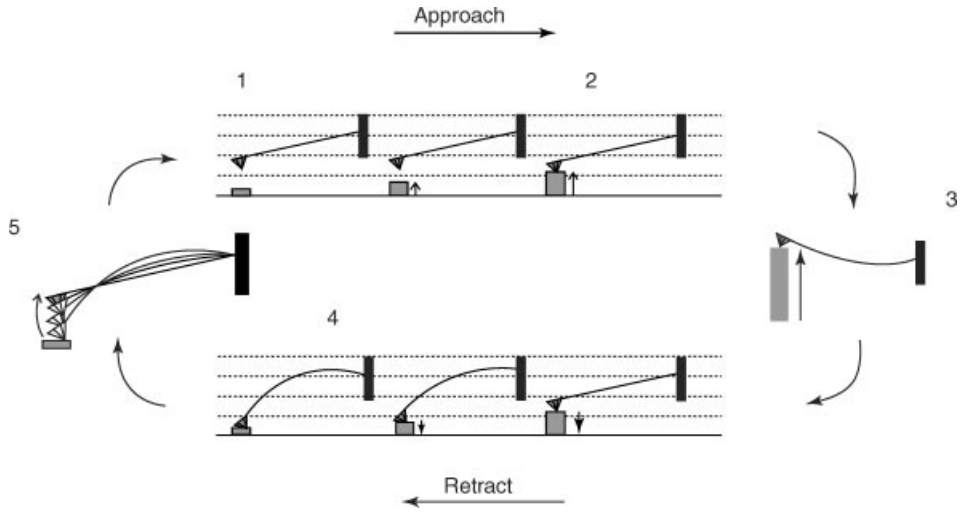

Fig. 4. Measurement of force–distance curves (schematic representation). The sample is approaching the tip (1); at some distance the gradient of the force overcomes the cantilever spring constant and the tip jumps into contact (2); further movement up causes a deflection of the cantilever (3), during the retraction the tip sticks usually much longer (4) and snaps off, when the spring constant overcomes the force gradient (5). Adapted with permission from Ref. 21.

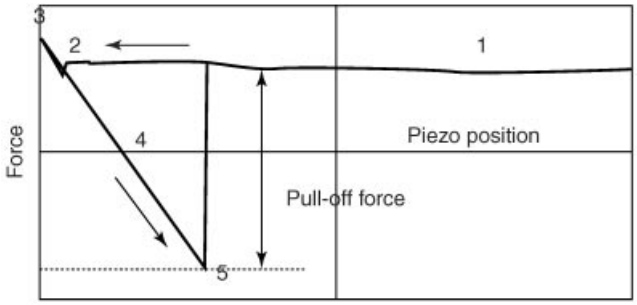

Fig. 5. Force–displacement plot. Adapted with permission from Ref. 21.

The adhesion between tip and sample is characterized by the so-called pull-off or pull-out force (Fig. 5) (73). A quantitative determination of forces requires a thorough calibration of the cantilever spring constant. Despite the large number of different methods (74–77), an accurate quantitative and nondestructive calibration remains difficult. The resolution limit for an optical detection system and spring constants used in experiments on typical commercial SFMs has been estimated to be in the order of 10^{-11} N (78). Depending on the detection system, the force constant, the stiffness, and the resonance frequency of the cantilever, even smaller forces are in principle measurable (79).

The pull-off forces obtained in f-d measurements can be related to the work of adhesion and the respective surface free energies utilizing, eg, (continuum) contact mechanics theories, such as the Johnson–Kendall–Roberts (JKR) theory (80). In particular for monomolecular model systems (65), but also polymers, this approach has yielded a satisfactory description of the experimental data, despite the fact that the contacting bodies are treated as purely elastic (81).

For the idealized geometry of a sphere with radius R interacting with a flat planar surface, the JKR theory predicts that the contact area is a function of R, the moduli of the sphere and surface material (through the reduced modulus K), the work of adhesion W_{12} and load L.

$$A = \pi\left(R/K\left(L + 3\pi R W_{12} + \sqrt{\left[6\pi R W_{12} L + (3\pi R W_{12})^2\right]}\right)\right)^{2/3} \tag{2}$$

where K is written as function of Young's moduli E_i and Poisson's number ν_i as

$$K = 4/3\left[\left(1-\nu_1^2\right)/E_1 + \left(1-\nu_2^2\right)/E_2\right]^{-1} \tag{3}$$

On the basis of equation 2 the force can be expressed for the situation at pull-off $F_{\text{pull-off}}$, ie, minimum contact area, as

$$F_{\text{pull-off}} = -3/2\,\pi R W_{12} \tag{4}$$

The work of adhesion (surface energy per unit area) W_{12} is a function of the surface free energies of the tip (γ_1), the sample γ_2, and the corresponding interfacial free energy γ_{12} (eq. 5). If the experiment is carried out in a medium, the

