where γ and β are numerical constants, respectively, c, the number concentration of the polymer, L, the length of the rigid-rod (polymer), and D_{t0} or D_{r0}, the translational or rotational diffusion constant in a sufficiently dilute solution, respectively (379,380). Many new models and theories of simulating studies for rigid-rod polymers have been emerging. For example, Mondescu and Muthukumar investigated the steady-state transport properties of a heterogeneous suspension of rigid-rod polymers and spheres without excluded volume interaction, by applying the multiple scattering formalism and the effective medium theory (381). Yu used the Galerkin method to solve the diffusion equation of the distribution function for rigid-rod polymers, in order to simulate the interactions between the rigid-rod polymers and the coherent structure in a mixing layer (382). La Penna used a mode-coupling expansion of the Smoluchowski generalized diffusion equation with hydrodynamic interactions to calculate the time correlation functions of molecular configurational variables and found the results to be in good agreement with those obtained by an analytical solution of the rotational diffusion equation of rigid-rod polymers (383). For a linear rigid-rod, the second-order mode-coupling diffusion theory gave good hydrodynamic results for the bond time correlation function of the rigid-rod polymer solutions (384).

Farmer computed the effect of protonation on the behavior of PBZT and PBZO rigid-rod polymers. A significant portion of the charge deposited on the molecules was delocalized into the phenyl ring when it was coplanar with the heterocycle. The delocalization resulted in a higher torsional energy barrier for the protonated molecules and a lower barrier for out-of-plane bending. Thus the flexibility observed in previous molecular dynamic simulations of the neutral molecules in vacuo appears to be reasonable depiction of the stiffness of the rigid-rod polymers, even in strong acid solution (385).

Computer simulation has become a strong tool to understand the molecular structure and predict the properties of rigid-rod polymers. Furthermore, the understanding of the dynamics of rigid-rod polymers also helps give insight and aids investigation of structure–function relationships of DNA and many other biomaterials (375). However, the computer simulation of real polymers and their solutions (especially for the concentrated solutions) is rather complicated. Many

structural factors, such as chain length distribution, orientation of the chains, various bonding between atoms (such as covalent bonds in the chain and secondary forces between the chains), the nonuniformity and anisotropy of the structure, the interaction of macromolecules and solvents, as well as the presence of impurities, will affect the results. In different situations, various factors or combinations of them may be important. With further progress in computer techniques and calculation methods, more accurate simulation results will emerge in the future.

Molecular Composites

An interesting developing direction for rigid-rod polymers is to prepare "molecular composites." A molecular composite is a molecular-level (or nano-level) analogue of a chopped fiber-reinforced composite. The aim is to form a homogeneous mixture of a rigid-rod polymer, as the reinforcement, and a flexible chain polymer, as the matrix, with improved stiffness. The concept of molecular composites first appeared in the 1970s–1980s (386–389). Today, molecular composites have been developed as a new generation of high performance materials (390). Two key factors, the aspect ratio of the reinforcing rigid-rod polymer and its miscibility with the flexible polymer, control the mechanical and physical properties of the molecular composites. Owing to reinforcing at the molecular level, a molecular composite exhibits a single uniform thermal expansion coefficient and isotropic characteristics, which are greatly different from the conventional unidirectional fiber-reinforced composite materials (391).

There are several approaches to making molecular composites: (*1*) Takayanagi finely pulverized and then mixed rigid crystalline polymer microdomains (such as PPTA) with different flexible polymer matrices (including nitrile–butadiene rubber, nylon-6, and nylon-6,6) (386,392); (*2*) using guidance from solution thermodynamics (theoretical (393) and experimental (387,388), Hwang and co-workers codissolved the rigid-rod polymers (such as PBZT) with various semiflexible polymers [such as aromatic heterocyclic semiflexible polymers, ABPBI (poly(2,5(6′)-benzimidazole)) or ABPBT (oly(2,5(6′)-benzothiazole)), with coil-like polymers, nylon or poly(*p*-phenylene quinoxaline)] as matrix, in strong acids (such as methanesulfonic), and then rapidly coagulated the isotropic solution to "quench" the dispersed state (387,388,394–396); (*3*) Lenke and co-workers polymerized rigid-rod molecules (such as polyazomethine, polyimides, and polycarbodiimides) in thermoplastic precursors (such as nylon-6), or thermoset precursors (such as epoxies), and then polymerized the precursors (as the matrix) to form an *in situ* molecular composite (397–399); (*4*) using poly(amideimide) or other rigid polymers that can form melts, instead of the rigid-rod polymers which cannot be melted, molecular composites were prepared with a melt process (53).

Fibers and films made by molecular composite processing display good mechanical and thermal properties, chemical and environmental resistance, as well as interesting optical and electrical behaviors. The molecular composite made from articulated rigid-rod PBZT with a thermoplastic pendant, poly(etherketone) (PEK), has significantly higher T_g and tensile properties than the neat PEK homopolymer (400). A PBZT/BBB (poly(benzimidazobenzophenanthroline))

molecular composite demonstrates good thermal stability (401). The ABA copolymers of carboxy-terminated PBZT and 3,4-diaminobenzoic acids show much better tensile strength (up to 33% increase) than simple blends (402,403). Graft copolymers of PEK and PBZT also improved the composite processability (404) and prevented the segregation of PBZT molecules (405). Therefore, the toughness of the molecular composites increases with the increase of rigid-rod polymer content (406). It has also reported that fibers spun from molecular composites with PBZT/PBZO were strong and stiff (252,407,408). In addition, molecular composites can eliminate the detrimental interface issues with conventional fiber-reinforced composites, such as CTE mismatch between fibers and matrix (409,410).

It should be noted that unless care is taken, the rigid-rod molecules would not completely disperse in the molecular composites, but form small coacervated domains (410). There remain several problems. Among them, the most critical one is the inability to consolidate without phase separation (6). Several new molecular composite systems are suggested and activity has been concentrated on the improvement of processability (2,114,151,337,409,411–415). Recently, Wiff has proposed making recyclable "nano" thermoplastic/liquid crystal composites (416). By a special processing technology, the thermotropic liquid-crystalline (rigid-rod) polymers (TLCP) were blended with thermoplastic resins to keep the liquid crystalline domains small enough that their size approached that of microvoids in the thermoplastic polymer systems. The uniform dispersion and small size were achieved through use of static mixers at temperatures where the TLCP is in the nematic state and the thermoplastic is a melt. Therefore the mechanical properties, including flexural and tensile strengths and moduli, as well as low temperature impact strength, of the nano composites were greatly improved. In particular, the fracture toughness is doubled. The possible explanation is that the reinforcements are not needle- or fiber-shaped but rather form an interconnecting network of nanoscale platelets (416).

End Uses of Rigid-Rod Polymers and Fibers

With the rapid technological progress in many engineering fields, the use of high performance polymer fibers is required. Because of their superior properties, various rigid-rod polymers have been developed and their applications have been explored. Taking advantage of their low density, excellent tensile properties, hydrolytic and chemical resistance, thermooxidative stability, and dielectric behavior, rigid-rod polymer fibers have great potential to be widely applied for composite materials. The fields include anti-ballistics, fire protection, athletic equipment, strings, cables, ropes, cordage, sails, multilayer circuits, safety gloves and pulps, especially for many in space and marine environments.

Generally rigid-rod fiber composites can provide potential significant advantages: (*1*) retention of a large fraction of tensile properties under static and cyclic conditions; (*2*) low density; (*3*) a good balance between lamination properties and impact damage tolerance; (*4*) high working temperature. PBZT and PBZO composites compare favorably in tension to other composites reinforced with Kevlar 49 or S-glass. They also show better behavior than the conventional aluminum matrix

composites. The environmental stability of rigid-rod fiber composites is generally excellent (369–371,417,418). The thermal behavior of rigid-rod fibers result in composite materials with good thermal insulating properties, such as thermal insulating support straps for cryogenic applications in space (73). The rigid-rod fibers are one of the best precursor materials for manufacturing ballistic products. Ballistic products made with rigid-rod fibers have the special features of low density, high strength, and high energy-absorption capability. Recently, ballistic products based on Zylon (PBZO) fibers have been introduced (419).

Although normally many of the rigid-rod fibers have relatively low compressive strength, their composites do not catastrophically fail at high bending as do those made with graphite or glass-fiber composites. It has been reported that the interfacial shear strength was 75% increased by the addition of a functionalized additive into PBZO fibers (420). Also, through synthesizing new PBZO copolymers to add new functional groups on the fibers, the interfacial adhesion between fiber and resin matrices has been enhanced (150,420–422). In addition, plasma treatments have also been applied to improve the surface adhesion of PBZT fibers in composites (423). The recently reported PIPD fibers have shown very good compressive properties. This opens a new way for rigid-rod polymer fibers to compete with carbon fibers for high performance applications economically and efficiently, especially in fields requiring high electrical resistance, such as electrical insulating ladders and satellite solar panels (73). In addition, the polarity of PIPD fibers results in good adhesion with many polymer matrix materials, including epoxy, unsaturated polyester and vinyl ester resins. It has been reported that PIPD fibers have better adhesion than that of adhesion-activated Twaron 1001 (PPTA) fibers and much better than regular Twaron 1000 (nonactivated) (13).

Their thermal stability leads to the use of rigid-rod polymers as catalyst supports. Polybenzimidazole (PBI), another member of PBX rigid-rod polymer family, has been chosen as a catalyst support for both reduction and oxidation, such as supporting palladium catalysts for Wacker-type oxidation and hydrogenation and Mo(VI) catalysts for epoxidation of propene (424). PBI-supported palladium dichoride exhibited a thermooxidative stability up to 400°C. N-cyanomethylated PBI/$PdCl_2$ is the most active catalyst for ketonization of terminal alkenes using air as oxidant and will not form Pb(O) up to 120°C (425). PBI–molybdenum(VI) oxide diacetate is a highly active, stable, recyclable, and long-life catalyst for the Halcon process (426). PBI–Pd^0 is an effective catalyst for the reduction of nitro-compounds or alkenes, and PBI–Cr(VI) is an active oxidizing agent for alcohols (427–431). Sulfonated PBI can also be applied to making high temperature-resistant synthetic papers (432). It was marketed under the trade name of Celazole by Hoechst Celanese Co. and used as a nonflammable and nonsmoking high performance material (433).

Rigid-rod polymers have demonstrated their potential for space materials. The rigid-rod polymer films are applied as advanced space durable materials for inflatable structures and thermal control applications (433,434). Woven fabrics comprising PBZO fibers blended with other selected fibers have shown combinations of their properties and in some space applications (such as light-weight parts and structures for protecting spacecraft against micrometeoroids), could be superior to those made by the component materials alone. By blending PBZO yarns with other high performance materials, enhanced performance was observed (434). In

addition, polyarylene ether benzimidazoles (PAEBI), first synthesized by NASA scientists and now produced by Triton Systems, Inc. under trade names TOR and TOR-LM, show significant resistance to erosion caused by atomic oxygen (15 times higher) compared to other thermal control polymer materials such as Kapton (polyimides (qv)) and FEP Teflon. This is due to the incorporation of a phosphorus–oxygen linkage in the polymer backbone to form an *in situ* protective layer on the surface. These materials still keep many advantages of the rigid-rod polymers, such as high T_g and good mechanical properties, coupled with high optical transmission (435).

Rigid-rod polymer material is one of the best candidates for membrane technology (qv), such as gas separation and fuel cells (436). The high chemical and environmental resistance and mechanical properties lead to the choice of the rigid-rod polymers (such as PBI) as reverse-osmosis membranes, which show high efficiency and long work-life (437). Many rigid-rod polymers can form films with extremely high permeability and selectivity for water vapor, making them potentially useful as pervaporation and dehydration membranes (438). When PBI was used as a pervaporation membrane a higher selectivity of aromatic compounds, such as toluene and chlorobenzene, was achieved (437). Because of the high affinity for acidic compounds, PBI was used for separation of acidic compounds from mixtures, and microporous PBI was used for sorption of aqueous sulfur dioxide or separation of carbon dioxide (439–441). Chemically modified PBI with chelating ligands has also been used as metal-selective sorbents for hydrometallurgical applications (442–447). PBI resin modified with mercaptoacetic acid has resulted in high metal sorption capacity (440,441).

The high dielectric strength of rigid-rod polymers coupled with good heat and moisture resistance provides high insulation efficiency, preventing electrical current leakage. The excellent dielectric behavior accompanied with low thermal expansion and high dimensional stability make the rigid-rod polymers applicable in specialized electronic applications. For example, most transmissivity problems in composite radomes are due to the reflection of the electromagnetic waves at the interface between the two components with different dielectric constants. The less the difference in dielectric constant, the smaller the reflection of the electromagnetic radiation. Rigid-rod fibers have lower dielectric constant and lower loss tangent than carbon fibers; hence they have lower radar observability (34).

Rigid-rod polymers have potential to work as conductive materials. Conducting materials have been prepared from the conjugated rigid-rod polymers with techniques of chemical/electrochemical doping as well as ion implantation (448–450). After implanting with $^{84}Kr^{+}$, PBZT and PBZO are changed significantly in molecular and morphological structures, which strongly affect their electric behavior. However, they still retain their excellent thermal and mechanical properties. A major change in molecular composition is the reduction or elimination of heteroatoms, resulting in a substantial carbonization. Morphological change is the formation of brush-heaps, mainly determined by the processing conditions. Implanted polymers exhibit metallic absorption with absorption coefficients less than those of the original materials in the UV–visible range. The conductivity of implanted PBZT and PBZO reaches 80–200 S/cm, being stable with time and temperature (207). PBZT conductive fibers have also been produced by doping with phthalocyanine (Pc) compounds, such as NiPc and $(SiPcO)_n$ (199,451,452).

Unfortunately, conventional doping techniques did not result in high conductivity (207). However, recently it has been reported that PBZT/silver conductive fibers, made by infiltration during processing, have electric conductivity over 10^4 S/cm and at the same time have maintained good mechanical properties, with a tensile modulus of 52 GPa and a tensile strength of 1 GPa (204).

In addition to the applications as molecular composites mentioned in the earlier section, rigid-rod polymers have also been used to synthesize nanoporous polymer hosts. Dhal reported template polymerization using bis(imidazole)–Cu^{II} complexes as templates (453). These templated copper-complexing rigid-rod polymers have the properties of selective binding and substrate recognition (453). It is obvious that by adding some other abilities, such as orientation of anchoring sites and shape selectivity, the nanoporous rigid-rod polymer hosts could become a promising technology for nanophase materials (454). Furthermore, as described in the next section, rigid-rod polymers have great potential for organic opto-electronic devices.

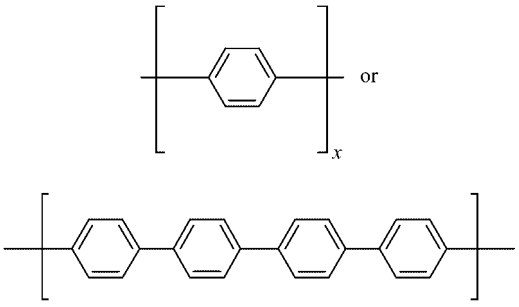
Other Rigid-Rod Polymer Systems

Rigid-rod polymers have attracted much interest for photonic and electronic applications as a result of their unique conjugated structure and superior properties (22,167,455–457). Recently, these conjugated rigid-rod polymers, because of their conducting behavior, are called the fourth generation of polymeric materials (171,458–460).

As described above, rigid-rod polymers offer excellent optical, electrical, and mechanical properties, chemical resistance, as well as high temperature, environmental, and dimensional stabilities. In addition, many rigid-rod polymers have the ability to form lyotropic (in their concentrated solutions) or thermotropic (in bulk state at elevated temperature) liquid crystals (461). In the liquid-crystalline state, high order can be introduced by the interactions between external electric or magnetic field and molecular dipole moments, diamagnetic anisotropy, interactions with a planar surface or inhomogeneous flow pattern. Many new rigid-rod polymers have been synthesized and studied for the potential applications in electronic/optical devices, such as field effect transistors, Schottky diodes, light-emitting diodes, electrochromic devices, photoactive films, high efficiency solar cells, push–pull amplifiers, batteries, optical data storage, and second- or third-order NLO materials (462–470). Unfortunately, little real usage has been reported because most rigid-rod conjugated polymers are insoluble, nonfusible, and have poor processability. However, research activities have continued, and in recent decades, so many new rigid-rod polymers have been synthesized and studied, such as PPP, Poly(*p*-phenylene ethynylene) (PPE), poly(*p*-phenylenevinylene) (PPV) (qv), polythiophene (PTh), polypyrrole (PPy), polyaniline (PA), and polyacetylene (PAc), that it is beyond the scope of this article to cover all of them. Here several model rigid-rod polymers are listed for reference. (see ELECTRICALLY CONDUCTIVE POLYMERS)

PPP, PPE, PPV, and Their Derivatives. PPP, PPE, PPV, and their derivatives are potential candidate rigid-rod polymer materials for advanced optical/electrical applications (18,22,24,471,472). The molecular structure of PPP is represented as **16**. Electronic conduction needs an electron delocalization

associated with high electron mobility between molecules, while nonlinear optical properties need a large electron delocalization and optical transparency. The polarizable π-electrons of PPP (PPE or PPV) conjugated structures can meet these requirements. In order to increase electronic/nonlinear-optical response, the rigid-rod polymers should have strong intermolecular electronic interactions so that the macromolecular backbones have to possess extended conjugation lengths and be well oriented (473). However, this kind of structure results in the polymers being insoluble and infusible, and prevents the formation of well-defined, high molecular weight rigid-rod polymers. These seriously limit their applications. In order to synthesize rigid-rod polymers with good processability, two major synthetic strategies have been taken: (*1*) the desired functional groups are part of the monomers, and the functional polymers are obtained directly from polymerization process (468,474,475); (*2*) PPP, PPE, or PPV is synthesized and then the functional groups are added or changed to make the functional polymers (21,169,468,476,477). For example, some organometallic pendants are attached to their conjugated frames not only for increasing solubility but also for enhancing the optical/electrical properties (478). Different synthetic methods, such as the conventional wet-chemical methods (479–482), and the Langmuir–Blodgett (LB) molecular process (483) are used to execute these strategies.



(**16**)

PPP, PPE, PPV, and their derivatives show high third-order susceptibility and electronic conductivity (474,484). The $\chi^{(3)}$ values of their oligomers and derivatives were measured in the range of 10^{-10} esu by Yamamoto and Moroni (485,486). As a result of triple bonds in the main chain, PPE and its derivatives (Fig. 27) have attracted special attention. The $\chi^{(3)}$ values of some PPE derivatives can reach the range of 10^{-10} esu (485), and even to 1.8×10^{-9} esu (487). In addition, rigid-rod PPP and its derivatives have also been studied as polyelectrolytes (19,488). One approach involves using PPP, as "hairy" rigid-rod reinforcing elements, with ethyleneoxide side chains (the "hairs"), as the separating liquid-like matrix, in which lithium salts are dissolved. This kind of material can offer the needed combination of ion conductivity and mechanical strength (471).

Polythiophene and Its Derivatives. Among many conductive rigid-rod polymers, such as PAc, PPP, PPE, PA, and PPy, PTh has rapidly become an intensively studied material for optical/electronic applications (20). The molecular structures of PTh and its derivatives are represented as **17** and **18**. Just like other conductive polymers, PTh has a π-conjugated electronic structure. Because of the

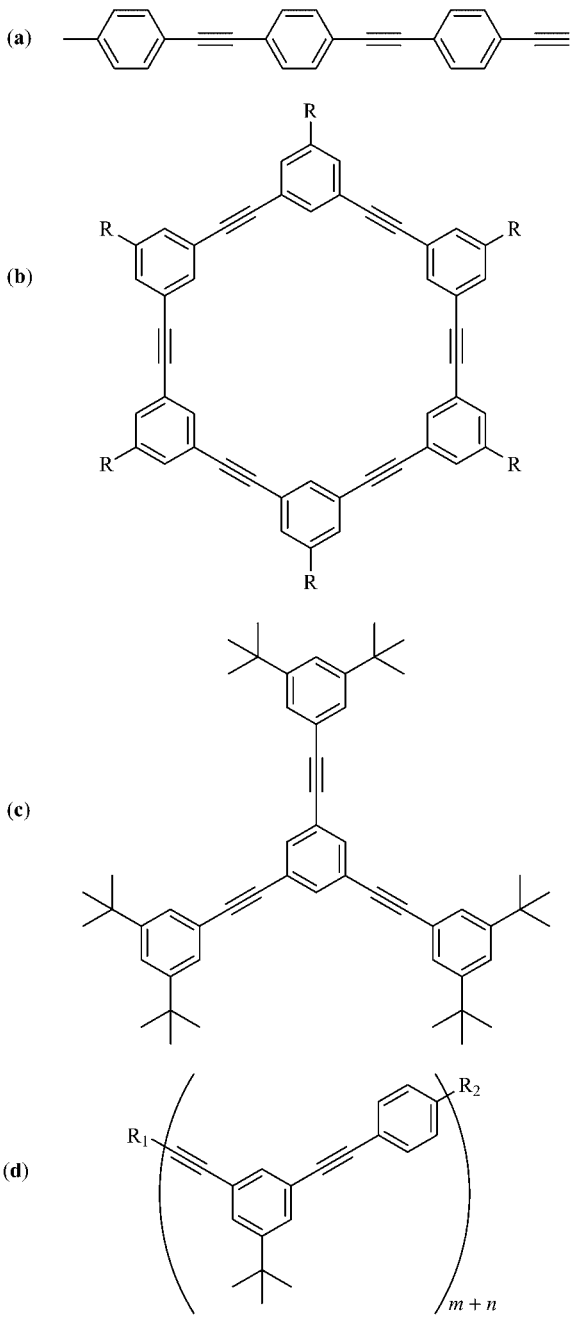


Fig. 27. Chemical structures of PPE and its derivatives: (**a**) molecular unit structure of PPE, (**b**) macrocycles, (**c**) dendrimers, and (**d**) nanoarchitecture.

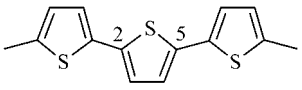
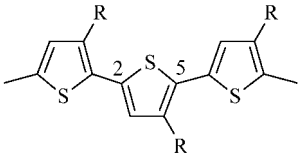
high stability of both doped and undoped PTh and its derivatives, many electronic and optical applications can be developed (147,489,490). Because of the insoluble and infusible nature of PTh and some of its derivatives, chemical modification of their structures is necessary. This can be done by methods such as attaching

flexible side chains (or groups) to the rigid polymer backbone by synthesizing alkylated PThs or polyalkylthiophenes (PATs) (491), and introducing flexible or kinked spacer units into the main chain or preparing random copolymers (492). Furthermore, different synthetic methods, such as electrochemical synthesis (493–496) and plasma-enhanced chemical vapor deposition (PECVD) (497–500), have been studied for making rigid-rod polymer films. For example, poly(3-alkylthiophene)s changed from the original board-like structure of PTh to a sheet-like geometry, because the polymer adopts a configuration with the side chains extending preferentially within a plane (501,502). In this case, the planarity depends strongly on the nature of the substituent, temperature, or the solvent (468). Based on the study of a series of phenylene-based conjugated polymers, Dufresne suggested that thermochromic and solvatochromic phenomena in the conjugated rigid-rod polymers can be driven by a delicate balance between steric intramolecular interaction and attractive interchain interactions. For these polymers, no planar conformation is accessible if the steric interactions are too strong. In the absence of significant steric interactions, nearly planar conformation can be maintained, even at high temperatures. In addition, small changes in the repeat unit of these conjugated polymers can result in great differences in their chromic behavior (470). Therefore, the conformational analyses on model compounds can be a highly valuable tool to understand structure–property relation and design new functional rigid-rod polymers (470).



(**17**)



(**18**)

PThs are very poor electrical conductors unless they are partially oxidized (p-doped) or reduced (n-doped). The p-doped PTh materials are stable in the absence of atmospheric moisture whereas the n-doped are very air-sensitive. The conductivity of p-doped PTh is about 10–100 S/cm (503). The conductivity of soluble poly(3-alkylthiophenes) is about 10^{-2} S/cm and that of I_2- doped HT-coupled PATs can reach 5×10^3 S/cm (504). Jin and Xue reported that the electrochemically synthesized PTh films from the thiophene/BF_3-ethyl ether solution have shown excellent two-dimensional electric conductivity, 100 S/cm. The free-standing films are flexible and have good mechanical properties. Their tensile strength of 140 MPa is greater than that of aluminum sheets (100–110 MPa). These properties are due to their highly anisotropic and conjugated structure, high degree of polymerization, and compact morphology. The thiophene rings in the macromolecular chains are nearly parallel to the electrode plate, with high coplanarity (496). The template-mediated polymerization of thiophene and pyrrole monomers down a nucleopore channel can make nanofibers with enhanced electronic conductivity

(505,506). The conductivity increases with the decrease of fiber size. The reasons for the enhancement of the optical and electronic properties have yet to be established. They may be due to the preferential orientation of the polymer chains along the fiber axis or the surface layers of the polymer chains (505,506). The solutions and films of PTh and its derivatives can exhibit interesting thermochromic and solvatochromic behavior (507). Existence of the electrochemical reversibility of the transition between the doped and undoped states and the resulting color change can lead to many sensor applications in electronic, chemical, and biotech fields (508–510). PTh and its derivatives have been studied for use in rechargeable batteries. They have shown high voltage, high energy and power densities, although self-discharge exists (511).

Organometallic Polymers. In order to enhance the ion conductivity, electroluminescence, and/or nonlinear optical properties, many new organometallic polymers have been synthesized and studied (19,23,25,512–515) (see METAL–CONTAINING POLYMERS). As a result of the delocalization of electron density along the backbone of the organometallic polymers (qv) causing a strong intramolecular interaction, most of them belong to the rigid-rod polymer families. There are mainly two kinds of organometallic polymers: (*1*) pendant organometallic fragments attached to the functionalized side chains or moieties with the polymer backbone containing a delocalized π system (516); and (*2*) the metal center is an integral part of the polymer backbone (517).

Unfortunately only limited work relating to this topic has been reported. However, more and more research is associated with these polymers. It has been observed that metals embedded in the polymer backbone do not block the delocalization of the electrons, but greatly improve the processability, such as decreasing melting point or increasing solubility (518,519). One good example is the transition-metal-containing polymers (520–522). Organonickel polymers have a rigid-rod structure with trans-geometry around the metal centers. These polymers have remarkable environmental and thermal stability. All of the lower molecular weight nickel oligomers are soluble in common organic solvents. The solubility of nickel-containing polymers decreases as solvent polarity decreases. At the same time, these polymers showed interesting optical nonlinearity and/or electron conductivity (505). The organometallic polymers have potential to be used in electronic and NLO devices, as well as in reactive materials and polymer catalysts (523–525).

Summary. Rigid-rod polymers and their derivatives show great potential for electronic and optical applications and many new rigid-rod polymer systems have been emerging. However, there are still significant gaps in the understanding of the structure–property relationships. More profound research is needed to create the capability of predicting and controlling the molecular architecture and optical/electronic behavior of various rigid-rod polymer systems. In addition, more processing methods should be developed to prepare rigid-rod polymer films and other products. The techniques should be able to accurately control the processing parameters and easily manipulate the morphology. However, the popularly used spin-coating technique for the preparation of organic films is quite inadequate for rigid-rod polymer systems, since manipulation to a specific film morphology is almost impossible. Although Langmuir–Blodgett (LB) (526) self-assembly, electrochemical, PECVD, and other techniques have been studied to fabricate rigid-rod

polymer films, all these methods still have serious limitations. In addition, to make excellent optical devices, the light scattering caused by rigid-rod polymer systems should be addressed. The anisotropy in the microscopic polarizability of the rigid-rod polymers can cause considerable light scattering, which can seriously affect the efficiency of many linear and nonlinear optical devices. However, building on the many merits exhibited by the rigid-rod polymer materials, it is probable that in the near future, these problems will be gradually solved and the rigid-rod polymers will play an even more important role in optical/electronic applications.

The Future

This brief review of the field of rigid-rod polymers does not exhaustively cover the whole area, since many new rigid-rod polymers have been synthesized and studied recently. We have tried to use several typical rigid-rod polymers, such as PBZT, PBZO, and PPP, as model compounds to describe the history, polymerization, structure, properties, applications, and the developing directions of the rigid-rod polymers. A few areas of present or potential novel levels of performance have been described to interest the readers in the great scope of the polymers.

Apparently, the aerospace industry has traditionally driven research and development of new, lighter, stronger, stiffer, tough, durable, and processable polymer fibers for use in structural composites for airplanes and spacecraft. The growing percentage of composites in flying aircraft are a glowing testament to their continuing progress. In addition to the aerospace industry, other fields, such as automobiles, ships, machinery, sporting equipment, and construction materials, are also increasing the use of high performance polymer composites. Conservative predictions of the demand for advanced composites in the world project that in the twenty-first century, other industrial applications will expand their share to 55% while the occupation of aerospace applications will be decreased to 45% (2). A 10-fold increase in consumption of high performance fibers was predicted in the late 1990s and projections of worldwide requirements for advanced composites could reach 500 million tons per year in the first decade of the 21st century. It is likely that the markets for replacement of high density structural materials have not yet been fully identified (2). When polymer performance meets the application requirements, then reducing processing and manufacturing costs, and sometimes, even making new low cost (rigid-rod) polymers becomes critical. If the cost of high performance rigid-rod polymers can be reduced, the demand will be much higher. If the cost of rigid-rod fibers can be decreased to less than $10/kg, demand can increase by a factor of 10 (2). With continual rapid progress in the science, engineering, and technology of materials and their processing, new rigid-rod polymers and novel processing methods should emerge to advance the existing technology. Clearly, rigid-rod polymers have excellent potential as novel structural materials.

Furthermore, because of the extensive π-electron delocalization in the conjugated structure of rigid-rod polymers, many novel applications in the rapidly growing computer information industry, as well as many other physical and chemical industries have also been stimulated. Today many new patents apply rigid-rod polymers in sensors, conductors for electrons and/or ions, special membranes, polyelectrolytes, catalysis, electrochromic devices, holography, optical switching,

image techniques, and data storage. The high second-order and/or third-order optical nonlinearities, excellent insulating behavior or conducting properties (after doping), and many other unique electric/optical properties, combined with their excellent mechanical and chemical properties, make the rigid-rod polymers potential candidates for electrooptical and multifunctional applications.

However, there still remain fundamental scientific and technical problems to be solved in understanding and applying rigid-rod polymers. For example, we need to understand the mechanisms of strength, stiffness, and compressive failure so that we can design new rigid-rod molecules and/or new processes to overcome the current limitations. Rewards for overcoming technical limitations will be considerable for both scientific knowledge and technological achievement. The tailorability of rigid-rod polymers, with the resultant enormous variations in properties makes them quite attractive for research addressing specific property goals. Furthermore, with the rapid growth of the computer and information industry, rigid-rod polymers for conductivity and nonlinear optical applications have serious and exciting challenges and opportunities for next generation optical/electronic materials. The relatively new class of rigid-rod polymers will continue to offer exciting opportunities for scientists and engineers for many decades to come.

SEMICRYSTALLINE POLYMERS

Introduction

Although scientific explanation of crystals can be traced back to the fifteenth century, it is not until the beginning of the twentieth century that the determinations of the arrangements of the fundamental units and their detailed shapes were possible, after the discovery of x-ray diffraction on crystals. Motifs and repetition schemes have been utilized to describe the detailed arrangements of crystals. For a crystal formed by polymers, a motif only includes part of a molecule. The difference between polymer crystals and small-molecular crystals is twofold. First, crystals formed by small molecules commonly possess more or less identical chemical and physical bonds constructed in a three-dimensional unit cell, while in polymer crystals they are usually anisotropic because of different chemical and physical bonds involved in different directions of a unit cell. Second, polymer crystals are not in a single phase having 100% crystallinity, but are only partially crystallized; therefore, they are called semicrystalline polymers. In a bulk semicrystalline polymer sample, one can find both crystalline and amorphous regions, and the crystalline region may form different aggregates in shapes in different length scales. As a result, many macroscopic properties are critically associated with different structural and morphological levels to complicate structure-property relationships. If one considers these different length scales in semicrystalline polymers, there are at least four levels that can be identified: crystal unit cells in a length scale of a few tenth to one nanometer; single lamellar crystals having at least one dimension size less than a few tens of nanometers; lamellar aggregates in a length scale of a few hundreds of nanometers; and crystallinity is a concept in the macroscopic

scale. This article focuses the discussion on these length scales in semicrystalline polymers; however, only some important concepts and experimental observations could be included here. Many detailed descriptions and discussions must be found in the references cited and other comprehensive books and reviews.

Crystal Unit Cells in Semicrystalline Polymers

Disregarding any detailed morphological models proposed for the lamellar crystals in semicrystalline polymers in the past half century, crystal unit cells in semicrystalline polymers exactly obey the rules of classical crystallography, which consist of 7 crystal systems and 14 Bravais lattices (more precisely, there are only 6 crystal systems in polymer crystals, and the cubic system does not exist). Most of the unit cell determinations of the semicrystalline polymers rely on the wide-angle x-ray diffraction (waxd) experiments on oriented polymer fibers and films. This is because of small crystal sizes in polymers, which lead to a difficult experimental task to obtain single-crystal waxd results on semicrystalline polymers. It is also possible to use electron diffraction (ed) method in transmission electron microscopy (tem) to determine polymer lamellar crystal unit cell structures, dimensions, and symmetries.

Chain Molecular Conformations. One of the most important exercises in studying polymer crystals is to determine what are the atomic positions in the crystal lattice. Since polymer chains are at least connected in one dimension via covalent bonds, polymer crystal unit cells are thus usually anisotropic and critically associated with chain conformations in the crystal lattices. It is believed that the chain conformations in a lattice must possess the lowest free energy after considering both intra and interchain interactions. The intrachain interactions of each chain conformation can be calculated using the rotational isomeric model of a single chain in vacuum (1), while interchain interactions require force fields of the chain molecules in crystal lattices (see CONFORMATIONS AND CONFIGURATION). All the chain conformations can be viewed to be helical conformations. In the case of polyethylene (PE), its zigzag conformation can be described as a 2_1 helical structure (2). The lowest free energy of the PE conformation is thus all trans conformation, although three possible conformations, trans, gauche+, and gauche−, can be identified in PE. Figure 1 shows the projected structures of the trans and gauche conformations and potential energy diagram for internal rotation around the C—C bond of *n*-butane. When PE crystallizes, its chain conformation adopts all trans conformation. This is also true in poly(vinyl alcohol) (PVA), where the replacing group of hydrogen (H) is hydroxy group (OH) that forms hydrogen bonding and is small enough not to disturb the trans conformation of the carbon backbones.

However, when all the H atoms in PE are replaced by fluorine (F) atoms, polytetrafluoroethylene (PTFE), the van der Waal's radius of the F is larger than that of the H and introduces steric hindrance. Therefore, a slight rotation of the C—C backbone has to take place (around 14° away from the trans conformation), which leads to a helical chain conformation (3,4). Usually, for a series of isotactic vinyl polymers having substituent groups, the lowest free energy conformations of individual chains are helical forms. One of their simplified forms, 3_1, is shown in Figure 2a. Figure 2b includes a series of 3_1 helical conformations in isotactic polypropylene (iPP), which possess an equal free energy (5). A general scheme

Therefore, four possible conformations exist with identical free energy: A. Right-handed *d* helix; B. Left-handed helical *l* helix; C. Left-handed *d* helix; and D. Right-handed *l* helix (6).

for discussing different helical conformations has been developed. Figure 3 shows examples of the point net projections of helical conformations (5).

Detailed atomic positions in polymer helical conformations can be determined using the rotational isomeric model developed (1). It helps to obtain a

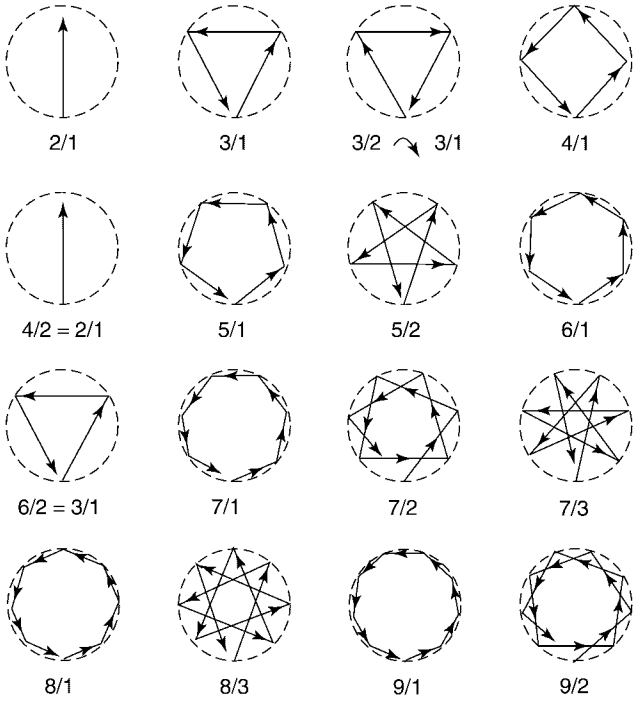

Fig. 3. Point net projections of different helical conformations (5).

free-energy minimum conformation for a specific macromolecule in vacuum. When one describes the lowest free-energy conformation of macromolecules, it is relatively easy to start with point group operations that originally represent the symmetry of low molecular weight (LMW) compounds. There are two different operations in point groups: rotation and inversion. However, it is also necessary to introduce space group operations such as screw axes and glide planes to illustrate chain conformations. Since macromolecular conformations are all considered as helical forms, the helical conformations can be distinguished as right- and left-handed helices. If there are distinct substituent groups on the backbones like in the cases of isotactic vinyl polymers, one may also have two different pointing directions of these groups if one artificially keeps all the C—C bonds in the trans conformation by looking along the long-chain direction (d and l). The total number of conformations is thus 4, which possess identical potential energies. A typical example is iPP, and its calculated potential energy is shown in Figure 4. It is evident that both angles of Φ_1 (rotation around CH_2—$CHCH_3$) and Φ_2 (rotation around $CHCH_3$—CH_2) possess two minima at $\Phi_1 = 120^\circ$ and $\Phi_2 = 0^\circ$ (right-handed helix) and $\Phi_1 = 0^\circ$ and $\Phi_2 = 240^\circ$ (left-handed helix) (6,7).

A nomenclature, which allows geometrically equivalent motifs of the four types of helices to be distinguished, has been proposed in a cylindrical coordinate (8). For each atom i of the repeating units, it can be described relative to its helical lattice point using three parameters: R_i (distance from the helix axis), $\Delta\Phi_i$ (rotation along the helical axis from the lattice point, which is defined as

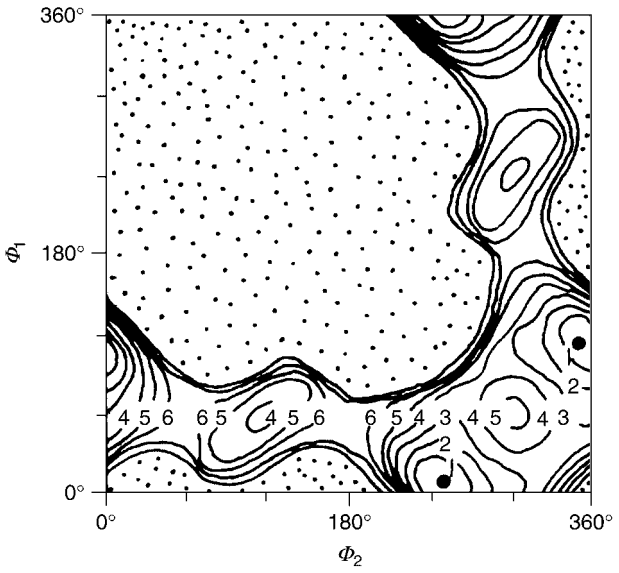

Fig. 4. Potential energy (kcal/mol) calculation of iPP as a function of rotation angles Φ_1 and Φ_2 (5).

$2\pi t/u$, where t is the number of turns of the helix and u is the periodicity about the helical rotational axis), and Δz_i (motion parallel to the helical axis from the lattice point, which is defined as c/u, where c is the crystallographic identity period along the z axis). Equivalent repeat units must have identical R_i for all atoms and can only differ in signs of $\Delta\Phi_i$ and Δz_i. When $\Delta\Phi_i$ and Δz_i are both same or both are of opposite sign for all atoms in two repeating units considered, they are isomorphous since they can be brought into coincidence with each other by simple translation and rotation. When they differ in sign in one coordinate only (either $\Delta\Phi_i$ or Δz_i), they are enantiomorphous since they can be brought into coincidence with each other only by reflection. All the atoms in two repeating units in which all Δz_i are of equal signs are called *isoclined*, while if they are of opposite signs, they are *anticlined*. Using this rule, one can identify clearly in Figure 2b that using the right-handed iPP *d* helix as a reference, helix A in Figure 2b, which is the right-handed isotactic *d* helix, is isomorphous isoclined; helix B is enantiomorphous isoclined; helix C, enantiomorphous anticlined, and helix D, isomorphous anticlined.

In general, as long as both directions of the macromolecule are identical, the repeat units of a single chain may be isoclined or anticlined to each other. In isotactic vinyl polymers, neighboring repeat units may be isomorphous isoclined or enantiomorphous anticlined without breaking the all-*d* or all-*l* sequence. In the latter case, however, the conformation must have planes of symmetry perpendicular to the chain axis, a condition only possible for the 2_1-planar zigzag conformation. For the same reason, successive repeat units in syndiotactic vinyl polymers may also be isomorphous anticlined or enantiomorphous isoclined. Macromolecules that are not identical in both directions of the chain can only consist of isoclined repeat units.

In summary, conformations of a regular sequence of equivalent motifs can only be generated in the following four specific ways:

(1) Isoclined isomorphous sequence can be generated only by the translation of c/u with simultaneous rotation by an angle of $2\pi t/u$ about an axis parallel to the direction of translation.
(2) Isomorphous pairwise anticlined sequence can be generated by helices that possess twofold axes of symmetry at right angles to the helical axis between adjacent motifs. By rotation with respect to the twofold axis of symmetry, the adjacent isomorphous anticlined motifs are generated.
(3) Enantiomorphous pairwise isoclined sequence can be generated only by repetition through a glide plane that contains the molecular chain axis. No helical repetition is possible in this case.
(4) Enantiomorphous pairwise anticlined sequence can be generated by successive centers of symmetry along the chain axis or by planes of symmetry at right angles to the chain axis. Both modes are incompatible with helical repetition.

Crystal Unit Cells. The crystal lattice is a purely imaginary construction that functions as a coordinate system and to which the actual structure is referred. There are six parameters used to construct the lattice: the three grid line directions a, b, and c to form a right-handed system and three angles α, β, and γ, each of which is between two axes (such as α is between the b and c axes). In forming a crystal unit cell, one has to deal with packing of macromolecules. In crystals, within a macromolecule, it must possess a regular, unique extended helical chain conformation of the lowest or near the lowest free energy (intrachain interaction). This structure is generally described by a single-chain conformation in the vacuum after certain modifications. Putting several helical chain conformations into a three-dimensional lattice to generate a crystal unit cell requires to consider interchain interaction among the chains, ie, the close packing energy. Generally speaking, intrachain interaction deals with rotational isomerism, and it possesses a higher energy compared with the packing energy. Specific cases may exist such as in the case of poly(ethylene oxide) (PEO) in which the interchain interaction is strong enough to distort the 7_2 helical PEO chain conformation (9).

A cylinder is the most symmetric body that approximates to some degree a macromolecule in its helical chain conformation. Close packing of cylinders leads to an array identical to a layer of spheres in cross section. The symmetry of this hexagonal packing with six coordination numbers is $6/mmm$, having a packing density of 90.7% (see Fig. 5a). Conversely, if more appropriately, one may consider the helical-shaped macromolecule that is similar to a solid screw. Now the handedness of the screws needs to be taken into account when they are closely packed together, as shown in Figure 5b. The close packing can be achieved between two screws only in the opposite handedness with almost rectangular threads. The coordination numbers for such close packing reduces to 4 and the maximum packing density that can be reached is 92%. However, these models cannot be precisely used to determine the macromolecular close packing in crystals. Detailed atomic positions in chain conformations and their interaction energies must be known before one can construct a crystal unit cell.

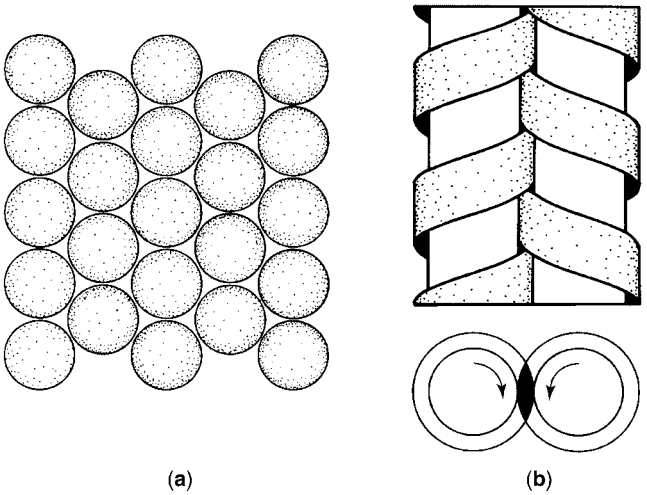

Fig. 5. (**a**). A hexagonal two-dimensional packing projected along both perpendicular and parallel to the cylindrical axis, and (**b**) a projection of a pair of close-packed screws having opposite handedness along both perpendicular and parallel to the long axis of the screws (5).

Three examples provided here are molecular packing, symmetry, and unit cells of orthorhombic form of PE (Fig. 6) (2,10), monoclinic α form of iPP (Fig. 7), (11), and orthorhombic form of syndiotactic polypropylene (sPP) crystals having antichiral packing in handedness (Fig. 8) (12).

Determination of Crystal Unit Cells. The most important technique to determine crystal unit cells is waxd. In these experimental procedures, a concept of reciprocal lattice has to be introduced. The relationships between the real and reciprocal lattices in three dimensions depend on the angles between the axes in the real lattice. Consider the cases of an orthorhombic cell, where the three real axes are mutually perpendicular to each other but the axial lengths are not the same. The planes (100), (010), and (001) are perpendicular to a, b, and c axes, respectively; their normals are thus along these axes. Hence, the reciprocal lattice point 100 can be considered to be on the a axis at a distance $1/a$ from the origin. The line connecting this point to the origin is one edge of the unit cell in reciprocal space and is thus a^*. In the same way the reciprocal axes b^* and c^* coincide with the corresponding real axes b and c, and all three reciprocal axes are also mutually perpendicular to each other. The result is a reciprocal unit cell with the relationships summarized in Table 1. (See further references for the relationship between real and reciprocal lattice.)

It should cause no surprise that for polymer crystals with very small sizes, a definitive structural analysis is difficult using only unoriented diffraction patterns. This is not only due to the small number of observable diffractions and their general broadening, but also to the fact that high angle diffraction rings often consist of the superimposition of several reflections of different indices. In certain special cases, eg, when a structural similarity to a known substance is suspected on the basis of chemical composition, it may be possible to make identification by comparison, but even this procedure contains possible errors.

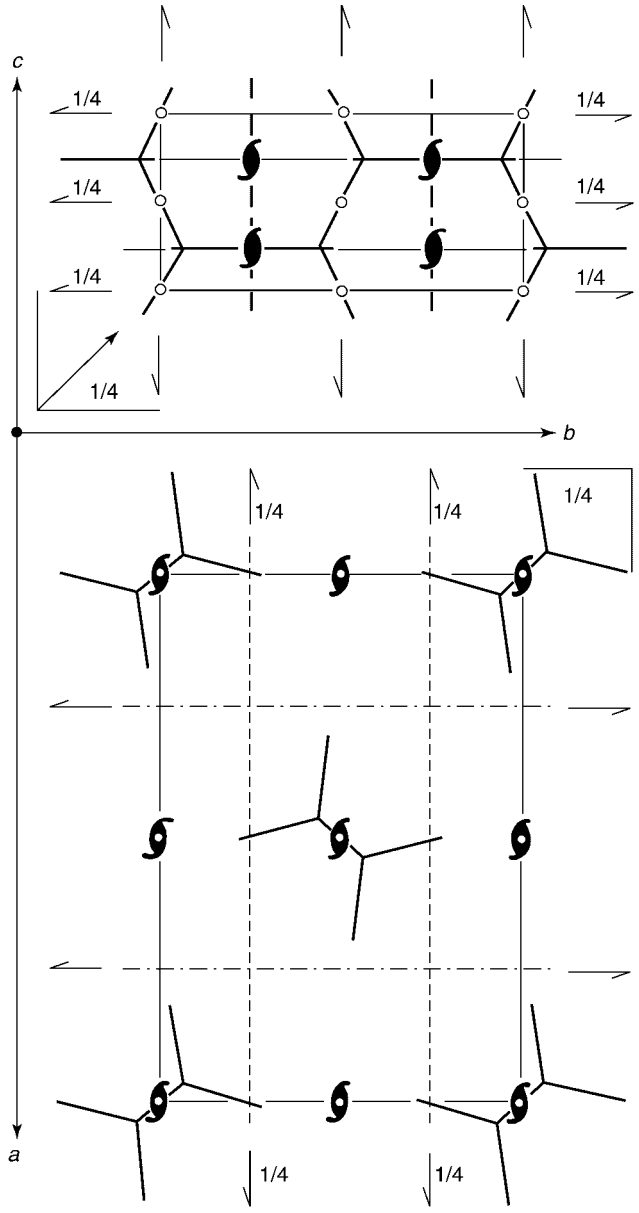

Fig. 6. Crystal unit cell of orthorhombic form of PE in three-dimensional real space (5).

In most cases, structural analysis of polymer crystals is carried out using uniaxially oriented samples (fibers or films). The basic procedures include (*1*) determination of the fiber period; (*2*) indexing (*hkl*) diffractions and determining the unit cell parameters; (*3*) determination of the space group symmetry; (*4*) structural analysis; and (*5*) Fourier transforms and syntheses and Patterson functions. The first three aspects of the procedure are discussed here, and the last two aspects are left for further references.

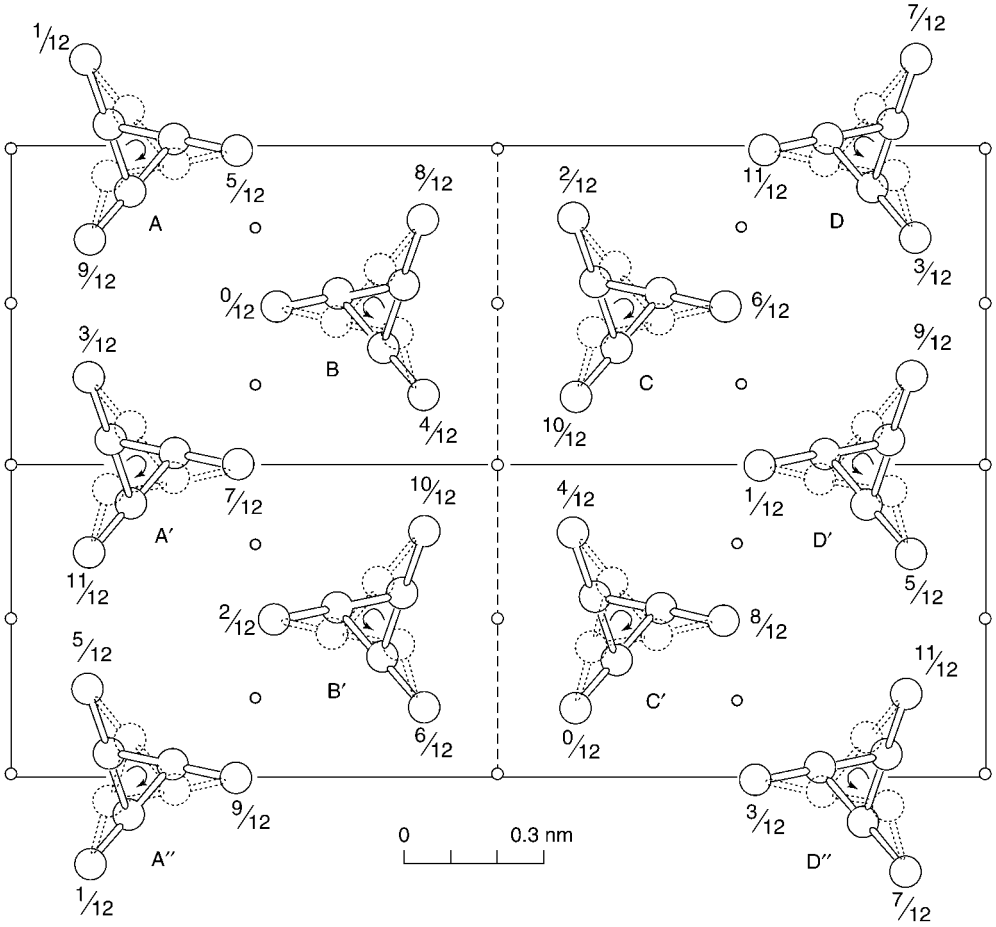

Fig. 7. Crystal unit cell of monoclinic α form of iPP in three-dimensional real space (11).

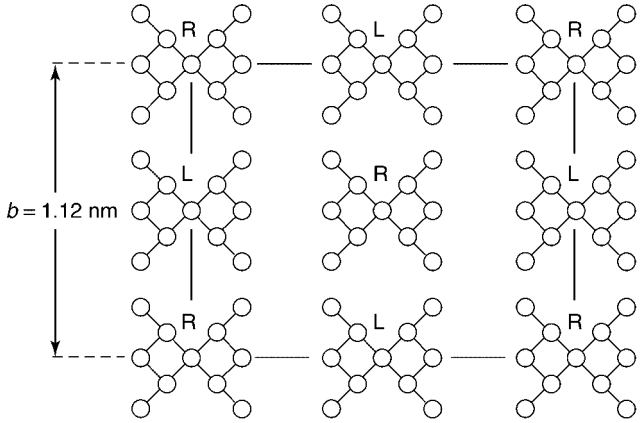

Fig. 8. Crystal unit cell of orthorhombic form of sPP having antichiral handedness packing projected along the chain direction (12).

Table 1. Real and Reciprocal Space Relationship in an Orthorhombic Unit Cell

$a^* = 1/a$	$a = 1/a^*$	$\alpha = \beta = \gamma = \alpha^* = \beta^* = \gamma^* = 90^\circ$
$b^* = 1/b$	$b = 1/b^*$	$V^* = 1/V = a^*b^*c^*$
$c^* = 1/c$	$c = 1/c^*$	$V = 1/V^* = abc$

Polymer chains usually align along the fiber axis during drawing and deformation, and the chain direction is commonly defined as the c axis [there are several exceptions due to hydrogen bonding, smectic domains in liquid crystals, and biopolymers (13–15)]. The fiber period for the fully extended conformation of the polymer by chain is calculated from the chemical structure of the repeat unit of the polymer by using standard bond angle and bond length data. The measured value of the fiber period can be compared with the calculated value. If the value agrees within the limit of experimental error, the chain is considered to be fully extended in the fiber. When the calculated period is slightly greater than the experimental value, this often indicates a twisted or loosely folded conformation of the molecular chains, and the degree of twisting or fold can be estimated from the discrepancy between the two values. Another possibility is that the chains are slightly inclined with respect to the principal axis of the unit cell. A large discrepancy often points to a helical conformation of the chains. Computer calculation of the chain conformation with the lowest free energy is a powerful tool to examine these discrepancies. However, in some cases, interchain interactions must also be taken into consideration. This may lead to complication in the crystal structure determination.

With perfect orientation, chain axis (usually, c axis) is aligned along the fiber direction, and a^* and b^* axes in the reciprocal space are perpendicular to the fiber axis. Therefore, diffraction spots on the equator come from $(hk0)$ planes. The first step to determine unit cell parameters is to index the diffraction peaks on the equator. Because in small-molecular single crystal rotating experiments several reflections close to the center are chosen, their distances to the center are measured to be ξ_1, ξ_2, ..., the smallest ξ, ie, ξ_1 is assumed to be on the a^* axis and is plotted on this axis to the right of the origin as the 100 reciprocal lattice point, at the appropriate distance on the chosen scale. An attempt is also made to find the b^* axis based on the second closest ξ_2, which is assumed to be the 010 reciprocal lattice point, and the third closest ξ_3, which is assumed to be representative of 110 reciprocal lattice point. A suitable combination of low index triangle reciprocal lattices may thus be constructed. Two sides of the triangle lattice are a^* and b^* axes, respectively. A complete two-dimensional lattice can thus be established by translating the triangle into the two-dimensional space. The crossover points in the reciprocal lattice, which represent 110, 210, 120, ..., reciprocal lattice points, must correspond to the diffractions observed along the equator direction (ξ_4, ξ_5, ...). It should be mentioned that reflection does not necessarily occur from all sets of planes associated with reciprocal lattice points, although they fulfill the conditions considered so far. There are other conditions, connected with the symmetry properties of the crystal, which may induce the systematic absence of certain reflections [extinction rule (16)].

The next step is to index the general reflections of the type hkl, which involves the c^* axis (the fiber period). The first layer reflections above and below the equator are the $hk1$ and $hk\bar{1}$ reflections, respectively. The indices to be determined in this case are h and k: if the third axis, ie, the c axis in this case, is normal to the ab plane, the c^* axis will coincide with the c axis, also being perpendicular to both a^* and b^* axes. In this case, the ξ values of all the reciprocal lattice points $hk1$ and $hk\bar{1}$ will be equal to the ξ values of the reciprocal lattice points having the same values of h and k in the equator plane. To index the points, therefore, a point whose ξ value is the same as that of an $hk0$ point is given the same indices h and k, and so becomes $hk1$ or $hk\bar{1}$. The indices h and k can be simply determined using the values of corresponding spots on the equator. If the third axis is not normal to the a^* and b^* axes, as in a triclinic unit cell, the procedure is more tedious. In this case the ξ values of the points on the layer lines are no longer the same as those of the $hk0$ points having the same values of h and k; namely, the projections of the lattice points on the equatorial plane do not coincide with the equatorial lattice points. However, since all the lattice layers are identical, provisional use of this equatorial plane can still be made. The origin (the point with both h and k zero) of the first layer of the reciprocal lattice is projected on the equatorial plane, and a new lattice is drawn about the projected point as lattice origin. It will therefore be slightly offset from the previous lattice. The original origin of the equatorial plane is taken as the center of the diffraction sphere, which is then rotated. The same result is obtained if the center of rotation of the diffraction sphere is moved from the origin by exactly the same amount as the offset of the points in the first layer, the diffraction sphere then being rotated in the usual manner. By repetition of this procedure for the first layer below the equator, and for the second, third, and other higher order layers, all the reflections hkl on the film can be indexed. Several examples of detailed determination in uniaxially oriented polymer unit cell parameters can be found in Reference 17.

X-ray diffractions from a crystal can only occur in directions defined by the reciprocal lattice points and with intensities that are governed by a structure factor of the form

$$F(hkl) = \sum_{j}^{N} f_j \exp[2\pi i(hx_j + ky_j + lz_j)] \tag{1}$$

where f_j is the atomic scattering factor of the jth atom in the unit cell, and x_j, y_j, and z_j are the coordinates of this atom in the unit cell. The summation is carried out over all the atoms in the unit cell. The atoms in the unit cell are not independent, but generally fall into groups within which the atoms are related by the symmetry of the crystal. Since comparatively simple relationships hold between the coordinates of the atoms in these groups, insertion of these relationships into equation simplifies the equation and reduces the number of terms in the summation. Certain symmetry operation will result in zero intensity for certain (hkl) planes, which is called extinction. Since it arises from the crystal symmetry, the space group of the crystal may be identifiable from the characteristic systematic absences. In an actual analysis, the indices of all the diffraction spots for the crystal are first tabulated. Regularities are then sought in the indices of observed

reflections. This is because sometimes a very weak reflection may not be observed owing to experimental limitations, obscuring the regularity of the indices of the completely missing reflections. The symmetry is determined by both the point and space groups, which include rotations, inversions, screw axes, and glide planes. They govern the extinction rules. Finally, the space group can be found by consulting International tables for x-ray crystallography.

It is difficult to determine the space group of polymer crystals, since the diffraction diagrams can often be obtained only for uniaxially oriented specimens. Quite often, it is impossible to verify the extinction rules because of difficulty of indexing due to overlapping of reciprocal lattice points, inability to observe the high order diffractions, etc. In such cases, one solution is to select a possible space group and carry out the analysis, assuming initially that the symmetry is high. If this fails, lower symmetries or other space groups are considered in an attempt to find the correct one. However, this is a trial and error method, and it is better to obtain as many independent $|F(hkl)|^2$ as possible, eg, by preparing biaxially drawn specimens, making inclined uniaxially oriented fiber photographs or Weissenberg photographs, or using x-rays of shorter wavelength, such as Mo radiation, to obtain data for higher order diffractions. Structural analysis and Fourier transform and Patterson functions are relatively complicated, and they are not discussed here.

In the modern waxd crystallographic analysis, waxd experimental results are always combined with conformational and packing energy calculations to obtain more precise crystal unit cell dimensions and atomic positions in a crystal lattice. Under constrained conditions, the least-square calculation reduces the error to a degree that the diffraction positions and intensities can be semiquantitatively fitted to the experimental observations. However, force fields between chain molecules in crystals are difficult to establishe and defects existing in real crystals limit the accuracy of the calculations.

Other experimental methods are also useful in determining crystal structures. Infrared–Raman vibration spectroscopy can, for example, be used in identifying atomic and molecular interactions. This method can detect local structural changes via force field changes. In a complete vibration spectrum of a semicrystalline polymer, there are two regions of vibration frequencies: the acoustic and optical regions. In general, the vibration bands in the acoustic region possess low frequencies, and therefore correspond to vibrations linked with molecular packing. The vibrations in this region are specifically characteristic of packing schemes and orders. For example, in PE, up to approximately 2×10^{13} Hz, the vibration motion can be visualized as a torsional and an accordion-like motion of the CH_2 backbones. These two vibration motions are generally associated with the skeletal vibrations. When the PE chain molecules are in crystals, crystal lattice vibration modes can also be determined, which are not seen in a vibration spectrum of an isolated chain. Both infrared and Raman-active lattice modes can be observed in the low frequency region. For example, in PE crystals, the infrared-active lattice mode is at 72 cm^{-1} with a perpendicular polarization at room temperature (18–20). The Raman-active vibration lattice mode at 137 and 108 cm^{-1} are also observed at very low temperatures (eg, at $-196^{\circ}C$) (21,22).

The vibration bands in the optical region are at higher frequencies, and they reflect specific modes of group vibrations. These vibration motions generally involve oscillations of relatively isolated groups of atoms along the polymer backbone

chains, such as stretching, bending rocking, wagging, and twisting between atoms and groups. In PE, between 2×10^{13} and 5×10^{13} Hz in the vibration frequency range, they are mainly associated with bending of the C—H bond and C—C stretching vibration. When the frequencies are above 8×10^{13} Hz, they correspond to the C—H stretching vibrations. Among these vibration frequencies in the optical region, one can find some vibrations that are observed only for crystals, ie, crystal-sensitive bands. For example, after annealing an amorphous PVA sample close to its melting temperature for a long period of time, the intensity of the stretching of PVA at 1141 cm^{-1} found in both infrared and Raman spectroscopic measurements increases with increasing crystal density as a result of annealing (23,24). This indicates that the crystal-sensitive band appears only when the PVA units along the chains are aggregated together to form regular conformational segments and/or when oscillators are arranged together in a regular way. The length of regular structural units necessary to detect the crystal-sensitive band can be determined by the relationship between the band intensity and the segmental length in copolymer samples (25).

In some cases, vibration bands are also conformation-sensitive. In particular, when a polymer exists in several crystal forms, different chain conformations may exist in these crystal modifications; one example is poly(vinylidene fluoride) (PVDF). At least four types of crystal modifications are known: forms I, II, II_{polar}, and III (26). Form I has nearly a zig-zag chain conformation. Forms II and II_{polar} exhibit the glide-type TGTG conformation, while form III has a $TTTGTTTG^-$ conformation. The ir spectra of these crystal modifications are shown in Fig. 9 (27). For example, the intensive bands observed in the spectra of form I are 1275, 840, and 510 cm^{-1}, and others correspond to the vibration modes intrinsic to long trans sequences of ...TTTT.... The bands at 800, 766, 610, and 530 cm^{-1} and others in the spectra of form II are attributed to the conformation sequence of TG. On the other hand, in form III, the TG and TT bands coexist in addition to the bands characteristic of the TTTG sequence (27).

In oriented polymer samples, polarized Infrared and Raman spectroscopy are also very useful in determining bond orientations in the crystals and oriented amorphous regions (28–34). Furthermore, surface enhanced Raman scattering techniques can also be used to obtain information regarding the molecular orientation at surfaces and interfaces.

Crystal Morphology: Polymer Single Crystals and Polycrystalline Aggregates

Although polymer crystals have been explained using the so-called "fringed micellar" model in the infant stage of polymer crystal physics, understanding of dendrites formed in solution and spherulites grown from the polymer melt, in close analogy with those in simple organic and inorganic substances, leads to a basic underlying building block—polymer single crystals. By using dilute polymer solutions, single crystals with regular shapes were observed first by optical microscopy and then by tem (35–37). The most well-known example is that of PE grown in dilute solutions, in which perfectly regular-facetted, lozenge-shaped single crystals with a thickness of about 10 nm are formed (38–41). Later, it was

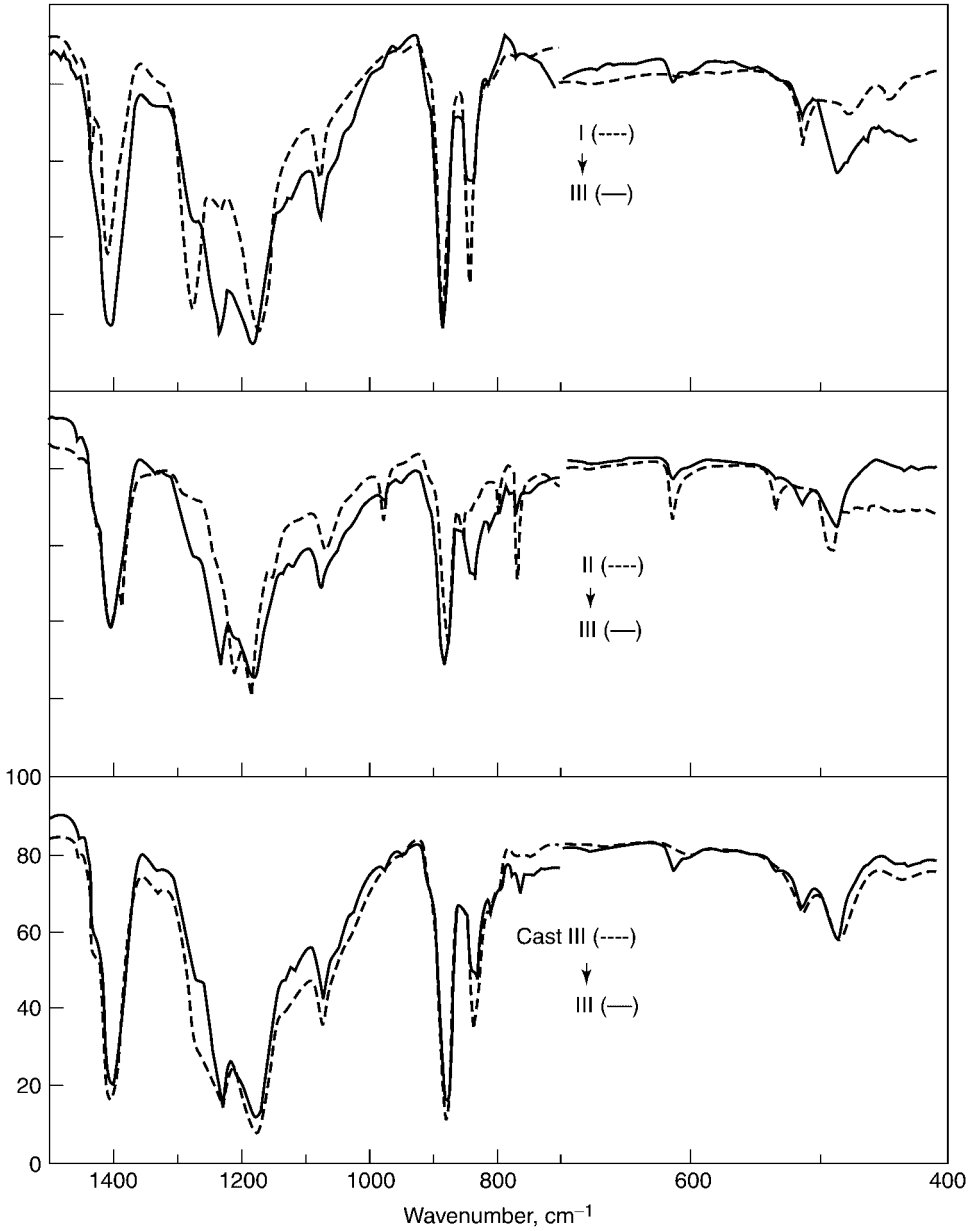

Fig. 9. Comparison of the ir spectra of PVDF forms I, II, and as-cast III (dashed lines) with that of form III (solid line) (27).

also observed that PE lamellar crystals are also the building blocks of melt-grown spherulites and other aggregates (41,42). The analysis of lamellar single crystals leads to the birth of the chain folding concept, which has been one of the most important advances in polymer crystal physics, and has been widely accepted in spite of some controversy. In the past half century, increasing numbers of

crystalline polymers were shown to form lamellar single crystals in dilute solution, blends, and the melt (see MORPHOLOGY).

The importance of observing polymer single crystals stems from their usefulness in analyzing crystal growth mechanisms. Crystallization of small molecules and polymers from solution or the melt on an existing crystal surface can be described using one of two mechanisms: lateral (layer) and normal growths (43,44). The former is nucleation-controlled, having an exponential dependence of growth rates with respect to undercooling (ΔT, having a nucleation barrier) and well-defined crystal habits. The latter implies a continuous growth with a rough surface (without an enthalpy barrier) having a linear relationship between growth rates and ΔT near the melting temperature. The crystal habit in this case is usually determined by temperature or concentration gradient, and thus the boundaries are curved. Therefore, the growth-rate dependence with ΔT and crystal growth habit become two important characteristics in distinguishing between these growth mechanisms. Furthermore, polymer single crystals are true crystals following any existing definition since they possess all the crystalline characteristics; yet, they are always chain folded and in a metastable state (45,46). This leads to a great interest in crystal metastability and its role in determining structure and properties of polymeric materials. It should be pointed out that polymer single crystals are important structural and morphological probes, which encompass broader length scales as compared with small molecular species. These probes include atomic positions and helical conformations (in most cases) in a close-packing scheme, lamellae, and aggregates. Lamellar single crystals in polymers are precursors in developing crystal aggregates such as dendrites and spherulites.

Observations of Single Lamellar Crystals. Polymer lamellar single crystals were first observed in PE crystals grown from dilute solution in the 1950s (35–41). Figure 10 shows a PE lamellar single crystal grown from a dilute solution and observed in tem. The crystal exhibits two large lateral dimensions and has a small thickness around 10 nm. The lozenge-shaped crystal reflects well-defined crystal growth fronts, and a so-called *sectorization*, which is associated with crystal planes. The four growth faces are the (110) planes. Besides PE, a number of crystalline polymers have since been reported to produce lamellar single crystals from dilute solutions. Some of them are highly facetted or nearly facetted, but others possess irregular shapes. Figures 11 and 12 represent two typical examples

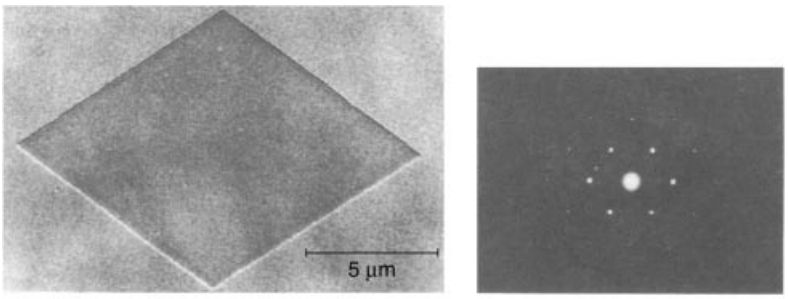

Fig. 10. Transmission electron micrograph of a PE single lamellar crystal grown from dilute solution. A [00*l*] zone electron diffraction of this single crystal is also included (47).

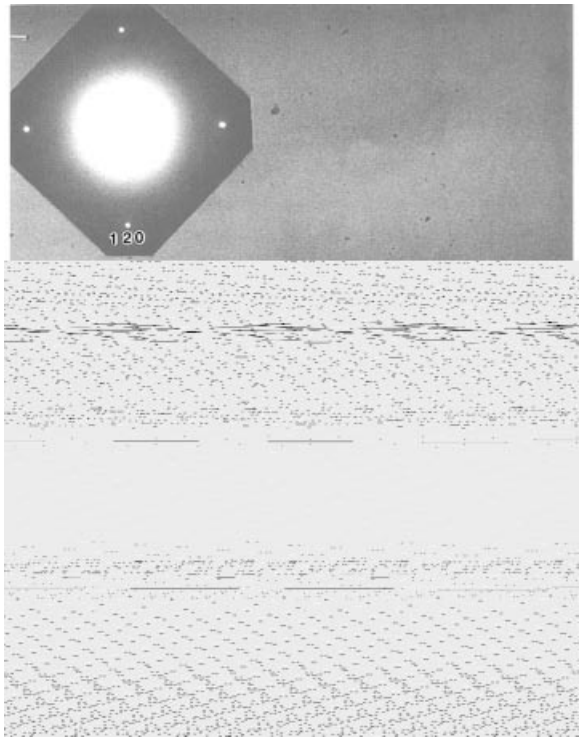

Fig. 11. Transmission electron micrograph of PEO single lamellar crystal grown from dilute solution. Note that this lamellar crystal exhibits a regular facetted square shape with four (120) growth faces. A [00*l*] zone electron diffraction of this single crystal is also included (48).

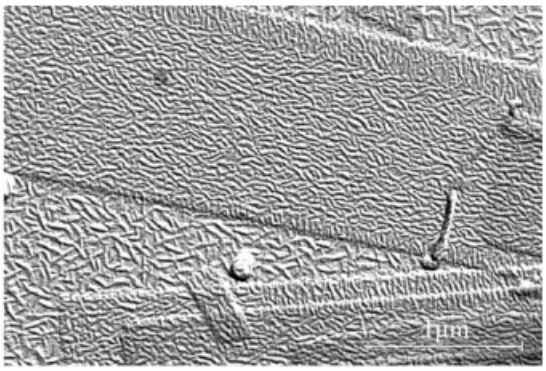

Fig. 12. Transmission electron micrograph of iPP single lamellar crystals grown from dilute solution (49). Note that this lamellar crystal exhibits an anisotropic elongated shape. PE decorations can be seen on the tops of these single crystals.

for PEO (48,50) and iPP (51,52). Note that these two examples possess very different single crystal shapes (isotropic vs anisotropic), which are discussed in the following section. Many crystalline vinyl and diene polymers, polyoxides, polyesters, and polyamides (5,47,53) form single crystals in dilute solutions.

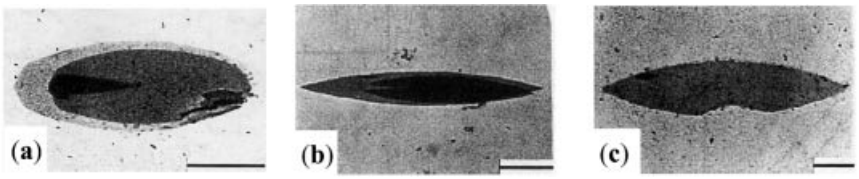

Fig. 13. PE single lamellar crystals grown from the bulk melt at different crystallization temperatures: (**a**) 123°C for 8 s; (**b**) 125°C for 30 s; (**c**) 128°C for 20 min (60,61). These single crystals were solvent extracted from the bulk sample.

Soon after the observation of solution-grown lamellar single crystals, it was found that lamellar crystals are also the basic building blocks of more complex crystal morphologies formed in melt-crystallized polymers. However, it was found that lamellar single crystals in polymers can also grow from the melt. One of the first examples in the 1970s is LMW PEO (54–58). For entangled polymers (ie, with reasonably high molecular weights), lamellar single crystals of PE were reported at the end of 1980s from both bulk samples and thin films (59–61). In bulk samples, PE was crystallized at low ΔT's and then quickly quenched to a low temperature cooling bath. Solvent extraction was used to dissolve the small and less stable PE crystals that were formed during the quenching process, the more stable lamellar single crystals with facetted shapes remain and can be observed under tem (Fig. 13). Lamellar single crystals of sPP were grown from the melt in thin-film samples, and the crystals showed an elongated rectangular shape (Fig. 14) (62–67). Other reports on lamellar single crystals include PVDF grown from blends (68–70), isotactic polystyrene (i-PS) grown from the melt on thin films (71,72), the poly(ethyl ketone) family grown from blends and the melt (73,74), and other polymers. It should be noticed that melt crystallization in the bulk and in thin films sometimes results in differences in single crystal morphologies. In fact, thin-film growth is one type of crystallization in confined geometrical space.

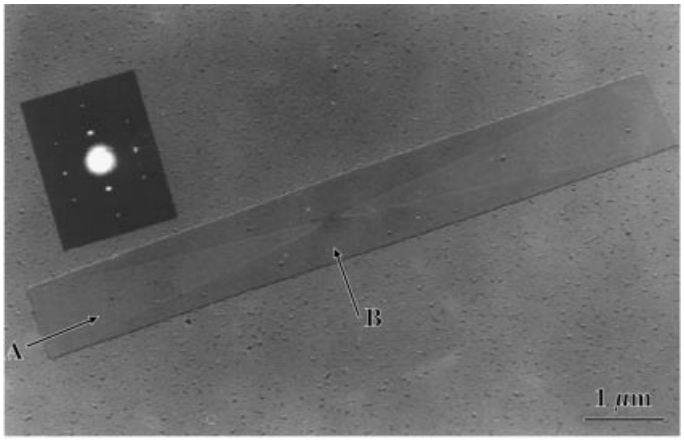

Fig. 14. Transmission electron micrograph of a sPP single lamellar crystal grown from the melt of thin film. Note that this lamellar crystal exhibits an anisotropic elongated shape with clear four sectors visible by the thickness difference in these sectors (63).

In general, a low symmetry unit cell generates a more anisotropic single crystal habit in the melt or in blends, as in the case for PE in the orthorhombic form (59–61,75), iPP in the monoclinic α-form (51,52), sPP in the high temperature orthorhombic form (62–67), PVDF in the orthorhombic α-form (68–70), and others, all of which show anisotropic single lamellae. This implies that the growth rate along one unique axis is much faster than along the other. On the other hand, polymers such as PE in the high pressure hexagonal form (76), polyoxymethylene (77,78), iPS in the hexagonal form (71,72), poly-4-methyl-1-pentene in the tetragonal form (79), and others possess higher rotational symmetry in their crystal unit cells, and thus exhibit more symmetric polygonal lamellar habits (80). These two types of lamellar single crystal precursors may follow different pathways to form transient aggregates that evolve into the ubiquitous spherulites (81).

In case of chain-folded lamellar crystals, it should not be forgotten that polymer single crystals can also be obtained in the form of extended chains. Ideally grown extended chain single crystals were first proposed by Sauter (82). Now it is known that under certain conditions, polymer chains can be extended to form extended chain single crystals. For example, PE at elevated pressures forms crystals having the hexagonal lattice as shown in Figure 15 (83). The chain molecules possess a large mobility along the chain direction in the crystals, and therefore the lamellar crystals thicken continuously to form extended chain single crystals (84,85). Extended chain single crystals can also be found for PTFE after annealing at elevated temperatures (86). Another type of extended chain single crystals is the so-called *whisker crystals*, which must not be confused with fibrous crystals. Note that the fibrous crystal may not be necessarily single crystalline. Examples of this class are *"shish" crystals* and whisker crystals obtained during polymerization from monomer vapors.

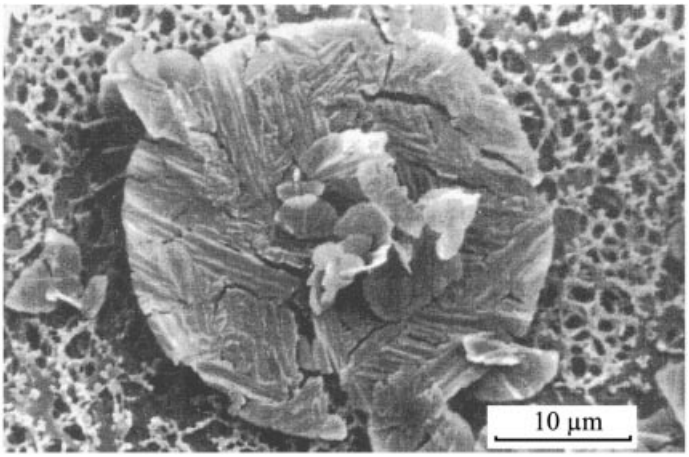

Fig. 15. Circular crystal of PE grown under an elevated pressure in the hexagonal structure, which has undergone a transition to the orthorhombic structure by reducing the pressure. The crystal was extracted from the bulk by a solvent extraction. The transformed crystal displays three sets of ridges, 60° apart, which indicate that three orientations of the *b* axis are generated by the hexagonal to orthorhombic transition (83).

Chain Folding Principle and Single Crystal Sectorization. How can a long-chain molecule be accommodated in this lamellar-shaped single crystals with a thickness of only 10–50 nm? Earlier, in an almost unnoticed paper by Storks (87), who is virtually unknown in the polymer field, noted that in gutta-percha thin films (of a 27-nm thickness) he could not directly see the crystals because an interferometer was used to measure the overall film thickness. However, he observed $hk0$ diffraction and stated that

> films of guttapercha are found to be composed of relatively large crystallites which are precisely oriented with their fiber axis direction normal to the film surface. It is presumed that the macromolecules are folded back and forth upon themselves in such a way that adjacent sectors remain parallel (87).

Since the late 1950s, ed experimental results on single crystals have clearly shown that the long chain direction is normal or close to normal direction since the chain direction is parallel to the electron beam (see the [00l] zone ed pattern of PE single crystals in Fig. 10). In agreement with Storks' conclusion, the only way to explain this experimental observation is that the chains are folded in the lamellar single crystals. This would also mean that what appears to be a single crystal should be composed of as many sectors as there are prism faces distinguished by the fold plane direction in each sector.

Following these early experimental observations and explanations of chain folding in solution-grown lamellar single crystals, several methodologies have been developed, which are specifically important in determining the chain folding. These include LMW PE decoration method (49,88), the breakage of single crystals under elongation (53,89), and lateral force mode in atomic force microscopy (afm) (90). For the LMW PE surface decoration, the basic principle is to use orientational ("soft") epitaxy of LMW species on a microscopically oriented surface. If chain folding possesses a uniform orientational direction, for example, in one growth sector, the chain direction of the LMW PE aligns parallel to the folding direction. PE molecules then crystallize into a needle-like shape with its long axis perpendicular to the folding direction of the lamellar single crystal. It was also shown that without folded chains such as in short n-alkanes, such orientational growth of the LMW PE crystals on the end surface of n-alkane single crystals is lost (49). This decoration experiments have been performed not only in PE, iPP (49), PEO (91), and other lamellar single crystals of polymers grown in solutions, but also in the lamellar crystals formed in the melt. After significant efforts of the past half century, now it is known that polymer crystallization from both solution and the melt can form sectors. Sectorization is a consequence of different crystal growth planes with individual chain-folding directions, as evidenced by the PE decoration experiments. Sectorization is also an indication of normal (nucleation) growth mechanism of polymer crystallization.

Later investigations showed a facetted crystal-habit dependence of the PE lamellar single crystals on different temperatures and solvents used. By changing from good solvents to poor ones, the single crystals with four (110) growth faces gradually changed to six planes having two extra (200) growth faces. The habit change continues and the four (110) growth faces gradually decrease in size

because of a faster growth rate along the [110] direction. This leads to a continuous change of the crystal's aspect ratio and curvature of the (200) planes with increasing crystallization temperature (92,93). A similar study for the melt growth of PE single lamellar crystals indicates an aspect ratio change with ΔT (see Fig. 12) (60,61,94). Some intriguing experimental observations related to sectorization involve lamellar single crystals of sPP. The sectorization takes place along diagonal directions in a lamellar crystal that possesses an anisotropic elongated shape. Four sectors are formed: the (010) [with the (010) free edge] and the (100) [with the (100) free edge] sectors, as observed by tem (see Fig. 14) and AFM. Although the crystals in both sectors are in the high temperature orthorhombic structure (62–65), direct observation of this sectorization is possible owing to a thickness difference of the sectors with different fold planes. AFM results show that the thickness difference depends on crystallization time. Similar but much smaller difference had been reported in PE solution-grown lamellar single crystals (95).

Epitaxy and Twinning in Polymer Single Crystals. *Epitaxy* and *twinning* are frequently observed in polymer single crystals. In most cases, they are always associated with traditional crystal defects. Epitaxy is generally applied to oriented growth of one crystalline substance on a substrate of a different substance. However, it is also common that epitaxy may occur within one crystalline substance at different (*hkl*) crystalline planes. By contrast, the twin contains an added element of symmetry over and above that which either component possesses. In other words, epitaxy only needs lattice match whereas twinning introduces an additional symmetry axis.

Extensive studies have been carried out regarding polymer crystallization on inorganic or organic (nonpolymeric) small-molecular crystal surfaces. The general rule is that at least one of the (*hkl*)—or more frequently the (*hk*0)—planes of the polymer crystal lattice must match with one of the crystallographic planes in the small-molecular crystals. Although most of the works do not provide polymer single crystals when they are epitaxially grown on the nonpolymeric crystals, they contribute to the development of nucleation agents, as in the case of the α-form of iPP (96). Using the epitaxy method to grow polymer single crystals with specific forms and orientations is, however, a powerful tool in understanding polymer crystallographic structures and its relationships with the nonpolymeric materials. One example is the β-form single crystal of iPP grown on substrates of γ-quinacridone and dicyclohexylterephthalamide that helps in analyzing the details of the β-form crystal structure (97).

For the polymers epitaxially grown on their own crystallographic planes, one example is the so-called *cross-hatching phenomenon*. The *daughter lamellae* (tangential lamellae in spherulites) are at about 80° or 100° with respect to the *parent lamellae* (radial lamellae along the radial direction in spherulites) observed in the α-form of iPP crystals. It is known that tangential lamellae grow epitaxially on the lateral (010) crystallographic plane of the radial lamellae by a satisfactory interdigitation of the methyl groups (the contact planes). This matching stems from the near identitical dimensions of the a and c axes in the α-form unit cell (98). A very special case, which reflects perfectly molecular epitaxy, is the γ-form of iPP. The real breakthrough in understanding the γ-form came (98) when it was realized that the chain axes in the unit cell are not parallel. Instead, the structure is made up of a succession of bilayers tilted 80° or 100° to each other, which is

similar to the cross-hatching crystals in the α-form but this time at the molecular chain-packing scale (99). This special relationship allows an epitaxial growth of the tilted γ-form on the α-form in iPP (100).

Lamellar single crystals can in some cases form epitaxially when two different ($hk0$) planes can be matched. This leads to a common chain direction (the c axis). An example is sPP lamellar single crystals grown from the melt in the thin-film form (101). This can also be found in the case of oligomer single lamellar crystals (102). Another example is shish–kebab structures. The kebab structure is generally made of lamellar crystals that grow along the orientation of the chain direction of the shish single crystals, and therefore, it is an epitaxy of a chain-folded polymer on its own extended chain crystals. Polymer crystals can also be epitaxially grown on other ordered polymer surfaces. A recent example is α-form of iPP epitaxially grown on PTFE and organic substrates (103), which may be recognized as some kind of morphological epitaxy. Detailed description can be found in a review article (104).

Twins in polymer single crystals have been observed as early as in the 1950s. In particular, when the self-seeding experiments were introduced, twinned lamellar single crystals were widely reported first in solution-grown PE and PEO single crystals (5). Melt-crystallized twin crystals were also found. An example is the PE crystallized at elevated pressure to form single crystals having the hexagonal structure, and thus its morphology possesses a rounded shape. With the release of pressure, the crystal structure undergoes a transition to orthorhombic structure; however, this rounded shape of the crystals cannot be changed. It thus forms an orthorhombic single crystal with three equivalent b axis orientations of the orthorhombic cell, 60° apart (see Fig. 15) (76), which is a very special case for generating twin crystals via a crystal–crystal transition. Twin crystals can also be found in oligomers crystallized from the melt (102). Molecular packing disturbances in the formation of the twin are usually invoked to explain these crystal defects (5).

Curved Crystals, Frustrated Crystals, and Helical Crystals in Polymers. Lamellar crystals are not always flat. Curved crystals have been observed and reported to form sometimes in dilute polymer solutions. The observations can be traced back to the early 1970s in poly-4-methyl-pentene-1 (P4MP) (105), polychlorotrifluoroethylene (PCTFE) (106), and polyoxymethylene (POM) (107). In particular, the crystals are more pronouncedly curved (they have a smaller radius of curvature), when the crystallization temperature decreases. It is believed that individual fold domains are nonplanar. A simple four or six sectored crystal is actually slightly conical in overall shape. Therefore, a hypothetical model pertaining to the origin of curved crystals in polymers has been proposed. In addition, scroll-like as opposed to curved- or band-like crystals were also observed, such as in nylon-6,6 (108), isotactic polybutene-1 (109), and recently, in chiral nonracemic (R)- and (S)-poly(epichlorohydrin) solution-grown single crystals (110). An interesting observation relates to PVDF lamellar crystals grown in the melt, although they are not strictly single crystals. The lamellar structures within PVDF spherulites in the γ-form have a curious architecture in which the lamellae adopt a highly curved "scroll-like" morphology, with the axis of the scroll parallel to the spherulite radius (111). It has been suggested that this scroll-like morphology results from an imbalance of the fold composition on opposite fold

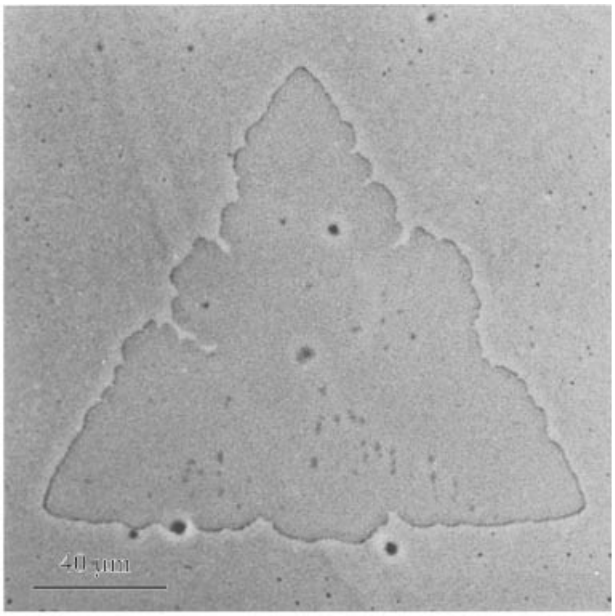
surfaces. The imbalance reflects the polarity of the γ-phase crystal structure and the steric constraints on the fold conformation (112).

The concept of frustrated crystals was introduced in materials science to describe the mutual orientation of magnetic spins in antiferromagnetic systems (113). Frustration exists wherever vicinal requirements are incompatible with packing requirements (eg, antiparallelism of spins in a triangluar or close-packed hexagonal lattice) (114). This concept was introduced in polymer crystallographic systems in the middle of 1990s (115). These frustrated structures are based on trigonal unit cells that contain three threefolded isochiral helices and in which the (nearly) similar azimuthal setting of two helices differs significantly from that of the third helix. In most cases, triangular single crystal morphology can be observed. Some of the morphologies also possess a hexagonal shape. This is a local consequence of the different azimuthal settings, which create different nucleation sites on opposite sides of any given growth plane (116). Examples include the β-form of iPP (117), isotactic poly(2-vinylpyridine) (118), poly(*tert*-butylethylene sulfide) (119), poly(L-hydroxyproline) (120), and α''-superstructure of syndiotactic PS (121). Figure 16 shows triangular single crystals of poly(L-hydroxyproline) and poly(*tert*-butylethylene sulfide) (120).

Because of the introduction of biomacromolecules and the development of asymmetric synthesis, chiral nonracemic polymer aggregates and single crystals become a new research topic. In biomacromolecules, double-twisted packing is similar to a stack of twisted β-sheets as is the case in several biopolymers (122–125). These twisted sheets pack closely with a twist that is perpendicular to the helical axis of the sheets themselves. Many examples possessing the double-twisted helical packing are in liquid crystalline states. Examples include dinoflaggellate chromosomes (in *Prorocentrum micans*) in an *in vivo* arrangement (122), DNAs (126), and poly-γ-benzyl-L-glutamate (127,128). Helical single crystals of the β-modification grown from *Bombyx mori* silk fibroin solution have been reported (129). Many chiral nonracemic polymers have been synthesized by an asymmetric synthetic method. The most recent example is that of chiral main-chain liquid crystalline polyesters that can form helical single crystals as shown in Figure 17 (130–134). It has also been found that the chain orientation in this helical single crystal is double-twisted. Furthermore, PE decoration indicates that there is no sectorization and that the chain-folding direction is along the long helical axis. These crystals can thus only be true crystals in Riemannian space (130).

Polycrystalline Aggregates: Dendrites and Spherulites. When the building blocks of single lamellar crystals aggregate together, different polycrystalline morphologies are generated. This introduces another length scale, usually in a range of a fractional micrometers up to, in some cases, fractions of centimeters. Two major factors determine the final morphology. The first is the polymer characteristics such as chain flexibility, molecular weight, and molecular architecture. The other is the outside environment such as crystallization from solution or melt, undercooling and pressure of crystallization, and external field applied. The most common polycrystalline morphologies are dendrites and spherulites. Fibrous crystals may be polycrystalline or single crystals.

Dendrites are branched crystals which in some cases take on a tree-like shape. Typically, polymer dedritic crystals form in solution, as shown in Figure 18 (135): either in dilute solution at relatively high undercooling or in polymer



(a)

solutions at slightly higher concentration. Although the branches in dendrites may sometimes show regular symmetry (see Fig. 18) or in most cases irregular growth, all of them possess crystallographic relationships. The formation of dendrites is linked with a local change in crystallization conditions. In principle, crystal growth can be influenced by concentration gradients caused by rejection of noncrystallizing species and temperature gradients generated by directional dissipation of the heat of crystallization. It is believed that the concentration effect is dominant (136,137). Using Fick's second law of diffusion, the concentration gradient at the crystal growth front can be represented quantitatively, which corresponds roughly to the ratio between crystal growth rate and diffusion coefficient. Only in the specific case of monoclinic α-form in iPP, the dendrites are due to a cross-hatching of the lamellae (138).

Spherulites, as first found to form in both organic and inorganic materials, are rounded crystalline bodies (5). They are circular in cross section and are composed of thin divergent crystal fibers that under polarized light microscopy (PLM) give rise to a Maltese cross pattern, with the arms parallel to the polarizer and analyzer. Spherulites in polymer crystals were first observed during the second world war. Figure 19 shows typical banded sperulites with Maltese cross of poly(trimethylene terephthalate) under PLM (139). The banded texture is due to lamellar crystals cooperatively twisting along the growth direction of spherulites, although the detailed mechanisms of twisting are still debated. Whatever the chain chemical structure and flexibility, almost all of the semicrystalline polymers form spherulites when they crystallize from the melt. Two general types of spherulites can be identified. Spherulitic radiation of the substructures can

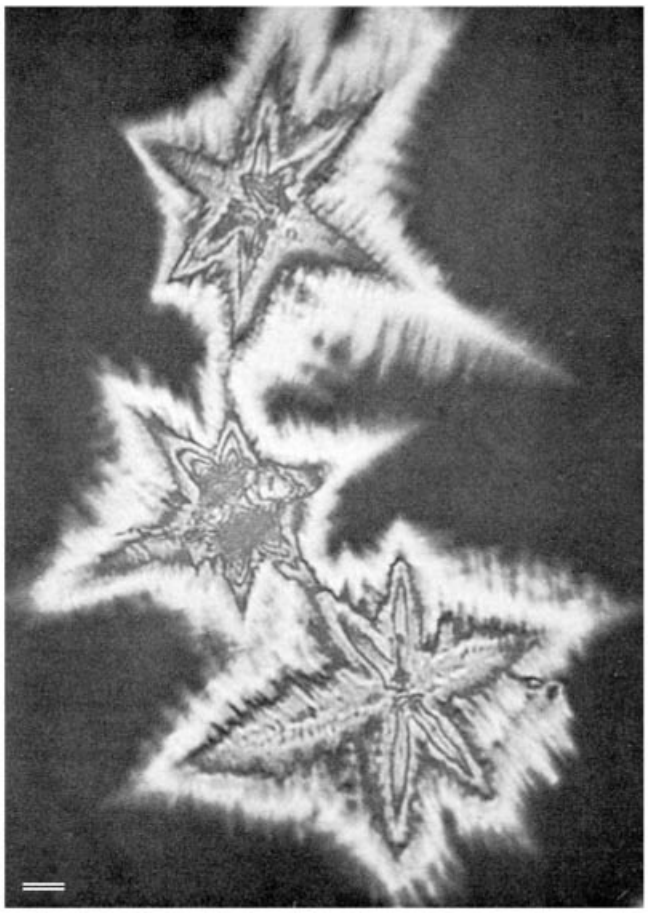

Fig. 18. Polyethylene dendrites grown from 0.05% solution in toluene at 70°C. They were observed under interference microscopy (135).

be achieved initially by a heterogeneous nucleus. The substructures then branch out in order to fill in space. However, the initial nucleus can be a simple one. In this case, lamellae initially start in two directions and then splay and diverge. The central portion has an inhomogeneous structure, commonly called the "eye" structure. It is readily apparent that the substructure in polymer spherulites is lamellar crystal. In fact, spherulites are aggregates of lamellar crystals cooperatively packed together. However, the mechanism of formation of polymer spherulites is complicated and actively discussed in the past several decades. In general, development of a spherulite from a single lamellar crystal must involve some sort of morphological instability.

It should be noted that dendrites and spherulitic aggregates are not completely crystalline. Certain amorphous regions remain even if macroscopically crystalline aggregates appear to have impinged. In some extreme cases of branched PE, the amorphous portions in spherulites can be as high as 90%. Two different types of amorphous regions can exist in these semicrystalline polymers,

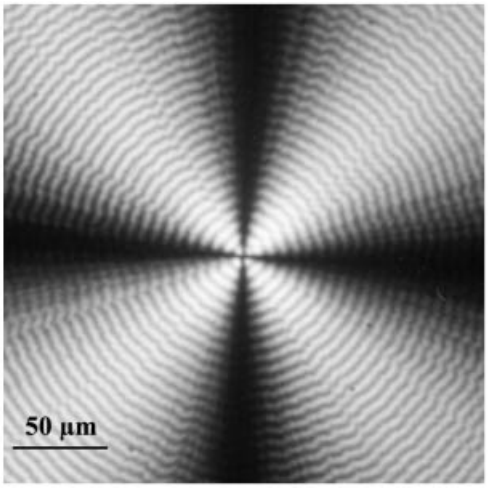

Fig. 19. Banded spherulite of poly(trimethylene terephthalate) crystallized from the melt at 150°C (139).

which are either located between neighboring lamellar crystals or segregated in separate pockets. These two types of regions are usually called microscopic and macroscopic amorphous regions. When linking these morphological observations with crystallinity concept, the usefulness and disadvantages of the two-phase model will be apparent.

Crystallinity Concept

The concept of the crystallinity of a semicrystalline polymer is based on the two-phase approximation of the polymer structure, which assumes that uniform crystalline and amorphous regions can be distinguished. It was adopted in the early years of polymer science with the first serious attempts to determine the ratio of the two phases in a polymer. The two-phase model successfully explained mechanical properties of semicrystalline polymers using continuous mechanics. Following the discovery of the chain folding, the two-phase concept was questioned. It seemed difficult to reconcile with the existence of layers with sharp folds at the interface between adjoining crystalline lamellae. Instead, the crystal defect model was proposed, according to which the amorphous phase is dispersed in the crystalline phase in the form of defects within the crystalline structure. As a result, the degree of crystallinity no longer had a direct obvious meaning, and other concepts such as "crystallinity index" or "degree of order" were proposed to quantify the phenomena associated with the presence of defects. However, as a result of increasing experimental evidence, the two-phase model was later restored, and was generally used to describe polymer morphology.

Crystallinity can vary widely in semicrystalline polymers. Three rough classes of polymers can be identified, which have high crystallinity (over 50%), medium crystallinity (between 20 and 50%), and low crystallinity (below 20%). High crystallinity polymers are seen in linear PE, iPP, PEO, etc; medium

crystallinity polymers are poly(ethylene terephthalate), poly(aryl ether ether ketone)s, poly(phenylene sulfide), and others; low crystallinity polymers are poly(vinyl chloride), some high temperature aromatic polyimides [poly(4,4′-oxydiphenylene pyromellitimide), etc] and ultralow density short-chain branched PEs, etc. Deviations from the two-phase model seem to occur in the sense that the phase boundary may occupy nonnegligible weight and volume in the materials, in which the structural order gradually changes between those of the crystalline and of the amorphous phase.

The crystallinity is thus apparently a meaningful quantity, and its determination is a matter of paramount importance in the investigation of semicrystalline polymer morphology. Either the weight w^c or the volume v^c fractions can be determined using the densities of the whole polymer, the crystalline phase, and the amorphous phase, given by ρ, ρ_c, and ρ_a, respectively. The following relations hold:

$$v^c = V_c/V \tag{2}$$

$$w^c = W_c/W \tag{3}$$

$$v^c = (\rho - \rho_a)/(\rho_c - \rho_a) \tag{4}$$

$$w^c = (\rho_c/\rho)v^c \tag{5}$$

To determine crystallinity in a semicrystalline polymer, diffraction, thermodynamic, and spectroscopic methods can be used. Diffraction method is mainly used with waxd methods. Thermodynamic methods include dilatometry, differential scanning calorimetry (dsc), etc, while ir and nuclear magnetic resonance (nmr), and other spectroscopic methods can also be used.

The most universal waxd method to determine crystallinity was developed by the introduction of a disorder function D (140).

$$4\pi \int_0^\infty s^2 I_c(s)\mathrm{d}s = w^c 4\pi \int_0^\infty s^2 \bar{f}^2 D\mathrm{d}s \tag{6}$$

In this equation, w^c represents the true weight fraction of crystals in the sample. The quantity $\bar{f}^2$ represents the mean square atomic scattering factor of the polymer summed over all atoms i (N_i is the number of atoms of type i)

$$\bar{f}^2 = \sum N_i f_i^2 / \sum N_i \tag{7}$$

The total scattering can be expressed as

$$4\pi \int_0^\infty s^2 I(s)\mathrm{d}s = 4\pi \int_0^\infty s^2 \bar{f}^2 \mathrm{d}s \tag{8}$$

and the weight fraction crystallinity that can be used to evaluate the experimentally obtained data is

$$w^c = \frac{\int_0^\infty s^2 I_c(s)\mathrm{d}s \int_0^\infty s^2 \bar{f}^2 \mathrm{d}s}{\int_0^\infty s^2 I \mathrm{d}s \int_0^\infty s^2 \bar{f}^2 D\mathrm{d}s} \tag{9}$$

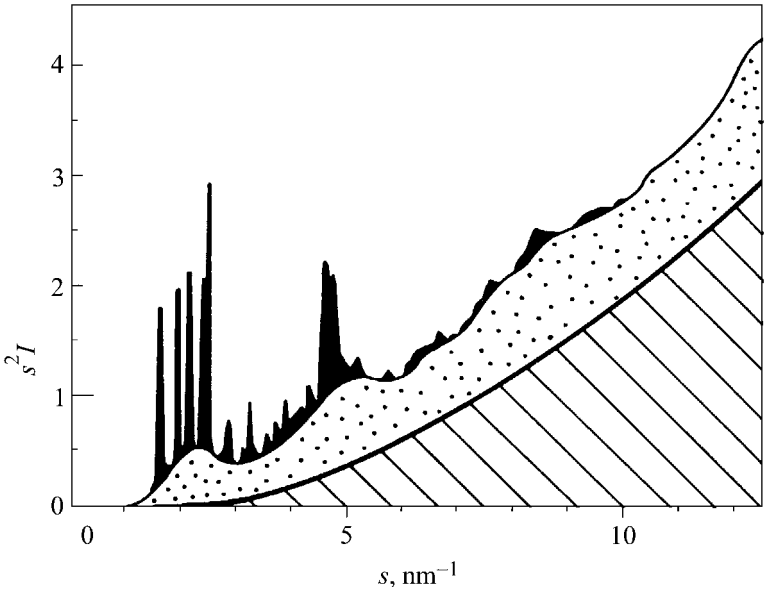

Fig. 20. Wide-angle x-ray diffraction crystallinity determination of iPP (5,140).

Application of the above equation requires either a sample with completely random orientation of crystals or a proper averaging of oriented samples. Averaging techniques have been described more than 30 years ago (141,142). Also, three-dimensional order is assumed to exist in the crystalline regions, so that the disorder is not strongly anisotropic. For the treatment of the anisotropic case, additional structural detail is needed to evaluate the amount of material which shows one- or two-dimensional order (143). An example of a $s^2I(s)$ curve computed directly from the experimental data of an iPP sample is shown in Figure 20 (5,144). Before using equation 9, the incoherent Compton scattering (shadowed area) must be subtracted. The crystalline portion $s^2I_c(s)$ can be delineated by subtraction of the undulating diffuse scattering area (drawn dotted). The separation line can be found by drawing a smooth curve through the minimum between the crystalline peaks along the general slope of the continuous scattering. According to Ruland, the procedure restricts the region counted as "crystalline" to sizes bigger that 2–3 nm.

A number of more approximate methods that avoid much of the complex computation described above have been used to estimate the crystallinity from x-ray diffraction data (145). A diffraction curve of an unoriented sample over a limited range of angle that contains most of the crystalline diffraction peaks and the major portion of the amorphous halo can typically be separated as indicated, for instance, in the case of iPP in Figure 21. A straight background line is drawn between the limits of the chosen interval of angles which should separate the incoherent scattering and others, largely not crystallinity-dependent, coherent scattering contributions. A line separating the sharp diffraction peaks is then drawn by connecting the minimum between well-separated crystalline reflections to a shape similar to that found (or expected) for a totally amorphous sample. The proportionality of the separated areas or amplitudes at suitably chosen angles to the crystalline or amorphous fraction is then determined by calibration. Much of the error introduced by integrating the diffraction intensity with respect to

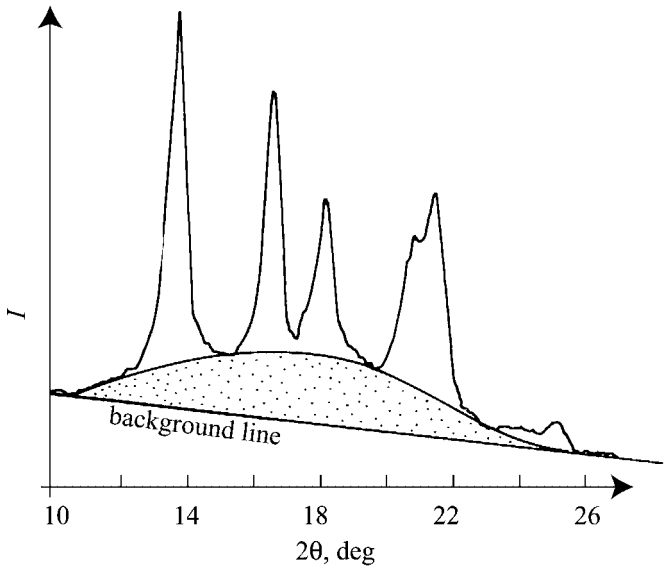

Fig. 21. Crystallinity of iPP determined using waxd method (144).

θ or using amplitudes at one angle rather than evaluating the integral over all reciprocal space is minimized by the calibration.

Thermodynamic approaches provide powerful tools to characterize the properties in identifying these metastable states to understand the effects of phase size, dimensionality, and composition on the materials properties. One well-known example is the density gradient column method to determine densities of semicrystalline polymers. Based on known equilibrium crystalline and amorphous densities, the crystallinity of a semicrystalline sample can be calculated by using equations 4 and 5. However, it should be noted that the determination of these equilibrium density data is not trivial. Proper extrapolations are necessary to ensure the equilibrium nature of the results. Detailed issues discussed can be found in Reference 146. Another commonly used method is to measure the heat of crystallization or fusion by using dsc. By knowing the equilibrium heat of fusion, the crystallinity of a sample can be easily calculated.

$$w^{c} = 1 - \frac{\Delta h_f(m)}{\Delta H_f} \tag{10}$$

where $\Delta\ h_f(m)$ is the measured heat of fusion and ΔH_f is the equilibrium heat of fusion of a specific polymer crystal. Again, this equilibrium heat of fusion can only be obtained using proper extrapolation methods, and corrected procedures and data treatments are necessary. Over 100 equilibrium heat of fusion data have been listed in Reference 147, which have been critically reviewed.

Spectroscopic methods like such as ir require finger printing vibration frequencies, which are specifically crystal- or amorphous-sensitive. The nmr method basically measures mobility of nuclei. Above the glass transition temperature of a semicrystalline sample, the amorphous part becomes mobile and the crystalline part is still rigid: the nuclei in these two parts possess different mobilities and thus can be detected by nmr (for detailed information, see Ref. 5).

However, if the two-phase model were strictly a precise description of a semicrystalline polymer, in which the crystalline and amorphous parts have sharp boundaries and do not have connections, its macroscopic mechanical response toward outside environments would be very weak. There must be some materials between these two parts, and therefore create interfaces. The characterization of the interfacial structures in semicrystalline polymers—identifying so-called *rigid amorphous fractions*—requires precise determination of crystallinity and the mobile amorphous portion of a semicrystalline sample. This concept can be traced back as far as 30 years ago. However, extensive studies have been carried out in the past 10–15 years only (148–155). On the other hand, researches on interface between crystalline and amorphous regions in bulk polymers have also been carried out using different experimental methods of small angle x-ray scattering, ^{13}C solid-state NMR, Raman spectroscopy, and tem (156–162). It is known that the crystallinity concept invokes the two-phase model, which simply divides the system into a perfectly ordered crystalline region and an amorphous region with sharp boundaries. In order to examine the validity of this two-phase (crystallinity) model, using for example, the dsc method, one needs first to establish the heat capacity data in solid and liquid states of the polymers. With these data, one could therefore predict that for a semicrystalline polymer

$$w^{c} = 1 - \frac{\Delta c_p(m)}{\Delta c_p(a)} \tag{11}$$

where w^c is the weight-fraction crystallinity and is usually obtained by dsc measurements, density determination, and/or waxd experiments. The terms $\Delta c_p(m)$ and $\Delta c_p(a)$ are the heat capacity increases at glass-transition temperature (T_g) for the semicrystalline sample and the amorphous sample, respectively. Surprisingly, a wide variety of behaviors that deviates from the ideal two-phase model exist. A positive heat capacity deviation is observed for practically all polymers long before the clearly recognized fusion endotherm begins. This has been linked to premelting and/or defect formation. For PE and PTFE, these positive deviations close to the melting temperatures are well-analyzed (147,163). The heat capacities of POM show, on the other hand, a negative deviation at somewhat lower temperatures relative to the melting temperature (T_m) (148,149). This reveals an extra fraction in the polymer that contributes neither to the glass transition at T_g nor to the heat of fusion at T_m. This fraction has been called the *rigid amorphous fraction*. In POM, this rigid amorphous fraction does not show any sign of softening up to the polymer melting. Similar measurements in iPP exhibit a rigid amorphous fraction that is gradually unfreezing, which in turn leads to the occasionally observed *double glass transition* (164). As a result, if a rigid amorphous fraction exists in a semicrystalline polymer, the two-phase model cannot be used to describe that system, and

$$w^{c} < 1 - \frac{\Delta c_p(m)}{\Delta c_p(a)} = f_r \tag{12}$$

The resulting difference between equations 10 and 11 is the rigid amorphous fraction in a polymer, $f_r - w^c$. Most of the thermoplastic engineering polymers such

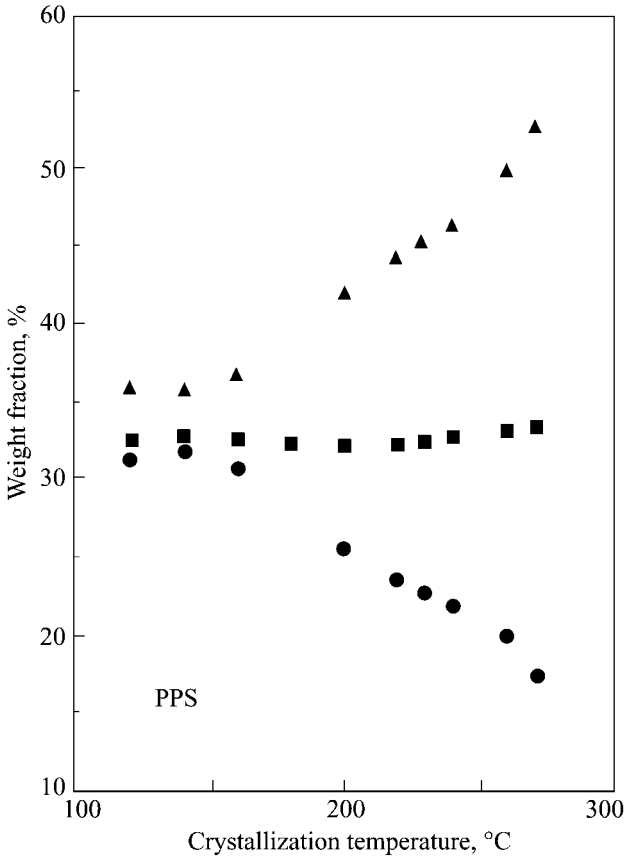

Fig. 22. Rigid amorphous, mobile amorphous, and crystallinity changes in PPS with crystallization temperatures (166). Mobile amorphous fraction;■ rigid amorphous fraction;● and weight fraction crystallinity ▲.

as PEEK (150), PPS (151), PPO (152), PET (165), PBT (154), PEN (153), and polyimides (155) show this kind of behavior that is critically dependent upon the thermal history of the samples. Figure 22 shows three fractions in a high molecular weight linear PPS sample, in which the nonmobile amorphous fraction above T_g represents the rigid amorphous fraction (166). More complicated situations may also be observed by combining both positive and negative deviations of heat capacities in a semicrystalline polymer. Other structural characterization methods are necessary to distinguish these deviations and to separate both effects.

Physical Properties Affected by Crystal Structures and Morphologies

Polymer crystals are always semicrystalline, and thus, they are far from perfect. Limited crystal sizes and complicated aggregates make the basic understanding of the structure-property relationships very difficult. To simplify, two types of properties in general exist for crystals of small molecules: structure-insensitive and structure-sensitive properties. The structure-insensitive properties include

density, heat of fusion, modulus, and refractive index whereas the structure-sensitive properties are deformation, chemical reactivity, electrolytic conductivity, etc. However, in polymer crystals, one needs to introduce morphology-insensitive and morphology-sensitive properties because of the existence of structures in different length scale. Although most of the properties in these two catalogs that were identified in small-molecular crystals are also more or less applicable in polymer crystals as recognized on the basis of morphological levels, the relationships obtained are certainly by far scattered.

The modulus of isotropic semicrystalline polymers is associated with crystallinity. Since the modulus is relatively morphology-insensitive, one can plot a relationship between modulus and crystallinity or density. Extensive studies have been carried out in linear PE and PE copolymers to establish structure-property relationships (167–175). Figure 23 shows such a relationship for a whole spectrum of PE over 9000 data points, including very low density branched PE and copolymers to high density PE (176). Interestingly, the data follow a consistent trend: lower density (crystallinity) samples have lower modulus and higher density (crystallinity) samples have high modulus. The deviation of the data is about ±50%. As the mechanical measurements are from very different sources, the correlation between density (crystllinity) and modulus can be viewed as excellent. The deviation may come from morphological dependence of the modulus with a constant density in addition to experimental errors in these measurements. However, this morphological dependence is weak, and therefore, this example provides a clear indication that the modulus is basically a morphology-less-sensitive, but crystallinity-more-sensitive property. However, no clear-cut correlation between the structure-sensitive property and crystallinity can be established. For example, these kinds of observations can be found in the measurements of heat of fusion. Although the melting temperature is crystal-size-dependent, which is closely

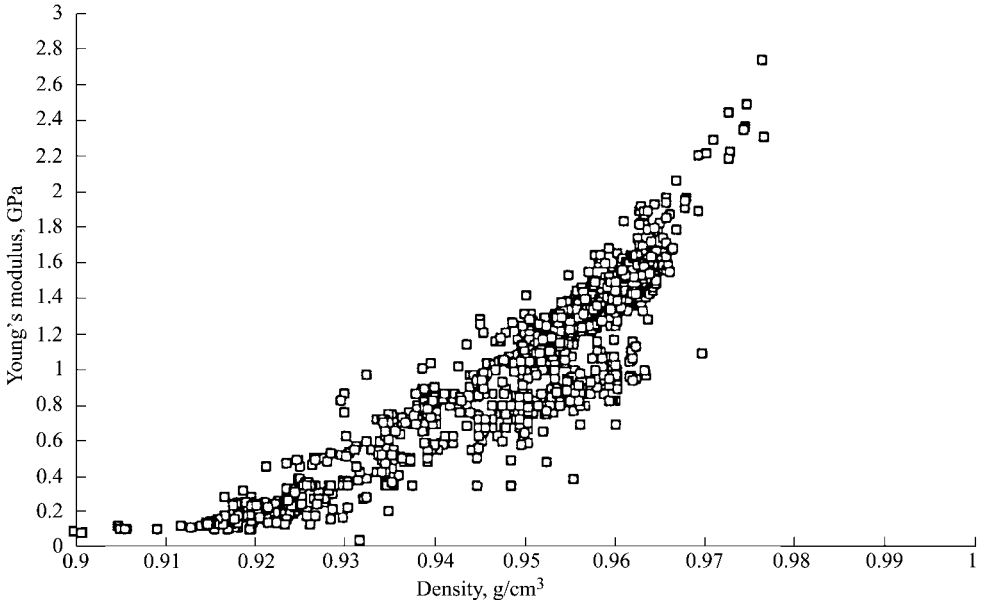

Fig. 23. Modulus versus density in various PE (176).

associated with crystal morphology, the amount of heat required to isotropize the crystal is a morphology-insensitive property.

Crystal modulus can also be associated with the molecular conformation in the polymer crystal. In order to determine the crystal modulus of polymers, oriented polymer samples are usually used. The basic assumption is that the stress applied on polymer samples is evenly transmitted through the sample. Various structural characterization methods are then applied to measure the lattice strain under stress, including waxd and Raman experiments. In waxd experiments, the d-spacing shift along the chain molecular direction can be observed at different tensile stress level. In Raman spectroscopic method, the vibration bands shift to lower frequencies with increasing tensile stress. Note that these types of measurements use macroscopic stress and microscopic strain to obtain Young's modulus. Other methods may also be applied, such as the velocity of acoustic phonon propagating within the polymer crystals from the frequency–dispersion curve measured by coherent inelastic neutron scattering. Table 2 shows crystalline modulus along the chain molecular direction for different semicrystalline polymers. The calculated modulus data in most cases are carried out using lattice dynamic treatment and deformation mechanism of the chain subjected to tensile stress (177–185).

Table 2. Crystallite Modulus (GPa[a]) along the Chain Axis

Form	Polymer[b]	Observed	Calculated
Planar-zigzag	PE	240 (290, 329)	316
	PVA	250	287
	Nylon-6 (α)	165 (20°C)	170
		270 (−150°C)	312
	PVDF (I)	177	237
	PDA (PDCHD)	45	40
Helix, glide	iPP	40	40
	POM	53 (75)	109
	PVDF (II)	59	77
	Nylon-6 (γ)	27	54
Aromatic polyester	PET	108	95
	PTMT (α)	13	10
	PTMT (β)	20	27
	PEOB (α)	6	2
	PEOB (β)		57
Rigid rod polymer	Kevlar	153, 200	182
	PBA	188	163 (GTGT)
			238 (TTTT)
	Nomex	88	117
	PBT	395	371
	P-p-P		275
	PBB		588
	PPPI		505
	Cellulose (I)	127	168
	Cellulose (II)	90 (109)	162

[a]To convert GPa to kbar, multiply by 10^5.

[b]PDA = polydiacetylene; PET = poly(ethylene terephthalate); PBA = poly(p-benzamide); P-p-P = poly(p-phenylene); PBB = polybenzobisthiazole; PPPI = poly(p-phenylenepyromellitimide).

In the past 50 years, substantial progresses in understanding of almost every aspect of semicrystalline polymers have been made. However, it is not a simple task, based on the knowledge of polymer crystal structures, to predict their macroscopic properties. This is because compared with crystals of small molecules, polymer crystals in bulk are generally in the form of polycrystalline aggregates. Their semicrystalline nature leads to broad structural length scales which in turn affect the final performances of the materials. Polymer single crystals are not only an essential step in understanding how long-chain molecules can be closely packed in three-dimensional space, but also are the most important step as a building block in the development and formation of the polymer aggregates in bulk materials.

SILANE COUPLING AGENTS

Introduction

The term *silane coupling agent* generally applies to silicon-containing species capable of forming chemical linkages between dissimilar materials, especially in reinforced polymer composites. The materials to be linked are often organic polymers and inorganic fillers, though silane coupling agents can also be useful with other kinds of fillers and polymers. Small amounts of silane coupling agents, used at an interface, can greatly improve the mechanical properties of composite materials. They may also be used on formed parts as coatings to alter the surface properties of materials, or copolymerized into organic polymers. Silane coupling agents are found in a broad range of applications as varied as metal coatings, dental materials, and contact lenses. The present article is focused primarily on their use in polymer composites, where they are used as interfacial modifiers.

In their most common form, polymer-reinforced composite materials consist of an organic matrix and inorganic filler (here the term filler will be used in a general sense, and can include reinforcing fibers). The polymer typically forms the continuous phase that protects the filler from environmental damage and holds the composite together. The filler reinforces (improves the strength and modulus) or simply takes up space without degrading the properties of the polymer. The transfer of stresses between the fiber and filler is critical in achieving reinforcement. Binary mixtures of polymer and filler can have poor mechanical properties because of poor interactions between them, which result in weak interfaces. These interfaces are often the source of failure in composites through delamination. Failure at interfaces is especially acute in the presence of small-molecule chemical species, such as water.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Given the widespread use of silane coupling agents, there have been a number of papers and reviews that have focussed on their chemistry, application, and effects. The cornerstone of these is the book by Plueddemann (1), which discusses most of the aspects of coupling agent application. A few symposium-based books have also been produced (2), as well as a few reviews (3,4). As Plueddemann points out, in many cases, with the use of the proper coupling agent under the proper conditions, the failure in composite materials no longer takes place at the interfaces between the dissimilar materials.

Chemical Composition and Reactions

Silane coupling agents generally have hydrolyzable and organofunctional ends. The general structure of the coupling agents can be represented as

$$X_3SiR$$

where the X represents the hydrolyzable groups that are typically chloro, ethoxy, or methoxy groups. The organo, R, group can have a variety of functionalities chosen to meet the requirements of the polymer. Chlorosilanes are very reactive; the liquids and vapors are extremely irritating to the body. There can be 1–3 X groups and the number of these can alter the way the silane bonds to an oxide surface or to other coupling agents. When the number of X groups are less than three, the remaining groups are replaced by additional (usually nonfunctional) alkyl groups such as methyl. Generally, coupling agents with three X groups are used in composite materials because of their greater stability on surfaces, but there are clearly other applications where it may be desirable to use one or two hydrolyzable X groups. In this report, we will focus on materials with three X groups. This trifunctionality is common for most coupling agents used in composites.

It should be noted that there are several generally accepted methods of naming silane coupling agents. No attempt will be made here to apply a systematic approach to the nomenclature (see SILICONES). A few common coupling agents are listed in Table 1 along with their Chemical Abstracts Registry Numbers and chemical formulas. For the species shown, the main differences in the coupling agents are the organo-functional groups. A variety of coupling agent species with different organo groups is available from commercial sources.

The choice of the coupling agent is typically based on the surface and the polymer used. It is of utmost importance that the organofunctional group is typically matched to the polymer. Tables of suggested coupling agents proposed for different resins are found in the literature from manufacturers (5) and will not be reproduced here.

The first step in the application of a silane coupling agent is the hydrolysis of the X groups. Generally water is required and the by-products are HCl or alcohol. The water for hydrolysis, which may be added intentionally, can be found as trace amounts in organic solvents, or can be located on the surface of the fillers. The hydrolysis of the alkyl groups may be acid- or base-catalyzed. In pH-neutral solutions, the reactions of alkoxysilanes can be quite slow. For many of the coupling agents, hydrolysis proceeds with the addition of the coupling agent

Table 1. Representative Silane Coupling Agents

Common name	CAS Registry Number	Formula
3-Aminopropyltriethoxysilane (APS)	919-30-2	$(CH_3CH_2O)_3Si(CH_2)_3NH_2$
4-Aminobutyltriethoxysilane (ABS)	3069-30-5	$(CH_3CH_2O)_3Si(CH_2)_4NH_2$
N-2-Aminoethyl-3-aminopropyltrimethoxysilane (AEAPS)	1760-24-3	$(CH_3O)_3Si(CH_2)_3NHCH_2CH_2NH_2$
Vinyltrimethoxysilane (VS)	2768-02-7	$(CH_3O)_3SiCH{=}CH_2$
3-Methacryloxypropyltrimethoxysilane (MPMS)	4369-14-6	$(CH_3O)_3SiCH_2CH_2CH_2OC(=O)CH{=}CH_2$
3-Acryloxypropyltrimethoxysilane (APMS)	160716-45-0	$(CH_3O)_3SiCH_2CH_2CH_2OC(=O)CH{=}CH_2$
3-Glycidoxypropyltrimethoxysilane (GPS)	2530-83-8	$(CH_3O)_3SiCH_2CH_2CH_2OCH_2CH(O)CH_2$

to a solvent (such as acetone) with water and acid (or base). In principle, there are three separate rate constants, one for each of the three X groups. The rates of hydrolysis can be followed by spectroscopic techniques such as NMR or FTIR. Many of the hydrolysis experiments have been reviewed with a special emphasis on how experimental conditions affect the rates of hydrolysis (6,7). Some coupling agents have functional groups that self-catalyze the hydrolysis, such as the amine group in 3-aminopropyltriethoxysilane (APS). Amine-functional coupling agents hydrolyze relatively quickly in the presence of water without the addition of acid or base.

Following hydrolysis, and in some cases competing with it, is the condensation of the silanols with other silanols or surface species. This typically occurs with the loss of water. Subsequent drying of the material may drive the reaction to completion. The ultimate condensed product of the coupling agents would have a formula $RSiO_{3/2}$. These compounds are called silsesquioxanes (8) and are highly cross-linked amorphous polymers. An idealized schematic representation of the resulting structures is shown in Figure 1 for the coupling agent 3-aminopropyltriethoxysilane. There are at least three separate hydrolysis reactions (one for each X group) and the condensation of the hydroxyl groups can occur before all three of the X groups are hydrolyzed. Thus, the kinetic scheme for hydrolysis and condensation is very complicated and is often described, not in terms of the individual species, but in terms of the total number of hydrolyzed or condensed groups.

Surface Reactions/Interactions

An additional level of complexity is encountered when silanes are added in the presence of solid surfaces. Hydrolyzed or unhydrolyzed coupling agents will interact with a variety of oxide surfaces. Even in the case of metal fillers, an oxide layer is often found at the surface. The presence of water at these interfaces may

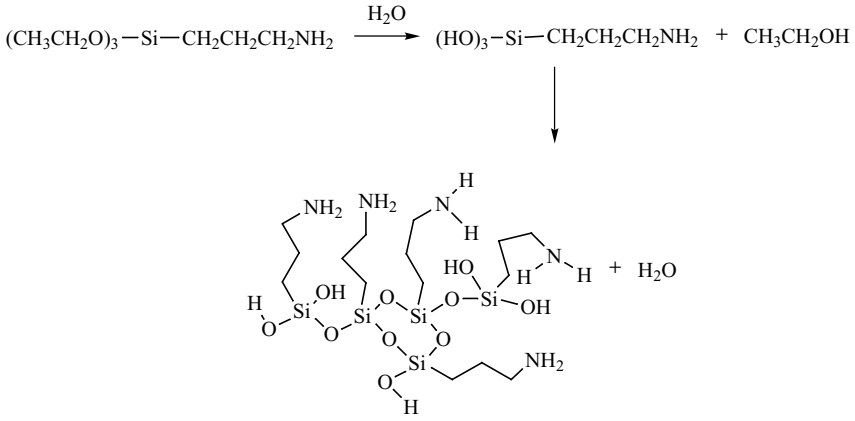

Fig. 1. Idealized representation of the hydrolysis and condensation of 3-aminopropyltriethoxysilane.

be sufficient to hydrolyze the coupling agents. Thus, the addition of "extra" water may not be necessary. Unless the concentration of the coupling agent in solution is very low, the adsorbed species will likely be small oligomers rather than monomers. There will be an attraction due to hydrogen bonding of oxide surfaces and the coupling agent's silanol groups. The organo group may also be attracted to the oxide surfaces. For example, APS appears to attach itself to oxide surfaces (alumina and silica), first via the amine group, then the molecule flips, allowing the silanols of the coupling agent to react (9). Presumably, this is why on iron, fresh films of APS can be rinsed off unless they are aged in some way (10). Generally, some kind of aging or heat treatment is required to fix the coupling agent to the surface. An idealized example of the ultimate surface structures formed is shown in Figure 2. It should be noted that the geometry of the surface is such that it is virtually impossible for all three of the SiO— bonds on the coupling agent to be attached directly to the silica. Bonding to other coupling agents or dangling hydroxyls is likely. There may be a mixture of physisorbed and chemisorbed species in thicker coupling agent layers.

The amount of coupling agent adsorbed on surfaces depends on the conditions present. Under highly controlled conditions and limited hydrolysis from very dilute solutions, "monolayers" may be produced (11). For 3-methacryloxypropyltrimethoxysilane (MPMS), it has been estimated that the surface area for the adsorbed molecule, lying flat on the surface and end adsorbed (functional group extending away from the surface), amounted to 55 and 24 Å^2,

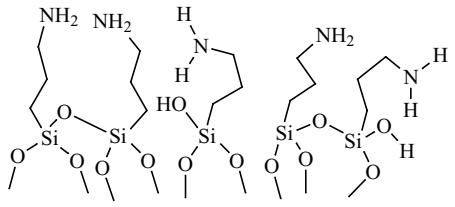

Fig. 2. Idealized structures of 3-aminopropyltriethoxysilane (APS) on a silica surface.

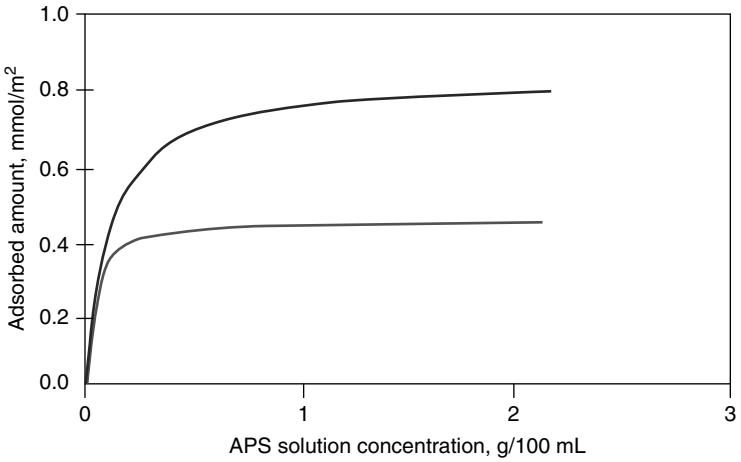

Fig. 3. Adsorption isotherms for 3-aminopropyltriethoxysilane in acetone/water mixtures. The two isotherms shown are indicative of the extremes in the measurements made at two different times on the same system.

respectively (12). Occupied areas for other coupling agents with similar structures are similar. For typical treatment conditions, the amount of coupling agent adsorbed depends on the state of the coupling agent in solution. Because of the complexity of the reactions and reaction conditions, this state is often difficult to control with great precision.

An example of an adsorption isotherm for solutions with oligomers present is shown in Figure 3 for APS adsorbed onto silica from acetone/water mixtures after washing. The two isotherms shown represent the extremes from a large number of replicate runs on the same system (see ADSORPTION) (7). Interestingly, the amount adsorbed does flatten out and has the shape of a typical polymer adsorption isotherm. The adsorption isotherm measurements had good precision within a single experiment, but maximum adsorbed amounts varied from run to run, possibly because of different levels of hydrolysis and condensation within the coupling agent solution. It was estimated that on average, about 0.65 mmol/100 m^2 of APS was adsorbed. The individual experimental results ranged between 0.4 and 0.8 mmol/100 m^2. The average amount corresponds to an area of about 25 $Å^2$ per coupling agent molecule, which is consistent with the coupling agent molecule standing on end. It is also roughly what one expects for one coupling agent molecule per surface silanol.

Silane coupling agents may also be directly used as coatings for a variety of applications (10,13,14). Coupling agents in coatings formulations can be used in either solvent- or water-borne systems, such as clear coats for automotive applications (13,15). Formulations can also be used to impart scratch and abrasion resistance to softer materials such as polycarbonate and poly(methyl methacrylate) (PMMA) (14). Applications of this type allow the use of materials whose bulk properties are desirable because the surface properties can be fine-tuned.

Often glass fiber or fabric can be treated in a continuous process by passing the glass through a solution (usually less than a few percent) of the coupling agent in a suitable solvent. The coated substrate is then heated and the coating dried and

reacted on the surface. This process normally puts much more coupling agent (an order of magnitude or more) on the surface than the "oligomeric monolayers" mentioned above. The equivalent of several monolayers may be required for optimal mechanical behavior of the resulting composites (see Mechanisms of Reinforcement). The multilayers (interphase) are likely to be fairly disorganized—more like highly cross-linked polymers than separate highly organized layers, though organized layers can be built with sequential deposition.

Analysis of Coupling Agents

The condensation of silanes on oxide surfaces occurs with the loss of water. The reactions, in principle, may be monitored by thermal gravimetric analysis (TGA) or spectroscopic means. The same technique can also assess the thermal stability of the resulting interphase. A TGA trace for 3-acryloxypropyltrimethoxysilane (APMS) condensed onto silica is shown in Figure 4. This analysis was done following an initial heat treatment to remove water and more fully condense the silanols. With a heating rate of 10°C/min, the organic portion of the coupling agent volatilizes off the surface between 300 and 600°C. At moderate temperatures, such as 100°C, the coupling agents are relatively stable. The SiO portions of the coupling agent molecule, along with the rest of the silica, remain intact on the surface (16). Knowledge of the beginning and ending weights provides a reasonable measurement of the amount of coupling agent bound to the surface. In the example below, the mass of coupling agent adsorbed is about 17% of the mass of the treated silica. With the knowledge of the specific surface area of the silica, the amount of coupling agent adsorbed corresponds to the equivalent of 4.5 monolayers in this case.

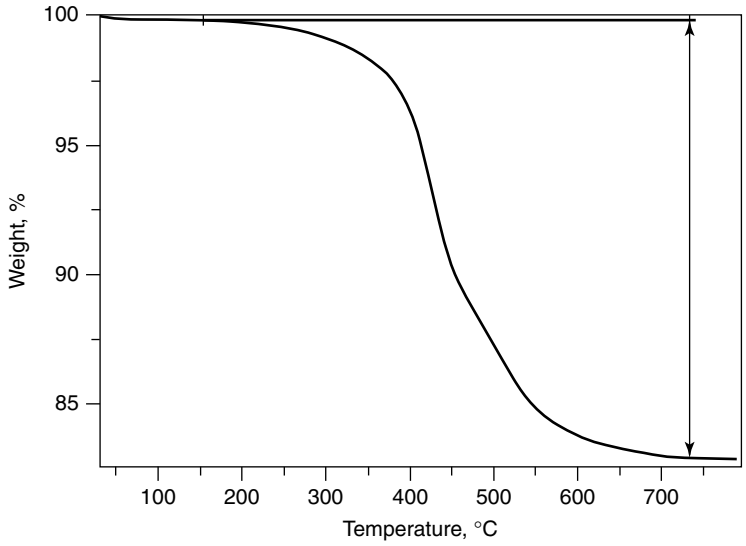

Fig. 4. Thermogravimetric analysis of surface-adsorbed 3-acryloxypropyltriethoxysilane on silica.

Although many forms of surface spectroscopy may be used for the characterization of the reactions of silanols, IR and NMR are perhaps the most informative, but are not reviewed here (3,4,17). Analyses of IR spectra provide a sensitive way of probing the state of the coupling agents from solution to on the surface. FTIR provides several advantages, including speed of measurement and high throughput. It also provides several different ways of probing the interfaces, such as transmission, diffuse reflectance, or internal reflectance. Some of the details that these studies have uncovered can be illustrated for APS. As early as the 1980s (18), FTIR was shown to identify the presence of internal hydrogen bonding, ring structures, and oligomers of this coupling agent in solution. On the surface, this material may also form ring structures, bicarbonate salts, and other species (11,19). These studies have been used to guide researchers in determining appropriate processing conditions.

NMR can be very informative relative to the details of the chemical species produced in solution and on the surfaces. Proton NMR has been used to follow hydrolysis reactions. It is especially easy to follow the alcohol produced. Proton NMR is not as useful in determining the exact nature of the species present during condensation, but silicon-29 NMR is, and it can provide information on the number of different groups attached to the silicon atom. The disadvantage is that the silicon-29 nucleus is not very abundant (4.7%), and so most of the silicon atoms are not NMR-active. For a model compound such as methyltrimethoxysilane, it is possible to identify all the different substituents on the silicon atoms at the early stages of hydrolysis and condensation. The relative amounts of the different components were shown to fit to a statistical model for hydrolysis (20).

Solid-state silicon NMR has also been a significant aid in the understanding of the reactions of the coupling agent with the surface of the filler. These investigations have been aided by detailed studies of the fillers alone (21). A number of studies have focused on the reactions with surface species and yield a detailed view of the species present, similar to that done for solutions, though with less resolution (22,23). More specifically, coupling agents with a single R group and three oxygen groups would be given the symbol T^i, with the superscript i denoting the number of O—Si species attached to the silicon in question. Thus, a T^3 species would represent a fully condensed silane. Under conditions of full hydrolysis, the other substituents would be expected to be hydroxyls. A silicon species with four oxygen atoms attached would be considered a Q^i species. Thus, a Q^4 would be a fully condensed silicon with no organic substituent.

The silicon-29 NMR spectra is shown in Figure 5 for adsorbed and heat-treated APMS on a silica surface (16). The spectra were taken with magic angle spinning and cross-polarization (CP-MAS). The clear separation of the T (-50 to -75 ppm) and Q (-90 to -115 ppm) groups is obvious in the spectra. For the 100°C heat-treated material, the coupling agent spectrum is dominated by the T^3 and T^2 species, showing a high degree of condensation. The Q region of the spectrum consists primarily of Q^3 and Q^4 species. It should be noted that the cross-polarization from protons increases the intensity of the Q^3 (surface hydroxyl containing) silicon atoms more than the Q^4 species. Upon heat treatment to 600°C, the Si-29 NMR spectrum shows the disappearance of the T resonances, and all of the silicon has been converted to Q species. The agreement between silicon NMR and gravimetric analysis is very good.

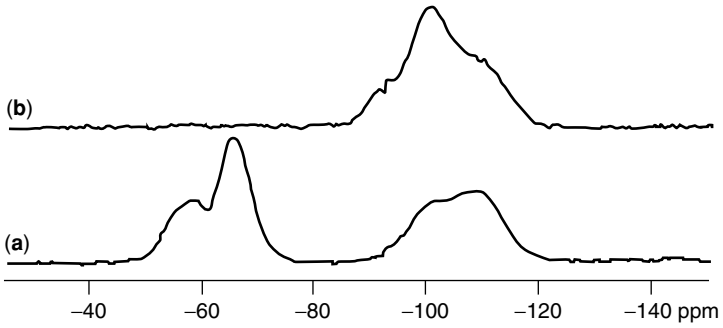

Fig. 5. Silicon-29 NMR spectra of 3-acryloxypropyltrimethoxysilane on silica (**a**) adsorbed and heated to 100°C and (**b**) after heating the sample in (**a**) to 600°C.

Mechanisms of Reinforcement

In principle, silane coupling agents can influence the mechanical properties of composites in several ways (see REINFORCEMENT). Without question, the adsorption and reaction of a silane with the surface changes the properties of the interface (see SURFACE PROPERTIES). The surface energies of inorganic fillers and polymers are likely to be rather different. A comparison of critical surface tensions for some polymers and coupling agent films (1,24) shows that the functional groups can vary the surface tension from very low (similar to polytetrafluoroethylene) to rather high (close to glass)(24). Indeed, the variation of surface energies and zeta potential with different treatments of the same coupling agent can even be large(25). The use of an appropriate coupling agent should allow the modification of a surface so that an organic polymer will wet it. In principle, this should ensure good contact between the polymer and filler at the interface (at least as far as the preparation of the composite is concerned). In addition, the choice of coupling agents with low surface tensions may help exclude high surface tension species (eg water from the interface). In spite of the matching of the surface tension between the polymer and the silane film, Plueddemann (26) has shown that when the composites were exposed to water, only reactive silanes gave high strengths in polyester–glass laminates. It seems reasonable to conclude that the presence of chemical bonds is very important for enhanced wet strengths in composites. The binding energy associated with chemical bonds, much greater than other interactions (eg van der Waals forces), is undoubtedly responsible for this effect.

It should be noted that surface energy and interactions can still play crucial roles in the production of composites. Many manufactures sell fibers and fillers with a variety of "sizings" deposited on the surfaces for compatibilization with resins and the protection of the fibers during production and handling. These sizings often contain silane coupling agents, and may also contain other chemical species. Discussion with the manufacturers or careful reading of their literature is important for selecting the proper filler with the proper surface treatment for a given application and polymer. Good dispersion of fibers is critical for effective reinforcement and this can be aided by the appropriate surface treatment.

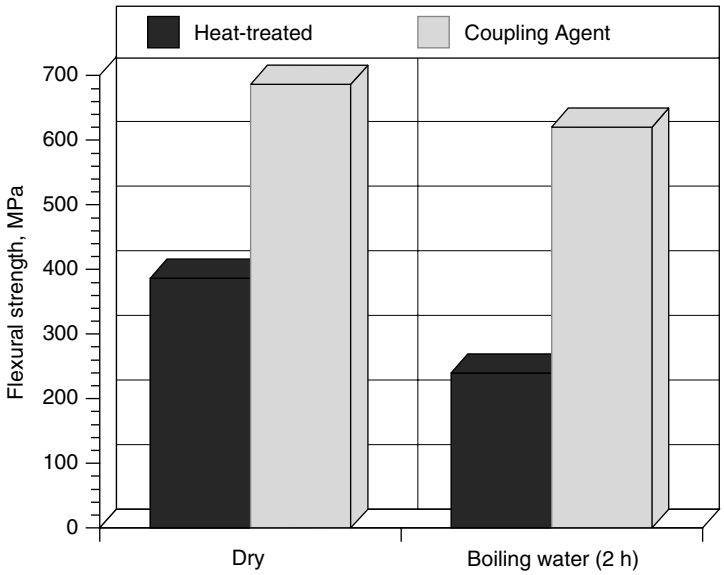

Fig. 6. Flexural strength of heat-treated and methacrylate coupling agent treated glass-fiber/polyester composites. The 2-h boiling-water test approximates longer-term water exposure (1).

In many cases, the mechanical properties of composites are compared for treated and untreated fibers. Generally, the preparation of an "untreated" fiber requires the removal of the sizing. Heat treatment is the most practical method of obtaining a bare fiber, especially with glass. Heat treatment can be followed with thermogravimetric analysis, which is also a convenient way of estimating how much coupling agent was adsorbed onto the surface, as mentioned previously.

An example of the effect of coupling agents in a polymer composite is illustrated in Figure 6, where the strength of a glass-fiber-reinforced polyester composite, with and without a coupling agent, is compared (1). Similar results can be found for other mechanical properties and other composite systems as well. It needs to be noted that the actual values of the strength are dependent on a number of parameters such as the amount of coupling agent and fiber geometry/content. The changes in mechanical properties are also especially dependent on the nature of the coupling agent. In fact, reductions in strength can be found with certain coupling agents (1). In any case, with the appropriate selection of a coupling agent, the main points are clear. Significant improvements can be found in dry strengths, with even more dramatic improvements found under conditions of water ingress. Clearly, the coupling-agent is able to withstand the effects of water.

Coupling agents are clearly effective at modifying the interface between the polymer and fillers. As noted by Plueddemann (1), with silane coupling agents, the failure mode of some composites can be altered so that failure no longer occurs at the interface. An example of the reinforcement of the interfaces is shown in Figure 7 for the fracture surfaces of a composite made of 3-AFMS-treated fibers with PMMA (27). The use of the coupling-agent increases the strength of the

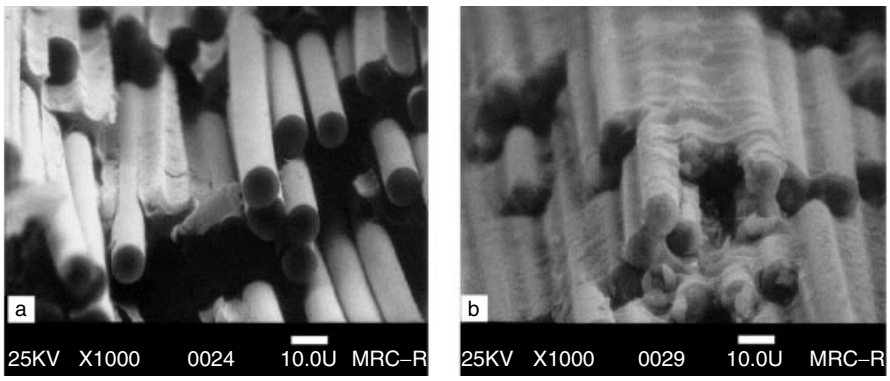

Fig. 7. Fracture surface for glass-fiber-reinforced PMMA for (**A**) untreated fibers and (**B**) 3-acryloxypropyltrimethoxysilane treated fibers.

composite. The fracture surface for the heat-treated fiber shows that the resin and fiber separated at the interface between them, resulting in the exposure of bare fiber. The fiber was pulled out of the resin. In contrast, the coupling agent-treated fiber shows a rough interface, with resin attached to the fiber, and the implication is that fracture occurred within the resin phase.

As previously noted in this section, the presence of a chemical bond is virtually required for improvements in mechanical properties. It is perhaps the most important requirement for enhancement of properties. One factor, not always recognized as important, is the mechanical properties of the adsorbed coupling agent layer. In most fiber and filler treatments, the coupling agent layers are the equivalent of many monolayers thick. They can be considered as an interphase. The mechanical properties of the interphase need to be considered in the optimization of the final properties.

The role of the physical nature of the interphase has been probed by comparing the properties of composites made with two coupling agents, APS and ABS. These two coupling agents have the same functional groups and are similar enough to have the same chemistry. NMR studies have shown that multilayers of each coupling agent on silica form an interphase that is graded in terms of mobility (28). The coupling agents bonded to or very near to the surface of the silica are more rigid than the coupling agents further away from the surface. Lower mobility correlates with a higher modulus and vice versa. Near the silica interface, both adsorbed APS and ABS behave similarly, but away from the surface, the outer layers of ABS are more mobile (lower modulus) than APS. The role that the different dynamics plays is apparent from mechanical property tests. In Figure 8, the critical energy release rate (fracture toughness) of the interphase for epoxy composites is compared. Both ABS and APS improve the properties of the composites over bare glass, but more improvement is found for APS (29). Qualitatively similar results are found for other mechanical property tests. It is believed that the APS interphase provides the best transition from the properties of the glass on one side of the interphase to that of the epoxy on the other. The ABS interphase was believed to be too flexible at the epoxy–ABS interface for optimum properties.

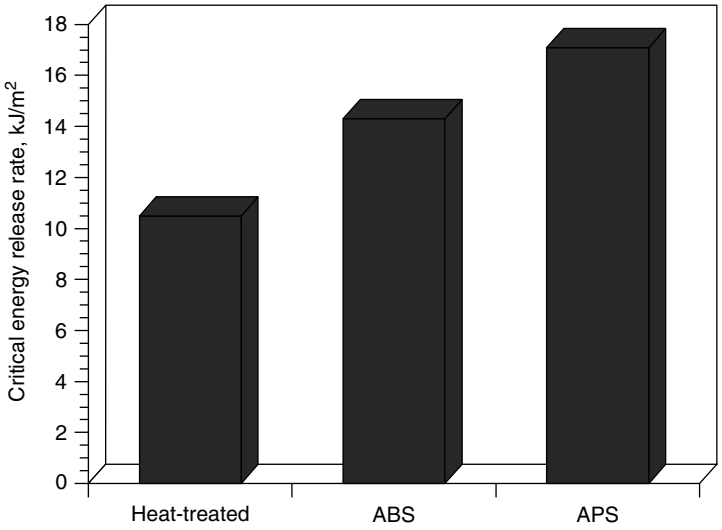

Fig. 8. Critical energy release rate (fracture toughness) of glass-fiber/epoxy composites, with the fibers being heat-treated (bare), and ABS- and APS-treated glass (29).

Application of Silanes in Advanced Materials

The silanes need not necessarily be linked to macroscopic fillers to be useful as coupling agents. For example, the fillers used do not necessarily need to be of large size. The use of hybrid materials goes back to the 1950s (15). Silane coupling agents are also useful in the production of organic/inorganic hybrid materials and some nanomaterials. In some cases, silane coupling agents can be used to functionalize nanomaterials made from different core structures.

There are a number of ways in which the coupling agent functionality can be incorporated into hybrid materials (8,14). Organic materials can be "embedded" in an inorganic matrix without chemical bonding. Interpenetrating networks may allow continuity of both species simultaneously. Covalent bonding between the two different materials on a nanometer scale can be achieved via coupling agents, which can be copolymerized or grafted with an organic polymer. Depending on the technique of integrating the dissimilar materials, property differences can be obtained in the final products.

Bridged polysilsesquioxanes are materials that have an organic moiety sandwiched between two silane functional species that can form the silsesquioxane linkages (30,31). These materials are effectively cross-linked by the inorganic moieties. The organo part can be changed readily, but is kept relatively short so that phase separation does not occur. Drying conditions and solvents can have a major effect on the porosity of the products formed, ranging from nonporous to microporous. These materials can have application in sensors, catalysts, optics, and coatings.

One final class of materials that is being increasingly considered for use in composites is that based on polyhedral oligomeric silsesquioxanes (POSS) (see HYBRID PLASTICS) (8,14,32–34). A variety of different cage structures have been discovered, but more recently the cubic structure is receiving increased attention

as its production costs are decreased. POSS molecules can be used to reinforce organic polymers with either functional or nonfunctional groups at any or all of the vertices of the cages. With the proper functionality, the POSS molecules can be incorporated into the backbone of organic polymers. With multifunctional reactive POSS species, the POSS material can also be effective as a cross-linking agent. The presence of the POSS in the polymer changes the glass-transition temperature, mechanical properties, and heat resistance. The small size of POSS means that it can be effectively dispersed in the polymer matrix.

Clearly, silicon-based building blocks are the foundation of a variety of materials. With other transition-metal species, these building blocks form a basic set of nanomaterials whose applications are still emerging (35,36).

SMART MATERIALS, MICROGELS

Introduction

The use of smart materials in the development of many technologically important devices and formulations is becoming increasingly widespread. However, as a result of their increased proliferation and relative novelty it is appropriate to ask: what are smart materials, how do they work, and what are their applications?

Smart materials may be broadly defined as any material that can respond to subtle changes in environmental conditions, eg, a change in temperature, pH, ionic strength, solvency, light intensity, or the influence of an applied electric field (1). One class of cross-linked polymers, often given the prefix of a "smart" or "intelligent" material, is colloidal microgel particles. These particles have been described as "smart" because of their ability to undergo, often quite dramatic, conformational changes in response to a change in their environmental conditions. Microgel particles have a high degree of sensitivity and they are capable of undergoing rapid changes in their physical properties, including changes in particle size and surface charge density. The rapidity of change comes about as a result of microgel particles having very high surface area-to-volume ratios, which allows rapid diffusion of a given stimulus, eg, a reduction in environmental pH, to facilitate a response throughout the matrix of a microgel over very short-time scales, typically of the order of a few seconds. This property has enabled particles of this type to find utility in many biomedical and industrial applications. This article aims to give the reader an understanding of how microgels may be prepared by outlining some of the synthetic strategies employed for microgel synthesis. Some of the techniques used in the characterization of these smart materials, such as calorimetry, light scattering, rheology, and neutron scattering, are also examined. Further, this article provides an overview of the diverse number of applications

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

for which smart polymeric microgels are currently finding utility. These range from enhanced oil recovery to drug delivery through sophisticated additives in the paint and coating industries.

Colloidal microgels may be defined as a disperse phase of discrete polymeric gel particles, which are typically in the size range of 1 nm to 1 μm, uniformly dispersed in a continuous solvent medium (2). Microgels are dispersions of particles—in contrast to true single-phase solutions—and as such they often display typical colloidal characteristics, eg, turbidity. They are of considerable academic and commercial interest because of their "sponge-like" properties and their ability to change molecular conformation, ie, shrink and swell in response to a number of different external stimuli. Microgels have similar properties to polymers and water-swollen gels (usually termed hydrogels or macrogels) but are discrete particles with characteristics that are dependent on the method of synthesis, cross-link density, monomer concentration, monomer composition, and solvency conditions (3,4) (see HYDROGELS).

Microgel Preparation

Several methods have been reported in the scientific literature for the synthesis of microgel particles. These include emulsion polymerization (5), inverse microemulsion polymerization (6,7), and anionic copolymerization (8) (see HETEROPHASE POLYMERIZATION).

Emulsion Polymerization. The most widely used method for the preparation of microgel particles is emulsion polymerization (1,9,10). The major limitation of this technique is that only low particle concentrations (hence dilute dispersions) can be prepared; however, a high product yield (typically around 95%) can be achieved. A surfactant may be added to the reaction to increase the concentration of particles that may be synthesized. The disadvantage of adding a surfactant to the reaction mixture is that smaller particles having typical diameters of the order of 150 nm are commonly produced (5). This occurs as small particles, formed as intermediaries in the reaction process, become stabilized by electrostatic forces originating from the added surfactant molecules. The surfactant molecules stabilize the small particles, thus preventing them from growing into larger microgels. The removal of any residual surfactant at the termination of the polymerization process can also be problematic. Remaining surfactant can affect the physicochemical properties of the microgel and can also lead to a contamination of the surface, making it irregular in composition. This in turn can affect the microgel behavior, eg, irregular deposition because of the blocking of certain surface sites.

Surfactant-free emulsion polymerization is often used deliberately to produce larger particles. This method has been reported extensively for the preparation of poly(*N*-isopropylacrylamide), ie, [poly(NIPAM)] microgel particles (10). In this procedure the microgel particles are prepared in a one-pot reaction involving the free-radical polymerization of the monomer NIPAM. The reaction is carried out in an aqueous solution in the presence of a cross-linking agent (usually *N*′,*N*′-methylenebis acrylamide) and an initiator (such as potassium persulfate), which undergoes thermal decomposition on heating to yield an anion radical. The reaction is carried out under an inert atmosphere of nitrogen and at a temperature of $\sim$70°C (or higher) to ensure the decomposition of the initiator and maintain

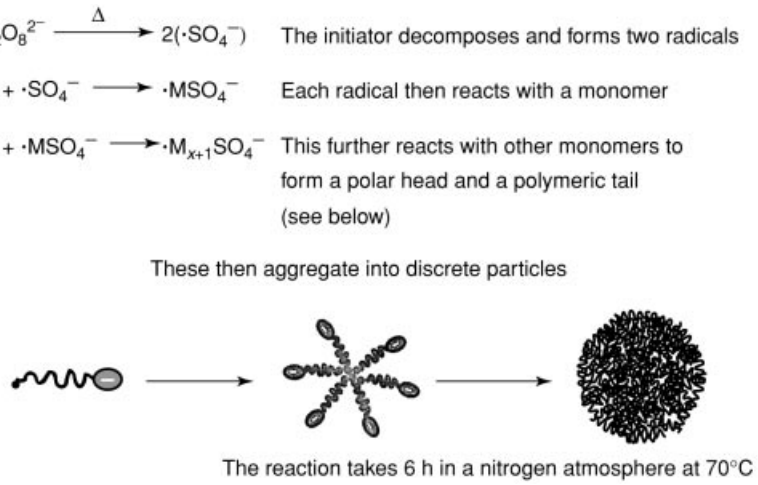

Fig. 1. Microgel preparation.

suitable reaction kinetics. The reaction is similar to that used in the preparation of a latex particle, such as polystyrene latex (11), but with the addition of a cross-linker.

The mechanism involved in the synthesis of microgel particles is shown in Figure 1 and starts with the thermal decomposition of the initiator to form free radicals. The free radicals are water-soluble and react with the monomer (across the double bond) to form monomeric radicals. These radicals participate in further reactions with other monomer units to form oligomeric radicals. The oligomeric radicals have polar end groups (originating from the initiator) and are solubilized in water until a critical chain length is reached. The oligomers aggregate and begin to mix with other oligomeric chains at which point small particles start to form. The particles grow in size until they are stabilized by electrostatic repulsion forces between charged groups on the surface of the particles. These charge repulsion forces originate from the ionic initiator. The particles continue to grow by the adsorption of further monomer units or other oligomers either until all of the monomer is used up or until another radical species enters the growing particle and terminates the reaction (10). This method yields microgels that are regular in both size and composition. Such particles are described as being monodisperse.

By the same mechanism reported for polystyrene latexes (11,12) anionic microgel particles can be prepared, with negative charges originating from a persulfate initiator, such as potassium persulfate or ammonium persulfate (1,9–13). The dominant surface charge group arising from the persulfate initiator is $-SO_3^-$, a strong acid group with $pK_a \sim 1.5$. Because of the low pK_a value the surface sulfate charges will remain ionized and hence the microgel will retain its negative charge over a wide pH range. Microgels having weaker acid surface groups, eg, $-COO^-$, may be prepared using, eg, 2,2′-azobiscyanovaleric acid as the initiator (11). The carboxyl groups have a $pK_a \sim 5$ as a result, at low dispersion pH, the microgel will have a lower charge density than at higher pH because of the lower dissociation of the carboxyl protons. This can have implications for microgel

interactions, both with themselves and with other surfaces, eg, during deposition where pH conceivably could be used to either enhance or diminish the extent of deposition which may occur through an increase or decrease in the charge density at the microgel surface. Cationic microgels can also be prepared by using a positively charged free-radical initiator [such as 2,2′-azobis-(2-amidio propane) dihydrochloride] (13–16), which gives the particles a positive charge in the form of amidine groups [ie, protonated amines (NR_3^+)].

Much of the work reported in the academic literature is based upon microgels prepared from poly(NIPAM), but there are, however, a number of microgels that have been prepared from other monomers. These include methyl methacrylate with other copolymers such as ethylene glycol dimethacrylate (17,18), methyl methacrylate with *p*-divinylbenzene (19), and methyl methacrylate with methacrylic acid (20). Other microgel particles have been prepared from poly(allylamine hydrochloride) (21), vinylpyrrolidinone and acrylic acid (22), acrylamide and acrylamide with methacrylamidopropyltrimethylammonium chloride (23), and acrylamide copolymerized with 2-acrylamido-2-methylpropanesulfonic acid (24).

Preparation of Microgel Particles Having Novel Morphologies. Some of the more recent research into novel microgels involves the synthesis of microgels having a structure resembling a flower (25). The preparation of one of these types of structures is shown in Figure 2. The flower microgels are prepared by using a suitable polymer having two distinctly different monomers. One

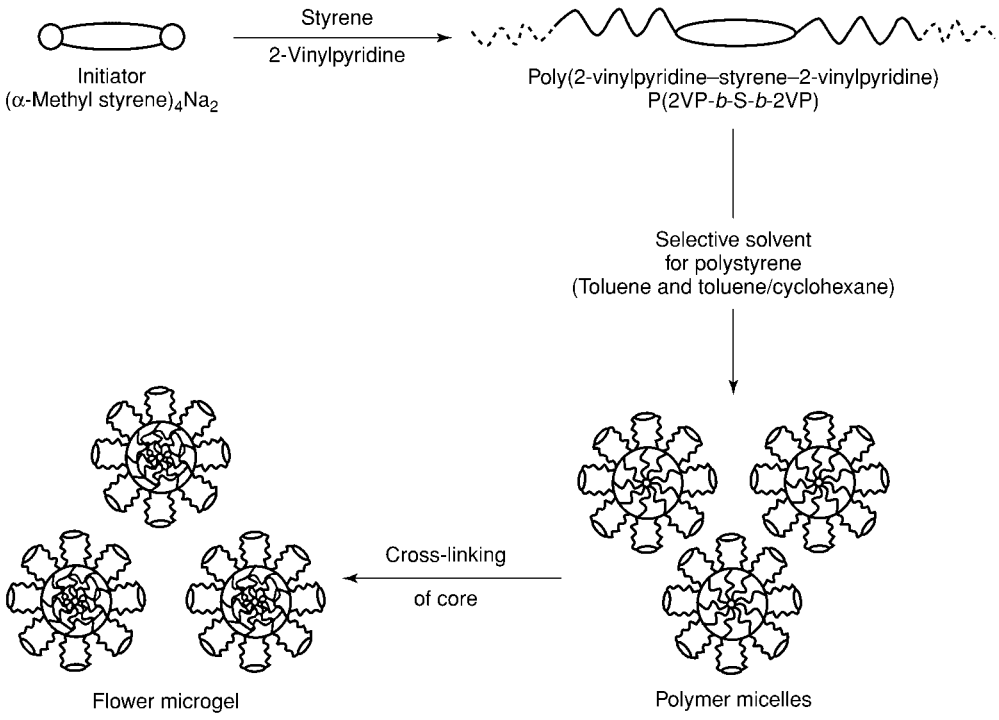

Fig. 2. Preparation of flower microgels. Redrawn from Ref. 26.

of the monomers is hydrophobic (A, which in this example is styrene) and the other is hydrophilic (B, vinylpyridine), which are copolymerized to form a triblock BAB copolymer. The resultant polymer chains are then exposed to a selective solvent, toluene and toluene/cyclohexane. In this particular case toluene is a good solvent for the A block and is a nonsolvent for the B block, which results in the formation of a polymer micellar structure. The central part of the flower micelle structure is then "fixed" by subsequent crosslinking with 1,4-diiodobutane, again using toluene as the solvent for the reaction.

The novel morphology and micellar structure of flower microgels allows them to be utilized as absorption centers for both hydrophilic and hydrophobic solutes. These structures permit the absorption of hydrophobic solutes into the hydrophobic domains within the microgel structure. It could be envisaged that a poorly water-soluble drug may be solubilized within the hydrophobic domains of the flower microgel structure. One advantage that flower microgels may offer over surfactant micelles is that their molecular structure is not concentration-dependent. Therefore, these materials may find application at concentrations lower than the critical micelle concentrations of many surfactants.

Poly(NIPAM) microgel particles have been used as a micromatrix for the polymerization of a second hydrophobic monomer, *N*-methylpyrrole (Mpy) (27). The microgel particles are synthesized first, and are then reacted with Mpy in the presence of an initiator (ammonium persulfate). The resultant poly(NIPAM)-*co*-poly(MPy) particles have a "raspberry" morphology, with poly(Mpy) particles located within the poly(NIPAM) structure. Small poly(Mpy) particles (15 nm) are found centrally, while larger 60-nm poly(Mpy) particles are located close to the poly(NIPAM) periphery. This is the first example of poly(NIPAM) microgel particles being used as a host for the preparation of particles from a second monomer. The poly(NIPAM)-*co*-poly(MPy) microgel particles are colloidally stable and exhibit a conformational phase transition at 32°C upon heating. Similarly to the poly(NIPAM) microgel particles described above, they also aggregate upon heating in an electrolyte solution (0.1 *M* NaCl).

Larger poly(NIPAM) microgels or "minigels" have been prepared by inverse suspension polymerization (28). These particles are much bigger than conventional microgel particles and are in the order of 2.5-μm diameter at 25°C and so have been given the name minigels. Minigels show physicochemical properties similar to those of microgels and have a reversible conformational phase transition as a function of temperature. Interestingly the reswelling of the minigels, on cooling, may take up to 15 min to reach a fully swollen state, showing the benefit of the rapid swelling/deswelling phase transition of microgel particles.

Preparation of Core–Shell Microgels. The preparation and electrokinetic and colloid stability behavior of styrene–*N*-isopropylacrylamide and styrene–*N*-isopropylacrylamide-*co*-aminoethyl methacrylate (AEM) core–shell latexes have been reported in Reference 29, where the particles having a core of polystyrene surrounded by layers of (*1*) poly(NIPAM) and (*2*) poly(NIPAM-*co*-AEM) were prepared. The particles were produced by first synthesizing the polystyrene core via a surfactant-free polymerization reaction and then, when the formation of the core was ~90% complete, the shell was generated by the addition of the NIPAM monomer and crosslinker N′,N′-methylenebisacrylamide (*1*). In the case of core–shell particles, NIPAM, aminoethyl methacrylate, and the

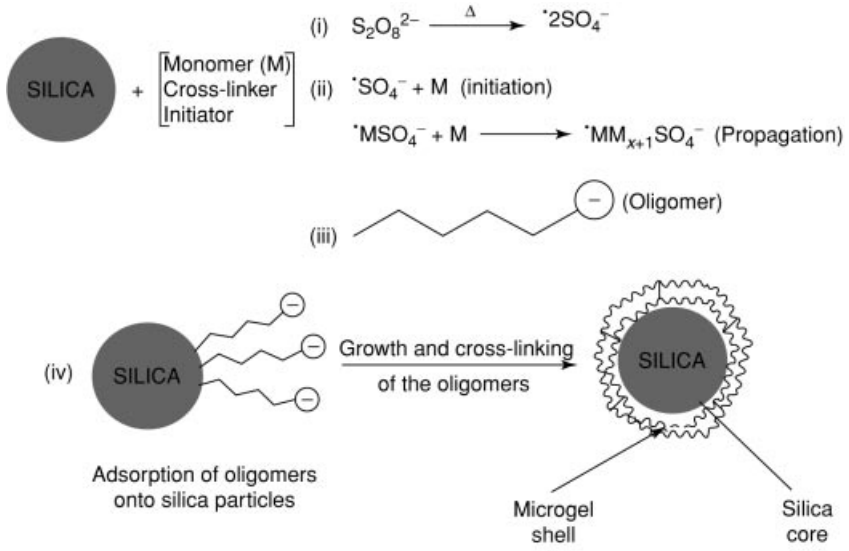

Fig. 3. Proposed mechanism for the preparation of core–shell microgels.

crosslinker were added (*2*) The thickness of the shell surrounding the core can be controlled by increasing or decreasing the environmental temperature of the dispersion, with the shell collapsing at a temperature above the critical solution temperature for poly(NIPAM). Under these conditions the particles could be made to destabilize and undergo an aggregation. A similar approach was adopted in Reference 30, where core–shell microgels were synthesized by polymerizing NIPAM and N′, N′-methylenebisacrylamide in the presence of potassium persulfate around a mondisperse silica core. The mechanism outlining the formation of core–shell particles is illustrated in Figure 3. The resultant particles formed via this process were found to be monodisperse. The thickness of the core was examined by a combination of neutron scattering and dynamic light scattering techniques, as a function of temperature. The distance over which the shell extended was also found to decrease with increasing temperature.

Characterization of Microgels

A number of techniques are commonly employed for the study of microgel dispersions. These include dynamic light scattering, differential scanning calorimetry, electron microscopy, nuclear magnetic resonance spectroscopy, and neutron scattering. These techniques provide information on particle size, shape and size changes, the thermodynamic processes which take place as the microgels undergo their conformational transitions, and fine detail regarding the polymer microstructure within the particles in addition to the relative hydrophobicity and hydrophilicity of the particles.

Dynamic Light Scattering. Dynamic light scattering is a particularly useful technique for monitoring the conformational behavior of microgels in different solvent environments. It allows the measurement of the hydrodynamic

diameter of the microgels by monitoring the diffusion coefficient (D) of the particles in dispersion:

$$D = \frac{kT}{6\pi\eta a}$$

where k is Boltzmann's constant, T is the temperature, η is the viscosity of the dispersion medium, and a is the hydrodynamic diameter.

There are numerous reports in the literature where dynamic light scattering has been used to follow microgel behavior (16,20,31,32). By comparing the hydrodynamic size before and after a transition it is possible to determine the swelling ratio of the microgel, which is useful in terms of potential applications including drug delivery and rheology modification.

Differential Scanning Calorimetry. The use of differential scanning calorimetry (dsc) to study microgel dispersions was pioneered at the University of Greenwich, London (33). The technique can be applied to microgel systems that undergo a thermally induced conformational transition. Poly(NIPAM) microgels, for example, undergo a thermal conformational transition at 34°C in water. A typical dsc output for the transition is shown in Figure 4. The instrumental output is an endotherm for the heating cycle and a mirror image exotherm for the cooling cycle. As the microgel is heated, a series of processes begin to take place. The major contribution to the calorimetric output is the expulsion of water from the

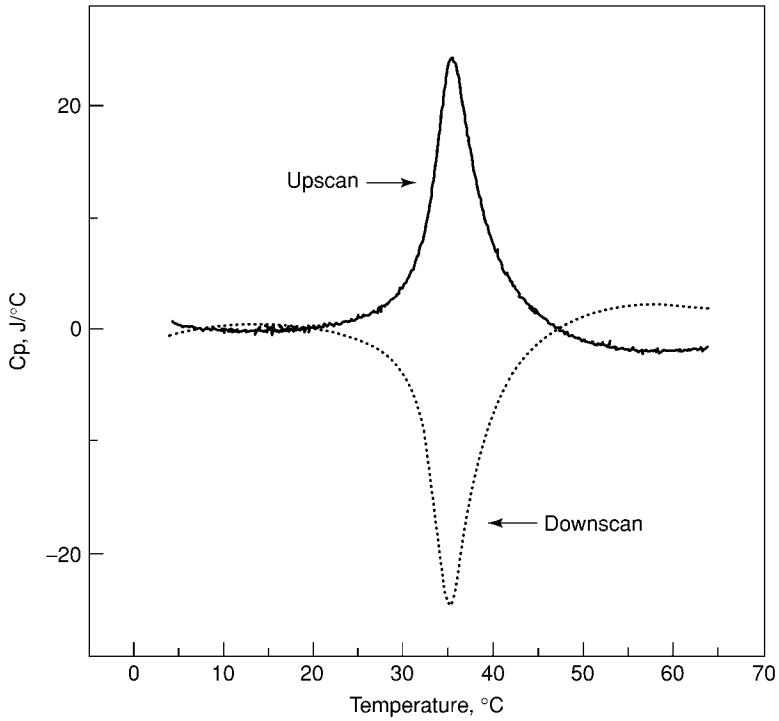

Fig. 4. A typical dsc output for a poly(NIPAM) microgel dispersion.

regions surrounding the polymer chains. This breaking of the polymer–solvent interaction is an endothermic process. In addition to the expulsion of water from the microgel structure some aggregation of the polymer chains will inevitably take place as the microgel structure collapses. From the calorimetric output information regarding the enthalpy change associated with the conformational transition, the precise temperature of the transition and some detail regarding the extent of chain aggregation within the microgel may be obtained.

Other Techniques. Small-angle neutron scattering has been used to study microgel behavior by a number of research groups (34,35). Fine details regarding the uniformity of the structure and the change in the dynamics of polymer–solvent interactions as a function of temperature may be determined using this technique. Further details regarding the nonuniform nature of microgel surfaces may also be obtained from neutron scattering measurements.

The diffusion and relaxation behavior of solvent both within and external to a microgel may be measured using nmr. The technique provides information regarding the internal environment of a microgel. For example, it has been reported that the internal environment of a microgel is considerably more hydrophobic than the exterior (36), a finding which may have application in the use of microgels as hosts for poorly water-soluble materials.

Transmission electron spectroscopy has been widely used to study microgel dispersions (37–39). The technique offers the advantage of being able to study a real image that illustrates both the size and the shape of the particles. One cautionary note, however, regarding the use of electron microscopy in studying microgels has been reported (40). In the electron microscopy chamber the microgels are exposed to high vacuum conditions and as a result the microgel particles, which are readily deformed, form pancake-like structures, thus misrepresenting their hydrodynamic shape which is much more spherical.

Properties of Microgels

Microgels differ from bulk gels in a number of fundamental ways. Some of these are illustrated in Figure 5, and include significant differences in bulk viscosity characteristics, rapidity of solution response, and surface area-to-volume ratios. Although bulk gels and microgels have very similar polymer chemistry, their physical molecular arrangement can give rise to the differences stated. This review focuses primarily on microgels; however, it is worth noting that some of the polymer chemistry behavior described may equally be as applicable to bulk gels as it is to microgels.

Microgels that are sensitive to pH, electrolyte concentration, light intensity, or the introduction of a cosolvent (nonsolvent) to their environment can be prepared. Table 1 shows a selection of different microgels reported in the scientific literature, which have been prepared to respond to specific external stimuli. The properties of some of these microgels are discussed below.

Effect of Temperature. Poly(NIPAM) microgels are by far the most widely investigated and reported systems (1,9,10). The first reported preparation of microgel particles of this type was by Pelton and Chibante in 1986 (13), where they used a surfactant-free emulsion polymerization process to produce a dispersion

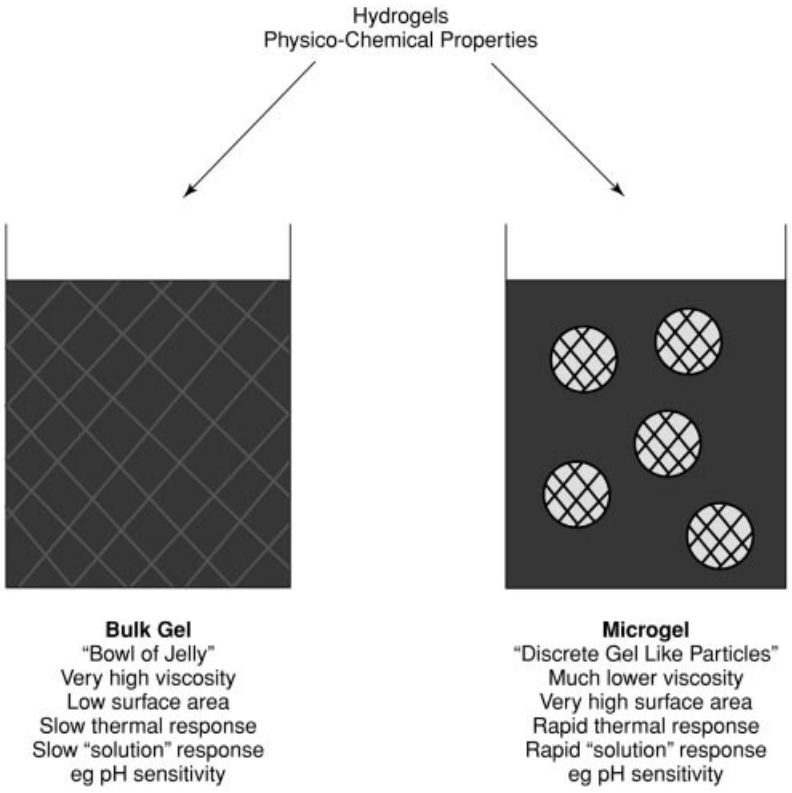

Fig. 5. A comparision of the physicochemical properties of bulk gels and microgels.

of monodisperse microgel particles. The particles formed were of interest because they showed a thermoreversible "conformational transition" in water at around 34°C. Below this temperature the microgels have a swollen conformation as a result of low van der Waals attractive forces and hydrogen bonding, with the interstitial spaces of the microgel being filled with water molecules. When the environmental temperature of the dispersion approaches the transition temperature of 34°C, the polymer–solvent interactions decrease dramatically and the particles begin to contract. The polymer chains collapse as polymer-polymer interactions dominate over polymer–solvent interactions. The polymer molecules now prefer to interact with themselves rather than with water molecules, and the hydrogen bonds that conferred stability are now disrupted. As the microgel shrinks, a high proportion of the entrapped water is excluded from the regions within the polymer matrix and the particle begins to form a hard sphere-like structure. When the microgel particles are in their collapsed state, they remain dispersed as a result of electrostatic repulsion between charged groups (originating from the initiator) on the microgel surface. The shrinking of microgel particles is a reversible process and so on cooling back to below 34°C, the polymer–solvent interactions ameliorate and the microgel returns to its original swollen conformation. Figure 6 shows the shrinking and swelling of poly(NIPAM) microgel particles.

Table 1. The Structure and Properties of Some Common Colloidal Microgels

Type	Structure	Specific environmental stimuli	References
Homopolymers	Poly(NIPAM), $[H_2C{=}CHCONHCH(CH_3)_2]_n$	Temperature (~34°C)	1,9,10
	Poly(*N*-ethylacrylamide), $[H_2C{=}CHCONHCH_2CH_3]_n$	Temperature (~78°C)	31
Copolymer microgels	Poly(NIPAM)–acrylic acid, $[H_2C{=}CHCO_2H]$	pH (swells between pH 4–6)	41
	Poly(NIPAM)–crown ether $[H_2C{=}CHCONHC_6H_3(O_6C_{10}H_{20})]$	Chemically responsive microgel (specifically K^+ and Na^+ ions)	42
	Poly(NIPAM)–vinyl imidazole $[H_2C{=}CH(NCH_2NCH_2)]$	Microgel behaves as a reaction centre	43
Flower microgel	Poly(2-vinylpyridine–styrene-2-vinylpyridine) 	Solvent hydrophobicity	25
Ampholytic microgel	Poly(vinylbenzyl chloride–*tert*-methacrylate–trimethylamine)	Specifically designed to be used as a catalytic medium	44,45

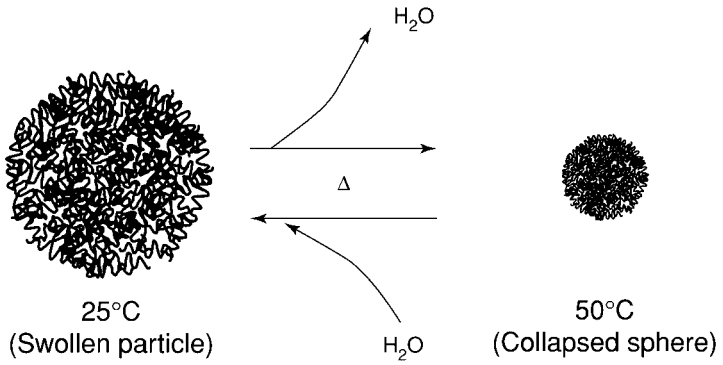

Fig. 6. Thermosensitive properties of a poly(NIPAM) microgel.

Microgel particles have also been prepared using poly(*N*-ethylacrylamide) [poly(NEAM)] (31), a monomer structurally similar to poly(NIPAM). Poly(NEAM) is less hydrophobic than poly(NIPAM), and the resulting microgel particles prepared from poly(NEAM) have a much higher transition temperature of 78.2°C. Therefore, the temperature at which the conformational transition occurs can be manipulated to suit a number of applications by simply changing the monomer used in the preparation. The more hydrophobic the monomer, the lower the temperature at which any conformational transitions will take place in water.

The advantage of using microgels over linear polymers and macrogels is the speed at which the conformational change occurs. It has been reported that the equilibration time for microgels is ∼1 s (26,46). This is much faster than the equilibration time needed for the typical swelling of polymers and macrogels in solution, which is in the order of hours or days. The cross-linking of the polymer chains in a microgel means that the distance between polymer chains in a microgel is a great deal shorter when compared with the distance between linear chains in solution, and this gives rise to the speed at which the polymer chains collapse. The large surface to volume ratio of microgels also aids rapid chain collapse, giving microgels an advantage over their macrogel and linear polymer counterparts. The phase transition of high concentrations of the linear polymer chains of poly(NIPAM) in solution have been shown to resemble the shrinking behavior of a microgel (47). At dilute polymer concentrations, the linear poly(NIPAM) has a phase transition resembling a random coil-to-globule collapse with a transition temperature of 34.1°C. However, at higher polymer concentrations linear poly(NIPAM) has a phase transition similar to that of a poly(NIPAM) microgel, where a transition resembling the diffusion of water from within the gel structure is observed.

Swelling Behavior. The extent of swelling (or deswelling) is the most useful property of microgel particles. The swellability of microgel particles is dependent on the cross-linker concentration (48) used in the preparation. High levels of cross-linker will result in a large microgel particle having a tight compact structure, with its center being difficult to penetrate. Higher concentrations of cross-linker will also give rise to a faster conformational transition as the polymer chains are closer together, thereby enabling a quicker collapse. However, at low cross-linker densities the microgel particles have properties resembling high

molecular weight polymers. Generally, microgels are prepared with an average cross-linker density somewhere between these two extremes, although the cross-linker density is usually uneven between each individual microgel particle and is given as an average cross-linker density per dispersion.

Colloid Stability. The stability of microgel particles in water at 25°C is a result of low van der Waals attractive forces coupled with some steric contributions from the polymeric chains at the periphery of the particles. The low van der Waals forces are a consequence of the particles being fully swollen with solvent molecules, and the microgel Hamaker constant resembles that of the solvent, thereby resulting in low van der Waals attractive forces. The Hamaker constant is the basis of the van der Waals attractive force. Its origins lie in the temporary and permanent dipoles, which exist within a macroscopic material. For a microgel-type particle, the macroscopic material consists of a combination of a polymer matrix and the water contained within its structure. In a swollen state, the fraction of water in the total structure is large and hence the Hamaker constant is much closer to that of bulk water, resulting in a negligibly small attractive force existing between the microgels. When the particle collapses, as a result, eg, of heating the dispersion, the fraction of water within the structure decreases and the Hamaker constant increases as it now reflects a larger percentage of polymer contributing to the overall structure. The van der Waals forces increase but the particles remain dispersed because stabilization is brought about by electrostatic repulsion between charged groups on the surface of the microgels. These originate from the initiator used during the preparation of the microgel particles.

The stability of microgel particles in electrolyte is somewhat different to that of other model colloids. Colloidal particles such as silica or polystyrene latex flocculate in electrolyte at room temperature when the concentration of electrolyte exceeds their critical flocculation concentration (49,50). Poly(NIPAM) microgels, however, are stable in electrolyte at room temperature but will reversibly flocculate when heated above their lower critical solution temperature (LCST) in an electrolyte solution. It has been shown that poly(NIPAM) microgel particles at 40°C flocculate at an NaCl concentration above 0.06 M (51). These particles were also found to redisperse on cooling back to 25°C. The stability of the microgel particles at 25°C in an electrolyte solution is, as a result of the low van der Waals forces, from the particles being swollen in solution. Therefore, the particles remain dispersed even though electrostatic repulsion has been reduced by the presence of electrolyte ions. At 40°C the solvent molecules are forced out of the microgel and van der Waals attractive forces subsequently increase. Since the ionic groups on the microgel are screened by electrolyte ions, the particles aggregate when heated, as van der Waals forces now dominate. This process is reversible and so on cooling, the particles reswell and the van der Waals attractive forces decrease, resulting in a stable dispersion.

Rheological Properties. The rheological behavior of microgel particles as a function of temperature has been investigated (52,53). Not surprisingly, the viscoelastic properties of poly(NIPAM) microgels change quite dramatically with temperature. At low temperatures poly(NIPAM) dispersions display a very elastic-type behavior. This, perhaps, is not surprising, as the particles are readily deformable below their critical phase-transition temperatures. A microgel can be envisaged as a sponge-like material having elastic properties when swollen.

Upon heating a dispersion above the critical phase-transition temperature, the dispersion becomes less elastic and displays the rheological characteristics typical of any particulate dispersion. The rheology of the dispersions as a function of the volume fraction of particles has also been examined (54), and the viscosity and shear thinning behavior increases as the volume fraction increases. This may be attributed to the microgel at elevated volume fractions effectively absorbing the dispersion solvent to within the polymer matrix, thus forming a putty-type material. The application of shear to this material results in a "squeezing" coupled with a deformation of the microgel, resulting in a reduction in volume and simultaneous solvent expulsion. This in turn causes the viscosity of the dispersion to decrease. Poly(NIPAM) microgels were shown to exhibit unusual behavior (55) when compared to the linear polymer poly(NIPAM). This difference comes about when the two systems are heated to their critical phase-transition temperature. The linear poly(NIPAM) is believed to undergo intermolecular aggregation, resulting in an effective increase in the molecular mass of the polymer, hence increasing its viscosity. Additional chain entanglement, around the LCST, will also contribute to an increase in viscosity. As the temperature rises further the linear polymer chains collapse; a sudden and dramatic reduction in viscosity is observed. In a microgel such behavior cannot readily take place as intramolecular aggregation is inhibited by the presence of the cross-links within the structure. Further, intermolecular aggregation is inhibited by increases in surface charge density above the critical phase-transition temperature, resulting in enhanced particle separation.

Osmotic Deswelling. Poly(NIPAM) particles have been reported to undergo osmotic deswelling in a good solvent by the addition of a nonadsorbing polymer to the microgel dispersion (56). The deswelling of the microgel particles in various polyethylene glycol–water solutions was found to be due to the loss of water from inside the microgel network so as to minimize the osmotic pressure of the solution outside the gel.

Addition of methanol to a poly(NIPAM) microgel dispersion has been shown to have a significant effect on microgel particle size (57,58). At 25°C, both pure water and pure methanol are good solvents for the microgel and the particles have a swollen conformation. The particles collapse in a volume fraction between 0.2 and 0.4 methanol, and then reswell at high volume fractions of alcohol. The decrease in particle size has been attributed to the removal of water molecules from within the microgel structure, to form distorted tetrahedral structures around the alcohol molecules. The hydrogen bonding and hydrophobic interactions within the microgel are disrupted and the microgel collapses. This is termed *co-non-solvency*. As the methanol volume fraction is further increased the microgel particles reswell. The alcohol molecules interact through hydrogen bonding and hydrophobic interactions, resulting in an increase in particle size.

Influence of Comonomers on Microgel Properties. The overall physicochemical properties of a microgel depend not only on the cross-linker concentration, but also on the concentration of monomer/comonomers used in the synthesis. The addition of a small amount of comonomer (typically 1–5 wt% monomer) can have a dramatic effect on the overall properties of the resultant microgel particles. For example, a pH- and temperature-sensitive microgel can be prepared by copolymerizing poly(NIPAM) with acrylic acid. These spherical particles undergo

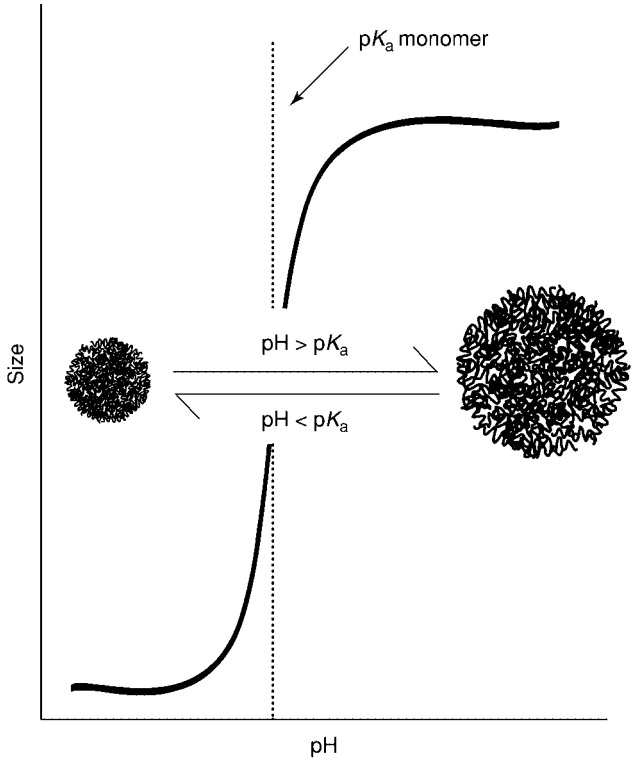

Fig. 7. Shrinking and swelling of a poly(NIPAM)-*co*-acrylic acid microgel.

a conformational transition in response to an environmental pH change (41). By selecting monomers that have pK_a values corresponding to the transition pH of interest, microgels having tailored pH-dependent transitions can be prepared. In the case of an acidic monomer (eg, acrylic acid), the microgels typically adopt a compact structure at a pH below the pK_a of the monomer. At a pH value above that of the pK_a, the polymer chains of the microgel become ionized, forcing the microgel to adopt a more extended conformation as a result of intramolecular charge repulsion. Under these conditions the microgel swells (Fig. 7).

When (NIPAM) is copolymerized with a vinyl crown ether monomer, the resultant microgel particles show a phase-transition dependency based upon the addition of certain metal ions (42). Addition of K^+ ions results in a notable increase in the phase-transition temperature, while the addition of Na^+ results only in a small increase (up to 7.5°C was observed for K^+ ions as compared to 1.5°C for Na^+ ions). This anomaly is attributed to the binding affinity and size of the metal ion used. Potassium ions have a higher affinity for the crown ether groups than the sodium ions, and can fit more easily into the cavity of the crown ether. Binding of the K^+ ions makes the microgel more hydrophilic, which increases the phase-transition temperature. Interestingly, Li^+ ions are not captured by the crown ether microgel and the phase-transition temperature in dispersions containing these ions remains unchanged.

Applications

Currently, microgels are being investigated for their potential use as drug delivery vehicles, binding/adsorption agents, catalytic media, and their ability to improve existing industrial formulations, eg, specialist paints. The next sections describe how microgels are utilized in these applications and also describe some of the newly investigated uses of these polymeric smart materials.

Drug Delivery Vehicles. The shrinking and swelling of microgel particles makes them particularly suited to applications such as drug delivery, where it can be envisaged that as a result of their porous matrix-like structure microgel particles can readily accommodate drug molecules. Drugs are known to partition into the interstitial regions of a microgel, especially if the drug has limited water solubility (59). It has been reported that ∼94% of the water inside a microgel is driven out during a phase transition (9) so that drug displacement, by solvent molecules, could occur following a triggered microgel conformational change. The period over which the drug is released will be dependent upon the size of microgel particles used and the level of crosslinker, which in turn affects the interstitial volume.

Copolymer microgels of poly(NIPAM)-*co*-acrylic acid-*co*-butyl methacrylate have been investigated with respect to their application for modulated insulin release (60). The butyl methacrylate within the microgel structure fulfills two roles. Firstly, butyl methacrylate confers improved mechanical properties onto the microgel. Secondly, the butyl methacrylate moiety gives rise to a high uptake efficiency of insulin as a consequence of the presence of specific insulin-binding regions on the butyl side chains of the butyl methacrylate. At low pH (pH 2), the rate of insulin release was found to be limited to ∼10 wt% of the loaded capacity of the microgel. However, upon raising the pH to 7.4 the majority of the remaining insulin was released. The acrylic acid component of the microgel facilitates an expansion of the microgel structure at higher pH, thereby enhancing the intramolecular pore dimensions and allowing a diffusion-mediated release of the insulin to take place. It is proposed that "polymeric beads" such as these may prove to be very useful vehicles for the delivery of peptides and proteins to the gastrointestinal tract. As the microgel will have a "closed" structure at the pH of the stomach (approximately pH 2), little or no diffusion of the encapsulated material will take place. On moving out of the stomach into the gastrointestinal tract, the pH will increase. This allows the pores of the microgel to open and the active material to be released into a much less acidic and aggressive environment, so that the higher order structure of the peptides/proteins may be maintained longer.

Microgel particles consisting of vinylpyrrolidinone copolymerized with acrylic acid have been prepared (61). These particles were designed to be used as an oral drug delivery vehicle. The microgel particles were loaded with a marker compound fluorescein isothiocyonate (FITC)-dextran and the release of this compound was monitored as a function of pH and temperature. The release of this compound was found to be slow in an acid solution but increased rapidly as the pH was increased. There was also a subsequent increase in FITC-dextran release when the particles were heated. At 4°C ∼18% of the FITC-dextrans were released while ∼50% was released at 37°C. The increase in the amount of FITC-dextran released is due to the microgel shrinking when heated.

Poly(methacrylic acid-*co*-acrylic acid) microgels (62) are also being investigated for their use as drug delivery vehicles. A study has been carried out on the influence of cross-linker density on the uptake and release of a drug/protein from these materials, for investigating the induced swelling of the microgels following changes in pH and NaCl concentration. This study concluded that the swelling ratio of the microgel increased as the mole fraction of the cross-linker decreased (ie, the microgel polymer chains become more restricted as the number of cross-links increases). The microgel therefore has less capacity to shrink and swell as the amount of cross-linker increases. The results also suggested that binding affinity, microgel dehydration upon loading, and drug packing were also important features in determining the uptake of the drugs/proteins. These microgels potentially show promise as uptake and release vehicles, but further experiments are needed to fully optimize and identify the types of substrates that will enable these materials to be fully utilized as controlled-release devices.

A review on the applications of thermally reversible polymers and hydrogels in therapeutics and diagnostics has been written (43). In this review, the author highlights a number of uses of poly(NIPAM) polymer and poly(NIPAM) gels. These include their use in the delivery or removal of drugs, toxins, pollutants, and dyes. They can also be used in combination with immobilized ligands for use in separations and diagnostics (see CHROMATOGRAPHY, AFFINITY). Finally, enzymes and other catalysts may be incorporated into the gels for use in therapeutics, diagnostics, bioreactors, chemical processes, and bioseparations.

Binding/Adsorption Agents. A new development of novel microgel structures involves the incorporation of low levels of a particular chemical entity within the polymer matrix at the preparation stage. By incorporating vinyl imidazole (63) as a comonomer with NIPAM during the synthetic reaction, it is possible to produce microgel particles that will specifically bind certain other molecules, eg, haems, at the derivative sites within their structure (Fig. 8). Under controlled environmental conditions, the microgel–haem complex may be investigated with respect to chemical reactions taking place at the immobilized haem groups. Such application has considerable potential with the highly specific functionalities within the structures, providing opportunity for chemistry to take place on a functional group immobilized within the microgel matrix. While this type of application remains in its infancy, it may find utility in sensor technology and/or as a model system, eg, for the study of drug-receptor binding.

Although not a microgel, poly(NIPAM) hydrogels have been prepared as a temperature-sensitive gel for use as a size-selective absorbant (44). Hydrogels are simply cross-linked polymer gels in aqueous solution. The poly(NIPAM) hydrogel swells by adsorbing water but does not adsorb large molecules such as proteins or other high molecular weight polymers/solutes (polyethylene oxide and gelatin). The dry gel is placed into a sample solution where it begins to swell, with water entering the microgel. Small solutes such as urea were found to be adsorbed; therefore, the separation efficiency in this solute is poor. However, high separation efficiency was observed for large solutes of polyethylene oxide, gelatin, and polyethylene glycol, showing that poly(NIPAM) hydrogels can be used as a size, selective separation process. Hydrogels (qv) offer an advantage over other separation techniques (such as silica gels) as they can be used in dilute solutions and can easily be reused. The swollen gel is removed by filtration and is warmed or dried

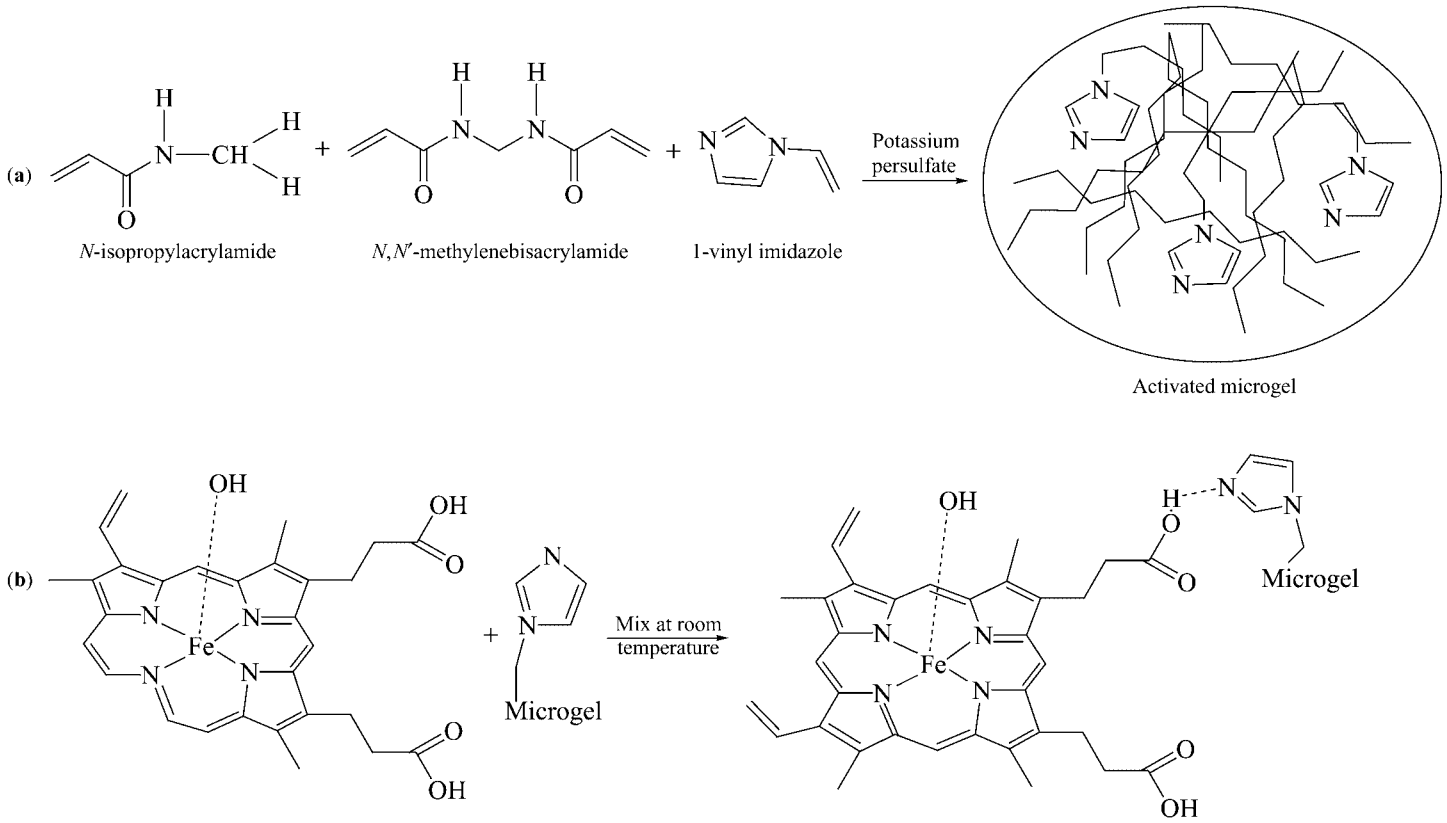

Fig. 8. Preparation and hydrogen bond formation of poly(NIPAM)-*co*-imidazole microgel particles. (**a**) Preparation of the microgel particles; (**b**) hydrogen formation: the modified microgel interacts with an aqueous solution of hematin to form a hydrogen bonded species.

to remove the water from within the hydrogel. The hydrogels behave like microgel particles, so that when heated, a hydrogel shrinks as a result of a decrease in solvent quality. The hydrogel is then ready for reuse.

Catalytic Media. Another class of microgel is a polyampholyte microgel, which has been studied with respect to its application as a colloidal catalytic media (45). For example, less than 1 mg/mL of a polyampholyte microgel based upon vinylbeznyl chloride–*tert*-butyl methacrylate–trimethylamine accelerates the rate of decarboxylation of 6-nitrobenzisooxazole-1-carboxylate ion 60–115 times faster than when carried out in water alone. The effect was reported to be similar to the catalytic activity of the more widely used hexadecyltrimethylammonium chloride micelles. These microgel particles were also found to be stable in a salt concentration of 4 *M* NaCl.

Microgel-bound oxzaborolidines have been prepared and used as catalysts in the enantioselective reduction of prochiral ketones (64). The selectivities of these microgel-supported catalysts are reported in most cases to be comparable to those achieved with low molecular weight polymers. The advantage of the application of microgel-bound catalysts is their good solubility, together with low viscosity characteristics. Microgels of this type can be easily removed by ultrafiltration because of their large size in comparison to linear polymers, making them particularly suitable for use in an on-line process system.

A further report concerning the use of microgels as catalytic centres involves microgel-stabilized palladium colloids (65). Microgels of this type can be conveniently loaded with Pd^{2+} ions, which become subsequently reduced. The resulting metal colloid can be readily precipitated out of solution and redispersed in suitable solvents for subsequent use. Preliminary experiments with these systems show them to be active catalysts for the vinyliation of aryl iodides and bromides.

Improving Existing Formations. Current industrial applications of microgels involve their use in the printing, pharmaceuticals, oil recovery, and coating technologies. Recent advances include the use of microgels in improving the coating properties of pigment particles (66). Negatively charged microgel particles have been shown to adsorb onto the surface of positively charged pigment particles, where they essentially have the role of stabilizers or dispersants. The use of microgels particles in this case promotes stability and also increases the shelf-life of these pigments. Microgels have also been added as a component in waterborne paints where they improve the film properties by increasing the tensile strength of the paint (67). Microgel dispersions are shear thinning and can be used to alter the rheological properties of a given formulation. The addition of microgels therefore fulfills a dual role within the paint, ie, acting as a strengthening agent and viscosity modifier.

New Applications. A new smart material that expands and contracts in response to certain proteins is being developed in Japan for use either as a drug delivery vehicle or as an artificial muscle (68). The material is a hydrogel prepared from two different types of polyacrylamide. At one end an immunoglobulin (IgG) protein, derived from rabbit, is attached and to the other end another antibody, derived from goat, is bound with a specific site for the rabbit IgG. In water, the two sets of molecules cross-link to each other via the IgG and antibody sites to form a tightly bound gel. The resultant gel swells in a solution of IgG because the free protein binds to the antibodies on the second type of polymer, thereby breaking the

cross-links and causing the structure to open. The gel has been designed for use in the treatment of cancer. Here, the gel could be forced to swell (release a cancer-treating drug) in the presence of cancer-specific proteins. But in the absence of the cancer protein, the gel stays in its contracted state, keeping the drug inside the gel. Therefore, these gels can be used to target and treat specific parts of the body that have been affected by cancer.

Researchers claim that they have "engineered a new class of gel with two levels of hierarchy." In fact, they have used microgels as building blocks to form macrogels with "new and unique" properties (69). They further suggest that such macrogels may lead to new technological applications, eg, in drug delivery, sensors, bioadhesives, and displays. A further novel development is the use of monodisperse hydrogel particles consisting of poly(NIPAM) chemically cross-linked with *N′*,*N′*-methylenebisacrylamide to form colloidal crystals and glasses in concentrated solution. This development is explored in an experimentally rigorous article (70).

A new possible application of colloidal microgels is as a support matrix for the immobilization of chemical entities. Solute molecules can freely enter the microgel structure, undergo a chemical reaction, and then the product can exit the polymer matrix. This offers a unique potential application for microgels as catalytic centers. Additionally, as the microgel can be used as an immobilized support and as a result of their characteristic high surface area-to-volume ratio (typically 10 m^2/g), they may find application for new approaches, eg, to peptide synthesis or combinatorial chemistry.

Conclusions

Microgels have become of enormous academic and commercial interest in recent years, with an exponential increase taking place in the number of published works on the subject. As the understanding of microgel structures and their physicochemical properties increases, their commercial utility expands simultaneously. Initial interest in these materials was suppressed because of their high manufacturing cost and limited availability. The development of high value products, such as cosmetics and specialist paints, incorporating microgels, allowed an expansion of their use. As the potential range of applications of these materials increases, the future utility of smart polymer matrixes seems unlimited, with innovation and invention being the controlling factor for their future utilization.

STATISTICAL THERMODYNAMICS

Introduction

The objective and mode of thinking of statistical thermodynamics, its elementary tools, and model building are directly relevant to polymer physics. This article introduces the subject and relevant key references from a modern point of view. Perhaps the best introductory material is the problem source book (1,2), while Reference 3 is a standard reference. Minimum prerequisites are the rudiments of thermodynamics (4,5), and mechanics (6,7). Understanding of probability is very helpful (8).

Objective and Mode of Thinking

Macroscopic objects contain many atoms and molecules. Although these elements may obey the laws of (quantum) mechanics, it is extremely costly, and often meaningless, to know the mechanical motion of each element. Fortunately, these objects obey their own macroscopic laws, as demonstrated empirically. Typical examples of these laws are thermodynamics and hydrodynamics. These laws describe relations among macroscopic observables. They are usually called phenomenological laws and are often regarded as less fundamental than, eg, the laws of mechanics. However, the laws of, eg, thermodynamics are asymptotically exact, and should not be regarded as an inaccurate approximation of something more fundamental. It should not be forgotten that the laws of mechanics are also empirical laws. The founding fathers of statistical mechanics, including Gibbs and Einstein, tried to justify thermodynamics with mechanics, but the subsequent history tells us that the mechanics they relied on was less reliable than thermodynamics.

To understand systems consisting of many elements with the aid of thermodynamics and mechanics is the objective of statistical thermodynamics. The advent of single macromolecule experimental methods emphasizes the importance of the study of mesoscopic systems and fluctuations. Macroscopic and mesoscopic observables (henceforth simply called macro-observables) are interpreted as sums of many microscopic quantities or coarse-grained stochastic quantities. Thus, elucidating macroscopic or mesoscopic behavior in terms of the properties of elements inevitably becomes statistical. The laws of large numbers and the large deviation principle (8) become the key mathematical tools.

The problems in statistical thermodynamics fall into two categories. The first category involves the study of the structure of phenomenological framework and the interrelations among macro-observables without calculating their actual values. The second category involves the calculation of the actual values of parameters appearing in the phenomenology from more microscopic parameters. The first category concerns finding and explaining the relationships among macro-observables appearing in the description of a class of states of materials. The two main problems are to recognize well-defined classes of phenomena, called universality classes, and to construct suitable models (the so-called minimal models) for these classes. These models are statistical but their elements need not be molecules or atoms. There is a wide range of choice of elementary objects; truly atomistic pictures can even be counterproductive. A typical problem in the second category is to compute phenomenological parameters, eg, viscosities or phase-transition temperatures, which, by definition, reflect the specificity of the individual systems. For the second-category problems, the source of the microscopic parameters is delicate; they are often obtainable only through macroscopic comparisons. Thus, it is difficult to obtain model-free conclusions, although practically useful results may be obtained.

Equilibrium Problems

The main theoretical framework of the static aspect of statistical thermodynamics is Gibbs statistical mechanics. The universal behavior of macroscopic objects

can be described phenomenologically with the aid of equilibrium thermodynamics with five major laws [(4,5); those who are serious about thermodynamics must read Ref. 9]: the existence of thermal equilibrium and temperature (the zeroth law); the conservation of energy (the first law); the variational principle for entropy (the second law); the inaccessibility of the absolute zero temperature (the third law); and the clear distinction between extensive and intensive quantities (sometimes called the fourth law). The equilibrium states of macroscopic objects comprise a universality class characterized by equilibrium thermodynamics, and statistical ensembles should be understood as minimal models for this class.

All macroscopic observables are obtainable from the distribution of microscopic states (henceforth, microstates) of elements that obey mechanics. Strictly speaking, this is the most basic assumption of statistical thermodynamics. However, to elucidate macroscopic phenomena, it is not necessary to know the true distribution of microstates of the system. Boltzmann introduced the concept of orthodic ensembles that are compatible with thermodynamics. In practice, an orthodic ensemble is established by demonstrating that it is compatible with the laws of mechanics and with the laws of thermodynamics. Gibbs demonstrated that the canonical distribution function

$$P(\{q\}) = \frac{1}{Z}\, \mathrm{e}^{-H(\{q\})/k_{\mathrm{B}}T} \tag{1}$$

with the micro–macro relation dictated by the expression for the Helmholtz free energy A:

$$A = -k_{\mathrm{B}}T \log Z \tag{2}$$

satisfies the above compatibility requirement. Here, $\{q\}$ collectively denotes the microscopic coordinates, $H(\{q\})$ is the Hamiltonian of the system, k_{B} is the Boltzmann constant, and T is the absolute temperature. Z is the normalization constant of the distribution called the canonical partition function:

$$Z = \sum \mathrm{e}^{-H/k_{\mathrm{B}}T} \tag{3}$$

where the summation is the sum (integral) over all the microscopic states. A physical derivation of the canonical ensemble was given by Einstein, whose starting point was the principle of equal probability: the probability of finding a microstate on a constant-energy surface is independent of the microstate (the microcanonical ensemble). Einstein introduced the canonical ensemble as a subensemble of a microcanonical ensemble. Then, he identified heat as the energy imported to the microscopic degrees of freedom, and derived equation 2 (for a historical account see Ref. 10). There are many arguments demonstrating the naturalness of the canonical distribution. Lenard (11) demonstrated, crudely put, that the distribution of microstates as given by the canonical distribution is equivalent to

the second law in the form of "passivity", $\Delta A \leq W$, where W is the work done to the system to change it from an initial to a final equilibrium state at the same temperature, with ΔA being the free-energy change between these two states. A stronger statement is possible [Jarzynski's equality (12)]

$$\left\langle \mathrm{e}^{-W/k_B T} \right\rangle = \mathrm{e}^{-\Delta A/k_B T} \tag{4}$$

Here, $\Delta A = A_b - A_a$, where A_s is the Helmholtz free energy of the equilibrium state with the Hamiltonian H_s ($s = a$ or b) with the temperature T, and $\langle\ \rangle$ implies the average over many experiments, where W is the work in each run of the experiment changing the Hamiltonian from H_a to H_b according to a fixed protocol with the initial ensemble given by the canonical distribution $\propto \mathrm{e}^{-H_a/k_B T}$. Although it is not easy to use this equality for a macroscopic system, it is practically useful for single-molecule experiments (cf. 13).

Mathematically speaking, statistical mechanics must study a system in the thermodynamic (large system) limit. In this limit, the system Hamiltonian does not exist. Thus, we need an indirect way to introduce the distribution (measure) in the thermodynamic limit. This is the theory of the Gibbs measure (14,15). If we wish to understand phase transitions as mathematical singularities of thermodynamic potentials, we must take the thermodynamic limit. When the Gibbs measure for a system is not unique the system exhibits a phase transition.

If we look at a small portion of a macroscopic system or study a mesoscopic system, we must study fluctuations. The probability of fluctuations is phenomenologically described by the thermodynamic theory of fluctuations (5). From the ensemble theory point of view, the fluctuation theory is the study of large deviations from the expectation value. This is the reason why large deviation theory is becoming increasingly important in statistical thermodynamics. Standard works on large deviation theory are References 16 and 17; perhaps as accessible introduction to the topic may be found in Reference 18.

Nonequilibrium Problems

Even more challenging problems than those discussed above arise from the consideration of time-dependent and nonequilibrium properties of macroscopic systems. Unfortunately, there is no general theoretical framework tantamount to the Gibbs statistical mechanics. Most likely, there is no universality class that can be called the macroscopic nonequilibrium class. There is, however, a class that may be called the linear nonequilibrium class. Its phenomenological framework is the linear nonequilibrium thermodynamics, which contains several fundamental laws: the second law as the positivity of entropy produced inside the system as a result of dissipation; phenomenological linear force–flux relations; and the Onsager reciprocity stating the symmetry relations among kinetic coefficients (19,20). We also assume that thermodynamic relations hold locally in space (this is called the local equilibrium assumption).

