Interference effects, which arise because of the extraordinary uniformity of thickness of the film over the spectrometer sample beam, superimposed on the absorption of incident light by parylene films, can be observed. Experimentally, a sinusoidal undulation of the baseline of the spectrum is seen, particularly in the spectral regions where there is little absorption by the sample. These so-called "interference fringe" excursions can amount to some 15–20% transmission and are uniformly spaced in frequency. Larger excursions indicate greater uniformity

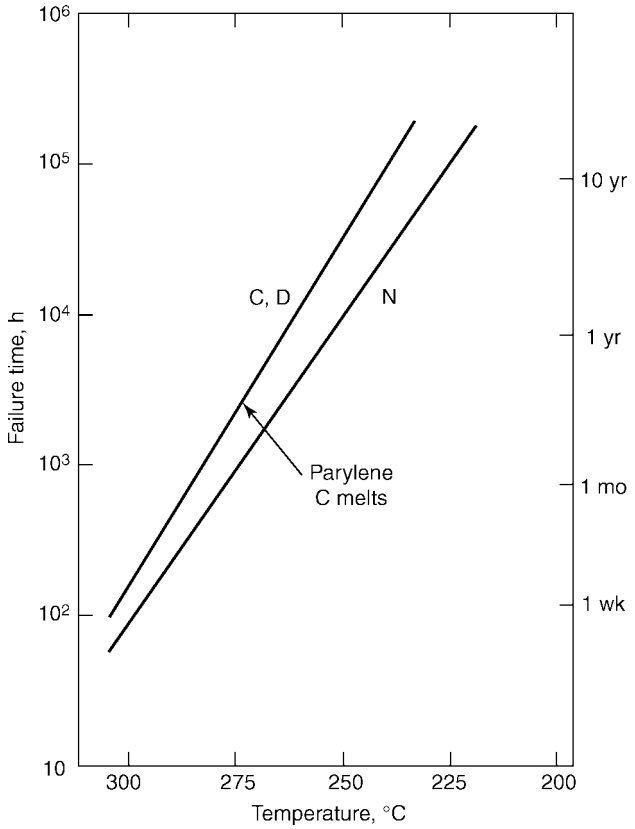

Fig. 10. Long-term effect of aging in vacuum on flexibility of Parylenes C, D, and N at elevated temperature. Failure = 50% loss in tensile strength.

in thickness. Such fringes are seen toward the left side of the experimental spectra of Figure 12. Although interference phenomena are also encountered experimentally in the visible and ultraviolet regions, their effects have been removed in the consolidation and replotting of the data of Figure 11. In transmission spectra, at the top of the interference fringes (the wavelengths of the sinusoidal maxima), constructive interference occurs in which all incident light that is not absorbed appears for detection. At the fringe troughs (the wavelengths of the sinusoidal minima), a condition of destructive interference exists, at which a portion of the incident beam is reflected back toward the source, thereby escaping detection even though it is not absorbed by the sample. By observing the wavelengths at which constructive interference occurs, the approximate thickness of the sample can be determined by using the expression

$$d = \frac{m\lambda_1\lambda_2}{2\,R(\lambda_1 - \lambda_2)}$$

where λ_1 and λ_2 are any two wavelengths at which interference transmission maxima (ie, constructive fringes) exist, separated by m-1 intervening

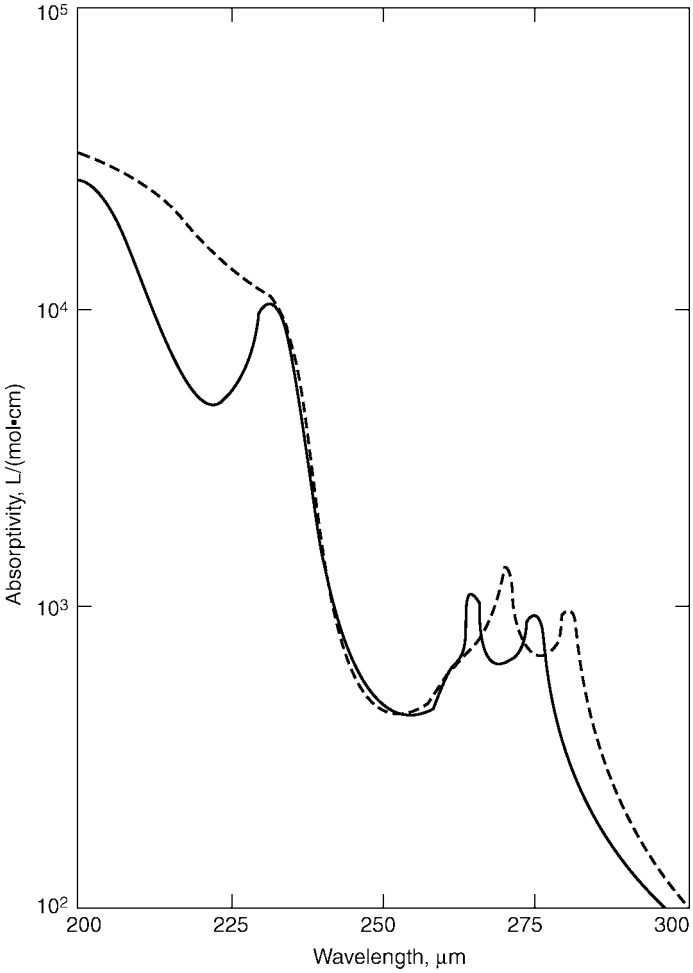

Fig. 11. Ultraviolet absorption spectra of Parylenes N (——) and C (– – –).

constructive fringes; R is the refractive index of the sample film. The thickness d takes the units of wavelength used for λ. At any condition of constructive interference (fringe), twice the thickness times the refractive index equals an integral number of wavelengths of the incident light. That integer is known as the order of the fringe. Much more precise and accurate thicknesses may be computed from the experimental optical spectra if the order of the fringe is known and if any variation of refractive index with wavelength is taken into consideration.

Unstretched PPX films exhibit an inherent negative birefringence, the optical axis of which is perpendicular to the plane of the film. The refractive index along the optical axis is lower than the refractive index observed in the plane of the film, the difference being $n_e - n_0 = -0.075 \pm 0.001$ (46). Where they are observed from the direction normal to the film plane, the films appear to be isotropic. Birefringence is observable only when the films are tilted, or observed in cross section. When stretched, PPX films exhibit a much greater birefringence. The

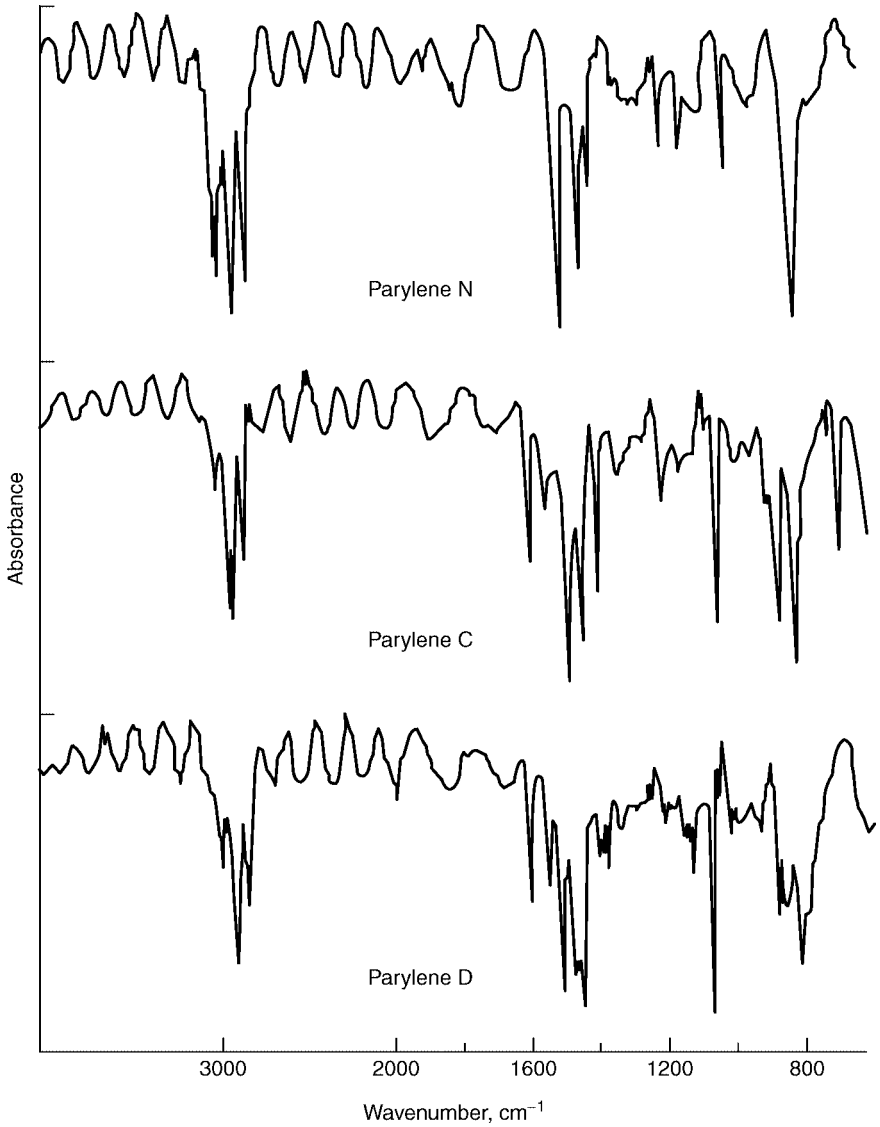

Fig. 12. Infrared absorption spectra of Parylenes N, C, and D films of 18-μm thickness.

stretch birefringence has an optical axis in the direction of stretch and is positive: $n_z - n_0 = +0.2$.

Surface Energy. The surface energies of Parylenes N, C, and D were measured by observing the contact angles for several standard probe liquids. All three have surface energies of approximately 45 mJ/m^2 (= dyn/cm), ie, all test liquids having less than 45 mJ/m^2 surface tension completely wet the as-deposited parylene surfaces (47).

Plasma treatments using reactive gases (N_2, O_2) as well as inert gases (Ar, He) seemed universally to lower the contact angle for water, an observation that

would imply that all such treatments raise the surface energy. Reflectance spectroscopy confirmed the presence of carbonyl in all plasma-treated specimens. Surprisingly, the inert-gas-plasma treatments affected the surface energies of the parylenes more than the reactive gas plasmas did, as indicated by a water contact angle. However, the surface energies of the plasma-treated specimens universally dropped toward the original value on standing in air, but stabilized in about 1 day, without recovering the original value. Plasma treatment of parylene surfaces markedly improves the adhesion of polyurethanes, a result that could be in part, at least, the result of the surface energy change.

Crystallinity. The crystallinity of the parylenes determines two of their most important practical characteristics: mechanical strength at elevated temperatures (see Fig. 5) and solvent resistance.

In a manner typical of crystalline polymers, the crystallinity of parylenes is confined to small-submicrometer domains that are randomly dispersed throughout an amorphous continuum. Adjacent polymer chains, in order to acquire greater overall system stability, exhibit a preference to be close to one another, but the extent to which they actually can be is limited by the tangles already present. Because a given polymer chain is long enough to participate successively in several crystallites, these crystallites function as cross-links to strengthen the bulk polymer. This structural role of the crystallites is retained as temperature rises, giving the bulk polymer physical strength even above its glass-transition temperature, where the amorphous phase is changed to a low modulus, rubbery consistency. Because the crystalline domains are much more resistant to permeation than the amorphous phase, they retain their reinforcing structural role even in the presence of permeants in the amorphous phase, thus giving the parylenes their resistance to solvent attack. The crystalline content increases in freshly deposited polymer as it ages, particularly when it is heated.

Parylene N (PPX) possesses a singularly complex crystalline morphology in which two distinct crystalline modifications are recognized. When deposited in the usual VDP fashion, the crystallites tend to be mostly of the α modification. On annealing at a temperature of about 220°C, the α form is converted to the β modification. This transition was originally thought to be irreversible, but studies have demonstrated that it can be made reversible (48). The crystalline phase undergoes further modifications at higher temperatures before reaching its melting point of 420°C; these modifications have not been fully explored. The detailed crystal structures of the α ($a = 592$ pm, $b = 1060$ pm, $c = 655$ pm, $\beta = 134.7°$ for two monomer repeat units per cell) (49) and β ($a = b = 2052$ pm, $c = 655$ pm, $\gamma = 120°$, for 16 monomer repeat units per cell) (50) modifications have been determined.

In Parylene C, the single crystalline form observed is very similar to the α form of Parylene N. Its detailed crystal structure has been determined [$a = 596$ pm, $b = 1269$ pm, c (chain axis) $= 666$ pm, $\beta = 135.2°$] (51). X-ray studies on the crystal structure of Parylene D have not been reported.

The diffraction pattern produced where X-rays or electrons are directed perpendicularly at the film is the familiar pattern of concentric rings (a powder pattern) produced where the crystallites within the sample are randomly oriented. When the incident beam is directed at an angle to the plane, however, the uniform rings break up into bands or spots, indicative of a preferred orientation of unit

Table 6. Swelling on Immersion in Various Solvents for the Commercial Parylenes at Room Temperature

	Volume change, %		
Solvent	Parylene N	Parylene C	Parylene D
Dichlorobenzene	0.2	3.0	1.8
Mixed xylenes	1.4	2.3	1.1
Monochlorobenzene	1.1	1.5	1.5
2,4-Pentanedione	0.6	1.2	1.4
Trichloroethylene	0.5	0.8	0.8
Acetone	0.3	0.9	0.4
Pyridine	0.2	0.5	0.5
Isopropyl alcohol	0.3	0.1	0.1
Freon	0.2	0.2	0.2
Water, deionized	0.0	0.0	0.0

cells. Tilted electron diffraction results (52) demonstrate that in Parylene N there is a preference for the ⟨100⟩ face of the unit cell to lie in the film plane. Because the polymer chain is oriented along the *c* axis of the unit cell with the benzene rings lying approximately in the plane of the ⟨100⟩ face, it follows that, at least among molecules within crystallites, there is a preference for the polymer chains and benzene rings to be oriented in the film plane. Within the film plane, however, the direction of the chains is random. That benzene rings are preferentially oriented in the plane of the film is supported by negative birefringence and by the Raman spectrum of the polymer (53).

Solvent Resistance. At temperatures below the melting of the crystallites, the parylenes resist all attempts to dissolve them. Although the solvents permeate the continuous amorphous phase, they are virtually excluded from the crystalline domains. Consequently, when a parylene film is exposed to a solvent a slight swelling is observed as the solvent invades the amorphous phase. In the thin films commonly encountered, equilibrium is reached fairly quickly, within minutes to hours. The change in thickness is conveniently and precisely measured by an interference technique. As indicated in Table 6, the best solvents, specifically those chemically most like the polymer (eg, aromatics such as xylene), cause a swelling of no more than 3%.