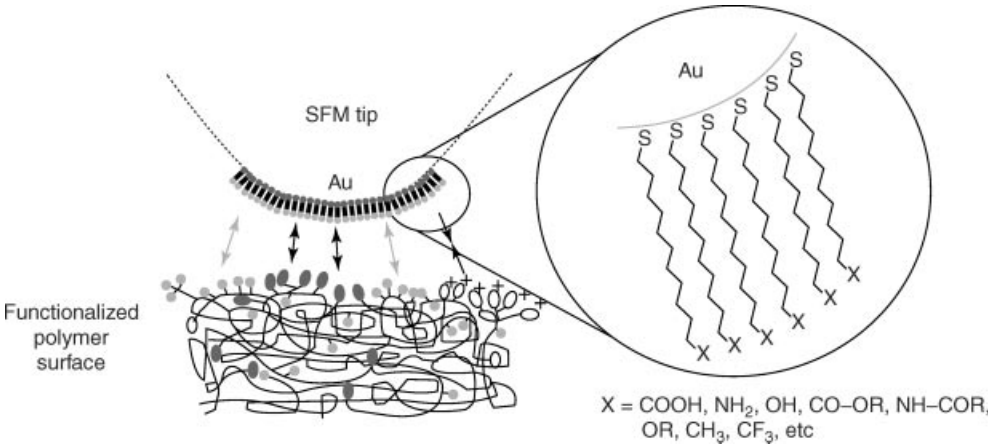

Fig. 6. Schematic of chemically modified SFM tip interacting with a functionalized polymer surface. The tip is coated with a thin layer of gold, which has been modified with a self-assembled monolayer of ω-functionalized alkanethiols. The wide range of functional groups that can be incorporated in these monolayers allows one to tune the chemical character of the tip; thus, by tuning the tip's surface free energy, the type and strength of the interactions with functional groups at the polymer surface can be controlled over a broad range. Adapted with permission from Ref. 21.

γ_i refer to the surface free energy for the surface i in contact with the corresponding medium.

$$W_{12} = \gamma_1 + \gamma_2 - \gamma_{12} \tag{5}$$

In the methodology termed chemical force microscopy (CFM), differences in long- and short-range forces are exploited for imaging under improved force conditions (82,83) or "chemical imaging" (7,65). This is achieved (*1*) via the control of the tip chemical composition by selective deposition of various materials or preferably the assembly of a functionalized monolayer (Fig. 6) (84), thus via control of γ_{tip}, and (*2*) via the control of the medium (7,65,66). Consequently, by correlating the pull-off forces extracted in laterally resolved f-d measurements with surface energies based on equations 4 and 5, it is possible to discriminate between different materials and material with different surface energies (7,53,64–66,85).

The correlation of pull-off forces with the cosine of contact angles measured with water clearly showed the applicability of this approach for various polar polymers (66,85). For apolar polymers, for example, the Lifshitz theory can be successfully applied to predict the "chemical" contrast. Feldman and co-workers demonstrated this powerful quantitative approach for different polymers probed with gold-coated and silicon oxide coated tips in perfluorodecalin (86), in which the dispersive van der Waals interactions are selectively amplified (see section Surface Forces and Energies).

Entropic and Enthalpic Elasticity. In recent years, SFM approaches and complementary force-sensing approaches, such as biomembrane probe and laser optical trap techniques, have been perfected to an extent that the study of individual (bio)macromolecules have become feasible as routine experiments in many

laboratories. In the field of polymer science, single molecule studies are particularly intriguing since statistical factors, such as molecular weight distribution, diverse morphologies, and interchain interactions can be ignored.

In particular, the measurement of the elasticity of single polymer chains by the SFM-based approach termed single molecule force spectroscopy (SMFS) (87, 88) is of importance in this context. SMFS has helped to shed light onto a number of interesting phenomena, including protein unfolding (89), DNA unzipping (90), force-induced conformational transitions in individual polymer chains (91), as well as the mentioned single-polymer chain elasticity (92).

In SMFS, f-d curves are recorded analogously to the experiment described in the section under Adhesive Forces on samples exposing isolated polymer molecules in a suitable medium (93–96). The measured intramolecular force vs extension characteristics of single polymer molecules include entropic and enthalpic elasticity, described well by the (modified) freely jointed chain (FJC) model or wormlike chain model (WLC) (87,88), as well as specific structural changes along the stretched polymer chain. In addition, the intermolecular forces may reflect the unbinding and desorption processes in which the interaction is transmitted through the surrounding medium. These interactions include the rupture of covalent chemical bonds and the unbinding of all kinds of intermolecular aggregates based on noncovalent binding interactions. Examples of the successful application of the FJC model are, for example, oligonucleotides (97), polydimethylsiloxane (PDMS) (98), and poly(methacrylic acid) (PMAA) (Fig. 7) (99).

Deviations of the force extension curves from FJC or WLC behavior, for example the kink in the force profile shown in Figure 8, often indicate conformational and configurational transitions along the polymer chain. As shown in Figure 8, Li and co-workers detected a force-induced chair-twist boat conformational transition, which cannot be measured by conventional methods, for α-(1,4)-linked polysaccharides (95).