The fundamental statistical thermodynamic idea for the linear nonequilibrium class is that fluctuations can spontaneously realize nonequilibrium states in

a (small) part of a large equilibrium system. A precise formulation was given as Onsager's regression hypothesis: the decay dynamics of fluctuations is on the average the macroscopic laws governing the time evolution of macro-observables. At least formally, for example, the Navier–Stokes equation (and the associated heat equation) may be derived as the equation governing the fluctuation of the velocity field (21). The statistical principle is given as Onsager's principle [so christened by Hashitsume (22)] that can be summarized, in modern terms, roughly as follows: the Lagrangian of the Onsager–Machlup path integral is given by the large deviation function for the microscopic fluctuations. This framework tells us that the response of an observable of a system to a small external disturbance is controlled by the fluctuation dynamics of the observable [fluctuation–dissipation relations (FDR) (23,24)]. The FDR of the first kind relates the flux–flux correlation function to the corresponding transport coefficient (the Green–Kubo relations), and the FDR of the second kind gives the relation between the autocorrelation of the noise and the mobility (25). The formula for the intrinsic viscosity in terms of polymer force flux may be a familiar example for polymer scientists (26). The FDR of the second kind is of supreme importance in the construction of minimal models to elucidate time-dependent properties of systems (27) close to equilibrium. Although FDR is often called the fluctuation–dissipation theorem, its derivation is always a combination of microscopic argument and phenomenological requirements, as clearly stressed by Nakano (24).

Needless to say, most interesting phenomena in nonequilibrium are not linear. These phenomena cannot be in the class considered above, but usually they are modeled in terms of nonlinear Langevin equations of the following form (Zwanzig's nonlinear Langevin equation):

$$\frac{\mathrm{d}A}{\mathrm{d}t} = v(A) - L\frac{\delta \mathcal{F}}{\delta A} + f \tag{5}$$

or the corresponding Fokker-Planck equation describing the time evolution of the distribution function (28–30). Here, $\boldsymbol{v}(\boldsymbol{A})$ is called the streaming term, L is the (bare Onsager) kinetic coefficient (matrix), $\mathcal{F}$ is the free-energy functional, and $\boldsymbol{f}$ is the noise satisfying the FDR of the second kind: $\langle \boldsymbol{f}\, \boldsymbol{f}(t)\rangle = 2k_{\mathrm{B}}TL\delta(t)$. It is assumed that the equilibrium distribution of $\boldsymbol{A}$ is described by the distribution function proportional to $\exp(-\mathcal{F}/k_{\mathrm{B}}T)$. The streaming term $\boldsymbol{v}$ in equation 5 is often expanded in terms of the polynomials of $\boldsymbol{A}$. When this expansion is truncated at the second order, equation 5 becomes the starting point of the mode-coupling theory and dynamical renormalization group theory, with a remarkable success in critical dynamics (31). The use of the mode-coupling theory for supercooled liquids and glasses seems to be an increasingly important topic with highly interesting results (32), but its microscopic foundation is still a difficult question.

It seems that all the successfully elucidated dynamical universality classes adopt as their minimal models the ones described in terms of nonlinear Langevin equations (33). This indicates the general correctness of Onsager's principle as a fundamental principle (beyond the linear regime). Just as equilibrium statistical mechanics is a statistical framework based on the principle (of equal

probability) compatible with the phenomenological laws (equilibrium thermodynamics), nonequilibrium statistical mechanics exhibits the same structure. Thus, to deepen our understanding of nonequilibrium phenomena and to go beyond the linear regime, we need clear phenomenological understanding of a wider class of phenomena. There are some attempts (34,35), but there is no consensus.

Synopsis and Examples

Statistical thermodynamics is a discipline that elucidates phenomenological laws of a class of phenomena (a universality class) from analyses of statistical models that capture the salient features of the class (minimal models). The principal objective of statistical thermodynamics is to recognize universality classes and to find corresponding minimal models. Examples follows from polymer solution theory.

Dilute Solution. If the interchain interactions can be ignored, the polymer solution is in the dilute regime. If we are interested in the global features of a polymer, we need not respect the discreteness of each bond; we may use the Wiener process to describe the chain [thanks to Donsker's invariance principle (36)]. The interaction among nonbonded monomer units gives the well-known excluded-volume interaction and is usually mimicked by a delta-function pseudopotential. Thus, a chain described by the Wiener process interacting with itself through a delta-function pseudopotential (with an interaction contour-range cutoff) is conceived as a minimal model for static properties of dilute solutions [the Edwards model (37)]. The partition function of a chain can be conveniently described in terms of the path integral (the Feynman–Kac formula) (38,39). RG theory (for general introduction, see Refs. 40–43) has given various quantitative results for universal properties; agreement with experiment looks satisfactory (44–46). That is, we can clearly recognize a universality class of dilute-solution statics with a good minimal model.

To understand dynamics and transport properties, a set of (nonlinear) Langevin equations describing the Edwards model and the solvent velocity field is proposed as a minimal model. Comparison of the outcome of the model with experimental results has revealed that this minimal model is reasonable (47); but closely studied, less than minimal. The importance of the direct chain–chain friction must not be underestimated (48). With this additional effect, the model seems minimal, but a more careful study may be needed.

Semidilute Systems. In more concentrated solutions, the interchain interactions (overlap) cannot be ignored. Even if the monomer number density of the solution is infinitesimal, long chains can overlap extensively. This regime is the semidilute solution recognized by des Cloizeaux. In this regime the interchain interactions may still be described by the delta-function pseudopotential. For equilibrium properties the many-chain version of Edward's minimal model seems appropriate (49,50). Thus, we have the universality class of semidilute solution statics with a reliable minimal model. For dynamics, since there is extensive chain overlap, the chain entanglement cannot be ignored. The straightforward

many-body version of the dilute-solution minimal Langevin model is intractable and it is fair to say that our understanding of semidilute-solution dynamics is incomplete (51). As a minimal model, a model of fluids with the strain field effect by Doi and Onuki should be studied seriously (33). To understand dynamics in polymer solutions in general, careful simulations would become increasingly important (52).

Beyond Semidilute Solutions. Further increase of concentration gives the concentrated regime and the melt regime. Beyond the semidilute regime, the minimal model mentioned above is not adequate, because the volume fraction is now finite and it really exerts entropic forces (53). If the static model is not in a good shape, it should be clear that we do not have a reliable minimal model for dynamics of nondilute solutions. We must take into account entanglement and direct friction as well as the hydrodynamic interactions. Thus, from the statistical thermodynamic point of view, real understanding of many polymer chain systems is still beyond our reach.

STRUCTURAL REPRESENTATION OF POLYMERS

Introduction

Since virtually the dawn of modern chemistry, scientists have found it desirable to represent chemical substances by name, and also, where possible, by a structure that shows how the atoms are connected. Storage of information about a substance, whether on paper or in a computer database, is of value only if a substance can be located, for example by use of its name, molecular formula, structure, or some combination of these; otherwise the substance record, together with any attached data, is essentially lost.

Knowledge of these three key properties of a substance affords versatility in its retrieval. This is relatively easy for substances that are nonpolymeric in nature; although the molecular formula of a substance is usually not unique, its molecular formula together with a unique systematic name, a unique structure, or both, are sufficient to distinguish a nonpolymeric substance from all other substances.

However, for polymers, these statements are not completely true. By its very nature, a polymer is usually not a single, discrete substance, but rather a mixture of somewhat different molecules. Although these have strong similarities to one another, at the molecular level probably no two individual molecules are identical in terms of such properties as chain length (molecular weight), linearity (degree of branching or cross-linking), arrangement of repeating units (alternating, block, random, statistical, etc), or conformation (spatial arrangement of atoms within a chain).

Thus, polymers are inherently different from nonpolymers, and many attempts have been made to define what constitutes a polymer. The International Union of Pure and Applied Chemistry (IUPAC), an international consortium

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

composed of professional scientists who propose and recommend standards for chemical nomenclature and structure representation, defines a *polymer* as "a substance composed of molecules characterized by the multiple repetition of one or more species of atoms or groups of atoms (constitutional units) linked to each other in amounts sufficient to provide a set of properties that do not vary markedly with the addition or removal of one or a few constitutional units" (1).

A polymer may be assigned a unique name, eg, poly(oxy-1,2-ethanediyl) (structure-based) or poly(oxirane) (source-based), but since such nomenclature (see NOMENCLATURE) incorporates no properties such as molecular weight, these names per se are insufficient to distinguish one sample from another. Likewise, any single complete molecular formula that represents a discrete molecule within the polymer is inadequate to describe the whole polymeric mixture, and to write a molecular formula for every distinct molecule present in a polymer would be hopeless. Therefore, compromises must be made. This article describes the current situation with regard to structural representation of polymers.

General Discussion

Polymer structural representation has two purposes:

(1) identification—to distinguish a given polymer from all others
(2) description—to record structural details that will enable the polymer to be retrieved in all searches for appropriate classes of polymers.

The ideal representation of a polymer is perhaps one that includes all known structural information; that is, the structure of the polymer itself *and* the structures of the substance(s) from which it was formed. This is usually impracticable; most polymers are represented in just one of these two ways.

Structure-based polymer representation: the polymer is represented in terms of the structure of its constitutional or structural repeating unit. Two common expressions are in use: "constitutional repeating unit" (CRU)—preferred by IUPAC; and "structural repeating unit" (SRU)—preferred by Chemical Abstracts Service (CAS) (2) (see Chemical Abstracts Service Information System); the two are virtually synonymous, and SRU will be used in this article. For example, polyethylene can be represented by the SRU$-(-CH_2-)_n-$ (the largest fragment that can be written without repetition) or by the SRU$-(-CH_2-CH_2-)_n-$ (obtained by opening the double bond in ethylene). (IUPAC recommends that in printed communications the subscript "n" as well as any other letters denoting multiplicities of polymeric sequences be printed in italic type or, in the absence of italics, be underlined. This article, which addresses primarily database records and their retrieval, indicates subscripts in the upright style without underlining.)

Source-based polymer representation (also called product-by-process representation): the polymer is represented in terms of the names and structures (where known) of the substance(s) from which the polymer was formed. For example, polyethylene is represented by the expression $(CH_2{=}CH_2)_x$, because the structure of the monomer, ethylene, from which it is made is $CH_2{=}CH_2$.

Source-based polymer representation preceded structure-based representation because polymers were made before they were structurally characterized. The

introduction of structure-based representation, however, did not render source-based representation obsolete, and currently the two complementary systems coexist. Source-based representation continues to exist for several reasons:

(1) For some polymers the method is preferable to structure-based representation. For example, the source materials used to manufacture Bakelite™ or Melmac™ are, in practice, more important than their structures; even if all the SRUs present in these highly cross-linked polymers could be delineated, to represent them thus would serve little purpose.
(2) Many source-based names are sufficiently explicit for the structures to be instantly deducible by scientists; therefore it is unnecessary to state them.
(3) For condensation polymers prepared from three or more monomers, it is impossible to write a meaningful SRU unless special additional rules are formulated to create an artificial or stylized one.
(4) Source-based names often lend themselves more easily to verbal and written communications, eg, "polycaprolactone" versus "poly[oxy(1-oxo-6-hexanediyl)]".
(5) Some problems concerning structure-based representation remain unresolved in terms of their delineation in a computer database. For example, the structure representation of an SRU within a larger SRU still poses software problems for CAS. The CAS Registry System, designed over 30 years ago, cannot handle a structural representation like the one shown in Figure 1a (SRU within a larger SRU). It does provide a source-based representation, as shown in Figure 1b, with two monomers of the type $(A{\cdot}B)_x$, one of which is an SRU with two hydroxy end groups and the other a dicarboxylic acid (2).

Thus, CAS can register an SRU within a polymer, eg, $[U{-}(A)_n{-}V{\cdot}B]_x$, and a polymer within a polymer, eg, $[(A)_x{\cdot}B]_x$, but not an SRU within an SRU, eg, $[(A)_n{\cdot}B]_n$.

Such complex structure-based representations pose no problems for more recent systems such as MDL's ISIS™ program with features designed expressly for polymer structure storage and retrieval.

In contrast, for many polymer classes, especially those that result from considerable chemical transformation of starting materials, it is more useful to represent them by structure than in terms of the source materials used to prepare them.

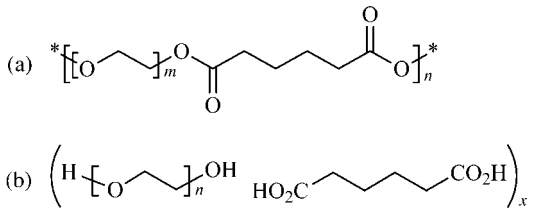

Fig. 1. Representations of polyester from hexanedioic (adipic) acid and poly(oxy-1,2-ethanediyl) [poly(oxyethylene)]; asterisks at ends of SRU denote unspecified end groups.

The structure of a polymer is generally displayed by representing it as a parenthesized expression with a subscript letter outside the closing parenthesis. Two such expressions are commonly used:

(1) For structure-based polymer representation, the expression used is $-(-A-)_n-$, where A represents the SRU of the polymer and the subscript n indicates that A is repeated an indefinite number of times. An SRU is an atom-by-atom or group-by-group representation of the smallest unit that, when repeated, in theory—and sometimes in reality—represents the polymer. Thus, poly(oxymethylene) can be expressed as $-(-O-CH_2-)_n-$.

(2) For source-based polymer representation, the expression used is $(A{\cdot}B{\cdot}\ldots)_x$, where A, B, etc, represent the atom-by-atom or group-by-group representation(s) of polymerizable substance(s) used to prepare the polymer and the subscript x indicates that A, B, etc, are repeated an indefinite number of times. Thus, nylon-6,6 can be expressed as $(H_2N-(CH_2)_6-NH_2{\cdot}HO_2C-(CH_2)_4-CO_2H)_x$.

Expressions such as $-(-O-CH_2-)_n-$ and $(H_2N-(CH_2)_6-NH_2{\cdot}HO_2C-(CH_2)_4-CO_2H)_x$ depict actual structures, not molecular formulae. Although expressions such as $(CH_2O)_n$ and $(C_6H_{16}N_2{\cdot}C_6H_{10}O_4)_x$ are used by CAS to represent the molecular formulae of poly(oxymethylene) and nylon-6,6 respectively, these expressions are, per se, neither structure-based nor source-based representations of these two polymers. There is a link, however, between the full structural representation and its molecular formula. The subscript n is used consistently for both an SRU and its molecular formula; similarly, the subscript x is used consistently for both a homopolymer (copolymer) structure expressed in terms of monomer(s) and its corresponding molecular formula.

These two types of representation, both of which are more theoretical than actual (although they can be actual), have advantages and disadvantages.

For structure-based polymer representation the advantages and disadvantages are as follows.

(1) **Advantages:**

a. The theoretical (which is sometimes the actual) repeating unit of the polymer is depicted precisely and unambiguously.

b. If structural irregularities in the polymer are ignored, there is presumably no doubt about the exact structure.

c. End groups may be indicated by modification of the expression $-(-A-)_n-$ to a format such as $U-(-A-)_n-V$, where U and V are structures of end groups; thus, α-methacryloyl-ω-methoxypoly(oxyethylene) is represented by the expression $CH_2{=}C(CH_3)-CO-(-O-CH_2-CH_2-)_n-OCH_3$. The corresponding molecular formula is written in the format $(A)_nW$, where A is the molecular formula of the SRU (exclusive of end groups) and W is the summation of molecular formulae of end groups U and V; thus, W (atom count) = U (atom count) + V (atom count). In the

latter case, however, without a name or structure, it is sometimes impossible to determine which atoms belong to U and which to V. Thus, the two SRUs α-methacryloyl-ω-methoxypoly(oxyethylene) and α-acryloyl-ω-ethoxypoly(oxyethylene) are represented by the same molecular formula expression $(C_2H_4O)_n\ C_5H_8O_2$.

(2) **Disadvantages:**

a. The method fails to indicate the monomers from which the polymer was prepared; for a polymer chemist this is frequently an important consideration.
b. For polymers prepared from asymmetrical monomers that give rise to a product containing several SRUs, the pedantry involved in naming every possibility can become tedious.

(3) For source-based polymer representation the advantage and disadvantages are as follows.

(4) **Advantage:**

a. A polymer can always be represented in terms of the monomers used to synthesize it, even if the structures of some of them are imprecisely defined (eg, castor oil). It must be pointed out, however, that monomers can never, per se, show the structure of a polymer containing them; the reader must use other knowledge to deduce it.

(5) **Disadvantages:**

a. The atom-by-atom structure of the polymer is not depicted, even when it can be deduced with some degree of certainty.
b. Scattering of information may occur from either or both of the following sources: (a) the same polymer may be synthesized from different monomers; (b) under different reaction conditions the same monomer(s) may give rise to more than one polymer structure.

Some polymers are traditionally represented by the structure-based method, some by the source-based method, and others by both methods, but always as separate expressions, rather than one all-encompassing expression.

Provided (*1*) both structure-based and source-based types of representation are stored, (*2*) all practical representational possibilities for both types are stored, and (*3*) the storage/retrieval system is capable of retrieving all stored representations when only one is specified, a key advantage of using separate expressions for representations of a polymer is that searchers can find a polymer by searching any possible representation. Currently, condition (*1*) is sometimes met, whereas conditions (*2*) and (*3*) are frequently not, which results in scattered data and frequent failure to retrieve critical information.

Seemingly random use of structure-based and source-based representations with no cross-referencing between them has resulted in decades of confusion.

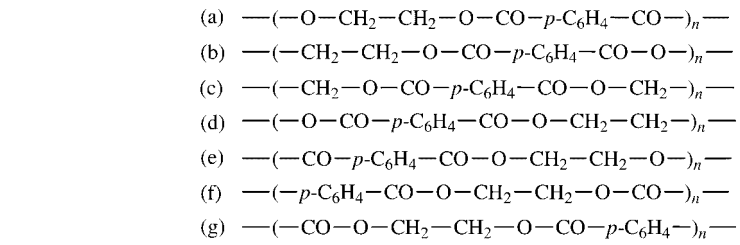

Fig. 2. "Phase-shift" versions of PET represented as an SRU. While it is possible to write seven structures, as far as CAS searching is concerned, both the human searcher and the CAS Messenger computer program recognize that (**a**) = (**e**), (**b**) = (**d**), and (**f**) = (**g**).

For even the simplest of polymers, a searcher is faced with three fundamental questions: (*1*) is the desired polymer represented as structure-based or source-based; (*2*) if it is structure-based, how is the structure drawn; (*3*) if it is source-based, what monomers were used? To take a polyester example, a question such as whether parent acids or simple derivatives (eg, methyl esters or phenyl esters or acid chlorides) were used is often far more important to a polymer scientist than the structure of the final polymer.

Any polymer representation used for identification must be predictable, ie, easily arrived at by a searcher applying a set of rational and invariable rules. Without knowledge of rules for determining the order of an atom-by-atom representation of an SRU, a searcher seeking information on poly(ethylene terephthalate) (PET), for example, would theoretically have to search for all seven structures shown in Figure 2.

Each of these would have a unique name, and so a search by name, vice one by structure, would not narrow the number of possibilities.

CAS (2) and IUPAC (3) have devised rules for the orientation of SRUs that, when followed, reduce a searcher's choices to one of the above seven; the preferred structure for PET is shown as Figure 2a.

Until September 2002, searchers faced an essentially insolvable problem in a search for source-based representations for PET. A searcher might think of searching only for the two representations shown as Figures 3a and 3b; the representation shown as Figure 3c, which represents PET synthesized by a modern, industrially significant route, would thus not be retrieved.

A search for source-based representations for a polymer therefore depended upon a searcher's ability to surmise how it might be represented; in other words, it was a guessing game.

The three above-listed questions arise for searches involving only simple polymers; for more complex polymers, further questions arise such as how many

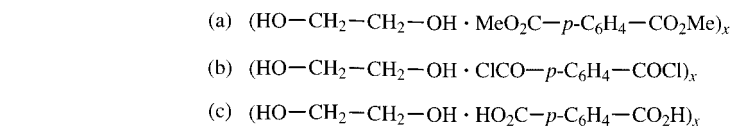

Fig. 3. Different expressions for source-based representations of PET.

comonomers were used to prepare them, whether end groups need to be considered, and whether the polymers are aftertreated (post-treated), block, branched, comb, cross-linked, dendritic, graft, star, etc.

To say that one polymer is or is not different from another will always require some arbitrary judgment of what is or is not significant in polymer identification. For example, are the two polymers represented by the source-based expressions shown as Figures 3a and 3c sufficiently "different" to be worthy of two separate representations? In terms of source-based polymer registration, CAS regards them as two separate polymers. Some industrial consumers of PET may find that the presence of carboxy end groups rather than methoxycarbonyl ones makes no difference for their particular application, while others may find that end group composition makes an appreciable difference to product properties; thus, the answer may depend upon many factors.

It must also be pointed out that neither structure-based nor source-based representation currently takes into account any structural irregularities. Real polymers, as synthesized, are seldom structurally perfect. Depending on the type of polymer, various kinds of structural irregularities may arise during a polymerization process.

Some examples are given below:

(1) PET may contain irregularities known as "ether defect," a colloquial name indicating the presence of some —O—CH_2—CH_2—O—CH_2—CH_2—O— moieties.

(2) Depending upon polymerization concentration, difunctional acrylic compounds (eg, ethylene diacrylate) may give polymers that are hyperbranched, hyper-cross-linked, or both.

(3) Low density polyethylene is irregularly branched.

(4) Polymers formed between simple diamines (eg, 1,5-pentanediamine) and simple dihalo compounds (eg, 1,5-dichloropentane) are frequently branched, cross-linked, or both.

Such irregularities, which may vary from batch to batch, can affect polymer properties appreciably.

Thus polymer structures represented on paper or stored in a database as ideal or theoretical representations are frequently not true representations of actual polymer structures. Before September 2002 all these problems and questions posed significant difficulties for the average polymer searcher. The following sections discuss what has been achieved to date in terms of organizing polymer structures and nomenclature, and of facilitating polymer searching.

In September 2002, CAS introduced a new on-line search-tool called POLYLINK, which is designed to solve the above problems regarding "phase-shift" and retrieval of structure-based representations and their source-based counterparts (4).

Organizations and Databases

Over the last 50 years, two major organizations, CAS and IUPAC, have tackled the daunting task of how best to represent polymer structures. Their achievements

are impressive, and the two organizations are in virtually complete agreement on structure-based and source-based representations of polymers, both on paper and in searchable on-line databases such as the CAS Registry File. However, much still remains to be done; some aspects of copolymer representation need enhancement, and such newer areas as aftertreated (post-treated), comb, dendritic, and star polymers are handled inadequately.

In addition to these organizations, computer software companies such as Daylight and MDL Information Systems, Inc. (MDL) offer for sale computer programs that are suitable for either mainframe or personal computers, and many companies use them to create their own proprietary databases containing agricultural chemicals, pharmaceuticals, polymers, etc. Some computer programs accommodate chemical structures only, while others accommodate textual data only. MDL's ISIS™/Host is a computer program that enables users to combine chemical structures from one file with textual data from another to produce an integrated product. MDL's ISIS program enables users to register a wide variety of polymer structures.

Storage and Retrieval of Polymer Structures

Storage of Polymer Structures. CAS has developed comprehensive sets of nomenclature rules and structure conventions that have become standards in the world of chemical literature (see Chemical Abstracts Service Information System). CAS selects polymers for indexing according to a set of rules (5). The Registry File records are created from chemical information published in books, patents, dissertations, scientific journal articles, etc.

MDL's ISIS program permits registration of polymer structure representations as source-based, structure-based, or both. Users who create their own databases with such a program are therefore free to store polymer representations in any way they wish within program limitations. The optionally available "duplicate detection" feature alerts a person registering a substance that the structure is already in the database. For example, the three possible representations of poly(oxy-1,2-ethanediyl) shown as Figures 4a–4c are "perceived" by MDL's ISIS program as being "phase-shift" versions of the same polymer; use of the duplicate detection feature during registration of any one of these three representations can alert a registrar that it is already registered as 4a, 4b, and 4c.

Retrieval of Polymer Structures. It is axiomatic that to conduct an efficient search, searchers need to know the rules of the database or file being searched. Although this article is not intended to be a teaching manual on how to search polymer files or databases, some basic differences between searching the CAS Registry File and searching an MDL database by means of the ISIS program merit discussion.

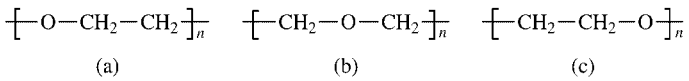

Fig. 4. "Phase-shift" versions of poly(oxy-1,2-ethanediyl).

Searchers who choose to search a publicly available file such as the CAS Registry File must learn the rules imposed on them by CAS (2). The CAS Registry File is remotely searchable via the Scientific and Technical Information Network (STN) in Columbus, Ohio. Anyone with an STN account and a computer equipped with the necessary hardware and software may access this file. As of September 2002, the Registry file contains names, structures, or both for over 42 million substances, of which nearly 934,000 are polymers.

Those who choose to search a private database such as one created with MDL's ISIS must learn a different set of search techniques. ISIS™/Draw, the ISIS chemical drawing package, is a presentation package for polymer structures. ISIS/Draw allows scientists to draw polymer structures with ease and speed, and then to search and share them. Researchers also have the enhanced capability of accessing 2D and 3D databases, with a wide range of search options and a link to global data. ISIS/Draw includes full annotation capabilities, which enable researchers to label collections of atoms or bonds with related function or process information (6).

To perform a polymer structure search using ISIS, the searcher uses ISIS/Draw to draw the desired structure, eg, a complete polymer or a fragment. Polymer structure queries may include any of the standard ISIS query properties, eg, atom lists, ring counts, substitution counts, or bond types. The searcher transfers the drawn structure to ISIS™/Base and initiates a search. Search modes are

(1) Current Mol (looks for the specific polymer only)
(2) Flexmatch (allows some flexibility in what is considered an "exact" match)
(3) SSS ("substructure search"; looks for all polymers that include the query structure)
(4) "Search by Form" (combines SSS with any other data provided in the query form, eg, physical properties).

MDL's ISIS program has an extremely valuable search feature: during a search for any given polymer, use of MDL's "flexmatch" program results in retrieval of all representations stored—both structure-based (regardless of "phase-shift") and source-based structures. Thus, for PET, assuming that the seven SRU structures shown as Figures 2a–2g and the three source-based structures shown as Figures 3a–3c were registered in a database, a search for any one of the 10 structures would retrieve all 10. The CAS Registry File added this feature in September, 2002 (4).

The rest of this article discusses structure representation for the types of polymers most commonly encountered. First, the principal CAS and IUPAC guidelines governing regular, single-strand, organic polymers are presented. This is followed by an overview of more complex substances–aftertreated (post-treated), alternating, block, comb, cross-linked, dendritic, graft, hyperbranched, hyper-cross-linked, star, and star-block polymers. There is also a section that summarizes stereochemistry in polymers, followed by another that reviews inorganic and quasi-inorganic polymers, double-strand (ladder) polymers, siloxanes and silicones, and oligomers and telomers.

Regular, Single-Strand, Organic Polymers

The word "regular" in the heading is used here to mean "ordinary", or, in the case of copolymers, random or statistical types with no special attributes such as "nonpolymeric spacer groups" (called junction units by IUPAC). As mentioned above, these are drawn usually as either structure-based, ie, —(—A—)$_n$—, or source-based, ie, —(A·B···)$_x$.

Structure-based versus Source-based Representation. There are no absolute rules that specify which types of polymers shall be represented as structure-based, which as source-based, and which by both methods. IUPAC makes no definitive statement about whether a polymer shall be represented as source-based or structure-based; thus, polymers may be represented both ways, and many examples of this can be found in both IUPAC's publications (1,6–13) and the CAS Registry File.

CAS states (2) that "specific polymers are named on the basis of the monomers from which they are formed and/or on the basis of their structure, as represented by an SRU." Since original documents do not always provide sufficient structural information to allow generation of the SRU name, the method most frequently used for describing polymeric substances is by citation of the component monomers. A few commercial polymers, each of which accounts for a large number of index entries, are indexed only at the SRU-based systematic polymer name. Systematic (SRU) nomenclature for polymers has been adopted from the system developed by the Committee on Nomenclature of the Division of Polymer Chemistry of the American Chemical Society (ACS) (14). Note: the IUPAC recommendations (*Pure Appl. Chem.* **48**, 373–385 (1976)) are in full agreement with CAS practice. Names derived by this system, in addition to monomer-based entries, are cited for polymers whose structural repeating units are well-documented or can confidently be assumed.

The "few commercial polymers" to which CAS refers (2,15) are the following:

(1) nylon-6
(2) nylon-6,6
(3) PET
(4) α-hydro-ω-hydroxypoly(oxy-1,2-ethanediyl) (polyethylene glycol)
(5) α-hydro-ω-hydroxypoly[oxy(methyl-1,2-ethanediyl)] (polypropylene glycol)

In accordance with CAS's policy (2,15), CAS assumes SRUs for such two-component condensation polymers as

(1) polyamides derived from a dibasic acid and a diamine
(2) polyesters derived from a dibasic acid and a dihydric alcohol
(3) polycarbonates from carbonic acid and a dihydric alcohol.

This is *not* limited to common polymers; as long as the criteria are met (15), uncommon polymers are also registered with both structure-based and source-based representations.

In contrast, CAS traditionally represents the following polymer types by only one method. These examples are illustrative only; the list is not meant to be exhaustive.

(1) **Source-based:**

a. Acetylenic
b. Acrylic and methacrylic
c. Alkyd
d. Ethylenic
e. Polyamic acids, polyamides, polyesters, polyimides, polyurethanes, and combinations of these types that are prepared from more than two monomers
f. Thermoset
g. Vinyl
h. Any other polymer for which the structure is unknown
Polymers in these eight groups are usually assigned source-based names, but these groups do not necessarily correspond to specific CAS polymer classes. A CAS publication (16) cites 42 specific polymer classes; an up-to-date list may be viewed by entering CAS Registry File online and executing the command: expand A/PCT.

(2) **Structure-based:**

a. Double-strand (ladder)

To take one example, the CAS principles—for both registration and searching—determine that a polymer such as poly(oxy-1,2-ethanediyl) is registered and named only as structure a in Figure 4; registration of structure 4b is forbidden by ordering rules. Structure 4c is the mirror image of structure 4a and is equated to structure 4a in the process of registration and naming.

It might therefore be assumed that retrieval of structures 4b and/or 4c during a search denotes incorrect indexing. However, owing to the way in which CAS's Messenger software operates, a search for structure 4c also retrieves the polymer with structure 4a. Some displayed images appear with the head atom on the left; others are mirror image when compared with the name. Regardless of which way round the on-screen image appears, retrieval of the desired polymer was historically likely to fail unless CAS's principles were followed. This search problem has been largely solved by the introduction in September 2002 of the POLYLINK search tool (4).

A comprehensive review of structure-based and source-based representations for regular, single-strand, organic polymers has been published (17).

Homopolymers.

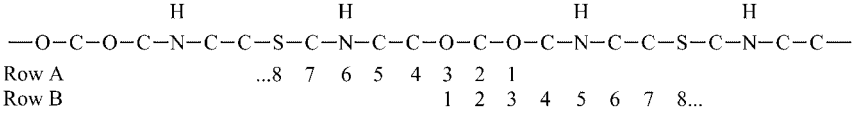
Structure-based Method. The CAS principles (2,14) and IUPAC (3) recomendations for structure-based polymers are as follows. The descending order

of priority of citation (and of structuring the SRU) is (*1*) heterocyclic rings, (*2*) acyclic heteroatoms in the order O, S, Se, Te, N, P, As, Sb, Bi, Si, Ge, Sn, Pb, B, Hg, (*3*) carbocyclic rings, (*4*) acyclic carbon chains. If substituents are present, otherwise identical parent radicals in the SRU are chosen by the principles, in turn, of maximum number, lowest locants, and earliest alphabetic order of substituents. The shortest path (smallest number of atoms) is taken from the most preferred multivalent radical to another occurrence of the same radical (if present) within the SRU, then to the next most preferred radical, and so on. For SRUs containing more than one heterocyclic ring, there are further rules for determining heterocyclic ring seniority (18).

The complete registration process may be summarized as follows:

(1) *Step 1:* The atom sequence that defines the SRU is identified.
(2) *Step 2:* The "head" atom or senior bivalent radical of the sequence is defined.
(3) *Step 3:* The SRU is oriented, ie, a decision is made on which way to proceed along the atom sequence.
(4) *Step 4:* The SRU is named.

As an example, consider the 12-backbone-atom SRU sequence:



Determination of the head atom, and subunit citation order, is as follows: O is senior to S, and S is senior to N; therefore, one of the two oxygen atoms must be the head atom. The SRU must therefore be either row A, atoms 1 to 12, or row B, atoms 1 to 12. The row A sequence places the N atom in position 6, whereas the row B sequence places it in position 5; the latter is therefore correct, and the final SRU is $-(-O-C-O-C-NH-C-C-S-C-NH-C-C-)_n-$.

Essentially the same steps should be followed by searchers in order to conduct an effective search for structure-based polymers.

For polymers in SCION, a DuPont proprietary database, the same four basic steps are used for SRU identification and orientation. However, the rules that control these steps are different; this results in names and structures for SRUs that are sometimes different from SRUs as defined and oriented by CAS principles (19).

Source-based Method. For source-based representations, CAS structures homopolymers by an expression such as $(A)_x$, where A is a monomer. A typical CAS source-based homopolymer representation is shown as Figure 5.

IUPAC makes no recommendations for formal source-based, one-component homopolymer nomenclature or structural representation. However, IUPAC recognizes that for common idealized structural representations such as polyethylene, polypropylene, and polybutadiene, these semisystematic or trivial names are approved for use in scientific work. Where the semisystematic name is an obvious

source-based name, the polymer referred to is derived from the indicated source (see Appendix A in Ref. 3).

Copolymers.

Structure-based Method. CAS does not generally index *unterminated* copolymers of SRUs by the structure-based method. Formats such as poly(oxyethylene)/poly(oxytetramethylene) or poly[(oxyethylene)/(oxytetramethylene)] are not used. Instead, a source-based representation is used (see Fig. 9 below).

IUPAC states (7) that a comprehensive structure-based system of naming copolymers would be desirable, but that such a system presupposes a knowledge of the structural identity of all the SRUs as well as their sequential arrangements within the polymer. They suggest that when this information is available, the structure-based nomenclature used for single-strand polymers (3,13) can be extended to copolymers. A separate publication (8) depicts many structure-based copolymer representations.

Source-based Method. The source-based structural representation of a copolymer is in the format $(A{\cdot}B\cdots)_x$, where A, B, etc, are monomers. Figures 6–8 illustrate the method.

Although poly(oxyethylene) and poly(oxytetramethylene) are represented as structure-based homopolymers, the poly(oxyethylene/oxytetramethylene) copolymer is represented as a source-based polymer (see Fig. 9).

CAS does not use words such as “random” or “statistical” to describe random or statistical copolymers; copolymers without special attributes such as “block” are assumed to be random.

A comprehensive IUPAC publication (8) discusses nomenclature for source-based copolymers.

Complex Polymers

Space limitations preclude more than an overview of these types: aftertreated (post-treated), alternating, block, comb and graft, cross-linked, dendritic, hyperbranched, hyper-cross-linked, star, and star-block. Comprehensive reviews of structure-based and source-based representations for them have been published (20,21).

Aftertreated (Post-treated) Polymers. CAS describes *post-treated polymers* as those polymers that are modified, either partially or completely, after the basic polymer backbone or skeleton has been formed. These modifications may result from a reaction or series of reactions of the main chain, end groups, and/or pendent functional groups of the polymer. Post-treatment is indicated by modification terms after the polymer name that describe the nature of the post-treatment. CAS divides post-treated polymers into two types: structurable and registrable; and nonregistrable (15). A third category, registrable and referred to as "nameable but not structurable" (15), is now provided with structures, and the backfile is being updated on an ongoing basis with structure-based access. (A description of the indexing enhancements is also available from CAS Customer Service and is offered on the world wide web (WWW) at http://www.cas.org/EO/enhanc.html.)

IUPAC discusses post-treated polymers in a 1994 publication (12), and several examples of structure-based representations are given. As of September 2002, IUPAC has made no recommendations regarding nomenclature or structural representation for post-treated source-based polymers.

Alternating (and Other Periodic) Polymers. Alternating and other periodic copolymers are viewed somewhat differently by CAS and IUPAC.

Neither "alternating" nor "periodic" is used as a modifier by CAS for alternating or periodic polymers named on the basis of their structure. The text descriptors "alternating" and "periodic" are not used with SRUs because any alternation or periodicity would be obvious in the structure and would not need to be differentiated from another similar structure by means of a text descriptor.

Registration by CAS of source-based representation of alternating copolymers with the term "alternating" as an integral part of the Registry record began with the 12CI (1987) (2). Alternating copolymers are distinguished in CA Registry File from random copolymers by including the term "alternating" in the Registry record of a given copolymer with its source-based name (see Fig. 10).

IUPAC recommends that an *alternating polymer* be named as a copolymer comprising two species of monomeric units (or monomers) distributed in alternating sequence (7). The arrangement ABABAB— or $(AB)_n$ thus represents an alternating copolymer. As far as possible, alternating and periodic polymers are treated as regular polymers (8). An alternating sequence arrangement of monomers is represented by (A-*alt*-B), and the corresponding polymer is named poly(A-*alt*-B).

For source-based representations, IUPAC recommends that alternating and periodic copolymer names contain the connectives -*alt*- and -*per*-, respectively.

Table 1 lists the source-based connectives recommended by IUPAC for alternating, periodic, and several other polymer types. According to the above IUPAC recommendations, the source-based name for PET and the trivial name nylon-6,6 represent alternating copolymers.

Block Polymers. This section discusses structure-based and source-based nomenclature for ordered, segmented, and unordered block polymers, and polymers with "nonpolymeric spacer units" or "junction units." Star-block polymers are discussed under star polymers.

When CAS began to register polymers in 1967, no distinction was made between block and other copolymers. The information might have been part of the descriptive "index modification," but it was not part of the Registry record. Registration of block copolymers with the term "block" as an integral part of the Registry record began with the 12CI (1987).

CAS makes no distinction among ordered, segmented, and unordered block polymers. For source-based representation, block polymers are distinguished from random polymers by indexing as copolymers at the monomer names. The term "block" is cited in a special modification after all other structural information (2).

IUPAC has published recommendations for structure-based and source-based representations of block polymers (7,8,12).

Comb and Graft Polymers. These two types of complex polymers are discussed together because there is overlapping technology, and it is not always possible to distinguish between them.

CAS does not recognize comb polymers as a type. Many (but not all) comb polymers are classified as graft polymers; for example, the comb polymer from

Graft	*-graft-*	polyA-*graft*-polyB

acrylonitrile, polyethylene glycol monomethacrylate, and styrene is classified as a graft polymer, whereas comb polymers from homopolymers of macromonomers are not.

Registration of graft copolymers with the term "graft" as an integral part of the Registry record began with the 12CI (1987). When CAS began to register source-based representations of polymers in 1967, no distinction was made between graft and other copolymers. The information might have been part of the descriptive "index modification," ie, the word "graft" might appear somewhere in the text, but it was not part of the Registry record. Comb and graft polymers comprising an SRU backbone and an SRU side chain are represented as graft polymers with source-based names (see Fig. 11).

Differentiation between the polymeric substrate and the applied monomer is not made. For example, whether 1-hexene is grafted onto 1-heptene homopolymer or vice versa, the preferred name is "1-heptene, polymer with 1-hexene, graft" with an additional name "1-hexene, polymer with 1-heptene, graft" (2). Thus, CAS makes no distinction between poly(A-*graft*-B) and poly(B-*graft*-A).

Application of the text descriptor 8:PM, GRAFT to graft polymers began with the 12CI (1987); earlier records are not so designated, but this is of minor importance to searchers because this descriptor is currently displayable but not searchable. The term "graft", which *is* searchable, is also part of the name.

IUPAC has proposed that graft polymers be named in the same way as regular polymers (4) or irregular polymers (12) but with minor modifications. IUPAC also gives recommendations for irregular polymers in which polymer chains are attached to the main chain through a constitutional unit (linking unit) different from the constitutional unit of the side chain (8). Graphic representations of graft polymers have been published (8).

An IUPAC publication (11) discusses both structure-based and source-based representations of comb polymers; a *comb polymer* is described as a macromolecule comprising a main chain with trifunctional points from which linear side chains emanate. If the subchains between the branch points of the main chain and the terminal subchains of the main chain are identical with respect to constitution and degree of polymerization, and the side chains are identical with respect to constitution and degree of polymerization, the macromolecule is termed a regular comb macromolecule. If at least some of the branch points are of functionalities greater than three, the macromolecule may be termed a *brush macromolecule*.

Fig. 11. CAS representation of an "all-SRU" comb (or graft) polymer.

Cross-linked Polymers. As the name indicates, these have two or more separate polymeric chains connected by a cross-link; it is *implied* that the cross-link is generally (*1*) relatively short (and not itself polymeric) and (*2*) at irregular intervals along the chains, but there seem to be no firm rules on these points. Ladder polymers comprising two linear strands cross-linked at regular intervals are discussed under Double-Strand (Ladder) Polymers.

The *Index Guide* (2) gives no information on how cross-linked polymers are indexed, because CAS treats them as copolymers.

IUPAC has published no specific recommendations on nomenclature or structural representations for cross-linked structure-based polymers. For source-based representations of polymers, IUPAC defines a cross-link as a small region in a macromolecule from which at least four chains emanate, which is formed by reactions involving sites or groups on existing macromolecules or by interactions between existing macromolecules (22). The small region may be an atom, a group of atoms, or a number of branch points connected by bonds, groups of atoms, or oligomeric chains. In the majority of cases a cross-link is a covalent structure but the term is also used to describe sites of weaker chemical interactions, portions of crystallites, and even physical interactions and entanglements.

Cross-links, the branch units of star macromolecules and other junction units, are optionally specified by their source-based names after the name of the

macromolecule, with the Greek connective ν separated by hyphens. When the content of the cross-linking monomer is high, the macromolecule is treated as a copolymer molecule (11).

Dendritic, Hyperbranched, Hyper-cross-linked, Star, and Star-Block Polymers. These groups of polymers are discussed together because there is overlapping technology that makes it difficult to discuss them separately. In the last decade there has been a sharp rise in interest of these types of polymers.

Tomalia and co-workers (23) describe a dendrimer as having three distinguishing architectural features: an initiator core, interior layers (generations) composed of repeating units radially attached to the initiator core, and an exterior or surface of terminal functionality attached to the outermost generation.

These dendrimers differ from classical monomers or oligomers by their extraordinary symmetry, high branching, and maximized (telechelic) terminal functionality. Dendrimer synthesis is accomplished by a variety of strategies involving time-sequenced propagation techniques. The resulting dendrimers grow in a geometrically progressive fashion. Chemical bridging of these dendrimers (24) leads to Starburst^{TM} [Dow Chemical Co. (25)] polymers. Tomalia and Durst have written a detailed account of Starburst/cascade dendrimers and hyperbranched structures (26).

Turner (27) considers hyperbranched polymers to be highly branched, noncross-linked polymers prepared by the step-growth polymerization of A_xB (or AB_x) polymers. Thus, A_2B means that for every two type A reactive groups there is one type B reactive group, while AB_2 means that for every one type A reactive group there are two type B reactive groups. AB_2 and AB_3 (or A_2B and A_3B) are the commonest; AB_x (or A_xB) types where $x > 3$ tend to be so sterically crowded that polymerization is difficult unless the reactive groups are well separated.

Voit (28) portrays the essential differences between dendrimers and hyperbranched polymers as follows:

(1) Dendrimers are prepared by a stepwise approach; they are structurally perfect or nearly perfect (ie, the branching ideality approaches 100%), their size is limited (ie, they cannot grow forever), and their molecular weight is dependent upon the number of generations.

(2) Hyperbranched polymers may be prepared by a one-step synthesis under conventional polycondensation conditions; their molecular weight is dependent upon the condensation reaction, not upon the number of generations, and the branching ideality is typically between 50 and 75%.

The terms "star polymer" and "star-shaped polymer" are used somewhat imprecisely. The same term is used to describe at least two physically different polymeric "clusters." A *star polymer* may be a polymer comprising a precise center of known structure from which radiate a known number of arms. The arms, which may contain one or more SRUs or polymerized monomers, may be random, statistical, or blocky; polymers containing the latter are usually called *star-block polymers*.

A star polymer may also comprise an unknown number of arms connected to the center of the cluster by addition to the reaction mass of a second, multifunctional monomer or SRU that ties all the linear growing polymer chains together

into a cross-linked (microgel) core. These are sometimes called *star-branch polymers* (29). Cloutet and co-workers (30) however, describe a star-branched polymer as a "dendritic block polymer." A third type of star polymer comprises a dendritic core from which emanate a known number of arms (31). In any of these types of star polymers, the arms may be all the same, or different arms may have different compositions; the latter known variously as heterostar (32), miktoarm star (33), or variegated star polymers (11).

CAS handles dendrimers as regular organic compounds or polymers, depending on the degree of polymerization. The number of nonhydrogen atoms is also a factor. Low generation dendrimers having 10 or fewer repeating units and a nonhydrogen atom count less than 253 are structured and named systematically as specific nonpolymeric compounds. Higher generation dendrimers having more than 10 repeating units or a nonhydrogen atom count greater than 253 (which thus forces a manual registration at a lower degree of polymerization) are structured and named as polymers.

Polymers having dendritic or starburst structure are indexed at the controlled term DENDRITIC POLYMERS, which was added as a new index heading starting with the CA 13th Collective Index Period in 1992. Additional index entries are made for specific dendrimers. The approach for preparing divergent or convergent dendrimers may be indicated in the text modification when so specified by the author of the source document. [Convergent and divergent refer to the two basic methods of forming dendrimers; as the names imply, convergent dendrimers (typified by the work of Fréchet and co-workers (34)) are built "inward," ie, from the periphery toward the core, whereas divergent dendrimers (typified by the work of Tomalia and co-workers (23,24)) are formed by building outward from the core.] Currently CAS has no specific nomenclature for polymeric dendrimers; they are named according to regular polymer nomenclature rules. The polyfunctional core used in either the divergent or convergent approach is not included in the polymer registration. CAS's policy on the indexing of dendrimers is described in more detail elsewhere (21).

IUPAC has addressed star and star-block polymer representations (8,11). As of September 2002, no specific recommendations on nomenclature or structure representation for dendrimers, hyperbranched, or hyper-cross-linked polymers have been published; an IUPAC document on this topic is close to completion. An IUPAC paper on source-based nomenclature (11) describes a star polymer as a macromolecule containing a single branch point from which linear chains (arms) emanate. In a regular star polymer all arms are identical with respect to constitution and degree of polymerization. A variegated star has different arms composed of different monomers.

Comprehensive reviews of nomenclature for structure-based and source-based representations for dendritic, hyperbranched, and hyper-cross-linked polymers (21,35–38), and for star and star-block polymers (21), have been published.

Stereochemistry in Polymers

CAS represents stereochemistry in polymers by text descriptor terms when the necessary information is reported; such terms include isotactic, syndiotactic,

threo-diisotactic, erythro-diisotactic, and disyndiotactic (2). The term "atactic" (for a random configuration) is not employed by CAS in indexing specific polymers. In addition to the special terms above, polymer stereochemistry is defined, when appropriate, by the stereo descriptors E, Z, R, S, R*, and S*.

The first extensive IUPAC publications on stereochemistry in high polymers were published in the early 1960s, and subsequently in 1966 as a single article (39). In addition to more conventional polymer names, eg, polyethylidene and polypropylene, the "-amer" nomenclature was introduced in 1952 (10). IUPAC basic definitions relating to stereochemistry, eg, tacticity and isotactic polymer, were published in 1974 (1).

A major 1981 IUPAC document (9) addresses polymer stereochemistry in depth. Key chapters of this document discuss basic definitions (configurational unit, configurational base and repeating units, stereorepeating unit, different types of tacticity, tactic block polymers, and stereoblock polymers); sequences; conformations; and supplementary definitions. Most of the illustrations use the rotated Fischer projections, but some three-dimensional representations are included.

Miscellaneous Polymer Types

These include inorganic and quasi-inorganic polymers, double-strand (ladder) polymers, siloxanes and silicones, and oligomers and telomers. A comprehensive review of structure-based and source-based representations for these types of polymers has been published (40).

Inorganic and Quasi-inorganic Polymers. A polymer need not be completely inorganic to be classified as an inorganic polymer; an inorganic backbone is sufficient, even if there are organic moieties attached to a backbone atom.

A regular linear polymer that can be described by a preferred SRU in which only one terminal constituent subunit is connected through a single atom to another identical SRU or to an end group is a *quasi-single-strand polymer*, ie, it does not fit the definition of a regular single-strand polymer, but it can be named in the same manner (13).

CAS represents single-strand inorganic polymers by both structure-based and source-based methods. Figure 12 shows a typical structure-based record;

Fig. 13. Source-based record; homopolymer from hexafluorotriazatriphosphorine. Poly[nitrilo(difluorophosphoranylidyne)] [28655-96-1], the corresponding structure-based representation, is also registered in the CAS Registry file.

nitrogen is senior to phosphorus and might be expected to appear on the left but (as explained under Structure-based versus Source-based Representation) this may not always occur.

Source-based representations of polymers are typically recorded as shown in Figure 13.

Some references on phosphazenes (41) show the structures with nitrogen mostly on the left, although some are drawn with phosphorus on the left.

When SRUs are bridged only by metals, systematic polymer nomenclature is not used; instead, the substance is indexed either at the monomeric salt name or by coordination nomenclature, with a modification phrase, in either case, such as "homopolymer" or "polymer with. . ." (2).

IUPAC (13) presents a system of nomenclature for regular single-strand and quasi-single-strand inorganic and coordination polymers. The system is based on the selection and naming of an SRU defined (1) as the smallest structural unit the repetition of which describes the polymer structure. The name of the polymer is the name of this repeating unit prefixed by the terms "poly," "*catena*", or other structural indicator, and designations for end groups, if desired. IUPAC has created sets of rules for (*1*) determining an unambiguous, although not necessarily unique, name for each SRU; (*2*) a unique name; and (*3*) resolving situations when further choice is needed for selection of a senior subunit in an SRU.

Double-Strand (Ladder) Polymers. Double-strand ladder and spiro polymers contain no open-chain bonds in the backbone. Polymers containing some open-chain backbone bonds (called partial ladder, imperfect ladder, step-ladder, or block ladder polymers) are not considered to be true ladder or spiro polymers.

The CAS and IUPAC nomenclature and structure representation systems are very similar. CAS's rules for ladder polymers are published in the *Index Guide* (2). IUPAC defines a ladder or spiro polymer as a double-strand polymer, the molecules of which are formed by an uninterrupted sequence of rings with adjacent rings having one atom in common (spiro polymer) or two or more atoms in common (ladder polymer). A comprehensive system is presented for (*1*) identifying, (*2*) orienting, and (*3*) naming the preferred SRU, and subsequently (*4*) naming

the polymer (42). The nomenclature and structure representation system used in SCION, a DuPont proprietary database, is novel and radically different (43).

Other prominent articles on double-strand polymers include those by Overberger and Moore (44), DeWinter (45), and Bailey (46); the latter reference contains a short "proposed nomenclature" section that is essentially a reprint of part of an ACS publication (14).

Siloxanes and Silicones. Although IUPAC classifies polysiloxanes as inorganic polymers (13), there is sufficient interest and diversity in them as a group for them to warrant discussion separate from other inorganic polymers.

Polysiloxanes occupy a virtually unique position in the world of polymers. Many polysiloxanes comprise a partly or wholly inorganic backbone built from alternating silicon and oxygen atoms; in contrast, pendent groups or side chains attached to silicon atoms are usually organic. Types discussed in this section include regular single-strand, hyperbranched, ladder, and spiro polysiloxanes.

Prior to 1994, polysiloxanes prepared by hydrolytic polymerization of alkoxysilanes or halosilanes were indexed in CAS's CA File at the index heading "Siloxanes and Silicones" with no polymer registration. Polysiloxanes described by authors only in terms of SRUs were indexed at this heading with no polymer registration. [A description of the indexing enhancements is also available from CAS Customer Service and is offered on the world wide web (WWW) at http://www.cas.org/EO/silox.html.]

Beginning with volume 121 (1994) of CAS Chemical Abstracts, structural representation and machine registration was begun for polymers previously handled only as text terms in the CA File. Backfile conversion is not planned.

This policy change affects the following areas [CAS's exact phraseology (including use of parentheses, vice brackets, for SRUs) is used below; in most cases, when words such as siloxanes or silsesquioxanes are cited, what is meant is polysiloxanes or polysilsesquioxanes]:

(1) siloxanes or silsesquioxanes prepared by hydrolytic polymerization of alkoxysilanes or halosilanes
(2) siloxanes described only in terms of single-unit SRUs of the type $(—O—SiRR'—)_n$ (R, R′ = monovalent radical)
(3) siloxanes described only in terms of multiunit SRUs of the type $(—O—SiR_2—)_x$ $(—O—SiR'_2—)_y$ or $(—R_2SiO—)_x(—R'SiO_{1.5}—)_y$ (R, R′ = monovalent radical)
(4) ceramers (hybrid organic–inorganic networks) prepared by hydrolytic polymerization (sol–gel process) of tetraalkoxysilanes containing organic moieties, which may be trialkoxysilyl-terminated organic polymers
(5) end groups for siloxane SRUs
(6) copolymers containing siloxane components
(7) tradenames for siloxanes and silsesquioxanes
(8) silicone rubbers.

A more detailed discussion of siloxane nomenclature and structure representation (40) includes further information on the changes introduced by CAS (http://www.cas.org/EO/silox.html).

For linear polysiloxanes, an IUPAC document (13) states that if there is a choice for the central atom, the element occurring *later* in the general element

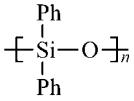

Fig. 14. Poly[(diphenylsilylene)oxy]. Polymer name: *catena*-poly[(diphenylsilicon)-μ-oxo]; Synonym: poly(diphenylsiloxane) (47).

sequence table (ie, the periodic table) is the central atom. Order of precedence begins in the top, right-hand corner of the periodic table and proceeds (in vertical columns) toward the bottom, left-hand corner; thus, atom seniority is F, Cl, Br, I, At, O, S, Se, Te, Po, N, P, As, Sb, Bi, C, Si, . . ., Li, Na, K, Rb, Cs, Fr, He, Ne, Ar, Kr, Xe, Rn.

The linear polysiloxane (diphenylsilylene)oxy is represented by the structure shown as Figure 14. The IUPAC name also differs appreciably from the CAS name. According to the rules for linear organic polymers, this polymer would be oriented and named poly[oxy(diphenylsilylene)] (13).

Lichtenwalner and Sprung (48) present some IUPAC nomenclature for polysiloxanes; most of their examples show silicon on the left. Other papers on polysiloxanes in a 1988 symposium publication (41) show the structures with silicon mostly on the left, although some are drawn with oxygen on the left.

Oligomers and Telomers. Qualitatively, *oligomers* are "short polymers", and *telomers* are "short polymers with specific end groups".

The terms "telogen" and "telomerization" were defined many years ago to describe an innovative method for the free-radical polymerization of ethylene (49,50). The essence of telomerization, described in a 1942 patent (50), involves reaction of a telogen XY (also called a chain-transfer agent) with an ethylenic molecule to give a telomer of structure X—$(A)_n$—Y. In the product telomer, fragments of the chain-transfer agent are attached to the termini of the molecule (49,50). Figure 15 illustrates the method.

CAS indexes oligomers of definite structures as specific compounds by the regular principles of organic nomenclature. When the precise structure is not known but the number of units is specific, "dimer", "trimer", etc, is expressed in the modification at the name of the monomer. The term "oligomeric" may be cited if this aspect is stressed in the original document (2). "Oligomeric," if applicable, is expressed in the text modification part of the index entry and is not part of the CAS Registry record, except for some records marked with an asterisk. [CAS Registry numbers appended with an asterisk (*) represent substances of unknown or variable composition, complex reaction products, or biological substances that do not meet the criteria for CA indexing. These substances generally have been registered for regulatory agencies and receive a CA Index Name. They have a special code of CTS or GRS in the Class Identifier (CI) field. The information in the Locator (LC) field and/or Source of Registration (SR) field provides an indication of the reason for registration.]

Telomers of unknown structure are indexed similarly to copolymers with the term "telomer with. . ." cited in the modification (see Fig. 15). Telomers with a definite structure are named systematically (2) rather than as telomers per se (see Fig. 16).

Fig. 16. Oligomeric poly(ethylene) telomer with CCl_4. The term "oligomeric" is part of the CAS Registry record name only in records marked with an asterisk (see text for details).

IUPAC defines an oligomer as "a substance composed of molecules containing a few of one or more species of atoms or groups of atoms (constitutional units) repetitively linked to each other for which the physical properties vary with the addition or removal of one or a few constitutional units from its molecules" (1). IUPAC defines "telomer" and "telomerization" essentially as follows (22):

(1) *telomer*: an oligomer obtained by a telomerization process
(2) *telomerization*: an oligomerization by chain reaction carried out in the presence of a large amount of chain-transfer agent, so that the end groups are essentially fragments of the chain-transfer agent.

No recommendations have been published on how oligomers and telomers are to be named and represented graphically by either structure-based or source-based methods.

IUPAC references to oligomers and telomers are rare, although examples of a telomer (51) and an oligomer have been published. (see Section 4.3, Example 4.3-E1, in Ref. 8). IUPAC uses subscript *a*, *vice* subscript *n*, to indicate oligomers.

Conclusions

Over a period of about 50 years, representation of polymer structures, both on paper and in databases, has developed from a virtually random system to a highly organized and sophisticated one. Polymers are represented sometimes by structure-based methods, sometimes by source-based methods, and sometimes by both. Both methods survive because each offers advantages and disadvantages. Both methods involve structural representation of polymers by a precisely defined set of rules developed over several decades by CAS, IUPAC, and the Committee on Nomenclature of the Division of Polymer Chemistry of the ACS. Areas still in need of improved representation are copolymers of unterminated SRU types: aftertreated (post-treated) polymers, and dendritic (52), hyperbranched, hyper-cross-linked, star, and star-block polymers. Also needed are hierarchical relationships between intellectually related polymers (53).

SUPERABSORBENT POLYMERS

Introduction

Superabsorbent polymers are very high molecular mass, cross-linked polyelectrolytes (qv) that can absorb or imbibe more than 10 times their mass of water or aqueous solutions. In order to absorb this large quantity of aqueous fluid, the polymers must be only slightly cross-linked so that the polymer chains can adopt widely spaced configurations. And in order to remain largely insoluble, while at the same time being highly expanded, the polymer chains must have very high molecular mass so that the small number of cross-links connect together all the chains. Cross-linked polyelectrolytes absorb more aqueous liquid than do neutral polymers as a result of the added osmotic, swelling pressure of the counterions that balance the high electric charge of the ionized functional groups spaced along the polymer chains (see POLYELECTROLYTES).

While any high molecular mass, cross-linked polyelectrolyte can function as a superabsorbent polymer, the commercially available superabsorbent polymers are alkali metal salts of poly(acrylic acid) cross-linked with multifunctional cross-linkers (see ACRYLIC (AND METHACRYLIC) ACID POLYMERS). Most often the cross-links are formed from comonomers that are incorporated into the polymer during the free-radical-initiated addition polymerization. Common cross-linkers are di- and triacrylates or methacrylates. The polymer chains can also be cross-linked after the main polymer chains have been formed. In this case, the cross-linker is multifunctional with groups that can react with the carboxylic acid or carboxylate groups present along the polymer chains. Examples of this type of cross-linker are polyols, polyepoxides, polyamines, and the like. Most commonly, the polymers are made by means of free-radical-initiated polymerization of an aqueous solution of the monomers, followed by drying the hydrogel that is formed and grinding the dry polymer to a granular powder.

The principal use of superabsorbent polymers is as a liquid absorbent in disposable hygiene products, which include baby diapers, feminine hygiene products, and adult incontinence products. Smaller volume uses include liquid absorbent pads for packaged meats and water-blocking tapes and coatings for electrical and telecommunication cables.

Physical Properties of Monomers

The monomers useful for making superabsorbent polymers are water-soluble monomers such as those listed in Table 1. Acrylic acid, methacrylic acid, and 2-acrylamido-2-methylpropanesulfonic acid (1,2) are the principal ionizable monomers useful for making superabsorbent polymers. Other comonomers such as acrylamide and *N*-isopropylacrylamide can also be incorporated into the polymer chain. For example, *N*-isopropylacrylamide imparts temperature sensitivity into the superabsorbent polymer (3,4). The useful cross-linkers include a variety of multifunctional monomers, such as those shown in Table 2. They can

be di-, tri-, or tetrafunctional, and can have mixed types of polymerizable groups such as methacrylate and allyl, as in allylmethacrylate. Mixed types of functional groups provide olefins with varying reactivity toward the main monomer. The mixed-functional cross-linkers can be used to control the incorporation of the cross-links during the polymerization. For example, the gel point of the polymerization can be made at lower conversion of monomers by using a cross-linker that is more reactive than the main monomer. Conversely, the gel point can be delayed to higher conversion of monomers by using a less reactive monomer compared to the main monomer.

Manufacture of Monomer

The principal monomer used in the manufacture of superabsorbent polymers is acrylic acid. Acrylic acid is made by the oxidation of propene in two steps (5). First, propene is oxidized to acrolein, and then the acrolein is further oxidized to acrylic acid. Different mixed metal oxide catalysts are used for each step to optimize the yield and selectivity of the oxidation reactions. Technical-grade acrylic acid is isolated from the steam-quenched reaction gas by means of solvent extraction and distillation, and is used principally in the further preparation of acrylate esters. The technical-grade acrylic acid is further purified by distillation or by crystallization from the melt to afford the polymerization-grade monomer.

Properties of Polymers

The principal useful feature of superabsorbent polymers is their ability to absorb aqueous liquids and expand or swell in size. The swollen polymer—a cross-linked polymer solution—holds tightly to the liquid and prevents the liquid from being easily squeezed from the expanded structure. The two principal properties of the polymer that define their usefulness are the swelling ratio and the elastic modulus of the swollen polymer.

Swelling Ratio. The swelling characteristic of superabsorbent polymers has been described in several ways. A volumetric swelling ratio is equal to the volume of solvent absorbed per unit volume of the polymer. The gravimetric swelling ratio, or specific absorbency, is equal to the mass of solvent absorbed per unit mass of unswollen polymer. The gravimetric ratio is most commonly used in the measure of swelling in commercial practice. These volumetric and gravimetric ratios can be easily interconverted by multiplication with the ratio of densities of the solvent and polymer. The molecular theories of swelling and elasticity of cross-linked polymer networks use the volume fraction of polymer in the gel phase as a measure of swelling extent. The reciprocal of the volume fraction, equal to the ratio of gel volume to polymer volume, is an alternative volumetric swelling ratio. The theory (6) yields equation 1 for the swelling ratio q_{m} in terms of the essential structural and polymer synthesis parameters of the system.

$$q_m^{5/3} = \frac{\left(\frac{1}{2} - \chi\right) 2M_{\mathrm{c}}}{V_1 \rho_0 \upsilon_{2^0}^{2/3} (1 - 3M_c/M_n)} \tag{1}$$

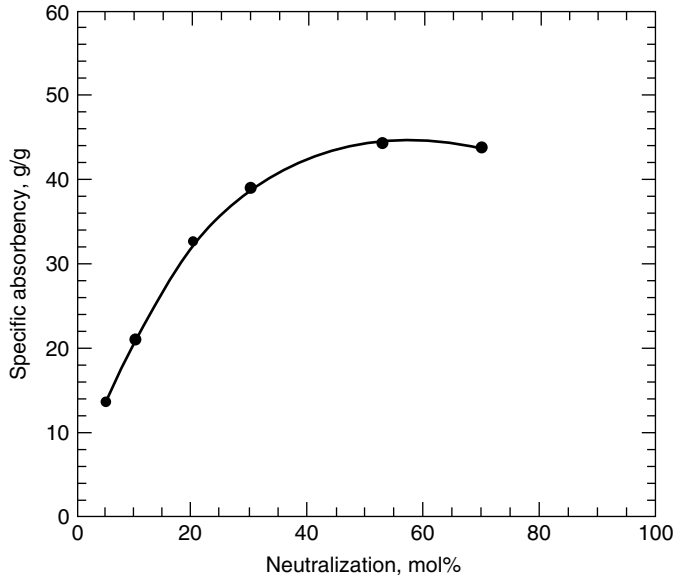

Fig. 1. Effect of neutralization on specific absorbency.

Assuming a randomly cross-linked, four-functional network, and including the ionic effects in an "apparent χ," the swelling ratio depends on the molecular mass of polymer chain between cross-links M_c, on the backbone molecular mass M_n, the molar volume V_1 of the solvent, and the density ρ_0 of the unswollen polymer. The volume fraction of monomer υ_{20} during polymerization influences the maximum swelling ratio through the term $\upsilon_{2^0}^{2/3}$.

Commercialized superabsorbent polymers are salts of weak polyacids; hence, their swelling varies with the pH of the swelling liquid or the ionization extent of the polymer, as shown in Figure 1. For superabsorbents made from strong acid monomer such as 2-acrylamido-2-methyl-1-propanesulfonic acid, the swelling extent does not depend on the pH of the swelling liquid (7).

The swelling ratio of any superabsorbent polymer depends directly on the cross-link density imposed during synthesis. The actual cross-link density often differs from the stoichiometry of reagents employed on account of inefficient incorporation of cross-linker, poor reactivity of cross-linker relative to acrylic acid, and the functionality (number of reactive olefinic groups) of the cross-linker molecule.

The swelling extent of all superabsorbent polymers is very sensitive to the salt concentration of the swelling liquid (8), as a direct result of their polyelectrolyte nature. The swelling extent decreases with increasing concentration of ions in solution. Divalent ions, such as calcium or magnesium, decrease the swelling of superabsorbent polymers much more than monovalent ions (per mole of ions) (9). The additional effect is so large that it has been erroneously believed that the divalent ions behave like cross-linkers. Measurements of both the swelling extent and elastic modulus of the swollen gels have disproved that notion (10). The gels, swollen in solutions of divalent ions, had equivalent modulus to the gels swollen

to the same volume fraction polymer in monovalent salt solution. However, many higher valence ions, such as ferric or chromic, add to the cross-link density of gels swollen in their solutions.

Modulus of Elasticity. When a swollen superabsorbent polymer particle is subjected to mechanical stress, it strains and changes shape. The elastic modulus of the material is the ratio of the applied stress to the resulting strain. For swollen superabsorbent polymers, the magnitude of the elastic shear modulus principally depends on the cross-link density established during synthesis of the polymer and on the extent of swelling during measurement of the modulus. Polymer swelling lowers the cross-link density by increasing the volume in which the cross-links reside.

The elastic modulus of the swollen superabsorbent polymer is important for several reasons. The powdered polymer is typically used in a physical blend with fibers such as cellulose and thermoplastic binder fibers. The resulting structure is called the absorbent core. The absorbent core relies on pore spaces between the fibers and polymer particles to provide liquid transport volume for the overall structure. When the swollen superabsorbent particles have low modulus, they are easily deformed by body pressures and can fill in the interfiber and interparticle pores. This prevents liquid flow and wicking of liquid into the drier portions of the core. Higher modulus limits the deformation of the particles and helps maintain the pore space.

The elastic modulus also influences the swelling kinetics of the superabsorbent polymer in the blend (11). For a cross-linked polymer, different shaped particles have different swelling kinetics. This results from the coupling between the diffusion of water into the polymer network through the surfaces of the particles, and the relaxation of the cross-linked polymer chains in the presence of the swelling agent. Of the simple shapes, spherical particles have the fastest kinetics whereas flat disks have the slowest kinetics. Spherical particles that are deformed into a disk-like shape swell more slowly, and therefore the more deformable swollen particles (lower elastic modulus) will be slower than similar sized particles with higher modulus that are less deformable.

The elastic modulus is controlled by the polymer network structure and synthesis conditions. The number of cross-links added per mole of main monomer helps define the molecular mass between cross-links. The molecular mass of the backbone polymer chain (obtained if no cross-linker was used) affects the effectiveness of the cross-links in forming a fully connected network with no soluble fraction and minimum content of dangling chains. The polymer volume fraction during cross-linking υ_{2^0} defines the extent of entanglement of the network chains, and therefore influences the elastic modulus.

From the molecular theory of networks, the shear modulus is given in terms of polymerization parameters according to equation (2)

$$G = \frac{\rho_0 RT}{2M_c}\left(1 - \frac{3M_c}{M_n}\right)\upsilon_{2^0}^{2/3}\upsilon_2^{1/3} \tag{2}$$

wherein the parameters have the same meanings as given above for the equation of the swelling ratio. The extent of swelling during measurement is expressed through the volume fraction of polymer in the gel υ_2. The gas constant R and the

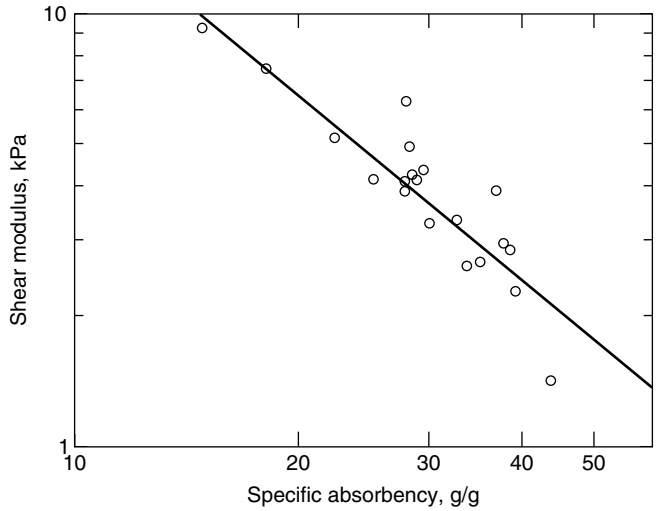

Fig. 2. Relationship of gel shear modulus to the specific absorbency. Polymers were swollen in 0.9% NaCl solution. To convert kPa to dyn/cm^2, multiply by 10^4.

temperature T also affect the magnitude of the modulus. By comparing equations 1 and 2, the swelling capacity and the elastic modulus are inversely related to the same structural parameters. This relationship is shown in Figure 2.

Swelling Kinetics. A first-order relaxation process in which the polymer chains relax and diffuse into the aqueous solution controls the swelling rate, which is given by equation 3:

$$\text{Rate of swelling} = \frac{dQ}{dt} = k(Q_{max} - Q(t)) \tag{3}$$

wherein Q_{max} and $Q(t)$ are the swelling ratios at equilibrium and at any time t, under the conditions of the experiment. The first-order rate (or relaxation) coefficient k depends on the diffusion coefficient of the polymer chains and on the particle radius. Integration over the total swelling time yields equation 4.

$$Q(t) = Q_{max}(1 - e^{-kt}) \tag{4}$$

The rate coefficient k depends on the elastic subchain length (between cross-links), decreasing with increasing chain length between cross-links (ie, lower cross-link density). The rate coefficient also decreases with increasing particle radius. Increasing the temperature hastens the thermal fluctuations of the chains, and hence increases the rate coefficient. The rate coefficients for the weak polyelectrolyte superabsorbent polymers vary with the pH (extent of neutralization) and the salt concentration as well. At higher pH, the chains adopt a stiffer conformation; hence, the rate coefficient increases with pH. Addition of monovalent salts has the reverse effect on conformation; hence, the rate coefficient decreases with increasing salt concentration.

Polymerization

Superabsorbent polyacrylates are prepared by means of free-radical-initiated copolymerization of acrylic acid and its salts with a cross-linker (12,13). Two principal processes are used: bulk, aqueous solution polymerization and suspension polymerization of aqueous monomer droplets in a hydrocarbon liquid continuous phase (14) (see BULK AND SOLUTION POLYMERIZATIONS REACTORS; HETEROPHASE POLYMERIZATION). In either process, the monomers are dissolved in water at concentrations of 20–40 wt% and the polymerization is initiated by free radicals in the aqueous phase (15). The initiators, freeradical (qv) used include thermally decomposable initiators, reduction–oxidation systems, and photochemical initiators and combinations. Redox systems include persulfate/bisulfite, persulfate/thiosulfate, persulfate/ascorbate, and hydrogen peroxide/ascorbate. Thermal initiators include persulfates, 2,2′-azobis(2-amidinopropane)-dihydrochloride, and 2,2′-azobis(4-cyanopentanoic acid). Combinations of initiators are useful for polymerizations taking place over a temperature range.

The copolymerization is conducted either at low pH with the acid-form monomers, which are neutralized after polymerization, or at roughly neutral pH with partially neutralized carboxylate salts. Sodium hydroxide and sodium carbonate typically are the neutralizing agents. The cross-linkers vary in functionality, from difunctional acrylate esters and methylenebisacrylamide, to trifunctional compounds, such as 1,1,1-trimethylol-propanetriacrylate and triallylamine, and to tetrafunctional compounds, such as tetra(allyloxy)ethane.

In the case of acrylic and methacrylic acids, the reactivity of the monomer toward polymerization is a complex function of the pH (extent of neutralization) and monomer concentration. The reactivity of ionized monomer being lower than the neutral carboxylic acid, polymerization proceeds more slowly as pH is increased (16–18). A minimum in the polymerization rate occurs at pH of 7 (19–21). Above pH of 7, the rate increases again because of electrostatic screening due to increased ionic strength.

Processing of Polymers

Gel Size Reduction. After polymerization, the gel intermediate must be dried. However, prior to drying, the size of the gel pieces must be reduced in order to increase surface area and speed drying. In some commercial processes, the gel size reduction is done in the polymerization vessel by means of high torque agitators or screws. In other processes, gel is sized in a separate unit operation of gel extrusion and cutting or mincing. Final gel particles are in the diameter range of 0.5–3 cm.

Drying. The water used as solvent in the polymerization is removed from the polymerized gel by evaporation in continuous-operation, hot-air convection dryers or in contact dryers such as steam-heated drum dryers. In hot-air convection dryers, the rate of moisture removal depends on the heating gas temperature, humidity and flow rate, and the diffusion characteristics of water from the gel. Drying occurs in three general stages. For high water content in the gel, the drying rate is constant, as the rate is limited by heat transfer into the gel. At low water

contents, the drying is limited by diffusion of water through the gel, and the drying rate falls as water is further depleted. In the intermediate or transition regime, some of the polymer is still in the constant-rate regime while other portions have entered the diffusion-controlled regime.

On rotating drum dryers, the drying energy is conductively transferred from the hot metal drum to the gel (22). The hydrogel must be applied to the drum in a sufficiently thin layer, accounting for the available heat transfer and drum size, so that it is thoroughly dry in about three quarters of a revolution of the drum roll, whereupon it is scraped from the drum with flaking knives. In order to spread the gel layer effectively onto the drum, the hydrogel must be soft enough to be deformable in the dryer nip.

Grinding and Sieving. Grinding or milling the very coarse dryer product, followed by sieving sets the particle size distribution of the dried superabsorbent polymer. The common polyacrylate superabsorbent polymers have a particle size distribution ranging from about 200 to 800 μm. Two-stage milling is frequently used in combination with sieving and recycle of the oversize particles in order to prepare a relatively narrow size distribution of the final granular powder. Knife mills, attrition mills, roll crushers, and the like are used in the first stage to provide a coarse but narrower particle size distribution feed for the second grinding stage. In the second stage, the final average particle size is attained. Sieving off both the coarse tail and the fine tail of the size distribution typically narrows the final size distribution further. The coarse tail is recycled to the grinder, and the fine tail may be used for other purposes or recycled back to the polymerization reactor.

Surface Cross-linking. Since small particles of hygroscopic polymer absorb water very fast, they can quickly form a thin, sticky layer of gel at the particle surface and then clump together or "gel block." The resulting interparticle adhesion causes the formation of large, sticky agglomerates with low interparticle porosity and drastically slower swelling rate. One remedy is to add a solution of multivalent cations to the surface of the dry particles, forming an ionically cross-linked surface layer (23). Alternatively, the particle surface can be coated with and reacted at elevated temperature with polyols, polyepoxides, linear or cyclic diesters or polyamines, as examples, forming a covalently cross-linked surface shell (24–26). This shell of higher cross-link density is less swellable, less sticky, more rigid than the untreated polymer surface, and prevents gel-blocking. This improves the permeability of the particle bed toward liquids.

A third method to produce these so-called structured particles is to first form a particle with higher cross-link density and then lower the cross-link density in the center of the particle. Cross-linked polymers made in the presence of oxidizing agents such as sodium or potassium chlorate have shown improvements in absorbency under load and swelling capacity after a high temperature heating step (27) wherein a portion of the polymer chains in the particle center are cleaved through the action of the oxidizers.

Economic Aspects

Cross-linked, partially neutralized poly(sodium acrylate) represents the overwhelming majority of the superabsorbents manufactured in the world today.

The global manufacturing capacity for these superabsorbent polymers in 2001 was estimated to be about 1.187 million metric tons per year. This quantity is split with 380 kt/year in Europe, 427 kt/year in the United States of America, and 380 kt/year in Asia. Total global usage of superabsorbent polymers in 2001 amounted to about 1093 kt, or just over 92% of the global manufacturing capability (28).

In 2001, there were six principal global manufacturers of superabsorbent polymers. BASF Aktiengesellschaft had about 305 kt/year of manufacturing capacity, followed by Degussa (Stockhausen division) with about 245 kt/year, Nippon Shokubai Kagaku Kogyo with about 230 kt/year, The Dow Chemical Co. with about 120 kt/year, SanDia (Sanyo and Mitsubishi joint venture) with about 95 kt/year, and Sumitomo Chemical with about 60 kt/year. Several more small manufacturers together made up another 132 kt/year of manufacturing capability. Included in this group of smaller companies are those who make slightly different superabsorbent polymers such as cross-linked, partially neutralized poly(potassium acrylate) and cross-linked, slightly ionized polyacrylamide, which are used mainly in the agricultural and horticultural industries.

Superabsorbent polymers are used mainly in disposable, personal care hygiene products. About 81% of total tonnage (885 kt/year) is used in infant diapers and child training pants. Another 14% of the total (157 kt/year) is used in adult incontinence products, and about 2% (22 kt/year) is used in feminine menstrual pads and napkins. The remaining 3% of total tonnage (32.8 kt/year) is used in other applications such as construction materials, cable wrapping tapes, agriculture, and horticulture.

Analytical and Test Methods

Swelling Capacity. Several methods have been used to measure the specific absorbency (mass of liquid absorbed per unit mass of superabsorbent polymer), swelling ratio, or swelling capacity (29). In the most common technique (30), a small quantity of superabsorbent polymer is placed in a porous, heat-sealable bag, which is then immersed in the desired aqueous liquid. The polymer is allowed to absorb liquid for a time long enough to reach maximum or equilibrium swelling, which is usually from 30 to 90 min. Then the porous bag and its contents are centrifuged under standard conditions to remove the unabsorbed liquid from the pore spaces between the swollen particles. The liquid absorbed is determined by gravimetry.

Elastic Modulus. The elastic shear modulus of swollen superabsorbent polymer is commonly measured by means of oscillatory rheometry, using any of a variety of commercially available instruments (31). The sample to be analyzed is screened to the desired particle size cut such that the swollen particle size is smaller than the gap between the measuring plates. The sample is swollen in the desired liquid, usually 0.9 wt% NaCl solution or synthetic urine. Excess liquid is removed from the swollen hydrogel by blotting to minimize interparticle slippage. The hydrogel typically is placed onto the lower circular plate. An upper conical plate is positioned at the proper sample gap, which is packed with the gel. An oscillating torque is applied at a known frequency to the upper plate and the

resulting angular displacement of the cone is determined. The shear modulus of the hydrogel is calculated from the ratio of the applied stress to the resulting strain (32).

Particle Size Distribution. The particle size distribution is determined by sieving. The Rotap sieving, similar to the ASTM method used for polymer powders (33) is typically used. The method consists of placing a known quantity of the powder in a stack of sieves that are shaken horizontally while being hit at the top with a hammer (34). Alternatively, vibrating sieve sets may be used. The mass of polymer on each sieve is measured gravimetrically. From this data, the size distribution may be plotted and the mass-median particle size calculated.

Bulk Density and Flowability. The polymer bulk density (35) and polymer flowability (36) affect conveying pipe and hopper design in the polymer manufacturing plants and dosing machine settings on diaper manufacturing lines. Flowability is typically evaluated by timing the flow of a 100-g granular sample from a funnel into a cylinder of known volume. The bulk density, taken from the same procedure, is the mass/volume ratio of polymer in the cylinder.

Swelling Kinetics Methods. Swelling kinetics for superabsorbent polymers may be measured by a viscometric method (37), based on the dependence of suspension viscosity on the volume fraction of the suspended particles. However, the swelling rate is most often measured by determining the specific absorbency as a function of time, for example, by means of the centrifuge capacity analysis. An absorption rate may also be obtained from data of swelling vs time using the demand absorbency method (38).

A simple, single-point measurement of kinetics has been used in the patent art (39–41) and its characteristics have been described (37). The method, referred to as the "vortex time" analysis, is based upon the earlier exponential kinetic equation, rearranged to obtain equation (5) for a characteristic swelling time in terms of the values of Q, Q_{max}, and the rate coefficient k.

$$t_v = -\frac{1}{k}\ln(1 - Q/Q_{max}) \tag{5}$$

When the relative swelling of the sample Q/Q_{max} is known or is held constant, then t_v is simply related to the rate coefficient.

In the original method (39), 2 g of polymer sample is mixed with 50 mL of the desired test fluid, which is stirred by means of a magnetic stirring bar in a small beaker. As the fluid absorption proceeds, the viscosity of the suspension increases until the stirring vortex disappears at time t_v. The volume fraction of swollen polymer in the suspension when the vortex disappears was estimated to be equal to 0.52 (42). For the most accurate and comparable results across samples with different swelling capacities, the mass of polymer added must be adjusted based on the value of the specific absorbency. As the specific absorbency increases, less polymer is used in the test so that each sample reaches the same relative swelling extent at time t_v (43).

Absorbency under Load. The absorbency under load is a commonly used measure of the performance of superabsorbent polymers in absorbent products

such as diapers. It is not so much a property of the superabsorbent polymer, but rather a swelling phenomenon of a compressed, packed bed of polymer particles. The test system consists of a short plastic cylinder with a fine mesh screen fixed over one end. A quantity of dry polymer particles is placed on the screen and covered with a loose-fitting plastic disk as a piston. A standard weight is placed on the plastic piston, and then the polymer is put into contact with a saline solution through the fine mesh screen. As the polymer absorbs liquid, the swelling particles fill the cylindrical cell and push up the piston. The gravimetric swelling ratio achieved in a standard time is determined. The test is thought to mimic the behavior of the polymer as it swells within the absorbent core, under compression applied by the baby's body. The test has been modeled in terms of the polymer properties and some characteristics of the particle bed (44).

Uses

The unique attributes of superabsorbent make them useful in many different applications. The liquid absorption and retention ability makes them useful in disposable hygienic products. These include infant diapers, feminine hygiene pads, and adult incontinence products. Other absorbent products suitable for superabsorbent polymers are paper towels, surgical sponges, meat trays, disposable mats for outside doorways, household pet litter, bandages, and wound dressings. Because the gels can slowly release water vapor to the atmosphere, they can be used in humidity controlling products or as soil conditioners. Superabsorbent polymers can also release water-soluble substances from within the network structure into surrounding solutions; hence, pharmaceuticals or fertilizers may be controllably released from within the gels. The rubbery nature of the swollen gels can control the consistency of cosmetics or concrete, and yield a soft and dry feel to hot or cold packs for sore muscles. The combination of swelling and soft rubber properties imparts sealing properties to products that may come into contact with water or aqueous solutions, such as, underground wires and cables. In the following paragraphs, additional details will be given of how the properties of superabsorbent polymers affect their utility in specific products.

Disposable Infant Diapers. A basic disposable diaper consists of an absorbent core sandwiched between a liquid permeable top-sheet and an impermeable back-sheet (45). The top-sheet, next to the baby's skin, allows urine to flow through it into the core. The back-sheet, made of impermeable plastic, helps keep the baby's clothing dry. The core takes in the liquid, distributes it within the core and holds the liquid under compression from the baby.

In a diaper, the polymer is mixed with 0.5–10 times its mass of cellulose pulp fluff (processed wood fiber) to make up the core (46–48). Cores containing superabsorbents are thinner because a smaller volume of dry superabsorbent polymer can absorb the same volume of aqueous liquid as a larger volume of fluff.

In addition to the specific absorbency of the superabsorbent polymer, the absorption rate of the diaper must be optimized to the urination rate of the baby. When the core absorbs too slowly relative to the urination rate, the liquid overflows

the core and leaks from the diaper. The absorption rate of the composite is influenced by the absorption rate of the superabsorbent polymer. Fast swelling of the polymer can contain the liquid quickly. However, in some diaper designs, fast swelling may cause the diaper to leak if the porosity and permeability of the composite is reduced too rapidly.

Adult Incontinence. Adult incontinence products include belted or fitted disposable garments and light incontinence pads, which are similar to feminine napkins. Similar design considerations are used as in baby diapers. In adults the liquid volume is larger and the urination rate is faster than in infants; therefore, polymers with larger specific absorbency and faster swelling rate are desired for this application (49). The market for these products is growing with the aging population.

Feminine Hygiene. The first personal-hygiene product commercialized with superabsorbent polymer was a feminine napkin in Japan. Perhaps the biggest challenge in using superabsorbent polymer in these products is the huge difference in properties between urine and menstrual fluid. Menstrual fluid is a complex, viscous mixture of water, salts, proteins, and cells. The cells are far too large to be absorbed into the superabsorbent polymer, and the proteins make the fluid very viscous and thereby slow the diffuse of liquid into the polymer. In other blood absorption applications, such as in surgery and surgical appliances, the polymers can be chemically modified to prevent undesired blood clotting (50). Incorporating similar additives into superabsorbent polymers may improve their performance in feminine hygiene products.

Agricultural and Horticultural Applications. Superabsorbents in agriculture and horticulture are used as a mulch, to help the soil retain moisture (51,52). To provide this function, the polymers optimally are mixed into soil at a concentration of about 0.1 wt%. The resulting mixture retains moisture longer than untreated soil and helps maintain optimum germination conditions. Superabsorbent polymer helps improve porosity in clay soils, as the polymer particles expand and contract during the moisture cycles. However, in wet and soggy soils with low oxygen content, superabsorbent polymers can prolong the unfavorable soil conditions. Salt-tolerant superabsorbent polymers may be more useful than the common polyacrylates for this application. An excellent review of superabsorbents in soil has been published (53).

Construction Materials. Superabsorbent polymers are used to control liquid water in a variety of construction-related products. Joint-sealing composites are made by blending superabsorbents into chloroprene rubber (54) or into poly(ethylene-*co*-vinyl acetate) (55). These composites are used like mortar in the concrete block walls of the structure. Gaps left during construction are subsequently filled as the superabsorbent swells in any water, and subsequent leaks are prevented. A water-blocking construction backfill has also been developed from cement, water absorbing polymer, and an asphalt emulsion (56).

The swelling property of superabsorbents also protects communication cables from water damage (57,58). Water-blocking tapes are wrapped around fiber-optic communication cables and power transmission cables to stop intrusion of water into the cables if the water-resistant coverings are cut or broken (59). The

swelling polymer seals the damaged area and slows water penetration further along the cable.

Food Packaging. Superabsorbent polymer can also absorb juice or water from raw chicken, shellfish and other meats, or from frozen foods as they thaw, reducing sogginess of the product (60). Chilled superabsorbent polymer gels can also be used as a dry-cooling medium to keep perishable foods cold (61). The humidity controlling property of superabsorbent polymer also can be used to maintain a constant humidity in vegetable and fruit storage and prevent water spotting on fruits (62).

Sensors. Superabsorbent polymers can be used in sensor systems by virtue of their swellability and rubbery nature, which are controllable by changes in water content, pH, and ionic strength. Because a small voltage may be induced in a soft hydrogel by applying mechanical stress to the gel, a pressure-sensitive switch is possible (63). The potential that develops between the stressed and unstressed parts of the gel generates a signal that can light a photo diode. The intensity of the light emitted by the diode depends on the magnitude of the applied stress. The application of a voltage across a polyelectrolyte gel conversely causes a volume change in the gel. This may be used to perform work in applications such as robotic fingers (64) or artificial muscle (65).

SYNCHROTRON RADIATION

Introduction

The application of x-ray scattering to elucidate the structure and phase behavior of biological and synthetic polymeric systems has been an established research field for a long time. Initially these experiments were performed with conventional x-ray sources such as sealed tube generators and later with rotating anode generators. Although polymers are in general weakly scattering, the pioneers of this field managed to resolve many problems by ingenious use of the existing equipment. However, when the higher intensity generated by synchrotron radiation (SR) sources became available, it did not take long for the huge potential of the highly collimated and intense x-ray beams generated by these machines to be recognized as extremely valuable. Not only can the morphology of polymers be elucidated to a higher degree of accuracy than with conventional x-ray sources, but also structural changes can be studied while varying parameters such as sample temperature, pressure, and shear field in a time-resolved way.

Fundamentally, there is no real difference between x-ray research performed with laboratory x-ray sources or with SR sources, apart from technical issues such as the higher x-ray flux, smaller x-ray beam divergence, or better collimation. The treatment and interpretation of data in both cases is consequently not fundamentally different. Therefore, this article focuses on issues that are related to those aspects in which the higher beam quality of SR beamlines is indispensable, although one should hasten to add that the use of SR should not be seen to be competitive with research performed with conventional x-ray generators, but a welcome complimentary extension of the experimental possibilities.

The higher flux, the wavelength tuneability, and the smaller beam sizes allow fast time-resolved experiments, the use of more complicated sample environments,

the simultaneous combination of scattering experiments with other, non-x-ray-based techniques, and also a high throughput of samples.

At present, SR sources have become so powerful that it has become feasible not only to perform real-time experiments on conventional polymeric systems, but also to perform much more sophisticated experiments on extremely small samples. This includes experiments on a single silk fiber spun by a spider or the changes in the fiber diffraction pattern generated by the fibers in the muscles from a live drosophila fly, which was persuaded to flap its wings in an x-ray beam.

In this article some of the possibilities for conventional x-ray scattering experiments and the insight these experiments have shed on polymers with the use of SR are discussed. It is impossible to comprehensibly cover the whole field where SR and polymer research intermingle. At present there are approximately 20–30 SR beamlines that are being used for x-ray scattering experiments. Experience tells that a week of experiments on such a beamline provide on average ample data suitable for publishing. This means that around 20 publications appear per week in which synchrotron scattering experiments on polymers are being described.

Synchrotron Radiation

Synchrotron radiation is the name given to the electromagnetic radiation emitted when highly energetic charged particles are led through a magnetic field and are thus forced to change their direction. The existence of this radiation was first predicted by the theoretical work of Schwinger and others (1) and subsequently experimentally observed by researchers from General Electric in 1947. The production of SR is not limited to particle accelerators. Astrophysicists also have found that it is generated when charged particles are spiraling toward a celestial body is its magnetic field.

First treated as an unwanted side effect in high energy physics research, because of the electron energy loss involved in the emission that is detrimental to the efficiency of accelerators used for high energy physics research, it was soon recognized to be an extremely valuable tool for researchers wanting to use the broadband wavelength spectrum, which ranges from infrared to the hard x-ray domain (from a few electron volts to scores of kiloelectron volts). Consequentially, the first experiments using SR were performed in a parasitic mode on high energy physics machines. However, the requirements regarding the electron beam size between high energy physics and x-ray research are not completely compatible, which led to the construction of machines dedicated to the production of SR, the so-called storage rings, in which the electrons emitting the radiation were made to circulate while keeping their energy constant. This approach contrasts with high energy physics where the electrons are continuously accelerated and thus the SR spectrum is continuously changing.

In the history of SR research, one generally groups the laboratories which used the radiation of high energy physics machines in a parasitic mode in the category of the first generation machines (eg, Desy at Hamburg, the Cornell Synchrotron, Nina in Daresbury). The second generation machines are those that were dedicated to the production of SR and in which care was taken to optimize the electron beamsizes (NSLS at Brookhaven, Photon Factory in Tsukuba, SRS at

Daresbury). In these machines, most beamlines relied on the photons produced by bending magnets. In the third generation of machines, the electron beamsizes are even further reduced and a large number of beamlines are constructed, not only on bending magnets but also on undulators or multipole wigglers (ALS in Berkeley, APS in Argonne, ESRF in Grenoble, Spring8 in Harima). On most websites of SR laboratories, one can find pages listing other known laboratories (eg, www.esrf.fr, www.aps.anl.gov, or www.spring8.or.jp).

The x-ray wavelength spectrum and the number of photons that is generated is a function of the energy of the electrons in the storage ring and the magnetic fields that are used to keep the electrons in a closed orbit. A detailed treatment of these aspects is beyond the scope of this article. The interested reader can find a large amount of literature on these subjects (2,3).

A table with operational SR sources can be found in Reference 4 and a table with operational x-ray scattering beamlines can be found in Reference 5. Since SR-based research is still a rapidly expanding field, these tables might become outdated within several years.

The basic "workhorse" of the earlier generations of storage rings is the bending magnet in which electrons were forced to move in a circular path upon which they emitted radiation. This type of magnet generates a relatively broad cone of radiation with a relatively high divergence (see Fig. 1a). It should be remarked that even with these magnets the divergence and collimation is superior to that with conventional x-ray generators. A typical example of an intensity versus wavelength curve is given in Figure 1b, where the spectrum of a bending magnet of the European Synchrotron Radiation Facility (ESRF) is shown.

The more recent generation of SR sources still uses bending magnets since these are indispensable for the construction of a storage ring. However, modern accelerator technology allows for the insertion of devices in the straight sections between bending magnets. Of the different types of insertion devices, such as wigglers, wavelength shifters, and undulators, only the last ones are of interest for soft condensed matter research. These devices consist of arrays of permanent magnets which force the electrons (or positrons) in the storage ring over a sinusoidal path. By choosing the appropriate periodicity of the path, the x rays emitted by the electrons will be coherent from one position of the path with respect to the following equivalent position in the sinus. This causes interference effects between the succesive undulations. The result is that highly intense and extremely collimated x-ray beams are generated. See Figure 2a for a description of this process and Figure 2b for an example of the energy/intensity spectrum, which is generated by an ESRF undulator.

Beamlines. The greatest advantage of SR beamlines over conventional sources, when dealing with soft condensed matter research, is maybe not even the larger amount of photons which can be thrown onto the sample, but more so the fact that these photons are in less divergent beams. This means that optical elements can be used to condition the beam, which is not feasible with conventional sources. Obviously there are some drawbacks as well, but apart from the higher harmonic problem, which is discussed later, these mainly have consequences for the construction of the beamline and should not concern users of these beamlines. However, it is a fact of synchrotron life that most experimenters using these facilities will one day encounter some problems due to technical failures connected

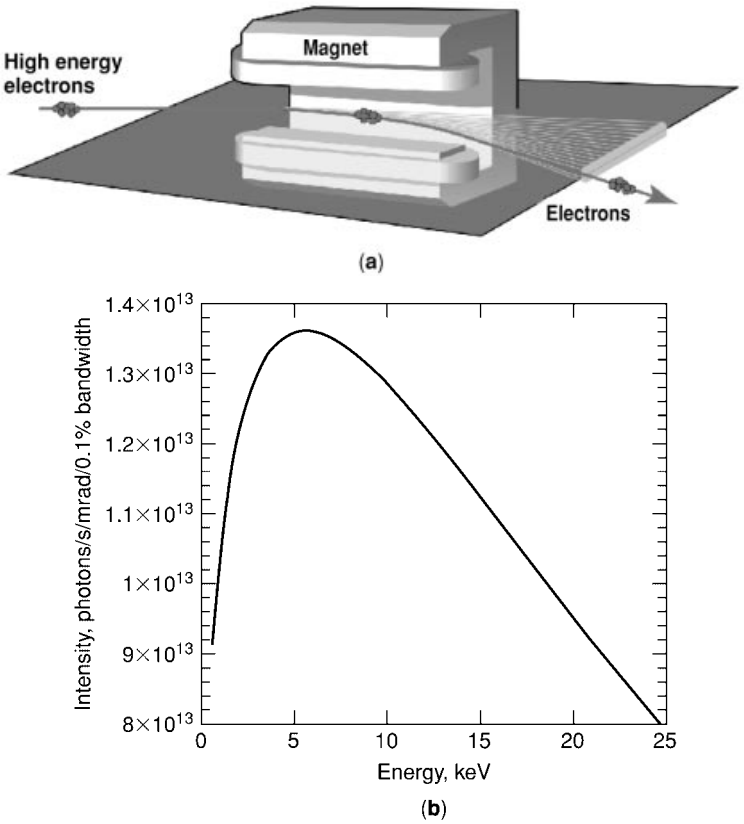

Fig. 1. (**a**) X rays are generated when charged particles with relativistic speeds are led through a homogeneous magnetic field. The Lorentz force forces the particles to follow a circular trajectory. In this process the particles emit radiation. (**b**) x-ray flux as function of energy generated by a bending magnet of the ESRF in Grenoble operating at 6 GeV and with a magnetic field of 0.8 T in the magnet. Similar curves of other third generation SR facilities can be shown. For second generation sources the flux is approximately a factor of 10 lower. However, even these second generation sources can generate a factor of 100–1000 more intensity when compared with conventional x-ray generators.

with the drawbacks. The mean time between failures of a beamline is shorter than that of a decent laboratory generator.

For conventional scattering beamlines there are three types of optical elements which are important. These are monochromators, mirrors, and slits. The functions of these are briefly discussed, since for an experimenter it is often detrimental if there is no basic understanding. Depending on the application, different types of elements can be used and they can be placed in different orders.

Monochromators. The x-ray spectrum emitted by a storage ring has been discussed in a previous section. For most scattering experiments the "white spectrum" emitted by the storage ring is not directly useful but one requires a monochromatic x-ray beam. Monochromators are available in several varieties with different properties. A conventional scheme uses a triangular monochromator which is circularly bent by clamping the base and pushing against the tip. This

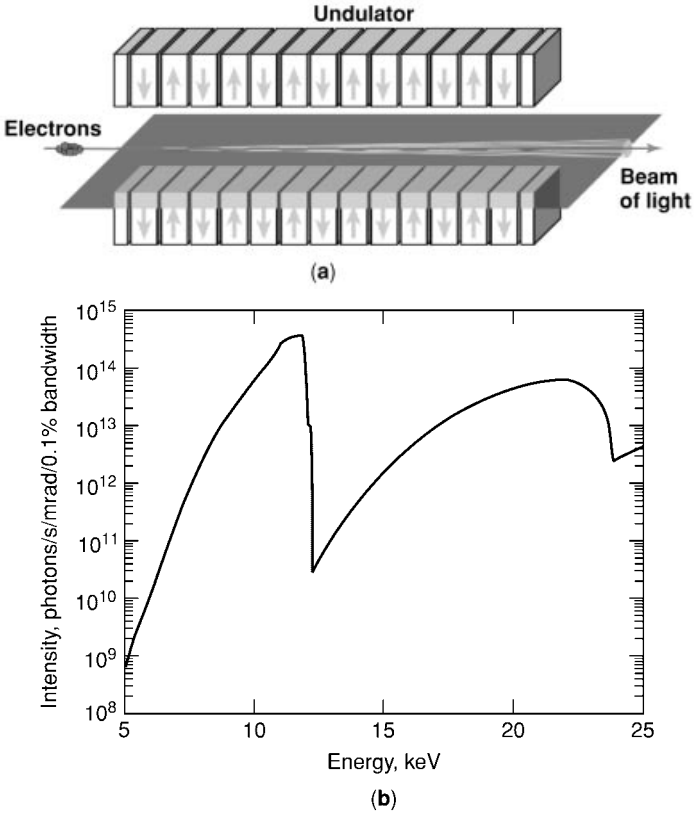

Fig. 2. (**a**) Undulators consist of a series of permanent magnets which are positioned to force the charged particles in the storage ring to follow an undulating path. With the appropriate period this radiation is coherent with respect to the radiation emitted by the next undulation. (**b**) Representative spectrum of an ESRF undulator. At the ESRF it is possible to place three of these undulators in series, thus enhancing the flux even further.

enables not only monochromatization but also focussing (6). Another commonly used design is the double crystal monochromator from which the second crystal is also sometimes bent for the same focussing purpose (*sagittal focussing*) (7). The monochromator material defines the bandwidth which is transmitted ($\Delta\lambda/\lambda$). One can use Si, with a narrow bandwidth, Ge, or alternatively monolayer systems. The last option allows a very high transmission at the expense of bandwidth. However, for x-ray scattering beamlines used for polymer research, the bandwidth is rarely an issue, not even with the monolayer systems in which the bandwidth is of the order of 0.01. In contrast with neutron scattering experiments, the raw data in general does not have to be treated for the bandwidth spread. The conventional energy range used in soft condensed matter research is 5–15 keV, which is equivalent to a wavelength range of 0.08–0.25 nm.

Mirrors. X rays can be focussed by letting the radiation impinge under grazing incidence upon a very smooth surface which is slightly bent. The material from which the mirror is made used to be special types of glass such as Zerodur or fused quartz but the tendency is to start using single crystal Si mirrors since these have

better mechanical and thermal properties. Other mirror substrates are in use as well. The angle of incidence lies somewhere between 1.0 and 10 mrad and, together with the substrate or coating material, determines the high energy cutoff. Over a certain energy, x rays are not reflected anymore. This property has become more important with the new generation of synchrotrons which operate at higher energies and therefore have a substantial amount of high energy radiation in the white spectrum. Monochromators transmit not only the primary energy but also the higher harmonics of these, and this has to be suppressed.

Average parameters for a mirror are a surface roughness of 0.15–0.4 nm and a slope error of 1–4 μrad. The dimensions can vary from several centimeters to 1.5 m. The surface quality is very important and therefore these mirrors are always mounted in a high vacuum vessel.

Slits. Slits are used to shape the beam and to reduce parasitic scatter around the primary beam. The latter is of overriding importance in small-angle scattering beamlines since it is the amount of parasitic scatter that is the most important factor in determining the possible low angle resolution and therefore the maximum size of the structures that can be observed (see Fig. 3).

Assembled Beamlines. The requirements for a beamline suitable for either wide-angle x-ray scattering (waxs) or small-angle x-ray scattering (saxs) do not differ much. One needs a beam size of around 0.5×0.5 mm^2 with a reasonable intensity ($>10^{10}$ photon/s). For saxs there is an extra requirement to reduce the parasitic scatter around the direct beam as much as possible. In time several design schemes, often dictated by the available x-ray source, have been used. These are based on a focussing element in the horizontal direction (often functionally combined with the monochromator) and a focussing element in the vertical direction (often a mirror). Examples of assembled beamlines can be found in References 8–12. This is a nonexhaustive list. A more extensive list can be found in Reference 5. A schematic description of a beamline can be seen in Figure 3. In this

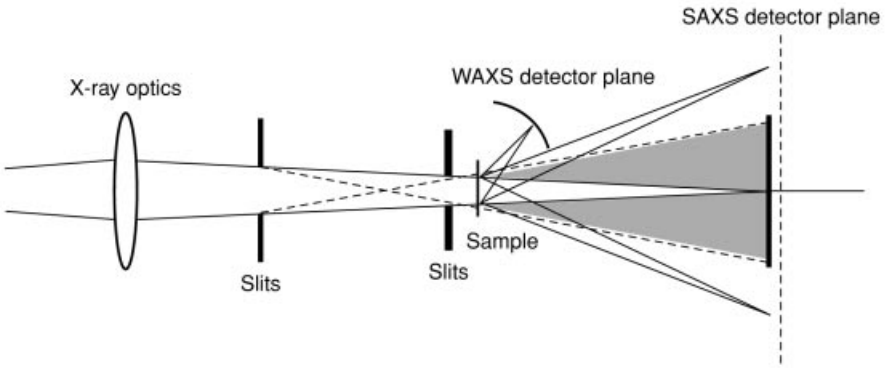

Fig. 3. Schematic description of an x-ray scattering beamline. The optical system is represented by a lens. The parasitic scatter cone is represented by the gray area. The scattering information which falls in this region is useless since the parasitic scatter is orders of magnitude more intense than the scattering pattern itself. The importance of the positioning of the slits in determining the extent of the parasitic scatter cone, which is the limiting factor in achieving low angle resolution, can be observed. Most beamlines are in fact equipped with three or more slit systems between the last optical element and the sample position.

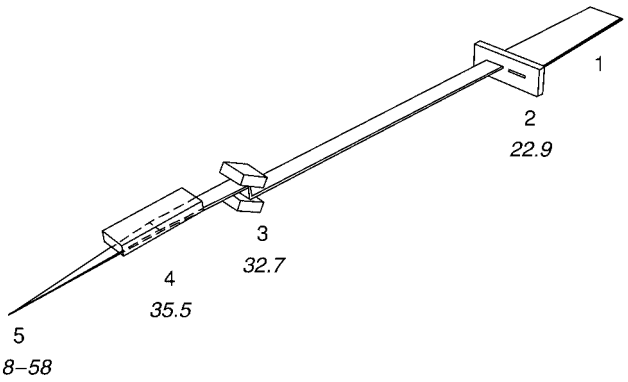

Fig. 4. Typical layout of the optical system of a scattering beamline constructed on a bending magnet source of the ESRF. The radiation fan (1) emitted by the bending magnet is used for two beamlines, each receiving 0.02 mGy of the total 0.09 mGy (2). A double crystal monochromator (3), from which the second crystal can be bent in order to allow horizontal focussing, is constructed in such a way that an energy range from 0.05 to 0.3 mGy can be covered. The long single crystal Si mirror (4) can also be bent in order to focus the beam in the vertical direction. Possibilities exist to insert an extra mirror in front of the monochromator which can be used to collimate the beam. This will enhance the energy resolution and will allow anomalous scattering experiments to be performed. The flux generated by this beamline is up to 10^{12} photons/s which can be focussed in a round 300-μm focal spot. Courtesy of I. Cerjah.

figure the optical system is represented as a lens ignoring the different schemes that exist. The most conventional systems at present are a combination of a vertically focussing mirror combined with an asymmetric-cut triangular monochromator that has the dual function of monochromatization and focussing in the horizontal plane (8,11) or, alternatively, a sagitally focussing double crystal monochromator combined with a vertical focussing mirror (12). A schematic example of one of the possible schemes to construct a saxs/waxs beamline is shown in Figure 4.

The use of optical elements that can focus the beam into a small spot is one of the main advantages of SR. This allows the user to generate a rather large x-ray flux on the sample in pseudo pinhole collimation. Until recently, the only other method to obtain sufficient flux was the use of a conventional generator equipped with a slit-collimated Kratky system (13). This unavoidably leads to the use of (mathematical) desmearing techniques. Nowadays, it has also become possible to utilize focussing elements such as Göbel mirrors on conventional generator equipment (14,15). In combination with efficient electronic detectors, one gains a lot in data quality, although the data quality obtained with SR is still unsurpassed.

A recent development is the use of helical undulators. These undulators can generate a very small beam size with a energy bandwidth of around 2%. For many scattering experiments this is still acceptable. This means that one can construct a beamline without further optics and thus without any flux losses. In this way it is possible to create a beamline that can generate 10^{17} photons/s on a sample (16).

However, in soft condensed matter such a beamline will only be useful in some special cases since technology to detect these enormous fluxes does not yet exist, and radiation damage on samples will be severe.

A rather special optical system, used when one wants to observe very small scattering angles, is the Bonse–Hart camera (17,18). This method is also sometimes called ultrasmall-angle x-ray scattering (usaxs) but this is rather arbitrary since in the literature one can find many examples where this term is used for data obtained with conventional beamlines. With the Bonse–Hart system one places the sample between two double crystal monochromators. The analyzing crystal behind the sample is (angular) step scanned over the transmitted beam. This technique requires a high photon flux and an x-ray beam with a very small divergence and is therefore most suitable to be used in third generation synchrotrons (19,20). Since the technique is step scanning, it is impractical to cover large angular ranges or time-resolved processes. Although the possibilities of Bonse–Hart cameras generate enthusiasm among users, the experience is that they do not reach a large audience. This is evidenced by the relatively small number of publications in this field. It is interesting to note that the number of neutron scattering experiments using the Bonse–Hart technique far outnumbers the x-ray scattering experiments.

X-ray Scattering

The most widely used x-ray techniques are saxs and waxs. The use of surface reflectivity is becoming more popular but will be treated in another article. There is a small niche for other techniques such as photon correlation spectroscopy in which one can study the dynamics of individual molecules. This technique is related to neutron spin echo experiments. However, the application is still fraught with difficulties and it is a very specialized subject.

The use of SR-based x-ray scattering on polymers was pioneered by H.G. Zachmann and co-workers in Hamburg around 1980 (21). This group was building upon the experience obtained with time-resolved experiments on biological materials such as contracting frog muscles and protein solution scattering (22). Initially the emphasis was on the static characterization of samples but soon time-resolved methods became more commonplace. When performing time-resolved experiments the role of the sample environment becomes more important. One needs to perturb the samples from the initial state in a controlled and homogeneously manner into another state. This is discussed in a later section.

Technology Detectors

One of the greatest problems that is encountered in SR-based experiments in soft condensed matter research is that the position-sensitive detector technology is lagging behind the development of beamlines by several generations. Different detectors can cope with different aspects but, at the time of writing, there is no detector that is capable of dealing with all the required aspects. For a better understanding of this problem it is convenient to first define the aspects that are important for performing experiments in soft condensed matter research: high count rate, time framing capacity, high dynamic range, large detection area, and spatial resolution.

At present the two main types of detectors that are used are based on either gas-filled wire chambers (23,24) or charge-coupled devices (CCDs) (25,26). In some cases, one uses photodiode arrays (27), and for static experiments the image plate detector can be utilized (28). However, only the two main types are discussed briefly.

Despite their obvious shortcomings, gas-filled wire chambers have been in use for a long time. This is because they have some very good properties. The most obvious shortcomings are that they have a limited count rate capacity and they require a good deal of maintenance. On the positive side they have a very large dynamic range, ie, the difference between the strongest and the weakest feature that can be detected, of more than six decades. The electronic time-frame rate can be as short as 10 μs/frame, and the dimensions of the active surface can be made large without incurring a penalty in the form of extreme costs. Also, they can be constructed in a variety of shapes—curved, quadrant—that can be suited to the experimental needs.

The CCD detectors have as main shortcomings the limited dynamic range, the slow time-frame rate, and the costs. The positive points of these detectors are that they can handle a large count rate, are relatively maintenance free, and the spatial resolution is superior to that of gas-based detectors.

To discuss these issues in detail is beyond the scope of this article. Practically, often one does not have the choice between different types of detectors since the cost of a detector system is so high that very rarely a beamline will be equipped with more than one system and so one has to accept what is offered. However, the experimental limitations imposed by the detector system can be assessed beforehand, as shown in the following section.

In Table 1 can be found a coarse summary of the properties of the two types of detectors.

An aspect that also requires some attention is the dimensionality of the detector. For a scattering pattern that is isotropic, ie, absence of orientational effects in the sample, in principle it is sufficient to utilize a linear, or one-dimensional, detector. Even in this case one often uses an area, or two-dimensional, detector since a polar integration over the diffraction pattern improves the statistics considerably. However, for fast time-resolved experiments, the larger data volume

Table 1. Properties of Two Types of Detectors

Property	Gas-filled wire chambers	Charge-coupled devices
	Counting	Integrating
Count rate	Relatively low	High
Spatial resolution	Low (200–300 μm)	High (25 μm)
Dynamic range	High (1:10^6 to 10^7)	Low (1:10^4 to 10^5)
Read-out noise	None	Weak signals will be influenced
Read-out speed detector	Fast (10 μs)	Slow (100 ms)
Maintenance	Not easy	Easy
Parallax problems	At wider angles	None
Efficiency	High (5–12 keV); low (>12 keV)	Low but much better than that of gas detector (>12 keV)

might be difficult to handle and unnecessarily complicate the experiment. In this case, one can revert to a so-called quadrant detector (24), which is essentially a linear detector but has an increasing, circular-shaped, active area as function of the radius. This provides the combined advantage of small data volumes while still retaining the benefits of the improved statistics at larger q-values. For (partially) oriented samples one requires a detector that can measure an anisotropic scattering pattern and one is obliged to use an area detector.

Time Resolution

When performing time-resolved experiments there are many experimental aspects that one has to consider. These range from the suitability of the x-ray equipment, such as detectors, to the sample environment that one is using. The latter especially deserves attention since in a time-resolved experiment one generally varies a physical or chemical parameter in order to study the response of the sample to this perturbation. The crucial aspect here is that this parameter should be varied in a controlled and uniform way. (See for this the section dealing with sample environments and technique combinations.)

Before starting to design a time-resolved experiment one has to check if it is possible to obtain the information that one needs with the available experimental equipment. Ultimately, this can only be determined empirically, but by carefully assessing the factors that influence the time resolution, it might be possible to see beforehand if there is not a parameter that inhibits the experimenter to perform the experiment at the time resolution needed in order to render relevant results, and thus avoid wasting the scarce time generally allocated to central SR facility users. The important parameters are

(1) **X-ray flux:**

With SR sources the flux is dependent on the photon energy. The higher the flux the faster an experiment can be performed.

(2) **Detector efficiency:**

Different types of detectors have different photon-energy-dependent efficiencies.

(3) **Maximum count rate a detector can handle:**

This is dependent on the physical process by which the photons are detected and on the detector electronics. If the value of this parameter is high, more photons can be detected in a single frame and will therefore have a positive effect on the time resolution.

(4) **Read-out time of the detector:**

This depends on the number of “pixels” to be read out and on the physical process by which the detector is read out.

(5) **Attenuation of x rays by windows around the sample and extra background scatter:**

In some cases, this factor can be eliminated by placing both sample and detector in a vacuum chamber. The smaller this number is the faster the experiment can be performed. However, even when x-ray flux is abundant, extra background scatter will have a negative impact on the quality of the data.

(6) **X-ray contrast:**

In an x-ray scattering experiment this is the electron density contrast giving rise to the scattering. If the contrast is high, one needs less time to obtain a statistically significant result.

(7) **Statistical accuracy:**

This parameter depends heavily on which parameters one wants to derive from the experiment, but in general this is also a human factor. Some people have "the eye of faith" and others do not. The higher this value, the better the data quality but the slower the time resolution.

(8) **Available memory to store the different time frames:**

This is a crucial consideration and might be a limiting factor in applications where it is crucial to use two-dimensional detectors. (Although computer memory is cheap nowadays it is still not trivial to store large data volumes rapidly.)

(9) **Dynamic range:**

The maximum intensity a detector can detect in comparison with the minimum is called the *dynamic range*. In scattering experiments, where the intensity generally falls as $1/q^4$, this is not a trivial issue. One should keep in mind that some types of detectors, such as CCDs, add dark current and read-out noise to the signal, which influences the dynamic range. A higher efficiency and low noise level will have a positive effect on the achievable time resolution.

(10) **Radiation damage:**

It is possible that the sample is destroyed by radiation damage before the statistical quality of the data is high enough.

All these parameters can be summarized in a symbolic formula as follows:

$$\text{Time resolution} = \frac{\text{readout} \times \text{statistics} \times \text{attenuation}}{\text{flux} \times \text{detector efficiency} \times \text{maximum count rate} \times \text{contrast} \times |\text{memory}| \times |\text{dynamic range}| \times |\text{radiation damage}|}$$

The higher the "value" of the time-resolution parameter, the longer the length of a time frame, and consequently the slower the experiment. In order to assess if an experiment is sensible, this "value" should, as mentioned in the previous section, be compared with the time scale on which it is possible to perturb the sample uniformly. The parameters "memory," "dynamic range," and "radiation damage" act as a type of delta functions. The fastest experiments, using conventional methods and noncyclic data collection, are at the moment limited to roughly 0.1 s/frame. When dealing with a process that can be accurately cycled, one can play different tricks and the time resolution can be pushed toward the millisecond/frame resolution at the expense of a very complicated experimental protocol (29).

Sample Environment

If one wants to measure samples at nonambient conditions, it is required to utilize a sample cell that can bring the sample in the required state. The most commonly and easily varied parameters are temperature and pressure. However, with the increasing degree of sophistication that SR users have brought to their experiments it is not uncommon to bring for instance reaction injection molding (RIM) or extrusion apparatus to the beamlines in order to mimic industrial processing conditions. Several examples of this are discussed in following sections. Also, the combination of time-resolved x-ray experiments with the other non-x-ray-based techniques, such as infrared spectroscopy or Raman scattering, has become more common. The often conflicting requirements of the different techniques increase the difficulties in constructing sample cells which are suitable for this type of experiment. A simple example of such conflicting requirements is the need for free x-ray access to a sample on which one wants to perform simultaneously differential scanning calorimetry (dsc). The latter technique requires the sample to be contained in an environment that inhibits uncontrolled heat flow toward or from the sample. This obviously is in conflict with the need for free x-ray access.

In the case of time-resolved experiments the sample has to be brought from an initial state to a final state. If this requires, for instance, a temperature change, it is crucial that during the experiment the temperature gradients over the sample are limited. This is illustrated in Figure 5. The problems that are depicted schematically in this figure can be of paramount importance in the interpretation of events occurring around a phase transition (30–32). It is obvious that an accurate knowledge of the actual temperature of the sample is of paramount importance. Often there is a difference between the set point of the temperature controller and that of the sample. Therefore, one often samples the read-out from a thermocouple attached to the sample at the same rate as the time frames of the scattering experiment. The same holds true for any other parameter that is used to initiate the sample condition.

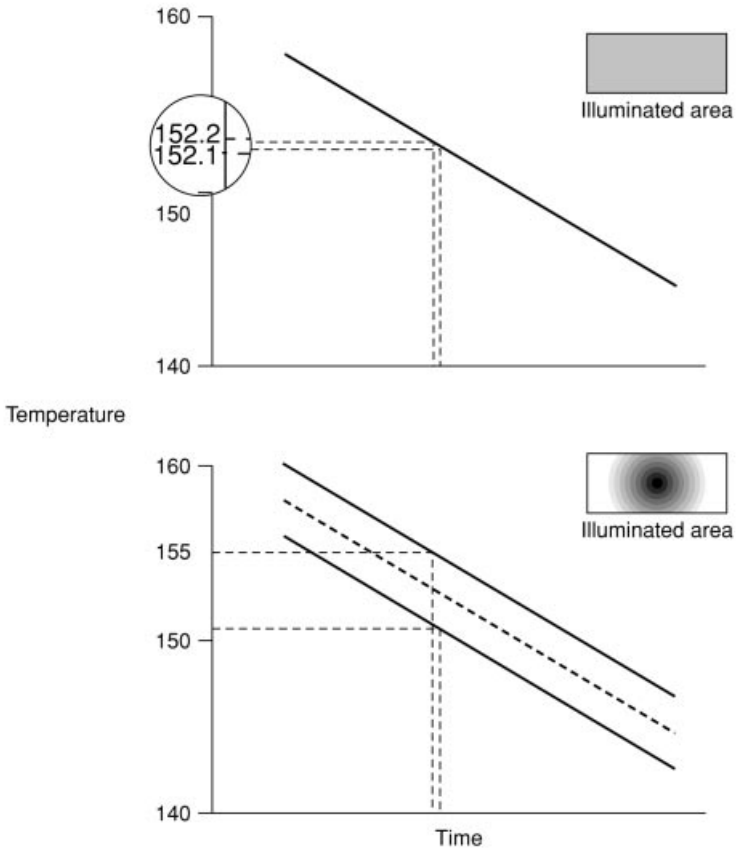

Fig. 5. The upper panel shows the ideal experiment in which the sample is cooled down and where the sample has an homogenoeus temperature. The inset, marked illuminated area, shows the temperature distribution over the sample in a gray scale. A small lapse in time corresponds to a minute change in the thermodynamic state of the sample, which therefore can be considered to be quasi-static. The accuracy is only limited by the length of the time frame. In the lower panel a situation is depicted where the sample does not have a homogeneous temperature over the x-ray region illuminated by the x-ray beam. It is now impossible to construct a temperature versus time diagram with the same accuracy as in the above panel. For every time frame, one will not observe the structure of a single thermodynamic state but a mixture of states. Obviously it will always remain of paramount importance to measure the exact temperature as well as being able to control the temperature gradients.

In the case where one wants to combine x-ray experiments with optical experiments, such as birefringence or light scattering, the problem of the quality of the sample windows is an important issue. This again is the case with high pressure experiments where the cell windows are made of diamond. Although this material contributes relatively small levels of parasitic scatter per unit window thickness, and is fairly transparent to x ray, the simple fact that one requires thick windows brings the parasitic scatter to a such level that the signal-to-noise ratio of the experiment becomes quite unfavorable. This is further discussed in the section on Pressure Cells.

The ideal window material for x-ray scattering experiments should have a high transparency for the x rays of the required wavelength, be an isotropic scatterer with no preferential orientation, be mechanically stable at the temperatures required, etc. This rules out many common materials. Al and Be windows, for instance, generate a large amount of parasitic scatter in the saxs region because of the presence of grain boundaries in the material. Ideal materials are composed of light elements either completely crystalline with a simple large unit cell, such as mica, or completely amorphous. However, this is only a rule of thumb since a material like amorphous (glassy) carbon has a very intense waxs pattern that can be order of magnitudes larger than that of the polymer under investigation. Unfortunately, no systematic study of this problem has been made so far.

Data Analysis

Data analysis for combined time-resolved experiments follows in principle the same path as that for non-time-resolved experiments. The difference is that there is often a nontrivial problem with respect to the amount of data that has to be analyzed. Careful data reduction (normalization, background subtraction, subtraction of the amorphous component from the crystalline peaks, etc) and analysis of a single scattering curve can take several hours. With time-resolved data it is nearly impossible to spend this much time on each individual frame. Although it is possible to develop software to automatically analyze time-resolved data, it is nontrivial and one cannot avoid many manual cross checks in order to obtain reliable results (33). An example of the problems that one can encounter is shown in Figure 6.

It is obvious that often the standards of analysis are lowered. This does not always have to be a problem. Much depends on what one wants to learn from the data. Static experiments for accurate determinations of the morphology is a minority class of experiments performed with SR beamlines. When kinetics are studied, it often suffices to concentrate on a small part of the data range and study the development of the scattered intensity in this region as a function of time and ignore, for instance, elaborate background subtraction routines that might be only second-order effects.

An aspect that is quite often overlooked in the analysis of data where a morphological change is taking place in the sample due, for instance, to crystallization or phase separation, is the fact that corrections that should be applied to the data often change in time. As an example, one can think of the situation in which a micellar system by a change in temperature converts to a cylindrical morphology. Then the so-called Lorentz correction for saxs data, required to calculate the real scattered intensity and compensate for the fact that calculations for the scattering profile are based upon one-dimensional projections in the direction of the periodicity, also changes. The terminology "Lorentz correction" is in principle not correct (34,35), but the use of it is so widespread that this article conforms to the standard practice. The correct Lorentz factors are for the different cases:

$I_c(q) = I(q)q^2$	for infinitely long and wide lamellae
$I_c(q) = I(q)q$	for long thin cylinders
$I_c(q) = I(q)$	for spherical particles

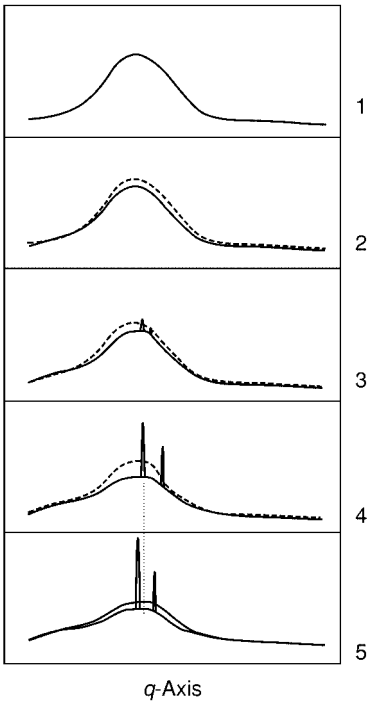

Fig. 6. This schematic diagram shows waxs patterns corresponding to the crystallization of a semicrystalline polymer. One can see the problems that one can encounter in the data analysis of time-resolved data. The first frame shows the amorphous ring characteristic of a molten polymer. In the second frame the previous frame is shown as a dotted line. The amorphous ring has slightly diminished in intensity and two small peaks have started to grow. In the following frames the diffraction peaks gain in intensity while the amorphous halo keeps diminishing. Between frames 4 and 5 the diffraction peaks move to lower q-values. If one now wants to follow the intensity of the diffraction peaks one has to subtract an ever changing background and also one has to take into account the peak movements. Mathematically this is a trivial problem but to do this in an automated way with software is nontrivial.

It is clear that to determine the point where one should cross over from the use of one correction to the other is a process which is not straightforward and is difficult to automatize.

Anomalous Scattering

In contrast to conventional x-ray generators, which only produce usable amounts of photons at discrete energies, SR beamlines can, when equipped with the appropriate monochromator, be tuned to any energy of the white spectrum generated by the storage ring. This has opened up the possibility to use the method of anomalous, or resonant, scattering. In this technique, one uses the property of x rays that the scattering cross section varies in the proximity of an elemental absorption

edge. This is not unlike the contrast variation in neutron scattering which is based on using different isotopes of the same element, notably hydrogen and deuterium in polymer research. Anomalous scattering is a technique that has become popular, for instance, protein in crystallography, where it is an important tool to solve the phase problem needed to solve the structure of a crystal unambiguously.

The x-ray scattering cross section is energy dependent and is given by

$$f(q,E) = f_0(q) + f_1(q,E) + if_2(q,E)$$

The first term is the Fourier transform of the electron density around the scattering atom, which is the only term to be considered in normal experiments. At small scattering angles this is equivalent to the number of electrons in the atom. The two other terms only have an appreciable magnitude at energies close to an absorption edge. The unfortunate fact is that the energy window practical for soft condensed matter experiments, 5–15 keV, does not contain absorption edges from the most common occurring elements in this type of research. This limits this type of research to polymers and colloids containing heavier elements, or, for instance, real-time experiments where catalysts are involved, or, for instance, liquid crystalline materials (36). In Figure 7 the variations in the scattering factors as function of the energy are shown. The elements with edges easily accessible are the elements with Z values between 20 and 36 for the K-edges and between 50 and 82 for the L-edges. It should be noted that the effects occurring in anomalous scattering are only small, unlike the large variations that are possible in neutron scattering when selective deuteration is applied.

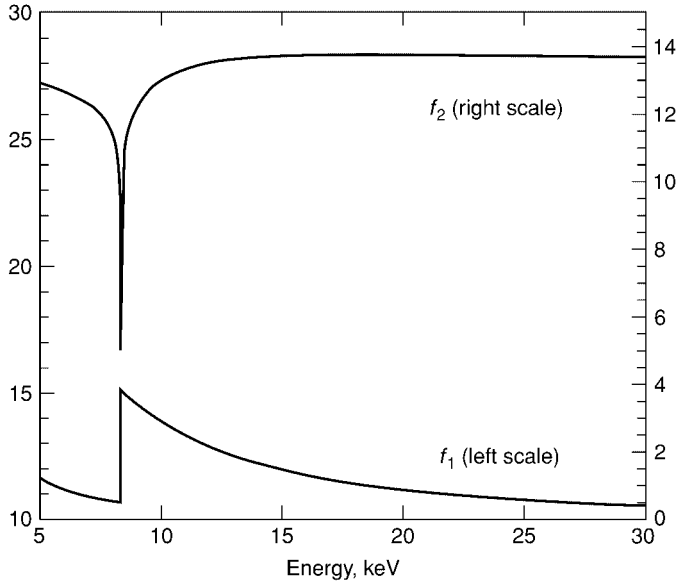

Fig. 7. Variations of the scattering factors f_1 and f_2 near the K-absorption edge of Ni (8.33 keV). The large variation in the parameter f_2 is responsible for the effects that can be used in anomalous scattering experiments.

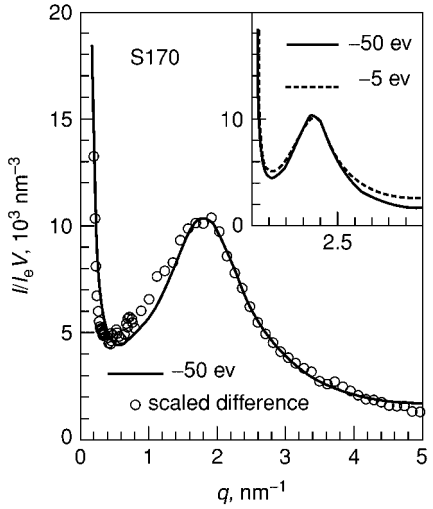

Fig. 8. Anomalous saxs data from a nickel-neutralized sulfonated polystyrene. The scattering curves were obtained at x-ray energies respectively 5 and 50 eV from the Ni K-edge (inset). The main figure shows the scattering curve obtained at 50 eV from the edge and the scaled difference pattern (open symbols). This illustrates the minute differences between the curves. This type of scattering data requires an energy tuneable x-ray source. Courtesy of R. Register.

An example of results of this technique is given in Figure 8 (37). This shows the minute differences between scattering curves taken at different energies close to the Ni K-edge from a nickel-neutralized sulfonated polystyrene. By using this technique, the authors could prove that the sample under investigation had an inhomogeneous distribution of ionic repeat units instead of explanations relying on artifacts due to precipitates or microvoids. Also, it was possible to determine the sign of the electron density difference between the crystalline and amorphous phases.

A more detailed treatment of contrast variation techniques, for both x ray and neutron scattering experiments, can be found in Reference 38 and in a book (39).

Another technique that makes use of the tuneability of SR sources is x-ray absorption spectroscopy (xas) (2). This is relatively rarely used in polymer research. One of the few examples found in the literature deals with *halato-telechelic ionomers* (40). These are short linear chains selectively terminated by a metal carboxylate or sulfonate ionic group. The local order of these groups could be determined by using extended x-ray absorption spectroscopy (exafs). More work using this technique applied to ionomer morphology is reported (41).

Radiation Damage

The damage to polymer samples by exposure to x rays is at present poorly documented. In biological research using SR, such as protein solution scattering and crystallography, this phenomenon is well known but unfortunately also rarely

quantitatively treated (42–46). With the advent of the third generation of SR sources that can generate very high fluxes of around $10^{12} - 10^{13}$ photons/s in a 0.1-mm^2 spot, this is not a problem that can be ignored by material scientists anymore. See for instance Reference 47, in which it is shown that starch samples are destroyed within 10 s of exposure to an x-ray beam of 10^{10} photons/s in a 2-μm spot, or the experiments in which it was shown that relaxation times in a coherent small-angle scattering experiment were influenced by the dose of x rays (48).

The exact mechanism that causes the radiation damage is not known. It is unlikely to be a local heating effect since a quick calculation shows that with the aforementioned fluxes a polyethylene sample can heat up by around 0.1°/s, assuming that no heat transfer takes place to the surrounding area. This might have implications for experiments in which one attempts to obtain isothermal conditions but in itself will not be the cause of the damage. More likely is that the ionizing radiation damages chemical bonds. This is supported by the observation that in carefully performed experiments on ionomers in solution it is possible to observe the effects due to the ionization of water (49).

Quite often the first sign of radiation damage is a discoloration of the sample surface. The occurrence of radiation damage in the bulk of the material can lead to loss of orientation in aligned samples and also diminishing intensity in diffraction (46). There are several methods to avoid radiation damage, but unfortunately all these require displacing the sample through the beam, which means that one is not continuously observing the same sample. For bulk polymers this is no problem, but when stretching or microfocus experiments are performed, one is well advised to use the most efficient detector available and reduce the intensity of the incoming beam. The interaction of x rays and radiation damage effects in the solid state are extensively treated in Reference 50.

A rather spectacular effect of radiation damage is shown in Figure 9. This example shows aligned rigid rod microtubule biopolymers in solution. Not only

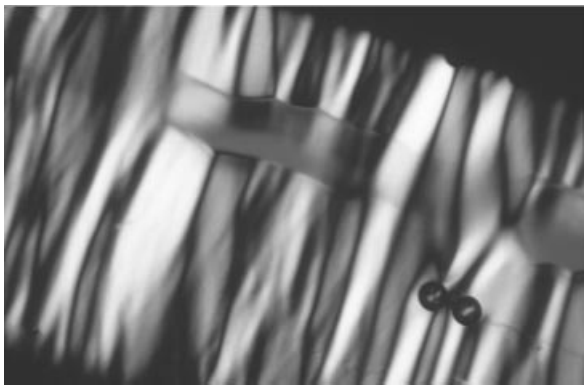

Fig. 9. An initially aligned sample of rigid rod microtubule biopolymers in solution after it has been hit by radiation. The sample is viewed between crossed polarizers. The burn mark is centrally placed. The alternating dark and light bands are domains that have a different orientation. The transition from uniform alignment to domains with different orientation takes place in seconds after the sample is irradiated. The burn mark has dimensions of roughly 0.5×3 mm^2. The shift of the domains with respect to each other is approximately 0.5 mm as witnessed by the distortions of the burn mark.

is the material at the spot where the beam hits the sample damaged, but also the previously homogeneously oriented region around it is broken up in several differently oriented domains many times larger than the actual burn mark itself. This is probably due to hydrodynamic instabilities (51).

The unfortunate fact is that serious studies of this problem would require large amounts of beam time and the subject itself is not very fashionable.

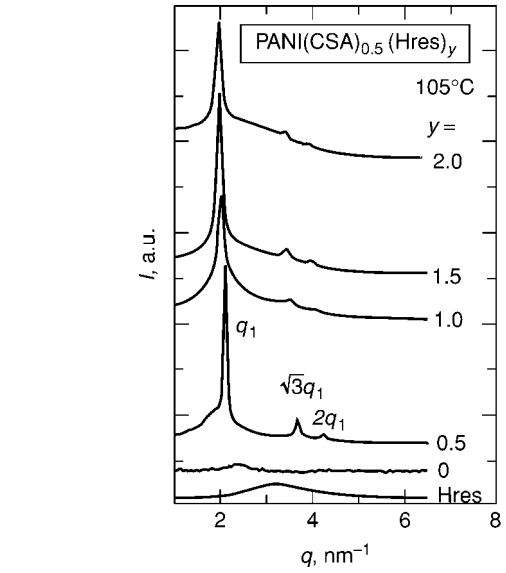
SAXS Experiments

SAXS experiments provide information on length scales from, arbitrarily, 1 nm and larger. This means that information regarding the long spacing in semicrystalline polymers, density fluctuations, interface shape, spherulite size, etc, can be accessed by this technique. On some conventional beamlines it is possible to observe dimensions comparable to small spherulites. However, in general one has to use a specialized Bonse–Hart usaxs camera to achieve this. The determination of the large-scale structure of a sample is a conventional way of using saxs. An example of this is the structure determination of a self-organized polyaniline sample that was doped with acid in order to create a conducting polymer. By attaching 4-hexylresorcinol via hydrogen bonding to the polyaniline salts, a supramolecular structure is formed. When the samples are heated above the crystallization temperature of 4-hexylresorcinol, the material self-organizes. On the basis of the saxs pattern it is possible to deduce that the organization is in the form of a hexagonal array of cylinders where the hexyl tails are microphase separated from the cylinders (52) (see Figs. 10a and 10b). The use of SR is crucial here since with conventional x-ray generators it would not be possible to obtain the required data quality in an acceptable time.

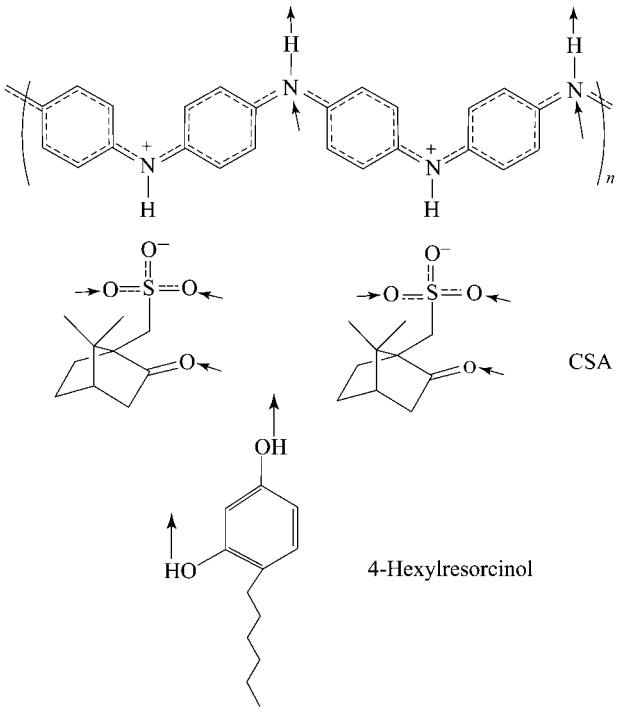
Solution Scattering. Solution scattering is a well-known saxs technique used to elucidate the shape and weight of molecules. It has been extensively used over the years (53).

The prerequisites for an accurate determination of the shape parameters are that the molecules in solution are monodisperse in size, identical in shape, and that the solution is sufficiently dilute so that no interparticle scattering is observed. In practice the first two conditions are rarely met, apart from the case where one deals with biological materials and more recently with some specially prepared colloids. The theoretical framework to deal with all the problems that one can encounter does not exist at the moment. The problem of interparticle scatter is especially hard to solve. Attempts to analyze the degree of polydispersity, assuming an identical shape function with a free parameter describing the size distribution of the particles, have been reported many times in the literature; see for instance References 54–57. The problem of interparticle scatter has attracted less attention probably because the problem is somewhat harder to solve; see for instance References 58 and 59.

The use of SR, with the higher intensity compared to that of conventional Kratky cameras, is indispensable in the accurate determination of saxs data at intermediate scattering angle (60). In the study of Kraton PS–PEP–PS (polystyrene–polyethylene–propylene) triblock copolymer in extender oil, although this complex is a gel, solution scattering methods can be applied to elucidate the structure. In



(a)



(b)

Fig. 10. Panel A shows saxs patterns obtained from a polyaniline salt–4-hexylresorcinol supramolecular arrangement in a hexagonal register, which is evident from the 1, $\sqrt{3}$, 2 q-spacing of the diffraction peaks. Panel B shows the structure that could be deduced from the diffraction patterns. The cylinders are formed of the polyaniline salt combined with the phenolic groups of the 4-hexylresorcinol. The hexyl tails microphase separate from the cylinders and act as spacers between them.

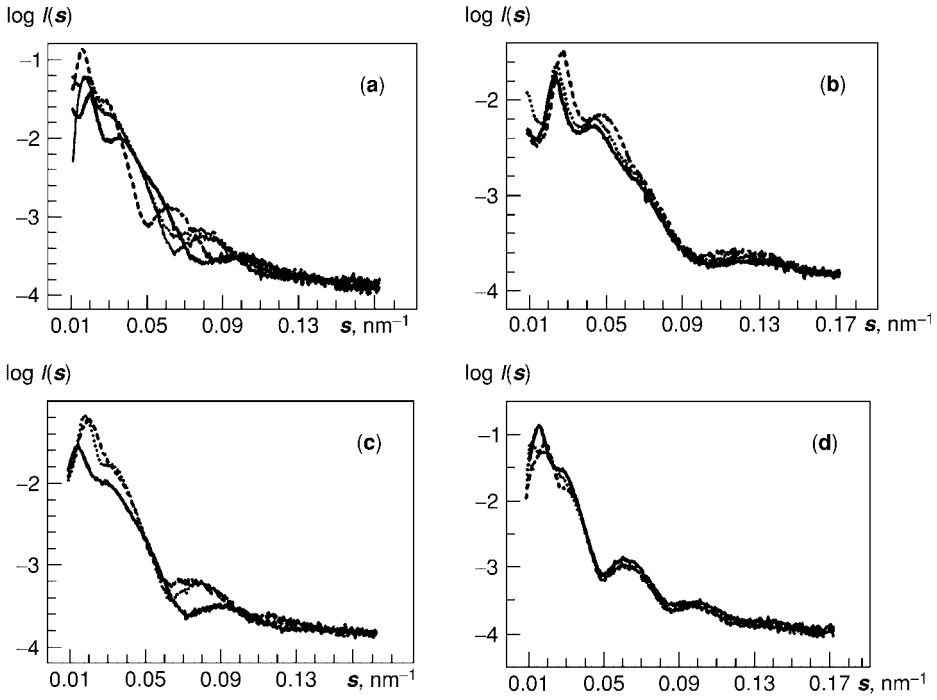


Fig. 11. SAXS curves for triblock copolymer gels with a PEP midblock and PS endblocks. The different tables represent curves obtained with molecular weights M_n = 100,000, 20,000, and 300,000 respectively. Clearly distinguishable are two scattering peaks at low angles due to interparticle scatter. The peak at wider angle is due to form factor scatter from the high electron density PS spheres which are insoluble in the extender oil. Only the use of SR allows one to obtain sufficiently accurate data in this scattering region to be able to perform a decent analysis. For further explanations one is referred to the text.

Figure 11 scattering patterns are shown from sample with a variable molecular weight and different PS contents. The scattering at low q is dominated by two peaks which are caused by interdomain scatter. The domains are being formed by the insoluble PS blocks. The distance between the domains is much larger than the domain size and so that the form factor intensity oscillations start at intermediate scattering vectors. The positive identification of the origin of these peaks was done by stretching the samples, which increased the interdomain spacing and thus moved the associated peaks to lower scattering angles, but left the form factor maxima at the same position. The analysis of this data was performed in two alternative ways. The first method starts from the assumption that there exists a short-range liquid-like order between the hard core domains with an equiprobable distribution around the central core. This is followed by the introduction of some nearest-neighbor coordination. The form factor of the domains is calculated according to classical methods (61). The equations to be fitted in this case are

$$I(s) = KN\langle P(s,r_0,\sigma)\rangle S(s,R,\eta)$$

$$\langle P(s,r_0,\sigma)\rangle = \int_0^\infty \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{(r-r_0)^2}{2\sigma^2}\right] P(s,r)\,\mathrm{d}r$$

where $\boldsymbol{s} = 1/d$ is the scattering vector, $I(\boldsymbol{s})$ is the scattered intensity, K a constant, N the number of scattering particles, r_0 the mean domain radius, and σ the dispersion factor. $P(\boldsymbol{s}, r)$ is the averaged form factor and $S(\boldsymbol{s}, R, \eta)$ is the structure factor of a monodisperse system. The second method consisted of the modeling of the short-range order with the Debye formula:

$$I(s) = K\langle P(s,r_0,\sigma)\rangle\left[N + 2\sum_k Z_k \frac{\sin(2\pi s R_k)}{2\pi s R_k}\right]$$

In the above equation the sum in square brackets represents the interference function of a distribution of spheres. The distribution is characterized by a discrete set of distance, R_k, with a frequency Z_k. By now replacing the starting set Z_k with a new set defined by a Gaussian distribution around R_k, one can search the best fit to the data.

In this particular case both methods produced satisfactory agreement. It should be pointed out that both these methods rely to a great extent on a high data quality in the intermediate scattering angle range. To obtain sufficient intensity in this region one has to collect the data per sample for about 10 min, with an equal or longer time for the background scattering pattern, on an SR beamline which produces approximately 10^{11} photons/s. Assuming the use of a rotating anode generator and a detector with an equal sensitivity, this translates to an exposure of approximately 20 h to obtain the same data quality, with an additional 20 h for the background pattern.

An attempt to analyze data from a system in which several components with different shapes, each with different size distributions, is described in Reference 62. A microemulsion of oil-rich sodium bis(2-ethylhexyl) sulfosuccinate exhibits a continuous phase transition from the droplet to the cylinder state as a function of salt concentration and temperature. In this extensive work, dealing with more than 500 scattering curves from samples with different composition and/or temperature, the authors managed to obtain reasonable fits even after assuming some physically less attractive simplifications regarding the interparticle interactions.

It is probably still not an understatement to say that the in-depth analysis of solution scattering data on real, not idealized, samples is still a specialized field.

An experimental method, intermediate between solution scattering and fiber diffraction, is used to prepare well-oriented samples in a solvent. An example of this is the partial orientation of tobacco mosaic virus (TMV) by subjecting the sample to electric field pulses between 1.25 and 5.25 keV/cm (63). TMV is a model system for rigid rod-like molecules. The x-ray studies, combined with transient birefringence measurements, render valuable information on the orientational effect of electric fields on these macromolecules with a time resolution which can be as short as 2 ms/frame. A similar method is to self-assemble rigid rod molecules in a magnetic field. The interaction of the diamagnetic moment, present in nearly every molecule, with magnetic fields over 10 T induces orientation which is not lost upon removal from the magnetic field owing to steric hinderances inhibiting rotational diffusion. Thus one obtains a sample which, although still in solution, is nearly perfectly oriented. This allows the structural determination of these

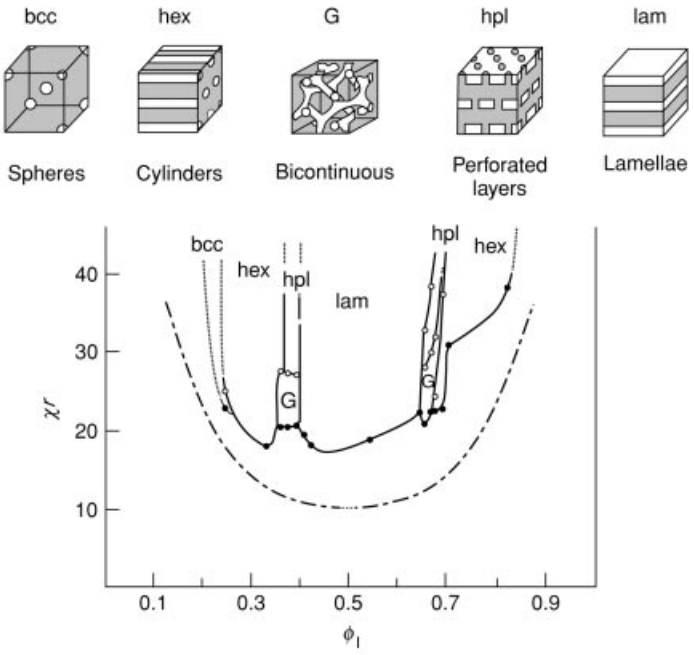

Fig. 12. Phase diagram of the PI–PS diblock copolymer system. The vertical axis is expressed in χN units (where χ the Flory–Huggins segment–segment interaction parameter and N the degree of polymerization). The determination of this phase diagram is based upon tem, saxs, and sans data. The α—. curve is the predicted order–disorder transition line. The open symbols are order-order transition points and the closed symbols order–disorder. The solid lines are drawn as guides for the eyes.

molecules in solution via fiber diffraction methods, which have an intrinsically higher information content than pure solution scattering (46).

Static Phase Diagrams. An example of the study of complicated phase diagrams in which synchrotron saxs experiments have been shown to be extremely useful is given in Reference 64. These authors have investigated the complex phase behavior of polyisoprene–polystyrene (PI–PS) diblock copolymers. In these experiments the compositional phase diagram was determined by heating samples with variable volume fractions of PI (Fig. 12). This type of experiment is also feasible with conventional x-ray sources. However, the data quality is much higher and the experiments can be performed in less than a day instead of many months required with conventional generators. It should be stressed that in principle it is possible to determine the phases unambiguously on the basis of saxs patterns alone in case the accessible q-range shows sufficient diffraction peaks. This is rarely the case because of the limited length of detectors, and therefore it is required to back up the conclusions by results from other techniques such as transmission electron microscopy (tem) and rheology. This underlines the complimentary nature of synchrotron experiments with other techniques which can be applied either independently or simultaneously.

Fiber Diffraction. Fiber diffraction is a well-known technique for the characterization of materials which possess fiber symmetry, ie, a one-dimensional

regular packing of subunits. In some cases this is a consequence of the production process but in other cases fiber diffraction can be used even if the sample under investigation is essentially not a fiber. This is the case when oriented objects are imbedded in a matrix and the interdistance between the objects is relatively large, such as in a composite material. The latter situation can be induced via several ways including shearing (65,66), electromagnetic fields (67,68), and centrifugation (69). The information content in such diffraction patterns is higher than in the case of randomly oriented objects. It should be noted that both saxs and waxs are being used for the study of fiber texture. In the 1950s and 1960s many polymer crystal structures and other crystallographic polymer problems were solved by using wide-angle fiber diffraction. However, this type of work, lacking the need for time resolution, is ideally suited to be carried out with conventional generators and therefore the research community occupying themselves with this type of work appears to have less demands for access to SR.

In the case where one performs time-resolved experiments on real fibers, be they natural or synthetic, the use of SR has some distinct advantages. Because of the nature of a fiber, the interaction section between the x-ray beam and the fiber, which determines to a great extent the quality of the diffraction pattern, is limited by the size of the fiber. It is clear that, for a fixed number of photons in the x-ray beam, the smaller the beam the better the experimental situation is.

The above is certainly the case in experiments where an extruder is placed on a beamline in order to survey the structural developments in the fiber as a function of the distance from the spinnerette. This specific subject is discussed in later sections. Complicated experiments on contracting muscles, gels containing viruses, oriented polymer nanocomposites, mechanically induced ordering in samples subjected to stress, etc, also fall under the remit of fiber diffraction.

A very elaborate theory exists for the analysis of fiber diffraction data, although no recent monographs on the subject exist; the book Diffraction of x-rays by Chain Molecules (70) contains still the most comprehensive treatment. A large part of the mathematical framework was developed for the famous studies that were done to unravel the structure of DNA (Fig. 13) (71). This subject has remained popular to this day (72). Unfortunately, although the theory exists, there are no standard data analysis packages. In the recent literature on SR-based synthetic polymer research, there are few examples to be found in which the authors extract more information than Hermans orientation functions or spacings of diffraction maxima from their data.

An example of analysis in which a more elaborate data analysis was performed is the analysis of stretched samples of poly(etherester) (PEE) (73,74). This material consists of hard and soft domains. By stretching this material the soft domains elongate and become needle shaped. The analysis performed here is in the form of projections which are, in this case, integral operators that map functions onto subspaces of the domain in which they are defined. The most well known of these projections is the one that maps the scattered intensity onto a zero-dimensional subspace, ie, a number or scalar. For instance,

$$\{I\}_0 = \int I(s) d^3 s$$

which is a mathematically correct way to define the well-known invariant.

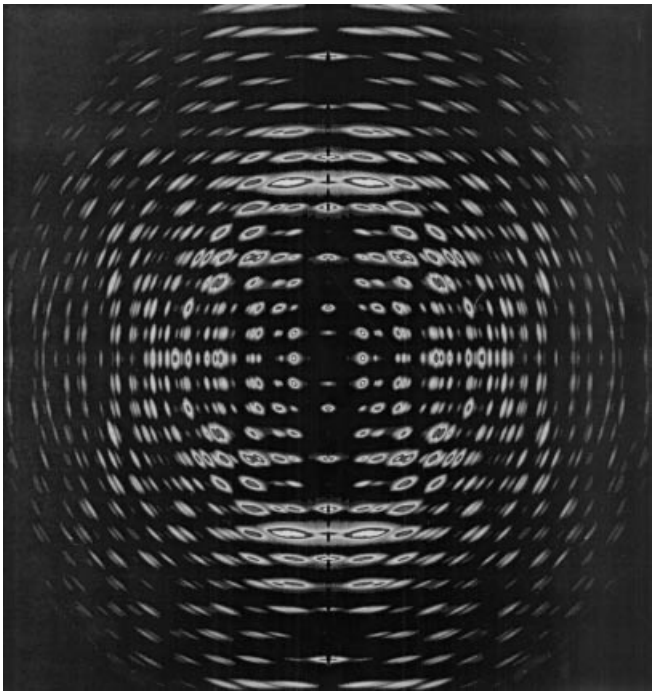

Fig. 13. X-ray fiber diffraction pattern recorded from polymeric DNA containing a well-defined alternating A-T repeat along each strand of the double helix. This conformation, known as the D conformation of DNA, has 8 bp per helix pitch. Diffraction pattern recorded on beamline 7.2 at the Daresbury SRS. At the center of the pattern one observes spacings up to about 3.5 nm while the edge of the pattern reveals structural details down to 0.22 nm. Pattern kindly provided by T. Forsyth.

In the case where one deals with fiber symmetry, one can express the three-dimensional fiber diffraction pattern in cylindrical coordinates with $I(\boldsymbol{s}) = I(\boldsymbol{s}_{12}, \boldsymbol{s}_3)$, where $\boldsymbol{s}_3$ is a vector parallel to the fiber axis and $\boldsymbol{s}_{12}$ the cylindrically symmetric direction at right angles to the fiber axis. The projection $\{I\}_1\,(\boldsymbol{s}_3) = 2\pi \int_0^\infty s_{12}\, I(\boldsymbol{s}_{12}, \boldsymbol{s}_3)\, \mathrm{d}_1$, which is a planar integration in the plane at right angles to the fiber axis, and therefore can be expressed as a function of $\boldsymbol{s}_3$, contains the information on the domain height and distribution of both the hard and soft blocks in the longitudinal direction. The projection $\{I\}_2\,(\boldsymbol{s}_{12}) = 2\int_0^\infty I(\boldsymbol{s}_{12}, \boldsymbol{s}_3)\, \mathrm{d}$ describes the fiber as a two-phase system in the direction at right angles (transverse) to the fiber axis. By using this methodology the author was able to comprehensively characterize the shape deformation of the soft domains as a function of the sample elongation. An illustration of this is given in Figure 14.

More examples of the use of fiber diffraction can be found in the following sections.

SAXS/WAXS Experiments

The combination of simultaneous saxs and waxs experiments has gained a widespread popularity in the last decade (11,21,75). As with many technique

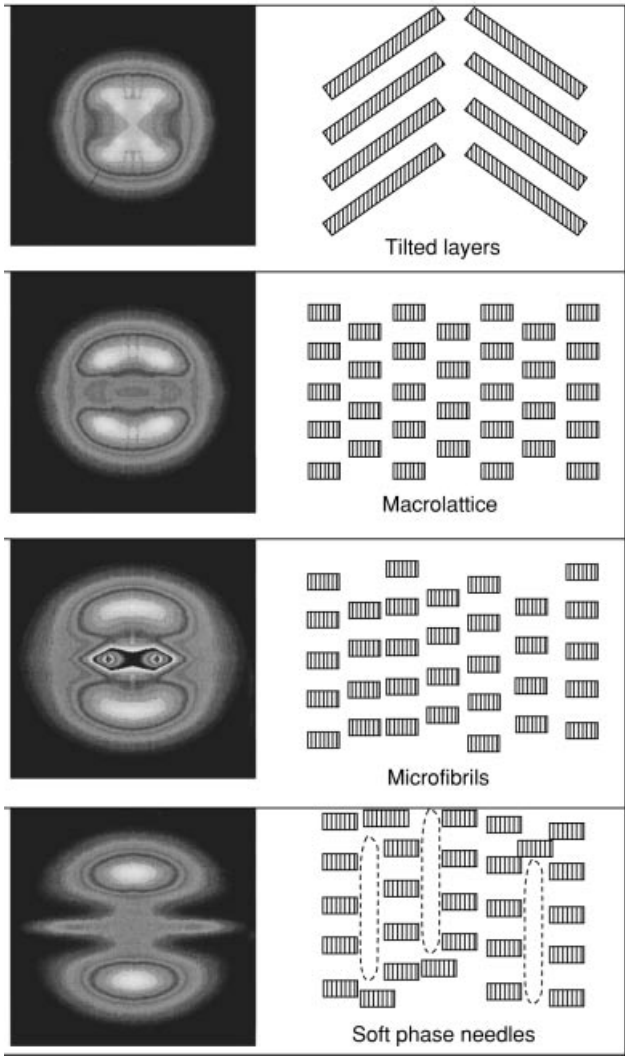

Fig. 14. Scattering patterns and derived structures from PEE under strain. The structures are derived using analyis methods given in Reference 73. Courtesy of N. Stribeck.

combinations it is unavoidable that the quality of the data obtained is not as good when compared with the quality that can be obtained when independent experiments are performed. In the case of combined saxs and waxs experiments, the main reason for this is that for optimized experiments one obtains the highest resolution when the x-ray beam is focussed on the detector. Apart from the special case when a microfocus beamline is used, one normally utilizes two detectors: one placed close to the sample, to collect the waxs, and the other one at several meters from the sample in order to collect the saxs. This means that one has to make a choice where to focus the beam. With modern beamlines the loss of data through over/under focus has become relatively unimportant. The intrinsically small beam

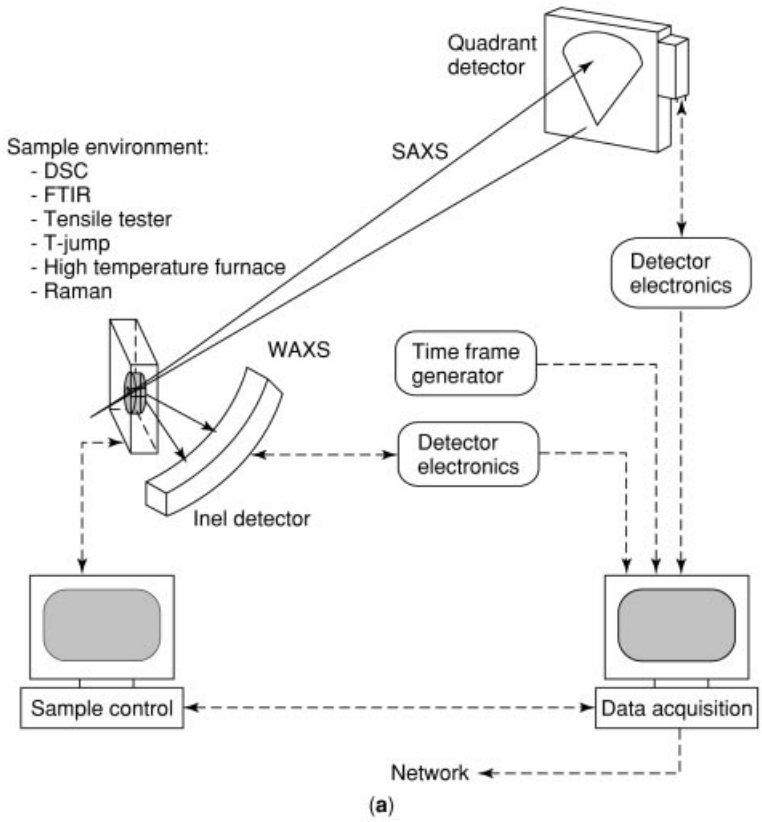

Fig. 15. Panel A shows a schematic diagram of a combined saxs/waxs experimental station suitable for time-resolved experiments. In this case the sample is placed at the center of a curved waxs detector which is placed such that the saxs scattering pattern is not obscured. The sample–saxs detector distance can be varied depending on the required q-range needed. The two independent detector systems are synchronized by the use of a single time frame generator. In panels B and C the simultaneously collected saxs and waxs curves, produced with the setup shown in panel A, from a heating/cooling experiment on HDPE are shown.

divergences allow the construction of scattering cameras with a very large depth of field.

An example of a saxs/waxs setup is given in Figure 15. In this example a curved detector is used to collect the waxs pattern. This has the advantage that no distortions in the scattering pattern can occur because of parallax problems. The distance between the sample and the saxs detector can be varied from 0.7 to 4 m, depending on the scattering vector range that one wants to study. The time resolution that can be practically achieved, without compromising with the data quality too much, is 0.1 s/frame, on a strongly scattering polymer sample. The q-range that can be observed depends on the particular beamline. A typical example is station 8.2 at the SRS in Daresbury, where it is possible to collect data in the range 0.06–30 nm^{-1}. This practically means that one covers the length scale of two hierarchical structural levels. The ordering of individual polymer

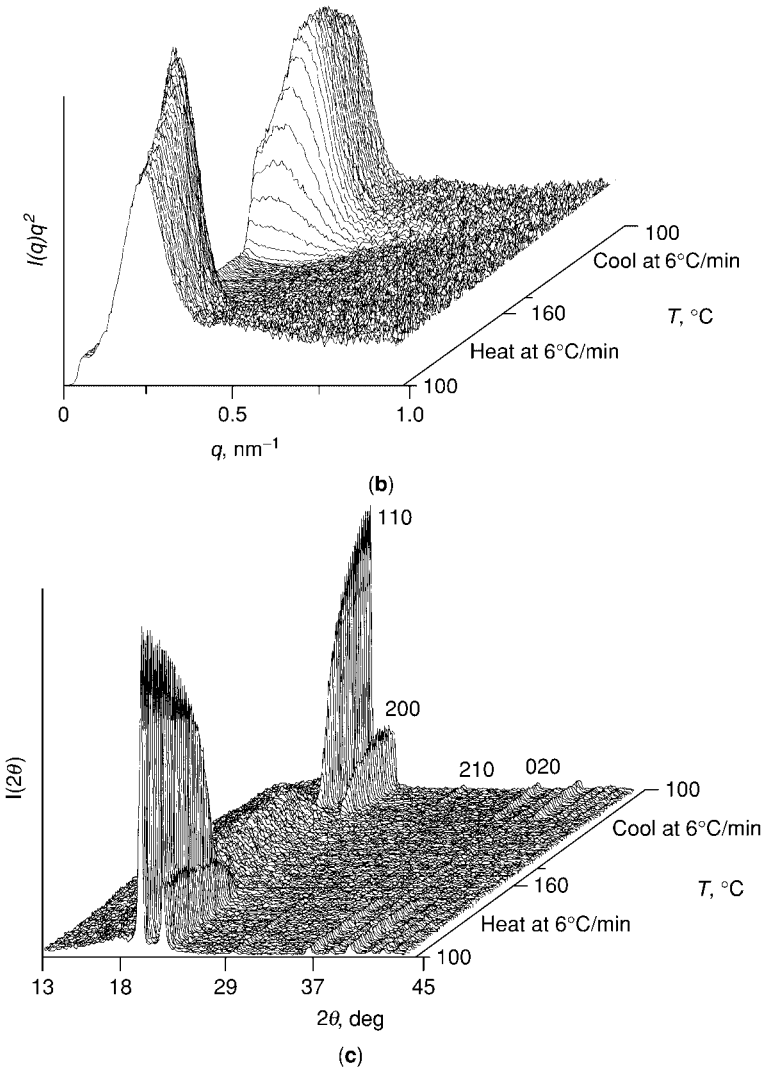

Fig. 15. (Continued).

chains with respect to each other and the level above where assemblies of ordered polymers, like lamellae, again exhibit ordering with respect to each other. The structural level above that, with length scales up to the micrometer range, such as spherulites, used to be the domain of light scattering (76,77) but on third generation SR sources it is sometimes possible to reach this level with x-ray scattering as well, although no systematic work in this field has been reported yet. The advantage of using x-ray scattering instead of small-angle light scattering (sals) in the study of spherulite formation is that the latter technique is limited to thin films while with the former bulk samples can be studied. However, this means that at present the data can only be obtained in two discrete q-ranges with a gap between them. There is no fundamental reason why this problem could not

be solved—only a financial one—since it requires the construction of a very large position-sensitive detector.

The simultaneous collection of waxs and saxs data has its obvious advantages. The most important is that one is able to correlate structural changes on different length scales with each other. In some cases there are extra advantages. In the case of a two-phase lamellar system, the invariant obeys the following relation:

$$Q = \int_0^\infty q^2 I(q) dq = \langle n_e^2 \rangle \phi(1-\phi)$$

with Q the invariant, n_e the electron density difference between the two phases, and ϕ the crystalline volume fraction. This clearly is an equation which is quadratic in ϕ and which has a maximum when the crystalline volume fraction reaches 50%. The crystalline volume fraction can be determined from the waxs data by conventional ways (55). In a recrystallization experiment one can, by coplotting the crystalline fraction together with the invariant, determine a linear scale based upon the 0 and 50% crystallinity points, which is internally completely consistent. [A minor correction might have to be applied for changes in n_e during crystallization (78)]. This procedure is illustrated in Figure 16.

In the case where one is not strictly dealing with a two-phase system because of, for instance, the polymer crystallizing in spherulites, a modification has to be made. The relative invariant is now given by

$$Q' = K X_s X_l (1 - X_l) \Delta\eta^2$$

where K is a constant, X_s is the volume fraction of spherulites, X_l the degree of crystallinity in the lamellar stacks, and $\Delta\eta$ the electron density difference between the crystalline and amorphous polymer. The relation $X_c = X_s X_l$ is valid in this case. In the molten state, $X_s = X_l = 0$. In isothermal primary crystallization it can be assumed that X_s varies approaching 1 while X_S is approximately constant. In the reverse situation, when heating the sample, it can be assumed that $X_s = 1$. This means that as limiting behaviors, upon crystallization X_l is a constant and Q' is a linear function of X_c while on melting X_S is a constant and Q' has a quadratic dependence on X_c. This method has been applied in crystallization studies of iPP (79). Referring back to the previous example on the melting of high density polypropylene (HDPE) it should be noted that at the point where $X_S = 1$, one has $X_c = 50\%$.

One of the topics that has generated heated debates (30–32,80–85) is the mechanism of primary crystallization in semicrystalline polymers which are, after a temperature quench, crystallized from the melt. According to the theories of Hoffmann and Lauritzen and Keller and co-workers (86,87), and references therein] the onset of crystallization is a nucleation and growth process. An alternative interpretation is that the process is more complicated than straightforward nucleation and growth and involves a mesophase characterized by behavior similar to spinodal decomposition. One of the implications of this latter scenario is that there should be long range order in the solidifying sample before one can observe crystalline structure. Combined saxs/waxs experiments can play a role here.

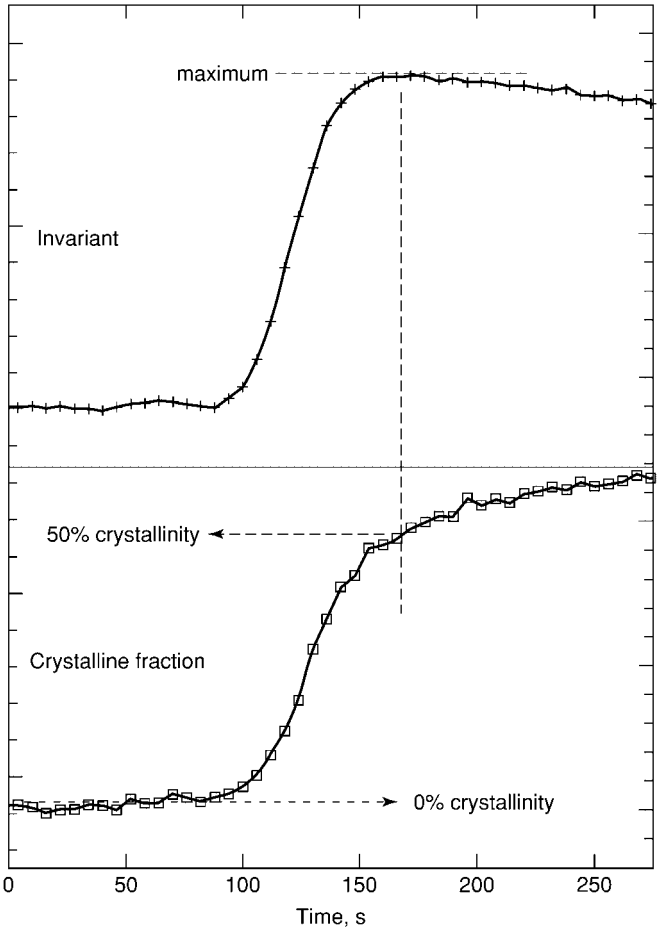

Fig. 16. Data obtained in a combined saxs/waxs experiment on the dynamic solidification of HDPE. The saxs invariant $Q = \int_0^\infty I(q)q^2 = \langle n_e \rangle^2 \phi(1-\phi)$ has a quadratic dependence on the crystalline volume fraction ϕ and reaches a maximum when the volume fraction reaches 50%. The integrated intensity of the waxs diffraction peaks has a linear relation with the degree of crystallinity. By taking the melt as the zero degree of crystallinity point and the maxium of the invariant as the 50% mark, it is possible to construct a degree of crystallinity scale which is internally consistent.

Small-angle scattering is an ideal tool to study the characteristic length scale of the long range density fluctuations occurring during phase-separation processes [eg, 88–91]. The crystalline structure can be observed with waxs.

That crystallization can occur via a spinodal mechanism in nonisotropic system, such as drawn poly(ethylene teraphtalate), is well known (92). The spinodal mechanism is characterized by the following development of the scattering intensity:

$$I(q,t) = I(q,0)\mathrm{e}^{2R(q)t}$$

in which $I(q, t)$ represents the time evolution of the scattered intensity and $I(q, 0)$ the scattered intensity at time $t = 0$. The factor $R(q)$ is the amplification factor (or growth rate constant) which is given by

$$R(q) = -Mq^2\left(\frac{\partial^2 G}{\partial \rho^2} + 2\kappa q^2\right)$$

with M the mobility term, G the Gibbs free energy, and κ a gradient free-energy term (31). However, this equation is not very useful in a scattering experiment. A more interesting derivable parameter is the effective diffusion coefficient D_{eff}, which can be derived from the growth constant as follows:

$$D_{\text{eff}} = \lim_{q \to 0} - \frac{2R(q)}{q^2}$$

Since $R(q)$ effectively has a q^4 dependence, one normally plots $R(q)/q^2$ vs q^2 to determine the effective diffusion coefficient (93).

The usefulness of SR becomes apparent when one realizes the important role that the amplification factors have in the spinodal formalism. To determine this factor properly one has to make a linear fit for every value of q to a $\log I(q, t)$ vs t plot. This requires many curves taken at different times with a reasonable fast framing rate matched to the transient nature of the phenomenon.

In Figures 17a and 17b, used to determine the D_{eff}, are shown data obtained from temperature quenches of quiescent iPP at different temperatures.

As mentioned earlier, one aspect of attempts to distinguish between a conventional nucleation and growth mechanism and a spinodal decomposition like mechanism in quiescent crystallising polymer is to investigate the absence or presence of a time lag between the onset of a rise in the invariant, which is dominated by data in the saxs regime, and the onset of the rise in crystallinity, which is evidenced by growing intensity of crystalline peaks in the waxs region. In Figure 18, in which one can see the results of a simultaneous saxs/waxs experiment on isothermal crystallization of iPP, one can clearly see that in this case the rise in the invariant precedes the rise in the crystalline peaks. This result highlights the question if the results of such an experiment are not influenced by the experimental method used. This influence can be twofold. In the first place one of the techniques can be intrinsically less sensitive than the other. In the second place the detector can introduce noise so that the real effects are hidden in the noise band. This is treated in somewhat more detail in a later section.

In crystallization experiments where one wants to study a short-lasting transient effect, with statistically relevant data, it is sometimes possible to translate the problem from the time domain to a spatial domain. In crystallization experiments this can be done very elegantly by using a scaled-down version of an industrial melt extruder. With appropriate extrusion rates one can obtain an unoriented melt just after the molten polymer has been extruded from the extrusion die. Further down the extruded film the polymer solidifies and crystallises. When mounted on an elevation platform it is now possible to choose the distance after the extrusion die where the x-ray beam intercepts the crystallising film. (Fig. 19). The distance from the die can be translated into a crystallization time. This method

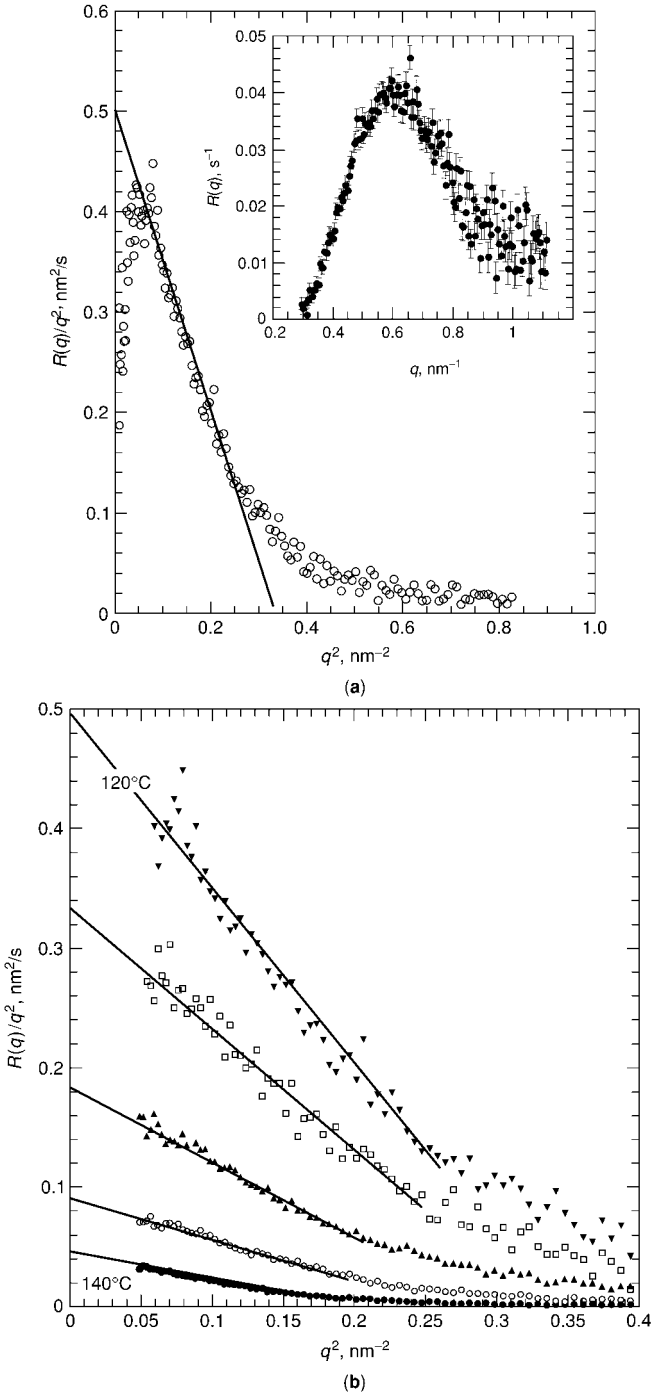

Fig. 17. Panel A shows a Cahn–Hilliard plot to estimate the effective diffusion constant D_{eff} from the intercept with the vertical axis for an isothermal crystallization experiment on iPP. The inset shows the $R(q)$ vs q. Panel B shows similar plots obtained at different crystallization temperatures from 120°C (top curve) to 140°C (bottom curve) in steps of 5°C (31).

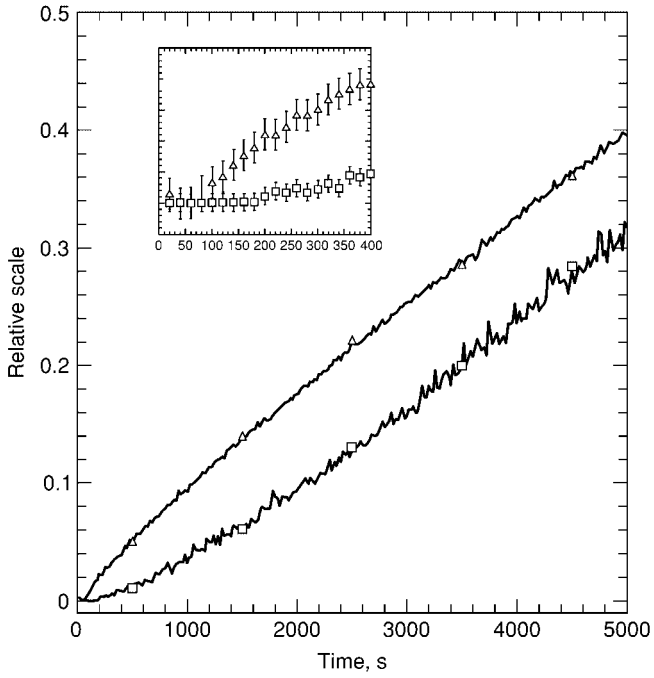

Fig. 18. SAXS/WAXS experiment on the isothermal crystallization of iPP. The saxs invariant and the crystallinity derived from the integrated intensity of the crystalline waxs peaks are coplotted with an arbitrary vertical axis. In this data set, the rise of the invariant precedes the rise of the crystallinity, which can indicate a spinodal-like crystallization mechanism. To base theories regarding crystallization solely on the outcome of such an experiment is dangerous since the results could be influenced by both instrumentation shortcomings and the physics behind the diffraction phenomena. —△— saxs invariant; —□— waxs crystallinity.

has been used (31,94) with the explicit goal of studying polymer crystallization. It is important to note here that in the latter case (31) one used similar detectors for the collection of the waxs and the saxs data. In principle it is not necessary to use two-dimensional detectors here, but in order to obtain the certainty that one is studying unoriented samples, area detectors are indispensable. For inappropriate flow rates one can obtain crystallization effects due to the sample deformation and shear.

The combination of saxs and waxs allows an experimenter to study hierarchical structural length scales from approximately 0.2 to 200 nm. The structural level above this is in some cases accessible with x-ray scattering by using the Bonse–Hart cameras, but this technique does neither provide time resolution nor a scattering vector range on an appreciable scale. Therefore equipment suitable for the combination of x-ray scattering experiments in combination with light scattering experiments has been developed (95,96). When using such a combination of techniques one encounters the situation where one has to make some concessions on the quality of the data for at least one of the techniques in order to be able to take any data at all. The optimum sample thickness for light scattering and for x ray scattering is considerably different. For polymers the optimum

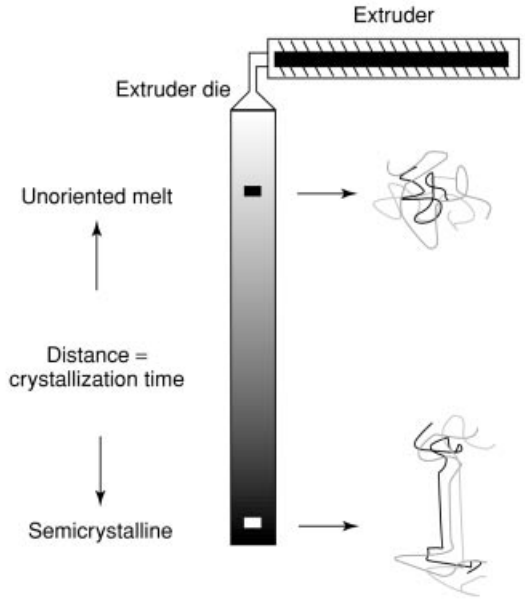

Fig. 19. Schematic description of experiments with an on-line extruder. The short transient phenomena are too short to be followed with a conventional scattering experiment. However, by prolonged measurements on different positions with respect to the extrusion die it is possible to obtain data with a good statistical significance in which the crystallization time is translated into the distance from the die.

thickness for x-ray scattering is around 1.5 mm (at $E = 8$ keV), and the optimum thickness for light scattering is around 10–100 μm. It is possible to obtain data from x-ray scattering with such thin samples but the signal-to-noise ratio from the data will not be very good. An alternative is to use a sample container that is tapered and in which one uses the thin end of the wedge for light scattering experiments and the thicker end for x-ray scattering. Care has to be taken that temperature gradients over the sample do not create essentially different thermodynamic states.

Microfocus

The third generation of SR sources allows the construction of beamlines with a very small beam size while still generating sufficient x-ray flux to be able to collect data on a reasonable time scale. Beam dimensions are still diminishing because of technological developments. At the time of writing it is possible to achieve a beam spot of 4 μm at the sample position for waxs experiments and down to 10 μm for saxs experiments. The reason for the larger beam size in the saxs experiments is that reduction in beam dimensions bears the penalty of a larger parasitic scatter cone which reduces achievable angular range at smaller scattering vector.

An interesting phenomenon in these experiments is that samples which appear to be completely homogeneous in experiments with a larger source size often

exhibit local orientational variations. This is most clearly seen in experiments on spherulite-forming polymers. By step scanning the sample through the beam it is possible to map the orientation of the lamellae inside the spherulite. This has been done on spherulites of poly(3-hydroxybutyrate) (97) (Figs. 20a and 20b). When viewed with a larger beam size one will only be able to probe the lamellar thickness averaged over all the orientations of the lamellar inside the spherulite.

Another advantage is that by using a detector with a high enough spatial resolution it is possible to observe on a single detector the long period as well as the region where the amorphous halo and crystalline peaks of a semicrystalline polymer are (Fig. 21). For time-resolved experiments this is not in all cases an option since the large number of photons hitting the sample in a small volume will unavoidably damage the sample. However, this method is useful when one wants to relate and calibrate the diffraction intensity of small-angle features with wide-angle features. A calibration sample measured both on a microfocus beamline and in a saxs/waxs setup with two independent detectors can be used for this. By using a combination of conventional saxs/waxs, microfocus saxs/waxs, and light microscopy, secondary crystallization during isothermal crystallization of iPP and PVF_2 has been studied (98). In the microfocus experiment a random point was chosen and this was illuminated till the growth front of a spherulite passed by. The increase in crystallinity during the following period was deemed to be due to secondary crystallization. These results were compared with the bulk measurements from the conventional experiments. The authors were able to show that the secondary crystallization was strongest directly behind the boundary between the virgin amorphous material and the spherulite.

Sample Environments and Technique Combinations

The early period of the application of SR in soft condensed matter research focussed mainly on structural determinations as function of easily varied parameters such as sample composition and temperature. Over the years the instrumentation has improved so much that one can state that this can now routinely be done. The challenge to extend the experimental possibilities by not only performing the scattering experiments, but also combining this simultaneously with techniques available in standard laboratories, was obviously felt by many experimenters. Doing these types of combined experiments has the advantage that for some samples the structural parameters can be correlated with thermodynamic or spectroscopic parameters obtained with the complimentary technique. These latter techniques can be repeated on a more extensive range of samples in the home laboratory. The combined experiments, obtained in the usually rather scarce experimental time allocated on the large-scale x-ray facilities, can then be used to extrapolate the structural information over the full sample range.

Combined experiments require a higher level of sophistication of the sample environment. Many examples can be found in the literature, for instance, fast stopflow cells (99), concentration gradient devices (100), and temperature jump cells (101). In the following sections some technique combinations and the implications for sample cell construction are discussed; see also Reference 5. Before treating

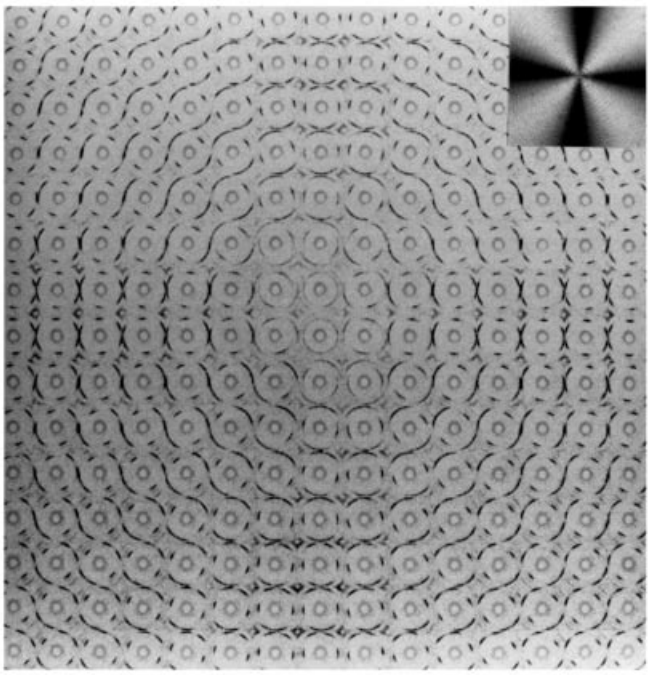

Fig. 20. In panel A diffraction patterns on different positions inside a spherulite of poly(3-hydroxybutyrate) are shown. The diffraction patterns are mapped onto the position inside the spherulite. The spherulite was mapped with a 10-μm beam on a microfocus beamline at the ESRF. The data presented here shows approximately 150 μm^2 of the spherulite. Panel B shows one of the diffraction patterns. It could be indexed to an orthorombic unit cell with dimensions $a = 0.576$, $b = 1.32$, and $c = 0.596$ nm. The degree of disorder increases toward the center of the spherulite. Courtesy of A. Mahendrasingam.

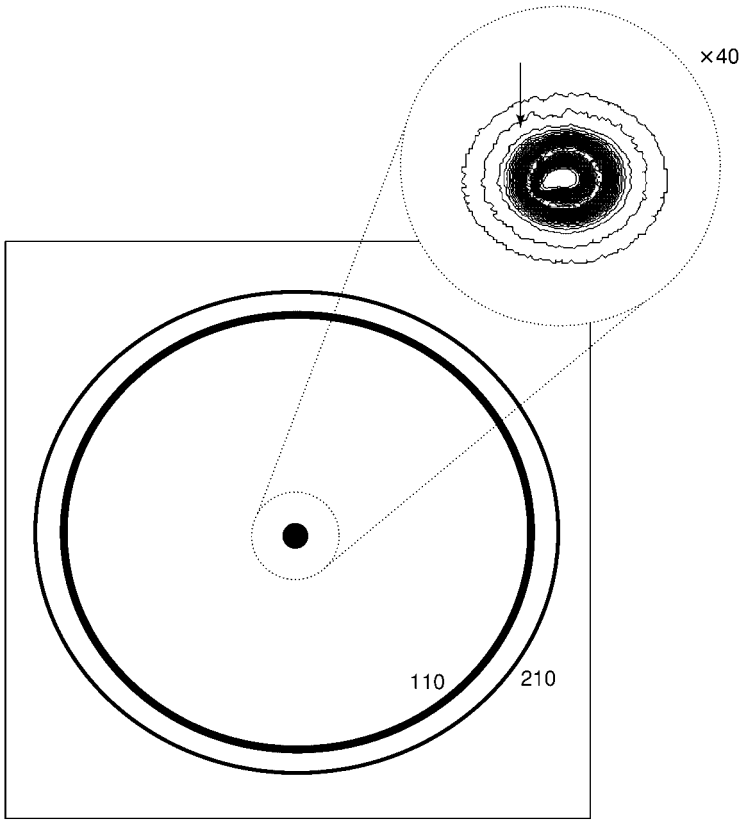

Fig. 21. Diffraction pattern and intensity trace of HDPE measured on a microfocus beamline. The diffraction intensity due to the lamellar thickness and the peaks due to the crystalline packing of the molecules can be obtained in a single diffraction pattern. The sample survives only a couple of minutes in the x-ray beam because of radiation damage. The photon flux can be as high as 1010 photons/s in a 10-μm diameter spot. Data taken in collaboration with M. Drakapopoulos/ESRF.

chosen subjects in more detail, some experiments that will highlight difficult experiments that require complicated sample environments and technique combinations are discussed. These examples include experiments performed either on second generation SR sources beamlines or on bending magnet beamlines of third generation sources, and therefore also serve to illustrate that by concentrating on sample environments it is not always required to have access to the superior quality of undulator beamlines at third generation SR sources.

The realignment process of liquid crystals in changing electric or magnetic fields has been studied in real time by techniques such as optical birefringence (102), nuclear magnetic resonance (nmr) (103), or x-ray diffraction (104). For samples requiring strong magnetic fields (>2 T) in combination with x-ray scattering, this is a nontrivial matter. In this case the field has to be generated by a superconducting magnet which, because of the cryogenic system required, has only limited possibilities for x-ray access. Split coil magnets with a large bore are expensive.

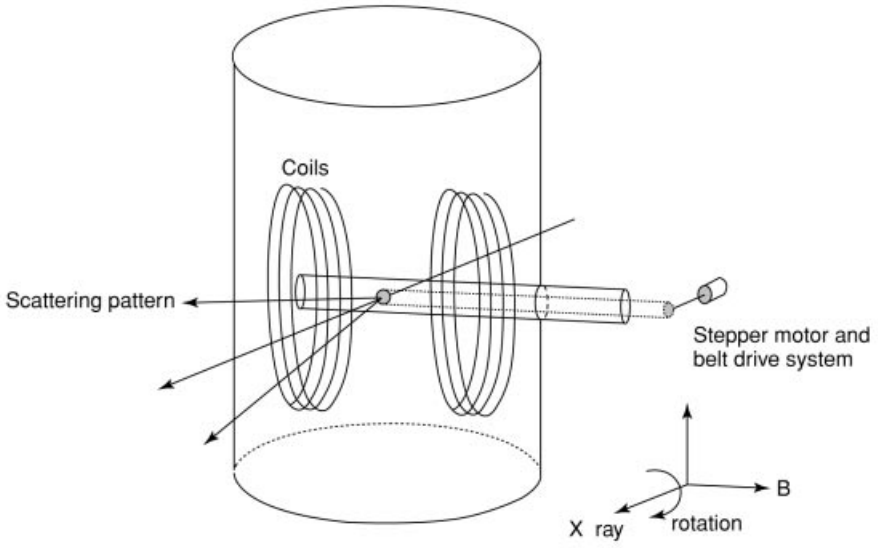

Fig. 22. Schematic representation of an experiment designed to study the reorienation mechanism of a smectic liquid crystal (8CB). The sample was placed in a magnetic field of 6 T at a temperature of 32°C. The magnetic field induces an alignment. By mechanically rotating the sample around the "x-ray axis" the reorientations due to the constant magnetic field can be studied.

The large bore is required since it allows thermal shielding between the cryogenic temperatures (≈4 K) required for cooling the coils and the sample temperature, which generally is >300 K. Moreover superconducting fields cannot be switched on time scales relevant for realignment studies (<100 ms). This implies that the sample has to be rotated in the field and so a rotation and temperature control mechanism has to be inserted in the coil (105). In Figure 22 the principle of this experiment is outlined. Experiments like this have been performed on a bending magnet beamline at the ESRF specifically designed to be able to accommodate large-scale sample environments for polymer processing experiments (12). In Figure 23 results of such experiments in a 5-T field on a smectic 8CB sample are shown. The sample temperature was set to 32°C. The sample was rotated in 70 ms and the realignment process was followed with a time resolution of 250 ms/frame. From these experiments it is clear that there is a transient phase occurring during the rotation in the magnetic field. The highest field that could be achieved in these experiments was 10 T. Such fields also allow the orientation of larger molecules with a small diamagnetic (46). In Figure 24 the fiber diffraction pattern of a biological microtubule polymer is shown. These polymers were self-assembled in the field by using a temperature jump from 4 to 37°C. The advantage of being able to perform such experiments is that one is able to obtain oriented diffraction patterns, which can be analyzed with fiber diffraction techniques, while the sample is contained in a buffer solution in which it retains its hydration and biological functionality.

The combination of saxs and waxs with light scattering has been discussed in the section on combined saxs and waxs experiments. However, light scattering

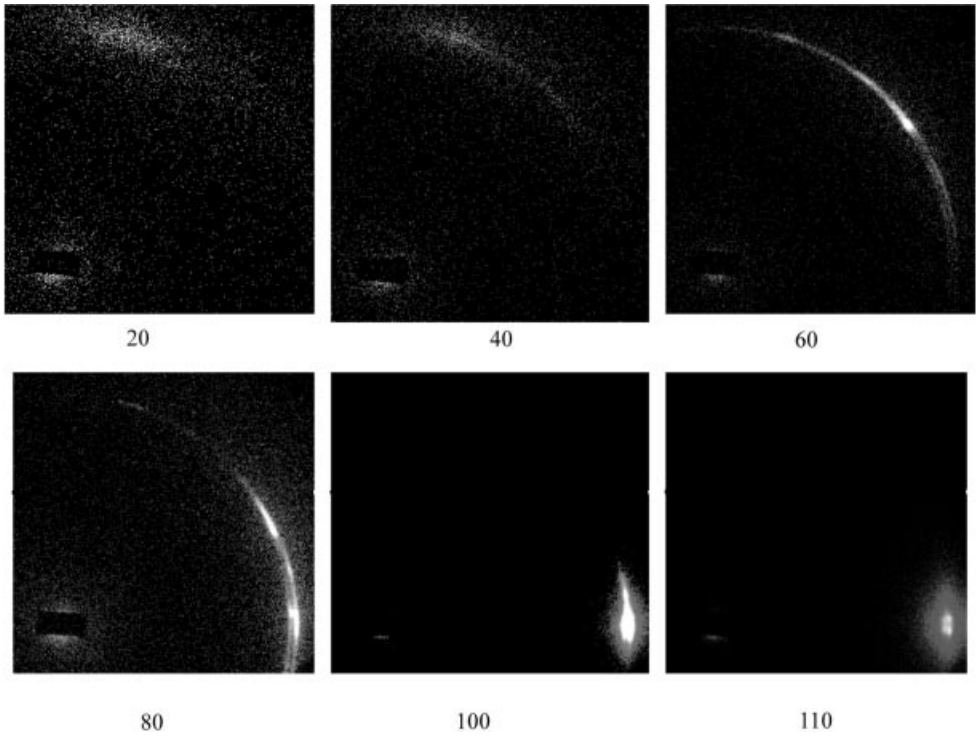

Fig. 23. Different stages of a realignment experiment on an 8CB liquid crystal oriented in a 6-T magnetic field. The unperturbed sample showed a diffraction peak in the lower right-hand corner. Once the sample is rotated inside the field the reflection moves to the top left-hand corner. The sample is forced to reorient to the original position by the magnetic field. The different time frames here show this reorientation effect. Interesting to notice is that when the sample is rotated back to about 50°, the x-ray reflection splits up in two discrete reflections. For this there is no explanation found yet. The time-frame rate was 0.25 s/frame. Unpublished data, courtesy of J. Seddon, B.A. Timimi, and W. Bras.

can be used for more complicated purposes or for obtaining a direct correlation between light transparency of a sample used in liquid crystal display units. In such a case one can correlate directly the transparency with the structural information contained in the x-ray scattering patterns. Strong electric fields are generated relatively easily. They are a common tool for the alignment of, for instance, liquid crystals. Modulated fields have found use both in the studies of liquid crystals and in solution scattering experiments (63). An example of a very complicated but elegant experiment can be found in Reference 106 which reports an experiment on a sample cell transparent to both optical and x-ray wavelengths used in the study of layer deformations in smectic liquid crystals during electric field induced switching. The electrooptic measurements provide information on the bulk motion of the liquid crystalline director while the saxs data is used to connect the liquid crystalline layer motion (Fig. 25). This experiment used bending magnet radiation from the SRS in Daresbury, which is a second generation SR source (107).

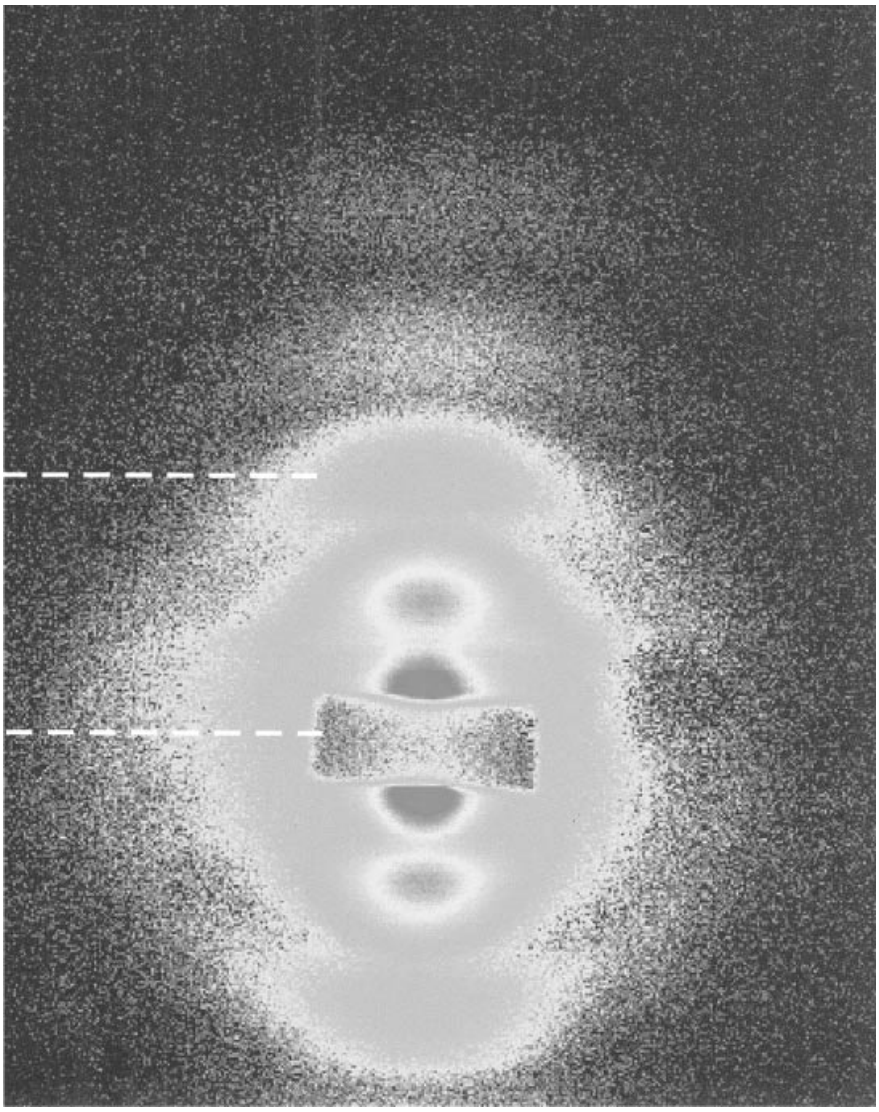

Fig. 24. Diffraction pattern of a magnetically aligned sample of microtubule biopolymers. The orientation was achieved by assembling the polymers, from the tubulin protein solution, in a 9 T on-line magnet. The diamagnetic moment of the tubulin protein is sufficiently high to induce orientation once several tubulin dimers have assembled. Unpublished data, courtesy of F. Díaz, G.R. Diakun, and W. Bras.

Temperature Control and Thermodynamic Experiments

Temperature control of the sample is one of the most basic requirements for an experiment. This is especially the case when one performs time-resolved experiments in which one wants to determine the structural phases in a temperature–composition diagram (64,108). The required accuracy is dependent

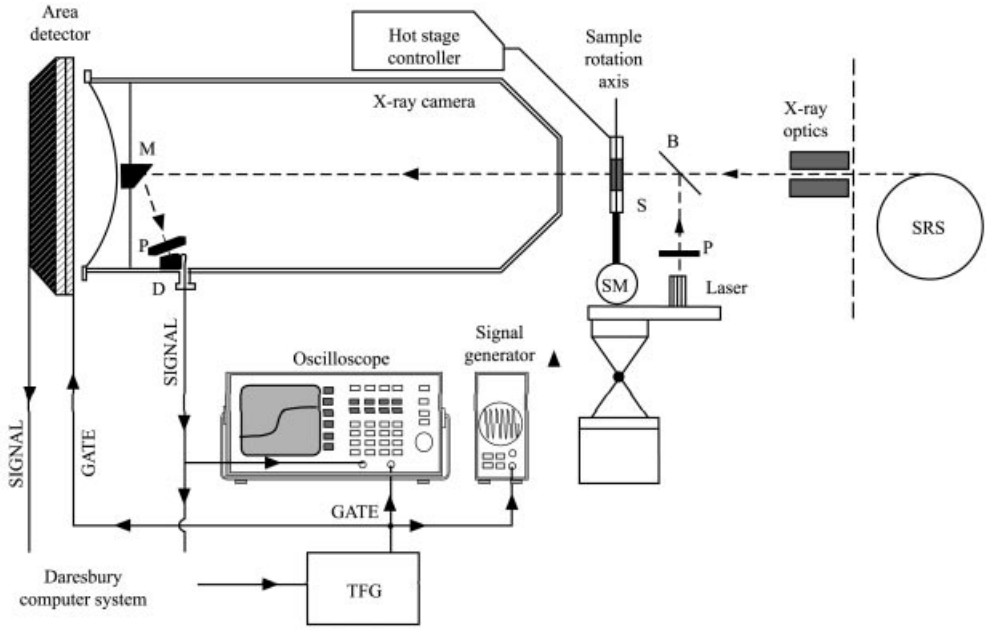

Fig. 25. Combined optical and x-ray experiment. By using a thin x-ray transparent mirror a polarized light beam is guided parallel to the x-ray beam through the sample. A second mirror mounted on the x-ray beam spot deflects the light onto a photodiode. The sample orientation can be influenced by using an electric field. Key: D = detector; P = polarizer; M = mirror; S = sample; B = beamsplitter; SM = stepper motor; TFG = time frame generator. Courtesy of N. Gleeson.

on the experiment but can be roughly 0.1°C in some cases. In principle this is no problem but one always has the complication that one requires access for the x-ray beam. This access often causes temperature gradients to develop. Also in processes where the temperature is changed as a function of time, not only spatial temperature gradients, but also temporal gradients exist, making an accurate control difficult.

A popular method for the investigations of crystallization kinetics is to rapidly quench the sample at a temperature below the melting point and then perform an isothermal crystallization experiment. Apart from the scientific merits, there is obviously an interest in such temperature quench techniques from an industrial point of view. The temperature control in a fast quench does not in general exist and only the start and final temperature can be controlled (109). An elegant way to perform a temperature quench experiment is to keep the sample above the beamline in a furnace at an elevated temperature and then, shoot, it into a second furnace which is mounted on the beamline (101). A time resolution of 0.1 s/frame is feasible at present (109). It should be stressed that the limitations here are more in the temperature control than in the SR beamlines.

Thermodynamic experiments on phase transitions by using differential scanning calorimetry (dsc) and differential thermal analysis (dta) are some of the most important tools of the polymer researcher which can be found in nearly every

laboratory. The accurate correlation of thermodynamic parameters with structural information increases the understanding of the basic phase transition under consideration. To be able to perform simultaneous experiments on a single sample for a set of reference samples, with, for instance, a variable content of copolymer, allows one to extrapolate these results to samples for which only dsc data is available. A data set obtained in the scarce time available on SR beamlines can thus be the basis for a full understanding in a systematic study in which the copolymer content can be varied more finely than in the time available on the SR beamline (110,111). Several manufacturers produce small thermal analysis instruments that have been designed to be used in combination with optical microscopy (5). With some slight modifications these instruments can be used in combination with x-ray scattering experiments.

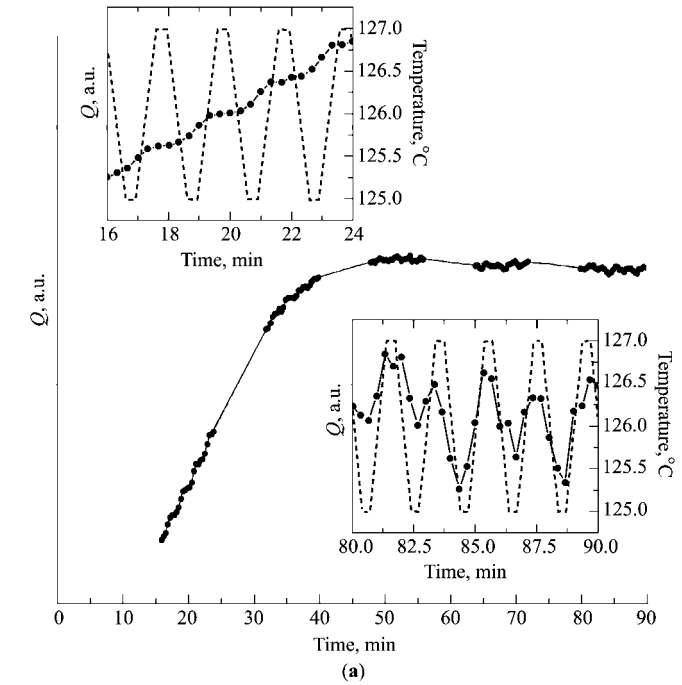
However, it is a misunderstanding that one can obtain data from combined experiments that can compete with that obtained from independently performed and optimized experiments. Especially the thermodynamic results are often more qualitative than quantitative. The rationale behind combining experiments is that the thermodynamic data obtained with, for instance, an on-line dsc will still show the strong features. The correlation of specific thermodynamic features with time frames of the scattering data enables correlation with an independently obtained high quality dsc trace. In such a case the on-line dsc acts as an accurate thermometer.

A good example of the above statement are experiments with temperature-modulated dsc (TMDSC) on samples of linear PE (112). Here a programmable temperature controller is set up in such a way that the temperature/time profile follows exactly the profile that in an off-line modulated dsc instrument is applied to the sample. By carefully assessing the correlation between the temperature profile and the influence this exerts on the invariant Q, as well as on the crystallinity derived from the waxs, it is possible to show that reversible melting and crystallization take place at the lamellar fold surface and not on the lateral surfaces of the crystallites (see Figs. 26a and 26b).

Spectroscopy and Reactive Processing

In previous sections the combination of x-ray scattering with thermal analysis methods and light scattering was described. These techniques complement the structural information by adding either direct or indirect information regarding a higher hierarchical level of organization. Structural information on shorter length scales is not accessible by x-ray scattering experiments. For additional information regarding conformational changes in larger molecules and chemical bonds between molecules one has to utilize spectroscopic techniques such as infrared absorption or Raman scattering, depending on whether one wants to study bond orientations parallel or perpendicular to the polymer chain. Especially when one is dealing with reactive processing of polymers the approach to combine time-resolved synchrotron x-ray scattering experiments with spectroscopy can be fruitful.

The simultaneous combination of x-ray scattering with spectroscopic techniques is still in its infancy. As an example a combination of Fourier transform



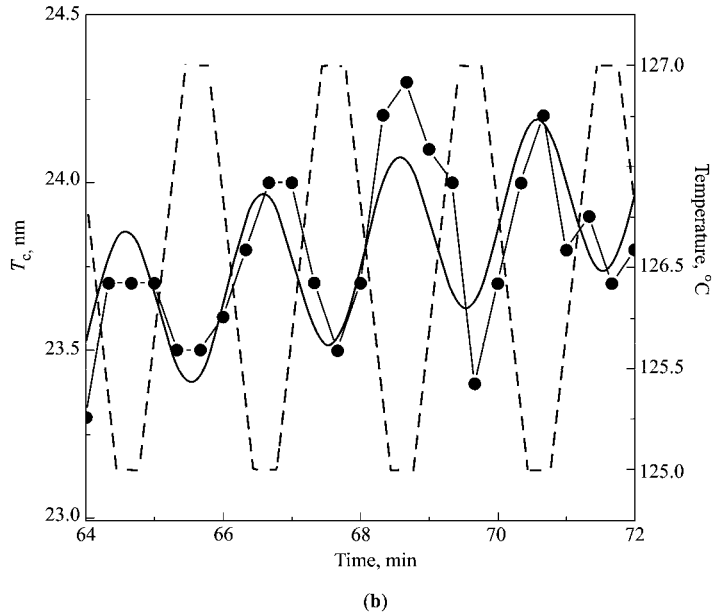


Fig. 26. Panel A shows the time development of the invariant Q in a temperature-modulated crystallization experiment on linear PE. The insets are magnified parts of the main figure at time 16–24 min (upper) and 80–90 min (lower). Panel B shows the thickness of the crystalline layer, T_c, as a function of temperature. The thick line represents a fit to the data points, and the dotted line is the applied temperature profile. The correlation between the two is obvious. Courtesy of B. Goderis

infrared spectroscopy (ftir) with saxs is discussed (113). In this example the information about vibration modes involving motions of chemical groups in molecules is used as a parameter directly linked to the chemical reaction during the formation of a polyurethane while the saxs pattern provides the information on the formation of structure in the sample.

One of the problems that one faces when combining ftir and x-ray scattering is that the optimum thickness for transmission experiments with both techniques differ by several orders of magnitude. For homogeneous samples the solution to this problem is to perform the x-ray scattering experiment in transmission and use of the method of attenuated total reflection (ATR) for the ftir experiment. With the ATR method the sample is mounted onto a zinc selenide or KRS5 crystal. This crystal acts as a prism and is illuminated with infrared radiation from the side. The infrared radiation is reflected several times in the crystal and upon each reflection penetrates superficially in the sample material. The multiple reentry enhances the absorption and increases the signal-to-noise ratio considerably. One can now choose to either provide x-ray access through the crystal or, the more elegant solution, extend the stainless steel support and temperature control. A small hole in this extension provides x-ray access (see Fig. 27).

An experiment describing the formation of polyurethane elastomers through the reaction of isocyanate with hydroxyl components is now discussed as a specific example. The experiment was set up to resolve the question whether hydrogen bonding between the carbonyl groups forced the structure formation or whether the hydrogen bonding was just a consequence of the formation of structure. The combined experiment showed unequivocally that the structure formation, as evidenced by the rise in the saxs invariant, preceded the hydrogen bonding, observed as a shift in the carbonyl absorbencies from 1720 cm^{-1} (free) to 1700 cm^{-1} (hydrogen bonded) (see Fig. 28). The importance of the simultaneous performance of the experiments on the same sample lies in the fact that with independently performed experiments the correlation between the time axis of the two experiments did not show this with sufficient degree of accuracy.

With the appropriate equipment the time resolution can be reduced to 1 s/frame. This improvement brings the time resolution inside the realm that is interesting for the combination with polymer processing techniques such as reaction injection molding (RIM). RIM processes have been studied independently by saxs and ftir (114,115). Here one faces the problem that the sample cell is rather large and has to be filled completely and homogeneously on a time scale which is short compared to that of the reaction that is taking place. Therefore time resolutions below 2–4 s/frame are not achievable. In Figures 29a–29c, the results from a similar reaction as described above, but now at industrially relevant temperatures and reaction rates, are shown. Having shown that these experiments are feasible from an experimental point of view, a remark can be made that every time that an experiment was done a new ATR crystal was required since they invariably break when one tries to free them from the formed polyurethane. This makes these experiments rather expensive.

Another spectroscopic technique which at times can be very useful to combine with x-ray scattering experiments is Raman scattering. This technique can

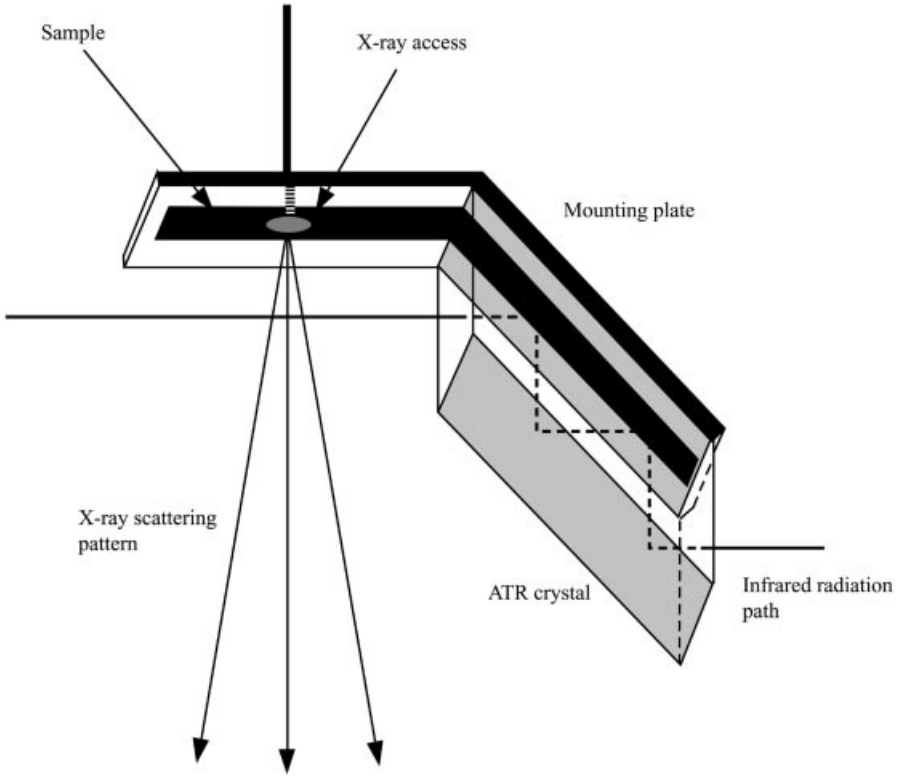

Fig. 27. Experimental layout for a combined ftir, saxs, and waxs experiment. By using the ATR method for the ftir it is possible to overcome the problem of incompatible optimum thicknesses for the different techniques. For slow reactions this method is suitable. For faster reactions, where it is more important that there is an exact coincidence of the positions on the sample where the data is obtained, one has to drill a hole in the ATR crystal in order to allow x-ray access.

be used in a similar fashion as ftir but is also usable with nontransparent samples and provides more information on the vibrations in the carbon chain of the polymer. This contrasts with ftir where the information content mainly relates to the substituents on the carbon chain.