Applications

Although there is ample evidence in the literature that several industrial groups had a research interest in the PPXs during the 1950s, industrial exploitation was for the most part prevented by the obstacle the parylenes present to conventional fabrication technologies. Because they are generally insoluble in most solvents, even at elevated temperatures, they cannot be used as solvent-based coatings; neither can they be cast as films nor spun as fibers from solution. Because of their high crystalline melting points, melt-working (molding, extrusion, calendering, etc) is also difficult. Yet it is often just these features of solvent resistance and

high temperature mechanical strength that constitute the advantages of PPX materials.

It had been recognized from the outset that polymer forms spontaneously on surfaces exposed to the gaseous monomer PX, but the recognition of VDP as an industrially viable process was not immediate. The public announcement, in 1965, of the convenient generation of pure monomer by the Gorham process from the dimer marked the beginning of a period of a gradually increased understanding and acceptance of the unique features of the parylenes.

As a coating technique, VDP offers certain advantages over other coating techniques such as brushing, dipping, or spraying. These advantages stem principally from the fact that the solid coating is formed from the gaseous monomer directly, without an intermediate liquid stage. As a result, the forces of surface tension, which would cause a pulling away from sharp edges and a filling in of troughs in conventional methods, are not operative and therefore do not affect the cross-sectional profile of VDP coatings. Coatings of PPX grow from the substrate surface outward, producing a conformal layer of uniform thickness. Extensive tests (54) demonstrate that the coating so formed is pinhole-free at thicknesses well below those achievable with conventional coating techniques (see COATINGS).

The PPX coatings are formed spontaneously on substrates at or near room temperature; a cure cycle at elevated temperature is not necessary to complete the polymerization chemistry. The substrate need not be subjected to any temperatures above ambient, and no further time is required beyond that needed for the growth of the film. Because the polymerization is spontaneous, no catalyst is necessary. Catalysts that promote other polymerizations are often ionic or ionogenic and, to the extent that they remain in the coating after cure, their residues are capable of participating in charge mobilization, with resulting detrimental effects in electrical properties. Because the coating is formed at room temperature, stresses that might be induced by differential thermal expansion between the temperature of cure and room temperature are avoided. Because PPX coatings are generally much thinner than conventional coatings, any stress that they impart on the substrate is proportionately less.

Circuit Boards. The most important application of parylenes is as a conformal coating for printed wiring assemblies. The parylene VDP process has the ability to produce a continuous, thin, truly conformal coating on geometrically complex, delicate articles. These coatings provide excellent chemical resistance, especially to solvent attack, and resistance to fungal attack. In addition, they exhibit stable dielectric properties over the wide range of temperatures in which military boards are expected to perform, as well as low dielectric constants, which together with thinness minimize the undesirable loading of high frequency tuned circuits. The reliability with which the process operates substantially reduces labor-intensive touch-up and inspection operations otherwise required for conventional coatings.

Parylene C was included among the earliest MIL-I-46058 (55) qualified coatings (as type XY) and has since enjoyed a reputation for superior performance in protecting and preserving the operation of electronic circuits against the detrimental effects of their operating environments. Environmental water is, of course, chief among these adverse factors. Although the rate of water transport through a parylene coating is finite and well documented, the hydrophobic nature of the

parylenes makes them excellent barriers to penetration by ionic species. Once the circuit board is clean to the extent that surface ionic contamination is minimized and weak surface layers are eliminated, the parylene coating adheres well to the organic substrate material between the conductors. Ionic conduction along the coating–substrate interface, which would otherwise impair electrical performance in the short run and promote galvanic corrosion and dendritic growths in the long term, is minimized.

The SEM photographs of Figure 13 show a conventional FR-4 printed wiring board, coated with an 8-μm film of Parylene C, on which the copper conductor trace has been peeled back. The peeling reveals the rough texture of the epoxy gel coat produced during the original lamination against etched copper in order to achieve maximum laminate peel strength. The region covered with Parylene C in Figure 13 was of the same texture before coating, a fact that, along with parylene's conformality, accounts for much of the texture in the upper surface. Of particular interest is the mode of Parylene C failure as the conductor is peeled. There is evidence of substantial yield prior to failure in the filamentous nature of the failed regions and the web of stretched Parylene C at the apex of the peel. Furthermore, all tensile failure is cohesive, ie, the adhesion of Parylene C to the underlying epoxy gel coat is greater than the cohesive strength within the coating material. The higher magnification (Fig. 13) shows the line of demarcation between the regions covered with copper and with Parylene C prior to the peel, revealing that the breadth of the failed Parylene C exceeded by far its original thickness.

The circuit board with all its components attached presents a variety of surface types for the conformal coating, ranging from plastics through ceramics and glass to metals, in particular aluminum and tin–lead solder. No single mechanism for adhesion can serve all sites effectively. Of particular importance for the epoxy board are the surfaces between conductor traces. Because epoxy is an organic material that is permeable to PX monomer, the growth mechanism of the parylene coating provides adhesion by the interpenetrating network it produces. Care must be taken in cleaning the board surface before coating of leakage-producing ionic contamination as well as organic soils, which interfere with a secure xylylene interpenetration lock. In the cases of ceramic and metal surfaces, monomer penetration is impossible, and other adhesion mechanisms must be engaged. Adhesion to metals is often not essential to the performance of the board, but it is usually desirable. Adhesion to ceramics or glasses is vital in situations where electrical leakage across their surfaces is to be minimized, and is particularly necessary in hybrids. Because the outside surface of common metals is an adherent coating of native oxide, adhesion to metals, ceramics, and glasses can often be achieved using the same approach, ie, treatment with a compatibilizing layer of an organosilane (56). γ-Methacryloxypropyltrimethoxysilane (A-174) is the organosilane most commonly used for the purpose. In action, the trialkoxysilane end of the molecule hydrolyzes and bonds covalently with the oxide on the substrate surface. The methacrylic end of the molecule provides a hydrophobic surface to accommodate parylene deposition, as well as the opportunity to form covalent bonds with the *p*-xylylene polymer through its double bond. It is, of course, essential to provide no more than a monolayer of the organosilane. Water plays an important role in the bonding chemistry between the organosilane and the oxide, and the treatment is often applied from aqueous solution. An alternative treatment is by exposure

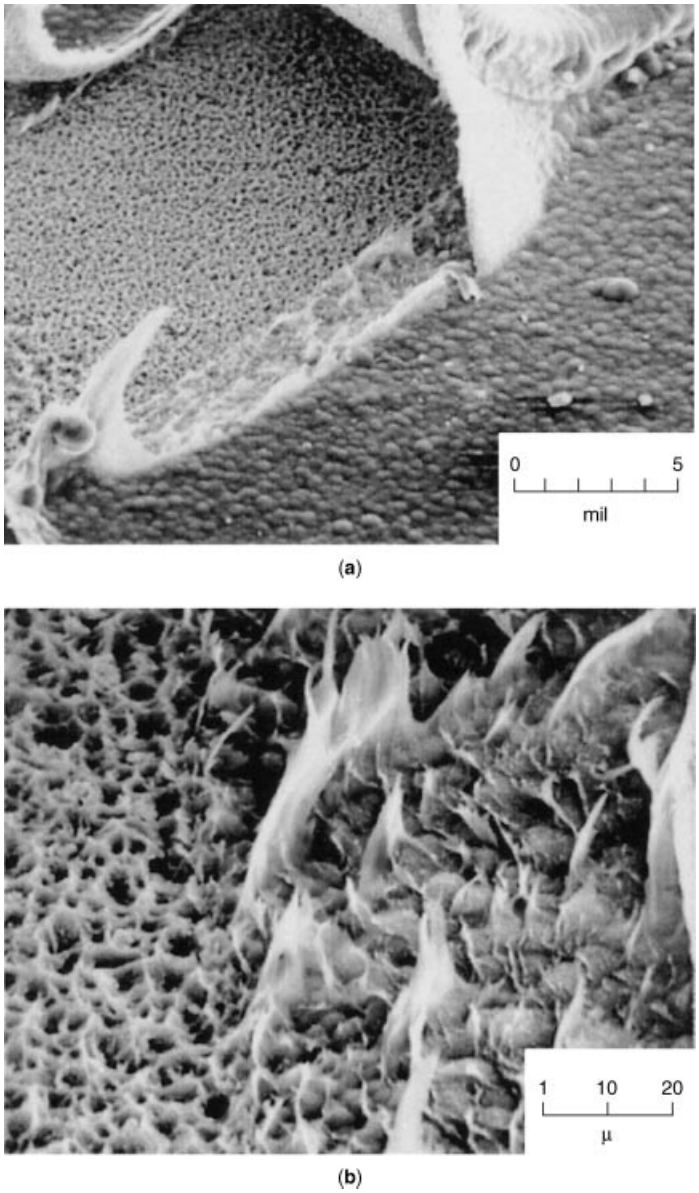

Fig. 13. Scanning electron microscope (SEM) photographs of Parylene C-coated printed circuit conductor peeled to demonstrate the adhesion of the coating to the substrate. To convert mil to meters, multiply by 2.54×10^{-5}.

of the substrate circuit boards to pure gaseous organosilane (57), a process which often takes several days to develop optimum adhesion.

Fluorescence is frequently required in a circuit-board coating to assist inspection of the board after it is coated. Fluorescent parylene coatings can be prepared by admixing a fluorescent agent into the dimer charge. The agent must have

just the right volatility to pass through the process and deposit with the polymer, yet it must be sufficiently stable that it survives the conditions it encounters during the process. Agents that have been used in this manner are anthracene and certain fluorescent whiteners of the Calcofluor family, the 7-dialkylamino-4-methylcoumarins.

Hybrid Circuits. The use of parylenes as a hybrid circuit coating is based on much the same rationale as its use in circuit boards. A significant distinction lies in obtaining adhesion to the ceramic substrate material, the success of which determines the eventual performance of the coated part. Adhesion to the ceramic must be achieved using adhesion promoters, such as the organosilanes.

In the coating of hybrid circuits, parylene provides certain other advantages. In certain technologies, chips are mounted with substrate clearances of as little as 10 μm. The parylene VDP process penetrates this narrow space, coating the underside of the chip as well as the substrate opposite it. Conventional coatings cannot flow into such a narrow space and must rely on simply sealing it off, leaving an air pocket under the chip. Where the fabrication technology uses wire bonds to connect the chips with substrate conductor patterns electrically, the fine (25-μm dia) wires are coated by the parylene VDP process to the same thickness as all other surfaces. A marked increase in wire-bond strength in pull tests on coated hybrids is observed. The increase in strength can be attributed to the strengthening effect of the coating on the wire (which typically exceeds in cross section the amount of metal in the wire) or to a reinforcement of the welded junction to the chip pad or substrate conductor.

A hybrid solid-state relay needed for a NASA space experiment underwent redesign to provide 2500-V dc isolation, input-to-output, while undergoing temperature cycling from -120 to $+ 180^{\circ}$C, as detailed in an instructive published case history (58). The electrical isolation requirement was met only by using a conformal coating, although several conventional coatings were evaluated along with parylene. These stresses in the thicker conventional coatings associated with temperature excursions resulted, in all cases other than parylene, in the rupture of the circuitry and the functional failure of the relay.

During the manufacture of hybrid circuits, it is possible to generate small metallic fragments such as wire chips and solder balls. If they are not removed before hermetic packaging, they can disrupt performance of the unit at some future time. In certain aerospace or military applications where no physical replacement of the unit is possible, such a failure could mean the loss of a mission. A program intended to improve the reliability of hermetic packages in critical systems concluded by finding a solution to this problem by applying a parylene coating to the inside of the hybrids. The coating confers electrical insulation to all surfaces and tends to anchor any loose particles; it also confers nonconductance should they break loose from their moorings. From the standpoint of coating technology, the most interesting part of this solution to the particle-immobilization problem is the throwing power, demonstrated by the fact that the entire internal surface of the hybrid is coated through a 0.5–1.0-mm hole in the lid of the hermetic package (59).

Semiconductors. The distinctive conformality of parylene is often regarded as a handicap for meeting the requirements of an interlayer dielectric (ILD) in large-scale integration (LSI) multilevel interconnection systems. After many

layers of successive patterning, a planarizing procedure is very much needed, not a procedure that would replicate the existing lumpiness. A polyimide, the first organic compound to be used in a commercial semiconductor structure, was selected for this application (60), because of the planarization inherent in its spinning application procedure. However, because parylene offers distinct advantages in purity and thickness control and low moisture absorption (particularly in comparison to the polyimides), it receives continued attention in the search for new fabrication techniques (61–63). Recognition of the need to lower the dielectric constant of ILD insulating materials as a means of improving device performance has generated a renewed interest in organics in general, and the parylenes in particular. To meet this opportunity, the intent to produce the dimer of the per-α-fluorinated version known as Parylene AF4, poly(α,α,α',α'-tetrafluoro-*p*-xylylene) [74952-03-7], has been announced (64). In addition to offering a dielectric constant in the vicinity of 2.35, its thermal stability is such that it can withstand back-end-of-line processing steps at temperatures up to 450°C without perceptible weight loss.

In an interesting extension of the conventional solid-state device concept, where a thin film covers the channel of a field-effect transistor (FET), the electron current in the channel may be made to respond to changes in the chemical environment on the opposite side of the film. Thus a silicon nitride film on a channel gives an ion-selective FET (ISFET) that responds to the pH of a solution with which it is in contact. The hydrophobic nature of parylene, on the other hand, enables the channel it covers to be independent of solution composition, and such a channel can be used as a reference electrode. An important advantage of parylene in this context is the thinness with which it can be deposited as a continuous film. The gate coatings are 0.1 μm thick, a thinness required if the sensor is to have a speedy response. An experimental probe-type all-solid-state pH sensor has been demonstrated (65). It was also demonstrated that chemically modifying the parylene surface with crown ether compounds can give an ISFET (known as a CHEMFET) that responds to potassium ion concentration.

Sensors for physical effects are also fabricated using standard semiconductor technology. A notable example is a silicon membrane pressure transducer, which, among its many other uses, is currently employed as a manifold pressure transducer in automobiles (66). The thin membrane of single-crystal silicon was prepared by etching most of the wafer thickness away, into which a resistive Wheatstone Bridge network that enables an electrical readout of the membrane's physical strain while flexing had previously been diffused. Although it is desirable to insulate the membrane electrically from the medium it measures, it is also desirable to do so without affecting the elasticity of the membrane, so that it retains its calibration of electrical output vs input pressure. A thin coating of Parylene C easily accomplishes both. In an inversion of roles, these same pressure transducers were used to sense the stresses imparted to coated substrates by a variety of MIL-I-46058C qualified coating materials (67). Whereas all other coatings, as a result of their cure shrinkages acting through their greater thicknesses modified by their assorted elastic moduli, affected sensor calibration in all cases, the presence of 13 μm of Parylene C was barely detectable.