Recent evidence based on SMFS experiments on collagen suggested that energy dissipation in the form of "hidden length" plays an important role in the stability of bone and thus led to an improved understanding of osteoporosis (100).

Indentation Measurements. Indentation force measurements utilize the indentation part of a f-d curve (compare Figs. 4 and 5). In the case of a noncompliant sample surface, the SFM tip does not indent significantly the sample, and hence the deflection vs piezo position curve in the contact region has a slope of 1.0. For compliant samples, the slope is <1.0 (Fig. 9) and can be used to obtain the elastic modulus of the sample by fitting the measured indentation to a suitable model. Knowledge of the tip shape/geometry and elastic constants of the tip is required to obtain the desired materials properties.

There have been many different approaches discussed in the corresponding literature. Hertz theory (see section Lateral Forces) is among the often used theories. For instance, Radmacher and co-workers used this theory to estimate the elasticity of lysozyme molecules on mica (102).

Van Landingham and co-workers reviewed the state of the art in nanoindentation of polymers (101,103) including a summary of the most common analyses of load-indentation data. Chief among these methods is an analysis of indentation load-penetration curves according to the Oliver–Pharr method (104). This method is based on relationships developed by Sneddon for the penetration of a

flat elastic half space by different probes with particular axisymmetric shapes (eg, a flat-ended cylindrical punch, a paraboloid of revolution, or a cone) (105). For details on the experimental procedures and analysis, including pitfalls, the reader is referred to the mentioned review (101). In practice it is found that the application of these methods to polymers often leads to overestimates of moduli compared to bulk measurements. This deviation and other effects have been largely attributed to neglected *viscoelastic* effects (106).

Lateral Forces. Lateral or friction forces can be measured simultaneously with the topography in constant force mode in *contact mode* SFM (for a review see Ref. 107). In order to maximize the sensitivity of friction force measurements, the sample is scanned typically at an angle of 90° with respect to the long axis of the cantilever. The torsion of the cantilever around its long axis is measured with a 4-quadrant photodiode (see Fig. 1). Quantitative nanotribology by friction force microscopy (FFM) requires consideration of the dependence of the photodiode output signal on laser alignment and accurate calibration (107) of the lateral force spring constant and the photodiode response. In many cases, when qualitative materials contrast is needed, FFM is a rapid and straightforward method for compositional mapping.

The corresponding output of the (lateral) photodiode signal is shown in Figure 10. The so-called friction loop (108) displayed allows one to calculate the

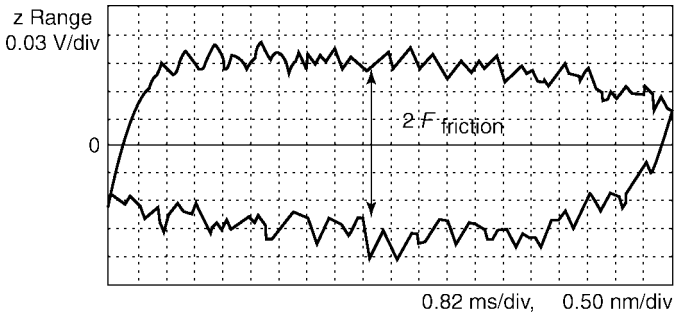

Fig. 10. Friction loop (friction force vs scanned distance plot) measured perpendicular to the polymer chain direction of oriented PE with a —CF_3 modified tip. The photodiode output signal in volts is directly proportional to the friction force range. Adapted with permission from Ref. 21.

friction force from the difference of the trace and retrace line multiplied by 0.5. In order to improve the statistics and exclude artifacts related to coupling of topography into the friction image, the mean friction forces are calculated typically from the corresponding difference image of complete scans acquired simultaneously for both relative scan directions (trace and retrace).

The understanding of the fundamentals of interfacial friction has been emerging in the last decades, and is in part based on measurements with the surface forces apparatus (109,110). In particular, friction was shown to be related to adhesion hysteresis rather than adhesion itself (110).

An early description of friction, Amontons' law, which describes the macroscopic friction between rough surfaces, gives a relation between friction force F_{friction} and applied load L (eq. 6).

$$F_{\text{friction}} = \mu L \tag{6}$$

where μ represents the friction coefficient. For presumed multiasperity contacts, this behavior is often observed also in SFM-based nanotribology. The equation has been modified to account for adhesion that is observed at zero load (111).

$$F_{\text{friction}} = \alpha L + F(0) \tag{7}$$

with constants α and $F(0)$ being related to the chemical composition of the interface.

For a single asperity contact the friction force F_{friction} is proportional to contact area A (eq. 8).

$$F_{\text{friction}} = \tau A \tag{8}$$

where τ denotes the interfacial shear strength (112).