In practice, the combination of Raman scattering with x-ray scattering is greatly facilitated by the possibilities of using fiber optics and microscopic techniques (116). One very elaborate study (117,118) used the combination of *in situ* saxs/waxs/Raman scattering to shed light on the very complex phase behavior of syndiotactic polystyrene (sPS) dissolved in reactive solvents. The verdict from this study was that it was crucial to combine these three techniques in a time-resolved way in order to obtain a clear picture of the complicated processes taking place in these systems. The changes in the crystalline conformation of sPS are monitored spectroscopically, the degree of crystallinity by the waxs experiments, and the phase separation process by saxs.

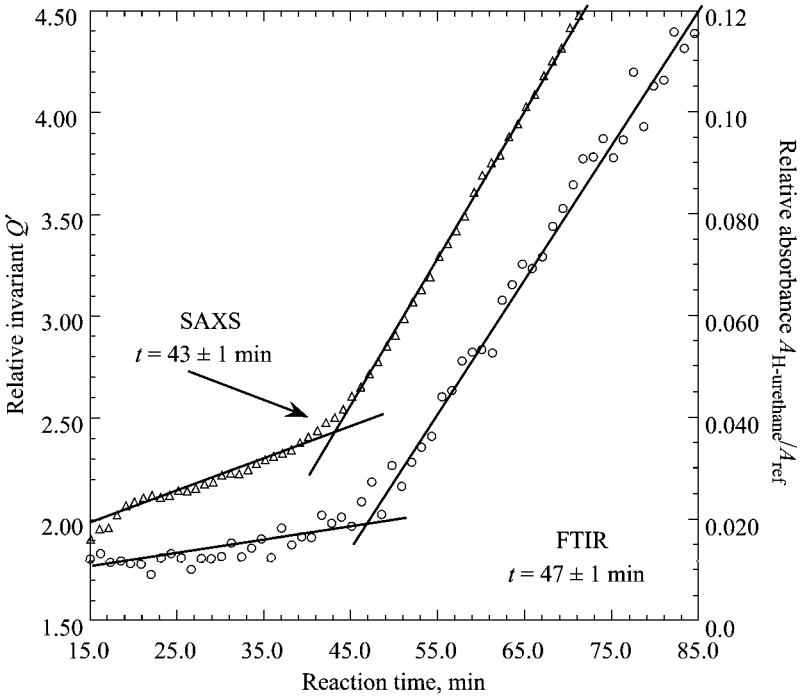

Fig. 28. Polyurethane elastomer formation studied by a combination of saxs and ftir. The chemical reaction forming the polyurethane can be monitored by following the changes in the infrared absorption bands. In this figure the intensity of the band associated with the hydrogen bonded urethane is coplotted with the saxs invariant. It is clear that the invariant increases before the ftir signal. By applying this method the possibility that structure formation is caused by hydrogen bonding could be excluded and it was shown that the hydrogen bonding is a consequence of the structure formation. △ Relative invariant Q'; ○ $A_{H-urethane}/A_{ref}$.

Deformation

In situ deformation of polymers via uniaxial drawing can be implemented on an SR beamline relatively easily (119,120). This was already mentioned in the section on Fiber Diffraction. In two-phase systems one can study the deformation of the constituent phases. Also of interest are damage effects due to cavitation and crazing (121,122). The main experimental problems with x-ray experiments on devices mounted in a tensile tester is to keep illuminating the same spot on the sample with the x rays and to properly normalize the scattering pattern since the transmission is continuously changing by the nature of the drawing process. Methods to keeping illuminating the same spot are in the first place by using devices which move both jaws with the same speed. Still the sample can slip in the jaws occasionally, causing a change in position of the material under investigation. This can be compensated by drawing small markers on the material and keeping a visual observation via a closed circuit television system.

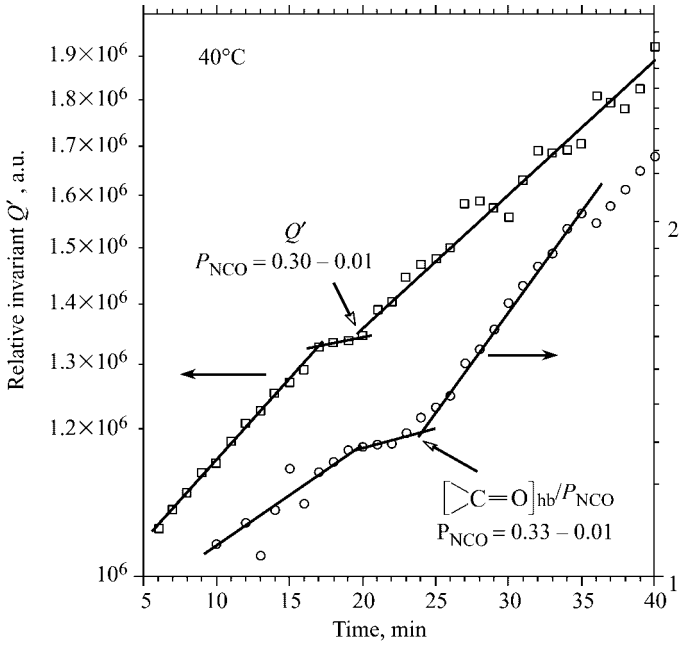

Fig. 29. Results from an on-line RIM/SAXS/FTIR experiment at different temperatures studying a similar reactive processing experiment on polyurethane formation. However, in this case the experiment was combined with an on-line RIM machine so that industrial processing conditions regarding temperature and reaction rate could be used. The ftir data was obtained via the ATR method. Shown are the isocyanate conversions (right-hand scales) and the invariants for different temperatures. From these experiments it can be concluded that at the microphase-separation point the chemical reaction kinetics change from second order to a diffusion control. Courtesy of M. Elwell.

The deformation of HDPE shows how a strain-induced phase transformation can be studied (122). In this experiment it is interesting to follow the large-scale changes induced by the strain and try to relate this to the changes in the crystalline unit cell of the material. In order to correlate these small- and large-scale events it is required to collect the saxs and the waxs data simultaneously. However, since we are dealing with a nonisotropic scatterer the use of area detectors over one-dimensional detectors is preferred. For simultaneous experiments this poses somewhat of a problem. In order not to intercept the saxs pattern the waxs detector has to be offset with respect to the direct beam which means that the complete scattering pattern can not be detected. Often the waxs detector will be tilted at an angle of 45° in order to intercept as large a q-range as possible. Such a mounting and the short sample–detector distance invariably creates a distorted pattern (see Fig. 30). As long as there are just geometrical distortions there is not a real problem, but in the case of gas-filled multiwire chambers one will encounter parallax effects as well. With CCD detectors one does not have this problem but, as mentioned in the section on Detectors, one has less dynamic range and might struggle to detect weak features (120). However, when one is interested in the order of events taking place, such a setup can be very useful. In Figure 30

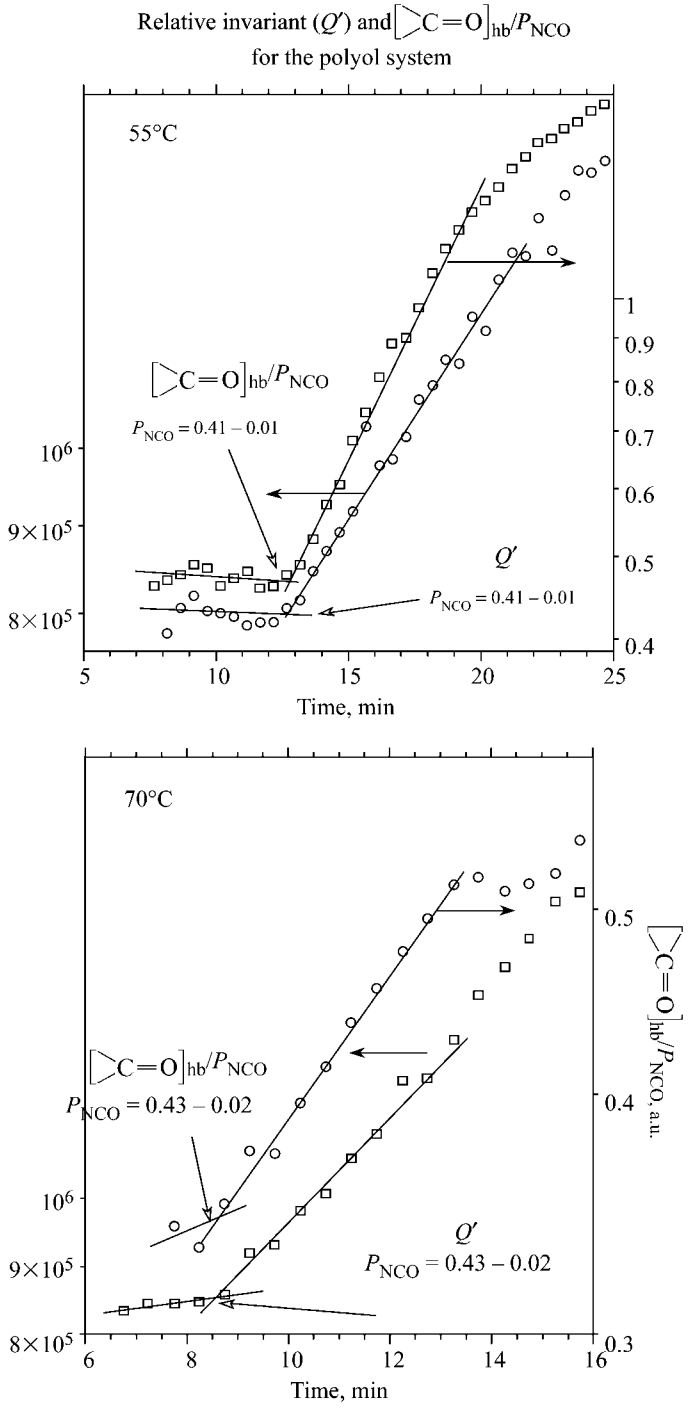

Fig. 29. (Continued).

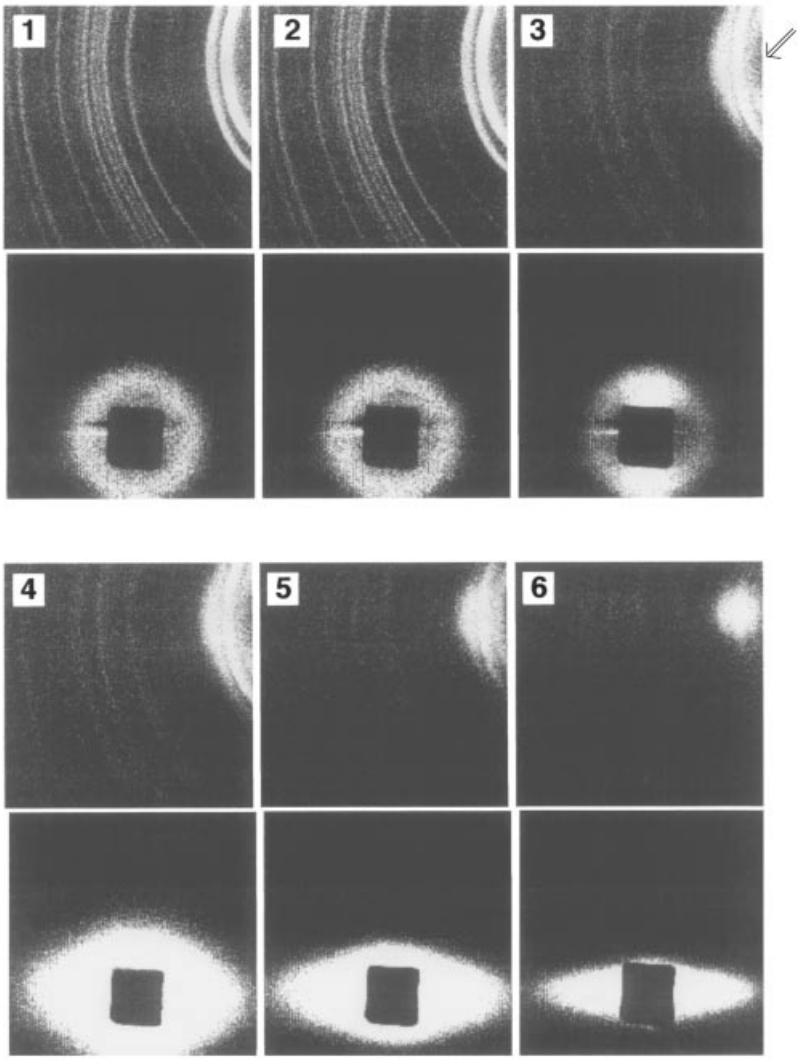

Fig. 30. A simultaneous saxs/waxs experiment on an oriented sample which requires both area detectors for the saxs and waxs region. An HDPE sample is stretched. The deformation induces a martensitic phase transformation as evidenced by the occurrence of extra reflections in the waxs region (top row of diagrams, see arrow). Void scattering is found in the saxs patterns (bottom row of diagrams). For a further explanation one is referred to the text and to References 122 and 123.

both saxs and waxs patterns are shown as a function of draw ratio (122). This data shows how the deformed HDPE first becomes oriented, as witnessed by the fact that the initially isotropic Debye Scherrer rings in the waxs pattern deform in noncontinuous arcs. At the same time the diffraction intensity in the saxs pattern, corresponding to the lamellar spacing, shows orientation. However, already at strains of 5% the intensity is dominated by very intense void scattering. Another interesting feature that can be observed is evidence of a martensitic phase

transition through the occurrence of extra reflections on either side of the 110 and 200 reflectons in the waxs pattern. This transition from a orthorhombic to monoclinic unit cell as already been discussed (124). With conventional x-ray sources it is very difficult to follow such transitions in real time. The high flux of an SR source and the associated instruments, such as high count rate detectors, are required here. An extensive study of deformation phenomena in polyethylene has been given (123). Crazing phenomena have been described quantitatively (121,125). The authors have made an attempt to elucidate the contributions that different effects might have on the anisotropically scattered intensity. Not all aspects of the interpretation of crazing data have been fully understood yet. A rigid mathematically acceptable framework is still lacking.

Biaxial drawing systems have been developed (126) but so far very few results can be found in the literature (127,128). The difficulties encountered in obtaining quantitative data have been described (126). However, most problems are not insurmountable and it can be expected that soon this technique will also be applied routinely. Complete uniform deformation, like in film blowing, is experimentally much more difficult to perform because of the fast changing thickness, and thus x-ray absorption of the sample, which makes normalization difficult. Also, one can expect the detector count rate to vary rapidly in unison with the sample thickness, thus requiring a detector with both a high count rate and a high dynamic range.

Pressure Cells

Pressure is undeniably one of the most interesting parameters that can be varied in real-time studies on polymeric samples. During processing polymers are often subjected to a combination of pressure and shear. Not only the industrial relevance makes structure/pressure studies interesting, but also the possibility to use pressure as a thermodynamic variable in time-resolved scattering experiments allows the structural determination of phases detected previously only by techniques with less direct information content, such as dsc. The application of pressure increases the melting temperature of the polymer, which facilitates a higher chain mobility. Thus a larger possibility exists, upon annealing at high P–T, for growing more perfect crystals or even forming new crystalline phases. In copolymers of polyethylene, side chains can crystallize in the more open hexagonal form, normally not stable at ambient pressure and temperature, instead of the normal orthorhombic form (129).

The problem with x-ray experiments at elevated pressures is the sample cell windows. These have to be able to withstand the high pressure and still be sufficiently transparent to x rays. In the general understanding there are some misgivings about the problems associated with these cell windows. The problem is not only a matter of absorption, as is often assumed, but also of signal-to-noise ratio and multiple scattering. In Figure 31 the transmission as function of energy of diamond and polypropylene is shown. There are two key issues:

(1) the sample plus windows still should show a decent x-ray transmission;
(2) the scattering signal of the sample should not be completely wiped out by the signal from the windows.

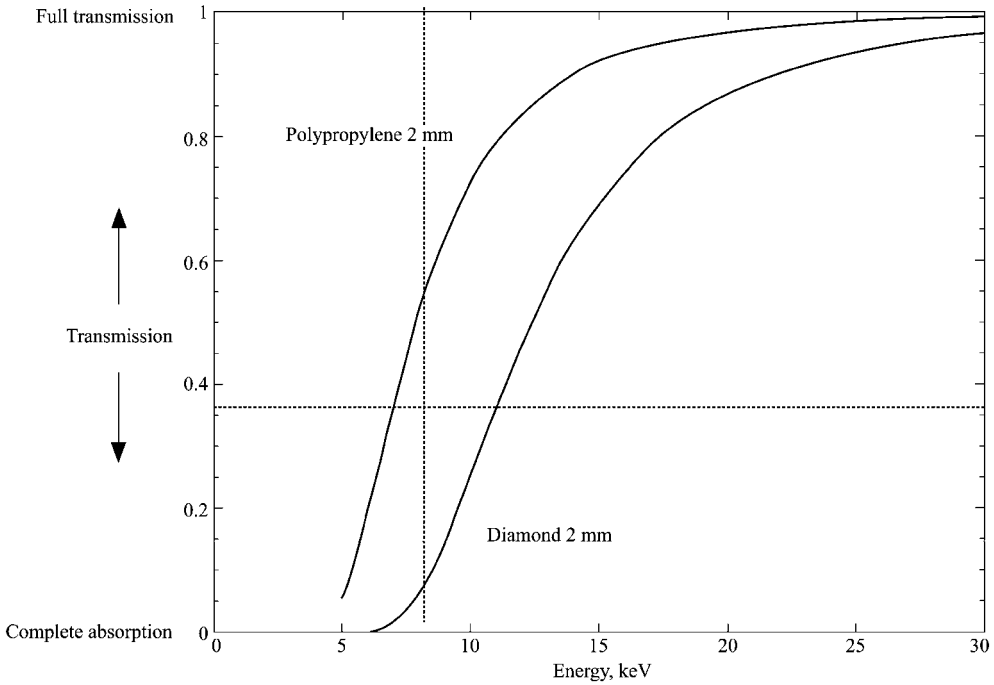

Fig. 31. Transmission of diamond, often used for x-ray windows in high pressure cells, compared with the transmission of PE as function of energy. Conventional x-ray generators most often use Cu Kα radiation (dotted vertical line). It is clear that the possibility to vary the x-ray energy is a most useful option when one needs to use less x-ray transparent windows. One is reminded that the optimum thickness for x-ray scattering is the one at which the ratio $I_t/I_0 = 1/e$.

From Figure 31 it can be seen that increasing the x-ray photon energy above the conventionally used 8 keV (ie, the Cu Kα line produced by most generators) allows a much higher transmission. The second point can be addressed by choosing a sample thickness that is matched to the thickness of the diamond windows in such a way that the sample signal is at least of the same order of magnitude as the signal from the windows. The reader is reminded that the optimum thickness for scattering is when the ratio of the transmitted beam, I_t, to the incoming beam, I_0, is

$$\frac{I_t}{I_0} = \frac{1}{e}$$

If the transmission is much lower than this value multiple scatter will occur and this gives rise to an uncorrelated background which can seriously affect the quality of the data. With too low a transmission, increasing the flux from the incoming beam is not going to be the solution since this will also increase the background proportionally. On most SR beamlines it is possible to vary the energy somewhat, and this explains why the field of high pressure diffraction has grown with the advent of SR and especially with the coming on line of the powerful third generation of SR sources.

An extensive study on the *P–T* phase diagram of polyethylene has been reported (130). This author has developed a cell which has been copied by several others (130). Pressures of up to 5 kbar can be reached with this *in situ* piston–cylinder sample cell, equipped with diamond windows. By using two cylinders it is possible to apply three-dimensional pressure which is regulated by pressurized nitrogen gas. One of the main conclusions of this work was that within the pressure and temperature range of this experiment the formation and growth of single crystals, in both the stable and metastable part of the phase diagram, took place in the mobile hexagonal phase. When allowed to transform from the metastable hexagonal to the orthorhombic phase all crystal growth stopped. Another very nice example of experiments using a similar type of pressure cell is given in Reference 131. These authors investigated the P–T phase diagrams of poly(4-methylpentene-1).

Rheology and X-ray Scattering

The response of a polymeric sample to an applied shear is obviously of interest since most industrial processing processes imply that the material is subjected to shear somewhere in the process before the final product is ready. Sometimes this induces crystallization (132), phase separation, or orientation in the final product. It is therefore not surprising that over the last decades extensive *in situ* studies of these induced structural changes whilst the shear is applied have been conducted, in preference over postmortem determinations of the structure. Independent of which type of shear geometry one uses, one encounters the problem that the sample has to be contained at a high temperature in a cell which is capable of withstanding the pressures intrinsic to the shear process (133). Optical microscopy has already been used for this type of work since the 1960s (134) but for length scales, only accessible via scattering, with wavelengths shorter than that of visible light, this type of studiys was till recently the domain of neutron scattering since the high penetration power of neutrons allowed the construction of sturdy cells whilst the high neutron scattering cross section for polymers enabled data collection with a reasonable signal-to-noise ratio (135,136). However, just as in the previous section in which pressure cells were discussed, nowadays it is possible to construct shear cells of many types which can be used in situ with x rays because of the availability of sufficient flux at shorter wavelengths (with sufficient penteration power) on the latest generation of SR sources. The intensity of the x-ray beam at these wavelenghts can be so high that it allows in some cases time-resolved experiments on time scales not accessible with neutron scattering experiments. This does not imply that x-ray scattering will replace neutron scattering experiments. They are essentailly complimentary tools in the toolbox available to soft condensed matter researchers.

A commercially available parallel plate shear device Linkam CSS (137) from which the windows were replaced with Kapton windows, in order to increase the x-ray transparency and reduce the parasitic scatter, was used in a study on the shear-induced crystallization behavior of iPP by saxs (138). By applying a short step shear it was found that the crystallization ratio could be increased by 2 orders of magnitude with respect to the quiescent mode. This increase can be attributed to orientation-induced primary nuclei. These are probably lamellae

(kebab) oriented parallel to the flow direction. After cessation of shear, strong x-ray scattering occurs indicative of the growth of crystals perpendicular to the flow direction (shish). This secondary crystallization growth is nucleated on the earlier formed shear-induced crystals. It is interesting to note that the final morphology, as observed by saxs and tem, does not show a full shish-kebab structure under most of the experimental conditions, ie, different shear step rates. The extended chain primary nuclei template the folded chain crystals but are apparently too tiny to be observed directly. This type of experiment can be performed with a time framing rate of approximately 10 s/frame using a CCD detector.

The parallel plate geometry is preferable from an x-ray scattering point of view (139). Only two x-ray windows are required to confine the sample. However, from a rheological point of view this is not the only required geometry. Couette cells have been used extensively in neutron scattering (140). With an appropriate material for the construction of the cylinders a similar approach can be used in saxs experiments (141). The absorption and scattering power of the cylinder material are of overriding importance since the x-ray beam has to traverse either four windows in the case where the incident x-ray wave vector is at right angles with the shear direction, or a considerable amount of material when the incident beam is parallel with the shear direction (Fig. 32). By using thin cylinders of polycarbonate this problem can be partially solved. However, that limits the usefulness of such a cell to a temperature range not exceeding the melting temperature of polycarbonate. An alternative can be to use very thin aluminum cylinders but this has as a consequence an increase in the background noise due to the crystalline grain boundaries in the aluminum which produce considerable small-angle scattering. The Couette geometry is not really useful for waxs experiments since the diffraction pattern is produced not by a single intersection of the beam with the sample but in two discrete spots separated by several centimeters. For saxs this is hardly a problem but in waxs, with the much smaller sample–detector distances, this difference is considerable.

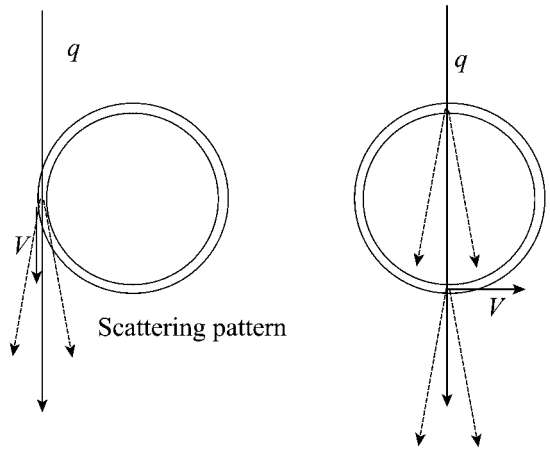

Fig. 32. Couette cell geometry used in on-line x-ray experiments. In the older generation SR sources, the use of a Couette cell is nearly impossible because of the lower x-ray flux which caused too much x-ray absorption. *V* indicates the flow direction.

The use of several other types of shear cells on x-ray beamlines has been reported in the literature. Recently the use of a 'cone and plate' type was reported (142). The other main type used in x-ray research is the reciprocating or oscillatory shear cell (143,144). This system can be mechanized in which the shear that can be applied is completely controlled. A charming example and result of improvisation, often required when using central facilities to which one has access for only a limited amount of time, can be seen in Figure 33. Only a small amount of shear and a slow cooling down was required to induce the hexagonal ordering in this diblock micellar system. This was achieved by drilling a hole in a stainless steel vacuum flange, gluing two pieces of mica as window material to the flange and a piece of brass, sandwiching the sample between the two windows, and reciprocally rubbing the sample for some seconds. The slow cooling was provided by heating the stainless steel flange with a hot air gun and letting the sample air cool so that the thermal mass of the flange allowed for a slow cool (145).

Industrial Polymer Processing Equipment

Real-time studies are, besides interesting for fundamental aspects of polymer behavior, obviously of interest for the polymer processing industries. How a material behaves and changes when subjected to flow, extension, pressure, temperature changes, etc, are all questions of great importance to processing. In these experiments the time resolution of the process is a parameter which can be influenced to a lesser extent than in more fundamental research. It is therefore not surprising that scaled down versions of processing equipment have been mounted on x-ray scattering beamlines where the higher flux enables a substantial part of these experiments to be performed.

In an earlier section the application of a scaled down version of an industrial-type extruder has already been mentioned in connection with crystallization experiments (30). This type of equipment can also be used for more applied experiments, where not the fundamental aspects of crystallization are studied, but more the influence of the spin rates, tension, and shape of the die heads on the final morphology that can be obtained (146,147). The importance of this is underlined by the fact that as early as 1964 researchers have attempted to do *in situ* experiments (148) using a rotating anode generator. Only in 1993 were these experiments taken to an SR source with consequently an increase in data quality (149). In this case the high photon flux is of crucial importance since what is required is that the cross section of the fiber with the x-ray beam remains unchanged over the complete time that one requires to obtain statistically significant data. With a higher photon flux this moment is reached much faster and thus the stability of the spin line does not have to be maintained over a period of days but rather over a period of up to 30 mins.

Experiments performed on poly(vinylidene fluoride) show a development of large-scale structure before a small-scale structure could be observed (149). The authors concluded that this was in agreement with earlier findings where in a nonquiescent sample, crystallization was initiated via spinodal decomposition. The final structure was reached via a two-step crystallization mechanism and resulted in a shish-kebab-like structure where it could be noted that there was

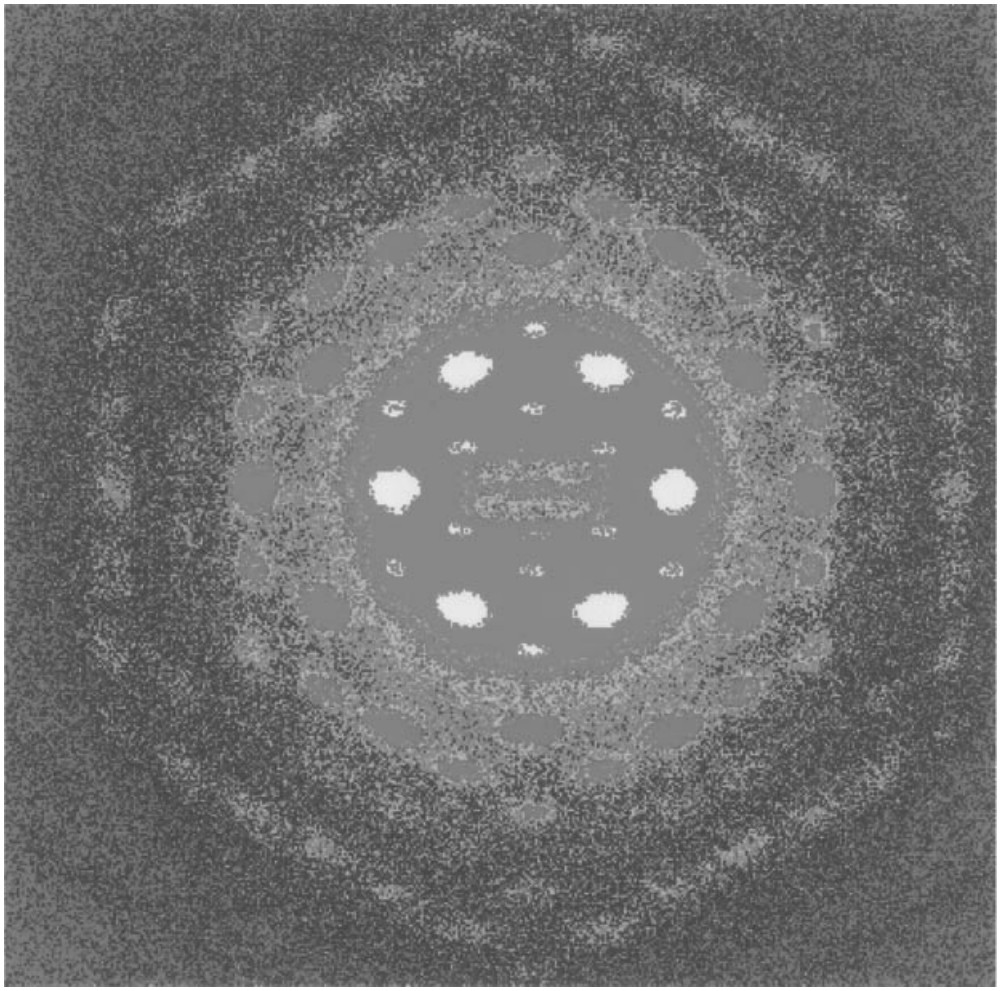

Fig. 33. Small-angle diffraction pattern of a sheared micellar-forming diblock copolymer. The sample was sheared and slowly cooled down on-line so that the formation of the hexagonal structure could be observed. The low angle resolution is about 120 nm. Unpublished results, courtesy of G.P.R Fairclough, R.N. Young, L.Messe, A.J. Ryan, W. Bras.

a noted increase in the *d*-spacing of the primary peaks in the saxs region with increased take-up speed from the fiber. However, this was not the case in the relaxed material from the final fiber.

Over the last decade the processing of polymers in supercritical CO_2 has gained some popularity (150). From a P–I phase diagram one learns that pressures in excess of 7 MPa (70 bar) are required to reach the supercritical state in CO_2. *In situ* experiments have therefore largely been restricted to neutron scattering experiments where the window thickness, when the appropriate materials are used, is not too large an issue. With x-ray scattering this is a problem, just as with the high pressure experiments discussed in an earlier section. However, again the

third generation of SR sources will allow the construction of cells suitable for fast time-resolved experiments. Shorter wavelengths will have to be used to maximize the penetration power and to minimize multiple scatter which will occur with the large sample path length in the windows and the sample (151–154).

RIM is a commonly used process in the production of polyurethane. Since the chemical process can be completed very rapidly it is necessary to use a scaled down RIM machine which can be mounted on a beamline in cases where one wants to follow the structure formation during the chemical reaction forming the polyurethane (Fig. 34). The design of such a setup requires some thought in order to have a bearing on the real industrial process (114). One of the experimental details to take care of is that in a real large-scale manufacturing plant the volume being formed is much larger with consequently different temperature distributions in the reaction chamber compared with a small-scale x-ray machine. This can be compensated by measuring the temperature development in a real plant and then mimicing this profile with programmable sample heaters in the x-ray equipment (155).

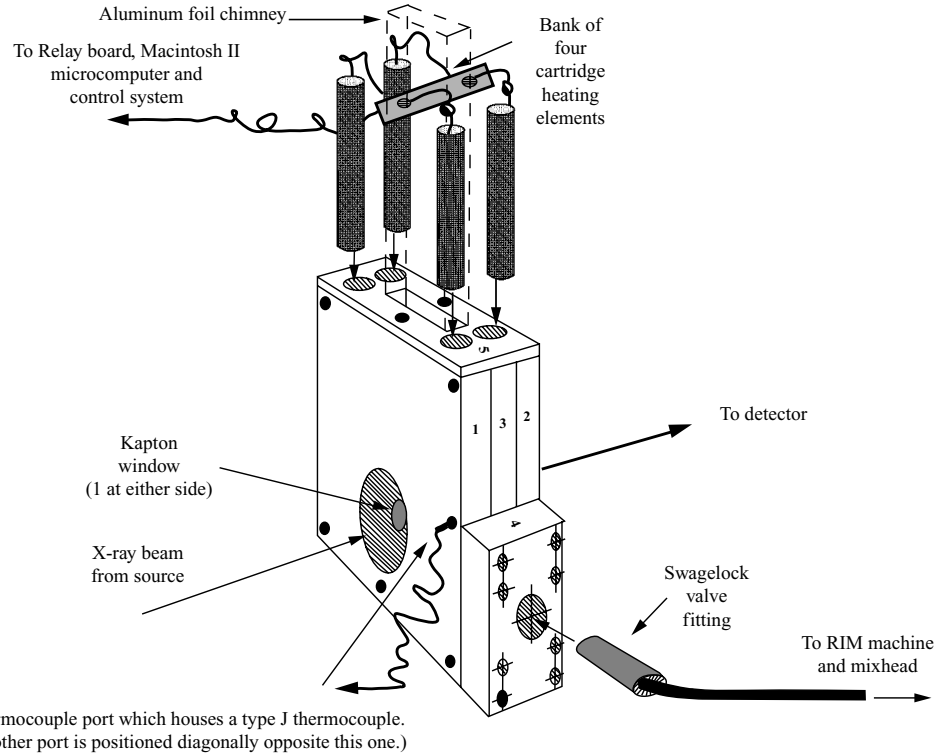

Fig. 34. Sample cell suitable for on-line experiments with a RIM machine. In a real RIM mold the temperature is determined by the thermal conduction in the reaction product and by the dimensions of the real mold. The temperature of this cell can be programmed to follow the temperature profile recorded in real RIM mold in order to obtain realistic results. Courtesy of M. Elwell.

The increasing quality of the x-ray beams that one can nowadays generate with SR beamlines and the increase in experimental infrastructure allows many experiments using processing equipment to be performed. Where some 15 years ago the insertion of a sample heater allowed time/temperature resolved experiments and was thus considered to be a novelty, one can now think of installing previously unthought of equipment, such as thin blown film lines, on SR beamlines.

Influence of Experimental Technique when Determining Simultaneity of Two Events

This section is inspired by the heated debate around the onset of primary crystallization in semicrystalline polymers (30–32,80–85) and the many discussions regarding experimental technique that have taken place because of this debate. Although this example will be used, the underlying idea is that many time-resolved experiments where technique combinations are used are performed to establish the relation between different parameters. This can be the order in which events happen but also differences in the time evolution of the values of parameters. The determination of the simultaneity of two events is typical of combined time-resolved techniques that are becoming more normal in SR experiments. Therefore some details in this specific experiment will be treated in a little more detail as an example of problems that can arise in time-resolved SR experiments. Another experiment where a similar question is addressed can be found in the section where spectroscopic techniques (ftir) in combination with saxs are discussed.

This primary stage of primary crystallization can be characterized either by the conventional nucleation and growth mechanism or by a spinodal decomposition like mechanism while the possibility cannot be excluded that yet another mechanism is involved. In this debate one of the distinguishing features between spinodal-like mechanisms and nucleation and growth is that the rise of the (saxs-dominated) invariant precedes the onset of the increase in the crystallinity as evidenced by the rise in the crystalline peaks in the waxs region.

There are two types of experimental problems that can influence the suitability of an experiment to determine if there is a time lag between the occurrence of two events. The first are the problems that are related to the experimental equipment used, and the second are the intrinsic problems related to the underlying physics of the problem. An example of each of these problems is described below.

An example of how the experimental equipment can influence the outcome of the experiment is in the choice of the appropriate detector system. More specific detector details have been discussed in the instrumentation section. When one is dealing with the onset of an effect one is generally dealing with a small effect on a large background. This means that one has to be very careful with the effects that a detector noise can have. In Figure 35 details of the isothermal crystallization experiment on iPP, described in an earlier section, are given. The two lower curves (open symbols) show the invariant and the degree of crystallinity obtained with low noise detectors. The time lag between the initial rise of the two curves is clear. The same data to which some background noise, not unlike the noise that will be introduced by an integrating detector or the statistical noise because of the

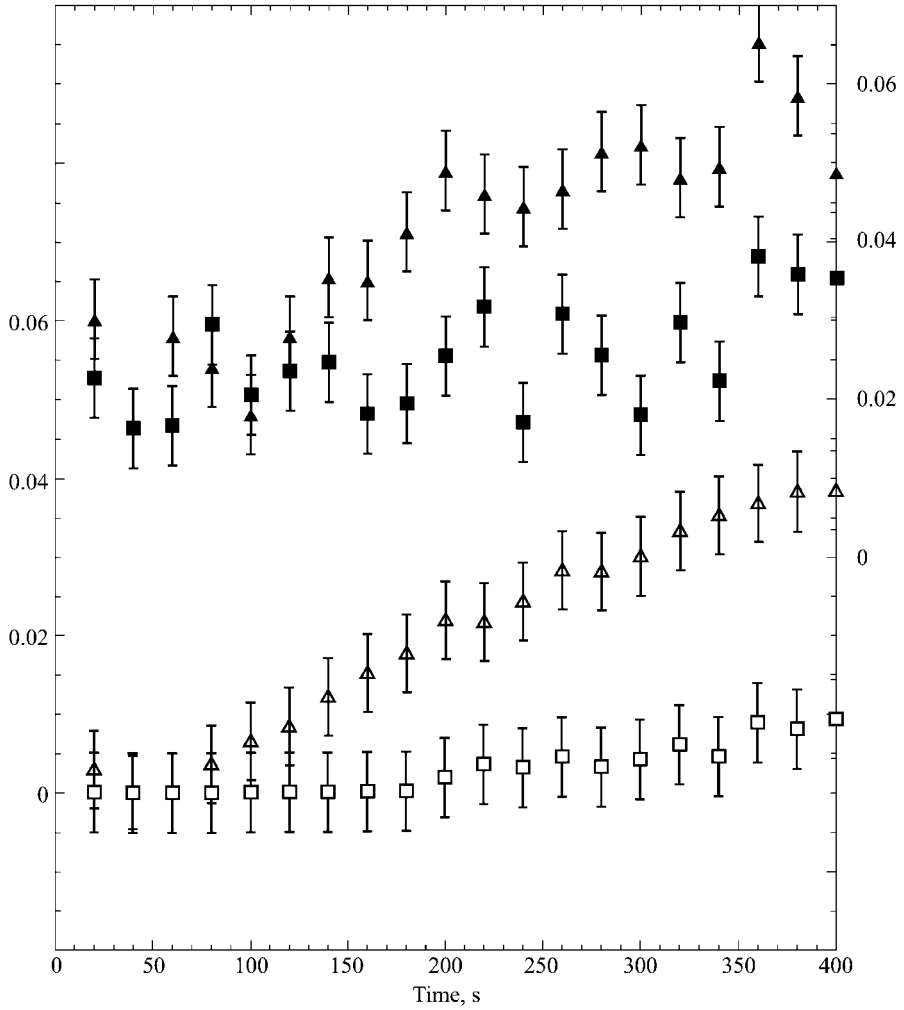

Fig. 35. Noise simulation on data intended to be used for the determination of which signal occurs first. This is a situation which is often encountered in time-resolved studies using technique combinations. The data represents the same event but with different levels of noise added. It is clear that the lower noise data is better suited fot this purpose. However, a higher noise level only invokes a larger experimental error in the determination of the point where the signals start to increase, but not a systematic tendency.

use of a low count rate detector, is added is shown by filled symbols. From these two curves it will be very difficult to assess if there indeed is a time lag.

A problem associated with the underlying physics is in the determination of the intensity of a crystalline peak in the waxs region. It is well known that below a certain threshold the size of a crystallite can influence the width of a diffraction peak (156). The broadening of a peak due to limited crystal size is given by

$$B = \frac{0.9\lambda}{t\cos\theta}$$

where B is the line broadening (in radians), λ the x-ray wavelength used, θ the scattering angle, and t the diameter of the crystalline particle. (t and λ should be in the same units.) In Figure 36, the relation of particle diameter with respect to line broadening at a fixed angle of $\theta = 20^\circ$ is given. For the type of experiments discussed here the use of a position-sensitive detector is indispensable. The best detectors of this type (157) have a spatial resolution that is roughly 0.1°. SR permits the elimination or reduction of most other causes of line broadening in diffraction so that the broadening due to the finite crystal size becomes the dominant factor. From Figure 36 it can now be deduced that for crystallites below a diameter of 80 nm the line broadening becomes measurable. Attempts to measure this effect can be found in the literature (112). The result of this is that the diffracted intensity, which is already small at the initial stages of crystallization, is smeared out over several detector channels at the onset of crystallization. The normal experimental background remains constant so that the signal-to-noise ratio becomes less favorable. Again it will be clear that any effect that the detector system might have on the signal-to-noise ratio should be eliminated as much as possible. It can be noted that crystallite size is not the only parameter affecting the width and

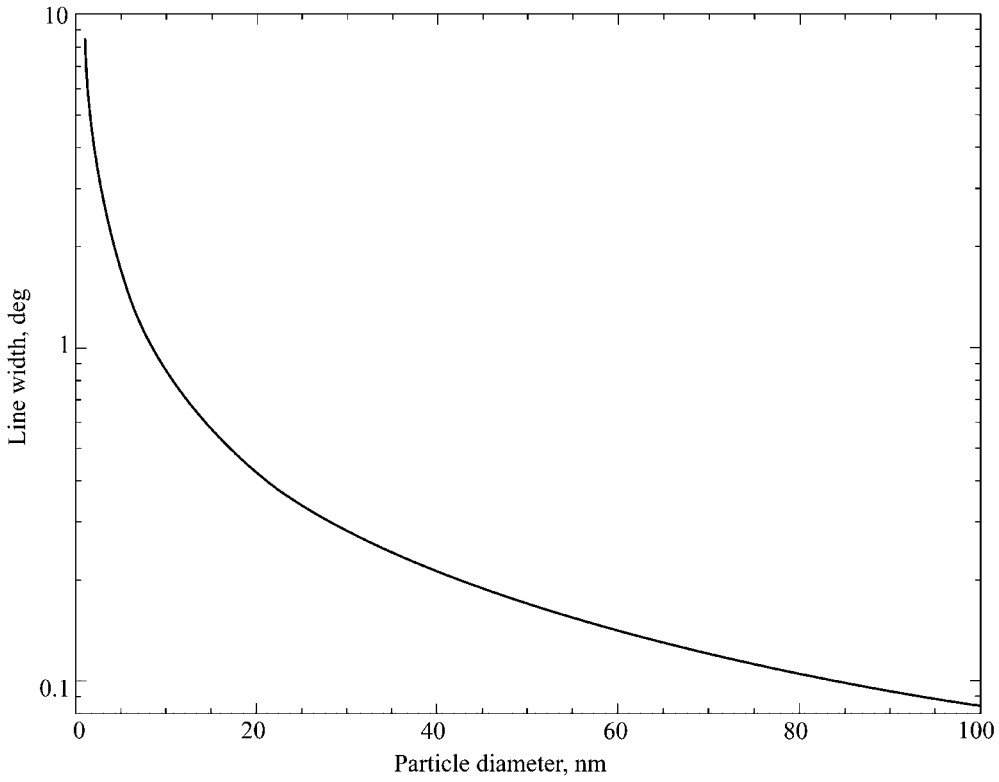

Fig. 36. The broadening of a diffraction line as a function of the particle size. This broadening is only relevant when one utilizes a detector and a sample–detector distance in which this is measurable. For most position-sensitive detectors this is not the case and the broadening is most of the times only measurable with a step-scanning diffractometer.

intensity of crystalline reflections. For a more detailed treatment one is referred to References 55,158, and 159.

The determination of the point where a curve changes slope is intrinsic to the problem sketched above. In the literature it is sometimes argued that a higher noise level could exert a systematic influence on the determination of such a point (32). Intuitively and visually one finds this correct. However, a closer inspection reveals some counterintuitive facts. Consider the case that a linear horizontal curve at a certain point in time starts to increase linearly with time. Now determine the exact moment in time where this occurs.

The horizontal part can be represented by

$$f(t) = c$$

and the other part by

$$g(t) = c + at$$

For the intercept

$$f(t) = g(t) \Rightarrow t = 0$$

If now a background or noise level Δc is added, it reads like

$$\begin{aligned} f(t) &= c \pm \Delta c_{\mathrm{f}}; \quad g(t) = c + at \pm \Delta c_{\mathrm{g}}; \\ f(t) &= g(t); \quad c \pm \Delta c_{\mathrm{f}} = c + at \pm \Delta c_{\mathrm{g}}; \\ \Rightarrow t &= \frac{\sqrt{2}}{a} \end{aligned}$$

Assuming the noise levels in both curves to be the same at the moment when the increase in intensity starts, apply conventional error analysis to this and estimate that the expected error margin is $\sqrt{2}$ times a single error margin. So variations in the position of the intercept are only due to the higher noise levels, which influence the accuracy of the linear fits and thus the position of the intercept. This ultimately leads to a larger error margin but not to a systematic tendency. This is easily verified by numerical simulations.

Summary

The advent of the third generation of SR sources has created many new options. To conclude this article two examples of highly sophisticated experiments, impossible to perform on earlier generations of SR sources, are discussed.

The first example refers back to the on-line melt-spinning experiments mentioned in an earlier section. These experiments are difficult to perform but the problems associated with this have been solved by different research groups. However, long before manufacturers were capable of spinning fibers, nature had developed several organisms which perform this feat. A spider is capable of routinely

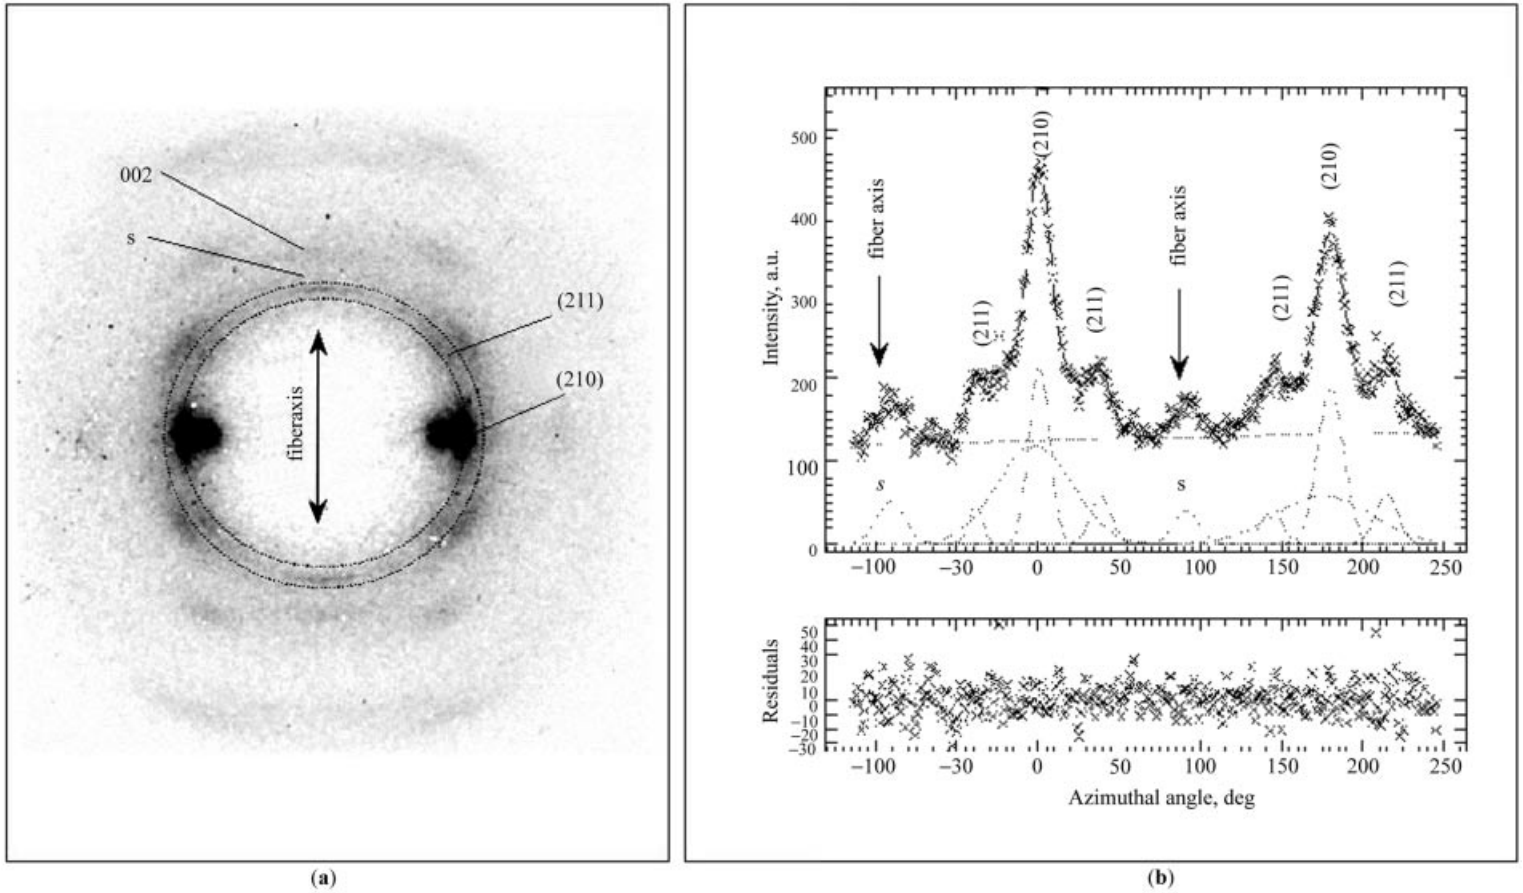

Fig. 37. Fiber diffraction pattern of spider silk obtained in real time by forced silking while the spider was placed close to the x-ray beam (panel A). The fiber is approximately 3.7 μm in diameter. The spot size of the x-ray beam is 7 μm. In panel B the diffraction intensity on the ring indicated in panel A is shown. The intensity can be fitted to Gaussian functions (160). Courtesy of C. Riekel.

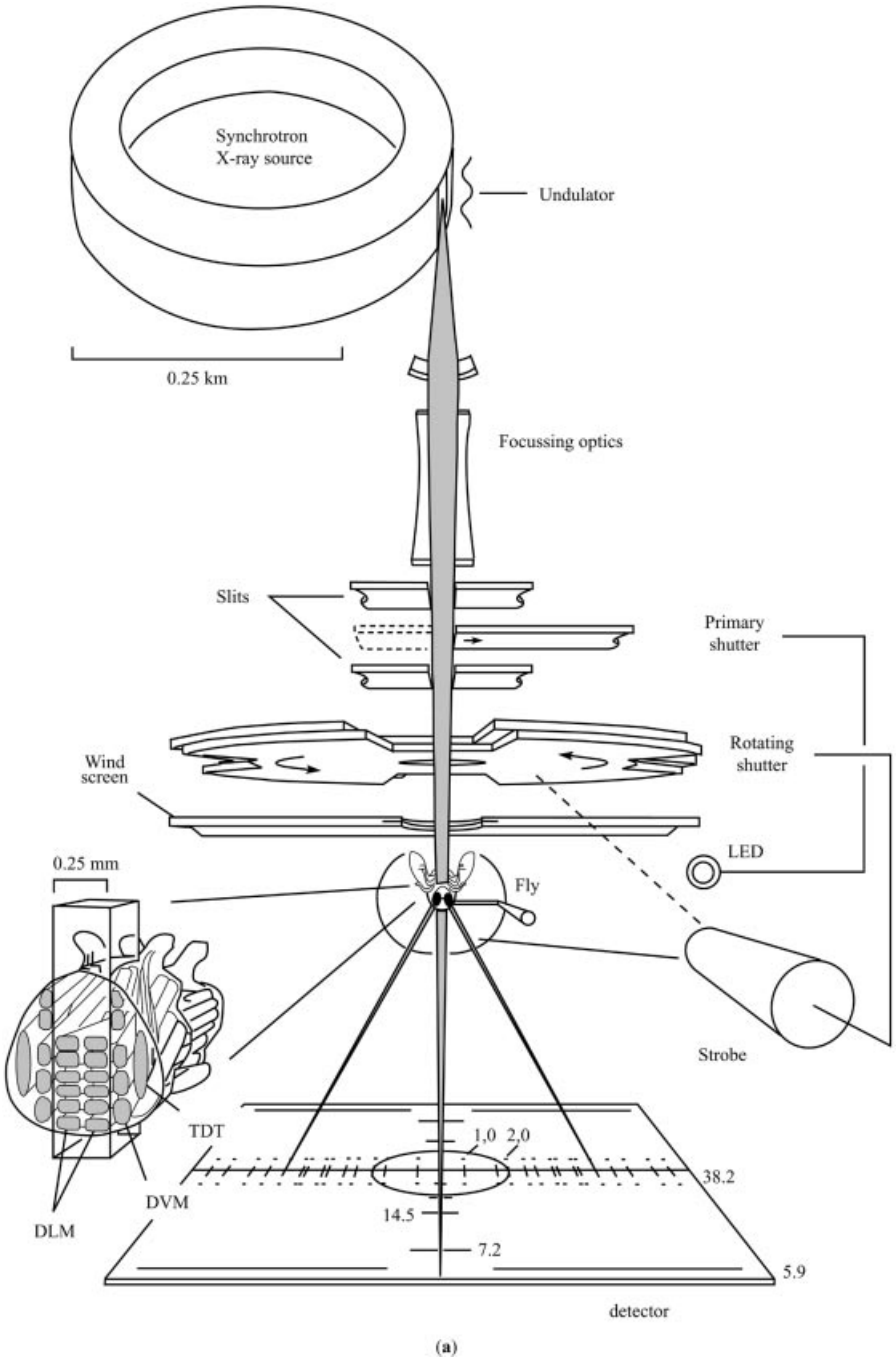

Fig. 38. Panel A shows the experimental layout for an experiment in which the changes in the diffraction pattern of the flight muscle of a fruitfly was studied in real time with a live fruitfly. The beat of the wings was synchronized with a fast shutter using a stroboscope. In panel B the difference pattern between the resting and active fruitfly muscle is shown (162). Courtesy of T. Irving.

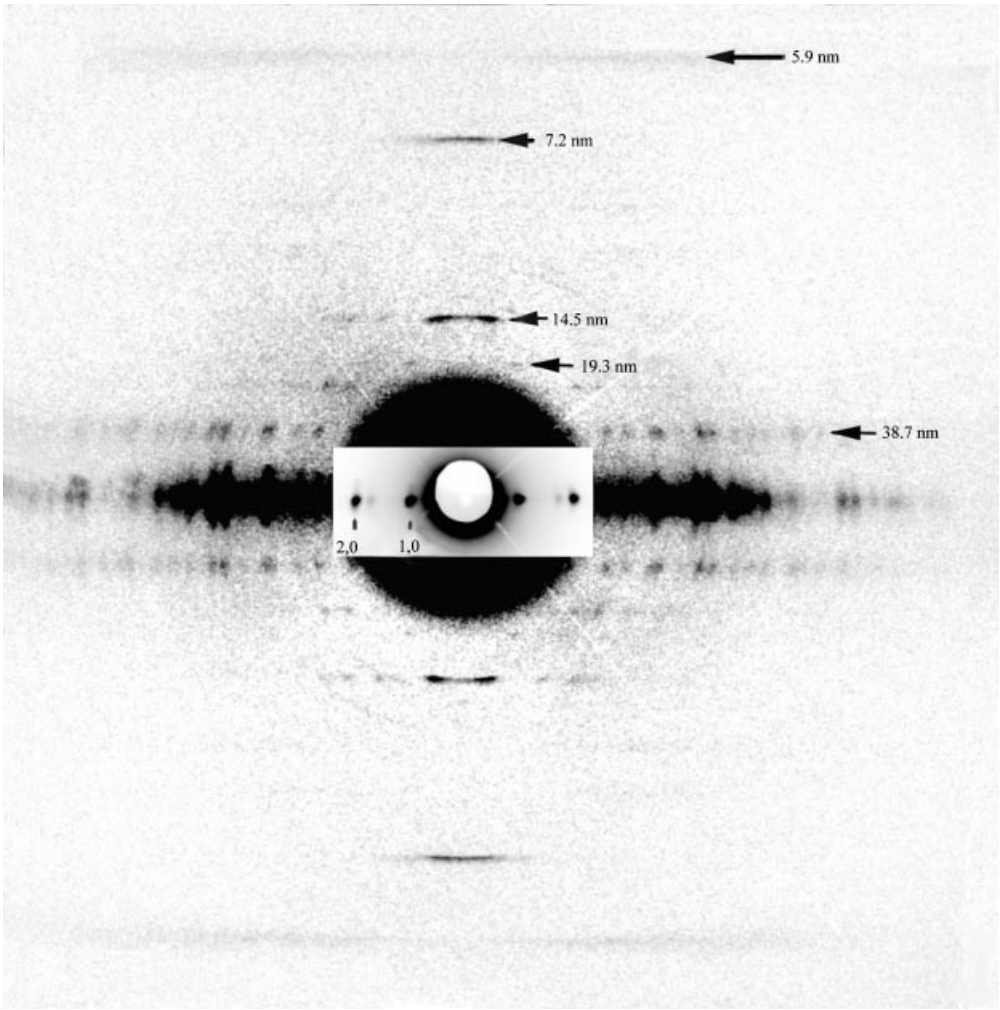

Fig. 38. (Continued).

spinning ultrastrong fibers with a diameter of around 10 μm. In a stunning experiment a spider was persuaded to play the role of extruder on a microfocus beamline (160). As such, it was possible to study the crystallization of natural silk (Fig. 37).

The second example is an echo of the earliest ground breaking time-resolved saxs experiments, performed in Hamburg, on muscles. The experience obtained with diffraction experiments on frog muscle fibers was gratefully absorbed by the polymer community. These experiments were later refined to the level that one could perform experiments on single frog muscle fibers (161). However, this is still a far cry from what has become feasible recently. In an experiment with a microfocus beamline it was possible to observe the changes in the diffraction pattern in the wing muscles of a live fruitfly. By carefully synchronizing the wing beat of the fly with the detector time frames one could observe the changes in the muscle diffraction pattern between the up and down stroke (162) (Fig. 38).

The ingenuity not only in the construction of the beamlines but also in the performing of these two experiments deserves to be applauded. The resilience of nature also can be applauded since both animals survived the experiment without apparent problems.

These two examples serve to remind the reader that it is possible to perform completely new experiments by using third generation SR sources and that one should see the beamlines there not only as a more powerful extension of the home laboratory but also as completely new tools suitable for experiments that so far were unthinkable.

TEST METHODS

Introduction

Plastics testing encompasses the entire range of polymeric material characterizations, from structure to material response to environmental effects. Whether the analysis or property testing is for quality control of an industrial plastic or for the determination of the relaxation response of a material to an imposed stress, a variety of test techniques is available for the researcher (see CHARACTERIZATION OF POLYMERS).

Polymer analysis continues to progress with improvements in instrumental techniques and computer-enhanced data analysis methods that allow detection of effects of side-chain rotations or localized variation in free volume of a polymer film. Combinations of instrumental analysis techniques such as pyrolysis–gas chromatography (pyrolysis–GC) or liquid chromatography–mass spectroscopy (LC–MS), used for separation and identification of polymer components and degradation products from complex systems have been further enhanced with the addition of thermal techniques that allow targeting narrow temperature ranges or microscopy techniques targeting localized areas of a sample for analysis. (See MASS SPECTROMETRY; CHROMATOGRAPHY, HPLC; CHROMATOGRAPHY, SIZE EXCLUSION.) Atomic Force Microscopy (AFM) allows determination of polymer morphology (qv) at the nano level (see ATOMIC FORCE MICROSCOPY). The use of microprocessors to capture transient signals from physical test methods, ie high speed impact, allows the observation of the complete impact event, while improvements in fracture mechanics techniques lead to increased understanding of material response to stress independent of geometry effects.

Composition and Structure

Fourier transform infrared (FTIR) is one of the most commonly used analysis methods for determining the composition of polymers (see VIBRATIONAL SPECTROSCOPY). Other routine applications are in fingerprinting contaminants, characterizing chemical property gradients, or mapping physical property anisotropy (1). The FTIR technique, which corresponds to the vibrational energies of atoms or specific groups of atoms within a molecule as well as rotational energies, identifies components by comparing the spectrum of a sample to reference spectra. The infrared spectral region is commonly from 2 to 50 μm, and the region of 7–15 μm is capable of differentiating similar isomers (2). The 7–8.5-μm region has been used in model hydrocarbon studies to show that the absorption of methylene groups is dependent on the size of the methylene sequences in compounds (3). FTIR has been used to study structural modifications of polypropylene during aging (4), determine crystalline forms of syndiotatic polystyrene through spectral subtraction methods (5), simultaneously monitor polymerization and microphase separation in a polyurethane system through identification of reaction products formed (6), and to quantitate grafting levels of succinic anhydride onto polypropylene (7).

Some examples of composition determinations using IR analysis of polymers are as follows. The N stretching mode has been used for quantitative analysis of acrylonitrile in butadiene–acrylonitrile copolymers (8). [Residual catalyst support in commercial polyethylene can be detected at levels as low as 100 ppm (9).] The short-chain branching distribution of an ethylene 1-olefin copolymer across the molecular weight distribution was determined using a combination of size exclusion chromatography (SEC) with FTIR (10). There are several excellent sources of spectra both in print and on computer disk for comparing and matching the fingerprints obtained from a sample (11,12).

Tracking of trans conformers in sub-T_g annealed amorphous poly(ethylene terephthalate) (PET) films by FTIR indicated that closer interchain packing and formation of new cohesional entanglements along the chains occur that are not apparent in quenched or slowly cooled material (13). Step-scan FTIR photoacoustic analysis was used in determining surface stratification of components within a thermoplastic olefin. The IR bands were used as analytical depth-profiling probes to establish the orgin of photoacoustic (PA) signals (14). FTIR monitoring of the stress relaxation of polyurethanes led to the determination that differences in phase separation was related to the structure of the polymer (15). The combination of FTIR with *in situ* WAXS (wide-angle X-ray spectroscopy (qv)) measurements during the drawing and annealing of PET film allowed the study of the development of molecular orientation and crystallization (16). Specular reflectance FTIR–microscopy has been used in studies of several polymers: liquid crystalline polymers, sidechain (LCP) (17,18), polyurethanes (19), carbon-filled polymers (20,21), and poly(aryl ether ether ketone) (PEEK) (1). Progress has been made in the development of on-line IR equipment for monitoring the extrusion of polymers using the near-IR range rather than mid-IR with resultant lower sensitivity to molecular fragments (22). Some work has been done on calibration of these systems against dynamic rheological standards (23). Real-time quantitative

monitoring of the level of filler in extruded polymers has been reported using near-IR spectroscopy (24).

Combination techniques such as microscopy–FTIR and pyrolysis–IR have helped solve some particularly difficult separations and complex identifications. Microscopy–FTIR has been used to determine the composition of copolymer fibers (25); polyacrylonitrile, methyl acrylate, and a dye-receptive organic sulfonate trimer have been identified in acrylic fiber. Both normal and grazing angle modes can be used to identify components (2–7). Pyrolysis–IR has been used to study polymer decomposition (27).

Raman spectroscopy is an emission phenomenon as opposed to IR absorption, and results from vibrations caused by changes in polarizability (see VIBRATIONAL SPECTROSCOPY). Raman spectroscopy had limited use until the advent of lasers as the exciting source. It can be complementary to IR and may be more useful when the sample for analysis is a filled polymer or composite containing silica, clay, other similar inorganic filler, or a piece of polymer, but particularly thermosets or rubbery products requiring no further sample preparation. Additional advantages over IR are the intensity advantage for the C=C band and the determination of thiol groups in sulfur polymers (28). Fluorescence is a significant interference in Raman spectroscopy because it occurs simultaneously in several commercial plastic products. Fourier transform of Raman spectroscopy and other techniques for reducing fluoresence (29,30) have expanded its applicability. FT-Raman spectroscopy has been used as an alternative technique to thermal gravimetric analysis (TGA) of filler content up to 75 wt% of the polymer (1). It has also been used to determine the isotacticity of polypropylene giving good correlation to FTIR and ^{13}C NMR data (31).

Studies of blends using Raman imaging and Raman microscopy have been used to determine miscibility and phase behavior of blends (32) and morphology in blends of linear and branched polyethylene (33). On-line Raman was used to monitor copolymerization of styrene and *n*-butyl acrylate by monitoring monomer concentrations (34). Raman longitude acoustical mode (LAM) was used to study stress-induced states of a blend of polyethylenes in a microfilm. Structure appeared to be the formation of straight tie molecules localized in neighboring crystals with amorphous layers between the crystals. Presence of all-trans sequences with length exceeding the mean crystallite size appeared to be due to stress-induced gauche to trans formations in the amorphous phase (35).

Nuclear magnetic resonance (NMR) requires an atomic nucleus that can absorb a radio-frequency signal impinging it in a strong magnetic field to give a spectrum. The field strength at which the nucleus absorbs is a function of both the nucleus and its immediate electronic environment. The atoms normally used for NMR analysis are as follows (36): ^{1}H, ^{19}F, ^{31}P, ^{11}B, ^{14}N, ^{29}Si, ^{13}C, ^{2}H, ^{17}O, ^{33}S, and ^{15}N. Of these, the most commonly used in polymer analyses are ^{1}H and ^{13}C. Solid-state ^{13}C NMR utilizing proton spin-lattice relaxation time in the rotating frame has been used for determination of composition, phase, and compatibility (misciblity) of blends (37–40). In combination with SEC, ^{13}C NMR is capable of quantitating both long- and short-chain branching in polymers (41). The technique has also been used for characterizing molecular structure differences in reject ethylene vinyl alcohol polymer that correlated to changes in thermal and mechanical properties (42). A combination of ^{13}C NMR and deuterium NMR were

used to determine the effects of low molecular weight additives on secondary relaxation processes in PET. The additives were found to reduce the number of phenyl ring flips that were shown by the deuterium NMR to closely relate to the relaxation peak observed by dynamic mechanical thermal analysis (43). Fourier transform has also been applied to NMR, allowing increased sensitivity on microsamples. Spectra can be obtained on as little as 10 μg (44). NMR techniques were used to study the reactions and catalytic activity of different agents for transesterification reactions between polymers (45). Two-dimensional time-domain proton NMR identified and characterized relaxation components over a temperature range. Phase transitions and different phases were observed (46). Similar analysis of high density polyethylene (HDPE) showed three phases, which have been tentatively identified as a crystalline region, an area of chain loops on the surface of crystallites and entangled chain segments, and the third phase of chains in the amorphous phase (47). Molecular chain dynamics, chain orientation, and molecular packing differences were determined in HDPE and isotactic polypropylene (48). Microphase separation in polyureas that were prepared by RIM (reaction injection molding) techniques were determined with solid-state NMR (49).

An additional technique that has been found useful in analysis of the composition of polymers and blends is liquid chromatography. Pasch and Rode used the critical point of adsorption of the least polar component of a blend to determine the liquid chromatographic conditions for separating blends of polymethacrylates into components (50). High pressure liquid chromatography (HPLC) in combination with mass spectroscopy was used to analyze the components of an epoxy resin (51). HPLC has also been used with a precipitation–redissolution technique to separate polymer molecular weights for several polymers as a shorter technique compared to SEC (52). Reverse-phase liquid chromatography with UV detection was useful in qualitative determination of brominated flame retardants in polymeric waste materials (53).

Pyrolysis techniques for thermally degrading polymers have high sensitivity, allow trace analysis of all organics in liquid or solid state, require minimal sample preparation and small amounts of sample, and allow simultaneous identification and quantification in one run. However, they may have limited reproducibility and limited applicability where inorganic fillers are present (54). There have been various types of pre- and post-pyrolysis derivations done to simplify analysis by GC separation and reduce interferences from surrounding materials (55).

Many studies have been published on the use of pyrolysis–GC: Determination of the primary degradation products of polyacrylonitrile (56), number-average molecular mass using end-group analysis (57), kinetic measurements of the thermal degradation of polymers using sequential pyrolysis (58), determination of stereospecific sequencing in polypropylene (59), composition and microstructure of styrene maleic anhydride (SMA) copolymers (60) are examples in addition to frequent use in determination of additives. Combinations of pyrolysis–GC with FTIR techniques have been used in the characterization of branching in comb-like polymers (61) and analysis of butadiene–acrylonitrile copolymers (62). Additional examples of use of pyrolysis–GC for polymer systems can be found in Wampler's (63) and Bart's (54) reviews.

Additives to polymers are important components affecting the polymer's performance in processing, aging, and maintaining properties under adverse

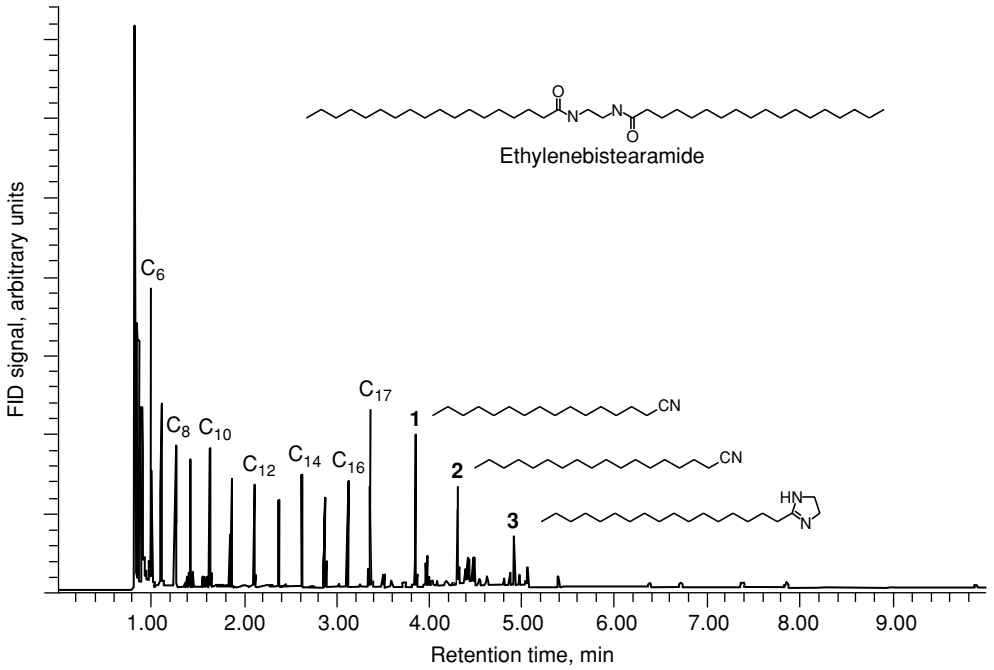

Fig. 1. The pyrogram of *N*,*N*′-ethylenebistearamide. The identification of peaks labeled in the pyrogram is 1 – hexadecanenitrile, 2 – octadecanenitrile, 3 – 1*H*-2-heptadecyl-4,5-dihydroimidazole. Reprinted from Ref. 67, Copyright (2000), with permission from Elsevier Science.

environmental conditions. In some cases it is possible to determine these in solid or molten polymer, but generally they must be separated from the polymer prior to analysis. Typical methods that have been used for obtaining a sample for additives analysis include solvent extracting, dissolving the polymer matrix, hydrolyzing the material, or thermally destroying the matrix. Samples are then analyzed using gas or liquid chromatography techniques alone or in combination with mass spectroscopy to identify specific components. pyrolysis–GC has been shown to be particularly useful for analysis of flame retardants (64,65), plasticizers (66), lubricants (67), antioxidants (68), and other stabilizers (69,70) in many polymer matrices. Figure 1 gives a pyrogram of a common lubricant, ethylenebistearamide.

Various techniques for extracting and analyzing low molecular weight components of polymers include static and dynamic heat extractions, headspace analysis, and thermochromatography (71). These are used primarily where solventless systems are required for analysis (72,73). Gas-phase mirage-effect spectroscopy has been used for measuring trace gases and organic volatiles up to parts per billion (ppb) levels during nondestructive characterization and photodecomposition studies (74). Packed column supercritical fluid chromatography (pSFC) with atmospheric pressure chemical ionization detection has been shown to detect and quantitate a variety of additives, including antioxidants, light stabilizers, and slip agents (75).

New technologies in the area of microscopy, such as atomic force microscopy (AFM) and electron spin resonance (ESR), have allowed the study of morphology of polymers and blends of polymers to extend to localized areas at interfaces of phases in semicrystalline polymers. Other techniques such as wide-angle and small-angle X-ray scattering (WAXS, SAXS), small-angle neutron scattering (SANS), small-angle light scattering (SALS), scanning and transmission electron microscopy (SEM, TEM) have been used for structure studies as well. WAXS has been used for examining the crystalline regions of semicrystalline polymers and composites (76–78). SAXS was used with linear correlation functions to determine the overall crystallinity and fraction of semicrystalline stacks during crystallization and melting of linear polyethylene (79) while crystallite size distributions were calculated from WAXS profiles in a similar polymer (80). By monitoring the surface structure of a PEEK composite, skin effects were observed using reflectance WAXS (81). SAXS allows the determination of morphology via domains and microstructure by varying electron density in different areas of a material or density differences between amorphous and crystalline phases (82,83). This has been shown to be useful in determining the phase behavior of blends of poly(vinyl methyl ether) with styrene–butadiene–styrene copolymers (84). Correlation of thermal and structural properties of a blend of polyamide with liquid crystal polymer over a range of compositions and thermal treatments (85) and determination of an ordered crystalline/amorphous lamellar structure in a blend of poly(ethylene oxide) and poly(vinyl acetate) (86) have used SAXS. This technique has also been used qualitatively in determining domains and component mixing with interpenetrating polymer networks (87). Other X-ray techniques were used to show the solid-state structures of aromatic copolyesters (88) and measure crystalline form transition under stress with poly(butylene terephthalate) (89).

Structure determinations in polymers have involved the use of SANS techniques to evaluate not only the radius of polymer molecule gyration where light or X-ray scattering is not usable, but also phase dimensions in multicomponent polymers and suggested mechanisms of phase separation (90). Applications in polymer melts as well as concentrated and dilute solutions of polymers and solid-state samples have investigated the nature of semicrystalline polymers, polymer blends, and the development of new theories of polymer solutions and networks (91). Another technique finding use in structure analysis is dielectric spectroscopy. A combination of X-ray scattering and dielectric spectroscopy has been used to study the noncrystalline regions of semicrystalline polymers; this technique uses semicrystalline and amorphous polymer blends in which the amorphous polymer, although miscible in amorphous regions, is excluded from the crystal–amorphous interphase region (92). SALS techniques have been able to distinguish between nucleation and growth and spinodal decomposition in phase separation mechanisms (93). SEM has been used to determine the location of compatibilizers at the interface of blends of thermoplastic urethanes and polypropylene (94).

AFM is used at the nanoscale to analyze structure of polymers. It has been used to determine spatial distribution of impact modifier in high impact polypropylene (95), follow pit growth in a film of a blend as a function of exposure time during degradation studies of coatings on metal (96), determine surface topography and molecular organization of liquid crystalline polymers (97), and observe

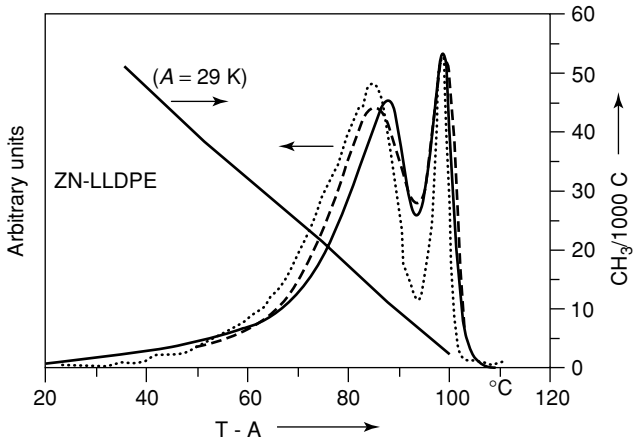

Fig. 2. Comparison of the short-chain branching distribution of ZN-LLDPE as obtained by TREE, CRYSTAF, and DSC. A calibration curve for the DSC data is plotted on the right axis. Reprinted from Ref. 101, Copyright (2000), with permission from Elsevier Science.

nanoparticles in polypropylene matrix (98). In combination with other techniques it allows the determination of composition versus depth of nano silica particles in a surface film, including the location of sub-surface nano silica particles (99). AFM in conjunction with SEM was used to study the influence of aging on morphology of polypyrrole films (100). The use of a vibrating, heating stage for mounting samples and observing the effects on the AFM cantilever allows the study of local elastic and viscoelastic properties (101). Figure 2 shows both topography and simultaneously acquired amplitude images with this technique. Scanning force microscopy of isotatic polypropylene under a moderate applied shear stress was used to study plasticity and damage mechanisms (102).

ESR techniques use nitroxyl radicals either dispersed in polymer matrix (spin probe) or covalently bonded to polymer chain (spin label) which are sensitive to the environment allowing molecular motion and microstructure of polymers to be identified from spectra (103). Quantitative methods of heterogeneous ESR spectra are divided into (*1*) outer hyperfine etrema, (*2*) signal intensities related to the relative concentration of the probe in different phases, and (*3*) simulation of the spectra. The presence of two well-separated outer maxima above the glass-transition temperature could be ascribed to two phases in natural rubber (104), miscible blends (105), immiscible blends (106), cross-linked polymers (107), and polyurethanes (108). ESR has used the measurement of the oxidation product to monitor the consumption of stabilizer in polypropylene (109).

Molecular Weight

The molecular weight and the distribution of multiple molecular weights normally found within a commercial polymer influence both the processibility of the material and its mechanical properties. For a few well-defined homopolymers,

an analysis of composition and molecular weight is sufficient to define the likely mechanical properties of the polymer.

Low-angle laser light scattering (turbidity) has been found to be the most accurate and reproducible technique for measuring polymer molecular weights (average molecular weight) as a primary method (110) (see MOLECULAR WEIGHT DETERMINATION). Most turbidimetric techniques use polymer solubility as a function of temperature for defining molecular weights (111). Dynamic light scattering has been used to obtain the distribution of hydrodynamic radius, which can be converted to molecular weight distribution with appropriate calibration. This technique can be performed in corrosive solvents or with polymers that dissolve only at high temperatures (112). Gel-permeation chromatography (GPC), although a secondary technique requiring careful calibration and interpretation of data, is the most frequently used commercial technique because of its ease of use, low cost, short time for analysis, and generation of excellent comparative data (113). Shifting of the polymer molecular weight peak or displacement in comparison to a standard or good material can indicate the presence of a higher molecular weight species by showing a shift to early elution, or a lower molecular weight species by showing a shift to later elution. These shifts can affect the processibility and physical performance of the material. Small sharp peaks that elute late from the GPC column may indicate the presence of low molecular weight oligomers, residual monomers, additives, or even residual moisture in the polymer.

A wide variety of polymers have been analyzed by gel-permeation or chromatography, size exclusion (SEC) to determine molecular weight distribution of the polymer and additives (114–117). Improvements in GPC include smaller crosslinked polystyrene beads having narrow particle size distributions, which allow higher column efficiency and new families of porous hydrophilic gels to be used for aqueous GPC (118). SEC in combination with FTIR has been used to monitor component content and compositional effects with changes in molar mass of HDPE and polypropylene (119). SEC fractionation followed by NMR and multiangle light scattering detector (MALDI) of random copolymers of acrylates with styrene maleic anhydride allowed determination of a model for composition and the ratio between number-average molecular weight (M_n) and weight-average molecular weight (M_w) of the SEC fraction (120). The combination of SEC with MALDI was also used to characterize branched polystyrene and poly(benzyl methacrylate) (121,122).

Temperature-rising elution fractionation (TREF) is a technique for obtaining fractions based on crystallizability independent of molecular weight effects (123,124) which allows qualitative analysis of short-chain branching in olefins. Determination of crystallizable lengths from TREF spectra led to the development of a quantitative method for short-chain branching (125). Single-step crystallization fractionation (CRYSTAF) has been developed for measuring composition or short-chain branching distribution by monitoring on-line polymer concentration in solution at decreasing temperatures (124). TREF, CRYSTAF, and differential scanning calorimetery (DSC) with specialized sample preparation were used to determine short-chain branching distribution and composition of blends of linear low density polyethylene (LLDPE). All three methods showed similar comonomer distribution (125) (see Fig. 3). Characterization of HDPE chain structure with SEC

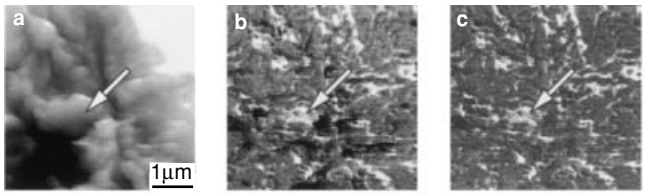

Fig. 3. (**a**) Topography, (**b**) amplitude (∼elasticity), and (**c**) phase (∼viscoelasticity) simultaneously acquired images of PES/SAN. The scale bar applies to all three images. Reprinted from Ref. 125, Copyright (2001), with permission from Elsevier Science.

and CRYSTAF methods was able to be correlated to environmental stress-crack resistance (126).

Thermal Properties

Thermal analysis involves techniques in which a physical property of a material is measured against temperature at the same time the material is exposed to a controlled temperature program. A wide range of thermal analysis techniques have been developed since the commercial development of automated thermal equipment as listed in Table 1. Of these the best known and most often used for polymers are thermogravimetry (TG), differential thermal analysis (DTA), differential scanning calorimetry (DSC), and dynamic mechanical analysis (DMA).

Thermogravimetric analysis (TGA), which monitors the change in the mass of a material during a controlled temperature ramp, is useful for both qualitative and quantitative analysis. It is used to help identify the types of polymers by comparison to degradation curves or when used with FTIR or pyrolysis–GC-MS (128–132), as well as identify and quantify additives such as carbon fillers, mineral fillers, plasticizers, antioxidants, stabilizers, UV absorbers, nucleating agents, and lubricants (133,134). Carbon black or graphite, which is commonly used as a colorant or filler in many plastics, may be analyzed using TGA by running the analysis in a nitrogen atmosphere to 600°C for measurement of the polymer component and then switching to an oxygen atmosphere and heating to 800 or 900°C to oxidize the carbon (133). The derivative curve of TGA can be used to improve the determinations of onset and end point of decomposition of low level components or in multipolymer systems (135). Refinements in computer control and instrument design have also led to commercial instruments having smooth changes in dynamic heating rate that varies as a function of weight loss, a low mass furnace for rapid response, and horizontal purge gas flow to better remove decomposition products, among other changes (136).

Differential thermal analysis (DTA) monitors the temperature difference between a specimen and a reference material, whereas differential scanning calorimetry (DSC) heats specimen and reference materials separately and measures the heat flow between the materials. DSC is the method of choice for determinations of melting point as well as the presence and level of crystalline phase

Table 1. A Survey of Common Thermal Analysis Techniques[a,b]

Technique	Abbreviation	Property measured (dependent variable)
Thermogravimety	TG	mass, m
Derivative thermogravimetry	DTG	dm/dt
Differential thermal analysis	DTA	dT/dt
Differential scanning calorimetry	DSC	dH/dt
Thermomechanometry		
Thermomechanical analysis	TMA	L, dL/dT
Thermal dilatometry	TDA	V, dV/dT
Dynamic mechanical analysis (including torsional braid analysis, TBA)	DMA	$G^*(\omega)$
Thermoelectrometry		
Thermally simulated conductivity	TSC	di/dt
Thermally stimulated polarization	TSP	
Thermally stimulated depolorization	TSD	
Dielectric thermal analysis	DETA	$Z^*(\omega)$
Thermophotometry		
Thermoluminescence (including oxyluminescence)	TL	dI/dt
Thermal microscopy	TM	
Emanation thermal analysis	ETA	Radioactive gas evolution
Thermosonimetry	TS	Acoustic emission
Evolved gas analysis	EGA	GC/MS/IR, etc
Thermomagnetometry	TM	Magnetic effect on TG

[a]From Ref. 127.

[b]Combined simultaneous techniques—many of these techniques can be combined to give simultaneous or sequential measurements on the same sample, eg, TG/MS, TG/IR, DSC/XDR, DSC/TG/MS, pyrolysis/GC, Differential photocalorimetry (DPC), etc.

in polymers. The effects of heating rate and oxygen flow rate on oxidative induction time of HDPE (137), applied strain during cooling (138), spherulitic crystal growth and crystalline structures (139,140), and curing of thermosets (141–143) have been studied using DSC techniques.

DSC has been found suitable for the determination of second-order transitions (T_g = glass transition) and, in some cases, β-transitions. Procedures for the determination of T_g are discussed in the literature (135,136), which includes data on the dependence of T_g on number-average molecular weight (M_n for polymers. This shows a significant effect until a critical M_n is reached with little or no effect beyond. A technique employing DSC to measure specific heat of rapidly quenched polyethylene samples, which are subsequently annealed at low temperatures, shows the formation of secondary crystals that melt near the annealing temperature with small endotherms. The endotherms increase and melting points rise as time increases, leading to the potential use of this technique for studying the thermal history of samples (144,145). Additional work on the correlation of enthalpy changes with the aging of samples has been completed on PBT (146). For amorphous polymers, changes in T_g can be used to determine aging that has

occurred below and near T_g. Accuracy is improved by matching the heating rates of DSC to cooling rates on specimen preparation (135,136). The T_g response to aging relates to the continued relaxation of frozen molecular structure that continues over time below T_g and results in changes in free volume (147). Reduction in free volume due to aging can be correlated to reduced impact strength and improved creep response at low strain rates for polymers.

The relative effectiveness of nucleating agents in a polymer can be determined by measuring recrystallization exotherms of samples molded at different temperatures (135). Effects of formulation change on the heat of rubber vulcanization can be determined by DSC; pressurized cells may be needed to reduce volatilization during the cure process (148).

Changes in heat capacity and measurement of T_g for blends have been used to determine components of copolymers and blends (149–152) although dynamic mechanical analysis has been found to give better resolution. Equations relating T_g of miscible blends and ratios of components have been developed from DSC techniques, eg, the Fox equation (eq. 1), where T_{g12} is the T_g of the blend, W_1 or W_2 is the weight fraction of component 1 or 2, and T_{g1} or T_{g2} is the T_g of the pure component 1 or 2 (153); the Gordon–Taylor–Wood (GTW) equation (eq. 2), where k is the best fit constant for empirical data (154); and the Couchman equation (eq. 3), where x_1 and x_2 are mass fractions and ΔC_p is heat capacity changes for neat polymers (155).

$$\frac{-1}{T_{g12}} = \frac{W_1}{T_{g1}} + \frac{W_2}{T_{g2}} \tag{1}$$

$$\mathrm{T_{g12}} = \frac{k(\mathrm{T_{g2}} - \mathrm{T_g})\mathrm{W_2}}{1 - \mathrm{W_2}} + \mathrm{T_{g1}} \tag{2}$$

$$\ln \mathrm{T_{g12}} = \frac{x_1 \Delta C_{p1} \ln \mathrm{T_{g1}} x_2 \Delta C_{p2} \ln \mathrm{T_{g2}}}{x_1 \Delta C_{p1} + x_2 \Delta \mathrm{C_{p2}}} \tag{3}$$

Modulated DSC has been used to evaluate correlations between polymer chain molecular characteristics and crystallization behavior in polyethylene (156). It has also been used in the study of thermal treatments of PET (157) and the kinetics of the T_g (158).

Thermomechanical analysis (TMA) measures the dimensional changes of a fabricated polymer part at a constant heating rate. First-order (T_m) and second-order (T_g) transitions may be measured from graphing length of specimen (L) versus temperature (T). This technique may also be used to determine the coefficient of linear thermal expansion (CLTE) for a material. TMA can be more sensitive to small changes in enthalpy typical of highly crystalline polymers than DSC (159). This technique has also been used for evaluating dimensional changes of polymers in fluid environments. Studies have been completed on water–nylon 6 at different temperatures (160), chlorobenzene–polyethylene (161), and elastomers in various fluid and oils.

DMA involves exciting a material with a periodic stress and monitoring the resultant strain for viscoelastic properties of the material with respect to temperature, humidity, vibration frequency, dynamic or static strain amplitude, or other parameter against time (162). The two primary uses are for determination of morphology including glass transitions and melts and checking polymer behavior at conditions simulating end use while maintaining temperature equilibrium. This method detects α- (first-order or glass) transitions, β- (side-chain motions) transitions, and γ- (crankshaft rotation of main-chain segments or single bond flips) transitions, and has about a 1000$\times$ greater sensitivity to DSC and about 100$\times$ greater sensitivity to modulated DSC for amorphous polymers. In this procedure, a specimen is placed under a fixed or free oscillatory stress and the strain with which the specimen responds is recorded. Polymers are typically viscoelastic in nature, and have a dynamic response to the oscillatory stress controlled by the viscous component, which results in a strain that continues to increase until the stress is removed, but is not recoverable. The other component is the elastic response, which reacts instantaneously to the applied stress and is completely recovered when the stress is removed. Polymers respond with elements of each, resulting in a strain with the same frequency as the applied stress, but out of phase by an amount, δ, dependent on the relative elastic and viscous nature of the material (see Fig. 4) (163). Samples can be tested under different stress configurations, ie, tensile, flexural, compressive, and shear, by using a varying resonance frequency under a constant temperature or constant rate of temperature change. The tangent of δ is known as the loss factor and is the ratio of E'', the loss modulus, over

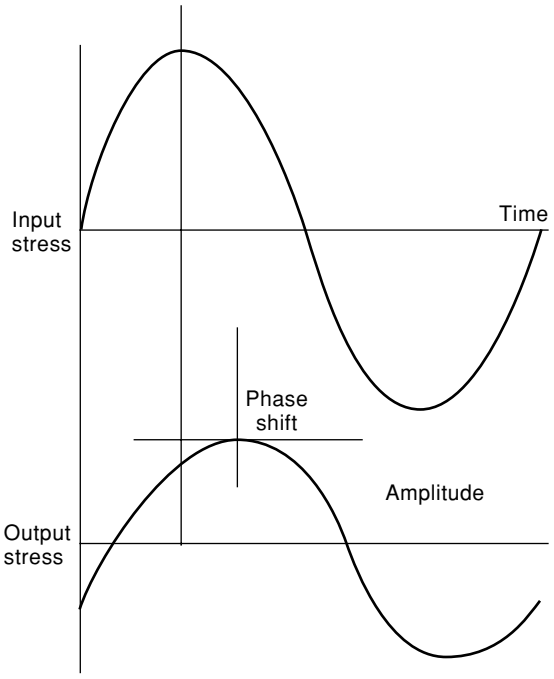

Fig. 4. Applied stress and resultant strain in DMA measurements.

E', the storage modulus; E is used for tensile (extensional deformation) whereas G is used for shear.

Stress levels are kept low within the elastic region of the material. Although solid-state testing is used most frequently, melt-state testing allows the examination of viscosity versus frequency at a set temperature and also shows the response of the shear storage and loss modulus (G' and G'') versus frequency. Solid-state testings of both amorphous and semicrystalline polymers by DMA have shown effects on tan δ values near the T_g for each type of material from differences in orientation by sample preparation method. For amorphous materials, the values of tan δ are higher in the temperature region slightly below the T_g as orientation increases in the sample; the same effect is seen for crystalline materials above the T_g (164). The interrelationship between temperature and frequency as well as time and frequency are well established (165). The equivalence of the effects of temperature and time in viscoelastic systems results in time–temperature superpositioning (166) and is related by the Williams–Landel–Ferry (WLF) equation (eq. 4) for amorphous polymers, where a_T is the shift factor, T is the measurement temperature, T_o is the reference temperature, and c_1 and c_2 are constants (167).

$$\log a_T = \frac{-c_1(T - T_0)}{c_2 + (T - T_0)} \tag{4}$$

This allows the production of master curves, which can be used to estimate changes in modulus or other properties over a long period of time by shorter tests over different temperatures. The Arrhenius relationship (eq. 5) for crystalline polymers or other transitions, where E_a is the activation energy and R the gas constant (8.3 J/mol), is as follows:

$$\text{Log } a_T = \frac{-E_a}{R(T - T_0)} \tag{5}$$

DMA of multiple frequency measurements over a range of temperatures allows the plotting of modulus versus time in similar master curves as generated by a series of short-term creep studies in a much shorter timeframe. There are potential problems with these predictions, such as internal stresses in amorphous polymers interfering in superpositioning loss modulus data near T_g (168), using data in temperature regions outside linear viscoelastic behavior (169), or strains outside the linear regions. Studies on blends have been documented on styrene block copolymers with poly(α-methylstyrene) (170), unsaturated polyesters with elastomers (171), polyethylene copolymers with low ethylene content (172), and polycarbonate–poly(butylene terephthalate) (173). Furthermore, DMA is used to study the curing of thermoset systems (174–176). DMA has also been used to study the effects of additives of filled polymers (177,178) and the relaxation mechanisms of polycarbonate, metallocene polyethylene, and polypropylene fibers (179–181). The nonlinear behavior and deformation mechanisms of closed cell olefin foams were determined with DMA techniques (182). There are series of established standards for a variety of DMA techniques available from both ISO and ASTM as shown in the table below.

Test area	Subject	ASTM	ISO
Physical properties	Specific gravity/density	D792, D1505	1183

	Radiation	E1027	

Recent developments have been in the area of microthermal analysis using thermal conductivity with thermal diffusivity signals or AFM to visualize specific areas or domains in the material and perform localized thermal analysis studies (183,184). Relaxational behavior over time and temperature is related to changes in free volume of the material. Positron annihilation lifetime spectroscopy (PALS) measurements of positron lifetimes and intensities are used to estimate both hole sizes and free volume within primarily amorphous phases of polymers. These data are used in measurement of thermal transitions (185,186) structural relaxation including molecular motions (187–189), and effects of additives (190), molecular weight variation (191), and degree of crystallinity (192). It has been used in combination with DSC to analyze the range of miscibility of polymethyl methacrylate poly(ethylene oxide) blends (193).

Another relatively recent development in thermal technique for polymers is equipment for reliable measurement of chemiluminescence. The luminescence is thought to be from the drop of an excited carbonyl group back to the neutral state after excitation from the termination of two peroxy radicals. Its use is primarily in determination of oxidation stability of polymers to determine an oxidative induction time (OIT) (194,195). It has also been used to monitor oxidation of polymers subjected to stress (196) and simulated weathering (197).

Another technique that is similar to DMA is dielectric thermal analysis which is covered under the Electrical Properties section.

Vicat softening temperature (ASTM D1525, ISO 306) uses a flat-ended needle penetration of 1 mm of the plastic specimen under controlled heating conditions to indicate short-term resistance to heat. For some plastics these curves can be extrapolated to zero force and zero rate of heat to give values in agreement with glass-transition data (198). Testing of deflection temperature under load (ASTM D648, ISO 75) determines bending resistance of plastic specimen under load and at a set rate of temperature increase. This test is highly influenced by the molded-in stresses and the thickness of the specimen tested. Annealing specimen to relieve stresses prior to testing improves reproducibility of the test but also results in higher values than unannealed specimen. Locati and co-workers have proposed monitoring of the complete deflection curve with both annealed and unannealed samples to obtain a $T_{0.25}$ that is a temperature characteristic of a material at zero stress (but dependent on deformation) and two stress sensitivity coefficients that are dependent on the thermomechanical history of the material to better indicate the material performance in applications (199).

Processing Properties

The flow properties of polymers, whether the viscosity of liquid thermosets prior to gelation or of molten thermoplastics, are important parameters for the proper processing of materials (see RHEOLOGY). Several test methods have been developed to predict or correlate to actual processing conditions or for quality control testing of polymers. For thermoplastics, the commonly used quality control method is melt flow rate (ASTM D1238 or ISO 1133). This technique can give values at melt index conditions that are inversely proportional to the molecular weight of homopolymers. However, the common addition of processing aids, lubricants, and

fillers makes this correlation highly unreliable. Procedures that determine melt flow under two loads have been used primarily with polyolefins as an indication of molecular weight distribution. Melt flow rate values, although useful for quality control, are not indicative of the actual response of the material during processing, primarily due to the viscoelastic nature of polymers. Because polymers are non-Newtonian in flow, large differences in shear rate of the melt flow rate test ($1–50\ s^{-1}$) versus that of processing equipment, eg, extrusion ($10^2–10^3\ s^{-1}$) and injection molding ($10^3–10^5\ s^{-1}$), can cause large changes in the viscosity of most polymers.

Because processing conditions cover a wide range of shear rates, tests that can simulate both temperature and shear rate conditions are more useful in predicting flow properties. Several studies have been conducted on correlating common processing techniques that use torque rheometers, capillary rheometers, high pressure capillary rheometers, and oscillating disk rheometers for both thermoplastics and thermosets (202–204). Capillary rheometers have been designed to reach shear rates of $10^7\ s^{-1}$ and are used to study flow behavior at high shear (202). A typical set of curves of viscosity versus shear rate is shown in Figure 5 (205). A study of flow testing of ABS resins showed similar flow ranking of different grades of resin by using capillary rheology (ASTM D3835, ISO 14133), spiral flow molding, and on-machine rheometry (206,207), the last technique using an injection-molding machine as a rheometer. Capillary rheology tests using a screw rheometer in place of a piston have been published as ASTM D5422. Work is in development at ISO for determining extensional viscosity data as well as drawing properties using a rheometer for improved understanding of extrusion processing (208). Some work has been completed on using capillary rheology

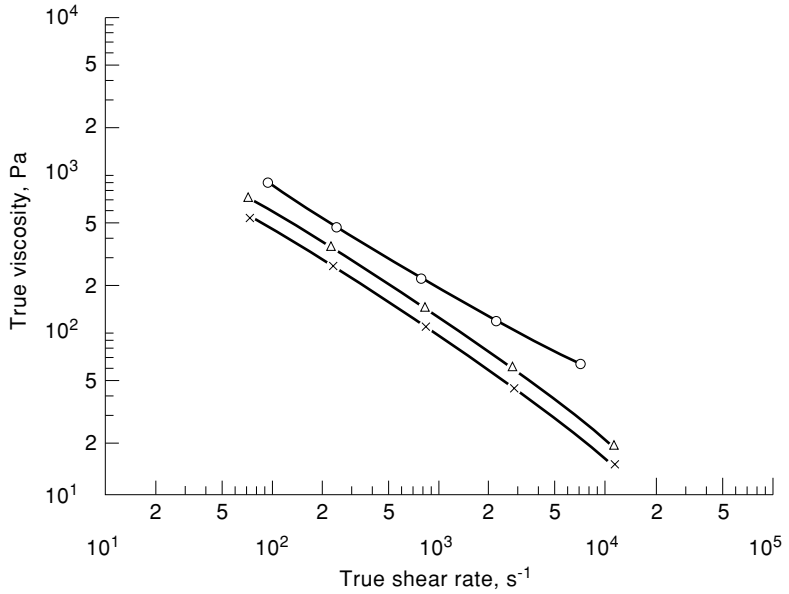

Fig. 5. Capillary melt viscosity; ○, = 300°C, △, = 320°C, and ×, = 340°C. Courtesy of The Dow Chemical Company.

measurments on-line to measure rheological properties during polymerization (209).

Flow tests designed for thermosetting resins include a cup flow mold for flash-molding of powdered phenolic and alkyd materials (ASTM D731), spiral flow for low pressure thermosets (ASTM D3123), and torque rheometer techniques (ASTM D3795). In addition to these, tests for measuring time to gelation (gel) are important for processors to understand usage time and pot life (210). Dilute solution viscosity testing of polymers requires complete dissolution in the solvent without degradation or interaction with the solvent within the chosen temperature range of the tests. Data from these tests have been used to determine relative molecular weight of polymers (211).

New standard tests for determining pressure–volume–temperature (PVT) properties of materials using rheometers and other techniques (212,213) are being established to discover the correlation for the fundamental properties of plastics. These in combination with no-flow temperature, ejection temperature, and capillary rheology data are useful in predicting the behavior of molten plastic as it enters and fills a mold. Several mold-filling prediction computer programs are commercially available (214,215) to assist mold designers and plastic processors in developing plastic parts that have reduced stresses from the molding process, and in improving productivity with easier start-up of new molds and fewer rejected parts.

Mechanical Properties

Mechanical properties of plastics can be determined by short, single-point quality control tests and longer, generally multipoint or multiple condition procedures that relate to fundamental polymer properties. Single-point tests include tensile, compressive, flexural, shear, and impact properties of plastics; creep, heat aging, creep rupture, and environmental stress-cracking tests usually result in multipoint curves or tables for comparison of the original response to postexposure response.

Tensile properties are those of a plastic being pulled in an uniaxial direction until sufficient stress is applied to yield or break the material. Standard tests are ASTM D638 and ISO 527 parts 1–4. For many materials, Hooke's law is valid for a portion of the stress–strain curve. If stress is relieved during this portion of the testing, any strain that has occurred is fully recovered. Elastomers generally do not show a linear response nor a true yield point. Tensile curves can be used as an indication of polymer strength and toughness. Figure 6 shows the relationship normally seen for the stress necessary for yield or break with strength, whereas elongation beyond yield shows ductility (toughness). Similar curves can be generated for tests in comparison, flex, shear, and some forms of impact.

Mechanical properties are determined on solid polymers in arbitrary forms defined precisely by standard test methods in ISO, ASTM, or other national standards organizations. Parts are formed by either injection molding, compression molding, or milling from extruded sheet or molded plaques. Viscoelasticity of polymers dictates that the technique used to make the part must have a significant effect on the mechanical behavior of the polymer. For valid comparison of materials, they should be prepared similarly and conditioned under the same

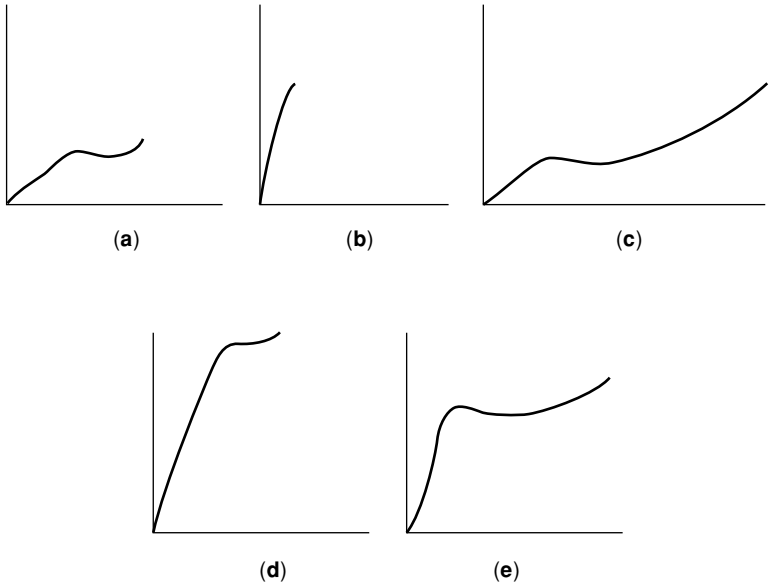

Fig. 6. Types of stress–strain curves: (**a**) soft and weak; (**b**) hard and brittle; (**c**) soft and tough; (**d**) hard and strong; and (**e**) hard and tough.

environment. Viscoelastic effects are also the reason for the rate of strain effects on the modulus values of materials under tensile, flexural, and compressive testing (216,217). The modulus of elasticity is also thickness-dependent, showing decreases as thickness increases in the plane-stress condition (0.1–2 mm) and the opposite effect at higher thicknesses where plane-strain conditions exist (218). Several types of impact testing have been developed to measure a plastic's response to a high rate of strain. Notched or Charpy Izod impact are pendulum impact tests essentially uniaxial in direction. Although both tests have been long established for quality control tests and material property data sheets, they are not useful in determining the impact response of a plastic in most applications. ASTM D256 lists multiple cautions on using data from these tests. Notched Izod's primary practical value in characterizing a plastic material is to establish notch-sensitivity of the material. Drop-weight impacts, either manual or instrumented, give more practical information because of the multiaxial stresses found in these test procedures which are closer to normal impact events. Instrumented impact allows the recording of the full impact event as a stress–strain curve, showing similar characteristics to tensile or other modes of stress–strain tests. Instrumented impact is preferred for monitoring ductile–brittle transitions and determining the effects of polymer composition on material toughness. Analysis of DMA analysis and impact properties of various compositions of impact-modified polypropylene showed a direct correlation between the loss tangent of DMA tests and impact properties (219).

Creep, creep rupture, and stress relaxation tests are multiple-point tests requiring long periods of time (1000 h minimum) to generate useful data; these are standard tests for determining more fundamental polymer properties. Data for

these tests are generated under several time–temperature–stress-level conditions in either tensile, flexural, compressive, or shear modes and combined into master curves using superpositioning theory (see AGING, PHYSICAL; VISCOELASTICITY). The low stress loads applied in creep tests, and thereby the low strain rates determined, require sensitive equipment for accurate measurements. Studies that normalize the stress required to produce a given strain in a given time to the stress producing that same strain after 24 h, have shown that plots of the normalized stress rates versus time over stress (24 h) give a single curve, which can be used with other short-term (days) creep tests at different stress levels to prepare master curves that can require up to 1 year for traditional data generation (220). Isometric curves can also be obtained similarly by using different temperatures for a given strain. Modulus values from these curves are used in plastic part design equations to predict part performance over the expected life of the part.

Fatigue testing of polymers may consist of static fatigue, ie creep rupture, or dynamic fatigue. Modes of cyclic fatigue include tension, compression, or shear, which use sinusoidal-, square-, and sawtooth-wave forms for applying stress, although varying strain can also be used in cyclic fatigue testing (see FATIGUE). Notching of specimen and high or low temperatures have been employed to accelerate the failure via embrittlement of the materials, but can lead to unwarranted extrapolation of the test data without additional tests (221).

Substantial work on the application of fracture mechanics techniques to plastics continues today (222–225) (see FRACTURE). The principle is based on failure stress proportionality to the square root of the energy required to create the new surfaces as a crack grows and inversely with the square root of the crack size originally determined with glasses. For the use of linear elastic fracture mechanics in plastics, certain assumptions must be met (226): (*1*) the material is linearly elastic; (*2*) the flaws within the material are sharp; and (*3*) plane strain conditions apply in the crack front region. The equation relating fracture toughness to modulus and energy release is given below for plane-stress and plane-strain conditions:

$$\text{Plane-stress} \qquad K_c = (E\ G_c)^{1/2} = Y\ \sigma_f a^{1/2}$$

where K_c = fracture toughness, E = Young's modulus, G_c = critical energy release rate per unit crack length, σ_f = nominal applied stress at fracture, a = crack length (or $\frac{1}{2}$ internal crack length), and Y = geometry factor.

$$\text{Plane-strain} \qquad K_c = \left(E/1 - \nu^2\ G_c\right)^{1/2}$$

where ν = Poisson's ratio.

ASTM D5045 has been accepted for the determination of the critical stress intensity factor, *KIC*. Although *KIC* is temperature- and rate-dependent and the dependence is specific for any material, it is relatively independent of specimen geometry. Single-edge-notched beams are typically used for the test, but other

geometries, eg, compact tension, short rod, and center-notched tension, have been used for the testing (227–231). Some plastics do not follow the mode outlined in D5045 at the thicknesses normally used in parts. These require the use of elastic plastic fracture mechanics using the *J*-integral parameter (232). More complex treatments of fracture incorporating nonlinear, viscoelastic effects have also been developed (233–235).

Hardness measurements such as Rockwell or Vicker's indentation properties are time-dependent as a result of the viscoelastic flow and relaxation processes (236) (see HARDNESS). Microhardness measurements have been used to correlate with other properties such as Young's modulus and compressive yield stress in polyethylenes (237) and glass-transition temperature of amorphous plastics (238). Scratch resistance in polyproplyene studies was found to have shear yielding as the main cause of plastic flow scratch pattern with tensile tear effects on the surface and shear-induced fracture on the subsurface (239).

Environmental Effects Tests

In practical applications of plastic materials, their mechanical properties can be significantly influenced by environmental factors of chemical exposure, temperature, radiation (photon and gamma ray), biological agents, and/or combinations of several of these factors at once. Few standard tests have been developed in these areas. Techniques and models used to extrapolate data from aging and environmental resistance tests on polymers have been proposed to predict service performance in various applications (240). This paper illustrates uses of Arrhenius, Avrami, WLF, and diffusion equations in evaluating exposure data and discusses their limitations. Mechanical properties can be determined by using ovens or cold-temperature chambers under the same procedures described in ASTM or ISO short-term tests to evaluate the effect of heat or cold. The length of exposure time, test conditions (at temperature or after being reconditioned to standard testing conditions after exposure), and reference material must all be stated to use these data. ISO 2578 addresses these variables, but allows the tester to choose the characteristic for testing and the threshold value (limit of decline in performance). It recommends testing for 20,000 h and performing the test under standard room temperature conditions after heat exposure. ASTM is developing a standard for comparative indexing of heat-aged materials to original properties, but does not indicate a minimum exposure time. Thermal expansion testing also addresses the physical dimensional changes in plastic parts exposed to temperature changes. The change must be measured in each orthogonal direction, because polymers are not generally isotropic or homogeneous. ASTM D696 has been used for coefficient of linear thermal expansion. Shrinkage measurements are not related to low temperature measurements, but refer to the dimensions of post-molded parts compared to the mold dimensions or to post-molding shrinkage that involves short-term, high heat exposure with post-exposure dimensional measurements. Melting points of crystalline materials may be determined by capillary tube or hot-plate techniques, whereas softening point (ISO 306, ASTM D1525) by penetration or deflection under load (ISO 75, ASTM D648) is generally used for amorphous and semicrystalline polymers.

Chemical exposure of plastics may exhibit a wide range of effects with one chemical and one type of polymer, depending on the concentration of chemical agent, temperature of exposure, molded-in stresses within the specimen, applied stress level to the part during exposure, and formulation of the specific polymer grade. Standardized tests have been developed to evaluate the effects of chemical agents on plastics with and without external stress. Tests such as ASTM D543 and ISO 175 propose procedures for evaluating the effects of suggested chemicals on dimensions, appearance, and mass of the polymer specimen after the specimen has been immersed for a set period of time. Mechanical properties may also be checked if the specimen has maintained sufficient integrity to test. Tests in which stress is externally applied include both stress and strain techniques. ASTM D1693 uses bent strips of polyethylene with a cut, exposed to an aggressive surfactant and exposed until failure or 48 h. Several improvements have been suggested, primarily in better defining specimen preparation (241) or control of the amount of strain used (242). For blow-molded polyethylene bottles, accelerated test conditions of higher temperature and pressure were found applicable (243). Amorphous poly(ethylene terephthalate) used aqueous sodium hydroxide and creep crack growth rates to determine environmental stress-crack performance (244).

The method of caustics has also been used to study the formation of cracks and crazes formed by exposure of PMMA to solvents (245). ISO 4599 has been developed to better control the application of stress using a jig having the curve of the arc of a circle for shaping the specimen and maintaining a set curvature during exposure to the agent. After a predetermined time the specimen is tested for tensile or flexural properties and compared to preexposure test values. ISO 4600 uses the technique of impressing an oversized ball or pin into a hole drilled in the specimen to apply a strain.

Tests using a constant stress (constant load) normally by direct tension have been described in ISO 6252. This test takes the specimen to failure, or a minimum time without failure, and frequently has a flaw (drilled hole or notch) to act as a stress concentrator to target the area of failure. This type of testing, as well as the constant strain techniques, requires careful control of specimen preparation and test conditions to achieve consistent results (246,247). Use of a slow strain rate with a four-point bend specimen configuration and constant load has been suggested as a method for ranking materials for environmental stress-crack resistance (248).

Weathering of plastic materials combines complex factors of temperature, radiation, oxidation, and moisture effects on a plastic part. Weathering effects vary with geography, time of year, and position of material being exposed. All of these effects make predicting the weatherability of a material extremely difficult. A recently completed study on the reproducibility of weathering data concluded that ranking of materials appears consistent although absolute data varies significantly from lab to lab (249). ISO 877 and ASTM G24 outline procedures for standardizing outdoor exposure of plastics under glass; ISO 4607 and ASTM D1435 are techniques for total exposure of plastic specimens to natural elements in racks and under specific climatic conditions. Frequently, only changes in physical appearance are measured after weathering; however, appropriate specimens can be exposed, mechanically tested, and compared to carefully stored control specimens

(250). The long time periods required for outdoor weathering studies have led to the development of several accelerated techniques. The use of extreme and consistent climates, eg, South Florida or Arizona, and intensifying techniques for natural sunlight have been suggested to accelerate tests. ASTM D4364 has established a method for the use of a follow-the-sun rack with flat mirrors to reflect sunlight uniformly onto the test specimen as an intensifying technique. Because these techniques still require long exposure times to obtain results, in-lab acceleration tests to weather materials artificially have been developed. Various lamp sources have been used, such as low and high pressure mercury, carbon arc, and xenon arc. Although carbon arc lamps are still used to weather materials, xenon arc lamps are the preferred lamp for plastics weathering. These lamps simulate sunlight closely when appropriate filters are used (Fig. 7). Various correlations have been reported between xenon testing and outdoor weathering. For several plastics, 500 h in xenon arc testing, provided high humidity and water spray are used, are equivalent to 1 year of outdoor exposure. Some equipment manufacturers indicate that the ratio is one hour of accelerated to 10 h of outdoor exposure, whereas experimenters have found that the ratio can range from 1 h accelerated/5 h outdoor to 1 h accelerated/9 h outdoor when evaluated by the change in plastic color. Accelerated tests should be used to compare the relative performance of materials and ranking resistance to exposure, rather than for any direct correlation to outdoor weathering. Both ISO and ASTM have established practices for the use of carbon arc and xenon arc accelerated equipment. Recently, suggestions have been made for use of higher temperatures and irradiance levels to further accelerate weathering (251).

Fluorescent UV lamps within an apparatus that allows condensation cycles rather than the water spray typical of xenon arc tests have been developed for

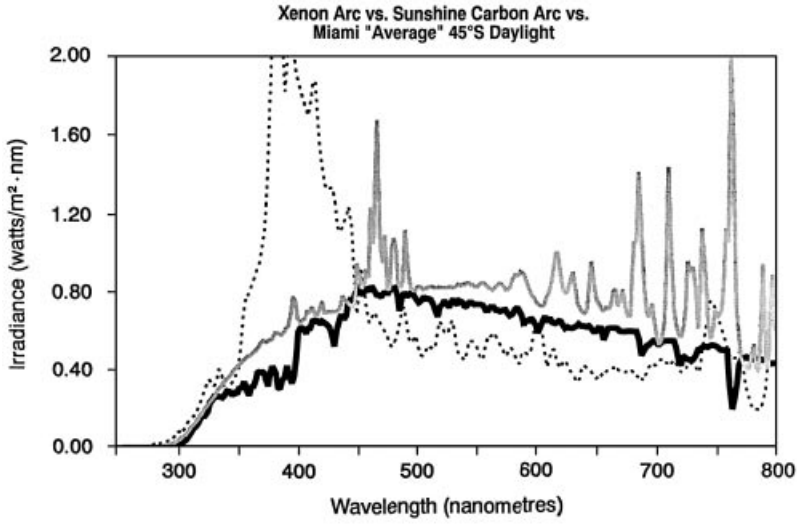

Fig. 7. Comparison of xenon arc, sunshine carbon arc, and Miami average 45°S daylight, where (▒) represents xenon with Type S high borate filters, 0.35 W/(m^2·nm) at 340 nm; (···) represents sunshine carbon arc with Corex; and (▬) represents daylight. Courtesy of Atlas Electric Devices Co.

plastics testing. The spectral cutoff wavelength of the lamps used in the apparatus determines the severity of the test. Ultraviolet B (UVB) 313 lamps allow a significant irradiance component below 290 nm, which is normally filtered out by the earth's atmosphere. Ultraviolet A (UVA) 340 lamps have shown better correlation to the spectral irradiance of natural sunlight, although the visible light range is missing.

Other environmental testing standards have been developed for evaluating the effects of biological agents, either strains of fungi (ISO 846 or ASTM G21) or bacteria (ASTM G22), on mold growth on the plastic material, or if the plastic material has a toxic effect on the fungi. Longer-term outdoor exposure tests for resistance to microbial attack require geographic locations favorable to microbial growth or burial of the material in soil. ASTM E1027 is used for exposure of polymers to ionizing radiation. This can be used for testing the resistance to gamma rays, electrons, neutrons, etc. These tests are important for plastics used in the medical area to determine the resistance to sterilization techniques. A set of standards have been introduced at ASTM and ISO for the evaluation of biodegradable plastic materials. These standards have recommended standard conditions for a variety of environments to substantiate environmental performance of this new type of plastic material.

Optical Properties

Transparency, gloss, color, refractive index, and reflectance are the properties normally associated with aesthetics of plastic materials. In some areas, changes in optical properties, increases in haze after abrasion testing, color differences after weathering, and birefringence analysis of residual stress within a transparent part (252) are all used to measure the effects of applied stresses. Measurements of color, gloss, refractive index, and haze apply to many products beyond plastics and use similar techniques. Reference should be made to this general topic for detailed information.

One of the most widely accepted measurements of color in plastics is based on standards developed by the Commission Internationale de l'Eclairage (CIE) for illuminants and observers to establish tristimulus values. A common color scale used to describe color in numeric terms of lightness and hue is the L-a-b tristimulus system, where L is scaled vertically from a perfect white with a value of 100 to a perfect black at 0; a is positive for red and negative for green; and b is positive for yellow and negative for blue. Spectrophotometers are used to measure the full reflectance of a colored material over the visible range and convert to the tristimulus values via microprocessors. Color as viewed under various CIE illuminants and/or observers can be determined by a single spectrophotometric analysis as the microprocessor computes the tristimulus values for each set of conditions. Color-matching of an object can be completed by comparing spectral curves generated through the use of the spectrophotometer. However, many factors, such as gloss, texture, opacity, and changes in illuminant and observer, complicate the visual appearance of a color with the spectral curve of a color. ASTM D1729 establishes procedures for visual evaluation of color and defines illuminant, viewing conditions,

and use of standards for comparison; ASTM D2244 describes instrumental color evaluation techniques. Specular gloss, the relative reflectance of a specimen in the specular direction, is usually measured at 60° angle of incidence for most plastics. High gloss materials may be measured at 20° incidence and low gloss specimens at 85° incidence using ASTM D523. For films, ASTM D2457 uses measurements at 20°, 60°, and 45° angles of incidence.

Electrical Properties

Dielectric analysis (DEA) or dielectric thermal analysis (DETA) is similar to DMA (see DIELECTRIC RELAXATION). In DEA, the movement of dipoles or other ionic species that can be electrically stimulated allows the monitoring of changes in ionic conductivity. Similar to DMA phase angle δ, in DEA this is related to the lag of the polarization induced in an insulator placed in an alternating electrical field. The energy dissipated as heat is proportional to the dielectric loss ε'', and the energy stored is the real part of the dielectric constant, ε'. The electrical technique is considered more sensitive to transitions below T_g than DMA (253). It is also more sensitive to β-transitions frequently linked to impact strength and long-term mechanical strength (254). Dielectric analysis has a broader and higher range of frequencies than DMA. Changes in permittivity with time in DEA measurements have been correlated with moisture content change in polymers (255) and have become an on-line technique for monitoring moisture in polymers. Thermally stimulated conductivity (TSC) uses the technique of polarizing a polymer at different temperatures, quenching the sample, and measuring the depolarizing current as the material is heated at a controlled rate (256). The rate of repolarization is related to the relaxation times of internal motions. When DEA was used to characterize the alpha relaxation process of an interphase formation in composite material, the process was found to be diffusional rather than a resin curing process (257). A combination of DMA and DEA in a study on the effects of low molecular weight additives in poly(ethylene terephthalate) was able to resolve that beta peak had two different relaxation processes correlating with different molecular motions in the polymer chain (258). DMA relaxation spectroscopy was also used to relate the structure of lateral groups of aromatic polyamides to molecular mobility (259). Inverse gas chromatography has been used to predict and measure diffusion coefficients using a method at finite concentration of solvent (260). It has also been used to examine surface properties of solid materials (261).

Excellent insulating properties, along with the ability to be structural components, make plastics the ideal candidate materials for electrical applications. Although generally used as insulators, carbon black or carbon fiber can be added to make plastic materials electrically conductive, thereby expanding their usefulness in the electronics area.

Standard testing of electrical properties of plastics includes dielectric strength, permittivity, dissipation factor, surface and volume resistivity, and arc resistance. Dielectric strength is the maximum voltage required for breakdown and is determined by one of three techniques: short-time, slow-rate or slow-rise, and step-by-step. The two last techniques use data from the short-time test to

determine a starting point. Dielectric strength is thickness-dependent with thin foils being used in specific space-saving devices.

Permittivity gives an indication of the electrical storage ability of a conductor (behaving as a capacitor). The thinner the material, the higher the permittivity or capacitance, allowing use of plastic foils in areas where high capacitance is required. However, when plastics are used as insulators, low permittivity is required. Resistivity testing can be either volume, relating to leakage of current through the body of the insulator, or surface, relating to a surface layer of moisture or contaminant leading to electrical loss.

Arc resistance or tracking resistance is the resistance of a material to a high voltage arc or discharge. ASTM has published three methods to test this phenomenon, depending on the conditions to be tested: D495 for high voltage, low current, dry arc resistance; D2132 for dust and fog tracking; and D2302 for liquid-contaminant inclined-plane tracking. A comparative tracking index (CTI) technique uses a low frequency, low level current applied between electrodes while allowing drops of aqueous solution to fall between electrodes at 30-s intervals. This technique is described in ASTM D3638. However, the results or values obtained from these tests cannot be used in design studies (262).

Electromagnetic interference (EMI) testing has become more prevalent for materials that either emit or are affected by EMI. Shielding efficiency (SE) of materials is determined by measuring electric field strength between a transmitter and receiver with or without the presence of the material under test.

Underwriters' Laboratories (UL) is an independent, nonprofit organization that develops standards for safety in electrical products. UL 746 A, B, and C describe tests and limits for materials used in electrical equipment; UL 746 D lists test requirements for the fabricated plastic parts (263).

Flammability Properties

Plastics have become an important material in the construction industry and are used in areas of insulation, wire coating, flooring materials, and piping; they are also considered for structural components as foam panels and plastic wood. As use in the industry has grown, so has concern about the fire properties of these materials. Tests to determine ignition resistance, flame spread, heat release, and smoke or toxic gas release have been developed. However, the results of these tests are not applicable to the performance of the materials under actual fire conditions. These small-scale tests are intended for quality control and potential hazard ranking. Several organizations that go beyond testing standard bodies such as ASTM or the International Electrotechnical Commission (IEC) have developed tests and/or regulations for the use of plastics in electrical appliances or buildings. A listing of some of these tests is given in ASTM D3814. General fire test terminology is given in ASTM E176. Ignition temperature tests ISO 871 and ASTM D1929 have procedures using small external pilot flames. The limiting oxygen index test has been used in quality control primarily for its good reproducibility, but cannot be used to predict fire performance. ISO 4589 and ASTM D2863 determine the minimum oxygen concentration required to support flaming combustion under set conditions.

UL 94 flame testing of plastics is similar to ASTM D635 for horizontal burn and ASTM D568 and D3801 for vertical burn. UL lists both materials and fabricated products meeting the various 94 requirements in a publication (264). Rate of heat release data are highly important in determining fire behavior, but few tests have been established. Equipment proposed by Factory Mutual has been used in fundamental fire modeling studies (265). The cone calorimeter as described by the National Institute of Standards Technology (NIST) utilizes both vertical and horizontal specimens (266). Refinements of this equipment have allowed testing in the reduced oxygen atmosphere typically found under fire conditions (267). Smoke generation tests have used changes in light absorption of a photoelectric cell within a confined chamber as the primary measurement. Results are reported as percent obscuration or smoke density. Flame or radiant panels can be used as the ignition source in these tests.

Nondestructive Testing

Nondestructive testing of materials is defined as any test that does not damage the plastic piece beyond its intended use. These can be visual and, in some cases, mechanical tests. However, the term is normally used to describe X-ray, nuclear source, ultrasonics, atomic emission, as well as some optical and IR techniques for polymers. Nondestructive testing is used to determine cracks, voids, inclusions, delamination, contamination, lack of cure, anisotropy, residual stresses, and defective bonds or welds in materials.

X-ray techniques can readily determine voids down to 1 mm in diameter and cracks (as long as the plane of the crack is close to the direction of the ray) (268). Nuclear sources and gamma and beta rays have been used to measure the thickness of extruded plastic sheet. For ultrasonics, the frequency used for plastics ranges between 0.5 and 5 MHz. However, isolated defects smaller than a wavelength are difficult to detect with this technique. Ultrasonics have also been used to determine elastic modulus, shear modulus, and Poisson's ratio via the relationship of sound wave velocities through a material (268,269). In studies with blends, the variation of the ultrasonic velocity with composition of a blend is nonlinear where the blend shows incompatibility and linear where it is compatible (270). Holographic interferometry uses an expanded beam of light from a laser source divided by a beam splitter, with one portion hitting the object and the other hitting a recording screen. When both beams are combined at the screen a unique interference pattern is formed. Comparison of this generated image with another of the object under stress produces a fringe pattern for analysis. The maximum depth/diameter ratio for a detectable defect is less than 0.2 (271).

Thermal imaging is sensitive to IR radiation that detects temperature changes over the surface of a part when heat has been applied. Thermal diffusion in a solid is affected by variation in composition or by the presence of cracks, voids, delaminations, etc; the effects are detected by surface temperature changes. Defects cannot be detected if their depth below the surface is more than two to three times their diameter. Nondestructive testing has been primarily used for composites and analysis of adhesive bonds or welds. Several studies are documented in the literature (272–274).

Other Tests

A variety of methods have been used to evaluate diffusion or permeability of gases and solvents with polymers: FTIR spectra of CO_2 allowed the determination of apparent diffusion coefficients of the gas in membranes of rubbery and glassy polymers from desorption kinetics (275); internal reflection FTIR was used to monitor water uptake by a polymer film (276); spin probe techniques have been used in the study of high permeability and high free volume glassy polymers (277); and an *in situ* gravimetric method using an electro-balance was used to determine solubility and diffusivity of gases in polymers over a range of temperatures and pressures (278).

There are other tests for polymers that are not included in this review including some density, filler analysis techniques and other physical tests. For convenience, a listing of ASTM and ISO standards for the major test in this work is provided in the references.

THERMOFORMING

Introduction

Thermoforming is the art and science of forming commercial products by heating plastic sheet to a softened, pliable state, pressing the sheet against a cool mold, holding the formed sheet against the mold until rigid, and trimming the formed part from the web or skeleton surrounding it. Nearly all unfilled or unreinforced thermoplastics are formed in this manner on conventional equipment. Newer forming technologies are used to form filled and reinforced thermoplastics and certain thermosetting polymers. In general, thermoforming is used when large surface area-to-wall thickness parts are needed, when rapid evaluation of product designs are sought, when very high production rates of thin-walled parts are desired, and when a few to a few hundred thick-walled parts are needed.

Although commercial thermoforming, sometimes called *vacuum forming* or *swedging*, was not developed until the 1870s, when cellulose nitrate was first cut into thin sheets, Egyptians, Pacific natives, and American Inuits formed naturally occurring tortoise sheet and tree bark or natural cellulose into bowls and boats long before then (1).

In the 1870s, cellulose sheet was formed using metal molds and steam as the heating and forming medium (2,3). The earliest products were baby rattles, toys, mirror cases, and hairbrush backs. In the early 1900s, piano keys were drape-formed over captive wooden cores. In 1930, Fernplas Corp. patented a bottle fabricated from two thermoformed halves. Relief maps for the U.S. Coast and Geodetic Survey were thermoformed of cellulose acetate in the 1930s. The first automatic roll-fed thermoformer was sold by Clauss B. Strauch Co., in 1938, to manufacture cigarette tips and ice-cube trays. The heating, bending, and shaping of plastic sheet were taught in high school industrial art courses in the late 1930s (4).

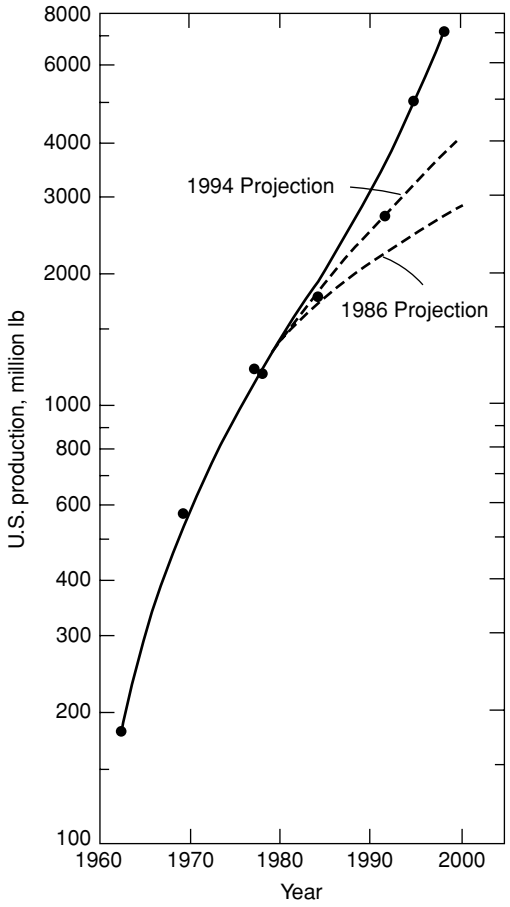

Fig. 1. Thermoforming production in the United States (7). 1 million lb = 455,000 t. Redrawn and used with permission of Hanser Publications.

The Second World War accelerated interest in thermoforming, with the demand for cast poly(methyl methacrylate) fighter/bomber windows, gun closure and windscreens (5).

By the mid-1950s, thermoformed blister packages and food containers of polystyrene were found in most grocery stores. In 1962, approximately 77,000 t of plastic was thermoformed in the United States. By 1998, approximately 2.9 million metric tons of plastic were thermoformed in North America (6) (Fig. 1). This is a sustained annual growth rate of about 10% over nearly four decades. An additional 4.55 million metric tons are thermoformed worldwide. The total world market is estimated to have a value of about US$ 35,000 million.

Thermoforming is typically bifurcated into thin-gauge thermoforming and heavy- or thick-gauge thermoforming. As seen in Table 1, thin-gauge thermoforming uses sheet 1.5 mm or less in thickness, with its primary products being packaging containers. Typical disposable products include blister packages, point-of-purchase containers, bubble packages, slip sleeve containers, auto/video

Table 1. Thermoforming Categorization[a]

Item	Thin-gauge	Heavy-gauge
Sheet thickness range	Less than 1.5 mm	Greater than 3.0 mm
Dominant products	Packaging, disposables	Cabinetry, industrial
Sheet handling	Rolls	Palletized cut sheet
Typical machine type	In-line former, trimmer	Shuttle or rotary press
Press size	To 0.8 × 2 m	To 4 × 6 m or more
Machine control aspects	Automated	Automated to manual
Controlling aspect, heating	Heater output	Conduction into sheet
Heater type	Electric, ceramic, quartz	Electric, catalytic gas, forced hot air
Pattern heating	Not usually done	Common
Part size tendency	Small	Medium to very large
Number of mold cavities	Many to a hundred	One or two, usually
Mechanical assist	Plug	Plug, billow, vacuum box
Mold type	Female, usually	Male, female, mixed
Mold materials	Aluminum, machined	Wood, plaster, syntactic foam, white metal, cast aluminum
Mold cooling	Active, controlled	Active to none for prototype
Free surface cooling	Ambient, usually	Forced air, fogging
Trimming aspects	Punch and die, rim roll	Multiaxis routing
Nonproduct trim level	About 50%	About 25–30%
Wall thickness tolerance, normal	20%	20%
Wall thickness tolerance, tight	10%	10%
Pressure forming application	Deep draw, formed rim	Textured surfaces, deep draw

cassette cases, hand and power tool cases, cosmetic cases, meat and poultry containers, unit serving containers, convertible-oven food serving trays, wide-mouth jars, vending machine hot and cold drink cups, egg cartons, produce and wine bottle separators, medicinal unit dose portion containers, and form, fill, and seal (FFS) containers for foodstuffs, hardware supplies, medicine, and medicinal supplies.

Heavy-gauge thermoforming uses sheet 3 mm or more in thickness, with primary products being permanent or industrial products. Typical products include equipment cabinets for medical and electronic equipment, tote bins, single and double deck pallets, transport trays, automotive inner-liners, headliners, shelves, instrument panel skins, aircraft cabin wall panels, overhead compartment doors, snowmobile and motorcycle shrouds, fairings and windshields, marine seating, locaters and windshields, golf cart, tractor, and RV shrouds, skylights, shutters, bath and tub surrounds, lavys, single- and double-wall shipping containers and pallets, storage modules, exterior signs, swimming and wading pools, landscaping pond shells, luggage, gun and gulf club cases, boat hulls, animal carriers, and seating of all types.

There is a growing but very still limited market for products formed from sheet between about 1.5 mm (thin-gauge) and 3.0 mm (heavy-gauge) thickness. Usually, products of this thickness are either too expensive to be disposable or too thin to be industrial or permanent products. One major application is in the manufacturing of very large volume drink cups (1/2 L or more).

Currently thin-gauge thermoforming accounts for about three-quarters of all sheet formed, in both tonnage and dollar volume. Thin-gauge thermoforming companies tend to be very large with broad spectra of products. Furthermore, companies that manufacture products may also do in-house thin-gauge thermoforming for the packages for these products. Heavy-gauge thermoforming companies tend to be small with narrow product lines. As a result, there are many more heavy-gauge thermoforming companies than thin-gauge thermoforming companies. In 2001, it was estimated that there were about 500 heavy-gauge thermoforming companies and less than 200 thin-gauge thermoforming companies in North America (9).

As outlined in Table 1, there are substantial differences in the characteristics of these two thermoforming categories. In addition to the sheet thickness criterion, there is a difference in the way the sheet is presented to the thermoforming machine. Thin sheet is usually delivered in rolls of up to 3000 m in length, weighing up to 2300 kg and having diameters up to 1.5 m. The sheet is fed continuously into the thermoforming machines that are usually called roll-fed machines. Thick sheet is usually guillotine-cut to size and palletized. The individual sheets are then loaded manually or pneumatically into the thermoforming machines, known as cut-sheet machines.

Thermoforming is a competitive technology. In thin-gauge it competes with paper, paperboard, plastic-coated paper and paperboard, paper pulp, expanded polystyrene foam, aluminum foil, and roll-sheet steel. It also competes with plastics extrusion, compression molding, stretch-blow molding, injection molding, and injection-blow molding. In heavy-gauge, it competes with injection molding, rotational molding, blow molding, fiberglass-reinforced polyester resin spray-up molding and lay-up molding, compression molding, sheet compound molding, bulk compound molding, sheet metal forming, and metal die casting.

When compared to other technologies, thermoforming offers many advantages: there is a wide variety of polymers from which to choose; molds are single-sided and are thus less expensive than injection molds; the time from concept to final part acceptance is usually quite short; there are many available mold materials; aluminum—the mold material of choice—is lightweight, has a high thermal conductivity, is relatively inexpensive, and is easy to machine and cast; processing temperatures are low; processing pressures are very low; mold detail replication is good; part surface area-to-wall thickness is extremely high; and there are many excellent trimming techniques (10).

However, thermoforming has some serious limitations. Among others, the polymer of choice may not be extrudable or may sag too much during heating in the thermoforming machine; there is additional cost in producing sheet; the unused portion of the sheet—the trim, web, or skeleton—must be recycled to keep sheet costs reasonable; because of the end-use of the product (medical, pharmaceutical, foodstuffs), recycling of the trim may not be acceptable, it may not be possible to stretch the sheet sufficiently to achieve the desired part shape, part wall thickness is not well-controlled or predictable, and is not uniform across the part; wall thickness cannot be changed locally through design; surface texture may be required on both sides of the part; the part performance criteria may required reinforced or highly filled polymers; the part tolerance, edge radii, and draft angles may be unacceptably tight for the thermoforming process; and there

may be other processes that are more economically attractive. A general comparison of four thermoplastic processes is given in Table 2 (see INJECTION MOLDING; BLOW MOLDING).

Machinery

The specific details of thermoforming machinery depend on whether thin-gauge or heavy-gauge parts are fabricated. However, all machines include some form of sheet handling device, some way of moving the sheet from one station to another, a sheet heating oven, a vacuum system, a forming press containing the mold assembly, a formed part removal region, and a system for controlling the various elements of the machine that allow sheet transfer from one station to another. In addition, the machines may include some form of sheet prestretching, such as a preblowing step or mechanical pushers or plugs, a pressure system, a mold cooling system, a trimming press, and some form of trim removal.

Thin-Gauge Machines. The schematic in Figure 2 illustrates the most common thin-gauge thermoforming machine arrangement. The sheet, delivered as a roll, is indexed through the machine on pins that are arranged along parallel or near-parallel lengths of continuous link chains. The sheet is usually uniformly heated from both top and bottom with infrared heaters. Most commercial machines use ceramic bricks or tiles, metal plate heaters, metal rod heaters, quartz tubes, or quartz plate heaters as energy sources. Typically, the ovens accommodate two or more "shots" or forming stops. Once the sheet is at the forming temperature, it is indexed into the forming press. The forming press contains at least one platen with the desired mold assembly. If the parts being formed require matched forming, as is the case with low density foam sheet, a second platen contains the matching mold assembly. If not, the second platen may contain a pressure box, a

Table 2. Comparison of Four Thermoplastic Processes[a]

Characteristic	Thermoforming	Injection molding	Blow molding	Rotational molding
Polymer form	Sheet	Pellets	Pellets	Powder
Variety of polymer	Good to excellent	Excellent	Good	Fair to limited
Raw material cost	Polymer + sheet extrusion	Standard	Standard	Polymer + grinding
Variety of mold materials	Very many	Very limited	Limited	Many
Mold cost	Moderate to low	Highest	High	Moderate to low
Production mold material	Aluminum	Steel	Aluminum	Aluminum, steel
Thermal cycling of mold	Gentle	Moderate	Moderate	Severe
Process key	Rubbery solid sheet	Viscoelastic liquid	Elastic liquid	Melting Powder
Cycle time	Moderate to short	Very short	Moderate	Very long
Man/machine interaction	Normally high	Nil to low	Low	Very high
Part wall uniformity	Fair to poor	Excellent	Poor to fair	Good to excellent
Major design problems	3D corner, wall thickness uniformity	Gating, weld line	Pinch-off, wall uniformity	Porosity
Part failure mode	Thin corners, microcracks	Weld line	Thin side walls, poor pinch-off	Poor tensile strength
Operating pressure, MPa[b]	−0.1 to 0.5	10 to 100	0.5 to 2.5	0 to 0.1
Operating temperature, °C	50 to 250	150 to 300	100 to 250	200 to 350
Filling methods	Manual to automatic	Automatic	Automatic	Manual
Part removal methods	Manual to automatic	Automatic	Automatic	Manual
Flash, trim	Highest	Low to nil	Moderate to high	Moderate to low
Inserts	Possible	Feasible	Feasible	Usual
Orientation in part	Highest	Moderate to high	High to moderate	Unoriented
Stress retention	Highest	High	High to very high	None to little
Shrinkage, warpage	High to moderate	Controllable	Moderate to high	High
Part design advantage	Very thin walls	Wide variation in part wall thickness	Hollow parts	Very large hollow parts
Part characteristic	Single-sided	Both sides finished	Single-sided	Single-sided
Part surface finish	Good to very good	Excellent	Very good	Good
Surface texture	Good	Excellent	Very good	Good to fair

[a] Ref. 11.

[b] 1 MPa equals approximately 10 atm.

mechanical plug assist assembly, and/or a clamping grid assembly. There are several ways of opening and closing the forming press. Mechanical and pneumatic toggles have been used for decades. Electrically driven platens have become quite popular recently.

The majority of thin-gauge parts are formed into female or negative cavities. For deep cavities or multiple-compartmented cavities, mechanical assists, called plugs, are used to prestretch the sheet before vacuum and/or pressure is used to force the sheet against the mold surface. Air pressure to 5 bar is used, in conjunction with vacuum, for deeply drawn parts or for parts requiring high surface detail or sharp radii.

In thin-gauge forming, there are three common ways of removing the formed part from the web, skeleton, or unformed portion of the sheet. In-mold trimming employs steel rule dies that are a portion of the clamping assembly holding the sheet to the mold surface. Once the parts are formed, the steel rule die assembly is activated to cut the parts free of the web. In-machine trimming employs a separate trimming station that is situated downstream of the forming press, but still within the machine frame. The sheet containing the formed parts is indexed from the forming press directly into this trimming station, where steel rule dies separate the parts from the web. In-line trimming employs a separate trimming press that is downstream from the forming machine, as shown in Figure 3 (12). The sheet containing the formed parts is fed from the end of the forming machine pin-chain assembly into a separate indexer on the trimming press. The sheet containing the formed parts passes between a punch assembly and a die assembly. The punch pushes the formed parts against a trim die, cutting the parts away from the web and pushing them onto a collection table.

FFS machines are used in for packaging pharmaceuticals, foodstuffs, and medical supplies. As seen in Figure 4, thermoforming is a small portion of the process (13). In these machines, the sheet is usually pulled through the entire

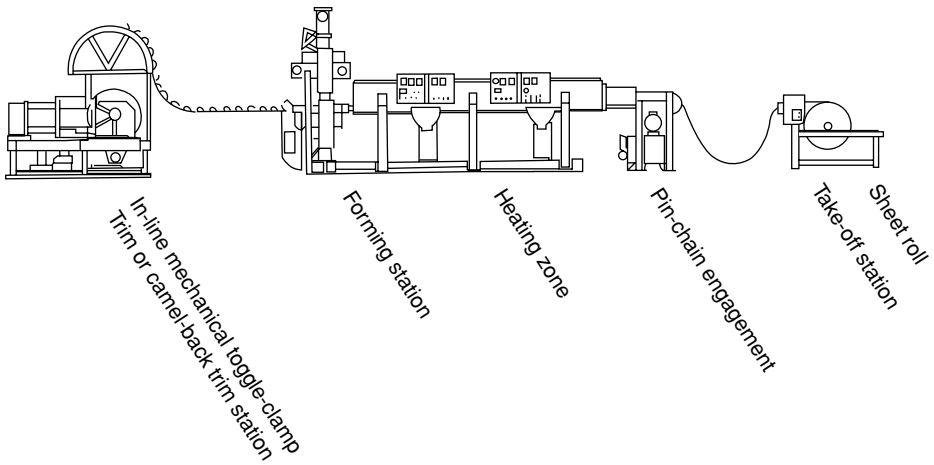

Fig. 3. Schematic of large thin-gauge thermoforming machine (Battenfeld—Glouster, Glouster, Mass.) (12). Used with permission of Hanser Publications.

FFS sequence. The sheet is heated by contact with heated plates or rolls. FFS technology is most effective when the sheet is on the order of 250 μm or so.

For all roll-fed applications, it is economically necessary to collect the web for regrinding and reprocessing into sheet. For the in-line trimming press, the web is guillotined at the press and the chips are vacuum-collected for reprocessing.

Heavy-Gauge Machines. There are several common designs for heavy-gauge thermoforming machines. The simplest and most widely used is the shuttle machine (Fig. 5) (14), where the sheet, cut to size and palletized, is loaded, one

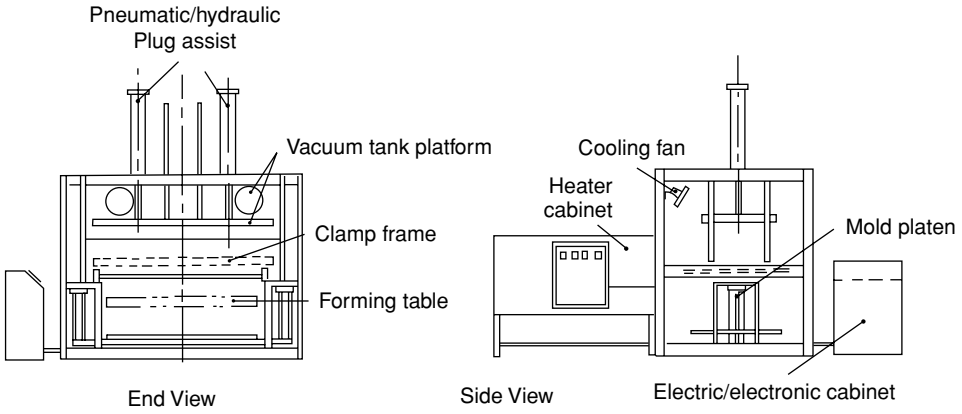

Fig. 5. Schematic of heavy-gauge shuttle thermoforming machine (Drypol/Zimco, no-longer in business) (14). Used with permission of Hanser Publications.

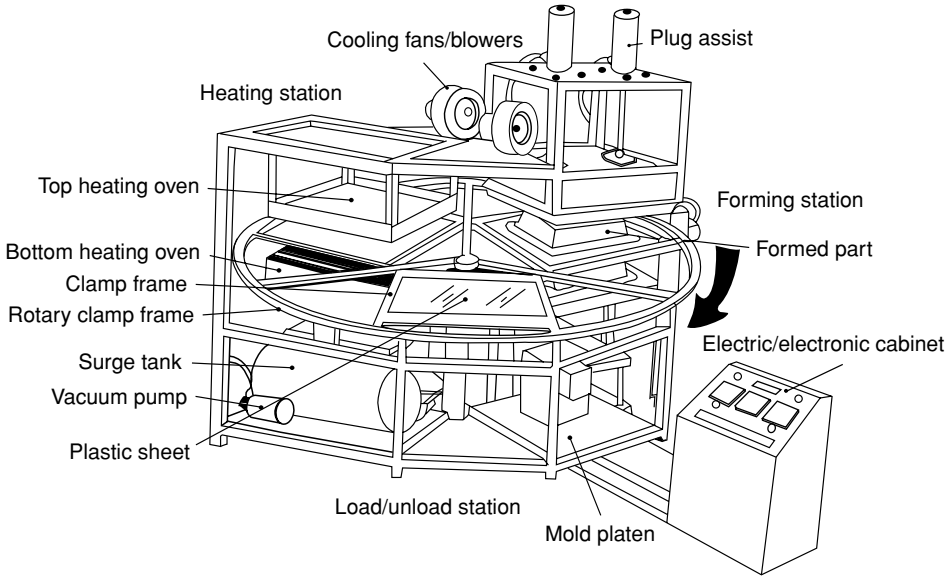

Fig. 6. Schematic of heavy-gauge rotary thermoforming machine (15). Used with permission of Hanser Publications.

sheet at a time, in a four-sided clamp frame and shuttled into the oven. When the sheet is at its forming temperature, it is shuttled to the forming press. When the sheet has been formed and cooled, it is removed from the clamp frame to a trimming fixture. Shuttle presses are very versatile and capable of forming parts of nearly unlimited dimensions. Shuttle presses with two forming stations and a central oven are used to overcome the economically inefficient operation of a single forming press machine. Rotary thermoforming machines, with either three or four stations, are quite energy efficient, but require more care in setting up. Figure 6 is a schematic of a three-station rotary machine (15). These machines are also limited in the size of the parts that can be formed.

A three-station machine has one heating station, in addition to the forming station and the load–unload station. The four-station machine has two heating stations. The sheet is usually uniformly heated from both top and bottom with infrared heaters. Most commercial machines use ceramic bricks or tiles, metal plate heaters, metal rod heaters, quartz plate heaters, or catalytic gas heaters as energy sources. As with thin-gauge thermoformers, once the sheet is at the forming temperature, it is indexed into the forming press. The forming press contains at least one platen with the desired mold assembly. The press may contain a second platen. For single-sheet forming, the second platen may contain a pressure box, a mechanical plug assist assembly, and/or a vacuum draw box to pneumatically prestretch the sheet. As with thin-gauge forming, the mold may be mounted on either the top or the bottom platen. The mold frame usually contains one to a few molds, which can be either male or female. Mechanical toggles or electrically driven chain with rack-and-pinion guides are used to raise and lower the platen. If a pressure box is used, the mold sections are mechanically locked and pressure bags are inflated to ensure an intimate seal against air pressures to 0.5 MPa.

Twin-sheet thermoforming is the method of forming hollow or semihollow parts such as pallets and door panels. Four-station machines are commonly used to form these parts. The first sheet is loaded in the clamp frame and rotated into the first oven. After a predetermined time, the second sheet is then loaded in the next clamp frame and rotated into the first oven. This action rotates the first sheet to the second oven. When the first sheet is at its forming temperature, it is rotated to the forming press and formed into the top mold cavity. When the part is sufficiently cooled, the clamp frames release the sheet. This allows the second sheet, in its clamp frame, to be rotated to the forming press, where it is formed into the top mold cavity. Then the platens close, are mechanically locked together, and air is forced under pressure between the two sheets. This forces the sheets against their respective molds and the clamping force provides for sealing of peripheral edges and any mating surfaces designed into the part. The welded-together sheets are then released from the clamp frame and removed to the trimming device (16).

There are many ways to trim the part from the surrounding plastic. Hand-held routers, band saws, and circular saws are commonly used. Hand-held drills are used for holes and slots. Computer numerical-controlled routers are used extensively for parts requiring dimensional accuracy along trim lines.

Process Characteristics

The Forming Process. Drape forming (*male* or *positive forming*; Fig. 7) and vacuum forming (*female* or *negative forming*; Fig. 8) are the earliest and simplest methods of thermoforming (17). Both methods yield parts with very nonuniform wall thicknesses. Free forming (*billow* or *free bubble forming*) uses no mold. The sheet is simply pneumatically stretched to the desired extent, and then allowed to cool in this shape.

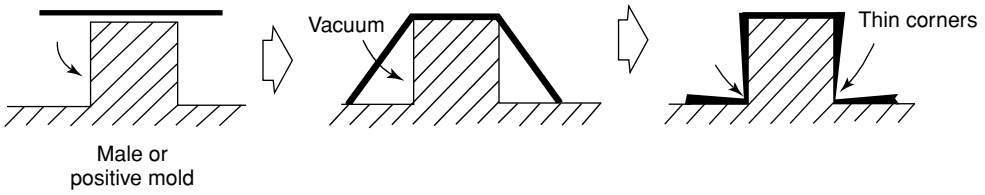

Fig. 7. Male or positive forming (17).

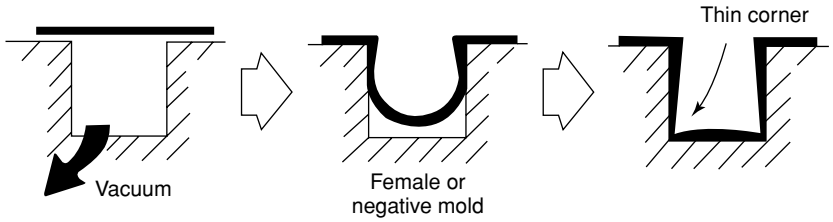

Fig. 8. Female or negative forming (17).

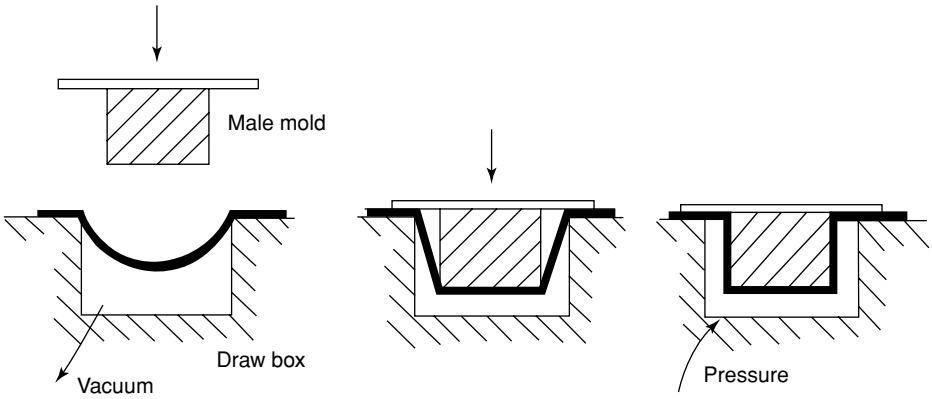

Fig. 9. Schematic of vacuum draw box prestretching, followed by male or positive mold insertion (18).

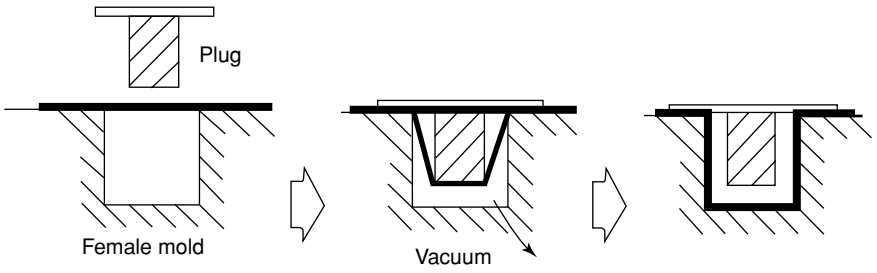

Fig. 10. Schematic of plug-assisted female or negative forming (18).

Prestretching is used to improve part wall thickness. Pneumatic stretching (*billow forming* or use of *vacuum draw box*; Fig. 9) is used with male molds. Mechanical stretching (*plug assist* or *push forming*) is frequently used with female molds (Fig. 10) (19). When the sheet has been stretched to near the bottom of the mold cavity, a combination of vacuum and compressed air is used to force the sheet off the plug and against the mold surface.

Pressure forming is used when the plastic is very stiff at the forming temperature, as with oriented polystyrene, when molded part requires surface detail and sharp radii or when the parts are deeply drawn. Thin-gauge pressure forming is commonly used for drink cups, deli containers, and pudding cups.

Matched mold forming is used when the plastic is very stiff at the forming temperature, as with highly filled or reinforced polymers or foamed polymers. Slip forming is used when the sheet cannot be easily stretched, as with continuous-glass reinforced polymers. During forming, the heated sheet is allowed to slide through the clamping frame. Diaphragm forming uses a heat-resistant neoprene or silicone membrane or bladder that carries the heated sheet into the mold cavity. The diaphragm is usually inflated with hot oil.

Twin-sheet forming produces hollow or semihollow parts. Both halves of a part are typically formed in female molds, and then pressed together to affect a

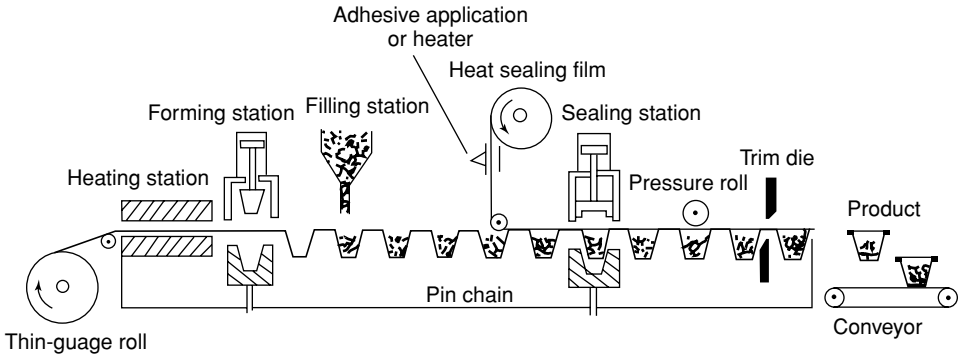

Fig. 11. FFS forming (19). Used with permission of Hanser Publications.

peripheral seal as well as internally welded regions. Both heavy-gauge and thin-gauge parts are twin-sheet formed.

Contact forming or trapped sheet forming is used primarily with thin-gauge FFS applications (Fig. 11) (19). The sheet is heated on one or both sides by direct contact with heated metal surface. The hot sheet is then drawn into the mold cavity. From that point, the sheet containing the formed parts is mechanically pulled through the filling, sealing, and trimming steps. Mechanical forming usually does not require a mold. The plastic sheet is machined to shape, and then locally heated and mechanically formed into the final part shape, where the open seams are glued. Cuspation also uses no mold. Instead the heated sheet is impaled at high speed with sharp projections (20). The product is a three-dimensional mat that competes with honeycomb and medium density foam.

In the 1970s, the Dow Chemical Co. developed a technique for forming shapes from sheet without the need to trim and regrind. In the scrapless thermoforming process (STP), the sheet is diced into squares (21). The squares are then coated with lubricant and heated in a conveyor oven. Each square is then placed in a forging press where it is formed into a disk. The disk is then pressure formed into an axisymmetric container. STP has merit when multilayer sheet trim cannot be successfully reprocessed. Billet forming also uses precut shapes, usually disks called billets. These are mechanically loaded into clamping fixtures that are then conveyed through an oven. Each tray containing the billets is then conveyed to a forming press where ring clamps secure the billets prior to plug-assist thermoforming into cavities. This technique is used to produce bottle liners, paint can liners, and condoms.

Heavy-gauge sheet stays at the forming temperature far longer than thin-gauge sheet or film. As a result, many more processing steps are possible with heavy-gauge sheet. The techniques are cataloged as to whether the mold is male or female, whether the sheet is prestretched with air or with a plug, and whether the stretching force is applied through pressure or vacuum (22).

Direct extrusion-to-forming is used in both thin- and heavy-gauge forming. Can lids and picnic plates are typical shallow-draw thin-gauge products produced by extruding sheet directly onto a wheel assembly that contains myriad molds. The key to quality wheel production is ensuring that the sheet is sufficiently cool

during stretching. In heavy-gauge forming, after exiting the extrusion die, the sheet is usually cooled until somewhat rigid, then reheated in the in-line thermoformer. Since the sheet is continuous, the thermoforming machine is similar to a traditional roll-fed thin-gauge thermoforming machine. This technology is employed when production runs are long, as with refrigerator door liners.

There are three essentially separate sequential phenomenological steps in thermoforming—heating, stretching, and trimming (technically mechanical breaking or fracture).

Heating. Three general methods of inputting energy to sheet are convection, conduction, and radiation.

Conduction is energy transfer by direct contact between the sheet and a heating source. Contact heating is used when the sheets are very thin. FFS machines frequently use contact heating with the forming station being integral to the heating plate. Polymer density, specific heat (enthalpy or heat capacity), thermal conductivity, and thermal diffusivity are important in conduction. Conduction is also the method by which energy moves through the plastic sheet. Polymers are thermal insulators when compared with metals. Conduction of heat from the sheet surface to its interior is a controlling factor for heavy-gauge plastic sheets.

Convection is energy transfer between moving air and the plastic sheet surface. Convective heat transfer is always present since the heating sheet is surrounded by ambient air, and the free surface of the formed part is in contact with ambient or fan-driven air. Typically, energy transfer is low when the air is quiescent and only slightly higher when air is positively moved across the sheet or formed part surface. Convective hot-air ovens are used to heat very thick sheet.

Radiation is electromagnetic energy interchange between hot and cold surfaces in view of each other. For most thermoforming processes, most of the radiant energy is in the far-infrared wavelength range, from about 2.5 μm to about 15 μm (Fig. 12) (23). Radiant heat transfer efficiency depends on the absorbing and emitting characteristics and the relative dimensions and spacing of the heating source and the polymer material. Radiation heat transfer provides the fastest and most versatile means for heating sheet in thermoforming. The energy output from

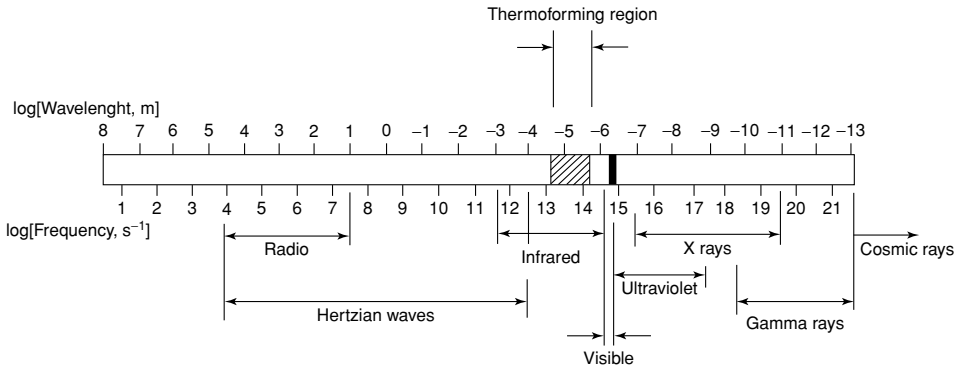

Fig. 12. Electromagnetic domain showing thermoforming region as portion of infrared band (23). Used with permission of Hanser Publications.

radiant heaters is typically in the range of 30–60 kW/m^2 with a temperature range of 150–900°C. The common thermoforming heating sources are as follows (24):

(1) Hot air (including convection toaster ovens)
(2) Hot water/steam
(3) Sun lamps (drugstore variety)
(4) Nichrome spiral wire (such as toaster wire)
(5) Steel rod heaters
(6) Steel or nichrome tape
(7) Quartz tube heaters (nichrome wire, tungsten wire or tape)
(8) Halogen heaters (halogen-gas filled quartz tubes with tungsten wire or tape)
(9) Steel plates with embedded resistance wire
(10) Ceramic plates with embedded resistance wire
(11) Ceramic bricks with embedded resistance wire
(12) Quartz cloth heaters backed with exposed nichrome wire
(13) Steel plates that reradiate combustion energy from gas flame
(14) Steel wire grids that reradiate combustion energy from gas flame
(15) Ceramic plates that reradiate combustion energy from gas flame
(16) Indirect gas combustion on catalytic beds
(17) Direct gas combustion

Only a portion of the energy emitted by the heater actually reaches the sheet, as seen in Figure 13 (25). The selection of an appropriate heater depends on several factors:

(1) *Day-to-day running costs*. Energy costs for gas combustion heaters are about one-fourth of those for electric heaters.
(2) *Maintenance costs*. Quartz tube heaters are fragile and must be carefully cleaned. Rod heaters are rugged but can rapidly lose efficiency.
(3) *Initial installation cost*. Plate and panel heaters require less electrical connections than ceramic brick heaters. Catalytic combustion heaters require both gas and electric connections.
(4) *Heater versatility*. Quartz and halogen heaters heat very rapidly, compared with panel and catalytic combustion heaters. Ceramic brick heaters allow ease of zoning or pattern heating.
(5) *Polymer characteristics*. The sheet thickness and the polymer infrared radiation absorption characteristics may influence the heating method. Polymers with high infrared radiant transmission levels heat slower than polymers with low levels. Thin polymer sheets heat slower than thicker sheets. Polymers with higher thermal diffusivity values heat more uniformly than those with lower values. Crystalline polymers such as polyethylene and polypropylene require more energy to reach forming temperature than amorphous polymers such as polystyrene and poly(vinyl chloride) (PVC). Crystalline polymers benefit by preheating, with the preheater being placed

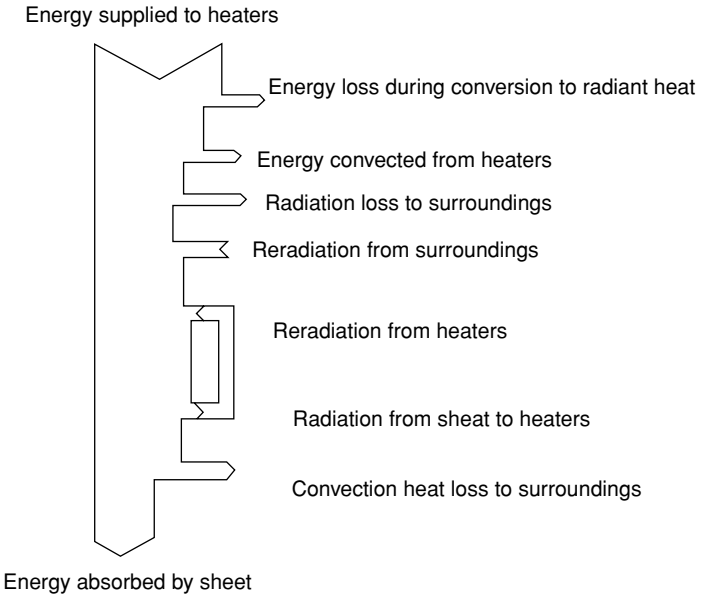

Fig. 13. Net energy transfer from heaters to sheet (25). Used with permission of Hanser Publications.

between the unroll stack and the pin-chain engagement on thin-gauge machines and as the first of two heaters on heavy-gauge four-station rotary thermoforming machines.

Most modern forming ovens heat sheet on both sides. Oven heater efficiency depends also on heater-to-sheet spacing, closed vs. open oven design, extent and reflective nature of nonheated surfaces, thermal protection of sheet clamping devices, heater-to-sheet area, and number of thin-gauge shots in the oven.

Sag bands or metal rods that run length of the thin-gauge oven have been used for polymers that sag excessively when heated. Some heavy-gauge shuttle thermoforming machines are equipped with ovens that completely seal the sheet between the heaters. These ovens are equipped with vacuum and compressed air, so that the sheet is lifted when it begins to sag.

Sheet Stretching. When the polymer sheet is at its forming temperature, it is transferred to the forming press where it is stretched against the mold surface. Technically, stretching is biaxial deformation of a nonisothermal rubbery elastic or viscoelastic membrane achieved through differential pressure across the sheet surface. Typical strain rates are up to 25 s^{-1}. The rubbery elastic characteristic of a polymer is described by its set of temperature-dependent stress–strain curves, as shown in schematic in Figure 14 (26).

The forming temperature region is the shaded portion. The polymer resistance to applied differential pressure and the polymer elongation at break determine the lower forming temperature. The level of sheet sag during heating determines the upper forming temperature. The maximum applied differential pressure is shown in Figure 14 as a horizontal line. The value represents the

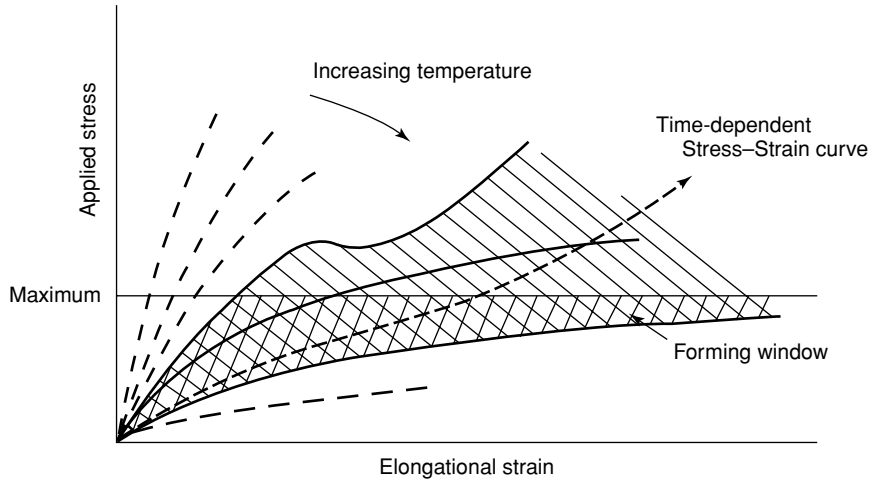

Fig. 14. Typical stress–strain schematic in thermoforming (26). Crosshatched region represents forming window. Used with permission of Hanser Publications.

applied vacuum in the case of vacuum forming or the extent of auxiliary air pressure used in pressure forming. The crosshatched area below this line represents the thermoforming window for a given polymer.

For most thermoforming operations using unfilled or unreinforced polymers, the differential pressure is less than 0.5–1.0 MPa (145 psi). Differential pressures of more than 3.0 MPa may be needed for high performance reinforced polymers.

Stretching against a mold surface is a differential process in that only that portion of sheet that is not in contact with the mold surface stretches. As a result, the part wall thickness varies substantially across the part surface, with the thinnest part being in the region where the sheet touches the mold last. There are two common ways of prestretching the sheet to improve wall thickness variation. In heavy-gauge thermoforming, the sheet may be prestretched using differential air pressure to inflate the sheet or draw it into a vacuum box. In both heavy-gauge and thin-gauge thermoforming, a solid shape or plug may be mechanically pressed into the sheet before differential pressure forces the sheet against the mold surface. The plug nearly uniformly draws the sheet between its bottom edge and the rim of the mold. As seen in Figure 15 (27), the effect is to pull material from the thicker regions of the part, thereby increasing the thickness of material in the region where the sheet touches the mold last.

Part wall thickness can now be predicted quite accurately with finite element analysis. The physical sheet is replaced with a two-dimensional mesh of triangular elements and nodes, which is then mathematically deformed under increasing load. When the nodes touch the electronic surface of the mold, they are affixed. Force continues to increase until all or most of the elements are rendered immobile. Currently the Ogden power-law model is used as the polymer elastic constitutive equation or response to applied load (28).

Although elastic stress–strain behavior describes sheet stretching for most thermoforming processes, sheet deformation during plug-assist prestretching is

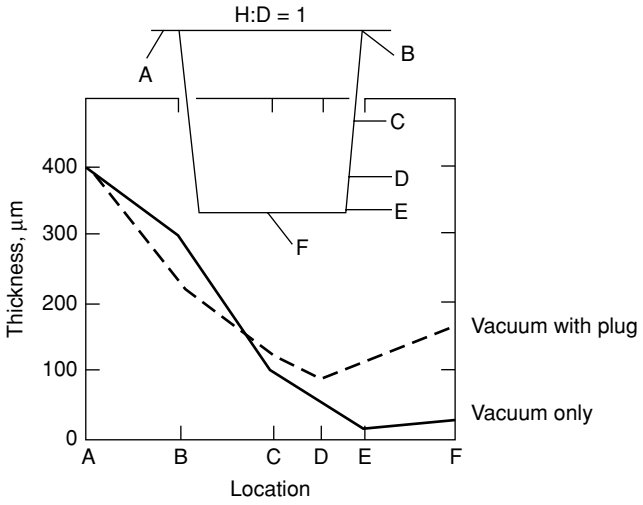

Fig. 15. Comparison of wall thickness variation with and without mechanical plug assist (27). Used with permission of Hanser Publications.

best described as viscoelastic. That is, the polymer responds as an elastic liquid with unrecoverable deformation occurring particularly in the contact region at the plug edge. Currently, the Kaye-Bernstein, Kearsley, Zapas model is used for the polymer viscoelastic response to applied load.

Rigidifying the Part. Commercial molds are temperature-controlled. In heavy-gauge thermoforming, cooling time on the mold surface may control the overall cycle time. Energy is removed from the polymer part by conduction through the single mold surface to recirculating coolant in the interior of the mold. Forced-air free-surface cooling helps reduce cooling time.

Trimming. *Trimming* is mechanical cutting or breaking of cooled plastic. Although there are many ways of cutting plastic, including laser and water jet cutting, most commercial thermoforming operations use either of two approaches (29). Compression cutting involves the mechanical pressing of a sharp metal edge against the plastic part. It is usually used to trim plastic less than 1.5 mm in thickness or low density foam plastic of any thickness. The sharp metal edge, usually a steel rule die, can either be pressed against an anvil or can squeeze the plastic between a forged die and a punch that has interference fit with the cutting edge (30).

Chip cutting involves mechanical breaking away of small pieces of plastic with a multitoothed blade or wheel, in a kerf between the desired part and the selvedge. It is generally used to trim plastic with thickness greater than 3 mm, and for filled and reinforced plastic. Bandsaws, hand-held drills and routers, and table-mounted circular saws are used for general cutting such as hogging the part from its trim. Computer-driven three-axis and five-axis routers are now used for more accurate trimming, especially where holes and slots must be cut into the part. The parts are usually tightly held with vacuum against a rigid fixture while being trimmed. The selection of the trim bits and the depth and speed of trimming depends strongly on the polymer being cut.

Process and Product Control. Machine control has steadily progressed from relay clock timers to programmable logic controllers controls to all-computer controls. On-board computers not only control the process variables but also are used extensively for inventory control. Even though infrared sensors have been used for years to measure single-point sheet temperatures during oven heating, exiting sheet on temperature alone is still novel. Recent line scanning of moving sheet has enabled operators to manually adjust heaters, but feedback heater temperature control has yet to find acceptance. Thermography or two-dimensional infrared imaging of hot surfaces is invaluable in determining heater performance, sheet temperature uniformity, effect of zone heating on sheet temperature, and mold temperature uniformity. The cost of these devices is a deterrent toward their wide acceptance as process monitors.

Thin-gauge all-electric machines were first developed for aseptic and clean-room medical packaging. In addition to minimizing lubricating and hydraulic oils, machine setup, including mold siting and in-press trim die adjustment, is far easier than with partially electric systems. Touch-screen setup programs and computer control have reduced setup time. For redoing previous jobs, these adjustments are automatic.

Incoming sheet quality control is of prime importance to the thermoformer. In addition to residual sheet orientation induced during extrusion, sheet quality monitoring must include gauge thickness, squareness for cut sheet, surface gloss or texture, color and color uniformity, identification and control of defects such as pits, gels, scratches, die lines, and optical distortion, melt flow characteristics of polyethylenes and polypropylenes, crystallinity level and intrinsic viscosity of poly(ethylene terephthalate), and mechanical properties such as impact strength, tensile strength and modulus, elongation at forming temperature, and tear resistance for thin-gauge sheet. In many cases, thermoformers may accept certification of many of these parameters from either the sheet extrusion house or the polymer supplier. In some cases, the thermoformer should run his/her own tests to ensure incoming product quality (31).

Mold design accuracy and part quality assurance have benefited from computerized coordinate measuring machines. Coordinate measuring machines provide valuable information on part reverse engineering and local part shrinkage value determination. Mold and plug design and fabrication now depend on computerized design and mold manufacture. And computer numerically controlled trimming devices in heavy-gauge forming have accelerated designer and user acceptance of thermoformed parts.

Material Characteristics

Usually if a polymer can be extruded or cast into sheet form, it can be thermoformed. Since the basic thermoforming processes use less than 1 MPa forming pressures, nearly all thermoformable polymers are unfilled or unreinforced. The thermoforming process relies on the “hot strength” of the polymer to minimize sagging during heating. As a result, most thermoformable polymers are amorphous (see AMORPHOUS POLYMERS). Styrenics,

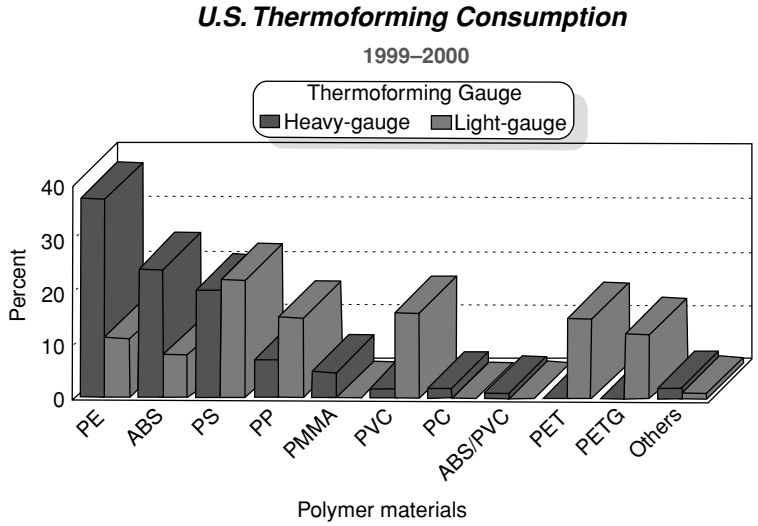

Fig. 16. U.S. plastic materials consumption for thin-gauge (2.1 million metric tons) and heavy-gauge (682,000 t) thermoforming (32). Redrawn and used with permission of SPE Thermoforming Division.

particularly polystyrene (see STYRENE POLYMERS) and ABS (see ACRYLONITRILE–BUTADIENE–STYRENE POLYMERS), amorphous poly(ethylene terephthalate) (see POLYESTERS, THERMOPLASTIC) [APET], PVC (see VINYL CHLORIDE POLYMERS), poly(methyl methacrylate) (see METHACRYLIC ESTER POLYMERS) [acrylic], and polycarbonates (qv) are commonly thermoformed. The only crystalline polymer in wide use is high density polyethylene, which has excellent elasticity in the melt state (see ETHYLENE POLYMERS, HDPE; SEMICRYSTALLINE POLYMERS). Newer grades of polypropylene are being designed specifically for thermoforming. Figure 16 shows current U.S. polymer usage in both thin-gauge and heavy-gauge thermoforming (32).

In addition to "hot strength" or elasticity at the forming temperature, other intrinsic polymer characteristics are important in thermoforming. The chemical makeup of the polymer dictates the extent of infrared energy absorption or its counterpart, infrared energy transmission. At the same thickness, polyethylene has a higher infrared transmission level and therefore lower radiant energy absorption than polystyrene. This is seen by comparing the infrared spectra of polyethylene (Fig. 17) and polystyrene (Fig. 18) (33). As expected, the fraction of energy transmitted through the polymer film decreases with increasing film thickness. Infrared energy transmission spectra are usually available from polymer material suppliers.

The forming window for a given polymer can be quantified by differential thermal mechanical analysis. Specifically, the temperature-dependent elastic modulus is key, as shown in Fig. 19, for typical thermoformable polymers (34). An adequate forming window is dictated if the modulus curve shows a flattening or

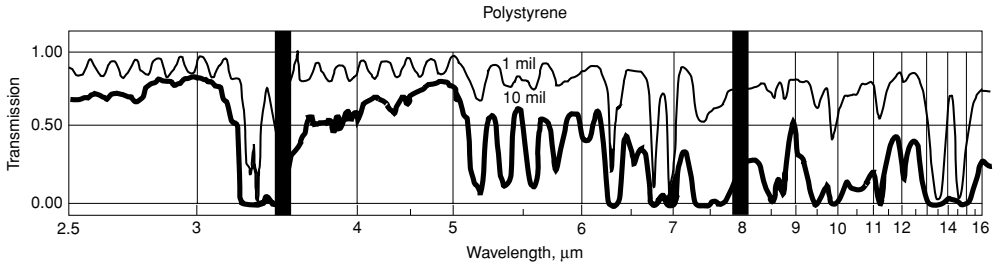

Fig. 17. Infrared transmission spectrum for two thicknesses of polystyrene (33). 1 mil = 25.4 μm. Used with permission of Hanser Publications.

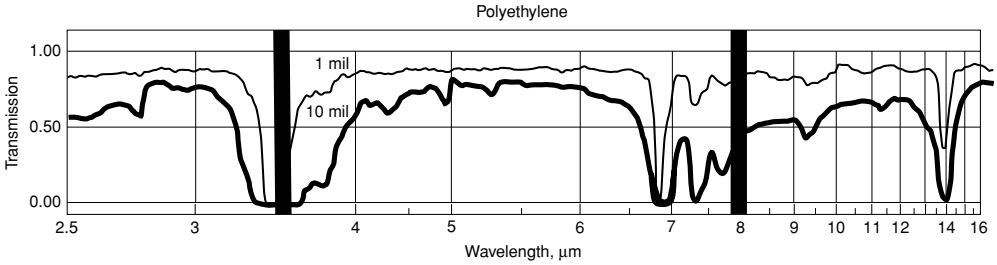

Fig. 18. Infrared transmission spectrum for two thicknesses of polyethylene (33). 1 mil = 25.4 μm. Used with permission of Hanser Publications.

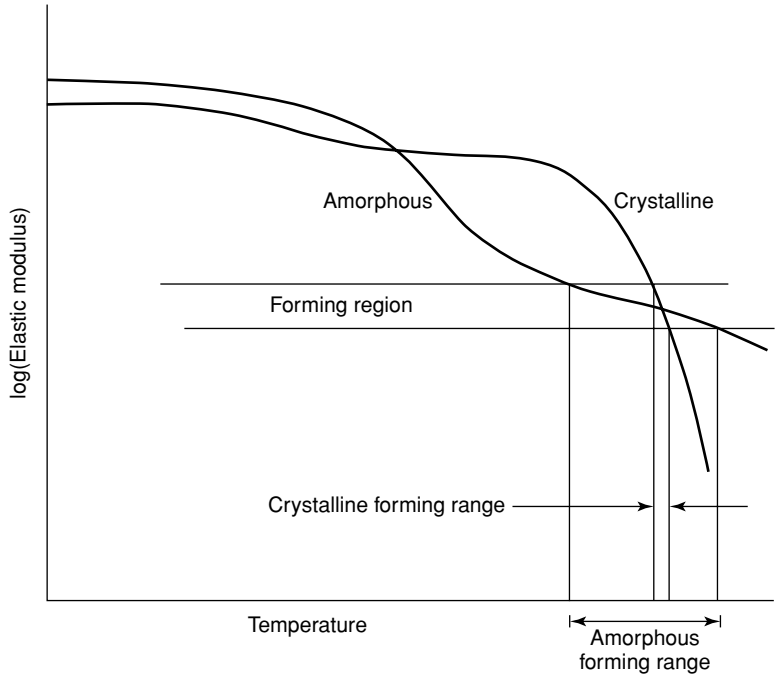

Fig. 19. Typical temperature-dependent elastic moduli of an amorphous and a crystalline polymer, showing forming regions for both (34).

plateauing at a value range consistent with normal thermoforming differential pressure. If the polymer modulus curve shows little flattening or if the flattening occurs at a very low value, the polymer may have a small forming window or none at all. If the flattening occurs at a very high value, normal forming pressures may be inadequate to stretch the polymer into detailed or complex molds.

Polymer thermal properties, such as temperature-dependent specific heat or enthalpy, thermal conductivity, and thermal diffusivity are also important. Although thermoforming is a thermally and mechanically gentle process insofar as the polymer is concerned, the general process of extrusion, thermoforming, regrinding, and potentially multiple reextrusions may lead to extensive molecular damage (35). This is particularly true with thermally sensitive polymers such as PVC and poly(ethylene terephthalate). Thus intrinsic polymer thermal stability and thermal and mechanical stability of the additives must be considered.

By far the majority of sheet formed does not contain fillers or reinforcing fibers. Fillers and fibers increase polymer stiffness but usually not polymer transition temperatures. Polymers containing up to 40 wt% talc, calcium carbonate, glass cullet, and diatomaceous earth are typically pressure formed at higher than usual temperatures. Polymers containing moderate levels of chopped glass and carbon fiber and certain types of nonwoven fibers are also pressure formed or matched mold formed. Fillers and fibers affect the radiative and thermal properties of the sheet. Organic dyes used to color transparent polymers usually do not affect the radiative characteristics of the polymers. Inorganic pigments have particle sizes that may interfere with volumetric radiant absorption.

And although thermoforming is basically a rubbery solid deformation process, the viscoelastic character of the polymer may need to be understood, particularly for the plug-assisted forming process. Computer-aided design programs also may need polymer viscoelastic properties. This may be particularly true for crystalline polymers such as polyethylene and polypropylene when formed above their melt temperatures. This is discussed below.

Excessive and/or inconsistent residual orientation in polymer sheet induced during the extrusion process can be a vexing problem in thermoforming. Thermoformers work with extruders to keep both machine-direction and cross-direction orientations to 5% or less. Table 3 gives advantages and disadvantages of several thermoformable polymers.

Mold Materials

Since thermoforming is a low pressure process, production molds are made of soft metals such as aluminum (36). Very large heavy-gauge molds and some thin-gauge molds are commonly sand-cast of A356 aluminum. Multicavity thin-gauge molds and some smaller heavy-gauge molds are machined from A6061 aluminum. For polymers requiring higher forming temperatures, such as polysulfones (qv) or polycarbonates (qv), machining grade A7075 aluminum is used. Machined 316 stainless steel is used on occasion for corrosive polymers such as rigid poly(vinyl chloride). Electroformed nickel molds are used when extreme mold detail is required. Regions far from cooling sources may be made of higher thermal conductivity metals such as copper–aluminum alloy or bronze. Pinch-off areas may be

Table 3. Advantages and Disadvantages of Thermoformable Polymers[a]

Polymer	Processing temperature range, °C	Advantage	Disadvantage
Polystyrene (TG)	150–190	Easily formed	Brittle
		Inexpensive	Tenacious trim dust
		Easily extruded	Plug mark-off
High-impact polystyrene (HG, TG)	160–205	Available	Limited elongation
		Good impact	Yellows at high temp
		Easily colored	May smoke
			Hazy, translucent
ABS HG)	150–205	Great toughness	Absorbs moisture
		Easily formed	Yellows at high temp
			Splitty at low temps
			FR grades stiff
Modified polyphenylene oxide (HG)	165–220	Forms like HIPS	Stiff at mod temps
		Fire-retardant	Odor at forming temp
		Great pressure-formed	Usually trim cold
			Tenacious trim dust
Oriented polystyrene (TG)	130–160	Superior surface gloss	Careful heating
		Great impact strength	Trimming difficult
		Great opticals	Expensive
			Direct contact heating
Poly(methyl methacrylate) (acrylic) (HG)	150–205	Great gloss	Somewhat moisture sensitive
		Readily formed	Easily scratched
		Excellent UV	Brittle in sharp corners
Poly(methyl methacrylate)/poly(vinyl chloride) (HG)	150–190	Great pressure-formed	Yellow at high temps
		Good fire retardancy	Brittle in trimming
			Good outdoor appl.
Extra tough polymer (hg, TG)	150–180	Good toughness	Expensive
		Good clarity	Not normally a stock item
		Good chem. resistance	
Flexible PVC (hg, TG)	105–150	Good drawability	Weak at high temps
		Fire retardant	Plasticizer odor
		Good automotive matl	Grain wash at high temps
Rigid PVC (HG)	120–180	Fire retardant	Yellows at high temps
		Easily colored	Low T_g
		Tough	Difficult prestretch
		Moderate transparency	Narrow processing window
		Outdoor appl.	Recycle times limited

Table 3. (Continued)

Polymer	Processing temperature range, °C	Advantage	Disadvantage
Low density polyethylene (TG)	125–175	Tough	Poor high temp char.
			Excessive sag
			Narrow forming window
			Haze at high temps
			Sticky on plugs
High density polyethylene (HG)	140–195	Tough	Excessive sag
		Good melt strength	Black heats fast
		Fractional melt index	
Polypropylene (hg, TG)	145–165	Tough	Narrow forming window
		High temp appl.	Excessive sag
		Can be transparent	Plug mark-off
		Best pressure-formed	Can be sticky
		Heavy-gauge matls now	Whiskers during trimming
EP copolymer (TG)	130–180	Forms like high denisty polyethylene	Sags at high temp
		Forms best cool	Clean trim difficult
Oriented polypropylene (TG)	145–160	Very low haze	Expensive
		High gloss	Must be heated very carefully
		Great impact strength	Sags, loses orientation
		Contact heat best	
Ethylene–vinyl acetate (TG)	135–150	Draws well	Easily torn
			Narrow forming window
Polypropylene – −20% talc (hg, TG)	150–205	Forms well	Stiff at forming temp
		Plug desired	Low elongation at high temp
		Best pressure-formed	Matte surface
Polypropylene – −40% glass-reinforced (HG, tg)	150–230	Best pressure-formed	Very stiff at forming temp
			Shallow draw best
			Plug assist questionable
Polycarbonate (HG)	180–230	Great UV resistance	Stiff at forming temp
		High temp appl.	Moisture sensitive
		Good forming window	Trim very difficult
		Good colors	

Table 3. (Continued)

Polymer	Processing temperature range, °C	Advantage	Disadvantage
Amorphous poly(ethylene terephthalate) (TG)	125–165	Tough thin-gauge	Sags, necks
		Orients, toughens	Crystallizes rapidly
		Transparent	Difficult cold trim
			Trim must be recrystallized
Crystallizable poly(ethylene terephthalate) (TG)	185–200	High temp appl.	Mold temp control
			Very stiff when hot
			Crystallinity control difficult
			Brittle when too crystalline
Glycol-modified poly(ethylene terephthalate) (HG, TG)	160–180	Good toughness	Somewhat costly
		Good colors	Limited sourcing
		Good forming window	Can yellow at high temp
			Not good outdoor matl
Cellulosics (TG)	140–165	Excellent clarity	Expensive
		Great toughness	Lost market to PVC, PET
		Good forming window	Somewhat moisture sensitive
			Limited availability
Thermoplastic elastomer (TG)	135–180	Draws well	Spring-back
		Many versions to choose	High rubber difficult
		Automotive darling	May tear at high temp
			Grain wash at high temp

[a]Key: HG = major heavy-gauge; TG = major thin-gauge; hg = minor heavy-gauge; tg = minor thin-gauge; no notation, not normally used.

made of carbon steel. Gaskets in pressure boxes are usually made of neoprene or silicone.

Thermoforming is one of the major processes used to produce prototype parts that may be made other ways, such as injection molding. Many materials are used to produce molds that are serviceable for a few to a few hundred parts. Traditional mold materials include wood, plywood, hard plaster such as Hydrocal (US Gypsum), and medium density fiberboard. Sprayed and cast white metal are used on occasion.

Recently, prototype molds are being fabricated from particle-filled polyurethane and epoxy syntactic foams using computer-aided multiaxis routers. Plugs, used to mechanically prestretch polymer sheet, are also usually machined from syntactic foams. For certain polymers, heated aluminum plugs or solid nylon plugs are desired.

Part Design

In general, thermoforming may be described as a differential stretching process. The sheet free of the surface continues to thin as it is drawn against the mold surface. As a result, the thickest portion of the part is where the sheet touches the mold first and the thinnest is where the sheet touches the mold last. Prestretching techniques move sheet from the thicker areas to the thinner ones, but in general, thermoformed parts have nonuniform wall thicknesses. Female parts tend to have thicker rims and thinner two- and three-dimensional corners. Male parts tend to have thicker two- and three-dimensional corners and bottoms and thinner rims. Multicompartment parts with both male and female sections, sometimes called androgynous parts, require careful mold design and proper sizing of plugs to minimize very thin sidewalls and internal webbing and to provide adequate internal draft angles.

Recently, computer-aided design programs have been devised that allow prediction of part wall thickness (37,39). These programs use finite element analysis, with the sheet being characterized as a two-dimensional mesh of nodes forming triangular elements. Although the earliest programs used Mooney-Rivlin constitutive equations of state to describe purely elastic polymer response to the applied differential load, current programs use the doubly infinite semiempirical Ogden model, with the series truncated at two or four elements. The K-BKZ constitutive model is used to describe viscoelastic behavior (39). An example of a computer-generated thickness profile is given as Figure 20.

Computer-aided wall thickness prediction is compromised by measured variation in actual part wall thickness due to the practical intrinsic variation in processing parameters, as seen in Figure 21 for thin gauge parts and Figure 22 for heavy-gauge parts (40).

Distortion-printed products have been used since World War II (41). Until recently, the standard technique involved thermoforming a polymer sheet to the desired shape, painting the desired design on the shape, and then reheating the shape to a flat sheet. This has been largely replaced with finite element computer programs that carry out the entire process electronically.

Most amorphous polymers linearly shrink about 0.4–0.6%. Crystalline polymers such as high density polyethylene and polypropylene linearly shrink about 2.0% (42). Thermoformed parts shrink away from female molds and onto male molds. Male molds must have typical draft angles of 2–5°, but sufficiently great enough to allow release of the formed parts. Female molds need minimal, if any, draft angles.

Many thermoformed parts contain undercuts. Detents and interlocking lugs are frequently used in thin-gauge packages with integral lids. Undercuts in

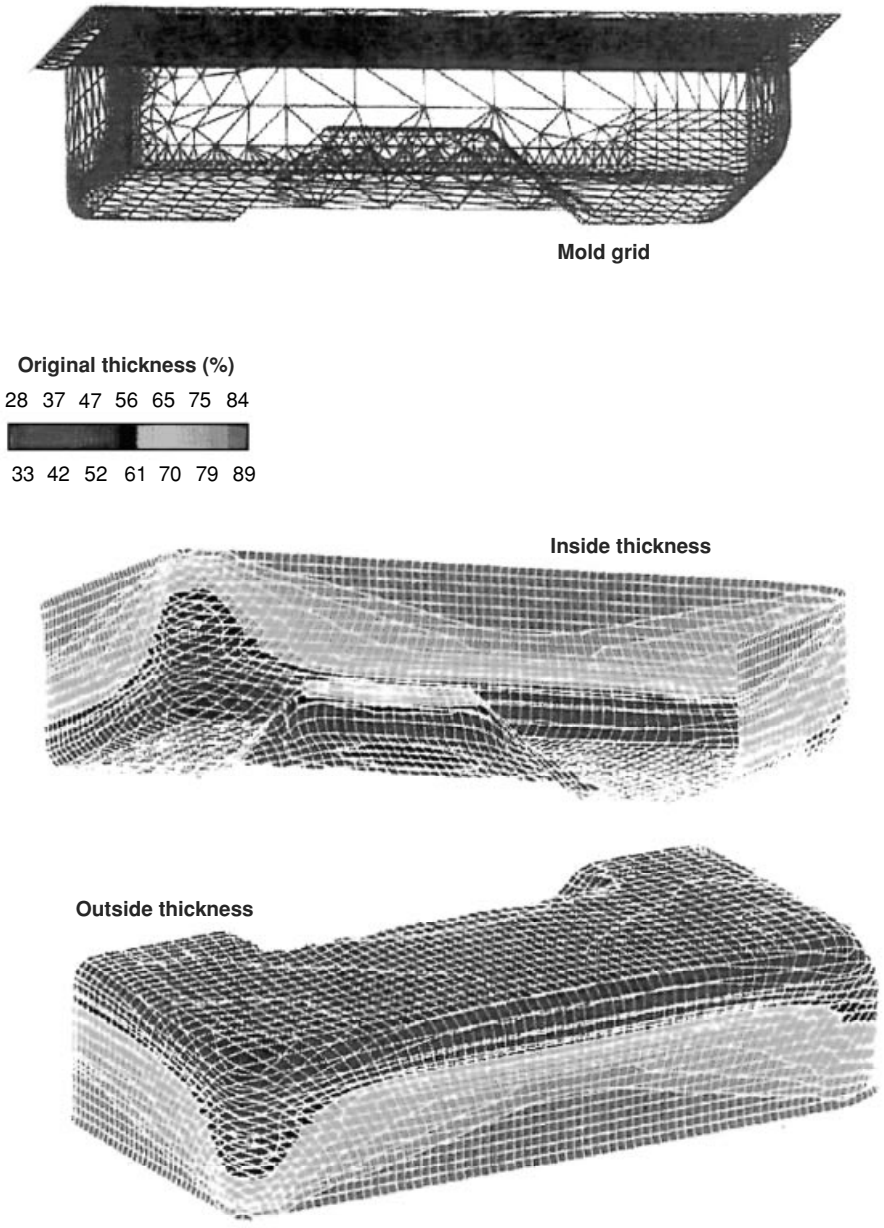

Fig. 20. Finite element analysis of local wall thickness for drawdown into negative mold (39). Used with permission of Institut für Kunststoffeverarbeitung, Aachen, Germany.

heavy-gauge parts are achieved with swing-away sections that are either manually or pneumatically activated (43).

Holes are machined into heavy-gauge parts in the post-forming, trimming operation. Holes are punched into thin-gauge parts just prior to cutting the parts from their web.

Newer Technologies

Twin-sheet thermoforming is more than a century old. Recent interest in returnable shipping pallets has rekindled this heavy-gauge technology. The competition is rotational molding and blow molding, major technologies for producing hollow parts. Twin-sheet forming forte lies in manufacturing high aspect ratio parts with many welded areas, such as shipping pallets, backboards, tabletops, and door panels. The key to quality twin-sheet parts is the integrity of the seal area between the two formed plastic sheets. This is particularly important in sequential forming, where the first formed plastic sheet resides on its mold half while the second sheet is being formed. High density polyethylene is the preferred polymer, since it remains tacky throughout this interval. Rigid PVC and ABS have also been twin-sheet formed economically. Although the earliest twin-sheet parts were of thin gauge, interest is only recently been rekindled in this area, with commercial successes in medical devices and liquid containers.

Multilayer polymer film and sheet are thermoformed into packages when moisture, odor, and/or oxygen barriers are needed. A typical multilayer package consists of a rigid outer polymer such as polystyrene, followed by an adhesive layer, an oxygen barrier film such as ethylene vinyl alcohol, another adhesive layer, and a moisture barrier inner polymer such as polyethylene or polypropylene. Although multilayer films and sheets are relatively easy to thermoform, the growth in the market has been limited by the difficulty in reprocessing the trim.

Thermoplastic foam sheet of polystyrenics or polyolefins are thermoformed into impact resistant packages. Typically, care must be taken to avoid overheating low density foam sheet. Foams are usually quite stiff at forming temperatures and matched mold tooling is normally used to achieve reasonable draw ratios (44). For advanced applications where the packages must act as both rigid containers and moisture absorbers, mechanical, thermal, and phase separation means are used to open foam cells. These foams are usually formed at higher temperatures on single-surfaced molds. Even when foamed, polylactic acid and polystarch derivative polymers thermoform well into compostable or degradable containers.

Heavy-gauge thermoforming owes much of its continuing success against injection molding to the adaptation of computer numerically controlled routers from the woodworking industry (16). Computer-controlled routing has allowed accurate nonplanar trim lines, reproducible slotting, and accurate hole drilling.

Even though lightly filled polymers have been thermoformed for decades, the majority of the sheet formed contains no fillers or fibers. Recent developments in forming reinforced thermoplastic sheet include a thermoformed all-composite bumper assembly for BMW (Jacob Composite GmbH, Dresden, Germany, 2002) and composite bed leaf springs (45). Currently, glass-reinforced polypropylene and nylons are the preferred polymeric materials. This work is being spurred by newer technologies in heating and bending the less-extensible sheet.

URETHANE COATINGS

Introduction

Polyurethanes (qv) are polymers containing urethane (—NH—COO—) linkages; carbamate is a synonym for urethane. Urethanes are usually formed by reaction of an alcohol with an isocyanate, but they can also be made by other methods. Commonly, urethanes made by a nonisocyanate route are called carbamates. To add to the confusing terminology, the terms *urethane* and *polyurethane* are applied to almost any binder derived from isocyanates even though only part, if any, of the reaction products are urethanes. The article on polyurethanes discusses synthesis and sources of various polyisocyanates.

An important advantage of most urethane coatings is the superior abrasion resistance of their films. The abrasion resistance results from the strong intermolecular hydrogen bonds between urethane groups. Under mechanical stresses, energy (about 20–25 kJ/mol of hydrogen bonds) may be absorbed by separation of hydrogen bonds, which re-form when the stress is removed (though probably in different positions). Energy absorption by this reversible process reduces the likelihood of irreversible breaking of covalent bonds, leading to degradation. This permits design of polyurethanes that are abrasion resistant while still resisting swelling with solvents. The isocyanate group is highly reactive, and so polyisocyanates can be used to make coatings that cure at ambient temperature or at moderately elevated temperatures. Coatings based on aliphatic diisocyanates exhibit exceptional exterior durability when stabilized with hindered amine light stabilizers (HALS). Resistance of urethane coatings to environmental etching is superior to that of many melamine–formaldehyde (MF) cross-linked coatings (1). The principal limitation of urethane coatings is cost relative to many other binders.

Isocyanates react with alcohols and phenols to form urethanes. In general, rates of urethane formation decrease in the following order: primary alcohols > secondary alcohols > 2-alkoxyethanols > 1-alkoxy-2-propanols. Isocyanates can react with urethanes to form allophanates. This reaction is much slower than the reaction of isocyanate with alcohol. Isocyanates react rapidly with primary and secondary amines to form ureas. The reaction is much faster than the reaction of isocyanates with alcohols. Isocyanates can react with ureas to form biurets. Biuret formation is slower than urethane formation, but faster than allophanate formation. Isocyanates react with water to form unstable carbamic acids, which dissociate into carbon dioxide and an amine. The amine is so much more reactive that it reacts with another isocyanate (in preference to water) to form urea. The reactivity of water with isocyanates is somewhat slower than that of secondary alcohols, but much more rapid than that of uncatalyzed reaction with urethanes or ureas.

Imines act as blocked amines because they hydrolyze to yield free amines, which react with an isocyanate. Ketimines also react directly with isocyanates to yield a variety of products, depending on the particular reactants and conditions. Aldimines react analogously with isocyanates to yield unsaturated substituted ureas. Since aldimines are more stable to hydrolysis than ketimines, the fraction undergoing direct reaction with isocyanate in the presence of water is greater than that with ketimines. Carboxylic acids react relatively slowly to form amides and CO_2. Hindered carboxylic acid groups, such as in 2,2-dimethylolpropionic acid (3-hydroxy-2-(hydroxymethyl)-2-methylpropanoic acid) [4767-03-7], react very slowly.

Isocyanates also react with each other to form dimers (uretdiones) and trimers (isocyanurates). Formation of uretdiones is catalyzed by phosphines. Formation of isocyanurates is catalyzed by quaternary ammonium compounds; trimerization of aromatic isocyanates is catalyzed by tertiary amines. Uretdiones decompose thermally to regenerate isocyanates and are used as blocked isocyanates. Isocyanurates are stable and isocyanurates of diisocyanates are extensively used as multifunctional isocyanates.

Reactions of isocyanates with alcohols are catalyzed by a variety of compounds, including bases (tertiary amines, alkoxides, and carboxylates), metal salts and chelates, organometallic compounds, acids, and urethanes. The most widely used catalysts in coatings are organotin (IV) compounds, most commonly dibutyltin dilaurate (DBTDL) (dibutylbis[(1-oxododecyl)oxy]stannate) [77-58-7] and tertiary amines, commonly diazabicyclo[2.2.2]octane (DABCO). Combinations of DABCO and DBTDL often act synergistically.

DBTDL is soluble in a wide range of solvents, comparatively low in cost, colorless, and, in general, highly effective at levels of the order of 0.05 wt%. DBTDL promotes urethane formation without promoting allophanate formation (2) or trimerization (3). While aromatic isocyanates are more reactive than aliphatic isocyanates in uncatalyzed reactions with alcohols, the reactivity of aliphatics can be roughly equal with DBTDL. On the other hand, amine catalysts are more effective with aromatic than aliphatic isocyanates. Carboxylic acids inhibit catalysis by organotin compounds.

Isocyanates also react with water; if this happens in a solventborne coating during application, CO_2 is generated, which may reduce gloss or result in

bubbling. Catalyst selection affects the relative rate of reaction of isocyanates with hydroxyl groups and water. A zirconium acetoacetate complex [$Zr(AcAc)_4$] catalyst is reported to be more selective than DBTDL (4).

Isocyanates Used in Coatings

Both aromatic and aliphatic isocyanates are used in coatings; the former are less expensive and the latter provide films with better color retention and exterior durability. Diisocyanates are used in two broad types of ways: (*1*) as raw materials in the synthesis of resins and (*2*) as cross-linkers for resins with multiple substituent groups that are reactive with isocyanate groups. Isocyanates are toxic materials. When used as cross-linkers for coatings, they are reacted to form higher molecular weight isocyanate products with lower toxic hazards.

The aromatic isocyanates most widely used in coatings are bis(4-isocyanatophenyl)methane [101-68-8] (MDI) and 2,4-toluene diisocyanate (TDI) (2,4-diisocyanato-1-methylbenzene) [584-84-9]. MDI is available in several grades: a mixture of 90% of the 2,4′ isomer and 10% of the 4,4′ isomer; and several oligomeric (frequently called polymeric) MDI with longer chains of methylene phenyl groups. The cost is lower than TDI. When used as a cross-linker in coatings, the monomeric grade is converted to a low molecular weight prepolymer by reacting with a polyol such as trimethylolpropane. The polymeric grades have lower toxicity.

The most common grade of commercial TDI consists of a mixture of about 80% 2,4- and 20% 2,6-diisocyanato isomers. Nearly pure 2,4-TDI is also available at a premium price. Because of toxic hazards, TDI is not used as such in final coating formulations. For coatings in which unreacted isocyanate groups are needed, TDI is converted into derivatives of higher molecular weight and higher functionality. Higher molecular weight reduces the toxic hazard, and the higher functionality yields solvent-resistant films more rapidly. TDI has the advantage of a differential in reactivity between the ortho- and the para-isocyanate groups with alcohols, which makes possible synthesis of isocyanurates and prepolymers with narrower molecular weight distribution than with diisocyanates in which the isocyanate groups are equally reactive. A prepolymer prepared by the reaction of trimethylolpropane (TMP) (2-ethyl-2-(hydroxymethyl)-1,3-propanediol) [77-99-6] with a large excess of 2,4-TDI and then removal of excess TDI by using a vacuum wiped-film evaporator is widely used. The isocyanurate derived from TDI made by trimerizing TDI also has a lower toxic hazard than monomeric TDI; the reaction is almost exclusively at the 4-position.

The principal aliphatic isocyanates used are 1,6-hexamethylene diisocyanate (HDI) (1,6-isocyanatohexane) [822-06-0], bis(4-isocyanatocyclohexyl)methane (H_{12}MDI) [5124-30-1], and isophorone diisocyanate (IPDI) (3-isocyanato-1-isocyanatomethyl)-1,3,3-trimethylcyclohexane [4098-71-9]. Tetramethyl-*m*-xylidene diisocyanate (TMXDI) [2778-42-9] and *m*-isopropenyl-α,α-dimethylbenzyl-isocyanate (TMI) (1-(1-isocyanato-1-methylethyl)-3-(1-methylethenyl)benzene [2094-99-7] are specialty products used on a much smaller scale. Diisocyanates are only used as higher molecular weight derivatives in coatings to increase functionality and reduce toxic hazard.

HDI is especially hazardous and is handled on a large scale only in chemical plants. The first less hazardous derivative was a biuret, which can be made by reacting HDI with a small amount of water and then removing excess HDI. The presence of oligomeric biurets makes the average functionality higher than 3. These polyfunctional isocyanates give coatings with good color retention and weather resistance. The viscosity of an early commercial product was about 11.5 Pa·s (115 P) at 20°C. Grades with lower average molecular weights (and average functionalities nearer to 3) are available with viscosities as low as 1.4 Pa·s (14 P). HDI isocyanurates are used on a larger scale. The isocyanurate gives coatings with greater heat resistance and even better long-term exterior durability than HDI biuret. Commercial products contain oligomeric material, and average functionality is over 3. Grades with lower oligomer content with viscosities as low as 1 Pa·s (10 P) are available.

Allophanate derivatives of HDI and IPDI are another type of polyfunctional isocyanate. They are made by reacting an alcohol or diol with excess isocyanate, then removing unreacted diisocyanate with a wiped film evaporator giving an isocyanate-terminated allophanate (5). The properties can be varied by using different alcohols or diols to make the starting urethane. For example, the cetyl alcohol urethane from HDI yields an allophanate diisocyanate that is soluble in aliphatic hydrocarbons. Derivatives with higher functionality are made by reacting a glycol with excess diisocyanate.

The uretdione dimer of HDI also has lower volatility with low viscosity and can be used for cross-linking in ambient cure coatings. Very low viscosity grades, <100 mPa·s (=cP), are reported to permit formulation of very low VOC coatings (6).

H_{12}MDI is less volatile than HDI and is sometimes used as a free diisocyanate in coatings to be applied by roll coating, but not by spray coating. It is a mixture of stereoisomers; since both isocyanato groups are secondary, reactivity is lower than HDI or IPDI. Combined allophanate–isocyanurate derivatives are available with low free monomer content. Reference 7 covers the chemistry and uses of H_{12}MDI.

Commercial IPDI is a mixture of Z-(cis) and E-(trans) isomers in a 75:25 ratio. The isomers are difficult to separate. Isocyanurate derivatives of IPDI and prepolymers with TMP are widely used.

TMXDI and TMI have aromatic rings, but give color retention and exterior durability equivalent to aliphatic isocyanates. Since the isocyanato group is on a tertiary carbon, the reactivity is lower than that of less sterically hindered aliphatic isocyanates. This difference can be offset by using higher catalyst levels and sterically accessible tin catalysts such as dimethyltin diacetate (DMTDA) instead of DBTDL. TMXDI is offered as a low molecular weight, essentially diisocyanate-free, prepolymer with TMP. TMI is used as a comonomer with acrylic esters to make 2000–4000 molecular weight copolymers with 40–50 mol% TMI; thus each molecule has several isocyanate groups (8).

Two Package Urethane Coatings

The largest volume of urethane coatings is two package (2K) coatings that are mixed just before application. One package contains the polyol (or other

coreactant), pigments, solvents, catalyst(s), and additives; the other contains the polyisocyanate and moisture-free solvents. Sometimes, the catalyst is in a separate third package so that cure rate can be adjusted for variations in ambient conditions. While the major reaction is formation of urethane cross-links, some urea cross-links result from reaction of atmospheric water with the isocyanate.

Any hydroxy-functional coreactant can be used; hydroxy-terminated polyester and hydroxy-substituted acrylic resins are most common. In general terms, polyesters permit higher solids and give films with greater solvent resistance and better adhesion to metals. Acrylics provide faster dry, lower cost (since their equivalent weight is usually higher than that of polyesters, resulting in the need for less of the more expensive polyisocyanate), and better exterior durability, resulting from superior hydrolytic and photochemical stability. Since alkyd resins have unreacted hydroxyl groups, their rate of dry can be accelerated by adding a polyisocyanate such as the isocyanurate trimer of IPDI just before application. Nitrocellulose (shipped wet with plasticizer instead of ethyl or isopropyl alcohol) is used in formulating cross-linking furniture lacquers. Bisphenol A epoxy resins are also cross-linked with isocyanates through their hydroxyl groups. Hydroxy-terminated polyethers are used with aromatic polyisocyanates in flooring, roofing, and containment coatings.

Urethane coatings for maintenance paint applications are generally cured at ambient temperatures, while those for automobile refinishing and aircraft applications are cured at ambient or modestly elevated temperatures. If the T_g of the partially reacted system is near the temperature at which the cross-linking must occur, the rate of urethane formation becomes mobility controlled and cure rate is slow. If the T_g of the fully reacted system is significantly above the cure temperature, the reaction virtually stops before the cross-linking reaction has gone to completion (9). Water can continue to diffuse longer through such a matrix, and the last stages of reaction are predominately with water. Since in many ambient cure coatings, one wants a coating with a T_g somewhat above the curing temperature, selection of a combination of polyisocyanate and polyol that provides an appropriate final T_g is critical. A polyisocyanate with relatively flexible aliphatic chains (such as the isocyanurate of HDI) is used with a relatively high T_g acrylic or polyester. On the other hand, a polyisocyanate that yields relatively rigid cross-linked segments (such as the TMP/TMXDI prepolymer) requires a lower T_g acrylic or polyester.

An important variable in 2K polyisocyanate/polyol coatings is the ratio of available isocyanate groups to available hydroxyl groups (N=C=O/OH). In ambient cure systems, it is often found that a ratio of the order of 1.1:1 gives better film performance than a 1:1 ratio. A probable reason is that part of the N=C=O reacts with water from solvent, pigment, or air to give urea cross-links. The excess isocyanate assures that essentially all of the hydroxyl groups react, and subsequently all the remaining isocyanate groups react with water. Solvent resistance is improved. Some finishes, for example aircraft finishes, are formulated with N=C=O/OH ratios as high as 2:1. The resulting reduced hydroxyl concentration gives longer pot life. It is possible that the high mobility of water and the reactivity of amine groups resulting from the water/isocyanate reaction favor faster reaction rates at higher T_g values than possible with only the hydroxyl/isocyanate reaction.