Capacitors. The outstandingly low dielectric loss of parylenes make them superior candidates for dielectrics in high quality capacitors. Furthermore, their

dielectric constant and loss remain constant over a wide temperature range. In addition, they can be easily formed as thin, pinhole-free films. Kemet Flatkaps are fabricated by coating thin aluminum foil with Parylene N on both sides and winding the coated foils in pairs (68).

Parylenes are also used to coat the rotor and stator plates of miniature variable-air-gap tuning capacitors (69). Coating the plate raises the voltage that must be applied between two parallel plates for a discharge to occur in the air gap. Thus, a closer plate spacing is permitted, and a smaller unit having the same electrical function can be built. This is also beneficial in improving design capacitance per unit volume. Compared to the alternative of interleaving dielectric films between the plates, the coated-plate technique offers the advantages of simplicity in assembly as well as reliability of the unit. Uniformity and thickness control are of paramount importance in this case.

The Bathythermograph. The thermistor sensing probe of a disposable bathythermograph is coated with parylene. This instrument is used to chart the ocean water temperature as a function of depth. Parylene provides the needed insulation resistance and is thin and uniform enough to permit a rapid and accurate response to the temperature of the surrounding salt water (70).

Miniature Electrical Components. In the manufacture of miniature transformers and motor armatures, it is often necessary that the winding be electrically isolated from the bobbin. The insulating varnish of fine copper wire often does not survive the rigors of the winding operation, and, particularly in the case of the smaller devices, the bobbin requires insulation. However, a thicker insulation than is absolutely necessary takes up space that otherwise could be used for more turns of wire. Thus, thickness control in the coating of the bobbin means better performance of the finished device. Parylene is used in the manufacture of high quality miniature stepping motors, such as those used in wristwatches, and as a coating for the ferrite cores of pulse transformers, magnetic tape-recording heads, and miniature inductors, where the abrasiveness of the ferrite is particularly damaging. In the coating of complex, tiny objects such as these, the VDP process has an extra labor-saving advantage. It is possible to coat thousands of such articles simultaneously by tumbling them during the VDP operation (71).

Medical Uses. Under the auspices of the National Institutes of Health Artificial Heart program (72), Parylene C received considerable attention as a component of a novel scheme for achieving blood compatibility in a flexible pump chamber wall by anchoring the endothelial tissue of the host to it. A microfiber nonwoven fabric anchored to the flexible wall by an overcoating of Parylene C provides scaffolding for cellular ingrowth (73). Although the scheme is not used today, the program contributed a significant amount of favorable biocompatibility data on Parylene C, particularly in the area of cytotoxicity (74). Parylene's minimal perturbance of cells growing in its vicinity can be ascribed to its high purity and its ability to slow down impurity species that might otherwise diffuse out of a substrate material. The corrosive biological environment does not affect parylene, which cannot be hydrolytically degraded.

Parylene's use in the medical field is linked to electronics. Certain pacemaker manufacturers use it as a protective conformal coating on pacemaker circuitry (75). The coated circuitry is sealed in a metal can, so that the parylene coating serves only as a backup should the primary barrier leak. There is also interest in

its use as an electrode insulation in the fabrication of miniature electrodes for long-term implantation to record or to stimulate neurons in the central or peripheral nervous system, as the "front end" of experimental neural prostheses (76). One report describes the 3-year survival of functioning parylene-coated electrodes in the brain of a monkey (77).

Artifact Conservation. As books age, the paper of their pages becomes brittle. A relatively thin coating of parylene can make these embrittled pages stronger (78). Parylene coats the fibers conformally and welds them together at crossing points, providing added structural strength. Although parylene does little to retard the chemical processes that make the paper brittle, it restores some physical strength. Furthermore, the parylene coating can be applied to the existing book without disturbing the binding, thus saving the labor of disassembly. The concept has been extended to other fragile artifacts, such as fabrics.

Laser Fusion Targets. In the search for new energy sources, some research is directed toward the thermonuclear fusion of deuterium–tritium (DT) mixtures. In laser-driven inertial confinement fusion, a single laser pulse crushes a target containing the DT fuel to one thousandth of its normal volume and achieves a temperature of 10^8 K. The energy per pulse in current lasers is small, which limits the experimental targets to a diameter of about 100 μm. The outer layer of the spherical target absorbs the omnidirectionally incident laser energy and ablates as it is thermally destroyed, imparting a reactive compressive force on the inner portions of the target, thus compressing it. The dimensions of the outer layer are central to achieving hydrodynamic stability during the implosion process. Concentricity, sphericity, and thickness (ca 10 μm) must be better than 5%, and surface roughness must be no greater than 0.1 μm. Parylene is a leading contender for the outer layer, and considerable ingenuity has been applied in several methods for experimental target fabrication (79,80).

Contamination Control. In a number of developing technologies, contamination by small particles is a serious problem. To the extent that the generation of freely mobile particles is reduced by securing them to their initial locations, parylene coating of critical system components can be useful. In the manufacture of Winchester disk drive units, large magnesium castings are coated with parylene. This increases system reliability (81), presumably because the large surface within the sealed unit, if not coated, is capable of producing particles of the same destructive potential that the system seal is supposed to prevent from entering.

Barrier Coating. The bulk permeabilities of parylenes, although finite, are generally lower than those of most other types of plastic materials. The further advantage of coating continuity inherent in the VDP process allows the parylenes to realize the benefits of their low permeabilities to the fullest, without leakage of the permeant through coating defects such as cracks or pinholes. Thus the parylenes are uniquely suited as protective encapsulants or barrier coatings (see BARRIER POLYMERS).

Where pieces of lithium metal are coated with Parylene C, and their subsequent reaction to water vapor follows, the steady-state generation of hydrogen can be controlled exactly by the rate of water transport through the coating (82). Pellets of nitronium perchlorate, a potent oxidizer useful as a solid-rocket propellant component, can be rendered less moisture-sensitive and compatible with organic binders by applying a coating of Parylene C (83). The absorption of water by

particulate ammonium nitrate could be reduced tenfold by as little as a 0.7% coating of Parylene C (84). Particles of ammonium nitrate remain free-flowing after long exposures to ambient conditions of temperature and moisture when coated with as little as 0.2% Parylene C. The thermal sensitivity of Parylene C–coated ammonium nitrate (time to explosion) is unaffected by the coating. On the other hand, the 1.5–8% coating of particulate military-grade RDX explosive, cyclotrimethylene trinitramine, produced significant changes in physical and explosive properties. The changes were attributed to the chemical properties of the protective Parylene C coating and to the virtual absence of encapsulated agglomerates of RDX crystals (85).

In a recent report (86), a 150–200 mg/cm^2 Parylene C coating provided protection against moisture uptake by three-phase—polyimide, microballoons, and air—syntactic foams. In a previously reported coating of a similar foam, the stated purpose was strengthening (87).

Corrosion Control. The oxygen and water permeability and thinness of the parylene coatings notwithstanding, the rate of corrosion of a coated surface is often significantly reduced. In one case, the corrosion of a plated wire memory was reduced to the point where no bits were lost during 30 cycles of a MIL STD 202D-106C test by overcoating the permalloy plating, which had been previously coated with a Ni–P anticorrosive layer, with Parylene N (88).

Dry Lubricant. The static and dynamic coefficients of friction for the parylenes are low and virtually the same. This feature is an advantage in the use of a parylene coating as a dry lubricant on the bearing surfaces of miniature stepping motors. Coating a threaded ferrite core significantly reduces the abrasion to coil forms (89).

Pellicles and Membranes. By separating the coating from the substrate after deposition, the unique coating features of parylenes, especially continuity and thickness control and uniformity, can be imparted to a free-standing film. In practice, a sheet of smooth glass is coated with a layer of a hygroscopic substance before being coated with parylene. The film is then lifted from the glass by water immersion to activate the release agent. In this manner, uniform, continuous, free-standing parylene films with thicknesses of less than 0.1 μm can be prepared. Applications of such films include optical beam splitters (90), a window for a micrometeoroid detector (91), a detector cathode for an X-ray streak camera (92), windows for X-ray proportional counters (93), a charge stripper for converting a portion of the H-output beam of a 50 MV LINAC to neutral H^0 for diagnostic purposes (94), and a massless support for projectile abrasion testing (95); proposals have included the membrane structure for a solar sail (96).

Health and Safety

In a world increasingly conscious of the dangers of contact with chemicals, a process that is conducted within the walls of a vacuum chamber, such as the VDP process for parylene coatings, offers great advantages. Provided the vacuum pump exhaust is appropriately vented and suitable caution is observed in cleaning out the cold trap (trace products of the pyrolysis, which may possibly be dangerous,

would collect here), the VDP parylene process has an inherently low potential for operator contact with hazardous chemicals.

To an experienced operator trained in the handling of industrial chemicals, the dimers present little cause for concern in handling or storage. The finished polymer coating presents even less of a health problem; contact with the reactive monomer is unlikely. In the ancillary operations, such as cleaning or adhesion promotion, the operator must observe suitable precautions. Before using the process chemicals, operators must read and understand the current Material Safety Data Sheets, which are available from the manufacturers.

Alpha Metals

YIELD AND CRAZING IN POLYMERS

Introduction

Polymers serve increasingly in structural applications as lightweight replacements for more traditional materials such as metals and wood. In light of this it is important to understand and be able to characterize the engineering or mechanical properties over the likely service conditions (see MECHANICAL PERFORMANCE). Typically when a material fails in service it is thought of in terms of a catastrophic brittle failure and these modes have been partially discussed elsewhere (see FRACTURE; FATIGUE). However, polymers (both thermoplastics and thermosets) can also fail by yielding, and while generally this is not necessarily a catastrophic event (ie the material remains intact) it does mean the material retains a degree of permanent deformation and is usually considered a failure criterion in terms of structural integrity. Furthermore, the yield response of polymers affects the plastic zone at the crack tip and this is important in fracture events.

Another deformation mechanism common to many polymers is that of crazing. Crazes are generally a precursor to brittle failure, though on the local scale they are the result of highly localized yielding phenomena. As such they provide a significant source of energy absorption and, further, since the crazes remain load bearing, the time for their initiation and growth can be a significant portion of the overall lifetime of the material.

The present article focuses on yield and crazing in polymers and does not deal directly with the viscoelastic response, though it is recognized that yield and viscoelasticity share many of the same features—strain rate and temperature dependence (1) and even concepts such as time–temperature superposition (2) (see VISCOELASTICITY; AGING, PHYSICAL). We first present a summary of conventional yield criteria, these being methods to quantify the yield stress as a function of

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

the applied stress field, ie uniaxial vs biaxial. Following this the phenomenology of yield is addressed by considering a number of models of the yield process in polymers, including the observation of strain softening and strain hardening. A brief overview of craze structure and morphology is given and several criteria for the initiation, growth, and failure of crazes are described.

Yield

A general definition of yield is the point at which a material ceases to deform elastically in a recoverable manner and undergoes permanent (irreversible) plastic deformation. Historically, the study of yield and the theories describing it were developed for metals (3) and, there, this definition works well, with elastic deformation arising from lattice distortions and plastic deformation from the motion of dislocations. In polymers the molecular processes involved in deformation cannot be so easily split into such distinct mechanisms. Further, it has long been recognized that polymers exhibit a viscoelastic response to deformation (4–7) and consequently the general mechanical properties are both rate and temperature dependent. Such a viscoelastic response is evidenced not only on deformation but also on recovery. The time-dependent nature of the recovery means that for polymers the determination of permanent (plastic) deformation can depend on how long one is prepared to conduct the relevant measurements. That said, general aspects of the large deformation behavior of amorphous glassy and semi-crystalline polymers can be usefully discussed in terms of conventional yield criteria.

We begin by examining general stress (load per unit area)–strain (fractional change in length) responses for polymers under uniaxial tensile loading and develop what is essentially an elastic–plastic analysis of the material behavior. Loading under compressive and shear forces is then considered. This is followed by general yield criteria: these can be considered macroscopic criteria relating the applied stress to some critical value for yielding (generally a critical shear stress) and their modification to introduce pressure dependence. While such criteria are useful engineering concepts, it is perhaps more satisfying to be able to describe yielding from a microscopic perspective, and this is addressed in the section on yield theories. Subsequent to the discussion of yield phenomena we present a section on another important aspect of polymer mechanical behavior, that of crazing. Crazing is a localized yielding process that may be dilatational in nature. It results in essentially load-bearing cracks that are generally a precursor to macroscopically brittle failure when the craze density is low.

Before describing the yield response of polymers in the next section, we remark here that polymer mechanical behavior depends strongly not only on the time (rate) and temperature, but also on the morphology of the material (8,9). Hence the yield phenomenology described below will approximately describe the behavior, but the details of the behavior will depend strongly on the morphology and where one is relative to the glass-transition temperature, T_g. For example, above the T_g, an amorphous polymer such as polystyrene does not yield but undergoes viscous flow. On the other hand, a material such as polyethylene, which is semi-crystalline, will undergo a yield process above the glass transition. Below T_g, both glassy amorphous and glassy semi-crystalline polymers can undergo

yielding, though the processes may differ between the two types of materials. Much of the development of the present article deals with yield of glassy amorphous polymers, though some discussion of yielding in semi-crystalline materials is also presented.

General Stress–Strain Curves under Uniaxial Tensile Loading. In uniaxial extension or compression, the true axial stress, σ_T, is given by the current load (P) divided by the current cross sectional area (A):

$$\sigma_T = P/A \tag{1}$$

If it is assumed that the deformation takes place at constant volume (a reasonable assumption under most conditions of plastic deformation where the volume changes are small compared to the total strain), then the instantaneous area (A) and length (l) are related to the original cross sectional area and length (A_0, l_0 respectively) by

$$Al = A_0 l_0 \tag{2}$$

We now define the engineering (or nominal) stress, σ_E, as

$$\sigma_E = P/A_0 \tag{3}$$

and the engineering strain, ε, as

$$\varepsilon = (l - l_0)/l_0 \tag{4}$$

so that

$$l/l_0 = (l + \varepsilon) \tag{5}$$

From equations 1-5 we find that

$$\sigma_E = \sigma_T/(l + \varepsilon) \qquad \sigma_T = \sigma_E(l + \varepsilon) \tag{6}$$

The deformation response of a material to a given loading regime is described by generalized equations known as constitutive relations. For uniaxial loading in the limit of small strains, the simplest of these is known as Hooke's Law and linearly relates the stress to the strain:

$$E = \frac{\sigma}{\varepsilon} \tag{7}$$

where E is Young's modulus.