Since friction forces are proportional to the tip–sample contact area for single asperity contacts, it is important to consider how the two contacting surfaces will be deformed during scanning in FFM. The simplest approach to describe the contact mechanics of two interacting bodies was derived by Hertz (113,114). In the Hertz theory only elastic deformations of the contacting surfaces are considered, and thus the adhesion is neglected. If adhesive interactions are considered as well, the already mentioned JKR theory of contact mechanics (80) can be successfully applied to estimate the contact area as a function of normal loading force (eq. 2). However, since friction forces are related to energy dissipation, these forces may depend on factors other than surface free energy or mechanical properties. Examples include polymer specimens with orientational order on various length scales (molecular, lamellar) or systems, which possess differences in conformational order. In these cases, FFM images may reveal subtle details of molecular scale organization (see section Lamellar Crystals). For a concise treatment of nanometer-scale friction measurements see also Reference 22.

Morphology of Semicrystalline Polymers

The hierarchical ordering of polymers from the molecular to the micrometer scale and the underlying morphology can nowadays be routinely addressed by SFM for countless polymer systems (115). Owing to the often important

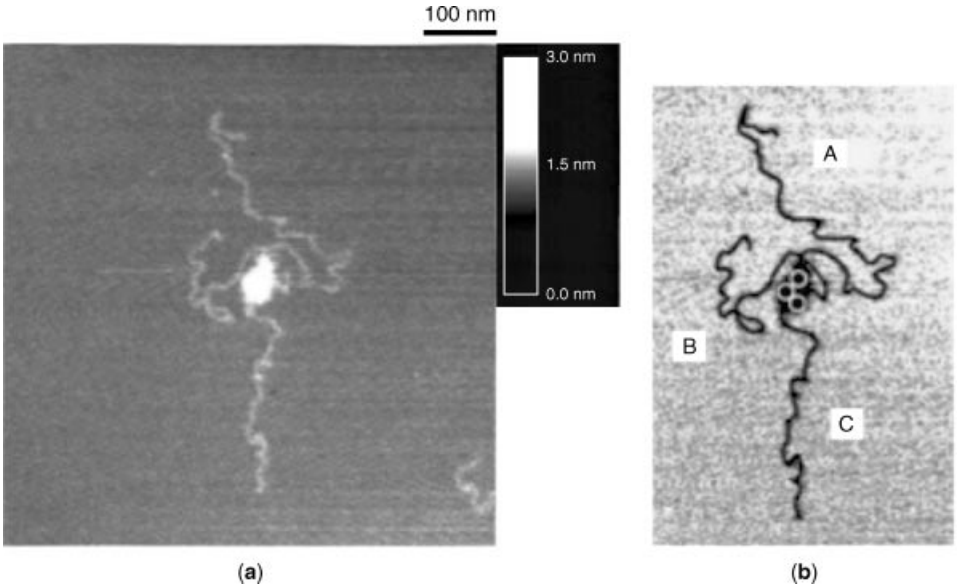

Fig. 11. (**a**) SFM image of a PS-*b*-PMMA monolayer deposited on mica (left). (**b**) Schematic representation of a possible molecular conformation. Reprinted with permission from Ref. 116. Copyright (1996) American Chemical Society.

relation of molecular or supramolecular organization and properties, this area of SFM on polymers is vital for many practical applications (see MORPHOLOGY; SEMICRYSTALLINE POLYMERS).

Single Macromolecules. The high resolution imaging capabilities of intermittent contact mode SFM allowed several groups to image and analyze the contour, ie, the shape and conformation, of *individual* adsorbed polymer molecules for selected systems. The first example of a successful imaging of the conformation of a flexible polymer was reported by Kumaki and co-workers, who studied a monolayer of polystyrene-block-poly(methyl methacrylate) (PS-*b*-PMMA) on mica (Fig. 11) (116). The interplay of interactions between the polymer segments with each other and the substrate were carefully adjusted to avoid the typically observed coiling of polymer chains on substrates. The structure of individual macromolecules was further studied for various shape-persistent polymers, including "hairy rods" (117), worm-like brushes (118), monodendron-jacketed chains (119), as well as biomacromolecules, including DNA (120). In a recent review (121), Sheiko and Möller provided a complete overview on the developments in this area that leads from structural analysis of the adsorbed macromolecules in 2-D confinement to controlled motility on the surface. In particular, the data reported by Sheiko and co-workers for individual molecular brushes showed the arrangement of the PMMA backbone and the pendant poly(*n*-butyl acrylate) side chains resolved to submolecular detail, which demonstrates the vast potential of SFM in these applications (Fig. 12) (121).

Further examples of imaging of individual macromolecules using SFM comprise dendrimers (122–125) and physisorbed or chemisorbed polymer chains (126,127). Owing to the softness of the macromolecules, as well as to tip

convolution effects (34) and thus limited spatial resolution (33), the *true* resolution of SFM does not allow one in general to resolve submolecular structural details of the studied macromolecules.