There is always a compromise between pot life and curing time. Several formulating variables are available to increase pot life with little effect on cure time. Concentrations of reactive groups should be kept as low as possible; this becomes more difficult as one formulates to increasingly higher solids. As noted in the preceding paragraph, using mixed polyol/moisture curing systems helps. Since isocyanate/alcohol reactions proceed most slowly in media with high levels of hydrogen-bond accepting groups, solvents which are strong hydrogen-bond acceptors should be selected to the extent possible, and resins should be designed, if possible, with low levels of hydrogen-bond accepting groups. After application, as the solvent evaporates, the medium becomes less hydrogen-bond accepting and the reaction rate increases accordingly. This strategy serves the purpose of both extending pot life and promoting reactivity after application. However, it should be noted that solvents with greater hydrogen bond accepting strength tend to have higher viscosities, higher solids and longer pot lives are obtained with solvents having intermediate hydrogen-bond accepting strength (10).

Organotin catalysts are generally preferable to amine catalysts because reaction rates depend on alcohol concentration to the one-half power with organotin catalysts and to the first power with amine catalysts. Since the effectiveness of tin catalysts is reduced by carboxylic acids, one can add a volatile acid such as acetic or formic acid to the formulation. The acid inhibits reaction during the pot life stage, but evaporates during application so that the inhibiting effect disappears. 2,4-Pentadione increases pot life by chelating with organometallic catalyst compounds.

Availability of lower viscosity isocyanate cross-linkers makes possible formulation of higher solids 2K coatings. However, one must consider not just the viscosity of the cross-linker, but also that of the combination of polyol and cross-linker. In some cases, a lower viscosity cross-linker also has a lower equivalent weight; this means that the weight ratio of cross-linker to polyol must be reduced to maintain the same stoichiometric ratio of N═C═O/OH (11). Since the polyol often has a much higher viscosity, this reduced ratio can give a higher viscosity coating, in spite of the lower viscosity of the cross-linker. Higher solids can be obtained using a somewhat higher viscosity polyisocyanate with a higher equivalent weight.

If very fast cure at relatively low temperatures is needed, reactive coreactants and/or high catalyst levels are used, and the pot life is short. Such formulations can be applied using special spray equipment in which the two packages are fed to a spray gun by separate proportioning pumps and mixed inside the gun just before they are sprayed. Care is required to assure that the proper ratios are fed and thoroughly mixed; such spray equipment can be expensive and complex.

Most amines react too rapidly for use in 2K coatings; however, hindered amines have been developed that permit their use. Polyaspartic esters are hindered amines that are used in high solids coatings (12). The aminoesters are synthesized by the addition of a diamine such as 4,4′-(aminophenyl)methane to diethyl maleate. The pot life of these combinations is increased by addition of DBTDL. On the other hand carboxylic acids and water accelerate reaction rates. By proper selection of isocyanate and aspartate and adjustment of catalysts, it is possible to formulate very high solids 2K coatings with a reasonable pot life and fast curing.

Imines react directly with isocyanates or with water followed by the reaction of the free amine generated; the ratio of the two reactions depends on relative humidity, the time between application and cure, and the curing temperature (12). The reaction with water releases amine to react with isocyanate and carbonyl compound, which volatilizes. In the direct reaction, carbonyl compound from the imine is not released, and hence, VOC (volatile organic compound) emissions are lower. The ratio of the two reactions depends on the relative humidity and on the time between application and baking. The direct reaction is catalyzed more than the water reactions by carboxylic acids, and water and tertiary amines reduce the rate of reaction. The imines have very low viscosities; for example, the bis(methyl isobutyl ketone) ketimine of ethylene diamine has a viscosity of 5 mPa·s (=cP) and an equivalent weight of 112. Direct reaction is more favored with aldimines, especially above 60°C. Imines permit formulation of 2K coatings with very high solids, better pot life, and faster drying than with polyols (12). They can be used alone or in combination with a hydroxy-functional polyester or acrylic resin (13).

Blocked Isocyanates

In early work on isocyanates in coatings, it was recognized that there would be advantages to develop systems supplied in one package with minimal toxic hazard. One-package coatings do not require costly mixing equipment, and eliminate concerns over controlling the ratio of mixing of two components. These objectives led to work on *blocked isocyanates*, taking advantage of reversible reactions of isocyanates. A di- or polyisocyanate is reacted with a monofunctional active hydrogen compound, and the adduct (a blocked isocyanate) is formulated into a coating with a coreactant resin. The coating is stable at ambient temperature, but when baked, the monofunctional reactant is released (and usually volatilized), and the coreactant cross-links. Many blocked isocyanates are sufficiently stable in the presence of water at storage temperatures for use in waterborne systems. However, use of blocked isocyanates has two drawbacks: relatively high temperatures are required for cross-linking and, in some cases, release of the blocking agent can cause a pollution problem. An extensive review citing over 1700 references has been published covering the structure, reactions, catalysis, and applications of blocked isocyanates (14).

The blocking agents most widely used commercially are phenols, oximes, alcohols, ε-caprolactam (hexahydro-2*H*-azepin-2-one) [105-60-2], 3,5-dimethylpyrazole, 1,2,4-triazole, and diethyl malonate (propanedioic acid diethyl ester) [105-53-3]. It is common to see tables of "unblocking temperatures." The implication is that there is some "magic temperature" above which the various blocked isocyanates abruptly unblock; however, no such temperature exists. Published unblocking temperature data are based on some measurement of extent of reaction under a specific set of conditions. Examples of such criteria are the lowest temperature at which free isocyanate can be detected spectroscopically or the temperature required to achieve a specified degree of solvent

resistance in cross-linking a coreactant resin in a specified time. The values depend on rate of heating as well as the time at a temperature. A variety of catalysts is used: organotin compounds, DABCO, and zinc octanoate are among them.

Phenols were the first blocking agents used commercially, despite their environmental problems. Blocked isocyanates made with phenol or alkyl-substituted phenols are less thermally stable than those blocked with alcohols. Blocked aromatic isocyanates are more reactive than blocked aliphatic isocyanates. A typical curing schedule with a phenol blocked aromatic polyisocyanate and a hydroxy-functional resin is 30 min at 160°C. Phenol blocked isocyanates are used for wire coatings, applied by running the wire through a coating bath and then through an exit die appropriately larger than the diameter of the wire. This process requires a coating with one package stability. Since wire is small and can be heated to high temperatures without major energy cost, high cure temperature is not a major disadvantage. Phenols had been used for many years as solvents in wire coating, and ovens were already engineered to incinerate the phenol, eliminating the pollution problem and providing some fuel value. The excellent abrasion resistance of polyurethane wire coatings justifies the cost. Phenol blocked isocyanates react with amines at room temperature. They are used as flexibilizing reactive additives in amine cured epoxy coatings.

Oximes, such as methyl ethyl ketone oxime (MEKO) (2-butanone oxime) [96-29-7], form less thermally stable blocked isocyanates than phenols. Their reactivity is such that reasonably stable one package coatings can be formulated with hydroxy-functional resins that can be cured in 30 min at 130°C or somewhat lower. Oximes are used as blocking agents in magnetic metal oxide coatings for application to oriented polyester tape. Such coatings must be cured in a short time at temperatures no higher than 80°C to avoid distortion of the plastic tape and yet must have sufficient pot life (at least a few hours) to permit application with a roll coater. An oxime blocked diisocyanate with an amine-terminated polyamide coreactant gives sufficient pot life, but still cures rapidly at 80°C. The excellent abrasion resistance and flexibility of polyurethane coatings are major advantages in this application.

Steric crowding on either oxime or isocyanate enhances the dissociation rates. Isocyanates blocked with diisopropyl and diisobutyl ketoximes dissociate faster than the same isocyanates blocked with MEKO (15). Oxime blocked TMXDI dissociates faster than other less sterically crowded aliphatic isocyanates and with comparable rates to aromatic isocyanates. Blocked TMI cross-linkers can be synthesized by first copolymerizing the TMI with acrylate esters, and then reacting the polyfunctional acrylate with an oxime such as MEKO. Alternatively, one can react TMI with the oxime and then copolymerize the blocked monomer with acrylate esters (16).

Oximes oxidize at elevated temperatures to yield colored products. As a result, in some cases, films made with oxime blocked isocyanates yellow during baking. The yellowing can be minimized by including a reducing agent such as a hydrazide derivative, for example, an oligomeric hydrazine adipate, in the formulation (17). Isocyanates blocked with 3,5-dimethylpyrazole (DMP) yellow less than with MEKO and give somewhat faster curing (18). 1,2,4-Triazole and mixtures of

1,2,4-triazole and DMP are reported to give low curing temperatures and freedom from yellowing (19,20). Concerns about possible toxic hazards with MEKO are serving to increase emphasis on evaluating other blocking agents, such as DMP and triazole.

The largest volume coatings with blocked isocyanates are cationic electrodeposition primers. They must be stable in water indefinitely. Alcohols are the most widely used blocking agents. 2-Ethylhexyl alcohol (2-ethylhexanol) was the most widely used but is being replaced by half ethers of glycols to obtain lower curing temperatures. Amine groups on the coreactant resin are neutralized with weak acids, such as lactic or formic acid. During electrodeposition, the protonated amine groups are converted into free amines at the cathode, causing the polymer to form a uniform coating on the cathode. The coatings are subsequently cured at relatively high temperatures.

Tris(alkoxycarbonylamino)triazine (TACT), a mixed methyl and butyl carbamate derivative of melamine, acts as an alcohol blocked isocyanate (21). TACT is much more reactive than conventional alcohol blocked isocyanates, since it is activated by the triazine ring. It cross-links hydroxy-functional acrylics at 125°C in 30 min, comparable to (or lower than) oxime blocked isocyanates. The reaction is not catalyzed by tin compounds; it is catalyzed to a small extent by dodecylbenzene sulfonic acid.

Diethyl malonate blocked diisocyanates cross-link with polyols at low temperatures, a typical curing schedule of 120°C for 30 min. However, reaction of diethyl malonate blocked isocyanates with alcohols does not yield urethanes, but rather transesterification occurs (22). Correspondingly, reaction with amines yields amides, not ureas. The transesterification proceeds fairly rapidly at 120°C; storage stable coatings can be formulated by using monofunctional alcohol in the solvent mixture. The monofunctional alcohol extends the stability by competing with the polyols for reaction with the blocked isocyanate. After the coating is applied, the monofunctional alcohol evaporates, and reaction with polyol gives a cross-linked coating. The active hydrogen of malonic ester blocked isocyanates reacts with MF resins (23). Clear coats for automobiles have been formulated with a combination of a hydroxy-functional acrylic resin, malonic ester blocked HDI and IPDI trimers, and an MF resin (24). Cross-linking reactions result from reactions of isocyanates from the blocked isocyanate with hydroxyl groups, MF resin cross-linking of hydroxyl groups, and MF resin reaction with the malonic ester blocking groups.

A large scale use of blocked isocyanates is in powder coatings. The principal blocking agent is ε-caprolactam. The most widely used isocyanate has been IPDI isocyanurate. Use of caprolactam is decreasing because of the high temperatures required for curing and oven buildup that is difficult to clean. Oxime blocked isocyanates cure at lower temperature, but there is concern about possible toxic hazards. A blocked isocyanate derived from 1,2,4-triazole and a mixture of monomeric HDI and HDI isocyanurate permits relatively low temperature cure of acrylic powder coatings while giving good mechanical properties (25). Blocking with a mixture of 1,2,4-triazole and 3,5-dimethylpyrazole is reported to give non-yellowing and low temperature cure (19,20). Polyol derivatives of IPDI uretdiones are used as cross-linkers in powder coatings; some will permit curing at lower temperatures than does caprolactam. The uretdione groups disassociate

to isocyanates at curing temperatures, providing cross-linking with no volatile blocking agent (26).

Moisture Curing Urethane Coatings

Polyurethane moisture curing coatings cross-link under ambient conditions by reaction of isocyanates with atmospheric water. Most such coatings use isocyanate-terminated resins made from hydroxy-terminated polyesters by reacting the terminal hydroxyl groups with an excess of a diisocyanate such as oligomeric MDI or, if color retention is needed, IPDI. So the coating does not contain unreacted diisocyanate; the resin is prepared utilizing a ratio of N=C=O to OH that is significantly less than 2 to 1. The coatings are stable when stored in the absence of water, but cross-link after application by reaction of the isocyanates with water to form amines, which react with another isocyanate to form substituted urea cross-links. Cure rates depend on the water content of the air; at low temperatures, higher relative humidity is required than at higher temperatures, since the relative humidity decreases with increasing temperature. At high humidity and temperature, cure is rapid, but the carbon dioxide released by the reaction of isocyanate with water can be trapped as bubbles, especially in thick films. See Reference 27 for discussion of the effects of temperature and humidity and other application considerations. Moisture curing urethane coatings are used for applications such as floor coatings, for which abrasion resistance and hydrolytic stability are important. They are called urethane coatings even though these cross-links are urea groups rather than urethane groups. Since urea groups also form intermolecular hydrogen bonds, presumably, they can affect resistance to mechanical stress similarly to urethane groups. Hydrolytic resistance of coatings is affected by several variables, including cross-link density and free-volume availability, as well as the functional groups present. Ureas and urethanes from aliphatic isocyanates are somewhat more resistant to hydrolysis than those from aromatic isocyanates. Both urea and urethane groups are generally more stable to hydrolysis than unhindered ester groups.

Moisture curing coatings are less susceptible to error in application than 2K coatings, for which there is a chance of incorrect ratios of packages affecting the stoichiometric ratios. A disadvantage is that solvents, pigments, and other components must be essentially water free. Use of moisture cure coatings is primarily in clear, gloss coatings since it is expensive to remove adsorbed water from pigments. Molecular sieves can be used to adsorb water, but can reduce gloss. Pigmented moisture cure coatings can be made using a water scavenger such as an alkyl orthoformate or *p*-toluenesulfonylisocyanate. Such water scavengers, especially sulfonylisocyanates, must be handled with care because of toxicity. Oxazolidines are reported to be effective moisture scavengers for aliphatic isocyanate-based coatings, presumably with less toxic hazard and lower cost (28). 4-Ethyl-2-methyl-2-(3-methylbutyl)-1,3-oxazolidine provides rapid water removal, while not adversely affecting stability or performance of a coating. Monomeric diisocyanates such as IPDI can also be used to react with water in the pigment dispersion before mixing it with the rest of the formulation; excess diisocyanate can be scavenged with a polyol (29).

Waterborne Polyurethanes

VOC emission regulations have led to work on waterborne polyurethane systems; a variety of approaches have been investigated (30,31).

Thermoplastic Polyurethane Dispersions. Polyurethane dispersion resins are predominantly linear, relatively high molecular weight polyurethane polymers dispersed in water. Such materials are latexes, but they are generally called *polyurethane dispersions* (PUDs). One way to prepare such dispersions is by the *acetone process* (30). An isocyanate-terminated polymer is made in acetone solution from a diisocyanate and a diol (or mixture of diols). This resin is chain extended by reacting with a sulfonate-substituted diamine, $H_2NCH_2CH_2NHCH_2CH_2SO_3^- Na^+$. The acetone solution is diluted with water, and the acetone removed by distillation. The sulfonate salt substituent acts as a charge repulsion stabilizer for the aqueous dispersion. The average number of sulfonate groups per molecule can be adjusted by using mixtures of unsubstituted and sulfonate-substituted diamines. One can incorporate a small amount of trifunctional isocyanate in making the initial isocyanate-terminated polymer. The result is a dispersed polymer with a low degree of cross-linking—low enough that the particles can still coalesce to a continuous film, but high enough that film properties are superior to those obtained with linear polymers (32). Since urethanes hydrogen bond strongly with water, the particles are swollen with water, plasticizing the polymer and thereby permitting film formation with higher T_g polymers than is possible with acrylic latexes (33).

The acetone process has the disadvantage that the removal of acetone is a time-consuming and expensive step. PUDs can also be made using a low volatility solvent. *N*-methylpyrrolidinone (NMP) has been the most widely used solvent. The cost of manufacture is lower but the VOC is obviously higher and the low volatility of NMP requires baking to remove the solvent. There is also concern about the possible carcinogenicity of NMP.

Dispersions can also be made by solvent-free processes. For example, isophorone diisocyanate, polycaprolactone diol, polytetrahydrofurandiol, and dimethylolpropionic acid are reacted with an NCO:OH ratio of 1.6:1 to make an isocyanate-terminated prepolymer. The prepolymer is neutralized with triethylamine and dispersed in water. The prepolymer is then chain extended by reacting with hydrazine hydrate.

One can also make combined acrylic/urethane (hybrid) aqueous dispersions (33). Acrylic monomers are emulsion polymerized in the presence of an aqueous dispersion of a hydroxy-terminated polyurethane. The polyurethane stabilizes the aqueous dispersion, minimizing need for surfactant. Coalescence requires balance of the T_g of both the urethane and acrylic parts of the system. Compositions based on an IPDI/polypropylene glycol/DMPA urethane with styrene/methyl methacrylate/butyl acrylate are reported to form films at low temperatures.

Cross-Linkable PUDs. Cross-linkable PUDs are also made. For example, a hydroxy-functional polyurethane can be made using a diisocyanate, a diol, a triol, and 2,2-dimethylolpropionic acid (DMPA) in a *one-step process*. The sterically hindered carboxylic acid group on DMPA is so low in reactivity with isocyanate that few amide bonds are formed. After neutralization of carboxylic acid groups with an amine, the resin is diluted with water to yield a dispersion stabilized by

the salt groups on the surface of polymer aggregates. Commonly, NMP is used as a solvent to reduce the viscosity of the resin. Such resins do not have the hydrolytic stability problems of water-reducible polyesters; also, the probability of formation of low molecular weight, cyclic, nonfunctional molecules is low. Lower viscosity PUDs can be made by a *two-step process* (34). First, a linear isocyanate-terminated polyurethane is made using a diisocyanate, a diol, and DMPA; then, in a second step, the terminal isocyanate groups are reacted with aminoalcohols such as diethanolamine to yield a hydroxy-terminated polyurethane.

Polyurethane dispersions can also be prepared by a nonisocyanate process (35). An aliphatic polyester diol is reacted with a bis(2-hydroxypropyl carbamate), a triol, and a transesterification catalyst, such as dibutyltin oxide. Carboxy functionality is then introduced by reacting some of the remaining hydroxy groups with an anhydride.

The hydroxy-functional polyurethane dispersions can be cross-linked with MF resins or blocked isocyanates. Blocked isocyanates can also be used with water-reducible anionic acrylic or polyester resins instead of an MF resin; oxime blocked isocyanates are commonly used, owing to their high reactivity. Oxime blocked aliphatic isocyanates are more stable to hydrolysis than oxime blocked aromatic isocyanates (32). As mentioned earlier alcohol blocked isocyanates are used in cationic electrodeposition coatings.

2K Waterborne Coatings. Since isocyanates react relatively readily with water, it was assumed for many years that they could not be used directly in waterborne coatings; however, in the last few years, 2K waterborne coatings have been developed. The Bayer Corporation was awarded a Presidential Green Award in 2000 for its work in developing 2K waterborne urethane coatings. Reference 36 is a review of the work on 2K waterborne urethane systems.

It is relatively easy to make 2K coatings with good properties in the laboratory; however, production use is more difficult. There are several potential problems. In some systems, it is difficult to assure that uniform stoichiometric ratios are obtained throughout the film. As with solventborne 2K coatings, waterborne 2K coatings can be expected to have limited pot life. In solventborne coatings, pot life can be determined by monitoring viscosity increases. In many 2K waterborne coatings, viscosity does not increase as reactions between N=C=O and OH take place, since they change the viscosity inside the aggregate particles, but not the bulk viscosity. In fact, the generation of CO_2 by the reaction of isocyanate decreases the pH, leading to shrinking of the aggregate particles, which can result in viscosity reduction. If reaction occurs to a significant extent before application, coalescence will be inhibited, and therefore, film properties may be poor. If there is too much reaction before volatiles are evaporated, complete coalescence of the dispersion particles may not occur. Since isocyanates also react with water, full reaction of the polyols requires an excess of isocyanate. Furthermore, the reaction with water results in formation of CO_2, which can lead to *blistering*, especially as thicker films are applied.

One approach to solving these problems is to combine conventional polyisocyanates with conventional, amine neutralized, water-reducible resins in a water-miscible solvent and then add water. A similar process is used for water-reducible coatings cross-linked with MF resins. Conventional water-reducible acrylic resins in solvents such as 1-methoxy-2-propanol acetate have been used. Water-soluble

glycol ethers do not significantly interfere since they are primarily in the water phase, with little chance to interact with isocyanates. Tertiary amines such as triethylamine or *N*-alkylmorpholines are used to neutralize the resin rather than the dimethylethanolamine widely used in MF cross-linked coatings. 2-amino-2-methyl-1-propanol is a particularly poor choice, since the primary amines are very reactive with isocyanate. The amine is added to the resin solution before the polyisocyanate. Finally, the coating is reduced to application viscosity with water. Mixing the polyisocyanate into the acrylic solution requires good agitation, and with conventional polyisocyanates, erratic results are common. It is necessary to use a high NCO/OH ratio, often above 2, to compensate for nonproductive reactions of isocyanate with water; the high ratio increases cost. Since TMXDI reacts more slowly with water than other commercial isocyanates, successful use of this approach is reported with lower NCO/OH ratios (37).

Alternatively, a conventional polyisocyanate can be mixed in after reduction with water, just before spraying. Spray equipment designed to provide in-line intensive mixing of the two components has been used to apply polyisocyanate 2K water-reducible OEM automotive clear coats with properties comparable to those obtained with solventborne 2K coatings (38). A large fraction of the water evaporates during flash off and initial baking, reducing the extent of isocyanate reaction with water, minimizing CO_2 evolution, and permitting lower ratios of NCO/OH.

Mixing conventional polyisocyanates into the polyol after reduction with water can result in problems resulting from nonuniform stoichiometry. Hydrophilically modified polyisocyanates made by reacting a fraction of the —NCO groups on a polyisocyanate (such as HDI or IPDI isocyanurate) with a polyglycolmonoether are more easily mixed. The modified polyisocyanate is stirred into an aqueous dispersion of a coreactant to form a heterogeneous dispersion in which the polyisocyanate and coreactant are in separate dispersed particles (39–41).

Although alcohols react more rapidly with isocyanates than water, in a water system, there is a very large excess of water, and so a significant fraction of the isocyanate groups react with water; but these reactions also give cross-links. To assure reaction of most of the hydroxyl groups, NCO/OH ratios of 2 or greater are recommended. Some applications, such as wooden kitchen cabinets, do not require that cross-linking be complete; in such cases, lower NCO/OH ratios can be used, permitting lower cost and longer pot life (42). Results are dependent on the process used to mix the two packages together; high, but not excessive, shear is required to obtain relatively uniform particle size with an average diameter of about 150 nm. Two-component mixing spray guns are reported to give the most dependable results. Hydrophylically modifed polyisocyanate 2K coatings give films with adequate performance for many applications, but the reduction in functionality resulting from the reaction with the polyetherpolyol results in films with inadequate properties for such applications as automotive clear coats.

Carboxylic acid-functional PUDs can also be cross-linked with polyaziridines in 2K coatings. For example, a group of patents cover use of trifunctional aziridines, such as trimethylolpropane tris(2-aziridinylpropionate), in 2K coatings for plastics (43). Carboxylic acid-functional PUDs can also be cross-linked with polycarbodiimides (44).

Uralkyds

Uralkyds are also called *urethane alkyds* or *urethane oils*. They are alkyd resins (qv) in which a diisocyanate, usually 2,4(6)-toluene diisocyanate (TDI), has fully or partly replaced the phthalic anhydride (PA) usually used in the preparation of alkyds. One transesterifies a drying oil with a polyol such as glycerol or pentaerythritol to make a "monoglyceride" and reacts it with some PA (if desired) and then with somewhat less diisocyanate than the equivalent amount of N=C=O based on the free OH content. To assure that no N=C=O groups remain unreacted, methyl alcohol is added at the end of the process. Just like alkyds, uralkyds dry faster than the drying oil from which they were made, since they have a higher average functionality (more activated diallylic groups per average molecule). The rigidity of the TDI aromatic rings also speeds up the drying by increasing the T_g of the resin.

Two principal advantages of uralkyd over alkyd coatings are superior abrasion resistance and resistance to hydrolysis. Disadvantages are inferior color retention (when aromatic isocyanates used) of the films, higher viscosity of resin solutions at the same percent solids, and higher cost. Uralkyds made with aliphatic diisocyanates have better color retention, but are more expensive and have lower T_g. The largest use of uralkyds is in architectural coatings. Many so-called varnishes sold to the consumer today are based on uralkyds; they are not really varnishes in the original sense of the word. They are used as transparent coatings for furniture, woodwork, and floors; applications in which good abrasion resistance is important. Since they are generally made with aromatic isocyanates, they tend to turn yellow and then light brown with age; yellowing is acceptable in clear varnishes, but would be a substantial drawback in light colored pigmented paints.

Water-reducible polyunsaturated acid-substituted aqueous polyurethane dispersions are also being used (45). They can be made by reacting a diisocyanate with a polyol, monoglyceride of a drying oil, and dimethylolpropionic acid. The carboxylic acid groups are neutralized with a tertiary amine and dispersed in water. If aliphatic isocyanates are used, good color retention can be obtained. They are much more resistant to hydrolysis than conventional alkyd resins. Films also have excellent abrasion resistance. Cost can be reduced by blending in 10–20% of acrylic latex.

Hydroxy-Terminated Polyurethanes

Diisocyanates can react with diols and triols at an N=C=O/OH ratio of less than 1 to make hydroxy-terminated polyurethanes, which can be cross-linked with MF resins or with other cross-linkers that react with hydroxyl groups. Urethane groups also cross-link with MF resins. Compared to polyesters, hydrolytic stability is better and coatings provide the toughness and abrasion resistance associated with urethane coatings. However, the solids at equal molecular weight and viscosity are lower because of intermolecular hydrogen bonding, and the urethane groups increase moisture absorption. Compared to hydroxy-functional

acrylic resins, they offer the advantage of abrasion resistance and the possibility of using lower molecular weight resins.

Hydroxy-terminated polyurethanes with low molecular weight and viscosity have been synthesized by reaction of cyclic carbonates with diols (46). These *urethane diols*, as reactive diluents, permit formulation of higher solids acrylic/MF coatings with good properties. It was also suggested that they may be useful in water-reducible systems, reducing the organic solvent requirement.

Carbamate-Functional Reactants

MF resins react with carbamate groups under approximately the same conditions as when they react with hydroxyl groups. Carbamate-functional acrylics can be cross-linked with MF resins to give films with better environmental etch resistance than MF cross-linked hydroxy-functional acrylics while retaining the advantage of mar resistance as compared to conventional urethane coatings. Carbamate-functional acrylics can be prepared by reacting acrylic resins with urea (47). They can also be prepared by ester interchange between a hydroxyl group on a hydroxy-functional acrylic resin and the carbamate from propylene glycol monomethyl ether (48). Carbamate-functional polyester oligomers can be prepared by reacting glycidyl neodecanoate with dimethylolpropionic acid, followed by transesterification of the hydroxyl groups with methyl carbamate. Clear coats cross-linked with MF resins are reported to give films with excellent environmental etch resistance and mar resistance (49).

Another approach using carbamate-functional reactants is to react a polyisocyanate such as IPDI isocyanurate or HDI isocyanurate with hydroxypropyl carbamate (50). These carbamates are used in automotive clear coats with an MF resin that has been partially reacted with butyl carbamate to reduce its functionality. The remaining methoxymethyl groups of the melamine resin react with the carbamate groups of the isocyanurate-derived carbamate to give cross-linked films with outstanding environmental etch and mar resistance. The use of a combination of a carbamate-functional acrylic resin, a polycarbamate derived from a polyisocyanate, and an MF resin has also been patented (51).

Urethane Vehicles in UV Cure Coatings

Acrylated urethane oligomers are used with mono- and polyfunctional acrylic esters in uv cure coatings. Any polyol or hydroxy-terminated oligomer (HO-R-OH) can react with excess diisocyanate (OCN-R′-NCO) to yield an isocyanate-terminated oligomer. This oligomer then react with 2-hydroxyethyl acrylate (2-propenoic acid 2-hydroxyethyl ester) (HEA) at ambient or moderately elevated temperature to yield an acrylated urethane oligomer. Such urethane oligomers are particularly used in coatings that require excellent abrasion resistance such as clear topcoats for flooring. A coating for polycarbonate plastics is a recent example of such coatings. The coatings are based on HDI isocyanurate reacted with HEA dissolved in 1,6-hexanediol diacrylate (52).

Markets

The U.S. market for urethane coatings in 1997 was reported to be 270×10^6 L with a value of $1.6 billion (53). The same report forecast the market in 2002 to be 290×10^6 L with a value of almost $1.9 billion. These figures do not include $320 million of isocyanate activators and flex additives used with acrylic and alkyd enamels in automobile refinish coatings.

The largest market is reported to be architectural paints, consisting primarily of uralkyds used as varnishes for furniture and floors and in floor paints. The major advantage of these coatings over alkyd paints is their higher abrasion resistance. Acrylic/urethane aqueous dispersions are a growing part of this market.

The second largest market is reported to be OEM automotive coatings. The most important components of this market are cationic electrodeposition coatings, which are all formulated with blocked isocyanate cross-linkers. Blocked isocyanates are also used in chip-resistant primers. Waterborne urethane base coats are used in several assembly plants. Clear topcoat is a growing part of the market; 2K solventborne acrylic resins with a polyisocyanate have been used for many years as have blocked isocyanate cross-linked acrylic one component coatings. A small but rapidly growing class of coatings is 2K waterborne urethane coatings. Urethane coatings are extensively used on plastic components of automobiles.

Other important markets include automotive refinish coatings, maintenance coatings, aircraft finishes, camouflage coatings for military vehicles, wire enamels, magnetic tape, and coatings for plastics.

UV STABILIZERS

Introduction

Ultraviolet stabilizers extend the service life of plastics and coatings by the inhibition of degradative processes photoinitiated by UV light from the sun and other UV sources.

Of the various chemical classes of UV stabilizers that have been developed, the benzophenone and benzotriazole UV absorbers, the hindered amine light stabilizers (HALS), and their combinations continue to satisfy the UV stabilization requirements of most of the large-volume outdoor polymer applications. In addition, many new stabilizer chemistries, such as UV absorbers based on hydroxyphenyl triazines, have been developed for more demanding applications or to satisfy specific market needs. Light stabilizers together with other additives (qv), such as antioxidants (qv), impact modifiers, colorants (qv), fillers, heat stabilizers (qv) and plasticizers (qv), have enhanced the properties and extended the service life of polymeric materials, resulting in the replacement of traditional materials in a multitude of outdoor weatherable applications.

The effective use of light stabilizer products requires a basic understanding of polymer photodegradation processes, UV stabilization mechanisms, desired end-use properties, and weathering testing program design. This article will provide a brief review of these various elements, together with some current application examples (1–6).

Polymer Photodegradation Processes

In order for photodegradation to occur, absorption of UV light energy is required by UV-absorbing chemical groups in the polymer formulation. These light-absorbing

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

groups are called *chromophores*. Excited states and radicals are generated from this photoinitiation process. In some polymers, such as polycarbonate, inter- or intramolecular reactions take place, resulting in appearance changes, such as the yellowing, and/or changes in physical properties, such as the loss in impact strength. In other polymers, such as polyolefins, the radicals react with oxygen, producing peroxy radicals which abstract hydrogens to generate hydroperoxides and new polymer radicals. Further photolysis of the hydroperoxides and carbonyl groups occurs, resulting in appearance changes, such as loss of surface gloss, and changes in physical properties, such as loss of elongation and tensile strength. This latter process is called photo-oxidation.

The sources of the UV-absorbing chromophores come from the chemical structure of the polymer, the thermal processing degradation products, colorants, fillers, other additives such as halogenated flame retardants, antioxidants and their transformation products, feedstock or process impurities, and residual catalyst.

The source of UV light energy is primarily from solar radiation. The UV light reaching the earth's surface ranges from 290 to 400 nm and consists of only 5% of the total solar radiation. However, the corresponding photon energy of 418–293 kJ/mol (100–70 kcal/mol) is sufficiently strong to break molecular bonds in most polymers and coatings. In Table 1, the relationship between the photon energy and the strength of many of the chemical bonds found in most plastics and coatings is given. Other environmental factors in polymer photodegradation are the surface temperature, moisture level, and atmospheric pollutants.

As shown in Table 2, the wavelength sensitivity of polymers has been measured using a series of UV light filters, confirming that each of the major polymers are sensitive to certain wavelengths within the 290–400-nm UV region (7,8). For example, the activation spectra maxima for polystyrene was found to be 310–325 nm, and for polypropylene there were three maxima at 290–300, 330, and 370 nm. Although a narrow wavelength maxima is reported for each polymer, the full polystyrene spectrum shown in Figure 1 illustrates that polymers are typically sensitive to a broader range of UV light energy.

As shown in Figure 2, the use of a UV filter to screen this harmful UV light energy can effectively prevent the photo-oxidation process and loss of breaking

Table 1. Relationship Between Photon Energy and Chemical Bond Strength

Wavelength, nm	Photon energy, kJ/mol[a]	Chemical bond	Bond strength, kJ/mol[a]
280	428	C═C	607
300	400	O—H	460

strength. Without the UV filter, the polypropylene monofilament degrades in only 600-h Xenon Arc Weather-O-Meter (WOM) exposure. This clearly shows the effect of UV light energy on the photo-oxidation process.

UV Stabilization Mechanisms and Strategies

The initial emphasis in light stabilizer development was the inhibition of the photoinitiation processes. This UV stabilization strategy consisted of the incorporation of additives into the polymer or coating formulation, which either absorbed UV light energy or acted as quenchers of the photoexcited states of the chromophores. In the former case the UV absorber competes with the chromophores for the harmful UV light energy, which is preferentially absorbed by the UV absorber and dissipated harmlessly as heat (9). In this competitive absorption mechanism, the UV absorber must have relatively high absorptivity at the wavelengths of UV light to which the polymer is photosensitive (activation spectra maxima). In the latter

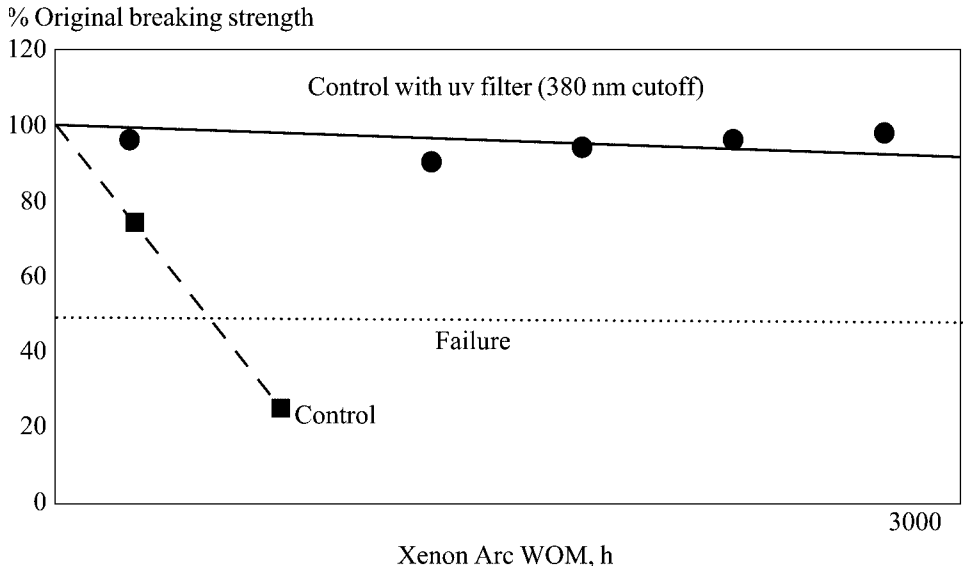

Fig. 2. Effect of a UV filter on the UV stability of polypropylene monofilament.

case, the quencher returns the excited states to ground states by energy transfer processes. In both cases, radical formation is inhibited and the outdoor service life of the polymer is extended, depending on the efficiency of these stabilization processes (see STABILIZATION).

Also, light stabilizers have been developed to inhibit the subsequent oxidative processes by radical scavenging and hydroperoxide decomposition mechanisms. In these processes, the light stabilizer molecules undergo chemical reactions with the propagating intermediates in the polymer photo-oxidation processes. In some cases the light stabilizer is gradually consumed and in others the stabilizing chemical groups are regenerated to some degree in the stabilization process. This latter process has been used to explain the effectiveness of HALS (10–12).

The third strategy is to combine a UV absorber with a radical scavenger or a hydroperoxide decomposer to provide more efficient and sometimes synergistic UV-stabilizing activity. Also, effective combinations of radical scavengers and hydroperoxide decomposers have been reported (13). And finally, as part of a total system strategy, melt-processing antioxidants can be added to the polymer formulation to minimize the formation of UV-absorbing chromophores from thermal oxidation during thermal processing.

An overview of stabilizer mechanisms and types of chemicals used for each mechanism is provided in Table 3. Further descriptions of these mechanisms follow. The three major classes of UV absorbers are 2-hydroxybenzophenones, 2-hydroxyphenylbenzotriazoles, and the newer 2-hydroxyphenyl-*s*-triazines. The nickel phenolates not only have excited state quenching capability, but also provide radical scavenging and hydroperoxide decomposing activity. The radical scavengers include hindered benzoates and hindered amines. The hindered amines have the added capability to decompose hydroperoxides. Another class of

Table 3. UV Stabilization Mechanisms and Chemical Stabilizers

Mechanism	Chemical agents
Competitive UV absorption	2-Hydroxy benzophenones
	2-Hydroxyphenyl benzotriazoles
	2-Hydroxyphenyl-*s*-triazines
	Other chemical classes
Excited state quenching	Nickel phenolates
Radical scavenging	Nickel phenolates
	Hindered amines
	Hindered benzoates
Hydroperoxide decomposition	Nickel phenolates
	Hindered amines
	Phosphites
Residual catalyst deactivation	Acid acceptors
	Metal deactivators

hydroperoxide decomposers are the phosphites. Residual catalyst deactivation has been reported (14,15) to be of some value in both thermal and light stabilization of polymers, and acid acceptors such as calcium stearate and metal chelators such as oxamides or hydrazides are the major chemical classes. Each of these mechanisms and stabilizer types can be applied depending on the photodegradation mechanism of the polymer and the performance requirements of the application.

Light stabilizers need to satisfy a number of technical, as well as commercial, requirements. Technical requirements include strong, broadband UV absorption (for UV absorbers), high inherent stability to UV light energy, good solubility–migration balance in the polymer substrate, low volatility and extractability, low color and odor, minimum adverse interactions with other system components, and good storage stability.

In addition to the primary light stabilization functional group, substituents are used to fine-tune performance as follows:

(1) To vary the molecular weight to change the volatility, solubility–migration balance, and extractability.
(2) To vary the chemical reactivity of the functional group.
(3) To enhance the UV absorption or the inherent light stability.
(4) To add a reactive group to achieve permanence.

Of course, commercial considerations, such as optimum cost–performance balance, food contact sanction, and technical support from suppliers are also important considerations in UV stabilizer selection.

There are numerous factors which will affect the performance of light stabilizers in each polymer and application. Therefore, although careful definition of specific application requirements can help to develop some initial stabilizer options, testing of these systems via accelerated weathering techniques is often required. Numerous useful references are available describing accelerated test

Table 4. UV Light Exposure Testing Methods

Accelerated weathering device

EMMA Test Method (ASTM G90-91)
EMMAQUA Test Method (ASTM D4362-94, G90-91)
Natural outdoor exposure
Direct (ASTM D1435-85)
Under Glass (ASTM G24-87)

methods to predict weathering performance (16–21) (see WEATHERING). Table 4 lists some of the commonly used accelerated and natural outdoor UV exposure conditions and ASTM test methods. Generally, the Xenon Arc WOM provides the best correlation with outdoor data because of the spectral match with the UV portion of the sun's energy. The carbon arc and fluorescent sunlamp weathering units provide greater acceleration in testing but correlate to a lesser degree because of their spectral energy differences with sunlight. With regard to the fluorescent accelerated units, the newer 340A lamp provides a better spectral match with sunlight than the 313B lamp. Actual outdoor exposure should be performed to establish a correlation not only with regard to ranking the performance of the various light stabilizer systems but also to determine the number of months or years equivalent to a given number of hours (or dosage of incident light energy, expressed as kJ/m^2 or alternate units) of accelerated exposure. Arizona and Florida are the major outdoor weathering sites in North America. Accelerated outdoor weathering is also available whereby the sun's light energy is concentrated on the sample surface with mirrors and a mounting device which follows the sun across the horizon to maximize the light exposure. Again, correlation studies with actual outdoor exposure are recommended.

UV Light Absorbers

A UV light absorber is a type of light stabilizer which functions by competitive absorption of the UV light energy, causing the photodegradation of a polymer formulation. The UV absorber competes with all chromophores in the formulation and dissipates the absorbed energy as heat. The chromophores are UV light absorbing chemical groups in the polymer formulation. These may include the polymer itself and other additives, such as halogenated flame retardants, fillers, and pigments. In effect, the UV light absorber inhibits the first step in the polymer photodegradation process, which is photoinitiation. The UV light absorber can be used in combination with other types of light stabilizers which are designed to inhibit the other, subsequent steps in the photodegradation processes. Also, UV light absorbers may function as UV screeners in plastics, coatings, and cosmetic sunscreens to reduce or eliminate the transmission of UV light energy, protecting UV-sensitive substrates.

The factors involved in the effectiveness of the competitive UV light absorption stabilization mechanism are as follows:

(1) The UV wavelength region causing photodegradation of the polymer formulation.
(2) UV absorptivity of the polymer formulation in this region.
(3) UV absorptivity of the UV absorber in this region.
(4) Thickness of the polymer.
(5) Concentration and dispersion of the UV absorber.
(6) Inherent light stability of the UV absorber.
(7) Permanence of the UV absorber.
(8) Chemical reactivity of the UV absorber in the photodegradation process.
(9) The UV light and thermal exposure conditions of the polymer formulation.

Several chemical classes of UV light absorbers are currently available (see Table 5). The major chemical classes are the 2-hydroxybenzophenones (such as 2-hydroxy-4-*n*-octyloxybenzophenone; CYASORB® UV-531 light absorber) and the 2-hydroxyphenylbenzotriazoles (such as 2-(2-hydroxy-5-*tert*-octylphenyl)benzotriazole; CYASORB® UV-5411 light absorber). Other chemical classes consist of the 2-hydroxyphenyl-*s*-triazines (such as 2-[4,6-bis(2,4-dimethylphenyl)-1,3,5-triazin-2-yl]-5-(octyloxy) phenol; CYASORB® UV-1164 light absorber), the cyanoacrylates (such as ethyl 2-cyano-3,3-diphenylacrylate; UVINUL® 3035), the oxanilides (such as 2-ethyl,2′-ethoxy-oxanilide; SANDUVOR® VSU), the benzylidene malonates (such as 4-methoxybenzylidene-malonic acid, dimethyl ester; SANDUVOR® PR-25), and the benzoxazinones (such as 2,2′-(1,4-phenylene) bis[4*H*-3,1-benzoxazin-4-one]; CYASORB® UV-3638 light absorber).

The UV light absorber chemical structure consists of a functional group and substituents. The functional group gives the UV absorber its characteristic UV absorption properties. As noted previously, the substituents are added to the chemical structure to modify its UV absorption properties, and other properties such as compatibility with the polymer substrate, color contribution, thermal volatility, extractability, chemical reactivity, and permanence.

CYASORB® UV-531 light absorber is used primarily in polyolefin and flexible PVC outdoor applications. Figure 3 shows an application example for this product, namely the improvement in the color stability of a flexible PVC film during accelerated Xenon Arc WOM UV exposure. CYASORB® UV-1164, an example of the newer generation of triazine UV absorbers, has higher molecular weight and lower volatility for use at higher processing temperatures and for greater permanence in thin film applications. CYASORB® UV-5411 is used primarily in molding grade polycarbonate and other applications, such as styrenics and thermoset polyester. Figure 4 shows an application example for this product, namely the improvement in the color stability of a polycarbonate plaque during accelerated Xenon Arc WOM UV exposure. In all three UV light absorber examples, the octyl substituent is used to increase molecular weight, lower the volatility, and increase the compatibility with polymeric substrates.

The optimum amount of UV absorber varies with each chemical type and application, but in most cases is in the 0.25–1.0% concentration range. Other factors to consider while selecting the proper type and amount of UV absorber are color contribution, FDA sanction for food packaging applications, and, of course, add-on cost. The UV absorbers are incorporated into plastic substrates by dry blending, extrusion compounding, and then conversion into the final product by various processes such as injection molding, blown film extrusion, multifilament spinning, and sheet extrusion. Also, UV absorber dispersions can be prepared and dyed onto textile fabrics, which will not only UV-stabilize the polymer substrate but also improve the color stability of the dyes used to color the fabric.

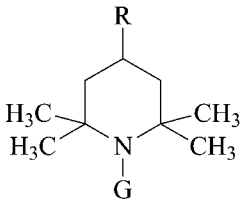
The use of UV absorbers as UV screeners is practiced in a multitude of applications, such as sunglasses, interocular lenses, auto windshield films, solar control

glazing films, photographic products, greenhouse films, product packaging, and cosmetic sunscreens. In each application, the polymer type, the UV absorber type, the thickness of the plastic product, and the concentration of the UV absorber need to be considered to meet the reduced UV percentage transmission requirements of the application. The UV transmission properties of a plastic product are governed by the Beer–Lambert Law, which states that the absorbance (A) is proportional to the absorptivity (a) of the medium times the thickness (b) of the medium times the concentration (c) of the UV-absorbing compounds in the medium (eq. 1).

$$A = abc \tag{1}$$

Hindered Amine Light Stabilizers

Hindered amine light stabilizers (HALS) have been well recognized for more than 25 years to be the most proficient UV stabilizers for a large number of polymers. This is particularly true for the protection of polyolefins against the degradative effects of light energy. The protective effects of HALS has enabled the growing use of polypropylene (PP) in the automotive industry. The main protective effect is the strong improvement in light stability achieved with the use of HALS. These stabilizers also impart thermal stability to plastics at temperatures below 130°C. Although there are wide structural variations in commercial HALS products, all share the 2,2,6,6-tetramethylpiperidine ring structure (**1**).



(1)

The nitroxide radical of this cyclic amine is the actual active light stabilizer. The nitroxide radical is generated *in situ* by photo-oxidation and photohydrolysis, depending on the substituent on the nitrogen atom. The mechanism of stabilization of hydrocarbons, eg PP, by HALS has been studied extensively (22–34). The kinetics of nitroxide generation and consumption in coating matrices has been studied by electron spin resonance (esr) (35–43). Nitroxide consumption in coatings has been used to measure photoinitiation rates for photo-oxidation. In a sequence of reactions known as the Denisov Cycle, the nitroxide radical combines with other radical species in the coating matrix to form amino ether intermediates, which further react with radical species to regenerate the nitroxyl radical and form nonradical chemical by-products. Thus the piperidinyl nitroxide radical may be thought of as a catalytic radical scavenger. An early representation of the Denisov Cycle is shown in Figure 5.

The knowledge of the degradation mechanisms of polyolefins has grown over the past few years owing to the scientific work of several industrial research groups

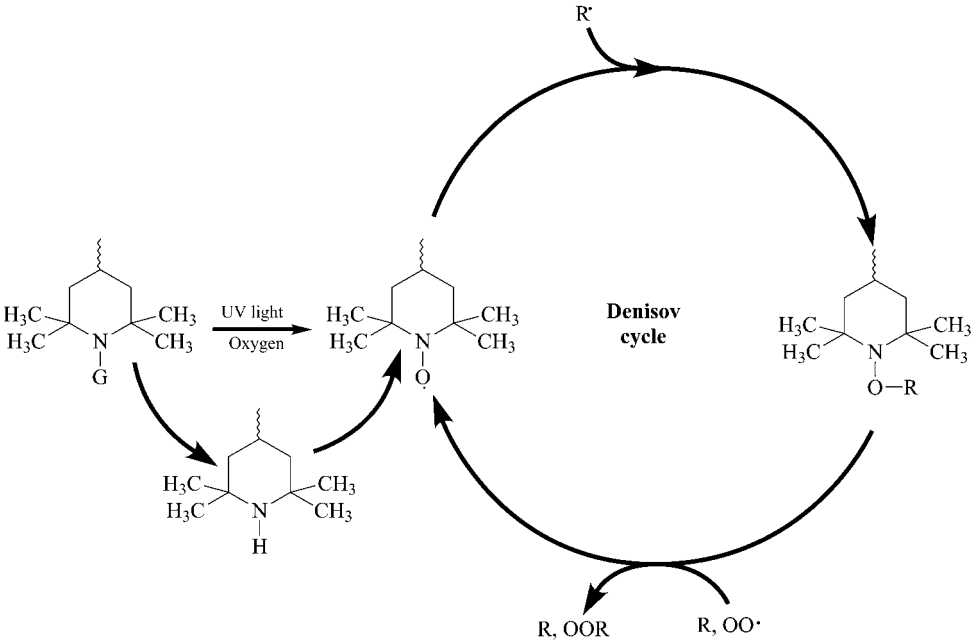


Fig. 5. Chemical mechanism of HALS activation and radical scavenging.

and universities. Concurrently, the influence of structural, chemical, and physicochemical characteristics of HALS has been understood and improvements in their performances made. These advancements have led to several generations of HALS intended to cover a wide variety of applications. With these improvements, the confidence in the correlation between accelerated and outdoor weathering has grown, thus reducing the time necessary for evaluation and approval of new stabilizing products and systems.

The consequence of this continuous growth in knowledge has been the appearance on the market of several generations of HALS, which can be historically summarized as follows: first generation – monomeric HALS; second generation – polymeric HALS; third generation – noninteractive HALS; and fourth generation – synergistic UV absorber – HALS combinations.

First Generation: Monomeric HALS. Several decades ago, physical organic chemists were entranced by the concept of stable free radicals and their potential as radical trapping agents. References on the use of nitroxyls as potential stabilizers for plastics had already been cited in the patent literature (44).

In pioneering work during the 1960s, 2,2,6,6-tetramethyl-4-oxy-piperidine *N*-oxyl (also known as *N*-OxylTAM) was synthesized (45), and found to be effective as a light stabilizer in plastics (46). See Table 6 for HALS structure. However, the molecule had a low melting point, had limited thermal stability, imparted color to substrates, and was highly migratory (47). Further improvements were needed. Subsequent studies by Sankyo Corp. led to the discovery that the amine analogs of the *N*-oxyl compounds were highly active as stabilizers, with fewer undesirable side reactions (48). Commercialization of the first HALS product, decanedioic acid

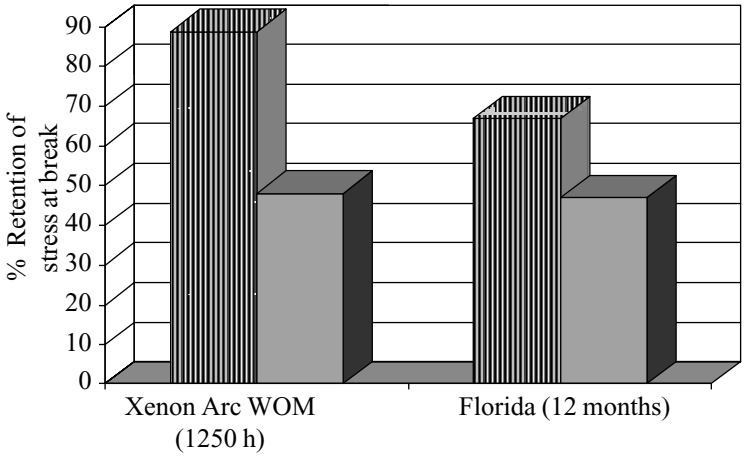

Fig. 6. UV stabilization of 1.5-mm injection-molded PP Homopolymer tensile bars. ▩ 0.15% CYASORB UV-3853, ▩ 0.15% Tinuvin 770. 0.1% CaSt, 0.075% Irganox 1010.

bis(1,2,2,6,6-pentamethyl-4-piperidinyl)ester (Tinuvin 770), occurred in 1974, and it has since become one of the most important monomeric HALS for the stabilization of plastics, especially PP. Its counterpart, Tinuvin 292 (same structure), is one of the most important HALS for coatings stabilization. This HALS is endowed with high mobility within polyolefins, owing to its small molecular size.

Another option, CYASORB® UV-3853 light stabilizer, is a mixture of three *n*-alkyl esters which affords enhanced polyolefin compatibility (reduced blooming) and solubility. These factors have been shown to have a dramatic effect on stabilization efficacy in some applications. For example, CYASORB® UV-3853 exhibits significantly better stabilization performance in PP despite only half the molar activity (piperidinyl groups per mole) as compared with Tinuvin 770 (Fig. 6). The comparable volatility of the products indicates that the difference in performance cannot be associated with that parameter. Also, in thick section parts, additive loss is generally controlled by diffusion and not by additive volatility. Since the products are similar in molecular weight (MW), one would expect their diffusion coefficients to be similar. If the solubility parameters of the products differed sufficiently, that could account for the performance differences; studies (49) have borne this out.

Second Generation: Polymeric HALS. One specific application that was of great interest in the development of higher MW HALS was PP fibers (50). PP fibers, by virtue of their high surface area-to-volume ratios and tendency to undergo postspinning treatments (tentering/backing) were often victims of stabilizer loss during processing. Economics and performance were compromised as a result of the fugitive nature of nonpolymeric, low molecular weight HALS. The necessity of a high molecular weight, low volatility HALS was, therefore, established.

In the early stages of commercialization of oligomeric HALS, the supporting structure for the piperidinyl functionality was clearly an area of focus. One product, Spinuvex A36 (no longer commercially available), had a polyamino backbone

with pendent piperidinyl groups. Another, butanedioic acid, a polymer with 4-hydroxy-2,2,6,6-tetramethyl-1-piperidine ethanol (Tinuvin 622), was a polyester, with the active sites incorporated into the backbone. With thermogravametric properties T-10% (defined as the temperature at which 10% of the molecule is lost gravimetrically) of 301 and 329°C for Spinuvex A36 and Tinuvin 622 respectively, versus 259°C for Tinuvin 770, both products satisfied the low volatility criterion (50). Still, further improvements were needed, as deficiencies in thermoxidative stability and UV performance after postspinning treatments were still evident in PP formulations containing these additives.

The introduction of triazine-type high performance HALS was the next leap in HALS technology. Triazine backbones made excellent carriers for piperidinyl groups, affording superior thermal and photochemical stability as well as low volatility. Two of the most commonly used HALS of this class are 1,6-hexanediamine, N,N'-bis(2,2,6,6-tetramethyl)-4-(piperidinyl)-, polymers with 2,4-dichloro-6-(4-morpholinyl)-1,3,5-triazine (CYASORB® UV-3346 light stabilizer) and poly-[[6-[(1,1,3,3-tetramethylbutyl)amino]-1,3,5-triazine-2,4-diyl][2-(2,6,6-tetramethyl-4-piperidinyl)imino]-1,6-hexane-diyl [2,2,6,6-tetramethyl-4-(piperidinyl)-imino]] (Chimassorb 944).

In the development of these high performance products, the optimal molecular weight for performance had to be defined. Significant effort was devoted to optimization. For example, in one study, oligomeric HALS with the empirical structure of CYASORB® UV-3346 were prepared, with different number- average MWs. The results indicated that oligomeric products with MWs in the 1600–1700 range afforded maximum performance under the test conditions (51). Molecular weight is a balance of acceptable volatility on the low end, and that of loss of translational mobility and matrix compatibility on the high end.

As an example, a Unipol (trademark of Union Carbide Corp.) LLDPE was compounded with a base stabilizer package, and 0.075% of CYASORB® UV-3346, Chimasorb 944, or Tinuvin 622. The resulting pellets were converted into tensile bars through injection molding. The tensile bars were exposed in a Xenon Arc WOM with water spray under ASTM G26 conditions, until failure. As expected, both high performance, triazine-class HALS outperformed the polyester HALS by a wide margin, as shown in Figure 7. The poor performance of the formulation containing Tinuvin 622 is thought to be directly related to its structure. In order to generate the active species for radical trapping, the backbone of the polyester HALS must first begin to cleave. Since the piperidinyl moieties are bonded to electron-withdrawing groups, the activation kinetics are not as favorable as they would be for a secondary or simply alkylated tertiary piperidinyl group (43,52,53). In addition, the polyester backbone is prone to photolytic and hydrolytic cleavage reactions, which can lead to additive loss. The latter reactions can be exacerbated in the presence of typical formulation components such as stearates.

A combination of monomeric and oligomeric products has shown improvement in UV performance as one might expect with a larger distribution of molecular weights. This distribution of molecular weights will give a better balance between mobility and efficiency in UV stabilization. Figure 8 demonstrates the improved performance that a 1:1 blend of a monomeric and a polymeric HALS can have compared with a single component system.

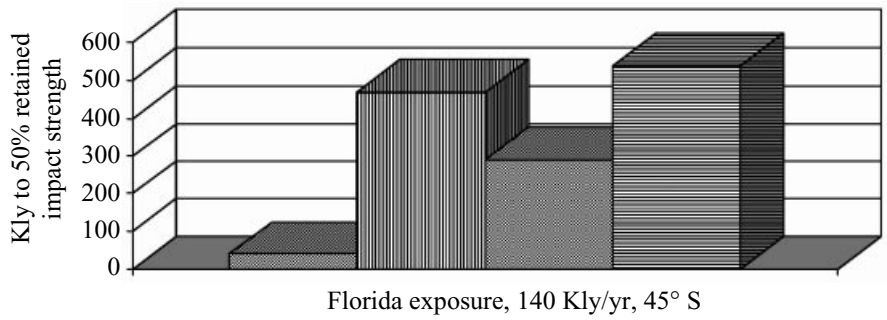

Fig. 8. UV stabilization of 2-mm injection-molded polypropylene plaques. ■ Control, ▩ 0.3% Tinuvin 770, ■ 0.3% Chimassorb 944, ▩ 0.15% Tinuvin 770 + 0.15% Chimassorb 944.

Third Generation: Noninteractive HALS. Although HALS have successfully displaced other types of UV stabilizers in many polyolefin applications, they are not without problems. In some applications, the basicity and nucleophilicity of secondary-amine HALS can sometimes contribute to undesirable side reactions. HALS can interact with other compounds in the stabilizer package and/or environmental agents to produce unanticipated and deleterious effects. Studies have shown that under certain conditions, HALS can be adsorbed to fillers in the polymer, resulting in a reduction in stabilization efficiency (54). A similar effect has been observed for some pigment classes. It has been proposed (55) that certain HALS can cause pigments to agglomerate, causing a reduction in color intensity. It was concluded (56) that in combination with certain antioxidants, some HALS will exacerbate the discoloration of polyolefins when exposed to oxides of nitrogen (gas fading). When used in agricultural films, HALS' effectiveness can be compromised by interactions with pesticides and fertilizers.

By alkylating the piperidinyl nitrogen, these interactions are minimized, and the basicity of the HALS is reduced. Tertiary HALS such as 1,6-hexanediamine, *N*,*N*′-bis(1,2,2,6,6-pentamethyl-4-piperidinyl)-, polymers with morpholine-2,4,

6-trichloro-1,3,5-triazine (CYASORB® UV-3529 Light Stabilizer) and 1,3,5-triazine-2,4,6-triamine,*N*,*N*″-[1,2-ethanediylbis[[[4,6-bis[butyl(1,2,2,6,6-pentamethyl-4-piperidinyl)amino]-1,3,5-triazine-2-yl]imino]-3,1 propanediyl]-bis[*N*′,*N*″-dibutyl-*N*′,*N*″-bis(1,2,2,6,6-pentamethyl-4-piperidinyl)] (Chimassorb 119) were developed to provide superior light stabilization performance while minimizing undesirable secondary interactions. Its lower basicity is also beneficial in controlling the discoloration rates of base-sensitive antioxidants like benzenepropanoic acid, 3,5-bis(1,1-dimethylethyl)-4-hydroxy-,2,2-bis[[3-[3,5-bis(1,1-dimethylethyl)-4-hydroxyphenyl]-1-oxopropoxy]methyl]-1,3-propanediyl ester (Irganox 1010), when the latter are exposed to exhaust gas fumes (NO_x).

It has been reported previously (57) that the light-stabilizing efficiency of CYASORB® UV-3529 is comparable to that of CYASORB® UV-3346 in most natural and pigmented PP fibers. The increased steric hindrance at the piperidinyl nitrogen in CYASORB® UV-3529 lowers the potential for interaction with pigments. With fewer tendencies for pigment agglomeration, color strength or yield is uncompromised when the HALS is added to the formulation.

Alkylating the piperidinyl nitrogen is also expected to reduce the HALS–pesticide interactions in greenhouse films. Figure 9 shows a comparison of the performance of CYASORB® UV-3346 and CYASORB® UV-3529 with Hostavin N-30, a reaction mixture of secondary and tertiary hindered amines, in acid-treated films. This test has been reported in the literature as a simulation for pesticide overspray. In this experiment, 50-μm LDPE greenhouse films were treated with 0.1 N sulfurous acid to simulate a sulfur-containing pesticide. The results show that substitution on the piperidinyl nitrogen alone is not sufficient to guarantee an elimination of undesirable secondary reactions. Differences in MW and MW distribution must also be considered.

Another class of low interactivity HALS is that based on NOR (alkoxyamine hindered amines) chemistry. These are also low basicity HALS which are claimed to provide stabilization efficiency and chemical resistance. Low MW products of this type, such as bis-(1-octyloxy-2,2,6,6,tetramethyl-4-piperidinyl) sebacate

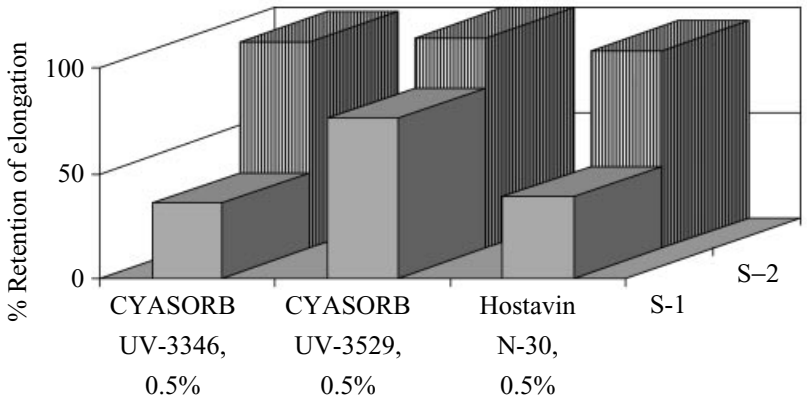

Fig. 9. UV stabilization of acid-treated 50-μm LDPE greenhouse films. S-1 (24-h dip-treated in 0.1 *N* H_2SO_3) vs S-2 (NON-TREATED). Xenon Arc WOM (1000 hours UV exposure).

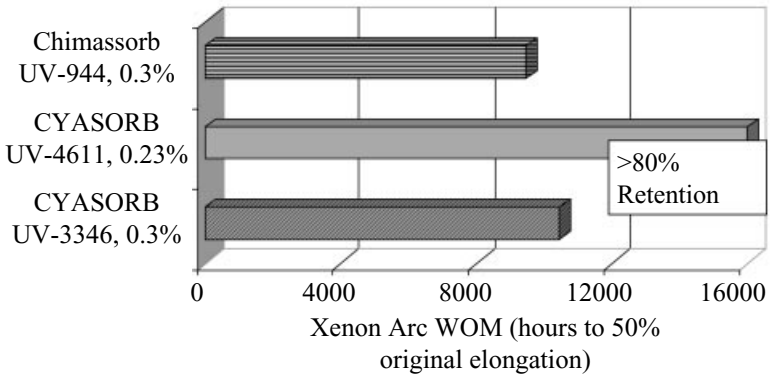

Fig. 10. UV stabilization of 1.5-mm injection-molded LLDPE tensile bars.

(Tinuvin 123), have been used extensively in automotive molding and coating applications. Higher MW versions have been developed and are targeted for greenhouse film applications (58), but commercial viability of these products is yet to be demonstrated.

Fourth Generation: Triazine–HALS Products. Combinations of triazine absorbers and HALS have recently been reported to show dramatic stabilization efficacy (59). Figure 10 shows a comparison of traditional oligomeric HALS with a Triazine–HALS blend (CYASORB THT^{TM}-4611 Light Stabilizer). These results demonstrate a significant performance advantage for the blend product. Investigations thus far have not discerned a mechanism consistent with the extent of synergism observed.

Other Light Stabilizer Types

In addition to UV absorbers and HALS, other types of UV stabilizers which inhibit degradation processes subsequent to photoinitiation are used. These include excited state quenchers, hydroperoxide decomposers, radical scavengers, and acid acceptors.

Excited State Quenchers. One of the first ideas beyond competitive UV absorption was to quench the excited states of the UV-absorbing chromophores, leading to radical formation. If the energy could be transferred to a molecule and dissipated harmlessly, radicals would not be formed. The nickel chelates have been reported to act primarily as excited state quenchers. However, most nickel UV stabilizers also have been found to provide hydroperoxide-decomposing or radical-scavenging activity. The nickel chelates usually add tan or green color to the polymer system. They perform better than UV absorbers in thin cross sections and in highly pigmented systems.

Nickel di-butyldithiocarbamate (Rylex NBC)(see Table 7) was introduced in the late 1950s. It had many drawbacks, such as high color contribution and volatility, but was a potent light stabilizer. It functioned mainly through hydroperoxide decomposition. It was used primarily in woven PP slit tape bags for the military. [2,2′-Thiobis(4-octylphenolato)]-*n*-butylamine nickel (CYASORB® UV-1084 Light

Stabilizer) was introduced in the early 1960s. This product continues to be used extensively in agricultural film applications, where its main advantage is resistance to deactivation by pesticides and soil fumigants, while providing good light stability. It is used alone in white on black mulch film products. Also, it is used in combination with 2-(2-hydroxy-4-octyloxyphenyl)benzophenone (CYASORB® UV-531 light absorber) in greenhouse film products usually at a 2:1 ratio. In this latter case, a bright yellow-green color is formed partially from the formation of the nickel complex of CYASORB® UV-531, which was found to be a very effective light stabilizer by itself. CYASORB® UV-1084 is also used in the stabilization of PP slit tape artificial turf.

Hydroperoxide Decomposers. Hydroperoxides were found to be a key UV-absorbing chromophore and an intermediate in the thermal and photooxidative mechanisms of many polymers. Reducing the hydroperoxide to a stable alcohol before it was thermolized or photolized into radical fragments was recognized to be very beneficial to polymer stabilization. Phosphites, nickel dithiocarbamates, cobalt dithiophosphinates, amidothiophosphates, and nickel thiobisphenolates (eg, CYASORB® UV-1084 Light Stabilizer) all are capable of decomposing hydroperoxides, and provide a significant amount of light stabilizing activity.

Since hydroperoxides are decomposed by heat and light to generate radicals which feed the degradation processes, it is essential that they be decomposed into nonradical products. Phosphites, such as di-stearyl pentaerythritol diphosphite (Weston 618), and sulfur compounds, such as nickel dibutyl dithiocarbamate (Rylex NBC), provide this function and both provide UV-stabilizing activity in polyolefin formulations. Phosphites usually are used in combination with other UV stabilizer types.

Radical Scavengers. Reacting with the radicals generated from the excited states before they would react with oxygen or reacting with the peroxide radicals before they would abstract a hydrogen from the polymer would certainly be beneficial to the stabilization process. Hindered phenolic antioxidant radical scavengers developed for thermal stabilization of polymers were found to offer very little light-stabilizing activity. However, the unique hindered benzoate class of radical scavengers was soon discovered. First there was the photorearrangeable aromatic benzoate 3,5-di-*tert*-butyl-4-hydroxybenzoic acid, 2,4-di-*tert*-butyl phenylester (Ionox 901) developed by Shell (60) and later commercialized by Ferro as UV Check AM-340, by Ciba as Tinuvin 120, and by others such as Seesorb 712 from Shipro Kasei in Japan. The aliphatic benzoate *n*-hexadecyl 3,5-di-*tert*-butyl-4-hydroxybenzoate (CYASORB® UV-2908 Light Stabilizer) does not photorearrange (61) to a benzophenone UV absorber, but does offer superior light-stabilizing activity, alone or in combination with other classes of stabilizers (62,63).

For example, a high MW hindered amine (eg, CYASORB® UV-3346 Light Stabilizer) combined with CYASORB® UV-2908 provides synergistic performance in PP slit tape applications during Xenon ARC WOM exposure (Fig. 11) (64). The use of this combination also allows improved processability in production of the slit tapes because of reduction in water carryover compared with HALS alone. It has also been demonstrated that, in thick section PP, long-term stability can be dramatically improved with CYASORB® UV-3346 combined with CYASORB® UV-2908.

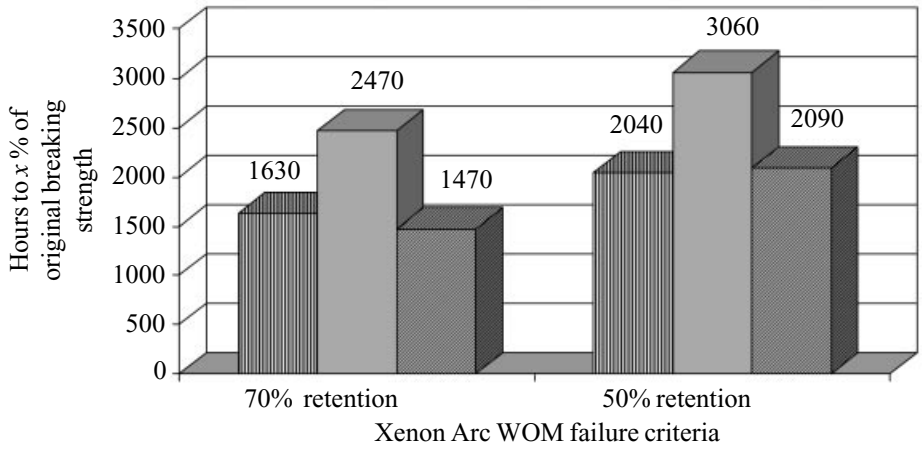

Fig. 11. UV stabilization of 65-μm PP slit tape. ▨ 0.3% CYASORB UV-3346; ▨ 0.2% CYASORB UV-3346, 0.1%. CYASORB UV-2908; ■ 0.3% Tinuvin 783.

Although HALS are recognized as one of the greatest advances in light stabilizer technology, their basicity and reactivity limits their use in many applications. Some examples are acid-catalyzed cross-linked automotive coatings, halogenated flame-retardant plastics, and interaction with pesticides in Ag films. Aliphatic benzoates can be substituted as radical scavengers in such applications where HALS cannot be used (65).

For example, the UV stabilization of blue, V-2 flame-retardant stadium seating was approached on the basis of the pigment and FR type. A benzophenone, 2-hydroxy-4-*n*-octyloxybenzophenone (CYASORB® UV-531 light absorber), was used at 0.5% to keep the blue pigment from fading and the aromatic bromine portions of the FR stable against UV radiation. CYASORB® UV-2908 was used at 0.5% in place of a HALS. An aliphatic phosphite (Weston 619) was incorporated at 0.5% to enhance the UV performance of UV-2 and to prevent degradation of the polypropylene during the extrusion and molding processes.

Pigments and Fillers. Other factors such as product cross-section and opacity affect UV stabilizer effectiveness, depending upon the chemical type and mechanism of action. In fact, carbon black and many white pigments, such as rutile titanium dioxide and zinc oxide, at sufficient concentration levels can limit the penetration of UV light energy, providing high levels of UV stabilization. In other situations, unfavorable interactions between pigments, fillers, and UV stabilizers result in reduced light stability.

Stabilization of Coatings

Coatings (qv) present a unique stabilization challenge because of their high surface-to-volume ratio. Coatings, like polymers, are classified as either thermoplastic or thermoset. Thermoplastic coatings are those that are composed mainly of individual polymer chains, sometimes partially branched. Examples of this type are acrylic latex paints, polyurethane dispersions, and nitrocellulose lacquers.

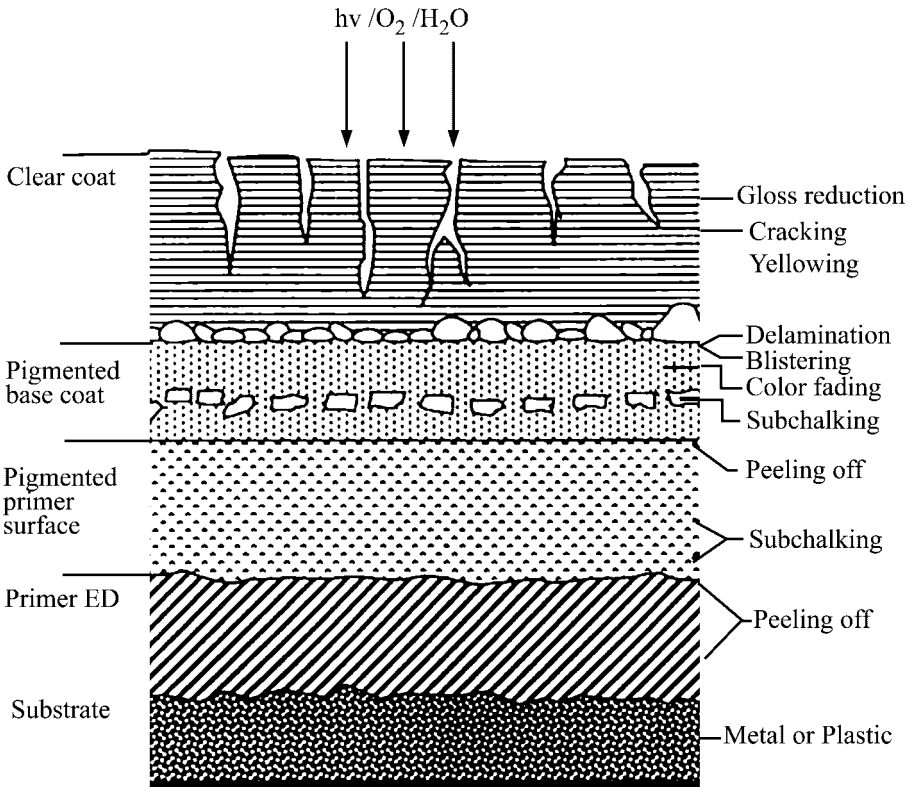

Fig. 12. Degradation phenomenon observed during weathering of a multilayer coating.

Thermoset coatings are those that are cross-linked to form an infinite polymer network. Examples of this type are acrylic melamines, two-component acrylic or polyester urethanes, alkyds, and epoxies. Coatings range in complexity from pigmented monocoats to multilayer coatings used on the exterior of automobiles. Any exterior coating is subject to degradation by the combined action of UV light, oxygen, and sometimes water, by the process of photo-oxidation. Modes of degradation of coatings are summarized in the idealized drawing of an automotive exterior coating of Figure 12. Before any organic coating film is applied, the steel is galvanized with a 0.2–0.6-μm layer of zinc, and then phosphated (0.3 μm). Then an E-coat (20 μm) is applied by electrodeposition (ED) and cured for corrosion resistance; a primer surfacer (25 μm) is applied for smoothing the surface and imparting adhesion; and a pigmented base coat (20 μm) is applied for the desired color. After a flash step (ambient or low temperature evaporation of solvent and/or water), a clear top coat (50 μm) is applied for an aesthetic high gloss appearance and the base coat/clear coat layers are simultaneously cured. UV radiation, oxygen, heat, and water have the following detrimental effects on the final coating film: reduction in gloss, yellowing, cracking, and blistering of the top coat; color fading of the base coat; and delamination at the base coat/top coat or other layer interfaces.

UV absorbers and HALS have found broad application in coatings for the slowing of these degradation processes, thereby extending the useful lifetime of

coatings. UV absorbers are most commonly used in clear coats, and also find use in pigmented coatings. UV absorbers can reduce pigment or dye fading, protect light-sensitive substrates from degradation, reduce blistering and delamination, and reduce yellowing. Benzotriazole is the most commonly used class of UV absorbers. 2-(2′-Hydroxy-3′,5′-di-*tert*-amylphenyl)benzotriazole (Tinuvin 328; CYASORB® UV-2337) is the largest volume UV absorber for coatings, followed by 2-(3′,5′-bis(1-methyl-1-phenylethyl)-2′-hydroxyphenyl)benzotriazole (Tinuvin 900) and benzenepropanoic acid, 3-(2*H*-benzotriazol-2-yl)-5-(1,1-dimethylethyl)-4-hydroxy-, C7-9 branched alkyl esters (Tinuvin 384). The use of benzophenones is restricted to some decorative and wood coatings. Recently, 2-hydroxy-phenyl-*s*-triazines have been introduced commercially. Examples are (i) 1,3-benzenediol, 4-[4,6-bis(2,4-dimethylphenylphenyl)-1,3,5-triazin-2-yl]-, C7-9 branched alkyl ethers (65% in xylenes) (CYASORB® UV-1164L light absorber) and (ii) 1,3-benzenediol, 4-[4,6-bis(2,4-dimethylphenylphenyl)-1,3,5-triazin-2-yl]-, reaction products with [(dodecyloxy)methyl]oxirane and oxirane mono[(C10-16-alkyloxy)methyl] derivatives (Tinuvin 400). This class of stabilizers exhibits strong UV-B (285–315 nm) absorptivity, low volatility, and synergy with HALS. In addition, it has the highest inherent light stability (66).

HALS play a major role in reducing the degradation that occurs on the coating surface, for example gloss reduction, cracking, and chalking (for pigmented coatings). They also help to reduce yellowing.

Monomeric HALS are almost exclusively used for coatings stabilization—polymeric HALS lack solubility in coatings and do not work as effectively as the monomeric type. Common HALS in commercial use for coatings stabilization include 3-dodecyl-1-(2,2,6,6-tetramethyl-4-piperidinyl)-2,5-pyrrolidine-2,5-dione (Sanduvor 3055; CYASORB® UV-3581 Light Stabilizer) and decanedioic acid, bis(1,2,2,6,6-pentamethyl-4-piperidinyl)ester (Tinuvin 292). These HALS are secondary (hydrogen-substituted) and tertiary (methyl-substituted) amines, respectively. Being basic in nature, these HALS interact with acid-curing catalysts commonly used in melamine-, benzoguanamine-, glycoluril-, and urea-formaldehyde resins, thereby interfering with curing. To overcome this limitation, nonbasic HALS were developed. Examples are 3-dodecyl-1-(1-acetyl-2,2,6,6-tetramethyl-4-piperidinyl)-2,5-pyrrolidinedione (Sanduvor 3058) and Tinuvin 123. Sanduvor 3058 has *N*-acetyl substitution (amide type HALS), and Tinuvin 123 has *N*-octyloxy substitution (amino ether type HALS). These HALS do not interfere with the curing of acid-catalyzed coatings.

Light stabilizers, including UV absorbers, HALS, and in some cases antioxidants, have been used to improve the weatherability of coatings and extend their useful lifetime. Unlike light stabilizers for plastics, light stabilizers for coatings must be soluble in common solvents used in solvent-borne paint, and compatible with the oligomeric and polymeric resins employed as paint binders. The ideal stabilizer is a liquid, for facile incorporation into the paint formulation. Example of liquid stabilizers are CYASORB UV-1164L (65% in xylenes) and Tinuvin 384. With the increased use of water-borne coatings, water-dispersible UV absorbers like a mixture of poly(oxy-1,2-ethanediyl)-α-(3-(3-(2*H*-benzotriazol-2-yl)-5-(1,1-dimethylethyl)-4-hydroxyphenyl)-1-oxopropyl)-ω-hydroxy, poly(oxy-1,2-ethanediyl)-α-(3-(3-(2*H*-benzotriazol-2-yl)-5-(1,1-dimethylethyl)-4-hydroxyphenyl)-1-oxopropyl-ω-(3-(3-(2*H*-benzotriazol-2-yl)-5-

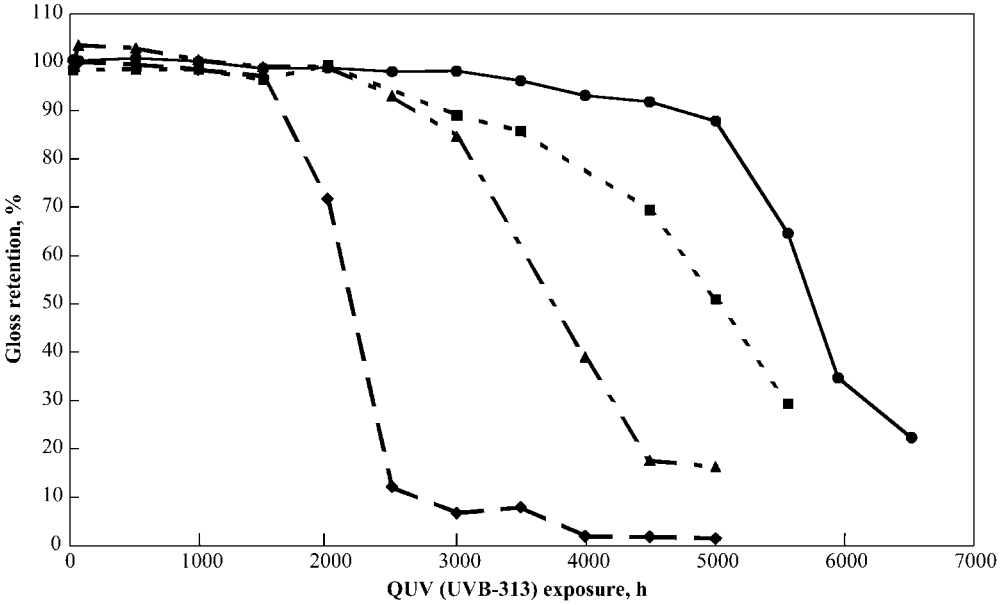

Fig. 13. Example of synergy between UV absorber and HALS. QUV weathering of Cymel® 303/Doresco® TA39-14 (styrene-free) acrylic clear coats. —◆ - Unstabilized; —▲ - 1% UV-1164; – ■- 1% UV-3581; —●— 0.5% UV-1164, 0.5% UV-3581.

(1,1-dimethylethyl)-4-hydroxyphenyl)-1-oxopropoxy, and polyethylene glycol, MW = 300 (Tinuvin 1130), are becoming increasingly important.

UV absorbers and HALS used in combination often exhibit a synergistic effect in coatings (67–70). 2-Hydroxyphenyl-*s*-triazines in particular also exhibit a synergistic effect (71,72). Thus they are typically used in combination. Figure 13 depicts an example of synergy between CYASORB UV-1164 and SANDUVOR 3055 under accelerated weathering conditions. In this case, the gloss retention of films containing 0.5% CYASORB UV-1164 and 0.5% SANDUVOR S-3055 is superior to films containing 1% of either stabilizer alone. The effectiveness of UV absorber/HALS combinations in Florida weathering has also been demonstrated. Florida weathering results for Joncryl® 510 (styrenated acrylic)/CYMEL® 303 acrylic melamine coatings containing 2% CYASORB UV-1164 in combination with SANDUVOR 3058 acetyl HALS over white base coats are given in Figures 14 and 15. The stabilized clear coats retain nearly 75% of their original gloss after 5 years of Florida weathering and exhibit a total color change (ΔE) of only 3 units after 6 years of Florida weathering.

Besides gloss and color changes, delamination is a major mode of failure, especially in multilayer coatings. For example, in an automotive original equipment manufacturer (OEM) multilayer coating as depicted in Figure 12, the ED primer coat is typically an aromatic epoxy resin. Aromatic epoxy resins are extremely light-sensitive, and decomposition of this layer can cause delamination at the ED primer/primer surfacer interface, or the ED primer/base coat interface. This was a major cause of automotive coating blistering and peeling in the 1980s. Although the real reasons will never be known, mechanisms of failure could have been any

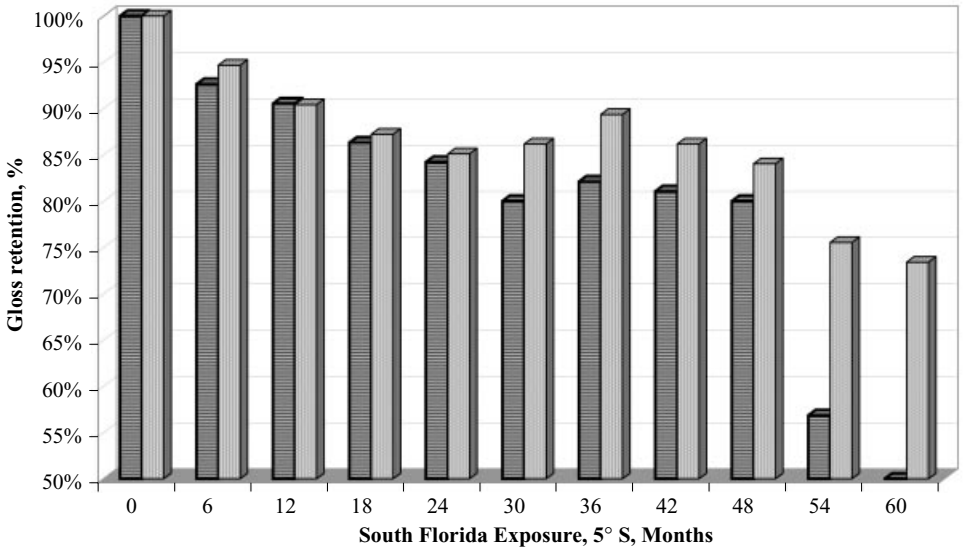

Fig. 14. % Gloss retention of 2% Cyasorb UV-1164L, 1% Sanduvor 3058, in Joncryl 510 (10% styrene acrylic)/Cymel 303 clear coat over white base coat. ■ Blank; ▨ 2% UV-1164L, 1% S-3058.

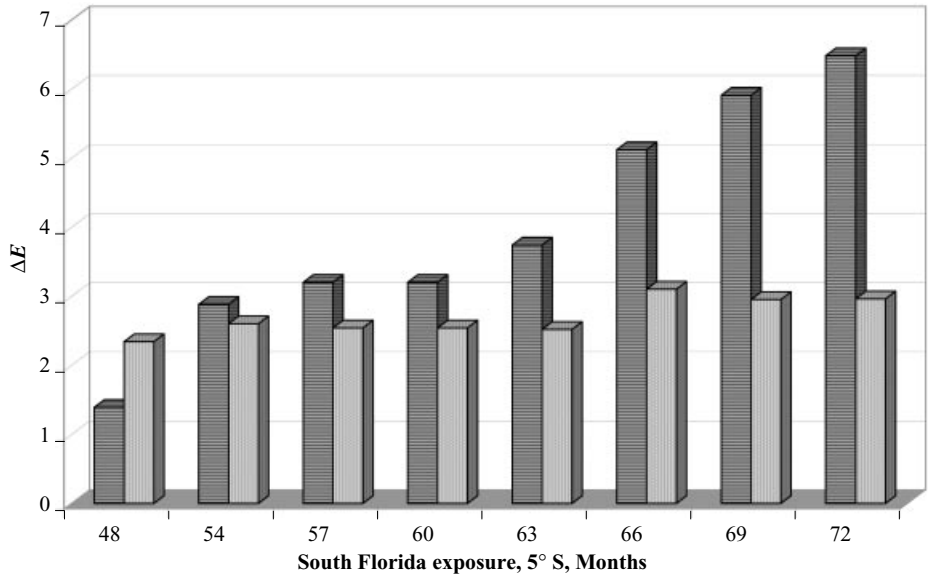

Fig. 15. ΔE with 2% Cyasorb UV-1164L, 1% Sanduvor 3058, in Joncryl 510 (10% styrene)/Cymel 303 clear coat over white base coat. ■ Blank; ▨ 2% UV-1164L, 1% S-3058.

one or a combination of (*1*) the absence of a heavily pigmented primer surfacer layer, (*2*) lower than normal film builds for the base coat and clear coat, affording less pigment screening of UV light (by the base coat) and less UV absorber screening of UV light (base coat and/or clear coat), (*3*) transmission of light in the

360-nm to visible regions due to UV absorbers with weak absorbance in this band, which also promotes degradation of epoxy resins, and (*4*) lower than normal UV absorber concentrations in the base coat and/or clear coat. Each of these conditions would lead to increased incidence of UV light onto the light-sensitive epoxy layer. Another mechanism of failure could have been over-bake conditions during curing, which would lead to thermal oxidation of the epoxy layer, the formation of radical species, and a "jump start" on photo-oxidation.

Since 1985 it has been recognized that light stabilizers can migrate in coatings, leading to concentration gradients as a function of depth. The concentration gradient can be across a single coating layer, between different layers of a multilayer coating, or between a coating and a permeable substrate such as plastic or wood. The microtome technique pioneered by Sandoz (now Clariant) chemists (73–77), and further utilized at Cytec Industries (78–83), involves the physical slicing of a coating film, parallel to its surface, in increments as small as 10 μm. The individual coating slices are then extracted with solvent or supercritical carbon dioxide and the extracts analyzed by glpc or hplc for stabilizer content. Alternatively, for clear films, UV absorber concentrations can be determined by UV spectroscopy. An example of migration of stabilizers between different coating layers is given in Figure 16 (80). The coating is an E-coat, base coat, and clear coat system. Only

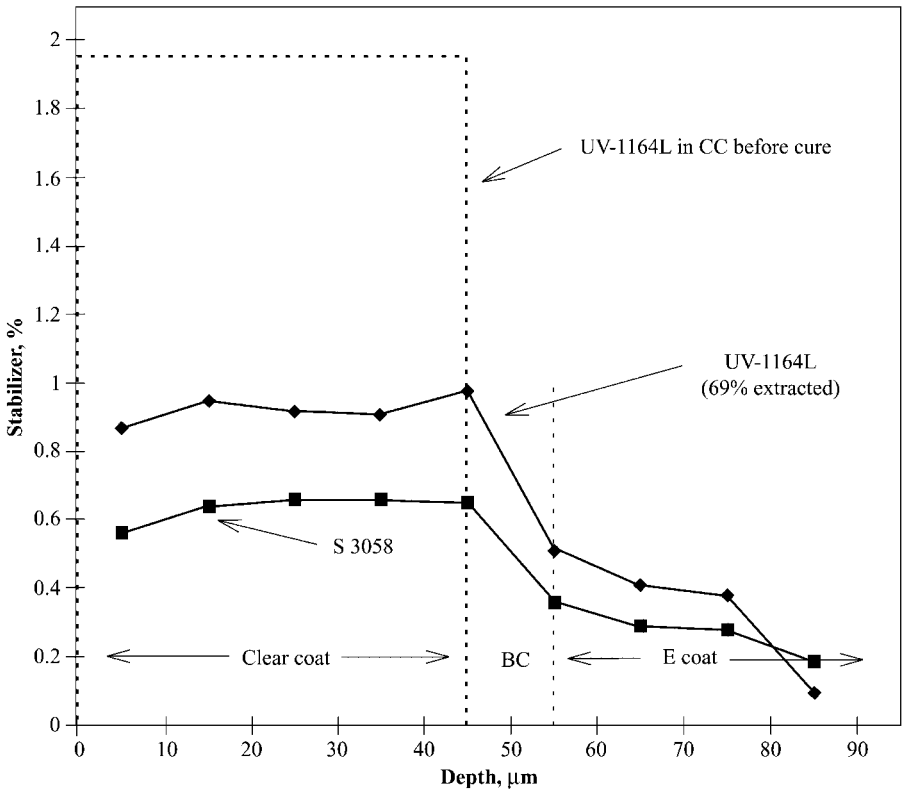

Fig. 16. Depth profile of stabilizer concentration in a clear coat/base coat/E coat system. Stabilizers were added to clear coat only prior to cure.

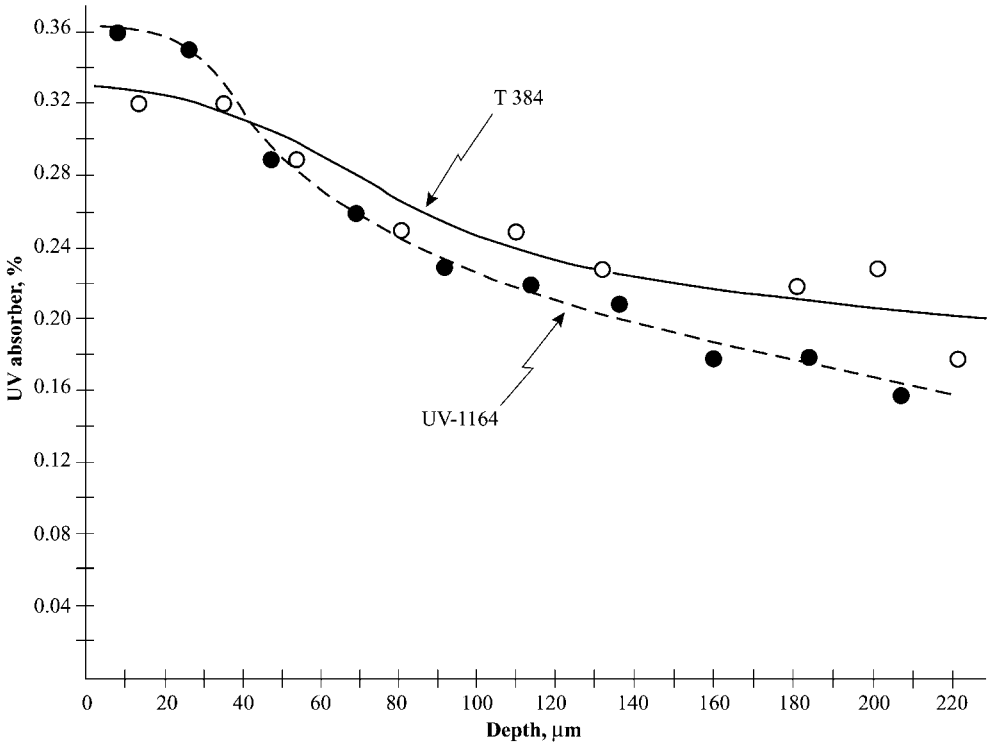

Fig. 17. Depth–concentration profile for Tinuvin® 384 and CYASORB® UV-1164L, showing migration into an RIM plastic substrate. A depth of 0 μm denotes the coating–RIM interface.

the clear coat was formulated with CYASORB UV-1164L and SANDUVOR 3058. But it can clearly be seen that during cure, both stabilizers have migrated not only into the base coat, but into the E-coat as well. Figure 17 depicts the results of two microtoming experiments of a RIM plastic, which had been painted with stabilized coatings (80). In one case, the RIM was coated with a film containing CYASORB UV-1164L, in the other, with a film containing Tinuvin 384. In each case, the coating–RIM interface is assigned a depth of 0 μm, and the stabilizers have migrated at least to a depth of 220 μm.

These data indicate that the amount of stabilizer actually present in any given coating film may be considerably less than originally formulated into the paint in multilayer coatings and coatings over plastics. This has led to a reevaluation of stabilization strategies for this application. One approach to minimize migration is to use a bondable light stabilizer. For example Tinuvin 400 has a secondary hydroxyl group, while 2-[(2-hydroxyethyl)amino]-4,6-bis[*N*-(1-cyclohexyloxy-2,2,6,6-tetramethylpiperidin-4-yl)butylamino-1,3,5-triazine (Tinuvin 152) has a primary hydroxyl group. With hydroxyl substituents, both stabilizers are capable of forming covalent bonds with typical coating cross-linkers, both melamine-formaldehyde resins and polyisocyanate resins, during cure. Thus they are locked into the coating matrix and prevented from migrating. Another novel

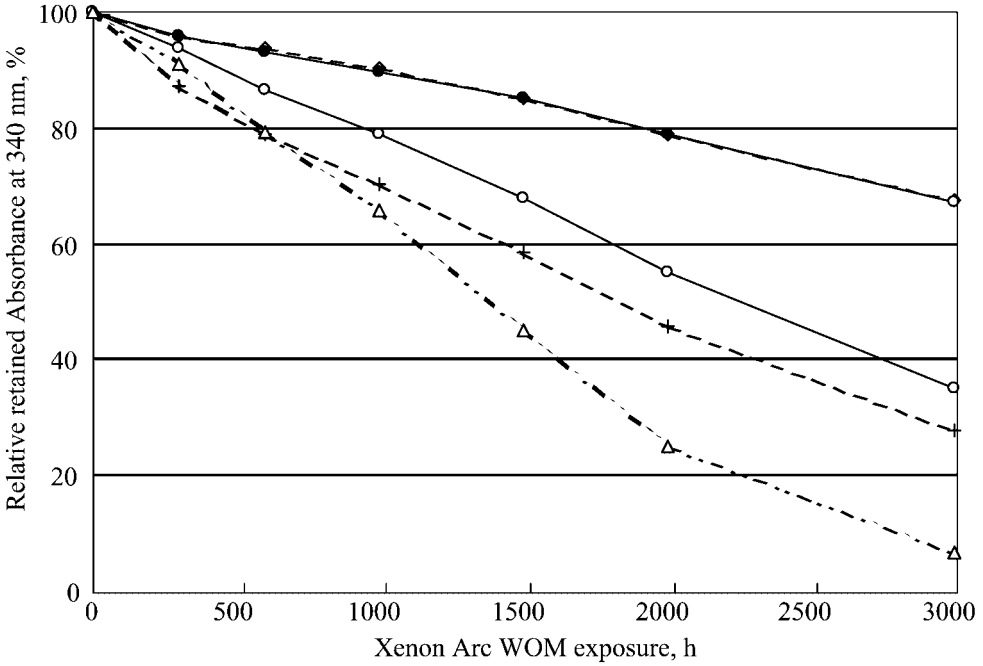

Fig. 18. Xenon weathering of UV absorbers in acrylic melamine clear coats (Copolymer N). – –◇– – CYASORB UV-1164, —●— CYASORB UV-1164L, —○— Tinuvin 1130, – –+– – Tinuvin 384, – -△– - Tinuvin 328.

approach is exemplified by propanedioic acid, [(4-methoxyphenyl)methylene]-bis(1,2,2,6,6-pentamethyl-4-piperidinyl) ester (SANDUVOR PR-31). This HALS forms a covalent bond with the coating matrix by a photochemical reaction upon exposure to light.

2-Hydroxyphenyl-*s*-triazines have excellent inherent light stability. This was demonstrated in an experiment in which acrylic melamine films containing various UV absorbers were drawn onto quartz slides and subjected to accelerated weathering (66). The loss of absorbance at the reference wavelength of 340 nm over time, an indication of UV degradation of the UV absorbers themselves, was measured. The stability of the UV absorbers in films containing a durable acrylic, Copolymer N, versus a less durable acrylic, Copolymer A, were compared. The results are given in Figures 18 and 19. In both cases, the 2-hydroxyphenyl-*s*-triazines CYASORB UV-1164 and CYASORB UV-1164L show the lowest rate of degradation compared with the other UV absorbers, all benzotriazoles. All of the UV absorbers had overall higher rates of degradation in the less durable acrylic, suggesting increased free-radical attack on the UV absorbers by the degrading coating matrix.

The ranking of stability of UV absorbers observed in the accelerated weathering studies was confirmed in Florida weathering of acrylic melamine automotive OEM coatings (84). The technique of microtoming was used to obtain 10-μm slices of the coating film (including both the top coat and base coat). Each slice was then analyzed by extraction and glpc for UV absorber content. UV absorber

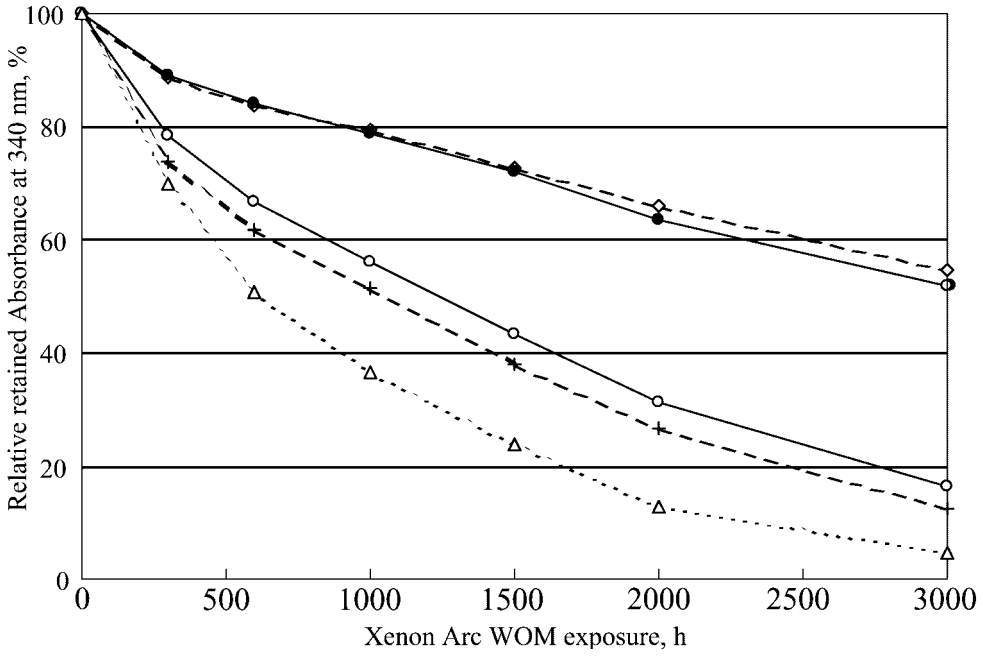

Fig. 19. Xenon weathering of UV absorbers in acrylic melamine clear coats (Copolymer A). – –◇– – CYASORB UV-1164, —●— CYASORB UV-1164L, —○— Tinuvin 1130, – –+– – Tinuvin 384, – -△– - Tinuvin 328.

concentration plotted as a function of depth for four coating films is shown in Figure 20. Two of the films contain CYASORB UV-1164L, microtomed after curing and after 3 years of Florida exposure, and two contain Tinuvin 900, likewise microtomed after curing and after 3 years of Florida exposure. It is evident from Figure 20 that additive concentration is not uniform throughout the coating film. The concentration of UV absorber tends to be less near the surface, because of volatilization during cure in the case of freshly cured films, and because of the combined effects of volatilization and degradation by UV light for the exposed coating films. Also, the loss of Tinuvin 900 is much greater than the loss of CYASORB UV-1164L after 3 years of Florida exposure, as predicted by the accelerated weathering experiment.

A series of papers published by the Research Staff at Ford Motor Co., Dearborn, Michigan, provides some insights into the photodegradation and stabilization of acrylic melamine and acrylic urethane coatings (35–43,85–97). These are the two most common thermoset (cross-linked) coating classes used for automotive OEM clear coats. These cross-linked materials derive their physical properties, eg hardness and chemical resistance, from chemical cross-links formed during the curing process between the backbone resin, usually a linear acrylic or polyester polyol, and a cross-linker (melamine-formaldehyde resin, or polyisocyanate), usually multifunctional. Conventional weathering of coatings to determine the durability of these coatings has its drawbacks. Outdoor weathering can take 5 years or more before physical failure. Accelerated weathering shortens the

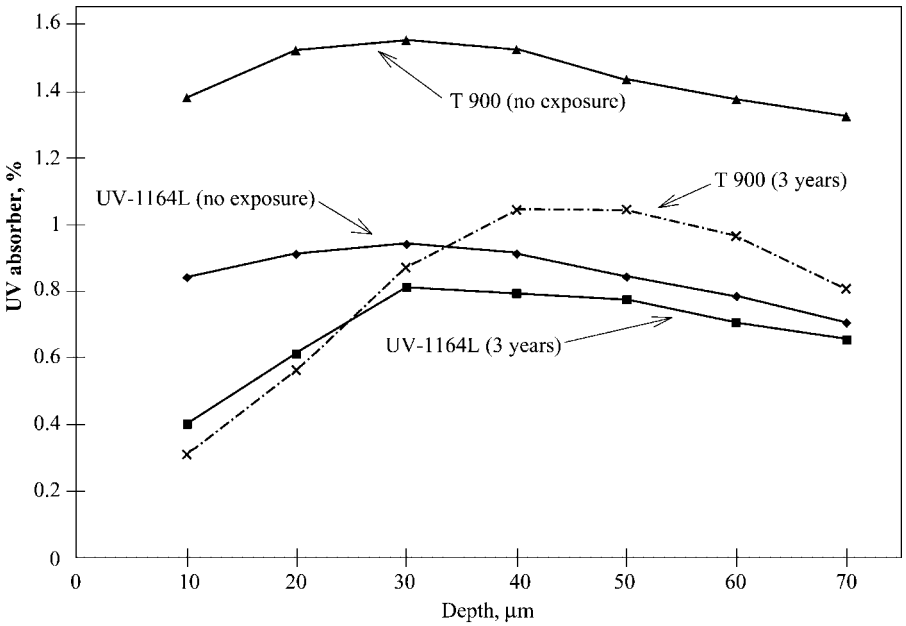

Fig. 20. Depth distribution of CYASORB® UV-1164L and Tinuvin® 900 in clear coat/base coat films after cure and after three years of florida exposure.

time to failure from years to several months, but the correlation of the results with outdoor weathering results depends upon the composition of the coating system. Since these cross-linked films can undergo a large amount of chemical changes (eg cross-link scission) before physical properties are affected, chemical tests have been used to rapidly track photodegradation without the use of artificially harsh accelerated exposure conditions. New chemical test protocols involving UV and ftir spectroscopy, iodometric titration, and esr have been used to assess coating weatherability.

VIBRATIONAL SPECTROSCOPY

Introduction

One of the most valuable realizations of a polymer scientist dealing with structural characterization is that use of many different techniques is required to fully understand polymer structures of different scales. Gel permeation chromatography, light scattering, and mass spectrometry (qv), particularly matrix assisted laser desorption mass spectrometry (MALDI), characterize overall molecular weight. Nuclear magnetic resonance can elucidate polymer chemical composition. Transmission electron microscopy is used to characterize density fluctuation within the sample to obtain detailed morphological features such as crystallite form and degree of phase separation in compatible systems. For information regarding atomic placement, X-ray and electron diffraction methods are generally utilized. Differential thermal calorimetric measurements provide insight regarding structural changes as functions of temperature and processing history. Vibrational spectroscopy is one of the oldest and most powerful technique for analyzing polymer composition and structure. In addition, the principal advantage for use of vibrational spectroscopy as a morphological tool is that it is extremely selective. Both crystalline and amorphous polymer structures can be characterized. Conformational order ranging from the shortest chemical repeat to several hundred angstroms can be measured. Unlike diffraction techniques which depend on long-range order or disorder, vibrational spectroscopy is characteristic of chain conformation at a more localized level. Although numerous techniques address polymer structure in the crystalline state, few provide information on the disordered state, a subject capable of being studied using vibrational spectroscopy. In fact, vibrational spectroscopy is routinely utilized to characterize polymer composition, segmental orientation, chain conformation, and intermolecular

interactions. Because of significant advances in instrumentation and simulation software, most laboratories possesses instrumentation capable of producing excellent data. Fibers, films, solutions, and melts can be analyzed with great confidence. The sample under examination need not be static in nature. Time-dependent phenomenon can be measured with time resolution as short as microseconds. It is also possible to measure samples in the range of micrometers or smaller with dedicated accessories. Vibrational spectroscopy provides information complementary to other characterization techniques and has proven of enormous value to studies in polymer science and engineering.

Applications of vibrational spectroscopy of polymers are generally divided into two subsets: infrared absorption spectroscopy and Raman scattering. Each offers particular advantages. The physical origin of the infrared and Raman effects are quite different, however. One depends on the dipole change and the other on changes in polarizability tensor (1). Different vibrational modes are therefore active in Raman and infrared. The more symmetric the molecule, the greater the difference between Raman and infrared spectra (1). The two techniques are truly complementary, however. For both cases, although more so for infrared, substantial literature exists regarding their utility for polymer characterization (2–8). Infrared spectroscopy is more appropriate for studies of chemical composition and side groups. Raman scattering is more effective for structural characterization since intense Raman scattering is often associated with the significant polarizability changes of the all-carbon backbone of the polymer chain and can be used much more readily to analyze chain conformation. They can be implemented in a broad spectrum of configurations including remote sensing and for studying solids, liquids, and gases. Intractable samples can be studied without much preparation. The power of vibrational spectroscopy, ie its selectivity and sensitivity, cannot be overestimated. Most research laboratories possess an excellent Fourier transform infrared and/or Raman spectrometer. These instruments are accurate, sensitive, durable, versatile, easy to use, and inexpensive to purchase. Extensive software is available for instrument control and to correlate spectroscopic features to the possible molecular functional groups from which they originate.

Infrared, Raman, and Normal Mode

Molecular spectroscopy is now a mature field of study. It is, however, difficult to find references superior to the classic treatise written by Herzberg nearly 50 years ago (1). The origin of vibrational spectra is usually considered in terms of mechanical oscillations associated with mass of the nuclei and interconnecting "springs" (9). Vibrational spectroscopy considers the frequency, shape, and intensity of internuclear motions due to incident electromagnetic fields. In the harmonic approximation, the vibrational bands are associated with transitions between nearest vibrational states. When higher order transitions, resonance, and coupling between vibrational motions require analysis, quantum mechanical treatment is mandated (1). Improvements and advancements in polymer spectroscopy are driven by the many problems of interest in the polymer community.

Infrared Spectroscopy. Infrared absorption spectroscopy is among the oldest and most widely used characterization techniques available to polymer

scientists. Without exaggeration, nearly every laboratory has an excellent Fourier transform infrared spectrometer. Sample preparation does not require significant effort. Polymers mixed with potassium bromide and then pressed into pellets or films prepared from melt or cast from solution can be easily studied. For bulk samples or powders, or if a concentration profile is needed for a film, the reflectance technique is perhaps more suitable (10). With the recent improvements in instrumentation, quantitative spectroscopic analysis of polymer solutions is not difficult to achieve. The availability of small yet powerful computers attached to instruments has provided new and powerful analysis routines for structural characterization.

Normal vibrations related to a change in dipole moment are infrared active. Groups with large dipole moments, such as C=O and N—H, typically have strong infrared absorptions. The majority of reported spectroscopic studies by infrared spectroscopy focus on determination of polymer molecular composition by analysis of characteristic vibrations of functional groups. The power of vibrational spectroscopy, ie its selectivity and sensitivity, cannot be overestimated. With accurately defined band assignment, particularly if the transition dipoles are well established, quantitative analysis of sample anisotropy in terms of segmental orientation can be accurately established.

Virtually all instruments employ an interferometer for infrared spectroscopy (11,12). Extremely accurate positions, intensity, and shape can be obtained. An interferometer generates information from the entire range of a given spectrum during each scan. The instruments, which are routine and extremely reliable, collect large amounts of energy at high resolution. Data are obtained in a relatively short time scale. Time resolution of milliseconds can be carried out with ease. With additional modifications, high temporal resolution as short as microseconds can also be accomplished with commercial instrumentation. Instrument improvements make far- and near-infrared spectroscopy feasible for structural characterization.

Tremendous advancements in a number of applications have been made possible by infrared spectroscopy. Specialized accessories facilitate surface studies. Developments in imaging techniques make high spatial resolution spectroscopy possible (13). High temporal resolution to follow kinetic developments can be accomplished with great precision and signal-to-noise ratio. Specialized techniques such as time-resolved spectroscopy and two-dimensional spectroscopy have contributed significantly to the understanding of molecular dynamics (14–16). Structural variations such as degree of crystallinity, segmental orientation, and composition at surface or bulk, can all be analyzed with the use of different types of spectroscopies. The development of photoacoustic spectroscopy should also be noted (17). This technique has contributed significantly to analysis of polymer structure, both surface and bulk, with sensitivity and speed. These application-driven developments are discussed below in greater detail.

Raman Scattering. Although the Raman effect was first reported in 1928 (18,19), its utility as a characterization tool was not realized until the advent of lasers in the early 1960s (20). With the recent advances in lasers, detection systems, and spectrometer design, a tremendous potential exists for use of the Raman technique as a characterization technique. Since it is a scattering technique, samples such as powder, film, solid, filament, or solution can all be studied

with little sample preparation. Biological samples can also be characterized since scattering from water is extremely weak. As virtually all polymers used commercially are carbon based, the change in polarizability along the backbone is large. Raman scattering is therefore particularly suitable for characterization of polymer backbone conformation. Confocal Raman microscopes are available with spatial resolution approaching the diffraction limit of the focused laser beam. The lasers generally used for Raman scattering produce highly polarized excitation radiation. The polarized or depolarized scattered radiation collected are especially suitable for analysis of segmental orientation. In fact, various Raman techniques have been used on-line to elucidate effects of changing processing parameters on morphology development in uniaxial and biaxial polymers.

Despite its capability for delivering detailed structural information, Raman scattering has not yet achieved equal status with other characterization techniques. Its development has been slow because of the high initial investment and maintenance costs (high power lasers, sophisticated spectrometers, sensitive detectors, etc). The Raman effect is extremely weak, eg, only 1 in 10^4 or many fewer incident photons result in inelastic scattering (21). Intense excitation sources are needed which may also cause fluorescence that overwhelms the Raman signals. The earliest Raman studies on polystyrene and poly(methyl methacrylate) were possible only because the samples were totally clear and fluorescence free. Raman spectra can today be readily obtained from most polymers. Recrystallization or extraction has been effective in removing impurities that cause fluorescence. Another alternative is to use long wavelength excitation (1.06 μm) as in most Fourier transform instruments. Nevertheless, the Raman technique yields tremendous structural information and effectively complements other characterization techniques. Many Raman instruments are designed around a dispersive spectrometer. In comparison to infrared instruments, this type of spectroscopy is much slower. There are, however, distinct advantages. These are

(1) Since many excitation sources are in the visible range, the optical elements are generally much simpler to deal with in comparison to infrared.
(2) The photomultiplier exhibits much flatter quantum efficiency.
(3) Lower frequency vibrations can be studied with ease.
(4) Because of the shorter excitation wavelength, high spatial resolution can be achieved for imaging studies.

In addition, with the tremendous improvements in multichannel charge-coupled device (CCD) detectors, high quality Raman data can be obtained efficiently.

The Raman effect, an absorption and emission phenomenon, can be described in the following fashion. Imagine placing a molecule in an electric field. This molecule will be polarized by the electric field; in other words a dipole will be induced in the molecule such that the electrons are distorted away from the direction of the field. If the electric field is oscillating (with frequency ω_0), the induced dipole will oscillate with the same frequency, ω_0; this is typical Rayleigh scattering. Now imagine the case where the molecule is already vibrating with some other frequency ω_i (for example, bond stretching). The interaction between the oscillating

molecule and the incident radiation will result in both elastic (Rayleigh) and inelastic (Raman) scattering.

The polarizability of the oscillating molecule is described by

$$\alpha = \alpha_0 + \sum_{i=1}^{i=3N-6} \frac{\partial \alpha}{\partial Q_i} Q_i + \cdots = \alpha_0 + \sum_{i=1}^{i=3N-6} \alpha_i' Q_i + \cdots \tag{1}$$

where Q_i describes the vibration of the molecule. The interaction of the oscillating molecule with the incident radiation can be expressed as

$$I_{\text{scattered}} = \alpha E = \left(\alpha_0 + \sum_{i=1}^{i=3N-6} \frac{\partial \alpha}{\partial Q_i} Q_i + \cdots \right) E \tag{2}$$

The incident radiation is described by $E = E_0 \cos \omega_0 t$ and the vibrational mode is described by $Q_i = Q_i^0 \cos \omega_i t$. After substituting these two expressions into the above equation, we get a description for scattered light by an oscillating molecule.

$$\begin{aligned} I_{\text{scattered}} = \alpha E &= \left(\alpha_0 + \sum_{i=1}^{i=3N-6} \frac{\partial \alpha}{\partial Q_i} Q_i + \cdots \right) E \\ &= \alpha_0 E_0 \cos \omega_0 t + \sum_{i=1}^{i=3N-6} \frac{\partial \alpha}{\partial Q_i} Q_i^0 E_0 \cos \omega_i t \cos \omega_0 t \\ &= \alpha_0 E_0 \cos \omega_0 t + \sum_{i=1}^{i=3N-6} \frac{\partial \alpha}{\partial Q_i} Q_i^0 E_0 [\cos(\omega_0 + \omega_i)t + \cos(\omega_0 + \omega_i)t] \end{aligned} \tag{3}$$

The scattered light includes both elastically scattered radiation (ie Rayleigh scattering) and inelastic scattering (Stokes and anti-Stokes Raman scattering), is dependent on the change in polarizability and is described by a tensor. In general, the scattering tensor (real and symmetric) is defined as

$$\alpha_{\text{mol}} = \begin{pmatrix} \alpha_{11} & \alpha_{12} & \alpha_{13} \\ \alpha_{21} & \alpha_{22} & \alpha_{23} \\ \alpha_{31} & \alpha_{32} & \alpha_{31} \end{pmatrix} \tag{4}$$

Six independent elements need be determined. In this case, we designate α_{ij}'s to represent the change in polarizability elements in respect to the displacement relative to the equilibrium positions. The elements depend on the molecular symmetry, functional groups, and degree of orientational order in the sample. When the symmetry of the translational repeat of polymers is known, analysis of polarized Raman scattering yields significant structural information. The chain segment orientation distribution, the parameters needed to achieve the degree of anisotropy, and assignment of particular bands can all be obtained (22–27).

Unless the sample is an oriented macroscopic single crystal (almost never the case), some polarization information in the scattered light is lost. Partially

oriented systems can be either uniaxially oriented such as in fibers or planarly (biaxially) oriented films. Here the relationship between the molecular and laboratory frames is partially lost. Thus, specific information about each of the six elements is lost. Instead the tensor elements combine forming a new set of four elements, each being a linear combination of the previous six elements (24). These are useful for structural analysis and band assignment.

The molecular orientation with respect to the laboratory frame can be completely random as in liquids or melts. Each scattering center is randomly oriented relative to the laboratory frame such that the scattering tensor is reduced to the relationship between the isotropic and anisotropic portions. Even under these circumstances, information about the scattering tensor elements associated with various modes can be obtained through measurements of the *depolarization ratio* ρ, defined to be the ratio of the scattered light intensity obtained when the scattered and incident beams are linearly polarized perpendicular to each other to that obtained when they are polarized parallel to each other (20). Careful analysis of polarized Raman spectra can still yield information regarding the local chain conformation, interaction with solvents, degree of chain extension, or amorphous portions of semicrystalline polymers or glassy solids (28–34). Since most polymers of interest involve carbon backbones, the differential polarizability tensor elements have large isotropic elements. In many cases, only the isotropic spectrum is used for structural characterization, thus eliminating vibrations unrelated to conformational analysis (35–38).

Nature of Normal Vibrations. The vibrations observed using either infrared or Raman deal with oscillatory movements of nuclei vibrating about their equilibrium positions. This is based on the fact that in the presence of an exciting electromagnetic radiation, electronic and nuclei motions can be considered separately (1) and is generally referred as the Born Oppenheimer approximation (1). Quantum mechanics and associated wavefunctions need be considered in order to analyze the intensity of vibrational transitions. In addition, coupling of vibrations and other second-order effects can only be addressed using quantum mechanical formalisms. The classical picture involving masses and spring constants is the norm, however. In this case, the equilibrium geometry of molecules and polymers is the basis for studies on the optical activity of various infrared or Raman active modes (9,39). Both infrared and typical Raman spectra characterize the absorption of energy from the incident beam by the relative motions of nuclei associated with a polymer.

Vibrations are considered in terms of the classical expressions governing motion of nuclei vibrating about their equilibrium positions with a simple harmonic motion (40). The potential and kinetic potential energies of molecules are defined in terms of the coordinates most appropriate to the molecular structures. All relative motions of atoms about the center of mass (vibrations) are linear combinations of a set of coordinates, known as normal coordinates. For every normal mode of vibration, all coordinates vary periodically with the same frequency and pass through equilibrium simultaneously.

Application of vibrational spectroscopy depends extensively on characteristic vibrations associated with functional groups (5). For composition analysis, the software associated with various spectrometers is capable of searching the extensive reference library to yield the best match for the measured spectra. For more

quantitative analysis of sample composition, changes in chain conformation, or packing, it is often necessary to consider the relative band intensity or bandwidth. A normal coordinate analysis (described below) is helpful in band assignment and interpretation of observed features.

For a nonlinear small molecule of N nuclei, there are $3N$-6 vibrations. The 6 degrees of freedom associated with the overall molecular translations and rotations cannot be considered as vibrations. However, the spectra obtained for polymers are not as complicated as might be imagined considering the extremely high molecular weight of most polymers of interest. In fact, for infinite polymers of well-defined conformation, there are $3N$-4 optically active vibrations, where N now refers to the number of nuclei per translationally equivalent structural unit (8,39,41). In comparison to small molecules, 2 additional vibrational transitions exist because only the rotation about the chain axis can occur without being drawn back toward the equilibrium position. The optical activity of expected vibrations can be analyzed based on the helical chain structure (8,39,41). For polyethylene, the translational equivalent repeat is $-CH_2CH_2-$; N is 6. For polypropylene N is 27, since there are nine atoms per chemical repeat and three units form a translationally equivalent repeat unit. For highly ordered polymers or oligomers, symmetry analysis or group theory is a powerful tool for determining the number of expected vibrations and their optical activities (40). The infrared and Raman spectra obtained for a highly crystalline polyethylene film are shown in Figure 1. Numerous studies have been carried out to elucidate the vibrational features of polyethylene or n-alkanes (42–44). Note that in Figure 1, none of the bands present in the infrared are Raman active. This mutual exclusion reflects the fact that the polyethylene chain conformation has inversion symmetry (1,6,8,45–47).

Most polymer solids contain both crystalline and amorphous regions. The number of vibrations observed is generally higher than expected purely from symmetry considerations of well-defined chain conformation. In polyethylene, for example, by measuring a series of samples containing different degrees of crystallinity, vibrational transitions associated with irregular chain conformations, presumably in the amorphous regions, can be found in the 1300 cm^{-1} region (Fig. 2). Since the structures are irregular, transition assignments cannot be made from symmetry considerations and numerical analysis is required as demonstrated below.

Coupled Oscillator Model. The theory that vibrations couple (such as crystal field splitting in ordered polymers) is generally accepted. Individual chemical repeats may vibrate independent of each other. As polymer spectra do not significantly differ from the constituent monomers, this is the basis for analysis of composition analysis using "fingerprint" features. Information regarding chain conformation, configuration, or packing in the condensed state may reside in the band splitting, band shape or position of the observed vibrations. The degeneracy of the vibrations of functional groups in each chemical repeat may be lifted due to the covalent interconnecting bonds. This strong interaction may introduce additional features expected from consideration of a single monomer unit. The presence of secondary intermolecular interactions may introduce additional features (7). This can be demonstrated most clearly in spectra obtained for an oligomer with well-defined chain conformations arising from the connectivity of the chain of repeat units. These additional spectroscopic features, found in both infrared and

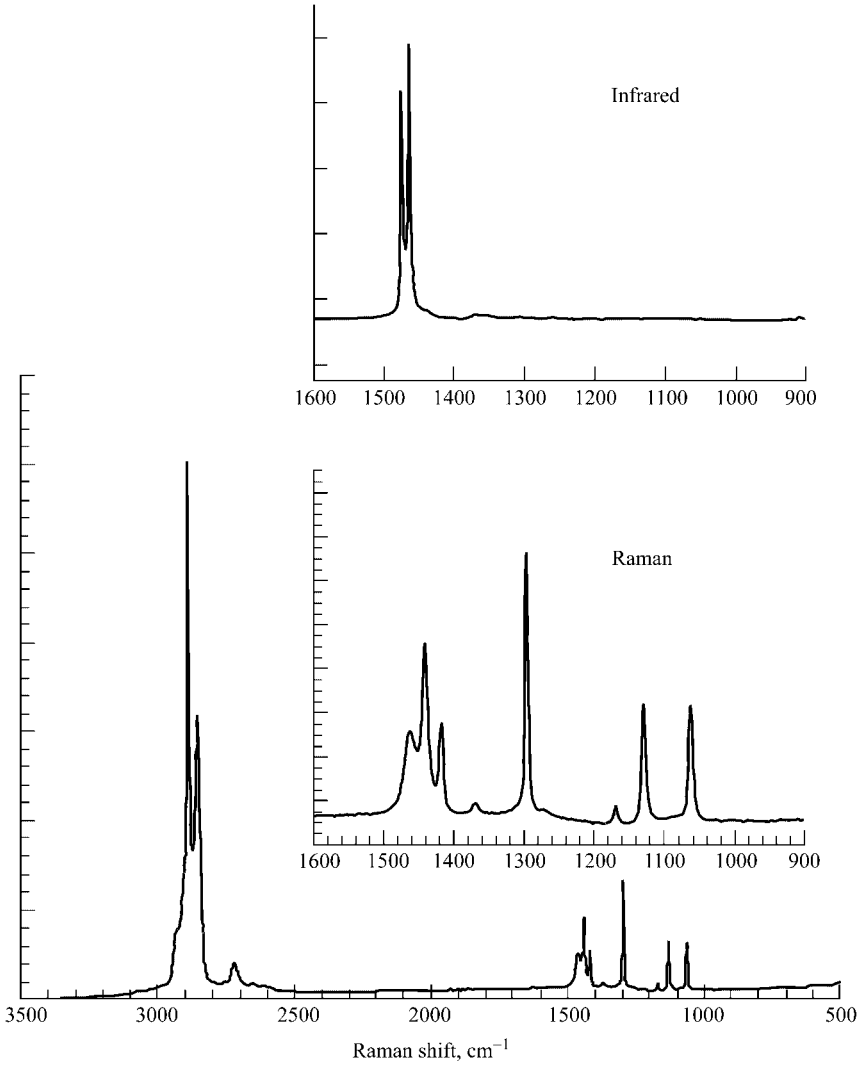

Fig. 1. Infrared and Raman spectra for polyethylene.

Raman spectra of oligomers, have been explained in terms of a coupled oscillator model (42,48). Detailed understanding of the vibrations found for oligomers yields considerable insight into vibrational spectra obtained for polymers.

The idea that vibrations can couple is quite general. For each vibration with frequency ω_0 found for the individual chemical repeat units, a series of vibrations arising from the backbone coupling may shift from the unperturbed value. For a chain with N chemical repeat units or N oscillators, instead of a set of N degenerate vibrations of frequency ω_0, a series or progression of vibrations may exist. Representative infrared and Raman spectra for $C_{20}H_{42}$ are shown in Figure 3. The frequency separation of the progression modes is inversely proportional to the unperturbed frequency ω_0. The localized vibration, such as the CH_2 stretching

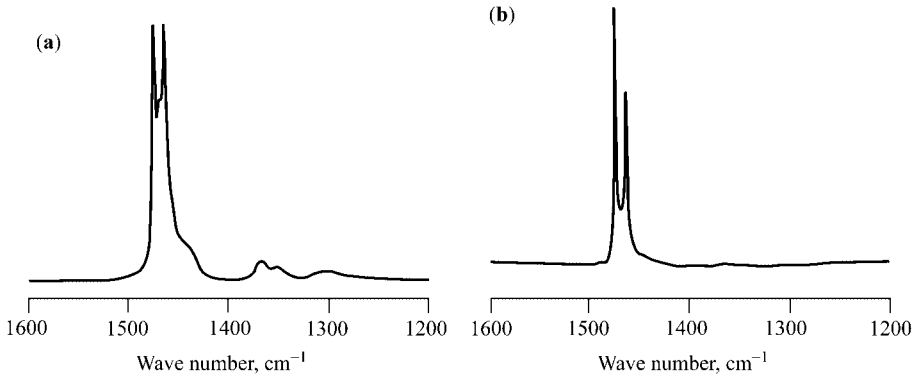

Fig. 2. Amorphous bands found for polyethylene: (**a**) polyethylene film quenched from melt; (**b**) same film after annealing.

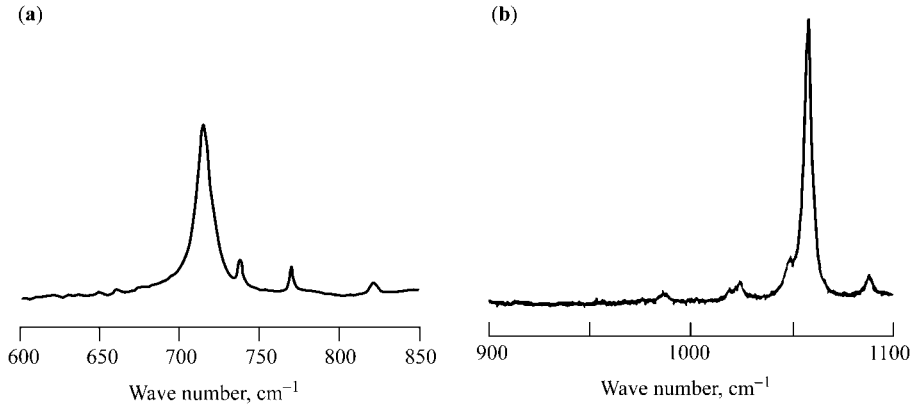

Fig. 3. Progression bands observed for $C_{20}H_{42}$: (**a**) infrared spectrum; (**b**) Raman spectrum.

vibration in the 3000 cm^{-1} region, is hardly perturbed by the interaction along the chain. In contrast, low frequency components such as the CH_2 rocking vibration at 700 cm^{-1}, can be perturbed significantly.

The frequency of individual vibrations can be expressed as

$$\omega_i^2 = \omega_0^2 + \Delta\omega_i^2 \tag{5}$$

where ω_0 is the unperturbed frequency of an oscillator in the chemical repeat. The ω_i is the frequency of the ith mode in the progression. $\Delta\omega_i^2$ is the perturbation dependent on geometric parameters (conformation) and interactions between adjacent units. Seldom is there a need to consider interactions beyond adjacent units. When molecular weight increases, the intensity is concentrated at the unperturbed position with an asymmetric band shape (7). For chains with well-defined conformation, the perturbing effects of coupling are clear and can be analyzed. Spectroscopic features can therefore be used to analyze chain conformation. For disordered structures, the vibrational spectra observed may be complex owing to

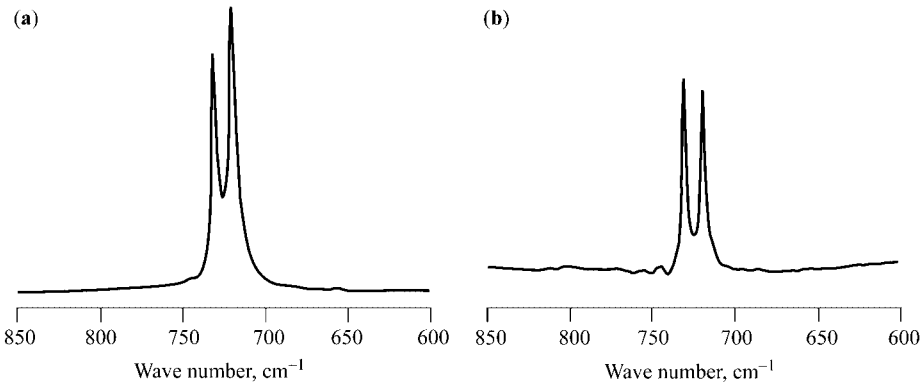

Fig. 4. Crystalline field splitting observed for polyethylene: (**a**) film quenched from melt; (**b**) film annealed at 80°C.

changes in both band frequency and shape. In this case, the vibrational mode can be quite complex because contributions of various internal coordinates to the vibration (character of the vibration) may change significantly as compared to an ordered structure. When understood, changing frequency and character of several vibrations provide tremendous insight into the structure of polymers in solution or melt.

Additional features are observed for highly crystalline polymers. The crystalline structure of polyethylene has been well characterized (45). There are two chains per crystalline unit cell. Just as strong coupling exists between vibrations along the polymer chain, coupling can also occur for equivalent vibrations in the crystalline unit cell. The nonbonded intermolecular coupling between the two chains effectively removes the degeneracy between the equivalent oscillators associated with the chemical units of the two individual chains. Instead of one component near 720 cm^{-1}, a doublet at 721 and 730 cm^{-1} is observed (Fig. 4). The magnitude of the splitting and the relative intensity of the two components depends on the specificity and magnitude of the nonbonded van der Waals interactions between the two chains in the unit cell. In *trans*-1,4-polybutadienes, the splitting, particularly at low temperatures, seen at 240 cm^{-1} is consistent with predictions from theoretical analysis (49). Similar observations have been found for crystalline structures of proteins and model polypeptides. There the hydrogen bonded amide units exhibit well-defined spectroscopic features due to transition dipole coupling (50,51). Similar effects in poly(lactic acid) have recently been observed (52,53). Even the isolated C=O stretching vibration is sufficiently perturbed to have at least three components. In this case, strong dipoles of the ester groups affect both chain conformation and chain packing.

The nature of intermolecular interactions can also be studied by analyzing the frequency and intensity of the external vibrations, or lattice modes, of the unit cell (49,54,55). The coupling of chains can be characterized by the whole chain segment movements which generally occur in the very low frequency region, ie, typically <100 cm^{-1}. These modes are in addition to the internal modes of each chain. The translatory modes can be seen in far-infrared absorption spectra. Fourier transform instruments have improved the signal-to-noise ratio, making

these measurements relatively painless. Since intermolecular interactions can be significantly increased by lowering the measurement temperature, the magnitude of crystal-field splittings may increase substantially and the shape of the lattice modes may narrow with an upward shift in frequency.

With a Raman instrument, measurement of these low lying bands is fairly straightforward. If the elastic Rayleigh scattering can be removed (for example the use of iodine gas filters (56) to selectively absorb the Rayleigh line), very low frequency vibrations in the range of a few cm^{-1} can be observed. Based on the unit cell parameters of polyethylene, a set of Raman active lattice vibrations has been observed for polyethylene and paraffins (57). Rotatory modes are seen in *trans*-1,4-polybutadiene (49). With analysis of these low lying vibrations in a quantitative fashion, a correlation between molecular and macroscopic properties such as heat capacity, thermal pressure, thermal expansion, P–V–T relations, and stress–strain behavior can all be established (58).

Normal Coordinate Analysis. Normal coordinate analysis provides information concerning the nature of vibrations. Accurate assignment is the basis for using characteristic frequencies of various functional groups. Detailed analysis of data obtained by normal coordinate analysis has traditionally been based on the symmetry of the equilibrium structure. The optical activity and characteristics of the normal vibration can be deduced from the constructed symmetry coordinates (9,40). Recent advances in computing have had a tremendous impact on analysis of vibrational spectroscopy. Vibrational modeling of polymers has traditionally involved use of a normal coordinate analysis (NCA) based on Wilson's GF matrices and force constants transferred from small molecules (42). Refinements in force field are often required to better fit the polymer system. Such analyses can only involve the specific chain conformation generated with well-established bond lengths and valence and torsional angles. The first computer programs, introduced in the 1960s, were followed by many variations (42,43,59,60). The generation of structures consistent with helical parameters obtained from diffraction data usually test the structural parameters. Only recently has calculation of vibrational spectra for all possible chain conformations sufficiently large to describe disordered chains become feasible.

A requisite for accurate NCA analyses is availability of a reliable force field. In general, only intramolecular potential energies are needed. The cartesian coordinate is most convenient to define all individual atoms in space. It is, however, most natural to consider the potential energy of the molecule in terms of bond, valence angles, and torsional angles, commonly referred to as internal coordinates. All force constants are defined in this coordinate system. The relationship between the two sets of coordinates is easily established (9). With few exceptions, such as polyethylene and *trans*-1,4-polybutadienes, explicit evidence of optically active intermolecular vibrations is unavailable (49). Therefore, interchain interactions are seldom considered, even though well-defined interatomic potentials can easily be incorporated (54,55). As the number of force constants (both diagonal and off-diagonal coupling) is much larger than the number of observations, few are determined with certainty. In both intra- and intermolecular interactions, the force fields are transferred from those established for small molecules. Among those refined for specific polymers, perhaps the most used are those for n-alkanes and polypeptides (42,43,59–61).

Analysis of disordered structures is of particular interest as these chains lack long-range order and may possess very specific chain conformational distribution depending on the environment. For example, changes in the solvent chain dimension can be monitored using the static light scattering technique. A detailed description of structural changes in this chain and specific interactions between chain and solvent can be accomplished only by use of vibrational spectroscopy.

Polymer conformation is often described using the concept of the rotational isomeric state (62). It is unrealistic to model polymers with randomly oriented bonds. Because of steric interaction of substituent atoms, some relative orientations of adjacent bonds are more favorable than others. The rotational isomeric model encompasses this idea and is generally used to describe polymer chain conformation. For example, the most favorable polyethylene chain conformation is the planar zigzag trans structure (rotational angle = 180°). Less favorable are the gauche and gauche′ states (60 and 240°). For polyethylene, the probability of obtaining the relative orientation of adjacent bonds in these states is much higher than others. An ensemble of chain conformation is most convenient to describe the amorphous structure. Vibrational spectroscopy is one of the few tools available for observation of both crystalline and amorphous structures. It should be noted that the marked increase in computing performance during the past few years has served, over the same time frame, as perhaps a prime impetus for progress of spectroscopy research. Experimental data are complemented by sophisticated calculations. In the past, large and challenging analyses of macromolecular systems were possible only on mainframe computers. The same calculations can be performed today and with greater speed on workstations or personal computers available in virtually every laboratory. With the support of simulation methods, spectroscopic analysis is again among the most useful characterization method of polymers.

Lack of a quantitative definition of disorder is a major obstacle in analysis of spectra from disordered polymeric chains. Rather than analyzing one specific chain conformation for an ordered chain, the analysis requires the vibrational spectrum of a conformational distribution. This problem is complex, even in relatively short-chain molecules. An extremely large number of possible conformers exist, each with a unique spectrum often only slightly different from another. The isotropic Raman spectrum for the disordered state was simulated as a composite of contributions from the ensemble of chains generated by a Monte Carlo procedure that assigned both a conformation and a total probability for each chain. The spectrum of each conformation is calculated from force constant and intensity data transferred from smaller molecules. These individual spectra are then weighted by their probabilities and combined into a composite spectrum. With a surprisingly small number of structural and intensity parameters (additivity in bond polarizability is always assumed), it is possible to accurately reproduce experimental infrared and Raman spectra of some *n*-alkanes (36). The same method has been applied to more complicated polymers lacking long-range order. The original code was designed for polymers with identical skeletal bonds. Subsequent program modifications were introduced to allow nonequivalent bonds along the chain (38,63). Disordered chains may include configurational defects. Generation of chains containing specific defect content is not as difficult as first envisioned. Flory developed methods for determining the probability of finding specific conformers along the

chain. These are incorporated into the programs. Polymeric chains containing both conformational and configurational defects can now be analyzed with confidence (64,65). In practice, rather large numbers (>2000) of finite chains are considered.

Structural Characterization

The use of vibrational spectroscopy to identify molecular functional groups of polymers has been historically successful. New types of problems and specific requirements demand that vibrational spectroscopy move beyond composition analysis to specific areas such as surface characterization, imaging at specific areas of interest, kinetics of phase transformation, and others. The examples presented below demonstrate the developments in the most basic structural characterization.

Chain Configuration. Infrared spectroscopy has many fingerprint bands characteristic of functional groups. Extensive collections of spectra have been published. In addition, libraries and efficient search routines can match experimental data to those in the collection and identify those present. Raman spectroscopy, unlike the infrared technique, has not been extensively utilized for composition analysis. For many functional groups, Raman scattering can, in fact, make composition analysis a relatively easy task. For example, cis–trans structures of polybutadienes, vinyl C=C stretching, compounds containing sulfurs, and perchlorates, all exhibit strong, easily identified Raman bands for analysis. Aromatic units typically exhibit strong Raman scattering.

Unique applications employ both types of spectroscopies for structural analysis. The complementary nature of infrared and Raman effects can be seen in the structure determination of 1:1 hexafluoroisobutylene and vinylidene fluoride copolymer. This problem is virtually impossible to solve with other techniques. The two monomers can be linked in two ways during polymerization, by formation of head-to-tail (normal linking) or head-to-head linkages. By comparing infrared and Raman spectroscopic data, it was concluded that the polymers formed are indeed alternating in nature (66). It was additionally concluded that only head-to-tail linkages were observed. The proposed chemical structure is shown below.

$$-(C(CF_3)_2CH_2CF_2CH_2)_n-$$

The CH_2 units are decoupled by the presence of a rather bulky CF_2 unit between them. If the copolymers were formed in a head-to-head linkage, considerable coupling of the stretching vibrations would be expected. In fact, in both infrared and Raman spectra, the CH_2 symmetric and antisymmetric vibrations were observed at 3040 and 2985 cm^{-1}. This coincidence provides proof that high frequency CH_2 vibrations are decoupled and thus degenerate. If the polymer were formed in a head-to-head linkage, mutual exclusion would be expected, contrary to observation. Similar configurational analysis can be extended to other polymers formed with substituted monomers.

Because of significant advances in catalyst design (67), synthesis of highly ordered polyolefins with fewer defects and improved control of defect distribution has become possible. These advances in chemistry have raised an even greater interest

in the study of polyolefin structure and development of more diverse applications. In a head–tail alternating copolymer, the possibility exists that a head–head or tail–tail defect linkage can occur. Specific spectroscopic features have been identified for analysis of chain–chain configuration in syndiotactic polypropylenes (sPPs) containing varying racemic content (37). The earliest method for characterization of sPP configuration was, in fact, infrared spectroscopy. That study suggested a structural parameter referred to as "syndiotacticity index" (68,69). Raman features sensitive to tacticity distribution were subsequently found. The Raman active skeletal bending modes in the 300–400 cm^{-1} region (Fig. 5) were sufficiently sensitive to differentiate between racemic and meso sequences for characterization of the overall chain configuration (37,70). Based on theoretical normal coordinate analysis, the syndiotacticity content of imperfect polypropylenes can be directly measured using the relative intensity of Raman active bands in the 300 and 400 cm^{-1} region (Fig. 5). The syndiotacticity index, which provides a fast and extremely easy parameter for determination of chain configuration, is shown in Figure 6. It was also demonstrated that those bands are sensitive to differences in chain configuration and insensitive to chain conformation (64).

Chain Conformation—Ordered. For sPP, the number of seemingly stable chain conformations and packing is intriguing. The relative volume fraction of each state is highly dependent on thermal history, time, processing, and, in many cases, type and number of configurational defects. At least three different crystalline forms are associated with sPP. The helical form I, with ggtt chain conformation, is the most common (71,72). Form II with an all-trans sequence can be obtained by quenching the polymer from the melt, followed by stretching (72). Form III, with conformational features of both forms I and II, has also been suggested. This form appears to have the conformation $(g_2t_2g_2t_6)_n$ (73–75). It was recently found that the planar zigzag structure forms spontaneously over an extended length of time by quenching from melt into ice water and storing at or below 0°C (76,77). Form III has also been observed when a drawn sample of form II is exposed to benzene, toluene, or xylene vapor (73,74). Both forms II and III are stable at room temperature, and then revert to form I spontaneously with heating.

Raman spectra obtained from polypropylenes of different conformational distributions can be simulated accurately (37). Identification of specific features such as those centered at 800 and 400 cm^{-1} enabled understanding of the change of polypropylene from a completely disordered state to a more ordered state or states including crystallization. Although the bands found in the 800 cm^{-1} region (Fig. 7) are generally referred to as regularity bands, they have only recently been accurately assigned (37). The bands at approximately 826 and 845 are suggested to be associated with form I and the amorphous chains, respectively (70,78). Based on simulation results, the 830 cm^{-1} band can only be associated with long helical ggtt chain conformations. All extremely short helical segments situated between either conformational or configurational defects contribute to the intensity in the middle 845 cm^{-1} region. The broad band at 845 cm^{-1} is the dominant feature of a polypropylene melt. With increasing configurational disorder, the 826 and 865 cm^{-1} bands decrease in intensity relative to the 845 cm^{-1} peak. The high frequency component is then assigned to an all-trans structure of fairly long length. Based on these experimental and simulated Raman features, it is possible to deduce that sPP crystallizes into a helical structure at crystallization temperatures

above 0°C (Fig. 7). Conversely, for sPP crystallized at temperatures below 0°C, only all-trans structures are formed. Raman data are clear regarding the structures formed (37,64). The mechanisms responsible for such behavior are still unavailable.

Vibrational spectroscopy can also determine chain packing and associated structural transitions in semicrystalline polymer solids. As mentioned above, intermolecular vibrations, lattice modes characteristic of whole chain segment movements, or delocalized skeletal modes of fully ordered crystalline states, are found in the low frequency region (49,54,55). For polymers with a well-defined crystalline state, the lattice modes are extremely sensitive to changes in the magnitude and specificity of intermolecular interactions (49). For highly crystalline *trans*-1,4-polybutadiene, the vibrations, which were observed below 200 cm^{-1} in the infrared and Raman spectra, can all be assigned to lattice modes (Fig. 8) (49). This is indicated not only by the fact that the single-chain calculation predicts no modes below 200 cm^{-1} (49,79), but also by temperature dependence. When

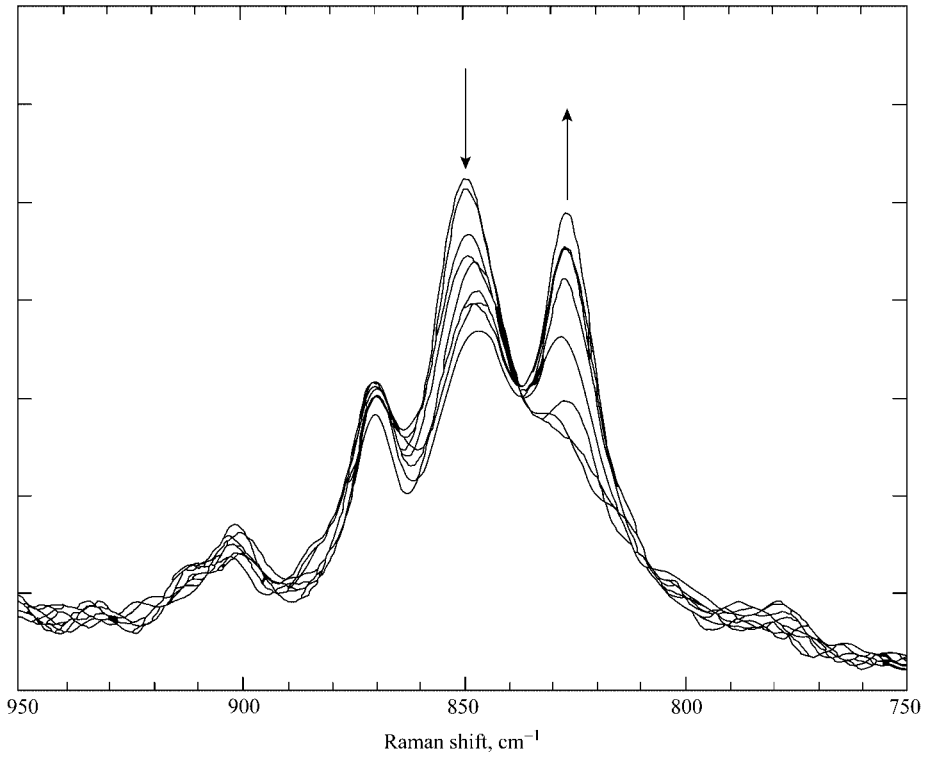

Fig. 7. Raman spectra obtained for syndiotactic polypropylene as a function of time at room temperature. The initial sample is obtained by quenching a molten sample into liquid nitrogen.

the temperature is lowered, the four Raman bands at 48, 70, 104, and 118 cm^{-1} all exhibit large shifts to higher frequencies. This is characteristic of interchain modes, since intermolecular interactions increase in magnitude as the distances diminish in the contracted unit cell. Crystal field splittings should also increase under these circumstances, as seen for the bands near 240 cm^{-1}. In addition, if the TPBD (*trans*-1,4-polybutadiene) sample is heated beyond the crystal phase transition, the four Raman bands disappear. This is as expected, since not only do distances between chains increase but torsional oscillations within the chain increase. Both features diminish the magnitude and specificity of interchain interactions. Several studies have used TPBD as a model to investigate intermolecular forces and their influence on chain conformation. By incorporating intermolecular atom–atom interactions derived by other characterization techniques, these lattice modes and crystal field effects are all satisfactorily accounted for (49,79). By studying TPBD in the highly crystalline state as well as in single crystals, bands associated with noncrystalline conformations were also assigned.

Chain Conformation—Disordered. An area of current interest is application of vibrational spectroscopy, particularly Raman, for analysis of disordered chains which may include polymers in solution, melt, or the solid state. These chains lack long-range order but may contain short ordered sequences. In addition, these disordered chains may adopt a specific conformational distribution,

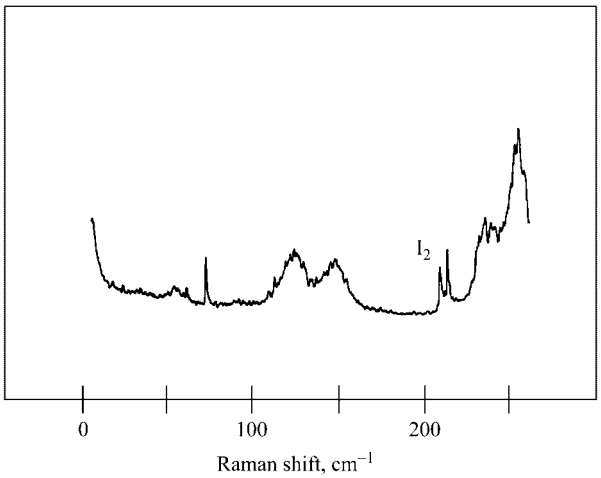

Fig. 8. Low frequency Raman spectrum of TPBD at 110 K, using an iodine absorption cell. Bandpass, 3 cm^{-1}, laser power, 150 mW at 5145.42 Å.

depending on geometric constraints such as surfaces or interfaces. Other constraints may include the presence of junctions such as in networks. Long-range electrostatic forces along the chain may reasonably be expected to further perturb the structure. Polyelectrolytes (qv) or polymeric electrolytes are such examples. Many characterization techniques are capable of measuring ordered structure. Few, however, match the capability of vibrational spectroscopy to quantitatively describe disordered chains. The frequency and relative intensity of observed vibrational bands are dependent on the relative concentration of specific localized structures. For samples involving well-defined structures and dependable band assignments, the method works well. However, when a broad distribution of a large variety of conformations is involved, the method is difficult to apply with confidence. The bands of disordered structures are broad, weak, and often overlap. Vibrational spectroscopy, particularly Raman, is ideal for studies involving disordered structures as polarizability changes associated with different carbon–carbon backbone conformations are directly reflected in the obtained spectra. Because it is a scattering phenomena associated with a tensor, the depolarized data still contain considerable structural information for samples of partial disorder or even in melt or solution.

Based on relative intensity and, particularly, bandshape of skeletal bands, it has become possible to obtain the relative energy difference between various rotational isomeric states. In the first study of this type, Snyder and co-workers analyzed low frequency (0–600 cm^{-1}) Raman spectra of *n*-alkanes in the liquid state (35). The method was subsequently applied to analysis of the low frequency Raman spectrum of molten state isotactic polypropylene. The vibrational spectroscopic analysis was successfully used to differentiate the correct model governing the chain (80) and has been extended to analysis of higher frequency vibrations (0–1500 cm^{-1}) of liquid *n*-alkanes (36).

The utility of Raman spectroscopy has proven useful in the study of poly(ethylene oxide) (PEO) in both aqueous solutions and molten states (38). The

structures of this family of polymers, either homopolymer or part of a copolymer, determine properties in numerous applications including thermoelastomers (81–83), polymeric electrolytes (84–87), and surfactants. Steric considerations alone suggest that the minimum energy conformer is all trans, designated ttt, in a notation that successively references backbone O—C, C—C and C—O bonds. However, the most stable conformation in the crystal includes a gauche conformation and is designated tgt (62). Since the conformation present in the crystal must be the result of the interaction of a number of factors, there is no way to use the crystal structure to predict with certainty the dominant conformation present in the melt or solution.

Chain structure departs from tgt and changes to ttt when PEO is blended with poly(methyl methacrylate) (88). The structure of adsorbed PEO chains in the air–solution interface was found to be very different from the disordered structure expected for the solution state (89–91). In fact, the vibrational bands for these adsorbed chains have characteristics similar to those in the crystalline state (90). Various theoretical studies have led to quite different results for chain conformations of PEO (62,92–98). Because of differences in the local dielectric environment, different sets of rotational isomeric states need be considered.

Several liquid systems of PEO, both molten state and solution, have been investigated using vibrational spectroscopy (99). The Raman spectrum of PEO in the melt as well as chloroform and aqueous solutions reveal that the conformations in an aqueous solution retain the tgt conformation that occurs in the crystalline solid. The Raman spectrum of the chloroform solution, however, more closely resembles that of the melt. The conformational distribution was not deducible due to uncertainty in band assignments.

The isotropic Raman spectra of PEO in the melt and aqueous solution shown in Figure 9 suggest new indicators for characterizing conformational distribution. Considerable differences are evident in band shape for the 850 cm^{-1} band and the region near 365 cm^{-1} (38). Although insignificant in the normal Raman spectrum, the shape and position of features in these two regions differ substantially in the isotropic spectrum. The strong bands in the 850 cm^{-1} region are almost mirror images in the two experiments (Fig. 9). The most intense feature in the 800 cm^{-1} region for the aqueous solution is located at 880 cm^{-1}. In contrast, the intense feature for the melt centers at 830 cm^{-1}. The shapes of the skeletal deformation in the 200 cm^{-1} region are also quite different in frequency and shape. These are to be correlated with differences in conformational distributions in the melt and aqueous solution of PEO (Fig. 9).

The relationship between the global chain conformation for polyelectrolytes, in terms of a persistence length and excluded volume parameter to chain conformation described by a rotational isomeric state model, is untested. Vibrational spectroscopy can partially close the gap by measuring conformational changes as chain stiffness is varied. Most previous solution characterizations of polyelectrolytes employed methods such as viscometry and light scattering which provide only global structural information. These studies were interpreted to show that chain stiffness increases with ionization. It has been suggested that in the extreme case the chain is fully extended. Polarized Raman spectroscopy is ideally suited to address issues of local structure and thus complement previous work (33,34). Information provided by polarization studies, which are sensitive to

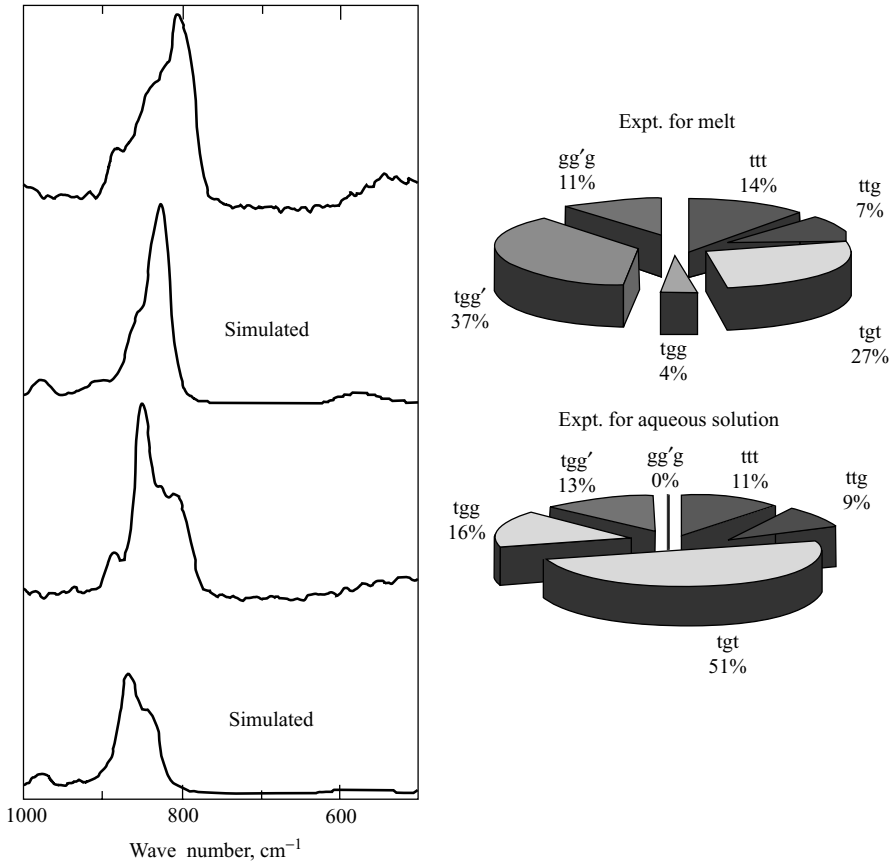

Fig. 9. Simulated and observed isotropic Raman spectra of poly(ethylene oxide). Different conformational distributions for melt and aqueous solution are described in text.

changes in conformational distribution, ie changes in the distribution of torsional angles among the various rotational states permitted in a vinyl chain backbone, can yield substantial structural information. Similar approaches have been pursued to study conformational changes in neutral polymer solutions, for example to identify the θ condition or quantify the enthalpy or entropy of helix formation (28–32). A direct calculation of the persistence length from depolarization data has been hampered by the absence of polarizability derivative values for different conformations, even in small molecules. Other studies (100,101) make it possible, in conjunction with a simplified form of the rotational isomeric state model, to calculate the persistence length using the CH stretching depolarization ratio of poly(acrylic acid) (PAA) (33,34).

Several interesting aspects of ionized structure were revealed by the Raman study (33,34). Based on polarization data, the ΔE, C_∞, and L_t values can be calculated from the depolarization data. The energy difference between isomers grows by a surprisingly low value of approximately 8% as compared to the initial value of 6155 J/mol (1471 cal/mol) for the unionized polymer to 6627 J/mol

(1584 cal/mol) for the fully ionized sample. In comparison, the energy change between the same isomers is 600 cal/mol for polyethylene at room temperature and reportedly 1100–2300 cal/mol for polytetrafluoroethylene (62). The small change in conformer energy upon PAA ionization indicates that the polymer does not stiffen appreciably upon ionization in a salt-free, semidilute solution. The lengths calculated from spectroscopic data fall within the range of persistence lengths determined via small-angle X-ray scattering (SAXS) (102). Such analysis demonstrates the potential for the Raman technique to contribute to the understanding of the interplay of local and nonlocal polyelectrolyte forces.

Analysis of Structural Unit-Size. The strength of vibrational spectroscopy lies in its ability to characterize chemical composition and localized structure of polymers. The observation of the intense longitudinal acoustic mode (LAM) in the extremely low frequency region ($<50\ cm^{-1}$) of the Raman spectra of semicrystalline polymers provides a very different morphological tool for measurement of structural subunits in the order of several hundreds of angstroms.

The earliest observation of a Raman active fundamental mode in *n*-paraffins was made in 1949 (103). The characteristics of this vibration are its extremely strong intensity and the fact that the observed frequency is inversely proportional to the straight chain segment length. This mode was hypothesized to be related to the longitudinal acoustic vibration along the backbone of the entire chain segment. The frequency of vibrations is then related by the expression shown below.

$$\nu = \frac{m}{2cL}\sqrt{\frac{E}{\rho}} \tag{6}$$

where m is the order of the mode (only odd modes are Raman active), c is the speed of light, L is the straight chain segment, E is Young' modulus, and ρ is the single chain density. The origin of this mode was explained by use of dispersion curves calculated for an infinite planar zigzag chain (104).

The first observation of such a vibration in polyethylene single crystals was seen some years later (56). A direct relationship was found between the central frequency of the observed mode and the long period in SAXS. The assumption is that the straight chain segment is the segment within the crystalline region or corresponds to the lamella thickness. It should be emphasized that these two techniques are extremely different in origin. The long period measured by SAXS measures the distance and how individual lamellae stack relative to each other. Thus the measured long period includes the contribution from the amorphous regions. The Raman technique measures the straight chain segment in the lamellae independent of the degree of tilt.

Despite numerous studies, the observation of LAM in other polymers proved elusive for quite some time (105,106). For isotactic polypropylene, LAM was not obtained until ~25 years after the initial observation. The first LAM observation was for an isotactic polypropylene prepared under special conditions of extrusion and orientation (107). Both sample transparency and the preferential reduction in Rayleigh scattering made the observation possible (Fig. 10). LAM has now been observed in a number of polymer systems such as PTFE, polyoxymethylene, PEO,

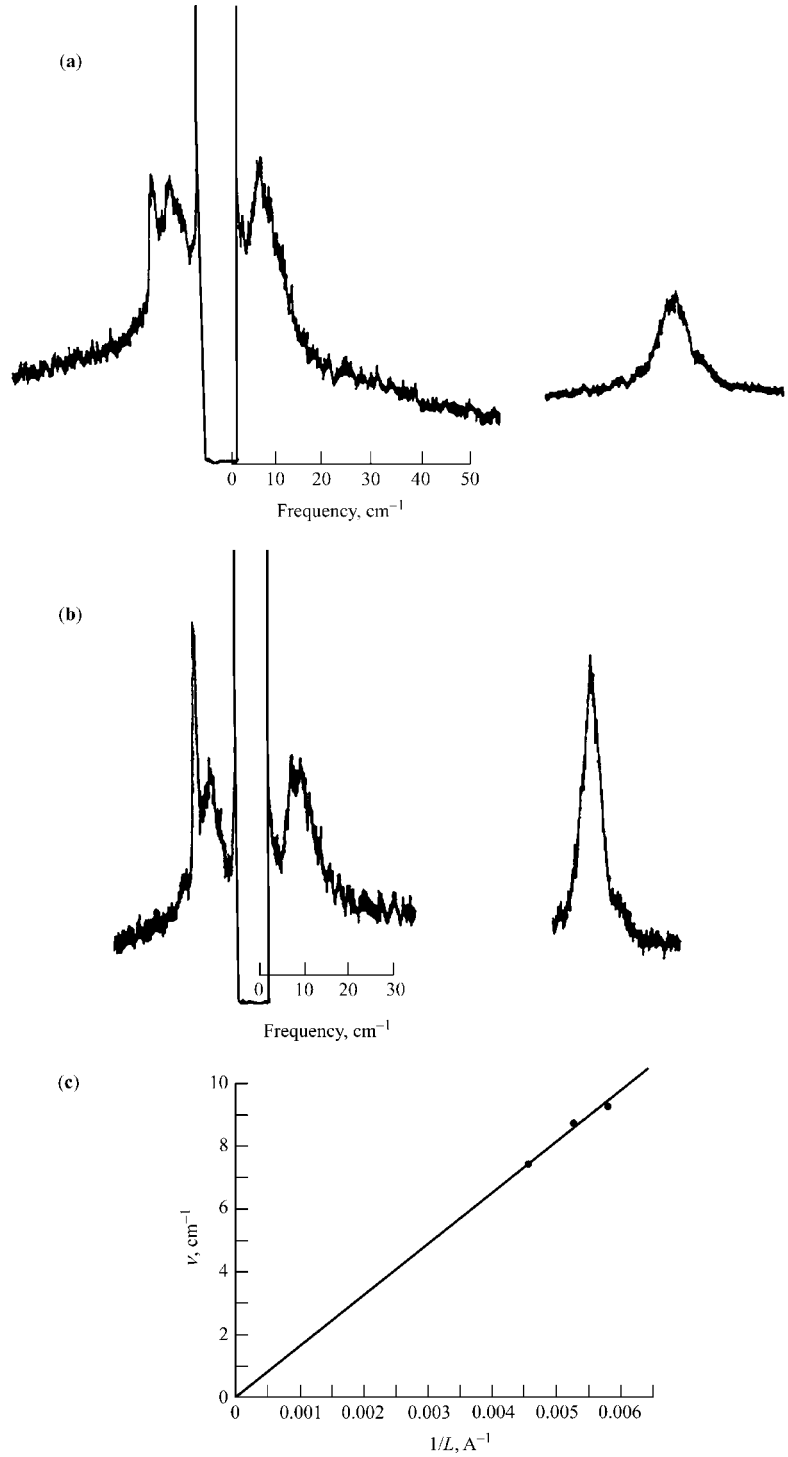

Fig. 10. Characteristics of the LAM found in highly oriented transparent isotactic polypropylene (**a**) at 300 K and (**b**) at 110 K; band at right is at 398 cm^{-1}; (**c**) plot of Raman frequency versus $L - 1$ (L is the Bragg spacing of the X-ray small-angle maximum).

and linear aliphatic polyesters (108–116). LAM has also recently been observed in a biodegradable thermoplastic, poly(β-hydroxybutyrate) (PHB) (117). This LAM observation is especially intriguing since the chemical structure and the equilibrium conformation of PHB differ significantly from those of all polymers known to exhibit LAM bands.

The fact that LAM is not easily found in other polymers can be explained by the fact that force as well as mass perturbations along the chain may lead to coupling of transverse and longitudinal motions (115). The effect of "perturbing" influences within chains such as methyl side-group placement on *n*-alkanes (118), double bond placement in *trans*-alkanes (119) and hydrogen bonds (120) has been studied and shown to affect this mode to varying degrees of intensity and frequency. A LAM-like vibration was also observed for these linear aliphatic polyesters (114–116). Based on a series of normal vibrational analyses, the masses placed off the main chain act as unbalanced mass units, which leads to the presence of several LAM-like modes, each with differing amounts of transverse and longitudinal character (115). With increased structural complexity, these structural perturbations may become more significant, leading eventually to the total disruption of any longitudinal acoustic mode. The presence of an amorphous or loosely folded layer of material at the lamellae surface has also been analyzed in terms of effective frequency and intensity (107,111,121–124).

The effects of intermolecular interactions are interesting to analyze. The earliest studies definitely established that the LAM of a planar zigzag chain conformation is a single chain phenomenon. Because of the planar zigzag structure, LAM in polymethylene systems is necessarily confined to the plane containing the skeletal backbone. The LAM is essentially independent of intermolecular interactions. Previous normal coordinate analysis of crystalline PEO has shown that, in contrast to all-trans polyethylene chains, LAM in helical chains has a significant interchain effect due to the large radial component present in the atomic displacement of LAM for such polymers (113). Unlike the planar symmetry case, the deformation of a helix must necessarily involve winding and unwinding of the entire chain segment. The temperature dependence of the frequency change observed as a function of temperature suggests that the influence of intermolecular interactions may be more important for helical chains of low modulus than those (such as polyethylene) of high modulus.

As mentioned previously, by using relation 6, the single chain elastic modulus within a crystalline lamella for various polymers can be calculated from the slope of the line fitted to the plot of ν versus $1/L$. This estimation requires the single chain density generally obtained from unit cell parameters. For example, the modulus for polyethylene is found to be 300 GPa (124). The fact that the upper limit of the modulus along the chain direction can be measured is particularly valuable when an estimation of processing efficiency is required.

The utility for use of LAM as a morphological technique stems from its ability to provide a different method to measure straight chain segment length. The X-ray technique is clearly sensitive to long-range order. The Raman technique is sensitive to short-range order or disorder. Thus the Raman technique provides very different morphological information by providing the straight chain segment distribution associated with crystalline regions. The central peak position may be related to the most probable chain length. The bandwidth of LAM can be related to the chain length distribution and may yield a chain length distribution when no

other technique is available. The conversion from the frequency space to the chain segment length space (weak broad LAM) may, however, require special attention (125).

Chain folding is perhaps one of the most fundamental concepts associated with polymer crystallization for semicrystalline polymers. From the kinetic theory of crystallization, the lamellar thickness is known to depend on the degree of supercooling (126). The nature of chain folds and end groups may greatly influence the lamellar thickness and folding scheme in formation of morphological subunits. DSC, wide-angle X-ray diffraction scattering, electron microscopy, and vibrational spectroscopy have been used to characterize many facets of the crystalline portion of semicrystalline polymers. LAM exhibits particular advantages in characterization of morphological features. For example, the integer fold scheme in PEO supports the idea first proposed based on X-ray data (127). This scheme indicates that the chain ends are not located within the crystalline lamellae but are rejected into the amorphous layers separating the crystals (127). All stems of a molecule are of the same length with chain ends located at the lamellar surfaces. Subsequent LAM studies of PEO, together with DSC and SAXS data, suggest the existence of lamellae containing a mixture of integer folded structures as well as lamellae composed of chains with simple fractional-integer folds (Fig. 11) (112). Such complex folding schemes are also indicated by results on ultralong *n*-paraffins (112). In this case, Raman contributes to a better understanding of a fundamental aspect of polymer structure.

Annealing of semicrystalline polymers is a difficult process to understand. Both microscopic and macroscopic defects are reduced upon sample exposure to temperatures somewhat below the crystalline temperature. Polymer crystals are metastable, ie the lamellae thickness and lateral size are generally determined by the degree of supercooling balanced by the side and end free energies. Therefore, as a function of time, chain-folded polymer crystals thicken on annealing to minimize the number of folds. Although the exact mechanism has yet to be determined

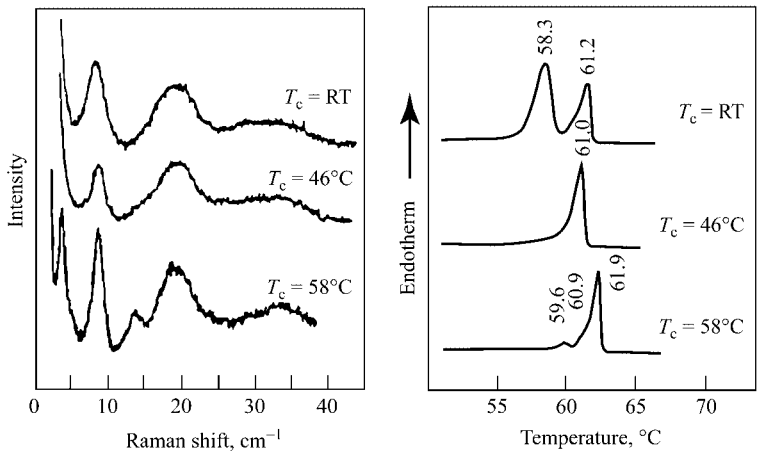

Fig. 11. (**a**) Low frequency Raman spectra and (**b**) DSC melting curves of PEO 3000 crystallized at different crystallization temperatures (T_c) (112).

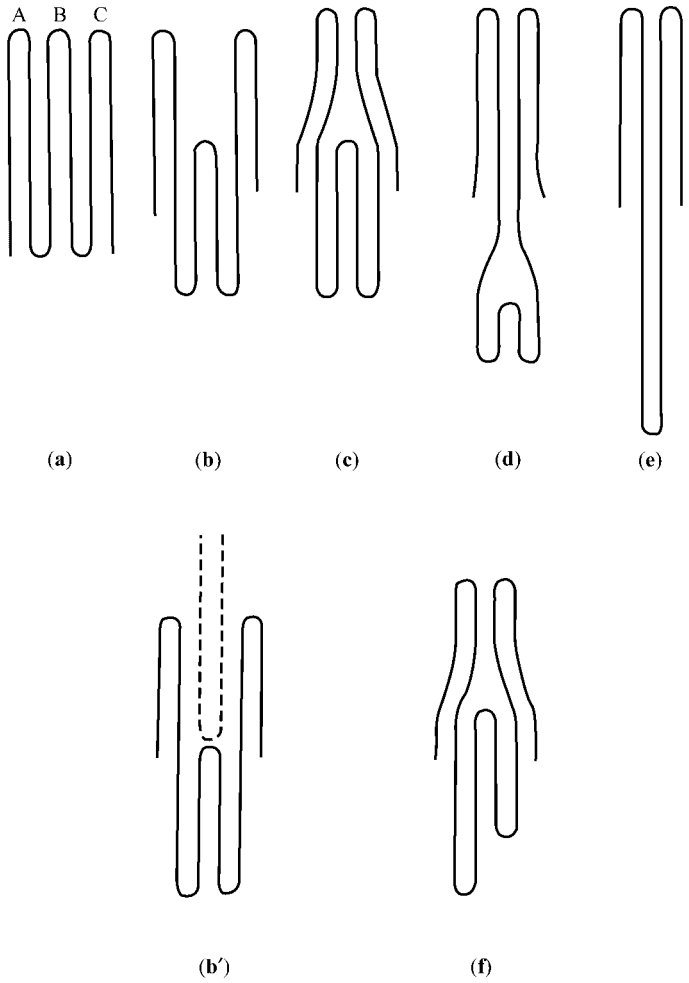

Fig. 12. Schematic representation of various stages of the fold length increase to a doubled fold length by the Dreyfus scheme as described in the text (129).

(128–131), one is shown in Figure 12. Traditionally thermal analysis can be used to follow changes in melting temperature when crystal volume increases. SAXS can be used to measure the long period when crystalline lamellae thicken. Density increases for annealed samples can also be measured. The utility of LAM in this area of study has proven particularly invaluable.

The most detailed study to characterize changes in segment length distribution (Fig. 13) employed the LAM technique (132). Unannealed samples had a most probable chain length of 100 Å with a distribution of less than 20 Å. Samples annealed for a longtime approach the well-defined chain length distribution of the initial material. The measured distributions as a function of time and temperature are extremely interesting in that they are quite asymmetric. For the annealed sample, the band is asymmetric and more intense on the low frequency side of the band maximum. After the sample was annealed at 120°C, the asymmetry was

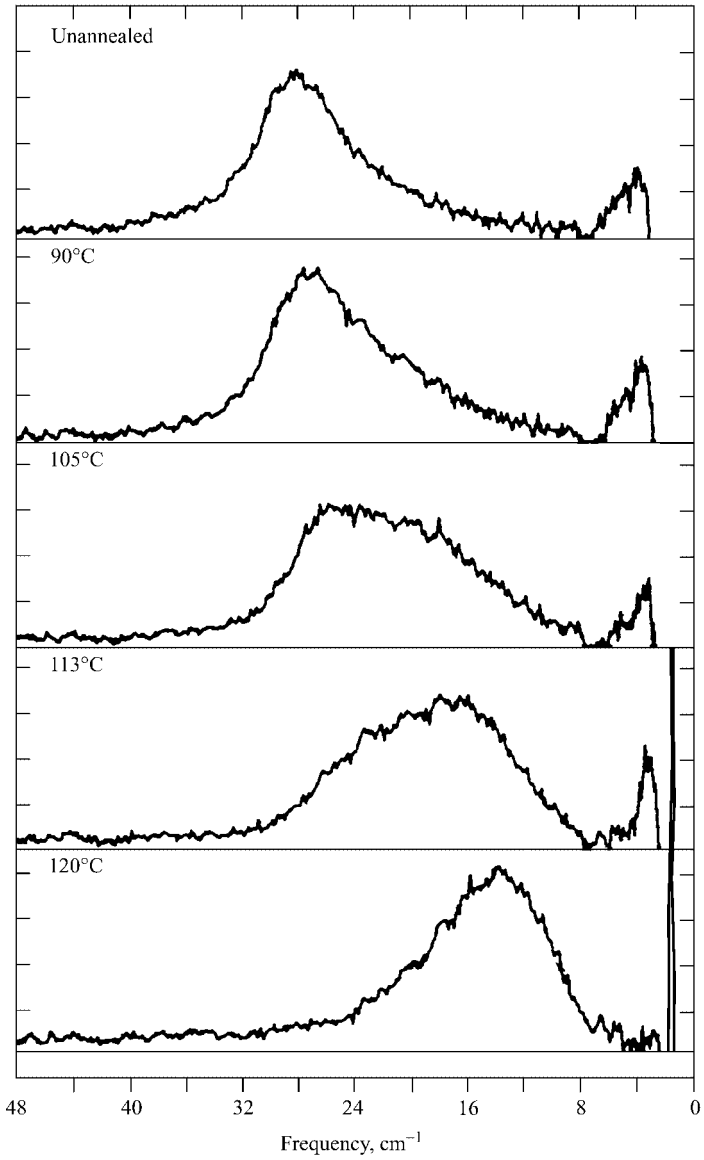

Fig. 13. Low frequency Raman spectra of polyethylene single crystal at 28°C after annealing at successively higher temperatures. Annealing time at each temperature was 6 h (132).

reversed so that the band became more intense on the high frequency side. Bands associated with intermediate annealing temperatures appear to have shoulders. They do not, however, appear to be consistent with the predictions of the model proposed earlier (129).

Because of the strong dipole–dipole interactions, one would expect that the formation and subsequent changes in polyester crystals would be different from polyethylene and possess some characteristics of nylons. LAM observed for various

as-crystallized and annealed linear aliphatic polyesters exhibits a fairly complex pattern. In linear aliphatic polyesters, the changes in Raman or SAXS are highly dependent on temperature and annealing time. In addition, for samples annealed at lower temperature (50°C), there can be changes in either Raman frequency or in periodicity measured by SAXS. Both need not change simultaneously. For long annealing time these data can also be described by a straight line function independent of initial crystallization temperatures. This observation illustrates the complementary nature of the Raman and small-angle X-ray techniques. The differences revealed may be important in structural studies of polyester single crystals.

A number of flexible polymers have been solid-state extruded or drawn to form ultraoriented, high modulus fibers. Information obtained from X-ray scattering, electron microscopy, vibrational spectroscopy, and calorimetric measurements has been used to form structural models, each differing in the description of crystallite size and connectivity. The deformation process involving measurement of LAM positions at various points of drawn polyethylene has been carried out (26,27,133–135). It was particularly interesting to examine the effect of temperature and draw ratio on chain orientation and extended chain length distribution during extrusion by removing a partly extruded billet and examining points within the die region and along the extruded fiber, thereby revealing various stages of deformation (26,27).

Structure analysis based on LAM is quite instructive regarding stability of highly deformed materials. As mentioned above, the most probable chain length and half-width in chain distribution have been established for a series of annealed polyethylenes. Among the most interesting observations for highly deformed materials is that the LAM bands exhibit considerable departure from the relationship found for annealed single crystals of polyethylene. It should be noted that the departure occurs only for samples extruded at low temperatures (Fig. 14). Samples extruded at 130°C follow the same trend as annealed single crystals. Although there is no fundamental reason to relate the half-width, $L_{1/2}$ to L_{MAX}, there appears to be a relationship that occurs for particular processing methods or history (26,27). The reduced half-width $L_{1/2}$ is a useful quantity showing obvious differences in various polyethylene structures. The degree of chain mobility is an important factor in removing structural defects introduced during mechanical deformation. For samples extruded at low temperature, limited chain mobility exists. For samples extruded at high temperature, more defects disappear, forming highly ordered structures which are dimensionally stable. The annealed polyethylene single crystals approach equilibrium and therefore contain fewer structural defects, resulting in smaller $L_{1/2}$ values.

Low Frequency Observations for Amorphous Polymers. Many amorphous materials studied by Raman exhibit an extremely broad band in the low frequency region. This is true for polycarbonate, poly(methyl methacrylate), and polystyrene (58). Low frequency Raman bands can potentially provide much information regarding the density of states (directly related to the intensity distribution of the broad Raman active band) as well as anomalous behavior observed for the specific heat (58). Often the separation of main-chain and side-chain bands is important in modeling of specific heat, making careful band assignment extremely meaningful (136,137). This separation is analogous to inclusion of optical

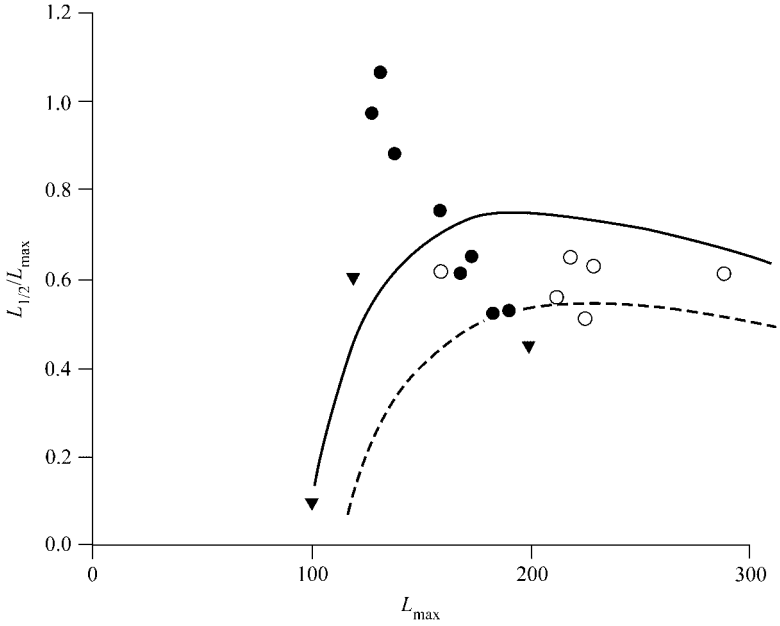

Fig. 14. Relationship for $\Delta L_{1/2}$ and L_{MAX} in variously prepared polyethylene; (●) 80°C sample; (○) 130°C sample; (▼) annealed single crystals (26,27). The solid lines refer to changes observed for annealed single crystals (132).

and acoustic transitions to specific heat calculations (138). The low frequency region is expected to contain both intrachain skeletal bending modes and interchain lattice modes.

The low frequency Raman spectrum can provide information on the density of states $g(\omega)$ in the low frequency region. In the quasi-harmonic approximation the specific heat is given by

$$C_V = k\int_{\omega_{min}}^{\omega_{max}} g(\omega)\left(\frac{\hbar\omega}{kT}\right)\frac{e^{-\hbar\omega/kT}}{(e^{-\hbar\omega/kT}-1)^2}\,d\omega \tag{7}$$

and the scattering intensity is related to the density of states by the following expression:

$$\frac{I}{\omega^2} \propto \sum_i g_i(\omega) \tag{8}$$

Thus the scattered low frequency intensity can be directly related to the specific heat calculation. Such calculations have been carried out satisfactorily for amorphous polycarbonate (58).

These low lying vibrations can be used to examine intermolecular interactions and associated steric hindrance to intrachain motions and thus provide information regarding free volume (139). Nearly 100% sPS has been reported (140). The solid-state structure includes several well-defined crystalline phases with at

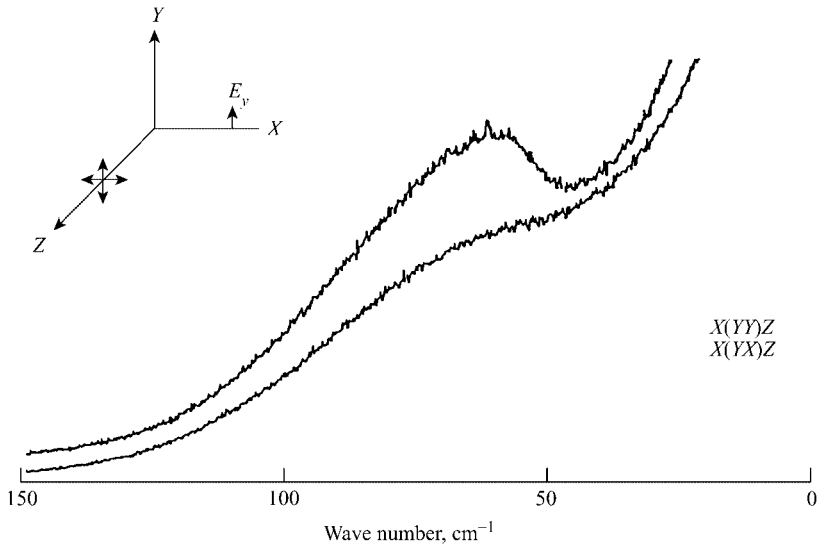

Fig. 15. Low frequency band observed for annealed syndiotactic polystyrene.

least two different chain conformations (141–146). A most striking spectroscopic feature is the extremely intense broad (bandwidth $\sim$100 cm^{-1}) vibration observed in the 20–200 cm^{-1} region for all polystyrene samples (Fig. 15) (139). The intense polarized vibration first observed for sPS is independent of molecular weight, degree of crystallinity, tacticity, or chain conformation (139). Since this band is independent of all polystyrene chemical structure, it is most likely associated with the torsional mode of an aromatic ring (139,147).

The frequency of this vibration is dependent on the exact location of substitution at the ring. A methyl group placed at the para position leaves the frequency unperturbed. Substitution at the ortho position will, however, change the frequency. The intensity of this motion has been reported to be related to the mass of substitution (147). The measured depolarization ratio for this vibration is $\sim$0.22 (Fig. 15). The optical activity is such that the first overtone is responsible for the observed intensity while the fundamental is forbidden (139). The change in polarizability tensor elements has also been predicted using ab initio calculations performed with the GAUSSUN 86 package for the related compound *p*-difluorobenzene to obtain the principal components. A quite strong $2 \rightarrow 0$ phenyl torsion transition has been reported in the 112–128 cm^{-1} region of the Raman spectrum of styrene. This mode has not been observed in the infrared spectrum. Although this vibration is intramolecular in origin, the bandwidth was found to be highly sensitive to the solvent-complexed crystalline state and therefore the intermolecular ring environment.

Phase Transformation. The utility of vibrational spectroscopy in measuring structure at a localized level cannot be overemphasized. TPBD has a first-order crystal–crystal phase transition at 76°C (148). Two crystalline forms are known to exist. One is stable below 76°C and transforms to the other above the phase-transition temperature. The transformation is reversible. The crystal

structure changes from a monoclinic unit cell to pseudohexagonal packing at high temperature. The conformational changes of the chain associated with this phase transition are

(1) There is a change in the —CH—CH_2— ϕ angle from 60–71° to 100°, causing a shortening of the repeat length from 0.0483 to 0.0466 nm;
(2) The molecular chain exists in a considerably distorted state due to torsional disorder about C—C bonds;
(3) The interchain distance in the unit cell increases from 0.0454–0.0460 to 0.0495 nm.

The distortion of the molecular chain may have the following consequences:

(1) Chains may exist with irregular conformations which have lost the inversion symmetry and cause breakdowns of the mutual exclusion principle.
(2) In some chain segments, the CH_2—CH_2 groups may no longer be trans to each other, which may result in observation of trans-gauche amorphous bands.

The similarity between high temperature and room temperature spectra indicates that no additional bands can reasonably be attributed to trans-gauche conformations (79). Although considerable distortions must be associated with the TPBD in the high temperature form, Raman spectra show the molecular chain has a large degree of conformational regularity, consistent with X-ray results. All observed lattice modes disappear when the sample is heated beyond the crystal phase transition. This is as expected since not only does the distance between chains increase but there is an increase of torsional disorder about the C—C bond as well as translational disorder along the chain axis. Close to the transition temperature, the 549 (skeletal angle bend), 1305 (CH_2 twist), 1340 (CH_2 wag), and 1433 (CH_2 bend) cm^{-1} bands all show a doublet in the observed Raman spectra. The two components are representative of the two structures above and below the phase transition. Only one band exists below 70°C or above 80°C. This fact indicates that the two forms coexist, even though this is considered to be a "sharp" crystal–crystal thermodynamic transition. This may not be surprising since X-ray patterns for single crystals indicate the two forms coexist between 55.5 and 69.5°C. This coexistence presents the possibility that the energy minima for TPBD are not as shallow as previously indicated (149).

One of the most interesting observations in vibrational spectroscopy is the effect of accidental degeneracy or Fermi resonance (150). This subject is introduced here to show its utility and stimulate further interest in this subject. Numerous studies have utilized the effects of Fermi resonance to characterize structural transitions in polymeric solids. These transitions can in fact be observed with a higher sensitivity than achieved by any other characterization technique. Fermi resonance may occur if two vibrational levels belonging to different vibrations have nearly the same energy, that is may be accidentally degenerate. As first recognized in the case of CO_2, such a "resonance" leads to a perturbation of energy levels. For example, in the case of CO_2 the fundamental of ν_1 (1337 cm^{-1}) has nearly

the same energy as the second harmonic of ν_2. The ν_2 fundamental is found at 667 cm^{-1} (1). The two vibrational levels having nearly the same energy "repel" each other and the actual level shifts from values expected from a harmonic oscillator model. Thus for CO_2 two vibrations are observed. At the same time a redistribution of band intensity occurs. The second harmonic, generally very weak, borrows intensity from the fundamental and may cause observation of two bands of similar intensity.

The vibrational spectra of polymers provide many opportunities for observation of Fermi resonance. In the 3300 cm^{-1} region of proteins and polypeptides, infrared active amides A and B are assigned to the fundamental NH stretching ($\sim$3300 cm^{-1}) and the second harmonic of the amide II vibration in the 1500 cm^{-1} (61). For synthetic polymers, the region of most interest is the C—H stretching region. To the first-order approximation, C—H stretching modes are highly localized and involve nearly pure hydrogen motion. They are essentially insensitive to the molecular conformation and environment, in sharp contrast to skeletal modes at lower frequencies. This hypothesis appeared intuitively sound and was supported by a half century of evidence from infrared spectroscopy. It is therefore surprising that changes in the C—H stretching region of Raman spectra are the first indications of changes in chain conformation and environment (151,152).

Other polymers exhibit similar changes during structural transformation. In *trans*-1,4-polybutadiene, at least six components are observed for the crystalline state at room temperature (79). Given the inversion symmetry of the chain, at most one =C—H and two CH_2 stretching modes are expected. When these crystals are heated to above 71°C, a solid–solid phase transformation occurs, causing changes in both chain conformation and packing. The changes in the overall infrared and Raman spectra are quite minimal at this transition. Most surprising is the observation that sharp defined features in the C—H stretching region evolve into a profile containing four bands. Similarly in lipid bilayers, the relative intensity of the $\sim$2900 cm^{-1} CH_2 asymmetric stretching to the 2850 cm^{-1} symmetric stretching band proves one of the most sensitive indicators of structural change. Many models are available for arrangement of proteins and lipids in biomembranes. An important difference between these models is the degree to which lipid bilayers, with ordered fatty acid chains, play a role in the structure. Better understanding of structural changes would provide better understanding of membrane functions (152,153).

The complexities observed in the Raman spectra of the C—H stretching region of polymethylene chains result from Fermi resonance interactions involving completely symmetric double excitations of fundamentals at lower frequencies with higher frequency C—H stretching of the symmetry. The sensitivity of C—H stretching vibrations to structural change results from the inherent *amplification* factor. Low lying vibrations are known to be sensitive to both chain conformation and chain packing differences. Because of the coupling between the second harmonics and fundamental at higher frequencies, small changes in the frequency of the lower vibrations may cause significant changes in the overall profile (1). The smaller the difference in the two components, the greater the anharmonicity of the potential well and the greater the mixing of the two modes. Thus small changes in the lower frequency component have the potential to considerably change the overall spectrum.

For polymethylene chains, the origin of these complexities may be described in terms of the appropriate binary combinations involving methylene bending modes interacting with the infrared or Raman-active symmetric stretching fundamental (154,155). Two levels of Fermi resonance interactions, intramolecular and intermolecular, need be distinguished, however. Unexpectedly, the Raman-active bands observed for different intermolecular packings are quite different (Fig. 16).

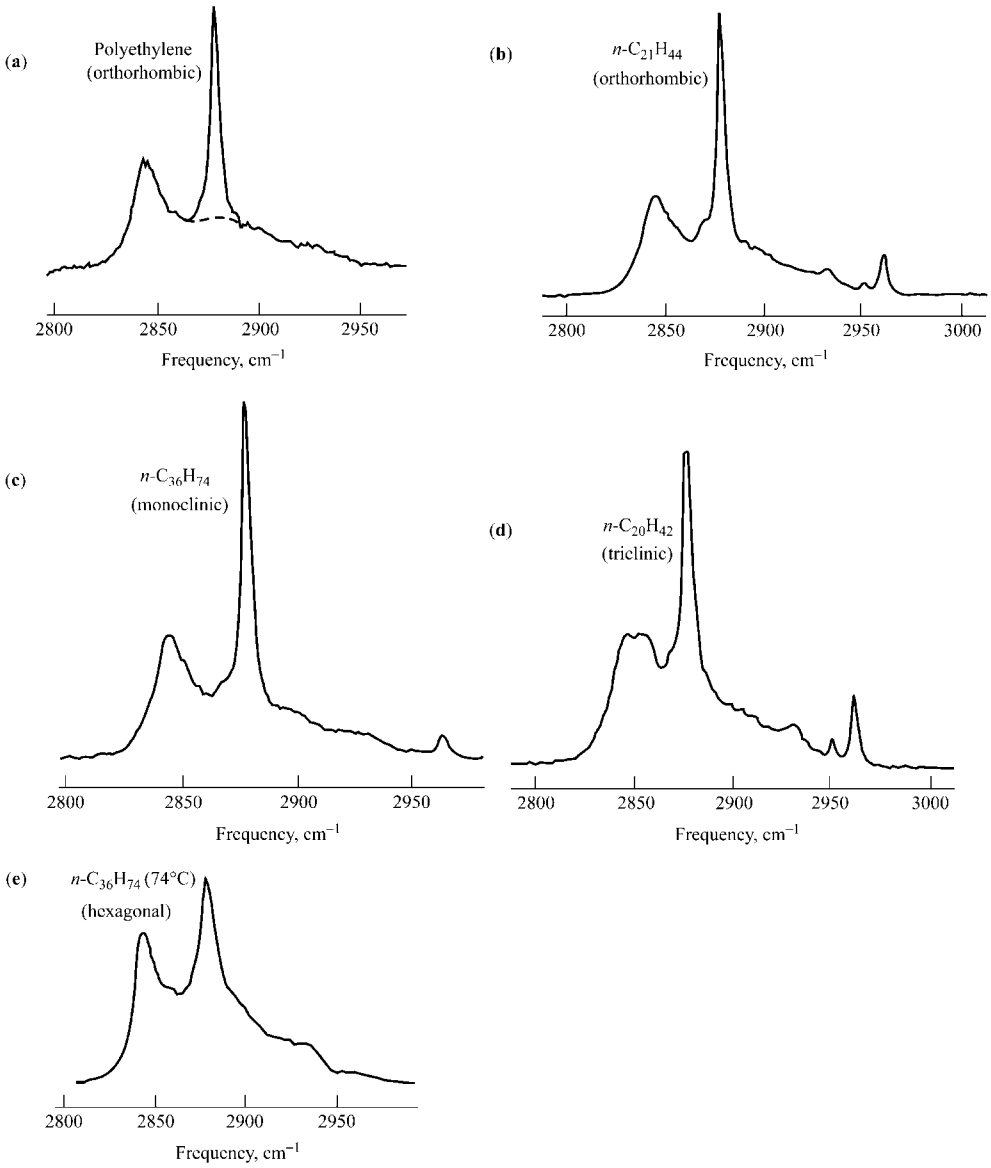

Fig. 16. C—H stretching region of the Raman spectra of (**a**) orthorhombic polyethylene at 110 K, (**b**) orthorhombic n-$C_{21}H_{44}$ at 110 K, (**c**) monoclinic n-$C_{36}H_{74}$ at 110 K, (**d**) triclinic n-$C_{20}H_{42}$ at 110 K, and (**e**) hexagonal n-$C_{36}H_{74}$ at 347.5 K. All Raman spectra were taken with bandpass 1.5 cm^{-1} at 510 nm. Laser power 200 mW at 514.54 nm.

For example, a multiplet exists at the 2850 cm^{-1} region for triclinic packing. It is also clear that upon structural transition, such as when chains disorder as in the hexagonal phase, the relative intensity of the dominant components changes. Thus if the interchain environment changes, Fermi resonance interactions amplify these, resulting in significant changes in relative band intensity.

Spectroscopic Characterization of Heterogeneous Polymers. Polymer physical properties can be altered by blending chemically and physically dissimilar components. Vibrational spectroscopy is often utilized to characterize the thermodynamic parameter governing mixing behavior. The morphology development can also be characterized based on the relative band intensity and frequency of specific features. Even relative chain dynamics can be monitored. The first example shown here involves polyurethanes. The wide-ranging applications of polyurethanes result from their versatile chemistry and attractive physical properties. These are formed from hard segments composed of isocyanates and soft segments such as polyethers. The hard segments phase-separate into domains creating junctions connecting soft polyethers. Polyurethanes therefore have many characteristics associated with elastomers. Both molecular architecture and chemical immiscibility are responsible for the formation of this phase-separated structure. A number of functional groups associated with both hard and soft segments can form interchain hydrogen bonds. Based on characteristics of the measured hydrogen bonds, vibrational spectroscopy yields much information regarding degree of phase separation, kinetics of phase separation, and perfection of hard domains.

Localized vibrations such as N—H or C=O stretching vibrations are strongly perturbed by formation of hydrogen bonds (156). Both frequency shifts and intensity changes are characteristics of the specificity or magnitude of the hydrogen bonds (157). The intensity of each type of hydrogen bonded vibration, if properly assigned, can potentially yield information regarding the degree of polyurethane phase separation (81–83). Infrared spectra of the carbonyl stretching region generally shows two distinct peaks. The higher absorbance observed for the 1700 cm^{-1} peak relative to the 1730 cm^{-1} component is characteristic of a phase-separated polyurethane structure. The peak at 1730 cm^{-1} is assigned to the free carbonyl. The peak clearly distinguishable at 1700 cm^{-1} is assigned to carbonyl groups hydrogen bonded to the N—H group.

Although polyurethane structure has been extensively characterized, experimental studies characterizing phase separation kinetics of segmented polyurethanes are scarce (158,159). Theoretical development of segmented block copolymers is also far from complete. Vibrational spectroscopy can also be of benefit in these studies. As mentioned above, hydrogen bonds form between the N—H and C=O groups of hard segments. A strong hydrogen bond between the N—H group of hard segment dispersed in the soft matrix and the C—O—C group of soft segment is also possible (81–83). A phase mixed state obtained at elevated temperatures can be preserved by rapidly quenching the sample to below the glass-transition temperature of the soft segments (81–83). Isothermal phase separation kinetics can then be studied by measuring changes in the infrared spectrum as a function of time at constant temperature (Fig. 17). Since most hard segments in the homogeneous state are surrounded by soft segments, the carbonyl groups are free of hydrogen bonding as characterized by the high absorbance of the 1730 cm^{-1} peak. During phase separation from a homogeneous single phase to

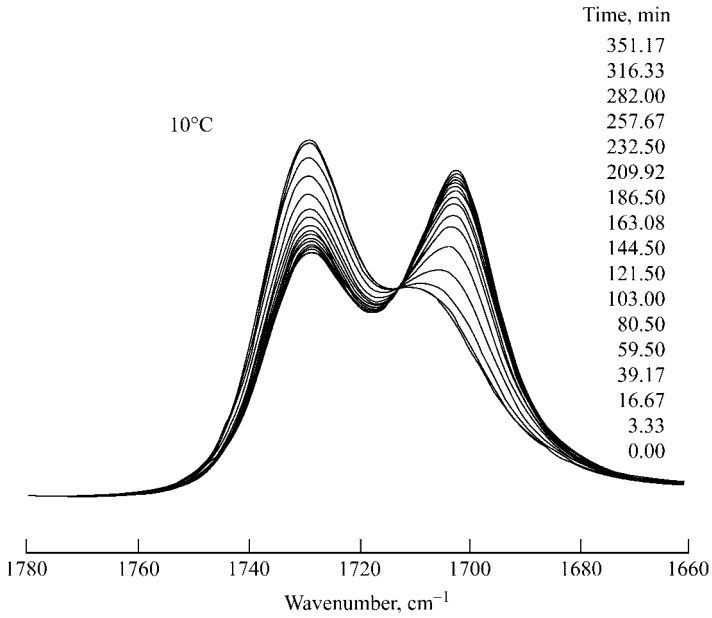

Fig. 17. Infrared spectra obtained for polyurethane undergoing phase separation.

a heterogeneous phase, the carbonyl group of hard segments is transformed from a free state to a hydrogen bonded state with N—H groups. Based on the relative intensity of the hydrogen bonded or free C=O stretching vibrations, the degree of phase separation has been analyzed as a function of time and temperature. The time dependence of the fractional decrease of the free C=O stretching vibration at 1735 cm^{-1} using the intensity of the observed C=O stretching components as a measure of structural change is shown in Figure 18. It is clear that the phase separation mechanism is changing as a function of time. There are no established mechanisms to explain the measured phase separation kinetics. One possibility is spinoidal decomposition which occurs in polymer blends at early stages of phase separation. However, the data obtained is not consistent with the prediction of Cahn–Hilliard expression (160).

In theory, the N—H stretching vibration should yield structural information complementary to the C=O stretching vibration. Generally speaking, the frequency of N—H groups free from hydrogen bonding is at 3450 cm^{-1}. The hydrogen-bonded component is usually measured near 3300 cm^{-1}. This shift is characteristic of the strength of hydrogen bonds formed (156). It is interesting to note that hydrogen bonds between hard and soft segments are stronger than those formed between hard segments. This observation suggests phase separation cannot be due to chemical immiscibility alone. N—H vibration is complicated not only by the two types of hydrogen bonding but also by other second-order spectroscopic effects involving the N—H stretching fundamental and combinations of lower lying amide vibrations. The intensity of these modes is also difficult to analyze because of resonance effects (161).

A most interesting contribution of vibrational spectroscopy is elucidation of the origin of specific interactions. Because of the large molecular size of polymers,

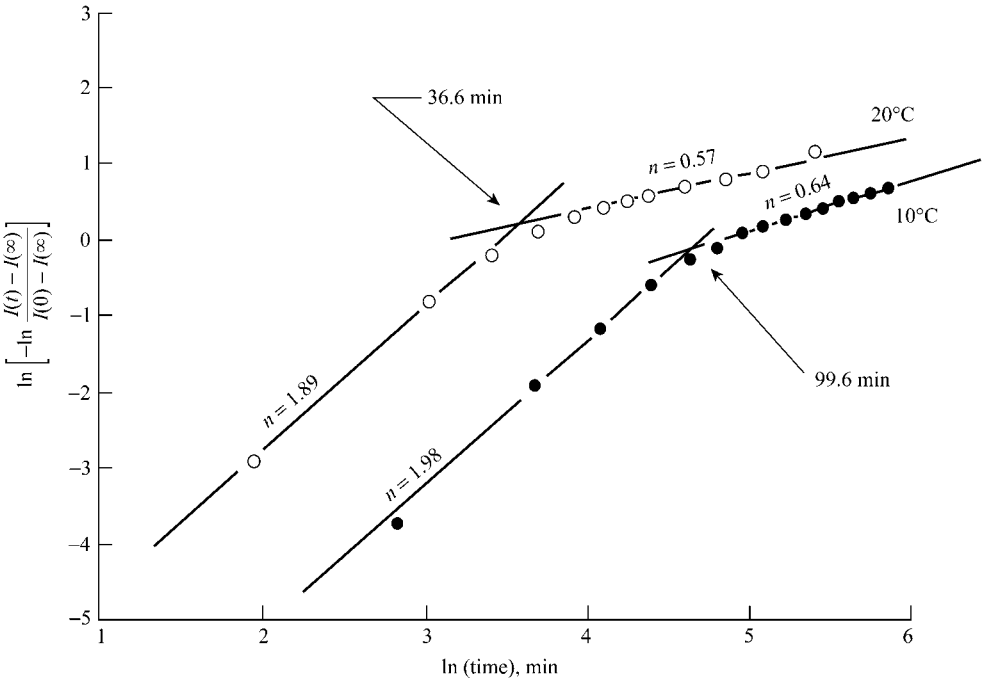

Fig. 18. The time dependence of phase separation kinetics observed for polyurethanes; (○) data obtained at 20°C; (●) data obtained at 10°C.

the entropy of mixing is relatively insignificant as a driving force in the mixing of polymers. Therefore the change in the overall free energy on mixing must arise principally from the term related to the heat of mixing, ie the interaction parameter χ. In some cases, molecular architecture also requires consideration (162). The enthalpic contribution to the free energy depends on the magnitude and specificity of the interaction between components. Spectroscopic features assigned to various functional groups of the polymer components may be affected by changes in intermolecular interactions, including permanent dipole interactions, transition dipole interactions, and, the strongest, hydrogen-bonding interactions. Interpretation of such spectroscopic features is useful in assigning a molecular origin to the thermodynamic parameter.

The most dominant specific interaction is hydrogen bonding. Its role in polyurethanes is documented above. This interaction has been used to obtain very detailed descriptions of polymer phase diagrams with strong interactions (163). These studies serve as valuable predictive tools for formulating miscible polymer blends. In most cases, the evidence of changing interactions is much more subtle and rather small changes in band position are generally observed. The experimental situation has improved since the use of Fourier transform infrared instruments has become relatively common. These instruments make extremely small differences in band position, shape, and intensity easier to detect. Difference spectra can be obtained by subtracting a spectrum of neat component from that of binary mixtures within the computer associated with the instrument. The spectroscopic differences are presumed owing to differences in intermolecular interactions

between neat and mixed states. However, the infrared spectra may show features not related to intermolecular interactions, ie band shape differences. These result from differences in the local index of refraction of the two components, sample thickness, and effects due to the optical properties of the sample substrate (164).

Blends of polystyrene (PS) and poly(vinyl methyl ether) (PVME) can be used to illustrate the use of vibrational spectroscopy to characterize specific interactions. A number of studies have shown that solvent, molecular weight, composition, and temperature can all affect compatibility of these two polymers (165). The nature of the intermolecular interaction between the two components has been established (166,167). Vibrations involving the oxygen atom are known to usually exhibit high sensitivity to blend compatibility. The skeletal vibrations involving oxygen are observed in the 1100 cm^{-1} region. In the infrared spectrum of PVME a strong doublet at 1085 and 1107 cm^{-1} with a shoulder at 1132 cm^{-1} shows the greatest change upon change of the molecular environment. Based on comparison of various blends and neat samples, it can be concluded that the frequency change and relative intensity are sensitive to structural changes and environment and possibly the miscibility of PS/PVME blends. It has been further suggested that the interaction between the components involves partial sharing of the ether lone-pair electrons with the benzene ring of polystyrene (167). Variation in the critical transition temperatures has further confirmed the earlier assignment (168,169). It should be mentioned that the changes in band positions are extremely small, in the order of a few wave numbers.

Among the large number of studies on polymer blends, one very interesting subset consists of binary mixtures with crystallizable components. Familiar examples include blends of chemically dissimilar polymers, eg poly(vinylidene fluoride) (PVF_2) with poly(methyl methacrylate) (PMMA), PVF_2 with poly(ethyl methacrylate), and poly(α-caprolactone) with poly(vinyl chloride) or blends of chemically similar polymers, eg isotactic PMMA with syndiotactic PMMA and PEO with poly(propylene oxide) (PPO) and isotactic polystyrene with poly(styrene-*co*-*p*-methylstyrene). Crystallization of neat polymers is already a complicated process. Crystallization of polymer blends is even more so. Several factors need be considered. The nucleation process depends very much on temperature and, particularly, on the difference between crystallization and melting temperatures. Because the second component, the suppression of the melting temperature can be significant, thus affecting the nucleation rate (170). Furthermore, from qualitative considerations, the crystal growth depends on the local concentration of the crystallizable component and on chain mobility.

The binary mixture of PEO and PMMA is an extremely interesting blend. From relative solubility considerations, it has been predicted and verified that PEO and PMMA are miscible in the melt (171). Few studies, however, have been conducted to better understand the crystallization kinetics, thermodynamic interaction parameters, and microstructures of this specific blend. Because of experimental constraints, the crystallization kinetics and microstructures of PEO/PMMA blends are most conveniently investigated by scattering methods. Therefore, most studies devoted emphasis to samples containing high percentages of PEO (172). It is to be expected that nucleation and subsequent crystallite growth rate are affected by blend composition. Few attempts have been made to characterize the crystallization behavior and microstructures of blends containing

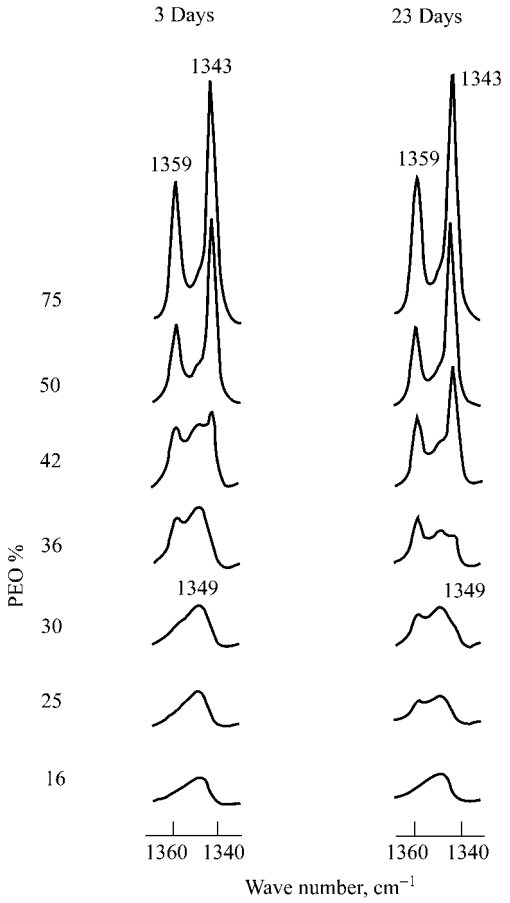

Fig. 19. Infrared spectra obtained as a function of time for PEO/PMMA blends with varying PEO compositions.

low PEO concentrations. Only infrared spectroscopy and now AFM can follow crystallization behavior (Fig. 19) (88,170). In addition based on the skeletal vibration in the 1300 cm^{-1} region, a different chain conformation was observed (88). This is important because the change in chain conformation implies the existence of long-range ordered crystallites. The reason that the gauche state is favored for neat PEO is due to the interaction between oxygen atoms and CH_2 groups (62). Perhaps a specific interaction with PMMA in the melt alters this interaction, causing the relative change in the microstructures.

Imaging Spectroscopy (Heterogeneous Materials: Impurities, Blends, Composites, and Laminates)

A most interesting development in vibrational spectroscopy is the growing use of microspectroscopy for the identification and quantification of very small amounts of polymer sample as well as composition of very small area (13,173). Sample size

or sampling area may be as small as 1–3 μm. By focusing on specific spectroscopic features, a chemical map may be obtained. This is particularly important when other imaging techniques are limited by experimental conditions or lack of contrast between area of interest and surrounding area. In many applications, it is important to have spatial resolution in the lateral direction. Spatial definition is sometimes required for all three dimensions. The depth profile along the propagating optical axis is often needed. Confocal spectroscopy enables such analyses. The signal from the small volume element of study requires better separation from signals arising from the surrounding material. The development of Raman or infrared microspectroscopy complements imaging techniques such as optical or electron microscopies. Applications of infrared or Raman microspectroscopy include contaminant analysis (synthetic and biological samples), identification of sample heterogeneity such as blends, or polymorphic structures introduced during processing. Parameters responsible for the high performance of laminates or composites can also be defined.

The limiting factor of spatial resolution is the wavelength of incident radiation. Infrared spectroscopy employs much longer wavelength radiation than the ones used in Raman spectroscopy. Diffraction effects cannot be overcome. Therefore, the resolution achievable is much less for infrared spectroscopy than Raman spectroscopy. If the sample is freestanding, the diffraction only gives rise to stray light, making quantitative analysis difficult. It does not normally affect sample identification to any great degree. If the small sample is embedded in some second substance, diffraction leads to spectral contamination by the substrate. Although Raman microspectroscopy has a spatial resolution of 1 μm in ideal cases, the spatial resolution in infrared spectroscopy is less easily defined because of difficulties arising with diffraction effects (long wavelength of the incident radiation). In these cases, diffraction effects can be quite important. For infrared, under most optimistic circumstances, the limiting size is approximately 10 μm and down to 3 μm in diameter. Although essentially unimportant in Raman microspectroscopy, sample thickness may be critically important in infrared transmission microspectroscopy. The sample must be about 10 μm thick to give good infrared results. Raman microspectroscopy can be used effectively to study very small samples or small areas within a transparent sample. Generally speaking, diffraction effects can be measured out to 50 μm from the central axis (173). The spectral contamination from material beyond perhaps 10–15 μm is sufficiently low, but not negligible.