The extreme temperature and rate sensitivity of polymers means that they can display a wide range of mechanical behaviors depending on the precise conditions under which they are tested. Figure 1 shows a set of typical engineering stress–strain curves that an amorphous polymer might be expected to exhibit as a function of rate or temperature in a uniaxial tensile test (10,11). At low temperatures or high rates polymers tend to fail in a brittle manner (Curve A)—the strain

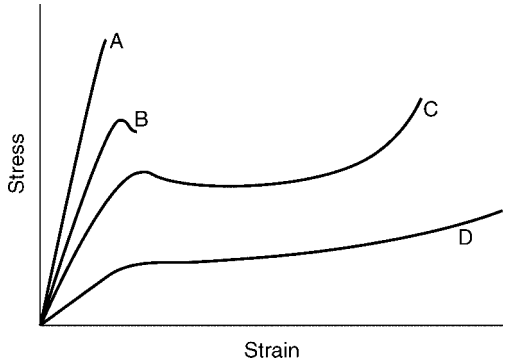

Fig. 1. Typical engineering stress–strain curves for an amorphous polymer as a function of temperature or strain rate.

to failure is low (of the order of a few percent) and the modulus high (of the order of a few GPa). As the temperature increases (or the strain rate decreases) the curves progress such that the material passes through a softening regime (Curve D), characterized by low moduli, an indistinct (or nonexistent) yield point, and large strains to failure (>100 percent). Ultimately, at a sufficiently high temperature (or low enough strain rate), the material may show a pure rubbery response with a modulus some orders of magnitude lower than those indicated in Figure 1 (curve omitted for clarity).

Of particular interest in this discourse is the behavior shown in Curves B and C. At small strains (typically <1%), the stress rises approximately linearly with increasing strain, ie the material displays Hookean-like behavior (note that this is not strictly true for polymers because of viscoelastic effects; however if the applied strain rate is faster than the relaxation time for the material then little relaxation will occur and it is a reasonable approximation). At larger strains (above the proportional limit) the engineering stress will continue to rise with strain, though less rapidly. Eventually, at a certain strain, the stress reaches a maximum and then falls with increasing strain. It is this peak stress which is generally taken to be the yield stress, σ_y, and the strain at which it occurs as the yield strain, ε_y. The nature of the load drop and the postyield behavior are discussed subsequently. Here it is sufficient to note that the peak in engineering stress is normally accompanied by macroscopic changes to the sample geometry. The plastic deformation is concentrated locally to a small portion of the specimen. This section is seen to reduce in width and to form what is called a "neck." Because of the change in cross-sectional area, the local stresses in the neck region can be significantly higher than the engineering stress and indeed may be rising while the load or engineering stress is falling (12,13). Accordingly it is instructive to look at the true stress–strain behavior. This is important because while strain localization is often associated with yield behavior, such localization is not necessary for yielding to occur.

Considère Construction (14). Referring back to equation 6 for the true and engineering stresses,

$$\sigma_E = \sigma_T/(1+\varepsilon); \qquad \sigma_T = \sigma_E(1+\varepsilon)$$

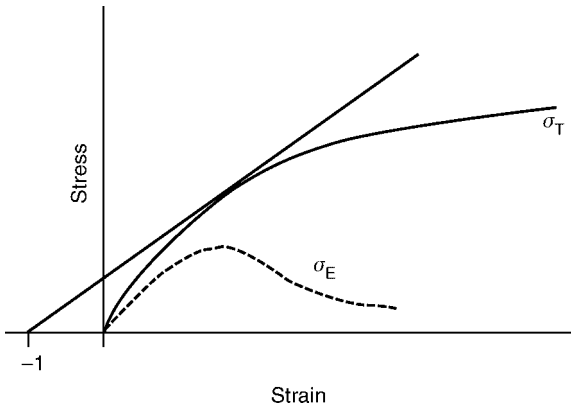

Fig. 2. Engineering (σ_E) and true stress (σ_T) as a function of strain in uniaxial tension. The Considère criterion for necking, that is the ability to draw a tangent to the true stress curve from $\varepsilon = -1$, is also shown.

we see that for all finite strains under uniaxial tensile loading, the true stress is greater than the engineering stress (for uniaxial compressive loading, the true stress is always lower than the engineering stress).

Figure 2 compares the engineering stress, σ_E, and true stress, σ_T, as a function of engineering strain for uniaxial tensile loading. As noted above, the neck is seen to form at the point where the load (or engineering stress) ceases to rise, ie where

$$\frac{d\sigma_E}{d\varepsilon} = 0 = \frac{1}{(1+\varepsilon)}\frac{d\sigma_T}{d\varepsilon} - \frac{\sigma_T}{(1+\varepsilon)^2} \tag{8a}$$

or

$$\frac{d\sigma_T}{d\varepsilon} = \frac{\sigma_T}{(1+\varepsilon)} \tag{8b}$$

In practice then, the point at which a polymer will form a neck is given by drawing a tangent to the true stress–strain curve from the point $\varepsilon = -1$, as illustrated in Figure 2. [We note here that in this condition, yielding is a localization phenomenon. It is also possible that yielding can be a material property unrelated to localization and this is touched upon in a subsequent section.]

Necking and Cold Drawing. Before further discussion of the Considère construction it would be useful to discuss the phenomenology of the yield and necking processes. As discussed above, yield in a material under uniaxial tensile loading is characterized by highly localized plastic deformation within the specimen and a corresponding decrease in the engineering stress. The exact position at which yield occurs on a nominally isotropic and uniform sample is impossible to predict. However, a small change in the local properties at some segment in the sample can lower the local yield stress such that yield will initiate there first. Alternatively, a flaw or inclusion can cause a stress concentration such that the

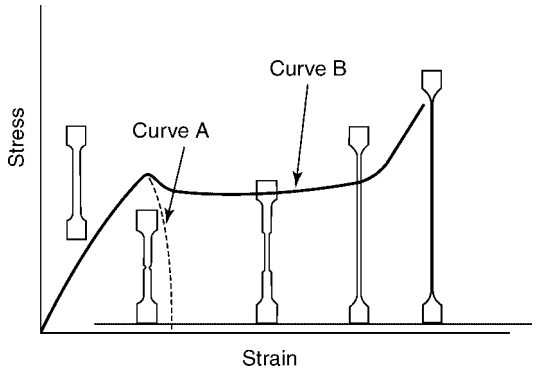

Fig. 3. Engineering stress–strain curves for a material showing, with increasing strain, strain localization(necking), cold drawing, and strain hardening. Also shown are schematics of the sample geometry at each stage.

local stress is higher than the yield stress. After this point one of two things may happen (refer to Fig. 3).

(1) The material in the neck may continue to draw down. As it does so, the true stress continues to rise in the segment, which leads rapidly to failure. This is the case shown in Curve A in Figure 3.

(2) The yielded material can undergo strain hardening. As the material yields and draws down, the polymer chains align along the stress direction, increasing the local stiffness (hence strain hardening is also known as orientation hardening). If the rate of strain hardening is greater than linear, this is sufficient to offset the increase in local stress due to area reduction, and the neck can stabilize. This is the case shown in Curve B in Figure 3. Also shown in Figure 3 are sketches of the deformation that would be seen in a typical tensile specimen as a function of cross-head displacement. Once the yielded material has hardened sufficiently to offset the increase in local stress, the stress (load) stabilizes to a constant value (the draw stress, σ_D) and the neck is seen to propagate along the remaining gage length of the sample until the whole sample has yielded. This process is known as cold drawing.

The oriented material in the strain-hardened section draws down to a characteristic extent under any given conditions and is known as the natural draw ratio, λ_D, and is given by the ratio of the length of the drawn section to its length before deformation. Further deformation can cause additional extension and hence further orientation and strain hardening, and the stress is seen to once again rise until eventually it exceeds the ultimate strength of the material and failure occurs.

In terms of the Considère construction, the criterion for a material to neck and cold draw is indicated by the ability to draw a second tangent to the true stress–strain curve from the point $\varepsilon = -1$ (Fig. 4). Another important aspect of yielding is that, while there is a clear drop in the engineering stress at (or near)

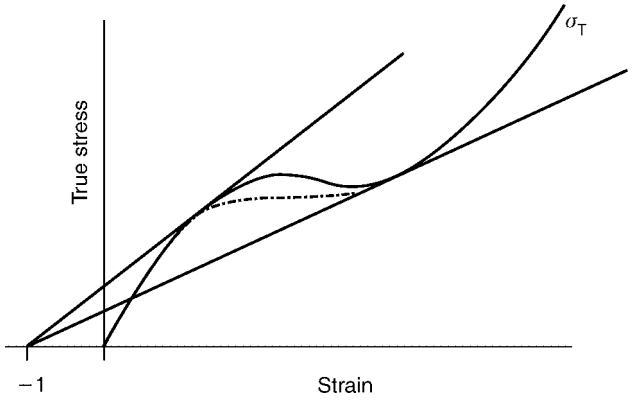

Fig. 4. True stress (σ_T) as a function of strain in uniaxial tension. The Considère criterion for cold drawing, that is the ability to draw a second tangent to the true stress curve from $\varepsilon = -1$, is also shown.

the yield point, there may also, though not necessarily, be a drop in the true stress after yield (Fig. 4). This drop in true stress is commonly referred to as strain softening. At the point of the second tangent, molecular orientation is sufficient to stiffen the material and strain hardening occurs.

Compressive Loading. The discussion above has been developed specifically for uniaxial tensile loading conditions, and this is still the most widely used method for testing of polymers. However, the formation of a localized neck means that it is difficult to measure the true strain at any given point and hence determine the true stress–true strain behavior. Moreover, because tests are generally carried out at a constant cross-head displacement rate, the spatially varying strain means the strain rate is poorly defined. G'Sell and co-workers (15,16) have gone some way to resolving this difficulty by using an optical system to monitor the local strain and a feedback mechanism to adjust the imposed deformation rate to perform constant true strain rate experiments. Alternatively, others (17,18) have used a video system to monitor the neck profile and so back-calculate the true stress–true strain rate profile in the neck region.

Some of the shortcomings of tensile testing are mitigated by the use of compressive loading, typically performed on cylindrical specimens. Since the localization seen when the sample necks is suppressed in this geometry it is experimentally easier to ensure a more uniform strain field; however, some care needs to be exercised to prevent buckling or barreling of the specimens. Barreling is caused by lateral constraint on the cylinder ends due to friction with the loading plates. A suitable (inert) lubricant or a thin PTFE film applied to the cylinder ends is often sufficient to prevent barreling. Buckling will occur if the aspect ratio of the cylinder (height-to-diameter) is too large—aspect ratios of 0.5 to 1 are typically used.

From tests conducted on polymer glasses under both tension and compression (19–23) the true stress versus true strain rate response can be determined and typical plots are shown in Figure 5 (19). As can be seen, qualitatively the true stress–true strain behaviors are similar for both deformation modes. Importantly

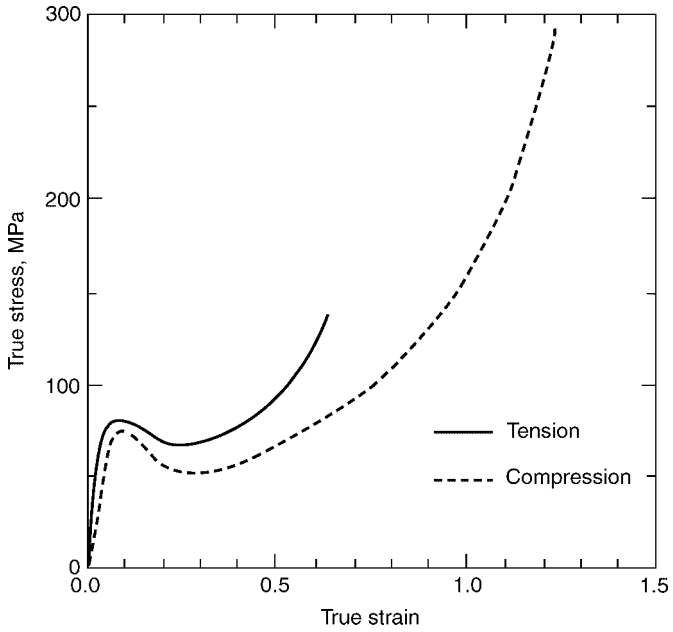

Fig. 5. True stress–strain curves for a polycarbonate under tension and compression. After Boyce and Arruda (19) with permission.

they both show a drop in true stress at the yield point. The observation of a drop in true stress without the localization (necking) seen in tensile tests confirms that the material is undergoing intrinsic strain softening. Importantly this shows that localization is not a necessary requirement for yield and further that the load drop seen in tensile tests is not necessarily simply the result of geometric changes.

While the true stress–true strain response is qualitatively similar in both compression and tension, the resulting deformation states are very different. Tensile loading leads to uniaxial molecular orientation along the loading axis. Compression on the other hand results in a biaxial orientation state in a plane perpendicular to the loading direction and so it is expected that quantitatively different stress–strain curves are seen. In addition, as discussed below, the hydrostatic pressure difference between tension and compression leads to differences in yield strength because yield in polymers is pressure dependent.

The preceding is a general overview of the main features of yield in polymers. From a practical point of view, structures are rarely subjected to simple uniaxial or shear loads and it is instructive to be able to determine when a material might yield under more complicated stress states. The following yield criteria attempt to do this from a phenomenological point of view, that is they do not address the fundamental mechanisms of yield but rather provide yield criteria for multiaxial loading conditions.

Yield Criteria. A practical yield criterion needs to describe the conditions under which yield will occur for a general stress state (eg tension, compression, shear, or some combination). Before we consider the various yield criteria which have been proposed, it is useful to very briefly recap the definition of the principal

stress components as these are generally the terms which are used to define the yield criteria (see VISCOELASTICITY for a more thorough introduction to the generalized stress and strain definitions).

If we take a small representative cube within a body, then the general stress state is given by the stress tensor of the forces acting on the faces of the cube:

$$\sigma_{ij} = \begin{bmatrix} \sigma_{11} & \sigma_{12} & \sigma_{13} \\ \sigma_{21} & \sigma_{22} & \sigma_{23} \\ \sigma_{31} & \sigma_{32} & \sigma_{33} \end{bmatrix} \tag{9}$$

and the generalized strain tensor as

$$\varepsilon_{ij} = \begin{bmatrix} \varepsilon_{11} & \varepsilon_{12} & \varepsilon_{13} \\ \varepsilon_{21} & \varepsilon_{22} & \varepsilon_{23} \\ \varepsilon_{31} & \varepsilon_{32} & \varepsilon_{33} \end{bmatrix} \tag{10}$$

where i refers to the axis normal to the plane on which the stress is acting and j the direction in which the stress acts.

For an isotropic, elastic material two elastic constants are sufficient to describe the material response, the elastic modulus E (eq. 7) and the Poisson's Ratio (ν), defined as the ratio of the axial to the (negative) transverse strain ($-\varepsilon_{11}/\varepsilon_{22}$).