Chain Packing and Crystal Structures. The chain packing and the submolecular arrangement of repeat units and pendant side groups of macromolecules in crystalline domains of polymers can be visualized using contact mode SFM. The resolution is in most cases not *true* resolution, since the area of the contact area (1 − few nm^2) exceeds the molecular scale and must be considered *lattice resolution* instead. The first example of molecularly resolved structures of a polymer dates back to 1988, when Marti and co-workers reported on an SFM study on a polydiacetylene film (128). Examples for resolved chain packing and polymer crystal structure determination at the surface of semicrystalline polymers include poly(tetrafluoroethylene) (PTFE) (129,130), polyethylene (PE) (131–133), polypropylene (PP) (134,135), poly(ethylene oxide) (PEO) (136), aramids (137,138), and poly(oxy methylene) (POM) (139).

In Figure 13, a typical high resolution contact mode SFM scan of uniaxially oriented POM is shown together with the corresponding 2-D fast Fourier transform filtered image (139). Since the polymer chain direction is in this particular case known a priori, the observed periodicities can be related to the well-established hexagonal crystal structure of POM in a straightforward manner. Uniaxially oriented or epitaxially crystallized specimens thus help in the analysis of the data, as has been discussed in recent review articles (140,141).

In most cases the surface crystal structures observed correspond to the structures found by diffraction techniques in the bulk (21,140). For isotactic PP, the groups of Lotz (142) and Vancso (143) succeeded to determine the handedness of the PP helices exposed at the specimen surface based on the arrangement of the methyl groups.

Besides the identification of the local polymorphic structure of the crystallized polymer, it is possible in some cases to detect new (minority) crystal structures. For aramid fibers, previously not detected, but predicted, crystal structures have been identified based on SFM data obtained on cleaved fibers (137). Noteworthy are also the studies by Lotz and co-workers who elucidated the frustrated crystal structure of β-PP with the help of SFM images with methyl group resolution (144). Finally, the mechanism of friction reduction on oriented PTFE films has been confirmed using SFM measurements with molecular resolution (145,146).

Lamellar Crystals. Chain-folded lamellar crystals are regarded as the intermediate hierarchical level in polymer morphology between macromolecule and higher order multicrystal aggregates, such as spherulites. Because of the central importance of lamellae in the field of polymer crystallization and the relation of polymer crystallization to, eg, mechanical properties, lamellae have been widely studied by SFM in all important imaging modes.

Solution-grown single lamellar crystals of, eg, PEO (147), POM (148), PE (149,150), syndiotactic PP, poly(dimethyl silane) (151), poly(4-methyl-pentene) (152), and poly[(*R*)-3-hydroxybutyrate] (153) deposited onto solid substrates have been studied by SFM. The habit and thickness of the lamellae in flat-on projection are directly accessible and in addition to these data, which have previously been typically provided by TEM in conjunction with shadow evaporation techniques (4), more subtle details of domain boundaries and fold direction orientation have been revealed. In Figure 14, the habit of a collapsed PE lamellae is depicted, as well as the anisotropic lateral force recorded in the different fold sectors (154).

Friction anisotropy in different sectors of lamellar crystals (154), which is thought to be related to the orientation of the folds at the fold surface, has also

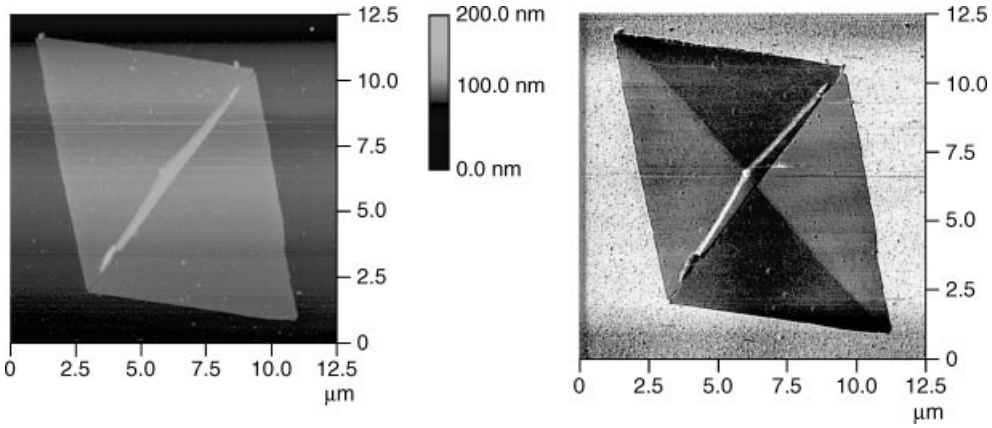

Fig. 14. Contact mode SFM height image of single lamellar crystal of PE deposited on mica (left) and friction image of the same PE lamella (right; friction forces increase from dark to bright contrast). Reprinted in part with permission from Ref. 154. Copyright (1999) American Chemical Society.

been reported for solution-grown lamellae of POM (115), various PEs (155,156) and poly(4-methyl-pentene) (152). For lamellae of poly(dimethyl silane) (151), molecular resolution SFM data provided direct evidence for an arrangement of the polymer chains consistent with an adjacent reentry model.