Infrared or Raman spectra can be obtained point by point to obtain a chemical map of the sample in two dimensions. The sample can be moved relative to the probing beam. These images are derived from a material's intrinsic vibrational spectroscopic features. Point-by-point or line-by-line scanning techniques may not be practical for many applications, however. The high laser power focused at localized areas may cause sample degradation. A more practical approach is to use the global illumination method (174). Most Raman imaging spectrometers employ CCD detection. By using specific tunable filters to let specific frequencies through (175), it is possible to obtain both the overall images generally obtained by optical microscopy and the Raman images generated with specific Raman-active bands. The images obtained are usually of the quality dictated by the diffraction limit of the employed optics. The experimental conditions to obtain these images are not significantly different from ordinary experimental conditions (176).

Both infrared and Raman microspectroscopy are useful for composite analysis. The commercial value of fiber-glass reinforced composites is undisputed. Incorporation of high performance fibers into low cost matrix material significantly increases overall mechanical properties at moderate cost. Raman is required for study of carbon and silicon carbide fibers, since the former has no infrared spectrum and that in the latter is extremely weak. Raman spectroscopy has contributed significantly to understanding stress distribution in the composites upon application of an macroscopic stress. The imaging capability of the Raman technique is a powerful technique to measure stress at each point along the reinforcement fiber for comparison to theories first developed nearly 50 years ago. One example presented here illustrates the advantages of the Raman microspectroscopic technique. The success of this study was dependent on several aspects:

(1) Several Raman-active bands of polymers exhibit a frequency shift when the sample is stressed.
(2) The Raman technique exhibits high spatial resolution so that Raman spectrum can be obtained from specific locations.
(3) High sensitivity can be obtained if resonance Raman spectrum can be obtained.

The initial study employing polydiacetylene single crystals proved extremely successful (177). This system is quite interesting for several reasons:

(1) The polydiacetylene single crystals are fiber-like with high aspect ratio.
(2) The shape of the fiber can be altered to test some basic assumptions of stress transfer mechanism.
(3) Since these fibers are single crystals, the stress experienced at any particular point is directly related to the strain.
(4) These polydiacetyelenes have an electronic absorption spectrum extending well into the visible range, making resonance Raman spectrum easy to obtain.

This last point is important because imaging optics can be dealt easily with high spatial resolution, using various lasers from 500 to 700 nm.

Because of the resonance conditions achieved, only skeletal stretching vibrations coupled to the electronic transitions are excited. Typical high quality Raman spectra of C=C stretching as a function of stress can be obtained readily. In order to obtain a spectrum from the embedded fiber in the matrix, it is necessary for the incident excitation to be propagated through the matrix and for the scattered Raman radiation back through the matrix to the collection lens. Because the relative intensity of the Raman scattering originates from the matrix versus the fiber, the signal from the fiber can be collected easily without interference from the matrix. Other polymers have been studied with various degrees of success.

This model system has shown the potential of the technique and has been very successful in validation of models developed for composites. The predicted stress distribution along the fiber axis x (shown below) is indeed verified (Fig. 20) (178,179).

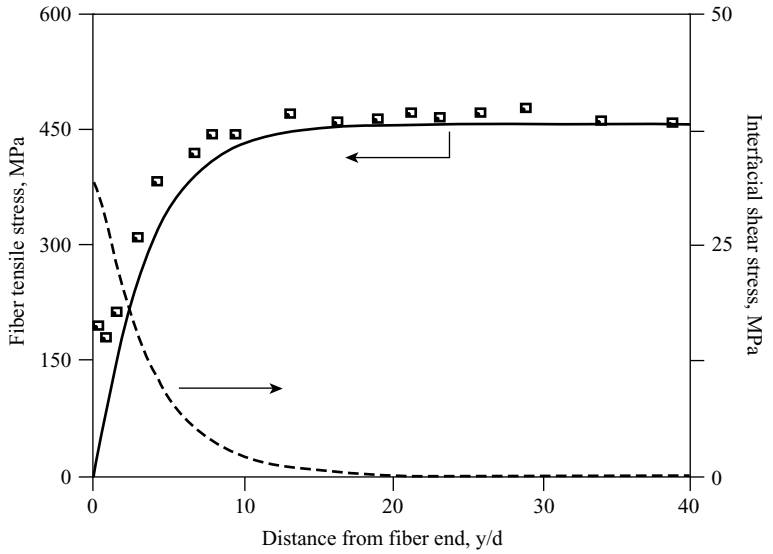

Fig. 20. Stress distribution along polydiacetylene fiber in model composite. Calculated tensile stress distribution from equation 9 (———); Calculated interface shear stress distribution (– – –); and experimental tensile stress distribution (▫).

$$\sigma_f = \frac{(E_f - E_m)\sigma_c}{E_m}\left[1 - \frac{\cosh\,\beta\left(\frac{l}{2} - x\right)}{\cosh\,\beta\frac{l}{2}}\right] \tag{9}$$

where E_f and E_m are the moduli of the fiber and matrix respectively, σ_f and σ_c are the stress along the fiber and applied stress respectively, l is the fiber length longer than the critical length, and β is related to the elastic constants and cross-sectional area. Several other aspects associated with stress transfer composites are of interest and need to be answered (180–183). For example, does fiber–matrix interface matter? The relationship between the magnitude of residual stress and the processing conditions has been analyzed. One interesting study deals with the shape of the reinforcement fiber. In theory, a fiber of tapered end can be an extremely effective reinforcement as shown by the measured stress distribution. Although kink bands associated with failures have often been observed, a direct relationship between this macroscopic observation and the critical compressive stress had been virtually impossible to establish until this spectroscopic technique was established (Fig. 21).

Microspectroscopic infrared spectroscopic studies have emphasized the role of the interphase in fiberglass-reinforced composites (184). Spectral subtraction along with two-dimensional mapping experiments revealed features characteristic of the interfacial region. Different glass fibers were used to observe spectral differences at the interphase. When as-received and heat-cleaned glass fibers were used, certain similarities were observed, although an inhibition of the curing occurred at the interfacial region of epoxy-heat-cleaned glass fibers. When the glass fibers were treated with an aminosilane coupling agent, spectral evidence indicated that the glass surface modified the epoxy-glass fiber interphase.

Polymers sometimes by design contain substantial impurities or contaminants introduced during processing. These heterogeneities are often very small, but many in number, resulting in degradation of desirable properties. Identification of the material causing the heterogeneity is normally a prerequisite to its removal or control. Microspectroscopy is a very powerful tool in this context.

During the processing of semiconductor silicon by deposition of polyimide insulating layers on silicon wafers, it was noted that small solid particles were present in the polyimide, which caused serious problems during further processing. The composition of these particles was identified by infrared microspectroscopy as dicyclohexylurea. This material is formed by reaction of dicyclocarbodiimide, a reagent used in preparation of polyimide, with water. Apparently excess dicyclocarbodiimide was used in preparation of certain batches of polyimide. This excess material reacted with moisture from the air over a period of time to form an impurity; if an impurty exists, the spectrum obtained for each isolated unit often provides positive identification.

Infrared and Raman spectroscopies have been used for many years to study phase-separated heterogeneous polymers. Most studies focused on thermodynamics and physical properties achievable. Morphological features have been studied with other microscopic techniques. The advent of Raman and infrared microspectroscopic methods has an potentially important effect on this field of study. Chemical mapping provides contrast when other microscopic methods fail. The micro-Raman technique has been used in conjunction with other techniques to characterize the somewhat controversial issue regarding miscibility behavior of linear and branched polyethylenes (185). By using specific Raman features of each component, it is possible to detect crystallinity variations and reveal a biphasic structure in quenched blends that displays a morphological phase structure when examined in the transmission electron microscope. The domains formed for copolymers and polymer blends have also been studied using infrared microspectroscopy. The variation in infrared features corresponds to the relative polymer concentration (186). A more general case is provided by the study of phase structure and composition of polymer blends by Raman microspectroscopy. The technique is illustrated with use of various polymer mixtures (187). A Raman image of rubber-toughened epoxy resin developed using 1665 cm^{-1} band is shown in Figure 22.

In another application, an interfacial profile of polymer gels during phase transition was examined (188). The interface profiles between *N*-isopropylacrylamide (NIPA) hydrogel and water were directly observed using the Raman microimaging technique. As the NIPA hydrogel undergoes the volume phase transition, the interface becomes thicker and smoother. The average interfacial thickness of the NIPA gel at room temperature is about 37 μm, but increases to 65 μm at 37°C, which is above the phase-transition temperature. The thicker interface may be related to a dense shell formation during the gel shrinking process. The repulsive energy between water and polymer is minimized when the total surface of the interface is reduced, a process which results in a smoother surface. Without microspectroscopy, it would be impossible to obtain such structural variation in the presence of water.

A related application requiring a two-phase treatment is that of polymer dispersed liquid crystals. The optical properties of these films may be electrically modulated and their potential for application is quite high (189). By controlled cooling, the size of the liquid crystal droplets in the polymer matrix may be varied between 1 and 30 μm or larger. Three commercial liquid crystals were dispersed in two thermoplastics [poly(vinylpyrrolidone) and poly(methyl methacrylate)] and epoxy. These were studied by infrared microspectroscopy, both polarized

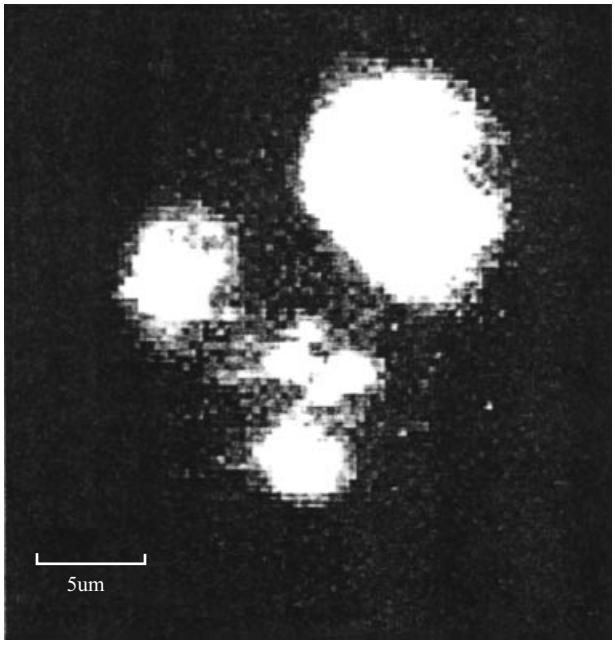

Fig. 22. Raman image at 1665 cm^{-1} (minus 1720 cm^{-1} background) of a thin film of rubber-toughened epoxy resin (187).

and unpolarized. Changes were observed in the droplets as a function of infrared polarization and applied electric field. Indications of partial solubility of the liquid crystal in the polymer matrix were obtained and orientational information about functional groups on the liquid crystal molecules as a function of the presence of the electric field were deduced.

Structural variation also exists as a result of differences in processing conditions. Phase structure, composition, and orientation of polycarbonate/poly(styrene-*co*-acrylonitrile) blends were studied by the Raman imaging technique. The existence of two-phase (PC-rich and PSAN-rich) microdomains was revealed. During drawing the microdomains are significantly deformed. In conjunction with polarized photoacoustic Fourier transform infrared spectroscopy, substantial orientation of the PC chains was revealed. In contrast PSAN chains exhibit only slight orientation. A similar study mapped the transition region in the neck of uniaxially drawn poly(vinylidene fluoride) with regard to crystalline structure as a function of stress (190,191). The morphology change as a function of position is shown in Figure 23. The stress exerted transformed the polymer from structure II (nonplanar, TGTG′ conformation) to structure I (planar, all-trans conformation).

Raman spectroscopy in conjunction with infrared dichroism has been used to characterize the segmental orientation at specific locations within processed polyethylenes (192). The variation of the segmental orientation through sample thickness was investigated for the cylindrical rods and an H-shaped molding produced by extrusion and rolling. The second moment of the segmental distribution

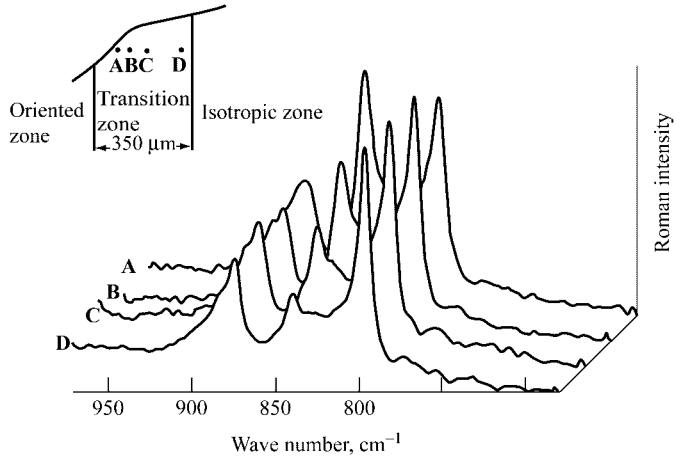

Fig. 23. Micro-Raman spectra of PVF_2 recorded in the transition zone at positions **A**, **B**, **C**, and **D** (191).

function, $\langle P_2 \rangle$, for both crystalline and amorphous regions was measured using a combination of X-ray diffraction, infrared, and Raman measurements. It should be mentioned that bands may be associated with specific chain conformation and not necessarily crystalline units. The fourth-order coefficient $\langle P_4 \rangle$ was also determined from X-ray diffraction and Raman spectroscopy for a series of cylindrical rods of draw ratios ranging from 6 to 20. The Raman spectroscopy results indicate that the all-trans chain conformations located in the amorphous phase are aligned perpendicular to the extrusion direction for the highly deformed rod, and gradually reorient towards the fiber axis for draw ratios up to 20. The $\langle P_2 \rangle$ and $\langle P_4 \rangle$ coefficients calculated for the crystalline phase remain constant for all draw ratios. Minor differences in the degree of molecular orientation were detected between the center and surface of the rods, whereas important variations were measured for the H-shaped sample. These are shown in Figure 24. In some cases, values obtained by Raman spectroscopy are lower than those calculated for the crystal phase from X-ray diffraction and polarized infrared, but are higher than the orientation determined for vinyl end groups. These differences can be explained by the fact that the vibrational bands assignable to the all-trans conformers can be found in both amorphous and crystalline regions.

Another application of microspectroscopy is characterization of laminated polymer films. Multilayer polymer films of different functionality are common in the packaging industry and identification of the different layers is of commercial importance. The layers vary from about 1 μm in thickness (adhesive) to 10–50 μm and there are often several layers. If there are only two layers, attenuated total reflectance (ATR) methods can be used for identification. For films with more than two layers, the normal procedure is to microtome a 10–20 μm cross section for edgewise analysis using microspectroscopy. A comparison of infrared and Raman microspectroscopies for some multilayer films has been published (Fig. 25) (193).

Clarification of the mechanisms of adhesion between two different polymers is an important field of study. Although investigations of the adhesive mechanisms of the polymer-to-polymer interface in painted surfaces have been undertaken, few

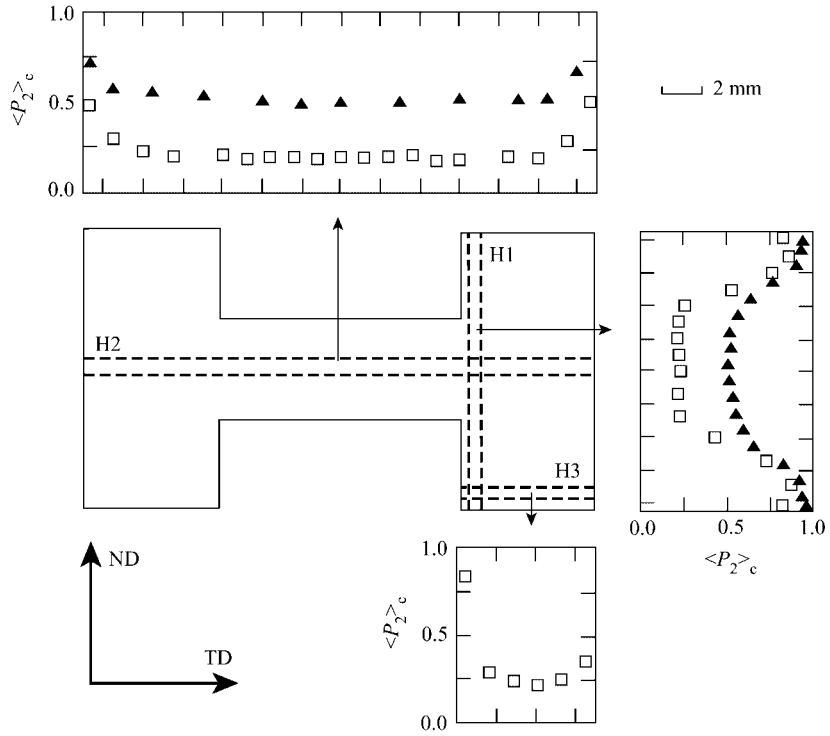

Fig. 24. $\langle P_2 \rangle_c$ coefficients measured by X-ray diffraction (110, 200, and 020 reflections) and Raman spectroscopy at different positions for the H1, H2, and H3 platelets (192) ▲ X ray; □ Roman.

studies are reported for structural changes caused by the adhesion. Fourier transform infrared microspectroscopy was used to analyze the interaction of the coated interface between two different polymers (176). The samples investigated were prepared by coating urethane paint on an ethylene–acrylic acid copolymer (EAA) and on an ethylene–ethyl acrylate copolymer whose ethylester group had been partially hydrolyzed (EAA/EEA). It was demonstrated that a mixed phase was formed along the coated interface between the urethane paint and the EAA and between the paint and the EAA/EEA. The interaction between molecules of the polyurethane and the EAA was observed (176). Using similar techniques, concentration profiles and interdiffusion coefficients of contacting compatible polymers have been established (194).

Assessment of Anisotropy in Polymers: Segmental Orientation

Motivation. Structural anisotropy in all materials, especially polymers, is a readily accepted concept. Physical properties such as thermal conductivity, optical transmission, electrical conduction, piezoelectricity, shrinkage stability, and, particularly, mechanical performance are all highly dependent on the degree of anisotropy. For many polymer applications, high modulus and strength are especially important. These qualities can be obtained by polymers with desired degrees

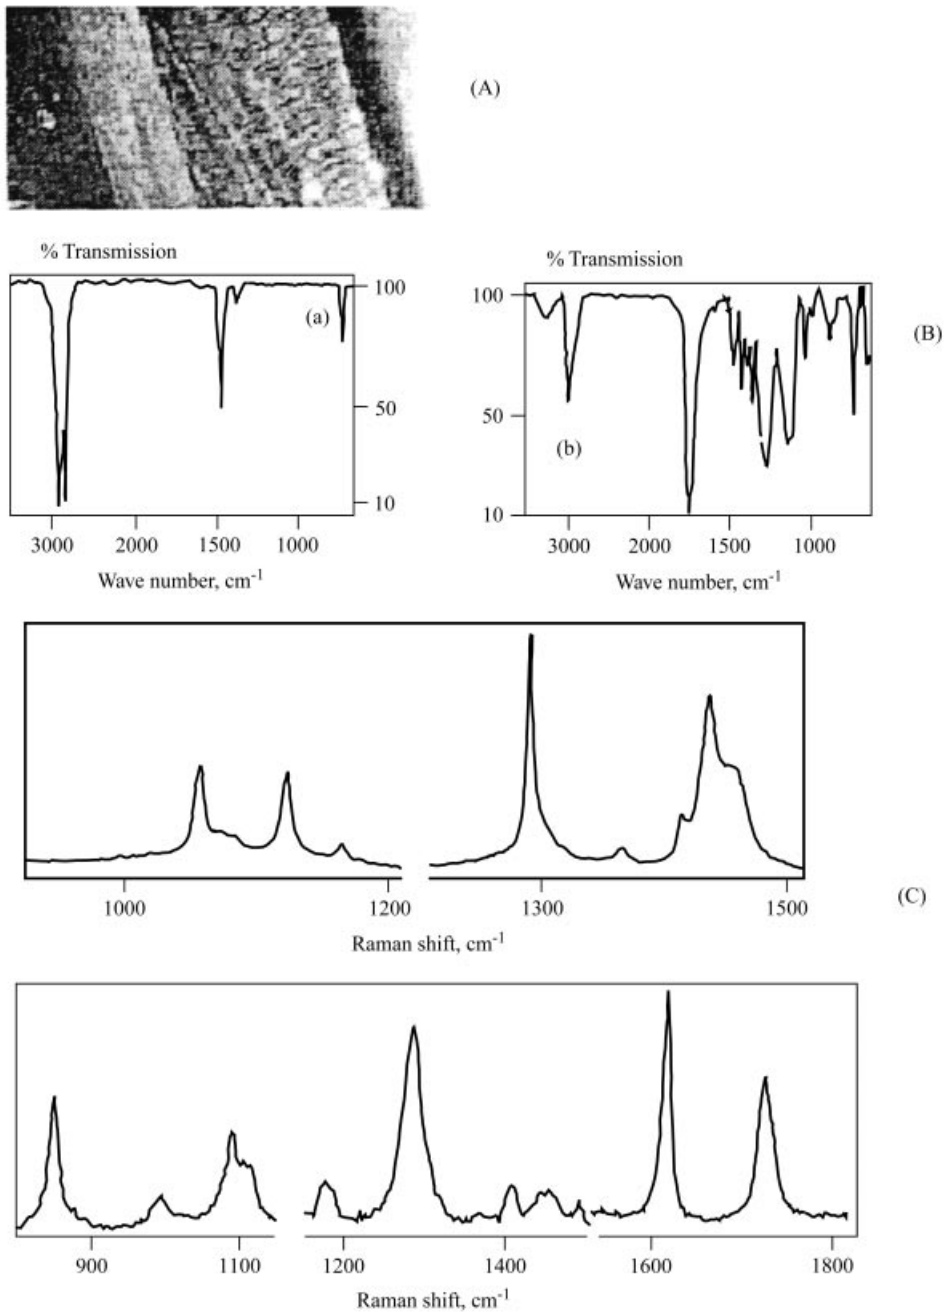

Fig. 25. Microspectroscopic studies of polyethylene and poly(ethylene terephthalate) laminate: (**A**) optical of micrograph; (**B**) micro-infrared spectra of the components obtained (left PE, right PET); (**C**) micro-Raman spectra obtained (top PE, bottom PET) (193).

of anisotropy. The deformation process, whether in the solid state, melt, or solution, induces the alignment of molecular chains along the elongation direction, which results in an increase in strength and modulus of the material in that direction. Uniaxial deformation can be utilized to achieve samples of a fibrous nature. Biaxial orientation along two perpendicular axes has been extremely successful in producing materials of interwoven fibers to yield films or sheets with desirable mechanical performance along the two plane axes. For amorphous samples, understanding the deformation behavior of individual chains is important. For crystalline polymers, the relationship between the overall deformation behavior must be related to the relative motion of amorphous chains and crystalline regions. The deformation process must be correlated to the deformation mechanisms available to the crystalline portion. The crystalline degree, size, perfection, and interconnectivity are all important in the overall consideration of deformation mechanisms. The absence of a well-formed model to describe the deformation process makes experimental studies extremely important in relating every aspect of the structure to the overall applied stress or strain.

A commonly used criterion to assess mechanical performance of processed polymers is modulus measured under extension. In most cases the experimental values generally fall substantially lower than theoretical estimates. The difference is undoubtedly due to both conformation and orientational disorder in the processed samples. The best illustration of the complex processing steps required and the resulting structure is polyethylene. With the tremendous developments in polymer processing methods, materials with controlled, and in some cases nearly perfect, chain segment orientation can be obtained. For example, gel spun polyethylene fibers and biaxially oriented blown films possess properties much higher than the isotropic state. The modulus of as-polymerized material generally is measured in the range of 1 GPa (195). It was shown that the modulus of polyethylene can be increased significantly to a value approaching theory, ~300 GPa (104,124). In processed fibers virtually all chains are perfectly extended and aligned with respect to the deformation axis, thus producing the extremely high modulus value. Generally speaking the force required to deform a backbone bond is approximately 10 times higher than that needed to deform a valence angle, which, in turn, is approximately 10 times higher than that needed to change the torsional angle of bonds along the backbone. If it is possible to orient and extend individual polyethylene chains into a planar zigzag conformation as in these highly deformed fibers, thus eliminating the torsional deformation of disordered chains, the modulus can be increased significantly (196).

Polymers are processed into anisotropic materials to lower the number of structural defects and achieve segmental orientation. Undoubtedly these two properties are correlated, making measurement of sample anisotropy crucial. Different characterization techniques measure segmental orientation of different morphological subunits. Some address overall sample anisotropy. Others address specific structural units, crystalline, amorphous, or interface. Different sample portions may possess different degrees of orientation. For example, the extrudate interior may yield a considerably different degree of orientation in comparison to sample surface. Measurement techniques include X-ray pole figure analysis (192,197), infrared dichroism, polarized Raman scattering, birefringence, NMR, fluorescence. Each technique can potentially yield different information regarding

orientation of morphological subunits, both crystalline and noncrystalline. The increase in sample anisotropy as a function of deformation can be assessed by measuring sample density, degree of crystallinity, birefringence, etc. The importance of vibrational spectroscopy in orientation analysis cannot be overestimated. Because they are capable of extremely high spatial resolution, fibers, films, and sections of large specimens can all be analyzed. On-line analysis is important. Raman with associated fiber optics presents interesting opportunities to obtain orientation data at different stages of deformation. No other technique is available for this purpose.

It is important to model the deformation process as a function of draw ratio. As mentioned above, even for highly deformed material, some imperfection in segmental orientation remains. Knowledge concerning the molecular mechanism and degree of segmental orientation achievable by various drawing, extrusion, or other deformation techniques is, in fact, quite limited. Therefore, two aspects concerning formation of anisotropic polymers are required: (*1*) a quantitative description of segmental orientation achieved; and (*2*) relationship between segmental orientation and draw ratio.

The distribution of chain segments relative to the reference axis yields the fraction of chains in each angular volume element and is expressed as (198)

$$\frac{\mathrm{d}n}{N} = f(\zeta,\phi)\ \mathrm{d}\zeta\ \mathrm{d}\phi$$

where ζ is defined as $\zeta = \cos\theta$, where θ is the angle measured with respect to the reference axis. In the three-dimensional space, the distribution function is often expanded as a series of spherical harmonics (199,200). If the system does not have angular dependence (uniaxially oriented system with a symmetry plane perpendicular to the deformation axis), the distribution function can be written as

$$f(\zeta,\phi) = \sum_{l=0}^{\infty} C_l P_l(\zeta) \tag{10}$$

and then

$$C_l = \int_{-l}^{l} f(\zeta) P_l(\zeta)\ \mathrm{d}\zeta \tag{11}$$

For an axially symmetric system, only even series of Legendre polynomials are retained. A full description of the segmental orientation function requires that the individual component be defined. The coefficients *C*'s, characteristic of the distribution function, represent the contribution from each Legendre polynomials. The second-order coefficient is the well-known *Herman orientation function* (201) and is generally the only one used for structural analysis in polymers.

$$C_2 = \frac{3\cos^2\theta - 1}{2} \tag{12}$$

This expression represents an average taken over all sample orientation. Practically speaking many methods can measure the second moment, which can range from −0.5 to 1.0. One extreme signifies that the segment is oriented perpendicular and parallel with respect to the deformation axis. A zero value is found for the case of random orientation. For infrared spectroscopy, the second moment can usually be given by the expression

$$C_2 = \left(\frac{D-1}{D+2}\right)\left(\frac{D_0+2}{D_0-1}\right) \tag{13}$$

where D is the dichroic ratio defined as the ratio of relative absorptions, $A_\parallel/A_\perp$, $D_0 = 2\cot^2\alpha$, and α is the angle of the transition moment with respect to the chain axis. Because of its sensitivity to short-range order or disorder, vibrational spectroscopy provides detailed information regarding orientation of chain segments, either in the ordered or disordered states, and for a large variety of samples, including fibers or films. Because an extremely fine focus can be achieved, samples such as fine fibers can be studied. In addition, surface versus bulk can be differentiated for larger samples.

Raman can produce higher moment, C_4. In practice, experimental difficulties severely limit applications of the eloquent theoretical expressions derived (202). In theory and practice, only X-ray diffraction is capable of measuring higher moments of the distribution function accurately (192,197). Even then, the high quality diffraction data necessary for determining higher moments in the distribution function are difficult to obtain. For smaller draw ratios, evaluation of the second moment is usually quite sufficient. Obviously, samples deformed to a higher degree require a precise determination of the orientation function.

The expressions presented above contribute to assessment of the segment distribution relative to any axis. From practical considerations, it is often desirable to relate this distribution function to the degree of deformation associated with polymer chain transformation from an isotropic to anisotropic state. This transformation may depend on the size, perfection, and interconnectivity of the morphological units. It is virtually impossible to define polymer structures sufficiently accurately to describe the deformation behavior analytically. The only case that can be determined in a closed form is to imagine the entire polymer sample being deformed to consist of a network of totally flexible chains and each chain to consist of totally flexible chain segments, ie Gaussian chains. Using this model, the calculated orientation of chain segments as a function of draw ratio is surprisingly low (199,200). However, if the number of connecting units between segments is small, or the structural unit is large, the change in orientation function can be seen to increase significantly as a function of strain (203). This model has been used in many infrared-deformation studies.

The specific utility of vibrational spectroscopy in these orientation studies is illustrated below. If a polymer film is oriented by drawing or extrusion, the polarized infrared spectra reveal tremendous differences in absorption for incident radiation polarized parallel or perpendicular to the drawing direction. Polarized infrared spectra of polyethylene are shown in Figure 26. The CH_2 rocking vibrations in the 700 cm^{-1} region, or the CH_2 wagging or CH_2 bending vibrations in the 1300–1400 cm^{-1} regions, exhibit very different polarization behavior.

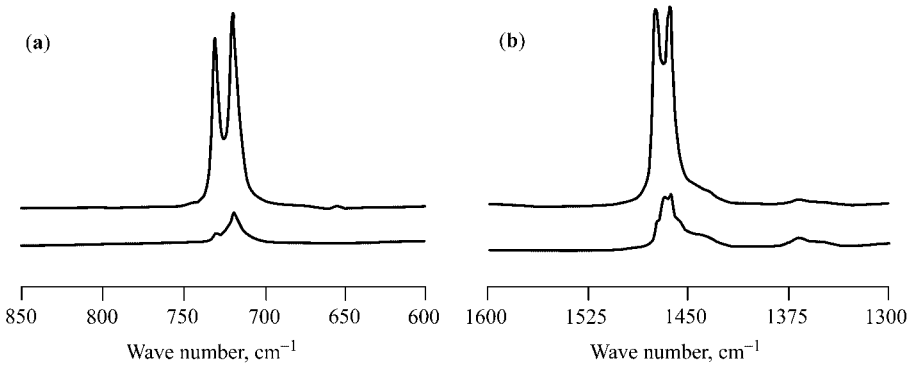

Fig. 26. Polarized infrared spectra of polyethylene: (**a**) CH_2 rocking region; (**b**) CH_2 wagging and bending regions; top is spectra with polarization parallel to the draw direction and bottom with polarization perpendicular to draw direction.

This observation highlights several important features of polarization spectra. First, and most importantly, the polarization measured is associated with the direction of the vibration transition moment. The direction of this transition moment relative to the chain segment must be considered in order to determine the overall chain segmental orientation. For some functional groups and extremely well-defined polymer structures the transition moment can be estimated. In many cases, however, this is difficult to accomplish. Orientation information obtained from spectroscopy is highly selective and can be used to characterize individual chain segmental orientation in both crystalline and amorphous regions. The relative orientation of the amorphous bands to the crystalline bands can provide much information regarding the deformation process in forming highly anisotropic fibrous samples. In a second example, polarized Raman scattering are shown in Figure 27. Isotactic polypropylene exists in a 3_1 helix. Its vibrations can be divided into 25 A modes and 26 degenerate E modes. The optical activity of the two optical active species are quite different and can exhibit quite different polarization characteristics. The classification of various normal vibrations into symmetry classes is greatly facilitated by performing appropriate Raman scattering experiments (22).

Surface Characterization

The importance of polymer interfaces and polymer–external surface interactions cannot be overemphasized. Interface performance to a large extent determines the overall mechanical properties of composites and heterophase polymers including polymer blends. Polymer interaction with external surfaces is also central to a broad range of applications such as corrosion inhibition, adhesive joint strength, fabrication of electronic components, and decorative plating. Several techniques, each with particular advantages or disadvantages, including contact angle, X-ray photon electron spectroscopy (XPS), and radioactive labeling, are available. Contact angle is perhaps one of the easiest to carry out, but the information obtained

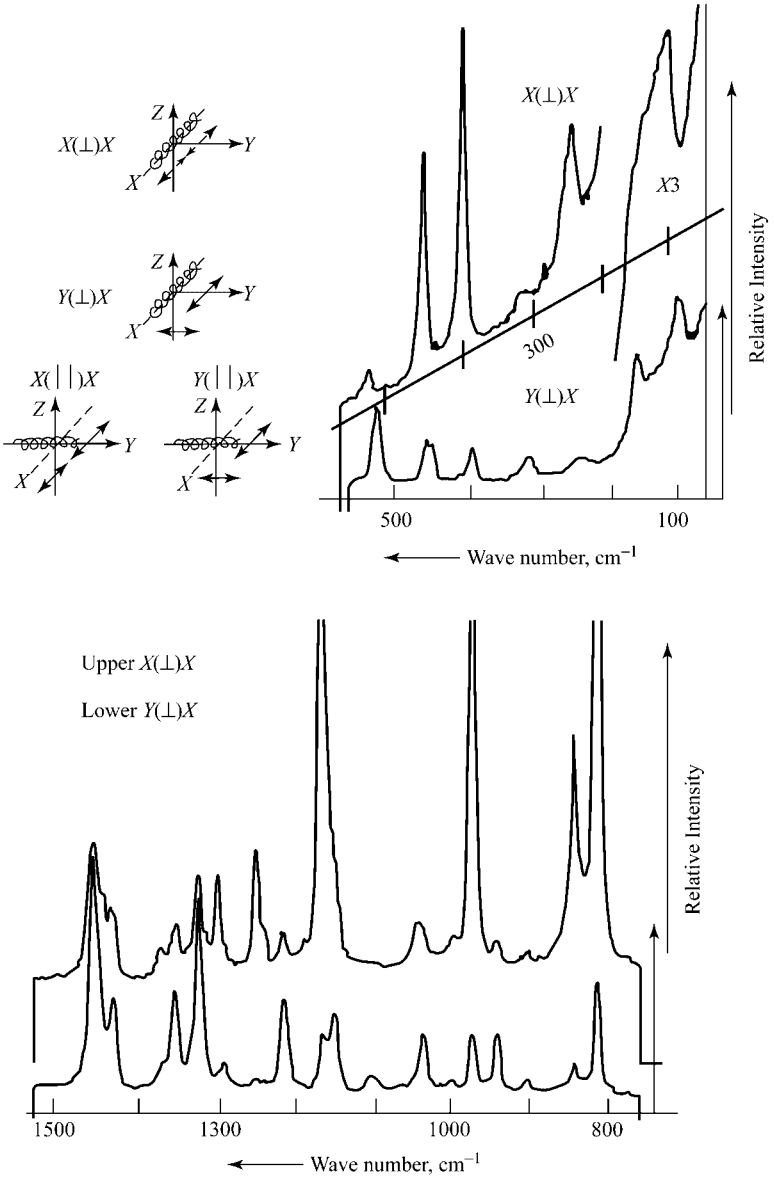

Fig. 27. Polarized Raman spectra of oriented isotactic polypropylene fibers (22).

is somewhat limited. XPS can be used to measure surface composition accurately with high spatial resolution, but the high vacuum requirement may make such experiments difficult to conduct. Vibrational spectroscopy has proven a useful technique in surface analysis, both chemical composition and structure.

Perhaps because of dramatic improvements in instrumentation or changing research perspectives, the study of surfaces has changed dramatically. Spatial resolution of surfaces or interfaces of a few micrometers is no longer sufficient.

Investigation of the mechanical, adhesion, and electrical behavior of ultrathin polymer films requires spatial resolution of the order of 10–100 Å. Specular reflectance spectroscopy is a most convenient technique for probing structures on either metallic or dielectric surfaces. Furthermore, techniques such as polarization modulation spectroscopy have significantly increased sensitivity and the possibility of photoacoustic spectroscopy is also available.

Because of the small amount of sample being probed and necessarily at the surface, transmission spectroscopy does not provide sufficient sensitivity to discriminate differences from samples at the surface from the remainder of the sample. Some type of reflection technique which localizes the probing radiation to the region of interest is desired. The contribution of infrared spectroscopy has perhaps been much more useful than Raman spectroscopy in surface analysis. Almost every laboratory using infrared spectroscopy has some type of reflection cell. These are well designed and sold through spectrometer manufacturers and independent firms making specialized accessories. In contrast, few laboratories with Raman instruments have the capability to measure Raman spectra from surfaces. Many specialized Raman techniques have been developed for surface analysis. The high power laser required, sample degradation, high cost, lack of construction capability have all limited its utility in general surface analysis. The infrared technique is generally the one of choice. It should be emphasized that different infrared techniques probe materials at different depth from surfaces. ATR has a sampling depth of approximately 1–10 μm (10). In contrast, grazing specular reflectance spectroscopy can probe film thickness as thin as 1 nm (204).

The attenuated reflectance technique presents an excellent example of how radiation at sample surface can enhance signal-to-noise ratio. Details of general optics and reflectance techniques can be found in the classic text (10). This technique is used extensively to determine differences between the structure of polymers in surface and bulk phases. Commercial accessories make these spectroscopic experiments easy to perform, although quantitative analysis of the data remains difficult. Examples of ATR applications include chemical composition analysis of polymers, surface orientation resulting from various processing methods, and chemical or thermal degradation of polymers. For samples such as powders or poorly defined surfaces, the diffuse reflectance technique can be used (11). In addition, the photoacoustic technique has been used to probe surface structure and multilayer structure commonly found in polymer laminates (17). In all these cases, optical effects can complicate analysis of infrared spectra. Nevertheless, these data have proven very useful in analytical applications.

The development of the reflectance technique and quantitative analysis of results demand thorough understanding. Knowing how the probing beam is reflected, refracted, or absorbed at the polymer–polymer, air–polymer, or polymer–solvent interface is crucial. This can be understood only if the optical property of the individual medium is carefully defined. The basic consideration for any analysis must consider the real and imaginary parts of the index of refraction for the polymer *films* and substrates being studied. The situation can be particularly complex if the film is highly ordered or oriented. Film thickness can introduce unexpected errors as well. Differences in band frequency, shape, and intensity between the transmission and reflection infrared data arise from optical effects associated with thin films, which may have no correlation with

structural differences (14). Computer algorithms have been developed to appraise these optical effects. In most analyses, the structural information is obtained from interpreting only a few isolated well-assigned infrared bands. Therefore, the exact calculation of optical effects for thin film or substrate need not be undertaken for the entire frequency range but rather a limited range of interest. Knowing film thickness, optical coefficients of the substrate, angle of incidence, and isotropic transmission spectrum, the spectra expected from the reflectance technique can be predicted.

If the substrate used is metallic in nature, the boundary condition for an incident electromagnetic wave is such that only the electric field with polarization in the plane of scattering (defined as the plane containing the incident and reflected rays) has energy at the surface (205). The intensity of the other component polarization is zero near the conducting substrate surface. Hence, only one of the two perpendicularly polarized radiations will be absorbed by the thin polymer film. The use of reflectance infrared spectroscopy to characterize the composition of chemically or physically absorbed layers on external surfaces can be easily appreciated. Only vibrations with components of the transition moments perpendicular to the metallic surface are expected to appear with enhanced intensity. Those having transition moments nearly parallel to the surface are expected to be weak or nonexistent. The most definitive studies undoubtedly involve highly ordered model compounds prepared by the Langmuir–Blodgett technique. When bands are accurately assigned, and particularly when the directions of transition moments are well defined, much information can be derived from the highly polarized reflectance infrared spectroscopy of such films on external surfaces (206).

In most cases, the dynamic range of a Fourier transform instrument is more than adequate to differentiate adsorptions of these two components. However, by using the double modulation technique together with phase-sensitive detection, a far better signal-to-noise ratio can be obtained (207) since the difference between the two components is measured directly. It should be mentioned that double modulation spectroscopy has also been used to elucidate structure of adsorbed films from dielectric surfaces (208).

By definition, most high frequency vibrations are well-defined localized vibrations involving few nuclei, making transition dipoles easy to define and understand. Examples are the C=O and CH_2 stretching vibrations in n-$C_{15}H_{31}CO_2H$ absorbed on Al_2O_3 (Fig. 28) (206). The significant difference between the reflectance and transmission spectra can be accounted for by preferential orientation of the carboxylate groups. Information on the exact orientation of the alkyl tail of the hexadecanoic acid can also be obtained from the high frequency spectra shown in Figure 28.

An example involving stacks of nematic liquid crystalline polymers (benzenehexa-*n*-alkanoates) on substrate is presented. Because of lack of suitable vibrations it is difficult to determine the orientation of the central benzene rings of BHn. Therefore another series of tetrakis(octanoyloxy)*p*-benzoquinone (QTE8), with C=O directly attached to the benzene ring, is prepared. Optical and X-ray diffraction studies reveal that the structure consisting of a rigid aromatic core and flexible side chains can be characterized as forming columns in a hexagonal array. The methylene sequences are nearly extended with an all-trans conformation in the crystalline phase (209). The degree of conformational order varies

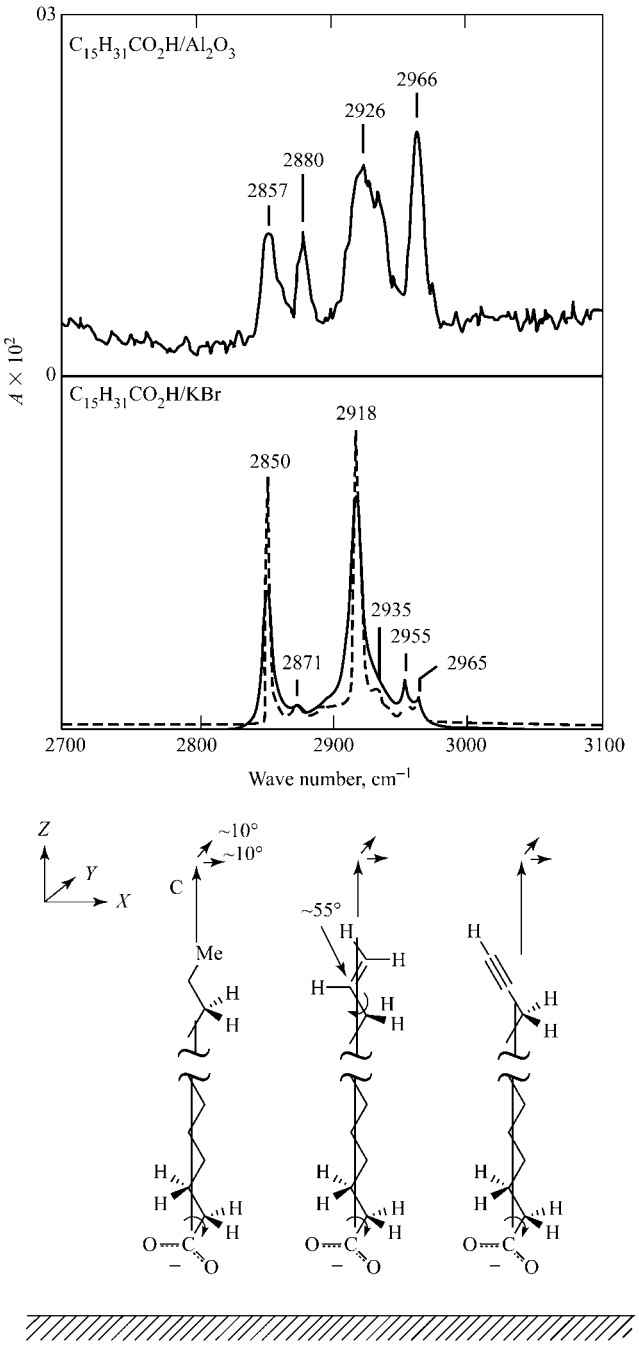

Fig. 28. Spectra and proposed structure of films absorbed onto substrate. (Top) Spectra in the mid-frequency region of n-$C_{15}H_{31}CO_2H$ as a film adsorbed on Al_2O_3 (top) and in a KBr matrix (bottom). The KBr experimental spectrum is accompanied by a deconvoluted spectrum (dashed curve), which represents enhanced resolution. n-$C_{15}H_{31}CO_2H$; (Bottom) Proposed structure of the adsorbed species having fully extended chains. The molecular orientation is defined relative to the surface coordinates (206).

considerably with temperature. Furthermore, conformational isomers are found for the ester groups. By using polarized reflection spectroscopy it is possible to deduce the structural transformation of individual subunits when overall phase transition occurs.

Structural changes corresponding to isotropic–nematic and nematic–crystalline transitions are expected to occur in the temperature range of 56–60°C. Bands assignable to methyl groups (2964 and 2873 cm^{-1} asymmetric and symmetric stretchings respectively) and methylene chains (2928 and 2858 cm^{-1} asymmetric and symmetric stretchings) are well known (Fig. 29). The relative intensities of the bands in this region change significantly as a function of temperature. Based on the relative intensity of the polarized spectra in the isotropic surface phase at 60°C, the methylene chains are mostly oriented at a slight angle relative to the external surface. The orientation of the skeletal plane is identically 0.0, supporting the view that these arms disorder quite quickly and completely in the isotropic phase. On decreasing the temperature from 60 to 56°C the orientation of the plane containing the methylene skeleton increases, indicating a substantial increase in this orientation function to above 0.2. Based on polarization studies of *n*-alkanes, the transition moment of the higher frequency component is parallel to the skeletal plane and that of the lower frequency component is normal to the skeletal plane. Both components contribute nearly equally to the band seen in the reflection spectrum of the isotropic melt at 60°C. As seen in Figure 29, the higher frequency component is much stronger than the lower frequency component in reflection spectra of the liquid crystalline and crystalline phases at temperatures at or below 56°C if the C—C—C skeletal plane is perpendicular to the metallic surface in the crystalline phase.

Furthermore, the relative intensity of the quinone C=O stretching vibration in the reflection spectrum at room temperature is much smaller than its intensity

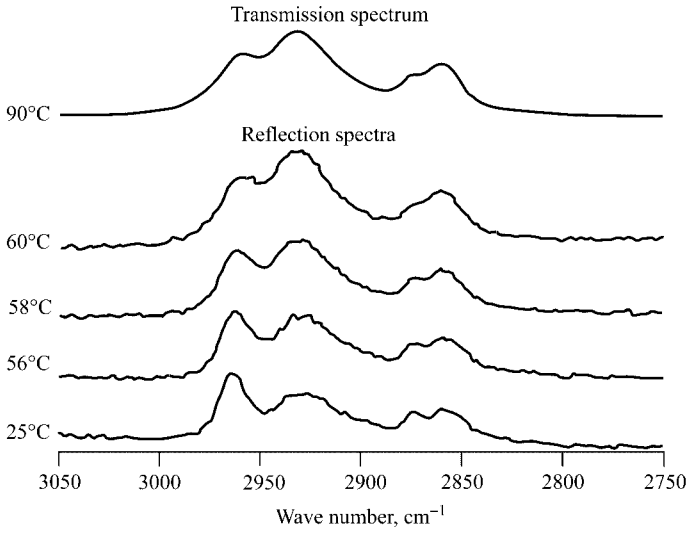

Fig. 29. Transmission spectrum of the isotropic melt and reflection spectra in the CH stretching region of adsorbed films of QTE8 as a function of temperature.

in the transmission spectrum of the isotropic state. This suggests that the transition moment of the in-plane C=O stretching 1690 cm^{-1} vibration tends to be parallel to the metal surface in nematic or crystalline phases. Semiempirical conformational calculations suggest that the transition moment angle of the ester C=O vibrations relative to the normal of the core plane is expected to be in the range of 31–53°. From our intensity data and these theoretical values, the possible range of the orientation function for the aromatic ring can be obtained. Even in the isotropic state (60–80°C), the aromatic core shows a slight tendency toward parallel orientation with respect to the substrate surface.

Potentially important ultrathin Langmuir–Blodgett films have been the focus of numerous studies (210). These are generally divided into two areas, those that concentrate on the film at the air–solution interface or on films which have been transferred to a supporting substrate (211–214). Most studies to date have focused on the second area. The first area is important for several reasons:

(1) The formation of the transferred films is dependent on the initial state at the air–solution interface.
(2) The changes in polymer conformation in constrained geometries is of fundamental importance and can be studied most conveniently at the air–solution interface.
(3) Reflectance spectroscopy developed for the air–solution interface is generally applicable to coatings on dielectric surfaces.
(4) Structural characterization of adsorbed chains is often complicated by substrate roughness.

Force–area relationships suggest the presence of varying structures (chain conformation, packing, and orientation) at the air–water interface, depending on the concentration of the molecules present. Detailed microscopic information such as changes in chain conformation is unavailable. The extremely small number of molecules present at the interface requires sensitive measurement techniques. Developments in the use of external reflection infrared experiments, however, allow spectra of molecules at the air–water interface to be obtained at nearly any concentration (215–217).

In contrast to the metallic substrate usually employed in reflection experiments, the complex boundary conditions that govern electromagnetic waves interacting with dielectric surfaces such as water make interpretation of spectra from the air–water interface more difficult (212). Several variations of computational methods for optical reflections from dielectric media have been reported (89,212,218,219). For a dielectric surface, both *s* and *p* polarized radiation within the film are present. Even though more spectroscopic information is available, the information obtained is more difficult to analyze. Infrared reflection studies of molecules at the air–water interface are most easily analyzed using isolated high frequency ($\sim$3000 cm^{-1}) C—H stretching vibrations. Phase transformations that involve chain packing and/or segmental orientation changes have been analyzed (89,215–217).

Insoluble polypeptide monolayer films at the air–water interface have been used as model compounds for biological systems to investigate chain

folding, molecular orientation, and domain formation (217). Little is known about the conformational state and stability of polypeptides confined at this interface. Poly(β-benzyl-L-aspartate) and poly(β-methyl-L-aspartate) usually form a left-handed 3.6_{13} α-helix (220,221). The relative stability of the left- and right-handed α-helical forms were estimated by molecular mechanics methods. Differences of only a few tenths of a kilocalorie per mole per residue were reported (222). The determining factor in inducing the left-handed helix appears to be the contribution of electrostatic energy that arises in the interaction between dipoles associated with the ester and amide groups. The calculation suggests that the interaction was more repulsive in the right-handed than left-handed form, thus destabilizing the right-handed helix. The similar conformational energies of left- and right-handed helices suggest that these forms may interconvert on heating or on altering the strength of the dipole–dipole interaction. The presence of water has been suggested to weaken interactions between effective charges on the atoms of the ester and amide groups, thereby destabilizing the left-handed helical structure and favoring the right-handed form. The circumstances in which right-handed α-helices form remain undefined.

The presence of different helical forms in polypeptide systems can be detected by infrared measurements of conformationally sensitive vibrational bands of the amide linkage. A correlation exists between the helix screw sense and frequencies of the amide I and amide II bands. The ranges of the amide I and II bands were respectively 1656–1659 and 1552–1555 cm^{-1} for the right-handed α-helix, 1664–1668 and 1555–1561 cm^{-1} for the left-handed α-helix, and 1675 and 1536 cm^{-1} for the ω-helix of poly(β-benzyl-L-aspartate). From external reflectance infrared spectra directly obtained at the air–water interface (Fig. 30), the conformation of poly(β-benzyl-L-aspartate) established that a right-handed α-helix, 4.0_{13} ω-helix, and a left-handed α-helix can all exist simultaneously at such an interface (217). The right-handed α-helix forms immediately when the film is cast on a surface of pure water. These helices persist at all compressions in a Langmuir trough. The helical screw sense can be reversed by lowering polarity of the aqueous phase. In addition, an alternate conformation similar to the ω-helix forms on addition of small amounts of 2-propanol to the aqueous subphase and appears to be an intermediate in the helix–helix transition.

A second example involves reflectance infrared spectroscopic structural analysis of polydimethylsiloxane at the air–water interface. Surface pressure versus surface area or surface concentration isotherms of polydimethylsiloxane on water have been studied since 1947 at least (223). Upon compression, the isotherm begins at zero surface pressure at surface concentrations significantly below 0.75 mg/m^2. Around Γ_1 0.75 mg/m^2, the surface pressure π jumps substantially to about 9 mN/m, where it exhibits a plateau until about Γ_2 1.6 mg/m^2, where a small π jump occurs followed by a smaller rise (Fig. 31). Structural features associated with the various transitions have often been debated. Particular controversy is associated with the π plateau around 9 mN/m between Γ_1 and Γ_2 (224,225). In conjunction with other techniques, such as epifluorescence microscopy, external reflectance infrared spectroscopy was used to study microstructural features (coexistence of two phases) of polydimethylsiloxane CH_3—$[Si(CH_3)_2$—$O]_n$—$Si(CH_3)_3$, spread at the air–water interface in the vicinity of the π plateau at 9 mN/m (226). A broad band containing several components is found in the 1000–1100 cm^{-1}

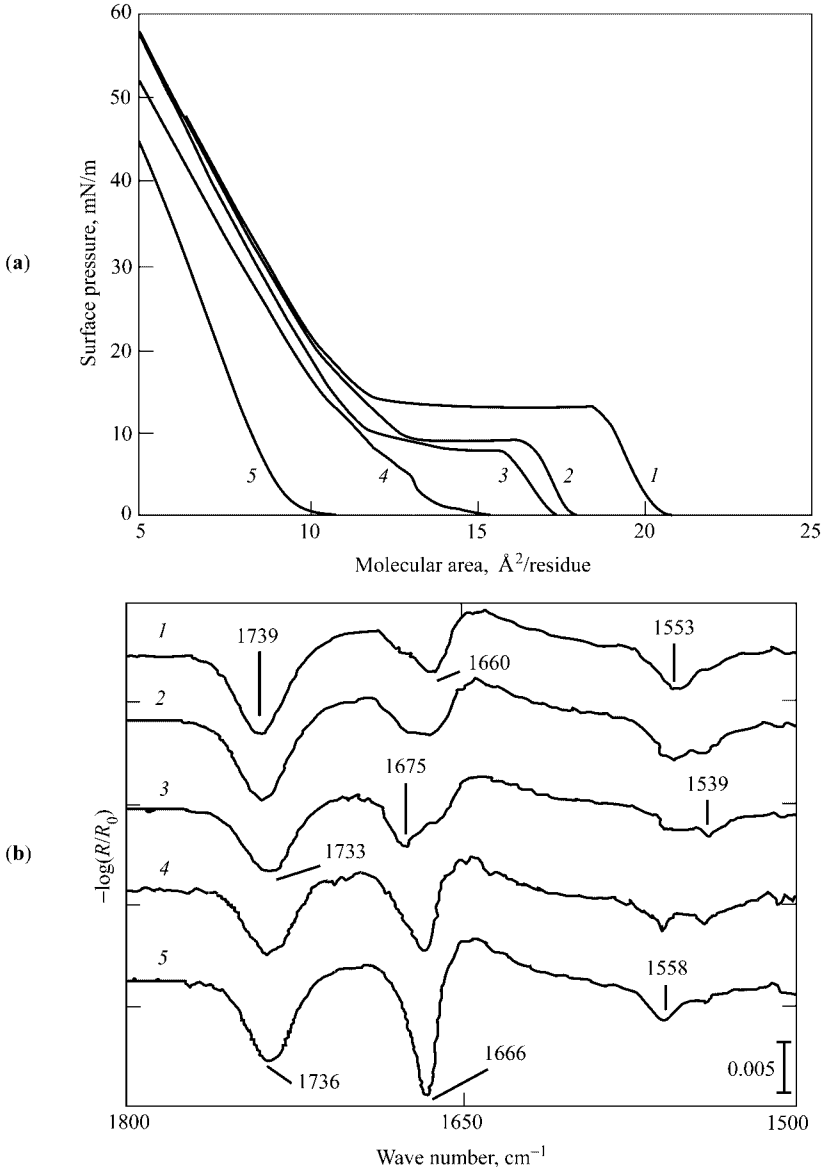

Fig. 30. (Top) Surface pressure–area isotherms for poly(β-benzyl-L-aspartate) films spread on water containing small concentrations of 2-propanol: (*1*) 0 vol%; (*2*) 0.4 vol%; (*3*) 0.5 vol%; (*4*) 0.85 vol%; and (*5*) 1.0 vol%. (Bottom) External reflection infrared spectra obtained at 40 mN/m from these films.

region. The spectra (Fig. 32) change significantly as surface concentration is varied between Γ_1 and Γ_2. At Γ_1 the most intense band is at 1005 cm^{-1}. At Γ_2, the most intense peak occurs at 1020 cm^{-1}. Weaker components are found around 1055 and 1090 cm^{-1}. All components persist to some extent at all concentrations studied. These spectra suggest that the 1020 cm^{-1} band originates in one

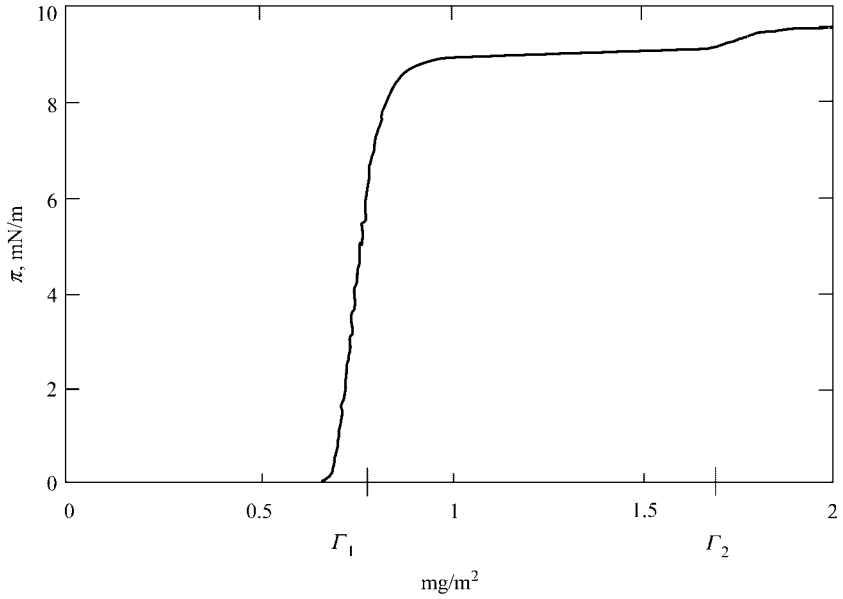

Fig. 31. A typical isotherm observed for polydimethylsiloxane film cast on a water surface.

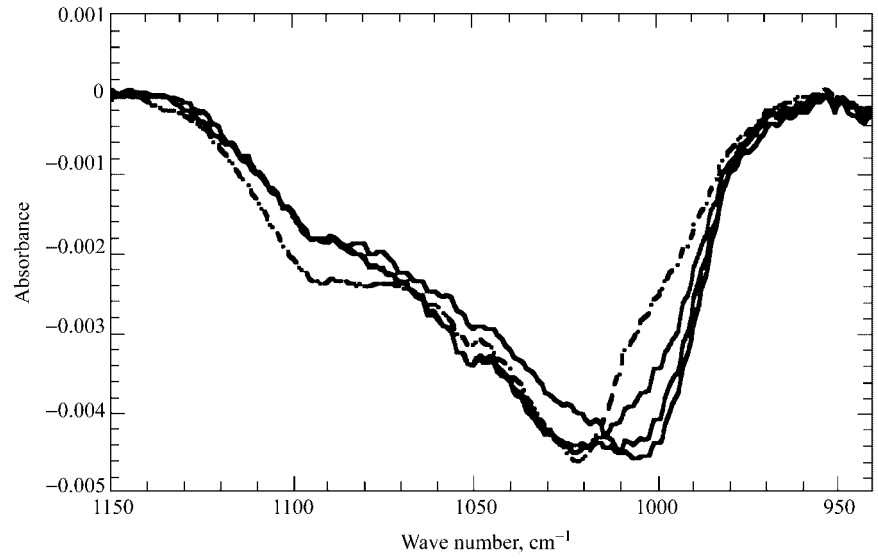

Fig. 32. Scaled external reflectance infrared spectra of the ν_{as} band for polydimethylsiloxane film spread on water at several concentrations between Γ_1 and Γ_2.

structure and the 1005 cm^{-1} band in another. In fact, these structures are consistent with the presence of a caterpillar-like structure at low surface pressure. For this structure, all the oxygen in the water and all the methyl groups point away from the water surface. The structure becomes considerably twisted with an initial jump in surface pressure to a helix with the helix axis parallel to the

water surface. The polarization characteristics of the infrared spectra obtained are consistent with transition moments calculated for these two models.

In a third example, polymer structural transition at interfaces has been demonstrated to significantly differ from that in bulk or solution (227). The polymer (designated poly[$(AG)_3EG$]) consists of 36 repeat units of an octapeptide sequence [$(AG)_3EG$] constituted from glycine (G), alanine (A), and glutamic acid (E) designed to adopt a folded-chain lamellar architecture in the solid state with the oligoalanylglycine segments forming β-strands and the periodic glutamic acid residues positioned in reverse turns at lamellar surfaces. Spectroscopic and X-ray diffraction analyses show that the crystalline polypeptide displays the expected architecture and the folding periodicity is as expected (228). In contrast, based on conformationally sensitive amide vibrations, poly[$(AG)_3EG$] in aqueous solution adopts a random coil conformation. The external infrared reflectance spectrum of poly[$(AG)_3EG$] at the air–water interface of a D_2O solution at pD 5.1 is quite different from the absorption spectrum of the same solution; the amide I′ band in the reflection spectrum appears at 1635 cm^{-1}, characteristic of the β-pleated sheet structure. Thus poly[$(AG)_3EG$] shows β-sheet character at the air–water interface but retains a random conformation in bulk solution. Furthermore, the amide I frequency of the polymer at the air–water interface shows a marked pH dependence. The amide I frequency shifts from about 1650 cm^{-1} at pH 13.6 to 1635 cm^{-1} at pH 5.0. Mild acidification drove a coil-to-sheet transition at the air–water interface. These results demonstrate that the conformational properties and transitions of adsorbed macromolecules can be very different from those in bulk solution. Adsorption of poly[$(AG)_3EG$] at the air–water interface allows a coil-to-sheet transition that is not observed in bulk.

Characterization of Silk Crystallization Behavior on Highly Oriented Substrate. The silk fibers produced by spiders and silkworms exhibit many impressive physical and mechanical properties which have inspired numerous attempts to spin such fibers from silk solutions *in vitro* (229). It is particularly interesting that silk originates from an aqueous solution. In the spinning process water-soluble silk fibroin is converted at room temperature to insoluble high performance fibers by a physical rather than a chemical process. Silk chains form a β-pleated sheet packed in an antiparallel fashion, referred to as silk II structure. The less stable water-soluble form is referred to as silk I. Either silk I or II structures can be obtained from solution, depending on crystallization conditions. In the substantial silk literature dealing with the mechanism of crystallization, parameters such as solvent, concentration, temperature, drying rate, and substrate are found to be important in determining chain conformation (229,230). Mechanical stress accompanying flow of the aqueous silk solution has been found crucial to the crystallization of b-form silk crystals from solutions of silk fibroin.

Orientation of silk molecules can be accomplished by shearing silk fibroin solution (231) or by adsorption to the air–water interface (232). The influence of an oriented substrate on the crystallization of silk from aqueous solution has been investigated by casting a film of silk from solution on a highly oriented poly(tetrafluoroethylene) substrate (233). This substrate is easily obtained by rubbing a poly(tetrafluoroethylene) block on glass slides under pressure at a suitable temperature. Transmission infrared spectroscopy has been used to characterize silk films since the early 1950s. External reflection infrared spectroscopy was

chosen to characterize both the microstructure of the substrate and that of the silk crystals. Silk films cast from either aqueous silk solution or aqueous silk-LiBr solution on the oriented poly(tetrafluoroethylene) surface exhibit more silk II structure than those cast on glass slides or on unoriented poly(tetrafluoroethylene) surfaces under identical conditions. Oriented poly(tetrafluoroethylene) films can therefore be used as templates to control cast film structures.

Double Modulation Spectroscopy

Some of the most interesting recent studies are designed around polarization modulation spectroscopy (16,207,234). Reflectance spectroscopy can be carried out with high sensitivity. Mechanical-vibrational spectroscopy has opened new areas relating polymer macroscopic behavior such as rheology to microstructural responses at the molecular level (235). The technique usually involves analysis of small differences. In the reflection experiment, for example, two different spectra are obtained using *s* and *p* radiations. The amount of energy absorbed by the film is extremely small with an absorbance unit in the third or fourth digit. Measuring the two spectra separately and analyzing their extremely small difference is a challenging task. The dynamic range of many instruments cannot differentiate differences beyond the signal to noise needed. Polarization modulation spectroscopy permits direct measurement of the difference.

The optical experiment setup used in other modulation experiments, shown in Figure 33, is quite similar to that used for vibrational circular dichroism experiments, described in detail elsewhere (234). Perhaps the experiment can best be understood from the following equations. Additional details can be found in the reference provided. The modulated beam is produced by the stress-induced difference in the index of refraction associated with the two perpendicular directions of a photoelastic modulator (PEM), in most cases a ZnSe crystal. Therefore, the

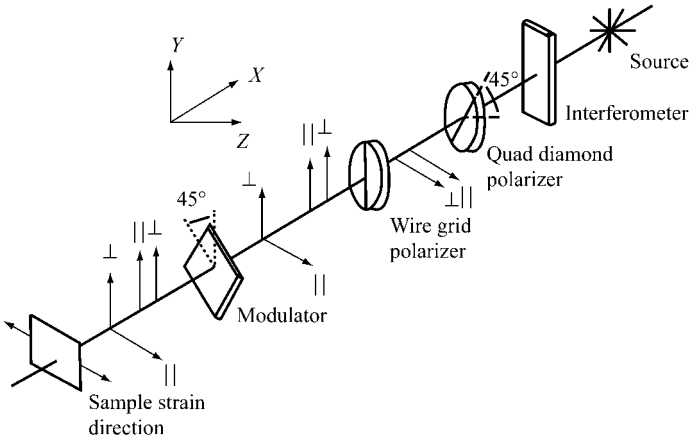

Fig. 33. Optical arrangement of elements in infrared modulation spectroscopy.

electric field E seen at the crystal is

$$E = \begin{pmatrix} \cos\alpha & \sin\alpha \\ -\sin\alpha & \cos\alpha \end{pmatrix} \begin{pmatrix} E_x \\ E_y \end{pmatrix} \tag{14}$$

For propagation along the z direction when only E_y is present, the PEM sees an electric field of

$$E = E_y \begin{pmatrix} \sin\alpha \\ \cos\alpha \end{pmatrix} \tag{15}$$

At any instant, the velocity of light through the PEM crystal with polarization parallel (p) and perpendicular (s) to the strain differ depending on the refractive indices, thus producing a phase difference δ between these two components. This phase difference depends on the wavelength, crystal thickness, and difference in index of refraction (122).

An additional phase $e^{i\delta}$ associated with the electric field along the p direction, leads to

$$E = E_y \begin{pmatrix} e^{i\delta}\sin\alpha \\ \cos\alpha \end{pmatrix} \tag{16}$$

After the crystal, it is necessary to consider radiation back into the laboratory frame, ie

$$E = \begin{pmatrix} \cos\alpha & -\sin\alpha \\ \sin\alpha & \cos\alpha \end{pmatrix} E_y \begin{pmatrix} e^{i\delta}\sin\alpha \\ \cos\alpha \end{pmatrix} = E_y \begin{pmatrix} (e^{i\delta}-1)\cos\alpha\ \sin\alpha \\ e^{i\delta}\ \sin^2\alpha + \cos^2\alpha \end{pmatrix} \tag{17}$$

Passing through the sample, the extinction coefficients for the incident infrared radiation may be quite different for the two axes. The intensity measured at the detector can be approximated by

$$|E|^2 = \frac{E_y^2}{2}(\varepsilon_s + \varepsilon_p) + \frac{E_y^2}{2}(\varepsilon_s - \varepsilon_p)\cos\,\delta \tag{18}$$

where ε_p and ε_s are the relative absorptions between two perpendicular axes in the polymer sample film. The two axes are usually defined as along and perpendicular to the applied strain. Since the crystal is being oscillated continuously at a frequency ω_m, the phase difference d is given as

$$\delta = \delta(t) = \delta_0\,\sin\,\omega_m t \tag{19}$$

and the intensity at the detector is

$$|E|^2 = I = \frac{E_y^2}{2}(\varepsilon_s + \varepsilon_p) + \frac{E_y^2}{2}(\varepsilon_s - \varepsilon_p)\cos\,\delta = I_{DC} + I_{AC}\,\cos(\delta_0 \sin\,\omega_m t) \tag{20}$$

Using the expansion for $\cos(\delta_0 \sin \omega_m t)$ in terms of Bessel functions, the intensity is written as

$$I = J_0(\delta_0) + 2\sum j_n(\delta_0) \cos(n\omega_m t) \tag{21}$$

Thus, it is possible to use a lock-in amplifier to select the time-dependent component and eliminate the -d-c component, and so the entire dynamic range of the infrared instrument is available to measure $\varepsilon_p - \varepsilon_s$ directly.

The power of this technique can be illustrated in the measurement of segmental orientation when polymers are deformed macroscopically. Despite the tremendous improvement of signal-to-noise ratio available with the Fourier transform instrument, it has not been possible to measure extremely small changes in segment orientation as a function of strain. The usual polarization measurements involve two separate measurements, one parallel and one perpendicular, followed by calculation of their difference to obtain the dichroic ratio, and then the calculation of the orientation function (eq. 13). For nearly isotropic materials this type of measurement is of marginal value. However, with the polarization modulation technique it is possible to obtain extremely accurate polarization changes when samples are mechanically deformed. Extremely accurate polarization measurements can be obtained in this way, even for amorphous segments in poly(butylene terephthalate-*co*-tetramethylene oxide) (236).

Other applications of modulation spectroscopy have been developed, ie two-dimensional infrared analysis (16). In this case, a spectrum is generated by a cross-correlation analysis of dynamic fluctuations of infrared signals induced by an external perturbation. The basic concept of two-dimensional infrared is somewhat analogous to that of two-dimensional NMR. The method for generation of a two-dimensional infrared spectrum is based on the ability to detect various relaxation processes occurring at much slower rates than vibrational relaxation. When a perturbation is applied to a system, various chemical constituents of the system are selectively excited. The excitation and subsequent relaxation toward equilibrium can often be monitored with polarized infrared radiation. It is often necessary to measure the relative phase shift between the periodic excitation of the piezoelectric modulator, the periodic excitation of the sample, and the interferometer of the spectrometer. The effect of perturbation-induced changes in a local molecular environment is manifested by time-dependent fluctuations of various spectra representing the system. In infrared spectroscopy, typical changes are the variation of intensities, frequency shift, and change in polarized absorbances. To simplify analysis, the amplitude of perturbation applied to the system is usually very small. Even with very small mechanical deformations, the energy dissipated in the sample may induce irreversible structural changes.

It is often important to correlate changes in polymer chain segments relative to the deformation axis in terms of the dichroic ratio. Typically, relative absorbances are measured for various functional groups. The differences represent the time-dependent reorientational rates of different structural units. The orientation of various functional groups may be dependent on the magnitude and specificity of various inter- and intramolecular interactions. Therefore, the rates of orientation and relaxation provide useful information of the local chemical environment. In polystyrene, a pair of strong cross peaks can be located at the lower left

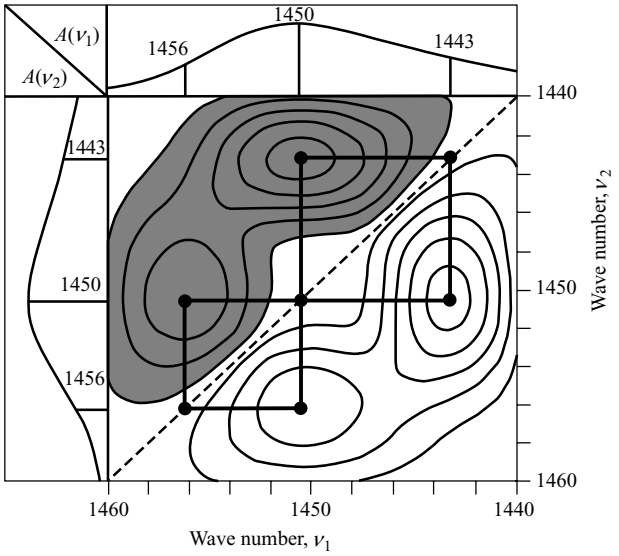

Fig. 34. Contour map of an asynchrous two-dimensional infrared correlation spectrum of atactic polystyrene near 1450 cm^{-1}.

corner of the spectrum (237). The cross peaks indicate the independent reorientation of the electric dipole-transition moments which give rise to the bands at 1490 and 1495 cm^{-1} (1). A similar cross-peak pair is developed at 1450 and 1495 cm^{-1}, suggesting the decoupling of bands. The transition moment giving rise to the band at 1495 cm^{-1} clearly exhibits a reorientation rate substantially different from the rest of the system.

Several peaks are observed (237) around the middle of the asynchronous spectrum between 1440 and 1460 cm^{-1}. The details of this region are more easily discernible in Figure 34. Four well-resolved peaks are located near the diagonal, which establish two correlation squares joined at 1450 cm^{-1}. The corresponding one-dimensional absorbance spectrum shows only a broad single peak. The two-dimensional infrared spectrum clearly resolves at least three distinguishable bands at 1443, 1450, and 1456 cm^{-1} by spreading them over the second dimension. The infrared absorbance peak of atactic polystyrene centered around 1450 cm^{-1} apparently is a triplet with its finer features obscured by the high degree of overlap. These bands have been suggested to originate from similar submolecular groups located in different local molecular environments. Others arise from vibrations of different structures.

Furthermore, at least six major distinguishable infrared bands located at 1443, 1450, 1456, 1465, 1490, and 1495 cm^{-1} have been identified (237). The obscure features of the ordinary spectrum consisting of two broad absorbance peaks with some shoulders can be clearly differentiated by use of the high resolution capability of the two-dimensional infrared spectrum. The six bands are grouped into three pairs of highly correlated bands reorienting at the same rate. For each pair, the cross peaks of the synchronous spectrum indicate reorientation.

When the sample is excited with a dynamic strain, the transition moments at 1443, 1450, and 1456 cm^{-1} reorient in the direction perpendicular to the strain direction; those at 1465, 1490, and 1495 cm^{-1} reorient parallel to strain. The

order of reorientation sequence is such that the coupled band pair at 1443 and 1495 cm^{-1} reorient first, followed by the pair at 1450 and 1490 cm^{-1}. There is approximately a 4 ms time lag between reorientations of the two. The last at 1456 and 1465 cm^{-1} moves about 5 ms behind the first. A detailed step-by-step description of the orientational relaxation processes of the transition moments should provide unique insight into the local molecular environment of the system.

The modulated technique is very general; it does not specify the physical nature or mechanisms through which the perturbation affects the system (15,16). Many different types of external perturbations could be used to stimulate the system of interest. For example, various molecular-level excitations may be induced by electrical, thermal, magnetic, chemical, acoustic, or mechanical excitations. Each perturbation affects the system in a unique and selective way, governed by the specific interaction mechanisms relating the macroscopic stimulus to microscopic or molecular responses of individual system constituents. The type of information contained in a dynamic spectrum is, therefore, determined by the selection of a perturbation method and electromagnetic probe. Recently, such modulation spectroscopy has been applied to Raman spectroscopy in which rheological properties of polymers have been measured. In addition, surface profile using modulated photoacoustic spectroscopy has proved successful. Lastly, it should be mentioned that modulation spectroscopy is not influenced by the purge quality of the instrument. The instrument chamber is often open during our reflectance experiments.

VINYL ACETAL POLYMERS

Introduction

Vinyl acetal polymers are made by hydrolyzing poly(vinyl acetate) [9003-20-7] to poly(vinyl alcohol) [9002-89-5] and the reaction of the latter with an aldehyde in the presence of an acid catalyst. These two reactions, hydrolysis and acetalization, can be conducted either sequentially or concurrently (1). The acetalization reaction, shown in Figure 1, strongly favors complete condensation of one molecule of aldehyde with the 1,3-glycol of two vinyl alcohol units of poly(vinyl alcohol) to form the 1,3-dioxane ring of one vinyl acetal unit.

The first reported vinyl acetal polymers were prepared in Germany by W. Haehnel and W. O. Herrmann in the 1920s by acetalization of poly(vinyl alcohol) (2). Commercialization of vinyl acetal polymers began during the 1930s and 1940s following development efforts by a number of companies, including Consortium für Electrochemische Industrie, I.G. Farbenindustrie, Wacker, Canadian Electro Products, Union Carbide, General Electric, DuPont, Shawinigan Chemicals and Monsanto (both now Solutia) (3–11). Poly(vinyl butyral) [63148-65-2] (PVB, R = C_3H_7) from butyraldehyde [123-72-8] is superior over the vinyl acetal polymers from either formaldehyde [50-00-0], acetaldehyde [75-07-0], or propionaldehyde [123-38-6] for laminated safety glass owing to its better cold temperature characteristics (1). PVB provides flexible toughness over a wide range of temperatures and at a lower cost than longer chain aldehydic carbon acetals. PVB and to a lesser extent poly(vinyl formal) [9003-33-2] (PVF, R = H) continue to be made in significant commercial quantities. Where stiffer performance at higher temperatures is required, PVF provides significant property advancement.

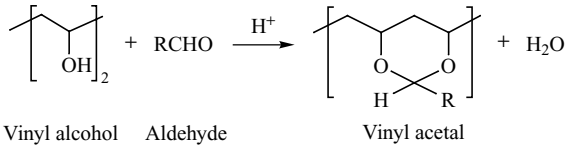

Fig. 1. Acid-catalyzed acetalization of two vinyl alcohol units of poly(vinyl alcohol).

Vinyl acetal polymers form hard, unpliable materials that are difficult to process without using solvents or plasticizers. PVF was developed for use in lacquers and impregnating materials and for wire insulation. PVF is combined with other reactive resins and cured to form tough, chemical- and abrasion-resistant coatings. The impetus for PVB development was the discovery of the greatly improved properties of laminated safety glass made with plasticized PVB interlayer over that offered by plasticized cellulose acetate then in general use. This application was expanded to include the architectural as well as automotive fields, and is today the largest single use of vinyl acetal polymer (12). Small amounts of PVB resin are used for a variety of adhesive, printing, and surface coating applications. Applications for PVF and PVB resins make use of the toughness, resilience, optical clarity, high pigment and filler binding capacity, and high adhesion the resins can provide when appropriately formulated.

Synthesis and Structure

Acetals are formed under conditions of acid catalysis by the reaction of aldehydes with alcohols (Fig. 2). The initial product of nucleophilic addition of alcohol to the carbonyl group is called a hemiacetal. In the net reaction, one molecule of aldehyde reacts with two molecules of alcohol (13).

Similarly, vinyl acetal polymers are manufactured by the reaction of aldehydes with poly(vinyl alcohol) in the presence of an acid catalyst. Reaction of the aldehyde with an alcohol, in this instance the polymeric alcohol poly(vinyl alcohol), yields the unstable hemiacetal. Complete condensation with loss of water is strongly favored to form the cyclic acetal. Poly(vinyl alcohol) used to manufacture vinyl acetal polymers is produced by hydrolysis of poly(vinyl acetate) homopolymer with methanol or ethanol. Both acids and bases catalyze the reaction, but base catalysis is usually done with methanol (14). The catalyst is either acid or base, depending on the process. Poly(vinyl acetate) is polymerized from vinyl

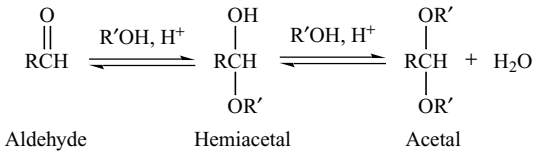

Fig. 2. One molecule of aldehyde reacts with two molecules of alcohol under conditions of acid catalysis to make an acetal.

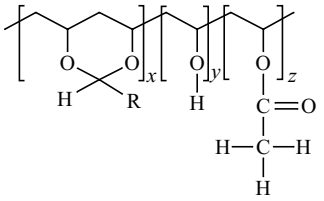

Fig. 3. Generalized terpolymer structure for vinyl acetal polymers, R = C_3H_7 for poly(vinyl butyral) PVB and R = H for poly(vinyl formal) PVF. Ranges for commercial grades of Butvar PVB from Solutia and Pioloform B PVB from Wacker include the following: *x*, vinyl butyral, is 52–74 mol% or 77–90 wt%; *y*, vinyl alcohol, is 26–45 mol% or 10–20 wt%; *z*, vinyl acetate, is 0–4 mol% or 0–3 wt% (19,20). For commercial grades of Vinylec PVF from Chisso: *x*, vinyl formal, is 73–79 mol% or 80–86 wt%; *y*, vinyl alcohol, is 10–14 mol% or 5.0–6.5 wt%; *z*, vinyl acetate, is 10–14 mol% or 9.5–13 wt% (21)

acetate by suspension or solution polymerization. (See VINYL ALCOHOL POLYMERS; VINYL ACETATE POLYMERS.)

Hydrolysis of poly(vinyl acetate) produces a poly(vinyl alcohol) with predominantly 1,3-glycol units. The derived poly(vinyl alcohol) can contain up to 2.3 mol% 1,2-glycol units that come from head-to-head placement of vinyl acetate monomer (15). Lower vinyl acetate polymerization temperature and conversion reduces the irregularities of the polymer, such as branching and the 1,2-glycol structure (16–18). Poly(vinyl acetate) hydrolysis is seldom complete, and for some applications, not desired. Therefore, vinyl acetal polymers are terpolymers, reflecting the three reactions that are used in their manufacture. The class can be represented by the generalized terpolymer structure (Fig. 3), with vinyl acetal, vinyl alcohol, and vinyl acetate units. A five-membered-ring acetal from acetalization of a 1,2-glycol unit is not shown.

A statistical estimate of the maximum degree of acetalization or mole fraction of isolated, unreacted hydroxyl units is 0.1840 for 1,3- and 1,2-glycol containing poly(vinyl alcohol) and 0.1353 for pure 1,3-glycol containing poly(vinyl alcohol) for irreversible acetalization (22). For acetalization with butyraldehyde, assuming no vinyl acetate component, this corresponds to an unreacted vinyl alcohol weight of 12.25% in PVB for the first case and 8.84% in PVB for the second case. As acetalization is reversible, interchange to higher levels of acetalization was also modeled (23). In practice, however, quantitative conversion is accompanied by intermolecular acetalization, which effectively limits higher levels of acetalization in commercial products.

The tacticity of hydroxyls in commercial poly(vinyl alcohol) is nominally atactic. However, an excess of *cis*-1,3-dioxane stereoisomers is formed during acetalization. Acetal formation depends strongly on process kinetics (24,25) and small quantities of other system components (26). During acetalization of poly(vinyl alcohol), for example, cis-acetalization is more rapid than trans-acetalization (27). In addition, the rate of hydrolysis of the trans-acetal is faster than for the more stable cis-acetal conformation (28). Because hydrolysis competes with acetalization during the acetalization process, a high cis/trans ratio is favored. The stereochemistry of PVF and PVB resins has been studied by proton and carbon NMR spectroscopy (29–32).

Manufacture

Although there are a number of potential methods for the manufacture of vinyl acetal polymers, in practice, only two basic processes with variants are used commercially today. By the solution process, formation of the acetal is as a solution in an organic solvent. By the aqueous process, the acetal is precipitated during the reaction of the aldehyde with an aqueous solution of poly(vinyl alcohol). These two reactions, hydrolysis and acetalization, can be conducted either sequentially or concurrently in the solvent process (1).

A solvent process with concurrent hydrolysis and acetalization is used to produce PVF resin (21,33–35). The hydrolysis of poly(vinyl acetate) and acetalization of the resultant poly(vinyl alcohol) to the formal are carried out concurrently in an aqueous acetic acid solution that also contains a strong mineral acid catalyst. Final polymer composition is controlled by the ratio of acetic acid, water, and formaldehyde in the starting mixture. When the reaction is complete, the mineral acid is neutralized. As water is added to the agitated mixture, the PVF resin precipitates. Color can be improved by adding antioxidants (qv) during acetalization (36). The resin is centrifuged and dried after washing with water to remove salt and organic by-products. Figure 4 is a flow diagram for the manufacture of PVF (33).

PVB resin can be produced by either a solvent process (37,38) or an aqueous process (11,39,40). The flow sheets for these processes are shown in Figures 5 and 6. In the aqueous process, poly(vinyl alcohol) is dissolved in water or an aqueous solution that contains acetic acid, then acidified with a mineral acid and reacted with butyraldehyde. During acetalization, PVB precipitates from the aqueous reaction mixture.

Courtesy of The Electrochemical Society, Inc.

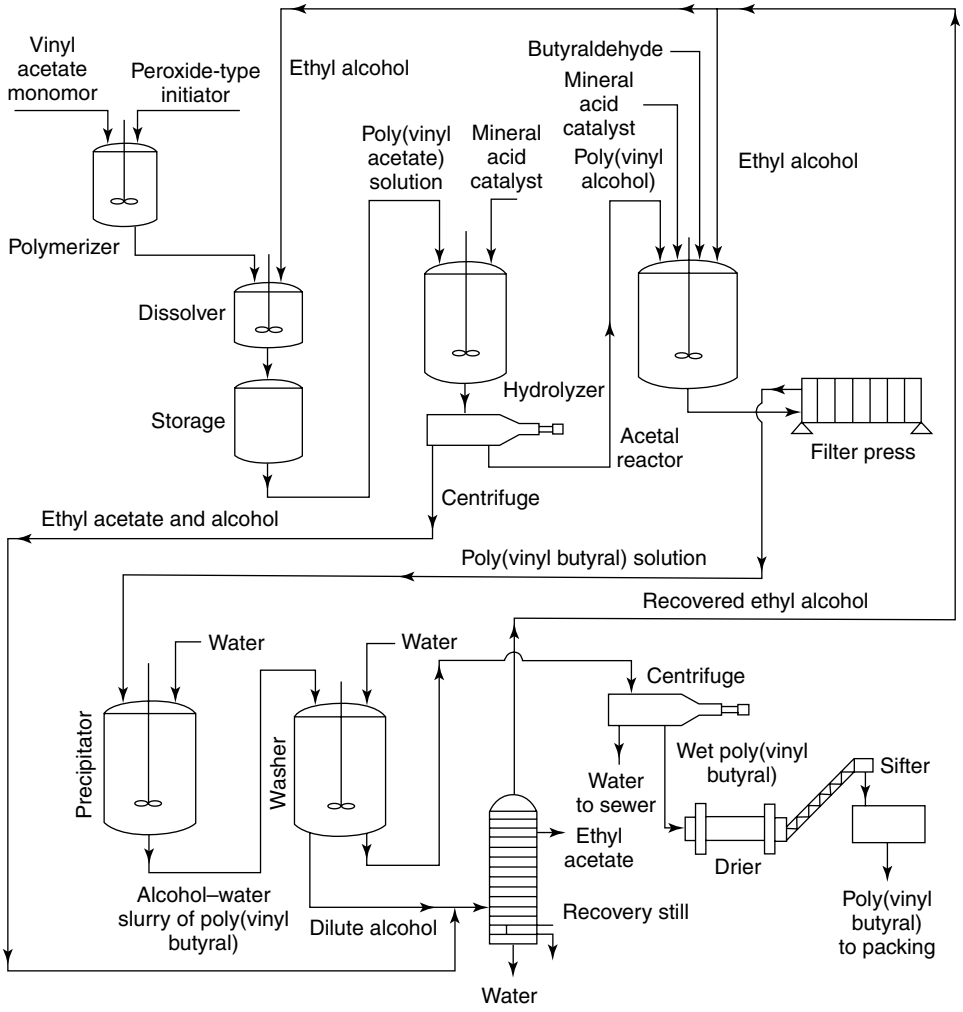

Fig. 5. Flow sheet for the manufacture of poly(vinyl butyral) by a solvent process using sequential hydrolysis and acetalization (38). Courtesy of McGraw-Hill, Inc.

In the solvent process to make PVB (Fig. 5), poly(vinyl acetate) is saponified by transesterification in the presence of ethanol and a mineral acid catalyst to produce poly(vinyl alcohol). The ethanol and ethyl acetate are separated from the precipitated poly(vinyl alcohol) by centrifugation. Because the desired properties of the final PVB require a low poly(vinyl acetate) content, concurrent hydrolysis and acetalization, employed for PVF manufacture, cannot be used. In a separate unit operation, poly(vinyl alcohol) is acetalized after being reslurried with ethanol, and heated with butyraldehyde and the acid catalyst. As the acetalization reaction proceeds in the solvent process, the slurry of poly(vinyl alcohol) dissolves as PVB in the ethanolic reaction mixture.

Upon completion of the acetalization reaction in both solvent and aqueous processes, the acid catalyst is neutralized. PVB is precipitated into water during

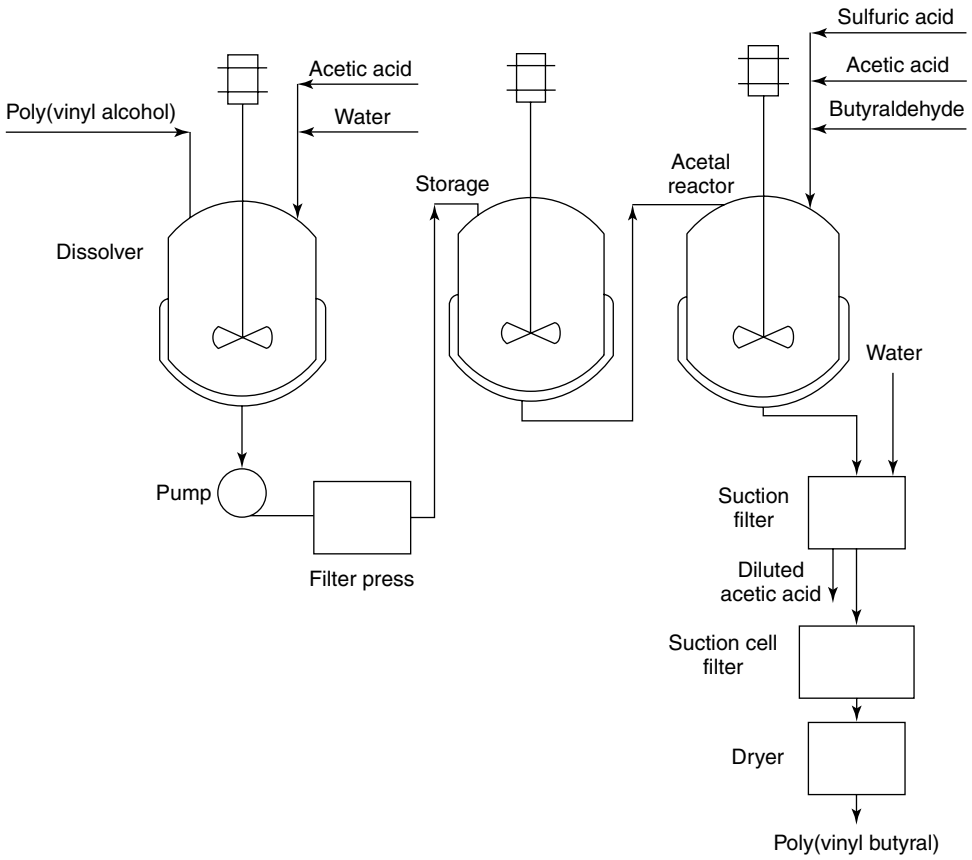

Fig. 6. Flow sheet for the manufacture of poly(vinyl butyral) by an aqueous process (39).

aqueous neutralization in the solvent process. In both aqueous and solvent processes, resin is then separated, washed, and dried. Neutralization, typically with sodium hydroxide or potassium hydroxide, and washing stages are necessary to remove the acid catalyst, salt, and to achieve a more alkaline resin pH for improved resin thermal stability (8,10,37).

For the solvent process, the ethyl acetate by-product can be recovered, refined, and sold as an additional product. This somewhat offsets the cost of sequential polymerization, hydrolysis, acetalization, and solvent recovery unit operations in one manufacturing plant. Because of the low capital investment required to produce PVB with market poly(vinyl alcohol) however, most of the recent published literature has dealt with the aqueous process.

Resin from the solvent acetalization reaction has very low levels of gel from intermolecular acetalization, whereas precipitated resin in the aqueous acetalization reaction has a tendency toward high levels of intermolecular acetalization. Cross-linking can be minimized by adding emulsifiers to control particle size (40–45), or substances like ammonium thiocyanate (46) or urea (47), to improve the solubility of PVB in the aqueous phase. To increase the average molecular weight

and polydispersity of the resin, small quantities of a dialdehyde or trialdehyde can be added during the acetalization step (48).

Properties

The properties of vinyl acetal polymers are a function of the relative amounts of the three randomly distributed units and the molecular weight. As indicated in Figure 3, manufacturers offer a variety of hydroxyl levels. Generally, PVB grades are produced commercially with either high (17–20 wt%) residual vinyl alcohol content or low (10–13 wt%) vinyl alcohol content. The acetate level for commercial PVB resins is usually low (0–3 wt%). However, comparatively higher acetate levels are produced for PVF resin grades to improve solubility at the expense of strength and dimensional stability (33). Residual vinyl acetate and vinyl alcohol contents are 9.5–13 wt% and 5.0–6.5 wt%, respectively, for commercial PVF grades available (21). Weight–average molecular weight ranges from about 25,000 to 100,000 Da for PVF resins and from 30,000 to 350,000 Da for PVB resins, depending on the grade.

Table 1 lists suppliers for PVB resins, commercial trade names, and reported 1999 plant capacities (49). The only major manufacturer of PVF resins is Chisso Corp. in Japan (trade name Vinylec). Chisso purchased Monsanto's PVF Formvar business in 1992. Wacker no longer manufactures PVF Pioloform F resins, only PVB Pioloform B resins. Table 2 lists reported properties of Vinylec PVF resins (21). The physical, mechanical, and thermal properties of various grades of Solutia's Butvar resins are listed in Table 3 (19). In general, resin melt and solution viscosity increase with increasing molecular weight and vinyl alcohol content, whereas the tensile strength of materials made from PVB increases with vinyl alcohol content for a given molecular weight.

The major use of PVB resin is for the manufacture of sheet used as an interlayer in laminated safety glass for automotive and architectural applications. PVB for laminated safety glass contains typically only 1–3 wt% of residual vinyl acetate units and 18–23 wt% vinyl alcohol units (49). The remaining hydroxyl

groups have reacted with butyraldehyde to form acetal units. Hydroxyl level provides the prime leverage on performance in most applications. Unacetalized hydroxyls take part in both intramolecular and intermolecular hydrogen bonding. Intermolecular hydrogen bonding helps bind individual macromolecules together, making it more difficult for chains to untangle and slip by each other. Resin glass-transition temperature (T_g), viscosity, modulus, and tensile strength increase with higher residual hydroxyl levels. Simultaneously, processability and resiliency are reduced. Backbone hydroxyl groups also can form hydrogen and covalent bonds to the surface of polar substrates and are largely responsible for the adhesion. It is postulated that both hydrogen bonds and silyl alkyl ether covalent bonds are formed between resin hydroxyl groups and silanol groups at the PVB interlayer–glass interface (50). Film is made by the addition of plasticizer and other additives to the resin. Resin functionalities as well as plasticizer and moisture level of the formulation are important to PVB's safety glass properties.

A wide range of thermal performance results from the selection of aldehyde in addition to the composition of hydroxyl and acetate units in vinyl acetal polymers. The thermal glass-transition temperature (T_g) of vinyl acetal polymers of aliphatic aldehydes can be estimated from equation 1. VOH and VAC are the weight percent of residual vinyl alcohol and residual vinyl acetate units and C is the number of carbons in the chain derived from the aliphatic aldehyde (51).

$$T_g = 65 + 1.26(\mathrm{VOH} - 19.0) - 0.6(\mathrm{VAC} - 1.5) + 46\ln(4/C) \quad (1)$$

The equation is set up for a typical PVB with 19% residual vinyl alcohol and 1.5% residual vinyl acetate. For this typical PVB ($C = 4$, VOH = 19.0, and VAC = 1.5) the equation reduces to a predicted thermal glass transition of 65°C. Vinyl acetal polymers of any glass-transition temperature between roughly 20 and 120°C can be obtained by formulating with mixed aldehydes. Glass-transition temperatures for mixed aldehyde polymers can be estimated using equation 1 by

computing an average chain length weighted by the respective aldehyde mole fractions.

Practical considerations have thus far precluded commercial manufacture of vinyl acetal polymers from higher molecular weight aldehydes or from mixed aldehydes. At an aldehyde chain length of more than four carbon atoms, the aldehyde becomes insoluble in water, with the result that washing and purification of the resin are extremely difficult. T_g drops with increasing aldehyde chain length and

Table 4. Solubility Parameter Ranges of PVF and PVB Resins

Resin[a]	Low hydrogen-bonding solvents	Medium hydrogen-bonding solvents	High hydrogen-bonding solvents

[b]Insoluble.

so drying and storage without agglomeration becomes impractical. In general, a reasonable compromise in properties can be reached by selection of a commercially available PVF or PVB resin combined with a suitable plasticizer. A close working relationship with the manufacturer can be helpful for applications development.

Vinyl acetal polymers form hard, unpliable materials that are difficult to process without using solvents or plasticizers. The solubility parameter ranges for commercially available PVF and PVB resins are listed in Table 4. For most applications, T_g is far more practically manipulated with plasticizers. However, acetalization with longer chain aldehydes (53–55) and polyoxyalkylene chains (56) provides a degree of internal plasticization to reduce T_g without relying exclusively on liquid plasticizers.

PVB resins are soluble in alcohols, glycol ethers, and selected mixtures of polar and nonpolar solvents. The low (10–13 wt%) vinyl alcohol content PVB resins are soluble in a wider range of solvents than are the high (17–20 wt%) vinyl alcohol content PVB resins. Solvent blends are commonly used, the exact solvent blend and resin composition dictated by the end use of the solution and the required drying properties (19,20). PVF resins are soluble in a more limited number of solvents and in certain mixtures of alcohols and aromatic hydrocarbons. Table 5 compares solvent compatibilities of PVF and PVB resins.

A wide variety of plasticizers are suitable for PVB and PVF resins. For many years, the universally used plasticizer for PVB was triethylene glycol di(2-ethylbutyrate) [95-08-9] (6). More recently this has been supplanted by triethylene glycol di(2-ethylhexanoate) [94-28-0], tetraethylene glycol diheptanoate [70729-68-9], dihexyl adipate [110-33-8], 2-ethylhexyl diphenyl phosphate [1241-94-7], and a variety of other oligomeric ethylene glycol esters and ethers, and other adipate, phosphate, phthalate, sebacate, and ricinoleate esters (19,20,57–62). For PVF, diethyl, diphenyl, and dicyclohexyl phthalates, as well as tributyl, triphenyl, and tricresyl phosphates are useful plasticizers (21). By proper choice of plasticizer type and level, the physical–mechanical, chemical, and adhesion properties of these resins can be tailored for a wide variety of applications (see PLASTICIZERS).

Vinyl acetal polymers can be formulated with other thermoplastic polymers and with a variety of multifunctional cross-linkers. Examples of polymers that are at least partially compatible with PVF or PVB resins include some types of polyurethanes, some types of celluloses, epoxies, isocyanates, phenolics, silicones, unsaturated polyesters, and melamine– and urea–formaldehyde polymers (19–21). Although vinyl acetal polymers are thermoplastic, hydroxyl groups permit cross-linking reactions with a variety of thermosetting resins, for example,

Table 5. Solvent Compatibilities of PVF and PVB Resins[a,b]

	PVF	PVB	PVB
Vinyl alcohol, wt%	5.0–6.5	10–13	17–20
Vinyl acetate, wt%	9.5–13	0–3	0–3

thermosets such as phenolics, ureas, melamines, and epoxies and chemicals such as dialdehydes and diisocyanates. In this manner, incorporation of even small amounts of the vinyl acetal polymer into thermosetting compositions markedly improves the toughness, flexibility, and adhesion of the cured composition. Alternatively, incorporation of smaller quantities of thermosets often gives the vinyl acetal polymer a better balance of properties. Illustrations of the mechanisms and formulation recipes for cross-linking vinyl acetal polymers can be found in the product literature (19,20).

Vinyl acetal polymers have adequate thermal stability for many applications. Thermogravimetric analysis indicates significant rate of weight loss, starting about 240°C in air or about 320°C in nitrogen for PVF (63,64) compared to about 280°C in air or up to about 320°C in nitrogen for PVB (65). In air, significant oxidative degradation occurs at lower temperatures with longer thermal exposure as evidenced by loss of solubility, color development, and increasing T_g attributed to the initial formation of unsaturated bonds and cross-linking (64,66). Mechanisms for degradation have also been studied employing combination techniques, including gas chromatography/mass spectrometry and infrared spectroscopy/thermogravimetry (65,67). For both PVF and PVB, the activation energy for degradation is much less in air than in nitrogen, suggestive of a reaction of oxygen resulting in structures more favorable for degradation (64,65). Side-group elimination, begun at about 280°C for PVB, by rupture of the acetal ring is proposed to occur by a free-radical mechanism involving hydroperoxide formation subsequent to an initial attack of molecular oxygen. This leads to the formation of carbonyl (C═O) groups and liberation of small molecules, including the original aldehyde. The first stage of PVB degradation in nitrogen (ranging from 320 to 355°C) is mainly due to the elimination of water from the vinyl alcohol with the formation of small amounts of butyraldehyde. The second stage of PVB thermal degradation (ranging from 355 to 450°C) is associated with side-group elimination and main-chain scission during which most of the polymer is degraded (67).

Health and Safety

The U.S. Food and Drug Administration regulates PVB resins used as indirect food additives (19,20). However, PVB resin is practically nontoxic by single-dose oral ingestion ($LD_{50} > 10.0$ g/kg for rats). Unformulated PVB and PVF resins have flash points above 370°C. The lower explosive limit for PVB dust in air is 20 g/m^3. Details on specific products are available with the manufacturer.

Economic Aspects

During 1998, about 107,000 t of unplasticized PVB was manufactured in the United States, Western Europe, and Japan (49). Of this amount, more than 87% was plasticized and extruded into sheet for use in laminated safety glass for vehicle windshields and laminated architectural glazing. The remainder, less than 13%, was used for noninterlayer applications. The U.S. list price for PVB non-sheet grade, specialty resins was $9.48 per kg in 1998 ($6.11–11.45 per kg in Japan). 2003 PVB specialty resins prices, as surveyed by the author, remain essentially unchanged from $6.50–9.50 per kg depending on grade in the United States and Europe. 2003 PVF resins range from $15.00–20.00 per kg, a significant increase over historical values when PVF resins were available at lower prices than PVB specialty resins. The only producers of PVB non-sheet grade, specialty resins, not captive for interlayer, are Solutia (Butvar) and Wacker (Pioloform B). Major producers of interlayer for laminated glass are Solutia (Saflex), the largest producer,

followed by DuPont (Butacite), Sekisui (S'Lec), and HT-Troplast (Trosifol). The only major manufacturer of PVF resins is Chisso Corp. (trade name Vinylec).

Applications

Laminated Glass. PVB sheet is manufactured by extrusion of an intimate mixture of PVB resin, plasticizer, and trace additives. Commercial PVB sheet is available in thicknesses from 0.038 to 0.152 cm, with 0.076 cm predominant. The sheet must have a surface topography to enable optimal handling and subsequent removal of air from between sheets while laminating at elevated temperature. Laminated to glass, PVB exhibits high adhesion, optical clarity, stability to sunlight, and high tear strength and impact-absorbing characteristics. It adheres to glass fragments after a glass-breaking impact, thereby helping to reduce injury from flying glass. After the glass is broken during an impact, the interlayer's high tear strength and resiliency acts like a safety net by absorbing enough energy to resist penetration by a projectile or a vehicle occupant's head (12). In addition to its safety features, laminated glass in automotive and architectural applications adds sound attenuation (68,69), heat insulation, and break-in security, and also blocks ultraviolet radiation.

For laminated safety glass, the strength of the adhesive bond between the glass and the interlayer is carefully controlled with additives, usually salts, to achieve the desired balance (70–80). Adhesion to clean glass is very high. If adhesion is too high, a projectile can easily penetrate the laminate because cracks made in the glass propagate through the interlayer. Group IA or IIA alkanoate salts as well as moisture are thought to reduce adhesion by competing with resin hydroxyls for bonding sites on the glass surface. If adhesion is too low, glass retention during an impact will be reduced even though the interlayer is not penetrated.

Interlayer with gradient color bands are made for automobile windshields (81–83). The band is printed on the interlayer surface or tinted by coextrusion with pigmented resin. Curvature for a windshield is accomplished by differentially stretching sheet heated at about 85–100°C over a tapered shaping drum. Rolls of sheet or precut interlayer blanks are usually stored or shipped refrigerated at 3–10°C, or shipped at ambient conditions with an interleaved thin sheet of plastic such as polyethylene to prevent blocking.

PVB composites layered with a film of poly(ethylene terephthalate), acrylic, or polycarbonate, or metal fabric, in addition to glass are designed for some specialty uses (84–87). Most laminated safety glazings are a trilayer composite of glass–PVB–glass, but some specialty applications can include a polymer film interlayer in the PVB to achieve decorative designs or solar reflective properties, or even a metal fabric to provide radio frequency shielding from external sources. For security applications, such as bullet- and projectile-resistant laminates, multi-ply PVB interlayer and glass composites are also designed.

Surface Coatings and Primers. The first and most extensive application for PVF resins starting in 1938 was for electrical insulation and this still remains its major application (5). In these applications the PVF resin component helps provide dielectric properties, toughness, as well as abrasion and thermal resistance. PVF is combined with other ingredients, such as phenolic, epoxy,

or melamine resins, to produce a thermoset coating solution for copper or aluminum wire. Coated wire is cured at elevated temperatures to give a cross-linked film coating with excellent uniformity, and electrical and chemical resistance (88–94).

Wash primer formulations with PVB form a good foundation for various types of topcoats (19,95,96). Wash primers provide good adhesion to metal surfaces and stabilize the metal surface by continuously supplying corrosion-inhibiting ions. Phosphoric acid with zinc chromate or chromic acid can be used to make anticorrosive wash primers. However, due to toxicity concerns associated with chromates, alternative anticorrosive formulations, such as with a pigment of zinc molybdate (97) or borate and phosphate pigments (98), have been recommended. Non-solvent-borne wash primer formulations have been obtained with self-emulsifying water-borne PVB dispersions (99). Water-borne PVB dispersions eliminate the need for volatile organic solvents.

The dispersion of plasticized PVB in water, marketed by Solutia as Butvar Dispersion BR, is used as a permanent surface size in textile applications where toughness of the butyral film lends outstanding abrasion resistance to the fabric (100). PVB dispersions can be applied to textiles by spraying, from a dilute bath by impregnation on a padder, or from a thickened dispersion by coating on spreading equipment. The dried dispersion imparts a soft, full-bodied finish to rayon, cotton, or nylon and helps prevent unraveling of filament yarns. PVB has also been used as a component of wash coats and sealers in wood finishing operations. It confers good holdout, intercoat adhesion, moisture resistance, flexibility, impact resistance, and protection against wood discoloration (19,101). Vinyl acetal polymers can also be used in coating formulations for other polymer surfaces (102,103).

Adhesives and Binders. The principal adhesive uses of vinyl acetal resins are in high performance thermosetting adhesives and in thermoplastic hot-melt formulations. PVB binds the glass beads used in retroreflective films for licence plates, decals, and road signs (104–106). PVB resin is formulated with plasticizers, waxes, and other resins to make hot-melt adhesives (107). Vinyl acetal polymers are used for green strength as a fugative binder in ceramic tapes for electronics (108–110), but the largest application is as the binder in the production of ceramic substrates used primarily for electronic devices (111–117).

Printing Inks and Toners. PVB resins have been used in printing ink formulations for many years. PVB resins are soluble in mild solvents, such as alcohols and esters, so can be used in solvent-based flexographic, gravure, screen, and ink-jet printing formulations as a binder to improve flexibility, adhesion, and toughness (19,20,118,119). Flexographic and gravure printing are the dominant processes employed for printing flexible packaging used mainly in the food-processing industry, and to a lesser extent in the pharmaceutical and chemical industries.

PVB is also used in toner formulations as a binder (19,120). PVB is added to the formulations to increase viscosity, to improve film integrity over the fuser roll, and to prevent blocking. The overall toughness of PVB enhances the integrity of the toner during the milling process and extended machine operation. This minimizes the level of fines without detracting from the flow properties.

VINYL ALCOHOL POLYMERS

Introduction

Poly(vinyl alcohol) (PVA), a polyhydroxy polymer, is the largest volume, synthetic water-soluble resin produced in the world. It is commercially manufactured by the hydrolysis of poly(vinyl acetate), because monomeric vinyl alcohol cannot be obtained in quantities and purity that makes polymerization to PVA feasible (1–3).

Poly(vinyl alcohol) was discovered by Haehnel and Herrmann who, through the addition of alkali to a clear alcoholic solution of poly(vinyl acetate), were able to obtain the ivory-colored PVA (4). The first scientific reports on PVA were published in 1927 (5,6).

The excellent chemical resistance and physical properties of PVA resins have resulted in broad industrial use. The polymer is an excellent adhesive and possesses solvent, oil, and grease resistance, properties matched by few other polymers. Poly(vinyl alcohol) films exhibit high tensile strength, abrasion resistance, and oxygen barrier properties which under dry conditions are superior to those of most polymers. The polymer's low surface tension provides for excellent emulsification and protective colloid properties.

The main uses of PVA are in textile sizing, adhesives, protective colloids for emulsion polymerization, fibers, production of poly(vinyl butyral), and paper sizing. Significant volumes are also used in the production of concrete additives and joint cements for building construction and water-soluble films for containment bags for hospital laundry, pesticides, herbicides, and fertilizers. Smaller volumes are consumed as emulsifiers for cosmetics, temporary protective film coatings, soil binding to control erosion, and photoprinting plates.

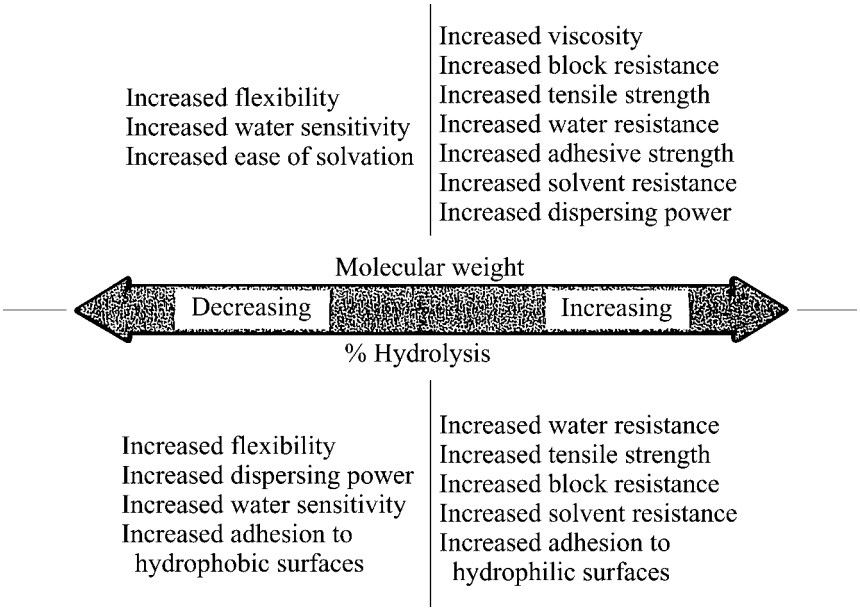

Fig. 1. Effect of molecular weight and hydrolysis on the properties of PVA (7).

Physical Properties

The physical properties of PVA are highly correlated with the method of preparation. The final properties are affected by the polymerization conditions of the parent poly(vinyl acetate), the hydrolysis conditions, drying, and grinding. Further, the term PVA refers to an array of products that can be considered to be copolymers of vinyl acetate and vinyl alcohol.

The effect of hydrolysis and molecular weight is illustrated in Figure 1. The variations in properties with molecular weight are for a constant degree of hydrolysis (mol%) (7), and the effect of hydrolysis is at a constant molecular weight. Representative properties are shown in Table 1.

Crystallization and Melting Point. The ability of PVA to crystallize is the single most important physical property of PVA as it controls water solubility, water sensitivity, tensile strength, oxygen barrier properties, and thermoplastic properties. Thus, this feature has been and continues to be the focal point of academic and industrial research (8–37). The degree of crystallinity as measured by x-ray diffraction can be directly correlated to the products density or the swelling characteristic of the insoluble part (Fig. 2).

The size of the crystals determines the melting point. Reported values for the melting point of PVA range between 220 and 267°C for fully hydrolyzed PVA (38–42). Exact determination of the crystalline melting point using normal data techniques is difficult as decomposition takes place above 140°C. The divergence in melting point may be ascribed to decomposition or prior treatment history. The melting point of PVA containing an appropriate amount of diluent or comonomer is less influenced by decomposition. Thus, the melting point of fully hydrolyzed PVA can be determined by the extrapolation of the measured values to 0% diluent.

Table 1. Physical Properties of Poly(vinyl alcohol)

Property	Value	Remarks
Appearance	White to ivory white granular powder	
Specific gravity	1.27–1.31	Increases with degree of crystallinity
Tensile strength, MPa[a] (98–99% hydrolyzed)	67–110	Increases with degree of crystallinity (heat treatment), and molecular weight, decreases with increasing humidity
Tensile strength, MPa (87–89% hydrolyzed)	24–79	Increases with molecular weight and decreases with increasing humidity
Elongation, %	0–300	Increases with increasing humidity
Thermal coefficient of expansion per °C	$7–12 \times 10^{-5}$	
Specific heat, J/(g·K)[b]	1.67	
Thermal conductivity, W/(m·K)	0.2	
Glass-transition temperature, K	358	98–99% hydrolyzed
	331	87–89% hydrolyzed
Melting point, K	503	98–99% hydrolyzed
	453	87–89% hydrolyzed
Electrical resistivity, Ω·cm	$(3.1–3.8) \times 10^{7}$	
Thermal stability	Gradual discoloration above 100°C; darkens rapidly above 150°C; rapid decomposition above 200°C	
Refractive index n_D(20°C)	1.55	
Degree of crystallinity	0–0.54	Increases with heat treatment and degree of hydrolysis
Storage stability (solid)	Indefinite when protected from moisture	
Flammability	Burns similarly to paper	
Stability in sunlight	Excellent	

[a]To convert MPa to psi, multiply by 145.
[b]To convert J to cal, divide by 4.184.

A more reliable melting point is obtained in this manner. The melting points determined by the diluent method are 255–267°C for commercial superhydrolyzed PVA (greater than 99% hydrolysis). The melting point determined by melting point depression caused by noncrystallizing comonomer units assumes as a first approximation that the vinyl acetate units are randomly distributed. This assumption usually does not apply to commercial PVA. The extrapolated values of

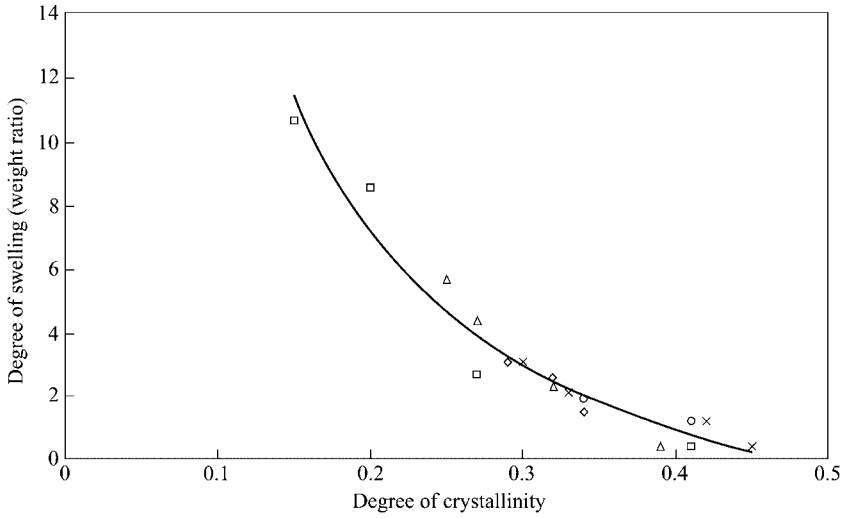

Fig. 2. Relationship between swelling and crystallinity. □, DP 304; △, DP 708; ○, DP 1288; ◇, DP 2317; ×, DP 4570.

heat of fusion and melting point obtained with this method are therefore highly dependent on the manufacturing method and the resulting blockiness (Fig. 3). The heat of fusion, determined by either of the above methods, has been calculated as 6.82 ± 2.1 kJ/mol (43–45).

Glass-Transition Temperatures. The glass-transition temperature of fully hydrolyzed PVA has been determined to be 85°C for high molecular weight material. The glass transition in case of 87–89% hydrolyzed PVA varies according to the shown formula (46):

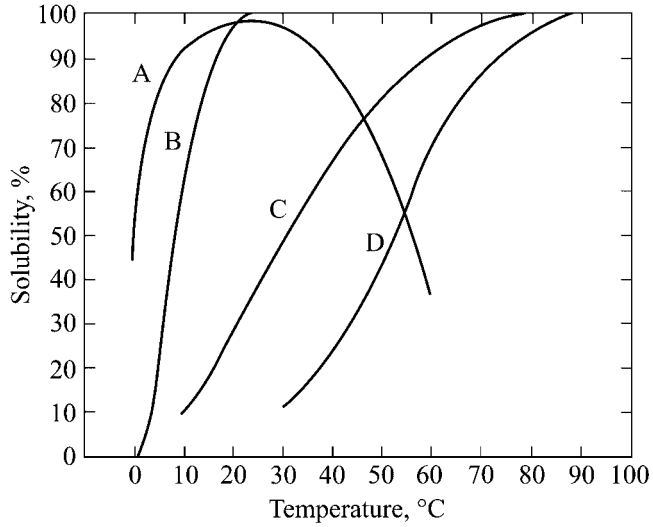

Fig. 4. Water solubility of PVA grades: A, 78–81 mol% hydrolyzed, DP = 2000–2100; B, 87–89 mol% hydrolyzed, DP = 500–600; C, 98–99 mol% hydrolyzed, DP = 500–600; D, 98–99 mol% hydrolyzed, DP = 1700–1800 (47).

$$T_g = 58 - (2.0 \times 10^{-3}/\mathrm{DP})[^\circ\mathrm{C}] \quad (1)$$

Solubility. Poly(vinyl alcohol) is only soluble in highly polar solvents, such as water, dimethyl sulfoxide, acetamide, glycols, and dimethylformamide. The solubility in water is a function of the degree of polymerization (DP) and hydrolysis (Fig. 4). Fully hydrolyzed PVA is only completely soluble in hot to boiling water. Partially hydrolyzed grades are soluble at room temperature, although grades with a hydrolysis of 70–80% are only soluble at water temperatures of 10–40°C. Above 40°C the solution first becomes cloudy (cloud point), followed by precipitation of PVA.

The hydroxyl groups in PVA contribute to strong hydrogen bonding both intra- and intermolecularly, which reduces solubility in water. The presence of residual acetate groups in partially hydrolyzed PVA weakens these hydrogen bonds and allows solubility at lower temperatures.

The hydrophobic nature of the acetate groups results in a negative heat of solution (48–50), which increases as the number of acetate groups is increased. This means that the critical θ temperature is lower, ie, the solubility decreases as the temperature is increased.

Heat treatment or drying of a few minutes increases crystallinity and greatly reduces the solubility and water sensitivity (Fig. 5). Prolonged heat treatment does not further increase crystallinity. The heat treatment melts the smaller crystals, allowing for diffusion and reformation of crystals with a melting point higher than that of the treatment temperature. The presence of acetate groups reduces the extent of crystallinity; thus, heat treatment has little or no influence on low hydrolysis grades. The influence of heat treatment is desirable in some applications such as adhesives and paper coatings where a greater degree of water resistance

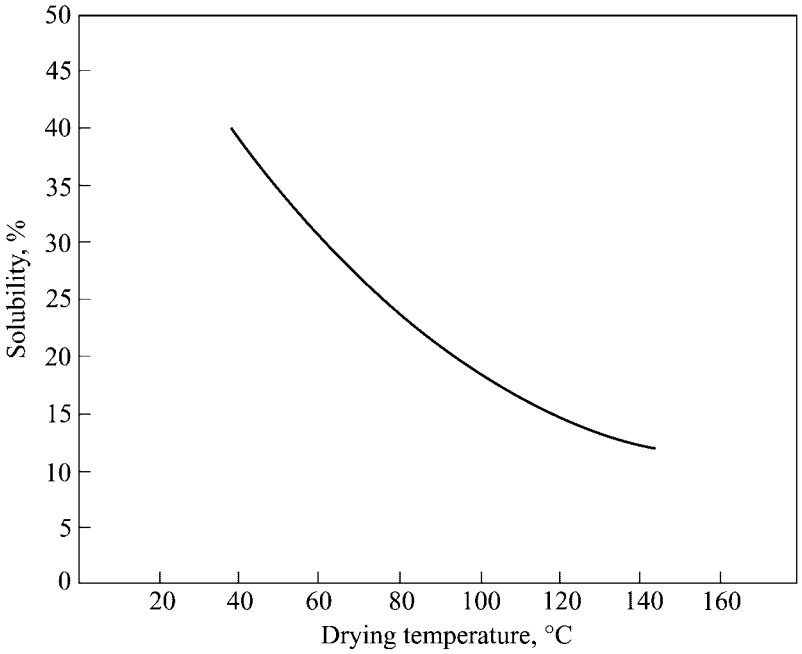

Fig. 5. Influence of heat treatment on solubility at 40°C; DP = 1700, 98–99 mol% hydrolyzed.

is needed, but is highly undesirable in textile warp sizing where the polymer must be removed after a drying cycle.

Poly(vinyl alcohol) solutions also exhibit high tolerance toward many electrolytes (Table 2).

Solution Viscosity. The viscosities of PVA solutions are mainly dependent on molecular weight and solution concentration (Fig. 6). The viscosity increases with increasing degree of hydrolysis and decreases with increasing temperature. Materials with a high degree of hydrolysis tend to show an increase in viscosity on standing and may even gel (47,51–55). The rate of increase depends upon dissolution temperature, concentration, and storage temperature. The lower the storage and dissolution temperatures and the higher the concentration, the higher is the rate of the viscosity increase (Fig. 7). Viscosity can be stabilized to a certain degree by adding small amounts of lower molecular weight aliphatic alcohols (56), urea, or salts such as thiocyanates. The solution viscosity of partially hydrolyzed PVA grades exhibit a greater degree of stability.

Mechanical Properties

The tensile strength of unplasticized PVA depends on degree of hydrolysis, molecular weight, and relative humidity (Fig. 8). Heat treatment and molecular alignment resulting from drawing increase the tensile strength; plasticizers reduce tensile strength disproportionately because of increased water sensitivity.

Tensile elongation of PVA is extremely sensitive to humidity and ranges from <10% when completely dry to 300–400% at 80% rh. Addition of plasticizer

Table 2. Minimum Salt Concentration for Precipitation of a 5% Poly(vinyl alcohol) Solution[a,b]

Salt	Concentration, g/L
$(NH_4)_2SO_4$	66

[b] 98% hydrolyzed, DP = 1700–1800.

can double these values. Elongation is independent of degree of hydrolysis but proportional to the molecular weight. Tear strength increases with increasing relative humidity or with the addition of small amounts of plasticizer.

Solvent Resistance. Poly(vinyl alcohol) is virtually unaffected by hydrocarbons, chlorinated hydrocarbons, carboxylic acid esters, greases, and animal or vegetable oils. Resistance to organic solvents increases with increasing hydrolysis. This resistance has promoted the use of PVA in the manufacture of gloves for use when handling organic solvents (57).

Gas-Barrier Properties. The oxygen-barrier properties of PVA at low humidity are excellent. However, barrier performance deteriorates above 60% rh (Fig. 9). No additives or chemical modifiers are known that can effectively reduce moisture sensitivity. The gas-barrier performance is affected by the degree of hydrolysis and rapidly diminishes as the hydrolysis is decreased below 98% (see BARRIER POLYMERS).

Surface Tension. The surface tension of aqueous solution of PVA varies with concentration (Fig. 10), temperature, degree of hydrolysis, and acetate distribution on the PVA backbone. Random distribution of acetyl groups in the polymer results in solutions having higher surface tension compared to those of polymers in which the blocks of acetyl groups are present (58–61). The surface tension decreases slightly as the molecular weight is reduced (Fig. 11).

Intrinsic Viscosity and Molecular Weights. The relationship between the intrinsic viscosity and molecular weight changes with degree of hydrolysis of the polymer (Table 3). Methods for determining molecular weight and molecular weight distribution using gpc and low angle laser light scattering detection have been developed and utilized (63,64). These methods show a polydispersity of 2.0

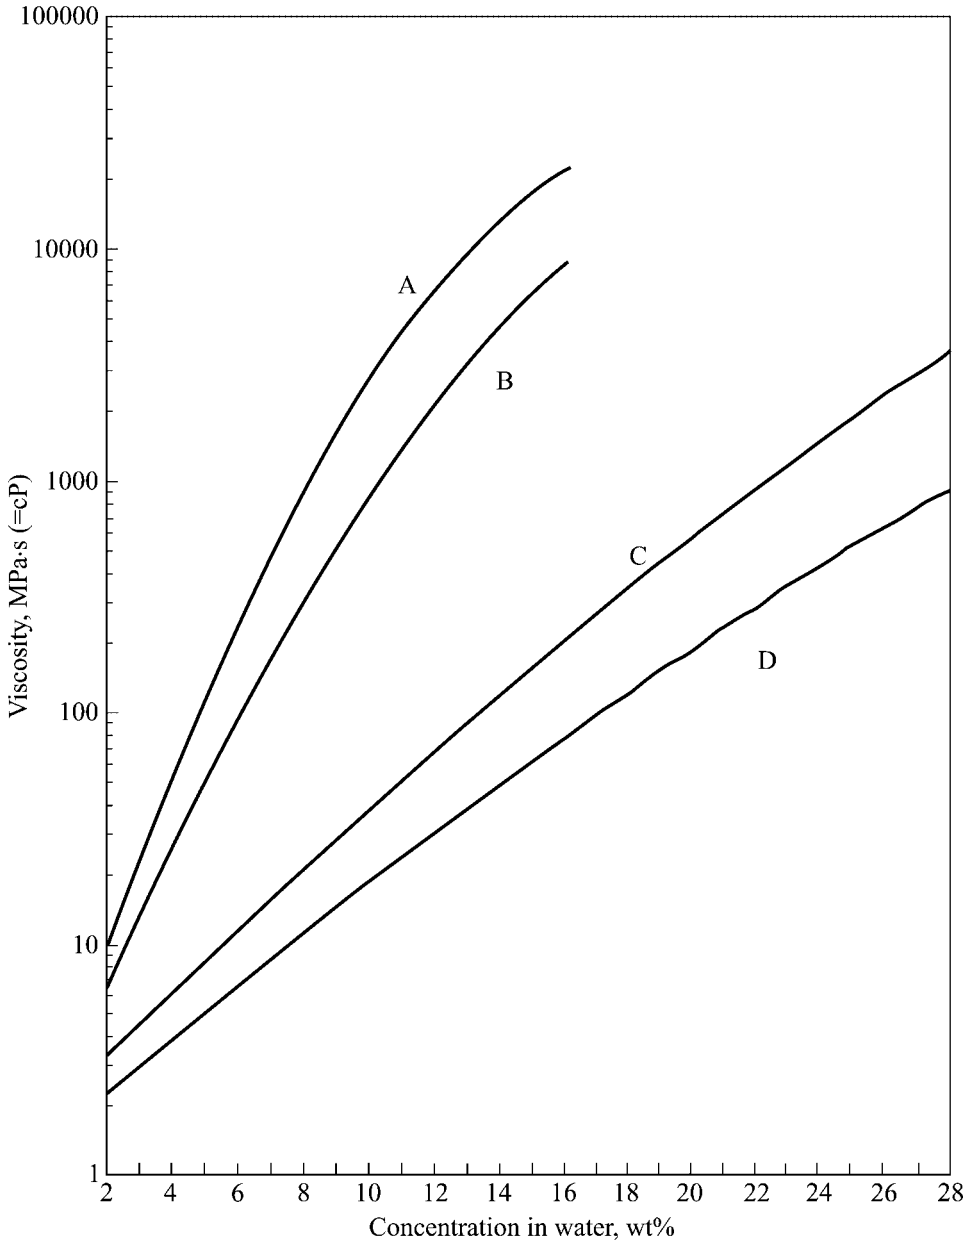

Fig. 6. Solution viscosity of 87–89 mol% hydrolyzed PVA at 20°C. DP: A, 2200; B, 1500; C, 550; D, 220.

or less, which indicates the presence of few long-chain branches. No long-chain branches are found in PVA samples that have a degree of hydrolysis higher than 80 mol%. The number of short-chain branches is identical to the mole percent of short-chain branches generated during the formation of the poly(vinyl acetate) in the range of 0.12–0.17 mol% (65).

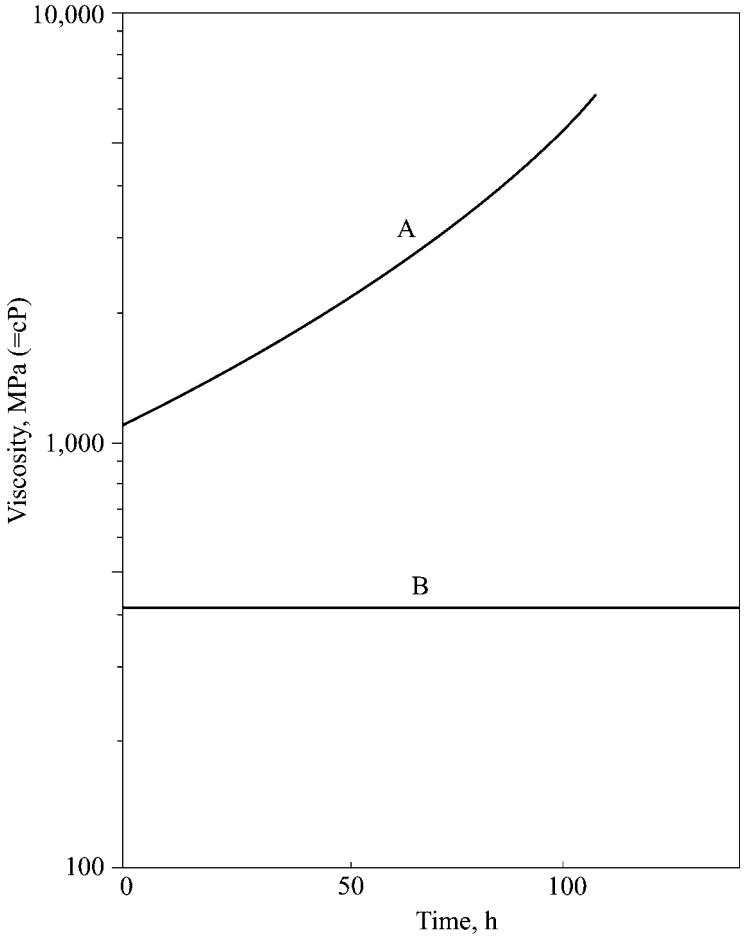

Fig. 7. Effect of aging on solution viscosity of PVA (47): A, DP = 1500, degree of hydrolysis, 98–99 mol%; B, DP = 1500, degree of hydrolysis, 87–89 mol%.

Chemical Properties

Poly(vinyl alcohol) participates in chemical reactions in a manner similar to other secondary polyhydric alcohols (66–68). Of greatest commercial importance are reactions with aldehydes to form acetals, such as poly(vinyl butyral) and poly(vinyl formal) (see VINYL ACETAL POLYMERS).

Table 3. Intrinsic Viscosity–Viscosity-Average Molecular Weight Relationship as a Function of Hydrolysis[a]

Hydrolysis, mol%	$[\eta]$
86.8	$(8.0 \times 10^{-4})\, M_v^{0.58}$
93.5	$(7.4 \times 10^{-4})\, M_v^{0.60}$
96.4	$(6.9 \times 10^{-4})\, M_v^{0.61}$
100.0	$(5.95 \times 10^{-4})\, M_v^{0.63}$

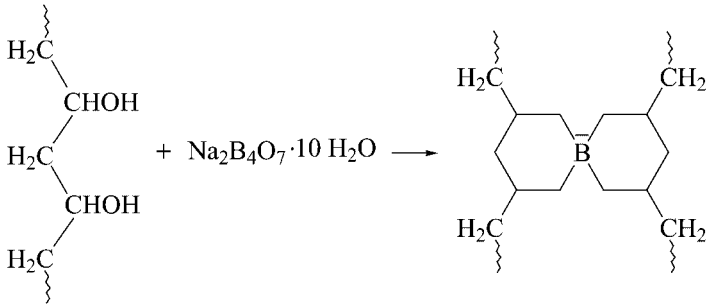
Esterification.

Inorganic Esters. Boric acid and borax form cyclic esters with PVA (69–76). The reaction is markedly sensitive to pH, boric acid concentration, and the cation-to-boron ratio. An insoluble gel is formed at a pH above 4.5–5.0.



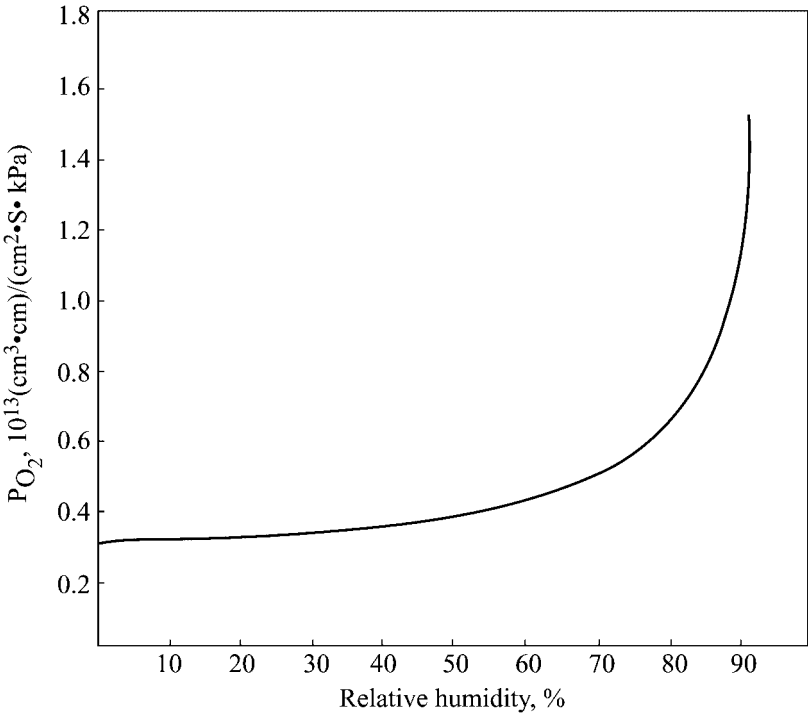


Fig. 9. Oxygen permeability of PVA as a function of humidity; degree of hydrolysis, 99.9 mol%, DP = 1750 (47).

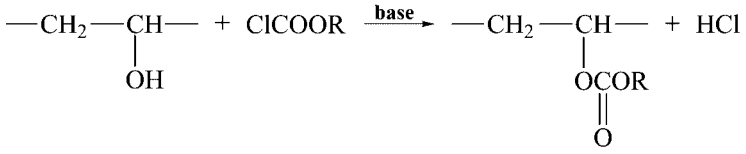
Similar complexes are formed between PVA and titanium lactate (72,77), titanyl sulfate (78), or vanadyl compounds (79).

Poly(vinyl nitrate) has been prepared and studied for use in explosives and rocket fuel (80,81). Poly(vinyl alcohol) and sulfur trioxide react to produce poly(vinyl sulfate) (82–86). Poly(vinyl alkane sulfonate)s have been prepared from PVA and alkanesulfonyl chlorides (87,88). In the presence of urea, PVA and phosphorus pentoxide (89) or phosphoric acid (90) yield poly(vinyl phosphate)s.

Organic Esters. An unlimited number of organic esters can be prepared by reactions of PVA employing standard synthesis (66,68). Chloroformate esters react with PVA to yield poly(vinyl carbonates) (91).



Poly(acrylic acid), poly(methacrylic acid), and maleic anhydride containing polymers react with PVA to form insoluble gels (92–94) useful as absorbents for water, blood, urine, etc.

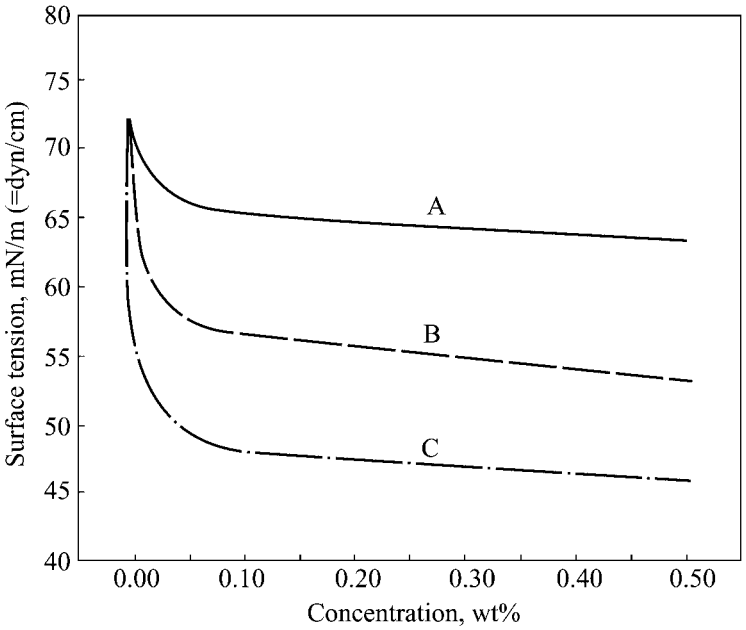


Fig. 10. Surface tension of aqueous PVA solutions at 20°C, DP = 1700. A, 98–99 mol% hydrolyzed; B, 87–89 mol% hydrolyzed; C, 78–81 mol% hydrolyzed.

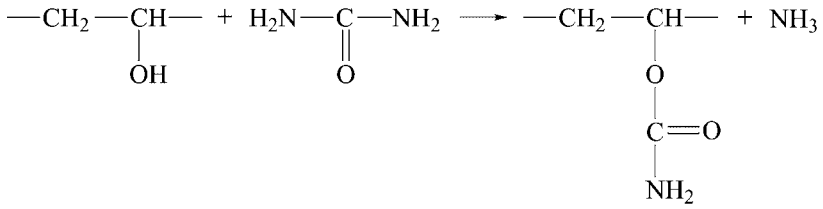
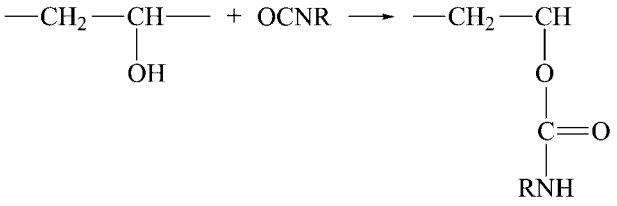
Urea and PVA form a polymeric carbamate ester (95–98):



Reaction between PVA and isocyanates yields substituted carbamate esters (99–103):



Etherification. Ethers of PVA are easily formed. Insoluble internal ethers are formed by the elimination of water, a reaction catalyzed by mineral acids and alkali.

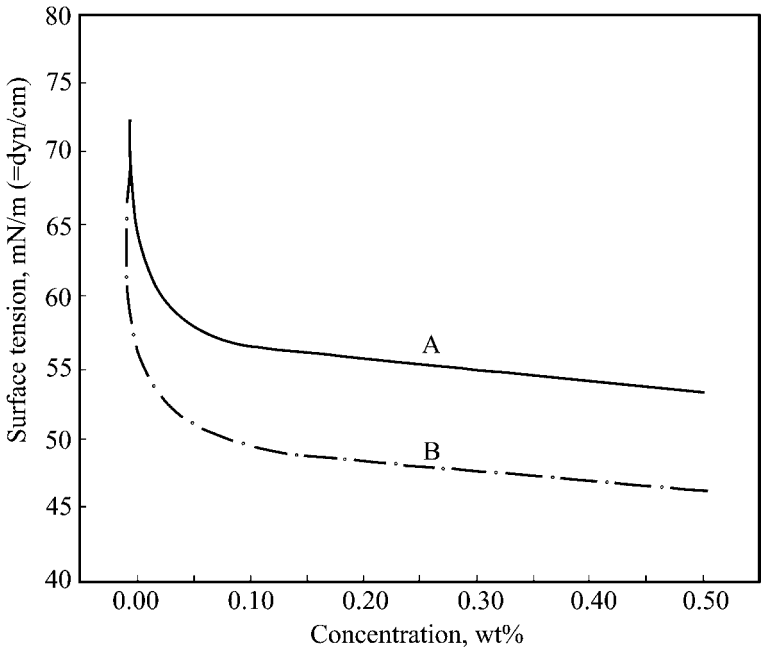


Fig. 11. Surface tension dependence on molecular weight at 20°C, degree of hydrolysis 87–89 mol%. DP: A, 1700; B, 550.

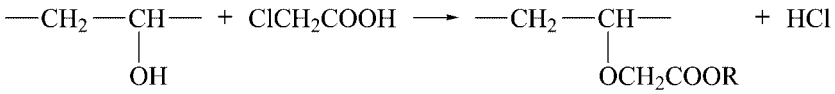
Ethylene oxide reacts with PVA under normal ethoxylation conditions (104–110). The resulting products have properties which make them useful as cold water-soluble films.

Cationic PVA has been prepared by the reaction of *N*-(3-chloro-2-hydroxypropyl)-*N*,*N*,*N*-trimethylammonium chloride and PVA and sodium hydroxide (111). Reactions between alkylidene epoxide and PVA in particulate, free-flowing form in an alkaline environment have been reported (112).

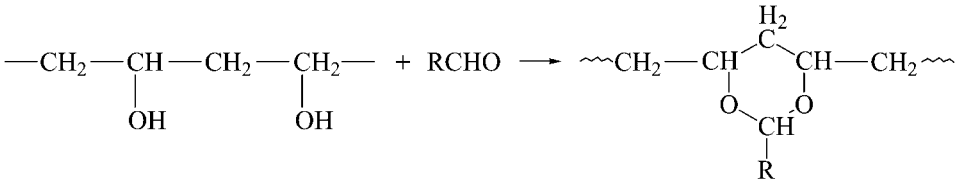
Poly(vinyl alcohol) undergoes Michaels addition with compounds containing activated double bonds, including acrylonitrile (115–117), acrylamide (118–120), *N*-methylolacrylamide (121–123), methyl vinyl ketone (124,125), acrolein (124), and sodium 2-acrylamido-2-methylpropanesulfonate (126). The reactions have been carried out under conditions spanning homogeneous reactions in solvent to heterogeneous reactions in the swollen powder or fiber.

Poly(vinyl alcohol) also reacts with monochloroacetates to yield glycolic acid ethers (127).

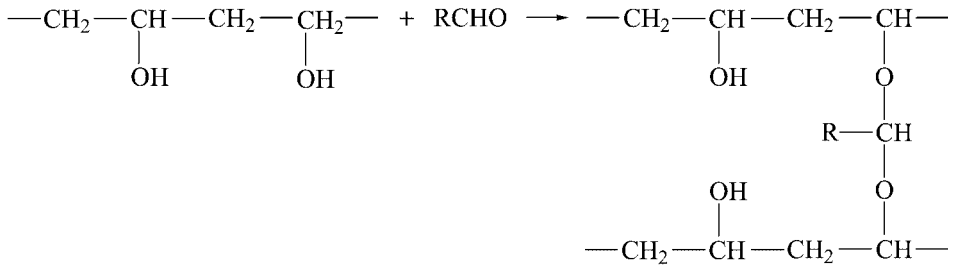


Acetalization. Poly(vinyl alcohol) and aldehydes form compounds of industrial importance.

(1) *Intramolecular acetalization*



(2) *Intermolecular acetalization*



Poly(vinyl butyral) prepared by reacting PVA with *n*-butyraldehyde finds wide application as the interlayer in safety glass and as an adhesive for hydrophilic surfaces (128). Another example is the reaction of PVA with formaldehyde to form poly(vinyl formal), used in the production of synthetic fibers and sponges (129).

Poly(vinyl alcohol) is readily cross-linked with low molecular weight dialdehydes such as glutaraldehyde or glyoxal (130). Alkanol sulfonic acid and PVA yield a sulfonic acid modified product (131).

Other Reactions. Poly(vinyl alcohol) forms complexes with copper in neutral or slightly basic solutions (132). Sodium hydroxide or potassium hydroxide forms an intermolecular complex with PVA (132,133) causing gelation of the aqueous solution.

Certain organic compounds form reversible gels with PVA. Congo red, for example, yields a red gel that melts sharply at about 40°C. Other organic compounds that form a temperature reversible complex with PVA include azo dyes, resorcinol, catechol, and gallic acid (133,134)

Fully hydrolyzed PVA and iodine forms a complex that exhibits a characteristic blue color similar to that formed by iodine and starch (135–137). The color of the complex can be enhanced by the addition of boric acid to the solution consisting of iodine and potassium iodide. This affords a good calorimetric method for the determination of PVA. Color intensity of the complex is effected by molecular weight, degree of hydrolysis, extent of branching, stereoregularity, 1,2-glycol content, and reagent composition. The higher the 1,2-glycol content and the lower the molecular weight, the weaker the color (138–140). Partially hydrolyzed PVA and iodine forms a red complex, which is sensitive to the sequence distribution of the remaining acetate groups. The color intensity increases with increasing blockiness (141–148).

Cross-linking. Poly(vinyl alcohol) can be readily cross-linked using a multifunctional compound that reacts with hydroxyl groups. These types of reactions

are of significant industrial importance as they provide ways to obtain improved water resistance of the PVA or to increase the viscosity rapidly. The most commonly used cross-linking agents include glyoxal, glutaraldehyde, urea–formaldehyde, melamine–formaldehyde, trimethylolmelamine sodium borate or boric acid, and isocyanates. Most of the reactions are either acid- or base-catalyzed.

The study of hydrogel formation and their properties is a field of active academic research (76,149–151). The PVA molecule is loosely cross-linked, using standard cross-linking agents as mentioned above, which prevents solubility but allows for swelling. Application areas of interest range from enhanced oil recovery to drug delivery.

Strongly chelating metal salts of copper and nickel, eg, cupric ammonium complexes, chromium complexes, and organic titanates and dichromates, can be effective insolubilizers for PVA. Heat treatment during drying of the PVA film or coating is generally sufficient to accomplish the cross-linking reaction. The dichromate reaction is catalyzed by ultraviolet light.

Poly(vinyl alcohol), even when insolubilized by cross-linking, swells in water and loses strength on extended exposure. Complete water insensitivity cannot be achieved.

Thermal Decomposition. The thermal decomposition of PVA in the absence of oxygen occurs in two stages. The first stage begins at about 200°C and is mainly dehydration, accompanied by the formation of volatile products (152–158). The residue is predominantly macromolecules of polyene structure (152,159,160). Further heating to 400–500°C yields carbon and hydrocarbons (152,158). The available data on the nature of the decomposition products show some disagreement (152–157). Differences in manufacturing conditions of the PVA can significantly impact the thermal stability of the PVA as both molecular structure and the presence of catalyst residues are known sources for decreased thermal stability. The most common decomposition products of vinyl alcohol – vinyl acetate copolymers are shown in Table 4. The formation rate of volatile vapors from PVA pyrolyzed at 185–350°C can be described using a first-order rate equation (159).

[a]Ref. 142.

The thermal degradation of PVA in the presence of oxygen can be described by the same decomposition scheme as in the absence of oxygen with one modification. Oxidation of the unsaturated polymeric residue from the dehydration introduces ketone groups in the polymer chain. These groups promote the dehydration of the neighboring units, producing conjugated unsaturated ketone structures (161). Cross-linking under these conditions has also been observed (162). The first-stage degradation is similar to that obtained during vacuum pyrolysis (160). Above 250°C in the presence of oxygen, induced decomposition with self-ignition may take place (163).

Biodegradation. Poly(vinyl alcohol) is one of the few truly biodegradable synthetic polymers with the degradation products being water and carbon dioxide. At least 55 species or varieties of microorganisms have been shown to degrade or take an active role in the degradation of PVA (164). Poly(vinyl alcohol) degrading organisms consist not only of 20 different genera of bacteria, but molds, yeast, and fungi as well. The microorganisms which degrade PVA exist in most environments including activated sludge, facultative ponds, anaerobic digesters, septic systems, compost, aquatic systems, soil, and landfills. The time period for PVA to degrade is dependent upon the physical properties of the polymer, the form in which the product exists and the environment in which it is degraded. PVA is rapidly degraded by activated sludge especially if the sludge has already been adapted to the PVA molecule (164–168). Many of the microorganisms which degrade PVA can be isolated from soil (169–173).

The mechanism of PVA degradation consists of a random oxidation of a hydroxyl group to a ketone through the influence of a secondary alcohol oxidize. The random oxidation is continued until a β-diketone is formed. This group is cleaved by a extracellular hydrolase, leading to a reduction in molecular weight and the formation of a carboxylic end group and a methyl ketone end group. Continued degradation eventually leads to the formation of acetic acid, which in turn is converted into carbon dioxide and water. The degradation is normally accomplished by means of symbiotic organisms. Symbiotic bacterial pairs known to degrade PVA include, for Type I, *Pseudomonas putida* VM 15A, *P. vesicularas* Va., *P. porolyticus* PH, and *P. alkaligenes*; and for Type II, *P. Sp.* VM15C, *P. vesicularis* XL, *P. vesicularis* XL, and *P. vesicularis* PD. More recent studies have shown that isotactic blocks in PVA molecule are more readily biodegraded than those having an atactic structure (174,175). The biological oxygen demand for degradation of a 0.1% PVA solution is approximately 5 ppm (170).

Manufacture

Poly(vinyl alcohol) can be derived from the hydrolysis of a variety of poly(vinyl esters) such as poly(vinyl acetate), poly(vinyl formate), and poly(vinyl benzoate) and from the hydrolysis of poly(vinyl ethers). However, all commercially produced PVA is manufactured by the hydrolysis of poly(vinyl acetate). The manufacturing process can be viewed as one segment that deals with the polymerization of vinyl acetate and another that handles the hydrolysis of poly(vinyl acetate) to PVA.

Production of Poly(vinyl acetate).

Chemistry. Vinyl acetate is polymerized commercially using free-radical polymerization in either methanol or, in some circumstances, ethanol. Suitable

thermal initiators include organic peroxides such as butyl peroxypivalate, di(2-ethylhexyl) peroxydicarbonate, butyl peroxyneodecanoate, benzoyl peroxide, and lauroyl peroxide, and diazo compounds such as 2,2′-azobisisobutyronitrile (176–179). The temperatures of commercial interest range from 55 to 85°C (176,177).

Propagation of the polymerization occurs nearly exclusively by head-to-tail with only a small fraction of head-to-head reactions. The relative ratio of the two reactions is only a function of temperature and has been found to be independent of molecular weight, polymerization solvent, and method of polymerization. The head-to-head addition yields a 1,2-glycol structure in the resulting PVA, which in turn can influence the degree of crystallinity, strength, solubility, and thermal stability.

Termination reaction with vinyl acetate is nearly exclusively by disproportionation (180), although there are reports that recombination increases in importance at lower temperatures (181). Termination by disproportionation produces a double bond at the end of one molecule and a saturated bond at the other. The presence of the unsaturated bond results in an aldehyde group once the associated acetate group is hydrolyzed (182–184). The resulting aldehyde group decreases the thermal stability of the PVA, because the activation energy for splitting off water is reduced on account of the increased ability for formation of conjugated double bonds. The higher color level, observed in lower molecular weight commercial PVA grades, is a result of this reaction.

Chain transfer to monomer is important during vinyl acetate polymerization (181,185,186). The reaction is an abstraction of the hydrogen on the acetyl group of the vinyl acetate (187–189). The growing radical is transferred to the vinyl acetate monomer, which then reinitiates the polymerization. The reaction results in an unsaturated end group, which is still polymerizable. The inclusion of this terminal end group in a growing chain leads to a trifunctional branch point with the incorporation of the entire polymer molecule as a long-chain branch (185–187,187–192).

Chain transfer to polymer is considerable in vinyl acetate polymerization. The intermolecular transfer of a growing radical to a polymer molecule results in a branch point. Several studies have determined the fraction of branch points through the acetate group compared to those generated directly on the main chain (191,193–197). The results reported in the literature have been highly variable, ranging from over 0.95 to less than 0.5 at 60°C. The main distinction between branches generated through the acetoxy group and those connected directly to the main chain is that the first type is cleavable upon hydrolysis, the latter is not.

It has been shown that intramolecular chain transfer to polymer occurs during the polymerization of vinyl acetate, leading to short-chain branching (65,198–201). The number of short-chain branches has been estimated by nmr to be in the range of 0.12–1.7 mol% (65). The number of short-chain branches increases significantly with decreasing monomer concentration.

Chain transfer to low molecular weight alcohols occurs readily. However, the resulting end groups are not known to affect the physical or chemical properties of the resulting PVA. Chain transfer to acetaldehyde results in the incorporation of a ketone end group. Acetaldehyde is formed as a result of the transesterification between vinyl acetate and the added alcohol solvent. A small amount of an acid

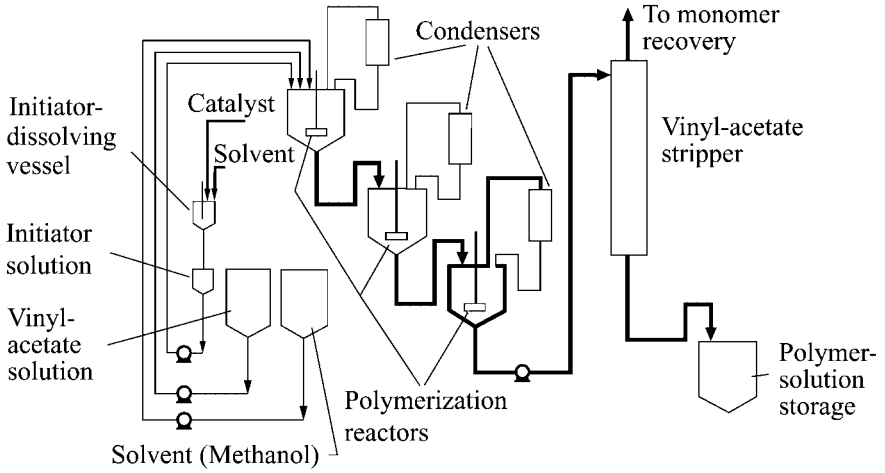

Fig. 12. Typical polymerization flow diagram for the continuous polymerization of vinyl acetate (208).

(2–50 ppm) may be added to the vinyl acetate in order to limit the transesterification (177,202–207). Suitable acids include phosphorous acid, oxalic acid, citric acid, and tartaric acid. The presence of the ketone end group in the resulting PVA facilitates the formation of conjugated double bonds and leads to color.

Commercial Manufacturing Processes.

Continuous Polymerization. A typical continuous flow diagram for the vinyl acetate polymerization is shown in Figure 12. The vinyl acetate is fed to the first reactor vessel, in which the mixture is purged with an inert gas such as nitrogen. Alternatively, the feed may be purged before being introduced to the reactor (176). A methanol solution containing the free-radical initiator is combined with the above stream and passed directly and continuously into the first reactor from which a stream of the polymerization mixture is continuously withdrawn and passed to subsequent reactors. More initiator can be added to these reactors to further increase the conversion.

The polymerization temperatures can range from 45 to 130°C; the preferred range is 55–85°C, which results in operating pressures of 0.1–0.5 MPa (1–5 atm). The heat of reaction is removed by condensing monomer and solvent vapors. Cooling coils show low efficiency because of the low heat transfer coefficient of the highly viscous material. Viscosity during polymerization can range from 10 to 500 P. Molecular weight is controlled by the residence time in the reactors, monomer feed rate, solvent concentration, initiator concentration, and polymerization temperature.

A stripping column is used to remove unpolymerized vinyl acetate from the poly(vinyl acetate) solution leaving the last reactor (Fig. 13). Methanol vapors are used to strip vinyl acetate from the solution (209,210). An inhibitor such as hydrazine, hydroquinone, sulfur, or quinone can be added to poly(vinyl acetate) solution leaving the reactor in order to prevent further polymerization in the stripping column (176). The overhead fraction from the stripping column consisting of solvent and vinyl acetate may be passed to a recovery system, or directly recycled

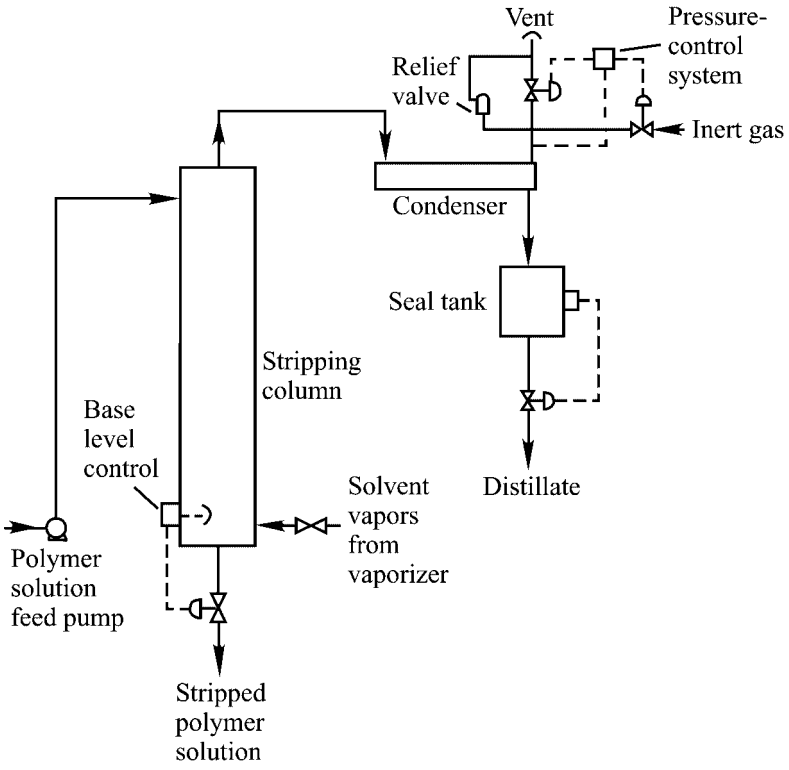

Fig. 13. Typical scheme for monomer stripping (209).

to the reactor. Vinyl acetate and methanol not recycled to the reactor must be separated and purified. Extractive distillation is normally used because methanol and vinyl acetate form an azeotrope. Suitable solvents include water and ethylene glycol.

The vinyl acetate content in the bottom effluent from the stripping column is reduced to less than 0.07 wt%. Higher concentrations of vinyl acetate will lead to yellowing because of acetaldehyde formation and subsequent aldol condensation during the hydrolysis reaction.

Batch and Semibatch Polymerization. The reactor is normally operated in a semicontinuous mode by delaying the addition of vinyl acetate, solvent, and initiator. The same reactor can be used for stripping the poly(vinyl acetate) solution, provided that careful addition of methanol is used in order to prevent the viscosity in the reactor from becoming excessive (211). The disadvantages of batch polymerization are the lack of product consistency and unsatisfactory economics in large-scale production. The true batch reaction, where all the reactants are added to the reactor at time zero, yields a product having a very broad molecular weight distribution of limited commercial value.

Production of PVA.

Chemistry. Poly(vinyl acetate) can be converted to PVA by transesterification, hydrolysis, or aminolysis. Industrially, the most important reaction is that

of transesterification, where a small amount of acid or base is added in catalytic amounts to promote the ester exchange.

The catalysts most often described in the literature (176,177,212) are sodium or potassium hydroxide, methoxide, or ethoxide. The reported ratio of alkali metal hydroxides or metal alcoholates to that of poly(vinyl acetate) needed for conversion ranges from 0.2 to 4.0 wt% (177). Acid catalysts are normally strong mineral acids such as sulfuric or hydrochloric acid (213). Acid-catalyzed hydrolysis is much slower than that of the alkaline-catalyzed reaction, a fact that has limited the commercial use of these catalysts.

The solution of poly(vinyl acetate) generated during the stripping operation is normally passed directly through to the alcoholysis system. This has limited the available solvents to methanol and ethanol (176,177). Substituting the alcohol used as solvent with the generated ester limits the hydrolysis and greatly affects how the remaining acetyl groups are distributed on the PVA chain (214–216). The distribution is often referred to as the blockiness of the PVA. The higher the methyl acetate concentration, the higher the degree of blockiness.

The presence of catalyst residues, such as alkali hydroxide or alkali acetate, a by-product of the hydrolysis reaction, is known to increase the thermal instability of PVA. Transforming these compounds into more inert compounds or removal through washing are both methods that have been pursued. The use of mineral acids such as sulfuric acid (217), phosphoric acid (218), and *ortho*-phosphoric acid (219) has been reported as means for achieving increased thermal stability of the resulting PVA.

Commercial Hydrolysis Process. The process of converting poly(vinyl acetate) to PVA on a commercial scale is complicated on account of the significant physical changes that accompany the conversion. The viscosity of the poly(vinyl acetate) solution increases rapidly and greatly as the conversion proceeds because the resulting PVA is insoluble in the most common solvents used for the polymerization of vinyl acetate. The outcome is the formation of a gel swollen with the resulting acetic acid ester and the alcohol used to effect the transesterification.

Continuous Saponification. There are several types of continuous systems, each with their own benefits and drawbacks. The basic premise is that continuous mixing is not required after the poly(vinyl acetate) and the caustic is mixed (220). Several designs for the high intensity mixing unit have been suggested in order to obtain efficient mixing and little fouling (221,222).

In the belt process, the mixture is cast onto the belt or conveyer (high temperature polyethylene) (223) where the gelling occurs (220,224). The gel is removed from the surface before syneresis, cut into smaller particles, and passed to a holding or washing tank (Fig. 14). The liquid is removed from the precipitate using common chemical deliquefying methods, and the resulting particles are dried in a continuous dryer.

In the slurry process, the hydrolysis is accomplished using two stirred tank reactors in series (225). Solutions of poly(vinyl acetate) and catalyst are continuously added to the first reactor, where 90% of the conversion occurs, and then transferred to the second reactor to reach full conversion. Alkyl acetate and alcohols are continuously distilled off in order to drive the equilibrium of the reaction. The resulting PVA particles tend to be very fine, resulting in a dusty product. The process has been modified to yield a less dusty product through process changes

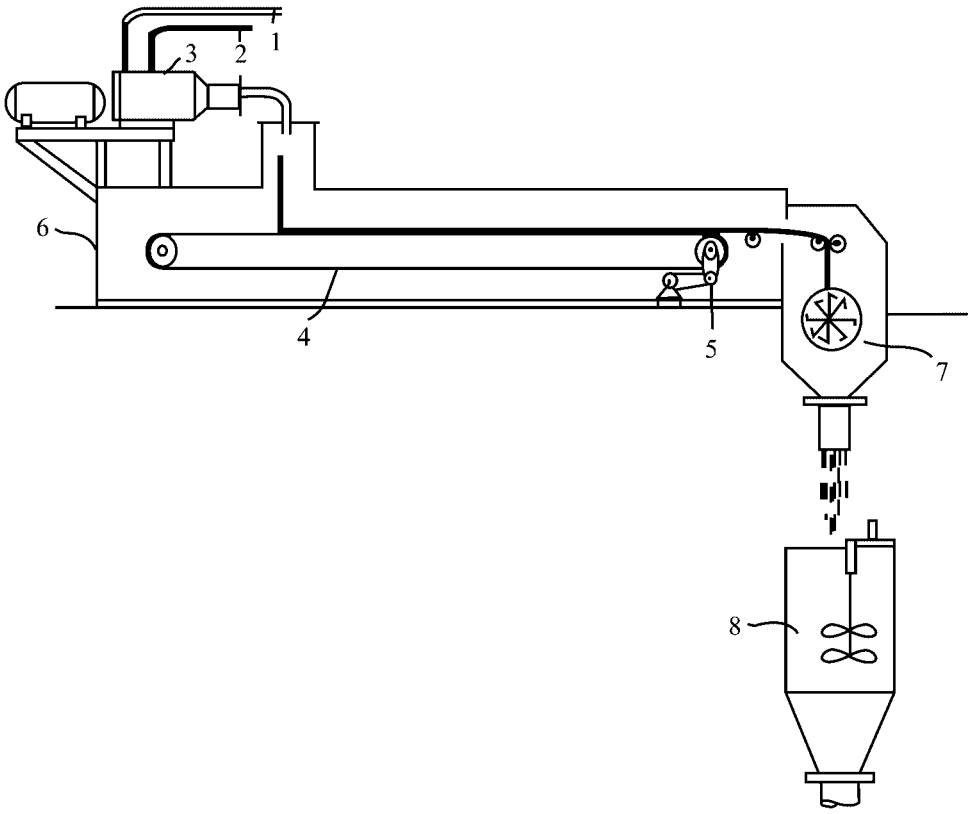

Fig. 14. The belt saponification process as used in the production of PVA (223). 1, Polyvinyl acetate/methanol mixture; 2, catalyst in methanol; 3, mixer; 4, belt; 5, drive; 6, housing; 7, cutter; 8, slurry tank (wash tank).

(226,227) and the use of additives (228). Partially hydrolyzed products having a narrow hydrolysis distribution cannot be prepared by this method.

In the screw conveyer process, solutions of poly(vinyl acetate) and catalyst are mixed in a high intensity mixer and continuously introduced to a screw-type saponification and conveyer system (229). Downstream details are similar to those found in the belt process.

Other methods also exist for handling the reaction mixture. For instance, an intermeshing, self-wiping, twin-screw extruder process has been proposed (230). The advantages described include higher saponification temperature (less catalyst), increased water solubility, and fewer impurities (231).

Batch Saponification. Batch saponification, the oldest PVA manufacturing method (232), is mainly used for the production of specialty products. The process uses a kneader in which the hydrolysis, washing, and drying operations are performed. This is the simplest method of saponification, but the production rates are low, and producing the product quality needed by many end uses is difficult.

Drying/Solids Separation. Separation of the polymer gel from the methanol/methyl acetate liquid is an important step, accomplished by using standard pieces of equipment such as filters, screw presses, or centrifuges.

Drying of the PVA is critical both to the color and solubility of the final product. Excessive drying temperatures result in high product color and an increase in the crystallinity, which in turn reduces the solubility of the product. Drying is initially subjected to a flash regime, where the solvent not contained within the particles is flashed off. This first phase is followed by a period where the rate is controlled by the diffusion rate of solvent from the PVA particles. Because the diffusion rate falls as the material dries, complete drying is not practical. The polymer is, therefore, generally sold at a specification of 95% solids.

Solvent Recovery. A mixture of methanol and methyl acetate is obtained after saponification. The methyl acetate can be sold as a solvent or converted back into acetic acid and methanol using a cationic-exchange resin such as a cross-linked styrene–sulphonic acid gel (233–236). The methyl acetate and methanol mixture is separated by extractive distillation using water or ethylene glycol (237–241). Water is preferred if the methyl acetate is to be hydrolyzed to acetic acid. The resulting acetic acid solution is concentrated by extraction or azeotropic distillation.

Copolymers

Numerous vinyl alcohol copolymers have been prepared (242). Copolymers with ethylene and methyl methacrylate are the only copolymers that have found sizable commercial utility. Ethylene–vinyl alcohol (EVOH) copolymers containing 20–30 mol% ethylene are used as an oxygen barrier in food packaging. However, a five-layer coextruded structure with polyolefins is needed in order to protect the EVOH from moisture. Vinyl alcohol–methyl methacrylate copolymers are used as sizing agents in the textile industry. The presence of the methacrylate unit disrupts the crystallinity making the product easier to remove during the desizing operation. The product is especially useful as an alkaline-resistant textile size.

Economic Aspects

The capacity of PVA in 2001 was greater than 625,000 t. The industry has experienced major changes since 1995, including the sale of the Air Products & Chemicals position to Celanese in September 2000, and the Clariant (formerly Hoechst) position to Kuraray in July 2001. New capacity, 40,000 t, was added by Kuraray and Nippon Gohsei in form of a joint venture, located in Singapore. Incremental expansion projects have also been initiated or completed by several of the current producers.

Approximately two-thirds of capacity is located in Japan, China, and Taiwan, with the remainder in the United States and Europe. Approximately 50,000 t of the Japanese and a large portion of the Chinese production is captively consumed for fiber production. The principal PVA producers in the world (capacity >30,000 t/year) are shown in Table 5.

The PVA process is highly capital-intensive as separate facilities are required for the production of poly(vinyl acetate), its saponification to PVA, the recovery of unreacted monomer, and the production of acetic acid from the ester formed

Table 5. Principal Poly(vinyl alcohol) Producers

Producer	Trade name	Capacity, t/year
Celanese	Celvol	90,000
Chang Chun	CCP	75,000
Chin-Shan Petrochemical		33,000
DuPont	Elvanol	68,000
Kuraray	Poval	194,000
Nippon Goshei	Gohsenol	77,000
Shi-Shan Vinylon		45,000

during alcoholysis. Capital costs are far in excess of those associated with the traditional production of other vinyl resins.

The PVA price has historically reflected the cost of ethylene, acetic acid, and energy. However, recent overcapacity has put strain on the pricing structure and lowered the return on investment. The price rose from $0.77/kg in 1970 to $2.20/kg in 1980, $2.75/kg in 1988, $2.65/kg in 1995, and $2.20/kg in 2001 for medium molecular weight fully hydrolyzed grade.

Specifications and Standards

The important commercial grades of PVA are distinguished by the degree of hydrolysis and molecular weight. The resins are most often categorized by degree of hydrolysis, ie, mole percent of alcohol groups in the resin (Table 6). Poly(vinyl alcohol)s having other degrees of hydrolysis are also produced, but maintain a much smaller market share than those shown in Table 6.

Poly(vinyl alcohol) is produced mainly in five molecular weight ranges expressed as degree of polymerization (DP) (Table 7). Several other molecular weight resins are available, but their market shares are relatively low. Industry practice expresses the molecular weight of a particular grade in terms of the viscosity of a 4% aqueous solution. An unlimited number of viscosities can be generated by blending the available molecular weights. Products having different degrees of hydrolysis can also be blended to obtain a particular performance characteristic. However, blended products have a broad distribution with respect to molecular weight and in some cases hydrolysis, which may be undesirable in some applications.

Table 6. Degree of Hydrolysis of Commercial Poly(vinyl alcohol) Grades

Grade	Hydrolysis, mol%
Super	99.3+
Fully	98.0–98.8
Intermediate	95.9–97.0
Partially	87.0–89.0
Low	79.0–81.0

Table 7. Viscosity and DP[a] of Principal Commercial Poly(vinyl alcohol) Grades[b]

Grade	Nominal DP	Viscosity of 4% solution, mPa·s (=cP)
Low–low	220	3–4
Low	550	5–7
Intermediate	900	13–16
Medium	1500	28–32
High	2200	55–65

[a]DP = Degree of polymergation.
[b]Grade = molecular range.

Table 8. FDA Regulations for Poly(vinyl alcohol) in Food Applications

Regulation	Description
181.30	Manufacture of paper and paperboard products used in packaging of fatty foods
175.105	Adhesives, no limitations
176.170	Components of paper and paperboard in contact with aqueous and fatty food; extractive limitations
176.180	Components of paper and paperboard in contact with dry food; no limitations
177.1200	Cellophane coating; no limitations
177.1670	Poly(vinyl alcohol) film
177.2260	Filters, resin-bonded where fiber is cellulose
177.2600	Filters, extractables must be less than 0.08 mg/cm^2
175.200	Resinous and polymeric coating
175.320	Resinous and polymeric coatings for polyolefin films; net extractable less than 0.08 mg/cm^2
177.2800	Textiles and textile fibers; for dry foods only
178.3910	Surface lubricants in the manufacture of metallic articles

PVA is an innocuous material with unlimited storage stability. It is most commonly supplied in 20-, 22.7- (50-lb), and 25-kg bags equipped with a moisture barrier to prevent caking. Poly(vinyl alcohol) is also available in bulk or in super sacks. The FDA regulations governing the use of PVA are shown in Table 8. Poly(vinyl alcohol) maintains an exemption for tolerance from the EPA.

Analytical and Test Methods

The important analytical test methods are those related to the determination of degree of hydrolysis, pH, viscosity, ash, and volatiles. Percent hydrolysis of the PVA is measured by placing the material in a mixture of water and methanol, adding a predetermined quantity of sodium hydroxide, and boiling under reflux to hydrolyze residual acetate groups. The moles of sodium hydroxide consumed are equivalent to the number of hydrolyzable acetate groups and are determined by back titration with strong acid.

The pH is measured using a 4% aqueous solution. Viscosity is normally measured using a Brookfield viscometer. Alternatively, a capillary viscometer or falling ball such as Hõppler may be employed. The type of viscometer used must always be noted.

Ash is a measure of residual sodium acetate. A simple method consists of dissolving the PVA in water, diluting to a known concentration of about 0.5 wt% and measuring the electrical conductivity of the solution at 30°C. The amount of sodium acetate is established by comparing the result to a calibration curve. A more lengthy method involves the extraction of the PVA with methanol using a Soxhlet extractor. The methanol is evaporated and water is added. The solution is titrated using hydrochloric acid in order to determine the amount of sodium acetate.

Volatiles such as residual methanol, methyl acetate, and water are determined as the loss in mass when the polymer is dried at 105 ± 2°C until constant mass is attained. Higher drying temperatures may cause decomposition and related weight loss.

Health and Safety Factors

Poly(vinyl alcohol) is a nonhazardous material according to the American Standard for Precautionary Labeling of Hazardous Industrial Chemicals (ANSI 2129.1-1976). Extensive tests indicate a very low order of toxicity when it is administered orally to laboratory animals (170). No toxicity was detected by oral administration of the maximum amount of 1500 mg/kg of two types of PVA (DP 1400, 99.5% hydrolyzed; and DP 1700, 86.8% hydrolyzed) or by subcutaneous injection of 3000 mg/kg to mice. PVA injected under the skin or into the lungs is not absorbed by the tissue and remains as a foreign body. The increase in growth and weight of mice given 1000 mg/kg every day during a 3-month chronic toxicity test was about the same as that of the control group animals. No histopathologic tensions were observed.

Poly(vinyl alcohol) has a low oral toxicity rating. The oral LD_{50} is higher than 10,000 mg/kg (rats). Concentrations of up to 10,000 mg/L in water were tested for toxicity to bluegill sunfish. No mortality or response indicative of intoxication was observed (243).

Short-term inhalation of PVA dust has no known health significance but can cause discomfort and should be avoided in accordance with industry standards for exposure to nuisance dust. The dust is mildly irritating to the eyes. There are no known dermal effects arising from short-term exposure to either solid PVA or its aqueous solutions.

During transport and handling, granular PVA may form an explosive mixture with air. However, the severity rating is 0.1 (Bureau of Mines Rating) on a scale in which coal dust has a rating of 1.0 (244). The explosive hazard does depend on particle size, and extremely fine dust has a higher explosive rating of 1.0–2.0. Residual methanol and methyl acetate can accumulate in the air space of bulk storage tanks; this is especially true at elevated temperatures. Precautions should be taken to ventilate the air space in large vessels and eliminate spark-producing equipment in the area. The issue of residual organic volatiles

has been addressed by a few PVA producers who have proactively implemented manufacturing specifications aimed at obtaining less than 1 wt% organic volatiles in the final product.

Processing

Poly(vinyl alcohol) is not considered a thermoplastic polymer because the degradation temperature is below that of the melting point. Thus, industrial applications of PVA are based on and limited by the use of water solutions.

Solution Preparation and Handling. Poly(vinyl alcohol) should be completely dispersed in water at room temperature, or lower, before heating of the water solution is commenced. Good agitation is important to prevent lumping during the addition of solid PVA to water. A large diameter, low speed agitator is preferred for providing good mixing at the surface without excessive air entrainment. Agitation requirements increase with solution concentration and with decreasing hydrolysis; the latter is associated with greater solubility in cold water and a tendency to lump.

The temperature of the slurry must be increased to 70–90°C in order to solubilize the PVA fully. Ways to increase the temperature includes direct steam injection, jet cooking, or heating with jacket or coil. Aqueous solutions of PVA are stable on storage but must be protected from bacterial growth. An increase in viscosity is commonly observed when storing fully hydrolyzed PVA solutions. Stainless steel or plastic containers are recommended for long-term storage. Many biocides are effective including FDA-approved compounds (245).

Prolonged heating of the PVA solution has negligible effect on its properties. However, the addition of strong acid or base to solutions of partially hydrolyzed PVA can increase the degree of hydrolysis.

Extrusion. Several attempts to introduce and produce extrudable PVA products have and continue to be made (246–260). However, these types of products have not achieved any significant commercial success. The main obstacles are thermal stability during extrusion and gels in the final product. A wide variety of high boiling water-soluble organic compounds containing hydroxyl groups have been used as plasticizers in order to lower the melt temperature and avoid decomposition. Glycerol and low molecular weight poly(ethylene glycol)s are most widely used. Water is an excellent plasticizer for PVA, although extrusion temperatures below 100°C are required in order to avoid the formation of foam at the extruder outlet.

Uses

The main applications for PVA are in textile sizing, adhesives, polymerization stabilizers, and paper coating, poly(vinyl butyral), and PVA fibers. In terms of percentage, and omitting the production of PVA not isolated prior to the conversion into poly(vinyl butyral), the principal applications are textile sizes, at 30%; adhesives, including use as a protective colloid, at 25%; fibers, at 15%; paper sizes, at 15%, poly(vinyl butyral), at 10%; and others, at 5%, which includes water-soluble films, nonwoven fabric binders, thickeners, slow release binders for fertilizer, photoprinting plates, sponges for cosmetic, and healthcare applications.

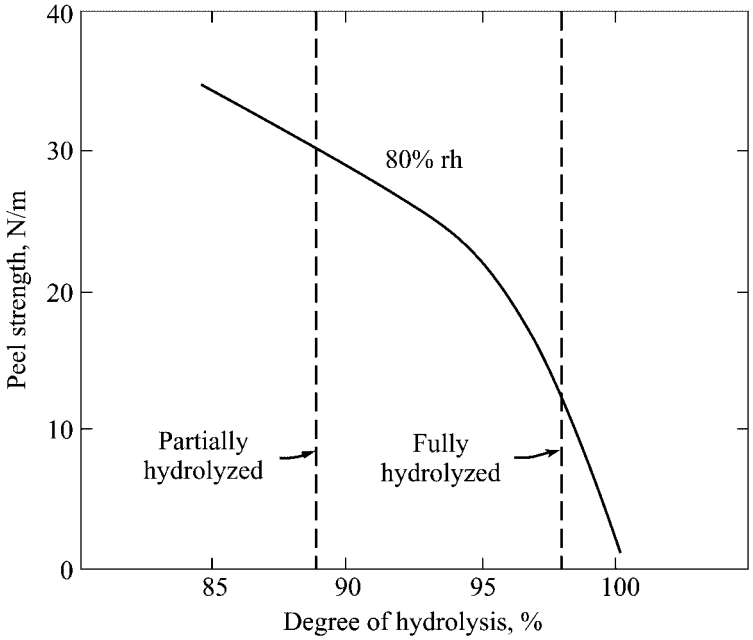

Fig. 15. Adhesion expressed as peel strength of PVA film on polyester film (7). To convert N/m to ppi, divide by 175.

Textile and Warp Sizing. Warps are sized to obtain increased abrasion resistance and strength in order to avoid breakage when passing through the loom. Yarn breakage during the weaving process reduces weaving efficiency and detracts from the quality of the finished cloth. The sizing material must allow for both easy splitting of the warp yarns after sizing and rapid desizing once the weaving process is complete. The typical sizing process consists of a size application box, squeeze rolls to remove excess size, drying drums, yarn-splitting rods, and beam-winding equipment.

Poly(vinyl alcohol) is an excellent textile warp size because of superior strength, adhesion, flexibility, and film-forming properties. The adhesion of PVA to natural or synthetic fibers or fiber blends depends on the degree of hydrolysis. Adhesion to such hydrophobic fibers as polyester is enhanced as the degree of hydrolysis is reduced (Fig. 15). Fully hydrolyzed grades adhere well to cotton and other hydrophilic fibers and impart the highest tensile strength for equivalent amounts added. However, there continues to be a trend away from fully hydrolyzed PVA because of its poor adhesion to synthetic fibers and the difficulty encountered when desizing heat-set fabric (176,261,262). The best hydrolysis grade for warp sizing is specific to each manufacturing operation and is controlled by factors such as yarn quality, yarn construction, and speed and type of loom.

The highest molecular weight grades provide the best protection at equivalent concentration for spun yarns. However, low solids sizing solutions are needed to maintain manageable viscosity; this increases drying cost and limits production. Desizing of the fabric is difficult because of the lower solubility rate of these grades.

Thus, the commonly used warp size grades for spun yarns are the medium to lower molecular weight resins because they provide balance, strength, solution viscosity, and desizing to yield the best possible economics. The best size for filament yarns are those PVA grades that have low degrees of polymerization.

Typical size formulations contain a lubricating wax, starch, and other processing aids. The role of these materials is to provide easy splitting of the yarns after drying, to decrease the sticking tendency of PVA to the drying drums, and to provide lubricity during the weaving process. The additives must to a large degree be incompatible with the dried PVA film to provide the desired function. However, a large degree of incompatibility can result in decreased encapsulation of the yarn and increased shedding during the weaving operation. Poly(vinyl alcohol) is normally used in 3–10-wt% concentrations in the aqueous size solution. Amount of size needed depends on both fabric and loom type, but is usually in the 5–10% range.

The fabric is desized after the weaving operation by passing it through a heated water bath to remove all the size. The rate at which this operation can be accomplished depends to a great degree on solubility rate of the PVA. Difficulties encountered in completely removing the lubricating wax, usually tallow wax, has led to the development of several wax-free size compositions (263–271). The main component contained in these blends is PVA in combination with a small amount of a synthetic water-soluble lubricant.

Poly(vinyl alcohol) can be recovered from the desizing liquid by means of commercial ultrafiltration equipment. Recovery rates and effluent losses are inversely proportional to the PVA solution viscosity and independent of the degree of hydrolysis.

Adhesives. Poly(vinyl alcohol) is used as a component in a wide variety of general- purpose adhesives to bond cellulosic materials, such as paper and paperboard, wood textiles, some metal foils, and porous ceramic surfaces to each other. It is also an effective binder for pigments and other finely divided powders. Both fully and partially hydrolyzed grades are used. Sensitivity to water increases with decreasing degree of hydrolysis and the addition of plasticizer. Poly(vinyl alcohol) in many applications is employed as an additive to other polymer systems to improve the cohesive strength, film flexibility, moisture resistance, and other properties. It is incorporated into a wide variety of adhesives through its use as a protective colloid in emulsion polymerization.

Adhesives for paper tubes, paperboard, corrugated paperboard, and laminated fiberboard are made from dispersions of clays suspended with fully hydrolyzed PVA. Addition of boric acid improves wet tack and reduces penetration into porous surfaces (73,272). The tackified grades have higher solution viscosity than unmodified PVA and must be maintained at pH 4.6–4.9 for optimum wet adhesion.

Poly(vinyl alcohol) is employed as a modifier of thermosetting resins used as adhesives in plywood and particleboard manufacture (273,274). The polymer is added to urea–formaldehyde or urea–melamine–formaldehyde resins to improve initial grab, increase viscosity, and in general to improve the characteristics of the board.

Poly(vinyl alcohol)s are used as components in vinyl acetate emulsions both as a protective colloid and as a means for improving adhesive properties. Addition

of PVA to the resulting emulsions is commonly employed to modify viscosity, flow properties, and the rate of formation of the adhesive bond as well as the quality. High addition rates of partially hydrolyzed PVA can be used to prepare remoistenable adhesive formulations. All PVA grades promote the acceptance of starch and clay fillers into a formulation, which in turn prevents excessive adhesive penetration into porous surfaces. The PVA also offers reactive sites that can be used to cross-link the adhesive and improve the water resistance. Cross-Linking is accomplished by means of either *N*-methylolacrylamide, copolymerized with the vinyl acetate (275,276), or other commonly used cross-linking agents, such as glyoxal. The performance of poly(vinyl acetate)-based wood glues is to a great extent dependent upon the presence of PVA to provide both the cohesive and adhesive properties.

Emulsion Polymerization. Poly(vinyl acetate) and poly(vinyl acetate) copolymer latices prepared in the presence of PVA find wide applications in adhesives, textile finishes, and coatings. The emulsions show excellent stability to mechanical shear and to the addition of electrolytes, and possess excellent machining characteristics.

Partially hydrolyzed PVA grades are preferred because they have a hydrophobic/hydrophilic balance that make them uniquely suited for emulsion polymerization. The compatibility of the residual acetate units with the poly(vinyl acetate) latex particles partly explains the observed stabilization effect. The amount of PVA employed is normally 4–10% on the weight of vinyl acetate monomer. The viscosity of the resulting latex increases with increasing molecular weight and decreasing hydrolysis of the PVA (277).

Paper Coating. The unique binding properties of PVA has made it a primary contributor to the development of higher quality, specialized paper products. Its use spans a great variety of grades, including silicone-coated release liners, grease-proof and glassine packaging papers, food-grade boards, carbonless grades, currency and banknote grades, offset printing papers, high brightness printing and writing grades, offset masters, ink-jet and thermal printing papers, and cigarette filter tip papers.

Poly(vinyl alcohol) is utilized principally as a surface-treating agent, as in clear sizing, pigmented sizing, and pigmented coating. Exceptions include its use as a creping aid in tissue and towel manufacturing, in dye encapsulation for carbonless papers, and in some wet-end addition applications. Poly(vinyl alcohol) imparts exceptional strength and outstanding resistance to oils, greases, and organic solvents, and is widely recognized as the strongest paper binder available (Table 9) (278).

The resistance of the polymer to oils and organic solvents can be directly attributed to the hydroxyl functionality and the film-forming properties of the polymer. Treated paper substrates display a significant amount of oil resistance which make them valuable for packing papers and food-grade paperboard containers. This performance improvement is achieved despite the fact that the 1–3 wt% add-on level, typical of size press applications, is too low to provide a continuous PVA film.

The fully and super-hydrolyzed PVA grades are preferred by the paper industry as they provide superior strength, greater adhesion to cellulose, better water resistance, and low foaming. However, the intermediate and partially hydrolyzed

Table 9. Relative Strength of Paper Binders

Binder	Parts for equal strength
Poly(vinyl alcohol)	1
Styrene–butadiene	2–2.5
Poly(vinyl acetate)	2–3
Soy protein	2.5–3
Casein	2.5–3
Starch	3–4

grades provide better surface-filming characteristics on many paper and paperboard substrates.

Poly(vinyl alcohol) is widely used on release liners for silicone topcoat holdout. The wide diversity in performance requirements of the various release liners has resulted in recommendation for add-on ranging from 1.5–2.0 (279) to 10 g/m^2. Ultimately, the characteristics of the base paper itself, as well as the level of release required of the finished sheet, determine the best add-on level of the PVA.

The role of PVA in ink-jet printing papers is described in numerous patents. The market has shown fast growth in recent years. Most of the technology has been developed in Japan, which by 1985 had filed 75% of the 400 issued patents (280). Requirements call for a hydrophilic, high porosity surface capable of absorbing ink-jet droplets quickly, with little spreading, wicking, or dye penetration. The coating on the base sheet primarily consists of silica powder using PVA as the binder of choice (281).

Building Products. Poly(vinyl alcohol) is widely used in connection with spray-drying of emulsions, in particular ethylene–vinyl acetate copolymer emulsions. The PVA is added both as a protective colloid during the polymerization and as a redispersing aid prior to the actual spray drying for a total amount of 2–15 wt% (282–285). The PVA contained in these products greatly enhances the adhesion to cementitious materials, improves water retention, and increases strength. The powder, when added to tile grouts, joint compounds, textured compounds, and cementitious repair mortars, improves the bond strength, abrasion resistance, and flexibility of the final construction.

Poly(vinyl alcohol) is used as an additive to dry-wall joint cements and stucco-finish compounds. Rapid cold water solubility, which can be achieved with finely ground PVA, is important in many dry mixed products. Partially hydrolyzed grades are commercially available in fine particle size. The main purpose of the PVA is to improve adhesion and to act as a water-retention aid.

Fibers. Poly(vinyl alcohol) fibers possess excellent strength characteristics and provide a pleasant feel in fabrics. The fiber is usually spun by a wet process employing a concentrated aqueous solution of sodium sulfate as the coagulating bath. Water insolubility, even in boiling water, can be obtained by combining stretching, heat treatment, and acetalization with formaldehyde. Super-hydrolyzed PVA is the preferred material for fiber production.

PVA fibers have found widespread industrial use in cement as replacement for asbestos in cement products, reinforcement of rubber material such as conveyer belts, and hydraulic rubber hoses used in cars, ropes, fishing nets, etc. Only a small

amount of fibers is used in the production of textiles. Several patents (286–288) have been issued, claiming processes for production of ultrahigh tensile strength PVA fibers, which have tensile strength comparable to that of Kevlar.

Other Applications. Poly(vinyl alcohol) film can be produced by solution casting or extrusion. Film casting is most common as unplasticized films of all molecular weights and extents of hydrolysis can readily be produced. Water solubility of the film can be controlled by selection of the proper degree of hydrolysis. These films can be made into bags used for packaging of detergents, insecticides, hospital laundry, and numerous other items that are to be placed in water.

Poly(vinyl alcohol) is useful as a temporary protective coating for metals, plastics, and ceramics. The coating reduces damage from mechanical or chemical agents during manufacturing, transport, and storage. The protective film can be removed by peeling or washing with water.

The ultraviolet cross-linking of PVA with dicromates is the basis for its use in photoengraving, screen printing, printed circuit manufacture, and color television tube manufacture.

Partially hydrolyzed grades are used in many cosmetic applications because of their emulsifying, thickening, and film-forming properties. Poly(vinyl alcohol) is also used as a viscosity builder for aqueous solutions and dispersions.

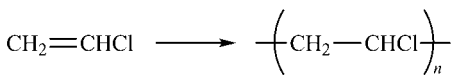
VINYL CHLORIDE POLYMERS

Introduction

Poly(vinyl chloride) (PVC), a polymer prepared from vinyl chloride monomer (VCM),



where $n = 700–1500$, holds a unique position among the polymers produced today. It is relatively inexpensive and is used in such a wide range of applications that its versatility is almost unlimited. However, if it were discovered today it would probably be shelved as a somewhat intractable and thermally unstable material. How can this apparent contradiction be explained?

The uniqueness of PVC can be considered under three headings: morphology, versatility, and molecular structure.

Morphology. As made, PVC is particulate in nature and comes in two main sizes depending on the process used. Suspension and mass polymerizations give grains (particles) of 100–180 μm in diameter, whereas the emulsion process affords a latex of particle size 0.1–3.0 μm. The latter is dried to yield friable grain-like structures of 5–50 μm.

Because of this unique particulate structure the most frequently used word in the vocabulary of the PVC technologist is morphology. In no other polymer is it as important as it is in PVC.

In its polymerization, a growing PVC chain becomes insoluble in VCM above a chain length of about 10 units (1) and so PVC is essentially insoluble in its monomer and the process is thus classified as a precipitation suspension

polymerization. However, PVC is heavily swollen and partly solvated by the monomer to the extent of 27 wt% (2) and this has a major influence on the polymerization itself as well as the final properties and end uses of PVC. Hence, the way the PVC separates from the monomer, its future growth mechanism, and the swelling of the polymer by the monomer are critically important in its formation, handling, and subsequent processing.

Versatility. Poly(vinyl chloride) is a generic name. Each producer makes a range of PVC polymers which vary in morphology and in molecular mass, depending on the intended end use. In industry, the K-value and viscosity number are used to represent molecular mass, and producers often reflect these parameters in the grade codes used to define different products (eg, S68/173 refers to a suspension type material with a K-value of 68, and VY110/57 to a resin with a viscosity number of 110). The calculation of the K-value is given in Reference 3 and the relationship between these parameters and molecular mass in Reference 4.

PVC with $K = 66$–68 can be processed in rigid formulations to give pipes, conduit, sheet, and window profiles; $K = 65$–71 in flexible formulations for flexible sheet, flooring, wallpapers, cable coverings, hoses, tubing, and medical products; and PVC with low K-values (55–60) in formulations for injection molding of pipe and conduit fittings, integral electrical plugs, and blow molding of bottles and other containers.

In contrast, poly(methyl methacrylate) of even very high molecular mass is still soluble in its monomer and produces only glass-like solid beads at the end of polymerization which have no internal morphology and as such are limited to a narrow range of end uses (eg, moldings for optical applications such as covers for car lights and illuminated signs).

Molecular Structure. Among the range of polymeric materials produced, PVC is unique because the bulky chlorine atom imparts a strongly polar nature to the PVC polymer chain, and the essentially syndiotactic conformation of the repeat unit in the chain leads to a limited level of crystallinity (5). This results in good mechanical properties, particularly stiffness at low wall thickness, high melt viscosity at relatively low molecular mass, and the ability to maintain good mechanical properties even when highly plasticized. This enables a wide range of softness and flexibility to be achieved and hence leads to an even wider variety of end uses.

Physical and Chemical Properties

Vinyl Chloride Monomer (VCM). Vinyl chloride monomer (VCM), bp -13.4°C, is a gas at room temperature and pressure. Therefore, it is handled as a compressed volatile liquid in all polymerization operations. Its vapor pressure over the typical polymerization temperature range of 50–70°C is 800–1250 kPa. As a result, PVC polymerization reactors are thick-walled jacketed steel vessels with a pressure rating of 1725 kPa. VCM is slightly soluble in water (0.11 wt% at 20°C). This has some influence on the suspension polymerization process and is critically important to the success of the emulsion polymerization process. The

Table 1. Typical Properties of Rigid PVC (UPVC)

Property	Test	Value
Tensile strength at 23°C, MPa[a]	BS 2782:301G ISO R527	55
Tensile modulus (1% strain, 100 s), GPa[b]	BS 4618 ISO R899	2.7–3.0
Tensile modulus (1% strain, 3 years), GPa[b]	ISO R899	1.7
Izod impact, J/m[c]	BS 2782:306A ISO R180	107 (unmodified) 534 (modified)
Specific gravity	ISO R1183	1.38–1.45
Coefficient of linear thermal expansion, K^{-1}	BS 4618:3.1	6×10^{-5}
Coefficient of thermal conductivity, W/mK		0.14
Flammability (oxygen index)	ASTM D2863 (Fenimore Martin)	45
Weathering resistance		Very good (especially white)
Resistance to concentrated mineral acids (at 20°C)		Excellent
Maximum continuous operating temperature	Field experience	60°C

[a]To convert MPa to psi, multiply by 145.
[b]To convert GPa to psi, multiply by 145,000.
[c]To convert J/m to ft·lb/in., divide by 53.38.

polymerization of VCM is strongly exothermic, and its specific heat and heat of evaporation of 1.352 kJ/(kg · K) and 20.6 kJ/mol, respectively, allow the removal of the heat of reaction by the use of a condenser as well as by the more conventional jacketed vessel systems. Its explosive limits in air are 4–22 vol% and plant design, particularly when handling unreacted VCM in the recovery system, must be designed and operated accordingly.

Poly(Vinyl Chloride) (PVC). Poly(vinyl chloride) is never used alone. It is always mixed with heat stabilizers, lubricants, plasticizers, fillers, and other additives to make processing possible, all of which can influence its physical and mechanical properties. Table 1 lists properties of rigid (unplasticized) PVC with a total additives content of <10%. Table 2 lists properties of flexible (plasticized) PVC where the range of physical properties varies widely, depending on the plasticizer content. Plasticizer content can vary between 20 and 100 phr and so as a guide properties typical of a plasticizer content of 50 phr are given.

In addition, the molecular mass of the PVC can also influence properties significantly. Molecular mass is expressed by *K*-values as explained in a later section.

PVC has extremely good chemical resistance to all but low molecular mass chlorinated solvents. Therefore, it is widely used in the construction and lining of chemical plants.

Table 2. Typical Properties of Flexible PVC

Property	Test	Value
Specific gravity	ISO R1183	1.19–1.68
Tensile strength, MPa[a]	BS 2782.320A	7.5–30
Elongation at break, %	BS 2782.320A	140–400
BS softness	BS 2782 365A	5–100
Cold flex temperature, °C	BS 2782 159B	−20 to −60
Volume resistivity at 23°C, Ω·cm	BS 2782 202A	10^{10}–10^{15}
Ageing resistance	Field experience	Excellent
Ozone resistance	Field experience	Very good

Raw Materials and Production

Monomer. VCM is produced industrially by two main reactions: (*1*) hydrochlorination of acetylene and (*2*) thermal cracking of 1,2-dichloroethane produced by direct chlorination or oxychlorination of ethylene in the balanced process. Presently, more than 90% of the VCM produced is based on this route.

In an ideal situation a PVC plant is fully integrated, beginning with ethylene and chlorine (salt), but various levels of integration are employed worldwide. Stand-alone PVC plants, supplied with VCM by sea, road, or rail, are well known as are ones making the bulk of their VCM requirements from scratch on site, with supplementary supplies of 1,2-dichloroethane for cracking to satisfy peak demand. Finally, there are fully integrated plants which have the benefit of uninterrupted supplies of base raw materials (ethylene and salt) and where the monomer is supplied by pipeline at a significant cost benefit. It can cost up to 65 Euro/t to transport VCM within continental Western Europe depending on distance and type of freight used, ie road, rail, or ship.

Polymer Production. There are three main processes used for the commercial production of PVC: suspension (providing 80% of world production), emulsion (12%), and mass, also called bulk (8%).

Suspension Polymerization

The layout of a typical suspension PVC plant is shown in Figure 1.

The suspension polymerization process is essentially a bulk polymerization process carried out in millions of small "reactors" (droplets). Liquid vinyl chloride under its autogeneous vapor pressure is dispersed in water by vigorous stirring in a reactor (autoclave) of 25–150 m^3 capacity, fitted with a jacket and/or condenser for heat removal and baffles for optimum agitation. This results in the formation of droplets of average diameter 30–40 μm, which are stabilized against coalescence by one or more protective colloids (granulating agent). The other essential ingredient is a monomer-soluble free-radical initiator.

The formulations charged to the reactors (otherwise known as autoclaves, kettles, or polymerizers) are normally referred to as recipes. A basic recipe for

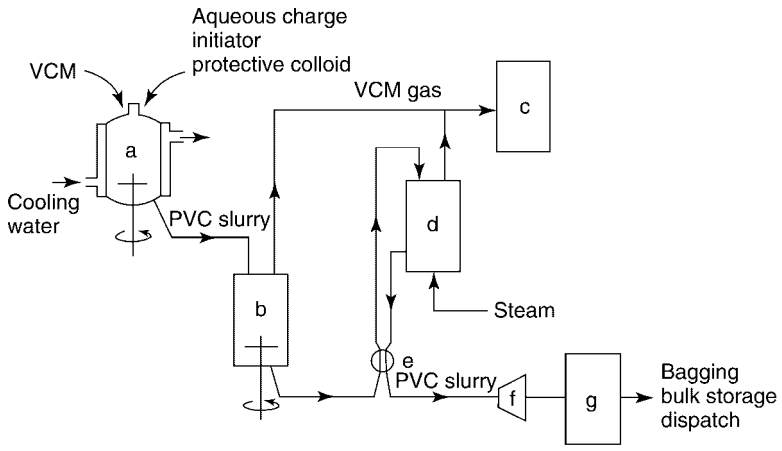

Fig. 1. Suspension PVC plant: a, reactor; b, blowdown vessel; c, VCM recovery plant; d, stripping column; e, heat exchanger; f, centrifuge; and g, driers.

suspension processes can be simply water, VCM, initiator, and suspension agent, for example,

VCM	100 parts
Water	90–130 parts
Protective colloid	0.05–0.15 parts
Initiator	0.03–0.08 parts

These quantities vary depending on the PVC grade, reactor size, plant type, etc.

Although this will produce a particulate PVC, it is unlikely to have the optimum morphology. This will only be achieved if other additives are employed, such as oxygen, buffers, secondary or tertiary granulating agents, chain-transfer or chain-extending agents, comonomers, antioxidants, together with the right level of agitation and homogenization, and the correct charging procedure and timing for each additive addition. A combination of just the right number and degree of the above parameters to achieve the optimum morphology usually determines the quality of a PVC grade.

After charging, the reactor contents are heated to the reaction temperature of 45–75°C. Reactors are 80–95% full at this stage. Heat causes some of the initiator to decompose into free radicals, and the monomer in the droplets begins to polymerize. The strongly exothermic reaction (1540 kJ/kg) is controlled by removing heat via the jacket and/or by boil-off into a condenser from which the condensed monomer is returned to the reactor.

Progress of the reaction in a jacketed reactor can be followed by continuously monitoring the water temperature in the jacket since the flow rate is constant and a constant batch temperature is maintained by progressively reducing the cooling water temperature (see Fig. 2).

Although PVC is insoluble in its monomer, the polymer is swollen by ca 27 wt% VCM to form a coherent gel (2). Therefore, as the conversion increases

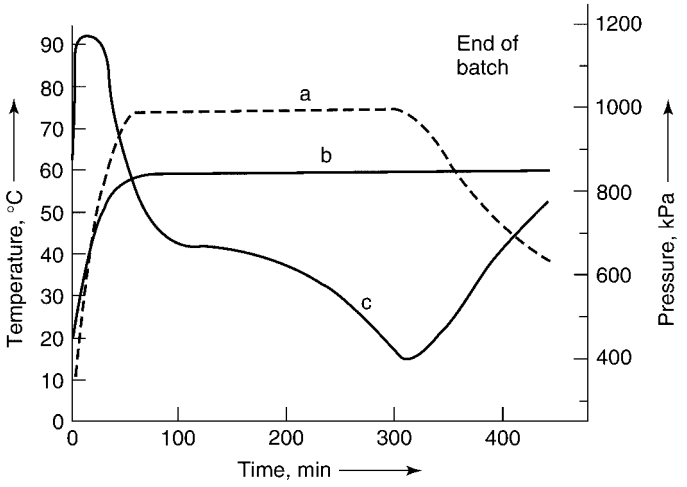

Fig. 2. Reaction profile for a typical suspension polymerization: a, pressure; b, batch temperature; and c, Jacket temperature.

toward 70% and beyond, the pressure in the reactor starts to fall, slowly at first, but then much more rapidly as the last of the free liquid monomer is consumed. Polymerization continues in the gel phase, very rapidly at first since chain termination is hindered by lack of mobility of the growing chain, but, as conversion increases beyond 80–85%, monomer starvation rapidly reduces the rate.

The reaction is terminated at a predetermined pressure by either adding a chain terminator and/or venting off the unreacted monomer to the recovery plant. After venting, the resin in the aqueous slurry can still contain 2–3% of unreacted monomer, which is removed by stripping, either batchwise (as in older plants) or continuously in a column. The batch is discharged from the reactor to a feed vessel and then fed continuously through a stripper column (Fig. 3). The unreacted monomer is recovered, liquified, and reused in later polymerizations. After passing through a heat exchanger the slurry is fed to a continuous centrifuge to give a wet-cake with 20–30% moisture content. The remaining water is then removed by conventional flash and/or fluid-bed drying to give a dry, free-flowing powder with a residual VCM content below 1 ppm.

Additives.

Water. The water used in the process should be demineralized (ie, of low conductivity) since ionic species, especially sodium ions, can affect the performance of other additives such as protective colloids and influence final polymer properties such as volume resistivity.

Protective Colloids (Granulating Agents). The protective colloids used in the suspension polymerization process are of two types: primary and secondary. The main function of the primary granulating agents is to control grain size, but they also affect porosity and other morphological properties. The demand for polymers with reduced residual VCM levels and better plasticizer adsorption led to the need for higher and more uniform porosity within each grain and this is achieved by using a secondary stabilizer in addition to the primary.

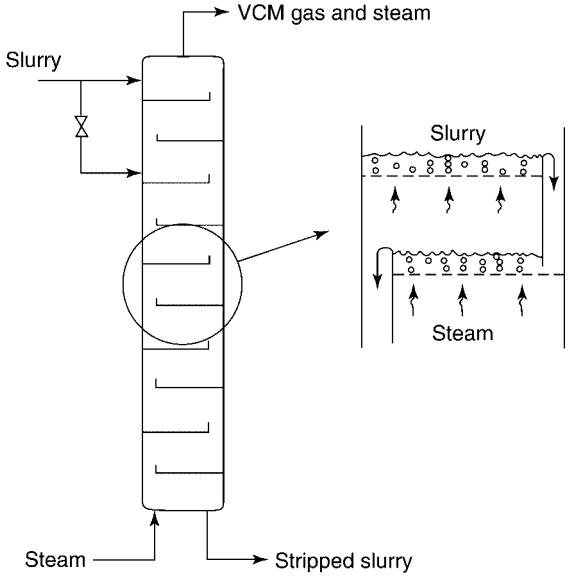

Fig. 3. Stripping column.

Although a wide variety of surface active materials have been or are still used, the substances most commonly used today are cellulose ether derivatives and partially hydrolyzed poly(vinyl acetates) or poly(vinyl alcohols) (PVAs). The latter are usually preferred and are used alone or in combination with the cellulose type, which they are gradually replacing. Typical PVA protective colloids are listed in Table 3.

As PVA primary granulating agents are prepared by alkaline hydrolysis of poly(vinyl acetates), they are complex mixtures containing fractions with different degrees of hydrolysis and molecular mass and having a block distribution of the OH groups (6). Because of this complexity, suspension processes need fine-tuning around the chosen agent since decreasing the average degree of hydrolysis of the PVA increases the porosity of the PVC grains and affects the grain size, as shown in Figure 4. This behavior is used in conjunction with agitation to achieve the optimum size and porosity. Below 70% hydrolysis the PVAs are insoluble in water and lose their ability to stabilize the VCM droplets adequately; so the normal range of PVA granulating agents used are in the range of 70–88%.

Many surfactants of low molecular mass have been claimed as useful secondary stabilizers, but in practice few can be used without adverse side effects. One exception is the nonionic sorbitan monolaurate. Again, PVAs are much more widely used. However, this family is prepared by acid hydrolysis of low molecular mass poly(vinyl acetates) and has a random distribution of acetate groups (6). Initially, these materials, which are insoluble in water, were prepared as methanolic solutions (eg, Polivic S202) but more recently aqueous-based, low hydrolysis PVAs (eg, Alcotex A55 and Polivic S 404W), which are safer to handle and are environmentally more acceptable, have been developed and are now very widely used in the industry. Typical secondary protective colloids are listed in Table 3.

Table 3. Typical Primary and Secondary Protective Colloids Used in the Suspension Polymerization of Vinyl Chloride

Trade name	Manufacturer	Degree of hydrolysis	Viscosity of 4% aqueous solution, mPa · s (=cP)
Primaries

Atlas G72143	ICI	50	Methanolic
Span 20 (sorbitan monolaurate)	ICI		Red-brown liquid, no solvent

The use of secondary granulating agents affects the mean grain size and grain size distribution and so the concentration of the primary ones must be adjusted to compensate. Since each producer uses autoclaves of different size and shape, equipped with different agitation and baffle systems, with or without condensers, and makes many different types of resin, no absolute formula is available which determines the magnitude of this change in primary concentration; this must be developed in-house by the suspension polymerization technologist.

Initiators. A range of initiators have been used, but currently a relative few are widely employed. At one time benzoyl peroxide and azo initiators were typically used, but diacetyl peroxides, peroxydicarbonates (PDC), and alkyl peroxyesters are now preferred (see INITIATORS, FREE-RADICAL). Typical initiators are listed in Table 4.

The half-life $t_{1/2}$ at a particular temperature is the main factor which determines the choice of an initiator for a given PVC grade. The initiator should have a half-life of ca 2 h at reaction temperature to optimize reaction time. Since the best plant output is obtained when the reaction profile (Fig. 2) is as square as possible, two initiators of different activity are often chosen to try to achieve this ideal. The more reactive initiator is used to start the polymerization but then as this exhausts itself the slower one takes over to completion. When preparing K 70–80 resins at temperatures at or below 52°C, a peroxydicarbonate (eg, **6**, **7**, **8**, or **9**) is used as the primary initiator, with an active initiator such as **1** or **12** helping to bolster the slow initial rate which is obtained at these low temperatures. In the intermediate range of K 63–68 a single PDC is usually sufficient, but at or below K 60 the PDC needs the extra radical flux of a slow initiator to prevent exhaustion

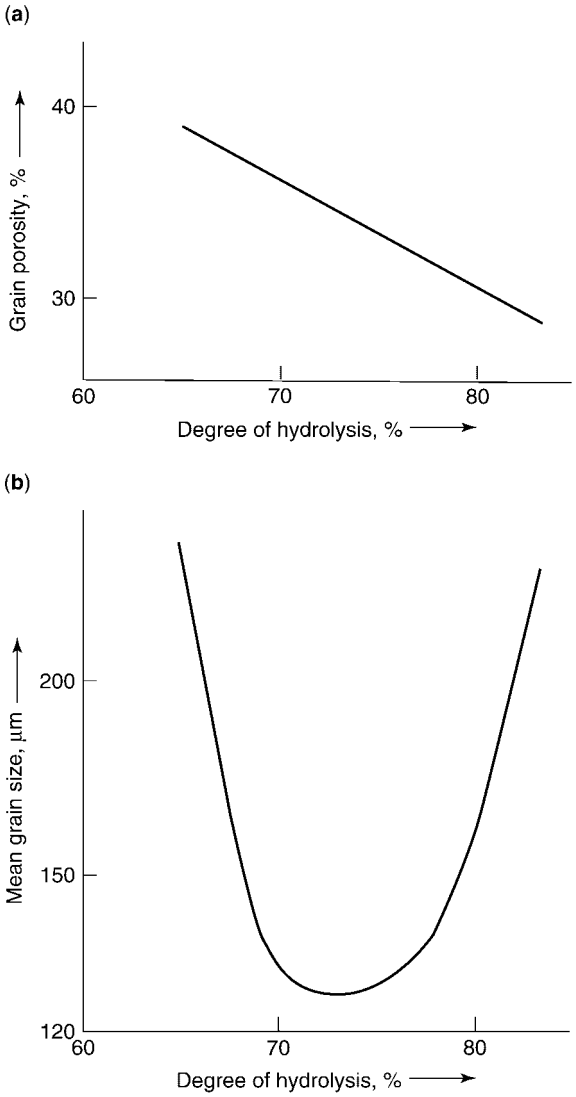

Fig. 4. The effect of the degree of hydrolysis of poly(vinyl acetate) on PVC grain properties. A, grain porosity and B, mean grain size.

of the reaction, and so a less active diacyl peroxide such as **4** or **13** is used as a secondary.

Three other factors are also important: water solubility, storage and handling, and reactor fouling.

The initiators' water solubility can affect their efficiency by making them more susceptible to hydrolysis and can affect their distribution between VCM droplets; the higher the solubility, the more homogeneous the distribution.

The ease of storage and handling has a major influence on the acceptability of an initiator to a PVC producer. In general, the shorter the half-life of the initiator,

Table 4. Initiators for Suspension or Mass Polymerization of VCM

[c] Approximate.

the more unstable it is, and the lower its self-decomposition temperature. The stability also depends on the radical energy and physical form. Solid crystalline initiators such as **8** (BCHPC) are more stable than their liquid analogues, eg **5** (EHPC). Many of the more active initiators must be stored under refrigeration, which tends to restrict their acceptability. Liquid initiators have the advantage that they can be automatically metered into reactors, which is essential in larger computer-controlled plants. However, the current trend is to use initiators as finely divided aqueous dispersions. This has the advantage of improving their homogeneity of distribution throughout the VCM droplets, allows them to be added at any time or temperature during the charging procedure, and renders them very safe to handle since their heat of decomposition is less than the heat of evaporation of the carrier. Dispersion of 25–40% are typical, and systems must be carefully designed to ensure that complete homogenization of the dispersion is maintained and accurate metering achieved. As the water solubility of the initiator increases so does its tendency to cause reactor fouling. This is of increasing importance as more and more processes switch from the open to the closed mode of operation.