Other mechanical functions such as the bulk modulus, K, and the shear modulus, G are interrelated by the following expressions:

$$\begin{aligned} G &= \frac{E}{2(1+\nu)} \\ K &= \frac{E}{(1-2\nu)} \\ E &= \frac{9KG}{3K+G} \end{aligned} \tag{11}$$

From equation 9, it is seen that the general stress state is described by nine independent components. However, if we assume that the sample is not undergoing rigid body rotation, then the shear components must give a net torque of zero, that is,

$$\sigma_{12} = \sigma_{21} : \sigma_{13} = \sigma_{31} : \sigma_{23} = \sigma_{32}: \tag{12}$$

Thus the stress state is defined by six independent components. Further, if the body is in equilibrium, then it is possible to define a set of orthogonal axes such that the shear components are zero. Such axes are termed the "principal axes"

and the resulting stress components the "principal stresses":

$$\sigma_i = \begin{bmatrix} \sigma_1 & 0 & 0 \\ 0 & \sigma_2 & 0 \\ 0 & 0 & \sigma_3 \end{bmatrix} \tag{13}$$

The sum of the three principle stresses is known as the first stress invariant (or trace), I_1,

$$\sigma_1 + \sigma_2 + \sigma_3 = \text{constant}$$

and the related quantity, the mean stress, σ_M

$$\sigma_M = \frac{\sigma_1 + \sigma_2 + \sigma_3}{3}$$

Tresca Yield Criterion. The earliest proposal for a yield criterion in metals is due to Tresca (24), and it stated that yield occurs when the maximum shear stress reaches a critical value. With $\sigma_1 > \sigma_2 > \sigma_3$ the criterion can be written as

$$1/2(\sigma_1 - \sigma_3) = \tau_s \tag{14}$$

For the simplest loading situation of a tensile test at a stress level of σ_1, with $\sigma_2 = \sigma_3 = 0$ we have

$$\tau_s = \sigma_1/2 \tag{15}$$

so that yield occurs when the applied tensile stress reaches twice the shear yield stress.

Von Mises Yield Criterion. The Von Mises yield criterion (also known as the maximum distortional energy criterion or the octahedral stress theory) (25) states that yield will occur when the elastic shear-strain energy density reaches a critical value. There are a number of ways of expressing this in terms of the principal stresses, a common one being

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = \text{constant} \tag{16}$$

If we again look at the case of simple tension, then we have $\sigma_2 = \sigma_3 = 0$. Defining the tensile yield stress as σ_Y, we see that the constant in equation 16 is $2{\sigma_Y}^2$.

If we look now at the case of pure shear, where we have $\sigma_1 = -\sigma_2 = \tau$ and $\sigma_3 = 0$, we find that

$$4\sigma_1^2 + \sigma_1^2 + \sigma_1^2 = 6\sigma_1^2 = 6\tau^2 = \text{constant} = 2\sigma_Y^2$$

ie

$$\tau = \frac{\sigma_Y}{\sqrt{3}} \tag{17}$$

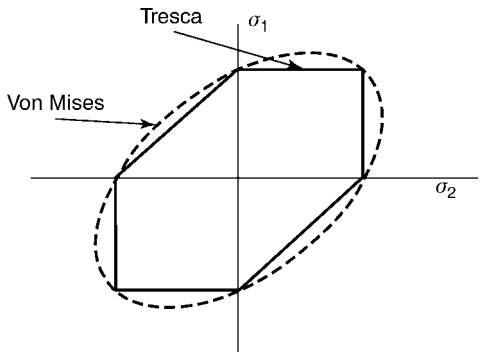

Fig. 6. The Tresca and von Mises yield criteria for plane strain conditions ($\sigma_3 = 0$).

Compare this to the prediction of $\sigma_Y/2$ from the Tresca criterion. The yield criteria for both the Tresca and Von Mises theories are shown graphically in Figure 6. For simplicity, the plots are shown for conditions of plane stress (ie $\sigma_3 = 0$). We can see that the Von Mises criterion describes an ellipse in stress space, with the Tresca criterion consisting of a series of straight lines bounded by the Von Mises limits.

Coulomb Yield Criterion. In 1773, Coulomb (26) identified two components important in the strength of building stone—cohesion and friction. He observed that the shear stress, τ, necessary to cause shear failure across a plane is resisted by the cohesion of the material S_0 and by the product, $\mu\sigma_N$, across that plane, where the constant μ is called the coefficient of internal friction and σ_N is the force normal to the shear plane:

$$\tau = S_0 + \mu\sigma_N \tag{18}$$

This criteria is often expressed in the form

$$\tau = \tau_c + \sigma_N \tan \phi \tag{19}$$

where τ_c is now the critical shear stress for yield and

$$\phi = 2\theta - \frac{\pi}{2} \tag{20}$$

and θ is the angle between the normal to the shear plane and the direction of the applied stress. Data from tensile, compressive, and torsional tests on a range of polymers under imposed hydrostatic pressure (20,27) have been successfully described by the Coulomb criterion, though it should be noted that the modified Von Mises criteria (see below) was equally successful.

Pressure-Modified Criteria. One major shortcoming of the criteria described above is that they predict that the yield stresses in tension and compression are the same. However, in practice it is generally found for polymers that the yield stress in compression is higher than that in tension. This effect is usually considered to be a consequence of the fact that the yield stress depends on the hydrostatic pressure that develops under load. The hydrostatic pressure component

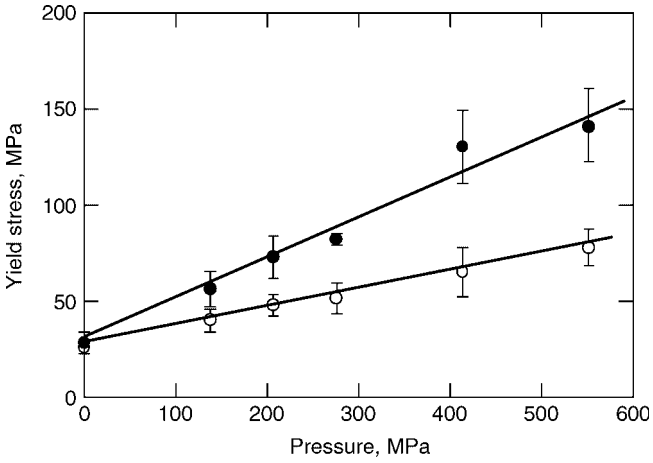

Fig. 7. Yield stress as a function of imposed hydrostatic pressure for polyethylene and polypropylene. Data from Ref. 28. ○, polyethylene, ●, Polypropylene.

of the load in tension is negative, while in compression it is positive. In fact, experiments in which measurements were made under imposed hydrostatic pressures exhibit a strong pressure dependence of the yield stress in polymers (27–29 see also the extensive review in Reference 30). In general it was seen that the yield stress increased linearly with imposed hydrostatic compression (Fig. 7).

Modified Tresca Criterion. A simple way to modify the Tresca criterion to allow for a pressure dependence is to make the critical shear yield stress a linear function of hydrostatic pressure:

$$\tau_T = \tau_T^0 + \mu_T P \tag{21}$$

where τ_T^0 is the critical shear stress with no hydrostatic pressure, P is the hydrostatic pressure, given by $P = -(\sigma_1 + \sigma_2 + \sigma_3)/3$ and μ is a constant. Substituting into equations 14 and 15, we find that the yield stresses in tension σ_{Yt} and compression σ_{Yc} are given by

$$\sigma_{Yt} = 2\tau_T^0/(1 + 2\mu/3) \tag{22}$$

$$\sigma_{Yc} = 2\tau_T^0/(1 - 2\mu/3) \tag{23}$$

Modified Von Mises Criterion. In the same manner as the modification to the Tresca yield criterion one can modify the Von Mises criterion by introducing a linear dependence of the critical shear stress on the hydrostatic pressure:

$$\tau_M = \tau_M^0 + \mu_M P \tag{24}$$

where τ_M^0 is the critical shear stress with no hydrostatic component, P is the hydrostatic pressure, and μ_M is a material constant.

It can be seen from the above criteria that for polymers under uniaxial loading, yield is essentially characterized as a shear-controlled process. There is good experimental evidence for this being the case, and is shown most clearly by the observation of the formation of shear bands on uniaxially loaded specimens. These are regions of locally strained material running at an angle to the applied load, typically at approximately 45°. For isochoric deformation in an isotropic material the angle is precisely 45°, which corresponds to the angle of maximum shear stress. Any preorientation in the material (which introduces an anisotropy to the material) or dilatation during deformation can cause the angle to change. Dilatation generally causes the angle to decrease in the loading direction, while the change due to preorientation depends on the direction of the applied load to the orientation direction.

The criteria discussed above are certainly useful from an engineering point of view and offer a method to estimate the likelihood of failure for a given loading situation. However, from a fundamental viewpoint, they are lacking as they provide no insight into the microscopic or molecular mechanisms that give rise to yield. The following section examines a number of theories that seek to explain yield to varying degrees of complexity.

Theories of Yield

Adiabatic Heating. As far back as 1949 (31–33) it was postulated that local adiabatic heating in polymers causes a temperature rise in the neck region, thereby lowering the local yield stress. While this may be a factor at high rates of deformation where the heat generated cannot be dissipated, experiments using, for example, thermal imaging techniques have shown that the temperature rise is not sufficient to account for yielding. In addition, experiments conducted at rates low enough such that the system is essentially under quasi-isothermal conditions still show yield behavior (34) and therefore simple heating is not an adequate explanation for polymer yield.

Strain-Induced Dilatation. An alternative view of yield in polymers comes from the fact that a tensile strain induces a hydrostatic tension in the material and a corresponding increase in the sample volume. This in turn translates to an increase in the free volume, which increases the polymer mobility and effectively lowers the glass-transition temperature (T_g) of the polymer (alternatively it can be looked upon as increasing the free volume to the value it would have at the normal measured T_g). The increased mobility results in a lowering of the yield stress. Knauss and Emri (35) used an integral representation of nonlinear viscoelasticity with a state-dependent variable related to free volume to model the yield behavior, with the free volume a function of temperature, time, and stress history. This model uses the concept of reduced time (see VISCOELASTICITY), where application of a tensile stress causes a volume dilatation and consequently causes the material time scale to change by a shift factor related to the magnitude of the applied stress. Yield occurs because the free-volume shift factor causes the molecular mobility to increase in such a way that yield can occur.

However yield and plastic deformation are also observed in uniaxial compression and shear (19–23). In the former case the hydrostatic component of stress is

compressive and this leads to a reduction in free volume. Further, as was shown above when discussing the yield criteria, yielding in either tension or compression seems, for polymers, to be associated with the deviatoric (shear) component of the stress tensor, and this intrinsically involves no volume change. Thus, it seems unlikely that strain-induced changes in volume are the underlying cause of yield.

Models of Yield Based on Activated Processes

Models put forward in the in the late 1960s and early 1970s (eg Robertson (36), Haward and Thackray (37), Argon(38)) suggested that for yield and large-strain plastic deformation to occur two distinct sources of resistance must be overcome. First, yield is thought to occur when the polymer is stressed sufficiently to be able to overcome intermolecular resistance to segmental motion. Once the material has started to flow, molecular alignment occurs and changes the configurational entropy of the system. This change in entropy of the system causes the second resistance and is seen physically as a strain-hardening effect.

Yield is generally taken to be an activated process, and the first three of the following theories address this aspect. Models are then presented which address not only the yield of the material but the subsequent strain-softening and strain-hardening events that are observed. The first of these is the Haward and Thackray (37) one-dimensional model, which, while not physically realistic, laid the groundwork for many of the theories that followed it. This is followed in some detail by the BPA model of Boyce, Parks, and Argon (39), which addresses the rate, temperature, and pressure dependence of the intermolecular resistance and also the temperature dependence of entropic hardening. The model proposed by Tervoort and co-workers (40) is then discussed as this addresses some of the shortcomings of the BPA model, specifically the omission of a spectrum of relaxation times to describe the material behavior. The section is finished by examining the model of Caruthers and co-workers (41,42), which approaches yield from the framework of Rational Thermodynamics and seeks to explain a range of behaviors using a set of unified constitutive equations.

Internal Viscosity Model (Eyring Model). If we think of amorphous polymers as essentially viscous fluids then it is reasonable to think of yield and plastic deformation as viscous flow. Eyring (43) in 1936 developed a theory for flow in viscous fluids based on transition-state theory and it is instructive to look at this in more detail as it shows the temperature and rate dependency of the flow process. The Eyring model treats segmental motion as an activated process in which for a given segment to "jump" to an alternative position it needs to cross an energy barrier of height E^*. In the unstrained state the likelihood of either a forward jump or backward jump is equal, ie the stable states on either side of the barrier are at the same energy level (Fig. 8). The rate at which the segments cross the barrier is given by the Arrhenius equation:

$$\nu_0 = A \exp\left[-\frac{E^*}{kT} \right] \tag{25}$$

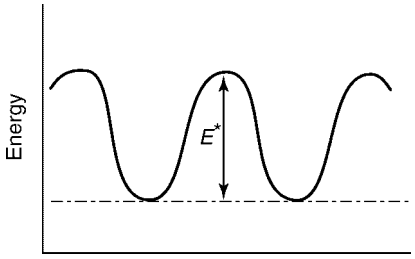

Fig. 8. Schematic of the energy landscape for an unstrained polymer for Eyring's model of viscous flow.

where A is a constant, E^* is the energy barrier height, k is Boltzmann's constant, and T the absolute temperature. According to the theory, application of a stress causes an asymmetric change in the stable energies on either side of the barrier of $+\tau V$ and $-\tau V$ for the forward and backward motions, respectively (Fig. 9). V is the Eyring activation volume and τ the applied shear stress. It is difficult to relate the activation volume V to a physical volume in the polymer, though the term τV in the model notionally represents the work required to move a polymer segment during flow. Under applied stress then, the frequency with which the segments jump in the forward direction is given by

$$\nu_f = A \exp\left(-\frac{E^* - \tau V}{kT}\right) \tag{26}$$

and the frequency they jump in the reverse direction is given by

$$\nu_b = A \exp\left(-\frac{E^* + \tau V}{kT}\right) \tag{27}$$

So, the net rate at which the segments jump is simply the difference in the forward and backward rates:

$$\nu_f - \nu_b = A \exp\left(-\frac{E^*}{kT}\right)\left[\exp\left(\frac{\tau V}{kT}\right) - \exp\left(-\frac{\tau V}{kT}\right)\right] \tag{28}$$

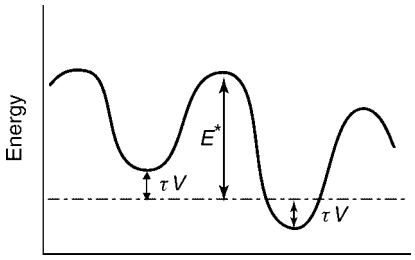

Fig. 9. Schematic of the energy landscape for a strained polymer for Eyring's model of viscous flow.