Crystallization from the melt also results in chain-folded lamellar crystals and for numerous polymers single lamellae have been studied by SFM approaches. Since typical lamellar thicknesses, depending on the polymer and the crystallization temperature, are in a range of 10 nm to several tens of nanometers, the finite size of the SFM probe tip leads to convoluted data, if lamellae are viewed edge-on (33). Among the countless examples are isotactic PS (157,158), PEO (159,160), PP (161–163), PE (164), polycarbonate (PC) (165), etc.

The determination of lamellar thicknesses (161) has been discussed in detail by Trifonova and co-workers (162). The cross-sectional analyses of contact mode SFM images acquired on permanganate-etched specimens of isotactic PP (100% β-modification) are shown in Figure 15.

From a thorough analysis the corresponding distribution of lamellar thicknesses can be directly accessed. In addition, the mechanism of lamellar branching via the action of screw dislocations (166,167), which eventually leads to a spherical envelope of spherulites (see section Multilamellar Crystals, Hedrites, and Spherulites), could be confirmed.

Lamellar thicknesses were also studied by Marand and co-workers, who reported on lamellar thickening of bisphenol A PC (168). The SFM data showed clearly that the most probable lamellar thickness shifts toward higher values with annealing time and provided support for the feasibility of isothermal lamellar thickening in this polymer, as also inferred by differential scanning calorimetry.

While contact mode SFM allowed several groups to image semicrystalline polymers at this level of resolution, intermittent contact mode phase imaging provides in many cases superior differentiation between the amorphous and the crystalline phase because of its stiffness-based contrast (169). For isotactic PP the

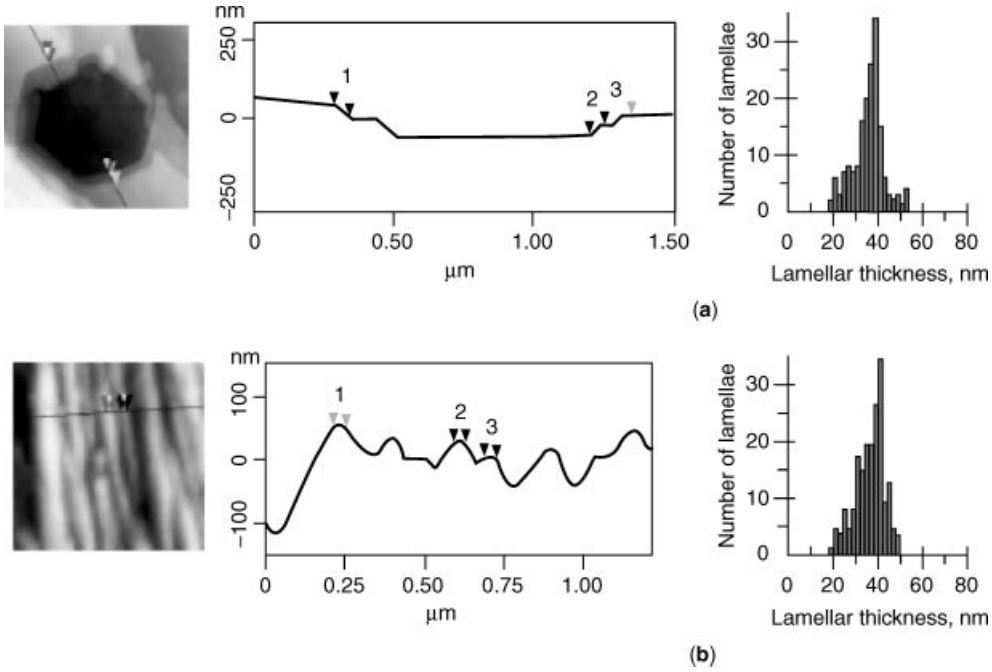

Fig. 15. CM-SFM images of β-iPP lamellae (crystallized isothermally in a thick film at 140°C for 1 h and subsequently exposed to $KMnO_4$ etching) viewed in flat-on projection (top) and in edge-on projection (bottom) together with corresponding section analyses and histograms of lamellar thicknesses. crystallization from the melt produces, depending on the crystallization temperature, and regio and stereo defect concentrations, the α modification of isotactic PP. This polymorph can be identified owing to the typical cross-hatched arrangement of the lamellae with an angle of 80.4° (170,171), as depicted in Figure 16 (172).

SFM studies of low crystallinity thermoplastic polyolefin elastomers based on polyethylene–alkene copolymers or stereoblock polypropylenes highlighted the importance of the crystalline regions as physical cross-links in these systems (173, 174). Even though crystallinity was very low in these materials, SFM provided sufficient contrast to interrogate the size and distribution of crystallites in the as-prepared and deformed materials (175). As will be discussed in the section under Polymer Crystallization, the crystallization process in such materials was also imaged in real time (176).