Kinetics. The kinetic profile seen in Figure 2 is typical of many VCM suspension polymerizations conducted at the lower end of the temperature range and exhibits the classical acceleration with conversion as shown by the gradually decreasing jacket temperature. At higher temperatures the reaction rate is more constant and a square-wave profile is obtained. Three different phases in the reaction can be identified:

Low Conversion (<5%). Polymerization occurs largely in the monomer phase because the quantity of polymer produced is so small. It is only this early stage that follows classical kinetics where the rate of polymerization is dependent on the square root of the initiator concentration:

$$\frac{-\mathrm{d[M]}}{\mathrm{d}t} = \frac{k_\mathrm{p}[\mathrm{M}] \cdot k_\mathrm{d}[\mathrm{I}]^{1/2}}{k_\mathrm{t}}$$

where
[M] = monomer concentration
[I] = initiator concentration
k_p = propagation rate constant
k_d = initiator decomposition rate constant
k_t = termination rate constant

As the amount of polymer phase increases with conversion the rate deviates more and more from this equation because of a decrease in k_t. A full description of the models used to explain the deviations from ideality is given in References 7 and 8.

Medium Conversion (5–65%). Polymerization continues in both the free monomer and polymer–monomer gel phases. This region shows the classical acceleration with increasing conversion (9). Since termination occurs primarily by the diffusion together and collision of two bulky macroradicals, it is considerably slower in the viscous polymer phase. As a result the termination rate constant is dramatically reduced and the rate of polymerization in this phase is much faster. As the amount of polymer phase increases, the rate of polymerization accelerates.

High Conversion (>65%). No free monomer is left to maintain the autogeneous pressure (which falls), and polymerization occurs in the polymer gel phase of rapidly increasing viscosity as the remaining VCM is consumed. Hence, the rate of polymerization increases still further to reach a maximum just after pressure drop but then decreases progressively owing to increasing monomer starvation. When the instantaneous polymerization rate falls below the overall rate of reaction the batch is terminated, either by venting off unreacted VCM to the recovery plant or by adding a chain terminator and then venting. Depending on the properties required, a conversion of 70–95% is chosen. It is uneconomic to continue to very high conversion, and as properties such as plasticizer absorption, dry-up rate (ie, the time taken to achieve a free-flowing PVC–plasticizer dry blend), and initial color/heat stability deteriorate rapidly above 85–90% conversion, most flexible resins are stopped at around 85% and rigid resins at around 90% conversion.

Morphology. Control of the morphology of each PVC grain is the main parameter controlling the quality of a PVC resin. This subject covers mean grain size, grain size distribution, and, most important of all, porosity (cold plasticizer absorption) and bulk density, which are closely interrelated.

Control of Grain Size. At the beginning of the batch the bulk vinyl chloride phase is broken down into droplets of 30–40 μm mean size under the influence of agitation and by the presence of the water-soluble protective colloid, which is adsorbed at the monomer–water interface. As polymerization proceeds, graft copolymerization of PVC onto the interfacial layer of protective colloid reduces its mobility and protective ability, and droplet coalescence begins to occur at around 4–5% conversion. As the conversion increases, changes in the surface layer of the droplet as a result of further polymerization suppress the droplet coalescence step, which ceases at 20% conversion, and the grain size remains largely constant for the remainder of the polymerization. Altering the stirrer speed after this point has no further effect on the mean grain size (MGS) (10) of the final product, which is controlled to between 100 and 180 μm, depending on resin type, by a combination of initial agitator speed and protective colloid(s) concentration and type.

Polymerizations with high concentrations of colloid and less agitation give spherical grains of low porosity ($\leq$10%) and very high bulk density ($\geq$700 g/L) and are of little interest, generally because of problems of VCM removal and poor gelation. Flexible resins are made with a low MGS (100–130 μm), rigid polymers with a higher MGS (150–180 μm), and low K resins with intermediate size (130–160 μm).

In extreme cases it is possible to stabilize the droplets to such a degree that no coalescence occurs. Specialized vinyl chloride monomer–vinyl acetate copolymers for gramophone record production fall into this category as do blending resins (30 μm MGS) for use as viscosity depressants in plastisols.

Alongwith achieving the desired MGS it is equally important to control the size distribution. A Gaussian distribution is normally produced and it is important to make this as narrow as possible since a coarse fraction (>250 μm) can give rise to fisheyes (dispersion faults), and make VCM removal difficult as well as result in loss of yield due to screen rejects, while fines (<60 μm) can be lost in aqueous and gaseous effluent or cause powder flow problems.

Control of Porosity and Bulk Density. Porosity in PVC grains is created by a complex series of interrelated steps in the formation and growth of the submicroscopic structure within each droplet and also depends on the unique nature of the VCM–PVC system.

PVC is insoluble in its monomer, and the growing oligomers start to precipitate when the chain length exceeds 10 monomer limits (1). This initial precipitation results in the formation of microdomains of about 15–20 nm in diameter (11). This occurs at as low as 0.001% conversion (12). The microdomains rapidly become unstable and aggregate to form domains (primary particle nuclei) of about 0.1 μm in diameter. After this stage no further domains are formed and the number of primary particles is fixed. All new PVC radicals that are produced in the monomer phase collide with and are precipitated onto the vast existing surface area of primary particles before a new domain can be formed. Since the existing PVC phase is swollen with monomer and contains initiator, initiator radicals, and growing chains undergoing chain transfer, primary particles grow rapidly by accretion of new microradicals and microdomains and by gel-phase polymerization. They in turn become unstable and a final agglomeration step to form 1–2 μm primary particle aggregates takes place. By the end of the polymerization the primary particles have grown to 1 μm within the aggregates, which themselves have grown to 2–5 μm. The whole mechanism is outlined in Table 5 and discussed in detail in Reference 13.

The arrangement of the aggregates of primary particles within each monomer droplet has a major influence on the morphology of the final PVC grain. The conversion of VCM of density 0.85 g/cm^3 at 52°C to PVC of 1.4 g/cm^3 produces a volume contraction of 39%. If the polymerizing droplets contract totally the final grain has no porosity. If, however, the contraction is prevented totally the final grain porosity can be as high as 39%. Therefore, the better the three-dimensional spatial arrangement of the aggregates relative to one another, the higher the porosity that is achieved.

The main aim of the polymer technologist is to create the best possible spatial network of aggregates relative to one another so that a network is formed that is strong enough to resist droplet contraction and hence maximize porosity. The sooner this is achieved in the polymerization the better the porosity attained. In practice 34–35% is easily achievable. At ca 65–70% conversion all of the free monomer is consumed, and the only VCM remaining is that swelling the polymer gel (27%) and in the vapor space and dissolved in the water. At this stage the voids in the grain (the porosity) are filled with batch water so that the quantity of water in interstitial spaces between the grains is reduced and a significant increase in slurry viscosity is observed since less mobilizing water is available to separate the grains.

The control of bulk density or apparent density (AD) is more important than even porosity to the processor. The latter is concerned with charge size and cycle times in high speed mixers, output rates, motor torque and degree of gelation in extruders, and mechanical properties of the article being produced. These parameters are very dependent on AD. The reason for introducing the control of porosity before control of AD is that the latter is very heavily influenced by the former. Apparent density depends on porosity, grain shape, and grain size distribution in order of priority and is best described by examining the packing fraction (PF)

Table 5. The Mechanism of VCM Polymerization[a]

Stage	Species		Conversion, %	Size	
				When formed	Finally
Initiation R1 + VCM →	Coiled macroradicals				
1st aggregation step			<1		
	Microdomain (ca 50 macroradicals)			10–20 nm	?
2nd aggregation step			1–2		
	Domain (primary nucleus) (ca 10^3 microdomains)			0.1–0.2 μm	
Growth (intraprimary)					
	Primary particle				0.6–0.8 μm
3rd aggregation step			4–10	(primaries now 0.2–0.4 μm)	
	Agglomerate			1–2 μm	
Growth (interprimary)					
	Fused agglomerate		90		2–10 μm

[a]From Ref. 13, courtesy of Elsevier Applied Science Publishers.

concept, ie, the ability of the somewhat irregular PVC grains to fill a space to the maximum efficiency.

$$PF = \frac{(1 + 0.014 \cdot CPA)(AD \cdot 0.1)}{1.4}$$

where CPA is cold plasticizer absorption (porosity).

Most extruders used in processing PVC are of the twin screw type and these operate like a simple pump: increasing the feed rate by 10% (10% higher AD) increases the discharge or output rate by 8–9% (see Chapt. 8 in Ref. 9). In practice, controlling porosity is relatively easy since a number of effective secondary stabilizers are available. Maximizing the AD is much more difficult since control of grain shape comes from a complex interaction of both agitation and choice of primary and secondary granulating agents together with in-house expertise of charging techniques and use of other additives. A range of grain shapes which can be produced is shown in Figure 5.

In practice typical property targets for porosity and AD are

(1) For flexible resins (K 70): porosity of ≥30% and AD of ≥500 g/L
(2) For rigid extrusion resins (K 66–68): porosity of 20% and AD of 580 g/L
(3) For bottle resins (K 57–60): porosity of 18–20% and AD of 560 g/L

***K*-Value (Molecular Mass).** PVC is again rather unique in its relationship between reaction temperature and *K*-value. With PVC the rate of polymer formation by chain–chain termination is small because of the influence of gel-phase polymerization described above. Instead, since chain transfer to monomer is a predominant step in the polymerization of VCM, the length of the polymer chain (degree of polymerization, DP) is determined by the ratio of the rate of chain propagation to chain transfer:

$$DP = \frac{\text{Rate of propagation}}{\text{Rate of chain transfer}} = \frac{k_P[R_n][M]}{k_{tr}[R_n][M]} = \frac{k_p}{k_{tr}}$$

where
[M] = monomer concentration
$[R\cdot_n]$ = radical concentration
k_p = propagation rate constant
k_{tr} = chain-transfer rate constant

As k_p and k_{tr} depend only on temperature the molecular mass of PVC is controlled by the reaction temperature (see Fig. 6).

If a particularly low molecular mass polymer is required or if a reactor's pressure rating is too low to operate at very high temperatures, an additional chain-transfer agent can be employed. This reduces the molecular mass by increasing the chain-transfer rate constant above that for monomer alone in the above equation. As a result DP decreases, depending on the quantity of chain transfer agent used.

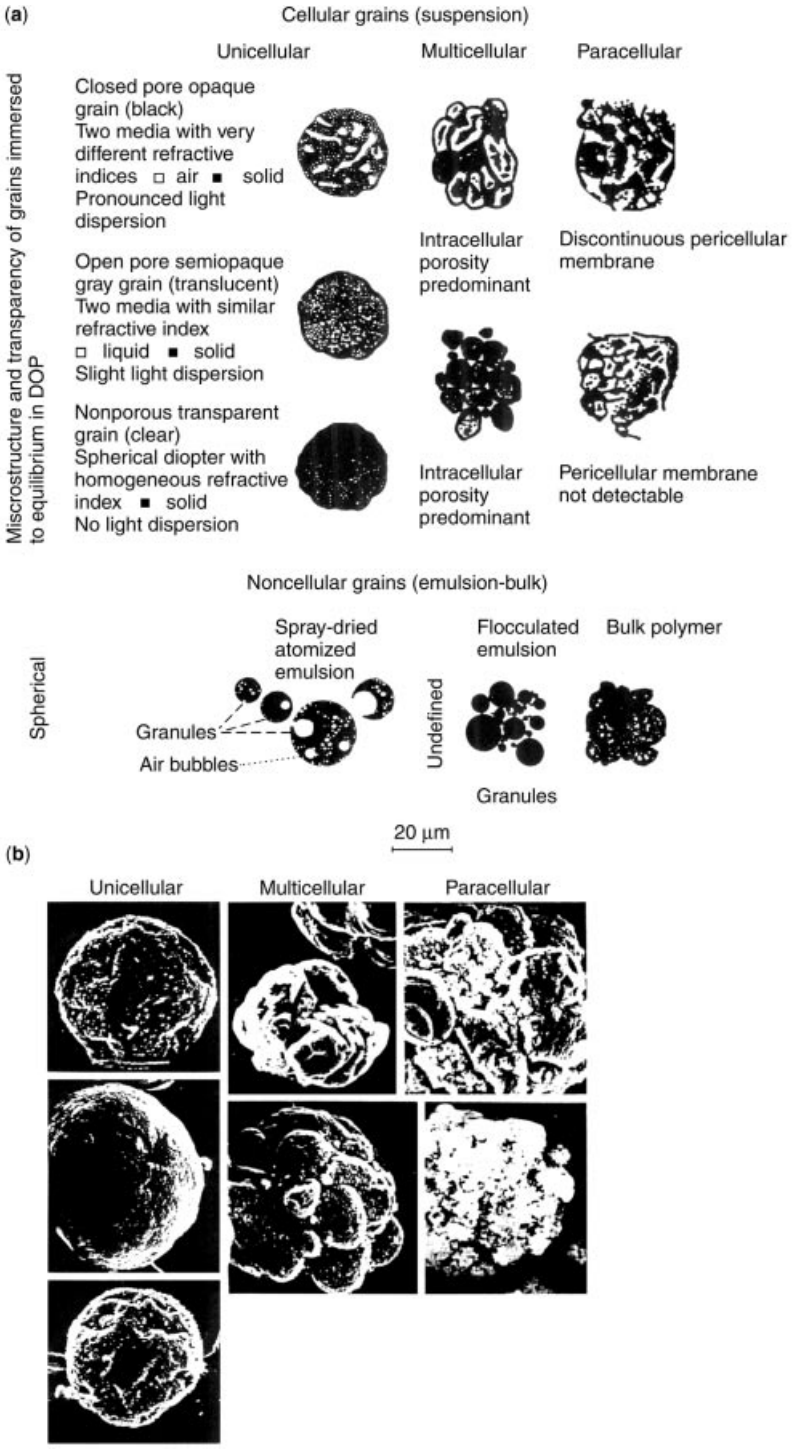

Fig. 5. (**a**) Classification of PVC grains and (**b**) typical cellular PVC grains—layout as in Figure 6a From Ref. 13, courtesy of Elsevier Applied Science Publishers.

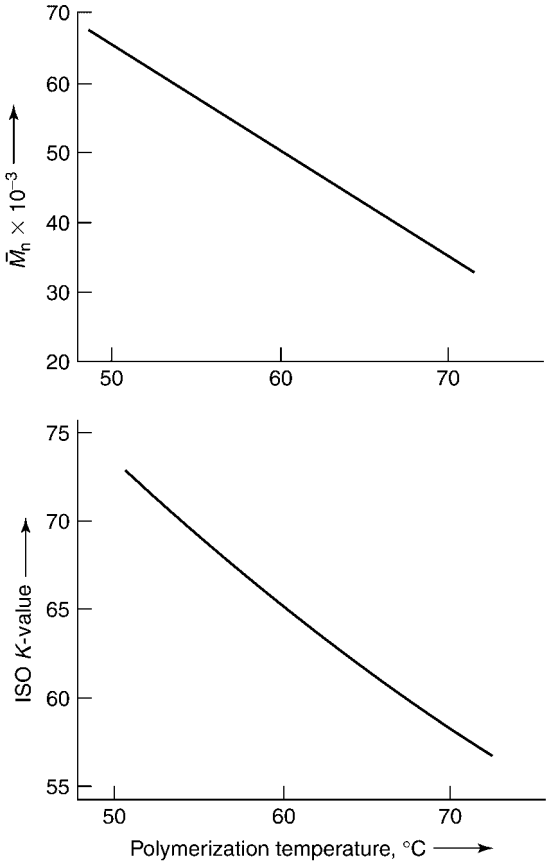

Fig. 6. The effect of temperature on molecular mass and *K*-value.

The general *K*-value range of commercial resins is K 55 to K 75, with a few producers providing speciality resins outside this range to K 50 and K 80 and with just one or two K 90–100 polymers also being available. Despite the relatively narrow *K*-value/molecular mass range of most commercial resins (see Table 6) the polar nature of the PVC chain gives rise to a considerable melt viscosity span. Mechanical properties increase slightly with increasing *K*-value; so wherever possible the highest *K*-value polymer is used. However, the power and mechanical robustness of equipment and the complicated melt-flow pattern requirements in molds often restrict the *K*-value which can be used. For example, most bottles are made from K 57 polymers, some from K 60, but this is the limit for the application because bottles are blow-molded, thus restricting the melt viscosity that can be handled.

Problem Areas. There are relatively few problems in the operation of the suspension polymerization process. However, to obtain the best possible quality and consistency some points need special attention.

In the past, reactor fouling was bad and mechanical cleaning between each batch essential. With the advent of clean-wall technology, high pressure rinse

[a]From Ref. 44, courtesy of Elsevier Applied Science Publishers.

systems, and improved recipes it is now possible to operate in a closed manner, thereby reducing problems of VCM exposure (see Chapt. 5 in Ref. 9). Reactor opening for cleaning is reduced to once in several hundred batches. It is essential to ensure that the reactor is rendered completely free of polymer between batches since this is the most common cause of fisheyes. Equally important is to ensure there is no chance of cross-grade contamination in the downstream operations of slurry handling, stripping, drying, and storage. Contamination of the product by foreign substances is eliminated by good housekeeping and plant management together with the right choice of metals of construction and design. Stainless steel is widely used in many sections of PVC plants.

Bulk or Mass Polymerization

The mass polymerization process is virtually identical to that taking place within each monomer droplet in the suspension process. As such the mechanism and kinetics are very similar to those described previously. The major difference is in the mechanical operation of the process.

About 10% of world PVC production is provided by the mass process. The process was developed by Pechiney St. Gobain (PSG) who are now part of the

French ATO Co. All mass producers are licensees of the PSG technology. The process is carried out in two stages:

(1) In the first stage monomer and initiator are charged and vigorously agitated in a vertical, stainless-steel autoclave (prepolymerizer) of 8–25 m^3 capacity, fitted with a water-cooled jacket and condenser. Rapid polymerization takes place at 62–75°C to give ca 100 μm aggregated spherical flocs composed of 0.1 μm primary particles, which form the basis or seeds of the final PVC grain. Conversion is taken to 7–12% in ca 30 min, by which time the initiator used is exhausted.

(2) The slurry from the prepolymerizer is discharged into the second-stage reactor, which has a volume of 12–50 m^3, with fresh initiator and more VCM. Up to five second-stages can be fed from one prepolymerizer. In the second stage the 0.1 μm primary particles making up each seed grow in size and fuse together to give the final grain of PVC of 130–160 μm diameter. As the conversion increases the physical nature changes from a wet powder at ca 20% to a dry one at 40% conversion. The heat of polymerization is removed from the growing grains by evaporation of the VCM and condensation on the cooled wall of the reactor or in a water-cooled reflex condenser(s). The second stage takes 3–9 h, depending on *K*-value.

Originally, the second-stage reactor was a horizontal jacketed vessel with one or more condensers, agitated by slowly rotating (6–10 rpm) ribbon blenders with some blades set very close to the reactor wall to keep it clean. However, it proved difficult to discharge and clean the reactor to a sufficiently high standard to prevent the formation of fisheyes (dispersion faults) in PVC grades intended for plasticized applications (15). The product can contain up to 10% of coarse material, which must be sieved out and recovered by grinding, milling, and reclassifying.

This led to the development in 1978 of a vertical second-stage reactor of up to 50-m^3 capacity fitted with two independent agitators designed to overcome the above discharge problems. However, there has been little interest in this development and all recent investment in new PVC plants has been in the suspension process. In theory the mass process should be cheaper since it does not need a drying stage. However, it is a two-stage process, it is difficult to remove traces of unreacted monomer, and it gives a significant amount of oversized material, all of which offset its advantages.

Several of the smaller and older mass-polymerization plants have closed in recent years because they find it more and more difficult to meet increasingly stringent environmental standards and are becoming less and less competitive compared to suspension-polymerization plants on the basis of production rate.

The mass process is discussed in more detail in References 15 and 16.

Emulsion Polymerization

The emulsion polymerization process involves the polymerization of monomer in an aqueous medium containing surfactant and a water-soluble initiator, producing PVC lattices. PVC lattices are colloidal dispersions of spherical particles, ranging

Table 7. World Emulsion PVC Production in 1989

Region	Production, 10^3t	Percentage
Western Europe	720	42
United States	292	17
Japan	149	9
Rest of the world	544	32
Total capacity	*1705*	*100*

in size between 0.1 and 3.0 μm. Most PVC lattices are spray-dried and then milled to obtain fine powders, made up of agglomerates of latex particles. When mixed with plasticizers they disperse readily to form stable suspensions. During mixing, most of the agglomerates are broken down into the original latex particles. Such dispersion of fine particles in plasticizers are known as plastisols or pastes, and the powder is called dispersion or paste polymer. The surfactant layer around the particle surface prevents their adsorbing the plasticizer at room temperature and so they can be used as liquids and may then be spread onto fabric or other substrates, poured on molds, or deposited on formers to produce flooring, wall covering, artificial leather, balls, toys, or protective gloves. There are other grades of PVC polymers, produced by emulsion polymerization, that do not form plastisols and that are used as blends with suspension PVC grades for extrusion application or in the manufacture of battery separator plates. These so-called emulsion polymers are of only minor economic interest. Sales in latex form are very limited; lattices are used in water-based paints, printing inks, and impregnated fabrics. The total production capacity of emulsion PVC is given in Table 7.

Emulsion Polymerization Processes. The ways to produce PVC lattices are

(1) The classic emulsion polymerization, in which the particle size and particle size distribution are controlled by a water-soluble initiator and a surfactant (17–21). They are monodisperse with a particle size typically less than 0.1 μm.

(2) Seeded emulsion polymerization, in which the particle size distribution of the final latex depends on the amount and the size of the latex used as seed and on the amount of surfactant and the way in which it is added (22,23). A typical material has 0.2 and 1.2 μm particles (see Fig. 7).

(3) Microsuspension polymerization, in which a monomer-soluble initiator is used. Polymerization takes place within the fine droplets in which the monomer is dispersed by passing a coarse emulsion of monomer, initiator, and surfactant through a mechanical homogenizer (24–26). The resulting particle size distribution is Gaussian between 0.2 and 1.2 μm.

(4) Polymerization of fine emulsions achieved by using a combination of a typical surfactant such as sodium dodecyl sulfate and a long-chain fatty alcohol. This gives rise to spontaneous emulsification of the monomer into very fine droplets. In this case the polymerization can be carried out by using a water-soluble or a monomer-soluble initiator (27). The latex particle size distribution is the same as for microsuspension polymerization.

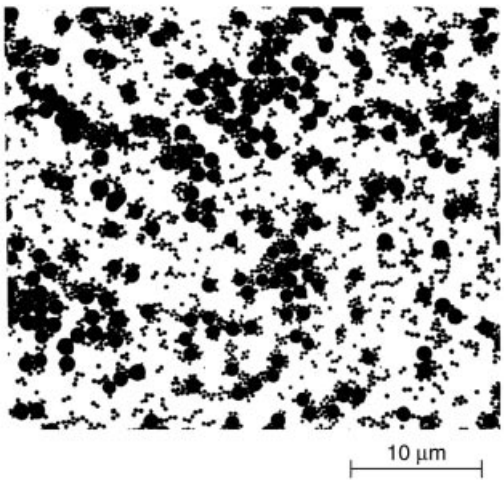

Fig. 7. Electron micrograph of latex particles obtained by seeded emulsion polymerization.

The industrial polymerization techniques used for carrying out these processes are the following:

(1) Batch polymerization where all the monomer is charged at the beginning
(2) Semibatch or semicontinuous polymerization, with the monomer added in stages or continuously as reaction proceeds
(3) Continuous polymerization where monomer and other components are fed continuously into the reactor and the latex is withdrawn from the bottom of the reactor

All these processes are in current use to achieve a wide range of latex characteristics, which are related to the rheological properties of the PVC plastisols (28).

Description of the Batch Process. The emulsion polymerization of PVC consists of the following stages: (*1*) polymerization, (*2*) VCM removal, (*3*) latex storage, (*4*) drying, (*5*) milling, and (*6*) packing and storage. Figure 8 shows a schematic representation of the stages required for a plant which produces all the emulsion, seeded, and microsuspension grades.

A recipe for a simple batch emulsion polymerization (in parts by weight) is as follows:

Demineralized water	110–140
Vinyl chloride	100
Emulsifier	0.1–1
Initiator	0.1–0.2

The polymerization takes place in an autoclave resistant to the VCM vapor pressure. Pressures of 6.4–10.0 bar correspond to polymerization temperatures of 40–60°C, depending on the desired molecular mass. The polymerization reaction

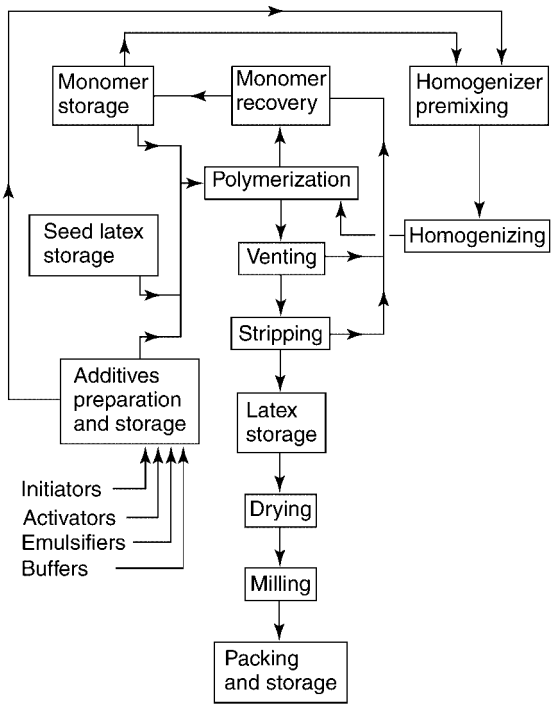

Fig. 8. Schematic representation of the stages required for a plant which produces all emulsion, seeded, and microsuspension grades.

is strongly exothermic with a heat of polymerization of 1534 kJ/kg. Heat removal can be a problem as the size of the autoclave increases because the ratio between surface area and volume becomes less favorable. For this reason industrial plants commonly use water cooling, and external condensers. Modern plants use autoclaves with capacities ranging between 30 and 80 m^3. Large autoclaves can present agitation problems because low shear rates are required to maintain mechanical stability of the latex and to avoid coagulation.

Initiators. Although organic peroxides slightly soluble in water such as methyl ethyl ketone peroxide and 1-hydroperoxy-1′-hydroxydicyclohexyl peroxide can be used, the most widely used initiators are ammonium or potassium peroxosulfate. Their decomposition in aqueous solution is first-order with respect to the peroxosulfate ion concentration (29). The rate may be increased significantly by using a reducing agent. Redox catalysis involves the use of transition-metal ions such as copper or iron (30). The systems widely used in emulsion polymerization of vinyl chloride are potassium peroxosulfate–sodium bisulfate–copper or iron. Redox systems can also be used in microsuspension, an example being dilauroyl peroxide–copper–ascorbic acid (31).

Emulsifiers. Emulsifiers are very important in the emulsion polymerization of vinyl chloride because they determine not only the latex characteristics but also the properties of the final product (32–34). Moreover, the nature and the

concentration of the emulsifier, together with the agitation, are major parameters controlling the mechanical stability of the latex during polymerization and handling, and the major cause of reactor wall encrustation and lump formation. Since the latex is dried by spray drying, the emulsifier remains in the resin and can influence properties of the product such as the flowability of the powder, plastisol formation, the viscosity of the plastisol, and also the properties of the final article such as heat stability, water adsorption, and coat adhesion. For this reason a wide variety of emulsifiers are used. During polymerization anionic types are usually used, while nonionics are generally added to the latex after polymerization. Typical emulsifiers are the sodium salts of alkyl sulfates, alkyl sulfonates, alkylbenzenesulfonates, dialkyl sulfosuccinates, alkyl ethoxysulfates, fatty acid soaps, alkyl phenol ethoxylates, and fatty acid ethoxylates.

Particle Formation. Emulsifiers are characterized by the critical concentration at which their molecules aggregate to form micelles (35,36). In Figure 9 a plot of surface tension versus emulsifier concentration is shown; the point at which the curve exhibits a marked change is known as the critical micelle concentration (CMC). Conventional emulsion polymerization is carried out at a concentration above the CMC. In this way, particle formation is controlled by the micelles, which solubilize the monomer by swelling and become the loci of polymerization. The nucleation phase stops when the micelles disappear, and the emulsifier is absorbed onto the surface of the particles. Depending on the balance between the hydrophilic and hydrophobic part of the molecule, each emulsifier plays a specific role in the emulsion polymerization, as they have different CMC values, surface covering powers, and stabilizing effects.

VCM Removal. The polymerization is terminated at 90% conversion and is followed by the venting of unreacted monomer to a gas holder. After degassing, the latex contains 3% vinyl chloride and further reductions must be made to fulfil legal requirements for environmental protection. The residual VCM is removed by stripping under vacuum in a stripping vessel. Although VCM loss from particles

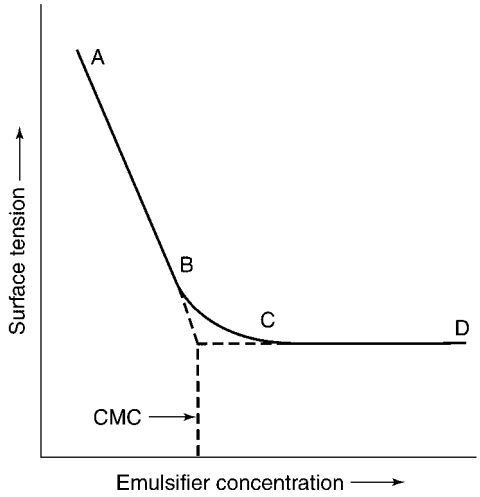

Fig. 9. Dependence of surface tension on emulsifier concentration.

by diffusion is fast, VCM removal from an emulsion is much more difficult than from suspension slurries as the surfactants lead to large amounts of foam formation. Continuous processes using a thin-film evaporator or which spray the latex into an evacuated chamber against a countercurrent stream of gas reduce considerably the problems of foaming and coagulation (37–40). The residual vinyl chloride monomer content of the latex after stripping ranges between 200 and 2000 ppm, depending on the type of latex and the operating conditions.

Drying and Milling. Although there are several different techniques to separate polymer from water, such as freeze drying, drum drying, or coagulation followed by centrifugation, the most widely used is spray drying because this confers a special structure to the dried particle that is important for the production of plastisols. A fine spray of latex is introduced into a hot air stream where evaporation takes place.

The spray is obtained by various types of atomizers, such as

(1) Spinning disks or wheels rotating at 15,000–20,000 rpm
(2) Single pressure nozzles operating at 10–50 MPa (100–500 bar)
(3) Two-fluid pressure nozzles using compressed air up to 0.4 MPa as atomizing fluid (41)

The drying air temperature at the inlet is 150–240°C and at the outlet, 55–80°C, depending on the quality of the required product and the type of latex. By varying the drying conditions it is possible to change the resin characteristics, and hence its use, even from a typical paste grade to a general-purpose emulsion resin, eg for rigid extrusion. The dry powder consists of spherical aggregates, with the size usually ranging from 1 to 100 μm in diameter with an average of 30–40 μm. The aggregates are called secondary particles, to distinguish them from those of the latex, which are known as primary particles. The way the aggregates form is complex and depends on many parameters such as primary particle size, type and amount of emulsifier, mean residence time in the drying chamber, droplet size of the spray, and temperature (42). Figure 10 shows a scanning electron micrograph of spray-dried PVC particles formed from bimodal seeded latex.

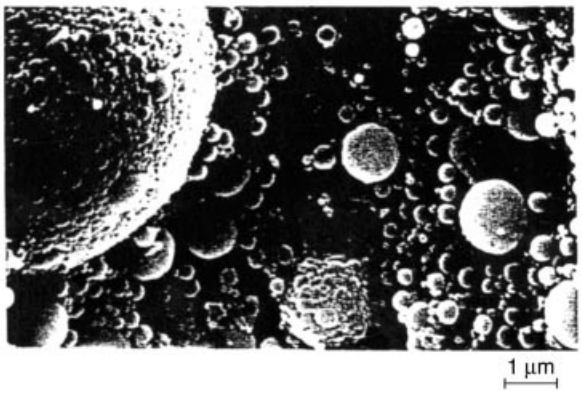

Fig. 10. Scanning electron micrograph of spray-dried PVC particles produced from bimodal seeded latex.

Plastisol-grade resins, usually made from multimodal latex (ie, with a Gaussian particle size distribution), are milled to reduce the size of the coarse fraction, which can cause problems in coating applications of the plastisol. Generally the viscosity of the plastisol increases when the polymer has been milled, and so it is desirable to reduce milling as far as possible and to use air classification to remove the coarse fraction (>65 μm) under control. In industrial production, air classifiers or mills or a combination of both are used. After milling, the average particle size of the resin is in the range of 5–15 μm.

Polymers for rigid extrusion and for manufacturing plate separators in batteries are sold in unmilled form. Resins are characterized by analysis of molecular mass, emulsifier and salt content, pH of aqueous extract, granulometry, and viscosity and rheological behavior of the pastes.

Plastisols. Plastisols, commonly called pastes, are dispersions of PVC powders in plasticizers. A wide range of plasticizers are used in plastisol formulations, but the most widely used are C_4–C_{12} esters such as phthalates, adipates, azelates, sebacates, trimellitates, and phosphates. Chlorinated paraffins are used as secondary plasticizers. A good plasticizer should have low volatility, low color value, neutral reaction, resistance to hydrolysis, insolubility in water, flame resistance, and nontoxicity. As no plasticizer can satisfy all these properties, several plasticizers are mixed to achieve the desired properties of the final product. Table 8 shows the influence of plasticizers on plastisol properties; Table 9, the influence of plasticizers on final product properties; and Table 10, the influence of resin characteristics on plastisol and final product properties.

The amount of plasticizer used in plastisol formulations plays a major role in determining the hardness and flexibility of the end product and can vary from 40

Table 8. Influence of Plasticizers on Plastisol Properties

Plastisol properties	Plasticizers[a]
Low fusion temperature	DBP, BBP, TCP
Low viscosity	DOA, DOS, DIPA
High viscosity	BBP, TCP, polymerics
High fusion temperature	DIDA, DOZ, DTDP, DOS, polymerics

[a]DBP = dibutyl phthalate, BBP = butyl benzyl phthalate, TCP = tricresyl phthalate, DOA = dioctyl adipate, DOS = dioctyl sebacate, DIDA = diisodecyl adipate, DOZ = dioctyl azelate, DTDP = ditridecyl phthalate.

to 130 phr. In Figure 11 the influence of plasticizer content on plastisol viscosity is shown.

The other essential ingredients in plastisol formulations are as follows:

(1) Heat stabilizers, which generally are the same compounds used for suspension polymers.

(2) Dyes and pigments suitable for coloring plastisols. The most widely used is titanium dioxide.

(3) Fillers, generally inorganic materials such as calcium carbonate, barite, silicate, kaolin, or china clay, are used primarily to lower costs and also to impart special properties such as hardness, abrasion resistance, and no sticking.

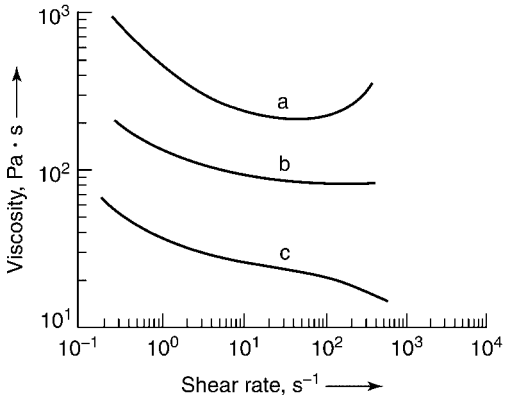

Fig. 11. Influence of plasticizer content on plastisol viscosity: a, PVC/DOP = 100/40; b, PVC/DOP = 100/50; and c, PVC/DOP = 100/60 [DOP = dioctyl phthalate].

(4) Blowing agents for foamed PVC production such as azodicarbonamide.
(5) UV adsorbers to prevent the decomposition action of sunlight.
(6) Esters of poly(ethylene glycol), phosphate esters, and fatty acid amines and amides are usually employed as antistatic agents.
(7) Viscosity depressants, such as white spirit, poly(ethylene glycol) monolaurate, alkylphenols, and low molecular mass paraffins.
(8) Extender resin or filler polymer—a PVC grade of spherical form, made by the suspension process and therefore cheaper than dispersion resin, which is used to reduce cost and viscosity of the plastisol (43,44).

In Table 11 the influence of plastisol ingredients on the final product characteristics is shown.

Polymer–Plasticizer Interaction. Figure 12 illustrates the types of dependence of viscosity on shear rate:

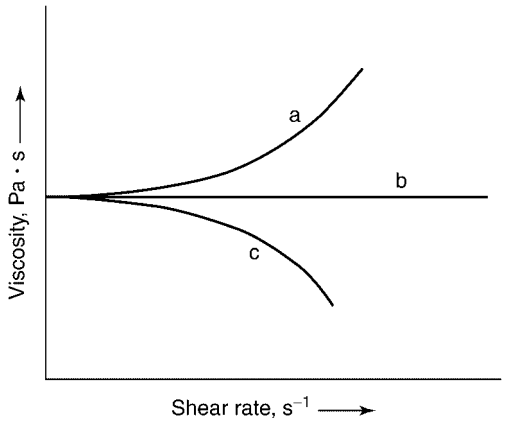

Fig. 12. Effect of shear rate on dilatant: a, Newtonian; b, pseudoplastic, and c, fluids.

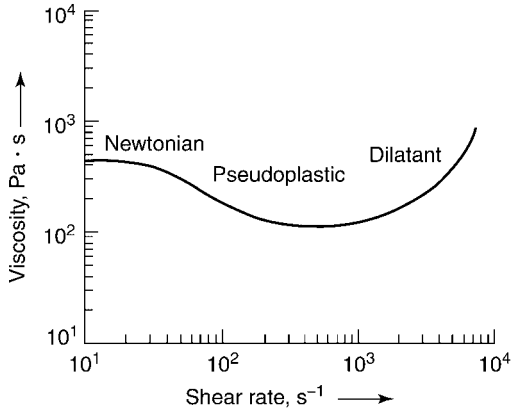

Fig. 13. Effect of shear rate on the PVC plastisol viscosity (DOP/PVC = 100/50 at T = 25°C).

(1) Newtonian (viscosity is independent of shear rate)
(2) Pseudoplastic (viscosity decreases as shear rate increases)
(3) Dilatant (viscosity increases with increasing shear rate)

Over a wide range of shear rate a plastisol may exhibit all three types of behavior since the viscosity of plastisols rarely displays true Newtonian behavior. At low shear rates they are generally pseudoplastic, at intermediate values they show dilatancy, and may sometimes become pseudoplastic again at higher shear rates, as shown in Figure 13. There is no certainty on the exact mechanism as the rheology of PVC plastisols is complex and affected by many factors such as

(1) Polymer/plasticizer mixing ratio
(2) Type of plasticizer and its interaction with polymer
(3) Particle size and their distribution of primary particles
(4) Structure, shape, porosity, and surface of the secondary particles
(5) Surfactants, added during polymerization or in the paste
(6) Molecular mass and molecular mass distribution
(7) Paste-making conditions such as mixing temperature, time, and intensity (45).

Gelation and Fusion. *Gelation* is defined as the change from liquid to semisolid state, and fusion, when a homogeneous phase at molecular level between polymer and plasticizer is reached. These processes have been examined by determining viscosity changes of the liquid system, the tensile strength, and changes in complex viscosity and viscoelastic properties over the temperature range 25–200°C.

At the beginning of heating, plasticizer viscosity decreases, as does the plastisol viscosity. At the same time, polymer particles adsorb plasticizer and swell, reducing the fraction of liquid plasticizer, and the viscosity then increases rapidly. When the liquid phase is completely absorbed by the particles, the system

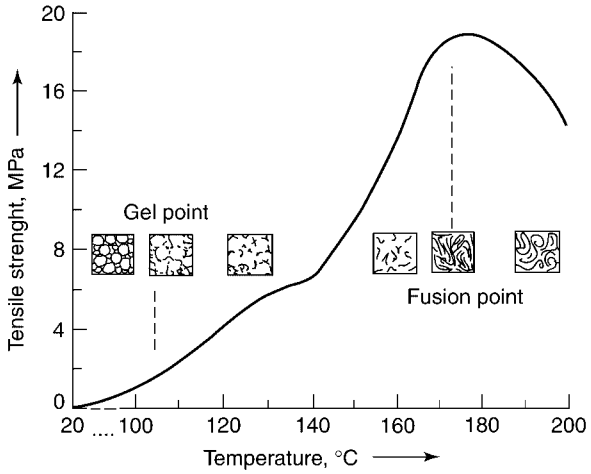

Fig. 14. Changes in morphology and mechanical properties of PVC plastisol during gelation and fusion.

becomes dry. As the process continues the interparticle boundaries disappear and the polymer chains become increasingly entangled and development of the physical properties begins. At this point the gelation stage is complete and the fusion process starts, as illustrated in Figure 14. Further heating of plastisol makes the polymer flow in a continuous mass. The melt viscosity, after having reached a maximum, starts to decrease and the process passes through the fusion stage. Morphology of the particles, particle size, particle size distribution, and molecular mass of the resin affect the viscosity behavior. Low molecular mass resin starts the gelation phase earlier and completes the gelation process at lower temperature. The same result is obtained by using plasticizers with higher solvating action, while larger particle size increases gelation temperature or time because it slows the penetration of the plasticizer into the resin (46).

Applications. Vinyl plastisols can be applied by spread coating, knife coating, roll coating, molding, dipping, and spraying; the most widely used application is coating.

Coating. Vinyl plastisol can be used to coat paper, fabrics, metals, felt, and glass fibers to produce wallpapers, floor coverings, vinyl leather, conveyor belts, and tarpaulins. Each application needs its own formulation, in which the appropriate resin grade and plasticizer must be used to give the required rheological characteristics. In the case of fabric coating where direct spreading is employed, it is important to avoid penetration of plastisol into the fabric; therefore, the viscosity behavior of the paste must be strongly pseudoplastic at low shear rate and have moderate viscosity at high shear rate. In wallpapers, where thin coatings are applied, a low viscosity resin with Newtonian behavior is required. In production of floor coverings, three or even four coatings are applied: an impregnation layer to saturate the fibers, one or two foam coats, and a wear layer with high mechanical strength. Each coat, which needs different grade resin to achieve the required properties, is gelled at 150°C before application of the next layer. When the last coat is applied the entire coating is fused in an oven at 200°C. The foam layer can

be chemically or mechanically foamed (47). Usually mechanical embossing is used to create surface textures and apply colored patterns.

Dipping. The product, mainly work, household, and surgical gloves, is obtained by dipping metal or ceramic molds or an article to be coated into the plastisol and then withdrawing it, draining it, and then curing it in an oven.

Molding. This is used for producing hollow articles such as balls, dolls, and toys. The process requires a plastisol with low viscosity at low shear rate that has a short gelation time and is easy to deaerate. In rotational molding the plastisol is poured into a cold mold that rotates around two perpendicular axes whilst entering an oven where it is heated with air to 200–250°C. After gelation and fusion, the mold is cooled in a waterbath.

Further information is given in References 28,35,36,41,44, and 48–50.

Chlorinated Poly(Vinyl Chloride) (CPVC)

The softening point (heat distortion temperature or T_g) of PVC can be increased by chlorination of the polymer, either in a solvent or as a suspension. The normal chlorine content of 56.7% is raised to 63–68%, depending on type, and this increases the softening point from ca 78–83°C (depending on formulation) to at least 120°C.

The older method involves chlorination of the PVC dissolved in a chlorinated solvent, but the process is expensive because of the need for an extensive solvent recovery system. However, it has the benefit of yielding a homogeneous material. The product is difficult to handle physically because of its very low bulk density.

The most common commercial process in use today disperses the PVC grains in water and swells them with a chlorinated hydrocarbon. The reactor is degassed to remove oxygen and heated to reaction temperature (50–60°C); chlorine is added continuously and the system irradiated with UV light to produce chlorine radicals. Hydrogen chloride is produced as a by-product and is removed at the end by washing with an inorganic base, after which the product is dried (51). The degree of chlorination is variable, with the surface layers of the grains being preferentially treated.

CPVC is less thermally stable than conventional PVC and requires higher temperatures to develop good mechanical properties. Hence, it is difficult to process and quite expensive, but blends with suspension PVC can be used to achieve a specific softening point. CPVC products have not been very successful commercially but have found a specific niche in the market. They are used for hot-water systems in mobile homes in the United States and for the manufacture of fibers, for use in thermal underwear, in France.

Environmental Protection

Potential problem areas associated with the production, handling, and use of PVC are small if a few simple measures to avoid environmental contact and pollution are followed.

Losses of VCM from polymerization plants have been reduced to extremely low levels following conversion to closed-lid operation as a result of toxicological problems (9). Although modern column strippers reduce VCM levels in PVC to less than 10 ppm, a small quantity of VCM is lost from the drier section. The older batch strippers present more of a problem since they cannot achieve such low residual VCM contents.

PVC powder can be lost in centrifuge and scrubber effluent and by overfilling stock tanks and from pipeline leaks. It is important that all plant drains which are likely to contain PVC are directed to settling pits where flocculation treatment can be used so that the final discharge is free of PVC. All wet waste is collected and reclaimed as second- or third-grade material for use in noncritical applications such as one-trip horticultural products and fencing.

Powder losses from drier stacks can be minimized by ensuring that drier cyclones are adequately sized to the air conveying rates used. Some modern plants use bag filter systems to meet current regulations that restrict the amount of PVC dust loss to 50 mg/m^3 air (52).

Compared to other polymers and typical metals PVC requires less energy per unit weight for its production (53). Although plastics in general are blamed for long-lasting litter problems, it is significant that only 12% of PVC is used for consumables, while 64% is incorporated into products with an expected useful life of 15 years or more, probably much more. Disposal is therefore less of an immediate problem than is often thought.

As landfill sites are used up more municipal waste is being incinerated. Though inherently nonflammable, PVC will burn in an existing fire to release hydrogen chloride gas, which can be scrubbed out satisfactorily. Fears about the increased release of dioxins during incineration owing to the presence of PVC in waste have proved to be unfounded (54).

Quality Specifications and Analysis

All PVC producers test a number of parameters on every batch produced as part of routine quality control operation. These include *K*-value, mean grain size and grain size distribution, apparent density, porosity, contamination, dispersion, color and heat stability, and residual VCM content. Most plants use statistical process control techniques to ensure that product consistency from batch to batch meets the stringent requirements of today's customers. It is difficult to give a typical testing regime since every plant makes batches of different size, has slurry blending facilities of differing degrees of sophistication, and has hoppers of different capacity on their drying plants. For a modern plant operating large autoclaves there is considerable testing of each polymerization batch (wet stage) together with additional testing of the dried and blended material as a cross check.

In-house tests have been collected and correlated by national and international standards organizations to make them universally applicable. ISO has defined tests and standards set up by other organizations such as the ASTM and DIN so that ISO methods are now widely accepted worldwide. ASTM D1755 defines a system for classifying general-purpose (mass and suspension) and dispersion (paste) resins (55).

Storage and Transportation

Most plants handle more than 80% of their production in bulk, and storage and supply in 25-kg bags is diminishing all the time as customers convert. After drying, the material is conveyed by blow-eggs (vessels in which the powder is pressurized and fluidized) of 2–15-t capacity via pipeline to the silo farm where it is stored in silos of capacity 100–500 t. PVC is discharged either directly or via a smaller loading hopper into 20-t road tankers, the most popular form of PVC transportation. Sometimes big bags made of woven polypropylene are used for 1-t lots of PVC, and 20-t ISO metal containers are used for long-distance deliveries. PVC is not a difficult material to handle and the logistics side of the operation is straightforward. It is essential to prevent cross-contamination of the PVC by other products and thorough intertrip cleaning is essential, since many operators use their tankers for back carriage of a wide range of products, many nonpolymeric.

Processing and End Uses

Because of its unique combination of properties PVC is never handled on its own. Instead a complex formulation incorporating several additives is used. A typical base formulation contains PVC resin, heat stabilizer(s), internal lubricant(s), external lubricant(s), processing aid, and additionally, impact modifier, filler(s), pigment, UV stabilizer, as well as primary and secondary plasticizers (see HEAT STABILIZERS; PLASTICIZERS; UV STABILIZERS).

PVC is intrinsically unstable because of molecular defects in some of the polymer chains (56,57) and when subjected to heat they initiate a self-accelerating dehydrochlorination reaction. Stabilizers neutralize the HCl produced and introduce nucleophilic substitution reactions that prevent further degradation (56,57) (see DEGRADATION).

The Ca–Zn stabilizer family is becoming increasingly popular as objections to the use of heavy-metal systems are increasing. In Europe withdrawal of cadmium stabilizers was planned for the end of 2001, and although it has been shown that use of the highly effective lead stabilizers is safe, adverse publicity will slowly erode their market position.

Table 12 gives a summary of the heat stabilizers in regular use.

The polar, highly viscous PVC melt sticks easily to metal walls of extruder barrels, calenders, mills, etc, and so an *external lubricant* is employed to assist the smooth passage of the melt. *Internal lubricants* help to reduce melt viscosity and prevent overheating and so help to ensure good color of the final product. *Processing aids* improve the surface appearance of extruded sections and reduce melt defects such as screw memory, where the helical nature of the screw can be seen as regular ripples in the pipe surface. Many other additives can be used, eg, *impact modifiers* for bottles and uv stabilizers and *fillers* (eg, TiO_2) for house sidings and window frames, to ensure the best possible in-service performance or longevity.

In all extrusion and some other conversion processes the PVC grain is not broken down to its constituent primary particles (58), unlike emulsion PVC processing. Instead the suspension grains (150 μm) gradually lose their original form

Table 12. Heat Stabilizers for PVC

Stabilizer	Properties
Lead stabilizers	
Lead soaps	Good heat stability
Lead salts	Sulfur staining
Liquid lead complex	Lead phosphites give good light stability
Lead one-pack systems	Kickers for chemical blown foam
Tin stabilizers	
Organo sulfur tin	Excellent heat stability, good clarity; poor light stability
Organo tin carboxylates	Medium heat stability; excellent light stability
Barium–zinc stabilizers	
Ba–Zn liquid	Good heat and light stability on high quality grades; general-purpose stabilizers.
Calcium–zinc stabilizers	
Ca–Zn soaps	Low toxicity
Ca–Zn liquid	Medium heat and light stability
Organic costabilizers	
Thiourea derivatives	Synergistic effects with epoxy plasticizer and/or Ca–Zn, Ba–Zn
Indol derivatives	
Amino crotonic acid esters	
Diketones	
Organic phosphites	
Antioxidants	
Epoxidized soybean oil (ESBO)	Synergistic effect with Ca–Zn and Ba–Zn
Epoxy esters	

by fusion and elongation under the influence of heat, pressure, and shear so that in badly processed PVC grain memory can be detected by optical microscopy of cross sections of extrudates (58). In practice, converters take great care to ensure that the degree of gelation (ie, lack of grain memory) in the final PVC article is very high. Degree of gelation can be measured by determining the degree of attack by a poor solvent such as acetone or methylene chloride or by measurement of flow pressure to assess the strength and elasticity of partially fused material directly (59).

The enormous subject of processing, including different aspects such as formulations, types of processing equipment, gelation, rheology, and mechanical properties is covered more widely in References 14,58, and 60–63.

Table 13. Typical End Uses for PVC

Application	Rigid PVC	Flexible PVC
Construction	Window frames, gutters, pipes, cars, housesiding, ports, roofing	Waterproof membranes, cable insulation, roof lining, greenhouses
Domestic	Curtain rails, drawer sides, laminates, audio and video tape cases, records	Flooring, wall coverings, shower curtains, leathercloth, hosepipes
Packaging	Bottles, blister packs, transparent packs and punnets	Cling film
Transport	Car seat backs	Underseal, roof linings, leathercloth upholstery, wiring insulation, window seals, decorative trim
Medical		Oxygen tents, bags and tubing for blood transfusions, drips and dialysis liquids
Clothing	Safety equipment	Waterproofs for fishermen and emergency services, life-jackets, shoes, wellington boots, aprons and baby pants
Others	Floppy-disk covers, credit cards	Conveyor belts, inflatables, sports goods, toys

The versatility of PVC can be gauged by the very broad summary of typical end uses given in Table 13.

Economic Aspects

Fear of litigation, the need to handle VCM (a known carcinogen), and reduced funding have all but eliminated fundamental research into VCM polymerization. Work on processing of PVC continues, but at a much reduced level. Many companies have scaled down R&D and process development, and raw material suppliers are now increasingly responsible for technological developments.

Since 1992 the main trend in the PVC industry has been survival by amalgamation. Some well-known companies, including pioneers from the 1940s (eg, B.F Goodrich/GEON, ICI, and Chisso) have disappeared through aquisition, and many others have formed larger conglomerates to survive. The current feeling in the industry is that a minimum capacity of 500,000 t/a is required for a viable operation.

Irresponsible investment in new plant near the peak of the economic cycle has resulted in overcapacity, weakened prices, lower company profits, and economic casualties, just as it did in ca 1990. Even the staid Japanese PVC industry has seen amalgamations and plant closures since ca 1995, and the former 15 companies have been reduced to just five major production groups. Changes in the Western European PVC scene are summarized in Figure 15.

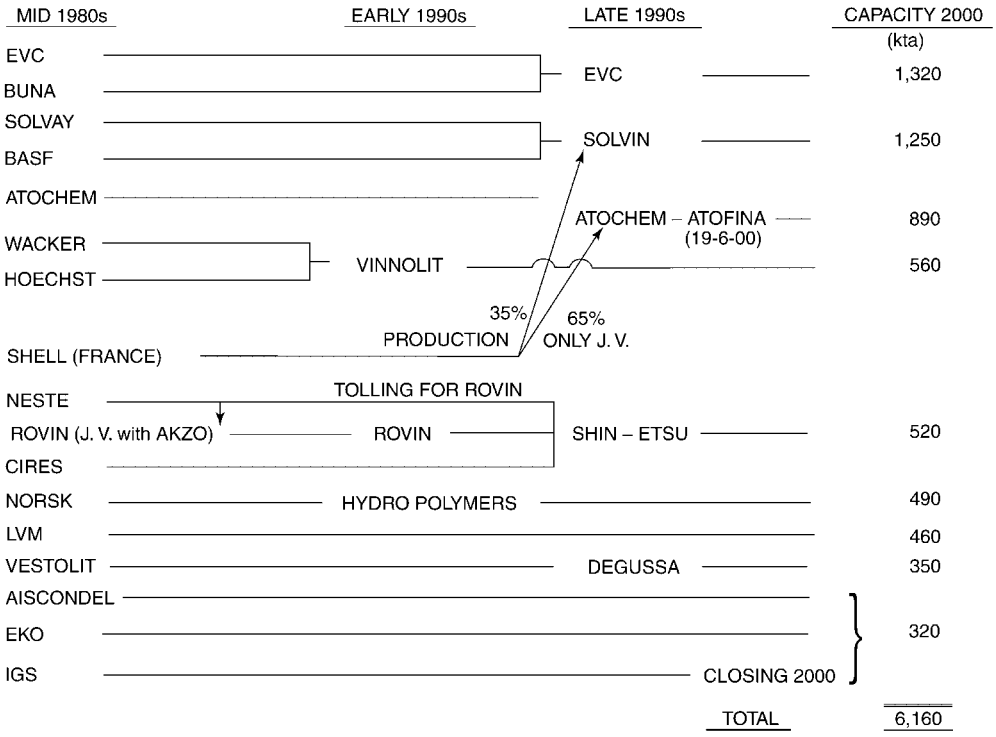

Fig. 15. Evolution of the PVC industry in Western Europe (J.V. = joint venture).

Table 14 lists the regional capacities (in 10^3 t/a) of the top 10 producers, which represent 48% of world capacity of 29.8×10^6 t/a. World production in 2000 was 23.3×10^6 t (78% of capacity).

Since ca 1990 China has emerged as a major force on the global PVC market, and its tremendous import capacity has had a large impact on the world price/consumption relationship. The eight main Chinese producers use

Table 14. Regional Capacities (in 10^3 t/a) of the Top 10 PVC Producers in 2000[a]

Company	S. America	Asia	NAFTA[b]	W. Europe	Total
Shin-Etsu	140	550	1500	520	2710
Formosa		1240	1170		2410
Oxy-Vinyls			2020		2020
Solvay	450	190		1250	1890

Atofina				890	890
Borden			690		690
L.G. Chemical		600			600
Taiyo Vinyl		600			600

Table 15. World Consumption of PVC Resin

Consumption of PVC esin (kt/a)		
	1997	2000
Japan	2030 (15 producers)	1750 (15 producer groups)
China	2250	3380
Consumption per Capita (kg) (200)		
"West" Germany	27.1	
North America	15.1	
Western Europe	14.6	
South America	3.6	
East Europe	3.5	
China	3.1	
Asia/Pacific	2.6	
Africa/Middle East	1.9	
India	1.0	

[a]The top 10 producers represent about 48% of world capacity of 29.8 million tons. World production in 2000 was 23.3 million tons (78% occupacity).
[b]NAFTA: North Atlantic Free Trade Area.

ethylene-based VCM and produce 42% of the total output, while about 70% of producers manufacture the remaining 42% using VCM from a calcium carbide based process. The 8 principal producers have plants with capacities $>100 \times 10^3$ t/a. These are 10 plants with capacities between 50 and 100×10^3 t/a and 51 plants with capacity of less than 50×10^3 t/a. Between 1996 and 2000 output of PVC increased on average by 12% per annum, consumption by 15%, and imports by 20% per annum.

The consumption of PVC resion in Japan and China in 1997 and 200 as well as the per given in Table 15.

World PVC production was 23.3×10^6 t/a in 2000, and growth ranged from −3% (Japan) to +8% (China). Overall long-term growth worldwide is estimated at ca 4%. Table 16 summarizes the world supply/demand balance.

Table 16. World Supply/Demand Balance for PVC in 1999 (in 10^3 t/a)

	Capacity	Operating rate, %	Production	Imports	Exports	Consumption
N. America	7480	91	6800	110	370	6540
S. America	1930	81	1560	470	460	1570

Toxicology and Occupational Health

Vinyl Chloride Monomer (VCM). Since vinyl chloride boils at −13°C it is handled as a compressed liquid. It has a vapor density greater than air and so precautions are taken in design not to contain the vapor in restricted areas. Protection of reactors by relief valves or bursting disks and double-valve isolation of all lines containing VCM are basic precautions taken in the design and construction of any PVC plant vessel which contains monomer. The gas is explosive between 3.6 and 25 vol% with air and 12 vol% oxygen is required for ignition (64). Therefore, a special series of working conditions must be satisfied in the working environment and great care is always taken to purge lines, pumps, valves, etc before any maintenance work is started. Thorough documentation (eg, clearance to work certificates) are always used to ensure that proper isolation of plant equipment is carried out before any entry. The whole plant is contained within a "red-fence" area where smoking is not permitted and where all electrical equipment is of a gas-tight and "flame-free" construction.

VCM has a narcotic effect at 8–12 vol% concentration and can cause death at higher concentrations (64). For this reason early VCM and PVC plants were designed to avoid buildup of gas above 1000 ppm in the atmosphere. VCM has a pleasant ethereal smell which is first noticed at concentrations of 500–2000 ppm.

Exposure to VCM has been shown to lead to two distinct problems. In the mid-1960s it became clear that a number of workers involved in reactor cleaning suffered from a bone condition called acroosteolysis (AOL), which affects mainly the hands and feet. Removal of the worker from exposure to VCM leads to an almost complete recovery. Since improvements to ventilating reactors and the introduction of high pressure water cleaning the incidence of AOL has ceased (65). A study of long-term exposure of rats to 30,000 ppm VCM did not reproduce any sign of AOL but they did develop cancers in various sites (66).

Subsequently, an extensive study with a wide range of dose conditions relating to occupational exposure was begun in 1971 at the Institute of Oncology in Bologna (67). This showed that a very rare liver cancer, angiosarcoma, could be formed in rats at levels of 250–500 ppm VCM. The first correlation between exposure to VCM and cancer in humans was made in 1973 when three workers at a plant in Louisville, Kentucky, were shown to have died from angiosarcoma (68). Since then other cases have been identified, all of which involved workers exposed to high concentrations of VCM as reactor cleaners or charging operators. As the period between first exposure to VCM and the appearance of angiosarcoma is 20–25 years it is likely that the incidence of the disease will soon decrease following improvements made to operation of PVC plants since 1973.

The knowledge that VCM is a human carcinogen has led to the introduction of very stringent controls by governmental and regulatory authorities to limit the exposure of workers and the general public to the monomer. In the United States, OSHA has set an 8-h TWA of 1 ppm VCM. During a shift an employee's exposure must not exceed 5 ppm over a period of 15 min or less (69). The European regulations, EC directive 78/610, require an annual average of <3 ppm in the plant's airspace with alarm values of 15 ppm over 1 h, 20 ppm over 20 min, and 30 ppm over 2 min.

Poly(Vinyl Chloride) (PVC). Strict limits have been set for the quantity of residual VCM in processed PVC articles intended for use in food contact applications.

In 1979 the EC set an upper limit of 1.0 ppm in the article and 10 ppb in the food. In 1986 the FDA suggested levels of $\leq$5 ppb in rigid and $\leq$10 ppb in plasticized PVC articles in food contact applications. To ensure these limits are met, PVC producers aim for these concentrations in the polymer grains themselves so that any further loss during processing ensures even greater safety.

There is little evidence that PVC powder itself causes any significant medical problems but steps are always taken to reduce powder emissions because of its nuisance value.

X-RAY MICROSCOPY

Introduction

Various types of microscopy have played a crucial role throughout the history of Polymer Science by elucidating the underlying organization and morphology of multiphasic polymeric materials and systems in real space. In many applications, there is often the need to not only visualize the morphology of a multicomponent system or material, but to also quantify the composition of the various phases in detail. Typically, techniques providing very high quantitative chemical information, such as infra red (ir), Raman, and nuclear magnetic resonance (nmr) spectroscopy, would be ideal for these tasks, but these techniques have very limited spatial resolution and achieve at best a resolution of the order of a micron. In contrast to this, electron microscopy has very high spatial resolution, but relies generally on heavy metal staining or only elemental contrast to provide qualitative compositional information. On surfaces, scanning force microscopy (sfm) has proven to be a very versatile characterization tool, but the compositional information obtained is only qualitative in nature. X-ray microscopy bridges this gap between ir, nmr on the one hand and electron and scanning force microscopy on the other, and fills a need by providing quantitative compositional information at a spatial resolution of presently 40 nm.

This article reviews Near Edge X-ray Absorption Fine Structure (nexafs) spectroscopy, which underlies the ability for quantitation of sample composition in x-ray microscopy. Also covered are state-of-the-art x-ray microscopy instrumentation techniques and a relatively complete overview of nexafs microscopy applications.

Near Edge X-ray Absorption Fine Structure Spectroscopy

The utility of x-ray microscopy is based on the range and subtlety of the spectroscopic and hence compositional information content of nexafs spectroscopy. As is true for all spectroscopies, the higher the chemical speciation capability that can be achieved, the better the compositional quantitation. In nexafs spectroscopy, the photoabsorption cross section for the excitation or photoionization of tightly bound core electrons is measured. NEXAFS spectra are necessarily element specific, as each element has a characteristic core binding energy (ie, carbon 1*s*: ∼290 eV, nitrogen 1*s*: ∼400 eV, oxygen 1*s*: ∼530 eV, etc). The spectral features observed in nexafs spectra correspond to transitions from the ground state to a core excited state. Figure 1 presents a schematic of the x-ray photoabsorption process for the carbon 1*s* nexafs spectrum of poly(styrene-*r*-acrylonitrile) (SAN). The most pronounced spectral features are intense and narrow peaks at the lowest energies in the spectrum. The first transition at ∼285 eV is a C $1s \rightarrow \pi^*$ transition corresponding to carbon atoms of the phenyl functional group. The second transition at ∼287 eV is a C $1s \rightarrow \pi^*$ electronic transition corresponding to the carbon atoms of the acrylonitrile functional groups. The energy of these features is dictated by the combination of initial state effects (core binding energies) and final state effects (energy of the optical orbital in the presence of the core hole). The relative magnitude of initial and final state effects in SAN can be gleamed from the energy diagram on the right-hand side of Figure 1. At higher photon energies in the spectrum, broad C $1s \rightarrow \sigma^*$ transitions are superimposed on the photoionization continuum.

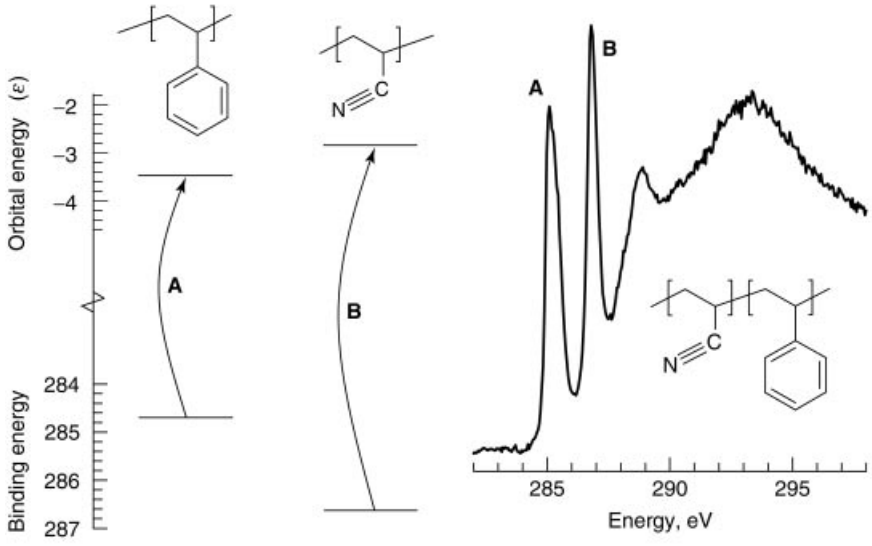

Fig. 1. Electronic schematic for the nexafs photoabsorption spectrum of poly(styrene-*r*-acrylonitrile). The C 1*s* binding energies were obtained from xps. Orbital energies of the C $1s \rightarrow$ LUMO(π^*) transition of the phenyl (A) and acrylonitrile (B) functional groups were obtained from ab initio calculations. Reproduced from Ref. 1.

A more broadly based illustration of the compositional sensitivity of nexafs spectroscopy can be seen in Figure 2 (1), displaying spectra from a number of unsaturated polymers that consist primarily of various aromatic functional groups, C=C bonds in the polymer chain backbone, as well as amide, ester, and carbonyl groups. It is readily apparent that the shape and intensity of the spectral features observed are unique for each polymer. Most nexafs spectra of these polymers are dominated by low energy C 1*s* $\rightarrow \pi^*_{C=C}$ transitions at 285–287 eV. The shape and intensity of this $\pi^*_{C=C}$ band varies with the chemical and hence electronic structure. An example of this chemical sensitivity can be observed in the C 1*s* nexafs spectra of polystyrene (PS) and poly(bromo styrene) (PBrS) (right panel of Fig. 2). In the PBrS spectrum, the core $\rightarrow \pi^*_{C=C}$ (LUMO) transition has two major components, a C 1*s*(C—H) $\rightarrow \pi^*_{C=C}$ component at ~285 eV and a C 1*s*(C—Br) $\rightarrow \pi^*_{C=C}$ component at ~286.2 eV, whereas PS has only one major component at ~285 eV. Note that in this notation, the core level is indicated parenthetically before the arrow (eg C—H), and the nature of the upper level of a given transition is indicated by the final subscript (eg C=C for phenyl). The inductive effect of the bromine shifts the C 1*s* ionization potential of the C—Br carbon atom to lower energy, increasing the energy of the C 1*s*(C—Br) $\rightarrow \pi^*_{C=C}$ transition to the common manifold of π^*(LUMO) states.

A similar situation applies to 4,4′-methylene di-*p*-phenylene isocyanate (MDI) and toluene diisocyanate (TDI) polyurea and polyurethane spectra, where the core $\rightarrow \pi^*_{C=C}$ (LUMO) transition has two major components: a C 1*s*(C—H) $\rightarrow \pi^*_{C=C}$ component at ~285 eV and a C 1*s*(C—R) $\rightarrow \pi^*_{C=C}$ component at ~286.5 eV. In TDI, the main, low energy π^* peak itself is furthermore split into two components. The inductive effect of a heteroatom can also be clearly observed by comparing the spectra of neoprene (NP) and polyisoprene (PI). A complementary series of nexafs spectra is shown in Figure 3, which presents the evolutionary trend of the spectral signature of carbonyl functional groups as the nearest neighbor environment is changed progressively and systematically from a keton to a carbonate (2).

Unfortunately, peaks attributable to different functional groups and specific carbon atoms have the tendency to overlap in a nexafs spectrum. Most of the spectroscopic information is compressed into a 6-eV wide energy window, while lineshapes are about 100 meV wide. Most notably, π^* spectral features corresponding to carbonyl, ester, and carbonate groups generally sit on top of C 1*s* (C—H) $\rightarrow \sigma^*$ transitions or the vacuum continuum.

Sometimes the shifts of slightly inequivalent carbon atoms are small and of the order of the intrinsic line width of a spectral feature (about 80–100 meV) that arises from the finite core-hole lifetime. Small chemical shifts can be found, for example, for the six inequivalent carbon atoms of the phenyl ring of PS. Further complicating matters, these small chemical energy shifts overlap with vibrational effects that have also similar energy shifts. The chemical shifts can thus not be observed in isolation from vibration and are furthermore convolved with the natural line width. The relative contributions of chemical and vibrational effects to the spectrum of PS has been explored (3). The magnitude of the shifts of these six carbon atoms based on calculations ranges from 50 to 400 meV. Figure 4 shows the lowest energy spectral features of PS and deuterated PS (d-PS). Difference of up to 15% in intensity can be observed that can be clearly attributed to vibrations.

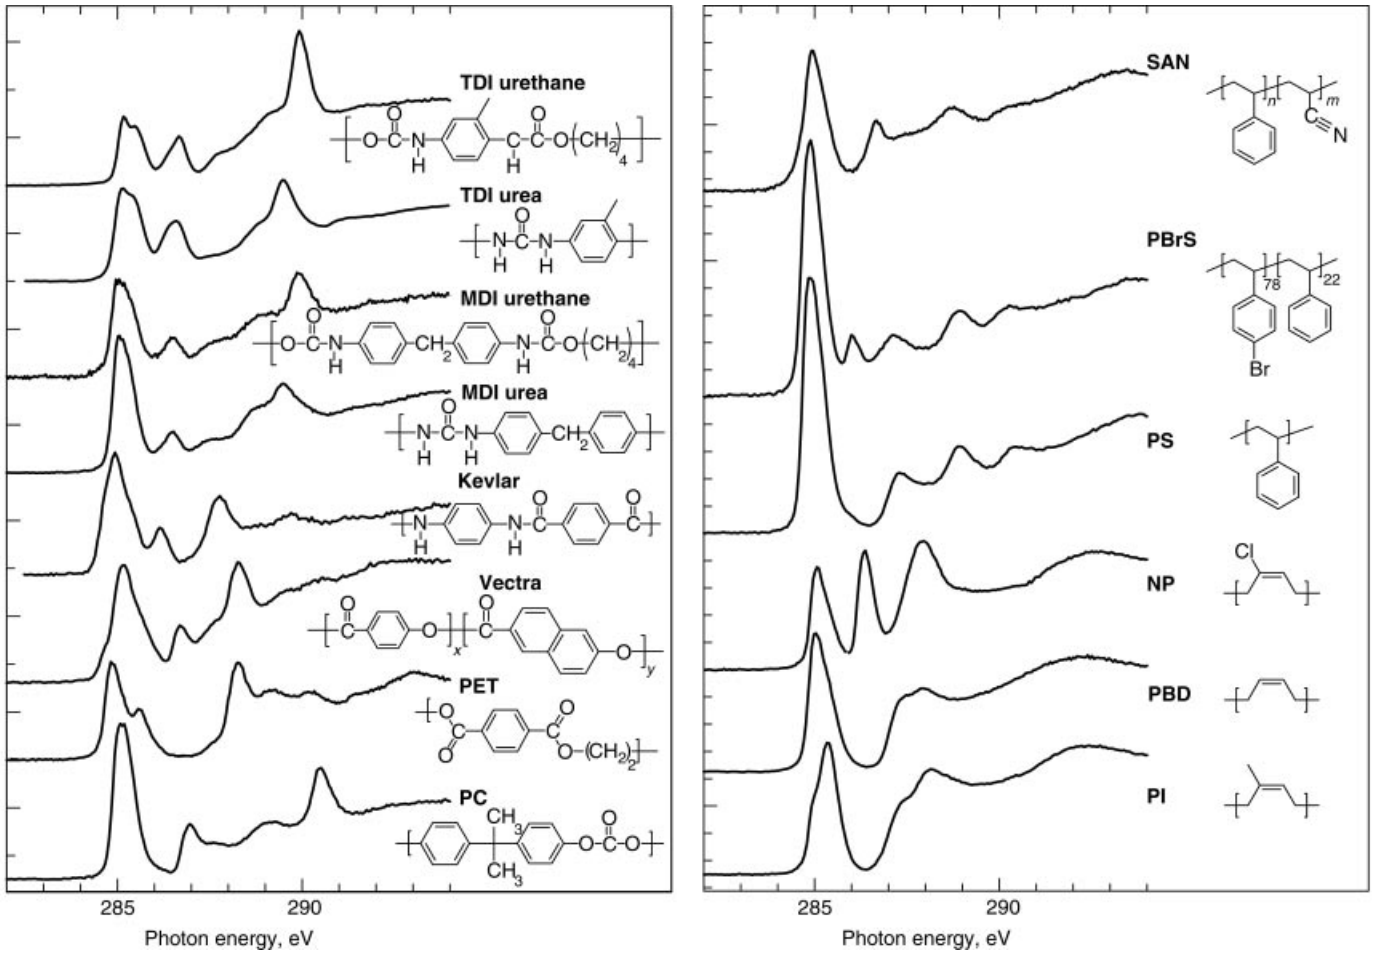

Fig. 2. C 1*s* nexafs spectra for a series of unsaturated polymers, recorded with the Stony Brook STXM. Reproduced from Ref. 1.

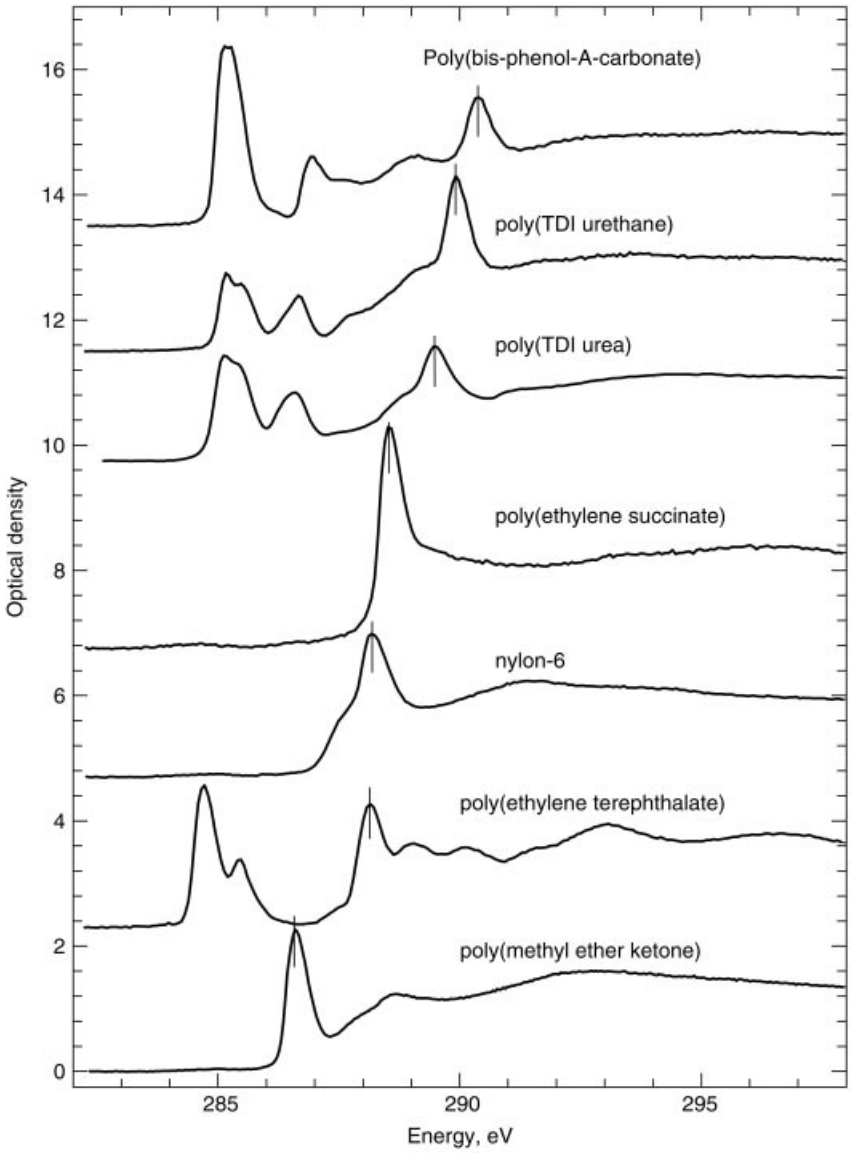

Fig. 3. C 1*s* nexafs spectra for a series of polymers that have carbonyl functional groups in different local electronic environments. (Data recorded with the Stony Brook STXM.) Reproduced from Ref. 2.

NEXAFS spectroscopy is also sensitive to differences in the chemical structure of saturated polymers (polyolefins and polyethers). The nexafs features in spectra of these materials are predominantly core $\rightarrow \sigma^*$ electronic transitions with some Rydberg character (4–6). In general, the spectral differences and variations observed for σ^* transitions as a function of chemical structure are not as great as those for π^* transitions. Only slight, although noticeable, differences in the

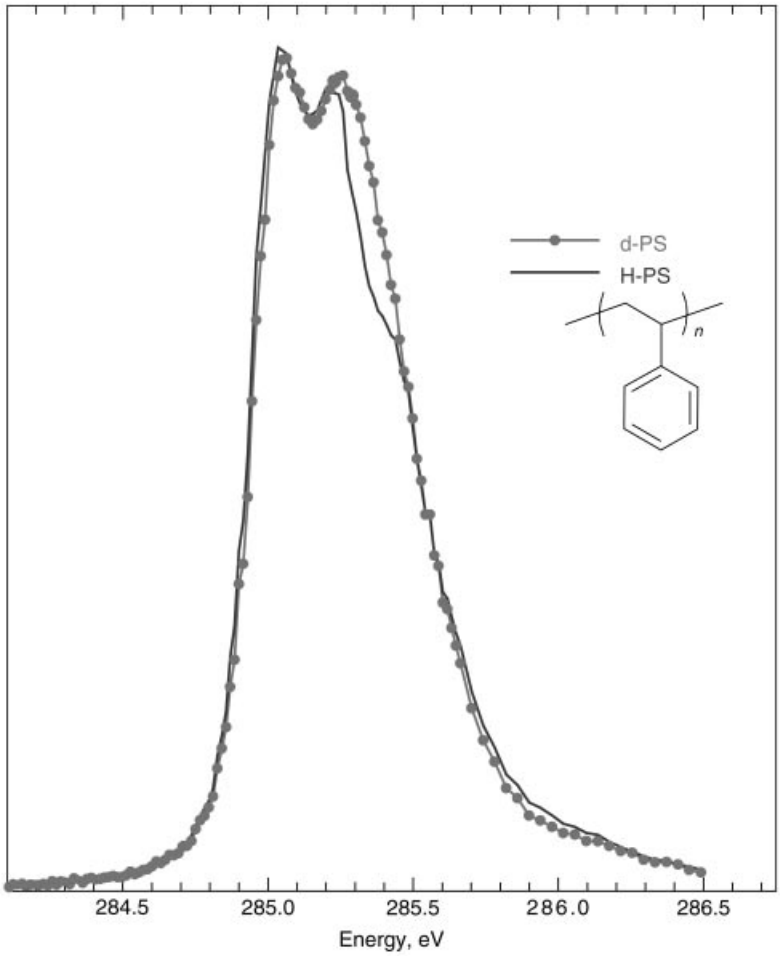

Fig. 4. C 1*s* nexafs spectra of polystyrene (blue line) and deuterated polystyrene (red line) recorded with a resolving power of about 6100. The area of the C $1s \rightarrow \pi^*$ transition is normalized so that absolute differences in the spectral intensity are chemically meaningful. (Data acquired with ALS BL7.0 STXM.) Reproduced from Ref. 3.

nexafs spectra of polyethylene (PE), polypropylene (PP), polyisobutylene (PIB), and ethylene propylene rubber (EPR) have been observed (1). The main chemical structural differences between these polymers are the number and distribution of methyl groups to the $(CH_2)_x$ backbone. The small spectroscopic differences are not surprising, since the structural differences involve bonds of the same C—C and C—H σ-bonded character. Nevertheless, spectroscopic differences have even been observed for PE of different density. These differences have been attributed to a matrix effect that varies between amorphous and crystalline regions of the semicrystalline PE materials (6). The largest spectral differences between the nexafs spectra of saturated polymers are observed when heteroatoms such as oxygen, chlorine, or fluorine are present. Substantial shifts of the corresponding features

of PE toward higher energy are observed in poly(ethylene oxide), polytetrafluoroethylene, polyvinylidine, or poly(vinyl chloride), primarily on account of shifts in the ionization potential because of the heteroatom.

NEXAFS experiments are almost exclusively performed with linearly polarized light from synchrotron radiation facilities. Since the discrete nexafs transitions obey dipole selection rules, oriented samples exhibit linear x-ray dichroism. This can be utilized to explore and measure orientation in polymeric materials. As an example, Figure 5 displays two nexafs spectra of an oriented long-chain hydrocarbon molecule (8). The orientation of the electric field vector with respect to the sample can be changed by rotating the sample relative to the x-ray beam. The spectra shown in Figure 5 correspond to glancing and normal incident radiation. Large spectral differences are observed, even though saturated molecules with only σ bonds tend to give less well-defined spectral features than polymers with π bonds.

The principles and underlying physics of nexafs spectroscopy and x-ray linear dichroism and their applications to small molecules and some polymers have been

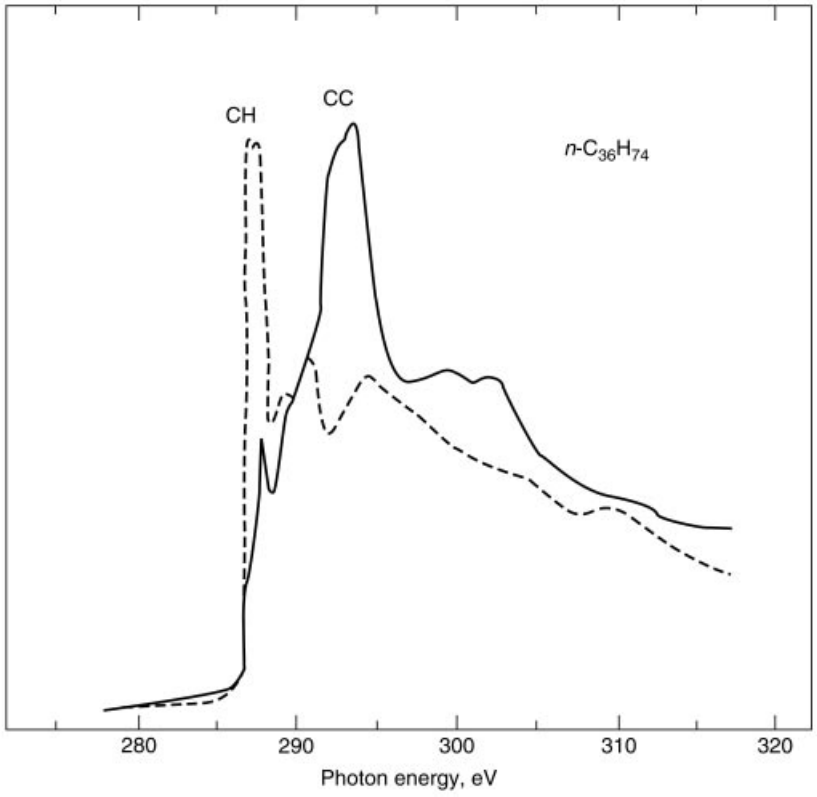

Fig. 5. Angle-dependent C 1*s* nexafs spectra of evaporated hexatriacontane-$CH_3(CH_2)_{34}CH_3$. Although this is not a polymeric substance, it provides a good illustration how large the linear dichroic signal can be even for fully saturated materials. The solid line data has the polarization vector aligned along the molecular axis of the oriented materials, while the dashed line data is for polarization perpendicular to the molecular axis. Reproduced from Ref. 7.

reviewed in a monograph (9). Complementary, but somewhat limited, overviews of polymer nexafs spectra have been presented (10–13). A more detailed "primer" of nexafs spectroscopy of polymers has also been provided (1). A carefully energy-calibrated library of nexafs spectra is presently being compiled by the North Carolina State University nexafs microscopy research group. Energy calibration is accomplished by leaking a small amount of CO_2 gas into the experimental chamber and by recording characteristic polymer features and characteristic features of the CO_2 gas simultaneously, thus reducing any ambiguity about the energy scale (14).

The chemical and orientational sensitivity of nexafs spectroscopy has been used for analysis in a variety of applications. Examples of studies involving nexafs spectroscopy are given below:

(1) Photoactive polymers: poly(phenylene vinylene) (15), poly-*p*-phenylenes and polyacenes (16), photo-oxidation of electroluminescent polymers (17), and uv-polymerized diacetylene (8)
(2) Polyurethanes and model compounds (18,19)
(3) Plasma and radiation damaged polymers: oxygen plasma damaged polypropylene (20) and argon plasma damaged polycarbonate (21). Electron and x-ray beam damaged or decomposing polymers: poly(methy methacrylate) (PMMA) (22–24), several polymers with carbonyl functionality (25).
(4) Metal polymer interfaces: chromium coated poly(ethylene terephthalate) (PET) (26) and metalized polycarbonate (PC)(27)
(5) Surface relaxation of PS (28)
(6) Surface structure of polyimides (29–34)
(7) Surface orientation and grafting density of semifluorinated polymers (35–39)
(8) Organic geochemical polymers: petroleum asphaltenes and coals (40,41) and kerogens and bitumens (42)
(9) Inorganic polymers: polydimethylsilane films (43,44) and poly(di-*N*-hexyldisiloxane) (45).

Additional studies comprise various forms of polyethylene $(CH_2)_x$, such as oriented homopolymer (7,46). Other examples include polytetrafluoroethylene homopolymer and models (7,47–50); poly(ethylene terephthalate) and the related polymers poly(butylene terephthalate) and poly(ethylene naphthalate) (51–53); and electrochemically polymerized thin films such as poly(3-methyl thiophene) (54) and polypyrrole (55). This is not intended to be a comprehensive list, but only an indication of the wide range of applications possible with nexafs spectroscopy.

Energy electron loss spectroscopy (eels) used under dipole approximation conditions is a closely related tool to nexafs spectroscopy as it measures the same electronic transitions (56,57). Indeed, most of the early polymer core excitation spectroscopy, work particularly at the C 1*s* core edge, was performed by eels (58–61). EELS can be performed in a scanning transmission electron microscope (stem) at high spatial resolution (62–64), or by energy filtered tem imaging (65). The relatively poor energy resolution in commercial instruments and higher beam damage (66) limits the use of these eels methods for compositional analysis of complex

polymeric materials. EELS is best used for elemental analysis or semiquantitative low loss spectroscopy (67–69). Specialized tem–eels instruments have demonstrated 0.2–0.4 eV FWHM energy resolution for semiconductors (70) and nickel aluminum intermetallics (71). The development of tem-monochromators capable of reaching 50 meV resolution is in progress (72–74).

NEXAFS Microscopy: Instrumentation and Analysis Tools

Having seen the power (and limitation) of nexafs spectroscopy in the preceding sections, one can readily envision the enhanced utility of nexafs spectroscopy as a characterization tool that would result from the addition of high spatial resolution capabilities. Since the spectroscopic sensitivity to specific moieties and functional groups can in many or even most cases be exceeded by ir, nmr, and Raman spectroscopies, nexafs microscopy will have to exceed the spatial resolution of these other spectroscopy techniques in order to be truly useful. To date, nexafs microscopy has surpassed a spatial resolution of 50 nm both in transmission to measure bulk properties (75–77) and in a reflection geometry to study surfaces (78,79). This level of spatial resolution is at least an order of magnitude better than what can be accomplished with complementary compositional analysis techniques. Future developments in nexafs microscopy might achieve a spatial resolution of a few nanometers (80,81). In addition, nexafs microscopy has exceptional surface sensitivity of about 10 nm, a sensitivity that could be improved to about 1 nm with photoemission electron microscopes (peem's) that incorporate a bandpass filter (80–82).

High spatial resolution nexafs microscopy is generally accomplished in two ways: (*1*) instruments for transmission experiments typically employ high resolution zone plate optics (83), whereas (*2*) surfaces are characterized with peem's (78,79,82). Zone-plate-based microscopes are true x-ray microscopes. PEEM's are essentially electron microscopies in which high spatial resolution is achieved with electrostatic or electromagnetic electron optics. The quality of the optics system is essential in both cases.

For zone-plate-based microscopes, the accuracy of the zone placement and the width of the outermost zone determines the spatial resolution achievable with these elements. The Rayleigh resolution of a perfect zone plate is 1.22 times the outermost zone width. Zone plates with outermost zone widths between 20 and 40 nm are presently in use with experimental spatial resolution in the range of 25–50 nm (77). Two types of instruments have been developed and are being continually refined and improved: (*1*) scanning transmission x-ray microscopes (stxm) and (*2*) full-field conventional transmission x-ray microscopes (txm) (see schematics in Fig. 6). Present stxm's generate a microprobe of about 40–50 nm in size, and the sample is raster scanned through the focus of the x-ray microprobe by mechanical means (84,85). In a txm, a zone plate downstream of the stationary sample magnifies the sample onto a 2-D detector (86–88). NEXAFS microscopy with good chemical sensitivity requires good energy resolution. For a stxm that is operated in the 200–900 eV energy range, this is achieved with a grazing incidence monochromator upstream of the microscope. Near the carbon edge, the most widely used edge for polymeric materials, a resolving power of 2000–5000 is

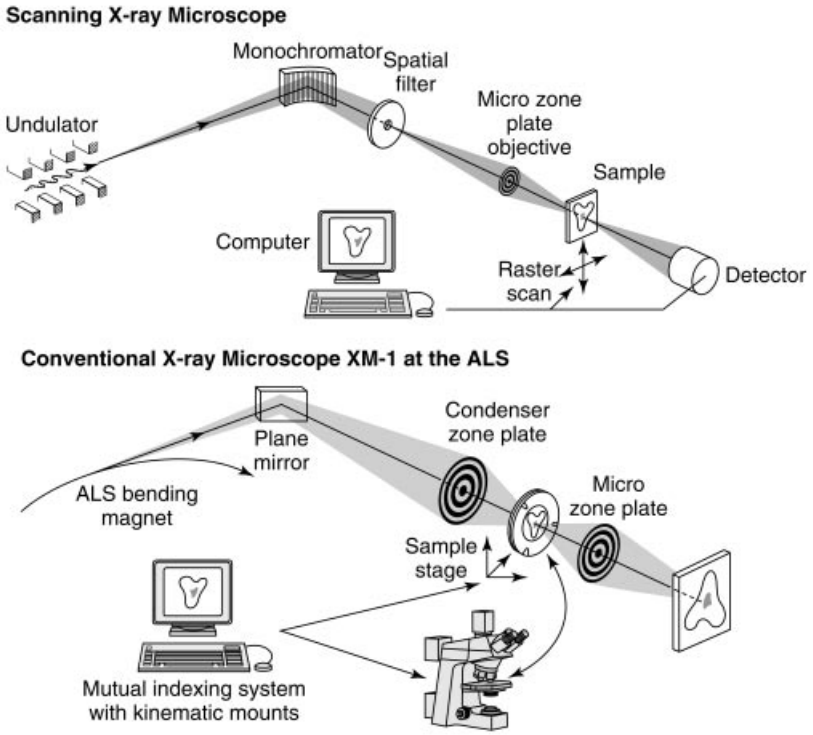

Fig. 6. Schematic of a scanning transmission x-ray microscope (stxm) and a conventional transmission x-ray microscope (txm). Courtesy of W. Meyer-Ilse, CXRO.

routinely available (85,89,90). TXM's presently employ zone plate monochromators in order to match the numerical aperture of the illumination at the sample to the numerical aperture of the objective. Present zone plate monochromators used in a txm have relatively low energy resolution ($\sim$0.5 eV), limiting the utility of txm for nexafs microscopy of polymers. Efforts are underway to improve this shortcoming of txm's.

Zone plates are highly chromatic, with a focal length proportional to the photon energy. As a result, continual refocusing is required during the photon energy change necessary for spectroscopy. This is accomplished by changing the sample to zone plate distance. If a high spatial resolution point spectrum is to be acquired, care and effort must be exercised to control the transverse motion of the scanned element (sample or zone plate) during refocusing to avoid blurring of the region from which the spectrum is acquired. Controlling this "run-out" is a technological challenge, and places severe constraints on the accuracy of the mechanical apparatus. An accuracy, stability, and repeatability consistent with the spatial resolution of the zone plate has not yet been routinely achieved in existing stxms. One way to work around these problems, at least partially, is to acquire image sequences at each photon energy in the spectrum (91). The images in these sequences can then be correlated to each other and shifted to provide the proper alignment. If one is only interested in spectra from a few locations, the image

sequence approach results in a time penalty: image sequences typically require between 0.5 and 3 h, while a few point spectra require a few minutes. Refocusing after a change in energy is also necessary in a txm, with similar requirements to an stxm regarding stability and alignment. In a txm, one has to translate both the zone plate objective and the detector in order to keep the magnification the same.

The first stxm had been operated at a relatively low brightness bending magnet beamline at the National Synchrotron Light Source (NSLS) uv ring (92), but was moved to an undulator beamline as these high brightness sources became available (93). This was motivated by the requirement to illuminate the zone plate coherently to achieve the highest spatial resolution possible. High intensity at high spatial resolution is thus most easily accomplished at the brightest sources available, ie, undulator sources at synchrotron radiation facilities (83,85,90). In order to increase stxm capacity at relatively low cost, an effort is underway to build an stxm at a bending magnet beamline at the Advanced Light Source (ALS) in Berkeley that is about two orders of magnitude brighter than a bending magnet at the NSLS uv ring. In order to achieve the best data rates for the majority of polymer experiments, the ALS bending magnet stxm and beamline has been optimized for C-nexafs (94). The brightness requirement for a txm is less severe than for an stxm. TXM's can be successfully operated with short exposure times at bending magnet beamlines even at second generation synchrotron facilities. Since most laboratory based x-ray sources do not have a continuous and stable emission spectrum, laboratory based nexafs microscopy, with its requirement for photon energy tunability, is an unlikely development in the near future.

To study surfaces, secondary processes, such as fluorescent photons and secondary or primary photoelectrons, that track the absorption cross section as a function of photon energy are utilized. All three of these secondary processes are already extensively employed in nexafs spectroscopy without spatial resolution, in what is called the fluorescent yield (FY), total- (TEY) or partial electron yield (PEY) mode, respectively (9). PEY traditionally refers to experiments that utilize a bias voltage on the channel plate or channeltron detector or an energy window set with an energy analyzer. Both methods strive to accept primarily electrons with kinetic energy in the 100–300 eV range near the minimum of the secondary electron mean free path in order to achieve high surface sensitivity of about 1 nm. In nexafs microscopy, only a modified version of PEY mode is presently available. In a peem, the photoelectrons emitted from the sample surface are accelerated in a cathode lens to high energies, and subsequent electrostatic or electromagnetic lenses magnify the image onto a 2-D detector (see Fig. 7 as an example). The peem instrument itself acts as a low pass energy filter with a bandwidth of a few electro volts near the photoelectron threshold. This energy window is not near the mean free path minimum and has a large sampling depth of about 10 nm associated with it. True energy filtering in a peem would allow operation near the mean free path minimum. However, the one instrument presently available with an energy filter, the spectroscopic low energy electron microscope (SPLEEM) developed by the group of E. Bauer, has not yet been utilized for nexafs experiments (95).

Several contrast mechanisms assert themselves simultaneously in a peem instrument: (*1*) composition, ie, the cross section difference between different materials at a given photon energy, (*2*) topography and (*3*) illumination effects. Topographic contrast arises from the modified collection efficiency in the peem from

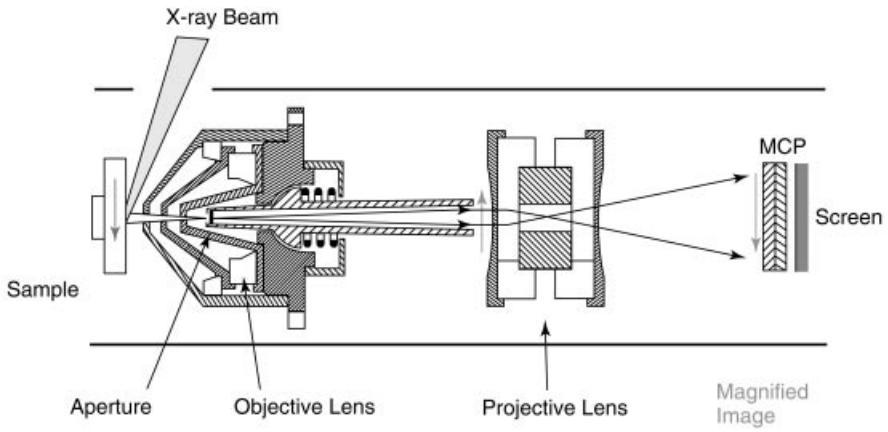

Fig. 7. Schematic of a photoemission electron microscope (peem). Courtesy of S. Anders, ALS, and B. Tonner, University of Central Florida.

sample locations that are not perpendicular to the optical axis. Concave round features tend to have reduced collection efficiency, while convex features are enhanced. Illumination effects arise because the sample is illuminated at a shallow angle of 30° or less. The local photon intensity of the sample depends thus on the topography. Even complete shadowing is possible. Typically, one is interested primarily in the compositional information, and analysis procedures are presently developed to disentangle the spectroscopic, ie, compositional, information from topography and illumination effects. Generally, these methods use pre- and post-edge normalization of the nexafs spectra acquired with the peem and reference spectra acquired with the same instrument (see, for example, Ref. 96)

Since peem's acquire information in parallel from all pixels in the image, and incoherent illumination of the sample is possible, the source requirements are generally not extreme. peem's can be successfully operated at any bending magnet beamline that provides sufficient energy resolution (78,79,97,98). PEEM's also do not require any refocusing during photon energy changes. However, for future ultrahigh spatial resolution (<10 nm) instruments, the necessary flux densities on the sample can only be provided with undulator beamlines.

Quantitative Microanalysis. In transmission nexafs spectroscopy, quantitative analysis can be achieved by inverting Lambert–Beer's law of x-ray absorption:

$$\mathrm{OD} = \mu\rho t = \alpha t = -\ln(I/I_0)$$

where OD is the optical density, μ is the energy-dependent mass absorption coefficient, ρ is the density, t is the sample thickness, and an energy scan from the sample (I) is normalized to another energy scan recorded without a sample (I_0). The product of μ and ρ is the linear absorption coefficient α.

For accurate quantitation, well-characterized nexafs spectra of carefully chosen analytical models of the polymer components are required. The basic and

well-founded assumption is that nexafs spectra of *non-interacting* moieties or components are additive. For a blend of two or more homopolymers, such as PS/PMMA, the analytical models can simply be the individual homopolymers. Even for quantitation of components in a random block copolymer, eg poly(styrene-*r*-acrylonitrile) (SAN), the spectra of the homopolymers PS and polyacrylonitrile (PAN) can be used, provided that the blocks do not interact electronically. Accuracy of a few per cent can presently be obtained for a variety of polymers including polyurethanes (19). In general, care must be exercised to choose models and reference spectra that indeed reflect noninteracting moieties (1). The utility and limitations of quantitative nexafs analysis for polymeric materials has recently been discussed (1).

Quantitative Image Analysis. Two methods are available if the composition of large sample areas is to be analyzed quantitatively: (*1*) singular value decomposition (SVD) of a few images at carefully chosen photon energies (98–101), or (*2*) acquisition of image sequences at many energies that provide nexafs spectra at each point (91). SVD requires prior knowledge about the sample and works only if the overall composition of the sample is known. In addition, the linear absorption coefficients of the components must be accurately known in order to minimize systematic errors in the analysis. The nexafs spectra used as standards must be free of spectral distortions caused by absorption saturation because of the presence of higher order spectral contamination and detector nonlinearity.

The SVD procedure requires a series of images acquired at a number of energies that equal or exceed the number of compositional components. The reference spectra provide crucial guidance for the selection of the photon energy. Usually energy values for images are chosen that correspond to large spectral differences between the constituent components. An example of raw transmission images is shown in Figure 8. Each transmission image is converted to an optical density (OD) image by computing $\mathrm{OD} = -\ln(I/I_0)$, where I is the transmitted intensity and I_0 is the incident intensity. The normalization with I_0 can be most readily and accurately accomplished if the image itself contains an open area (see Fig. 9), but recording a separate I_0 spectrum is also possible. Since $\mathrm{OD} = \alpha t = \mu\rho t$, each pixel in an OD image can be described by a linear combination of the product of the linear absorption coefficient α and the thickness t for each component respectively. This results in a set of linear equations that can be solved for the thickness of each component. Since SVD utilizes only a limited and small number of images, it results in the smallest (and minimum) dose to the sample to extract the desired information. Since $\alpha t = \mu\rho t$, one could alternatively use the mass absorption coefficient as the known quantity and calculate the mass-thickness ρt, rather than the thickness itself. The latter is advantageous if the same component might be present in the sample with different densities, ie, a polymer in an amorphous and crystalline form. The relative contrast and intensities of the images derived from the SVD analysis are not affected by this change in perspective, only their interpretation.

Acquisition of image sequences has the advantage that complete spectroscopic information is acquired from all sample areas (91). Hence the spectra extracted from image sequences can be compared *post facto* to a large number of possible reference spectra, and the existence and identification of unknown species can be more readily accomplished than with SVD (see, for example, Ref. 96).

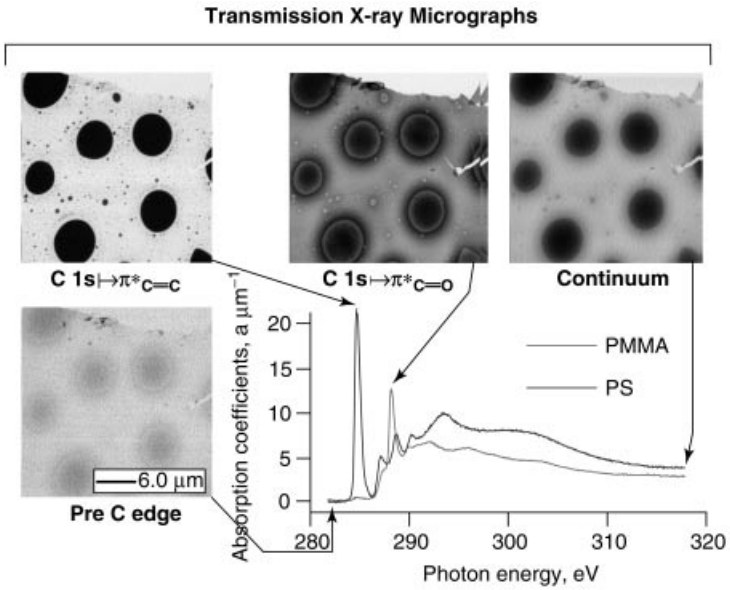

Fig. 8. Basic data set for SVD analysis, with reference spectra of PS and PMMA and transmission images of a PS/PMMA sample at the four energies indicated. Generally, each image has a weighted absorption for each substance present, based on the cross sections at the particular photon energy and the abundance of the substance, even though the absorption in some x-ray micrographs can be dominated by one or the other chemical substance, eg 285.2 eV is dominated by PS absorption. (Data acquired with the Stony Brook STXM.) Courtesy of D. A. Winesett, NCSU.

For C-NEXAFS transmission, optimum signal-to-noise ratios are achieved with sample thicknesses of 50–200 nm. For bulk materials, these sample requirements can usually be met using well-developed electron microscopy (em) preparation techniques such as ultramicrotomy or cryomicrotomy. Alternatively, thin films can be spun-cast to the right thickness and transferred to em grid for x-ray microscopy inspection. Thin samples and section of samples can also be examined in a completely hydrated/solvated state sandwiched between two very thin Si_3N_4 membranes (102). For surface analysis in a peem, polymer thin films typically show the propensity to charge. Generally, only thin polymer films with a thickness of less than 200 nm on top of a conducting substrate can be investigated. Precise temperature control in an stxm and txm is not yet routinely available. PE samples have been melted near 120°C (6), and biological materials have been examined in the frozen state (103). Temperature range in a peem can be from −70 to >1200°C. However, accuracy for near room temperatures is not very good.

NEXAFS Microscopy: Applications

NEXAFS spectroscopy and microscopy provide a new approach to study carbon-based materials. During the last couple of years, nexafs microscopy has been successfully applied to materials characterization in a variety of fields ranging from polymer science and biology to meteoritics (1,83,99). Here, the discussion is focused

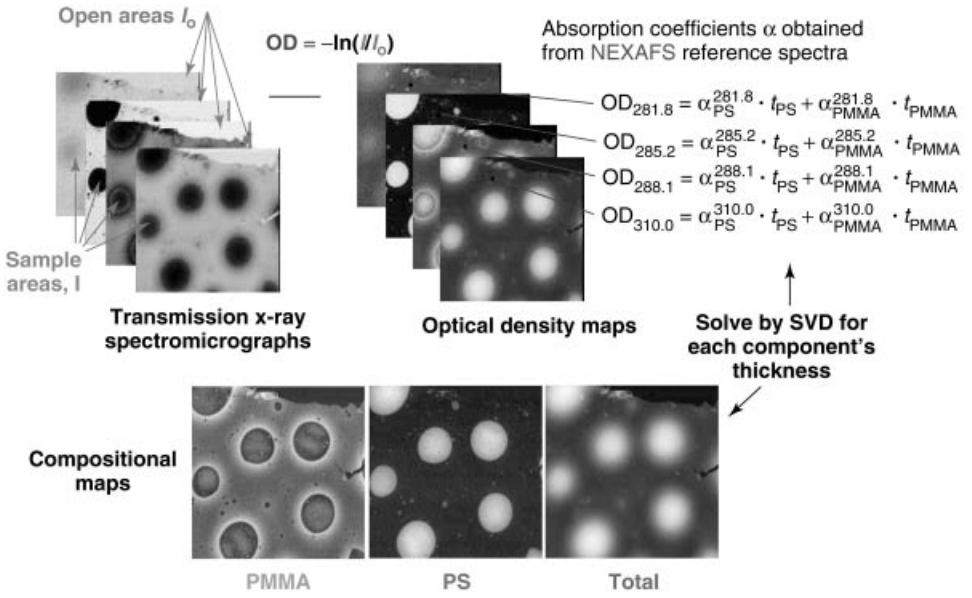

Fig. 9. The transmission images shown in Figure 8 are normalized to optical density (OD) images by inversion of Lambert–Beer's Law. These OD images are now linear in the absorption coefficients α and thickness t. A set of OD images can subsequently be processed via a singular value decomposition (SVD) procedure to yield quantitative composition maps in terms of the thickness t. (Data acquired with the Stony Brook STXM.) Courtesy of D. A. Winesett, NCSU.

on synthetic polymeric materials. Organizing the presentation by separating it into compositional and orientational analysis does not work well, as several studies of one material combine both aspects of nexafs spectroscopy. The discussion progresses thus from the "simple" to the apparently or supposedly "more complex" without regards as to whether compositional or orientational information is sought. The discussion starts with homopolymer surfaces, then progresses to single or multicomponent thin polymer films and structured spheres, followed by bulk properties of multicomponent polymers. The latter might involve formation of "unknown" compounds during processing, presenting a challenge that necessitates careful selection of nexafs reference spectra. These applications will be complemented by a short discussion of research on polymer fibers.

Homopolymer and Polymer Blend Surfaces and Ultrathin Films. Because of the various technological applications of polymer thin films, ranging from multicolor photographic printing to flat panel and liquid crystal displays, it is important to understand thin film and polymer surface characteristics in order to improve performance or to develop entirely new applications or processing methodologies. Polymer and block copolymer thin films and surfaces thus enjoy continued research interest from both a technological and fundamental perspective.

NEXAFS spectroscopy, on account of its excellent surface sensitivity (about 1–10 nm) and its polarization dependence, can and has been utilized to study

a variety of surface properties. Some recent, nonexhaustive examples of nexafs spectroscopy applications are the investigation of the alignment and orientation of polymers and its functional groups in polyimide surfaces after rubbing with a buffing cloth (29–34), the surface relaxation of PS (28), and the orientation of semifluorinated polymers and block copolymers (35–38,104,105). The potential for nexafs characterization of polymer surfaces even without spatial resolution is in fact enormous. A large number of polymer surface characterizations, eg in adhesion science, are currently performed with laboratory x-ray photoemission spectroscopy (xps), even though nexafs spectroscopy might be much more suitable to the task because of increased chemical and surface sensitivity. NEXAFS microscopy has been utilized to investigate the stability and dewetting behavior of bilayers, the phase separation in polymer thin films, and the orientation produced by buffing and rubbing polyimide films. Several examples are provided below.

Polyimide Films and Surfaces. In flat panel displays, polyimide films typically about 0.2-μm thick are coated onto the electrode surfaces. To prepare a surface that aids the alignment of the liquid crystal (LC) molecules in the final device, the polyimide surface is buffed with a velour cloth. Valuable information about the function and the possible improvement of flat panel displays is provided by understanding the conditions and factors that cause LC alignment. Numerous nexafs studies without spatial resolution have investigated the effect of the buffing (29–34). In addition, nexafs microscopy in a peem was utilized to characterize the inhomogeneity of the surface orientation produced by buffing (106). Stripes several microns in width were observed with contrast based entirely on differences in local orientation of polymer chains, chain segments, or moieties. While it was clearly observed that buffing does not orient the surface homogeneously, polyimide films produced under the same rubbing conditions than the samples observed in the peem resulted in LC films with the liquid crystal oriented uniformly over the entire sample surface. The separation distance between the oriented stripes of polymers was less than the correlation length of the liquid crystal and the heterogeneous distribution of the pinning centers is sufficient to align the liquid crystal.

Local stress during buffing is an important parameter that might cause the polymer to orient. However, the local stress cannot be estimated well for buffing with a cloth. Hence, BPDA-PDA polyimide surfaces rubbed with a stylus of well-defined shape and with a known load were also investigated with nexafs microscopy. Stylizing with a radial tip is an ideal model case that produces an ellipsoidal stress profile on the polymer surface. The nexafs micrographs of a track from the stylus are shown in Figure 10, acquired at two different sample orientations relative to the polarization orientation of 285.3 eV x-rays. Spectra from inside the track from the two different sample orientations relative to the polarization orientation of the x-rays are displayed in Figure 11 and clearly demonstrate the dichroic nature of the contrast in Figure 10. By measuring the width of the track that resulted in alignment and comparing it to the expected stress profile, the minimum stress necessary to cause alignment of the BPDA-PDA film was determined to be 45 MPa. This stress is much lower than the bulk yield stress of 200–300 MPa. The low surface value was attributed to a reduction of polymer entanglement at the surface.

Confined Free-Standing Homopolymer Thin Films. Free standing thin polymer films (eg of PS) can form holes when annealed, driven by dispersion

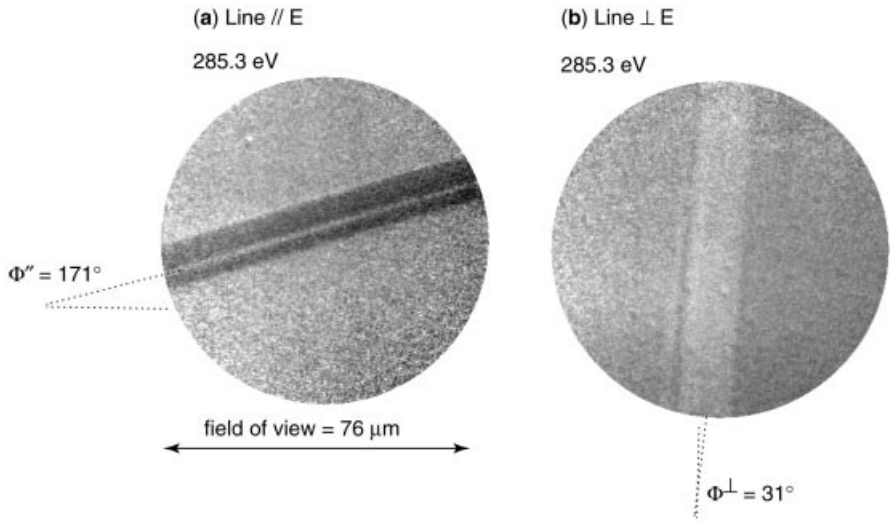

Fig. 10. PEEM images of a stylus track on a polyimide surface at a photon energy of 285.3 eV and two different orientations as indicated. Contrast is based on differences in functional group alignment between the stylus track and the virgin surface. The uniform gray outside the track corresponds to isotropic chains (106). (Data acquired with ALS PEEM-I.) Courtesy of A. Cossey-Favre.

forces that amplify structural instabilities at the film surface. Mechanical confinement offers the possibility to control these instabilities, and raises the possibility to generate unique self-assembled structures. While thin (∼50 nm) PS films confined between continuous layers of silicon oxide (SiO_x) are prevented from hole formation, aggressive annealing at temperatures well above the PS glass-transition temperature generates an in-plane microstructure (107). The formation of the microstructure is driven by the attractive dispersion force between the SiO_x–air surface. To properly model the mechanisms for this spontaneously generated lateral morphology, it is important to measure the thickness of the trapped polymer film throughout the structure. This requires a quantitative tool that can measure the thickness of the polymer inside the trilayer system. While it might be a reasonable assumption that there is almost a complete exclusion of the PS in the thin regions of the pattern, nexafs microscopy indicated ∼30% residual PS in the thinnest parts of the sample (see Fig. 12) (108). This fact can now be incorporated into models of the structure formation.

Superabsorbent Polymers: Lightly Cross-Linked Homopolymers. Third generation superabsorbent polymers (SAP) are a class of highly engineered cross-linked polymers widely used as gels in a variety of fields. SAPs are designed to simultaneously provide high fluid absorption capability, retain the fluid in a weight bearing mode with high gel strength, provide attrition resistance during manufacture, be compatible with other manufacturing materials, and remain safe for hygienic uses (109–111). SAPs are made from partially neutralized polyacrylic acid which is lightly cross-linked throughout small (<0.5 mm) beads to form an insoluble, hydrophilic gel. Several different methods have been developed for surface cross-linking SAP gels as means to improve materials properties (112,113).

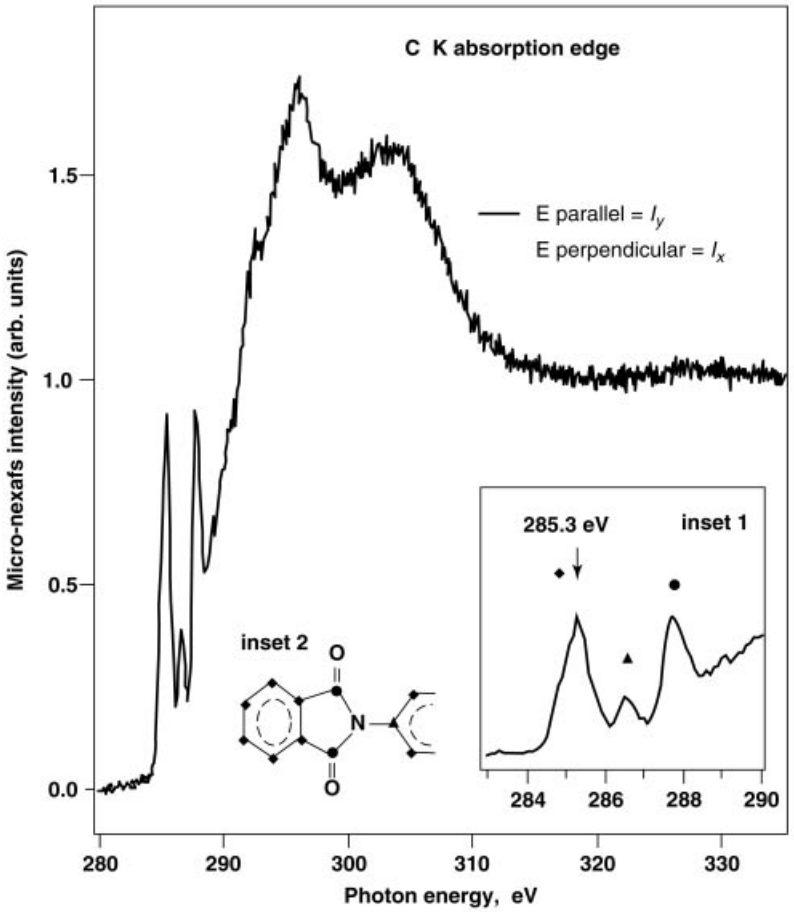

Fig. 11. Linear dichroic nexafs spectra from within the stylus track in Figure 10 at two orientations. Spectral differences are due to differences in orientation and alignment of the polymer functional groups (106). Primary peak assignment is indicated by the symbols. (Data acquired with ALS PEEM-I.) Courtesy of A. Cossey-Favre.

Until now, however, the outcome of these different surface cross-link processes, and the resulting core/shell structure and cross-link density gradient could not be directly visualized and quantitatively assessed.

Crosslinking involves the change in only a very small number of bonds and cannot be monitored directly via spectroscopic differences. A more indirect method, that nonetheless can provide quantitative cross-link density, has to be used. The swelling of SAP beads (polyacrylic acid, sodium salt) and particularly of the more highly cross-linked surface shell depends on the cross-link density of the polymer. Regions or beads with a high cross-link density will expand less in water and therefore will have a higher carbon density when examined in the swollen state. A wet cell was developed and used to characterize cross-link density in thin sections from SAP beads (102,114). NEXAFS resonances were used to provide the highest image contrast possible: The π^* spectral feature of the carboxylic acid

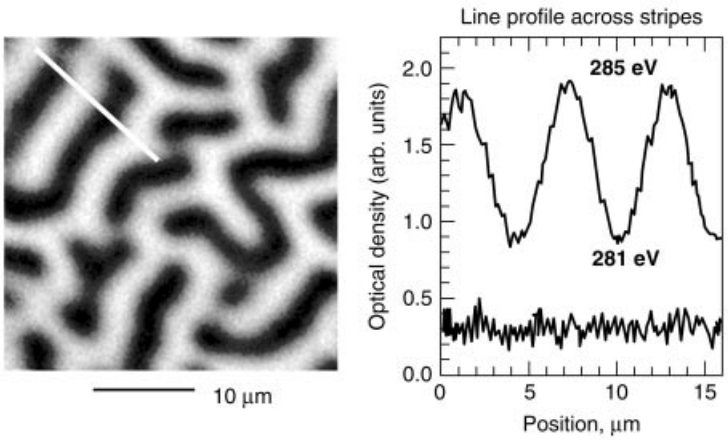

Fig. 12. Image acquired at 285.2 eV of a trilayer structure consisting of a 60-nm thick film of polystyrene (PS) coated on each side with 30 nm of SiO_x. Annealing above the glass-transition temperature of PS results in the observed morphology. Profiles that emphasize PS (top profile labeled 285 eV) and spectra show that significant amounts of PS remain in the thin regions. Note that the preabsorption edge profile at 281 eV is essentially flat. (Data acquired with the ALS BL7.0 STXM.) Courtesy of A. P. Hitchcock, McMaster University, and J. Dutcher, Guelph University.

increased the signal by a factor of 2 with respect to the core edge jump. Core/shell structures in SAP beads prepared by chemically cross-linking the surface of SAP beads were directly visualized, and variations in surface cross-link density resulting from different cross-link protocols were observed and compared on a common, quantitative cross-link density basis. Figures 13 and 14 compare the results of two different processes that resulted in a gradient and abrupt surface cross-link density profile, respectively. The direct observation of these cross-link density profiles can now be used to optimize the manufacturing and development process of these polymers.

Thin-Film Blends and Bilayers. Generally, the properties of polymer blends when they are processed into thin films are not as well understood as those of bulk polymer blends. The constraints imposed by the two close-by interfaces alter the equilibrium morphology as well as the polymer mobility and phase separation dynamics. Numerous studies (115–124) have elucidated some aspects of these effects. Interfacial energies are important since they determine thermodynamic equilibrium structures. The viscosity and diffusion near surfaces and attractive interfaces can be substantially modified (125), which will influence the dynamics, and possibly cause the formation of kinetically trapped morphologies. A number of morphologies that evolve during the phase separation process in polymer thin films have been previously observed (117–123,126). NEXAFS microscopy provides an additional tool to study such systems (100,127–129). The two primary beneficial aspects of nexafs microscopy for these applications are (*1*) quantitative mapping that can be translated into thickness profiles, and (*2*) compositional analysis of surfaces.

The first nexafs microscopy characterization of phase-separated thin-film blends was performed by two groups (127,130,131). The first group observed good

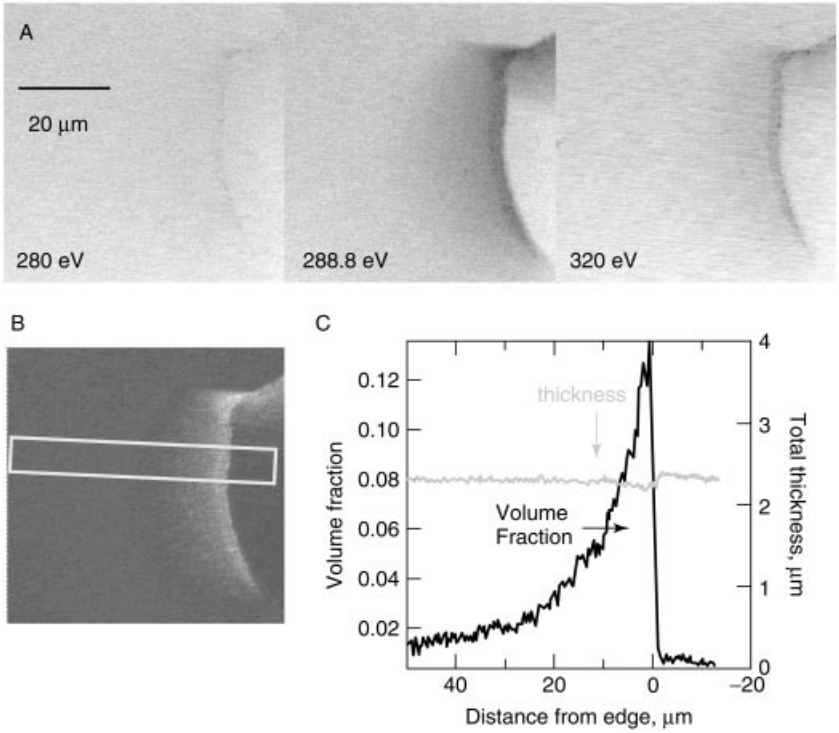

Fig. 13. (**A**) Transmission nexafs images of a saline-swollen microtomed thin section of an SAP bead that was surface cross-linked with ethylene glycol diglycidyl ether. The images were recorded at 280, 288.8, and 320 eV, as indicated; (**B**) Quantitative map of the polymer volume fraction derived via SVD from the three images; (**C**) Profiles of the polymer volume fraction and the total sample thickness (water and polymer) across the edge of the SAP bead, derived from the SVD analysis in the indicated region. chemical contrast between PS and PBrS phases in phase-separating PS/PBrS blends, and made a strong suggestion that the PS encapsulates the PBrS after sufficient annealing (130,131). The second group used a peem to observe chemical surface contrast in annealed, phase-separated PS/PVME (PVME – poly(vinyl methyl ether)) and PS/SAN thin-film blends (127). Additional peem observations concluded that the formation of protrusions in the PS/PVME film are not accompanied by a total dewetting of the polymers from the Si substrate.

PS/PBrS Thin-Film Blends and Bilayers. Initial nexafs microscopy investigations explicitly exploring the time evolution and composition of domains in thin films focused on morphology formation during spin-casting and annealing of PS and PBrS blends. Emphasis was placed on elucidating the late stage morphology after annealing above the glass-transition temperature of both components for samples with different PS/PBrS composition ratios (128). Quantitative nexafs maps derived via SVD composition procedures were compared to atomic force afm topographs and complemented with secondary ion mass spectroscopy (sims) depth profiling. NEXAFS microscopy of annealed samples showed directly that the

morphology changes from "PS droplets" to "PS surface holes" in a continuous PBrS matrix layer as PBrS becomes the majority phase. SIMS data indicated a continuous PS layer at the substrate and the surface interface. The observed continuous PS layer for all blend compositions explained the observed "droplet" and "hole" structures formed for different PBrS fractions. Although the interfacial energy could have been minimized in the bulk if the PS formed spheroidal domains in the

PBrS-rich phases, the continuity constraint of the PS at the interfaces requires the formation of the hole morphologies at high PBrS volume fraction. From the morphologies formed, constraints for the values of the various interfacial energies could be deduced.

PEEM from surfaces can provide a much more direct and unambiguous means of showing PS encapsulation of PBrS than the combination of area averaged sims, surface afm (atomic force microscopy), and bulk stxm measurements. Direct evidence for encapsulation was observed during the dewetting of a PS/PBrS bilayer consisting of a 50-nm thick PBrS film on top of a 30-nm thick PS film (98). These investigations were the first combination of surface (peem) and quantitative bulk (stxm) characterization of a polymeric system to assess and reconstruct the 3-D morphology. As the PBrS is dewetting the PS sublayer, holes form randomly in the PBrS top layer and subsequently grow to form Veronoi tesselation patterns. These patterns consist of an interconnected network of spines that eventually break up to form droplets. The mass thickness maps of the constituent polymers PBrS and PS, as well as the total thickness maps of the bilayer annealed for 1 week, reveal that these "spines" consist of sharply delineated PBrS, which are at least partially wetted, if not encapsulated, by PS walls. PEEM studies of the same type of sample provided surface nexafs spectra from the top 10 nm of the surface from sample areas that included the spines and droplets. Since the PBrS C 1*s* to π^* characteristic spectral feature at 286 eV was not observed from any sample areas (see Fig. 15), one can conclude that the PBrS spines are completely encapsulated. The time taken for evolution (from 0 to 11 days of annealing) of the dewetting process furthermore revealed the encapsulation pathway and also allowed one to know whether polymer diffusion or viscous flow was the dominant encapsulation process: A sufficient number of holes have to form in the PBrS layer through which the PS can penetrate the PBrS film and subsequently flow along the PBrS/air and PBrS/PS interfaces.

Related studies showed that the apparent contact angle at the polymer/air interface decreases exponentially with the PS film thickness, with a constant that depend upon the radius of gyration R_g. The droplets consist of a PBrS core fully

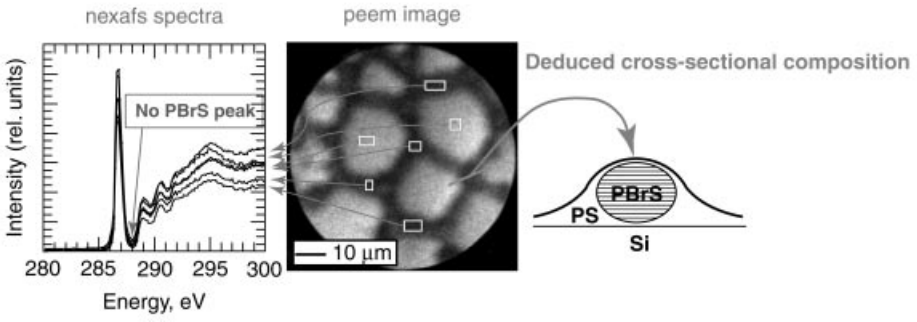

Fig. 15. PEEM images and spectra from a dewetting PBrS/PS bilayer after one week of annealing at 180°C. Spectra from the sample locations are indicated. The combination of stxm and peem characterization allowed the deduction of the 3-D morphology with certainty. (Data acquired with the ALS PEEM-I.) Adapted from Ref. 98.

encapsulated by PS for substrates thicker than R_g while only partial encapsulation is seen with nexafs for substrates with a thickness less than R_g (132).

PS/PMMA Thin-Film Blends. Another excellent model system to investigate the dynamics and the morphologies formed during phase separation in thin films are PS/PMMA blends. A variety of interesting morphologies during both the early and late stages of the phase separation process in PS/PMMA blends have been observed and characterized by a combination of quantitative nexafs mapping and lateral force microscopy (100). Films (143 nm thick) of monodisperse, 50/50 (w/w) PS/PMMA blends spun cast out of toluene solution onto Si substrates were annealed in a vacuum, quenched to room temperature, and subsequently characterized. The composition of the mixed phases resulting from solvent spin casting were determined with quantitative nexafs microscopy. After very short annealing times at 180°, a sudden rearrangement into domains smaller than those originally formed was observed. Subsequently, unique, jagged patterns formed during the early stages of coarsening. These patterns resemble turbulent hydrodynamic mass flow, although they might have an entirely different physical origin. A 50-nm thick 50/50 (w/w) blend of PS/PMMA 27K/27K film on Si annealed at 165°C, and a 50-nm thick 50/50 (w/w) blend of 90k PS and 27K PMMA on Au showed the same kind of ragged morphology, while a 50-nm layer of the 90K/27K blends on Si did not (129). Complicated polymer/polymer interface morphologies persisted in several cases even after extended annealing. These were explained by the dependence of polymer viscosity on film thickness and the constraints imposed by the substrate (100). An example is shown in Figure 16 that shows trapped PMMA spikes inside the PS droplets.

As shown by numerous studies, the initial morphologies from spin casting as well as the final morphologies after annealing depend on the substrate utilized. The dependence of PS/PMMA morphologies and phase separation dynamics on Si, Au, and Co surfaces has been investigated (129). Clearly phase-separated domains are observed on Si and Au surfaces. The morphologies on Co surfaces, however, are more complex. They have a layered appearance and do not evolve much during

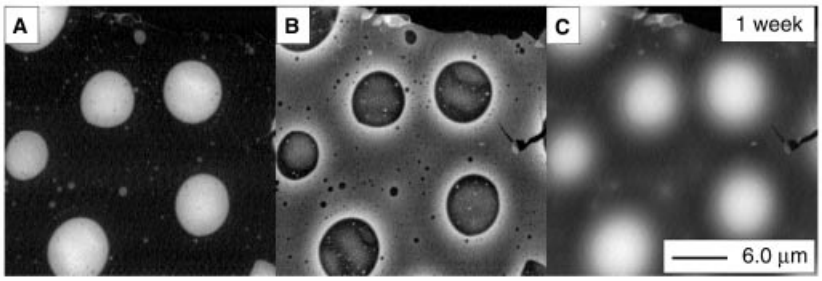

Fig. 16. Quantitative compositional maps derived via an SVD procedure of a nominally 143-nm thick 50/50 (w/w) PS/PMMA blend annealed for 1 week: (**A**) PS mass thickness, (**B**) PMMA mass thickness, and (**C**) total thickness maps, ie, PS plus PMMA maps. All images are individually scaled for good contrast, with Black = 0 and White = maximum mass-thickness. The maximum total thickness of the films increases from the initial 143 nm to 460 nm in Figure 16C due to surface roughening. (Data acquired with the Stony Brook STXM at the National Synchrotron Light Source.) Adapted from Ref. 100.

annealing, presumably because of a lack of either a PS or PMMA wetting layer on the substrate.

PS/PMMA blends spun to different film thickness onto SiO_x surfaces showed that time-temperature superposition is observed. Indirectly, this indicates that the influence of the film thickness on the dynamics is relatively small (133).

While most work on annealed PS/PMMA blends support the formation of phase-separated domains right to the surface, a recent study (134) reports that an encapsulating layer of PS-skin forms over the PMMA domains. The stxm and peem might be a good complementary tool to afm, xps, and nexafs spectroscopy to further elucidate PS/PMMA thin-film blends, their phase separation dynamics, and their surface composition (96).

PS/PMMA with PS-*b*-PMMA Copolymer Thin-Film-Blends and Bilayers. Polymer blends when processed into thin films are typically rough when produced by spin casting on a substrate and roughen even further when annealed. The surface modulation amplitudes of certain spatial frequencies might actually get much larger than the original film thickness. This is due to the phase separation between immiscible polymers, and the effect can be readily observed from Figure 16. This roughening would be a serious problem in many applications and limits the use of polymer blends as materials in ultrathin films. A common strategy to improve miscibility of polymer blends is to add copolymer compatibilizers. The compatibilizer will reduce the interfacial tension if located at the polymer/polymer interface. The tendency of the compatibilizer to form micelles in one of the phases often limits the amount of copolymer that locates at the interface. For relatively strongly segregating systems, formation of a microemulsion has never been achieved. Relying on entropy as a driving mechanism, rather than interfacial energies, it was shown that PS/PMMA thin films can be compatibilized with a PS-*b*-PMMA diblock copolymer (135). Samples of a bottom PMMA layer and a top layer of a blend of PS and 30% of a PS-*b*-PMMA diblock copolymer were annealed. When the top PS/PS-*b*-PMMA layer thickness was comparable to or less than the size of bulk micelles, the film evolves toward a stable 2-D microemulsion. The two-dimensionality of the film was established by showing with nexafs microscopy that the microemulsion phases extended throughout the thin film. It was observed (135) that the loss in configurational entropy as a result of confinement can change the micellar transition for copolymers. Mixing in thin films in the presence of block copolymers can thus be achieved independently of the specific polymer chemistry by making the films thin enough.

The dynamics of the formation of the microemulsion has been assessed (136). The initial growth of the domain size had a growth exponent of 1/3, using the inverse of the wave-vector with maximum amplitude q_{max} derived from Fourier transform analysis as the measure of the domain size. At long annealing times, domain growth slowed dramatically as the block copolymer was forced to the interface, lowering the interfacial energy and thus reducing the driving force for further phase separation. NEXAFS microscopy of the microemulsion thin films that had the PS preferentially washed with cyclohexane revealed directly that the PS-*b*-PMMA diblock copolymer is located at the PS/PMMA interface (see Fig. 17).

Polystyrene/Poly(*n*-butyl methacrylate) Thin-Film Blends. The morphology of polystyrene/poly(*n*-butyl methacrylate) (PS/PnBMA) thin-film blends, and whether encapsulation occurs in this system has been assessed by using SFM,

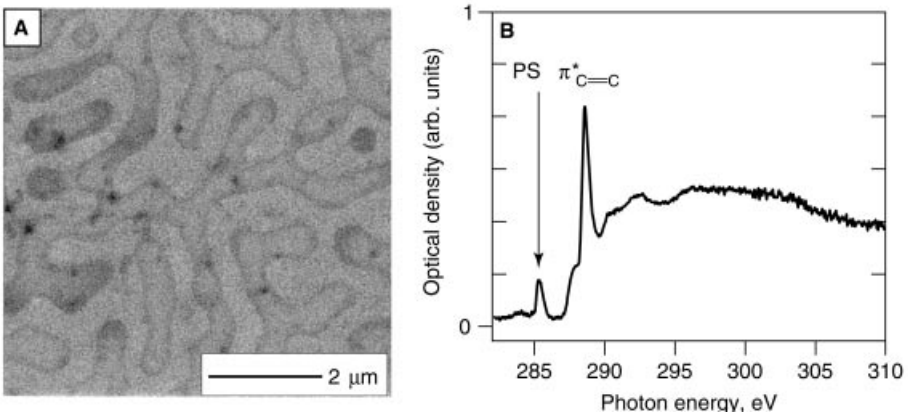

Fig. 17. (**A**) PS $\pi^*_{C=C}$ image acquired at 285.3 eV from a 168-h annealed PS/PMMA/PS-*b*-PMMA microemulsion thin film washed with cyclohexane to remove all PS. At this photon energy, only the aromatic content of styrene will appear dark. Enhanced absorption, although at low contrast, can be detected at the domain interfaces that directly shows that the highest PS-*b*-PMMA block copolymer concentration is located at the PS/PMMA domain interface; (**B**) The nexafs spectrum acquired from 10 μm^2 area of this sample. The PS and PMMA intensities reveal that cyclohexane washing is removing essentially all PS. The remnant 285 eV signal is consistent with expected signal from the PS-*b*-PMMA block copolymer. (Data acquired with the Stony Brook STXM.)

txm, and peem (137). The same droplet-to-hole transition found in the earlier studies by Slep and co-workers (128) with PS/PBrS blends as a function of composition was observed in the PS/PnBMA blends. This strongly suggests that one of the two polymers preferentially segregates to both the substrate and air interface. Investigations of the PS/PnBMA thin films with peem were indeed interpreted to have preferential PnBMA segregation to the surface. Based on the surface composition and morphology observation, one would expect PnBMA to also segregate to the substrate, although no direct measurement regarding preferential segregation to the substrate has been made (137).

Block Copolymer Thin Films. NEXAFS microscopy is also a tool that can provide complementary and unique information for block copolymer organization, which traditionally has been investigated using a wide variety of analytical techniques, including electron microscopy, x-ray scattering, and optical microscopy. These traditional techniques yield considerable information about the morphology and organization of block copolymer materials, but occasionally the information provided is incomplete and provides only "circumstantial" evidence for a conclusion. For example, the novel molecular organization of a high molecular weight rod-coil block copolymer has been investigated (138). This block copolymer has a PS coil block of 9K molecular weight and a main-chain poly(hexyl isocyanate) (PHIC) rod block of 245K molecular weight. Homopolymer PHIC is known to behave as a lyotropic nematic liquid crystal in a wide range of solvents with a persistence length of 50–60 nm. Rotational motion along the backbone of the PHIC is limited by short-range interactions, leading to inherent chain stiffness. The PS behaves as a typical coil polymer with a low persistence length. Combined as a block copolymer, there is competition between the microphase separation of the

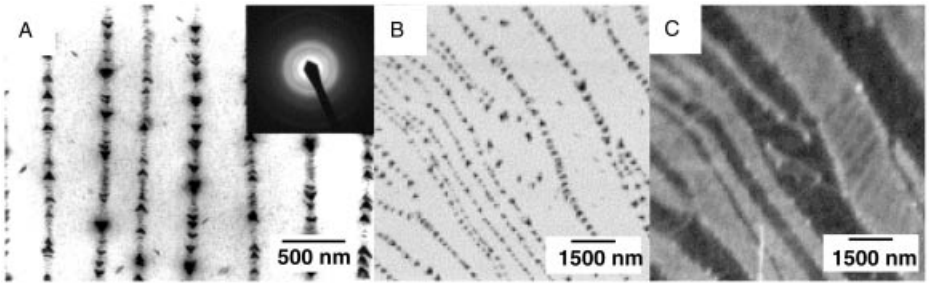

Fig. 18. (**A**) tem image of PS-*b*-PHIC diblock copolymer and small area electron diffraction pattern averaged over several lamellae; (**B**) nexafs image at 285.2 eV (PS dark); and (**C**) nexafs image at 288.5 eV, where the PHIC layers have altering contrast because of differences in orientation. (Data acquired with the Stony Brook STXM.) Courtesy of C. Zimba, NIST, and E. Thomas, MIT.

PS and PHIC blocks into periodic structures and the tendency of the PHIC block to form anisotropically ordered structures, giving rise to new morphologies. A typical tem image from solution cast thin films is shown in Figure 18A and clearly shows a microphase-separated morphology with long-range order over tens of microns. The PS domains, stained with RuO_4, appear as dark regions shaped somewhat like arrowheads while the PHIC regions appear as largely featureless light regions between rows of PS domains. An interesting feature in this image is the orientation of the PS arrowheads which changes direction between adjacent PS-rich layers. On account of radiation damage, the small area electron diffraction (SAED) pattern had to be obtained from a sample area of 10–20 lamellae. The SAED pattern (inset of Fig. 18A) shows a superposition of two distinct single crystal-like PHIC patterns rotated relative to each other by approximately 90°, indicating that the PHIC chain axis alternates between +45° and −45° with respect to the geometric normal of the lamellae layers. While the evidence for the alternating 45° PHIC oriented layers is quite strong, it is only indirect, and the orientation could not be observed directly with tem.

To directly investigate the orientation of the PHIC lamella, thin film samples cast from 0.05% solutions in toluene onto uncoated tem grids were examined with nexafs microscopy (139). Using an x-ray energy corresponding to the phenyl carbon resonance of the PS (285.2 eV), nexafs imaging clearly shows a similar arrowhead morphology as the tem image, albeit at lower spatial resolution (see Fig. 18B). At the carbonyl resonance of the PHIC at 288.5 eV, nexafs images reveal the structure of the PHIC layers in ways not available with tem (Fig. 18C). The PHIC domains appear as layers of alternating intensity separated by the PS domains that appear as white pearls. The intensity variation of the PHIC layers arises from differences in dichroic absorbance of the polarized synchrotron radiation because of orientation of the carbonyl moiety, and thus also the backbone, of the PHIC. In contrast to the average SAED pattern, the nexafs image is able to give detailed information about the orientation of individual PHIC domains. NEXAFS microscopy furthermore reveals previously unsuspected microstructure within the PHIC domains that are clearly not entirely homogeneous, but show striations in a direction across the lamellae.

Multicomponent, Multiphasic Polymers

Many polymeric materials of academic and industrial interest are multicomponent polymers that have multiple phases in the bulk. Control over the composition and size distribution of the domains and their interface properties is often very important in determining the materials properties. A variety of blends and multiphasic polymers have already been investigated with nexafs microscopy. These include studies of

(1) the morphology of PET/PC (140), low density PE/PET/Kraton (141), and PC/(acrylonitrile butadiene styrene) blends (141,142), and macrophase-separated random block copolymer/homopolymer blends (143);
(2) the morphology and composition of mechanically alloyed PET/poly (oxybenzoate-*r*-oxynaphthoate) [Vectra (Celanese Corp.)] blends (144), mechanically alloyed and rubber-toughened PMMA (145), mechanically alloyed poly(ethylene-*alt*-propylene) (PEP)/PMMA and PI/PMMA blends (146–150), and the assessment of recycling of tires by mechanical alloying (151);
(3) the characterization of phase separation during processing, such as the formation of precipitates in polyurethanes (13,19,152) and multiphase liquid crystalline polyesters (141);
(4) single- and multistep synthesized latexes and structured microspheres (153–155); and
(5) various multilayers (156,157).

Included here as examples is a discussion of the characterization of PET/Vectra blends, blends produced by cryogenic mechanical alloying, various polyurethane polymers, multilayers and structured spheres, as well as rubber composites. The discussion of the PET/Vectra blends is particularly instructive, as this study combined chemical and orientational analysis.

NEXAFS Microscopy of Mechanically Alloyed Blends. Mechanical alloying of polymers has the potential of becoming an alternative, novel means of producing and recycling polymer blends (144,146–148,150,151,158). The efficacy of such a new method is best assessed by direct visualization of the morphology of the generated materials.

Since incorporation of liquid crystalline polymers (LCPs) into commodity thermoplastic polymers remains an ongoing challenge in the design of new high performance, low cost polymeric blends, the feasibility of blending of PET and Vectra A950 [73/27 (mol/mol) oxybenzoate/2,6-oxynaphthoate] with mechanical alloying was investigated (144). The morphology and composition of dispersions in PET and Vectra blends are difficult to assess with conventional microscopies, because of a lack of staining agents for electron microscopy, and spatial resolution limitations of optical and ir microscopy. Despite the presence of similar functional groups in each polymer, such as aromatic and carbonyl groups, nexafs microscopy can readily delineate the morphology. After mechanical alloying, the resulting powders were melt-pressed at 285°C (above the melting points of PET and Vectra) for 5 min and cryomicrotomed at −100°C to obtain sufficiently thin sections for nexafs microscopy. Melt-pressed films of PET/Vectra alloyed blends

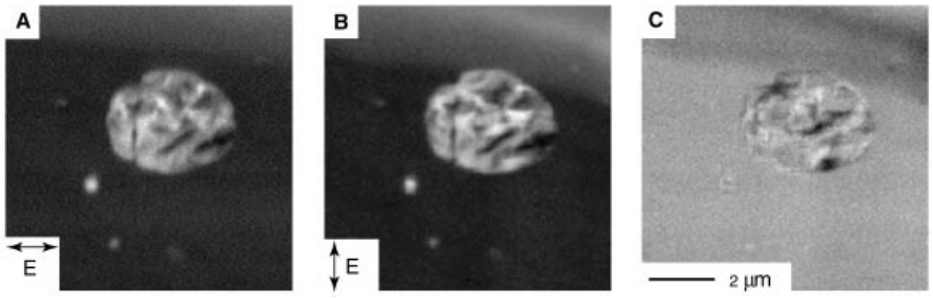

Fig. 19. NEXAFS images acquired at 286.7 eV of a 99/1 (w/w) PET/Vectra blend subjected to post-milling melt pressing. Images (**A**) and (**B**) have been converted to optical density. In images (**A**) and (**B**), the electric polarization vector $\vec{E}$ is rotated by 90° with respect to each other, as indicated. Changes in the relative intensity in these images are primarily due to anisotropic molecular orientation. The ratio of these images (**C**) reveals the linear dichroism of the specimen. Small Vectra domains appear gray and possess no discernible orientation, whereas the large dispersion exhibits a measurable degree of molecular orientation (black and white areas) because of the nematic nature of this liquid crystalline polymer. (Data acquired with the Stony Brook STXM.) Reproduced from Ref. 144.

varying in composition from 75/25 to 99/1 by weight percent were investigated. The frequency and size of the Vectra dispersions increased with increasing Vectra concentration (144). The distribution in size ranged from 100 nm to about 20 μm in diameter. The presence of these small, 100-nm Vectra domains demonstrated that mechanical alloying is capable of pulverizing Vectra. The PET/Vectra blends retained much of the initial degree of mixing during post-processing in the molten state. Point nexafs spectroscopy showed that the Vectra domains contained little, if any PET. Molecular orientation in the Vectra domains was characterized with linear dichroism microscopy. Figure 19 shows x-ray micrographs of the 99/1 (w/w) PET/Vectra blends acquired at 286.7 eV. The image contrast between Vectra dispersions and the PET matrix is based on differences in the nexafs spectra of the two polymers (see Fig. 2). Some of the contrast within the larger Vectra domains arises from molecular orientation and thickness variations. The dichroic ratio image (Fig. 19C), derived from the two orientations displayed in Figures 19A and 19B, cancels thickness and compositional effects: anisotropic orientation inside Vectra domains was only observable in domains larger than about 2 μm.

Other blends produced by mechanical alloying and investigated with nexafs microscopy included blends of poly(ethylene-*alt*-propylene) (PEP), polyisoprene (PI), and PMMA (146–150). PI can be readily differentiated from PMMA with electron microscopy by heavy metal staining of the PI, but PEP and PMMA cannot be differentiated. In the blends investigated, intimate mixing at the nanoscale was accomplished. Since mechanical alloying is a highly nonequilibrium, high energy method with effects that resemble those of high energy radiation (159), it seems likely that bonds are breaking, and radicals, and maybe even new bonds in new chemical configuration, are forming during alloying. It is the detection of these chemical modifications where nexafs microscopy might be particularly useful. However, the extent of any chemical changes occurring has been below the sensitivity limit of nexafs microscopy.

In the PEP/PMMA blends an anomalous phase inversion was observed (148). Phase inversion in polymer blends is typically encountered under conditions of melt flow. However, the unexpected phase inversion occurred upon quiescent annealing in an asymmetric blend of PMMA and PEP prepared by cryogenic mechanical alloying, where there is very little flow. For short milling times, consolidation of the cryomilled powders at temperatures above the glass-transition temperature of PMMA exhibited dispersions of PEP in 75/25 (w/w) PMMA/PEP blends. However, as the milling time increased to 10 h, the consistency of the blends changed from rigid to pliable. nexafs microscopy revealed that for the long milling times the PMMA becomes the dispersed phase upon consolidation, and it directly confirmed that phase inversion occurs during consolidation. The transition from PEP dispersions to a continuous PEP phase as observed with nexafs microscopy is shown in Figure 20.

The strategy of producing highly dispersed blends of thermoplastics and tires was also investigated in an effort to provide a potentially new route by which to recycle discarded tires (151). NEXAFS microscopy showed that cryogenic mechanically alloyed tires can be dispersed in PET and PMMA matrices with submicron domains. The tire and thermoplastic did not appear to interact chemically. For the milling conditions employed, there was also no significant chemical interaction between constituent polymers in PI/tire/PMMA ternary blends. Based on the ability to produce good dispersion of the tire material, the results indicated that

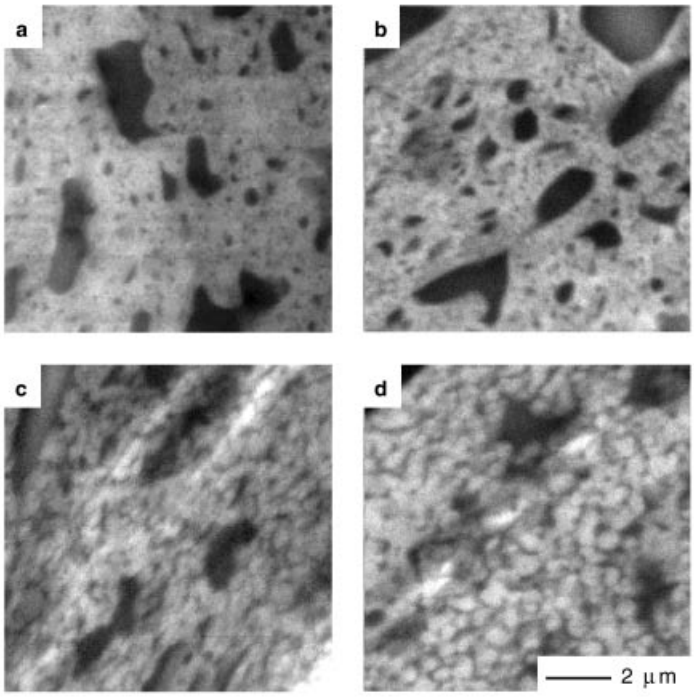

Fig. 20. NEXAFS images at 288 eV (PEP appears dark) of a 25/75 PEP/PMMA blend cryomilled for 10 h and annealed at 150°C for different times (in min): (**a**) 1, (**b**) 2, (**c**) 5, and (**d**) 30. (Data acquired with the Stony Brook STXM.) Adapted from Ref. 148.

cryogenic mechanical alloying constitutes a viable alternative for recycling elastomeric materials.

Engineered Polyurethane and Polyurea Polymers. Polyurethane polymers constitute a versatile class of engineered polymers of great economic value. Despite the ubiquitous utilization and considerable past research, several fundamental aspects of these polymers are not well understood because of the complex chemical reactions and physical processes during production. Over the past few years it has become clear that x-ray spectromicroscopy can uniquely address some complex issues in polyurethane research (19,66,160–163).

The urea distribution in polyurethanes is presumed to have a major influence on the mechanical properties of polyurethane foam (modulus, compression set, load bearing, etc), yet relatively little is known beyond the average size and nanoscale distribution of the so-called hard-segment urea as measured with x-ray and neutron scattering techniques. The mesoscale hard-segment urea distribution in polyurethane materials might be connected to physical properties and is strongly influenced by the relative amounts of urea and carbamate (urethane) present, which in turn is closely linked to formulation and processing. The urea/urethane ratio and its distribution through the material is thus an important quantity. In certain formulations, macrophase separation occurs. Using polymer reference standards with known chemical composition, the spectral signal corresponding to the urea and urethane components (typically only $\sim$20% in systems of interest) can be isolated and quantified (18,19). Based on similar quantitation, the composition and sharpness of precipitates in two high water TDI polyurethane plaques made with different polyols have been assessed at the submicron level (164). The precipitates in both materials were highly enriched in urea. One of the materials had a fuzzy interface to the polyether-rich matrix, while the second material had a more sharply delineated interface. The fuzzy precipitates were more isolated, while the sharper "precipitates" appear to have formed a network of urea-rich domains. These observations will lead to an improved understanding of structure–property–processing relationships in polyurethane polymers.

Another key parameter influencing physical properties in polyurethane foams is the distribution of additive or modifier phases. These modifier phases are typically smaller than a few microns in size. Two compositionally different, common modifier particles, polyurethane-rich, polyisocyanate polyaddition (PIPA) based and styrene-acrylonitrile (SAN) based particles, were dispersed in a TDI-based, polyether-rich polyurethane matrix. Both particles have the same contrast in tem and cannot be distinguished. In contrast, nexafs micrographs of this material show clear differences: at 285 eV, both types of particles are dark dispersions, while at 287 eV, only the SAN particles are highly absorbing relative to the matrix. The uniformity of their composition and the size distribution could thus be determined (165). Discrimination between the two types of particles has also been achieved at the nitrogen absorption edge and, to a lesser extent, the oxygen edge. The chemical composition of the largest SAN particles was found to be independent of particle size. It was furthermore determined that the SAN particles contain about 12 wt% polyether.

Structured walls of complex capsules based on polyurea chemistry have been investigated (166). Polymer capsules are frequently used to encapsulate other chemicals for a variety of purposes, including controlled release of drugs, nutrients,

or pesticides. In these applications, the structure and composition of the capsule wall is of paramount importance. The capsules investigated were produced by a polymerization reaction between amine- and isocyanate-based chemicals at the interface of organic and aqueous phases. In addition to the amine–isocyanate reaction that produces an asymmetric aromatic urea, a competing reaction between the isocyanate and water produces a symmetric diaromatic urea. These competing reactions can lead to the formation of compositional gradients in the submicrometer thick capsule wall. Figure 21 shows reference spectra of model urea compounds, compositional maps, and line profiles of two capsule walls produced by different protocols. The asymmetry of the urea and diurea functionalities can be clearly observed. Comparison of these compositional profiles with diffusion and reaction kinetics will allow the detailed modeling of the capsule wall formation.

Multilayers and Structured Spheres. Multilayer structures are used extensively in photographic applications, such as optical and x-ray photography and xerographic processes, as well as in packaging materials. Several such materials were so far investigated with nexafs microscopy.

The degree of spatial uniformity of a nitrogen containing charge transfer compound present in a protective polycarbonate (PC) capping layer above the image sensing layer of a test photoconductive thin-film structure from Xerox Research Center of Canada has been determined with nexafs microscopy. A simple, 5-min measurement consisting of an image at 407 eV of the film and a nitrogen 1*s* linescan energy sequence showed that the ($\sim$10%) nitrogen content of the PC layer was distributed throughout the PC layer with a relatively uniform ($\pm$20%) distribution, but with some gradient in density toward the exterior of the thin film. By comparison, it was barely possible to detect any nitrogen, and thus impossible to analyze the spatial distribution of the charge transfer component, by either energy loss or x-ray fluorescence spectroscopy in a state-of-the-art JEOL 2010 analytical tem (168).

Several multilayer polymer films used in photography have been characterized with nexafs microscopy. In one structure, consisting of four layers of 0.7–3 μm in thickness coated on a base layer, nexafs images clearly showed each of the layers. The nexafs spectra from closely spaced points showed no significant interpenetration between two layers of interest, poly(styrene acrylonitrile) and a porous carbon black (156). The nexafs microscopy of another laminate consisting of nine layers on a base layer revealed a microstructure of undetermined origin dispersed throughout the fourth layer (169,170). The domains of these microstructures are elongated in the direction parallel to the layer boundary. This microstructure is not observed in the tem, and is likely due to a compositional microphase separation or a preferential orientation of the aromatic groups present in some of the compounds.

A commercially available multilayer used as food container provided a suitable test structure for nexafs microscopy, particularly since this multilayer had been previously characterized with ir microscopy. Because of the spatial resolution limitations of ir microscopy, a special procedure had to be used to analyze the thinnest of the nine layers, about 4 μm thick. The objective of an x-ray microscopy study of this multilayer was to further elucidate the chemical composition of the thinnest layers within the sample, and to provide a basic comparison between ir and nexafs microscopy (157). NEXAFS microscopy could acquire spectra from all

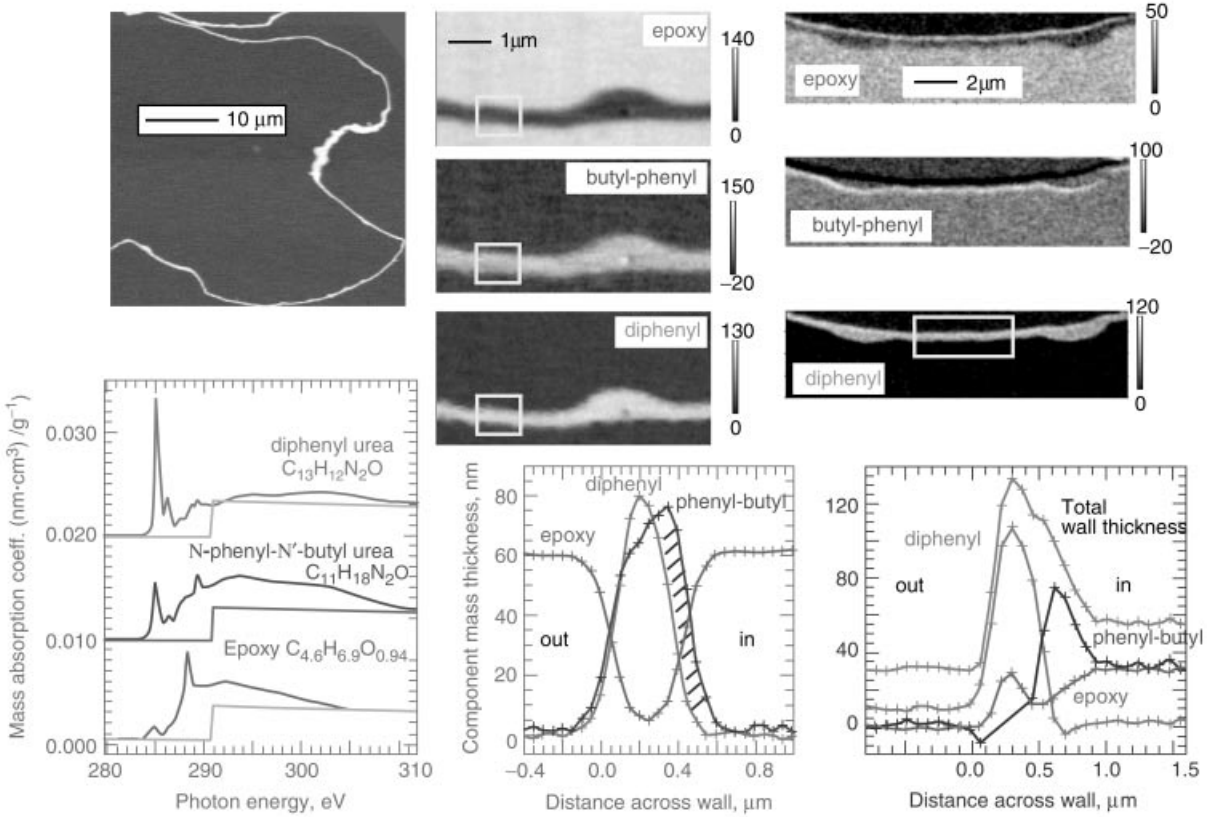

Fig. 21. NEXAFS characterization of polyurea capsules. The upper left shows a low resolution image acquired at 285 eV of a microtomed section containing a nearly complete capsule embedded in epoxy. The lower right shows the C 1*s* spectra of the epoxy, butylphenylurea (asymmetric model) and diphenylurea (symmetric model). The center panel displays (top) component maps derived from image sequences and (bottom) average line profiles of each component across the capsule wall in the indicated region. The right panel shows the corresponding signals for a capsule wall prepared with a longer emulsification step. This process leads to a thick outer skin of symmetric urea. (Data acquired with the ALS BL 7.0 STXM.) Courtesy of A. P. Hitchcock. Adapted from Ref. 166 and 167.

layers without interference from adjacent layers. It established that several of the thin layers had virtually the same composition, a result not obtained from the ir measurements. Unfortunately, the present lack of a comprehensive and accurate nexafs spectroscopy database of polymers prevented the positive identification of some of the layers.

Structured polymer microspheres are attractive for a wide number of applications, including biomedical devices and controlled release reservoirs. Particular morphologies desired for different applications require control over internal porosity and core–shell structures. In order to optimize the internal or core–shell morphologies of such composite materials for particular applications, quantitative compositional analysis is often required. Structured latex spheres have first been analyzed using nexafs microscopy (153). More recently, core–shell microspheres have been investigated (155). In the latter experiment, a two-step precipitation polymerization resulted in 3.2 μm polydivinylbenzene-55 (DVB55) cores coated with $\sim$0.4–0.9 μm wide shells composed of poly(DVB55-*co*-EDMA), a copolymer of DVB55 and ethylene glycol dimethylacrylate (EDMA). Singular value decomposition of images recorded at selected photon energies yielded quantitative maps of the DVB55 and EDMA components. The EDMA concentration in the shell as determined by nexafs microscopy was in good agreement with that predicted from the comonomer composition. It was shown that the precision of compositional quantitation is adequate to be useful in guiding the development of structured polymeric systems for particular applications.

Elastomeric Composites. Blends and composites based on styrene–butadiene rubber (SBR) and butadiene rubber (BR) are widely used throughout the rubber industry in order to get a balance of properties that cannot be achieved through the use of a single elastomer. Typically blends are formed using immiscible elastomers. The vast majority of these blends are heterogeneous on some length scale (171,172), and their mechanical properties are determined, in part, by their phase morphology. Many blends are further complicated by the addition of both fillers and curatives. In addition to determining the polymer phase structure itself, it is desirable to determine the distribution of fillers and curatives in each of the elastomer phases.

Most present automobile and truck tires are made from SBR and BR mixtures. These application requirements are severe and tires are constantly being improved. For example, poly(isobutylene-*co*-4-bromomethylstyrene) can be blended with highly unsaturated general-purpose rubbers to impart unique barrier or dynamic properties and enhanced oxidative stability. The final properties of such a blend are the result of a complex series of compounding, mixing, and curing stages. These stages profoundly impact the homogeneity of the mixed components, which include the polymers, the filler, and the curatives. The characterization of the phase morphology of blends of commercial rubbers like polybutadiene (PB), polyisoprene (PI), poly(butadiene-*co*-styrene), and brominated poly(isobutylene-*co*-4-methylstyrene) (BIMS) continues to represent a problem for conventional techniques, especially in the case of filled rubbers. The utility of nexafs microscopy for these applications have thus been explored and it was found that the phase morphology of various blends and the distribution of silica and carbon black fillers can be determined based on spectroscopic differences (173). However, the size of most filler particles is still below the present spatial resolution of nexafs microscopy.

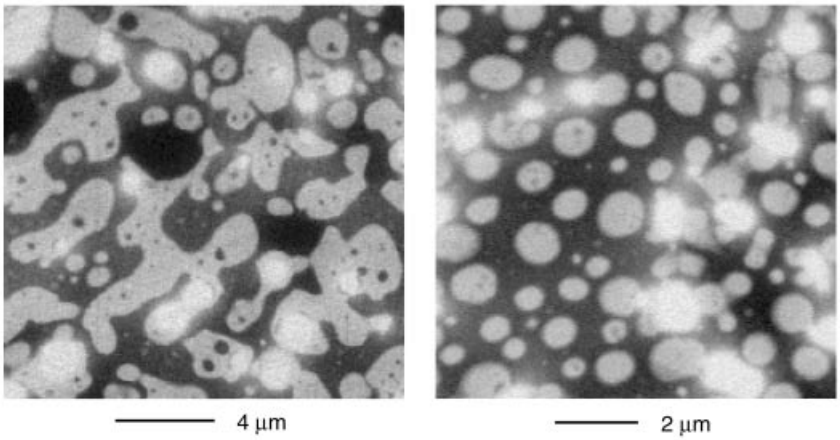

Fig. 22. NEXAFS micrographs of (**A**) d-PB/BIMS-1 [50/50 (w/w)] and (**B**) d-PB/BIMS-1/hSBR [45/45/10 (w/w)] blend supported by a Si_3N_4 membrane. The film was annealed in a vacuum oven for 18 h at 150°C. The dark areas correspond to the dPB phase. (Data acquired with the Stony Brook STXM.) Adapted from Ref. 174.

These kinds of applications will greatly benefit from future technical advances and improvements in spatial resolution.

Similar elastomer blends were also studied (174). The interfacial properties of PB and BIMS blends were determined with a variety of tools including neutron scattering and microscopy. The interfacial width decreased with increasing bromine functionality. The effects of a styrene butadiene random copolymer (SBR) on the miscibility were also investigated. The results show that SBR enhances the compatibilization of the PD/BIMS blends. NEXAFS micrographs of annealed PB/BIMS and PB/BIMS/SBR blends are shown in Figure 22. The smaller BIMS domains in the PB/BIMS/SBR blends indicate that SBR indeed compatibilizes PB/BIMS blends, which is consistent with the observations and conclusions drawn from neutron reflectivity and afm measurements. The effects of carbon black and silica on the interfacial properties of PB/BIMS blends have been investigated with neutron reflectivity, ultra-small angle neutron scattering, spm, and nexafs microscopy (175).

Fibers

NEXAFS microscopy is also well suited to study the composition and structure of fibers. The qualitative orientation of functional groups in poly(*p*-phenylene terephthalamide) [Kevlar (DuPont)] fibers has been investigated and it was found that aromatic groups are, on average, pointing radially outwards (176). Subsequently, the relative quantitative orientational order was characterized in three different grades of Kevlar fibers and it was found that Kevlar 149 is 2.3 and 1.6 times as radially orientated as Kevlar 29 and Kevlar 49, respectively (177). This variation in orientation is relatively large, given that the crystallinity of all fiber grades is above 85%. More recent work on these fibers combined absorption spectroscopy at the carbon, nitrogen, and oxygen edges. This combination, in conjunction with

theoretical calculations, can estimate the absolute degree of radial orientation in these fibers. Preliminary analysis indicated that Kevlar 149 is about 50% radially orientated (178,179).

NEXAFS microscopy has been used to study the effect of heat treatment on polyacrylonitrile fibers (180). In heat-treated fibers, a clear core-rim structure was observed in images at several photon energies. A decrease in the nitrile group concentration was measured in the core of these fibers when compared to the untreated fibers.

Conclusion and Future Outlook

NEXAFS microscopy has moved well beyond proof-of-principle experiments and has evolved into a tool that has been used in a variety of polymer science and technology projects. It is particularly noteworthy to remark that numerous industrial partners have participated over the last few years in nexafs microscopy experiments. Some of these industrial experiments performed, some with high industry internal impact, will remain unpublished, because of proprietary concerns.

While nexafs microscopy capabilities are continually improving, the field has not yet reached any fundamental performance limits. For example, the far-field wavelength-limited spatial resolution for zone-plate-based microscopes is about 3 nm for carbon K-edge energies, about an order of magnitude better than the resolution presently achieved. Similarly, several aberration corrected peem's with a projected spatial resolution of about 2 nm are planned or under construction (80,81), while the best peem's to date have a spatial resolution of 20 nm. Significant technical challenges have to be overcome for both peem and, in particular, zone-plate-based microscopes to achieve these substantial improvements in spatial resolution. Nonetheless, improvements and further technological developments can be confidently anticipated in the next few years.

Several new operating modalities such as tomography (181,182), cryomicroscopy (103,182), and dark-field microscopy (183) have already been implemented in transmission. Because of their limited routine availability, they have not been discussed in detail in this review. These operating modes should prove very beneficial for certain applications in polymer science and technology. In particular, the radiation dose will have to increase as the spatial resolution improves. This might evolve into a relatively serious issue for the study of the more sensitive polymeric materials. Procedural improvements, more efficient detector development, and use of cryomicroscopy might have to be used extensively to minimize damage.

Applications beyond those possible today might be enabled through the use of higher energy resolution that reveals subtle spectral features. Studies on PS and deuterated PS have shown, for example, that nexafs of polymers can be sensitive to vibrations (3). This might serve as an additional contrast mechanism in several applications. The establishment of a nexafs spectroscopy database similar to the spectroscopy database available in the ir community would greatly facilitate quantitation and analysis of materials for which prior knowledge is very limited. In parallel to the development of a spectroscopic database, improved theoretical modeling would expand the ability to interpret nexafs spectra and the chemical structural information that they provide.

Improved and more dedicated facilities are about to be commissioned at the ALS in Berkeley and BESSY-II in Berlin, and are under development at the Canadian Light Source in Saskatoon. While there remain many scientific questions that can be addressed with the present performance of existing nexafs microscopes, improved capabilities and the increasing availability of nexafs microscopy will result in significant growth of applications in polymer science and related fields.

Based on the progress made to date and the improvements that can still be achieved, we are confidently looking forward to continuing growth of the nexafs spectroscopy and microscopy community and to exciting applications that have not yet been conceived.

ZIEGLER–NATTA CATALYSTS

Introduction

Ziegler–Natta catalysts have had enormous impact on the polymer industry in the past 50 years, with current world production of polyolefins using Ziegler–Natta catalysis amounting to more than 50 million tons per annum. The vast advances made during the past decades stem from breakthrough discoveries made by Karl Ziegler and Giulio Natta in the early 1950s. It was in 1953 that Ziegler and co-workers, at the Max Planck Institute in Mülheim, were investigating the "Aufbau" reaction in which triethylaluminum reacts with ethylene to give higher aluminum trialkyls (1). Unexpectedly, one experiment led not to the oligomerization of ethylene via the Aufbau reaction, but to the formation of 1-butene. It turned out that this dimerization reaction had been catalyzed by traces of nickel present as a contaminant in the reactor. Soon afterwards, a revolutionary breakthrough was achieved when combinations of transition-metal compounds and aluminum alkyls were found that could polymerize ethylene under mild conditions, yielding high density polyethylene (2,3). In 1954 Giulio Natta and co-workers at Milan Polytechnic succeeded not only in polymerizing propylene with the Ziegler catalyst combination $TiCl_4/Al(C_2H_5)_3$, but also in fractionating the resulting polymer to obtain and characterize isotactic polypropylene (4–6). This demonstration of stereoregular polymerization led to an explosive growth of new polymers and industrial applications as the full scope of Ziegler–Natta catalysis was realized (7–9); Ziegler and Natta were jointly awarded the Nobel Prize for Chemistry in 1963.

Ziegler–Natta catalysts for polyethylene and polypropylene have progressed from first-generation titanium trichloride catalysts, used in the manufacturing processes of the late 1950s and the 1960s, to the high activity magnesium chloride supported catalysts used today. Improvements in catalyst performance have

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

facilitated the development of efficient gas-phase and bulk processes for polyethylene and polypropylene, and at the same time have led to ever-increasing control over polymer composition and properties.

Early Catalysts

Titanium Trichloride. One of the first catalysts found by Ziegler to be effective in ethylene polymerization was the product of the reaction of titanium tetrachloride with triethylaluminum. At low Al/Ti ratios, this reaction yields titanium trichloride as a solid precipitate. $TiCl_3$ exists in four crystalline modifications, the α, β, δ, and γ forms, of which the β-modification has a linear (chain-like) structure and the α, δ, and γ forms have a layered structure (10,11). The reaction product of $TiCl_4$ and AlR_3 is β-$TiCl_3$, which can be converted to the γ form by heating. The latter catalyst has much higher stereoregulating ability in propylene polymerization, while β-$TiCl_3$ is an effective catalyst for the production of *cis*-1,4-polyisoprene. α-$TiCl_3$ can be prepared by reduction of $TiCl_4$ with hydrogen or with aluminum powder. The δ form can be prepared by prolonged grinding of γ- or α-$TiCl_3$ and has a more disordered structure as a result of sliding of Cl–Ti–Cl triple layers during mechanical activation (12).

The first-generation Ziegler–Natta catalysts used in early manufacturing processes for polypropylene (PP) comprised $TiCl_3$ and cocrystallized $AlCl_3$, resulting from reduction of $TiCl_4$ with Al or an aluminum alkyl. The cocatalyst used in the polymerization process was $Al(C_2H_5)_2Cl$ (DEAC). Catalyst activity was relatively low, giving polymer yields of around 1 kg PP/g cat., necessitating removal (deashing) of catalyst residues from the polymer. In many cases, extractive removal of atactic polymer was also required.

Other Early Developments. In addition to the breakthrough by Ziegler, two other discoveries of ethylene polymerization catalysts were made in the early 1950s. A patent by Standard Oil of Indiana, filed in 1951, disclosed reduced molybdenum oxide or cobalt molybdate on alumina (13). At the same time, Phillips discovered supported chromium oxide catalysts, prepared by impregnation of a silica–alumina support with CrO_3 (14–16). Both the Phillips catalyst and titanium chloride based Ziegler catalysts are widely used in the production of high density polyethylene (HDPE).

The various discoveries made independently by different industrial research groups in the early 1950s resulted in intensive patent litigations (8,17,18), which in the case of PP continued up to the 1980s, when a composition of matter patent on PP was awarded in the United States to Phillips, because a fraction of crystalline PP was found to be present in a polymer prepared using a $CrO_3/Al_2O_3/SiO_2$ catalyst (19). However, despite the importance of the Phillips catalyst for HDPE, it was unsuitable for PP, which is produced entirely using Ziegler–Natta catalysts and (to a much smaller extent) metallocene-based catalysts.

Second-Generation Catalysts. In the 1970s, an improved $TiCl_3$ catalyst for PP was developed by Solvay (20). Catalyst preparation involved reduction of $TiCl_4$ using DEAC, followed by treatment with an ether and $TiCl_4$. The ether treatment results in removal of $AlCl_3$ from $TiCl_3 \cdot nAlCl_3$, while treatment with $TiCl_4$ effects a phase transformation from β- to δ-$TiCl_3$ at a relatively mild

temperature (<100°C) (21). Using catalysts of this type, it was possible to obtain PP yields in the range 5–20 kg/g cat. in 1–4 h of polymerization in liquid monomer (22). Commercial implementation of second-generation catalysts was, however, overshadowed by the advent of third- and later-generation magnesium chloride supported catalysts (discussed under Ziegler–Natta Catalysts for Polypropylene).

Polymerization and Particle Growth

Polymer Chain Growth. The essential characteristic of Ziegler–Natta catalysis is the polymerization of an olefin or diene using a combination of a transition-metal compound and a base-metal alkyl cocatalyst, normally an aluminum alkyl. The function of the cocatalyst is to alkylate the transition metal, generating a transition-metal–carbon bond. It is also essential that the active center contains a coordination vacancy. Chain propagation takes place via the Cossee–Arlman mechanism (23), in which coordination of the olefin at the vacant coordination site is followed by chain migratory insertion into the metal–carbon bond, as illustrated in Figure 1.

Regulation of polyolefin molecular weight is effected by the use of hydrogen as chain-transfer agent. Chain transfer can also occur via β-hydrogen transfer from the growing chain to the transition metal or to the monomer, and to a lesser extent via alkyl exchange with the cocatalyst (Fig. 2).

In propylene polymerization using titanium chloride catalysts, chain propagation takes place via primary (1,2-) insertion of the monomer. For isospecific propagation, there must be only one coordination vacancy and the active site must be chiral. Corradini and co-workers have demonstrated that the asymmetric

$$\text{Ti-CH}_2\text{-CH}_2\text{-Polymer} + \text{CH}_2{=}\text{CH}_2 \longrightarrow \text{Ti-CH}_2\text{-CH}_3 + \text{CH}_2{=}\text{CH-Polymer}$$

$$\text{Ti-CH}_2\text{-CH}_2\text{-Polymer} + \text{AlR}_3 \longrightarrow \text{Ti-R} + \text{AlR}_2\text{-CH}_2\text{-CH}_2\text{-Polymer}$$

Fig. 2. Chain transfer in ethylene polymerization.

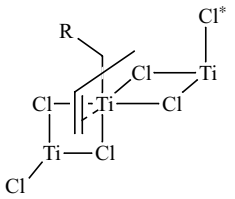

Fig. 3. Model for stereospecific polymerization of propylene. The orientation of the growing chain is influenced by the chlorine atom marked with an asterisk.

environment of the active site forces the growing chain to adopt a particular orientation so as to minimize steric interactions with (chlorine) ligands present on the catalyst surface (24). This in turn leads to one particular prochiral face of the incoming monomer being preferred, as illustrated in Figure 3, leading to isotactic polymer.

An elegant demonstration of the above mechanism has been provided by Zambelli and co-workers (25), who showed that the first insertion of propylene into a Ti—CH_3 bond generated by chain transfer with Al alkyl using the system $TiCl_3/Al(CH_3)_3$ is *not* stereospecific, whereas the second insertion (ie into Ti–isobutyl) *is* stereospecific. The importance of the combined effects of the steric bulk of the Ti–alkyl group and the halide ligand is apparent from the very high stereospecificity observed using TiI_3 (26). Particularly high stereospecificity (but low activity) was also found by Natta when $TiCl_3$ was used in combination with $Al(C_2H_5)_2I$ (27).

In contrast to the isospecific titanium-based catalysts, vanadium-based catalysts give predominantly syndiotactic PP. At very low polymerization temperature (-78°C), living polymerization can be obtained using homogeneous catalysts obtained by reaction of a vanadium compound (eg VCl_4 or a V(III) β-diketonate) with R_2AlCl (28,29). With these catalysts, syndiospecific propagation occurs via secondary (2,1-) insertion of the monomer. The overall stereo- and regioregularity of the polymer is poor, comprising not only syndiotactic blocks resulting from secondary insertions but also short, atactic blocks arising from sequences of primary insertions. This polymer has not been developed commercially, but vanadium catalysts are used in ethylene (co)polymerization (outlined under Ziegler–Natta Catalysts for Ethylene (Co)polymerization). C_s-symmetric metallocene catalysts (30) have been developed for the production of syndiotactic polypropylene having significantly higher chain regularity.

Polymer Particle Growth. A very important feature of any heterogeneous catalyst used in slurry and gas-phase processes for polyolefin production is particle morphology. Heterogeneous Ziegler–Natta catalysts are microporous solids, with particle sizes typically in the range 10–100 μm. Each particle comprises millions of primary crystallites with sizes of up to about 15 nm. On contacting the catalyst components, at the start of polymerization, cocatalyst and monomer diffuse through the catalyst particle and polymerization takes place on the surface of each primary crystallite within the particle. As solid, crystalline polymer is formed, the primary crystallites are pushed apart as the particle grows, analogous to the expanding universe. The particle shape is retained, and this phenomenon

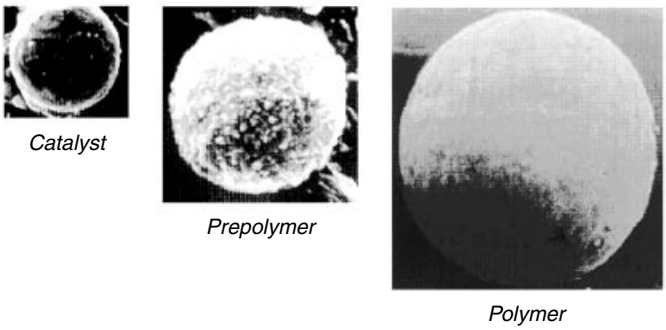

Fig. 4. "Replication" phenomenon during polymerization.

is therefore referred to as replication (Fig. 4). Ideally, the catalyst particle should have spherical morphology and controllable porosity. It is important that the mechanical strength of the catalyst is high enough to prevent disintegration but low enough to allow progressive expansion as polymerization proceeds (31). Further implications of particle morphology and porosity are discussed under Ziegler–Natta Catalysts for Ethylene (Co)polymerization and also under Reactor Granule Technology.

Ziegler–Natta Catalysts for Ethylene (Co)polymerization

Ziegler–Natta catalysts are widely used in the production of high density and linear low density polyethylene (HDPE and LLDPE). More than half the world production of HDPE is based on Ziegler–Natta catalysts, chromium catalysts also being widely used. Less than 1% of HDPE production utilizes metallocene or other single-site catalysts. In LLDPE production, Ziegler–Natta catalysts occupy a dominant position, accounting for more than 90% of the total production. Single-site catalysts currently account for less than 10% of this market, but increased use of such catalysts is expected throughout the next decade.

The most important titanium-based catalysts for HDPE and LLDPE are those comprising a titanium component on magnesium chloride or on a magnesium chloride containing support. Toward the end of the 1960s, catalysts obtained by reaction of $TiCl_4$ or a derivative thereof with a magnesium compound such as Mg(OH)Cl, $Mg(OH)_2$, or $MgCl_2$ were found to give very high activity in ethylene polymerization, eliminating the need for deashing of the polymer (31,32). The most effective support was found to be active magnesium chloride, prepared by co-milling of $MgCl_2$ and titanium halides or by chlorination of organomagnesium compounds (32). Numerous catalyst systems and methods of preparation have been disclosed (33), and the characteristics of magnesium chloride as a support for Ziegler–Natta catalysts are discussed in depth under Ziegler–Natta Catalysts for Polypropylene. Magnesium chloride can also be used in combination with a silica support, for example by impregnation of the porous support with a solution of $MgCl_2$ and $TiCl_4$ in tetrahydrofuran (34).

An important manufacturing process for HDPE that makes use of high mileage catalysts is the cascade process, in which polymerization reactors in series are used to give reactor blends with improved properties for film and pipe applications (35). Broad molecular weight distribution (MWD) can be obtained by the use of different hydrogen concentrations in each reactor. In addition, the process can be designed to give low molecular weight homopolymer in the first reactor and a high molecular weight copolymer in the second. The high molecular weight copolymer chains function as tie molecules linking the crystalline, homopolymer domains, thereby leading to high stress crack resistance of the polymer. This process allows an "inverse" comonomer distribution to be obtained, in the sense that the comonomer is in the high molecular weight fraction, counteracting the general tendency of Ziegler–Natta catalysts to incorporate the comonomer mainly in the low molecular weight chains. The latter feature is an important consideration in Ziegler–Natta catalyst design for LLDPE. Comonomer incorporation is highest at the most open catalytic centers, whereas sterically hindered centers will tend to give polyethylene chains with little or no comonomer. The best catalysts for LLDPE are therefore those that have relatively uniform active center distribution, lacking excessively hindered or unhindered active sites.

Vanadium catalysts have also been developed for polyethylene and ethylene-based copolymers, particularly ethylene–propylene–diene rubbers (EPDM). Homogeneous (soluble) vanadium catalysts produce relatively narrow MWD polyethylene, whereas supported vandium catalysts give broad MWD (36). Polymerization activity is strongly enhanced by the use of a halogenated hydrocarbon as promoter in combination with a vanadium catalyst and aluminum alkyl cocatalyst (36,37).

Ethylene polymerization, in contrast to the polymerization of propylene and other alpha-olefins, is often affected by diffusion limitations, which occur if the monomer reactivity in polymerization is high relative to diffusivity through the catalyst particle. This can result in the formation of an "onion" particle structure as polymerization first takes place at the external surface of the particle, particle growth occurring step by step as the monomer reaches the inner parts of the catalyst particle. This mechanism of particle growth is associated with a kinetic profile in which an initial induction period is followed by an acceleration period, after which, in the absence of chemical deactivation, a stationary rate is obtained.

Ziegler–Natta Catalysts for Polypropylene

Worldwide manufacture of PP, currently around 30 million tons per annum, is dominated by high activity $MgCl_2$-supported Ziegler–Natta catalysts. The first- and second-generation $TiCl_3$ catalysts have all but disappeared, and the recently developed metallocene catalysts still account for less than 1% of all PP produced, although they are likely to grow in importance. The development and implementation of $MgCl_2$-supported catalysts in bulk (liquid monomer) and gas-phase processes has led to the advent of simple, low-cost (nondeashing, nonextracting) manufacturing processes for PP (18).

The basis for the development of the high activity supported catalysts lay in the discovery, in the late 1960s, of "activated" $MgCl_2$ able to support $TiCl_4$ and give

high catalyst activity, and the subsequent discovery, in the mid-1970s, of electron donors (Lewis bases) capable of increasing the stereospecificity of the catalyst so that (highly) isotactic PP could be obtained (32,38,39). A further feature that has contributed greatly to the commercial success of $MgCl_2$-supported catalysts is the development of spherical catalysts with controlled particle size and porosity (40), which not only replicate their morphology during polymerization as the polymer particle grows, but which have now opened the way to a broad range of homo- and copolymers and multiphase polymer alloys via what has been termed Reactor Granule Technology (41).

Catalyst Structure and Composition. In the early stages of $MgCl_2$-supported catalyst development, activated magnesium chloride was prepared by ball milling in the presence of ethyl benzoate, leading to the formation of very small ($\leq$3 nm thick) primary crystallites within each particle (21). Nowadays, however, the activated support is prepared by chemical means such as complex formation of $MgCl_2$ and an alcohol or by reaction of a magnesium alkyl or alkoxide with a chlorinating agent or $TiCl_4$. Many of these approaches are also effective for the preparation of catalysts having controlled particle size and morphology. For example, the cooling of emulsions of molten $MgCl_2 \cdot nC_2H_5OH$ in paraffin oil gives almost perfectly spherical supports, which are then converted into the catalysts (18). A typical catalyst preparation involves reaction of the $MgCl_2 \cdot nC_2H_5OH$ support with excess $TiCl_4$ in the presence of an "internal" electron donor. Temperatures of at least 80°C and at least two $TiCl_4$ treatment steps are normally used, in order to obtain high performance catalysts in which the titanium is mainly present as $TiCl_4$ rather than the $TiCl_3OC_2H_5$ generated in the initial reaction with the support. Catalysts obtained via chemical routes generally have a BET surface area of around 300 m^2/g and pore volumes in the range 0.3–0.4 cm^3/g (18).

High activity Ziegler–Natta catalysts comprising $MgCl_2$, $TiCl_4$, and an internal donor are typically used in combination with an aluminum alkyl cocatalyst such as $Al(C_2H_5)_3$ and an "external" electron donor added in polymerization. The first catalyst systems containing ethyl benzoate as internal donor were used in combination with a second aromatic ester such as methyl *p*-toluate as external donor (39). These were followed by catalysts containing a diester (eg diisobutyl phthalate) as internal donor, used in combination with an alkoxysilane external donor of type $RR'Si(OCH_3)_2$ or $RSi(OCH_3)_3$ (42). The combination $MgCl_2/TiCl_4$/phthalate ester–AlR_3–alkoxysilane is currently the most widely used catalyst system in PP manufacture. The most effective alkoxysilane donors for high isospecificity are methoxysilanes containing relatively bulky alkyl groups branched at the position alpha to the silicon atom (43–46). Typical examples include cyclohexyl(methyl)dimethoxysilane and dicyclopentyldimethoxysilane (47). Of these, the latter gives particularly high stereospecificity (48) and broader MWD (49). High PP stereoregularity and broad MWD have also been obtained by the use of dimethoxysilanes containing polycyclic amino groups (50,51).

The function of the internal donor in $MgCl_2$-supported catalysts is twofold. One function is to stabilize small primary crystallites of magnesium chloride; the other is to control the amount and distribution of $TiCl_4$ in the final catalyst. Activated magnesium chloride has a disordered structure comprising very small lamellae. Giannini (32) has indicated that, on preferential lateral cleavage surfaces, the magnesium atoms are coordinated with four or five chlorine atoms, as

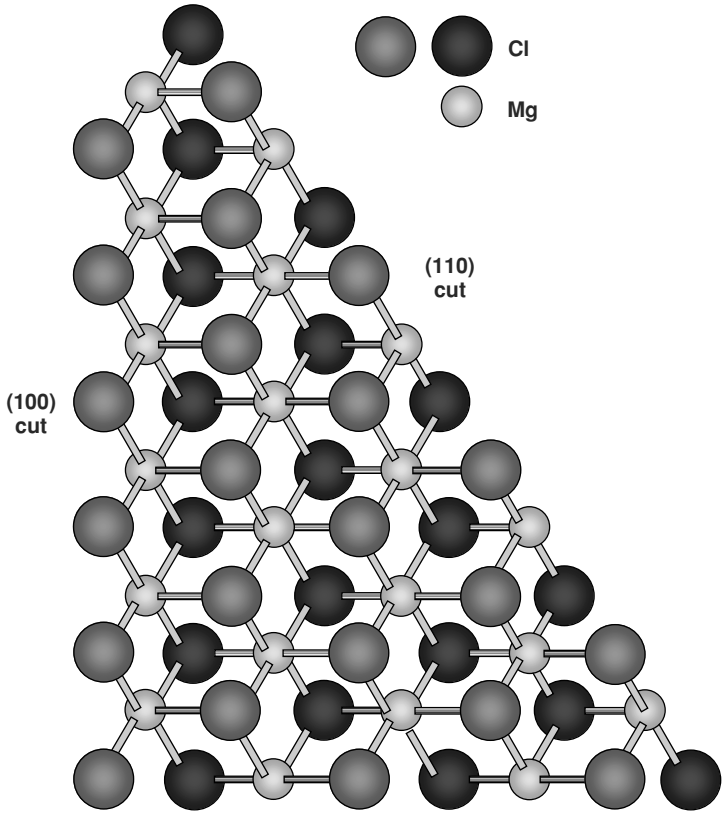

Fig. 5. Model of a $MgCl_2$ layer showing the (100) and (110) lateral cuts. Based on Ref. 31.

opposed to six chlorine atoms in the bulk of the crystal. These lateral cuts correspond to (110) and (100) faces of $MgCl_2$, as shown in Figure 5.

It has been proposed that bridged, dinuclear Ti_2Cl_8 species can coordinate to the (100) face of $MgCl_2$ and give rise to the formation of chiral, isospecific active species (Fig. 6), it being pointed out that Ti_2Cl_6 species formed by reduction on contact with $Al(C_2H_5)_3$ would resemble analogous species in $TiCl_3$ catalysts (52, 53). Accordingly, it has been suggested (18) that a possible function of the internal donor is preferential coordination on the more acidic (110) face of $MgCl_2$, such that this face is prevailingly occupied by donor and the (100) face is prevailingly occupied by Ti_2Cl_8 dimers.

Analytical studies (54) have indicated that a monoester internal donor such as ethyl benzoate is coordinated to $MgCl_2$ and not to $TiCl_4$. In the search for donors giving catalysts having improved performance, it was considered (55) that bidentate donors should be able to form strong chelating complexes with tetracoordinate Mg atoms on the (110) face of $MgCl_2$, or binuclear complexes with two pentacoordinate Mg atoms on the (100) face. This led to the development of the $MgCl_2/TiCl_4$/phthalate ester catalysts, used as indicated above in combination with an alkoxysilane as external donor. The requirement for an external donor when using catalysts containing a benzoate or phthalate ester is due to

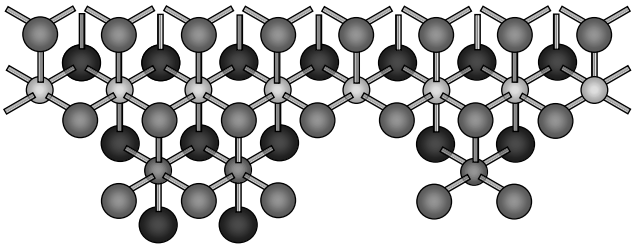

Fig. 6. Model showing dimeric and monomeric Ti species on a (100) lateral cut of $MgCl_2$. Based on Ref. 31.

the fact that, when the catalyst is brought into contact with the cocatalyst, a large proportion of the internal donor is lost as a result of alkylation and/or complexation reactions. In the absence of an external donor, this leads to poor stereospecificity because of increased mobility of the titanium species on the catalyst surface. When the external donor is present, contact of the catalyst components leads to replacement of the internal donor by the external donor, as has been shown (56,57) with $MgCl_2/TiCl_4$/ethyl benzoate–$Al(C_2H_5)_3$–methyl *p*-toluate and with $MgCl_2/TiCl_4$/dibutyl phthalate–$Al(C_2H_5)_3$–$C_6H_5Si(OC_2H_5)_3$. The most active and stereospecific systems were those which allowed the highest incorporation of external donor (58), the effectiveness of a catalyst system depending more on the combination of donors rather than on the individual internal or external donor. For example, the use of a monoester rather than an alkoxysilane as external donor with a phthalate-containing system is ineffective (59), as in this case very little of the external donor is adsorbed (58). Further studies (60,61) showed that a phthalate-containing catalyst adsorbed alkoxysilanes to a greater extent than a catalyst without internal donor.

Recently, research on $MgCl_2$-supported catalysts has led to systems not requiring the use of an external donor. This required the identification of bidentate internal donors that not only had the right oxygen–oxygen distance for effective coordination with $MgCl_2$ but that, unlike phthalate esters, were not removed from the support on contact with $Al(C_2H_5)_3$ and that were unreactive with $TiCl_4$ during catalyst preparation. It was found (55,62–64) that certain 2,2-disubstituted 1,3-dimethoxypropanes met all these criteria. The best performance was obtained when bulky substituents in the 2-position resulted in the diether having a most probable conformation (65) with an oxygen–oxygen distance in the range 2.8–3.2 Å. The successive "generations" of high activity $MgCl_2$-supported catalyst systems for PP are summarized below:

(1) $MgCl_2/TiCl_4$/ethyl benzoate–AlR_3–aromatic ester
(2) $MgCl_2/TiCl_4$/phthalate ester–AlR_3–alkoxysilane
(3) $MgCl_2/TiCl_4$/diether–AlR_3

Catalyst performance has improved considerably with each generation. The PP yield obtained under typical polymerization conditions (liquid monomer, in the presence of hydrogen, 70°C, 1–2 h) has increased from 15–30 kg/g cat. for

the third-generation ethyl benzoate containing catalysts to 30–80 kg/g cat. for the fourth-generation phthalate-based catalysts. With the recently developed fifth-generation catalysts containing a diether as internal donor, yields of 80–160 kg/g cat. can be achieved. These different catalysts also display different kinetic profiles in propylene polymerization. The catalysts containing a diether as internal donor exhibit very stable activities during polymerization. A low rate of catalyst decay during polymerization is also obtained with the catalyst system $MgCl_2/TiCl_4$/phthalate ester–AlR_3–alkoxysilane, whereas the system $MgCl_2/TiCl_4$/ethyl benzoate–AlR_3–aromatic ester has a very high initial polymerization activity but also a high decay rate, limiting the final polymer yield. The rapid decay in activity can at least partially be ascribed to the use of an ester as external as well as internal donor, the ester being able to react with titanium–hydrogen bonds formed in chain transfer with hydrogen, generating Ti—O bonds inactive for chain propagation (66).

Most recently, a further family of $MgCl_2$-supported catalysts has been developed (67,68), in which the internal donor is a succinate rather than a phthalate ester. As is the case with the phthalate-based catalysts, an alkoxysilane is used as external donor. The essential difference between these catalysts is that the succinate-based systems produce PP having much broader MWD (discussed under Catalyst/Polymer Relationship).

Mechanistic Aspects. It is well established that effective external donors not only increase the isotactic index of the polymer (the proportion of polymer insoluble in boiling heptane or in xylene at 25°C), but can also increase in absolute terms the amount of isotactic polymer formed. This has been demonstrated by Kashiwa (69) for the catalyst system $MgCl_2/TiCl_4$–$Al(C_2H_5)_3$. An increase in the molecular weight and stereoregularity of the isotactic fraction was also noted. Similar trends are apparent with catalyst systems of type $MgCl_2/TiCl_4$/phthalate ester–AlR_3–alkoxysilane (70). Kakugo (71) has used elution fractionation to demonstrate that the external donor not only decreases "atactics" formation but also increases the degree of steric control at isospecific sites. Soga has reported that an almost aspecific $MgCl_2/TiCl_3$ catalyst, with a very low content of (probably isolated, monomeric) Ti species, could be rendered isospecific by the addition of ethyl benzoate as external donor (72) or by using $Cp_2Ti(CH_3)_2$ as cocatalyst (73). It was suggested (74) that in both cases aspecific sites having two coordination vacancies could be converted to isospecific sites by blocking one of the two vacancies.

A powerful technique to study the effects of electron donors on site selectivity in Ziegler–Natta catalysts is the determination of the stereoregularity of the first insertion step in propylene polymerization. Sacchi and co-workers (60,75) have investigated the effect of Lewis bases on the first-step stereoregularity resulting from propylene insertion into a Ti—C_2H_5 bond formed via chain transfer with ^{13}C-enriched $Al(C_2H_5)_3$. First-step stereoregularity is particularly sensitive to the steric environment of the active center, because the stereospecificity of the first monomer insertion is always lower than that of the following propagation steps. For example, with a $MgCl_2/TiCl_4$/diisobutyl phthalate catalyst it was found (60) that the mole fraction of erythro (isotactic) placement in the isotactic polymer fraction was 0.67 with no external donor, 0.82 with $CH_3Si(OC_2H_5)_3$, and 0.92 with $C_6H_5(OC_2H_5)_3$. It could be concluded that the alkoxysilane external donor

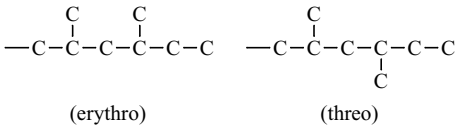

Fig. 7. Erythro (isotactic) and threo (syndiotactic) placement resulting from insertion into a Ti–ethyl unit.

was present in the environment of at least part of the isospecific centers (Fig. 7). Subsequent studies (76,77) indicated that similar considerations apply to diether donors.

Recently, significant advances have been made in understanding the fundamental factors determining the performance of state-of-the-art $MgCl_2$-supported catalysts. Studies by Busico and co-workers (78) have shown that the chain irregularities in isotactic PP prepared using heterogeneous catalysts are not randomly distributed along the chain but are clustered. The chain can therefore contain, in addition to highly isotactic blocks, sequences that can be attributed to weakly isotactic (isotactoid) and to syndiotactic (syndiotactoid) blocks. This implies that the active site can isomerize very rapidly (during the growth time of a single polymer chain, ie in less than a second) between three different propagating species. The same sequences are present, but in different amounts, in both the soluble and the insoluble fractions. The polymer can therefore be considered to have a stereoblock structure in which highly isotactic sequences alternate with defective isotactoid and with syndiotactoid sequences. A mechanistic model has been formulated in which the relative contributions of these sequences can be related to site transformations involving the presence or absence of steric hindrance in the vicinity of the active species. ^{13}C NMR studies have indicated (79) the presence of C_1-symmetric active species in $MgCl_2$-supported catalysts, with a mechanism of isotactic propagation which is analogous to that for certain C_1-symmetric metallocenes, in the sense that propylene insertion at a highly enantioselective site tends to be followed by chain "back-skip" rather than a less regio- and stereoselective insertion when the chain is in the coordination position previously occupied by the monomer. The probability of chain "back-skip" will increase with decreasing monomer concentration, and it has indeed been confirmed that increased polymer isotacticity is obtained at low monomer concentration. It is proposed (78) that a (temporary) loss of steric hindrance from one side of an active species with local C_2-symmetry, giving a C_1-symmetric species, may result in a transition from highly isospecific to moderately isospecific propagation. Loss of steric hindrance on both sides can lead to syndiospecific propagation in which chain-end control becomes operative. The model is illustrated in Figure 8.

If it is considered that the steric hindrance in the vicinity of the active species can result from the presence of a donor molecule, and that the coordination of such a donor is reversible, the above model provides us with an explanation for the fact that strongly coordinating, stereorigid donors typically give stereoregular polymers in which the highly isotactic sequences predominate. Several types of active species in which the presence of a donor in the vicinity of the active Ti atom is necessary for high isospecificity have been proposed (80), although the exact structure of the active species is still by no means resolved. Isospecific active

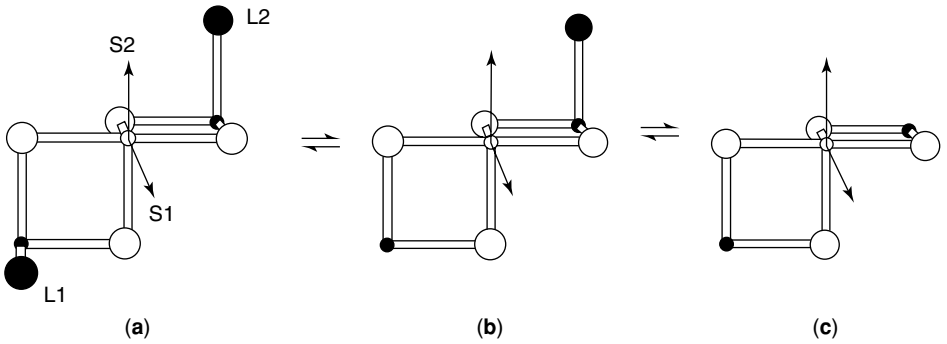

Fig. 8. Model of possible active species for (**a**) highly isotactic, (**b**) isotactoid, and (**c**) syndiotactic propagation (78).

species not requiring the presence of a donor for high stereospecificity have also been proposed (81).

In PP production, hydrogen is used as a chain-transfer agent for polymer molecular weight (melt-flow rate) control. The effect of hydrogen (concentration) on polymer molecular weight is dependent on the catalyst system. An advantage of catalysts containing a diether donor, in addition to very high activity, is high sensitivity to hydrogen, so that relatively little hydrogen is required for molecular weight control. This effect can be ascribed to chain transfer after the occasional secondary (2,1-) rather than the usual primary (1,2-) insertion, a 2,1-insertion slowing down a subsequent monomer insertion and therefore increasing the probability of chain transfer (82). Reactivation of "dormant" (2,1-inserted) species via chain transfer with hydrogen also explains the frequently observed activating effect of hydrogen in propylene polymerization, giving yields which may be around three times those observed in the complete absence of hydrogen. These conclusions have been based on the ^{13}C NMR determination of the relative proportions of *i*-C_4H_9 and *n*-C_4H_9 terminated chains, resulting from chain transfer with hydrogen after primary and secondary insertion respectively:

$$\mathrm{Ti{-}CH_2{-}CH(CH_3){-}[CH_2{-}CH(CH_3)]_nPr + H_2 \rightarrow Ti{-}H + \mathit{i}{-}C_4H_9{-}CH(CH_3)[CH_2(CH_3)]_{n-1}Pr}$$

$$\mathrm{Ti{-}CH(CH_3){-}CH_2{-}[CH_2{-}CH(CH_3)]_nPr + H_2 \rightarrow Ti{-}H + \mathit{n}{-}C_4H_9{-}CH(CH_3)[CH_2(CH_3)]_{n-1}Pr}$$

Other studies have demonstrated that chain transfer is dependent not only on regio- but also on stereoselectivity (48). This is in keeping with the tendency that, with catalyst systems of type $MgCl_2/TiCl_4$/phthalate ester–AlR_3–alkoxysilane, the silanes that give the most stereoregular isotactic polymer also give relatively low hydrogen response.

Catalyst/Polymer Relationship. By varying the catalyst composition, and in particular the nature of the electron donors (esters, silanes, diethers) present in the catalyst system, it is possible to control the PP tacticity, molecular weight, and MWD to produce a range of polymers having the processing and end-use properties required for very different applications. Ziegler–Natta catalysts typically give broader MWDs than are obtained with homogeneous

(metallocene) catalysts. This is because Ziegler–Natta catalysts contain a range of different active centers, each center giving different relative rates of chain propagation and chain transfer. Each individual site produces a Schulz–Flory distribution with $M_w/M_n = 2$ and $M_z/M_w = 1.5$, and the overall polymer MWD represents a combination of these individual distributions. The dominant effect of active center distribution has been demonstrated by the use of stopped-flow polymerization (83), where the polymer MWD was shown to be unaffected by the polymerization time. Stopped-flow polymerization has also been used to determine active site concentration ($C*$) and propagation rate constants, k_p. For $MgCl_2$-supported catalysts, $C*$ values of around 4% (of total Ti present) have been obtained from stopped-flow experiments (84). $C*$ values obtained by other techniques, notably ^{14}CO quenching of propylene polymerization, have ranged from 1% or less (85) to more than 20% (86). Clearly, there are large differences in $C*$ values obtained by different groups, but it is consistently found that the major proportion of the Ti present in Ziegler–Natta catalysts is inactive. The k_p values for isospecific active sites are around an order of magnitude greater than those for weakly specific sites (85,86). The value of k_p increases significantly in the presence of hydrogen (87), in accordance with the reactivation of "dormant" (2,1-inserted) centers by chain transfer.

Recent work by Terano and co-workers (88) has shown that, under stopped-flow conditions, hydrogen is only effective as chain-transfer agent when catalyst and cocatalyst have been precontacted. These and subsequent (89,90) results indicated that effective chain transfer with hydrogen requires the presence of species able to promote the dissociation of H_2 to atomic hydrogen.

The donors present in the catalyst system play an active role in the formation or modification of isospecific sites, and the polymer MWD depends on the relative contribution and hydrogen response (ie sensitivity to chain transfer with hydrogen) of each type of active site. The incorporation of an external donor into the catalyst system generally leads to an increase in molecular weight, the magnitude of the MW increase depending on the nature of the donor. The characteristics of different catalyst systems with regard to PP MWD are as follows (68):

Internal donor	External donor	M_w/M_n
Diether	—	5–5.5
Phthalate	Alkoxysilane	6.5–8
Succinate	Alkoxysilane	10–15

It can be seen that the diether-based catalysts give relatively narrow MWD. A narrow MWD, and relatively low molecular weight, is advantageous in fiber spinning applications. In contrast, extrusion of pipes and thick sheets requires high melt strength, and therefore relatively high molecular weight and broad MWD. A broad MWD, along with high isotactic stereoregularity, is also beneficial for high crystallinity and therefore high rigidity. The new succinate-based catalysts enable very broad MWD PP homopolymers to be produced in a single reactor and are also of interest for the production of heterophasic copolymers having an improved balance of stiffness and impact strength, taking into account that the incorporation

of a rubbery (ethylene/propylene) copolymer phase into a PP homopolymer matrix increases impact strength but leads at the same time to decreased stiffness.

The relatively narrow PP molecular weight distributions obtained using diether-based catalysts can be attributed to the fact that in these systems even the most highly stereospecific active sites are not totally regiospecific. A proportion of approximately one secondary insertion for every 2000 primary insertions at highly isospecific sites has been noted for the system $MgCl_2/TiCl_4$/diether–AlR_3 (82). The probability of chain transfer with hydrogen after a secondary insertion is such that this is sufficient to prevent the formation of very high molecular weight chains, taking into account that the highest molecular weight fraction of the polymer is formed on the active species having the highest isospecificity. The broader MWDs obtained with catalysts containing ester internal donors are likely to be due to the presence of (some) isospecific active sites having very high regiospecificity and therefore lower hydrogen sensitivity. Such results illustrate the profound effect of catalyst regio- and stereospecificity distribution on both molecular weight control and polymer MWD and properties.

Reactor Granule Technology. As indicated in the section Polymer Particle Growth, particle morphology and porosity are very important features of a Ziegler–Natta catalyst used in modern bulk (liquid monomer or gas-phase) polymerization processes. Under appropriate polymerization conditions, polymer particles can be obtained that have an internal morphology that can range from a compact to a porous structure (91). In what is termed Reactor Granule Technology (RGT), porous polymer particles can be produced, which can then function as a microreactor for the polymerization of other monomers within the solid matrix. A polypropylene skin encloses the second polymer phase, thereby preventing coalescence of particles in which the second phase is an amorphous, low-melting material (92). RGT has been defined as "controlled, reproducible polymerization of olefinic monomers on an active $MgCl_2$-supported catalyst, to give a growing, spherical granule that provides a porous reaction bed within which other monomers can be introduced and polymerized to form a polyolefin alloy" (93).

Today, RGT is able to provide products ranging from superstiff, high fluidity PP homopolymers to stiff/impact or clear/impact heterophasic copolymers and supersoft alloys, produced using the *Catalloy* process (31,68). The feasibility of producing heterophasic alloys containing up to 70% of multimonomer copolymers arises from the use of a controlled porosity catalyst and the ability to control the porosity of the growing polymer particle during the early stages of polymerization. Prepolymerization is applied to give the particles sufficient heat capacity to withstand injection into a gas-phase polymerization step.

Several models have been put forward to explain the mechanism of particle growth during polymerization. One of the most popular models is the "multigrain model," put forward by Ray and co-workers (94), in which the monomer diffuses into the catalyst macroparticle and polymerizes on the surface of the microparticles within, causing the macroparticle to expand progressively as polymerization proceeds. An investigation by Kakugo and co-workers (95) of nascent polymer morphology obtained using a $TiCl_3$ catalyst showed that the polymer particle comprised numerous globules, each of which contained some tens of much smaller primary particles. Recently, a model for particle growth with $MgCl_2$-supported catalysts has been proposed by Cecchin (68,96), who has also provided evidence for

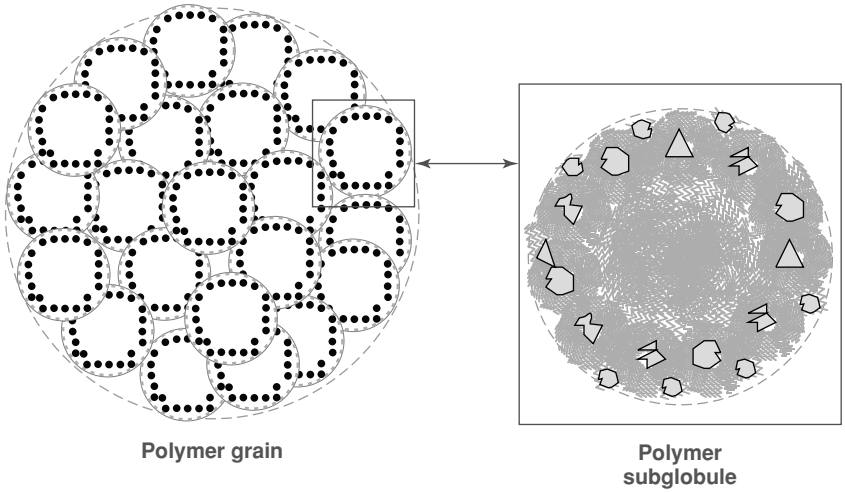

Fig. 9. Particle growth model for propylene polymerization with a $MgCl_2$-supported catalyst (96).

polymer "subglobule" formation within the growing particle. Again, these subglobules originate from clusters of primary crystallites, but the crystallites themselves are pushed to the surface of each subglobule as the polymer forms. This model, illustrated in Figure 9, explains the fact that, in the preparation of heterophasic copolymers via propylene homopolymerization followed by ethylene/propylene copolymerization, the rubbery ethylene/propylene copolymer is formed at the surface of the homopolymer subglobules, gradually filling up the pores within the particle. Clearly, the higher the porosity of the homopolymer matrix, the greater the proportion of (rubbery) copolymer that can be incorporated into the particle without running into problems of stickiness if the rubber phase blooms to the surface. Evidence for drifting of catalyst microparticles to the surface of polymer (sub)globules has been provided by scanning electron microscopy studies of prepolymerized catalyst particles (97).