In a solid, the backward jump rate is negligible in comparison to the forward jump rate (the term τV being sufficiently large such that the term $e^{-\tau V/kT}$ becomes small), and taking the net jump rate $(\nu_f - \nu_b)$ to be proportional to the strain rate, $\dot{\varepsilon}$, then

$$\dot{\varepsilon} = A^* \exp\left(-\frac{E^*}{kT}\right)\exp\left(\frac{\tau V}{kT}\right) \tag{29}$$

As shown earlier, a simple criterion for yield is that the maximum shear stress reaches a critical value given by $\tau = \sigma_y/2$, where σ_y is the tensile yield stress (ie the Tresca yield criterion). Substituting and rearranging equation 29 gives

$$\sigma_Y = \left[k \ln\left(\frac{\dot{\varepsilon}}{A^*}\right) + \frac{E^*}{T}\right]\frac{2T}{V} \tag{30}$$

Equation 30 shows that the yield stress is both rate and temperature dependent, hence it captures some important features of yield in polymers. For example, Figure 10 (44) shows a plot of σ_Y/T (or σ_e/T in the notation of Reference (44)) as a function of log strain rate and, as predicted by equation 30, a linear relationship is seen at each temperature. It is worth noting that the Eyring equation (typically in the form of two activated processes acting in parallel) has been successfully applied not only to the yield behavior of polymers but also to the creep rupture behavior of isotropic and oriented polymers (45–48).

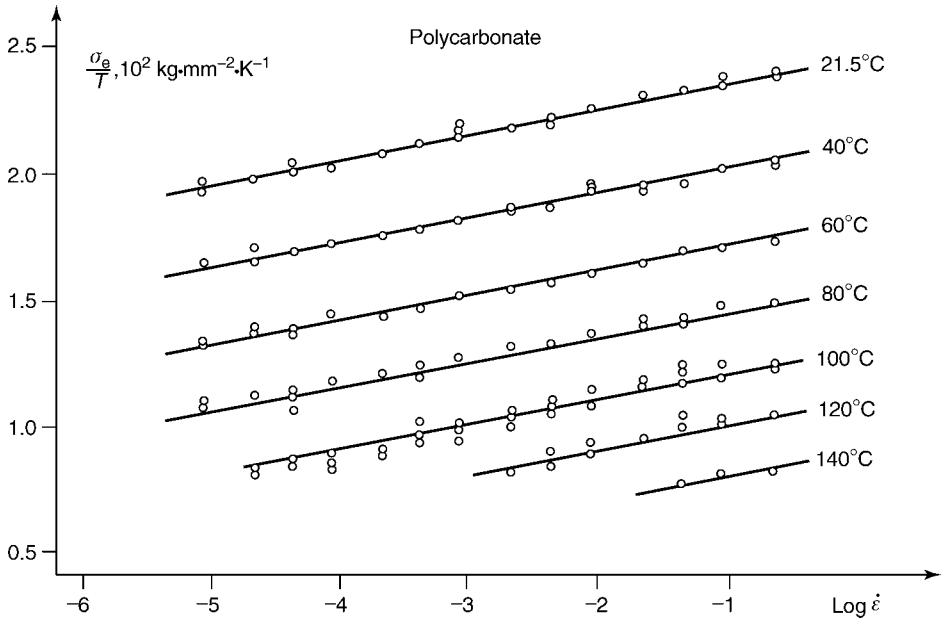

Fig. 10. Yield stress normalized to temperature as a function of logarithmic strain rate for polycarbonate. After Bauwens-Crowet and co-workers (44) with permission.

Robertson Model. The model developed by Robertson in 1966 (36) is also based on an activated process. He stated that the rigidity of a glass is a result of the intermolecular forces between adjacent chains, though for polymer glasses they suppose that the intramolecular forces are also important. Thus, to cause a glassy polymer to move into the liquid state it is necessary to reduce the effect of either the intramolecular or intermolecular forces. Robertson posited that a shear stress alone could achieve this and so induce Newtonian flow in the material. A shear stress field set up in the material can increase the number of flexed bonds (conformations) to a level above the preferred level of the equilibrium glass and may increase to the level that would be typically seen in a polymer liquid.

The model introduces the strain energy as a bias on the energy difference between bonds in the preferred (trans) and flexed (cis) conformations, with the simplifying assumption that the bonds can only exist in one of these two stable states. A polymer below the glass-transition temperature has a fixed, or "frozen-in," distribution of bond conformations in either the high energy (cis) or low energy (trans) states, with the difference in energy between the two states denoted as ΔE. Application of a stress causes conformations to shift from the trans to the cis state, effectively increasing the mobility to liquid-like levels. At sufficiently high stress levels the mobility is sufficiently increased such that yield can occur. More specifically the shear component of the stress (τ) causes a change in the energy difference between the two states by an amount $\tau v \cos \phi$, where v is the "flex volume" and is approximately the average volume of chain segments containing two bonds, and ϕ is the angle between the applied stress and vector displacement of the flexed bond (Fig. 11). The resulting energy difference between the two states (ΔE^*) is now given by

$$\Delta E^* = \Delta E - \tau \mathrm{v} \cos \phi \tag{31}$$

An assumption is then made that the material can be described by a term θ_g, which is the temperature at which the polymer structure in the glass would be an equilibrium structure and can be conveniently set to T_g. By performing a statistical average, the maximum number of flexed bonds for a given applied stress can be calculated and the current structure related to an "equivalent temperature," θ_1.

Using the WLF (49) equation to model the effect of temperature on the material viscosity Robertson went on derive an equation for the maximum shear strain

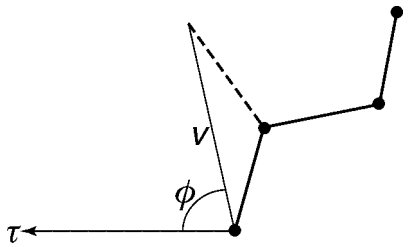

Fig. 11. Schematic of the Robertson (36) model for a shear-induced conformation change.

rate, $\dot{\gamma}_{MAX}$, induced by the shear stress, τ, as

$$\dot{\gamma}_{MAX} = \frac{\tau}{\eta_g} \exp\left\{-2.303\left[\left(\frac{c_1^g c_2^g}{\theta_1 - T_g + c_2^g}\right)\left(\frac{\theta_1}{T}\right) - c_1^g\right]\right\} \tag{32}$$

where c_1^g and c_2^g are the "universal" constants from the WLF equation, η_g is the "universal viscosity" at T_g, and θ_1 is as discussed above.

The model can be used to predict the shear rate as a function of shear stress for a range of temperatures. In the original paper a lack of shear stress data meant that the predictions were compared to tensile stress–strain data by decomposing the tensile data into shear and biaxial components. The point on the tensile stress–strain data that Robertson took to be the most appropriate stress to compare with the computed strain rate was the yield point. The model gives values for the yield stress and the temperature dependence of the yield stress that agree well with experiment for a number of polymers.

The model is attractive since the six parameters required above can be obtained independently and thus no fitting to the data is required. Of these six parameters, only two relate directly to the individual polymer, namely the glass-transition temperature, T_g, and the parameter v, the average volume of chain segments containing two bonds (though in practice Robertson took this to be the volume of a monomer unit in the glassy state at room temperature).

The Robertson model was extended by Duckett and co-workers in 1970 (29) to account for the pressure dependence of the yield stress. By their argument, if the two states are trans and cis and the effect of stress is to increase the number of cis conformations, then this implies a lower resulting density since the packing is less efficient. This in turn implies the change in conformations has an impact on the hydrostatic component of the applied stress. They further suggest that the hydrostatic component of the stress, p, will do work during the activation process leading to an overall energy difference between the two states of

$$\Delta E - \tau v + p\Omega \tag{33}$$

where p is positive in compressive loading and negative in tensile loading. The term Ω has units of volume. Using this modification they successfully correlated the torsional yield stress dependence of PMMA under hydrostatic pressure with the variation in the yield stress under compressive and tensile stresses as a function of temperature and strain rate.

Argon Model. Argon in 1973 (38) developed a molecular model for the initial yield based on the Gibbs free energy of the system. Again it considers that yield does not occur until the resistance to segmental rotation can be overcome by the application of stress. Strain in the sample is proposed to occur by the rotation of small molecular segments from an initially random orientation to a preferential orientation along the load axis. Such a process is modeled by introducing a "kink pair" into the molecule. The resistance to this kink formation is primarily from the surrounding molecular chains, and is modeled as an equivalent elastic medium. Argon derived an expression for the change in free energy, dG^*, required to produce

segmental rotation:

$$dG^* = \frac{3\pi G\omega^2\alpha^3}{16(1-\nu)}\left[1-\left(\frac{\tau}{\frac{0.077G}{1-\upsilon}}\right)^{5/6}\right] \tag{34}$$

where G is the temperature-dependent shear modulus, ν is Poisson's ratio, ω is the net angle of rotation between the two configurations, α is the mean molecular radius, and τ is the applied shear stress. This leads to an energy maximum as a function of the distance between molecular kinks and defines an energy barrier for kink formation. The rate of transfer between the ground and activated states is then modeled in a manner similar to that of a thermally activated Arrhenius process.

This leads to a plastic strain rate given by

$$\dot{\gamma}_P = \dot{\gamma}_0 \exp\left(\frac{-\mathrm{d}G^*}{kT}\right) \tag{35}$$

where $\dot{\gamma}_0$ is a pre-exponential factor having the units of s^{-1}, k is Boltzmann's constant, and T the absolute temperature.

Equation 35 can be rewritten as

$$\dot{\gamma}_p = \dot{\gamma}_0 \exp\left\{-\frac{As_0}{T}\left(1-\left(\frac{\tau}{s_0}\right)^{5/6}\right)\right\} \tag{36}$$

where

$$A = 39\pi\omega^2\alpha^3/16\kappa$$

and

$$s_0 = 0.077G/(1-\nu)$$

s_0 is termed the athermal shear yield strength and is the value of the shear yield strength as the temperature approaches absolute zero (and assuming finite strain rates). The above equation can be rearranged to give

$$\tau = s_0\left[1-\frac{T}{As_0}\ln\left(\frac{\dot{\gamma}_0}{\dot{\gamma}_P}\right)\right]^{6/5} \tag{37}$$

Equation 37 thus captures both rate and temperature dependencies of the shear yield stress.

Haward and Thackray Model. In 1968 Haward and Thackray (37) developed a one-dimensional model for yield using a spring in series with a parallel arrangement of a spring and dashpot (Fig. 12). The dashpot, rather than being Newtonian as with the standard Maxwell/Kelvin models, was instead an Eyring

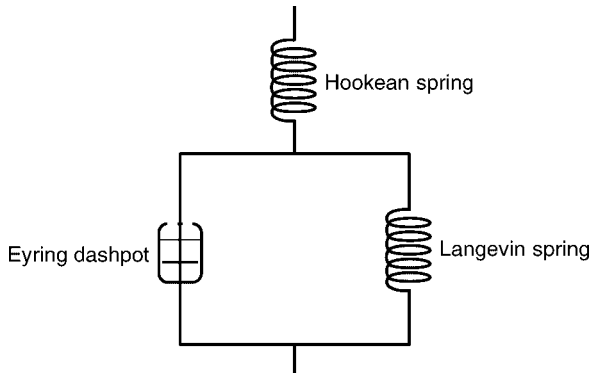

Fig. 12. Schematic of the one-dimensional model of Haward and Thackray.

dashpot. The standard Hookean-type spring was replaced with a Langevin (finite extensible) spring to account for the strain hardening (entropic resistance) observed at larger strains. The initial elastic response remains modeled with a Hookean spring in series. While the model correctly gives the dependence of the yield stress on strain rate it gives only a somewhat simple approximation to the realistic stress–strain response. Also, in common with all the previous models (Eyring, Robertson, and Argon), it does not address the issue of strain softening. However, the general principle of the model has been widely accepted and has been further refined and extended to address some of the shortcomings as discussed in the following sections.

Boyce, Parks, and Argon model (BPA Model). In a fashion that is conceptually the same as the Haward and Thackray (37) model, the BPA (39) model assumes that after an initial elastic response, the plastic resistance can be separated into a resistance to flow due to an activated process and an entropic resistance due to molecular alignment. The model builds on the Argon model to describe the initial yield in terms of the resistance to segmental motion and extends it to include pressure and strain-softening effects. It then goes on to model the second component of resistance to (large-strain) deformation, that of entropic resistance, in terms the "three chain" non-Gaussian (inverse Langevin) statistical model of Wang and Guth (50).

In the BPA model, it is the athermal shear strength given in the Argon model, s_0, which is modified to explain the observed strain-softening behavior. The reasoning behind this is that as the material undergoes the initial stages of plastic flow some restructuring of the molecular chains is assumed to occur and these changes are in turn assumed to cause a reduction in the athermal shear resistance. The evidence for this is discussed in detail in the paper by Boyce and co-workers (39). Briefly, tests carried out on polycarbonate after different thermal treatments and tested under identical conditions give different peak yield stress levels. However, the post-yield strain softening generally brings the stress levels down to the same value and this is interpreted as the material achieving a "preferred structure" during plastic flow. The decrease in the athermal shear resistance with strain is modeled phenomenologically by the following

expression:

$$\dot{s} = h\left(1 - \frac{s}{s_{ss}}\right)\dot{\gamma}_P \tag{38}$$

where s is the current value for the athermal shear resistance and is a function of the instantaneous structure, s_{ss} is the value s reaches at steady state, ie in the preferred structure, and $\dot{\gamma}_P$ is the plastic strain rate. Note that s_{ss} can itself be temperature and rate dependent. h is the slope of the yield drop with respect to strain, with the yield drop defined as the difference in the maximum stress before softening and the lowest stress level after plastic flow. The yield drop depends on temperature and strain rate and varies with strain as a function of structure and strain rate.

As noted above in discussing yield criteria, the shear yield strength generally increases linearly with applied hydrostatic pressure. Similar to the modified Tresca or von Mises yield criteria, where the shear yield stress is modified by a term linearly dependent on pressure, the BPA model introduces a term to modify the current athermal shear yield strength, s:

$$\tilde{s} = s + \alpha P \tag{39}$$

where α is the pressure coefficient, P the hydrostatic pressure, and s the athermal shear resistance modified for strain softening.

Thus the term s_0 in the original Argon model for yield (eq. 36) is replaced by $\tilde{s}$ to give

$$\dot{\gamma}_P = \dot{\gamma}_0 \exp\left\{-\frac{A\tilde{s}}{T}\left[1 - \left(\frac{\tau}{\tilde{s}}\right)^{5/6}\right]\right\} \tag{40}$$

where the pressure and strain-softening effects are contained in the $\tilde{s}$ term.