Multilamellar Crystals, Hedrites, and Spherulites. Upon crystallization from the quiescent melt (or concentrated solution), polymers exhibit higher order supramolecular structures, including stacks of lamellae, hedrites, and finally spherulites (167). Hedrites (177) are entities composed of multiple lamellar crystals and as such correspond to intermediate stages of spherulitic growth. SFM in various modes was used to determine spherulite sizes and details of lamellar arrangement within spherulites for a wide variety of polymers and polymer processing conditions. SFM data acquired at free surfaces, at the surface of microtomed

Waymouth, and C. W. Frank (172).

specimen exposing the bulk morphology, as well as at the surface of thin and ultrathin films of crystallized films, were reported.

Harron and co-workers reported on the crystallization of PC films induced by solvent using both *ex situ* contact and intermittent contact SFM (165). The growth of spherulites was followed in ultrathin films for different exposure times to butyl acetate vapor and the growth rates were quantitatively determined.

Viswanathan and Marr complemented SFM studies with small-angle light scattering to confirm the quantitative spherulite sizes obtained in contact mode SFM measurements in high density PE films (178). In addition, individual PE lamellae were resolved.

Figure 17 shows two typical examples of well-developed spherulites of PP grown from the quiescent melt under isothermal conditions.

Banded spherulites, eg in PE (179,180), poly(vinylidene fluoride) (PVDF) (181), or polyhydroxyalkanoates (182), have also been studied in detail. The periodic bands detected in optical microscopy correspond typically to periodic corrugations along the radial direction of the spherulite. Particularly interesting is the case of PVDF (181). On the basis of a careful analysis it was found that the slopes of the observed multilayer terraces of lamellar crystals are retained in each half of a banded spherulite. This evidence confirmed the macroscopic selection of one-handedness in the formation of spiral terraces in each growth direction of the sheaf at the center of banded spherulites of PVDF (181).

In addition to the characterization of the morphology formed as a result of different thermal history, the role of interfaces and shear in transcrystallization (Fig. 18) (164,183) and thin films (184), as well the confinement effects of ultrathin films (185,186) on polymer crystallization, have been addressed by SFM approaches.

Fibers, Latex Particles, and Polymer Processing. In addition to the typical morphologies displayed by semicrystalline polymers, the morphologies formed or present in polymers used in important applications or subjected to various processes, namely fibers (141) and latex particles (187), were investigated by SFM.

The mapping of fiber surface morphologies (188), as well as internal structures of fibers exposed, eg, by microtoming, and the determination of fiber diameters for very thin fibers (136,189) are among the versatile applications of SFM. Various types of oriented PEs have been investigated by SFM, revealing the fibers and their corresponding fine structure with great detail. For instance, the microfibrillar architecture of PE fibers was visualized by Magonov and co-workers (190). The fibrillar morphology of the uniaxially oriented material was found to be parallel to the orientation direction. In addition, microfibrils with diameters between 20 and 90 nm were also found parallel to this direction.

In a different study, gel-drawn ultrahigh molecular weight PE was analyzed by SFM. The images showed different well-defined levels of the underlying fibrillar morphology (132). These include bundles of microfibrils (diameter between 4 and 7 μm), microfibrils (diameter between 0.2 and 1.2 μm), nanofibrils, and regular chain patterns on the molecular level (Fig. 19).

In drawn thin films of PE, shish-kebab crystals have been investigated by Miles and co-workers (191). Using contact mode SFM at minimized forces in liquid, the arrangement of the lamellae and the polymer molecules comprising the lamellae were resolved in molecular detail. Similar morphologies were also observed for poly(1-butene) (192), as well as many processed polymers, because of orientation effects during the production process (193,194).

The deformation mechanisms in various polyolefins have been studied in great detail. Kravchenko and co-workers have reported on the deformation behavior of elastomeric PP, for which the orientation and deformation of lamellae during tensile testing could be followed with high resolution using intermittent contact mode SFM (175).

The development of a quasi-single crystal texture during plastic deformation of high density PE has been elucidated based on a combination of high resolution contact mode SFM and X-ray scattering techniques. In particular, the absence of a block-like long period comprising crystalline lamellae and amorphous regions, as well as the presence of different crystal facets at the surface of microtomed specimens, was observed (133).

The process of latex assembly in thin films and drying of latex-based paints has attracted tremendous attention, and many SFM studies have been published (187,195,196). Patel and co-workers analyzed latex films composed of hard and soft latex particles and showed by following the distribution of the hard latex beads for different compositions that voids in the film interior were responsible for the observed transition of transparency to turbidity (197).

Juhue and Lang investigated the effect of surfactant post-added to surfactant-free poly(butyl methacrylate) latex dispersions on film formation. The particle ordering and packing was determined by SFM, which allowed these authors to determine the optimal surfactant concentration corresponding to fully covered latex particles (198).