Polymerization of Other Monomers Using Ziegler–Natta Catalysts

In addition to their widespread use in the production of polyethylene and polypropylene, Ziegler–Natta catalysts play an important role in the production of poly-1-butene and are also widely used in the manufacture of synthetic rubbers such as *cis*-1,4-polybutadiene and *cis*-1,4-polyisoprene, the synthetic equivalent of natural rubber. Ziegler–Natta catalysts for the manufacture of butadiene rubber, based on titanium, cobalt, nickel, or neodymium systems, are described elsewhere (see BUTADIENE POLYMERS). Isoprene rubber is produced using β-$TiCl_3$ (98), typically prepared by reaction of approximately equimolar quantities of $TiCl_4$ and Al-*i*-$(C_4H_9)_3$ in the presence of a small quantity of an ether. Increased catalyst activity can be obtained by incorporation of a sterically hindered phenoxyaluminum cocatalyst component (99). The latter component also gives increased activity in propene polymerization using $TiCl_3$ (100); in both cases the improvement

in catalyst performance can be attributed to selective complexation of the catalyst poison $RAlCl_2$. In addition to aluminum alkyls, poly(*N*-alkylaluminoxanes) have been found to be effective cocatalysts in isoprene polymerization (101). These components have cage structures (eg $[HAlN\text{-}i\text{-}C_3H_7]_6$) in which both Al and N atoms are tetracoordinated (102).

Cis-1,4-polymerization of conjugated dienes requires the presence of two coordination vacancies on the transition-metal atom, allowing bidentate coordination of the diene. β-$TiCl_3$ has a fiber-like structure in which the titanium atoms in the lattice are octahedrally coordinated to six chlorine atoms. The terminal titanium atoms are, however, incompletely coordinated and are linked to four or five chlorine atoms. Alkylation of the tetracoordinated titanium atoms will generate the double-vacancy species active in isoprene polymerization. Stereospecificity in diene polymerization can change dramatically if one of the coordination vacancies is blocked by a Lewis base. An interesting illustration of this (103) is that the addition of an external donor in isoprene polymerization with $TiCl_4$–$Al(C_2H_5)_3$ or $MgCl_2/TiCl_4$–$Al(C_2H_5)_3$ changes the catalyst stereospecificity to give mainly *trans*-1,4- rather than *cis*-1,4-polyisoprene. At the same time, a notable increase in isospecificity in propylene polymerization is observed.

$TiCl_3$-based and $MgCl_2$-supported catalysts have been developed for the production of poly-1-butene. $TiCl_3$ catalysts are used with dialkylaluminum halide cocatalysts, $Al(C_2H_5)_2I$ giving higher isotacticity than $Al(C_2H_5)_2Cl$ (104). Very high isotacticity has been obtained using $TiCl_3$ in combination with $Cp_2Ti(CH_3)_2$ (105). Much higher polymerization activity, as well as high isotacticity and broad MWD, is obtained using $MgCl_2$-supported catalysts, for example the catalyst system $MgCl_2/TiCl_4$/diisobutyl phthalate–$Al(C_2H_5)_3$–alkoxysilane (106).

Ziegler–Natta catalysts have also been developed for the polymerization of 4-methyl-1-pentene (107) and higher alpha-olefins. Polymerization activity decreases with increasing steric bulk of the monomer. For example, with the catalyst system $MgCl_2/TiCl_4$/ethyl benzoate–$Al(C_2H_5)_3$–ethyl benzoate the relative activities in propylene, 1-butene, and 4-methyl-1-pentene polymerization were 100:80:15 (108). For catalyst systems of type $MgCl_2/TiCl_4$/phthalate ester–AlR_3–alkoxysilane, the type of silane required is dependent on the steric bulk of the monomer. An active center having high stereospecificity in propylene polymerization may be too sterically hindered for effective polymerization of a bulkier monomer, propylene/1-butene copolymerization studies having shown (109) that the incorporation of 1-butene into the polymer chain decreases with increasing site stereospecificity. This phenomenon is also illustrated by the fact that nonbulky alkoxysilanes such as $(CH_3)_3SiOCH_3$ are effective donors in 4-methyl-1-pentene polymerization (110), whereas such donors are relatively ineffective in propylene polymerization.

Concluding Remarks

The dominant position of Ziegler–Natta catalysts in the manufacture of polyolefins, in particular PP, is likely to continue for a considerable length of time, despite the many developments taking place in the field of metallocene and other single-site catalysis. Indeed, the range of polymer types and grades is so varied

that there is ample scope for further development and implementation of both Ziegler–Natta and single-site catalysts.

It will be clear that the composition and characteristics of a Ziegler–Natta catalyst must be tailored such that the required polymer molecular structure and properties are obtained. Different catalysts are required for different polymer applications, and the recent development and implementation of $MgCl_2$-supported catalysts containing diether and succinate donors, for the production of narrow and broad MWD PP respectively, illustrates the ongoing activity in Ziegler–Natta catalyst research. The ability to control catalyst particle size, morphology, and porosity has allowed the development of advanced and versatile polymerization process technologies, so that the characteristics of the catalyst can be tuned to both process and product requirements.

Ziegler–Natta catalysts are complex systems and are still by no means fully understood, but significant advances in basic understanding have recently been made. This will continue, with both experimental and molecular modeling studies providing additional mechanistic insight, which in turn can be applied in the further development and implementation of these catalysts.

ACRYLIC FIBERS

Introduction

The first reported synthesis of acrylonitrile [107-13-1] and polyacrylonitrile (PAN) [25014-41-9] was in the 1890s (1). The polymer received little attention for a number of years, until shortly before World War II, because there were no known solvents and the polymer decomposes before reaching its melting point. The first breakthrough in developing solvents for PAN occurred at I. G. Farben in Germany, where fibers made from the polymer were dissolved in aqueous solutions of quaternary ammonium compounds, such as benzylpyridinium chloride, or of metal salts, such as lithium bromide, ammonium thiocyanate, and zinc

chloride (2). In the United States, DuPont discovered an organic solvent for PAN, *N,N*-dimethylformamide (DMF) (3,4). The same solvent was discovered independently by I. G. Farben at about the same time (5) (see ACRYLONITRILE AND ACRYLONITRILE POLYMERS).

Using DMF as the spinning solvent, DuPont produced the first commercial acrylic fiber under the trade name Orlon® in 1950. Orlon® was spun using a "dry spinning" process at a plant in Camden SC. Shortly afterward, Chemstrand, a joint venture of Monsanto and American Viscose (now Solutia), introduced Acrilan® acrylic, produced using Monsanto polymer technology and American Viscose wet spinning technology with *N,N*-dimethylacetamide (DMAc) solvent. As is common with new technologies, both products got off to rocky starts, Orlon with poor dyeing performance, Acrilan with fibrillation, but by the late 1950s each had solved the initial problems and established viable markets.

Modacrylic fibers (defined in the United States as those with 35–85% by weight acrylonitrile units) can be dissolved by more conventional solvents, such as acetone, and so were earlier on the market. Union Carbide introduced the first flame-resistant modacrylic fiber in 1948 under the trade names Vinyon N and Dynel. Vinyon N was a continuous filament yarn; Dynel was the staple form. Both were based on 60% vinyl chloride – 40% acrylonitrile copolymer.

During the 1950s, at least 18 companies began production of acrylic fibers. Because acrylic fibers require a spinning solvent, and newly discovered solvents received patent protection, the range of technology used commercially is far greater for acrylics than for any other fiber. The most significant were American Cyanamid's aqueous sodium thiocyanate wet spinning process, and Asahi's nitric acid wet spinning process. In the 1950s and 1960s, world production was concentrated in western Europe, Japan, and the United States. By 1960, annual worldwide production had risen to over 100 million kilograms. Once staple processes were developed, acrylic fibers became a significant competitor in markets held primarily by woolen fibers. By 1963 the carpet and sweater markets accounted for almost 50% of the total acrylic production. In the 1970s, the growth rate in the United States and Western Europe decreased sharply. This was due to the maturing of the wool replacement market and loss of market to nylon in carpeting and to polyester in many apparel applications. In the 1970s there was rapid growth of acrylic fiber production capacity in Japan, eastern Europe, and developing countries. By 1981 an estimated overcapacity of approximately 21% had developed. The 1990s saw significant shrinkage of acrylic production in the United States as DuPont and Mann Industries (formerly Badische) exited the business. Significant change has continued into the new century. In 2002, Sterling (formerly Cytec) significantly reduced production of commodity acrylics at their Pace FL plant. These changes have left Solutia as the principal U.S. supplier. In Europe, the changes have been mainly swaps of ownership, with Acordis now having both the Courtaulds and Hoechst businesses, and Fraver, an Italian firm, taking over Bayer's business. Aksa in Turkey, with the world's largest acrylic fiber plant, has become an important supplier to Europe. Explosive industry growth has taken place in the Far East, particularl y China, where plants based on DuPont and Sterling (Cytec) processes have proliferated. China now has 22% of world capacity, versus 9% 10 years earlier. Japan has reduced capacity, with Asahi Chemical being the latest to announce closure (March 2003) of their

business. Modacrylics have all but disappeared from the marketplace, as demand for flame-retardant textiles have been met by treated cotton or other synthetics at lower cost. A few new markets have emerged, such as carbon-fiber precursors and asbestos replacement fibers, but the volume is small compared to that of the markets lost. For acrylic producers, profit will continue to be sparse.

Physical Properties

Acrylic fibers are sold mainly as staple and tow. Staple lengths may vary from 25 to 150 mm, depending on the end use. Fiber fineness may vary from 1.0 to 22 dtex (0.9–20 dpf; dpf = denier per filament), 2.2 dtex (2.0 dpf), and 1.3 dtex (1.2 dpf) are the most common forms. Tow is sold as a bundle of up to 2.2 million kilotex (2.0 million total denier).

The fiber cross-section under microscopic examination is generally one of three shapes (Fig. 1)—round (wet spun, slow coagulation), bean (wet spun, fast coagulation), or dogbone-shaped (dry spun). It is also possible to produce acrylics with special shapes, such as ribbon or mushroom, by use of shaped or bicomponent spinnerettes. The cross-section may show particles such as TiO_2 added to reduce luster or other pigment to provide coloration. The surface of acrylic fibers is fibrillar, with the fibril size dependent on the spinning process (Fig. 2).

The physical properties of these fibers are compared with those of natural fibers and other synthetic fibers in Table 1.

The elastic properties of these fibers can be characterized as wool-like, with high elongation and elastic recovery. The tensile strength of acrylics and modacrylics is about the same, both considerably lower than that of other synthetics but higher than that of wool, of and about the same as that of cotton. These elastic properties rank acrylics and wool as compliant fibers, yielding fabric with a characteristically soft handle. Acrylics with tenacities as high as 80 cN/tex (9 gf/den) can be produced (8), but these are usually from higher molecular weight polymers, with low comonomer content and higher stretch orientation. Specialty products such as carbon-fiber precursor and cement-reinforcing fiber are produced using this technology.

The mechanical properties of acrylic fiber are deficient under hot-wet conditions. This is primarily due to the fact that the wet T_g of acrylonitrile copolymers is lower than the boiling point of water. Textile wet-processing must be carried out in such a way as to minimize yarn or fabric distortion. Shape retention and maintenance of original bulk under the lower temperatures in home laundering cycles are acceptable. Typical stress–strain curves for acrylic fiber in air and in wet conditions are shown in Figure 3.

Moisture regain, a property that has a great effect on wear comfort, at about 2%, is reasonably good though not as high as that of cotton (7%) or wool (14%). This property can be enhanced by adding hydrophilic comonomers or by generating a porous internal structure in the fiber. Dunova, an acrylic formerly marketed by Bayer, achieved moisture absorption and transport by internal porosity. The adequate regain plus their high compliancy make acrylics competitive in the wear-comfort markets. However, acrylics cannot match the wrinkle resistance and crease retention of polyester.

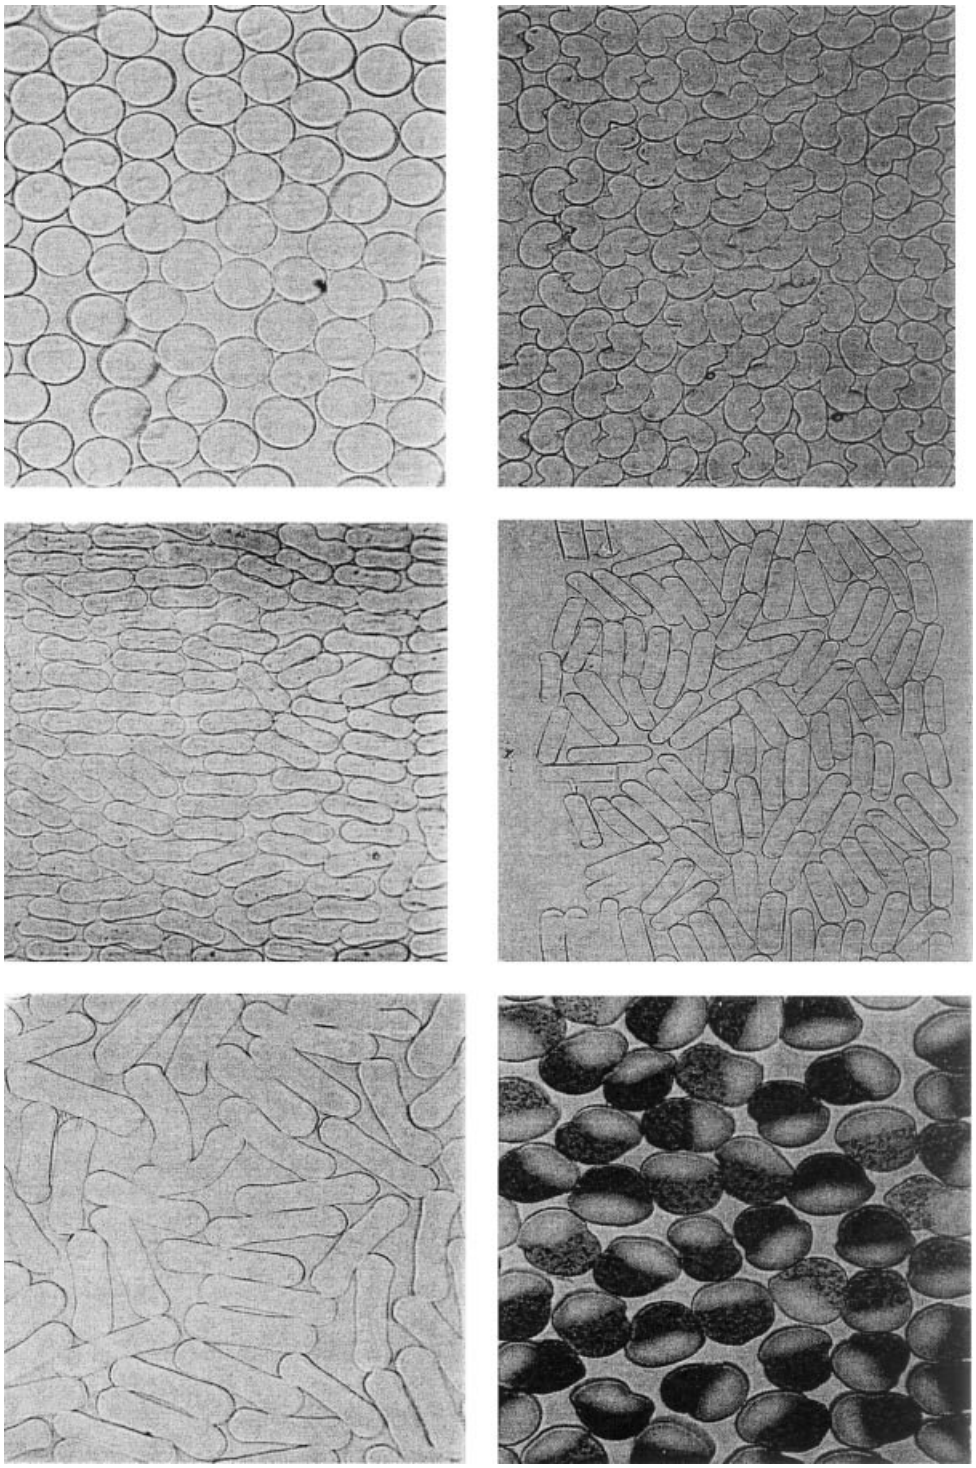

Fig. 1. Acrylic fiber cross sections (Scale: 1 mm = 10 μm).

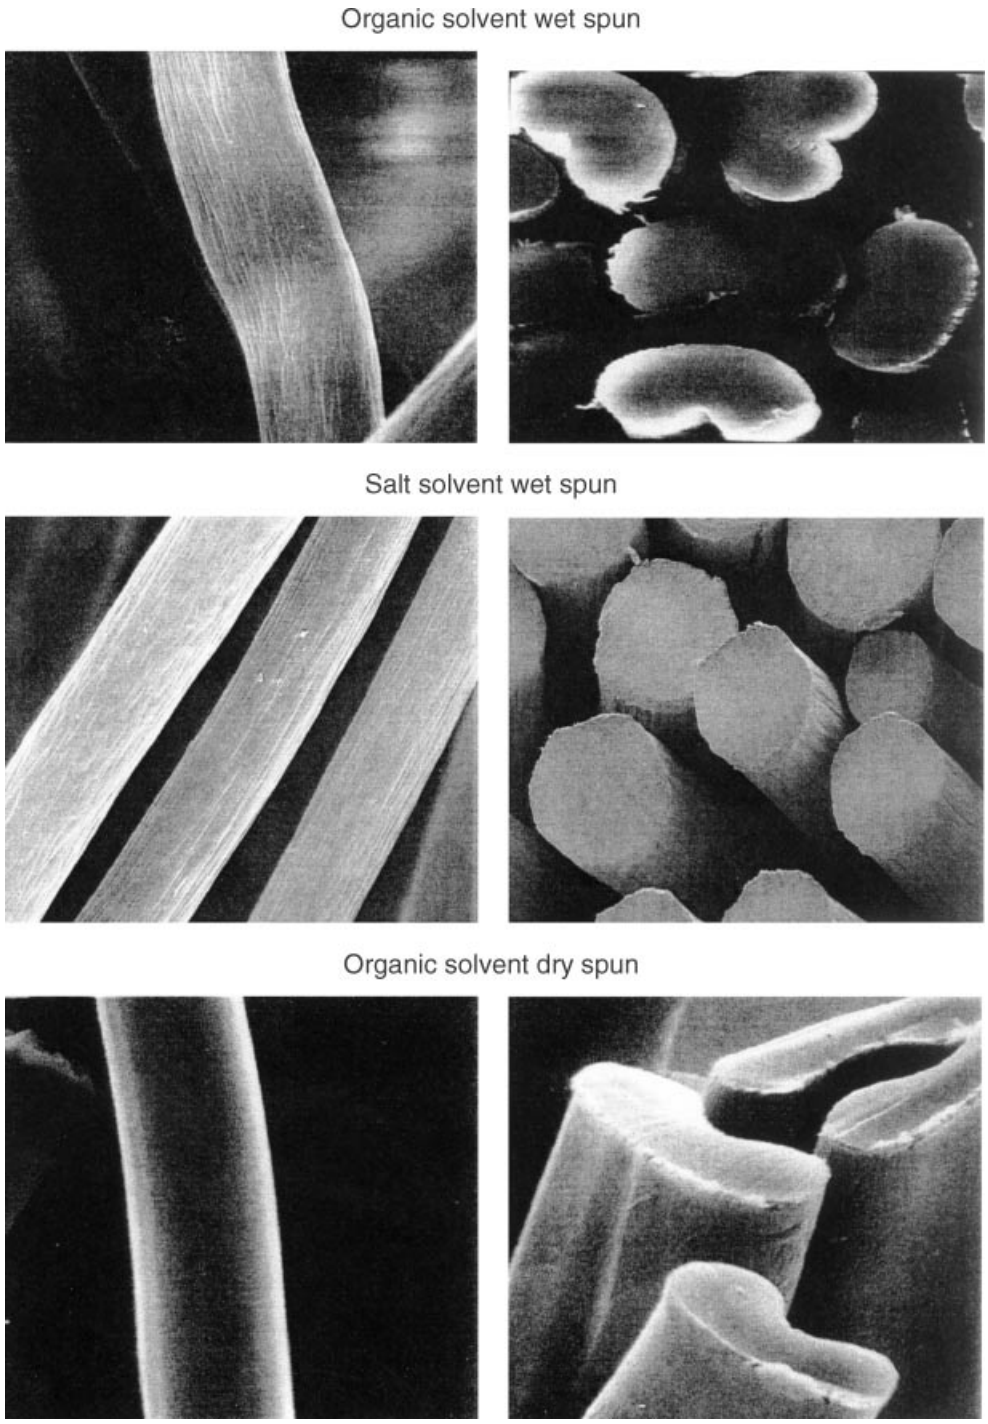

Fig. 2. Acrylic fiber structure comparisons (Scale: 1 mm = 0.5 μm).

Table 1. Physical Properties of Staple Fibers[a]

Property	Acrylic	Modacrylic	Nylon-6,6	Polyester	Polyolefin	Cotton	Wool

Chemical Properties

Among the outstanding properties of acrylic fibers is their very strong resistance to sunlight. One study (9), found that the acrylic fibers resisted degradation eight times longer than olefin fibers, over five times longer than either cotton or wool, and almost four times longer than nylon. This property makes the acrylics particularly useful for outdoor applications, such as in awnings, tents, and sandbags, as well as for upholstery for autos and outdoor furniture. Pigmented acrylic or modacrylic fibers with lightfast colors are particularly useful for outdoor applications.

Acrylic fibers are also resistant to all biological and most chemical agents. Weak acids or bases, organic solvents, and oxidizing agents affect acrylics very little. They are attacked by strong bases and highly polar organic solvents such as DMAc, DMF, and DMSO (dimethyl sulfoxide). Acrylic fibers tend to be much more susceptible to chemical attack by alkali than by acid. For example, acrylic fibers are stable for up to 24 h at 100°C in 50% sulfuric acid: these same fibers begin degrading with <0.5% sodium hydroxide at the same exposure time and temperature (10).

In resistance of fibers to oxidizing agents, Orlon acrylic (a former DuPont product) was compared to cotton and acetate yarns (10). The acrylic yarn is far superior in strength retention. After 6 h of exposure to bleach, the cotton and acetate yarns had completely deteriorated, whereas the acrylic retained approxmately 92% of its original strength.

The excellent chemical resistance of acrylic fiber stems from its laterally bonded structure. Dipole bonds, formed between nitrile groups of adjacent chains,

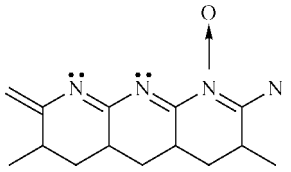

Fig. 4. Structure of air-oxidized PAN.

must be broken before chemical attack, melting, or solvation can occur. In addition, the repulsive forces between adjacent nitriles in one chain result in a very stiff polymer backbone, which yields very little entropy gain when the bonds between adjacent chains are broken in solvation or melting. Therefore, relatively high temperatures are required for solvation and melting.

Acrylic fibers discolor and decompose rather than melt when heated. The discoloration process involves formation of a ladder structure containing conjugated C=N double bonds. Some color formation accompanies fiber production; commercial acrylics often contain low levels of blue dye or pigment to mask the yellow tinge. In comparison to polyester, acrylic fiber whiteness stability in sublimation dyeing is deficient; this limits acrylic utility in fleece and sheeting markets. Extensive heating in air leads to a color progression, ending in a black fiber having the structure shown in Figure 4. This product, termed Panox, is useful as a flame-resistant textile. Conversion of acrylic fiber to Panox is the first step in carbon fiber production.

Flammability. Most apparel uses either do not have any flammability standard, or only a modest one which serves to eliminate "torch" fabrics. More rigorous standards are applied for end uses such as carpet, children's sleepwear, drapery, and bedding. Fibers for these applications must be self-extinguishing after removal from the ignition source. Cotton, rayon, and acrylics burn with the formation of a char. The char acts as a wick that feeds additional fuel to the flame. Nylon and polyester meet some flammability tests by melting away from the ignition source. Modacrylics self-extinguish by generation of chlorine radicals, which interfere with the flame-propogation mechanism. This is generally achieved by incorporating vinylidene chloride or vinyl chloride comonomers. Blends of a char-forming fiber with a meltable one require incorporation of an active fire-retardant to meet any stringent flammability test (see FLAMMABILITY; FIRE RETARDANTS).

A measurement used to compare the flammability of textile fibers is the limiting oxygen index (LOI). This quantity describes the minimum oxygen content (%) in nitrogen necessary to sustain candle-like burning. Values of LOI, considered a measure of the intrinsic flammability of a fiber, are listed in Table 2 in order of decreasing flammability.

Polymer Analysis

Many techniques are available for characterizing acrylic and modacrylic materials in order to establish the dyesite content, molecular weight, and chemical

Table 2. Limiting Oxygen Index of Textile Fibers[a] in Order of Decreasing Flammability

Fiber	LOI	Ignition temperature, °C
Cotton	18.0	400
Acrylic	18.2	560
Rayon	19.7	420
Nylon	20.1	530
Polyester	21.0	450
Wool	25.0	600
Modacrylic	27.0	690
Verel modacrylic	33.0	Self-extinguishing
100% PVC	37.0	Self-extinguishing

[a] Ref. 11.

composition. The dye-site content of the polymer may be determined by dyeing a polymer suspension with a cationic dye of known molecular weight. The dye attached to the polymer dye sites may be measured directly of by difference. The dye sites themselves, in most acrylics and modacrylics, are sulfonate and sulfate end groups derived from the free-radical initiator used in polymerization. Therefore, the dye site content of the polymer can be measured by potentiometric titration of the strong acid groups or by determining the sulfur content of the polymer. The low levels of sulfur normally required for fiber dyeability can be measured accurately by X-ray fluorescence. Some acrylics have added "dye receptors"—acidic monomers such as sodium *p*-vinylbenzene sulfonate (SSS) or itaconic acid (IA). This sulfonate can be determined directly using ultraviolet spectroscopy. Sulfur analysis will yield a total dye-site value including the end groups and the SSS. Potentiometric titration of a polymer containing IA will yield two breaks, one for the sulfonate/sulfate end groups, and a second for one of the IA carboxyls. Dyeing of polymers containing weak-acid dye receptors such as IA does not give an accurate value for total sites, as the dyeing of the IA is incomplete.

The weight-average molecular weight of the polymer can be measured using gel-permeation chromatography with low-angle-light-scattering detection (see CHROMATOGRAPHY, SIZE EXCLUSION). Solvent systems such as DMF–LiCl are employed to eliminate ionic effects (12). Osmometry may be used to obtain number-average molecular weight (13). These methods are useful to provide absolute values and to determine changes in molecular-weight distribution. However, methods based on solution viscosity are the most popular in commercial practice. The simplest method is to measure the viscosity of a solution of the polymer at a specified concentration and temperature. This may be done using a capillary viscometer. For quality assurance purposes, usually a single point ("specific viscosity") determination is sufficient. The viscosity-average molecular weight may be obtained by extrapolating specific viscosities at several concentrations to zero concentration. The intrinsic viscosity thus derived is then used in the Staudinger equation (14) or Cleland–Stockmayer equation (15) to give the viscosity-average molecular weight (see MOLECULAR WEIGHT DETERMINATION).

Typical acrylic polymers have number-average molecular weights in the 30,000–40,000 range, or roughly 700 repeat units. The weight-average

molecular weight is typically in the range 90,000–120,000, with a polydispersity index (M_w/M_n) between 2.0 and 3.5. Fiber producers favor the lowest molecular weight and broadest distribution that is consistent with acceptable fiber physical properties, as that will result in the highest number of sulfate and sulfonate dye sites.

Analytical methods for identifying and quantifying the chemical composition of acrylic and modacrylic materials are numerous. The usual comonomers found in acrylics—vinyl acetate, methyl acrylate, and methyl methacrylate—can be identified using NMR. They may be quantified using infrared (IR) spectroscopy by the absorbance of the carbonyl group; calibration of the method is sometimes accomplished by preparation of C^{14} tagged polymer standards. Sulfonated monomers, such as SSS or sodium *p*-(sulfophenyl) methallyl ether, can be detected by strong ultraviolet absorbance due to the phenyl group. Halogen monomers can be quantitatively measured by pyrolyzing the polymer and analyzing the pyrolysis products by halide titration. X-ray fluorescence may also be used to determine the concentration of specific halogens. Comonomer content may also be quantified by differential scanning calorimetry of a water–polymer slurry. The mole fraction of comonomer depresses the melting point linearly (16).

Fiber Characterization

To establish whether a fiber or fabric is acrylic or a blend containing acrylic, a portion should be separated into the individual filaments and introduced in a density gradient column [ASTM DI505-8ST (density gradient)]. Acrylic fibers have a density of 1.17 ± 0.01. An IR scan of a KBr pellet of ground fiber can be used to identify the presence of nitrile groups. It is more difficult to establish the fiber supplier. A library of cross sections, known comonomer type, and other specific information is required. Since many producers now use almost identical technology, it may not be possible to achieve positive identification unless the fiber contains a marker.

In addition to characterizing the properties introduced by the choice of comonomers and the polymerization process itself, further characterization is required to describe the properties imparted by spinning and subsequent downstream processing. These properties relate to the order and microstructure of the fibers, and the resultant performance characteristics, such as crimp retention, abrasion resistance, and mechanical properties. Mechanical testing, to determine breaking elongation, tenacity, and modulus of elasticity, is carried out using devices such as the Instron. Dry-heat shrinkage and shrinkage in boiling water are measured by determining the difference in the length of a section of fiber after treatment at specified conditions. Other properties important to ease of processing or the end use include finish level, crimp frequency and amplitude, whiteness, and dyeing rate.

Acrylonitrile Polymerization

Virtually all acrylic fibers are made from acrylonitrile combined with at least one other monomer. The comonomers most commonly used are neutral comonomers,

such as methyl acrylate [96-33-3] and vinyl acetate [108-05-4] to increase the solubility of the polymer in spinning solvents, modify the fiber morphology, and improve the rate of diffusion of dyes into the fiber. Sulfonated monomers, such as sodium *p*-(vinylbenzene)sulfonate [27457-28-9] (SSS), sodium methallyl sulfonate [1561-92-8] (SMAS), and sodium *p*-(sulfophenyl) methallyl ether [1208-67-9] (SPME) are used to provide additional dye sites or to provide a hydrophilic component in water-reversible-crimp bicomponent fibers. Halogenated monomers, usually vinylidene chloride [75-35-4] or vinyl chloride [75-01-4], impart flame resistance to fibers used in the home furnishings, awning, and sleepwear markets.

Polymerization Methods. Acrylonitrile and its comonomers can be polymerized by any free-radical method. Bulk polymerization is the most fundamental of these, but its practical use is limited by its autocatalytic nature. Aqueous dispersion polymerization is the most common commercial method; solution polymerization, where the spin solvent serves as the polymerization medium, is the other commercial process. Emulsion polymerization is used for certain modacrylic compositions.

Aqueous Dispersion Polymerization. By far the most widely used method of polymerization in the acrylic fibers industry is aqueous dispersion (also called suspension). When inorganic compounds such as persulfates, chlorates, or hydrogen peroxide are used as radical generators, the initiation and primary radical growth steps occur mainly in the aqueous phase. Chain growth is limited in the aqueous phase, however, because the monomer concentration is normally low and the polymer is insoluble in water. Nucleation occurs when aqueous chains aggregate or collapse after reaching a threshold molecular weight. If many polymer particles are present, as is the case in commercial continuous polymerizations, the dissolved radicals are likely to be captured on the particle surface by a sorption mechanism. The particle surface is swollen with monomer. Therefore, the polymerization continues in the swollen layer and the sorption becomes irreversible as the chain end grows into the particle.

Since polymer swelling is minimal and the aqueous solubility of acrylonitrile is relatively high, the tendency for radical capture is limited. Consequently, the rate of particle nucleation is high throughout the course of the polymerization, and particle growth occurs predominantly by a process of agglomeration of primary particles. Unlike emulsion particles of a readily swollen polymer, such as polystyrene, the acrylonitrile aqueous dispersion polymer particles are massive agglomerates of primary particles which are approximately 100 nm in diameter.

Redox initiation is normally used in commercial production of polymers for acrylic fibers. This type of initiator can generate free radicals in an aqueous medium efficiently at relatively low temperatures. The most common redox system consists of ammonium or potassium persulfate (oxidizer), sodium bisulfite (reducing agent), and ferric or ferrous ion (catalyst). The mechanism is shown in Figure 5. This redox system works at pH 2.0–3.5, where the bisulfite ion predominates and the ferric ion is soluble. The sulfate and sulfonate ion-radicals react with monomer to initiate rapid chain growth. Termination occurs by radical recombination or by chain transfer. Bisulfite ion is both a reducing agent, and a chain-transfer agent; it reacts by transferring a hydrogen radical to terminate the chain, thus producing a bisulfite radical to initiate a new chain. The bisulfite concentration has a pronounced effect on polymer molecular weight with virtually

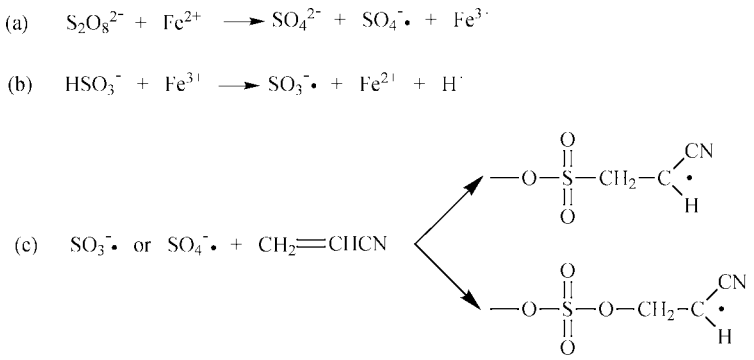

Fig. 5. Persulfate redox initiation mechanism.

no effect on the overall rate of polymerization (17). The ratio of bisulfite to persulfate in the reaction mixture has a strong effect on the dye-site content of the polymer (17,18). Bisulfite chain transfer increases the total dye-site content of the polymer by reducing the polymer molecular weight but at the same time produces chains with just one dyesite. At a given molecular weight the dye-site content of the polymer can, in theory, vary from two per chain at low bisulfite levels to one per chain at very high bisulfite levels.

In commercial practice, excess reducing agent to oxidizing agent ratios are used, for example, molar ratios of bisulfite to persulfate ranging from 5 to 15. These high ratios give narrower molecular weight distributions and, for a given molecular weight, relatively low conversion to polymer. Low conversion is an effective means of minimizing branching and color producing side reactions.

A comprehensive review of aqueous polymerization has been published (19). Many reviews of acrylonitrile polymerization have been published (20–23).

In commercial practice, polymerization is effected in a continuous-stirred-tank reactor (CSTR), a system in which all components are fed continuously and mixed, and the product is continuously discharged. For start-up, the reactor is charged with a certain amount of pH-adjusted water or the reactor is filled with overflow from another reactor already operating at steady state. The reactor feeds are metered in at a constant rate for the entire course of the production run, which normally continues until equipment cleaning or maintenance is needed. A steady state is established by taking an overflow stream at the same mass flow rate as the combined feed streams. The reaction vessel is normally an aluminum alloy; this minimizes scale buildup as the wall provides a sacrificial surface. The reactor is jacketed; steam may be introduced to heat the contents for start-up, but once the polymerization is initiated, water is circulated in the jacket to remove the heat of polymerization and maintain a constant temperature, usually 50–60°C.

An example of a continuous aqueous dispersion process is shown in Figure 6 (24). A monomer mixture composed of acrylonitrile and up to 10% of a neutral comonomer, such as methyl acrylate or vinyl acetate, is fed continuously. Polymerization is initiated by feeding aqueous solutions of potassium persulfate (oxidizer), sulfur dioxide (reducing agent), ferrous iron (promoter), and sodium bicarbonate (buffering agent). Alternately the system may employ a sodium bisulfite/sulfur

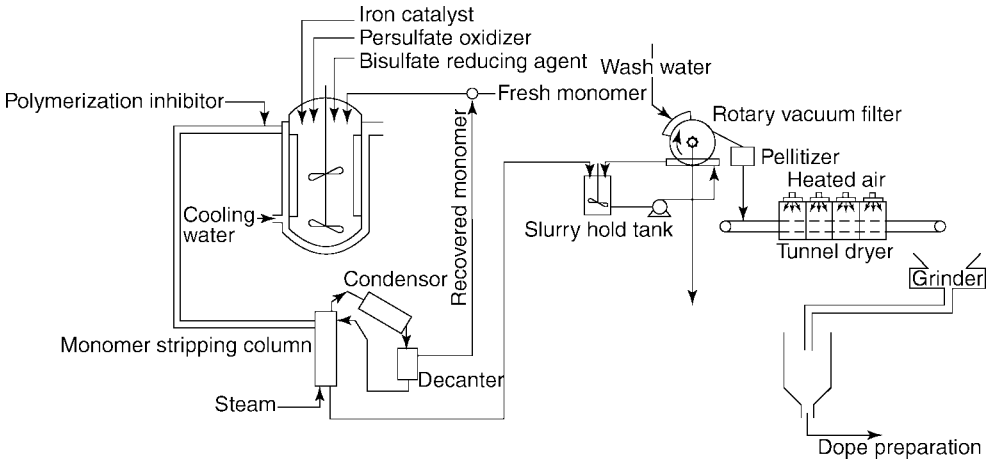

Fig. 6. CSTR Dispersion polymerization process.

dioxide or a sodium bisulfite/sulfuric acid buffer. The aqueous and monomer feed streams are fed at rates that give a reactor dwell time of 40–120 min, and a feed ratio of water to monomer in the range 2–5. The reactor overflow, an aqueous slurry of polymer particles, is mixed with an iron chelating agent, or the pH is raised to stop the polymerization. The slurry is then fed to the top section of a baffled monomer-separation column. The separation of unreacted monomer is effected by contacting the slurry with a countercurrent flow of steam introduced at the bottom of the column. Monomer plus water is condensed from the overheads stream and the monomer separated using a decanter, the water phase being returned to the column. The stripped slurry is taken from the column bottoms stream, and the polymer separated using a continuous vacuum filter. After filtration and washing, the polymer is pelletized, dried, ground, and then stored for later spinning.

A less desirable recovery process is to filter or centrifuge the slurry (with washing) to recover the polymer and then pass the filtrate plus wash water through a conventional distillation tower to recover the monomers. Delaying monomer removal may increase operator exposure, results in monomer in drier emissions, and reduces acrylonitrile yield through emissions and a side reaction. The need for monomer recovery may be minimized by using two-stage filtration with the first stage filtrate recycled to the reactor. Nonvolatile monomers, such as SSS, can be partially recovered in this manner. This makes process control more difficult because some reaction by-products can affect the rate of polymerization and the concentration of the recycle stream may vary.

Cost reduction has been a focus of fiber producers since the overall market for acrylic fibers in developed countries has not grown. A significant savings is realized by operating continuous aqueous dispersion processes at very low water-to-monomer ratios. Mitsubishi Rayon, for example, has reported ratios as low as 1.75 (25,26). This compares to ratios of 4–5 widely used in the 1970s. The low water-to-monomer ratios produce a change in the nucleation and particle growth mechanisms that yields denser polymer particles. The dense particles yield a fluid

reaction mass, so long as conversion is relatively high. Removal of the heat of polymerization is more difficult in low water-to-monomer polymerizations as there is more heat generated per unit volume. The cost reduction comes in the drying step. While conventional water-to-monomer ratios give wet cake moisture levels of 200% (dry basis), the modified process yields wet cake moisture levels of 100% or less. Thus a savings in drying cost is realized. The low water-to-monomer process has the added advantage of increased reactor productivity.

After monomer removal by slurry distillation, salts are removed from the polymer by washing, either on a rotary vacuum filter or centrifuge. In the case where fiber will be produced from aqueous salt spin solvents such as sodium thiocyanate (NaSCN), the polymer cake may be used without drying to make a spin dope. With organic solvents, a drying step is required. Both belt dryers (with a pretreatment of pelletizing the polymer) and cyclone dryers are used; the former is most common. After drying, the pellets are again reduced to a powder and sent to bin storage. To ensure uniformity, the contents of several bins may be fed to the dope preparation area simultaneously.

Solution Polymerization. Solution polymerization is used by a few producers in the acrylic fiber industry. The reaction is carried out in a homogeneous medium by using a solvent for the polymer. Suitable solvents are aqueous NaSCN used by Acordis and dimethyl sulfoxide [67-68-5] (DMSO) used by Toray. The homogeneous solution polymerization of acrylonitrile follows the conventional kinetic scheme developed for vinyl monomers (27–29) (see BULK AND SOLUTION POLYMERIZATIONS REACTORS).

Thermally activated initiators such as azobisisobutyronitrile (AIBN), ammonium persulfate, or benzoyl peroxide can be used in solution polymerization, but these initiators are slow acting at temperatures required for fiber-grade polymer processes. Half-lives for this type of initiator are in the range of 10–20 h at 50–60°C (30). Therefore, these initiators are used mainly in batch processes where the reaction is carried out over an extended time. Redox initiators, such as the ammonium persulfate/sodium bisulfite/copper system, have much higher initiation rates and are reported to be employed in the Acordis NaSCN process. A typical continuous solution polymerization equipment diagram is shown in Figure 7.

Chain transfer is an important consideration in solution polymerization. Chain transfer to solvent may reduce the rate of polymerization as well as the molecular weight of the polymer. Other chain-transfer reactions may introduce dye sites, branching, and structural defects which reduce thermal stability. The organic solvents used for acrylonitrile polymerization are active in chain transfer. DMSO and DMF have chain-transfer constants of $(0.1–0.8) \times 10^{-4}$ and $(2.7–2.8) \times 10^{-4}$ respectively—high when compared to a value of only 0.05×10^{-4} for acrylonitrile itself and 0.006×10^{-4} for aqueous zinc chloride.

Of the two common comonomers incorporated in textile-grade acrylics, methyl acrylate is the least active in chain transfer, whereas vinyl acetate is as active in chain transfer as DMF. Vinyl acetate is also known to participate in the chain transfer-to-polymer reaction (31). This occurs primarily at high conversion, where the concentration of polymer is high and monomer is scarce.

The advantage of solution polymerization is that the polymer solution can be converted directly to spin dope by removing the unreacted monomer.

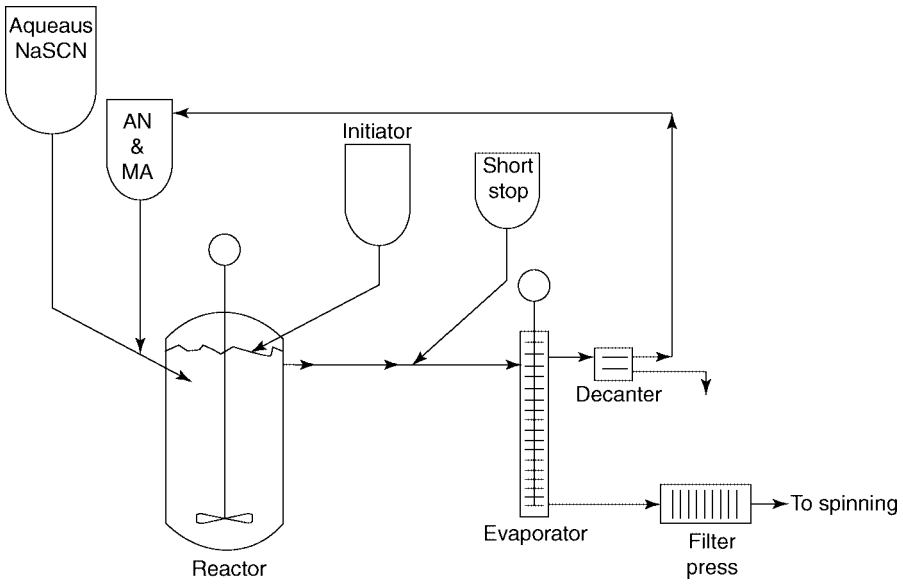

Fig. 7. CSTR NaSCN solution polymerization process. AN = acrylonitrile; MA = methyl acrylate.

Incorporation of nonvolatile monomers, such as the sulfonated monomers, can be a problem. The sulfonated monomers must be converted to a soluble form such as the amine salt. Nonvolatile monomers are difficult to recover or purge from the reaction medium. Monomer recovery systems based on carbon adsorption have been developed. However, the usual practice is to maximize the single-pass conversion of these monomers.

Subsequent to the polymer reactor, acrylonitrile and volatile comonomers are removed in a thin-film evaporator. Additives such as pigments or stabilizers may be incorporated using a static or active mixer before the dope is transferred to the spinning area.

Bulk Polymerization. The idea of bulk polymerization is attractive, since the polymer would not require water removal and the process would not have the low propagation rates and high chain transfer rates of solution processes (see BULK AND SOLUTION POLYMERIZATIONS REACTORS). But bulk polymerization of acrylonitrile is complex. Even after many investigations into the kinetics of the polymerization, it is still not completely understood. The complexity arises because the polymer precipitates from the reaction mixture barely swollen by its monomer. The heterogeneity leads to kinetics that deviate from normal.

When initiator is first added, the reaction medium remains clear while particles 10–20 nm in diameter are formed. As the polymerization proceeds, the particle size increases, giving the reaction medium a white milky appearance. When a thermal initiator, such as AIBN or benzoyl peroxide, is used the reaction is autocatalytic. This contrasts sharply with normal homogeneous polymerizations in which the rate of polymerization decreases monotonically with time. With acrylonitrile bulk polymerization, *three* propagation reactions occur simultaneously,

accounting for the anomalous autoacceleration (32,33). These are chain growth in the continuous monomer phase, chain growth of radicals that have precipitated from solution onto the particle surface, and chain growth of radicals within the polymer particles (30,34).

Bulk polymerization is not used commercially because the autocatalytic nature of the reaction makes control difficult. This, combined with the fact that the heat generated per unit volume is very high, makes commercial operations difficult to engineer. Last, the viscosity of the medium becomes very high at conversion levels above 40–50%. Therefore, commercial operation at low conversion would require an extensive monomer recovery operation. A bulk process was developed (35) by MEF, which limited conversion to ~50%; it reportedly reached pilot-plant stage but was not commercialized.

Emulsion Polymerization. The use of emulsion polymerization in the acrylic fiber industry is limited to the manufacture of modacrylic compositions. One notable example of an emulsion process was the former Union Carbide process for Dynel (36,37). The mechanism of emulsion polymerization was first developed qualitatively (38) and later quantitatively (39,40) (see HETEROPHASE POLYMERIZATION). It was shown that the emulsifier disperses a small portion of the monomer in aggregates of 50–100 molecules approximately 5 nm in diameter called *micelles*. The majority of the monomer stays suspended in droplet form. These droplets are typically 1000 nm in diameter, much larger than the micelles. Since a water-soluble radical initiator is used, polymerization begins in the aqueous phase. The micelle concentration is normally so high that the aqueous radicals are rapidly captured (41). The micelle is essentially a tiny reservoir of monomer; therefore, polymerization proceeds rapidly, converting the micelle to a polymer particle nucleus. Since the halogen-containing monomers have little water solubility, the micelle promotes their ability to react. The ability of emulsion polymerization to segregate radicals from one another is of great importance commercially. The effect is to minimize the rate of radical recombination, allowing high rates of polymerization to be achieved along with high molecular weight. This is important in modacrylic polymerizations where chain-transfer constants of the halogen monomers are high. Comprehensive reviews of emulsion polymerization technology have been published (42–44), and emulsion polymerization reactor modeling has been reviewed (45). The polymer for Kanekaron modacrylic is reported to be prepared by emulsion polymerization.

Copolymerization.

Homogeneous Copolymerization. Virtually all acrylic fibers are made from acrylonitrile copolymers containing one or more additional monomers that modify the properties of the fiber. Thus copolymerization kinetics is a key technical area in the acrylic fiber industry. When carried out in a homogeneous solution, the copolymerization of acrylonitrile follows the normal kinetic rate laws of copolymerization. Comprehensive treatments of this general subject have been published (46–50). The more specific subject of acrylonitrile copolymerization has been reviewed (51). The general subject of the reactivity of polymer radicals has been treated in depth (52).

For textile end- use acrylics, the most common comonomer is vinyl acetate, followed by methyl acrylate. The monomer pair acrylonitrile–methyl acrylate is close to being an ideal monomer pair. Both monomers are similar in resonance,

polarity, and steric characteristics. The acrylonitrile radical shows approximately equal reactivity with both monomers, and the methyl acrylate radical shows only a slight preference for reacting with acrylonitrile monomer. Many acrylonitrile monomer pairs fall into the nonideal category, for example, acrylonitrile–vinyl acetate. This example is of a nonideality, sometimes referred to as kinetic incompatibility. A third type of monomer pair is that which shows an alternating tendency. This tendency is related to the polarity properties of the monomer substituents (53). Monomers that are dissimilar in polarity tend to form alternating monomer sequences in the polymer chain. An example is the monomer pair acrylonitrile–styrene. Styrene, with its pendent phenyl group, has a relatively electronegative double bond whereas acrylonitrile, with its electron-withdrawing nitrile group, tends to be electropositive.

Copolymer composition can be predicted for copolymerizations with two or more components, such as those employing acrylonitrile plus a neutral monomer and an ionic dye receptor. These equations are derived by assuming that the component reactions involve only the terminal monomer unit of the chain radical. The theory of multicomponent polymerization kinetics has been treated (46,47).

Heterogeneous Copolymerization. When copolymer is prepared in a homogeneous solution, kinetic expressions can be used to predict copolymer composition. Bulk and dispersion polymerization are somewhat different, since the reaction medium is heterogeneous and polymerization occurs simultaneously in separate loci. In bulk polymerization, eg, the monomer-swollen polymer particles support polymerization within the particle core as well as on the particle surface. In aqueous dispersion or emulsion polymerization, the monomer is actually dispersed in two or three distinct phases: a continuous aqueous phase, a monomer droplet phase, and a phase consisting of polymer particles swollen at the surface with monomer. This affects the ultimate polymer composition because the monomers are partitioned such that the monomer mixture in the aqueous phase is richer in the more water-soluble monomers than the two organic phases. Where polymerization occurs predominantly in the organic phases, these relatively water-soluble monomers may get incorporated into the copolymer at lower levels than expected. For example, in studies of the emulsion copolymerization of acrylonitrile and styrene, the copolymer was richer in styrene than copolymer made by bulk polymerization, using the same initial monomer composition (54–56). Analysis of the reaction mixtures (57) showed that nearly all of the styrene was concentrated in the droplet and swollen particle phases. The acrylonitrile, on the other hand, was distributed between both the aqueous and organic phases. The monomer compositions in the droplet and particle phase were found to be essentially the same. The effect of monomer partitioning on copolymer composition is strongest with the ionic monomers, since this type of monomer is usually soluble in water and nearly insoluble in the other monomers. Reviews of emulsion copolymerization kinetics and the effects of reaction heterogeneity on reaction locus have been publis hed (58,59).

In a CSTR dispersion process, the percentage of the less reactive monomer increases until steady state is reached. For example, if a reactor is fed monomer composed of 91% acrylonitrile and 9% vinyl acetate and the process is carried to 75% conversion, the polymer will contain 7.4% vinyl acetate. The unreacted monomer composition will be 86.2% acrylonitrile and 13.8% vinyl acetate.

Table 3. Polymer Concentrations Suitable for Solution Spinning

Solvent	Polymer Concentration, %
Dimethylformamide (DMF)	20–32
Dimethylacetamide (DMAc)	20–27
Dimethyl sulfoxide (DMSO)	20–30
Ethylene carbonate (EC)	15–18
Sodium thiocyanate (NaSCN) 45–55% in water	10–15
Zinc chloride ($ZnCl_2$) 55–65% in water	8–12
Nitric acid (HNO_3) 65–75% in water	8–12

Solution Spinning

As the acrylic fiber industry has matured, the wide range of spin solvents that were commercialized in the 1950–1960s has narrowed. DMSO and zinc chloride are each limited to one producer; no processes based on ethylene carbonate solvent remain in operation. Most newer plants are based on either DMAc or NaSCN wet spinning. Table 3 shows commercial solvents and the dissolved polymer concentration range for a spin solution.

For dry polymer, the dope-making process may use chilled solvent to form a slurry and wet out the polymer particles before they begin to dissolve, or may use hot solvent so that the solutioning process occurs immediately. Additives such as thermal stabilizers and delusterant (TiO_2) are added at this time. In both cases, active mixing is required. Subsequently, the suspension is pumped through a shell-tube heat exchanger to complete dissolution. The resulting dope is degassed and filtered (plate and frame) before being pumped to the spin area.

Dry Spinning. This was the process first employed commercially by DuPont in 1950. It is shown schematically in Figure 8. For acrylic fibers, the only dry-spinning solvent used commercially is DMF. The DMF spin dope coming from the dope preparation unit is filtered and then heated to approximately

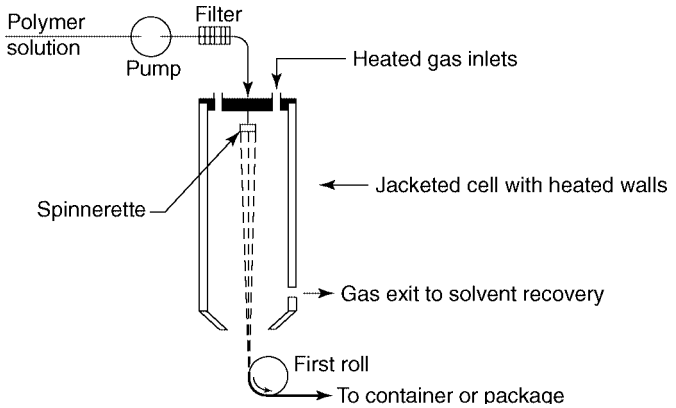

Fig. 8. Schematic of dry-spinning tower.

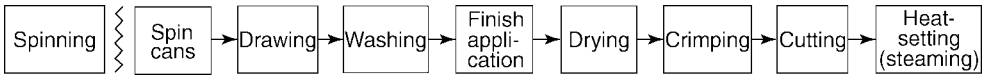

Fig. 9. Conventional wash-draw-dry-relax fiber process.

140°C. It is pumped through spinnerettes of up to 2800 holes placed at the top of a solvent removal tower. The DMF is evaporated by circulating an inert gas through the tower at 300–350°C. The tower walls are also heated to prevent any solvent condensation. With such a high boiling solvent (b.p. 153°C) it is not possible (or desirable) to remove all solvent in the tower. Consequently, the fiber from the bottom of the tower contains 10–25% solvent. In discontinuous processes, the fiber exiting the tower is wet with water and combined with the product from other threadlines into a rope; the rope is plaited into a can. The residual DMF is removed in a second step by passing the rope via roll sets through a series of hot water baths. A more modern process, introduced by Bayer, washes the fiber by sprays while passing on a belt. The as-spun fiber has little orientation, and so it is stretched three- to sixfold either before or concurrent with the washing step. The fiber is crimped to improve bulk and textile processing, then dried by heated air on a moving belt. During drying, the fiber structure collapses to the same density as solid polymer and the length decreases as the structure relaxes. A "finish" comprising an antistatic agent and a lubricant are applied by spray or kiss rolls and the product is either cut to staple or packaged directly as tow. Figure 9 shows the subsequent process steps.

The filament microstructure in dry spinning is derived from gelation exclusively. As evaporation proceeds, the polymer concentration in the filament increases until gelation occurs. This may happen within a few centimeters of the spinneret face. Since no nonsolvent is used, precipitation does not occur during solvent removal. Fiber densities from wet and dry spinning have been compared (60); density of as-spun fiber is much higher in dry-spun fiber. The fiber cross-section shape is typically a "dogbone" (Fig. 2). Very little fibrillar structure, characteristic of wet-spun fibers, is observed in the dry spun filaments. During stretching, however, the dry spun fibers develop a fibrillar network similar to that of the wet spun fibers but finer in diameter. This mode of fiber formation is economical for commodity fibers of 1–5 dtex but has severe limitations for other products:

(1) Solvent removal is not fast enough to produce fibers of 12–20 dtex suitable for the carpet industry.
(2) The limitation on the number of holes per spinneret makes production of fine filaments (<1 dtex) expensive as, unlike the wet-spinning process, the number of holes per spinneret is limited.
(3) The compact structure makes producer dyeing of fiber more difficult.
(4) The gelation process does not work well to produce special-shaped filaments; the dogbone cross-section is not suitable as a carbon fiber precursor; and it is not possible to produce a fibrillated product for the asbestos-replacement market.

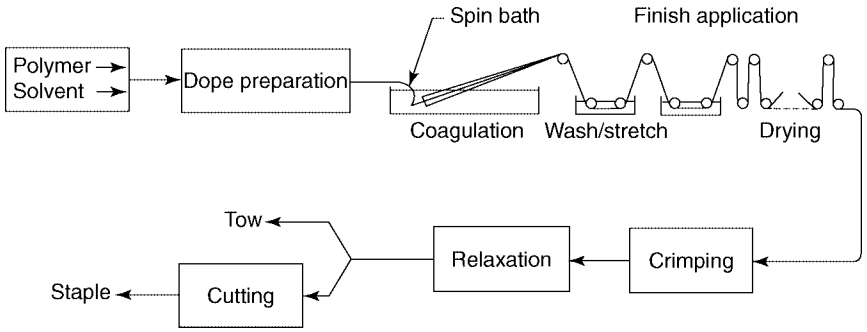

Fig. 10. Wet-spinning organic solvent process.

Wet Spinning. Wet spinning differs from dry spinning primarily in the way solvent is removed from the extruded filaments. Instead of evaporating the solvent in a drying tower, the fiber is spun into a liquid bath containing a solvent/nonsolvent mixture called the coagulant, as shown in Figures 10 and 11. The solvent is the same as the dope solvent and the nonsolvent is usually water. Filament fusion is less of a problem in wet spinning, and so the number of capillaries in wet spinning spinnerettes is much larger than in dry spinning. The spinnerettes in commercial processes may have anywhere from 3000 to 100,000 + capillaries, which may range in diameter from 0.05 to 0.25 mm; it is common to use multiple spinnerettes in a single spinbath.

Because the fiber microstructure is established in the spinbath, the coagulation conditions employed are the result of extensive optimization. The critical part of this process is the transition from a liquid to a solid phase within the

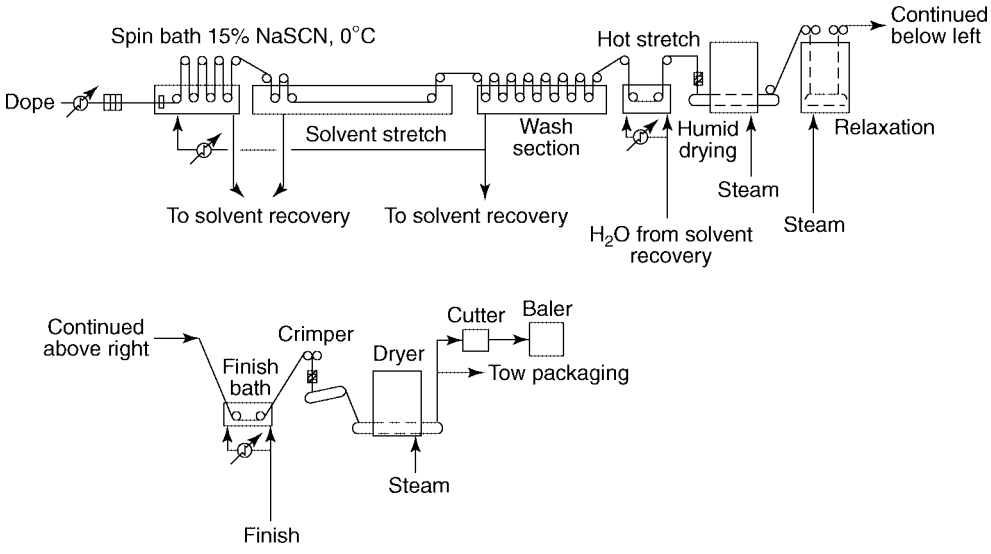

Fig. 11. Wet-spinning NaSCN salt process.

filaments. Two liquid-to-solid phase transitions are possible. The first is precipitation of the polymer to form a microporous solid phase. In extreme cases, precipitation produces a structure with macrovoids which must be "healed" in later processing, or the fiber lateral properties will suffer. Precipitation is favored when the solvent is organic and the nonsolvent is water, as the solubility of polymer decreases abruptly with water concentrations of only a few percent. The second and more desirable solid phase is the gel state, characterized by hydrogen and dipole bonding between the polymer and solvent. The gel state is desirable because it gives rise to a finer microstructure once the solvent is removed. Thus, the conditions in the spinbath should be optimized so that gelation of the polymer precedes precipitation. Studies (61) have shown that gelation occurs more rapidly at high dope solids and lower spinbath temperatures.

Low spinbath solvent concentration promotes initial rapid solvent extraction but also produces a thicker filament skin, that ultimately reduces the rate of solvent extraction and may lead to the formation of macrovoids. High spinbath solvent concentration gives a denser microstructure, but solvent extraction is slow and filament-to-filament fusion may occur. Other spinbath conditions that affect coagulation and microstructure are dope solids, spinbath temperature, jet stretch (the ratio of actual filament speed to theoretical speed in the capillary), and immersion time.

The fiber emerging from the spinbath is a highly swollen gel containing both solvent and nonsolvent from the spinbath. The fibers are essentially unoriented except at the fiber skin. The microstructure consists of a fibrillar network. The spaces between fibrils are called microvoids. Depending on the conditions of coagulation, the filaments may also contain large voids radiating out from the center of the fiber. The best combination of tensile properties, abrasion resistance, and fatigue life is realized when the coagulated fiber has a homogeneous, dense structure with small fibrils and no macrovoids (62).

Fiber cross-sectional shape is determined by the coagulation conditions. A thick skin characteristic of most organic solvent-spun fibers will generate a bean-shaped cross-section as the solvent is removed from the interior. The thinner skin characteristic of inorganic solvent-spun fibers can contract with solvent removal and retain the round shape. It is possible, however, to produce the opposite shape in either system. Examples of these shapes were shown in Figure 1. Special cross-sections, such as rectangular or oval, can be made from nonround capillaries by controlling coagulation conditions. Control of die swell is of critical importance. Die swell occurs because most spin dopes are viscoelasic in nature. After undergoing stretching deformation during extrusion through the small spinnerette hole, the dope partially rebounds to a larger, preextrusion diameter. To maintain a non-round shape, the tension on the filament at the spinnerette face must be great enough to counterbalance die-swell.

After the spin-bath or spin-tower step, the tow processing is similar for both wet- and dry-spun yarns. Wet-spun tows however, may contain 100–300% of solvent/nonsolvent, while dry-spun tows generally hold only 10–30% solvent. Therefore, the initial washing steps differ in their details. The key wet-spinning steps are washing, stretching, finish application, collapse, drying, crimping, and relaxing. The washing step consists of several countercurrent stages, with the effluent being recycled to a solvent recovery process. Various wash units are

employed including baths, sprays, and proprietary devices (63); washing efficiency is a key aspect of cost, as it impacts recovery of solvent from the effluent. The wash step may also be combined with stretching. In one variation of this method, the tow is drawn between sets of godets and passed through a series of solvent extraction baths at the same time.

The washing step may be followed by additional stretching. The porous fibrillar structure of wet-spun fibers increases in density with stretching. In-line dyeing of fiber using cationic dyes is usually carried out after almost all solvent is removed. Because of the open structure of wet-spun fiber, dye penetration and fixation is rapid. An additional wash step removes auxiliaries and unfixed dye. After the fiber is washed, stretched, and optionally dyed, finish may be applied using a bath or similar device. If drying is accomplished on heated rolls (Fig. 10), a predrying finish is required to prevent fiber fusion. In other processes (Fig. 11), finish application may be postponed until the fiber is dried and collapsed.

The collapsing-drying step can be accomplished with the tow held at constant length by contacting the tow on heated rolls or by passing the tow through an in-line oven using a conveyor belt. For fiber that contains a large void structure, roll drying is necessary to effect collapse of the voids. After collapse, boiling water shrinkage is reduced and higher temperatures are required for subsequent relaxation.

After drying/collapsing, the tow is relaxed. Relaxation is essential because it reduces the tendency for fibrillation and increases the dimensional stability of the fiber. Relaxation also increases fiber elongation while reducing strength and increases dye diffusion rate. Relaxation can be done in-line or in batches in an autoclave. For fiber that has been belt dried, relaxation can be accomplished by an atmospheric process (Fig. 11). However, for roll-dried fiber, saturated steam is used because the moisture reduces the process temperatures required. This process can be accomplished in-line, but more commonly it is done batchwise in an autoclave. Fiber shrinkage during relaxation ranges from 10 to 40% depending on the temperature, the polymer composition, and the amount of prior orientation. The amount of relaxation is tailored to the intended application of the product.

Fiber crimping using a stuffer box device may be done before in-line relaxation or before autoclaving. The relaxation process tends to "set" the crimp. In some autoclave processes, a second crimping step is employed subsequent to relaxation. Fiber may be cut to staple at the machine end for in-line relax processes or batchwise for autoclave processes. Tow can be produced from either process type, although large packages of one ton or more are produced more readily from the in-line relax process.

Process speeds for wet spinning vary from 55 to 260 m/min. The limitations are the speed at which the fiber can move through the spinbath without filament breakage and the equipment line length required to complete the washing and drying processes. A single machine may have up to 48 spinnerettes (6 rows of 8) with a total productivity of 50 ton/day.

Air-Gap Spinning. This process, also termed dry-jet wet spinning, is used to provide filament yarn either for textile use or as a carbon fiber precursor. It is suitable for producing the small bundles required for these end uses because the filament has been drawn before it enters the bath, and so drag forces are less likely to cause breakage; thus, much higher line speeds can be achieved. In theory, any

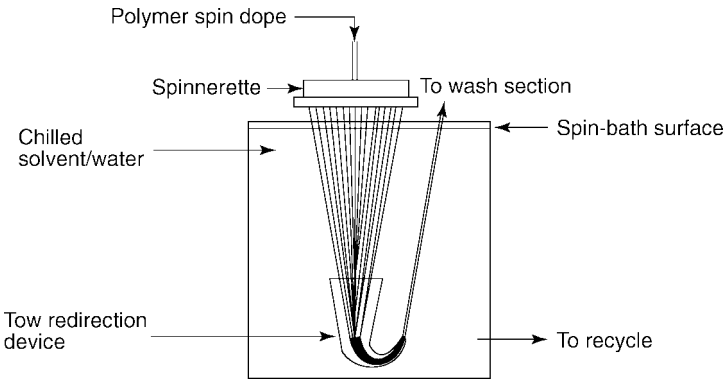

Fig. 12. Air gap coagulation.

acrylic solvent can be used in air gap spinning. Commercial examples are known from DMAc, NaSCN, and DMSO.

The dope solids for air-gap spinning are higher than for wet spinning, the intent being to achieve quick gelation on extrusion. The spinnerette is positioned a short distance above the bath, which is a solvent/nonsolvent mixture, typically at low temperature. The fiber is spun vertically into the bath, and then rerouted out via a tube or pulley as shown in Figure 12. Spinnerettes may be less then 1000 holes for a textile product or as many as 4000 for a carbon fiber precursor. The remainder of the process resembles the wet-spinning process, except that there are many small bundles that must be kept separate and the final product is taken up on bobbins. Final line speeds may be up to 500 m/min, but because of the small bundle size, machine productivity may be only 5 ton/day.

Solvent Recovery. Efficient use of solvent and water are key elements in an economic process. With most spinning processes practiced on a large scale, less than 1% solvent is not recycled, based on fiber produced. Since the ratio of solvent to fiber is in the range of 4:1, this means less than 0.25% of the solvent employed is expended per pass. Solvent loss is of several types: (*1*) solvent remaining in final fiber; (*2*) solvent lost as vapor; (*3*) solvent decomposed; (*4*) solvent lost in reprocessing or maintenance.

The main means of solvent recycling is distillation, either atmospheric or vacuum. With the organic solvents, the water is distilled, perhaps in several steps; then the higher boiling solvent is distilled, leaving behind dissolved salts and low molecular weight polymer. Amide solvents such as DMF and DMAc are subject to hydrolysis and may require a step to remove the acid generated; the recovered water may require removal of dimethylamine before reuse. Figure 13 shows a DMF recovery train (64). Salt solvents such as NaSCN are concentrated by water removal in multieffect evaporators, then may have an ion exchange and/or crystallization step to remove impurities. Recycled water may have the pH adjusted by addition of acid or base to assure neutralization of the fiber in the washing step.

Melt Spinning. Compared to most other synthetic fibers, acrylics have always had the disadvantage of extra process steps and cost incurred because

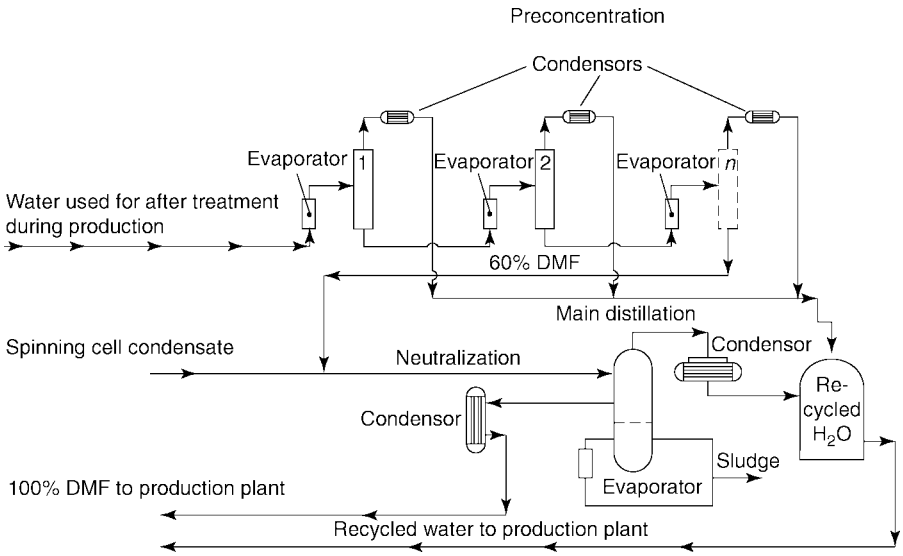

Fig. 13. Diagram of DMF recovery unit.

they could not be melt spun. Several approaches to eliminating this limitation have been proposed. Plasticization of the polymer with DMSO was proposed (65) as this lowered the melting point. This only reduced the amount of solvent to be recovered but did not eliminate the washing and solvent recovery steps. A more promising approach was plastization with water (66). This eliminated the process steps, but it was necessary to heat the plasticized mass to 200°C under pressure. The fiber had to be extruded into a chamber also under pressure, or the result would be a foam structure as the water vapor flashed.

A true melt spinning process has been developed by a group at Standard Oil (67). Their approach was to make a polymer containing substantial comonomer content by a process which minimized "blocking" of acrylonitrile groups. The resultant polymer was melt-processible without degradation. Possible limitations of this approach are that the high comonomer content leads to high relaxation shrinkage as well as lower softening and sticking temperatures. These are disadvantages in modern textile processes. No commercial applications of this technology have appeared.

Modifications of Properties.

Reduced Pilling. Staple fabrics, in general, develop small balls of fiber or pills on the fabric surface as a result of abrasive action on the fabric surface. However, the pills build up more on acrylic fabrics than on comparable woolens. Pilling can be reduced by increasing the likelihood that the pills will break or wear off. Thus, the most effective approaches include reducing fiber strength, incorporating defects in the fiber, increasing fiber brittleness, and reducing shear strength. Using the same polymer base, wet-spinning processes can be modified by using low solvent concentration in the spin-bath and high spin-bath temperature to give more brittle fibers with high void content. Other possible approaches are lower draw ratios, which result in low tensile strength, and less complete relaxation,

which reduces fiber elongation to break. Commercial examples include Dralon L930 (Fraver), Super Camelon (Mitsubishi Rayon), and Acrilan® Pil-Trol™ (Solutia).

Improved Abrasion Resistance. Abrasion resistance is generally improved by reducing the microvoid size and increasing the initial fiber density. Abrasion-resistant fibers have been produced by incorporating hydrophilic comonomers or comonomers with small molar volumes. Sulfonated monomers, acrylamide derivatives, and *N*-vinylpyrolidinone are some of the hydrophilic comonomers that can be used to slow coagulation, thus reducing the void content. Vinylidene chloride, with its relatively small molar volume, is effective in increasing fiber density. The spinning process itself has a significant effect on initial fiber density and abrasion resistance. Dry spinning, for example, produces a denser initial fiber structure than conventional wet spinning. Wet-spinning techniques used to improve abrasion resistance generally do so by promoting gelation. Examples include high spinbath that concentration, low spinbath temperature, and additives to the dope or spinbath that slow coagulation. Spinbath additives include nondiffusing nonsolvents, such as poly(ethylene glycol) or high molecular weight alcohols, such as *tert*-butyl alcohol, in place of water.

Commercial Products

The majority of acrylic fiber production is 1.0–5.6 dtex (0.9–5 den) staple and tow furnished, undyed, in either bright or semidull (~0.5% TiO_2) luster. The principal markets are in apparel and home furnishings. Within the apparel sector these fibers are used in sweaters and in single jersey, double-knit, and warp-knit fabrics for a variety of knitted outerwear garments such as dresses, suits, and children's wear. Other markets for acrylics in the knit goods area are hand-knitting yarns, deep-pile fabrics, circular knits, fleece fabrics, and half-hose. Acrylics also find uses in broadwoven fabric categories such as blankets, drapery, and upholstery. Minor tufted end uses include area rugs and carpets.

Acrylic Tow. A significant proportion of acrylic fiber, perhaps 25% in the United States and more than 50% in Europe, is sold as tow for conversion to yarn through stretch-breaking using the Superba, Seydel, or similar equipment. Tow packages may be as large as 1 ton, with no break in the bundle. The larger the tow package, the higher the tow customer's productivity. Ability to offer a large tow package implies that a producer has a highly stable process, as no knots are allowed. Producers with continuous relaxation have no limit on the package size they can offer; the only limits are those arising in package handling. In Europe, many fiber producers convert tow to "tops"—stretch broken product that is ready for yarn spinning.

Acrylic Filament Yarns. Continuous filament acrylic yarns face stiff competition from nylon and polyester. Since they are more costly, acrylics have penetrated only those markets where they have a clear advantage in a critical property. In Japan, continuous filament yarns in very fine deniers are valued as a silk replacement. In this market, the yarn is a premium product used in high fashion dress fabrics, satins, and poplins, or to produce a cloth suitable for surface raising to give a suede or fine velour effect.

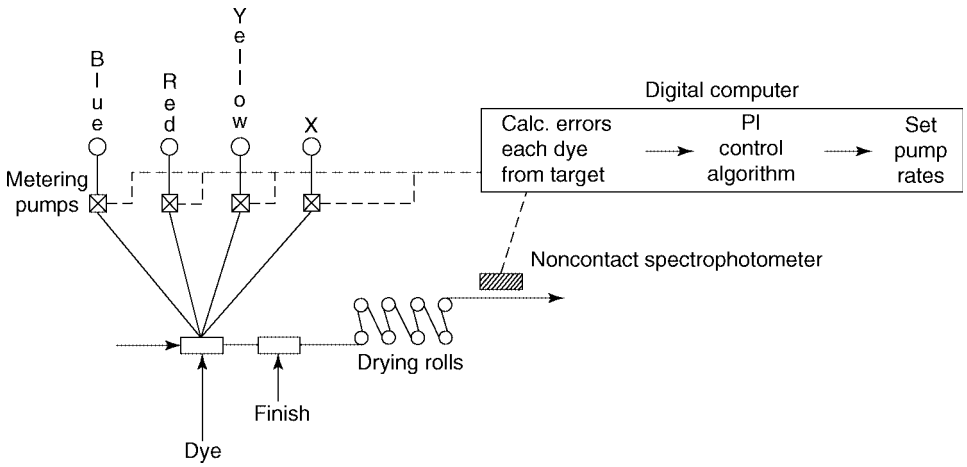

Fig. 14. Color control in a producer-dyed fiber process.

Producer-Dyed Fiber. The largest volume "specialty" product offered by acrylic producers is producer-dyed fiber (PDF). Producer dyeing decreases systems cost by elimination of a process step for the customer, but it complicates the inventory. PDF is usually made in an on-line process as shown in Figure 14 (68). The dye is applied using a device which promotes rapid penetration of the fiber mass, as acrylics have a high strike rate and very poor leveling qualities. The process is automated to maintain constant color (shade and depth) by real-time color analysis and correction. Since the final color is influenced by relaxation and crimp, further monitoring and testing may be required. Alternately, the dyes are premixed and a mixed stream is injected into the dyeing device. If the shade is right, then only depth needs adjustment. PDF fiber spun using this dyeing technology is usually sold as "lots," as color from one production run to the next may not match sufficiently for critical end uses. Dry-spun fibers are difficult to dye in-line as their compact structure makes dyeing too slow to be compatible with the required process speeds. For dry-spun acrylic, the only practical process is dope dyeing. For colors with only a low demand, some producers may use post-production dyeing with a device such as a Serricant Tow-Fix-R. More than 20 producers worldwide offer PDF acrylic.

Pigmented Fiber. Pigmented acrylic and a small amount of modacrylic are used in outdoor applications where outstanding light stability provides a competitive advantage. Pigmentation provides more stable coloration than dyeing through the lifetime of the fabric. End uses include awnings, tents, and lawn furniture. Modacrylic is used where local codes require a flame-retardant fabric. The technology involves mixing of the pigments with the spin dope prior to extrusion. The same feedback mechanism of color control described for PDF may be used with pigmented fiber. About a dozen producers offer pigmented fiber; however, some only sell one color—black. Generally, pigmented fiber commands a higher price than does PDF owing to the high cost of organic pigments. This coupled with the decreased luster of the pigmented products means they do not usually compete in the same end uses.

Fibers with High Bulk and Pile Properties. High-bulk acrylic fibers are commonly made by blending high shrinkage and low shrinkage staple fibers, or by blending relaxed and unrelaxed sliver from tow. The two staple products are made by variation in the fiber stabilization process. When the resulting yarn is allowed to relax, the high shrink component causes the low shrinkage (relaxed) fiber to buckle and add bulk to the yarns.

Another method of producing high bulk yarns is the use of bicomponent fibers. Bicomponent fibers have developed from a desire to match the bulkiness and handle of wool. The three-dimensional crimp of animal fibers in general comes from the presence of two components on the fiber surface. Acrylic bicomponent fibers achieve three-dimensional crimp by spinning two copolymer dopes into a single fiber. If the two streams are present in the same proportion in each spinneretto hole, the process is "true" bicomponent; if the proportion varies from filament to filament, then it is a "random" bicomponent. To generate the spiral crimp, the two polymers must have different responses to heat or moisture. For example, if one polymer is more moisture absorbent than the other, a crimp develops when the fiber is dried. The copolymers for this type of bicomponent may be acrylonitrile–vinyl acetate and acrylonitrile–vinyl acetate–sodium *p*-(vinylbenzene) sulfonate. In this combination, the copolymer containing the sulfonate moiety is the more moisture absorbent and therefore shrinks the most on drying. This type of crimp is reversible because it can be renewed by wetting and redrying. Solutia's A-21 and B-21 are examples of commercial water-reversible-crimp fibers. Crimp can also be imparted by using polymers that react differently to heat. By using copolymers of different compositions, the crimp is imparted permanently when the fiber is heated. The copolymers for this type of bicomponent have a single comonomer, such as vinyl acetate or methyl acrylate, incorporated at two different levels.

True bicomponents require special spinneretters that provide the required dopes to each hole. In random-bicomponent technology, the second component is incorporated through a layering device prior to the spinnerette. This concept is based on the fact that the viscous spinning solutions can be merged without complete mixing (69). When passed through a standard spinnerette, bicomponent fibers are produced ranging in composition from 100% component A to 100% component B. For many years, this was the only bicomponent technology available to wet spinners.

Flame-Resistant Fibers. Acrylics have relatively low flame resistance, comparable to cotton and regenerated cellulose fibers. Additional flame resistance is required for certain end uses, such as children's sleepwear, blankets, carpets, outdoor awnings, and drapery fabrics. The only feasible route is copolymerization of acrylonitrile with halogen-containing monomers such as vinyl chloride, vinyl bromide, or vinylidene chloride. Modacrylics were developed for uses where a high resistance to burning is required. In such fibers, the level of halogen-containing units was up to 60%, as in Dynel, one of the earliest modacrylics. This fiber, no longer produced, was 40–60 acrylonitrile–vinyl chloride copolymer. Tennessee Eastman's Verel, an acrylonitrile–vinylidene chloride copolymer, has also been discontinued. Solutia's SEF modacrylic is the only remaining U.S.-produced modacrylic flame-resistant fiber. It is produced solely in pigmented form as SEF FR for the commercial awning business. Kanekaron, another acrylonitrile–vinyl

chloride composition produced in Japan by Kanegafuchi, finds use in wigs, toys, pile, and industrial filter fabrics.

There have been reviews of flammability (70–74), methods that can be used to enhance the flame resistance of acrylic and modacrylic fibers (75), and the mechanism of flame-retardant additives (76).

High Strength Fibers by Conventional Solution Spinning. As a reinforcing material for ambient-cured cement building products, acrylics offer three key properties: high elastic modulus, good adhesion, and good alkali resistance (77). The high modulus requires an unusually high stretch orientation. This can be accomplished by stretching the fiber 8- to 14-fold above its glass-transition temperature, T_g. Normally this is done in boiling water or steam to give moduli of 8.8–13 N/tex (100–150 gf/den) (78,79). Alternatively, the stretch orientation can be achieved by a combination of wet stretch at 100°C and plastic stretch on hot rolls, or in a heat-transfer fluid such as glycerol. This technique is reported to give moduli as high as 17.6 N/tex (200 gf/den) (80,81). Mitsubishi Rayon Co. reported an acrylic asbestos-replacement fiber with a tensile strength of almost 600 MPa (87,000 psi) (82). Many patents have been obtained for acrylic-reinforcing fibers (83–85). The Acordis fiber, marketed under the trade name Dolanit, is offered in several forms (Table 4).

Acrylic fibers such as Dolanit (86) are blended in ambient-cured cement at a rate of 1–3%, compared with 9–15% by weight for asbestos. The flexural strength of cement sheets of acrylic-reinforced cement is equivalent to asbestos-reinforced cement and nearly double that of untreated cement (87). Two factors limiting the rapid development of acrylic asbestos-replacement fibers are a high manufacturing cost (compared to asbestos) and uncertainty as to the long-term stability of the acrylic fiber. Loss of modulus and chemical degradation may be significant over a period of decades. Other studies of acrylic fibers for concrete reinforcement have been carried out (88).

Table 4. Properties of Dolanite Asbestos Replacement Fibers[a]

	Dolanite Type 10	Dolanite Type 12			
Filament fineness, dtex[b]	1.5	0.7	1.7	2.2	8.2
Staple length, mm	6, 12	40	50	60, 80	80
Tenacity, cN/tex[c]	80–87	65–70	65–70	54–58	43–47
Elongation to break, %	8–12	15–20	15–20	13–16	14–17
Boiling water shrink, %	1.5				
Hot air shrink, % @ 150°C	1–2				
Same, yam form @ 200°C	3–4				
Hydrolysis resistance	Very good—after 350 h @ 130°C—93% tenacity remains				
Resistance to acids	Very good—after 8 weeks @ 20°C in 50% sulfuric acid—85% tenacity remains				
Heat resistance	Good—200 h @ 150°C, 75% tenacity remains	Good—permanent operating temperature up to 125°C, peaks up to 140°C

[b] To convert dtex to den, multiply by 0.9.
[c] To convert cN/tex to gf/den, multiply by 0.113.

Carbon Fiber. Carbon fibers (qv) are valued for their unique combination of extremely high modulus and strength and low specific gravity. Precursors for carbon fiber can be pitch, rayon, or acrylic fiber. Rayon offers a very low yield of carbon fiber and is no longer used as a precursor. Pitch is useful for generating carbon fiber of exceptionally high modulus, but the predominant precursor is acrylic. Precursors are converted into carbon fibers in a two-stage thermal treatment—a medium temperature "oxidation" stage in air that renders the fiber infusible, and a high temperature "carbonization" treatment in an inert atmosphere, where the fiber is converted into nearly pure carbon. The polymer composition generally has about 98% acrylonitrile and 2% of a weak acid such as itaconic or acrylic acid. The function of the acid is to provide a site to initiate the "ladder" formation in the oxidation step, and thus lower the temperature at which the reaction occurs and reduce the exotherm. Acrylic precursors are usually made by air gap spinning, as it allows higher line speed and the small bundle size is not a serious drawback. One exception is the Courtaulds (now Acordis) process, which uses wet spinning to produce a splittable tow; Toray is reported to use both wet- and air-gap processes to produce precursor. Increased stretch orientation is required to generate the high tenacity and modulus required in a precursor. It has been shown that precursor properties translate directly to carbon fiber properties (89). Precursor fiber is roll dried and not relaxed subsequent to drying. Special attention must be paid to the electrolyte content of the fiber and to drying conditions in order to produce a precursor which will perform well in oxidation and carbonization. The use of PAN as a carbon fiber precursor has been reviewed (90,91).

Other Specialty Fibers.

Microdenier. In the late 1980s, producers of polyester introduced "microdenier" products, that offered softer, more luxuriant handle to fabrics. Some acrylic producers have followed. There are no appreciable technical hurdles to producing a fiber with a denier of 0.6–0.9 (0.66–1.00 dtex), but unless commensurate changes are made in line speed or the number of spinneret holes, productivity will suffer. Acrylic microfibers on the market are all staple products, with Sterling in the United States producing a 0.8 dpf acrylic staple product named MicroSupreme and Solutia a 0.95 dpf product called Ginny. Mitsubishi Rayon offers H-129 (1.0 dtex).

Antimicrobial. For certain end uses such as half-hose, the ability to inhibit the growth of bacteria and fungi provides a marketing advantage. Several producers offer acrylics which have this characteristic. The antimicrobial effect is achieved by incorporating an additive such as chitosan (from chitan, a polysaccharide from the exoskeleton of crusteations), metal ions or chlorinated phenols. Commercial examples are New Tafel and Parclean from Mitsubishi Rayon and BioFresh from Sterling.

Fibrillated Fibers. Acrylic fibers are sold in the form of fibrillated pulps for use as highly efficient binders. These fibrillated fibers have a tree-like structure with "limbs" (fibrils) attached to the main "trunk" (fiber). The trunk is 20–50-μ diameter and the limbs range from a few microns to submicron. The product is generated from a special precursor fiber by intense mechanical action. Commercial examples are CCF from Sterling Fibers, Acri-Pulp from Solutia, and Dolanit 10D from Acordis.

Dry pulps are used in dry mix compounding applications such as non-asbestos friction materials. In these applications the product provides green strength for friction material performs. As little as a few percent pulp is required.

Wet pulps are used in specialty paper applications such as speaker cones, filtration, and specialty papers. These pulps have been successfully processed on cylinder, rotoformer, and Fourdrinier paper machines. As little as 15% of a highly fibrillated pulp can interlock other fibers or powders without the need for resin binders.

Conductive Fibers. Acrylic conductive fibers are used in areas where electrostatic discharge is a problem such as electronic device manufacture. Here the applications include dissipative clothing, flooring and work surfaces. Another application is solids/air filtration where discharge has the potential to trigger an explosion. Sterling Fibers manufactures Contructrol, which utilizes a combination of condutive carbon in the fiber and a conductive polymer attached to the fiber surface. Tex-Stat markets Thunderon, which uses a chemically bonded copper sulfide technology.

Economic Aspects

As has been mentioned earlier, the focus of acrylic production has moved to Asia which now accounts for 46% of world capacity. The most recent information on world acrylic capacity is listed in Table 5 (92). China leads in building new acrylic capacity with 16 plants as of 2000 and 19% of world capacity versus 8 plants and 9% of world capacity only 7 years earlier (93). Conversely, Europe, which had 38% of capacity in 1993 now has 29%. The changes in capacity and ownership of the major producers are shown graphically in Figure 15.

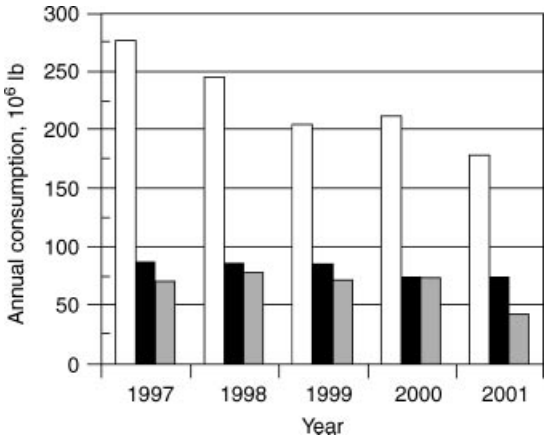

Fig. 16. U.S. acrylic fiber consumption (excluding carbon fibers). □ Apparel; ■ home furnishings; ▭ industrial and nonwovens.

Markets for acrylic fiber in developed countries have been stagnant or declining as shown in the example for the United States in Figure 16. Many acrylic articles such as sweaters come into the United States as finished goods from Asia. The volumes consumed in U.S. apparel markets are shown in Table 6. All developed countries face a similar situation due to the disparity of labor costs. Losses of volume in western Europe in the late 1990s have been less severe than in the United State, but still ominous as shown in Table 7 (94). The next decade will likely continue the exodus of capacity from the United State, Europe, and Japan.

Table 6. U.S. Shipments of Acrylic and Modacrylic for Apparel Markets, 10^3 t

Year	Sweaters	Socks	Craft	Pile	Fleece
1995	24.1	9.5	11.8	6.4	28.6

Acknowledgments

The authors wish to thank Dr. Fred Kanel and Dr. Ashesh Agrawal for their many helpful suggestions in the preparation of this article. We also appreciate the assistance of Dr. Raffaele Tedesco and Mr. Shimpei Haratake in constructing the table of plant capacities. Finally we acknowledge a debt to Dr. Ray Knorr, the prior author of this work, whose words and references we have built on.

CARBON BLACK

Introduction

Carbon black is a generic term for an important family of products used principally for the reinforcement of rubber, as a black pigment, and for its electrically conductive properties. It is a fluffy powder of extreme fineness and high surface area, composed essentially of elemental carbon. Carbon black is one of the most stable chemical products. In a general sense, it is the most widely used nanomaterial, with its aggregate dimension ranging from tens of nanometers to a few hundred nanometers, and imparts special properties to composites of which it is a part. Plants for the manufacture of carbon black are strategically located worldwide in order to supply the rubber tire industry, which consumes 70% of carbon black production. About 20% is used for other rubber products and 10% is used for special nonrubber applications (1). World capacity in 2001 was estimated at over eight million metric tons (1). U.S. capacity was approximately 24 million metric tons. Over 42 grades, listed in ASTM 1765-01 (2), are used by the rubber industry. Many additional grades are marketed in the nonrubber markets.

Carbon blacks differ from other forms of bulk carbon such as diamond, graphite, cokes, and charcoal in that they are composed of aggregates having complex configurations, quasigraphitic in structure, and are of colloidal dimensions. They differ from other bulk carbons in being formed from the vapor phase by homogeneous nucleation through the thermal decomposition and the partial combustion of hydrocarbons. Carbon black is the product of a technology incorporating state-of-the-art engineering and process controls. Its purity differentiates it from soots that are impure by-products from the combustion of coal and oils and from the use of diesel fuels. Carbon blacks are essentially free of the

inorganic contaminants and extractable organic residues characteristic of most forms of soot.

A number of processes have been used to produce carbon black including the oil furnace, impingement (channel), lampblack, the thermal decomposition of natural gas, and decomposition of acetylene (3). These processes produce different grades of carbon black and are referred to by the process by which they are made, eg, oil-furnace black, lampblack, thermal black, acetylene black, and channel black. A small amount of by-product carbon from the manufacture of synthesis gas from liquid hydrocarbons has found applications in electrically conductive compositions. The different grades from the various processes have certain unique characteristics, but it is now possible to produce reasonable approximations of most of these grades by the oil-furnace process. Since over 95% of the total output of carbon black is produced by the oil-furnace process, this article emphasizes this process (1).

History of Carbon Black Manufacture

Carbon blacks' use as a pigment dates back to prehistoric times. Wall paintings from Paleolithic caves are the earliest known use. The Egyptians used carbon black to pigment paints and lacquers. In China, about 3000 BC, carbon black for pigment use was made by burning vegetable oils in small lamps and collecting the carbon on a ceramic lid.

Prior to 1870 the dominant carbon black manufacture was by the lampblack process where oil from animal or vegetable sources was burned in a shallow pan with a restricted air supply. Starting in 1870, natural gas began to be used as the feedstock for carbon black manufacture. The resulting blacks were much darker and better covering than lampblacks. Over a couple of decades, the channel process was developed in which small gas flames burning in restricted air supply impinged on iron channels. The black adhered to the cool channel surface and was recovered by scraping it from the channel. Carbon yields were poor—a few percent. In part this was from the inefficiency of methane as a feedstock, but it also reflects the very poor capture efficiency of the early channel black process. Reportedly the smoke plumes from channel black plants could be seen for 50 miles. The last channel black plant in the United States was closed in 1976. Two plants remain in the former Soviet Union, and a related but much evolved process is still operated in Germany.

A critical event in the development of the carbon black industry was the discovery of the benefits of carbon black as a reinforcing agent for rubber in 1904 (4). As the automobile became ubiquitous during the decade of the twenties, the application in pneumatic tires grew rapidly and soon by-passed other applications, causing rapid growth in consumption. During the 1920s, two other processes were introduced, both using natural gas as feedstock, but having better yields and lower emissions than the channel process. One was the thermal black process in which a brick checker-work alternately absorbs heat from a natural gas air flame, and then gives up heat to crack natural gas to carbon and hydrogen. The other process was the gas-furnace process which is no longer practiced.

The oil-furnace process was first introduced by Phillips Petroleum at its plant in Borger, Texas, in 1943. This process rapidly replaced all others for the

production of carbon black for use in rubber. In this process fuel is burned with air in a primary combustion flame which contains excess air. A heavy, highly aromatic oil is then atomized in the hot gases leaving the primary combustion flame. A portion of the oil is burned by the excess oxygen, providing the heat to maintain temperature and pyrolyze the remainder of the oil. In a modern version of the oil-furnace process, carbon yields range from 65% downward, depending on the surface area of the product. Product recovery is essentially 100% as a result of high efficiency bag filters. The overwhelming majority of carbon black reactors today are based on the oil-furnace process.

The wide adoption of radial tires during the decades of the 1970s and 1980s caused a major contraction in demand for blacks for tire use as the expected life of an automobile tire moved from 20,000 miles with bias ply tires to over 40,000 miles with radial tires. This brought about considerable consolidation in the carbon black industry, particularly in North America and Europe.

Properties and Characterization

The structure of carbon black is schematically shown in Figure 1. The primary dispersable unit of carbon black is referred as an "aggregate," which is a discrete,

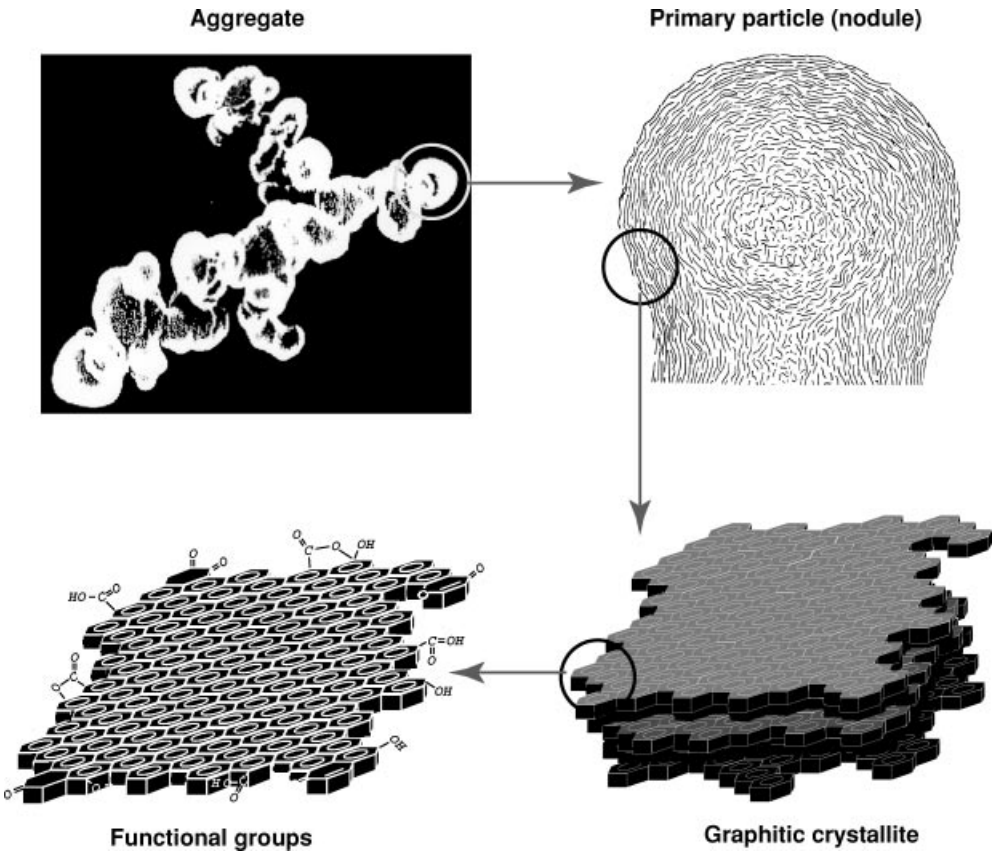

Fig. 1. Structure of carbon black.

rigid colloidal entity. It is the functional unit in well-dispersed systems. The aggregate is composed of spheres that are fused together for most carbon blacks. These spheres are generally termed as primary "particles" or "nodules." These nodules are composed of many tiny graphite-like stacks. Within the nodule the stacks are oriented so that their *c*-axis is normal to the sphere surface, at least near the nodule surface.

The carbon blacks are characterized by their chemical compositions, microstructure, morphologies, and the physical chemistry of the surface. Morphology is a set of properties related to the average magnitude and frequency distribution of the nodule diameter, aggregate diameter, and the way nodules are connected in the aggregates.

Chemical Composition. Oil-furnace blacks used by the rubber industry contain over 97% elemental carbon. Thermal and acetylene black consist of over 99% carbon. The ultimate analysis of rubber-grade blacks is shown in Table 1. The elements other than carbon in furnace black are hydrogen, oxygen, sulfur, and nitrogen. In addition there are mineral oxides, salts, and traces of adsorbed hydrocarbons. The hydrogen and sulfur are distributed on the surface and the interior of the aggregates. The oxygen content is located on the surface of the aggregates as C_xO_y complexes.

Since carbon blacks are produced from hydrocarbon materials, the dangling bonds at the edges of the basal planes of graphitic layers are saturated mostly by hydrogen. The graphitic layers are large polycyclic aromatic ring systems.

Oxygen-containing complexes are by far the most important surface groups. The oxygen content of carbon blacks varies from 0.2–1.5% for furnace blacks to 3–4% for channel blacks. Some speciality blacks used for pigment purposes contain larger quantities of oxygen than normal furnace blacks. These blacks are made by oxidation in a separate process step using nitric acid, ozone, air, or other oxidizing agents. They may contain from 2 to 12% oxygen. The oxygen-containing groups influence the physicochemical properties, such as chemical reactivities, wettability, catalytic, electrical properties, and adsorbability. Oxidation improves dispersion and flow characteristics in pigment vehicle systems such as lithographic inks, paints, and enamels. In rubber-grade blacks surface oxidation reduces pH and changes the kinetics of vulcanization, making the rubber compounds less scorchy and slower curing.

A convenient method for assessing the extent of surface oxidation is the measurement of volatile content. This standard method measures the weight loss of the evolved gases on heating up from 120 to 950°C in an inert atmosphere.

Table 1. Chemical Composition of Carbon Blacks

Type	Carbon, %	Hydrogen, %	Oxygen, %	Sulfur, %	Nitrogen, %	Ash, %	Volatile, %
Furnace rubber-grade	97.3–99.3	0.20–0.80	0.20–1.50	0.20–1.20	0.05–0.30	0.10–1.00	0.60–1.50
Medium thermal	99.4	0.30–0.50	0.00–0.12	0.00–0.25	NA	0.20–0.38	
Acetylene black	99.8	0.05–0.10	0.10–0.15	0.02–0.05	NA	0.00	<0.40

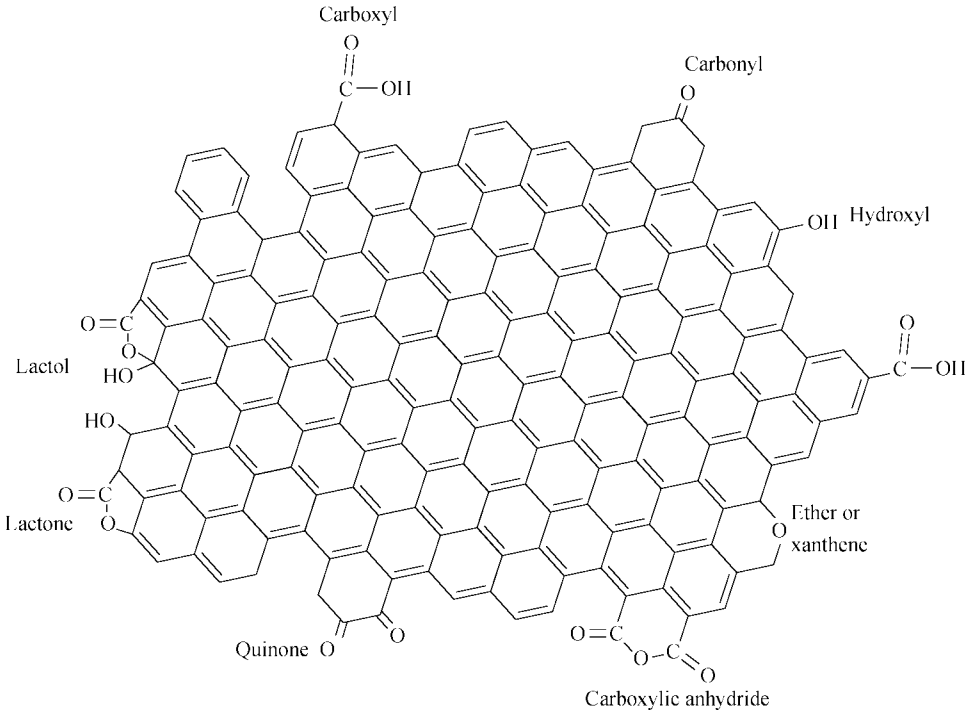

Fig. 2. Aromatic layer plane with functional groups.

The composition of these gases consists of three principal components: hydrogen, carbon monoxide, and carbon dioxide. The volatile content of normal furnace blacks is under 1.5%, and the volatile content of oxidized special grades is 2–22%.

The origin of the volatile gases is the functional groups attached to carbon black, especially those on the surface. Surface oxides bound to the edges of the of carbon layers are phenols, hydroquinones, quinones, neutral groups with one oxygen, carboxylic acids, lactones, and neutral groups containing two oxygens (5). Figure 2 shows an idealized graphite surface layer plane with the various functional groups located at the periphery of the plane. Carbon blacks with few oxygen groups show basic surface properties and anion exchange behavior (6,7).

In addition to combined hydrogen and oxygen, carbon blacks may contain as much as 1.2% combined sulfur resulting from the sulfur content of the aromatic feedstock that contains thiophenes, mercaptans, and sulfides. The majority of the sulfur is not potentially reactive as it is inacessibly bound in the interior of carbon black particle and does not contribute to sulfur cross-linking during the vulcanization of rubber compounds.

The nitrogen in carbon blacks is the residue of nitrogen heterocycles in the feedstocks. Thus carbon blacks derived from coal tars have far more nitrogen than petroleum-derived blacks.

The ash content of furnace blacks is normally a few tenths of a percent but in some products may be as high as 1%. The chief source of ash is the water used to quench the hot black from the reactors during manufacture and for wet-pelletizing the black.

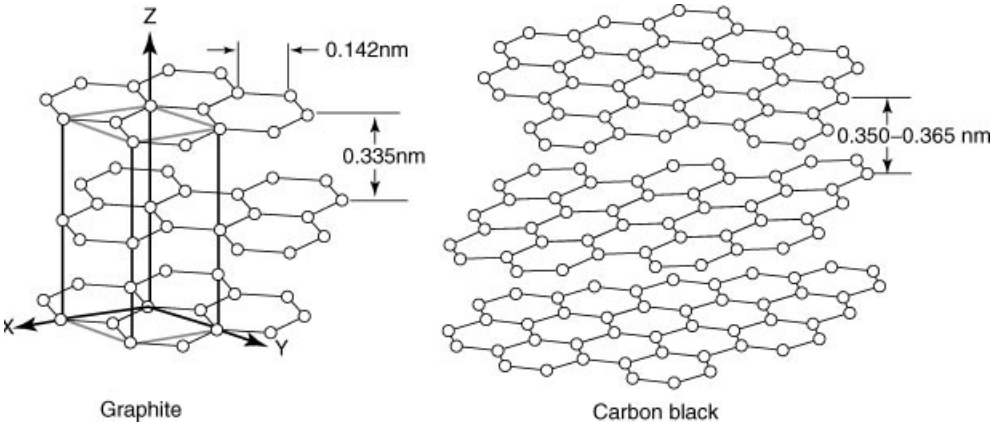

Fig. 3. Atomic structural models of (**a**) graphite and (**b**) carbon black.

Microstructure—Molecular and Crystallite Structure. The arrangement of carbon atoms in carbon black has been well-established by x-ray diffraction methods (8,9). The diffraction patterns show diffuse rings at the same positions as diffraction rings from pure graphite. The suggested relation to graphite is further emphasized as carbon black is heated to 3000°C. The diffuse reflections sharpen, but the pattern never approaches that of true graphite. Carbon black has a degenerated graphitic crystalline structure as defined above. While graphite has three-dimensional order, as seen in the model structures of Figure 3, carbon black has two-dimensional order. The x-ray data indicate that carbon black consists of well-developed graphite platelets stacked roughly parallel to one another but random in orientation with respect to adjacent layers. As shown in Figure 3 the carbon atoms in the graphitic structure of carbon black form large sheets of condensed aromatic ring systems with an interatomic spacing of 0.142 nm within the sheet identical to that found in graphite. However, the interplanar distances are quite different. While graphite interplanar distance is 0.335 nm that results in a relative density of 2.26, the interplanar distance of carbon black is larger, in the range of 0.350–0.365 nm, as a consequence of the random planar orientations or so-called turbostratic arrangement. The relative density of commercial carbon blacks are 1.76–1.90 depending on the grade. About half of the decrement in density is attributed to L_c in the crystallites. X-ray diffraction data provide estimates of crystallite size. For a typical carbon black, the average crystallite diameter L_a is about 1.7 nm and average thickness L_c is 1.5 nm, which corresponds to an average of four layer planes per crystallite containing ca 375 carbon atoms.

It was originally suggested that these discrete crystallites were in random orientation within the particle. This view was later abandoned when electron microscopy of graphitized and oxidized carbon blacks indicated more of a concentric layer plane arrangement which can be described by a paracrystalline model. This structure has been confirmed by the use of high resolution phase-contrast electron microscopy that made possible the direct imaging of graphitic layer planes in carbon black (10). Figure 4 shows a phase-contrast electron micrograph of carbon

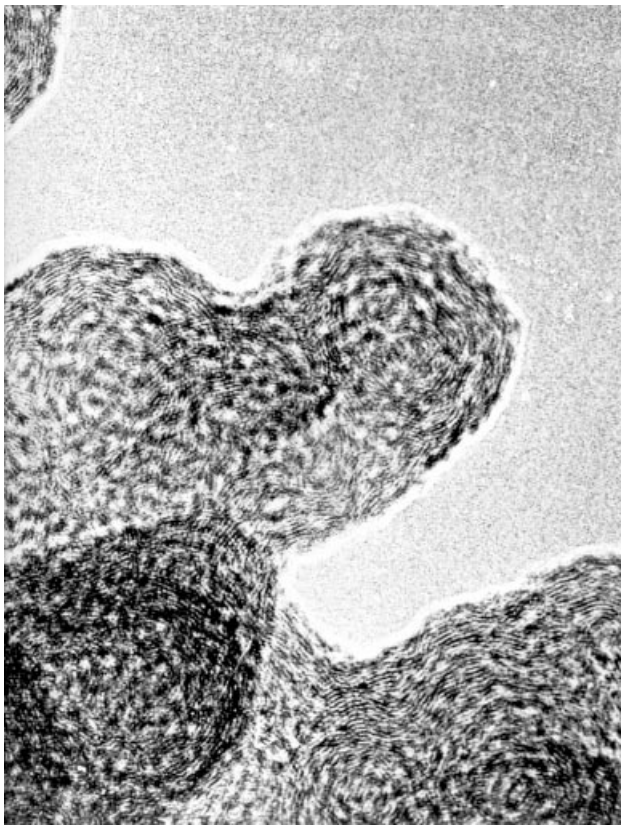

Fig. 4. High resolution (3,000,000×) electron micrograph of N220-grade carbon black. Courtesy of W. M. Hess.

black at high resolution that displays the marked concentric arrangement of the layer planes at the surface and around what appear to be growth centers.

More recently, the microstructure of the carbon black surface has been investigated by means of scanning tunneling microscopy (STM) (11,12). Figure 5 shows the STM images obtained in the current mode for graphite, graphitized carbon black, and normal carbon black N234. Compared to graphite, the structure of carbon blacks graphitized for 24 h at a temperature of 2700°C in an inert atmosphere still remains in a certain imperfect state, shown by different tunneling current partterns in the organized domains. The surface structure of carbon black can be classified into two types: organized domains and unorganized domains. The organized domains occupy the majority of the carbon black surface, and its size generally decreases with decreasing particle size.

Morphology. Morphologically, carbon blacks differ in primary "particle" or nodule size, surface area, aggregate size, aggregate shape, and in the distribution of each of these.

Primary "Particle" (Nodule) Size. Although the smallest discrete entity of carbon black is the aggregate, the particle size, and its distribution is one of the most important morphological parameters with regard to its end-use applications,

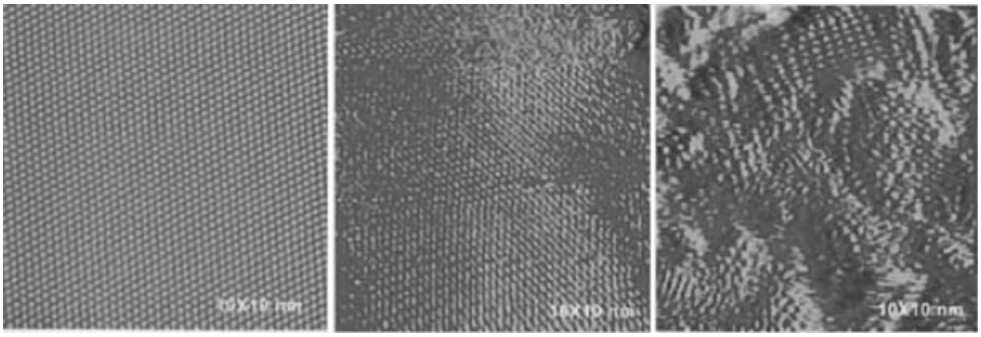

Fig. 5. STM images of graphite, graphitized carbon black and carbon black N234.

even though the particles do not exist as discrete entities except for thermal black. The particle size is of critical importance to the specific surface of the carbon blacks and has been taken as the principal parameter for grade classification of rubber blacks in ASTM. In almost all types of carbon black, the primary particles within a single aggregate are similar. However, the types of blacks can differ in the uniformity of the primary particles of different aggregates. While many types do show a quite narrow range of primary particles, others are clearly quite broad mixtures of aggregates of differing primary particle size or specific surface area. The electron microscope is the universally accepted instrument for measuring particle size, aggregate size, and aggregate morphology. Typical electron micrographs of rubber-grade carbon blacks are shown in Figure 6.

Particle size measurement is based on the visual electron microscope counts for several thousand particles on electromicrographs of known magnification (ASTM D3849). Automated image analyzers provide measurements of a variety of particle parameters.

Surface Area. The surface area is one of the most important features influencing the performance of carbon blacks. It is an extensity factor that determines the interfacial area between carbon black and the medium in which a given volume of black is dispersed.

The surface area can be calculated from particle size measured with transmission electron microscope (TEM) (ASTM D3849). Generally, for rubber grade, the surface areas determined by TEM are in reasonable agreement with surface areas determined by nitrogen adsorption measurements. However, for those carbon blacks that have highly developed micropores such as special pigment blacks and blacks used for electrical conductivity, the surface areas calculated from their particle diameters are smaller than those calculated from gas absorption, as the internal surface area in the micropore is excluded.

While the TEM images contain very detailed statistical information, such images are expensive and time-consuming to obtain. Direct measurement of specific surface area is much faster and cheaper. Such measurements are most easily made by gas- and liquid-phase adsorption techniques that depend on the amount of adsorbate required to form a surface monolayer. If the area occupied by a single-adsorbate molecule is known, a simple calculation will yield the surface area.

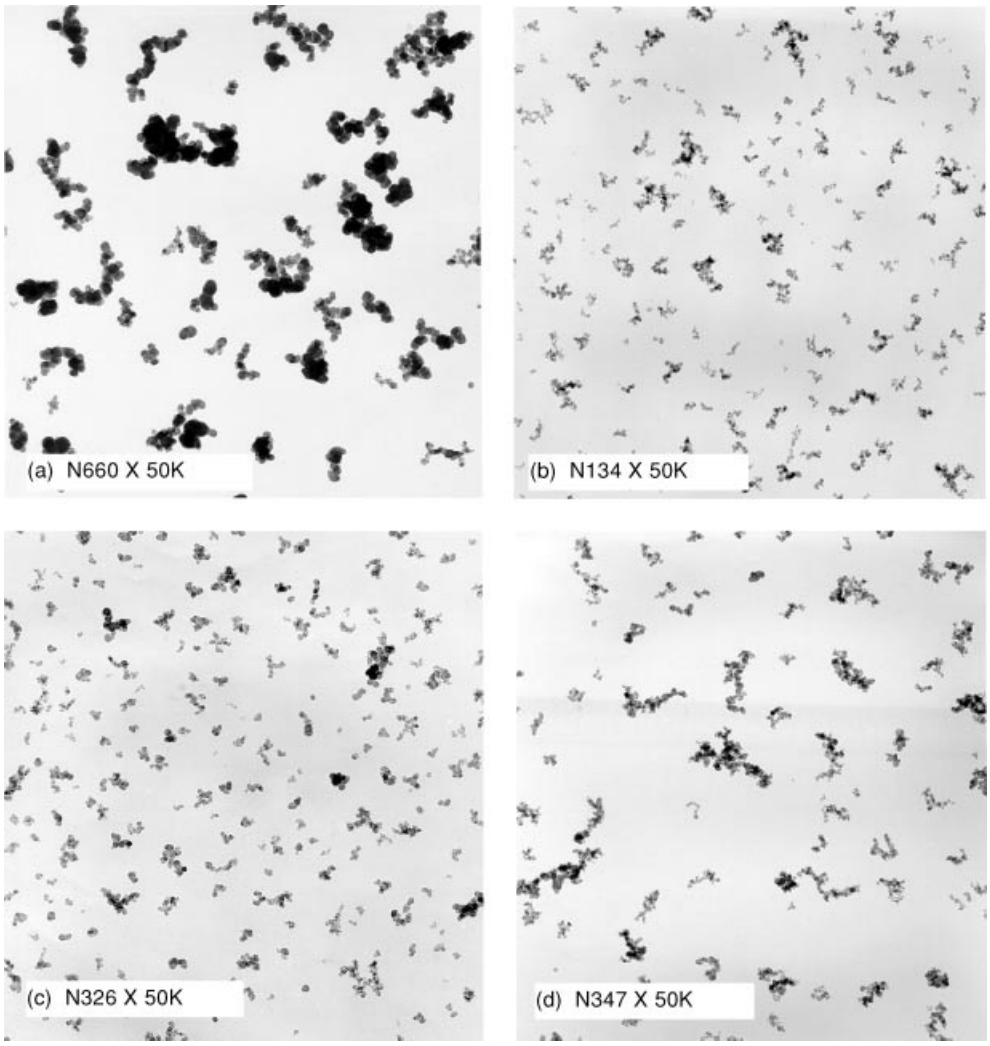

Fig. 6. Electron micrographs of rubber-grade carbon blacks.

A low temperature nitrogen adsorption method, based on the original method of Brunauer, Emmett, and Teller (BET) (13), has been adopted by ASTM as standard method D6556. It is not sensitive to changes in the surface chemistry of carbon black such as those that result from surface oxidation and presence of trace amount of tarry material. With a molecular diameter of less than 0.5 nm, nitrogen is small enough to enter the micropore space so that the surface measured by BET is the total area, inclusive of micropore. For some application, such as rubber reinforcement, the internal surface area in the micropore with less than 2 nm diameter is inaccesible to large rubber molecules, and thus it plays no part or has a negative effect on rubber reinforcement. The specific surface area that is accesible to rubber is defined as "external" surface area. This is conveniently

measured by a multilayer nitrogen adsorption, also defined in ASTM D6556 and known as the statistical thickness surface area (STSA) (14).

Liquid-phase adsorption methods are also widely used. The adsorption of iodine from potassium iodide solution is the standard ASTM method D1510. The surface area is expressed as the iodine number whose units are milligrams of iodine adsorbed per gram of carbon blacks. The test conditions such as adsorbate concentration and the amount of carbon black sample used are specified in such a way that the values of iodine numbers turn out to be about the same as the values for surface areas in square meters per gram that is measured by nitrogen adsorption for nonporous and nonoxidized furnace carbon blacks. The iodine number is raised by porosity and decreased by surface oxygen or adsorbed organics. Still it is the most easily measured surface area estimate and is used extensively, especially for process control.

Another standard industry method for surface area measurement is based on the adsorption of cetyltrimethylammonium bromide (CTAB) from aqueous solution. This is ASTM method D3765 and has largely been replaced by STSA in the last decade.

Aggregate Morphology (Structure). The aggregate morphology is another important characteristic that influences performance. The term "structure" is widely used in the carbon black and rubber industries to describe the aggregate morphology. It was originally introduced in 1944 (15) to describe the ensemble of aggregates that is a stochastic distribution of the number and arrangement of the nodules that make up the aggregates.

Structure comparisons of grades with different surface areas cannot be made. It is now known that the properties associated with structure are associated principally with the bulkiness of individual aggregates. Aggregates of the same mass, surface area, and number of nodules have high structure in the open bulky and filamentous arrangement and a low structure in a more clustered compact arrangement. Therefore, the structure is now used to describe the relative void volume characteristics of grades of black of the same surface area. Structure is determined by aggregate size and shape, and their distribution. They are geometrical factors which affect aggregate packing and the volume of voids in the bulk material. Therefore, in composite systems, it is also a principal feature that determine the performance of carbon black as a reinforcing agent and as a pigment (16). In liquid media structure affects rheological properties such as viscosity and yield point. In rubber, viscosity, extrusion die swell, modulus, abrasion resistance, dynamic properties, and electrical conductivity are affected by structure.

The direct method for structure measurement of carbon black is TEM (ASTM D3849). It is unique in furnishing information about the aggregate size, shape, and the distribution of these. Typical electron micrographs of rubber-grade carbon blacks are shown in Figure 6. There is an enormous range in aggregate size. The size of the aggregates is generally related to the size of the particles. The shapes of the aggregates have infinite variety from tight grape-like clusters to open dendritic or branched arrangements to fibrous configurations.

A useful method for determining relative aggregate sizes and distributions is by centrifugal sedimentation. For a sphere, the diameter can be derived from the sedimentation rates in the gravitational field according to Stokes equation. For the nonspherical particles such as carbon black aggregates, an equvalent Stokes

Table 2. Carbon Black Morphology

ASTM designation	Particle size[a] D_{wm}[b], nm	Aggregate size[a], D_{wm}[b], nm	D_{st}[c], nm	Surface area[a], m^2/g
N110	27	93	76–111	143
N220	32	103	95–117	117
N234	31	109	74–97	120

[a] Measured by TEM.
[b] D_{wm} = weight mean diameter = $\sum nd^4/\sum nd^3$.
[c] Stokes diameter by centrifugal sedimentation from various sources.

diameter D_{st} can be obtained as the diameter of a sphere of carbon black having the same settling behavior. A convenient instrument for these measurements is the Joyce Loebl disk centrifuge photosedimentometer (DCP) (17). Large aggregates sediment at a faster rate than smaller ones. The sedimentation rate is also influenced by the bulkiness of the aggregates. At constant volume or mass, a bulky aggregate sediments more slowly than a compact aggregate because of frictional drag. The DCP curve is characteristic of the black structure but the measured diameters need to be viewed with suspicion.

Table 2 lists average D_{st} values and the weight mean diameter D_{wm} for the aggregates calculated from their estimated volumes measured by TEM. There is reasonable agreement between the two diameters. Aggregate size distributions from centrifugal sedimentation analysis are very useful for assessing the differences in this characteristic within a given grade or at constant surface area.

By far the most intensively investigated measure of structure is the maximum packing fraction. In fact the amount of void at the maximum packing has almost become synonymous with carbon black "structure." At least two approaches are widely used. The first determines the amount of liquid that is needed to just fill all the spaces between aggregates when the aggregates are pulled together by the surface tension forces of that liquid. This is done by means of an absorptometer with dibutyl phthalate (DBP) as the liquid (ASTM D2414). This is based on the change in torque during mixing of carbon black and the liquid as there is a sharp increase in viscosity of the mixture, when it changes from free flowing powder to a semiplastic continuous paste. The viscosity, hence the torque, will drop as the liquid is continually added, because of the lubrication effect. The volume of DBP needed for a unit mass of carbon blacks to reach a predetermined level of torque is termed the DBP number. In order to eliminate the effects of pelletizing conditions, the DBP absorption test has been modified to use a sample that has been precompressed at a pressure of 165 MPa (24,000 psi) and then broken up four successive

times (24M4) (ASTM D3493). This procedure causes some aggregate breakdown and is claimed to more closely approximate the actual breakdown that occurs during rubber mixing. The DBP numbers measured for compressed samples are also termed crush DBP (CDBP) number.

The maximum random packing for mono-sized spheres is a volume fraction of 68%. This is equivalent to a DBP number of 25 mL/100 g of carbon black. The types of blacks with the lowest DBP number, and therefore highest packing, have values around 30–35 mL/100 g. The types with the highest structure, and therefore lowest packing, have a DBP number of around 140 mL/100 g. Grades with significantly higher DBP number do not have solid primary particles and the fluid is absorbed both within the primary particles and between the aggregates.

The second way of estimating the maximum packing fraction is mechanical compression. Most commonly this is practiced in uniaxial compression. The test is termed the void volume measurement (ASTM D6086). With both liquid and mechanical compaction, the measured value can be influenced to some degree by either the speed of the compaction, ie, the time the particles have to rearrange, and the final pressure to which they are subjected.

Tinting strength, adopted by ASTM as D3265, is another industry method used for the classification of carbon blacks. In this test a small amount of carbon black is mixed with zinc oxide and an oil vehicle to produce a black or gray paste. The reflectance of this paste is measured and compared to the reflectance of a paste made with a reference black. The ratio of the reference black paste reflectance to the sample black multiplied by 100 is the tint strength. It provides a rough estimate of the reinforcing potential of carbon black in rubber. Tint strength is closely related to carbon black morphology. The carbon blacks with smaller particle size, ie, larger surface area and smaller size of the aggregates (ie, lower structure), show a greater ability to cover the typically larger size zinc oxide particles, giving higher tinting strength. The tinting strength is also related to the aggregate size distribution. The narrower the aggregate size distribution, the higher is the tinting strength.

Surface Activity. Surface activity is also an important factor in performance. This factor can, in a chemical sense, be related to different chemical groups on the carbon black surface. In a physical sense, variations in surface energy determine the adsorptive capacity of the carbon blacks and their energy of adsorption. However, compared with the morphologies, a satisfactory description of surface properties of carbon black is still lacking because only a limited number of tools have been available to assess the carbon black surface in terms of ensemble properties.

With regard to rubber reinforcement, the surface activity of carbon black has traditionally been measured by bound rubber. *Bound rubber*, sometimes termed "*carbon gel*," is defined as the rubber portion in an uncured compound which cannot be extracted by a good solvent of the polymer owing to the adsorption of the rubber molecules onto the filler surface. This phenomenon has been studied extensively and is recognized as a typical feature of carbon black surface activity. For given polymer systems and for the carbon black with comparable surface area, the higher the bound rubber content, the higher is the polymer–filler interaction, and hence the higher is the surface activity of carbon black. Generally speaking, bound rubber is a parameter that is simple to measure, but the factors that influence

the test results are highly complicated. It has been recognized that carbon black – polymer interaction leading to the formation of bound rubber involves physical adsorption, chemisorption, and mechanical interaction.

It is generally found that the surface energy of carbon blacks have a much greater effect on the mechanical properties of filled elastomers than the chemical composition, particularly when general-purpose hydrocarbon rubbers are concerned. The surface energy γ is defined as the work necessary to create a unit new surface of liquid or solid. This energy is caused by different types of cohesive forces, such as dispersive, dipole–dipole, induced dipole–dipole, and hydrogen bond forces. In the case of all these cohesive forces being involved in independent ways, the surface energy can be expressed as the sum of several components, each corresponding to a type of molecular interaction (dispersive, polar, hydrogen bond, etc). Since the effect of the dispersive force is universal, the dispersive component of the surface free energy γ^{d} is particularly important. If a solid substance can have only dispersion interaction with its environment, its surface energy γ_s is identical with its dispersive component $\gamma_s{}^{d}$. For most substances, the surface energy of a solid is the sum of $\gamma_s{}^{d}$ and $\gamma_s{}^{sp}$ that is the sum of the other components of surface energy and is termed "specific component" or "polar" component. The higher the $\gamma_s{}^{d}$ of the carbon black, the stronger is the interaction between carbon black and non- or less-polar polymers such as hydrocarbon rubbers. The higher polar component of the surface energy leads to higher interaction with polar polymer or polar groups in the polymer chains.

Several methods to measure the solid surface energy can be used for carbon black. However, inverse gas chromatography (IGC) has recently been shown to be one of the most sensitive and convenient methods for measuring carbon black surface energy (18). In IGC, the filler to be characterized is used as the stationary phase and the solute injected is called a probe. When the probe is operated at infinite dilution, the adsorption energy of the probe on the carbon black surface and hence the surface energy of the black can be calculated from the net retention volume (18). If, however, the surface is energetically heterogeneous, the values of parameters obtained from IGC measurement are mean values over the whole surface of the fillers, but they are "energy-weighted," ie, the high energy sites play a very important role in the determination of adsorption parameters measured (19). When the probe is operated at finite concentration, the adsorption isotherms of the probes on carbon black surface can be generated from the pressure dependence of the retention volume and, hence, the distribution of free energy of adsorption of the probe chemicals can be derived from the isotherm (19).

Other Methods for Carbon Black Characterization. There are many other test methods used to characterize carbon blacks for quality control and specification purposes. Table 3 lists some of these methods which, with a few exceptions, have been adopted by ASTM.

Classification of Carbon Black

Carbon blacks have been classified by their production process, by their production feedstocks such as acetylene blacks, by their application field, such as rubber blacks, color blacks, electric conductive blacks, and by properties of end-use

Table 3. Special Analytical Test Methods for Carbon Black

Test method	Standard	Comment
Iodine adsorption, mg/g	ASTM D1510	Amount of iodine adsorbed from aqueous solution as a measure for the specific surface area; not applicable for oxidized or highly porous carbon blacks
N_2 surface area and external surface area, m^2/g	ASTM D6556	Determination of the total surface area (NSA) by BET theory of multilayer gas adsorption behavior using multipoint determinations and the external surface area based on the statistical thickness surface area (STSA) method
CTAB surface area, m^2/g	ASTM D3765	Amount of cetytrimethylammonium bromide adsorbed from aqueous solution as measure of specific nonporous (outer) surface area
Aggregate dimension and aggregate size distribution	ASTM D3849	Determination of aggregate dimensions (unit length, width, etc) by electron microscope image analysis.
Aggregate size distribution		Diameters of equivalent solid spheres that sediment at same rate as aggregates during centrifuging
DBP absorption, mL/100 g	ASTM D2414	Determination of the void volume with dibutyl phthalate in a special kneader as measure of structure
24 M4-DBP absorption, mL/100 g	ASTM D3493	Determination of DBP absorption after four repeated compressions at 165 MPa (24,000 psi)
Compressed volume index	ASTM D6086	Determination of compressed volume of carbon black under a specified compression force.
Jetness		Light absorption of a carbon black paste in linseed oil; determination by visual comparison against standard blacks or by measuring the absolute light emission
Tint strength, %	ASTM D3265	Ability of a carbon black to darken a white pigment in an oil paste. The tinting strength is the reflectance of the tested carbon black paste with respect to the reflectance of the reference carbon black paste.
Volatiles, %		Weight loss when calcined at 950°C for 7 min
Heating loss (moisture), %	ASTM D1509	Weight loss on drying at 125°C for 1 h
pH	ASTM D1512	pH of an aqueous slurry of carbon black; pH is mainly influenced by surface oxides
Extractables, %	ASTM D1618	Amount of material which can be extracted by a boiling solvent, usually toluene
Extractables, %	ASTM D4527	Determination of the total material extracted from carbon black by toluene under specified conditions. The procedure is also applicable to other solvents

Table 3. (continued)

Test method	Standard	Comment
Ash content, %	ASTM D1506	Amount of noncombustible material after burning the carbon black at 675°C
Sulfur content, %	ASTM D1619	
Sieve residue, %	ASTM D1514	Amount of coarse impurities that cannot be purged through a testing sieve by water
Pour density, g/L	ASTM D1513	Measure for the densification of carbon black
Tamped density, g/L		Similar to bulk density; however, void volume is reduced by temping
Pellet crush strength	ASTM D5230	Automated individual pellet crush strength
Pellet crush strength	ASTM D3313	Individual pellet crush strength
Pellet mass strength	ASTM D1937	Pellet mass strength
Pellet size distribution	ASTM D1511	Determination by means of sieve shaker
Fines content, %	ASTM D1508	Only for pelletized blacks; percentage passing through a sieve of 125 μm (mesh) width

products such as high abrasion furnace black and fast extrusion furnace black. From their applications, the carbon black is classified into two groups: one used for rubber products, and another for non-rubber applications. They are referred to as special blacks. Generally, special carbon blacks cover a wider range of morphology and surface chemistry than rubber blacks.

The rubber industry is by far the major consumer of carbon black. For rubber grades, a classification system issued by ASTM is based essentially on particle size, structure, and their effect on the cure rate of filled rubber compounds which is related to the degree of surface oxidation (ASTM D1765). It is composed of a letter followed by three numbers. The N series are for the normal-curing furnace and thermal blacks and S for slow-curing blacks with higher degree of oxidation, such as channel black and oxidized furnace blacks that are acidic in nature. The first number of the three-digit suffix identifies particle size and is inversely related to the surface area. The range of particle sizes from 0 to 500 nm has been grouped into 10 categories, covering surface areas from 0 to 150 m^2/g. The remaining two digits are assigned arbitrarily by the carbon black manufacturers. A selected list of typical properties, taken from ASTM D1765 of rubber-grade carbon blacks, is shown in Table 4. In addition to the assigned ASTM N-numbers, the list includes the old letter designations, pour densities, structure, surface areas, and tint data. The structure–area relationships of these grades, called the carbon black spectrum, is illustrated in Figure 7, which shows a diagram of DBP numbers for compressed samples versus the nitrogen surface areas.

Carbon Black Formation

The formation of particulate carbon involves either pyrolysis or incomplete combustion of hydrocarbon materials. Enormous literature has been published

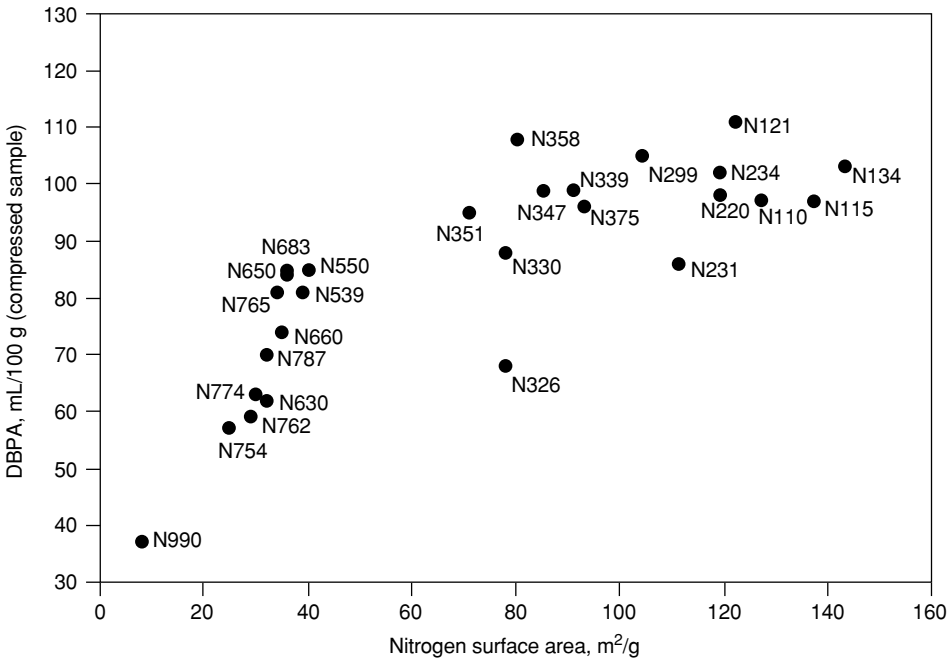

Fig. 7. Rubber-grade carbon black spectrum.

to describe the mechanism of carbon black formation, from a series of lectures by Michael Faraday at the Royal Institution in London in the 1860s (20) to a recent intensive review (21). Since Faraday's time, many theories have been proposed to account for carbon formation, but controversy still exists regarding the mechanism.

Mechanisms of carbon black formation must account for the experimental observations of the unique morphology and microstructure of carbon black. These include the presence of nodules, or particles, multiple growth centers within some nodules, the fusion of nodules into large aggregates, and the paracrystalline or concentric layer plane structure of the aggregates. It is generally accepted that the mechanism of formation involves a series of stages as follows:

(1) Formation of gaseous carbon black precursors at high temperature. This involves dehydrogenation of primary hydrocarbon molecular species to atomic carbon or primary free radical and ions which condense to semisolid carbon precursors (or polynuclear aromatic sheet) and/or formation of large hydrocarbon molecules by polymerization, which then is dehydrogenated to particle precursors.

(2) Nucleation. Because of increasing mass of the carbon particle precursors through collision, the larger fragments are no longer stable and condense out of the vapor phase to form nuclei or growth centers.

(3) Particle growth and aggregation. In the system, three processes go on simultaneously: condensation of more carbon precursors on the existing nuclei,

coalescence of small particles into larger ones, and formation of new nuclei. Coalescence and growth seem to predominate. The products of this stage are "proto-nodules."

(4) Surface growth. Surface growth includes the processes in which the small species attach to or deposit on the surfaces of existing particles or aggregates, forming the nodules and aggregates with their characteristic onion microstructure. The surface growth represents about 90% of total carbon yield. It is responsible for the stability of the aggregates because of the continuous carbon network formation. Aggregates are formed and cemented in this stage.

(5) Agglomeration. Once no more carbon is forming and aggregation ceases, aggregates collide and adhere from van der Waals forces but there is no material to cement them together, hence they form temporary structures.

(6) Aggregate gassification. After its formation and growth, the carbon black surface undergoes reaction with the gas phase, resulting in an etched surface. Species such as CO_2, H_2O, and of course any residual oxygen attack the carbon surface. The oxidation is determined by gas-phase conditions, such as temperature, oxidant concentration, and flow rates.

Practically, the carbon black morphology and surface chemistry can be well controlled by changing the reaction parameters. For furnace carbon blacks, the reaction temperature is the key variable that governs the surface area. The higher the temperature, the higher is the pyrolysis rate and the more nuclei are formed, resulting in an earlier stop of the growth of the particles and aggregates because of the limitation of starting materials at given feedstock. Therefore, with higher reaction temperature, that can be achieved by adjusting air rate, fuel rate, and feedstock rate, the surface area of carbon black can be increased. Addition of alkali metal salts into the reactor can modify the aggregation process, influencing carbon black structure. At the reactor temperature, the salts of alkali metals, such as potassium, are ionized. The positive ions adsorb on the forming carbon black nodules and provide some electrostatic barrier to internodule collisions, resulting in lower structure (22).

The time scale of carbon black formation varies substantially across the range of particle sizes found in commercial furnace blacks. For blacks with surface areas around 120 m^2/g, the carbon black formation process from oil atomization to quench takes less than 10 ms. For blacks with surface areas around 30 m^2/g, formation times are a few tenths of seconds.

Manufacture

Oil-Furnace Process. The oil-furnace process accounts for over 95% of all carbon black produced in the world. It was developed in 1943 and rapidly displaced prior gas-based technologies because of its higher yields and the broader range of blacks that could be produced. It also provides highly effective capture of particulates and has greatly improved the environment around carbon black plants. As indicated in the mechanism discussion, it is based on the partial combustion of

residual aromatic oils. Because residual oils are ubiquitous and are easily transported, the process can be practiced with little geographic limitation. This has allowed construction of carbon black plants all over the world. Plants are typically located in areas of tire and rubber goods manufacture. Because carbon black is of relatively low density, it is far less expensive to transport feedstock than to transport the black.

Over the 50 years since its invention, the oil-furnace process has undergone several cycles of improvement. These improvements have resulted in improved yields, larger process trains, better energy economy, and improved product performance. A simplified flow diagram of a modern furnace black production line is shown in Figure 8 (23). This is intended to be a generic diagram and contains elements from several operators' processes. The principal pieces of equipment are the air blower, process air and oil preheaters, reactors, quench tower, bag filter, pelletizer, and rotary dryer. The basic process consists of atomizing the preheated oil in a combustion gas stream formed by burning fuel in preheated air. The atomization is carried out in a region of intense turbulent mixing. Some of the atomized feedstock is combusted with excess oxidant in the combustion gas. Temperatures in the region of carbon black formation range from 1400 to over 1800°C. The details of reactor construction vary from manufacturer to manufacturer and are confidential to each manufacturer. Leaving the formation zone, the carbon black containing gases are quenched by spraying water into the stream. The partially cooled smoke is then passed through a heat exchanger where incoming air is preheated. Additional quench water is used to cool the smoke to a temperature consistent with the life of the bag material used in the bag filter. The bag filter separates the unagglomerated carbon black from the by-product tail gas which contains nitrogen, hydrogen, carbon monoxide, carbon dioxide, and water vapor. It is mainly nitrogen and water vapor. The tail gas is frequently used to fuel the dryers in the plant, to provide other process heat, and sometimes is burned to manufacture steam and electric power either for internal plant use or for sale.

The fluffy black from the bag filter is mixed with water, typically in a pin mixer, to form wet granules. These are dried in a rotary dryer, and the dried product is conveyed to bulk storage tanks. For special purposes, dry pelletization in rotary drums is also practiced. Most carbon black is shipped by rail or in bulk trucks. Various semibulk containers are also used including IBC's and large semibulk bags. Some special-purpose blacks are packed in paper or plastic bags.

While the reactor and its associated air-moving and heat-exchange equipment are where the properties of the black are determined, they tend to be dwarfed by the bag collectors, the dryers, and particularly the storage tanks.

Feedstocks. Feedstocks for the oil-furnace process are heavy fuel oils. Preferred oils have high aromaticity, are free of suspended solids, and have a minimum of asphaltenes. Suitable oils are catalytic cracker residue (once residual catalyst has been removed), ethylene cracker residues, and distilled heavy coal tar fractions. Other specifications of importance are freedom from solid materials, moderate to low sulfur, and low alkali metals. The ability to handle such oils in tanks, pumps, transfer lines, and spray nozzles is also a primary requirement.

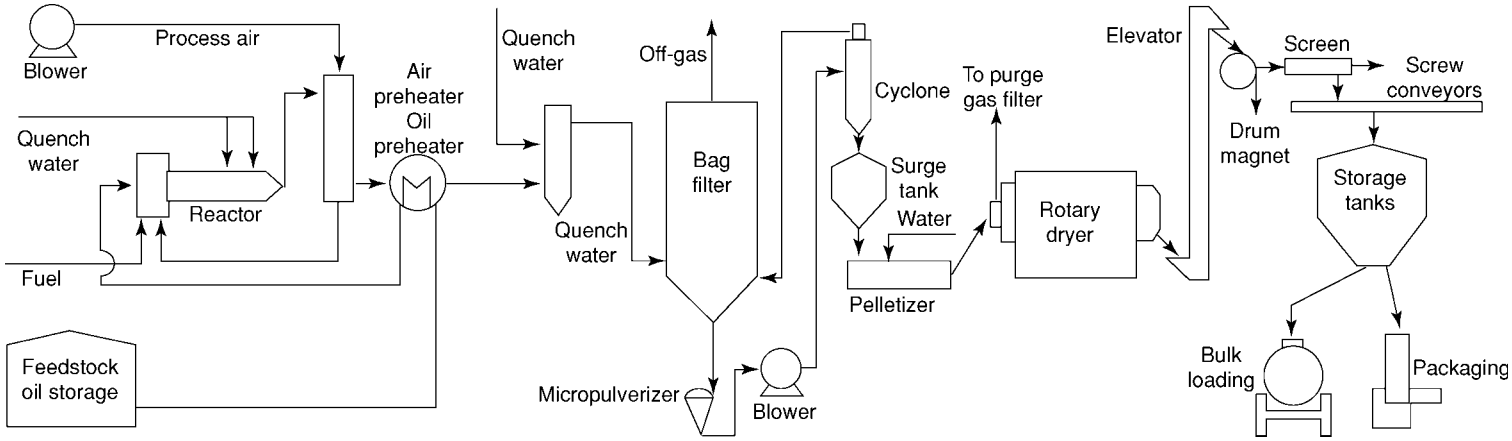

Fig. 8. Flow diagram of oil-furnace black process.

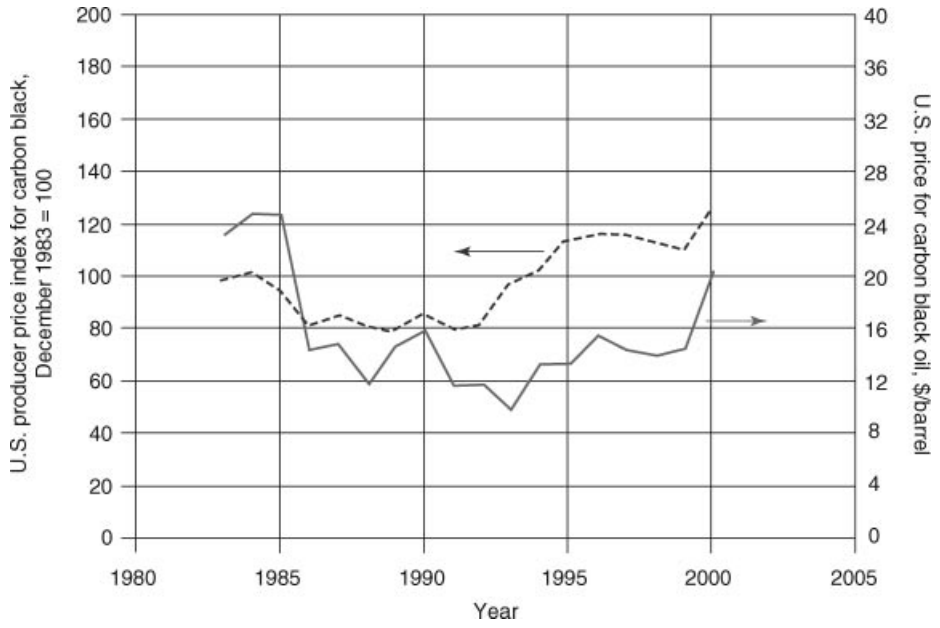

Fig. 9. Carbon black price and raw material cost in the United States (1983–2000) (1).

The pricing of carbon black feedstocks depends on their alternate market as residual fuel oil, especially that of high sulfur No. 6 fuel oil. The actual price is determined by the supply/demand relationships for these two markets. Feedstock cost contributes about 60% of the total manufacturing cost. The market price of carbon black is strongly dependent on the feedstock cost, as shown in Figure 9.

Reactor. The heart of a furnace black plant is the furnace or reactor where carbon black formation takes place under high temperature, partial combustion conditions. The reactors are designed and constructed to be as trouble-free as possible over long periods of operation under extremely aggressive conditions. They are monitored constantly for signs of deterioration in order to ensure constant product quality. The wide variety of furnace black grades for rubber and pigment applications requires different reactor designs and sizes to cover the complete range, though closely related grades can be made in the same reactor by adjusting input variables. Reactors for higher surface area and reinforcing grades operate under high gas velocities, temperatures, and turbulence to ensure rapid mixing of reactant gases and feedstock. Lower surface area and less reinforcing grades are produced in larger reactors at lower temperatures, lower velocities, and longer residence time. Table 5 lists carbon formation temperatures and residence times for the various grades of rubber blacks.

A key development in the carbon black reactor technology was the development of the zoned axial flow reactor for reinforcing blacks in the early 1960s (22). The reactor consists of three zones. The first zone is a combustion zone in which fuel and air are completely burned to produce combustion gases with excess oxygen. This gas flow is accelerated to high velocity in a throat zone with intense turbulent mixing. The feedstock is injected either into this throat zone or just

Table 5. Reactor Conditions for Various Grades of Carbon Blacks

Carbon black	Surface area, m^2/g	Temperature, °C	Residence time, s	Maximum velocity, m/s
N100 series	145	1800	0.008	
N200 series	120		0.010	180–400
N300 series	80	1550	0.031	
N500 series	42		1	30–80
N700 series	25	1400	1.5	0.5–1.5
N990 thermal	8	1200–1350	10	10

ahead thereof. The reacting gases issue from the throat into a second cylindrical zone as a turbulent diffusion jet. Depending on the desired black, the jet may be allowed to expand freely, or may be confined by bricking. Downstream of the reaction zone is a water quench zone. The throughput of a single reactor train varies from manufacturer to manufacturer and with grade of black. The largest reactors in operation have capacities of over 30,000 t/year. Many producers operate smaller reactors in parallel. Reactors are typically designed to make a series of related blacks. Air and gas may be introduced to the primary combustion zone either axially, tangentially, or radially. The feedstock can be introduced into the primary fire either axially or radially in the high velocity section of the mixing zone. The high velocity section may be venturi-shaped or consist of a narrow diameter choke. Plants may have from one to several operating trains.

Carbon black reactors are made of carbon steel shells lined with several courses of refractory. The most severe services are in the combustor and in the throat zone. Different manufacturers take different approaches to these elements, some using exotic materials or selected water-cooled metal surfaces, others using conventional materials and limiting temperatures to what their materials can stand. Most manufacturers achieve refractory life of one to several years. For the rubber-grade carbon blacks, at least three different reactor designs must be used to make this range of furnace blacks. Figures 10 and 11 show the designs of commercial reactors based on the patent literature.

The quality and yield of carbon black depend on the quality and carbon content of the feedstock, the reactor design, and the input variables. Surface area in particular is controlled by adjusting the temperature in the reaction zone. Structure is adjusted by introducing potassium into the combustion gas. This may be done in any of a variety of ways.

The energy utilization in the production of 1 kg of oil-furnace carbon black is in the range of $(9–16) \times 10^7$ J, and the yields are 300–660 kg/m^3 depending on the grade. The energy inputs to the reactor are the heat of combustion of the preheated feedstock, heat of combustion of natural gas, and the thermal energy of the preheated air. The energy output consists of the heat of combustion of the carbon black product, the heat of combustion and the sensible heat of the tail gas, the heat loss from the water quench, heat loss by radiation to atmosphere, and the heat transferred to preheat the primary combustion air.

The Thermal Black Process. Thermal black is a large particle size, low structure carbon black made by the thermal decomposition of natural gas, coke

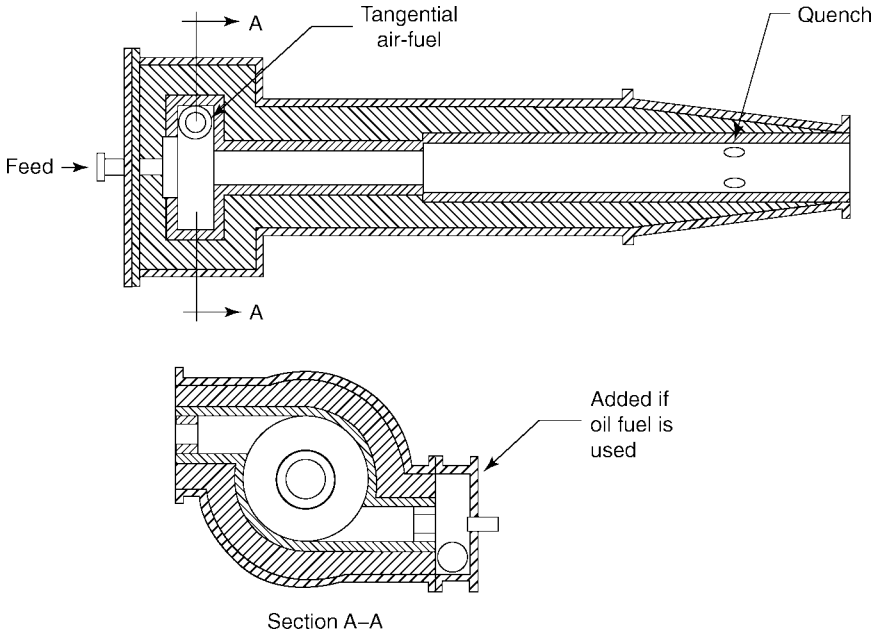

Fig. 10. Reactor for N300–N200 carbon blacks (24).

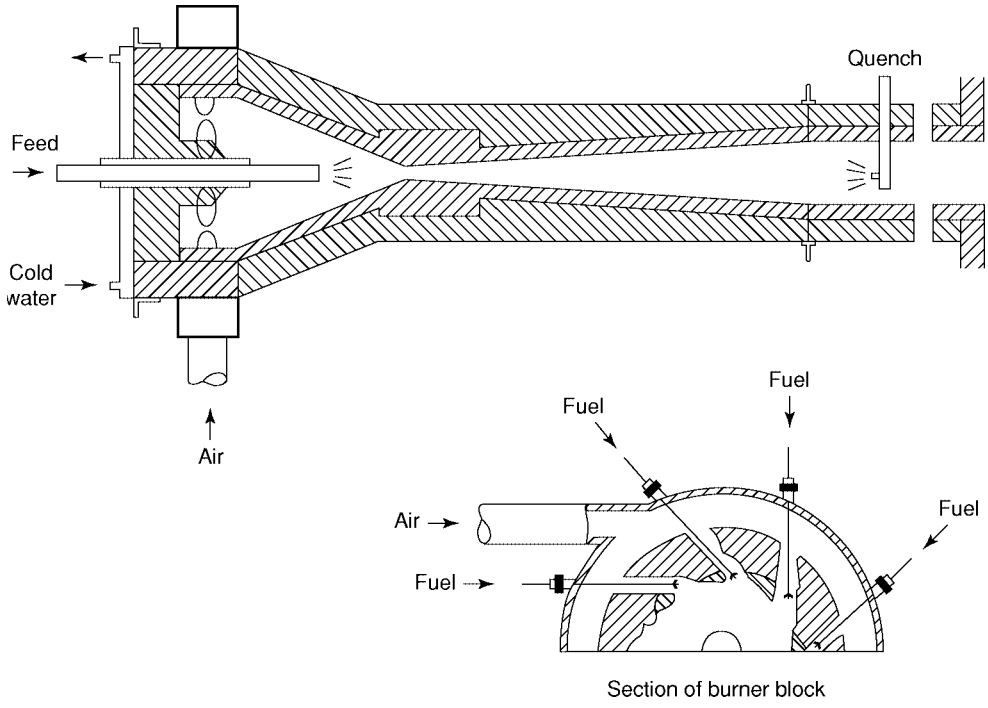

Fig. 11. Reactor for tread blacks (25).

oven gas, or liquid hydrocarbons in the absence of air or flames. Its economic production requires inexpensive natural gas. Today it is among the most expensive of the blacks regularly used in rubber goods. It is used in rubber and plastics applications for its unique properties of low hardness, high extensibility, low compression set, low hysteresis, and excellent processability. Its main uses are in O-rings and seals, hose, tire innerliners, V-belts, other mechanical goods, and in cross-linked polyethylene for electrical cables.

The thermal black process dates from 1922. The process is cyclic using two refractory-lined cylindrical furnaces or generators about 4 m in diameter and 10 m high. During operation, one generator is being heated with a near stoichiometric ratio of air and off-gas from the make generation, whereas the other generator, heated to an average temperature of 1300°C, is fed with natural gas. The cycle between black production and heating is 5 min alternating between generators, resulting in a reasonably continuous flow of product and off-gases to downstream equipment. The effluent gas from the make cycle, which is about 90% hydrogen, carries the black to a quench tower where water sprays lower the temperature before it enters the bag filter. The effluent gas is cooled and dehumidified in a water scrubber for use as fuel in the heating cycle. The collected black from the filters is conveyed to a magnetic separator, screened, and hammermilled. It is then bagged or pelletized. The pelletized form is bagged or sent to bulk loading facilities.

There are thermal black plants in Canada, the United States, the United Kingdom (1), and Russia. Two common grades are manufactured. These are Medium Thermal Black N990 and Fine Thermal Black N880.

Acetylene Black Process. The high carbon content of acetylene (92%) and its property of decomposing exothermically to carbon and hydrogen make it an attractive raw material for conversion to carbon black. Acetylene black is made by a continuous decomposition process at an atmospheric pressure of 800–1000°C in water-cooled metal retorts lined with refractory. The process consists of feeding acetylene into the hot reactors. The exothermic reaction is self-sustaining and requires water cooling to maintain a constant reaction temperature. The carbon-black-laden hydrogen stream is then cooled followed by separation of the carbon from the hydrogen tail gas. The tail gas is either flared or used as fuel. After separation from the gas stream, acetylene black is very fluffy with a bulk density of only 19 kg/m^3. It is difficult to compact and resists pelletization. Commercial grades are compressed to various bulk densities up to 200 kg/m^3.

Acetylene black is very pure with a carbon content of 99.7%. It has a surface area of about 65 m^2/g, an average particle diameter of 40 nm, and a very high but rather weak structure with a DBP number of 250 mL/100 g. It is the most crystalline or graphitic of the commercial blacks. These unique features result in high electrical and thermal conductivity, low moisture adsorption, and high liquid absorption.

A significant use of acetylene black is in dry cell batteries where it contributes low electrical resistance and high capacity. In rubber it gives electrically conductive properties to heater pads, tapes, antistatic belt drives, conveyor belts, and shoe soles. It is also useful in electrically conductive plastics such as electrical magnetic interference (EMI) shielding enclosures. Its contribution to thermal conductivity has been useful in rubber curing bags for tire manufacture.

Lampblack Process. The lampblack process has the distinction of being the oldest and most primitive carbon black process still being practiced. The ancient Egyptians and Chinese employed techniques similar to modern methods, collecting the lampblack by deposition on cool surfaces. Basically, the process consists of burning various liquid or molten raw materials in large, open, shallow pans 0.5–2 m in diameter and 16 cm deep under brick-lined flue enclosures with a restricted air supply. The smoke from the burning pans passes through low velocity settling chambers from which the carbon black is cleared by motor-driven ploughs. In more modern installations the black is separated by cyclones and filters. By varying the size of the burner pans and the amount of combustion air, the particle size and surface area can be controlled within narrow limits. Lampblacks have similar properties to the low surface area oil-furnace blacks. A typical lampblack has an average particle diameter of 65 nm, a surface area of 22 m^2/g, and a DBP number of 130 mL/100 g. Production is small, mostly in Western and Eastern Europe. Its main use is in paints, as a tinting pigment where blue tone is desired. In the rubber industry lampblack finds some special applications.

Impingement (Channel, Roller) Black Process. From World War I to World War II the channel black process made most of the carbon black used worldwide for rubber and pigment applications. The last channel black plant in the United States was closed in 1976. Operations still exist and are even being expanded in Europe. The demise of channel black was caused by environmental problems, cost, smoke pollution, and the rapid development of oil-furnace process grades that were equal or superior to channel black products particularly for use in synthetic rubber tires.

The name channel black came from the steel channel irons used to collect carbon black deposited by small natural gas flames impinging on their surface iron channels. Today tar fractions are used as raw material in addition to natural gas. In modern installations channels have been replaced by water-cooled rollers. The black is scraped off the rollers, and the off-gases from the steel-box-enclosed rollers are passed through bag filters where additional black is collected. The purified exhaust gases are vented to the atmosphere. The oils used in this process must be vaporized and conveyed to the large number of small burners by means of a combustible carrier gas. Yield of rubber-grade black is 60% and 10–30% for high quality color grades.

The characteristics of roller process impingement blacks are basically similar to those of channel blacks. They have an acidic pH, a volatile content of about 5%, surface area of about 100 m^2/g, and an average particle diameter of 10–30 nm. The smaller particle-size grades are used as color (pigment) blacks, and the 30-nm grade is used in rubber.

Recycle Blacks. The pyrolysis of carbon black containing rubber goods has been promoted as a solution to the accumulation of waste tires. In the processes in question, tires are pyrolyzed in the absence of oxygen, usually in indirect fired rotary kiln-type units. The rubber and extender oils are cracked to hydrocarbons which are collected and sold as fuels or petrochemical feedstocks. The gaseous pyrolysis products are burned as fuel for the process. Steel tire cord is removed magnetically and the remainder of the residue is milled into a “pyrolysis black.” This contains the carbon black, silica, and other metal oxides from the rubber and some newly created char. Typically these materials have 8–10% ash, and contain

a lot of coarse residue. Most are difficult to pelletize. They have, on average, the reinforcing properties of a N300 black but because they are a mixture of N600 and 700 blacks with N100 and N200 blacks, they are not particularly suitable for either reinforcing or semireinforcing applications. To date they find application in relatively nondemanding uses such as playground and floor mats.

Surface Modification of Carbon Blacks

For most of its long history, the carbon black industry had concentrated on the morphology as the key factor controlling product performance and grade differentiation. Recently the importance of the composition of the interface between the carbon blacks and the medium in the composite in which the carbon black is used has been recognized.

The early stages of surface modification can be traced back to 1940s and 1950s. The approaches include physical adsorption of some chemicals on carbon black surface, heat treatment, and frequently oxidation. During 1980s and 1990s, some work on plasma treatment was reported. For chemical and polymer grafting modifications, a great deal of academic work was done in 1950s and 1960s in France, United States, and Japan, using surface oxygen groups as functional groups. However, because of rapid development applications of carbon black in different areas and the challenge from other reinforcing particles in its traditional applications, the surface modification technology for carbon black has been developing very rapidly over the last decade. These include surfactant-treated surfaces, chemically modified surfaces, and deposition of other phases during or after black formation. Today there is active commercial development and new product introduction in all areas.

Attachments of the Aromatic Ring Nucleus to Carbon Black. Two approaches characterize this area. A number of patents have been issued to Cabot Corp. (26,27), which describe that the decomposition of a diazonium compound derived from a substituted aromatic or aliphatic amine results in the attachment of a substituted aromatic ring or chain onto the surface of the carbon black. This results in a stable attachment which is not sensitive to moisture. Examples show attachment of amines, anionic and cationic moieties, polysulfide moieties that can be attached into an elastomer network, and alkyl, polyethoxyl, and vinyl groups. Practically, the surface chemistry and physical chemistry can be tailored according to the applications of carbon blacks. Some applications are claimed in aqueous media for dispersion (28), in oil-based coatings and inks for dispersion (29), and in rubbers for reduction of hysteresis and wear-resistance improvement (30). The initially attached groups can also function as sites for further chemical substitution. Another approach has been developed by Xerox Corp. in which oligomers of the polymer of one's choice are prepared using stable free-radical polymerization and these are attached to the carbon black surface by reaction of the stable radical (31).

Attachments to the Aromatic Ring Structure Through Oxidized Groups. The acidic surface groups that result from surface oxidation of carbon black are natural synthons for the attachment of functionality. Generally, chemistry is done through either phenolic or carboxylic acid groups on the surface. Some

of these groups are present in most blacks, but their density can be increased by treating with various oxidants such as ozone, nitric acid, or hypochlorite (32–34). Compared to the previous class, these C—O attachments are somewhat more labile, being particularly susceptible to hydrolysis. The concept of using phenolic groups as points of attachment for conventional silane treating agents has been described in several patents with the particular aim of attaching polysulfide moieties that can be vulcanized into elastomer networks for hysteresis reduction (35). Recently, patents have been issued on using the acidic sites on carbon black surfaces as points of reaction of amines. In the particular case in point, the attachment was used to improve compound stability and dispersion in conductive plastics applications (36).

Metal Oxide Treatments. The carbon black industry has worked on ways to respond to the challenge of silica in tire treads for low rolling resistance (replacing all or some of the carbon black). Cabot has filed on and widely published a class of dual-phase fillers in which silica or other metal oxides and carbon are coformed in a carbon-black-like reactor (37). In the particular product they describe, the carbon black and silica are intimately intermixed on a scale that is about the same size as the carbon black crystallite. In more recent variants, materials where the silica location is more on the exterior of the particle are described (38). In these materials, the silica is the minor constituent. The main characteristics of these carbon blacks are their lower filler-filler interactions. Filler-polymer interactions are also increased, but by incorporating coupling agents these interactions can be adjusted as required. These materials are used as fillers for low rolling resistance, higher wet skid resistance, and improved wear resistance in tire treads when used with conventional sulfide–silane coupling agents (39,40), or as fillers for silicone rubber when used with alkyl silane and vinyl silane agents (41). The patent literature suggests that other applications have been considered as well (42). Patents have also been issued on coated carbon black by depositing silica on the black surface in an aqueous solution of sodium silicate by adjusting pH with acid (43,44).

Applications

U.S. consumption of carbon black in 2000 by various market sectors is shown in Table 6. About 89% of total consumption is in the rubber industry and 70% for tires. About 10% is consumed for other automotive products and 9% for rubber products

Table 6. U.S. End-Use Consumption of Carbon Black in 2000[a]

	Millions of metric tons	Percent of total
Automotive rubber uses tire and tire products	1.17	70
Belts, hoses, and other automotive products	0.17	10
Industrial rubber products	0.16	9
Nonrubber uses	0.18	11
Total	*1.67*	*100*

[a] From Ref. 1.

unrelated to the automotive industry. The automotive industry accounts for 80% of consumption. Eleven percent of the blacks is for nonrubber uses and its main applications are related to pigmentation, ultraviolet absorption, and electrical conductivity of other products such as plastics, coating, and inks. These carbon blacks are also termed special blacks (1).

Rubber-Grade Carbon Blacks. Carbon black is a major component in the manufacture of rubber products, with a consumption second only to rubber itself. It is by far the most active rubber-reinforcing agent owing to its unique ability to enhance the physical properties of rubbers. Table 7 lists the principal rubber grades by their N-number classification, general rubber properties, and typical uses.

The consumption of the various carbon black grades can be divided into tread grades for tire reinforcement and nontread grades for nontread tire use and other rubber applications. Table 8 shows the distribution of production of types for these uses. A typical passenger tire has several compounds and uses five to seven different carbon black grades.

The behavior of different grades in rubber is dominated mainly by surface area, structure (DBPA), and surface activity. All these parameters play a role in rubber reinforcement through different mechanisms, such as interfacial interaction between rubber and carbon black, occlusion of the polymer in the internal voids of the aggregate, and the agglomeration of carbon black aggregates in the polymer matrix.

Table 7. Application of Principal Rubber-Grade Carbon Blacks

Designation	General rubber properties	Typical uses
N110, N121	Very high abrasion resistance	Special tire treads, airplane, off-the-road racing
N220, N299, N234	Very high abrasion resistance, good processing	Passenger, off-the-road, special service tire treads
N339, N347, N375, N330	High abrasion resistance, easy processing, good abrasion resistance	Standard tire treads, rail pads, solid wheels, mats, tire belt sidewall, carcass retread compounds
N326	Low modulus, good tear strength, good fatigue, good flex cracking resistance	Tire belt, carcass, sidewall compounds, bushings, weather strips, hoses
N550	High modulus, high hardness, low die swell, smooth extrusion	Tier inner liners, carcass, sidewall, inner tubes, hose, extruded goods, V-belts
N650	High modulus, high hardness, low die swell, smooth extrusion	Tire innerliners, carcass, belt, sidewall compounds, seals, friction compounds, sheeting
N660	Medium modulus, good flex fatigue resistance, low heat buildup	Carcass, sidewall, bead compounds, innerliners, seals, cable jackets, hose, soling, EPDM compounds
N762	High elongation and resilience, low compression set	Mechanical goods, footwear, innertubes, innerliners, mats

Table 8. Carbon Black Production (10^3 t) by Grade in the United States for 2000[a]

N330 high abrasion	0.623
N550 fast extruding	0.138
N762 semireinforcing	0.129
N660 general-purpose	0.356
N110 super abrasion	0.061
N220 intermediate super abrasion	0.170
N990 thermal	0.014
Total	*1.493*

[a] From Ref. 1.

One of the consequences of the incorporation of carbon blacks into a polymer is the creation of an interface between a rigid solid phase and a soft elastomer phase. For rubber-grade carbon blacks, whose surfaces exhibit very little porosity, the total area of the interface depends on both filler loading and the specific surface area of the filler. Owing to the interaction between rubber and filler, two phenomena are well documented: the formation of bound rubber and a rubber shell on the carbon black surface. Both are related to the restriction of the segmental movement of polymer molecules.

The effect of filler structure on the rubber properties of filled rubber has been explained by the occlusion of rubber by filler aggregates (45). When structured carbon blacks are dispersed in rubber, the polymer portion filling the internal void of the carbon black aggregates, or the polymer portion located within the irregular contours of the aggregates, is unable to participate fully in the macrodeformation. The partial immobilization in the form of occluded rubber causes this portion of rubber to behave like the filler rather than like the polymer matrix. As a result of this phenomenon, the effective volume of the filler, with regard to the stress–strain behavior and viscoelastic properties of the filled rubber, is increased considerably.

The filler aggregates in the polymer matrix have a tendency to associate to agglomerates, especially at high loadings, leading to chain-like filler structures or clusters. These are generally termed secondary structure or, in some cases, filler network, even though the latter is not comparable to the continuous polymer network structure. The formation of filler network is dependent on the intensity of interaggregate attractive potential, the distance between aggregates and polymer–filler interaction (46).

From the point of view of carbon black morphology, high surface area produces high reinforcement as reflected in high tensile and tear strengths, high resistance to abrasive wear, higher hysteresis, and poorer dynamic performance, while high structure leads to higher viscosity, lower die swell, and high modules. Listed in Table 9 are the effects of surface area and structure which can be a guideline for choice of carbon blacks according to the processability and property requirements of rubber products.

A present day challenge to carbon black technologists is to optimize the balance between tire wear, tire hysteresis that determines the rolling resistance, and wet skid resistance. It is now recognized that besides the morphology, while the wear resistance is closely related to the polymer-filler interaction and dispersion

Table 9. Effect of Carbon Black Morphologies on the Properties of Filled Compounds

Surface area increase	Rubber properties	Structure increase
Higher	Abrasion resistance	Depend on severity
Higher	Hardness	Higher
Higher	Tensile strength	Lower
Not main factor	Modulus	Higher
Lower	Elongation	Lower
Lower	Rebound	Not main factor
Higher	Viscosity	Higher
Lower	Dispersibility	Higher
Not main factor	Dimensional stability	Higher

of the carbon blacks, the hysteresis is mainly deterimined by filler networking or agglomeration. For tread compounds of tire, depression of filler networking results in lower hysteresis at the temperatures from 50 to 80°C, leading to low rolling resistance, and in higher hysteresis at lower temperature which is in favor of wet skid resistance. Some progress on this problem has been made by using new furnace designs and other process variables that broaden the aggregate size distributions and lower the tint strength while maintaining surface area, and structure (47,48). A substantial improvement in global tire performance can be achieved through surface modification of carbon blacks, such as carbon-silica dual phase fillers (39,40,49).

Special-Grade Carbon Blacks

Besides reinforcement for rubber, the principal functions that carbon black imparts to a compound material are color, ultraviolet damage resistance, electrical conductivity, nondegradation of polymer physical properties, and ease of dispersion. The carbon blacks used for these purposes are classified as special-grade blacks. Smaller volume applications exploit other principal attributes, such as chemical inertness, thermal stability, and an open porous structure. The secondary attributes include chemical and physical purity, low affinity for water adsorption, and ease of transportation and handling.

In 2000, 11% of U.S. consumption of carbon black was special blacks. About 51% of special blacks are used in plastics, 32% in printing inks, 5% in paint, 3% in paper, and 9% in miscellaneous applications (1).

Dispersion. The ability to disperse the special grades is an important consideration in almost all applications. The customer's milling costs can be comparable to the purchase price of the carbon black. In other cases, the inability to achieve an excellent dispersion impairs the ability to realize the full performance of the blacks or it creates other undesirable characteristics. For example, a black plastic part will not appear as dark nor have a smooth surface if the black cannot be fully dispersed.

The term "dispersion" is used in several ways in actual applications. It may refer to the amount of work required to achieve a specified level of imperfections or it may refer to the level of imperfections per se. When a black is referred to as "easily dispersed" it can mean that relatively low shear mixers can achieve a compound that is relatively free of imperfections. Or it may mean that with a given mixing protocol the compound achieves an imperfection count below a specified level.

The "level of imperfections" is most often assessed in one of two ways. Most often it refers to the size distribution of surface imperfections on an extruded or injection-molded part. It may also refer to the rate of pressure buildup on an extrusion screen pack.

Undispersed material is one of three types. The first is non-carbon contaminants that come either in the feedstock or the result of corrosion of the manufacturing train. The second are carbon contaminants that occur when the feedstock droplets fail to evaporate. If the residual material in the droplet fails to evaporate, but is pyrolyzed in place, the contaminant is referred to as a coke ball. If the droplet reaches the wall before it is completely pyrolyzed, the resulting buildup is termed wall coke and it can flake off and contaminate the carbon black product. Finally the aggregates of carbon black can remain agglomerated or undispersed. Too often the concepts of contaminant-free and the difficulty of separating agglomerates into aggregates are not clearly distinguished. Detailed microscopy is required to determine the nature of defects and therefore resolve if the problem is contamination or true difficulty in dispersion.

In most cases the properties of special carbon black aggregates that engender performance are antagonistic to achieving a good dispersion. High pigmenting strength for both light and ultraviolet radiation implies high surface area. High surface area increases the difficulty of dispersion. Achieving an electrically conductive network at low concentration implies a black with high structure. High structure, per se, is an asset in dispersion. However, most carbon black formation technologies will not make high structure blacks unless the surface area is also high and the trade-off means that the best conducting grades are difficult to disperse.

Pigmentation. Carbon black is an excellent pigment. It is considerably more effective in absorbing light than any other material on either a weight or a cost basis. It is also environmentally stable.

Black pigments are used both alone and with other pigments. In the first the measure of performance is termed mass tone and is simply the ability to prevent the transmission or reflection of light. The second is called tint tone and it is the ability to soften or darken other colors.

How black is black? Two aspects can be important. The first is the total amount of white light that is either transmitted or reflected by a black material. The second is variation in these values with the frequency or color of the light. In almost all cases, relatively higher red light adsorption is valued as it gives the material a blue "undertone." Various measures are used to equate blue tone with overall absorption. These color metrics are based on subjective judgments and are most highly developed for automotive paints.

Surface area and structure, or aggregate size, play a role in determining color strength. Pigmenting carbon blacks are used at quite low concentrations. Single

particle Mie scattering theory is reasonably applicable. In applying the theory, an aggregate of carbon black is viewed as a composite of carbon and the resin or polymer. The refractive index of the carbon is taken as 1.84(1-0.46i) (50). And the index of refraction of the composite particle is the volume average of the carbon black and polymer values. The difficulty in using single- particle scattering theory is in evaluating the size and carbon content of the "scattering particle." Various methods are used to estimate aggregate size and to divide the CDBP value into "intra" and "inter" aggregate parts. The "intra-aggregate" part is considered to form part of the composite scattering particle.

Because aggregate and primary particle size cannot be controlled independently in carbon black reactors, and because the ability to achieve complete dispersion depends upon morphology, the coloring properties of carbon blacks are often treated empirically.

The theory works best when carbon black is used with other pigments, ie, in tinting applications. In these applications, both theory and experiments indicate that smaller primary particles and aggregates absorb more light and have a bluer tone.

Table 10 shows the entire range of properties of blacks sold for color applications. Blacks with large primary particle sizes are used in news inks and other nondemanding applications. The extremely fine blacks are used in high performance enamels and automotive paints.

An emerging application is as the colorant in jet printer inks. The requirement of extremely high quality dispersion meant that the original black inks were dyes. The image permanence of carbon blacks lead to the displacement of dyes when techniques were developed that assured the stability of excellent, water-based dispersion.

The blacks used for UV protection of polymers have very small primary particle sizes. The industry standard for UV protection is primary particle sizes of less than 20 nm.

Conductivity. Carbon black is added to polymer or resin compounds to achieve electrical conductivity. If their concentrations are high enough, carbon black aggregates will form interconnected paths through the compound material. These networks can have resistivities in the range of 1–10 $\Omega \cdot$ cm.

Concentrations that are too low will not form percolation networks. The Jansen equation (51) predicts that the critical concentration occurs when volume of polymer equals four times the volume of the CDBP value. The compounds are continuous when the amount of polymer is the CDBP value or greater and contain continuous carbon networks when the volume of polymer is between the CDBP value and four times that amount.

In general it is desirable to achieve percolation at low loading to reduce the negative effects of the presence of the carbon black on the physical properties of the compound. Therefore blacks with high CDBP values are used in conducting application. Figure 12 shows the percolation threshold of a number of carbon blacks with widely varying CDBP values.

One of the most demanding applications for conducting compounds is as a layer around the center conductor of a high voltage cable. The purpose of the compound is to smooth any surface imperfection that would otherwise result in high electric field gradients and the breakdown of the insulating layers. These

Table 10. Types and Applications of Special Pigment Grades of Carbon Blacks

Type	Surface area, m^2/g	DBP number, mL/100 g	Volatile, %	Uses
Normal grades				
High color	230–560	50–120	2	High jetness for alkyl and acrylic enamels, lacquers, and plastics
Medium color	220–220	70–120	1–1.5	Medium jetness and good dispersion for paints and plastics; ultraviolet and weathering protection for plastics
Regular color	80–140	60–114	1–1.5	For general pigment applications in inks, paints, plastics, and paper; gives ultraviolet protection in plastics, high tint, jetness, gloss, and dispersibility in inks and paints
	46	60	1.0	Good tinting strength, blue tone, low viscosity; used in gravure and carbon paper inks, paints, and plastics
	45–85	73–100	1.0	Main use is in inks; standard and offset news inks
Low color	25–42	64–120	1.0	Excellent tinting black–blue tone; used for inks-gravure, one-time carbon paper inks; also for paints, sealants, plastics, and cements
Thermal blacks	7–15	30–35	<0.5	Tinting-blue tone; plastics and utility paints
Lamp blacks	20–95	100–160	0.4–0.9	Paints for tinting-blue tone
Surface oxidized grades				
High color	400–600	105–121	8.0–9.5	Used for maximum jetness in lacquers, coatings, plastics, fibers, record disks
Medium color, long flow	138	55–60	5	Used in lithographic, letterpress, carbon paper, and typewriter ribbon inks; high jetness, excellent flow, low viscosity, high tinting strength, gloss, and good dispersability
Medium color, long flow	96	70	2.5	Used for gloss printing and carbon paper inks; excellent jetness, dispersibility; tinting strength, and gloss in paints
Low color	30–40	48–93	3.5	Used for tinting where flooding is a problem; easy dispersion

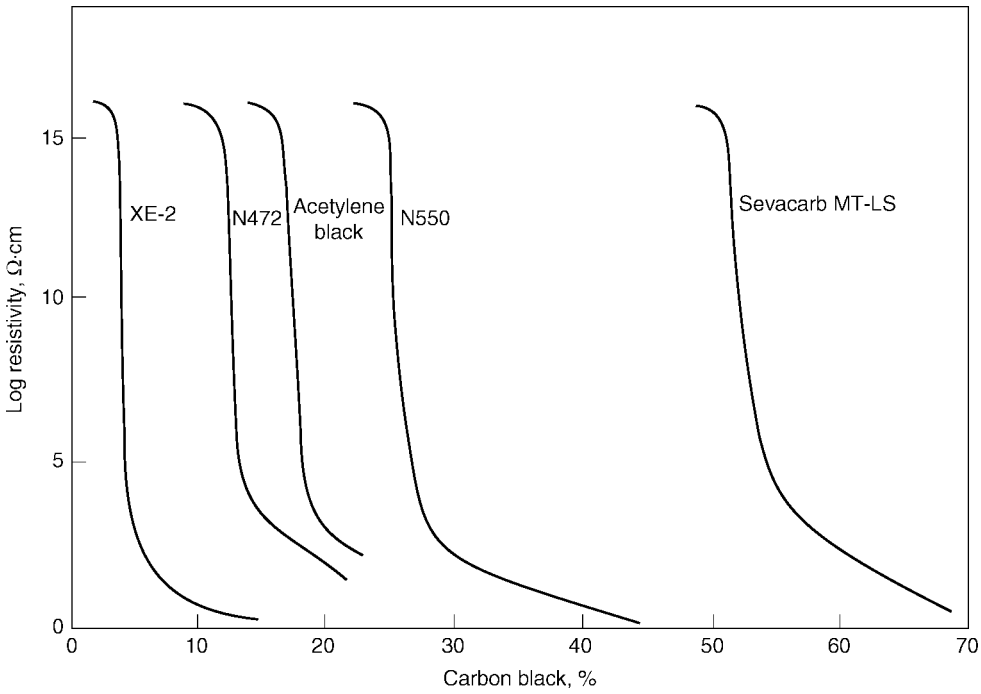

Fig. 12. Electrical resistivity–concentration curves for various carbon blacks (52).

compounds have the highest loading of carbon blacks to achieve the lowest possible resistance. Two very important secondary requirements are that the black is quite hydrophobic, free of inorganic salts, and has extremely low contaminant levels.

Other applications of carbon-black-filled polymers do not require as low a level of conductivity. The purpose is the dissipation of static electricity. These types of compounds are used in carrying containers for microelectronic components and in containers and pipes for combustible liquids such as gasoline. The newest application is adding enough conductivity to automobile panels to enable coatings of electrostatically charged paint particles.

Other Uses. Carbon blacks are used to make highly porous structures for catalyst supports. Most supports are metal oxides rather than carbon, but in certain circumstances a chemically inert support is required. The open structure of the carbon black aggregates allows control of the pore size distribution within the consolidated carbon body.

Fuel cell electrodes are a particularly interesting catalyst application. The active layers of the proton conducting membrane fuel cells must have the ability to transport both gases and hydrogen ions to the catalyst as well as conducting water away. Mixtures of carbon blacks with special polymers create the desired hydrophilic and hydrophobic pore structures.

The so-called boundary layer capacitors are also electrochemical devices that rely carbon blacks to achieve the appropriate pore structures.

Special carbon blacks are also used in batteries, with the largest use in old technology nonrechargeable cells.

Table 11. U.S. Production of Carbon Black (1971–2000)[a]

Year	Production (millions of metric tons)
1971	1.380
1976	1.415
1981	1.285
1986	1.200
1991	1.230
1994	1.475
1997	1.660
2000	1.665

Manufacturers and Production

Starting with the oil crisis of 1973, consumption of carbon black in the United States decreased to 1.2 million tons in 1986 (1). A number of events had contributed to decreased consumption by the rubber and tire industries including tire radialization, increased tire mileage, downsizing of tires, and increased imports of foreign cars. The negative influence of these events have pretty much run their course, and during the last two decades there has been a modest growth in carbon black production. Production for the period 1971–2000 is shown in Table 11.

The shrinkage in demand has resulted in a restructuring of the carbon black industry. Several of the principal multinational oil companies have left the business including Ashland, Cities Service Co., Phillips, and Conoco. Some plants have changed ownership. Decreased margins, rising feedstock, and environmental compliance costs have led to further restructuring in the late 1990s and early 2000 time period. ECI and Degussa consolidated their operations in 2002. Today's U.S. industry consists of five principal producers. Rated capacities of the six U.S. manufacturers is shown in Table 12. Cabot Corp., ECI–Degussa, and Columbian Chemicals are the leading producers, followed by Continental Carbon Co. and Sid Richardson.

Table 12. U.S. Carbon Black Manufacturers and Capacities, 2000[a]

	Furnace black		Total carbon black	
	Millions of metric tons	% of Capacity	Millions of metric tons	% of Capacity

[b] Including Mexico.
[c] Including Eastern Europe, Africa and the Middle East.

World carbon-black-rated capacities are shown in Table 13. North America has the largest capacity, and Africa and the Middle East have only a small production. The growth areas are predicted to be the Asian and Eastern European markets.

Health, Safety and Environmental

Health. There is a long history of health studies, many of them sponsored by the carbon black manufacturing industry and a number of authoritative publications on carbon black SH&E aspects. In particular, Patty's Handbook chapter on Industrial Hygiene and Toxicology of carbon black is a recent authoritative reference (53). Mortality and worker health have been extensively studied, often in studies sponsored by the carbon black industry. These studies have included mortality (54,55) and health (55–57) in workers in the carbon black industry against unexposed controls in the same industry as well as those in nonindustry populations. The North American mortality studies (54) have logged about 55,000 worker exposure years since the first studies were first undertaken in 1939. They show no elevation in death rate among carbon black workers and no elevation in cancers of the respiratory organs because of occupational exposure to carbon black. In the United kingdom a study of workers in five carbon black plants (55) shows that among this population there is an elevation of the death rate from cancers of the respiratory organs which is significant versus the U.K. population, but the study indicated clearly that there was no correlation of the incidence of disease with exposure to carbon black. In other words, some other factor rather than carbon black exposure appeared to be the source of the excess cancers. Studies of worker health among both U.S. and European workers have been completed in the last decade and publications of the results of these studies continue to appear. These show no evidence of clinically significant health effects due to occupational exposure to carbon black. While there are some differences in the exposure metric between the North American Studies and the European studies, they show very similar effects. Over the course of time covered by these various studies, there has been a marked improvement in the workplace air quality.

In 1995, IARC (International Agency for Research on Cancer) revised its evaluation of carbon black from category 3, "not classifiable as to its carcinogenicity to

humans" to category 2B, "possibly carcinogenic to humans" based on lung tumor formation in two long-term inhalation studies in rats (58–60). Comparable studies in mice and golden hamsters have failed to find any elevation of tumor incidence of lung or any other tissue (61). Other insoluble respirable materials have shown similar positive responses in rats, but not in other rodent species.

There are two major areas of carcinogenic concern with carbon black. Of these, the one that has historically attracted the most attention is the few tens to hundreds of ppms of polynuclear aromatic hydrocarbons (PAH) that are adsorbed on the surface of most blacks. An extract made by exhaustive extraction of these materials with aromatic solvent has been shown to cause skin tumors in rodents. The PAH on carbon black is very tightly adsorbed and is not liberated by biological fluids. Hence this material is believed to have little or no bioavailability (62). This is supported in the companion studies to those referenced by IARC (59,63). Attempts were made to get a dose response to PAH by using PAH-free black and doping it with high levels of PAH. There was no statistically significant difference in the tumor incidence or type between the two groups.

The second carcinogenic mechanism seems to be common to all inert respirable insoluble particles. Positive carcinogenic responses have been shown with TiO_2, talc, carbon black, and diesel soot in the female rat (64). There is evidence that a common mechanism is at work in all these cases involving a process of damage to the lung epithelium, inflammatory response, saturation of the body's defense mechanisms, proliferation of new epithelial cells, recruitment of activated polymorphonuclear (PMN) cells, secretion of radical-forming species by the PMN cells, and damage to the DNA in the dividing epithelial cells. Studies by Driscoll and co-workers are building a strong case for this mechanism and are ongoing (65). These data indicate that the distinction between the rat and other rodents is the nature of the inflammatory response which appears quite intense in the rat compared to other species. If indeed this proves to be the explanation, a strong case can be made for a threshold and establishment of a no observed adverse effect level (NOAEL). It is also clear that in the rat, an overload mechanism is at work in which above a certain critical loading, the mechanisms which normally clear dust particles from the lung lose effectiveness. Again this suggests a threshold and a NOAEL.

Carbon black inhalation is currently regulated by Occupational Safety and Health Administration (OSHA) in the United States at 3.5 mg/m^3 (total dust), by the Health and Safety Executive (HSE) in the United Kingdom at 3.5 mg/m^3 (inhalable dust), by the MAK Commission in Germany at 6.0 mg/m^3 (inhalable dust) for an 8-h time-weighted average (53). Reviews of these occupational exposure levels are currently underway by the MAK Commission, the HSE, and the American Conference of Governmental Industrial Hygienists (ACGIH). It is unlikely that any of these reviews will be completed before 2005.

Safety. Carbon blacks will burn in air if ignited and once ignited, are difficult to extinguish. In bulk storage, local hot spots can exist for very long periods. Great care needs to be exercised where a smoldering fire is suspected as there can be accumulations of carbon monoxide in enclosed spaces.

Carbon black dust clouds in air are not considered flammable. Carbon blacks have a high ignition energy requirement, and entrained dust clouds do not propagate flame, nor exhibit substantial overpressures. This is presumably because

they have essentially no combustible volatile matter. Carbon black in air can be incinerated but only with difficulty, requiring long burnout times.

Environmental. The carbon black industry takes extreme efforts to confine the product during all stages of manufacturing and transport. Highly efficient bag filters are used to collect the product. After collection the fluffy carbon black is densified and pelletized to minimize dusting during shipment and use by customers. The process gas leaving the bag filter contains primarily water, nitrogen, carbon monoxide, carbon dioxide, and hydrogen. There are also traces of hydrogen sulfide, carbon disulfide, carbonyl sulfide, and various nitrogen-containing species. A portion of these gases is burned for internal plant fuel, and the residual gas is generally burned in a flare or incinerator. Where local conditions warrant, the remaining gas may be used to generate power or steam, either for the plant itself, or for merchant sale.

Like all other operators of combustion equipment, carbon black plants are subject to the usual pressures for reduced sulfur and nitrogen oxide emissions. It appears that the use of lower sulfur feedstock is the most economic way of reducing sulfur emissions. Redesign of combustion equipment for nitrogen oxide reduction is showing some promise. The primary NO_X issues arise from the combustion of tail gas since the carbon black production process is exceedingly fuel-rich.

CARBON FIBERS

Introduction

Carbon fibers continue to be the main reinforcement materials in advanced composites (qv). The ability to manipulate their physical, chemical, electrical, and thermal properties makes carbon fibers suitable across a wide range of commercial applications, including military [aircraft and missiles (1)], structural [concrete reinforcement (2,3) and automobile body panels], sports equipment (golf

clubs, skis, surfboards, and softball bats), energy storage [batteries and capacitors (4,5)], and activated carbons (catalysis, gas storage, and purification) (6,7). The ultimate properties of the carbon fiber directly depend on the selection and processing of the precursor materials, the formation of the fiber, and subsequent processing of the fiber. Figure 1 shows a comparison of carbon fiber strengths and moduli as a function of precursor selection and treatment temperature.

Carbon fibers are defined by the International Union of Pure and Applied Chemistry (IUPAC) as "fibers (filaments, tows, yarns, rovings) consisting of at least 92% (mass fraction) carbon, usually in a non-graphitic state (9)." Carbon fibers are produced either through carbonization (the controlled pyrolysis of a fiber precursor in an inert atmosphere) or through growth from gaseous hydrocarbons. The carbonization process is preceded by a stabilization step in which precursor fibers are converted to thermally stable forms that will not melt during carbonization. During the carbonization process, inorganics and aliphatic carbons are driven off, leaving a fiber consisting of graphene layer planes. An idealized carbon fiber is shown in Figure 2.

Real carbon fibers cannot achieve the graphitic ideal. Instead the graphene planes are uneven and wavy, with a mean interplanar spacing significantly greater than the 0.335 nm of graphite. This turbostratic structure of carbon fibers is shown in Figure 3.

The carbon fiber production process involves a series of steps including spinning of the precursor fiber, stabilization, carbonization, and post-carbonization treatments that include sizing and surface treatments. The specifics of these steps vary greatly, depending on the precursor material and the desired properties of the carbon fiber. Figure 4 shows a schematic of the carbon fiber production process.

In the United States, carbon fibers are classified into two broad categories: high performance (HP) and general performance (GP) (12). High performance fibers are further classified into high tensile (HT) and high modulus (HM). Table 1 summarizes the tensile properties of HT and HM fibers.

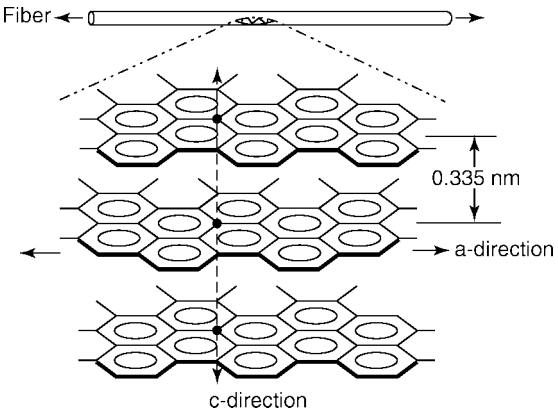

Fig. 2. Idealized carbon fiber structure. Adapted from Ref. 10.

Table 1. Properties of High Performance Carbon Fibers[a]

Fiber type	Tensile strength, GPa	Young's modulus, GPa
High tensile (HT)	3.0–7.1	150–300
High modulus (HM)	0.2–3.0	400–900

[a] Ref. 12.

This categorization of carbon fibers is not uniform. In the United Kingdom, the fiber categories are Type I (HM), Type II (HS), and Type III (GP) (13). Some researchers refer to fibers at the higher end of the Young's modulus range as ultra-high modulus (UHM) fibers (14). Fibers are also distinguished as being graphitizable or nongraphitizable. Graphitizable fibers can, upon heat treatment, be converted to graphene layer planes with a mean interlayer spacing of less than 0.34 nm (9), compared to the 0.335-nm spacing for pure graphite. Although there is an objective standard for graphitizable fibers, many researchers incorrectly use the term to describe any carbon fiber that develops measurable three-dimensional order. The Inorganic Chemistry Division Commission on High Temperature and Solid State Chemistry Subcommittee has developed recommended terminology to alleviate the confusion in nomenclature (9), but the multiple terminologies remain embedded in the culture of carbon fiber research.

The majority of commercial carbon fibers are produced from polyacrylonitrile (PAN) fibers. In fact, HTA-12K PAN-based carbon fibers are the most commonly used commercial carbon fiber (15). PAN-based fibers are the strongest commercially available carbon fibers and dominate structural applications. Mesophase pitch-based carbon fibers represent a smaller but significant market niche. These fibers develop exceptional moduli and excel in lattice-based properties, including stiffness and thermal conductivity (1). Rayon-based fibers are used in heat shielding and in missile nosecones (16). Carbon fibers made from high performance polymers (17–19) or from chemical vapor deposition of hydrocarbons, such as benzene or methane, display unique properties that make them potentially attractive future alternatives (20–22).

PAN-Based Carbon Fibers

PAN-based carbon fibers develop exceptional tensile strength [in excess of 7000 MPa (23)] and are more resistant to compressive failure than high performance polymers (24). These factors combine to make PAN-based carbon fibers the ideal choice for applications requiring significant fiber strength. However, PAN-based fibers are less appropriate than mesophase pitch-based fibers for applications in which molecular order-dependent properties are key.

Commercial PAN is actually a copolymer of acrylonitrile and another monomer (vinyl acetate, methyl acrylate, or acrylic acid) that is added to lower the glass-transition temperature of the material and control its oxidation resistance (see ACRYLONITRILE AND ACRYLONITRILE POLYMERS). The repeat unit of PAN is shown in Figure 5. The copolymer is formed through a wet-spinning process in which the polymer solution is extruded directly into a liquid bath. A blend of

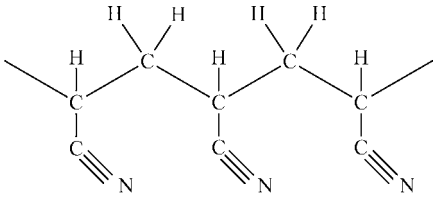

Fig. 5. The molecular structure of PAN.

phase separation and chemical reaction in the liquid results in solidification of the polymer. A concentrated copolymer solution containing 93–95 wt% acrylonitrile is dissolved in a solvent (typically dimethylacetamide) to form a concentrated polymer solution that is fed to a storage tank (25). The solution is filtered to minimize impurities and passed through a spinnerette.

The fibers emerge through the small capillary holes directly into a coagulation bath containing ethylene glycol that extracts the solvent from the fiber. The solvent extraction rate is governed by complex thermodynamic and kinetic relationships but can be influenced by the selection of coagulation liquid, temperature, and the circulation rate of the fluid within the bath. Figure 6 shows a schematic representation of the wet spinning of PAN fibers.

The development of internal voids or flaws in the fiber as well as the shape and texture of the fiber are controlled by the solvent removal rate. Concentration gradients can occur during the solvent extraction process, resulting in a warping of the fiber. For example, dog-bone–shaped fibers result from removing the solvent too rapidly (23). The fiber that emerges from the coagulation bath undergoes a series of post-spinning steps including washing, drawing, and drying during which the fiber solidifies into its final form. These processes play a crucial role in developing the internal morphology of the fibers (26).

Before the acrylic fibers (qv) produced in the wet-spinning process can be subjected to the elevated temperatures of carbonization, they must be converted to a thermally stable form that will not melt through oxidative stabilization. Stabilization is usually performed in air at temperatures between 200 and 300°C (27) and under tension to prevent fiber shrinkage (28).

During the stabilization process, dehydrogenation, oxidation, and nitrile cyclization reactions result in the formation of a condensed pyridine ring "ladder" structure that is suitable for subsequent carbonization (29). The general mechanism is shown in Figure 7. The details of the stabilization mechanism are highly

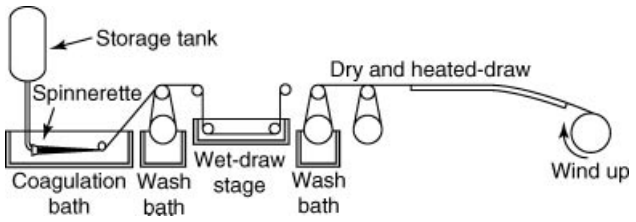

Fig. 6. Wet spinning of PAN fibers. Adapted from Ref. 24.

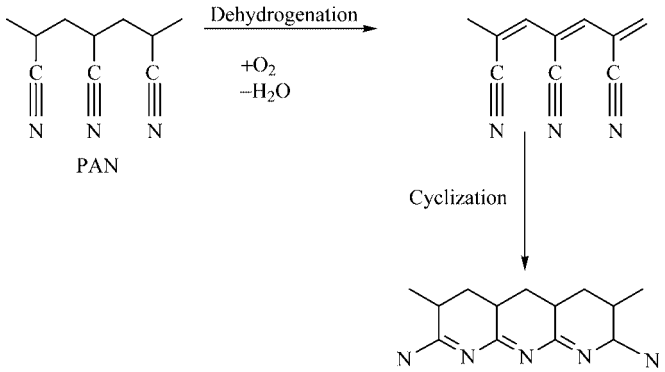

Fig. 7. General mechanism for the stabilization of PAN. Adapted from Ref. 12.

complex and have been the subject of many studies (30–33). All studies agree that control of the heating rate is essential because the reaction is highly exothermic. The stabilization time varies greatly with the size of the fiber bundle, the temperature, and the oxidizing environment. Studies of stabilization at elevated temperatures (350–400°C) show the development of additional intermolecular crosslinking, resulting in improved strengths (34,35). The stabilized fiber is carbonized in an inert atmosphere at temperatures ranging from 1000 to 3000°C, depending on the desired properties. During the pyrolysis, nearly all inorganic and nonaromatic carbons are driven off. Primary off-gases include hydrogen cyanide, carbon dioxide, water, ammonia, methane, and hydrogen (35). The carbon yield during the process is generally in the range of 40–45% (36).

Heating rate plays a major role in controlling the release of gases. A decrease in tensile strength is generally observed at temperatures above 1500°C (37), which corresponds to the final major release of nitrogen (38). As a result, many of the highest strength PAN-based carbon fibers contain residual nitrogen. Although heat treatments of PAN-based carbon fibers above 1700°C are often referred to as graphitization, these fibers are not graphitizable and do not develop highly ordered graphene planes.

Because PAN-based carbon fibers are commonly used in applications requiring high tensile strength, great care must be taken to preserve the potential for high tensile strength during the spinning of the precursor fibers. A fiber is often viewed as a chain consisting of interlocking links. If there were no misalignments or flaws, each link would fail at essentially the same tensile load. However, flaws in the fiber act as weak links in the chain, lowering the observed tensile strength of the fiber (39). As a result, the actual strength at which a given fiber will fail depends on both the frequency and severity of these flaws (40,41). Macroscopic flaws can result from inclusions, large voids, or damage from handling. Microscopic flaws can also lead to premature failure but are more difficult to quantify. Johnson (42) attributed many flaws to the misalignment of crystallites that interlink and result in voids. Highly ordered fibers are far more sensitive to these crystallite misalignments. As a result, fibers with high moduli tend to have lower tensile strengths than less-ordered, less–flaw-sensitive lower modulus fibers.

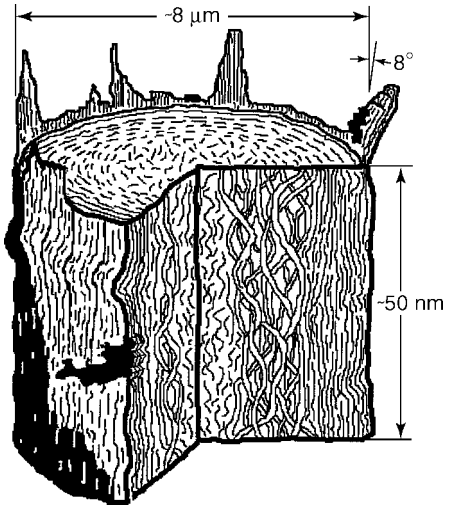

Fig. 8. Schematic representation of a carbonized PAN fiber. Adapted from Ref. 43.

Diefendorf and Tokarsky (43) showed that carbonized PAN fibers have a fibrillar microstructure as shown in Figure 8. This microstructure may be viewed as undulating ribbons and is highly resistant to premature tensile failure because of its flexibility. Therefore, PAN-based carbon fibers are well suited to developing high tensile strengths, but are not likely to develop the high level of three-dimensional order associated with high modulus precursor materials such as mesophase pitch. As such, PAN-based carbon fibers are considered nongraphitizing and maintain a highly turbostratic organization of the graphene layer planes, even when exposed to very high treatment temperatures (42).

Recent research in Poland is helping PAN-based carbon fibers find new applications as biological implants. Low temperature carbonized fibers have found use in ligament and tendon prostheses and in surgical sutures (44,45). These fibers are heat treated to temperatures below 1300°C and are far less crystalline than traditional carbonized PAN fibers (46,47). Despite the promise of these studies, low temperature carbonized PAN fibers do not share the commercial success of their high performance cousins.

Mesophase Pitch-Based Carbon Fibers

Pitch consists of a heavy fraction of predominantly aromatic hydrocarbons that is the residue of petroleum or coal tar distillation following the removal of creosote oil and anthracene (48). Table 2 provides a list of the major components in coal-tar fractions. The pitch consists of hundreds of thousands of different species with an average molecular weight of several hundreds. Many of the species are heterocyclic and are formed by a complex variety of chemical reactions, including thermal decompositions, hydrogen transfers, and oligomerization reactions (49). Pitch is a glassy solid at room temperature, but softens upon heating to form a

Table 2. Major Components in Coal-Tar Fractions[a]

Boiling Temperature, °C				
<200	200–250	250–300	300–350	>350

viscous liquid. Pitches are often characterized by determining their solubility in different organic solvents. Solvent fractionation also serves as a critical method of altering the composition of pitches prior to fiber spinning (48).

Certain pitches can be spun directly into isotropic pitch fibers with only minor devolitization. Carbonized isotropic pitch fibers cannot be graphitized and develop mechanical and thermal properties that are substantially inferior to those produced by other precursors. However, isotropic pitch fibers are very inexpensive and have found commercial applications in areas that do not require the exceptional mechanical and thermal properties of mesophase pitch-based carbon fibers. Isotropic pitch-based carbon fibers are used in filters, brake pads, activated carbons, and as substrates for chemical vapor deposition (23). Table 3 summarizes properties of isotropic pitch-based carbon fibers.

The physical explanation for why some precursors produced graphitizable carbons while others did not was developed by Brooks and Taylor (51). During thermal treatment of aromatic hydrocarbons between 400 and 550°C, an intermediate liquid crystalline phase (mesophase) of spheroids with a mosaic structure formed within the continuous isotropic phase. Selected-area electron diffraction patterns show that each mesophase sphere has a single direction of preferred orientation as shown in Figure 9. As the pyrolysis progresses, the spherules grow and coalesce. Ultimately, a phase inversion occurs and the mesophase becomes the continuous phase (52). There are no grain boundaries in the mesophase, though disclinations do exist. The composition of each phase changes continuously during the pyrolysis and when the entire material is mesophase, polymerization continues with the release of volatiles (48). The formation of the mesophase can be

Table 3. Properties of Isotropic Pitch-Based Carbon Fibers[a]

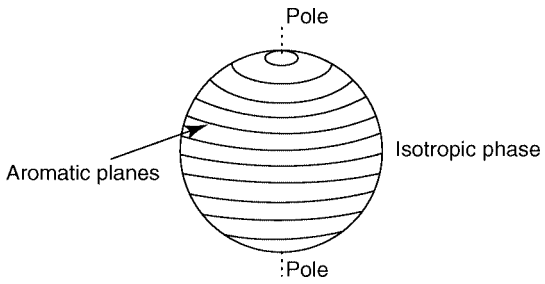

Fig. 9. Lamellar structure of mesophase spherule

influenced by numerous factors including the presence of insoluble particles, the presence of oxygen or sulfur, the applied pressure, the nature of the pitch itself, and the temperature of the heat-soak treatment. Partial oxidation of the pitch is particularly troubling because it results in the presence of inclusions of isotropic pitch which persist in the carbonized product and will not convert to mesophase at any treatment temperature (51).

The two main processes for producing mesophase from pitch are heat soaking and solvent extraction. The first heat-soaking process was developed at Union Carbide in 1977 to convert 50 wt% of low cost Ashland 240 isotropic pitch into a spinnable mesophase by heating the pitch for approximately 40 hours at 400–410°C (53). During this process, the higher density of the mesophase fraction caused it to collect on the bottom of the vessel. Agitating the pitch during pyrolysis led to a homogeneous emulsion of the mesophase and isotropic fraction that resulted in a more uniform and spinnable product (54). Chwastiak and Lewis (55) produced 100% bulk mesophase by using an inert gas to agitate the mixture and remove volatile components. Subsequent research by Otani and Oya (56) produced a mesophase pitch with a lower softening temperature by adding a hydrogenation step either before or after the production of the mesophase. Figure 10 shows a typical molecule of mesophase pitch formed during the heat-soaking process.

Mesophase is also produced through a solvent extraction technique. A portion of an isotropic pitch is extracted with an organic solvent such as benzene, hexane, or toluene. The remaining insoluble fraction is pyrolized for 10 min (as opposed to 40 h in the Lewis heat-soaking process) in a temperature range from 230°C to 400°C, yielding a 75–100 wt% mesophase product (57). Both production strategies convert inexpensive pitch feedstocks to spinnable mesophases, but neither can overcome some fundamental limitations of the feedstocks themselves. Pitch is a mixture of components refined through a complex process of feedstocks that are inherently variable, making batch-to-batch consistency extremely difficult. Further, during every step of pitch production and pyrolysis, impurities are concentrated in the retained fraction. These problems have spurred interest in alternative mesophase production strategies.

Mochida (58) developed a process in which a synthetic mesophase is produced from the HF/BF_3 catalyzed polymerization of naphthalene or methyl naphthalene. HF/BF_3 is a Bronsted acid that has been used to catalyze coal liquifaction and aromatic condensation. The aromatic resin (AR)-mesophase produced through this process is both more spinnable and more easily oxidized than that produced from

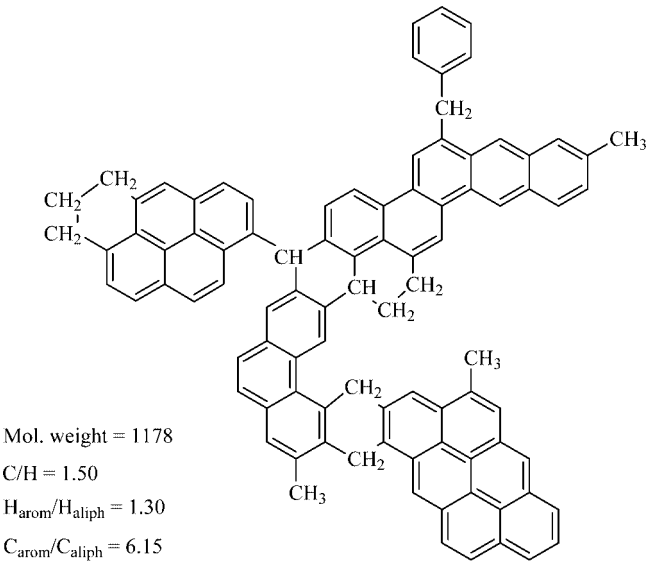

Fig. 10. A typical heat-soaked mesophase molecule. Adapted from Ref. 55.

traditional pitch precursors. Mochida (59) reports that the thermal and mechanical properties of the carbonized AR-mesophase fibers are comparable with those of the best commercial fibers. AR-mesophase has a much narrower molecular weight distribution than a mesophase formed from natural pitch and is free from sulfur and other impurities that present problems in traditional pitches. Figure 11 shows representative benzene-soluble fractions of AR-mesophase.

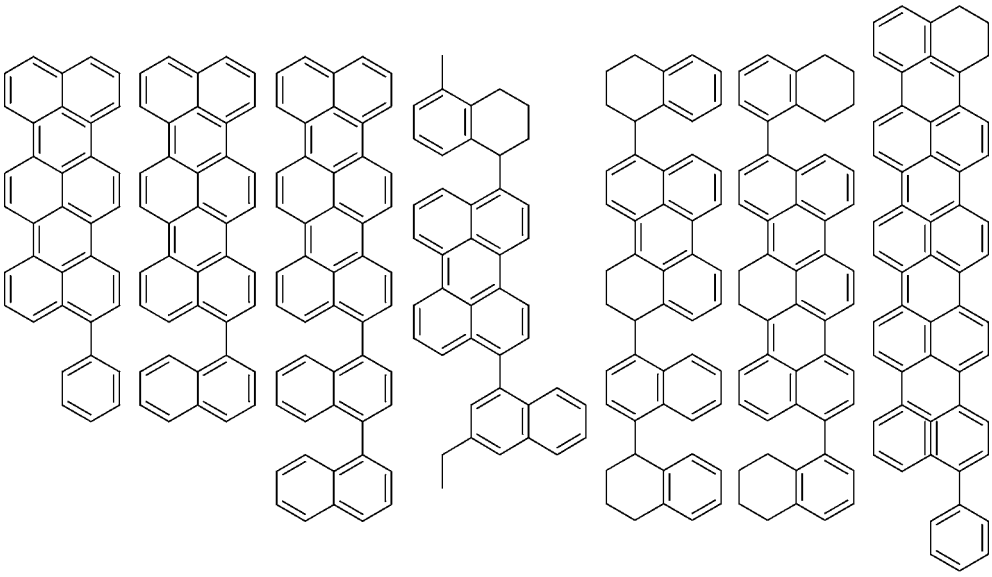

Fig. 11. Representative benzene-soluble fractions from AR-mesophase. Adapted from Ref. 12.

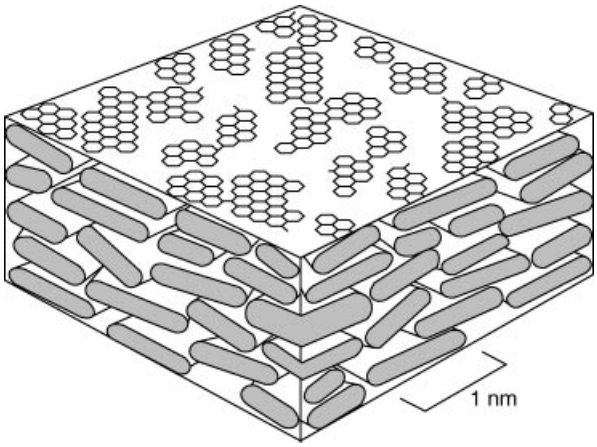

Fig. 12. The stacking behavior of mesophase pitch. Adapted from Ref. 64.

Another approach to improving the quality of the mesophase precursor involves supercritical fluid extraction, which has been shown to fractionate isotropic petroleum pitches into fractions of different compositions, some of which contain 100% mesophase (60). When using supercritical fluids, both temperature and pressure can be used to alter the strength of the solvent (61). Continuously varying the temperature and pressure allows selective fractions of relatively narrow molecular weight distributions to be isolated (62). Supercritical fluid extraction offers several advantages in mesophase preparation including lower solvent requirements and the ability to use a single, cost-effective solvent to produce a variety of pitch fractions (63).

Once the mesophase pitch has been prepared, the next step in processing is spinning it into fibers. This process is particularly important because when mesophase pitch is carbonized, the morphology of the pitch is the dominant factor in determining the microstructure of the resulting graphitic fiber. This results from the stacking behavior of the mesophase molecules (64), as shown in Figure 12.

Mesophase pitch fibers are produced through melt spinning that is essentially the same as that used to spin commercial polymers. Figure 13 shows this process in which an extruder melts pitch particles and pumps the molten pitch through a multiholed spinnerette. The high extensional shear orients the liquid crystalline mesophase molecules as it approaches and flows through the spinnerette. The fibers emerging from the spinnerette are drawn by a windup spool.

Although there are considerable similarities between melt spinning pitch and polymers, the rheological behavior of mesophase pitch is far more complex than that of most polymers. First, the viscosity of mesophase pitch displays an extreme sensitivity to temperature (65–67). This has direct impact on fiber spinning because pitch fibers achieve their final diameter within a few millimeters of exiting the spinnerette, unlike most polymeric materials. These data provide no insight into the texture in the developing fibers, but provide a basis for determining appropriate spinning temperatures for pitches. Mesophase pitch exhibits shear-thinning behavior at low shear rates and becomes increasingly Newtonian

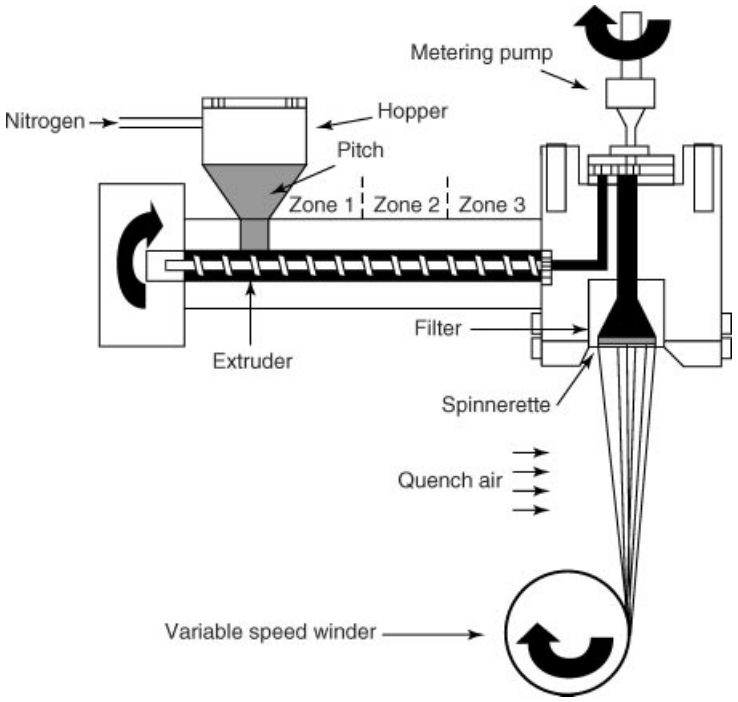

Fig. 13. Melt spinning of mesophase pitch fibers.

as shear rate increases (65). The pseudoplasticity of the mesophase likely relates to the alignment of the liquid crystalline mesophase domains at elevated shear (67). Mesophase pitch has been reported to display thixotropic behavior, but no clear basis for this behavior has been developed (68,69).