The second part of the BPA model concerns the entropic resistance resulting from molecular orientation and which leads ultimately to strain-hardening behavior. This is strictly a post-yield phenomenon and indeed the physics of the development of chain orientation and subsequent material behavior alone is the subject of books (eg Ward I.M. (51)). The BPA model uses the development of three-dimensional entropic resistance as first modeled by Parks and co-workers (52). Consider an amorphous polymer that is plastically deformed below its glass-transition temperature (T_g). If this material is then heated to above T_g it will recover to its original undeformed state. In order to prevent the material returning to the undeformed state at temperatures above T_g, it would be necessary to impose a stress on the sample. This restraining force then acts to counteract the shrinkage force or 'back stress' B_i. For the plastically deformed material below T_g, this back stress can be considered to be frozen-in to the deformed polymer at temperatures below T_g and is the source of resistance to further deformation. The recovery of the material deformation above T_g clearly has parallels with rubber elasticity and the orientation hardening is modeled using the statistical mechanics theories of rubber elasticity (Treloar 1975 (53)). For low

stretch ratios, the standard Gaussian statistical model of Treloar (53) is sufficient. However, the BPA model as originally developed used the non-Gausssian statistical mechanics network (Three-chain model) of Wang and Guth (50). This gave an expression for the back stress, B_i, as a function of the number of statistical segments between entanglements, the plateau rubber modulus (through which the temperature effects are taken into account) and the change in entropy as a function of the principal plastic stretches. The reader is referred to the original paper (39) for the specific details and development of this aspect of the model. The model has since been incorporated into commercial finite element codes (ABAQUS).

The model has been subsequently refined (Arruda and co-workers (54)) to more accurately describe the three-dimensional spatial orientation of the stretched molecular network using the eight-chain model (though comparison of the predictions from the eight-chain model with experimental results from natural rubber and polydimethylsiloxane has called into question the physics of that model (55)). The BPA model has been further developed (56) to account for aging effects (see, eg Reference 57). A model using the same underlying concepts, but again developed to improve the description of the strain hardening (entropic resistance), has been given by Wu and van der Giessen (58) using a "full chain" model.

Tervoort and co-workers Model. While the above models make reasonable predictions of the stress–strain behavior in monotonic loading conditions, a main drawback to them is that they use only a single stress-dependent characteristic (relaxation) time. As a consequence, the predicted behavior tends to show a sharp transition between elastic (solid-like) and plastic (fluid-like) behavior. However, it is found in practice that all polymers exhibit behavior consistent with a spectrum of relaxation times and this is clearly going to affect the stress–strain response at constant strain rate. In an effort to address this inconsistency Tervoort and co-workers (40) have developed a "modified compressible Leonov model."

The model is based on an earlier one by the same authors, the "compressible Leonov model" (59). In this, the behavior is modeled with a single Maxwell element where the dashpot and spring now have a relaxation time that is a function of the applied shear stress. This is similar in principle to the change seen in the relaxation time with a change in temperature (time–temperature superposition, (see VISCOELASTICITY), leading to the concept of time-stress superposition and a "stress clock" within the material. The model is developed with thermodynamically consistent constitutive equations by assuming that the free energy of the system (a measure of the stored energy) is given by two state variables, the relative volume deformation and the isochoric strain tensor. The volume deformation is coupled to the hydrostatic component of stress while the isochoric strain is determined by the deviatoric stress. It is assumed that the volume deformation remains elastic, whereas the accumulated isochoric elastic strain is reduced over time because of a plastic strain rate. This plastic strain rate is described by a three-dimensional Eyring equation. The single-element model is essentially an elastic–plastic model and still exhibits a sharp transition between the two behaviors. To make the model more realistic, it was extended (40) to include a discrete relaxation

spectrum by using an array of 18 Leonov modes, each with a unique relaxation time.

Tervoort and co-workers tested the multimode model using polycarbonate since it could be described with a single relaxation mechanism having a distribution of relaxation times at the temperature of interest. The model parameters for the Eyring term were determined from plateau creep rates and the linear Leonov parameters from a linear shear relaxation curve (obtained from inversion of the creep compliance curves). The resulting model predictions agreed excellently with stress–strain curves over a range of strain rates up to approximately 8% strain. However, the model lacks any term to account for the entropic resistance (strain hardening) and so is valid only up to the yield point.

In subsequent work, Govaert and co-workers (60,61) specifically address the postyield large-strain phenomenon of strain hardening, again for a polycarbonate. In an effort to minimize the effects of a localized, inhomogeneous strain deformation (neck), they adopted a technique of mechanical preconditioning. This technique aims to reduce the strain-softening characteristics of the material by conditioning the material through plastic deformation (61,62). The resulting true stress–true strain curves show a markedly reduced yield drop, while maintaining the same large-strain response. Interestingly, the authors found that the large-strain data could be modeled as simple neo-Hookean behavior and this was true up to the failure point (at a draw ratio of approximately 3). As the authors observed, this is in contrast with the results of eg Arruda and co-workers (63) for a different grade of polycarbonate where there was a deviation from neo-Hookean behavior indicating finite extensibility effects (ie a rapid upturn in the true stress–true strain response).

Caruthers and co-workers Model. The group of J.M. Caruthers at the Chemical Engineering Department of Purdue University has, over the last decade or so, been developing a set of unified constitutive equations that aim to realistically model a wide range of rheological and mechanical properties (41,42). A detailed description of the model is beyond the scope of this article and we mention here only the main ideas behind the development of the model (see also VISCOELASTICITY). The model addresses the time, temperature, and history (thermal and mechanical) dependence of the material behavior using a set of thermoviscoelastic constitutive equations based on Rational Thermodynamics (64,65). The model introduces a material (or reduced) time, where the material timescale is determined by the instantaneous thermodynamic state of the material, using the Adam–Gibbs (66) model, which relates the relaxation time to configurational entropy. This is a potentially important development in the context of this article, as it allows the prediction of nonlinear mechanical behavior including yield. The model is still in development, but has successfully predicted a range of behaviors including specifically isobaric volume relaxation, yielding under uniaxial extension, shear thinning, and stress overshoot in transient shear (42).

A particularly appealing aspect of the model is that all the model parameters can be determined from independent experiments and further that they are relatively few in number. Thus a material can be characterized in a relatively short period of time, though the mathematical framework of the model is somewhat intensive.

Dislocation Plasticity

The observation of microscopic shear bands in polymeric materials, coupled with the highly successful application of dislocation theory to plasticity in ductile metals, has led to the concept of dislocation plasticity in polymeric materials. The first application of dislocation mechanisms was, not surprisingly, to semi-crystalline polymers (67). Predeki and Statton (68,69) looked at the effect of chain ends on crystalline regions and introduced the idea of screw and edge dislocations occurring in nylon-6,6 (68). They further examined the effect of shear stress on such dislocations in polyethylene (69). Direct evidence for the presence of dislocations in polymer crystals was obtained by Petermann and Gleiter (70) from the electron microscopy of single crystals of polyethylene. Gilman (71,72) further suggested that dislocation mechanisms can be applied to amorphous solids such as glasses and polymers. Bowden and Raha (73) developed a model of yield in which micro–shear bands are created by the formation and growth of dislocation loops, the energetics of which are influenced by the shear stress and the thermal energy. Unlike metals, where the dislocations or defects are inherent, the dislocations in polymers are formed under the action of an applied stress. Once formed, they may grow with the aid of thermal activation, ultimately leading to yield. The authors emphasize that the dislocation process they envision as occurring in an amorphous solid is not the same as in the classic concept of crystal plasticity, though it is a close analogy.

The energy U of a dislocation loop of radius R is

$$U = (2\pi R)\frac{Gb^2}{4\pi}\ln\left(\frac{2R}{r_0}\right) - (\pi R^2)\tau b \tag{41}$$

where r_0 is the radius of the dislocation core, τ the applied shear stress, G the shear modulus and b the Burgers vector (essentially equal to the magnitude of the shear displacement). The first term in equation 41 is the elastic strain energy associated with a loop of length $2\pi R$ and the second term the work done by the applied stress to expand the loop to radius R (of the order of 1 nm). As the loop expands the energy at first increases then reaches a maximum at some critical radius (R_c), then will monotonically decrease. As expected, the height of this energy barrier decreases with increasing shear stress. The Bowden and Raha model is thus a thermally activated model whereby both the rate and temperature dependence are captured in the term U/kT. Interestingly, the model also implicitly accounts for strain softening—as the dislocation loop overcomes the peak in the energy barrier, further growth leads to a lower energetic state with the implication of reduced resistance to further extension. As the model is presented, the reduction in resistance (and hence the degree of strain softening) is monotonic, that is there is no limit to the extent to which the material will strain soften. This is clearly a major limitation of the model, though the authors have suggested a number of mechanisms that may limit the degree of strain softening.

The above model based on dislocation-type defects in polymer glasses is attractive in that it allows one to put some order and physical interpretation to

the (obviously complicated) processes occurring during deformation. Care must be exercised though in taking the analogy with dislocations in metals too far—the ordered structure of metals is not seen in polymers, hence the meaning of a defect such as a dislocation is unclear.

Ultimate Shear Strength

The maximum theoretical strength of a crystal had been estimated by Frenkel as far back as 1926 (74), and the same general ideas have been applied to amorphous polymers (73,75,76). Briefly, if an equilibrium crystal lattice is sheared to a strain of 1, each atom will have moved to a new equilibrium position. At a strain of 0.5, the atoms will be between one equilibrium position and the next and the shear stress required to hold it in position will be zero (albeit in an unstable state). Consequently, the maximum shear stress is assumed to occur at a shear strain of approximately 0.25. Since the initial slope of the stress–strain curve is the shear modulus G, this gives an estimate of the maximum shear stress to be approximately $G/6$. While the structure of an amorphous polymer is far from that of an ideal crystal it is reasonable to suppose that the molecular segments are at some equilibrium position and at a high enough shear stress most, if not all, will fall into a new equilibrium position (though the energy landscape, and hence equilibrium potentials, will not be as uniform as those in a crystal). The model as proposed did not allow for thermal fluctuations (ie it was effectively for a material at 0 K) and it is expected that taking account of such fluctuations would reduce the theoretical strength.

Other estimates of the ultimate shear strength of amorphous polymers have been made by a number of authors and generally all fall within a factor of 2 of each other (38,77,78). Stachurski (79) has expressed doubt as to the validity of the concept of an intrinsic shear strength based on the value of the shear modulus, G, for an amorphous solid. He questions which modulus is the correct value to use—the initial small strain value or the value at higher strain (the yield point or the ultimate extension). Further, the temperature and strain-rate dependence of both the yield strength and modulus (however defined) suggests that perhaps the ratio of yield strength to modulus is not a true intrinsic material property. We remark however that the temperature and strain-rate dependence of both the yield stress and the shear modulus are often similar.

A related issue is that the modulus is a viscoelastic property, as evidenced by the temperature/strain-rate dependence, and that for most polymers (at least those without a large beta transition near the alpha transition) time–temperature superposition of, for example, the shear relaxation modulus is valid (80). Further, G'Sell and McKenna (81) have shown that the yield stress vs strain rate also seems to obey time–temperature superposition. Hence there is a correlation between the viscoelastic properties and the yield response of polymers, though one that is not generally stated explicitly. We note that some of the models mentioned previously, such as those of Caruthers' group (41,42), Tervoort and co-workers (40), and Knauss and Emri (35), are (nonlinear) viscoelastic models that have yield arising due to the nonlinear response induced by the material clock (see VISCOELASTICITY).

Calorimetry and Dilatometry

When a polymer is deformed, work is necessarily done in the material. On subsequent unloading, the stress–strain curve does not generally follow the loading curve and the difference in the areas under the two curves gives the net work done on the material (W). This work can be subdivided into work done in changing the internal energy of the material ($\mathrm{d}U$) and heat liberated (Q):

$$W = \mathrm{d}U + Q \tag{42}$$

By measuring both the heat flow generated during deformation (Q) and the engineering stress–strain data (and from this the quantity W) it is possible to estimate the change in the internal energy of the sample. A pioneer in this field of study is Oleinik (also spelled Oleynik) (82). In a series of experiments, samples of polystyrene placed in a calorimeter were compressed to varying levels of strain (up to approximately 40%) and unloaded, and the W and Q were calculated. The total work (W) rises somewhat linearly with applied stress while the amount of heat liberated (Q) rises at an initially slower rate then increases to become parallel to the W curve at a strain of approximately 25%. This means that the stored internal energy ($\mathrm{d}U$) rises at lower strains then plateaus out at strains above 25%, with an inflection point at or near the yield strain of 12%.

The same effect can be observed by performing DSC tests on previously strained samples. Hasan and Boyce (83) subjected annealed polystyrene to compressive strains up to 170% followed by DSC scans up to and through the glass-transition temperature (T_g). Comparing the results to freshly annealed samples, it was seen that for samples that had been strained, a pre-T_g exotherm appeared that increased with increasing compressive strain. This pre-T_g exotherm increases in magnitude up to a strain of 25% and remains constant thereafter up to the maximum strain of 170%, in excellent agreement with the data of Oleinik. They also note that the exotherm is spread over a wide temperature range (starting at approximately T_g -35°C), which they attribute to the distributed nature of the structural state. In addition, there appears to be a similar inflection point at a strain near the yield strain (within the range 10–15%).

The exact nature of the storage mechanism that is reflected in the increase in internal energy remains unclear. Indeed it is not clear that the energy term $\mathrm{d}U$ can be considered simply as a storage term, especially at the higher strains where energy could be expended on chain scission or processes akin to phase changes occurring at and above yield.

Polymers are inherently viscoelastic, compressible materials and under conditions of dilatational deformation (eg uniaxial tension or compression) a full description of their behavior needs to take into account the volume changes due to, at least, the hydrostatic component of the stress (84). One of the earliest works on volume effects on yielding in glassy polymers was by Whitney and Andrews (85), who examined a range of polymers under uniaxial compression. In the study, the authors observed a volume contraction upon loading up to the yield point, after which the volume remained approximately constant. More recently (86), subyield tension and compression tests were performed on two commercial grades of polycarbonate (PC). These tests were performed under stress relaxation conditions and

showed that under tension the volume increased somewhat monotonically with strain while under compression the reverse was true, ie the volume decreased monotonically. While the volume at a small strain was found to recover toward the initial state, at strains approaching yield and in tension the material actually densified to a state of higher density than the undeformed polymer. It was postulated that the mobility that allowed the material to densify was related to its propensity to yield rather than fail in a brittle manner. A number of studies have been performed on the volume evolution during mechanical deformation [eg (87–89)]. Also studies on the changes in "free volume" with deformation using positron annihilation spectroscopy (PALS) (90–92), have been carried out. The reader is referred to the texts for further details.