Butt and Geharz reported on the morphology of individual latex particles adsorbed on mica (199). Homogeneous and composite latex particles, made of different amounts of poly(butyl acrylate) and PMMA yielding different viscoelastic properties and different morphologies, were studied (Fig. 20). The latex particle shape was shown to depend on the original latex morphology and viscoelastic properties. The packing of the particles during adsorption and subsequent drying was concluded to be determined by capillary forces, while the particle deformation was caused by interfacial forces.

The analysis of oriented morphologies resulting from polymer processing was already mentioned above. In addition to the characterization of the fibrillar

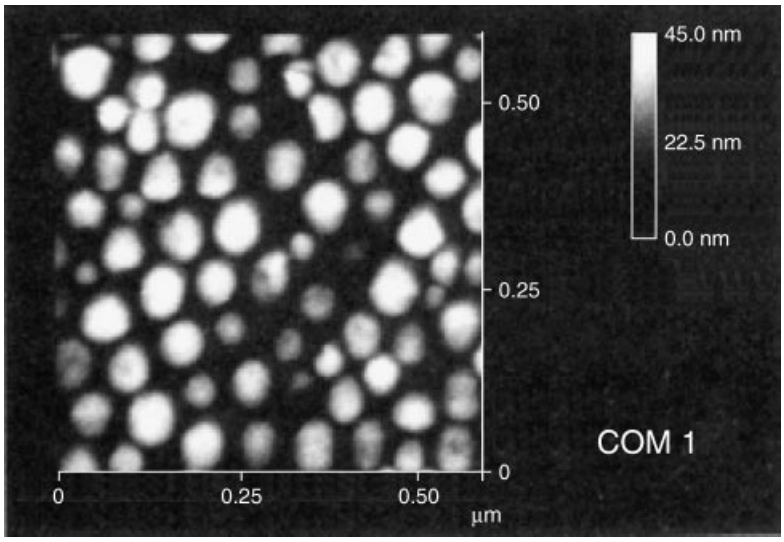

Fig. 20. Contact mode SFM image of dried composite latex particles of *n*-butyl acrylate and methyl methacrylate on mica. Reprinted in part with permission from Ref. 199. Copyright (1996) American Chemical Society.

arrangement in processed polymer, SFM is useful to analyze changes in surface morphology and roughness owing to surface treatments. For example, Vancso and co-workers reported on a SFM study of the surface morphology of commercial polymer films. The effects of flame-treatment of HDPE, corona treatment, and metallization of PP have been unraveled. The thickness and orientation of the exposed lamellae were determined (194).

The roughness analyses of blown PE films yielded useful insight into the origin of optical properties (200). The results showed that the haze is related predominantly to surface roughness and can be reduced by changing the processing conditions. In full agreement with WAXS (wide-angle X-ray scattering) studies, the SFM images unveiled lamellar features, which were oriented predominantly in the transverse direction.

The effects of surface treatments on roughness and more importantly surface energy have been addressed by various groups (see also section Mapping of Surface Properties and Composition). The roughening of PP owing to plasma treatment (201,202) and oxyfluorination (203,204), as well as the surface erosion of LDPE during chromic acid oxidation, have been described (205). Surface roughness can be estimated based on quantitative image analysis procedures (25) and can often be coupled to important mechanical properties (206).

Mapping of Surface Properties and Composition

In addition to a quantitative determination of the surface topography, SFM has proven to be a unique approach to simultaneously map surface properties with high spatial resolution. The resulting maps are particularly useful

to characterize intrinsically heterogeneous systems, such as polymer blends, microphase-separated block copolymers, particulate-filled polymers, but also chemically modified polymers, where a heterogeneous distribution of, for instance, surface functional groups, is not a priori expected (see SURFACE PROPERTIES; SURFACE ANALYSIS).

Surface Forces and Energies.

Miscellaneous Forces. Force measurements on polymer surfaces or between chemically modified SFM tips and polymer surfaces yielded important insight into fundamental force vs separation distance relationships for, eg, polymer colloidal particles (207), mechanochemical behavior of individual macromolecules (see section Entropic and Enthalpic Elasticity) (87–96,99), but also adhesion information directly relevant for practical applications, such as electrochemically controlled adhesion (208) or toner particle–rubber interactions relevant for xerographic applications (209,210).

For example, Segeren and co-workers used SFM cantilevers that were functionalized directly with a toner particle to study the adhesion between particle and different rubbers (Fig. 21) (211). Hodges and co-workers utilized a similar approach to investigate the particle size dependence of forces between polystyrene particles in water (212,213).

Typical forces present in polymeric systems, such as bridging forces and steric forces, play an important role in many applications and have been successfully interrogated by SFM. Briggs studied bridging and steric forces between zirconia spheres coated with poly(acrylic acid) (214), while the groups of Butt and Rühe measured steric forces of polymer brushes as a function of solvent quality and temperature (215). Upon tip–sample approach, exponentially decaying repulsive forces were observed and when the temperature was increased, a linear increase of the decay length, eg, for PS in cyclohexane resulted. These results confirm that the observed repulsion is of entropic origin. Measurements of forces on polymer surfaces in liquids have also been reviewed by Hodges (207).