McHugh and Edie (68) demonstrated that the microstructure of carbonized mesophase pitch-based carbon fibers can be predicted through the application of continuum theory. Leslie (69) and Ericksen (70) proposed a continuum theory that applies to the flow of nematics. In addition to the standard conservation equations (continuity and the equation of motion), a conservation of angular momentum equation (known as the balance of torques) is also considered. Unfortunately, the shear stress is not proportional to the shear rate. Instead, the viscous stress tensor is the sum of six terms, each with its own unique viscosity coefficient. Although these equations are quite complex, they can be solved for a unique analytical solution for a given geometry. When applied to fiber spinning, the Leslie and Ericksen model can predict the flow-induced orientation of the aromatic planes in the as-spun fiber. For example, the equations predict and explain the development of the radial texture observed for fully developed flow of discotic mesophase through a circular capillary (ie, a spinnerette hole). The balance of torques requires the mesophase to flow with a radial orientation as shown in Figure 14.

As a result of the ability to predict fiber texture as a function of geometry, improved spinning geometries can be evaluated. McHugh and Edie (68) showed that a capillary with a tapered entry forms a more ordered fiber as a result of

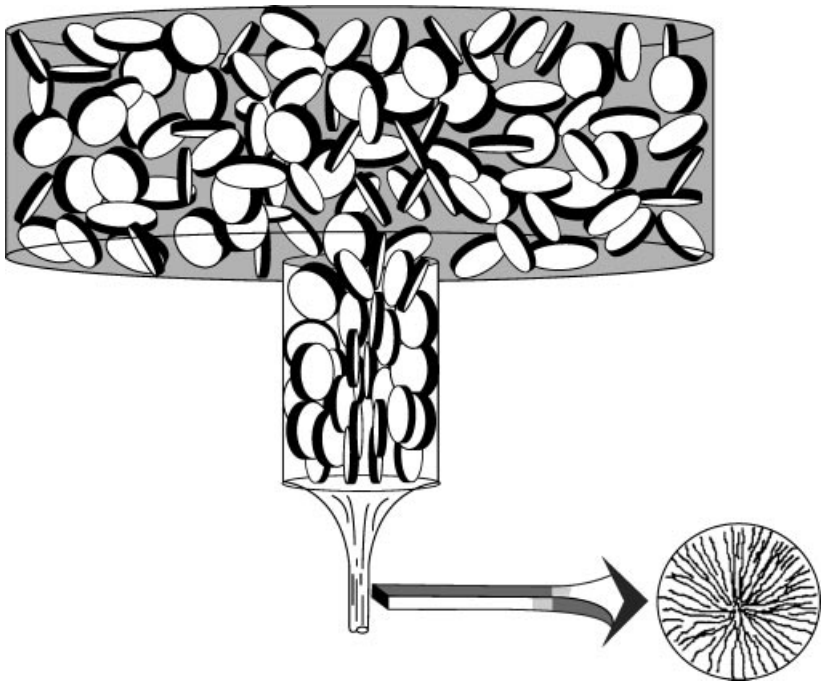

Fig. 14. Origin of radial structure in mesophase pitch fibers. From Ref. 23.

creating less disruption to the fully organized flow assumed by the Leslie and Ericksen model. Spinning fibers through a rectangular capillary generates fiber with a highly linear texture that results in fibers with higher thermal conductivity (71). The line-origin texture of these "ribbon fibers" is shown in Figure 15. Figure 16 shows the Leslie and Ericksen model solution to flow of discotic mesophase flowing through a rectangular channel. The edges within the channel represent the edges of the aromatic planes (68).

Regardless of the shape and texture, the as-spun fibers must be stabilized prior to carbonization. During this process, oxygen reacts with side groups in the pitch fiber, creating cross-linkages and adding weight. Typically, a 6% weight gain is needed to completely stabilize mesophase pitch fibers (72), while an 8% weight gain is more typical for PAN (73). Lower heating rates and lower temperatures

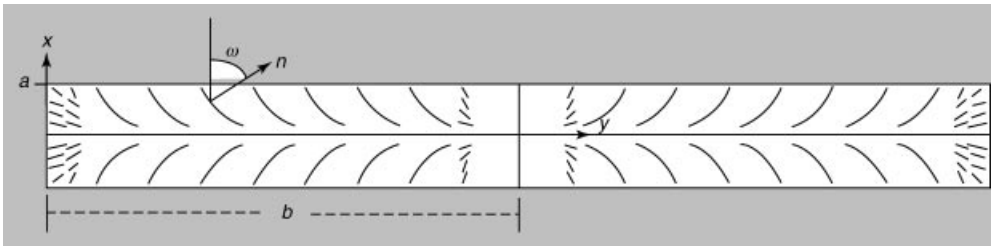

Fig. 15. The line-origin texture of ribbon fibers.

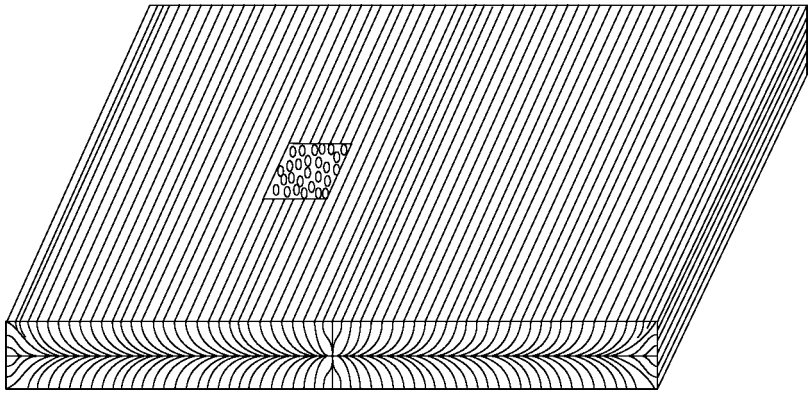

Fig. 16. Orientation developed in discotic mesophase flow through a rectangular channel. Adapted from Ref. 68.

during stabilization result in a more uniform stabilization, but also add to processing time (74).

The carbonization of mesophase pitch-based fibers closely resembles that which is previously described for PAN, but occurs in two stages. Typically, fibers are heated to approximately 1000°C and held there allowing for the evolution of off-gases. The rate-limiting step in this low temperature carbonization is the free-radical breaking of carbon–hydrogen bonds. Following the release of gases, the fibers are heated to their final treatment temperature, which may be as high as 3000°C.

Unlike PAN-based carbon fibers, mesophase pitch-based fibers experience significant graphitization during which dislocations in the turbostratic carbon stacks are gradually annealed, resulting in the formation of a three-dimensional lattice. Fischbach (75) presented a detailed study of graphitization which characterizes the process as a combination of atomic diffusion and crystallite growth. Table 4 provides a comparison of properties for some commercial pitch- and PAN-based carbon fibers.

Table 4. Properties of Commercial Carbon Fibers[a]

Fiber type	Precursor material	Tensile strength, GPa	Young's modulus, GPa
T-300	PAN	3.66	231
T-650/35	PAN	4.28	241

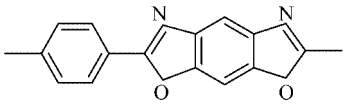

Fig. 18. The repeat unit of PBO.

Carbon Fibers from High Performance Polymers

The primary factor limiting the increased commercial application of carbon fibers is their high production cost, a significant portion of which is directly attributable to the lengthy stabilization process required by both pitch and PAN (77). The rigid-rod structure and high degree of aromaticity allow Kevlar (poly *p*-phenylene terephthalamide) and PBO (poly *p*-phenylene benzobisoxazole) fibers to be converted directly to carbon fiber without any stabilization (17–19). The repeat units of Kevlar and PBO are shown in Figures 17 and 18 (see POLYAMIDES, AROMATIC; RIGID-ROD POLYMERS). Surprisingly, PBO-based carbon fibers also show some capacity to graphitize (19). However, the commercial development of high performance polymer-based carbon fibers is impeded by their comparatively poor tensile strength. Table 5 compares the properties of PBO- and Kevlar-based carbon fibers with typical pitch- and PAN-based fibers.

In spite of the relatively poor tensile strengths of the fibers, carbonized Kevlar possesses characteristics that make it an ideal candidate as a substrate for chemical vapor deposition of silicon carbide including a compatible coefficient of thermal expansion, sufficient tensile strength to survive the coating process, availability from a reliable domestic supplier, and a smooth, even diameter of less than 7 μm (78).

Table 5. Properties of High Performance Polymer Based Carbon Fibers[a]

Precursor material	Product designation	Tensile strength, GPa	Young's modulus, GPa	Electrical Resistivity, $\mu\Omega$-m
PBO	Batch, 1800°C	0.52	245	13
PBO	Continuous, 1800°C	0.85	183	10
Kevlar-29	1600°C	0.94	143	23
PAN	T-300	3.66	231	18

Rayon-Based Carbon Fibers

The first carbonization of cellulose-based fibers dates back to Thomas Edison, who carbonized a natural cellulose filament for use as an incandescent lamp filament. In the mid-1950s, the Carbon Wool Corporation introduced the first commercial carbonized rayon fibers (79). PAN- and pitch-based carbon fibers have replaced rayon-based fibers in most high performance applications; however, they continue to find use as ablative materials in missile nosecones and heat shielding (16). Additionally, the combination of low cost, ease of handling, and high natural porosity makes rayon an attractive precursor for activated carbon fibers (see CELLULOSE FIBERS, REGENERATED).

Activated carbon fiber (ACF) offers several advantages over traditional granular and powdered carbons as an absorbent material. Rayon-based ACFs (80) possess

(1) smaller fiber diameters, which encourages rapid adsorption and desorption by minimizing diffusion limitation;
(2) more concentrated and controllable pore size distributions; and
(3) excellent adsorption capacity at low adsorbate concentrations.

Rayon-based ACFs are used in the adsorption of many volatile organic compounds including formaldehyde (80), methyl ethyl ketones (81), and benzene (81). ACFs are also finding uses in natural gas storage (82), electrodes for batteries (83), catalyst supports (84), and NO_x removal (85). Stabilized rayon fibers are carbonized and then activated with air (80), steam (86), or carbon dioxide (87), much as in granular carbon activation. The extent of pyrolysis governs the pore structure, carbon yield, and surface area of the fiber, while activation impacts the presence of functional groups on the pore surface (12). Properties of some commercial ACFs are summarized in Table 6.

ACFs develop a pore structure with micropores (<60 nm) open directly to the surface, unlike granular carbons where extensive surface oxidation results in macropores on the surface (88) with microporosity only in inner zone, as shown in Figure 19. The presence of extensive surface microporosity has a significant impact on the adsorption of volatile organic compounds. The overlap of attractive forces on opposite micropore walls are primarily responsible for the adsorption of gases at low concentrations (89).

Carbonized rayon fibers present one drawback as an ACF precursor. Nearly 82% of the mass of the original fiber is evolved during pyrolysis, resulting in a

Table 6. Properties of Commercial Active Carbon Fibers[a]

Fiber	Precursor	Surface area, m^2/g	Mean pore size, nm	Benzene adsorption, wt%	Tensile strength, MPa
Toyobo KF Series	Rayon	1000–1600	0.5–10	30–60	60–130

loss of both strength and flexibility (90). Rayon carbonization consists of a blend of depolymerization and dehydration reactions. The depolymerization involves the formation of *l*-glucosan and volatile products, while the dehydration reaction inhibits *l*-glucosan and volatile production, resulting in a higher carbon yield (91–93). The inclusion of Lewis acids such as $AlCl_3$ and $ZnCl_2$, during low temperature carbonization enhances the carbon yield by favoring the dehydration reactions (94).

Vapor-Grown Carbon Fibers

Vapor-grown carbon fibers (VGCFs) have been produced by decomposing benzene or methane over transition metal catalyst particles within a temperature range of 1000–1300°C (95–97). Fibers produced in this manner develop an annular ring texture (often referred to as a tree trunk structure) with graphene planes running parallel to the fiber axis (98), as shown in Figure 20. This microtexture facilitates graphitization and leads to excellent electrical, thermal, and mechanical properties (99,100).

The production strategy with the greatest potential for scale-up into mass production may be the "floating reactant method." This technique disperses catalyst particles with the reactive hydrocarbon in a reaction chamber, resulting in a high yield of relatively uniform diameter fibers of 0.1 to 0.2 μm (101). Fibers produced in this fashion are considered submicrometer VGCFs (s-VGCFs) and are much smaller than VGCFs produced by the traditional seeding techniques. Typical diameters range from 10 to 20 μm, about the size of carbonized PAN fibers. The high surface-to-volume ratio and electrical conductivity make the submicrometer fibers exceptional candidates to be anode materials in lithium batteries. Table 7 summarizes the properties of s-VGCFs.

The development of soot as an unwanted byproduct is a problem in the "floating reactant method" of producing s-VCGFs (102). The addition of gaseous ammonia to the hydrocarbon feed along with hydrogen sulfide and iron particles improves the length and uniformity of the fibers while reducing soot production (103).

While substantial research has focused on developing submicron VGCFs, significant interest also exists in developing large, rapidly-produced, inexpensive VCGFs for use as filler materials in carbon composites. Koyama and co-workers (104) first reported achieving vapor grown carbon fibers of 25 cm in length from the thermal decomposition of benzene in a hydrogren atmosphere in 1972. More recently, Masuda and co-workers (105,106) have developed a liquid pulse injection technique that produces VCGFs with lengths of up to 5 cm in less than 30 s. By adding phenyl silane to the benzene feedstock, the oxidation resistance of the resultant fibers increased without reducing the mechanical or electrical properties of the fibers (107).

During heat treatment, VCGFs (both traditional and submicrometer) undergo significant topological changes. During the growth process, the hydrocarbon feed molecules decompose and the carbon would diffuse into the catalyst particle. This diffusion of atomic carbon into the metal particle is generally considered to

be the rate-limiting step of the process (108). In fact, fiber yield has been shown to increase greatly near the melting point of the metal catalyst (108). Once the carbon has diffused to the active site, the central core growth of the new fiber would occur in the first seconds, terminate, and then the fiber would begin thickening (109). This thickening process is primarily responsible for determining the surface texture of VGCFs. When heat-treated to 2000°C, the smooth surface containing small pores transforms into a rope-like texture as a result of the sudden density increase in the material corresponding to the decrease in mean interlayer spacing. As the graphitizing fiber becomes less turbostratic, the contraction results in an anisotropic shrinkage. By 2800°C, well-developed microdomains form throughout the fiber and appear to be limited primarily by the diameter of the fiber (109).

Summary

Carbon fibers have advanced greatly from Edison's early experiments with carbonizing cellulose as an iridescent light bulb fiber. PAN-based carbon fibers dominate commercial high performance applications where the tensile strength of the fiber is paramount, but the same fibrillar microtexture that enables carbonized PAN to achieve exceptional tensile strengths limits its long-range order. For applications requiring exceptional molecular-order–dependent properties such as stiffness and thermal conductivity, mesophase pitch-based fibers are preferred. Pitch-based fibers are made from the high molecular weight remains of petroleum or coal-tar distillation, though synthetic aromatic resins have been developed that can be converted to graphitized fibers while avoiding the problems inherent in conventional pitches. Application of transport phenomena principles to the liquid crystalline flow of mesophase have enabled researchers to explain the development of structure in the fiber and to suggest improved spinnerette designs.

For applications that do not require exceptional mechanical properties, carbon fibers made from high performance aramid polymers show considerable potential. These aramid fibers do not require stabilization prior to carbonization, which substantially simplifies the production process. Rayon-based carbon fibers continue to appear in some composite applications, but have become key substrates for the development of activated carbon fibers. These ACFs develop a microporous surface structure that is ideal for adsorption of low levels of volatile organic compounds.

Carbon fibers are also produced from the catalytic decomposition of hydrocarbon gases. These vapor-grown fibers can be produced at submicrometer diameters and show great potential in battery applications. Larger vapor-grown fibers can be produced rapidly by pulse injection and show promise as filler material in composites.

Despite the continued commercial dominance of pitch- and PAN-based fibers, the carbon fiber field is continuously changing. Significant current research is focused on the production of carbon nanotubes. Other researchers continue to enhance the understanding of the processes and mechanisms governing the fiber production today. As researchers are better able to understand and manipulate fiber microstructures, the commercial applications for carbon fibers will continue to expand.

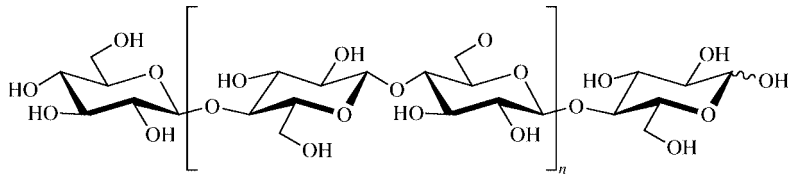
CELLULOSE ESTERS, INORGANIC

Introduction

Cellulose (qv) plays an extremely important structural role in nature. Cellulose is a linear polysaccharide comprised of β-1,4-linked cellobiose repeat units (Fig. 1). The three free hydroxyls present on each anhydroglucose unit provide the biopolymer with the ability to form strong structures through hydrogen bonding. This vast network of hydrogen bonds that link the individual polymer chains into more complex structures greatly reduces the solubility of cellulose in conventional organic and aqueous solvents. Derivatization of cellulose as esters and/or ethers modifies the solubility profile of the cellulosic while maintaining many of the polymeric properties of the molecule. Cellulose esters have found numerous commercial applications, including plastics, coatings, and ion-exchange applications. Esters of cellulose can be either inorganic or organic. The focus of this article is on inorganic esters of cellulose. This report covers both the synthesis and the use of inorganic esters of cellulose.

Inorganic esters of cellulose have been known for well over 100 years and are still commercially viable products. Cellulose nitrate, commonly called



1

nitrocellulose, is the ester with the most significant historical importance. Cellulose nitrate led to the birth of the plastics industry, the film and motion picture industry, and major improvements in explosives and coatings applications. Additionally, cellulose nitrate played a prominent role in numerous biochemical discoveries, including elucidation of the genetic code.

Because of its historical importance cellulose nitrate has traditionally dominated the content of articles devoted to inorganic esters of cellulose. While not understating the importance of cellulose nitrate, this report emphasizes the value of other inorganic esters of cellulose, including cellulose phosphate, cellulose sulfate, and cellulose sulfonates.

Preparation of Inorganic Esters of Cellulose

Inorganic esters of cellulose include all esters where the atoms linked directly to the cellulosic oxygens are non-carbon, for examples, cellulose nitrate, cellulose sulfate, cellulose sulfonate, and cellulose phosphate.

Nitrogen-Containing Esters of Cellulose.

Cellulose Nitrate. Cellulose nitrate, without question the most commercially important inorganic ester of cellulose, was first prepared in 1833 (1). Schonbein prepared the first stable form of cellulose nitrate in 1846 (2). The preparation of cellulose nitrate, most commonly called nitrocellulose, has been reviewed in the literature numerous times (3,4). Several nitration techniques have been reported for the preparation of cellulose nitrate, including $HNO_3/H_2SO_4/H_2O$, HNO_3 (>75%), N_2O_4 (g), HNO_3/H_3PO_4, $HNO_3/H_3PO_4/P_2O_5$, $HNO_3/Mg(NO_3)_2$, HNO_3/CH_2Cl_2, and $HNO_3/HOAc/Ac_2O$ (5–11). Cellulose nitrate is still manufactured using a mixture of nitric acid, sulfuric acid, and water.

A number of versions of cellulose nitrate are commercially available. Variations in nitrogen content and viscosity are the main differences between nitrocellulose product lines. The amount of water present during the preparation of cellulose nitrate directly influences the final nitrogen content of the product (Fig. 2). The viscosity of the final product is determined by selecting a starting material with the appropriate degree of polymerization and/or by performing a viscosity reduction step following nitration. Cellulose trinitrate has a degree of substitution (DS) of 3 and a nitrogen content of 14.15%. Cellulose dinitrate (DS = 2) and cellulose mononitrate (DS = 1) have nitrogen contents of 11.11 and 6.76%, respectively (12). The maximum DS_N of commercial nitrocellulose is approximately 2.9 (about 13.8% N). The hydroxyl group at C6 is nitrated much faster than those at C2 and C3. The relative rates of nitration of the hydroxyl groups on cellulose are as follows: C6 = 5.8, C2 = 1.8, C3 = 1.0 (13).

Sulfur-Containing Esters of Cellulose. Cellulose sulfate and cellulose sulfonates are examples of sulfur-containing esters of cellulose. The sulfur is linked directly to an oxygen atom contained within an anhydroglucose unit of cellulose (see Fig. 3).

Cellulose Sulfate. Sulfation of cellulose has been accomplished via a number of procedures. Three forms of cellulose sulfate have been described in the literature: surface modified cotton fabric or fibers, water-swellable cellulose sulfate, and

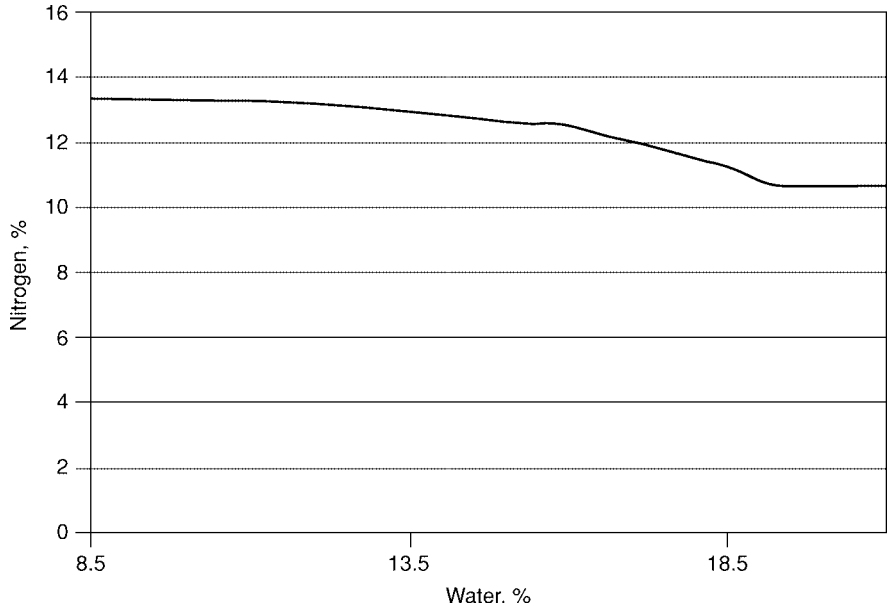

Fig. 2. Influence of water on degree of nitration of cellulose.

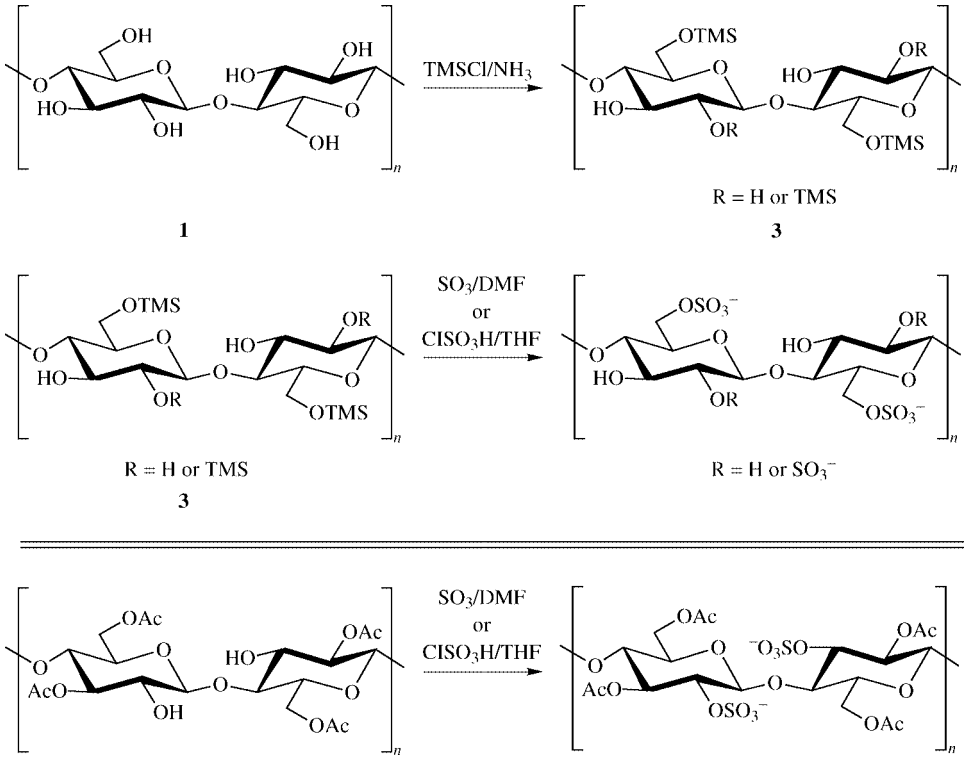

Fig. 3. Synthesis of cellulose sulfate from silylated and acetylated cellulose.

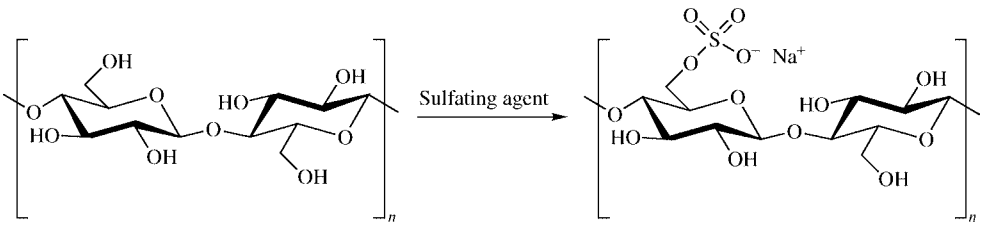
Table 1. Preparation of Cellulose Sulfate Using H_2SO_4

Sulfation system	DS
H_2SO_4	1.0–2
$H_2SO_4 + SO_2$	0.9
H_2SO_4 + chlorinated hydrocarbon	0.3
H_2SO_4 + diethyl ether	0.2–0.4
H_2SO_4 + low aliphatic alcohol	0.05–1
H_2SO_4 + low aliphatic alcohol + inert solvent	0.35–0.7
H_2SO_4 + chlorinated aliphatic alcohol	0.5
$H_2SO_4 + Ac_2O$	0.6–2.8
$H_2SO_4 + Ac_2O$ + HOAc + salt	0.1–0.5
$H_2SO_4 + Ac_2O$ + HOAc + inert solvent	0.3–1.0
$H_2SO_4 + Ac_2O$ + pyridine + dioxane	2
H_2SO_4 + aliphatic carboxylic acid C3-C4	
H_2SO_4 + HOAc + salt	0.3
H_2SO_4 + HOAc + benzene	0.6

water-soluble cellulose sulfate. Sulfation of cellulose is commonly accomplished using sulfuric acid, chlorosulfonic acid, or sulfur trioxide/pyridine (eq. 1).



1 3 (1)

Philipp and Wagenknecht compiled a list of 50 sulfation strategies for the preparation of cellulose sulfate (Tables 1–5) (14). The methods described in Tables 1–5 produce cellulose sulfate with various degrees of substitution. A common theme in the synthesis of cellulose esters (both inorganic and organic) is the trade-off between esterification and polymer degradation. Preparation of cellulose sulfate is no exception to this rule. Increasing the temperature during the sulfation

Table 2. Preparation of Cellulose Sulfate Using $ClSO_3H$

Sulfation system	DS
$ClSO_3H$	
$ClSO_3H + SO_2$	1.8
$ClSO_3H$ + chlorinated hydrocarbon	
$ClSO_3H$ + pyridine	1.9–2.8
$ClSO_3H$ + pyridine propanolamine	1.6
$ClSO_3H$ + pyridine + toluene	2.8
$ClSO_3H$ + formamide	2

Table 3. Preparation of Cellulose Sulfate Using SO_3

Sulfation system	DS
SO_3	3
$SO_3 + SO_2$	2.2
$SO_3 + CS_2$	3
SO_3 + chlorinated hydrocarbon	0.5–0.9
SO_3 + diethyl ether	1.3–2.1
SO_3 + DMSO	1.3–2.0
SO_3 + DMF	1.5–2.6
SO_3 + pyridine	
SO_3 + pyridine + various solvents	0.1–2.2
SO_3 + aliphatic amine + DMF + chlorinated hydrocarbon	0.4–2.0
SO_3 + aliphatic amine + pyridine	1.5
SO_3 + triethylphosphate	3
$SO_3 + N_2O_4$ + DMF	0.3–1.1
$SO_3 + N_2O_4$ + DMF + various solvents	<2.0

Table 4. Preparation of Cellulose Sulfate Using SO_2Cl_2

Sulfation system	DS
SO_2Cl_2 + alkali cellulose	
SO_2Cl_2 + benzene + alkali cellulose	
$SO_2Cl_2 + ClCH_2COOH$ + alkali cellulose	
SO_2Cl_2 + DMF, formamide	0.2–0.5
$SO_2Cl_2 + N_2O_4$ + DMF	0.4–0.8

reaction produces a more homogeneous mixture and thus more complete sulfation, but the rate of polysaccharide chain degradation is also rapidly increased. The rate of sulfation for the following sulfating agents is as follows: $H_2SO_4 < SO_3 < SO_2Cl_2 < HSO_3Cl$, with SO_2Cl_2 generating the most chain degradation during sulfation (14). Chlorosulfonic acid is generally considered the most effective sulfation agent with regard to both sulfation and retention of chain length. Excess sulfuric acid

Table 5. Preparation of Cellulose Sulfate Using Miscellaneous Reagents

Sulfation system	DS
$NaSO_3Cl$ + HOAc	
$NaSO_3Cl + Ac_2O$ + HOAc	
$NaSO_3Cl$ + pyridine	
$EtSO_3H$ + pyridine + nitrobenzene	2.8
NH_2SO_3H + urea	
FSO_3H + pyridine	
FSO_3Na + benzene + EtOH + alkali cellulose	
FSO_3NH_4 + benzene + EtOH + alkali cellulose	
Na-acetylsulfate	
$NOSO_4H$ + DMF, DMSO, DMAc	0.7–1.2
$NOSO_4H$ + diethyl ether, various solvents	0.02–0.4

is typically used during sulfation reactions; however, stoichiometric amounts of acetylsulfuric acid can be used to prepare cellulose sulfate (15).

Cellulose sulfates with a wide range of degree of substitution can be water-soluble, for example, cellulose sulfates with DS_S as low as 0.25 can be water-soluble. The solubility of the final product is influenced by the method of preparation. The regioselectivity of sulfation can affect the properties and end uses of cellulose sulfate. A heterogeneous process, a homogeneous process, or a protection–deprotection strategy can be used to regioselectively derivatize cellulose (16). Generally, a bulky substituent is required to achieve reasonable regioselectivity in a heterogeneous process, and so either a homogeneous process or a protection–deprotection strategy is preferred for the preparation of regioselectively substituted cellulose sulfate. Cellulose sulfates can be prepared under homogeneous conditions by first converting cellulose to the trimethylsilyl ethers (17) (Fig. 3). Water-soluble cellulose sulfates were obtained by applying this strategy. The TMS ethers apparently act as reactive intermediates resulting in SO_3-induced sulfation only at sites previously silylated. The free hydroxyls present in the TMS cellulose ($DS_{Si} = 1.5–2.5$) are unreactive during sulfation. When a similar sulfation strategy is applied to cellulose acetates ($DS_{Ac} = 1.8–2.5$), the free hydroxyls are readily sulfated. It has been suggested that the TMS groups effectively shield the unreacted hydroxyl groups, thus preventing sulfation (18). Sulfation of TMS cellulose derivatives with SO_3 or HSO_3Cl in DMF possibly occurs via insertion of SO_3 into the Si—O bond with the sulfate generated by subsequent hydrolysis and neutralization (17,19). Wagenknecht (20) and Mischnick (21) have developed routes to evaluate the substitution pattern of cellulose sulfates.

There are numerous synthetic strategies available for preparing cellulose sulfates with a wide range of properties.

Cellulose Sulfonates. Cellulose sulfonates are inorganic esters of cellulose and sulfonic acids in which there is a sulfur–oxygen bond formed to link the cellulose and sulfonic acid moieties. Figure 4 depicts the three most common cellulose sulfonates described in the literature, cellulose methanesulfonate (mesylate) (**4**), cellulose toluenesulfonate (tosylate) (**5**), and cellulose dansylate (**6**) (22–25). Cellulose tosylate is the most commonly described cellulose sulfonate in the literature. Cellulose sulfonates are typically prepared in a homogeneous process by dissolving cellulose in a dimethylacetamide/lithium chloride (DMAc/LiCl) mixture and reacting the cellulose with sulfonylchloride in the presence of triethylamine (Fig. 5) (25). Cellulose sulfonates can also be prepared *in situ* for use as reactive intermediates (26,27). The use of cellulose tosylate as a reactive intermediate is be discussed in more detail later in this report.

Cellulose deoxysulfonates have been described in the literature, but is not be discussed further in this report (28).

Phosphorus-Containing Esters of Cellulose.

Cellulose Phosphates. There are a number of strategies for preparing cellulose phosphate. Reaction of cellulose with tetrapolyphosphoric acid in the presence of triethylamine produced cellulose phosphate with $DS_P \leq 1.75$ (29). Treatment of cellulose with $POCl_3$ resulted in cellulose phosphate with low DS_P, but also resulted in introduction of chloride to the cellulosic backbone (Table 6) (30). Phosphorylations of cellulose with *N*-phosphoryl-*N*′-methylimidazole and a

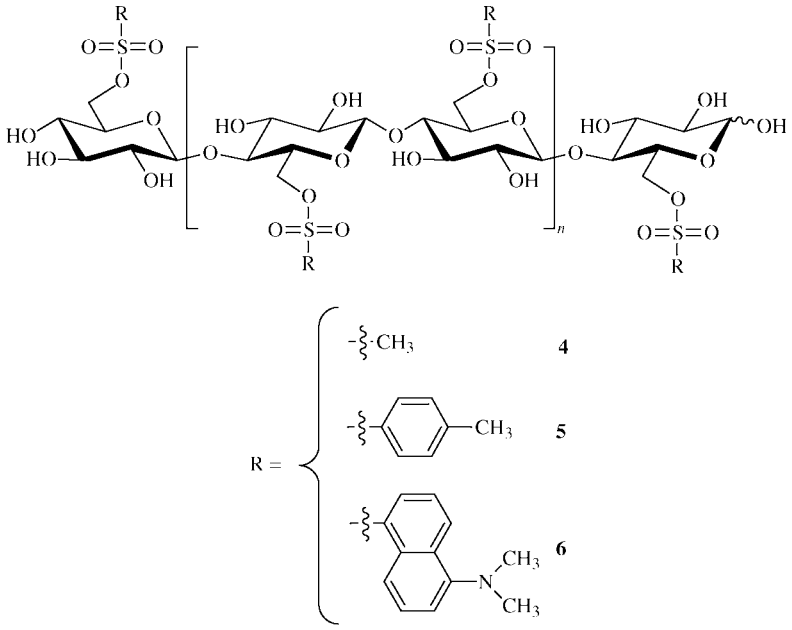


Fig. 4. Structures of cellulose sulfonates.

mixture of phosphorus pentoxide, triethyl phosphate, and phosphoric acid have been reported (Fig. 6) (31,32).

Properties of Inorganic Esters of Cellulose

In general, inorganic esters of cellulose have significantly different solubility profiles than native cellulose. Cellulose has poor solubility in most organic or aqueous systems, while inorganic esters of cellulose are typically more soluble. Inorganic esters of cellulose that are soluble in organic or aqueous solvents are available.

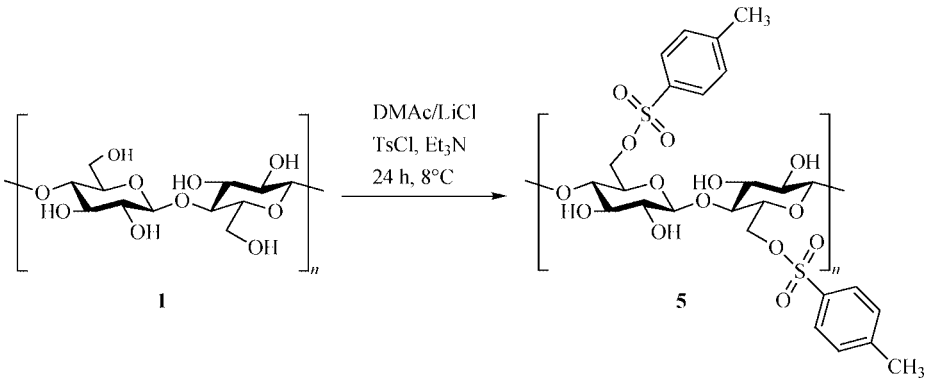

Fig. 5. Homogeneous synthesis of cellulose-6-tosylate.

Table 6. Phosphorylation and Chlorination of Cellulose with $POCl_3$

Reaction Temp.	$POCl_3$, %	DS_P	DS_{Cl}
50	2	0.09	0.02
	4	0.08	0.03
	8	0.03	0.03

	12	0.07	0.55
100	2	0.22	0.04
	4	0.18	0.12
	8	0.20	0.37

The solubility of inorganic esters of cellulose is dependent upon the identity and degree of substitution of the substituents, the number of unreacted free hydroxyls, and the degree of polymerization of the cellulose backbone.

Solubility. Cellulose sulfate and cellulose phosphate can be either water-soluble or water-swellable depending on the conditions used during preparation (*vide supra*). Cellulose nitrate and some cellulose sulfonates are generally more hydrophobic and are typically soluble in organic solvents. In general, the level of esterification of cellulose directly impacts the solubility of the product in various solvents and solvent blends.

Film Formation and Rheology. The ability to form films is the most important property of cellulose nitrate. When cellulose nitrate is dissolved in an organic solvent and then applied to a substrate (eg, wood, metal, glass), a clear

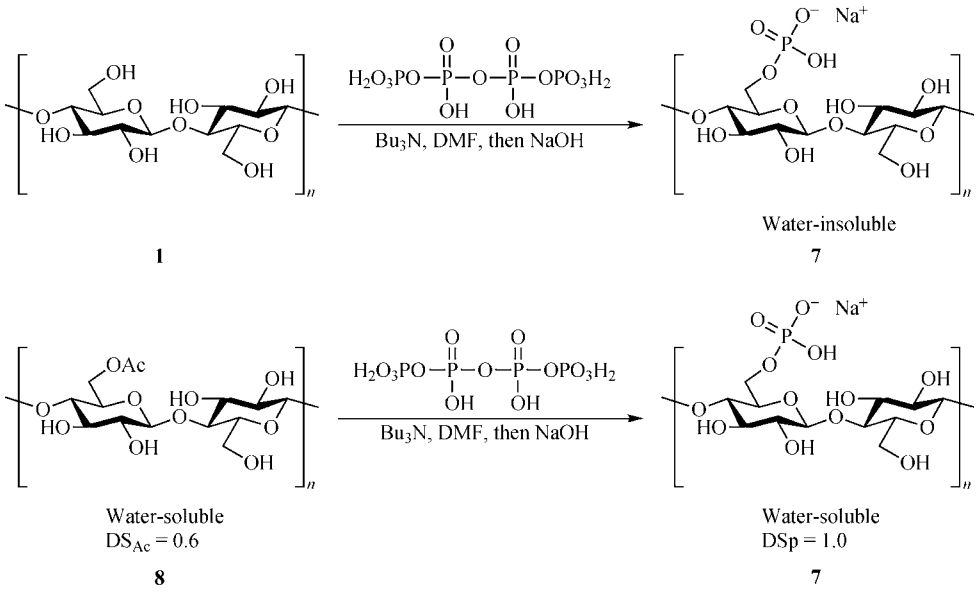

Fig. 6. Synthesis of water-insoluble and water-soluble cellulose phosphate.

film is formed on the substrate once the solvent evaporates. Coatings of this nature are referred to as lacquers. Coatings applications are the largest commercial applications for cellulose nitrate and will be discussed further in the applications section.

Applications of Inorganic Esters of Cellulose

Nitrocellulose is the most commercially important inorganic ester of cellulose. The use of nitrocellulose led to development of the plastics industry, the motion picture industry, and powderless ammunition. In most cases nitrocellulose has been replaced over the years by less expensive or less flammable materials. Although considerable market share for nitrocellulose has been lost to alternate products, nitrocellulose remains a commercially viable product and should be for many years.

Coatings, Adhesives, and Inks. The largest market for cellulose nitrate is in the coatings industry. Relatively clear and workable (ie, sandable or removable) lacquers are generated when cellulose nitrate is used in a coatings application. Cellulose nitrate lacquers dry rapidly, have excellent flow properties, and the final coating has excellent appearance, with reasonable strength and durability. Cellulose nitrate became a commercially viable product in the 1920s and rapidly replaced slower drying varnishes that were used in both automotive and wood coatings (33). Cellulose nitrate has played such a significant role in lacquer coatings applications that cellulose nitrate based lacquers are simply referred to as lacquers and it is assumed that a lacquer is cellulose nitrate based unless stated otherwise. Over time, cellulose nitrate was replaced in automotive topcoats by more durable acrylic lacquers. Cellulose nitrate maintained much of its market share in applications where high temperature curing is not acceptable, for example in wood coatings (33). Cellulose nitrate is still used in some automotive primer refinish applications, but currently its primary use is in wood coatings. Cellulose nitrate provides enhanced wood grain appearance, rapid drying, and easy damage repair to wood coatings. Cellulose nitrate has also been used as an additive to improve the performance, appearance, and drying time of coatings based on other resins, such as acrylics, vinyls, polyamides, epoxies, and polyesters (34). Cellulose nitrate aids in pigment dispersion and acts as a binder following solvent evaporation.

Cellulose nitrate used in coatings applications is commercially available in three general forms based on nitrogen content: SS (10.7–11.3% N), AS (11.3–11.7% N), and RS (11.7–12.2% N) (33). Additionally, each product type is available in low, medium, and high viscosity grades. According to product literature from ICI Nobel Enterprises (Scotland, UK), low and medium nitrogen grades are typically used in ink applications. Medium nitrogen content is used for film coatings. High nitrogen content cellulose nitrate is commonly used in wood coatings, general-purpose lacquers, and automotive refinish applications. Cellulose nitrate-based lacquers have many advantages over other coatings. They are easily applied, have good adhesion, good solvent release properties, and excellent pigment dispersion. The problems with nitrocellulose lacquers include yellowing, flammability, and that they must be sprayed at low solids levels. Nitrocellulose based lacquers found

use in cloth book bindings (34). Nitrocellulose is also used in adhesives and inks (34,35).

Explosives. Cellulose nitrate with a nitrogen content of 12.3–13.5% N ($DS_N = 2.25–2.5$) is used in explosive and propellant applications. Cellulose nitrate was initially developed for use in explosives and propellants and this remains one of the largest markets for cellulose nitrate today.

Plastics. In 1847 it was discovered that cellulose nitrate could be dissolved in a mixture of ether and alcohol to produce a solution called collodion. Collodion is still in use today in pharmaceutical applications. Combination of nitrocellulose with castor oil and eventually camphor by Parkes (1862) and Hyatt (1870) led to the production of celluloid and ultimately the birth of the plastics industry.

Flame Retardants. Flame-retardant cotton fibers are prepared by surface modification of cotton cellulose via phosphorylation or phosphorylation/halogenation, producing cellulose phosphate and deoxychlorocellulose phosphate, respectively. Surface modification of cotton fibers generates flame-retardant fabrics by increasing the char content of the fiber. This in turn produces a lower percentage of flammable volatiles. Since the phosphorylated/halogenated fibers break down to produce acidic products, the overall thermal stability of the fabric is greatly reduced, and the material breaks down at a lower temperature and ultimately reduces the potential of the fabric bursting into flames (36).

Ion-Exchange Separations. Inorganic esters of cellulose have been used in ion-exchange applications and as chromatographic adsorbents since the late 1950s (37). Cellulose sulfate and cellulose phosphate are excellent ion exchangers. Exposure of the ester to a salt of a metal ion (eg NaCl, KCl) or neutralization of the acid with a base (eg NaOH, KOH) will result in exchange of the metal ion from the salt or base onto the sulfate or phosphate attached to the cellulose backbone (Fig. 7).

Cellulose phosphate is the most widely used cellulose inorganic ester for ion exchange. Cellulose phosphate is an effective cation-exchanger used in the bioprocessing industry (38). Cellulose phosphate and cellulose polyphosphate effectively remove Al^{3+} contamination from ATP (39). A number of products are commercially available, most notably from Whatman, for use as stationary phases in column chromatography and filtration applications. Whatman P1, P11, and P81 are examples of commercially available cellulose phosphate based ion exchangers.

The ion exchange nature of cellulose sulfate resulted in its use to concentrate viruses (40).

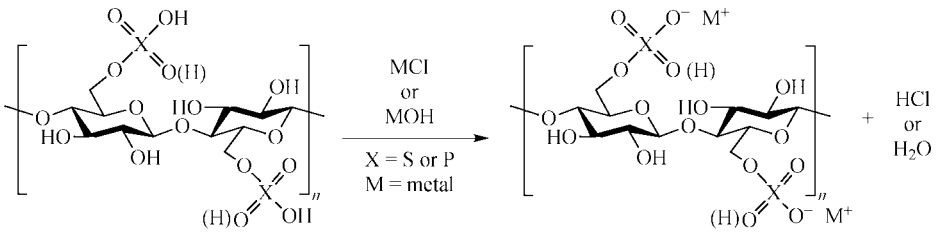

Fig. 7. Use of cellulose phosphate and cellulose sulfate as ion exchangers.

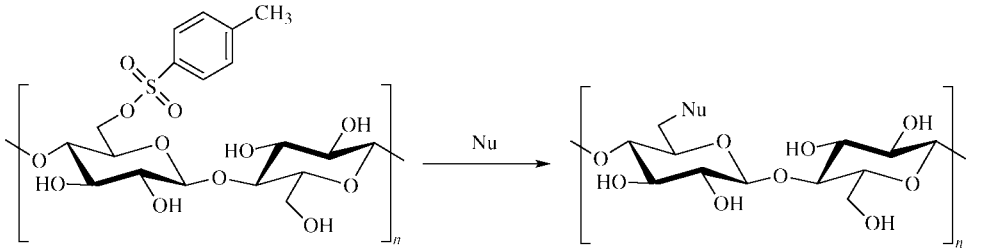
Membrane Applications. Cellulose esters are effective in membrane applications. Ultrafiltration membranes based on cellulose nitrate were first described by Collander in 1924 (41). Cellulose nitrate films cast from mixtures of methyl acetate or acetone with glycerol and mixtures of ether and ethanol produce microfiltration and ultrafiltration membranes, respectively (42). Cellulose nitrate microfiltration membranes typically have 0.02–10 μm diameter pores and 4×10^{-3} – 15 $cm^3/cm^2 \cdot s \cdot atm$ permeability. Cellulose nitrate ultrafiltration membranes typically have 0.003–0.03 μm diameter pores and $(1–100) \times 10^{-4}$ $cm^3/cm^2 \cdot s \cdot atm$ permeability (42). Nitrocellulose membranes are used in numerous biochemical and diagnostic applications and is discussed later.

Cellulose sulfate, in particular C6 sulfates, can be used for preparing polyanion–polycation complexes for pervaporation membranes (43–45).

Synthetic Intermediates. Cellulose sulfonates have been evaluated as synthetic intermediates (27,46–49). Cellulose tosylate activates the C6 hydroxyl for substitution with various nucleophiles (eq. 2 where Nu = Cl^-, N_3^-, $NH_2{-}(CH_2)_m{-}NH_2$, or other nucleophiles).



(2)

Additionally, cellulose sulfonates can also function as a protecting group to prevent reaction of the C6 hydroxyl during esterification reactions (Fig. 8). Cellulose tosylates with degrees of substitution from 0.38 to 2.30 have been reported. Although an effective synthetic tool, the expense of organic solvents utilized and the cost and corrosive nature of tosyl chloride have limited the use of this methodology on a commercial scale.

Medical Applications. Inorganic esters of cellulose have been evaluated in a number of medical/pharmaceutical applications. A few examples include treatment of hypercalciura, use as antiviral agents, reduction of cholesterol levels, orthopedic applications, and blood stabilization.

Sodium cellulose phosphate is used in the treatment of adsorptive hypercalciura and nephrocalcinosis (both a common cause of kidney stones). The ability of inorganic esters of cellulose to function as ion exchangers, described previously, is the key to the use of sodium cellulose phosphate in the treatment of adsorptive hypercalciuria. Hypercalciuria is an increased level of calcium in a patient's urine. This disorder commonly results in painful kidney stones. Sodium cellulose phosphate has been used to complex the calcium ions and thus remove them from the patient and minimize the risk of stone formation (50–54).

It is well established that sulfated polysaccharides play important biological roles (55–63). Cellulose sulfate displays heparin-like activity and to a lesser

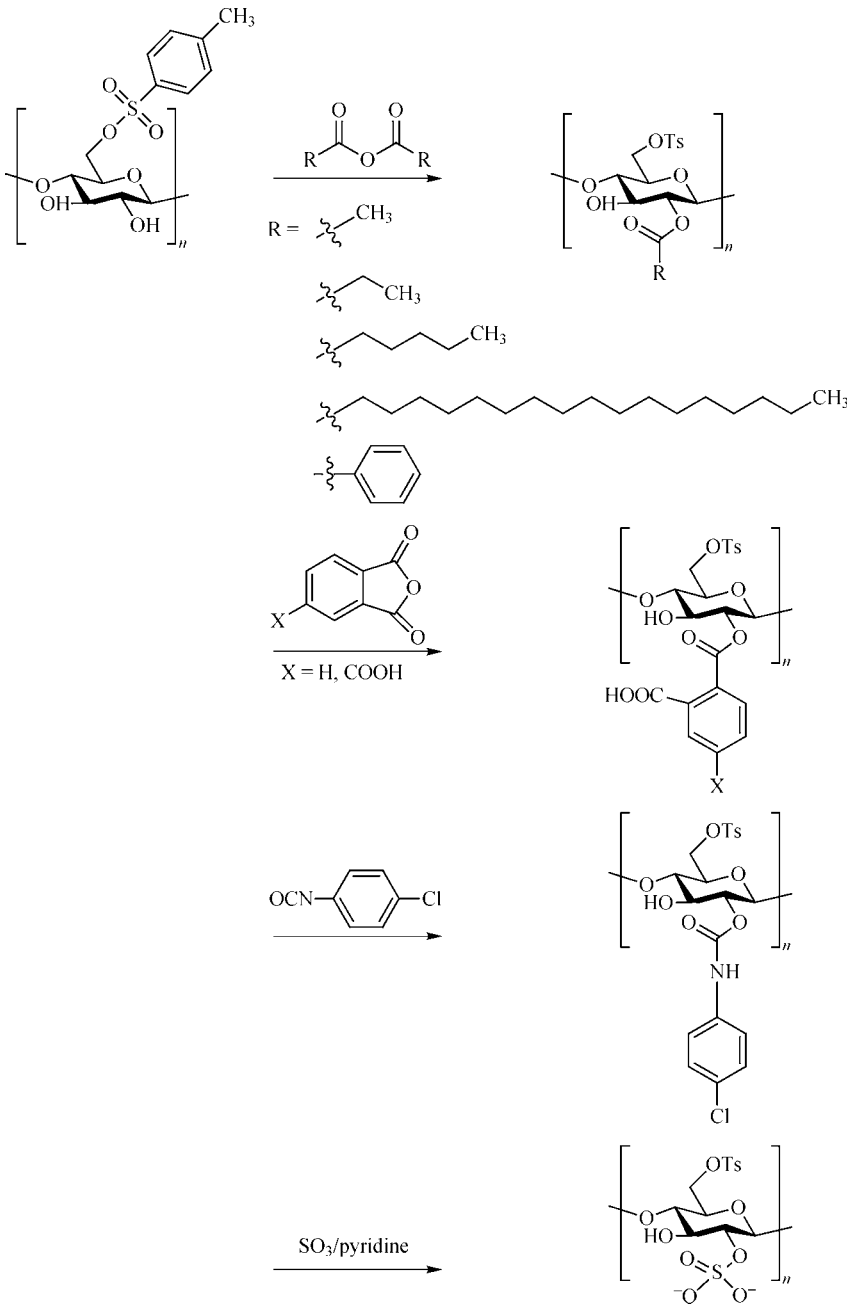


Fig. 8. Subsequent chemical modification of cellulose tosylate.

extent antiviral activity (64). More specifically, cellulose sulfates with a medium to high degree of sulfation at the C2 and C6 positions of the anhydroglucose units are the most active forms of the ester. High molecular weight cellulose sulfate lowers cholesterol levels in humans by inhibiting pancreatic cholesterol esterase

(65,66). Contamination of high molecular weight cellulose sulfate with its low molecular weight counterpart results in a toxic, unusable product. A method to prepare and isolate high molecular weight cellulose sulfate without contamination with low molecular weight cellulose sulfate has been developed (65). Ushercell (a commercial form of sodium cellulose sulfate marketed by Polydex Pharmaceuticals) has been evaluated in the treatment of papilloma virus infection (67). Usher and co-workers have also investigated the use of sodium cellulose sulfate as an antimicrobial agent and a contraceptive (68). Cellulose sulfate with a DS $>$ 1.0 and sodium cellulose sulfate when complexed with (β-hydroxy-γ-trimethylaminopropyl)hydroxyethyl cellulose chloride show excellent anticoagulative property (69,70).

Encapsulation of microorganisms, enzymes, plant cells, and animal cells (including mammalian cells) has been accomplished using a mixture of sodium cellulose sulfate with polydiallyldimethyl ammonium chloride (71,72). Encapsulation of hydridoma cells with cellulose sulfate has provided a means of subcutaneous delivery of monoclonal antibodies. The implant vascularized as early as 15 days after implantation and the "neoorgan" remained an active source of antibodies in mice for several months (73).

Cellulose phosphate has been evaluated in femoral implants to improve the mineralization of biomaterials used in orthopedic applications (74). Cellulose phosphate (with or without bound antimicrobial agents) and cellulose phosphate borate effectively stabilize blood for over 4 years (75).

Biochemical Applications. Cellulose phosphate paper (P81), also called phosphocellulose paper, has been used for enzyme assay applications (76). As with many other applications of cellulose phosphate, the ability of the material to act as an ion exchanger is the key property that leads to its use in enzyme assays. Cellulose phosphate paper quantitatively binds small peptides that contain at least two basic residues and a free amino terminus. This allows for protein kinase assays to be performed and ^{32}P-labeled cofactors [γ-^{32}P]ATP and nonpeptidic byproducts [^{32}P]Pi to be washed away (77).

Even though a number of applications have been demonstrated for cellulose phosphate in the biotechnology laboratory, the use of cellulose nitrate dominates the field. Cellulose nitrate filters and membranes have played key roles in numerous biochemistry and molecular biology discoveries and still play important roles in these laboratories today. Protein and glycoprotein immobilization, absorption of single-stranded DNA (Southern blotting), absorption of single-stranded RNA (Northern blotting), binding of transfer RNA linked to ribosomes, tissue printing, and dialysis are common practices accomplished through the use of nitrocellulose membranes or filters (78–83). The binding of ribosomes and tRNAs to nitrocellulose was used to elucidate the genetic code. Cellulose nitrate is an efficient binder of antibodies and can be used as a solid support for immunoaffinity chromatography (84).

Diagnostic Applications. The binding characteristics of cellulose nitrate membranes have led to their use in numerous biosensor applications, such as in an electrochemical microbial biosensor for EtOH (85) and in glucose oxidase based glucose sensors (86). Cellulose nitrate continues to play an important role in the development of new biosensors as both a solid support and a method for removal of unbound reagents (87–93).

Additionally, cellulose nitrate has been utilized in nonbiological detectors including an indoor radon gas detector. The cellulose nitrate portion of the film-based detector is the active portion for the detection of α-particles (94).

Conclusion

Inorganic esters of cellulose have a valuable place in history, from the birth of the plastics industry to elucidation of the genetic code. It is important not to forget the large number of applications in which these materials have played a role: coatings, explosives, pharmaceuticals, membranes, and synthetic intermediates. Although inorganic esters of cellulose have been around for over 100 years, these materials remain important tools for coatings scientists, explosives experts, and biochemists.

CELLULOSE ESTERS, ORGANIC

Introduction

Cellulose (qv) is one of nature's most abundant structural materials, providing the primary framework of most plants. For industrial purposes cellulose is derived from two primary sources, cotton linters and wood pulp. Linters are derived from the machine by the same name used for removing the short fibers adhering to cotton seeds after ginning and consist essentially of pure cellulose (see COTTON). Wood, on the other hand, contains 40–60% cellulose, which must be extracted by the chemical degradation of the wood structure.

The chemical structure of cellulose is relatively simple (Fig. 1). The simplicity lies in the repetitive utilization of the anhydroglucose unit $C_6H_{10}O_5$ as the building block for chain structure. The term *cellulose* does not designate a specific chemical or homogeneous substance but serves to characterize the homologous series of compounds having specifically a (1→4) β (diequatorial) linkage between each anhydroglucose unit. Many other polyglucoside structural isomers exist (Fig. 2), but few have achieved the widespread commercial applications of cellulose. Thus two samples of cellulose contain the same relative amounts of carbon, hydrogen, and oxygen, but may vary considerably in chemical reactivity and physical properties. Molecular weight and, consequently, the number of anhydroglucose units per molecule or degree of polymerization (DP) vary as a function of the type of cellulose. Molecular weight determinations by the ultracentrifuge method have assigned a molecular weight average of 570,000 to native cellulose. In the synthesis of cellulose derivatives, however, chain cleavage determines the molecular weight of the product and, hence, many of the observed physical properties.

Cellulose esters are commonly derived from natural cellulose by reaction with organic acids, anhydrides, or acid chlorides. Cellulose esters of almost any organic acid can be prepared, but because of practical limitations esters of acids containing more than four carbon atoms have not achieved commercial significance.

Cellulose acetate [9004-35-7] is the most important organic ester because of its broad application in fibers and plastics; it is prepared in multi-ton quantities with degrees of substitution (DS) ranging from that of hydrolyzed, water-soluble

monoacetates to those of fully substituted triacetate (Table 1). Soluble cellulose acetate was first prepared in 1865 by heating cotton and acetic anhydride at 180°C (1). Using sulfuric acid as a catalyst permitted preparation at lower temperatures (2), and later, partial hydrolysis of the triacetate gave an acetone-soluble cellulose acetate (3). The solubility of partially hydrolyzed (secondary) cellulose acetate in

Table 1. Relationship of Cellulose Acetate DS to Acetyl Content and Combined Acetic Acid

DS[a]	Acetyl, wt%[b]	Combined acetic acid, wt%[c]
0.5	11.7	16.3
0.75	16.7	23.2
1.0	21.1	29.4
1.5	28.7	40.0
2.0	35.0	48.8
2.5	40.3	56.2
3.0	44.8	62.5

[b] Unit molecular weight of acetyl group CH_3CO is 43.
[c] Degree of acetylation is often expressed as percent combined acetic acid.

less expensive and less toxic solvents, such as acetone, aided substantially in its subsequent commercial development.

During World War I, cellulose acetate replaced the highly flammable cellulose nitrate coating on airplane wings and the fuselage fabrics. After World War I, it found extensive use in photographic and X-ray films, spun fibers, and molding plastics.

Although cellulose acetate remains the most widely used organic ester of cellulose, its usefulness is restricted by its moisture sensitivity, limited compatibility with other synthetic resins, and relatively high processing temperature. Cellulose esters of higher aliphatic acids, C_3 and C_4, circumvent these shortcomings with varying degrees of success. They can be prepared relatively easily with procedures similar to those used for cellulose acetate. Mixed cellulose esters containing acetate and either the propionate or butyrate moieties are produced commercially in large quantities by Eastman Chemical Co. in the United States. In mid-1987, Bayer AG discontinued the production of mixed esters at Leverkusen in Germany, citing poor economics as the reason for the closing.

Cellulose esters of aromatic acids, aliphatic acids containing more than four carbon atoms, and aliphatic diacids are difficult and expensive to prepare because of the poor reactivity of the corresponding anhydrides with cellulose; little commercial interest has been shown in these esters. Of notable exception, however, is the interest in the mixed esters of cellulose succinates, prepared by the sodium acetate catalyzed reaction of cellulose with succinic anhydride. The additional expense incurred in manufacturing succinate esters is compensated by the improved film properties observed in waterborne coatings (4).

Mixed cellulose esters containing the dicarboxylate moiety, eg, cellulose acetate phthalate, have commercially useful properties such as alkaline solubility and excellent film-forming characteristics. These esters can be prepared by the reaction of hydrolyzed cellulose acetate with a dicarboxylic anhydride in a pyridine or, preferably, an acetic acid solvent with sodium acetate catalyst. Cellulose acetate phthalate [9004-38-0] for pharmaceutical and photographic uses is produced commercially via the acetic acid–sodium acetate method.

Properties

The properties of cellulose esters are affected by the number of acyl groups per anhydroglucose unit, acyl chain length, and the degree of polymerization (DP) (molecular weight). The properties of some typical cellulose triesters are given in Table 2. In this series, with increasing acyl chain length from C_2 to C_6, the melting point, tensile strength, mechanical strength, and density generally decrease, whereas solubilities in nonpolar solvents and resistance to moisture increase. Fewer acyl groups per anhydroglucose unit, ie, increased hydroxyl content, increase the solubility in polar solvents and decrease moisture resistance. The physical and chemical properties of mixed esters vary according to the ratio of the esters used, eg, acetyl to butyl or acetyl to propionyl. General trends of the properties of mixed esters, such as cellulose acetate butyrate [9004-36-8] (CAB), as a function of composition are illustrated in Figure 3, in which increasing butyryl (decreasing

Table 2. Properties of Cellulose Triesters[a]

Cellulose ester	Shrinking point, °C	mp[b], °C	Water tolerance value[c]	Moisture regain[d],%			Density, g/mL	Tensile strength, MPa[e]
				50% rh	75% rh	95% rh		
Cellulose[f]				10.8	15.5	30.5	1.52	
Acetate		306	54.4	2.0	3.8	7.8	1.28	71.6
Propionate	229	234	26.9	0.5	1.5	2.4	1.23	48.0
Butyrate	178	183	16.1	0.2	0.7	1.0	1.17	30.4
Valerate	119	112	10.2	0.2	0.3	0.6	1.13	18.6

[b] Char point is 315°C or higher unless otherwise noted.
[c] Milliliters of water required to start precipitation of the ester from 125 mL of an acetone solution of 0.1% concentration.
[d] At 25% rh, moisture regain for cellulose is 5.4%; for the acetate, 0.6%; for the propionate and butyrate, 0.1%; all others are zero.
[e] To convert MPa to psi, multiply by 145.
[f] Starting cellulose, prepared by deacetylation of commercial, medium viscosity cellulose acetate (40.4% acetyl content).
[g] Char point = 290°C.
[h] Char point = 301°C.

acetyl) content increases flexibility, moisture resistance, and nonpolar solubility, and decreases melting point and density.

The common commercial products are the primary (triacetate) and the secondary (acetone-soluble, ca 39.5% acetyl, 2.45 DS) acetates; they are odorless, tasteless, and nontoxic. Their properties depend on the combined acetic acid content (acetyl, see Table 1 and Fig. 4) and molecular weight. Solubility characteristics of cellulose acetates with various acetyl contents are given in Table 3.

Cellulose triacetate [9012-09-3] has the highest melting point (ca 300°C) of the triesters; CA melting points generally decrease to a minimum of ca 230°C as the acetyl content decreases to 38–39% (secondary acetate).

Table 3. Solubility Characteristics of Cellulose Acetates

Acetyl, %	Soluble in	Insoluble in
43.0–44.8	dichloromethane	acetone
37–42	acetone	dichloromethane
24–32	2-methoxymethanol	acetone
15–20	water	2-methoxymethanol
≤13	none of the above	all of the above

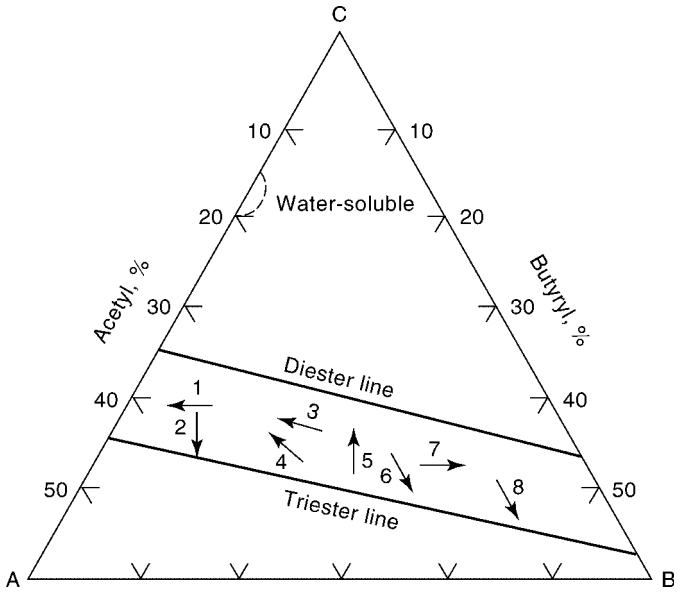

Fig. 3. Effects of composition on physical properties. A, acetyl; B, butyryl; C, cellulose. 1, increased tensile strength, stiffness; 2, decreased moisture sorption; 3, increased melting point; 4, increased plasticizer compatibility; 5, increased solubilities in polar solvents; 6, increased solubilities in nonpolar solvents; 7, increased flexibility; 8, decreased density (6).

Moisture sensitivity and vapor-permeability rate of cellulose acetate increase with decreasing acetyl (increasing hydroxyl) content. Thermoplastic characteristics are greatly improved as the acetyl content is increased from ca 20% [DS (acetyl) = 1] to ca 39% [DS (acetyl) = 2.4] (8).

The bulk density of cellulose acetate varies with physical form from 160 kg/m^3 (10 lb/ft^3) for soft flakes to 481 kg/m^3 (30 lb/ft^3) for hammer-milled powder, whereas the specific gravity (1.29–1.30), refractive index (1.48), and dielectric constant of most commercial cellulose acetates are similar.

In fibers, plastics, and films prepared from cellulose esters, mechanical properties, such as tensile strength, impact strength, elongation, and flexural strength, are greatly affected by the degree of polymerization and the degree of substitution. Mechanical properties significantly improve as the DP is increased from ca 100 to 250 repeat units.

Liquid Crystalline Solutions. Cellulose esters, when dissolved in the appropriate solvents at the proper concentration, show liquid crystalline characteristics similar to those of other rigid chain polymers (9) because of an ordered arrangement of the polymer molecules in solution. Cellulose triacetate dissolved at 30–40 wt% in trifluoroacetic acid, dichloroacetic acid, and mixtures of trifluoroacetic acid and dichloromethane exhibits brilliant iridescence, high optical rotation, and viscosity–temperature profiles characteristic of typical aniostropic phase-containing liquid crystalline solutions (10). Similar observations have been made for cellulose acetate butyrate (11), cellulose diacetate (12), and other cellulose derivatives (13,14). Wet spinning of these liquid crystalline solutions yields fibers

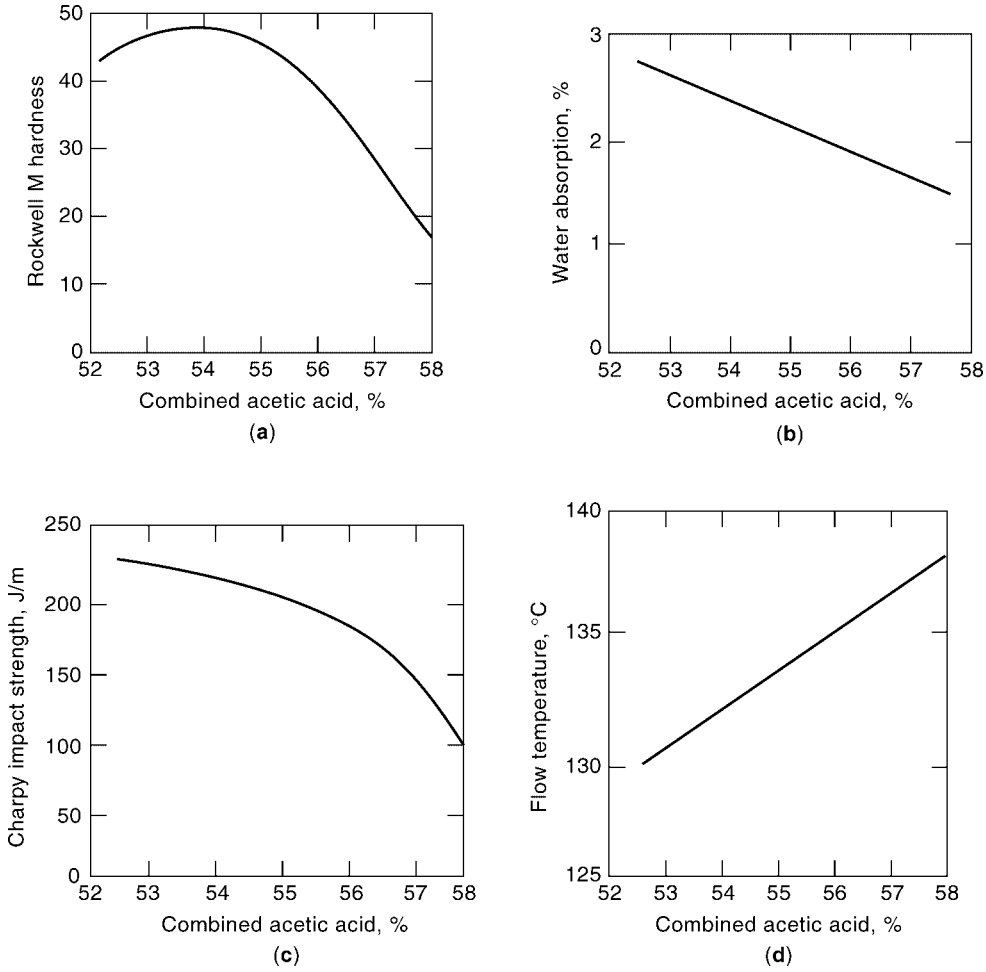

Fig. 4. Effect of combined acetic acid content on (**a**) hardness, (**b**) absorption, (**c**) impact strength, and (**d**) temperature of cellulose acetate (7). To convert J/m to ft·lb/in., divide by 53.38.

with much higher strength properties than fibers normally obtained from cellulose esters (15,16).

Manufacture and Processing

Simple triesters such as cellulose formate [9036-95-7] (6), cellulose propionate [9004-48-2] (8,17), and cellulose butyrate [9015-12-7] (18) have been prepared and their properties studied; none of these triesters is produced in large quantities. Cellulose formate esters, prepared by reaction of cellulose with formic acid, are thermally (19) and hydrolytically (6) unstable. Cellulose propionate and cellulose butyrate triesters are synthesized by methods similar to those used in the preparation of cellulose acetate with propionic or butyric anhydride in the presence of

an acid catalyst (20). These anhydrides, especially butyric, react more slowly with cellulose than acetic anhydride. Therefore, the cellulose must be activated and the temperature must be controlled to avoid degradation. Esterification rates decrease with increasing acyl chain length, and degradation becomes more severe in the following order: acetic < propionic < butyric < isobutyric anhydride. Esterification with isobutyric anhydride is normally so slow that highly activated cellulose must be used and the sulfuric acid catalyst must be distributed uniformly. Swelling agents, eg, water, containing dissolved acid catalyst are used to ensure uniform catalyst distribution for the preparation of isobutyrate esters. The swelling agent is removed by solvent exchange, leaving sorbed acid uniformly distributed in the activated cellulose (21).

Cellulose activated with ethylenediamine [107-15-3] is used to prepare high molecular weight cellulose butyrate (22). Cellulose so activated has a larger measured surface area (120 m^3/g) than cellulose activated with acetic acid (4.8 m^3/g). The diamine is removed with water, followed by solvent exchange with acetic acid and butyric acid before esterification.

More recently, however, a process for the manufacture of ultrahigh molecular weight cellulose esters has been developed by reaction of nonactivated, secondary cellulose with trifluoroacetic acid, trifluoroacetic anhydride, and either an organic acid or acid chloride (23). This process is amenable to a larger variety of organic esters not normally available through conventional means. The technique requires less reaction time and less excess solvent, and it is easier to control the extent of the reaction than conventional sulfuric acid activation. Unfortunately, the handling and toxic nature of trifluoroacetic acid and the anhydride currently limit its utility.

Cellulose valerates have been synthesized by conventional methods using valeric anhydride and sulfuric acid catalyst (24,25). Alternatively, the cellulose is activated by soaking in water, which is then displaced by methylene chloride or valeric acid; the temperature is maintained at $<38^\circ C$ to minimize degradation.

Cellulose esters from aromatic acids are usually prepared from highly reactive regenerated cellulose, and their physical properties do not differ markedly from cellulose esters prepared from the more readily available aliphatic acids. Benzoate esters have been prepared from regenerated cellulose with benzoyl chloride in pyridine–nitrobenzene (26) or benzene (27). These benzoate esters are soluble in common organic solvents such as acetone or chloroform. Benzoate esters, as well as the nitrochloro- and methoxy-substituted benzoates, have been prepared from cellulose with the appropriate aromatic acid and chloroacetic anhydride as the impelling agent and magnesium perchlorate as the catalyst (28).

Cellulose chloroacetates (29) and aminoacetates (29,30), acetate sorbates (31), and acetate maleates (32) have been prepared but are not commercially important. These esters are made from hydrolyzed cellulose acetate with the appropriate anhydride or acid chloride in pyridine.

Cellulose esters of unsaturated acids, such as the acetate methacrylate, acetate maleate (33), and propionate crotonate (34), have been prepared. They are made by treating the hydrolyzed acetate or propionate with the corresponding acyl chloride in a pyridine solvent. Cellulose esters of unsaturated acids are crosslinkable by heat or UV light; solvent-resistant films and coatings can be prepared from such esters.

Amine-containing cellulose esters, eg, the acetate *N,N*-diethylaminoacetate (35) and propionate morpholinobutyrate (34), are of interest because of their unique solubility in dilute acid. Such esters are prepared by the addition of the appropriate amine to the cellulose acrylate crotonate esters or by replacement of the chlorine on cellulose acrylate chloroacetate esters with amines. This type of ester has been suggested for use in controlled release, rumen-protected feed supplements for ruminants (35,36).

Mixed esters, such as cellulose acetate propionate and cellulose acetate butyrate, have desirable properties not exhibited by the acetate or the high acyl triesters. These mixed esters are produced commercially in multi-ton quantities by methods similar to those for cellulose acetate; they are prepared over a wide range of acyl substitutions and viscosities. The ratio of acetyl to higher acyl in the product is proportional to the concentration of components in the esterification solution (Figs. 5 and 6). Thus it is possible to esterify cellulose with propionic or butyric anhydride in the presence of acetic acid to produce the mixed esters. In a similar manner, acetic anhydride can be used in the esterification with either propionic or butyric acid to produce a cellulose ester containing both acyl moieties. The commercial production of cellulose acetate butyrate has been described (37), and the different reactivities of lower anhydrides toward cellulose have been investigated in detail. Cellulose butyrate has been prepared in homogenous solution by the reaction of cellulose in dimethyl sulfoxide (DMSO)–paraformaldehyde with butyric anhydride and pyridine catalyst (38). The maximum degree of substitution is ca 1.8, and the products are soluble in common organic solvents. Dichloromethane has been used in the preparation of cellulose acetate butyrate to prevent excessive degradation and provide an ester with higher molecular weight (39).

Mixed esters containing the dicarboxylate moiety, eg, cellulose acetate phthalate, are usually prepared from the partially hydrolyzed lower aliphatic acid

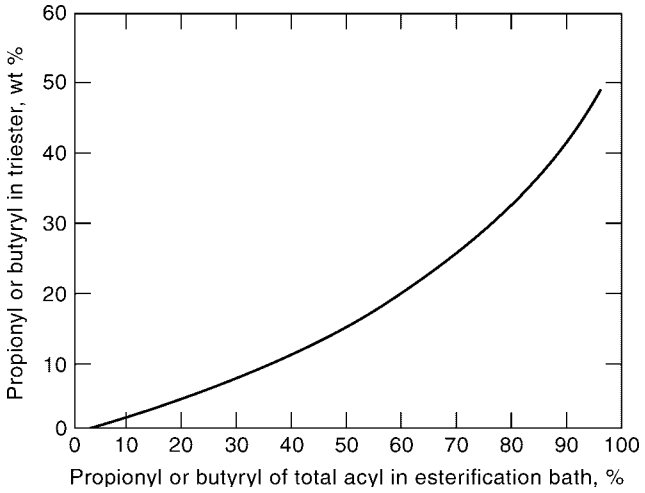

Fig. 5. Composition of cellulose acetate butyrate (propionate) as a function of butyryl (propionyl) content of esterification bath.

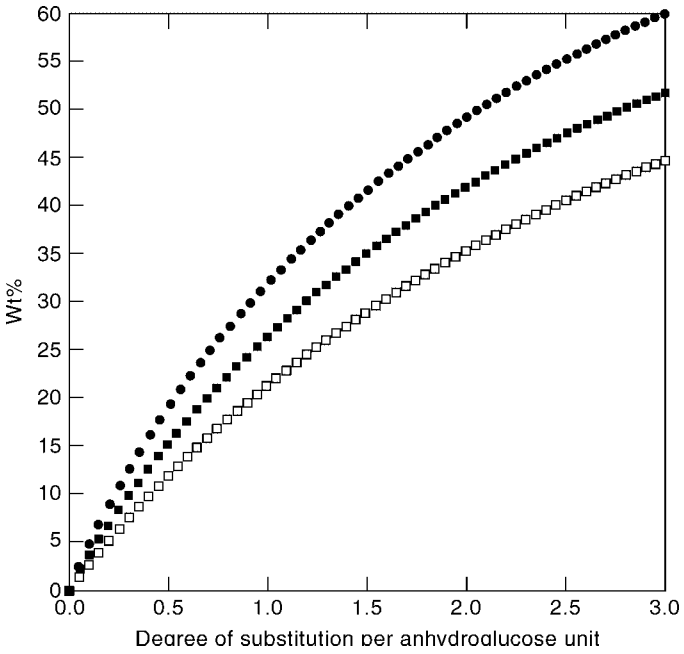

Fig. 6. Conversion of weight percent to degree of substitution per anhydroglucose unit (max. = 3.0), where • is butyryl, ♦ is propionyl, and ◊ is acetyl.

ester of cellulose in acetic acid solvent by using the corresponding dicarboxylic acid anhydride and a basic catalyst such as sodium acetate (40,41). Cellulose acetate succinate and cellulose acetate butyrate succinate are manufactured by similar methods as described in Reference (42).

Other mixed esters, eg, cellulose acetate valerate [55962-79-3], cellulose propionate valerate [67351-41-1], and cellulose butyrate valerate [53568-56-2], have been prepared by the conventional anhydride sulfuric acid methods (24). Cellulose acetate isobutyrate [67351-38-6] (43) and cellulose propionate isobutyrate [67351-40-0] (44) have been prepared with a zinc chloride catalyst. Large amounts of catalyst and anhydride are required to provide a soluble product, and special methods of delayed anhydride addition are necessary to produce mixed esters containing the acetate moiety. Mixtures of sulfuric acid and perchloric acid are claimed to be effective catalysts for the preparation of cellulose acetate propionate in dichloromethane solution at relatively low temperatures (45); however, such acid mixtures are considered too corrosive for large-scale productions.

Mixed esters are hydrolyzed by methods similar to those used for hydrolyzing cellulose triacetate. The hydrolysis eliminates small amounts of the combined sulfate ester, which, if not removed, affects thermal stability. Sulfuric acid is the preferred catalyst for hydrolysis since it is already present in the esterification mixture. On a large scale, partial neutralization of the catalyst may be necessary before hydrolysis. Increasing the amount of water during hydrolysis reduces the rates of viscosity reduction and acyl hydrolysis of cellulose acetate propionate and acetate butyrate esters (46). Several methods of hydrolyzing cellulose esters

of higher aliphatic acids are described (47,48). Acetate phthalate mixed esters preferentially lose acetyl groups when hydrolyzed in aqueous acetic acid media with sulfuric acid catalyst. On the other hand, hydrolysis with a basic catalyst such as sodium or potassium acetate in aqueous acetic acid results in preferential loss of the phthaloyl moiety (49). Ester properties can be modified by changing the DS, ie, by removing acyl groups.

Stabilization. After hydrolysis, precipitation, and thorough washing of the cellulose esters to remove residual acids, the esters must be stabilized against thermal degradation and color development, which may occur during processing, such as extrusion or injection molding. Thermal instability is caused by the presence of oxidizable substances and small amounts of free and combined sulfuric acid (50). The sulfuric acid combines with the cellulose almost quantitatively and most of it is removed during the latter stages of hydrolysis. The remaining sulfuric acid can be neutralized with alkali metal salts, such as sodium, calcium, or magnesium acetate, to improve ester stability. The combined sulfate ester may also be removed by treatment in boiling water or at steam temperatures in an autoclave. Treatment with aqueous potassium or calcium iodide reportedly stabilizes the cellulose acetate against thermal degradation (51).

Dialkyl esters of 3,3′-thiodipropionic acid (52), cyclic phosphonites such as neopentylphenyl phosphite, derivatives of phosphaphenathrene-10-oxide (53), secondary aromatic amines such as diphenylamine (54), and epoxidized soybean oils (55) are effective stabilizers for preventing discoloration of cellulose esters during thermal processing.

Chemical cellulose esters are relatively stable to UV radiation since they lack aromatic chromophores. Even so, exposure to UV radiation may cause some chain scission and loss of physical properties in cellulose esters exposed to outdoor environments; esters formulated for such use must be stabilized accordingly. Some resorcinol and benzophenone derivatives, such as resorcinol monobenzoate and 2-hydroxy-4-methoxybenzophenone, are reportedly excellent UV-light stabilizers for cellulose esters (56,57). Other stabilizers include piperidine derivatives (58) and substituted triazole compounds alone (59) and in combination with resorcinol monobenzoate (60).

Cellulose Acetate. Almost all cellulose acetate, with the exception of fibrous triacetate, is prepared by a solution process employing sulfuric acid as the catalyst with acetic anhydride in an acetic acid solvent. The acetylation reaction is heterogeneous and topochemical wherein successive layers of the cellulose fibers react and are solubilized in the medium, thus exposing new surfaces for reaction. The reaction course is controlled by the rates of diffusion of the reagents into the cellulose fibers, and therefore the cellulose must be swollen or activated before acetylation to achieve uniform reaction and avoid unreacted fibers in the solution (61).

Cellulose dissolved in suitable solvents, however, can be acetylated in a totally homogeneous manner, and several such methods have been suggested. Treatment in dimethyl sulfoxide (DMSO) with paraformaldehyde gives a soluble methylol derivative that reacts with glacial acetic acid, acetic anhydride, or acetyl chloride to form the acetate (62). The maximum degree of substitution obtained by this method is 2.0; some oxidation also occurs. Similarly, cellulose can be acetylated in solution with dimethylacetamide–paraformaldehyde and

dimethylformamide–paraformaldehyde with a potassium acetate catalyst (63) to provide an almost quantitative yield of hydroxymethylcellulose acetate.

Several derivatives of cellulose, including cellulose acetate, can be prepared in solution in dimethylacetamide–lithium chloride (64). Reportedly, this combination does not react with the hydroxy groups, thus leaving them free for esterification or etherification reactions. In another homogeneous-solution method, cellulose is treated with dinitrogen tetroxide in dimethylformamide (DMF) to form the soluble cellulose nitrite ester; this is then ester-interchanged with acetic anhydride (65). With pyridine as the catalyst, this method yields cellulose acetate with DS $\leq$ 2.0.

In the fibrous acetylation process, part or all of the acetic acid solvent is replaced with an inert diluent, such as toluene, benzene, or hexane, to maintain the fibrous structure of cellulose throughout the reaction. Perchloric acid is often the catalyst of choice because of its high activity and because it does not react with cellulose to form acid esters. Fibrous acetylation also occurs upon treatment with acetic anhydride vapors after fiber impregnation with a suitable catalyst such as zinc chloride (66).

An apparatus for the continuous fibrous acetylation of cellulose in benzene has been described (67,68). The process involves continuous activation, acetylation, partial saponification of the resulting triacetate, and drying of the product.

Activation of Cellulose. The activation required depends on the source of cellulose (cotton linter or wood pulp), purity, and drying history. Typical specifications for an acetylation-grade cellulose are given in Table 4. Cellulose that has never been dried or has been mildly dried to ca 5% moisture requires little, if any, further activation.

Normally, water or aqueous acetic acid is the activating agent; glacial acetic acid may also be used. Water is more effective because it swells the fibers more than other agents and alters the hydrogen bonding between the polymer chains to provide a greater surface area for reaction. When water or aqueous acids are used, the cellulose must be dehydrated by displacing the water with acetic acid

Table 4. Typical Specifications for Acetylation-Grade Pulp[a]

before the start of acetylation. Commercially, it is not unusual to activate cellulose with glacial acetic acid containing a small part of the total required sulfuric acid catalyst; this reduces the molecular weight of the cellulose as needed to obtain a satisfactory product. The efficiency of activation is increased by increased temperature, time, amount of catalyst, and lower acetic acid–cellulose ratio. Several other swelling agents and methods for cellulose activation have been reported but have little commercial value because of cost and performance considerations.

Ethylenediamine (69,70), benzyl alcohol and acetone (71), ethylene glycol (72), and C_2–C_{18} carboxylic acids (73) are claimed to increase the reactivity of cellulose toward acetylation. Sodium hydroxide and liquid ammonia (70) are excellent swelling agents and have been used to activate cellulose before esterification. Ultrasonic treatment of cellulose slurries (74) reportedly swells the fibers and improves reactivity.

In one process to produce highly activated cellulose for acetylation, cellulose is treated with NaOH (mercerization) followed by a hydroxyalkylating agent, eg, ethylene oxide or propylene oxide, to give a cellulose hydroxyalkyl ether with a DS of 0.05–0.3 (75). The resulting water-insoluble material is highly reactive to conventional acetic anhydride–sulfuric acid acetylation.

Catalysts for Acetylation. Sulfuric acid is a convenient catalyst for esterifying cellulose. The role of sulfuric acid during acetylation has been discussed (76,77). In the presence of acetic anhydride, sulfuric acid rapidly and almost quantitatively forms the cellulose sulfate acid ester (76). Even in the absence of anhydride, the sulfuric acid is physically or mechanically retained (sorbed) on the cellulose. The degree of absorption is a measure of the reactivity or accessibility of different celluloses.

Sulfuric acid reacts with acetic anhydride to form acetylsulfuric acid (78). This reaction is favored by low temperature and high anhydride concentration. In cellulose acetylation, probably both sulfuric acid and acetylsulfuric acid exist and react with cellulose to form cellulose sulfate acid ester.

Perchloric acid is a well-known acetylation catalyst, especially in the fibrous method of preparing cellulose triacetate. Unlike sulfuric acid, perchloric acid does not combine with cellulose (79), ie, it does not form esters, and therefore virtually complete acetylation (DS 3.0, 44.8% acetyl) occurs. However, the extremely corrosive nature of perchloric acid and explosive nature of its salts have precluded its use industrially as an acetylation catalyst.

Zinc chloride is a Lewis acid catalyst that promotes cellulose esterification. However, because of the large quantities required, this type of catalyst would be uneconomical for commercial use. Other compounds such as titanium alkoxides, eg, tetrabutoxytitanium (79), sulfate salts containing cadmium, aluminum, and ammonium ions (80), sulfamic acid, and ammonium sulfate (81) have been reported as catalysts for cellulose acetate production. In general, they require reaction temperatures above 50°C for complete esterification. Relatively small amounts ($\leq$ 0.5%) of sulfuric acid combined with phosphoric acid (82), sulfonic acids (eg, methanesulfonic), or alkyl phosphites (83) have been reported as good acetylation catalysts, especially at reaction temperatures above 90°C.

Hydrolysis. The primary functions of hydrolysis are to remove some of the acetyl groups from the cellulose triester and to reduce or remove the combined acid sulfate ester to improve the thermal stability of the acetate.

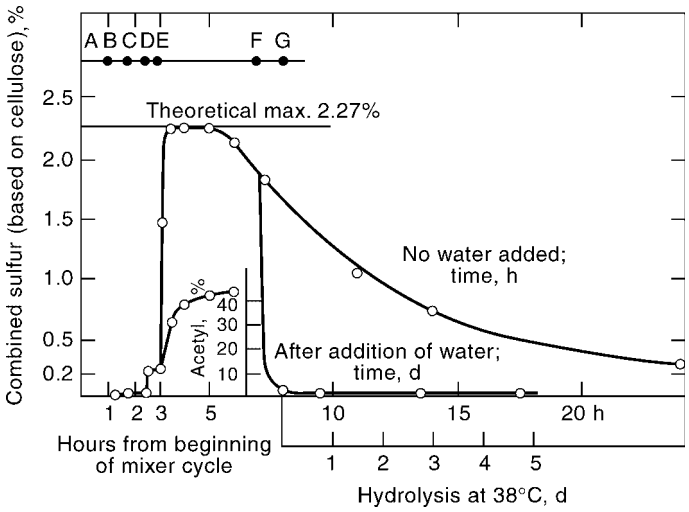

Fig. 7. Combined sulfur during preparation of cellulose acetate; hydrolysis of sulfate and esters (5). Acetylation schedule: **A**, mixer charged with linters and acetic acid; **B**, minor portion of catalyst added; **C**, began cooling to 18°**C**; **D**, acetic anhydride added and continued cooling to 16°**C**; **E**, significant portion of catalyst added; **F**–**G**, water added during 1 h.

The acetylation reaction is stopped by the addition of water to destroy the excess anhydride, causing rapid hydrolysis of the combined sulfate acid ester (Fig. 7). This is followed by a much slower rate of hydrolysis of the acetyl ester groups. The rate of hydrolysis is controlled by temperature, catalyst concentration, and, to a lesser extent, by the amount of water. Higher temperatures and catalyst concentrations increase the rate of hydrolysis. Higher water content slightly increases the hydrolysis rate and helps minimize degradation (84). The amount of water also influences the ratio of primary to secondary hydroxy groups in the hydrolyzed cellulose acetate; high water content favors primary hydroxyl formation (85).

In commercial processes, the water content during hydrolysis ranges from 5 to 20 wt% based on total liquids and depends on the temperature and the final product desired. Hydrolysis reactions can be performed at temperatures ranging from ca 38°C to pressurized reactions at 229°C (86). In a continuous process at 129°C, a triacetate solution is passed vertically upward through three consecutive chambers containing rotating disks to maximize plug flow of the solution (87). Kinetics of cellulose triacetate hydrolysis have been investigated (88) and, with sulfuric acid as the catalyst, the rate constant was found to be linear for both catalyst concentration and water content.

The rate of hydrolysis of cellulose acetate can be monitored by removing samples at intervals during hydrolysis and determining the solubility of the hydrolyzed acetate. When the desired DS is reached, the hydrolysis is stopped by neutralizing the catalyst with magnesium, calcium, or sodium salts dissolved in aqueous acetic acid.

Precipitation and Purification. During the hydrolysis, control tests are made by turbidimetric titration of samples taken intermittently. When the desired degree of hydrolysis is reached, the ester is precipitated from the reaction

solution into water. It is important for the precipitate to have the proper texture for subsequent washing to remove acid and salts for thermal stabilization. Before precipitation, the reaction solution is usually diluted with additional aqueous acetic acid to reduce the viscosity. If a flake texture is desired, the solution is poured into a vigorously stirred, 10–15% aqueous acetic acid. To precipitate the acetate in powder form, dilute acetic acid is added to the stirred reaction solution. In both cases, the precipitated ester is suspended in 25–30% aqueous acid solutions and finally washed with deionized water. The dilution, precipitation temperature, agitation, and strength of the acid media must be controlled to ensure uniform texture.

Another method for direct precipitation of cellulose acetate powder suitable for extrusion into plastics is described (89). The reaction solution is precipitated with dilute aqueous acetic acid at 80–85°C in the presence of a coagulant such as isopropyl acetate. The resulting powder particles have a higher bulk density and absorb plasticizers more readily than powders obtained by the usual methods.

Granules can be precipitated and formed by extruding the viscous reaction mixture through a circular die containing several holes over which a knife blade rotates to cut the strands into granules (90). The granules are simultaneously slurried in dilute acetic acid to harden the particles for further washing.

Solution Process. With the exception of fibrous triacetate, practically all cellulose acetate is manufactured by a solution process using sulfuric acid as the catalyst with acetic anhydride in an acetic acid solvent. An excellent description of this process is given (84). In the process (Fig. 8), cellulose (ca 400 kg) is treated with ca 1200 kg acetic anhydride in 1600 kg acetic acid solvent and 28–40 kg sulfuric acid (7–10% based on cellulose) as catalyst. During the exothermic reaction, the temperature is controlled at 40–45°C to minimize cellulose degradation. After the reaction solution becomes clear and fiber-free and the desired viscosity has been achieved, sufficient aqueous acetic acid (60–70% acid) is added to destroy the excess anhydride and provide 10–15% free water for hydrolysis. At this point, the sulfuric acid catalyst may be partially neutralized with calcium, magnesium, or sodium salts for better control of product molecular weight.

The cellulose acetate is hydrolyzed in solution at 40–50°C for varying lengths of time (4–20 h) until the desired DS is obtained; at this point, the ester is precipitated with dilute aqueous acetic acid. The precipitate is hardened in 25–30% aqueous acetic acid, which is drained off and recovered.

The ester is washed thoroughly in iron-free water to remove acid and salts; these wash liquids are sent for acid recovery. The final wash may contain some sodium, calcium, or magnesium ions to stabilize traces of sulfate esters remaining on the cellulose acetate.

Recent Developments. A considerable amount of cellulose acetate is manufactured by the batch process, as described previously. In order to reduce production costs, efforts have been made to develop a continuous process that includes continuous activation, acetylation, hydrolysis, and precipitation. In this process, the reaction mixture (ie, cellulose, anhydride, catalyst, and solvent) passes continuously through a number of successive reaction zones, each of which is agitated (91,92). In a similar process, the reaction mass is passed through tubular zones in which the mixture is forced through screens of successively small openings to homogenize the mixture effectively (93). Other similar methods for continuous acetylation of cellulose have been described (94,95).

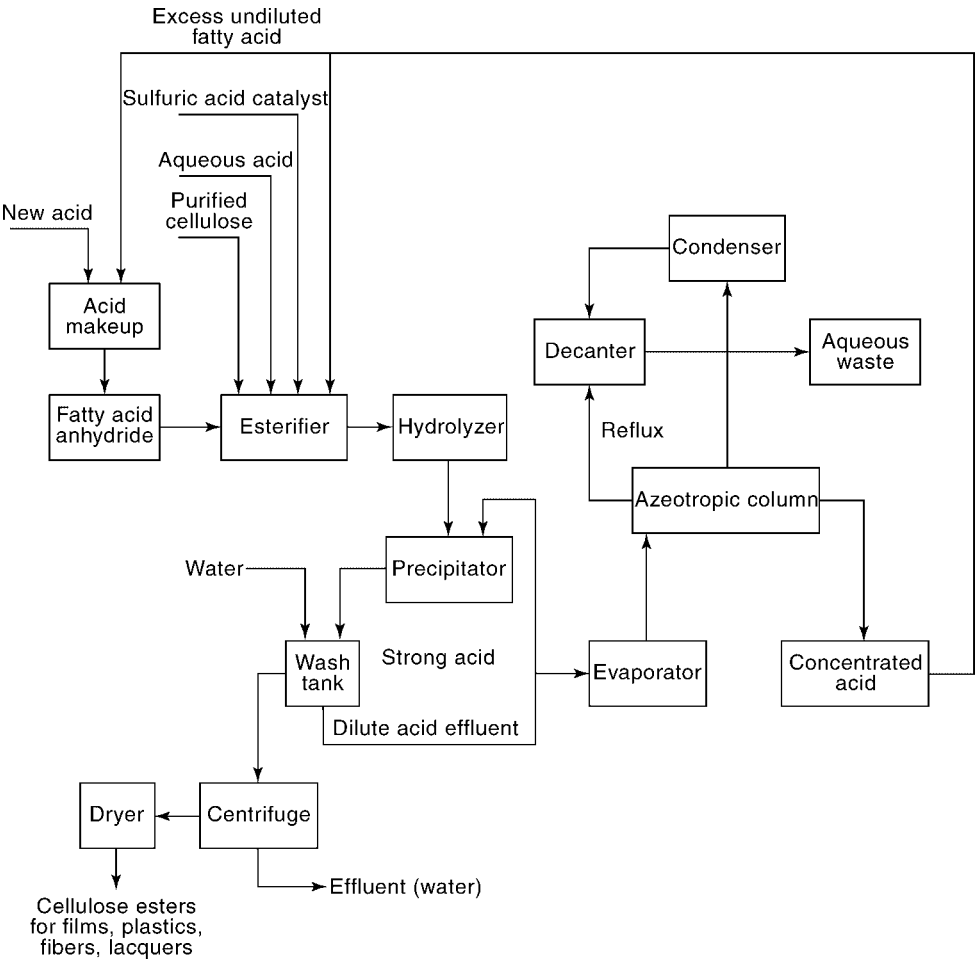

Fig. 8. Process flow sheet for cellulose esters.

Cellulose acetate with improved solubility properties can be prepared from low quality wood pulps by multistage addition of the components (96) or by interrupting the reaction in the early stages, filtering, and continuing the acetylation with fresh reactants (97,98).

In an integrated continuous process, cellulose reacts with acetic anhydride prepared from the carbonylation of methyl acetate with carbon monoxide. The acetic acid liberated reacts further with methanol to give methyl acetate, which is then carbonylated to give additional acetic anhydride (99,100).

High temperature acetylation of cellulose above 50°C produces cellulose acetate from low purity wood pulp cellulose in shorter reaction times. In a high temperature method recently disclosed (101), cellulose reacts with 200–400% acetic anhydride in the presence of <5% acid catalyst at 68–85°C for 3–20 min. After the acid catalyst is neutralized with magnesium acetate, the cellulose acetate is

hydrolyzed at 120°C for 2 h (102). Several modified catalyst systems have been developed for acetylation of cellulose above 90°C (88,89).

Economic Aspects

The principal use of cellulose acetate flake is in the production of filter tow. Other uses include the manufacture of textile fibers and in compounding to produce sheet, molded products, film, and LCD displays.

In 2001, the global cellulose acetate fiber industry was valued at $2.8 billion. Cigarette filter applications accounted for $2.2 billion, and textile yarns accounted for $0.6 billion (103). In 2002, the total consumption of cellulose acetate flake in the United States, Western Europe, Japan, and China was 655×10^3 t (104).

Cellulose acetate is a mature product and growth has declined in many areas of the world except China. In 1987, the Chinese government decided to produce filtered cigarettes. Production of filtered cigarettes in China grew from almost 0% in 1987 to 97.3% on 2000. Per capita cigarette use is growing in Eastern Europe and other Asian countries. China's demand for cellulose acetate tow is only partially supplied by domestic product. Increased manufacture in China is expected, but will just replace imports since the market is now mature (103).

The global supply of cellulose acetate fibers is controlled by a few companies. These companies produce both tow and textile fibers. Celanese Acetate holds 29% of the world supply. Voridian, a division of the Eastman Chemical Co., follows with a 24% share. The remaining 32% of supply is manufactured by Rhodia, Daicel, Mitsubishi Rayon, and Acordis. There has been a recent trend of these companies closing down their smaller flake-production units and getting their product from larger and more efficient locations (104).

The oversupply of polyester fibers and the trend toward casual dress has had a negative impact on the cellulose acetate textile market. Use in plastics applications has also declined. Worldwide demand for fiber declined at the rate of 9% per year for the period 1996–2001. It is estimated that the decline will continue at the rate of 3% per year during the period 2001–2006.

Analytical and Test Methods

Standardized test methods for analyzing the chemical composition, viscosity, and physical properties of cellulose esters have been adopted by the ASTM and are described in substantial detail (105).

Degree of Substitution and DS Distribution. For cellulose esters, the substitution level is usually expressed in terms of degree of substitution (DS); that is, the average number of substituents per anhydroglucose unit (AGU). Cellulose contains three hydroxyl groups in each AGU unit that can be substituted; therefore DS can have a value between 0 and 3. Because DS is a statistical mean value, a value of 1 does not assure that every AGU has a single substituent. Any given cellulose ester molecule is a mixture of tri-, di-, mono-, and unsubstituted monomers. The physical properties commonly associated with commercial cellulose acetates,

cellulose acetate butyrates, and cellulose acetate propionates are, in many cases, directly related to the degree of substitution as well as the overall substitution pattern. The degree of substitution or acetyl content of cellulose acetate has traditionally been determined by saponifying a known amount of the ester with an excess of standard sodium hydroxide solution in the presence of swelling agent or solvent. The excess sodium hydroxide is back-titrated with a standard solution of hydrochloric acid to determine the total acetyl content. The relative amounts of acetyl, propionyl, and butyryl in cellulose mixed esters, however, are determined by partition analysis in butyl acetate–water mixtures. The esters are saponified in sodium hydroxide, and phosphoric acid is added to liberate the organic acids from their sodium salts. The acids are partitioned between butyl acetate and water and their mole ratios are determined by comparison to carefully prepared control standards.

The acetyl content of cellulose acetate may be calculated by difference from the hydroxyl content, which is usually determined by carbanilation of the ester hydroxy groups in pyridine solvent with phenyl isocyanate [103-71-9], followed by measurement of UV absorption of the combined carbanilate. Methods for determining cellulose ester hydroxyl content by near-infrared spectroscopy (106) and acid content by NMR spectroscopy (107) and pyrolysis gas chromatography (108) have been reported.

With the advent of high resolution proton and carbon nuclear magnetic resonance spectroscopy, however, determining the DS and the DS distribution of mixed ester systems by aqueous saponification has become obsolete. Numerous studies have shown NMR to be a fundamental tool for probing the microscopic behavior of a wide variety of synthetic polymers and biomacromolecules (109,110). In the past, however, most spectral assignments required laboriously prepared derivatives containing a trideuterioacetyl or trideuteriomethyl group at a predetermined position or by comparison to spectra of mono- or oligosaccharides (111). These methods proved to be limited in detail because of line broadening and small differences in chemical shifts. Understanding the basic relationships between macroscopic properties and the microstructure of these biopolymer derivatives through NMR is the direction of much cellulose esters research.

Determining the degree of substitution using standard proton NMR relies on the integral ratio between the cellulosic ring protons ($\sim$5.0–2.9δ) and the ester alkyl protons ($\sim$ 1.2 δ for butyryl and propionyl and $\sim$2.0δ for acetyl methyl groups). This simple procedure is used extensively to determine the extent of esterification and is currently the fastest, easiest way for determining the DS of mixed cellulose esters.

Standard proton NMR techniques provide information on the degree of substitution and ester ratios in mixed ester systems, but it has been the development of two-dimensional techniques that has allowed the greatest insight into the microstructure of the cellulosic polymer (112–115). The combination of ^{1}H and ^{13}C NMR spectroscopy has, for example, been applied to cellulose triacetate for determination of its configuration (116), identification of the chemical shifts of ring protons and carbons (113), and determination of the distribution of acetyl groups over C_2, C_3, and C_6 (114,117). More complex experiments such as insensitive nuclei assigned by polarization transfer (INAPT) and nuclear Overhauser exchange

spectroscopy (NOESY) have been successfully applied toward the spectral assignments of most common triesters, the results of which are listed in Table 5. With INAPT, the lack of sensitivity that is commonly associated with two-dimensional NMR techniques is generally avoided. This increased sensitivity circumvents the need for ^{13}C enrichment and decreases the demand on instrument time.

Other two-dimensional techniques, such as correlation spectroscopy (COSY) (118), DEPT (119), Homonuclear Hartmann–Hahn (HOHAHA), solid state (120), etc, give varying degrees of success when applied to the structure-property relationship of cellulose triesters. The recent application of $^{1}H—^{13}C$ multiple-bond correlation (HMBC) spectroscopy for the unambiguous assignment of cellulose mixed esters has successfully demonstrated the utility of NMR for the structure elucidation of complex cellulose esters (121). It is this unique ability to provide detailed information on intermolecular interactions of cellulose esters in coatings (115) or in polymeric blends that continues to put NMR spectroscopy well ahead of other analytical techniques.

Viscosity. The viscosity of cellulose esters, a measure of the degree of polymerization, is determined by the falling-ball method. The time in Saybolt units (SU) required for an aluminum or stainless-steel ball of specified diameter to go through a specified distance in a solution of the cellulose ester is determined. The choice of solvents used to prepare the solutions for viscosity determination depends on the DS of the cellulose ester; the concentration of ester in the solution is normally 20wt%. Dilute-solution viscosity (intrinsic viscosity) is determined by using a solution of 0.25-g ester dissolved in 100 mL of solvent. The flow time of the solution through a specially designed capillary viscometer is compared to that of the pure solvent. Methods of calculating molecular weight from intrinsic viscosity of cellulose esters have been reported (122,123).

Thermal Properties. The thermal stability of cellulose esters is determined by heating a known amount of ester in a test tube at a specific temperature for a specified length of time, after which the sample is dissolved in a given amount of solvent and its intrinsic viscosity and solution color are determined. Solution color is determined spectroscopically and is compared to platinum–cobalt standards. Differential thermal analysis (DTA) has also been reported as a method for determining the relative heat stability of cellulose esters (124).

The thermal transitions of a cellulose ester such as the glass-transition temperature and the melting point are usually determined by differential scanning calorimetry (DSC) (Fig. 9), which measures the flow of heat into and out of a sample. Generally a first heating run is necessary in order to erase any previous thermal processing characteristics, ie, regions of crystallinity. A slow cool followed by a reheat above the melt temperature provides information on the glass-transition temperature, crystallization temperature (exothermic), and the melting temperature (endothermic). This information is essential for the development of new thermoplastics.

Similar information can be obtained from analysis by dynamic mechanical thermal analysis (DMTA). DMTA measures the deformation of a material in response to vibrational forces. The dynamic modulus, the loss modulus, and mechanical damping are determined from such measurements. Detailed information on the theory of DMTA is given (125).

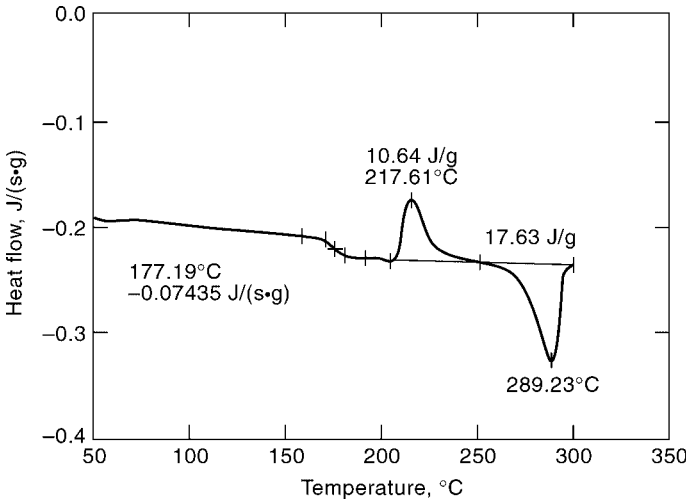

Fig. 9. Differential scanning calorimetry of cellulose triacetate. Second heating at 20°C/min.; glass-transition (T_g) temperature = 177°C; crystallization on heating (T_{ch}) = 217°C; melting temperature (T_m) = 289°C. To convert J to cal, divide by 4.184.

Determination of the thermal decomposition temperature by thermal gravimetric analysis (TGA) defines the upper limits of processing. The TGA for cellulose triacetate is shown in Figure 10. Comparing the melt temperature (289°C) from the DSC in Figure 9 to the onset of decomposition in Figure 10 defines the processing temperature window at which the material can successfully be melt extruded or blended.

Molecular Weight. The molecular weight distribution of cellulose esters is normally determined by gel-permeation chromatography (GPC) (126) in which the ester, dissolved in a suitable solvent, is eluted through a column of porous crosslinked polystyrene. The elution profiles are compared to narrow molecular weight polystyrene standards to obtain the molecular weight or DP distribution. Other

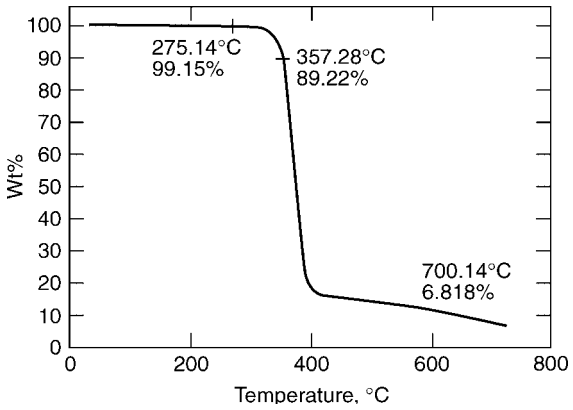

Fig. 10. Thermogravimetric analysis of cellulose triacetate. Method: 20°C/min to 700°C, in (N_2), at a purging rate of 40 mL/min.

methods, such as fractional precipitation and fractional extraction, although considerably more laborious, may be used to determine DP and DS distribution of cellulose esters (127). The DP of cellulose triacetate has been determined by GPC using a styrene–divinylbenzene copolymer column with an assigned peak molecular weight of approximately 60,000. Other solvents such as tetrahydrofuran (THF) and NMP have also been shown to solvate secondary cellulose acetates and mixed esters for GPC analysis (128).

Health and Safety Factors

The vapors of the organic solvents used in the preparation of cellulose ester solutions represent a potential fire, explosion, or health hazard. Care should be taken to provide adequate ventilation to keep solvent vapor concentrations below the explosive limits. Mixing equipment should be designed to ensure that solvent temperatures do not approach their flash point during the mixing cycle. All equipment must be electrically grounded to prevent static discharge, and appropriate precautions should be followed as recommended by the manufacturer of the solvents.

Mixing cellulose esters in nonpolar hydrocarbons, such as toluene or xylene, may result in static electricity buildup that can cause a flash fire or explosion. When adding cellulose esters to any flammable liquid, an inert gas atmosphere should be maintained within the vessel (129). This risk may be reduced by the use of conductive solvents in combination with the hydrocarbon or by use of an antistatic additive. Protective clothing and devices should be provided.

Cellulose esters, like most dry organic materials in powder form, are capable of creating dust explosions (130). The explosion at Bayer's cellulose acetate plant at Dormagen, Germany, in 1976 can attest to the explosive potential of dust. Damage to the plant was estimated at between DM 5–10 million (131).

Cellulose esters are considered nontoxic and may be used in food-contact applications. However, since cellulose esters normally are not used alone, formulators of coatings and films for use in food packaging should ensure that all ingredients in their formulations are cleared by the United States Food and Drug Administration for such use.

Uses

The cellulose esters with the largest commercial consumption are cellulose acetate, including cellulose triacetate, cellulose acetate butyrate, and cellulose acetate propionate. Cellulose acetate is used in textile fibers, plastics, film, LCD displays, sheeting, and lacquers. The cellulose acetate used for photographic film base is almost exclusively triacetate; some triacetate is also used for textile fibers because of its crystalline and heat-setting characteristics. The critical properties of cellulose acetate as related to application are given in Table 6.

Large quantities of secondary cellulose acetate are used worldwide in the manufacture of filter material for cigarettes. Because of its excellent clarity and ease of processing, cellulose acetate film is widely used in display packaging and

Table 6. Uses and Critical Properties of Cellulose Acetate[a]

	Use[b]

[c] Concentrated solution viscosity higher than predicted for the intrinsic viscosity.

extruded plastic film for decorative signs. Injection-molded plastics of cellulose acetate are used in toothbrush handles, computer brushes, and a large variety of other applications (6).

Low viscosity cellulose acetate is used in lacquers and protective coatings for paper, metal, glass, and other substrates and as an adhesive for cellulose photographic film because of its quick bonding rate and excellent bond peel strength (132) (see COATINGS). Heat-sensitive adhesives for textiles have also been prepared from cellulose acetate (133). Extruded cellulose acetate film makes an excellent base for transparent pressure-sensitive tape (134) (see ADDITIVES).

Cellulose acetate films, specially cast to have a dense surface and a porous substructure, are used in reverse osmosis to purify brackish water (135–138) in hollow fibers for purification of blood (artificial kidney) (139), and for purifying fruit juices (140,141) (see MEMBRANE TECHNOLOGY).

Compaction of cellulose acetate desalination membranes, causing reduction in throughput and performance with time, can be significantly reduced by irrigation grafting of styrene onto the membrane (142).

Eyeglass frames made of cellulose acetate plasticized with diglycerol esters do not exhibit opaqueness at the frame–lens junction with polycarbonate plastic lenses (143,144).

Biodegradable film (145), foam-molding compositions (eg, sponges) (146), tobacco substitutes (147), and microencapsulated drug-delivery systems (148) are potentially new and useful applications for cellulose acetate esters.

With the renewed interest in environmentally friendly products, cellulose esters are being reevaluated as a natural source of biodegradable thermoplastics. Cellulose acetates are biodegradable, with the rate of biodegradation increasing with decreasing DS (149). Films prepared from a cellulose acetate with a DS of 2.5 were shown to require only a 10–12 day incubation period for extensive degradation in an *in vitro* enrichment assay. Similarly, films prepared from a cellulose acetate with a DS of 1.7 saw 70% degradation in 27 days in a wastewater treatment facility, whereas films prepared from a cellulose acetate with a DS of 2.5 required approximately 10 weeks for similar degradation to occur. The results of this work demonstrate that cellulose acetate fibers and films can be designed to be environmentally nonpersistant.

Cellulose acetate propionate and butyrate esters have numerous applications, such as sheeting, molding plastics, film products, lacquer coatings, and melt dip coatings. The properties of propionate and acetate propionate esters ordinarily lie between those of cellulose acetate and acetate butyrate. The acetate propionate mixed esters have traditionally covered a narrow composition range compared to the range of acetate butyrate esters. Table 7 shows uses and a range of commercial compositions of cellulose acetate butyrate esters. Through proper variation of acetyl and butyryl contents, the esters can be adapted to a broad range of applications. Cellulose acetate propionate and acetate butyrate are thermoplastic; properly formulated, these esters are processible by methods such as injection molding and extrusion, and can be dissolved and cast into films from a variety of solvents (see FILMS, MANUFACTURE). The mixed esters are generally more compatible with various plasticizers (qv) and synthetic resins than the acetates, and their films possess excellent clarity and toughness. For example, cellulose acetate butyrate is compatible with polyester, acrylic, vinyl, and alkyd resins (qv), depending on the amount of butyryl substitution and the degree of hydrolysis of the esters.

Cellulose acetate butyrates with high butyryl content and low viscosity are soluble in inexpensive lacquer solvents. They are widely used in lacquers for protective and decorative coatings applied to automobiles and wood furniture.

Higher butyryl esters, formulated with acrylic polymers, provide coatings with excellent weather resistance, good colorfastness and dispersibility, and good flow properties (151). Formulations for a typical automotive refinishing lacquer and a wood furniture lacquer are given in Tables 8 and 9, respectively. Low viscosity, high butyryl cellulose esters tolerate substantial amounts of alcohol solvent without appreciable increase in solution viscosity. An alcohol-soluble cellulose acetate butyrate containing ca 50% butyryl and ca 4.5% hydroxy is available commercially.

Low viscosity cellulose propionate butyrate esters containing 3–5% butyryl, 40–50% propionyl, and 2–3% hydroxyl groups have excellent compatibility with oil-modified alkyd resins (qv) and are used in wood furniture coatings (152). Acetate butyrate esters have been used in such varied applications as hot-melt adhesive formulations (153), electrostatically spray-coated powders for fusible, noncratering coatings on metal surfaces (154–156), contact lenses with improved oxygen

permeability and excellent wear characteristics (157–159), and as reverse-osmosis membranes for desalination of water (160).

In a relatively new decorative-coating technique called wet-on-wet coatings, cellulose acetate butyrate ester as the pigmented basecoat provides good pigment and metal-flake control before applications of the clear topcoat (161,162). Such coatings provide good appearance and excellent resistance to weathering and are expected to find broad use in automotive decorative coatings.

Because of certain properties, such as a high melting point, high tolerance for alcohol solvents, low odor, and excellent surface hardness, cellulose acetate propionates are used in printing inks (flexographic and gravure) (163) (Table 10). Alcohol-soluble cellulose acetate propionate ester tolerates substantial quantities of water in the solvent blend and thus provides an environmentally desirable system for flexographic ink coatings (164).

Acetate propionate esters are nontoxic, exhibit excellent clarity and high tensile strength, and can be formulated into hot-melt dip coatings for food (165). Alternatively, they may be dissolved in volatile solvents and applied to foods in the form of a lacquer coating (166).

Desalination membranes with improved, rigid, and stable surfaces have been prepared from cellulose acetate propionate (167). These films are generally more resistant to hydrolysis than those from cellulose acetate.

Cellulose esters, especially acetate propionate and acetate butyrate mixed esters, have found limited use in a wide variety of specialty applications such as in nonfogging optical sheeting (168), low profile additives to improve the surface characteristics of sheet-molding compounds (SMC) and bulk-molding compounds (BMC) (169,170), and controlled drug release via encapsulation (171).

CHARACTERIZATION OF POLYMERS

Introduction

Over the last 50 years, systematic investigation has established a number of structure–property relationships for polymeric materials, which allow prediction of their physical properties from a knowledge of the chemical structure of the repeat units and molar mass of the material. All polymeric materials can be divided into a series of subclasses, reflecting either their method of synthesis or some particular characteristic of the material. Using this classification, it is possible to quickly identify how the material will respond to external factors such as change of temperature, pressure, stress, impact, etc.

The term *polymer* (*poly*–many, and monomer–low molar mass unit) reflects the simplicity of the high molecular weight macromolecular structure. *Natural polymers*, although they may have complex sequences of repeat units, can exhibit physical properties that obey the same physical laws as their equivalent *synthetic polymers*. The increased use of polymers in everyday life has come with the discovery of simple synthetic routes to the raw materials and the ability to tailor their physical properties to particular applications. Despite the wide range of methods available for their synthesis, the physical characteristics of many polymers can be predicted by recognizing certain generic features in their structure.

Many polymers are created from the reaction of monomers that contain an unsaturated carbon (ene/vinyl) bond. For example, polyethylene [$-(CH_2{=}CH_2)_n-$], where n is the degree of polymerization and indicates the number of the repeat units in the chain. Synthesis of the polymer can be achieved using either free-radical processes, ionic (anionic or cationic initiation), or using a coordination polymerization route that uses an *addition reaction*. These synthetic routes produce macromolecular chains that have similar chain lengths and well-defined physical properties. Polymers with heteroatoms in the polymer backbone are frequently produced by a step-growth method that may either involve ring opening or elimination of a low molecular weight molecular species; eg, poly(ethylene oxide) produced by ring opening of ethylene oxide and poly(ethylene adipate) produced by the condensation of ethylene diol and adipic acid with the elimination of a molecule of water. *Step-growth* methods produce materials with a broad spread of lengths, and consequently a range of physical properties. The distribution of chain lengths is reflected in a range in the physical properties.

Knowledge of the chemical structure of the monomer and the distribution of chain lengths allows prediction of the method used for the production of that polymer. If the monomer is effectively difunctional, then the polymer will have a linear backbone structure and is a *thermoplastic*. Such polymers can be heated to an elevated temperature and shaped. If the monomer has functionality greater than two, then a cross-linked three-dimensional matrix can be created and the material is a *thermoset*, which cannot be reshaped by heating to an elevated temperature. Thermoplastics and thermosets (qv) can be created using similar chemistry, the only difference being the number of functions associated with the primary monomer unit.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

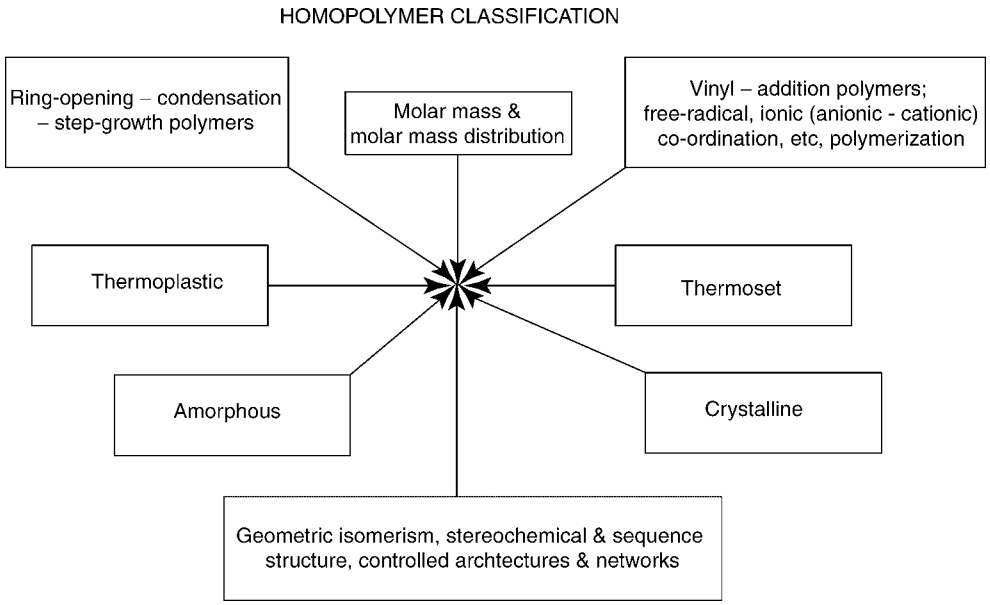

Fig. 1. Classification of homopolymer types.

The chemical structure of the repeat unit has a dominant effect on the ability of the polymer chains to pack together to form an ordered structure. If there is either a high level of symmetry or relative simplicity of the polymer backbone, then packing is encouraged and a *crystalline* structure generated (see SEMICRYSTALLINE POLYMERS). If the monomer structure is asymmetric and/or contains bulky pendant groups, packing may be inhibited and the solid structure is disordered and *amorphous* (see AMORPHOUS POLYMERS). Being able to differentiate between these different types of organization can help with prediction of the physical properties of the solid.

A useful classification of the polymers is presented in Figure 1.

Blending together two different types of compatible polymer material will create physical properties that are different from those of the individual materials (see POLYMER BLENDS). Polymeric materials may be formed using more than one repeat unit, and these are classified as *copolymers*. In real polymeric materials, there may be present a range of additives (qv): plasticizers (qv), antioxidants (qv), processing aids, fillers (qv), reinforcement (qv), antistatic modifiers, pigments, dyes, etc. These additives will influence the physical properties of the material, and understanding their influence is critical to understanding the properties of the material.

The questions that need to be asked in order to fully characterize a polymeric material include the following:

(1) What is the chemical structure of the repeat units from which the polymer is constructed? Does the polymer have a specific geometrical isomeric structure, particular sequence or branched-chain structures?

(2) Is the sample a thermoplastic or a thermoset?
(3) What is the average length of the polymer chains present? Are these chains of the same length or is there a broad distribution of lengths present?
(4) Is the solid a crystalline or an amorphous material?

In addition, knowledge of a number of physical properties is required to determine whether the polymer is suitable for a particular application.

Sample Preparation

All methods used by organic chemists for the determination of molecular structure are appropriate for the characterization of polymers. However, the simple analysis may not be able to differentiate between a homopolymer, a copolymer, or a blend of polymers. Even with a homopolymer, such as a commercial polypropylene, the solid may contain varying amounts of polymers with different molar masses and stereochemical and block sequence structure. Therefore it is desirable to be able to dissolve the polymer in selective solvents and extract species on the basis of solubility.

To obtain an unambiguous characterization of a particular material, it is often essential to fractionate a material (1–3). Synthetic polymers are rarely homogeneous chemical species, but have multivariate distributions in molecular weight, chemical composition, chain architecture, and functionality (4). For a precise characterization of a synthetic polymer, all the distributions need to be determined, which is a difficult, if not virtually impossible, task. Traditionally, fractionation has allowed separation of polymers on the basis of molecular mass or chemical composition (2). With proper techniques it is often possible to separate and characterize complex homo- and copolymer species on the basis of chemical heterogeneity and molar mass.

Separation by Solubility. Fractionation (qv) of a polymer has traditionally been based on solubility using precipitation, fractional dissolution (extraction), coacervate extraction, thin-layer chromatography, counter current distribution, and turbidimetry (5).

Two methods have been developed that are in common usage and aid the fractionation of polymer materials. These are temperature rising elution fractionation (TREF) (6–8) and Field Flow Fractionation (FFF) (9).

TREF was developed to separate semicrystalline polymers according to differences in molecular structure or composition that influence the crystallinity and solubility. TREF can be divided into crystallization and elution stages. In the crystallization stage, the polymer is dissolved in a good solvent, and then allowed to crystallize under controlled conditions by slowly decreasing the temperature. Crystallization may take place on an inert support or the support may be added later. In the elution step, solvent is pumped through a column packed with the polymer-support mixture, while the temperature is increased. Polymer elutes in the reverse order that it was crystallized, with less crystalline material eluting at lower temperatures followed by more crystalline polymer at higher temperatures and has been used for polyalkenes (6,8). In preparative TREF (P-TREF) polymer

fractions are collected at predetermined but different elution temperature intervals from those used in the crystallization (8). Critical, isobaric temperature rising elution fractionation (CITREF) is carried out using supercritical fluids, such as propylene and propane, in a column containing a high surface area stainless steel mesh packing in a manner analogous to P-TREF (10,11).

FFF is based on the simultaneous action of the effect of field forces and the carrier liquid flow on the fractionated species inside a belt-shaped fractionation channel (9,12). FFF is used to fractionate polymers or mixtures. Separation is based on the use of intensive properties, such as chemical composition and structure of the polymer chains, electrical charge, density, etc. Separation is influenced by application of a temperature gradient (ThFFF) (13) or an electrical field (EFFF) (14), and separation is aided by flow. In ThFFF, a temperature difference between the walls of the channel produces a flux, known as the Soret effect, usually towards the cold wall. In the EFFF, an electric potential across the channel generates a transverse flux of charged macromolecules or particles (14). In preparative FFF, a lower dilution of the separated species during the elution occurs as compared with flow FFF, due to partial depletion of the liquid due to the cross-flow. Two-dimensional thermal field-flow fractionation (2D-ThFFF) is devised for continuous fractionation of macromolecules (15). The sample introduced into a disc-shaped channel undergoes radial and tangential flow. Random copolymers of styrene and acrylonitrile (SAN) in toluene have been fractionated. (16). Polymer Brushes (qv) with poly(methyl methacrylate) (PMMA) backbone and polystyrene side chains have been separated using continuous counter-current extraction (17). FFF is applicable for the separation of polymers with molar mass in the range 10^3–10^8 and variants include sedimentation as an applied field (18–20). For small-scale analysis, components are sometimes quickly and conveniently separated by thin-layer chromatography (TLC), (21).

Molecular Size. Separation of soluble macromolecules can be achieved in size-exclusion chromatography (SEC) or gel-permeation chromatography (GPC) as a consequence of the differential permeation of the molecules into the porous solid column packing (see CHROMATOGRAPHY, SIZE EXCLUSION). Small molecules will penetrate more effectively and are eluted last from the column; the large species are eluted first. The separation is based on the size of the polymer molecule in solution—*hydrodynamic volume* that is directly related to molar mass of the polymer molecule. Since the hydrodynamic volume takes into account the polymer–solvent interactions, it is possible to create a universal calibration that takes into account variations in size due to change in polymer–solvent interaction. Care must be taken to ensure that size exclusion is the only separation mechanism operating in the column and to avoid errors arising because of Adsorption (qv) and aggregation (22). The SEC/GPC technique is used for the determination of the molar mass relative to some calibration standards, but can also be used for the separation of the mixtures into narrow molar mass fractions.

Molecular Structure Characterization

The first step in any analysis is determination of the elemental composition of the polymer. Combustion analysis can establish the presence of carbon, hydrogen,

halogen, sulfur, and the Kjeldahl oxidation for nitrogen and, occasionally, phosphorus. The structure of the polymer will then usually be determined by a combination of spectroscopic and mass spectroscopic analysis of degradation products.

Infrared and Raman Spectroscopy. Identification of the type of functional groups present in a polymer is effectively achieved by infrared and Raman analysis (23–28). The spectroscopic selection rules for infrared and Raman activity are respectively a dipole moment or polarizability change during interaction of electromagnetic radiation with the atomic grouping (see VIBRATIONAL SPECTROSCOPY). A vibration that gives a strong infrared signature may be weak in the Raman spectrum and vice versa. It is relatively easy to identify the occurrence of carbonyl, ethers, aromatic functions, hydroxyl groups, epoxy rings, carbon–halogen, and carbon–hydrogen bonds. The techniques are applicable to the study of solids (usually as very thin films), powders, and solutions. Raman spectroscopy is particularly useful when studying aqueous solutions, wet samples, or where differentiation between polymers with similar structures is necessary. Using laser sources, depolarization data associated with the Raman spectra can be obtained and conformational differences in molecular structure determined. At low frequencies, ca 100 cm^{-1}, the longitudinal acoustic mode (LAM) is observed in the Raman and is characteristic of the all trans structure of the polymer backbone and used to study the lamellar structure in crystalline polymers, such as polyethylene (29–32). Shifts in the Raman spectra have been used to indicate how local stresses are distributed within a sample (29,33).

Application of stress can induce changes in the infrared spectrum (34,35). Fourier transform infrared (FTIR) spectroscopy, in which rapid multiple scanning of the sample is possible (22,29), has allowed real-time observation of changes in the spectra. Studies have been reported of materials subjected to an applied external stress or used to follow the cure reaction of a thermoset. Computer libraries allow assignment of the spectra and identification of various functional groups within the polymer. Attenuated total reflection (ATR) attachments allow the surface of films to be explored (36). The ATR technique uses a glancing angle and total internal reflection of the infrared beam to collect information on the groups that lie close to the surface of the film (5–10 μm). Data manipulation techniques such as difference spectroscopy (spectral subtraction), factor analysis, spectral deconvolution, and least squares fitting of calibration plots allow quantitative determination of the species present.

Nuclear Magnetic Resonance Analysis. Nuclear Magnetic Resonance (qv) (NMR) provides both qualitative and quantitative analysis with respect to monomer composition and the average configuration of the polymer chain (22,37, 38). Both solid-state and conventional NMR techniques provide information on molecular structure, dynamics of the chain, crystallinity, network formation, and chain entanglement (39–41). Many types of nuclei may be observed; but proton (^{1}H) and carbon-13 (^{13}C) are usually investigated. Other useful nuclei studied include silicon (^{29}Si), nitrogen (^{15}N), fluorine (^{19}F), and phosphorus (^{31}P). The use of FTNMR with superconducting magnets and wide bore magnets has allowed a wide range of materials to be studied.

Proton (^{1}H) NMR, initially, was used for structural characterization, and use of the Karplus equation has allowed conformational and configurational analysis to be carried out on a wide range of polymers in solution (42). The advent of

various pulse sequences has enhanced the signal sensitivity and consequently the popularity of carbon-13 NMR spectroscopy. The natural abundance of ^{13}C is 1.1% and although there are problems of sensitivity, the spectra are simplified because carbon–carbon coupling is rarely observed in naturally-occurring materials. ^{1}H decoupling leads to spectra that consist of a series of single lines indicative of the types of chemical environment present. The inherent spectral separation of carbon chemical shifts is generally greater than for protons, ie, 0–220 ppm for ^{13}C compared with 0–10 ppm for ^{1}H, making assignment relatively easy. The ^{1}H decoupled line width is typically about 2–10 Hz for solution spectra. Grant and Paul (43) established that since the shifts are dependent on the s-orbital density, the observed shifts can be used to characterize the sequence structure of the polymer backbone. (22,44–50). Many molecular modeling packages contain software which will predict the ^{13}C spectrum. Subtle differences in both configuration and conformation of the polymer chain and changes in the dynamics of the chain backbone as a consequence of substitution can be observed (22,45).

Use of various pulse sequences has allowed solid-state NMR to be used to explore morphological features in solids. Studies of diblock copolymers of poly(styrene)–poly(methyl methacrylate) indicate domain sizes from 1 to 100 nm (51). Studies of the morphology and dynamics in poly(ethylene terephthalate) (52) and polyethylene (53) indicate the presence of a number of different phases. Motional heterogeneities within the phases of core shell particles composed of poly(*n*-butyl acrylate) (PBuA) and poly(methyl methacrylate) (PMMA) have also been demonstrated (54). The scope of the technique is continuing to develop and provide insight into the way in which chain–chain interactions influence the polymer morphology (55).

Detailed analysis of ^{1}H and ^{13}C NMR coupling constants obtained from solution spectra has allowed characterization of the chemical composition and conformation of racemic and meso dyads in glassy polystyrenes (56), and the stereoregularity in poly(methyl methacrylates) (57). With sufficient resolution, detection of tacticity at a pentad and higher level is possible, allowing validation of Bernouillian, Markov, or other statistical models for the description of polymerization processes and the tendency for block formation in copolymers. Geometric isomerism is readily detected in polybutadiene or polyisoprene, which form cis and trans double bonds in the polymer backbone as well as undergoing 1,4 or 1,2 addition. Imaging has allowed the mapping of the diffusion of labeled species in solids (58,59).

Pyrolysis. Spectroscopic methods can provide an identification of the monomeric species present; however, pyrolytic degradation plays an important role in the final assignment of the structure. Pyrolysis-gas chromatography is used extensively for the analysis of synthetic (60–63) and natural polymers (64). Application of heat to a sample leads to degradation (qv) and release of low molecular mass fragments. The composition and relative abundance of the pyrolysis products are characteristic of a given polymer. The technique is used in conjunction with other analytical methods, such as mass spectroscopy, infrared, and combinations such as pyrolysis-gas chromatography-mass spectroscopy. Pyrolysis can be carried out either in a continuous or a pulse mode; the latter has the advantage of minimizing the effects of secondary reactions on the fragmentation products. Small samples, in the microgram to milligram range, are rapidly heated either

directly in the inlet of a gas chromatograph or separately in an attached unit. For pyrolysis-mass spectroscopy, the pyrolysis is carried out in vacuum in the mass spectrometer. In a pulse mode pyrolyzer, the sample is frequently heated by resistive heating of a filament or by radio frequency inductive heating of a ferromagnetic metal (Curie-point pyrolyzer). The sample may be deposited as a thin film obtained by drying a solution or a small sample placed on the filament.

Pyrolysis of poly(methyl methacrylate) at low temperature produces monomer, whereas other acrylics fragment with loss of side chains, scission of the chain backbone, elimination or rearrangement of the products. Knowledge of the degradation pathways for particular polymer sequences is required to interpret the fragmentation patterns obtained from pyrolysis (65–70).

UV Spectroscopy. UV spectroscopy is appropriate for characterization of aromatic or conjugated systems (22). The high sensitivity allows study of species at high dilution and is useful for intrinsically conducting polymers and light-emitting species (71,72). The absorption is characteristic of the π–π^* transition; fluorescence and phosphorescence lifetimes are influenced by the state of aggregation and the matrix structure in which the absorbing species is localized. Many pigments and dyes have characteristic absorption and emission spectra. Luminescence techniques are valuable for the study of degradation and aging in polymers. Rotation and local motion of groups in dilute solution on the order of 10^{-10}–10^{-8} s in amorphous polymers and orientated films may be studied by fluorescence depolarization. Doped polymer films excited with polarized light will exhibit fluorescence depolarization, which is characteristic of the motion in the system.

Luminescence may be suppressed by the presence of antioxidants, light stabilizers, and pigments, which are able to transfer energy form the excited state to other nonfluorescing electronic states. Quenching of excited states also occurs when either oxygen or moisture is present.

Mass Spectrometry. Direct observation of polymers by means of mass spectrometry (qv) has traditionally been limited to molecules with molar mass of about 5000 or less. However, the advent of matrix-assisted laser desorption/ionization (MALDI) (73) has allowed accurate analysis of high molecular mass species to bed one (22). A high powered pulsed laser is used to transfer into the vapor phase the polymeric species which has been dispersed in a low molar mass matrix. The matrix, present in large excess (molar ratio 1:2000), is chosen for its ability to absorb the laser energy and protect the analyte, transferring energy to it in a way that allows desorption and ionization of molecules without significant fragmentation. Surprisingly, this simple change in handling technique has allowed species of up to 10^6 to be studied. Delayed extraction techniques enhance resolution (74,75). Calibration is necessary to quantify the intensities, lighter molecules are preferentially desorbed and ionized with respect to those having higher mass, and correction to the data is necessary. The resolution achievable has been enhanced by the use of time-of-flight mass spectroscopy to give TOF-MALDI (76,77). TOF-MALDI has also been applied successfully to biopolymer systems with precise molecular weight determination being possible up to 400,000 Da (78).

Electrospray mass spectroscopy (ESMS) is used for the study of biological macromolar species (79,80). Spraying produces droplets of the polymer solution which are ionized in an applied electric field and the charged species measured using a mass spectrometer.

Molar Mass and Molar Mass Distribution Determination

The GPC/SEC approach can be used for the determination of the molar mass or the distribution of molar masses. Traditionally, refractive index detection has been used and allows concentration of polymer to be measured as a function of elution volume. Using this approach, and calibration with narrow molar mass distribution samples, it is possible to determine the *relative* molar mass. Use of more complex detector arrays allows internal calibration of the system to be achieved and *absolute* molar mass determination (22,81). The usual triple detector combination uses refractive index, capillary viscometry, and light scattering (82–88). The latter provides an *absolute* calibration of the instrument; the capillary viscometry data gives through the intrinsic viscosity and hydrodynamic volume, information on the polymer–solvent interactions. Using this approach, studies have been carried out on multibranched star-shaped polyethers having poly(ethylene oxide)s (PEO) arms (82) which illustrate how the method can provide information on the architecture as well as molar mass. Due attention must be given to validating the accuracy of the theory for the particular type of polymer being studied (82–88). The multidetector systems are able to provide information on the size of the polymer molecule in solution (89).

Average Molar Mass. The molar mass of a polymer is usually described by an average molar mass. If the chains are counted by number it is the number-average molar mass $\bar{M}_n$, whereas if it is counted by weight it is the weight-average $\bar{M}_w$; higher averages, $\bar{M}_z$, etc, can also be calculated. The parameter M_w/M_n, known as the molar mass distribution, is characteristic of the method of synthesis. Ionic and coordination polymerization will have an M_w/M_n approaching 1.05, whereas a polymer produced using a radical initiated reaction has values between 1.5 and 4.5. Insertion polymerization, eg Ziegler–Natta olefin polymerization, yields values between 5 and 20. With condensation and ring opening step growth polymers, the value of M_w/M_n will be between 3 and 20. The distribution parameter can indicate whether the material is a blend of polymers or is a single material.

Three types of polymer distribution are typically observed in samples obtained from polymerization: logarithmic normal, Poisson, and Schulz–Flory distributions. The Poisson distribution can be very narrow and occurs when a constant number of polymer chains grow simultaneously and addition of the next monomeric unit is independent of previous units and is found in anionic polymerization (qv). The Schulz–Flory distribution, typical of radical polymerization (qv), arises when a constant number of chains growing ends exist and when termination and chain initiation processes are also active. This is in contrast to the Poisson distribution. A logarithmic-normal distribution is found for the polymerization of polyethylene and polypropylene (90,91).

For simple quality assurance, GPC/SEC with a simple refractive index detector is used, as the shape of the trace indicates directly the distribution of molar masses. Comparison of the distribution that is obtained from GPC/SEC with MALDI-TOF has helped clarify the validity of both techniques, especially in the case of low molar mass calibration samples. Simpler traditional methods are often more appropriate where a specific average is required to correlate variations in a polymer material with a physical property. Solution viscosity measurements

Table 1. Methods for Determination of Average Molar Mass

Method	Absolute or relative	Average measured	Molar mass range, g/mol	Characteristics
Ebulliometry	A	M_n	Up to 10^4	Low sensitivity
Cryoscopy	A	M_n	Up to 10^4	Small samples size, fast
Membrane osmometry	A	M_n	5×10^3–10^6	Suitable membranes required
Vapor phase osmometry	R	M_n	$<3 \times 10^4$	Suitable standards for accurate calibration required
End group analysis	A	M_n	$10^2 \sim 3 \times 10^4$	Low sensitivity at higher molar masses
Light scattering	A	M_w	$3 \times 10^4 \sim 10^7$	Low sensitivity at low molar mass
Ultracentrifugation	A	M_n/M_w	$2 \times 10^2 \sim 10^7$	Small samples, time-consuming, difficult technique
Dilute solution viscometry	R	M_v	$10^2 \sim 10^7$	Fast, low cost small samples
SEC/GPC	R	M_n/M_w	$10^2 \sim 10^7$	Popular, small samples, requires calibration samples
SEC/GPC–triple detection	A	M_n/M_w	$10^2 \sim 10^7$	Requires skill and care to obtain reliable results, expensive
MALDI-TOF	A	M_n	$10 \sim 10^7$	Sensitivity varies with molar mass

provide a method of monitoring the effects of degradation (qv) caused by polymer processing and the assessment of physical aging (qv) when polymers are exposed to extreme environments.

Some of the traditional methods are listed in Table 1.

In order to obtain accurate data it is essential that care be taken in the sample preparation. Because M_n is more sensitive to low molar mass components, removal of residual solvents, monomers, salts, catalysts, etc, from a sample before measurement is essential. M_w is more sensitive to the higher molar mass components, as are the higher averages M_z. Incomplete dissolution of a sample often leads to meaningless results. Similarly, polymer degradation during solution preparation or in the process of molar mass measurement must be prevented. Use of ultrasound to aid production of a solution is strongly discouraged. The issues associated with the measurements are discussed in detail elsewhere (22,92–94). Analysis of complex structures, branched chains, dendritic molecules, and regular copolymers has been successfully undertaken by combining data from a series of different methods (95–100). MALDI-TOF, in conjunction with other approaches, is allowing considerable detail to be obtained on copolymer composition changes

during reaction, probability of branching reactions, sequence structure within polymers with more than one reaction mechanistic possibility, etc (101,102).

The importance of knowing the molar mass of a polymer and its distribution of molar masses cannot be overemphasized. Commercially, many polymers, such as polystyrene, are available in different grades. Often the difference between these grades is their molar mass and/or molar mass distribution. One grade will be ideal for injection molding, another for compression molding. Incorrect selection of the grade of polymer would lead to selection of a material that is unsuitable for the application for which it is intended.

Solution Characteristics of Polymers. The molar mass characterization techniques often provide additional information on the nature of the polymer species in solution. In most cases, the solutions used are sufficiently dilute so that the properties being measured are those of the "isolated" molecule. At infinite dilution the size of the polymer coil is dictated by both inter- and intramolecular interactions, the nature of the solvent used, and the temperature. In a viscosity or GPC/SEC experiment the properties being observed can be related to the hydrodynamic volume of the polymer coil. This hydrodynamic volume is the "effective volume" which the polymer occupies in solution. The hydrodynamic volume is implicit in the Mark-Houwink relationship, which describes the value of the limiting infinitely dilute increment to the viscosity—the intrinsic viscosity $[\eta]$ to the molar mass:

$$[\eta] = K.\bar{M}_{\eta}^{\alpha}$$

where K and α are constants valid over a limited molar mass range and specific to a particular temperature–solvent combination. Generally, the value of α is between 0.5 and 1.0, and depends on the conformation of the polymer in solution. For random coil conformations, obtained at theta conditions, α is around 0.5, and extended conformations resulting in rod-like molecules give values approaching 1.0. Because α usually falls somewhere between 0.6 and 0.8, the viscosity average molar mass $\bar{M}_{\eta_v}$ is always somewhere between $\bar{M}_{\mathrm{n}}$ and $\bar{M}_{\mathrm{w}}$. The value of $\bar{M}_{\eta_v}$ is often closer to $\bar{M}_{\mathrm{w}}$ than $\bar{M}_{\mathrm{n}}$. The value of K is typically 1×10^{-4} dL/g, and values of the constant are to be found in the *Polymer Handbook* (103). Because the values of α and K reflect the *hydrodynamic volume* and are sensitive to changes in the polymer architecture, long-chain branching will lower the values in comparison to an equivalent linear polymer.

The concentration dependence of many physical properties indicates the quality of the polymer–solvent interactions, through the second virial coefficients. Study of the concentration and temperature dependence of these parameters provides information on the theta temperature, radius of gyration, and the mean square end-to-end distance for a polymer coil. The *radius of gyration* is defined as the root mean square distance from the center of mass of a polymer chain to a given mass element. The characteristic ratio is a measure of the ratio of the square of the average random-flight end-to-end distance to the product of a number of backbone units times the interactions along the polymer chain. These parameters provide useful information on the validity of a particular theoretical model and its ability to describe the architecture and conformation of a polymer (104).

Molecular Organization and Dynamic Behavior of a Polymer

The ability to produce fractions of polymers has allowed their true physical properties to be determined. Polymer chain interactions are determined by the local interactions and longer range effects that scale with the molar mass of the species. The former will dictate whether it is possible to achieve sufficient favourable interactions for *crystallization* to occur or whether local interactions are sufficiently strong to inhibit ordering and an *amorphous* material is generated. Relatively small changes in the size and distribution of these ordered regions can be responsible for dramatic differences in the physical and mechanical properties of ostensibly the same polymer. The degree of ordering depends on the local organization; hence it is not uncommon to find that an isotactic form of a polymer may be very different to that observed in a syndiotactic molecule. In polypropylene the isotactic form of the polymer has a helical structure that crystallizes, whereas the syndio or atatic forms are unable to pack and have rubbery characteristics (105,106).

The ability of a material to absorb energy reflects the mobility of the chemical entities it contains and the types of interaction that are broken as the temperature is increased. In crystallizable polymers, the interactions between chains depend on the chemical structure and range from the relatively weak van der Waals interactions found in polyethylene to the strong dipole and hydrogen bonding interactions found in nylon and polyurethanes. In between these extremes lie a range of materials with interactions of a dipole–dipole nature and associated with ester, amide, nitro, chloro, and ether groups which may or may not form crystalline phases, depending on the ability of the chains to form a regular packed structure. Hydrogen bonding is the strongest of the interactions and has a dominant effect on the structures formed. In the case of aromatic containing polymers, significant contributions can arise from dipole–induced dipole and higher order interactions associated with the delocalized electronic structure of the molecules. Typically the organized regions, even for the most crystalline of polymers, will be disrupted by conformational (*gauche*) defects. The clustering of these defects will allow the chains to loop or deviate from the lower energy (trans) extended structure that is incorporated into the ordered regions. As a consequence of the defect structure, the size of the crystalline domains will be typically of the order of a few tens of nanometers. Higher order structures are created by organization of these primary lamellae structures. Because of the possibility of chains folding back on one another, the number of chains bridging from one crystallite to another will be fewer than those reentering the structure from which they originate. These bridging chains form a disordered structure that is *amorphous*. The geometry (spherulitic or row-nucleated), size, and distribution of crystalline regions are complex and affect physical properties in a complex way.

In other polymer systems, such as polystyrene, the steric constraints associated with the group pendant to the chain backbone inhibit packing and create a disordered, *amorphous*, structure. Chain–chain interactions, however, can achieve a level of packing density that leads to motion of the backbone being inhibited. In this state, the polymer has properties of a glass. Increasing the temperature leads to expansion, increased chain separation, and a decrease in the strength of the interactions, and the solid exhibits flexible-rubbery characteristics. This

transformation is associated with the inclusion of volume for the chains to move and is known as the glass–rubber transition T_g (see GLASS TRANSITION). The relationship between supermolecular order/disorder and physical or mechanical properties depends on the thermal and mechanical history of a polymer (107).

Thermal Methods. Heating a polymer sample allows observation of the changes in physical properties, associated with changes in the degree of packing and chain–chain interaction. In thermal analysis, the properties are measured as a function of temperature or time at constant temperature. Methods include differential thermal analysis (DTA), differential scanning calorimetry (DSC), thermogravimetric analysis (TGA), evolved gas analysis (EGA), adiabatic calorimetry (AC), and a recent variant of DSC: modulated DSC (MDSC) (108–121). Use of sophisticated mathematical techniques and adaptation of the microscanning techniques have allowed mapping of thermal properties at the micron level. These techniques are not yet widely available, but will make a significant impact on our understanding of the way in which one aspect of morphology influences another in phase-separated materials and apparently homogeneous materials.

Amorphous Materials. The characteristic feature of amorphous polymers (qv) is the observation of a glass–rubber transition temperature (T_g). The glass transition (qv) temperature is associated with cooperative motion of the backbone chain of a polymer and involves the collective motion of between six and 12 chemical bonds on average. (122). The important difference between the T_g and other transitions that are observed below this temperature is that the T_g process requires *free volume* in the region into which the chains are going to move. The free volume is produced by the expansion of the solid as a consequence of the increase in chain–chain separation. As a consequence, the T_g is sensitive to pressure; increasing the pressure to which a material is subjected leads to an increase in Tg. In contrast, the motion of groups attached to the backbone via a flexible linkage exhibits simple Arrhenius/thermal activation behavior, the rate of the motion varying linearly with temperature. The rate of chain motion associated with the T_g does not vary linearly with temperature, usually showing a marked temperature dependence that reflects the limitations imposed by the free volume. The T_g process reflects a dramatic change in physical properties of the material, changing from being a rigid glass to a flexible rubber. The T_g is usually reported as a single value; however, the nature of the processes and its kinetic nature dictates that it occurs over a broad temperature range. The process is complex, and hence different methods of observation lead to a slightly different value being reported for the same material (22,122). In addition, the length of the polymer chains can have an influence on the value observed. The chain ends will require less free volume than the motion of the center of a long chain. As a consequence, it is observed that for many amorphous polymers, the value of T_g varies with molar mass according to the relationship

$$T_g(M) = T_g^{\infty} - \frac{K}{\bar{M}_n}$$

where $T_g(M)$ is the value for that material, K is a constant characteristic of that material, $T_g{}^{\infty}$ is the limiting value observed for a very high molar mass polymer, and M_n is the molar mass of the sample being studied. Recognition of the

sensitivity to the molar mass is very important in understanding how commercial polymers with the same chemical structure have apparently different physical properties. Low molar mass fractions will lower the glass transition temperature and soften the material.

Sub-T_g processes are very important in defining the physical properties of a polymer. The side chain motions can occur below the T_g and absorb energy, helping to dissipate the energy associated with impact and allowing the material to demonstrate ductile fracture behavior. The ability of a polymer to resist impact can be designed into the chemical structure by changing the nature of the side groups, their ability to move, and the efficiency with which they absorb energy. Backbone elements, such as aromatic entities, rotate about the backbone axis without being involved in the collective T_g process and impart high impact resistance to the material, eg, polycarbonate. Backbone and side-chain motions can become closely coupled on certain time–temperature scales, eg, poly(methyl methacrylate). The value of T_g is sensitive to changes in the chemical structure of the backbone and varies between ~160 to ~570 K. Because it is a kinetic process, the T_g is sensitive to the thermal history of the sample. The fabrication process will usually involve the freezing in of a level of entropy reflecting the processing temperature. Heating the sample up close to the T_g will allow slow reorganization of the chain conformations, leading to changes in the bulk physical properties. The time dependence of the physical properties has been extensively studied and is called *physical aging* (107). The side-chain relaxation, designated T_β, often occurs at a temperature of about $0.75T_g$. This correlation reflects the connectivity of the nature of the potential functions responsible for the processes that are taking place. Cross-linking of the polymer structure leads to an increase in the T_g and the introduction of certain fillers can also increase the value of T_g. The presence of low molar mass additives will have the reverse effect and swell the matrix lowering the value of the T_g.

Crystalline Materials. Polymers do not form perfect crystalline structures; however, many polymers, eg polyethylene, exhibit the characteristics of materials in which large elements of the material are regularly packed (see SEMICRYSTALLINE POLYMERS). As in the case of low molecular weight materials, it is possible to observe alignment of the polymer chains that lead to optical characteristics of typical *nematic* or *smectic* liquid crystal phases. The extreme degree of organization is the crystalline phase. Only in solution-grown, low molar mass polymers are nearly perfect crystalline phases observed. In the typical polymer sample, there will be frozen in, at the freezing point, a certain amount of disorder. Order in the crystalline phase is usually associated with the all trans conformation of the backbone, whereas disorder is associated with the gauche conformation. A coincidence of gauche conformations will loop the chain back in its original direction and develop a folded crystalline structure. The loops form a disordered-amorphous interface between the crystalline regions, which are packed into lamellae. The lamellae will in turn organize themselves into spherulite structures. The morphology of crystalline materials is varied and reflects the nature of the nucleation process and the thermal history. As in the case of amorphous polymers, post-thermal treatment can lead to changes in the size of the crystalline content with subsequent variation in the physical properties. The mechanical properties of polyethylene are thus dictated by the ratio of the crystalline to amorphous content. Just below and

above the melting point T_m, the polymer chains can undergo extensive translational movement or flow. The melting of semicrystalline polymers (qv) as observed by DSC indicates that the melting process often occurs over a range of temperatures. The breadth of the distribution is a reflection of the distribution of sizes of the crystallites in the material. The value of T_m is a function of a number of properties that include molar mass, molar mass distribution, percent crystallinity, and dimensions of the polymer crystallites.

An empirical rule which has been observed for many polymers is that $T_g \sim 2/3T_m$, where the temperatures are in Kelvin. This rule is applicable to most vinyl, vinylidene, and condensation polymers. This ratio is lower for polymers with unsubstituted backbones and higher for poly(α-olefins) with long alkyl side groups. $T_{\alpha c}$ occurs in crystalline and semicrystalline polymers and is ascribed to an oscillation about the chain axes within the chain-folded crystals or a translation along the axis. $T_{\alpha c}$ is related to T_m by

$$\frac{T_{\alpha c}}{T_m} = 0.85 + \frac{25}{T_m}$$

where all the temperatures are in Kelvin (123–125). The introduction of branches and bulky side chains into linear polymers can inhibit crystallization and in the case of polytetrafluorethylene aids the processing of the polymer by introducing amorphous structure.

The usual approach to the study of the transitions is by the use of thermal methods (see THERMAL ANALYSIS). The instruments for DTA and DSC are different in construction. In DTA, the temperature difference between a sample and a reference chamber is measured as a function of time or temperature as heat is supplied to both chambers. In DSC, the heat flow into or from a sample chamber compared to a reference chamber is measured as a function of time or temperatures. Modern instrumentation is capable of measuring the heat input or output of samples in the 0.2–30-mg range with high accuracy. The information obtained from DSC and DTA with proper and suitable calibration is in many cases similar, if not identical. Modulated DSC (113–116) is an adaptation of the DSC method in which the heating, instead of being carried out in a linear manner, is applied in an increasing sigmoidal fashion. Fourier transformation of the heat flux against the heat flow allows separation of real and imaginary components. The real part of the transform function is a direct measure of the heat capacity, whereas the imaginary component is a measure of nonreversible heat flow. The latter can be associated with crystallization, cure in the case of a not completely cured thermoset resin, polymer degradation, and other similar types of process. The curves can be used to directly measure the energy associated with the T_m, or the entropy associated with the T_g or parameters characterizing other transitions. The melting behavior can strongly influence the physical properties, and DSC and DTA studies allow quantitative investigation of phase structure in a polymer sample.

Plasticizer efficiency may be evaluated by studying the effects of plasticizers on T_g using thermal methods. The effects of the addition of nucleating agents on the rate and extent of crystallite formation can similarly be quantified. Current

instrumentation can approach the temperatures which materials approach during processing and allow modeling of the processes that occur at a microscopic level.

Thermal stability can be determined in DSC by measuring the temperature of reaction or degradation under isothermal or scanned temperature conditions. Other conditions include an inert or an oxidative atmosphere at ambient or elevated temperature. It is also possible to study the effects of increased pressure using pressurized DSC cells. By varying the conditions, thermooxidative processes can be separated from thermodegradative processes. The induction time before reaction begins is taken as a measure of the stability. The effect of antioxidants and stabilizers on this time may be readily studied.

Mechanical Properties. The measurement of mechanical properties is concerned with load–deformation or stress–strain relationships. Forces may be applied as tension, shear, torsion, and compression and bending. *Stress* is the force divided by the cross-sectional area of the sample. *Strain* is the change in a physical dimension of the sample divided by the original dimension. The ratio of the stress to strain is referred to the *modulus*. Stress may be applied continuously or periodically at varying rates for different tests. The characteristic stress–strain curve, stress relaxation, or impact behavior is very important in determining the applications and limitations of a polymer.

The condition, size, and history of a sample are of great importance in performing mechanical measurements. Samples should be uniform and free of imperfections that can act as stress concentrators. Mechanical properties depend on production techniques. For example, an injection-molded test specimen may be strongly influenced by the molecular orientation resulting from flow in the mold. Sample size should be controlled and is often set for a given test. The thermal history of a sample is very important because aging often produces change; eg, crystallinity may develop in a supercooled polymer over time, or oxidation may produce an alteration of the polymer structure. It is usual with mechanical tests to measure a number of samples and average the results. Even taking the average of a set of data must be carried out intelligently as sometimes there are good reasons; eg, differences in morphology within a sample which are reflected in the measurements. Samples may be subjected to equilibration prior to measurement at some set humidity and temperature; however, this process in itself may be inducing changes in the structure. A myriad of mechanical tests are available, some standardized (126) and some not. A comprehensive list of standards is available on the Web site www.astm.org. It is important to select a test which is applicable to the conditions in the material is going to be used (see MECHANICAL PERFORMANCE).

Stress–Strain Tests. The steady application of a stress (force per unit area) to a material will lead to a measured strain (change in length). The initial slope for many materials is linear, and with reduction in the stress there is also a reduction in the strain. The material is behaving as a simple linear Hookian solid. However, application of higher levels of stress will ultimately lead to the material breaking, and for a hard material this occurs rapidly at a limiting value of the strain. The failure of such a material is designated as being brittle. Some polymers may exhibit curvature in their stress–strain plots at high stresses and this nonlinear behavior is often indicative of ductile behavior (see YIELD AND CRAZING). A further characteristic of a ductile material is the observation of uniform extension or a yield point where the stress remains constant or even decreases

as the strain (elongation) increases. This type of behavior is typical of a necking-down or reduction of sample cross-section at the yield point due to cold drawing of the specimen. A levelling of stress may often occur after the yield point until the break point is reached. As the material takes on a more rubbery characteristic, the length of the region over which the stress remains constant is increased. The initial slope of the stress–strain curve allows measurement of the modulus of the material. The area under the curve indicates the energy required to fracture the sample and is directly related to the toughness of the material. A good elastomer is capable of exhibiting ultimate elongations before failure approaching 1000%.

As the temperature of a sample is raised, the polymer will be transformed from exhibiting brittle to ductile and eventually rubbery characteristics, provided the material is of sufficiently high molar mass. A material that shows tough ductile behavior when stress is applied slowly often behaves as if it were brittle when a large stress is applied rapidly. This observation reflects the ease with which the polymer chains are able to reorganize to redistribute the stress. Similarly, when the temperature is lowered, the tough ductile specimen often becomes brittle even if the stress is applied slowly. The mechanical properties are a direct reflection of the mobility of the chains and can be described by the Williams–Landel–Ferry (WLF) equation. The WLF equation relates through a shift factor a_T, the ratio of the time constant τ of a particular response at a temperature T to a corresponding time constant τ_0 at a reference temperature T_0. Because of the relevance of T_g to defining large-scale molecular motion, this is often selected as the reference temperature. The WLF equation is

$$a_T = \frac{-A(T - T_g)}{B + (T - T_g)}$$

where A and B are constants specific for a given polymer. The constants obtained are typically 17.4 for A and 51.6 for B (127). In practice, slight variations in the values of the constants are observed which reflect the differences in the processes that are responsible for the shift factors.

Dynamic Mechanical Thermal Analysis. Dynamic mechanical thermal analysis (DMTA) subjects the sample to a low amplitude cyclic stress and observes the corresponding strain induced (see DYNAMIC MECHANICAL ANALYSIS). By comparison of the amplitude and the phase of the response, it is possible with suitable calibration to deduce the dynamic modulus, storage modulus (energy dissipated per cyclic of the stress), and tan δ, the ratio of storage to the dynamic modulus for a particular form of deformation. In the typical apparatus it is possible to subject samples to bending, shear, or torsion. Mapping these values of the physical parameters obtained as a function of the temperature allows identification of the major transitions and quantification of the modulus of the glass and rubbery states. The technique is ideally suited for the detection of phase separation in polymers, where two values may be observed for the T_g. These tests are highly sensitive to crystallinity, orientation, morphology, dependence on molar mass in thermoplastics, degree of cure in thermosets, and miscibility of multiphase systems including composites and polymer blends (22,110).

Creep Tests. Creep tests measure deformation upon the application of constant stress such as that obtained by hanging a weight on a sample and noting the change in elongation as a function of time. Creep tests may be performed by applying stress in tension, compression, flexural bending, shear, or torsion (twisting) modes in such a way that the deformation increases with time. Dimensional stability under static loads can be estimated in this manner and this information is very useful to designers, fabricators, and engineers using plastics. Creep results are often reported as the inverse of modulus or compliance (strain divided by the applied stress), which for the reasons outlined above will be a time-dependent quantity. If the level of stress is small it is possible to observe recovery of the original dimensions, creep recovery.

Stress Relaxation Tests. Stress relaxation involves measurement of the stress required to hold a given deformation as a function of time. The deformation is initially applied as rapidly as possible to strain the sample to a certain degree. The modulus calculated from such an experiment decreases with increasing time, reflecting the polymer structure ability to redistribute the stress.

Both creep and stress relaxation is modeled using computer simulation software based on simple spring (elastic deformation) and dashpot (viscous flow) models. Many polymers, when they approach the T_g, will exhibit *viscoelastic* behavior in which the physical characteristics are best described by considering the material as having both solid- and liquid-like properties. Viscoelasticity is an important property to be found in polymeric materials (see VISCOELASTICITY).

Impact Testing. Although not a fundamental materials property, the impact strength is a very valuable parameter when attempting to determine the suitability of a material for a particular application (128). Impact tests usually involve striking a sample of a specified geometry with an object that is travelling at high velocity. The most common tests are the Izod, Charpy, and falling weight. The Izod and Charpy tests both employ a weighted pendulum. In the Izod test, a bar of the polymer is suitably notched to act as a stress concentrator. The notched bar is held vertical while clamped at one end. Charpy test has the specimen clamped at both ends. The falling weight test is usually conducted with a weighted dart or ball striking either a sheet or plate of material (see IMPACT RESISTANCE).

The underlying theme that emerges from the mechanical testing is the requirement to characterize the molecular organization at various levels (129). This organization–morphology is a function of the thermal history and various chemical and molar mass parameters implicit in the material being studied.

Visualization of the Morphology of Polymer Materials

Amorphous materials are defined by a lack of organized structure, but crystalline materials exhibit a range of levels of organization (22,130–133). Visualization of the structure of the polymer is therefore an important component of the characterization of any material that is capable of showing order.

X-Ray Diffraction. Improvements in diffraction methods have allowed the rapid characterization of the order within polymer solids. Synchrotron Radiation (qv) has allowed real-time examination of the creation of order as polymers are

cooled from the melt (134). The X-ray diffraction techniques can be subdivided, depending on the range over which the scattered electrons are collected. The major structural types that are of interest are single crystals, polycrystalline aggregates with crystals, randomly orientated "powder samples," and polycrystalline aggregates in which the crystals show a preferred orientation. The typical distances that are responsible for diffraction can be anywhere between 1 and 20 nm, which requires measurement of very small angles (5°–15°) close to the incident beam. With synchrotron sources it is possible to measure such small angles, whereas with conventional sources this is difficult. The technique is referred to as *small-angle X-ray scattering* (SAXS). Studies of aromatic polyesters indicate that even with these relatively complex molecules, regions of crystalline order can exist and have a profound effect on their physical properties. The extension of the technique, which scans a broader range of angles (∼10°–40°), is designated *wide-angle X-ray scattering* (WAXS) and provides information on spacing between 0.1 and 1 nm. This technique can provide valuable information on the crystalline packing within the crystallites. Whereas in single crystals diffraction spots can be observed, in many polymers halos are observed and these may have bright spots which reflect the preferred orientation of the crystallites within the sample (see X-RAY MICROSCOPY).

Neutron Diffraction and Inelastic Scattering. Use of neutron scattering (qv) can, in principle, allow observation of the location of hydrogen atoms in a lattice (135). The contrast between the scattering cross-section of hydrogen and deuterium allows the distribution of a single labeled chain within a low scattering matrix. Although in principle deuteration leaves the structure of the polymer essentially unchanged, there are distinct thermodynamic differences between the protonated and deuterated polymer raising the question whether the structure may have been changed by the insertion of the labeled polymer (136). Although publications have been produced on neutron diffraction from polymeric single crystals, most of the research has been carried out on inelastic scattering measurements. The latter are concerned with energy transfer processes between the neutron and the matrix and are ideal for the study of dynamic processes, but are less easily interpreted in terms of the structure of the polymer. The one application where neutron scattering has proved to be useful is for the determination of the size of a labeled polymer coil in a nonlabeled matrix. It has been shown that the dimensions of an amorphous polymer in the solid state approximate to those of the ideal random coil dimensions that would be predicted to occur in near-ideal interaction conditions. Low energy or long-wavelength neutrons (0.4–2.0 nm), unlike X-rays, produce little damage and can penetrate samples of up to 1-cm thickness, which is thicker than those used for X-ray analysis.

Electron Scattering and Electron Microscopy Techniques. High energy electrons can be scattered by the molecule in the polymer structure and the diffraction patterns will resemble those obtained from X-rays. Electron diffraction is only really possible on very highly crystalline materials. If the sample is sufficiently thin, then the analogue of the optical microscope can be used in which the electron beam is passed through the sample and imaged on a sensitive photographic, or now an image, plane. The resolution of such a system can be at the 0.1-nm level and provides useful information that is below the resolution limit of the conventional optical microscope. A problem with this method is that the high

energy electron beam (100–200 kV) can produce degradation of the sample, and resolution that is usually associated with high acceleration voltages has to be balanced against the time required to produce an satisfactory image. Transmission electron microscopy (TEM) method has allowed visualization of the chain packing in polyethylene-type of polymer (137). The TEM method requires that the sample be thinned to dimensions which allow the electron beam to pass through the material which is typically below 100 nm. This requirement usually necessitates that the section be prepared using a cold working microtome which generates wafers that are of the order of a few tens of nanometers thick. The TEM method can be used to provide electron diffraction data that can be used to calculate the molecular spacing in crystalline phases in the polymer material. This type of information is very complementary to that obtained from X-ray diffraction, and with the use of computer models of the order structure it is impossible to obtain quite a precise definition of the chain-packing dimensions and orientation (138). The alternative and slightly lower resolution approach to electron microscopy is scanning electron microscopy (SEM) (139). In SEM, the back-scattering of electrons used to provide information on the structure of polymers has resolution limits and cannot normally provide molecular resolution data. The back-scattered electron has an energy which is characteristic of the atoms that produce the scattering, and imaging selective on a particular atomic distribution is possible (140). However, for polymers this is, not usually used as the resolution of light atoms such as carbon and oxygen is very difficult and the method is only useful for heavy atoms. It is, however, possible to identify the segregation of metal catalyst residues in polyolefins. Electron microscopic techniques usually require that the sample be coated with conducting media to avoid loss of resolution as a consequence of the buildup of trapped charge, and hence sample preparation can be problematic.

Supermolecular Organization. Both in biological and synthetic polymer systems, the local order at the nanometer scale very rarely extends to the micro level (140). Interruption of the chain packing occurs by either chain folding or conformational defects leading to major disruption in the perfection of the chain packing. A variety of models have been formulated to assist visualization of these structures, an example of which is the so-called fringe micelle model. Much of our knowledge of the organization at this lengthy scale is obtained from either TEM or SEM studies combined with X-ray diffraction measurements. The SEM technique is ideally suited for the study of polymers allowing the magnification to be changed from relatively low values, where the object can be imaged at optical resolution, to length scales which are submicron to those where the resolution approaches the subnanometer scale. The organization of the polymer chains observed at this scale reflects the packing of smaller scale crystallites and allows visualization of liquid crystalline order within extended domains of the polymer. The discussion of this level of organization is often referred to under the general heading of textured polymer and may, in the case of a polymer such as cellulose, be constrained to the microfibrils. In polyethylene, the organization of the crystalline lamellar structures within domains leads to the creation of microcrystallites that can have micron-size dimensions or larger (130,131) but from the point of view of their mechanical properties are distinct entities. The dimensions of the range of the structure at this level are defined by the extent to which the entity can be considered to have identifiable physical properties. In polyethylene, the cool deformation

of the substrate can lead to significant alignment of the crystallites and enhancement of the modulus in the direction of the applied stress. The alignment of the crystallites, however, has a negative effect: enhancement of the modulus in one direction leads to a reduction in the strength in the direction transverse to the draw direction (130). The development of anisotropy in a crystalline solid can be visualized from examination of the angular dependence of the X-ray scattering plots. The "pole" diagrams (131), which is a plot of scattering intensity as a function of the direction of the draw axis to the X-ray beam axis, allow the extent of the anisotropy to be determined.

Optical Microscopy. Traditionally, light microscopy has played an important role in the visualization of ordered polymers, and a range of different approaches can be adopted to enhance the contrast, phase contrast, polarized light microscopy, orientation birefringence, strain birefringence, modulated contrast, interference microscopy, etc (132,141–144). Light microscopy rarely provides resolution better than several micrometers but can give a quick and easy assessment of the extent of order in the polymer material.

Scanning Atomic Force Microscopy and Related Methods. Whereas the characterization of the structure of the bulk solid is of relevance to the mechanical properties, a knowledge of the surface structure may be important in understanding adsorption (qv), tribology, friction, adhesion, and other surface-dominated phenomena (145,146) (see SURFACE PROPERTIES). The development of atomic force microscopy (qv) (AFM) has allowed imaging at better than a nanometer resolution of phase-separated and similar structure (147) (see also SCANNING FORCE, MICROSCOPY). The surface analytical techniques will not be included in this review but do provide a very important part of the characterization of atomic composition and alignment and segregation of the polymer chains in the surfaces (22) (see SURFACE ANALYSIS).

Positron Annihilation Lifetime Spectroscopy (PALS). A positive electron of very high energy can penetrate matter and through inelastic collisions be slowed down until it has thermal energies. The inelastic collisions will often produce damage resulting in the emission of electrons. The combination of a positron (+ve electron) with an electron forms positronium. Positronium is only stable if thermalized within a void of molecular dimensions. The para-positronium can undergo spin allowed annihilate with the generation of energy. The ortho-positronoium does not have the correct spin and will usually annihilate through spin exchange with the electrons that form the walls of the cavity in which it resides. The process allows determination of the size of the molecular cavity through the lifetime of the ortho-positronium annihilation and the intensity is directly proportional to the number density of the events. The voids measured by this method are essentially those associated with the free volume in an amorphous polymer. Study of PALS can indicate the mechanisms of aging, plasticization, gas diffusion, and other processes that are morphologically controlled in a disordered material (148).

Molecular Dynamics of Polymer Systems

Physical properties are a reflection of the degree and extent of the freedom of the polymer molecule to undergo spatial rearrangement as a consequence of thermal

or an applied perturbation. A variety of methods exist which allow the direct probing of these molecular motions.

Nuclear Magnetic Resonance—Relaxation Time Measurements. The NMR method is usually used in solution for the determination of the structure of a polymer; however, when used in the Fourier transform model it can also probe the rate at which nuclei reorientate within the applied magnetic field (22,122). The relaxation of a particular nucleus can be used to characterize the motion of a specific group. ^{1}H NMR signals are usually not sufficiently decoupled from one another to allow the motion of individual groups to be characterized, and it is usual to limit the discussion to gross differences as between aliphatic and aromatic protons. The low natural abundance of the ^{13}C nucleus allows separation of the resonance of individual groups, and hence the relative rates of the motion between individual atoms can be probe (122). In practice, this level of detailed information can only be obtained for polymer molecules dispersed in solution; the equivalent solid-state spectrum reflects a more highly coupled state in which motions are not resolved. Solid state is sensitive to short-range interactions and has been used to study crystallinity, rotational transitions, relative orientations of polymer chains, solid glassy polymers, compatibility of solid polymer blends, and cross-linking and entanglement (149,155).

Dielectric Relaxation Spectroscopy. Many polymers contain polar groups and the internal motions of these groups lead to fluctuations in the local dielectric permittivity. Measurement of the dielectric relaxation (qv) spectrum over a broad frequency range (10^{-3}–10^{10} Hz) can provide valuable information on the dynamic nature of a polymer at any given temperature (156–162). As with other relaxation measurements, it is conventional to combine temperature and frequency to allow calculation of activation energies and map the dynamics of the polymer system. Because of the breadth of most relaxation processes, it is desirable to explore the influence of factors such as molar mass and morphology on the distribution parameter describing the motion of the dipoles. Various approaches have been used to describe the distribution parameter; however, the most adaptable is that of Havriliak and Negami (163,164). The parameters obtained have no molecular significance, but provide a method of characterizing the influence of various factors on the process being investigated. In amorphous polymers, DRS has been extensively used for the study of sub-T_g processes and, in particular, the effects of physical aging on the nature of these relaxation processes. In the case of thermosets, DRS can be used to monitor the cure process (165,166). In solution, DRS has the capability of probing the backbone local dynamics, and studies as a function of molar mass allow an understanding of the development of cooperative motion as the chain length is increased.

Electron Spin Resonance Spectroscopy. Through the use of stable free-radical species, it has been possible to follow the relaxation processes of these labels and infer the nature of the motion of the elements of the polymer chain to which they are attached. This technique is limited, in that it does not see the actual motion of the linkage to which the probe is attached to the polymer but can provide important information on the nature of the effects of the matrix on the motion of the probe (167–175) (see ELECTRON SPIN RESONANCE).

Luminescence. Many polymer groups, eg naphthalene, are able to exhibit fluorescence, or even phosphorescence, when exposed to light of a suitable

excitation frequency. If the excitation is polarized, it is possible to follow the subsequent motion of the probe during the fluorescence or phosphorescence lifetime. The technique has been successfully applied to the study of a range of polymer systems.

Combining the data obtained from a range of dynamic observations of polymers, it is possible to develop an understanding of the factors that influence the physical properties of these materials. It is clear that short-range forces can control both side-chain and local motion of the polymer backbone. However, in an amorphous solid, provided the motions of the backbone are thermally labile, it is free volume which dictates the temperature at which the T_g occurs (176–180).

Rheology and Melt Flow Behavior. In many applications the ability of the polymer to undergo flow under the influence of an applied force is critical in understanding whether or not that material can be processed using a particular technology. A variety of different types of equipment exist for the measurement of flow under particular constraints: constant shear stress, constant strain, elongation flow, normal force measurements, oscillatory stress, capillary flow, etc. A typical polymer when subjected to oscillatory shear will exhibit a viscosity that reflects the ease with which it can move. Low molar mass polymers exhibit flow characteristics which are similar to simple liquids and are said to be Newtonian. However, as the chain length increases, cooperative motions of the chain become possible leading to the so-called *normal mode* relaxation processes. These collective motions of a flexible polymer chain are a function of the length of the chain and molar mass. These motions will contribute to the flow resistance at low rates of shear but, as the frequency is increased, cease to be able to contribute and lead to the observation of a lower effective viscosity-shear thinning. This phenomenon is observed in many polymer systems and is molar mass dependent. If the chain is sufficiently long, then entanglement is possible and additional constraints are imposed on the flow, and a marked increase in viscosity is observed. For low molar masses the viscosity (η) varies as $\eta \propto M_n$ whereas for polymers above a certain critical molar mass M_c, the viscosity varies as $\eta \propto M_n^{3.5}$. Many applications of polymers in the melt phase require knowledge of M_c that typically has a value of 1.5×10^4 to 6×10^4 for most materials (181–184) (see RHEOLOGICAL MEASUREMENTS).

Thermosetting Polymer Systems

An important group of polymers are classified as being thermosetting materials (165) (see THERMOSETS). The chemistry associated with their formation is often the same as that used for thermoplastic materials, except that in the case of these polymers the monomers used have more than two functions per monomer unit. It is therefore possible to have two materials that ostensibly look chemically similar, but one is a thermoplastic and the other a thermoset. This situation is to be found in Polyurethanes (qv) where, depending on the functionality of the isocyanate or soft block used, the resulting material may be a thermoplastic or a thermoset. In most cases it is desirable to monitor the cure process to avoid either too slow a formation of the three-dimensional network, and hence poor production efficiency, or too quick a cure with the possibility of excessive exotherms and possible degradation of the material. The formation of a network for a material that has a T_g above

the cure temperature can also lead to trapped stresses, and these will usually have to be relieved by post-thermal treatment. A number of rheological, thermal, dielectric relaxation, and spectroscopic methods exist for the monitoring of the cure processes. The techniques used for the study of thermoplastics are generally appropriate for the study of thermosets, provided flow is not required to make the observation.

Other Important Characteristics of Polymers

In terms of application, polymers are used in a variety of different ways that lead to the requirement to measure specific physical properties.

Electrical Characteristics. Although polymers have been traditionally used as insulators, in recent years the ability to achieve intrinsic conductivity has been demonstrated and is associated with systems in which the backbone has developed an extended delocalized electronic structure, eg polyacetylene. Other materials such as poly(vinyl chloride) or polyethylene are used in electric insulation applications. In the latter it is their ability to inhibit electron migration that is the important characteristic. A range of tests exists to help measure such features as the electric breakdown resistance. Other specific types of property observed in polymers include semiconductivity, photoconductivity, piezoelectricity, pyroelectricity, and static electrical charging (triboelectricity). Each of these features is a direct consequence of a combination of chemical and specific morphological feature in the polymer or composite material. These properties have been used to specific effect in microphones, load speakers, photocopying, display technology, etc (185–188) (see ELECTRICALLY ACTIVE POLYMERS; PIEZOELECTRIC POLYMERS).

Stability. Polymers are used in a wide range of environments and their ability to resist environmental factors is often a determining factor in their application. The factors which will lead to degradation include mechanical stresses due to handling, radiation, light, X-rays, and gamma rays; exposure to various gases including oxygen, ozone, sulfur dioxide, nitrogen dioxide and to solvents and corrosive chemicals; and strong acids and strong bases. A variety of different specific tests exist for the study of these features and relate to specific problems. The most commonly encountered problem is thermal degradation associated with injection molding and similar methods and directly related to the relative stability of particular bonds forming the backbone and side chains (189) (see DEGRADATION; STABILIZATION).

Permeability. Many polymers are used in packaging and, in particular, for food. In this latter case the permeability to gases and vapors is of prime importance. The permeation or transmission of a gas or vapor is a function of the solubility of a gas or vapor in the polymer and the rate of diffusion through the matrix. The permeability coefficient, diffusion constant, and solubility coefficients can all be measured and are influenced by the chemical structure and morphology. In order to achieve the required permeability characteristics it is common to co-extrude a series of polymers to form a laminated structure. Such materials allow selective permeation of a specific species and enhance the life of the product (190,191) (see TRANSPORT PROPERTIES).

Flammability. The ability to withstand exposure to fire is often a critically important feature when selecting a specific plastic for a particular application. The *oxygen index*, defined as the percentage of oxygen in an oxygen/nitrogen mixture required to sustain combustion, is often used to rank plastics. The higher the value the better the material's ability to withstand exposure to heat. TGA data is often used to assess the degradation characteristics of a polymer; however, specific simulation tests are required to determine how factors such as heat flow, thermal conductivity, drip, etc, in reality influence the burning characteristics of a material (192) (see FLAMMABILITY; FIRE RETARDANTS).

Solubility. Solubility of a polymer will reflect the compatibility with the solvent. For a polymer to be dissolved there is a requirement for the forces between the solvent to match those between the elements of the polymer itself. If the match is close, then it is possible to create a situation in which the dissolved polymer is in a collapsed state corresponding to the thermodynamic requirements of the theta condition. At this point the forces between the segments balance the forces between the segments and the solvent. If the strength of the interaction is increased, the quality of the solvent is improved and the effective size of the polymer increases; it swells. Thermoplastic polymers can be completely dissolved in a good solvent, whereas thermoset materials are only able to swell to a size that reflects the cross-link density of the matrix. It is possible for two nonsolvents to combine to form a solvating mixture, and this phenomenon is termed co-solvency (see MISCIBILITY).

Density. The ability to achieve a particular level of packing is critical in determining the density of a material and is directly related to the morphology of the polymer. The density may be measured directly or alternatively by determination of the composition of a liquid in which the material is just buoyant (193).

A comprehensive survey of test methods is to be found in the *Handbook of Polymer Testing* (194).

CHLOROPRENE POLYMERS

Introduction

Polychloroprene [9010-98-4] was discovered in 1930 at E. I. DuPont de Nemours & Co. in Wilmington Delaware. The discovery grew out of a need to develop a synthetic substitute for natural rubber. DuPont first marketed this first commercially successful synthetic elastomer as DuPrene in 1933. In response to new technology development that significantly improved the product and manufacturing process, the name was changed to Neoprene in 1936. The current commercially acceptable generic name for this class of chlorinated elastomers is CR or chloroprene rubber.

Since the time of its introduction to the marketplace, Neoprene has been more than a simple replacement for natural rubber. Like natural rubber, Neoprene is rubbery, resilient, and has high tensile properties. However, Neoprene has better heat stability, better resistance to varying environmental weathering conditions, superior flex life, excellent solvent and oil resistance, and reasonable electrical properties when compared to natural rubber. This unique combination of properties poised Neoprene for solving many of the potential problems besetting the automotive, construction, footwear, specialty apparel, transportation, and wire and cable industry throughout the twentieth century and beyond. The good balance of properties has made the polymer useful in a large divergent list of applications including aircraft, appliance, automotive, bridge pad, chemical-resistant clothing, home furnishings, machinery, mining and oil field belting, underground and undersea cables, recreation, and tires. Current worldwide consumption of polychloroprene approximates 239,239 ton with a value of more than $1.5 billion.

Polymerization Processes

Chloroprene, 2-chloro-1,3-butadiene [126-99-8] monomer undergoes dimerization and autopolymerization when stored at ordinary temperatures. These reactions occur simultaneously by different mechanisms. Free-radical processes normally initiate autopolymerizations. The dimerization reactions are thermally initiated.

Dimerization. The dimerization reactions follow second-order kinetics and involve 2 + 2 and 4 + 2 concerted and nonconcerted cycloaddition reactions. Alternate mechanisms involving Cope rearrangements account for the formation of dichlorocyclooctadiene. The rate of dimer formation is affected both by the temperature and the monomer concentration. Owing to the high (20.9–24 kcal mol^{-1}) activation energy, storage tank temperature is a powerful tool for controlling rates of dimerization (1,2). Free-radical inhibitors do not inhibit chloroprene and dichlorobutadiene dimerization (3–6). As dimerization is one of the major sources of the exothermic heat of reaction, storage vessel temperature control is of primary concern in avoiding uncontrollable runaway reaction during commercial monomer synthesis and storage of chloroprene and dichlorobutadiene.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Dilution of monomer with inert solvents aids the safe shipment of these reactive monomers.

Free-Radical Polymerization. Autopolymerization of chloroprene monomer occurs readily under free-radical and photochemical conditions (see RADICAL POLYMERIZATION). The electron-rich and electronegative chlorine atom facilitates the high reactivity of this monomer. Over the temperature range 20–80°C, the initiation depends on the formation of di-radicals or the added free radical that initiates polymerization (see INITIATORS, FREE-RADICAL). Polymerization proceeds at a rate that follows first-order kinetics with an activation energy of 82 kJ mol^{-1} (19.6 kcal mol^{-1}) and a heat of polymerization of 68–75 kJ mol^{-1} (16–18 kcal mol^{-1}) (1,3,7,8).

$$k(p) = 4.8 \times 10^{-8} s^{-1}$$

Bulk Polymerization. Bulk polymerization is strongly catalyzed by peroxides such as cumene hydroperoxide or chloroprene peroxides. Chloroprene peroxides are formed either by deliberate or adventitious exposure of monomer to oxygen (4,9). Maynard showed that less than 0.1% polymer was formed when specially purified chloroprene monomer was allowed to age in the dark at ambient temperatures for 8 weeks. When chloroprene monomer was exposed to 0.1 mol% oxygen and aged in a similar manner, 19% polymer was formed in only 3 days. Thus, oxygen absorption leading to peroxide formation is a major safety concern in the large-scale manufacture and storage of chloroprene and dichlorobutadiene. Thiodiphenylamine (0.05%) mitigates the problem by reducing the oxygen absorption rate at 25°C by more than four orders of magnitude.

Emulsion Polymerization. Commercial polymers are made by aqueous batch, semicontinuous (semibatch), or continuous free-radical emulsion polymerization. The emulsion system is composed of five components: monomer, surfactant, water, chain-transfer agent, and initiator (2) (see HETEROPHASE POLYMERIZATION). Organic fatty acid salts, sulfonic acid salts, or substituted diterpene salts (sodium abietate) derived from synthetic or natural (eg pine trees) sources constitute the surfactants most commonly employed to stabilize the colloid for emulsion polymerization. Water forms the continuous phase that provides low emulsion viscosity, aids in heat transfer, and compartmentalizes polymerization to allow the rapid formation of high molecular weight polymer where branching can be effectively controlled. Emulsion polymerizations are faster than bulk, solution, or suspension and yield polymers having a much higher molecular weight (10). When used at 0.01–1.5 wt% concentrations, dodecylmercaptan, iodoform, or dialkyl xanthogen disulfides are efficient chain-transfer agents. The molecular weight of chloroprene sulfur copolymers is controlled by a different strategy. Copolymerization of chloroprene with 0.1–2% sulfur followed by cleavage and capping thionyl ends with a combination of 1.0–5.0% tetraethyl thiuram disulfide and 0.25–2.0% sodium dibutyl dithiocarbamate yields a polymer having number-average molecular weights that range up to 500,000 a.m.u. (11).

Polychloroprene emulsion polymerization follows the Smith–Ewert kinetics, developed initially for polystyrene (2). On mixing the monomer, water, and surfactant under high shear, the surfactant molecules will cluster into monomer

swollen micelles and monomer droplets. The micelles number 10^{17}–10^{18} micelles dm^{-3} having diameters ranging from 50 to150 Å. The bulk of the monomer resides in the surfactant-stabilized monomer droplets that number 10^{9}–10^{11} dm^{-3}, with particle diameter ranging from 1 to10 μm. The initiators are generally formed *in situ* by redox reactions of oxidants such as alkali persulfates or peroxides and reducing agents such as alkali sulfites, reducing carbohydrates, or reducing acids. Upon addition of the initiator to the emulsion, free radicals are formed in the emulsion aqueous phase at a rate of 10^{16}–10^{18} radicals dm^{-3} s^{-1}.

Harkins's theory suggests that emulsion polymerization occurs in three intervals. During interval I, or the particle formation phase, the free radicals from initiators either react with monomer in the aqueous phase to propagate oligomeric chains (homogeneous nucleation), enter the micelles to initiate polymerization (micellular nucleation), or less frequently initate polymerization in the much larger and sparser monomer droplets (droplet nucleation). As polymerization continues all micelles continue to grow and are ultimately converted into polymer particles, signaling the start of interval II. During interval II, the polymer particles continue to grow as more monomer diffuses from the droplets to the locus of polymerization. When all monomer has diffused from the droplets to the particles, the monomer droplets disappear, signaling the beginning of interval III. During interval III, polymerization rates initially decrease as the concentration of the monomer has been reduced significantly. At the latter stages of interval III, polymerization rates increase again (Tromsdorff gel effect) because of decreased termination frequency of growing radicals resulting from high internal viscosity (12). At a desired conversion of the monomer, the polymerizations of mercaptan, iodoform, and xanthogen disulfide modified polymerizations or chloroprene–sulfur copolymerizations are quenched with the aid of hindered phenols, alkyl hydroxylamines, or thiodiphenylamine. Typically, an emulsion will contain 30–60% solids at the end of polymerization.

In addition to electrostatic colloid stabilization generated by anionic surfactants, liquid dispersions are also made from nonionic surfactants. Stabilization of the emulsion is achieved by electrosteric stabilization or by pure steric stabilization (2,13). Polyoxyethylene dodecyl ethers, polyoxyethylene nonyl phenyl ethers, and polyoxyethylene nonyl phenol ethers are a few surfactants typically used in emulsion polymerization with nonionic surfactants (14–16). Non-ionic emulsion polymerizations are characterized by lower critical micelle concentration than their ionic counterparts. Thus, the emulsion particle sizes are generally much larger than in the ionic polymerizations. The mechanism of radical entry and exit in polymeric surfactant stabilizer systems are different than in anionic systems. With water-soluble initiators, the kinetics depends on initiator concentration.

Chain-Transfer. In emulsion polymerization, polymer chains grow rapidly to achieve a very high molecular weight. The ultimate polymer molecular weight can, however, be conveniently controlled by chain-transfer agents (AX). A chain-transfer agent, AX, intercepts a growing polymer radical.

$$\mathrm{Rn}\cdot + \mathrm{AX} \xrightarrow{k_{\mathrm{tr,\,AX}}} \mathrm{RnX} + \mathrm{A}\cdot$$

$$\mathrm{A}\cdot + \mathrm{M} \xrightarrow[\text{fast}]{k_{\mathrm{p,\,A}}} \mathrm{R_1}\cdot$$

The active center of the chain-transfer agent reacts with the growing chain to stop further chain propagation. A new free radical, A, is formed from the chain-transfer agent. The new free radical initiates a second polymer chain by reacting with more monomer, M. Thus, the ultimate polymer molecular weight depends on the concentration of the chain-transfer agent (17).

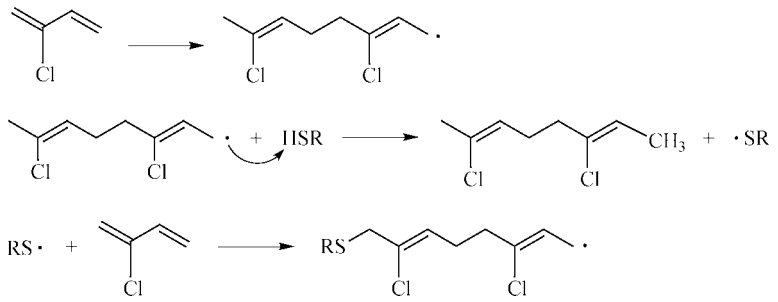
There are at least two conditions that define a chain-transfer agent. A compound becomes a chain-transfer agent if the rate of polymer chain propagation exceeds the rate of chain-transfer.

$$k_p[M] \gg k_{tr,AX}[AX]$$

This condition allows the polymer chain to propagate to a high molecular weight. Secondly, the rate constant for polymer chain propagation, k_p, must be of similar magnitude to the rate constant for re-initiation of the polymer chains by the chain-transfer agent (17). In instances where one or the other condition is not satisfied, the agent could be considered an inhibitor.

$$k_p \geq k_{pA}$$

Thios (eg dodecyl mercaptan), halogenated compounds (eg CBr_4, CCl_4), and activated disulfides such as xanthogen disulfides are normally employed in commercial polychloroprene polymerization.



The mechanism of this series of reactions involving dodecyl mercaptan chain-transfer during a high pH polymerization was elucidated using radio-sulfur-tagged dodecylmercaptan (18). The use of multiple chain-transfer agents of different reactivities yielded polymer of more uniform structures (19).

The chain-transfer rate constants, k_{tr}, are determined from the average molecular weight in a polymerizing system. The intercept of a Mayo plot of number-average molecular weight against $[I]/R_p$ where [I] is the initiator concentration and R_p is the polymerization rate (20). Extensive compilations of k_{tr} values are found in the open literature (21). Dodecyl mercaptan is used in the manufacture of commercial Neoprene W. The chain-transfer rate constant for dodecyl mercaptan with chloroprene was determined using the Mayo plot technique (22) as follows:

$$k_{tr,DDM} = 368 \text{ dm}^3/(\text{mol} \cdot s) \text{ at } 40^\circ\text{C}$$

The choice of chain-transfer agents can have an impact on vulcanizate properties. Mercaptan chain-transfer agents yield polymer having nonreactive and dangling end groups. Xanthogen disulfide chain-transfer agents produce polymers having reactive end groups that participate in the vulcanization reaction, contribute to the network structure, and thereby contribute to high modulus of the polymer.

Copolymerization. In free-radical copolymerization (qv), the composition of the copolymer is controlled by the comonomer reactivity ratios (23). The monomer reactivity ratio is defined as the quotient of the rate constants for chain homopropagation to the rate constant for chain cross-propagation.

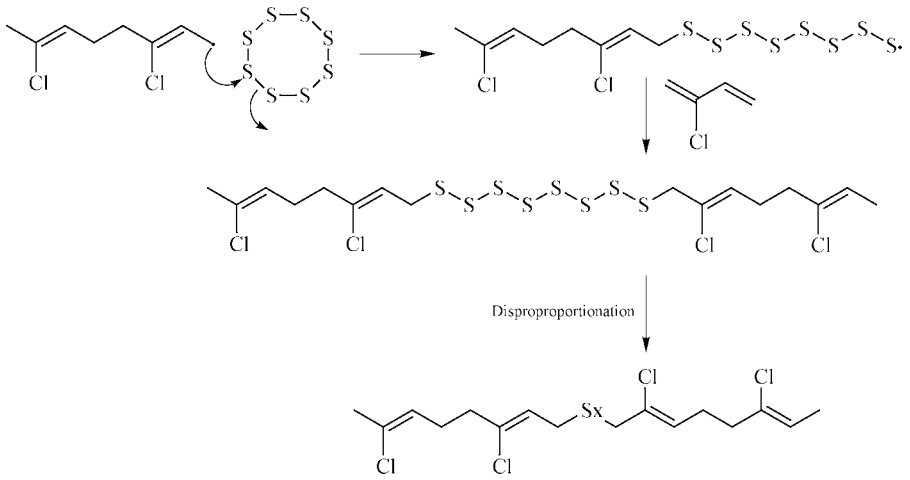
$$r_A = k_{AA}/k_{AB} \quad r_B = k_{BB}/k_{BA}$$

The expressions are an outcome of the "terminal model" theory with several steady-state assumptions related to free-radical flux (14,23). Based on copolymerization studies and reactivity ratios, chloroprene monomer is much more reactive than most vinyl and diene monomers (Table 1). 2,3-Dichloro-1,3-butadiene is the only commercially important monomer that is competitive with chloroprene in the free-radical copolymerization rate. 2,3-Dichlorobutadiene or "ACR" is used commercially to give crystallization resistance to the finished raw polymer or polymer vulcanizates. α-Cyanoprene (1-cyano-1,3-butadiene) and β-cyanoprene (2-cyano-1,3-butadiene) are also effective in copolymerization with chloroprene but are difficult to manage safely on a commercial scale. Acrylonitrile and methacrylic acid comonomers have been used in limited commercial quantities. Chloroprene–isoprene and chloroprene–styrene copolymers were marketed in low volumes during the 1950s and 1960s. Methyl methacrylate has been utilized in graft polymerization particularly for vinyl adhesive applications. A myriad of other comonomers have been studied in chloroprene copolymerizations but those copolymers have not been used with much commercial success.

Table 1. Chloroprene (M1) Reactivity Ratios

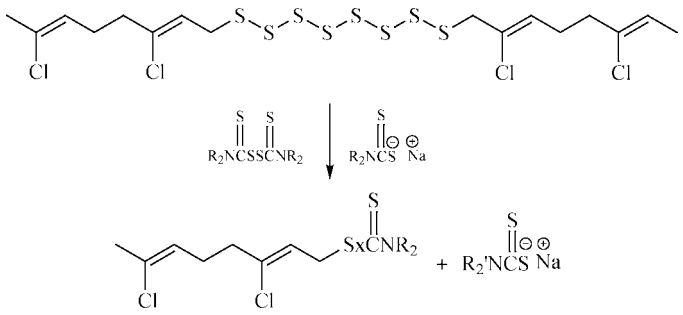
Comonomer M2	r_1	r_2
Acrylonitrile	5.38	0.056
Butadiene	3.41	0.06
2,3-Dichloro-1,3-butadiene	0.31	1.98
1-(2-Hydroxyethylthio)-1,3-butadiene	1.00	0.20
2-Fluoro-1,3-butadiene	3.70	0.22
2-Cyano-1,3-butadiene	0.14	2.8
Diethyl fumarate	6.51	0.02
Isoprene	2.82	0.06
Methacrylic acid	2.7	0.15
Methyl acrylate	10.40	0.06
Methyl methacrylate	6.33	0.08
2,3,3-Trifluoro-1-vinyl cyclobutane	2.71	0.64
Styrene	5.98	0.025
Sulfur	2–4	0.18

Chloroprene–Sulfur Copolymerization. The high reactivities of chloroprene and dichlorobutadiene permit copolymerization with sulfur to yield toluene-insoluble and partially gelled copolymers of high molecular weight. Gelled polymers are highly cross-linked polymers that are insoluble in toluene. In solution or aqueous emulsion polymerization, a growing polychloroprene radical reacts with rhombic (nonpolymeric) sulfur (24) or suitable sulfur donors such as 1,2,3,4-tetrasulfocyclohexane (25) or polysulfides (26) to yield a copolymer. Reaction with elemental sulfur involves cleavage of the eight-membered sulfur in a ring-opening reaction to yield a thionyl-terminated radical.



The radical will initiate another homopolymer chain by reaction with more monomer. Finally disproportionation occurs and the sulfur rank is reduced to 3–6 sulfur atoms per block unit. The average number of sulfur atoms between polychloroprene chains or sulfur rank has been explored by ^{1}H NMR. The chemical shift of the methylene hydrogen atoms adjacent to the polythionyl linkages vary from 3.45 to 3.9 ppm (27). It is believed that the sulfur rank for a typical chloroprene–sulfur copolymer contains a predominance of S_3 to S_6 units. The assignment is consistent with ease of reaction of dialkyl polysulfides ($S_x > 2$) with the chemicals normally used in the peptization reactions that follow.

In order for the chloroprene-sulfur copolymer to be useful for rubber processing and curing, the molecular weight or Mooney viscosity must be reduced to approximately 500,000 a.m.u. This molecular weight corresponds to approximately 45 Mooney viscosity, where Mooney viscosity was determined according to ASTM D-1646-96A with a large rotor at 100°C test temperature for 5 min total test time. Molecular weight reduction is achieved by cleaving the sulfur–sulfur bonds of the copolymer through a process termed peptization.



In solution or at the end of emulsion polymerization, tetraalkyl thiuram disulfides are added to the emulsion. Very little reaction occurs at this point. Alkali metal salts of dithiocarbamates, secondary amines, or alkali salts of mercaptobenzothiazole (28) are added to initiate the peptization reaction through sulfur–sulfur bond cleavage. The polychloroprene sulfide ion reacts with the tetraalkyl thiuram disulfide to cap the end of the polymer and generate a second dithiocarbamate salt. The second dithiocarbamate salt propagates the peptization reaction. Thus, the final polymer molecular weight and bulk Mooney viscosity will depend on initial sulfur concentration in the copolymerization and the concentration of tetraalkyl thiuram disulfide and dithiocarbamate salt added during the peptization step.

Interpenetrating Polymer Networks (IPN). Polymerization of vinyl and diene monomers over an already formed molecule held in a polymer particle represents a special case of copolymerization. The interpenetrating polymer networks (qv) thus formed overcome many of the miscibility and other problems associated with physical blends of individual copolymers and leads to new compositions that are useful for coatings, adhesives, and caulks (14). Polychloroprene IPNs have been made by co-curing copolymers of 1-chloro-1,3-butadiene [627-22-5]. The 1-chloro-1,3-butadiene comonomer polymerizes in a fashion to increase the allylic chloride concentration in the copolymer backbone. The butadiene copolymer with 1-chloro-1,3-butadiene (29) and octyl acrylate copolymer (30) improved the low temperature brittleness, oil resistance, and heat resistance of polychloroprene.

Block Copolymers. Block copolymers (qv) have been made in two-step processes. First a mixture of chloroprene and *p*-xylene-bis-*N*,*N*′-diethyl dithiocarbamate was photopolymerized to form a dithiocarbamate-terminated polymer which was then photopolymerized with styrene to give the block copolymer. The block copolymer had the expected morphology of spherical polystyrene domains within the polychloroprene matrix (31). Other routes to block copolymers involved hydrolysis of xanthate or thiocarbamyl end-capped polymers followed by oxidative coupling of the two different homopolymers. Core–shell technology is another potential route to block copolymers.

Graft Polymerization. Graft polymerization is related to block copolymerization. A block copolymer contains long sequences of two monomers (ie AAA monomer blocks followed by BBB monomer blocks) along the copolymer chain. Graft copolymers (qv) consist of long chains of one monomer with occasional branches consisting of long chains of a second (grafted) comonomer. The branched points are normally formed by allylic atom (typically hydrogen) abstraction by free-radical initiators (eg peroxides) to yield a resonance-stabilized free-radical.

The free radical initiates the addition polymerization of a second monomer beginning at the locus of the free radical. Generally grafting is performed to significantly modify polymer properties. In the production of emulsion-polymerized acrylonitrile–butadiene–styrene tripolymer, styrene and acrylonitrile are grafted onto rubbery polybutadiene to improve compatibility between the thermoplastic and rubber matrix used in impact modification (12). Methyl acrylate, acrylonitrile, alkyl methacrylates (eg methyl, octyl, lauryl), fumaronitrile, methacrylic acid, and dichlorobutadiene have been employed in solution and emulsion graft polymerization with polychloroprene. In general, solvent resistance, heat resistance, and hydrolytic resistance were improved. Solution graft polymerization of methyl methacrylate to polychloroprene is a commercially important process for making adhesives finding utility for bonding to vinyl-containing plasticizers that migrate to the surface of the substrate with time.

Other Modes of Polymerizations.

Popcorn Polymerization. ω-Polymerization frequently referred to as popcorn polymerization owing to the physical appearance of the polymer, can be a dangerous side reaction for monomer storage vessels. The polymerization appears to proceed without external initiation (32–34), and is catalyzed by the tightly gelled polymer seeds that are a product of the polymerization. Once seeds are present and immersed either in the liquid or vapor phase of monomer, their weight increases exponentially with time.

Fresh radicals are formed continuously by mechanical rupture of the polymer chains that are swollen by dissolved monomer (32,35). Termination of polymer radicals, in turn, is inhibited by the rigidity of the polymer network. The reaction is temperature sensitive, and can be minimized with adequate cooling (32). On the other hand, heat transfer may be impaired as the mass of material grows. Polymerization continues until the available monomer is consumed or gross amounts of inhibitor are added to the system. A number of inhibitors such as organic nitrites, nitroso compounds (32), oxides of nitrogen (36), alkali metal mercaptides (37), or nitrogen tetroxide adducts with unsaturates (78,79) have been recommended. The best control, however, is routine inspection and clean up of equipment to eliminate seeds.

Non-Free-Radical Polymerization. Nonradical polymerizations have not produced commercially useful products, although a large variety of polymerization systems have been studied. The structural factors that activate chloroprene toward radical polymerization often retard polymerization by other mechanisms.

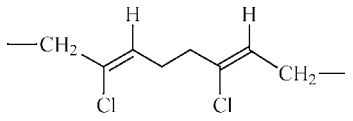
Cationic polymerization with Lewis acids yields resinous homopolymers containing cyclic structures and reduced unsaturation (41,42,171) (see CARBOCATIONIC POLYMERIZATION). Polymerization with triethylaluminum and titanium tetrachloride gave a product thought to have a cyclic ladder structure (43). Anionic polymerization with lithium metal initiators gave a low yield of a rubber product. The material had good freeze resistance compared with conventional polychloroprene (44). Alternating copolymers of chloroprene have been prepared from a number of donor–acceptor complexes in the presence of metal halides. Frequently this enables preparation of copolymers from monomers having unfavorable reactivity ratios in radical polymerization. Triethylaluminum sesquichloride with a vanadium oxychloride cocatalyst yielded alternating copolymers of chloroprene with acrylonitrile, methyl acrylate, and methyl methacrylate when equimolar amounts

of the two monomers were used (45). Polymer composition tended to follow the composition of the monomer mixture (46). The chloroprene units were shown to be in the trans-1,4-configuration (46) on the basis of infrared spectra. Variables affecting the acrylonitrile copolymerization were studied in detail (47) by infrared spectra. The alternating copolymer of acrylonitrile and chloroprene is resinous. A copolymer containing 35 mol% acrylonitrile was a soft, oil-resistant elastomer (47). Stability constants have been determined for complexes of acrylic monomers with ethylaluminum sesquichloride, and related to the kinetics of copolymerization with chloroprene (48). Kinetic data have been determined for polymerization in the presence of a manganese cocatalyst (49).

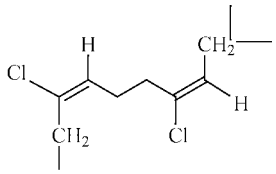
A series of graft polymers on polychloroprene were made with isobutylene, iso-butyl vinyl ether, and α-methylstyrene by cationic polymerization in solution. The efficiency of the grafting reaction was improved by use of a proton trap, 2,6-di-tertiarybutyl pyridine (50).

Polymer Microstructure

Unsymmetrical diene monomers such as chloroprene polymerize by four reaction pathways: 1,4-head-to-head, 1,4-head-to-tail, 1,2-and 3,4-polymerization (Fig. 1). The concentrations of microstructure vary with polymerization temperature (51) (Table 2). The (Z)- or trans-configuration predominates at conventional polymerizations carried out in the range of 10–45°C.



Zusammen, *Z* (or trans)



Entgegan, *E* (or cis)

Table 2. Microstructure of Polychloroprene by ^{13}C NMR[a]

Polymerization temperature, °C	1,4-Addition			1,2-Addition tertiary allylic chloride	1,2-Addition isomerized primary allylic chloride	3,4-Addition
	Z or trans	Head to tail (inverted)	*E*- or cis			
+90	85.4	10.3	7.8	2.3	4.1	0.6
+40	90.8	9.2	5.2	1.7	1.4	0.8

−150	∼100	2.0	<0.2	<0.2	>0.2	<0.2

[a]Refs. 51,64.

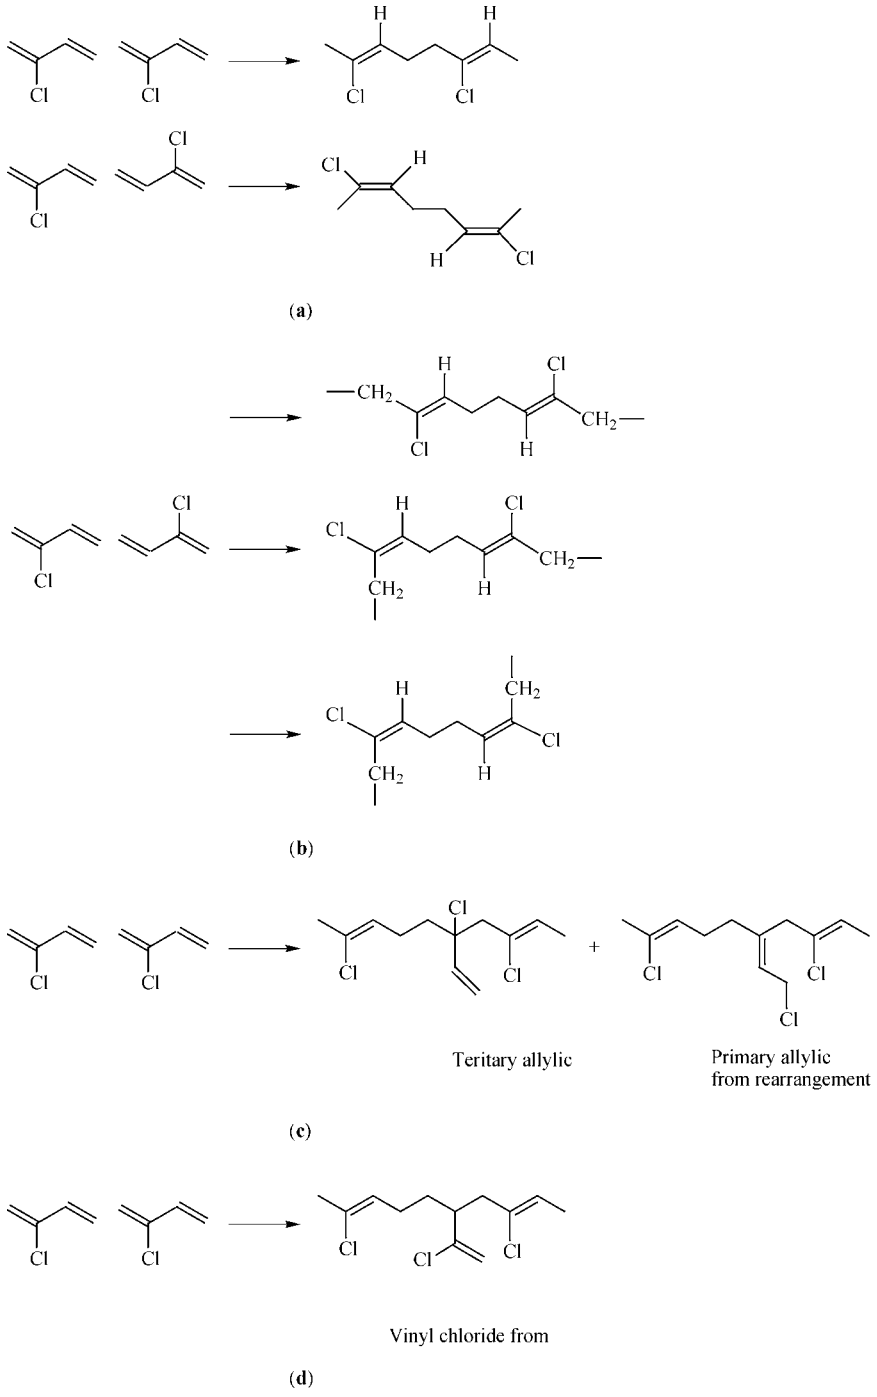

Fig. 1. Four modes of addition resulting in different microstructures. (**a**) 1,4-head-to-head polymerization leading to (*Z*) and (*E*) vinyl chlorides along the main chain; (**b**) 1,4-head-to-tail polymerization leading to (*Z*) and (*E*) vinyl chloride along the main chain; (**c**) 1,2-polymerization leading to allylic chloride; and (**d**) 3,4-polymerization leading to vinyl chloride.

The concentration of (Z)-configuration varies indirectly proportional with the polymerization temperature whereas the other three configurations vary directly proportional with the polymerization temperature. The total amount of *E*-, 1,2-, and 3,4- configurations vary from 5% at −40°C to 30% of the total polymer backbone at 100°C polymerization temperatures. Other structural studies have involved 2,3-dichloro- butadiene homopolymer (52), the free-radical random copolymer with methyl methacrylate (53) with chloroprene, and the alternating copolymer of sulfur dioxide with chloroprene (54). Petiaud and Pham studied the thermodynamics of the various modes of unit addition (55).

The four modes of polymerization result in microstructures that have profound effects on polymer properties and processability. The increased proportion of (Z)-configuration at low temperature leads to more stereoregular polymer chains that crystallize rapidly. This rapid crystallization rate results in a polymer of almost thermoplastic behavior. The polymer hardens rapidly at 25°C and has utility for fast bond-developing adhesive applications. At intermediate and high polymerization temperatures, the higher concentrations of the allylic chloride, pendant vinyl chloride, and head-to-head and head-to-tail moieties provide a degree of crystallization resistance. As the (Z)-configuration is always in high concentration, polychloroprene polymers will crystallize under stress (eg stretching) and providing increased strength to vulcanizates used as mechanical goods.