Computer Modeling

With the advent in recent years of increasingly powerful and cheap computing power, molecular modeling of the deformation response of polymers has come to be of increasing importance (76). Molecular mechanics uses the Newtonian equations of motion to calculate the step-wise displacement of individual atoms within a molecule in small time intervals (typically of the order of femtoseconds). On each step, the atom's position is modified with reference to its previous state (position, velocity, etc) and taking into consideration, for example, its bond length and bond angle (bonded interactions) and Van der Waals forces (nonbonded interactions) with its nearest neighbor. The system as a whole is then optimized using potential energy functions to determine the equilibrium conformation. Molecular mechanics calculations are performed on systems that are generally considered to have little, if any, thermal energy (ie at low temperature). As such, the optimization procedure may only find the conformation representing the *local* minimum in the energy landscape and this will not necessarily (indeed rarely) be the lowest possible energy. Molecular dynamics, on the other hand, considers not only the force interactions but also the thermal motions of the molecule. By doing so, the molecule is allowed to overcome energy barriers and so explore its surroundings more effectively, assisting in finding the *global* energy minimum. Importantly, in molecular dynamics the thermal motion is always active and the molecules tend to oscillate about the energy minimum, giving additional information about the time-dependent motion of the molecules.

As noted, the field of molecular simulation is relatively new, and a detailed review of it is beyond the scope of this text and we introduce here a few of the more relevant references. One of the first applications of molecular mechanics to polymers was by Theodorou and Suter (93,94), who modeled atactic polypropylene as an amorphous cell subjected to a range of stress conditions (hydrostatic pressure, pure strain, and uniaxial strain). Such modeling generally gives reasonable estimates of the elastic constants of a material [within 15% (79)], providing the density of the glass is correctly modeled.

Argon and co-workers (95,96) have developed an atomistic mechanics model of polypropylene and related it to experiments performed at a temperature of 10°C below the glass-transition temperature. Stress–strain curves calculated after small strain increments showed a series of generally monotonically increasing

stress versus applied strain sections (elastic response), interspersed with sudden step-wise drops in the load (plastic events). Significantly, the authors note that the plastic events are not associated with any deformation process invoked by many of the molecular theories discussed above (ie a sudden conformation or configuration change, a dislocation motion or kink propagation). However, because this was an athermal model, the meaning of these events for a real viscoelastic or viscoplastic polymer is unclear.

Computer modeling can clearly help in the understanding of the deformation and yield behavior of polymeric systems by giving an insight into the individual molecular, indeed atomic, movements that occur. However, the simulations are typically run over a few tens of picoseconds at most and in a volume of a few cubic nanometers—such scales of time and dimensions cannot fully capture the processes involved in yield at the present state of development.

Semicrystalline Materials

The propensity of a polymer to crystallize is chiefly determined by its molecular architecture, specifically the regularity of the polymer chain. Polymers consisting of the same repeat unit, the simplest example being linear polyethylene, can fit together neatly to form the ordered crystalline phase and typically have 70–80% crystallinity. For polymers where a hydrogen from the ethylene monomer is replaced by a bulky side group [for example the methyl group ($-CH_3-$) in polypropylene or the phenyl group ($-C_6H_5$) in polystyrene], the polymer chain can exist in one of three forms of handedness, or tacticity. If all the side groups lie on the same side of the main chain the material is called isotactic; if they lie in a regularly alternating fashion left and right of the main chain the material is termed syndiotactic; and finally, if they occur randomly positioned along the main chain they are termed atactic. The least regular, atactic form generally does not crystallize to any degree, while both the isotactic and syndiotactic forms can crystallize, though the degree to which either form does so depends on the structure, polarity of the side group, etc.

Early X-ray studies on the structure of Semicrystalline Polymers (qv) showed that the longest dimension of the crystallites was typically of the order of a few tens of nanometers. This is a small fraction of the length of a typical polymer chain, which may be of the order of several thousands of nanometers, and it was originally thought that the polymer chain moved successively between different regions of amorphous and ordered crystalline phases in what is termed the "fringed micelle model." However, later work on single crystals grown from dilute solutions revealed that the polymer backbone was perpendicular to the longest dimensions of the crystal. Such a structure could only be produced if the polymer chains were folding back upon themselves.

The current prevailing view is that the crystalline regions in semi-crystalline polymers are made up of plate-like structures formed from mostly chain-folded molecules. These plate-like structures are termed lamella and are typically some 10–20 nm thick. As the molecules forming the lamella chain fold, they may either reenter adjacent to the current position, reenter at some position farther along the lamella, or stay in the amorphous region. Ultimately, farther along the molecular

chain, such molecules may enter another lamella thus forming "tie molecules," akin to entanglements in amorphous polymers. These lamellae may in turn form supramolecular structures called spherulites—aggregations of lamellae forming and growing from a central nucleation point.

Below the crystalline melting point, semi-crystalline polymers are then essentially two-phase systems consisting of a stiff, rigid crystal phase embedded in a more flexible amorphous phase. The amorphous phase may be either above its glass-transition temperature (semi-crystalline/rubber) or below it (semi-crystalline/glass). The yield behavior of semi-crystalline polymers depends critically on a number of factors, eg the degree of crystallinity, the lamellar thickness and interlamellar spacing, spherulite size, the number of tie molecules and, of course, temperature. That said, however, they still show the same general behavior as depicted in Figure 1: brittle at low temperatures, yield and possible strain hardening at intermediate temperatures, and rubbery or viscous flow behavior at higher temperatures.

At temperatures below the T_g of the amorphous phase, the crystallites and associated tie molecules can severely reduce the mobility of the polymer chains and thus tend to embrittle the material. This generally leads to a brittle-like failure (Fig. 13, curve A) though at slow enough rates yielding and drawing may be observed (Fig. 13, curve B).

At temperatures above the T_g of the amorphous phase, the crystallite regions still act to prevent the free movement of the amorphous region and the material does not behave in a rubber-like fashion as would be expected for a pure amorphous polymer. Under these conditions, where the amorphous fraction would not be expected to show a yield point, yield is associated purely with the crystallites. On initial deformation, the crystallites act as hard inclusions, and the strain in the material is carried predominantly within the amorphous fraction. Given that the yield strain in these materials is typically of the order of 0.25 it is unlikely that the (rubbery) network has been sufficiently stretched and strain hardened to

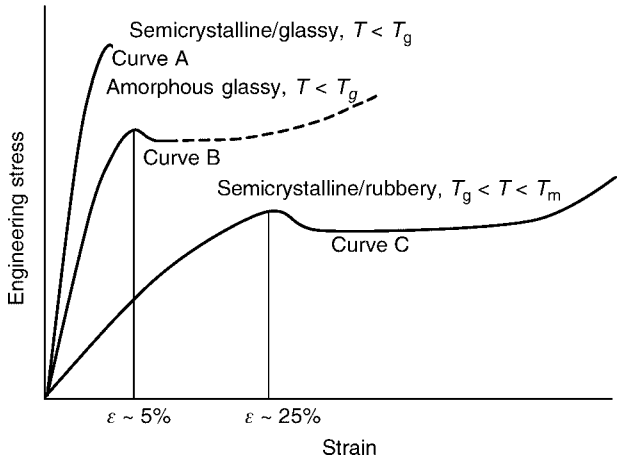

Fig. 13. Representative engineering stress–strain curves for a semicrystalline polymer as a function of temperature.

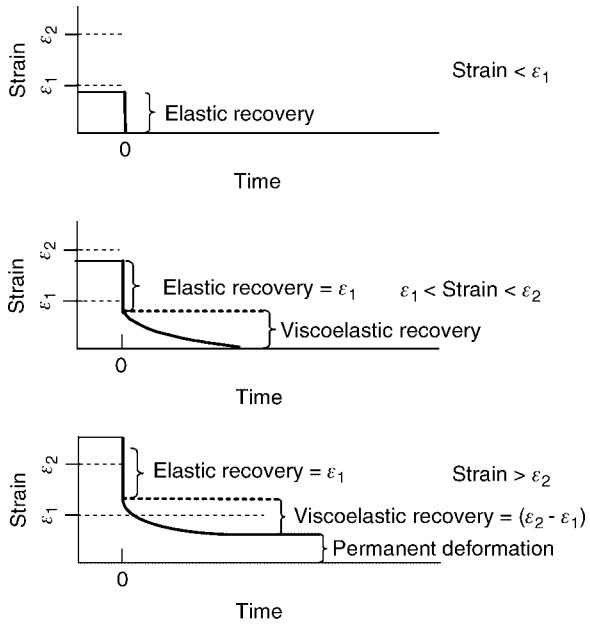

Fig. 14. Schematic of the strain recovery with respect to the double yield point observed in some semicrystalline materials (stress removed at time 0).

load the crystallites to yield. However, it is expected that the network has been sufficiently stretched, such that the tie molecules associated with the lamellae have become taut and so are able to transfer the load to the crystallites. The precise mechanisms associated with the subsequent yield of the crystallites are still not well understood. However, the observation of two yield points (double yield) in polyethylene (97–99) has provided some insight into the molecular processes at work. Up to the first yield point, the material is elastic and deformations are fully recoverable (Fig. 14). The first yield point occurs at low strains (∼5%) and marks the onset of recoverable deformation. This process has been associated with an interlamellar shear process or martensitic transformation within the lamellae and leads to a reorientation of the lamellae, with little or no destruction of the lamellae themselves. The second yield point occurs at a higher strain (20–50%) and marks the onset of permanent plastic deformation and is generally associated with the formation of a neck. At this point coarse slip occurs within the lamellae leading to fragmentation and destruction of the lamellae themselves. The post-yield behavior is largely associated with the amorphous regions and, like a pure amorphous polymer, is controlled by the entangled network. As such, phenomena such as strain hardening and cold drawing are commonly observed as discussed previously (Fig. 13, curve C).

Phenomenologically, the rate and temperature dependence of the yield stress of semi-crystalline polymers can be described by the Eyring activated state model, as discussed earlier, with either one (100,101) or two (46,102) activated processes. However, developing a theory for the yield of semi-crystalline polymers is clearly complicated by the presence of two distinct phases. It is unclear at present whether

the models discussed above are even applicable to the amorphous phase present in semi-crystalline polymers because of the topological constraints that the crystalline regions impose. Nevertheless, in light of the fact that above the T_g of the amorphous region, it is the crystallites that dominate the yield behavior the ideas of classical crystal plasticity are obviously attractive. Young (103) developed a theory along such lines in which the energy required to initiate a screw dislocation in the crystal lamellae determines the yield stress. The model correctly predicts the observed linear relation between yield stress and lamellar thickness, though the quantitative agreement with experiment is controversial (104–107). A model has been recently developed (108) wherein the driving force for the screw dislocations are thermally activated "chain twist" defects that transfer along the chain backbone.

In the early 1990s Bartczak, Argon, and Cohen conducted a series of tests on what they termed "single-crystal textured high density polyethylene" (109,110). These were samples that had been compressed under plain strain conditions, producing an axisymmetric texture that approximated to a macroscopic single crystal. X-ray scattering studies were conducted on the material at various stages of deformation (up to a strain of 1.86, after recovery) to monitor the structural evolution. The resulting material showed distinct crystallographic features indicating unique crystallographic planes, with the *c*-axis of the crystallites aligned along the flow direction (indicating that the lamellae are, broadly speaking, oriented perpendicular to the flow direction). Samples were then cut from the textured samples at particular orientations in order to investigate specific deformation mechanisms. Significant differences in the stress–strain response of samples tested at differing angles to the chain axis were observed under both tension and compression. The papers offer considerable insight into the contribution from different crystallographic deformation mechanisms. Interestingly, when such mechanisms could be isolated, it was found that the Coulomb criterion was an adequate description of the yield surface. The specifics of the various deformation mechanisms and their relation to the specific crystallographic planes is beyond the scope of this article, and the reader is referred to the original papers (109,110) for details.

Crazing

The previous section was concerned with what may be termed "macroscopic yield," which is the shear yield over an entire sample ligament area (albeit localized in the case of neck formation). Another mode of deformation that is commonly observed in thermoplastics is that of crazing. Unlike the shear yielding discussed above, crazing is a microscopically localized phenomenon. The crazes that result from the localized process can be looked upon as load-bearing cracks, where the load-bearing capacity is provided by highly drawn fibrils of material spanning the two interfaces. This is a unique aspect of crazing in polymers as the fibrils can support the crack and help prevent or delay failure.

Crazing generally occurs where the stress on the sample has become highly concentrated owing to, for example, surface defects such as flaws, scratches, or inclusions within the material such as dust or other contaminants. Crazes can also occur in homogenous polymers, ie those without any contaminants or additives

and which are flaw-free. An elegant series of experiments by Argon and co-workers (111) using samples carefully prepared from single pellets has shown that crazing can still occur without any tell tale origins relating to contaminants, a behavior denoted as "intrinsic crazing." While no obvious cause for the craze nucleation may be evident, it must nevertheless originate at a particular point because of an intrinsic local heterogeneity in the molecular structure, such as a local density variation. The stress required to craze such samples is higher than that observed in bulk (and implicitly contaminated) samples and indicates that while flaws or inclusions are not a necessary condition for crazing, they do lead to premature crazing.

The appearance of crazes in a material is generally a precursor to brittle failure. While such a mode is normally to be avoided, the presence of crazes can provide some beneficial effects. Because the crazes contain highly drawn fibrils of material, considerable plastic deformation and hence energy goes in to their formation and this can be a major source of fracture toughness. Indeed, the deliberate inclusion of small, typically rubber, particles into inherently brittle polymers is commonly undertaken to produce tough materials (112–115), because the presence of the particles dramatically increases the craze density.

The following is a brief overview of the subject matter which introduces the reader to the main features of craze morphology and current theories on their initiation, growth, and failure. The reader is pointed in particular to excellent reviews on many aspects of crazing by Kramer (116), Kramer and Berger (117), Kambour (118), and Donald (119,120), and much of the subsequent discussion follows the development in those reviews.

Crazing in polymers follows three distinct stages: craze initiation where the craze is nucleated, craze growth where the craze continues to grow in a direction perpendicular to the applied stress, and finally craze failure, the precursor to ultimate failure. Before discussing these three aspects of crazing, a general overview of craze morphology is given to familiarize the reader with the structure of the craze and the salient features involved in craze growth. The specific details and evolution of the structures are discussed in the relevant subsequent sections.

Craze Morphology. Figure 15 shows a schematic of craze nucleation and growth. The presence of an intrinsic or extrinsic heterogeneity causes the bulk stress to be locally modified. This results in an increase in the local triaxial stress field and forms a localized plastic zone (Fig. 15**a**). Small voids form in this plastic zone and, as the voids grow, they eventually coalesce with the original material between the voids forming the fibrils (Fig. 15**b**). The final craze structure (Fig. 15**c**) consists of the two surfaces bridged by a network of fibrils of drawn (highly anisotropic) polymer with a voided region at the craze tip from which craze growth may continue. Such fibrils typically have a diameter of a few tens of nanometers and a length (craze thickness) of the order of a micron. As the craze continues to grow, the fibrils extend by either a creep mechanism or by drawing in additional material from the bulk–fibril interface (Fig. 16) under the influence of the local stress at the craze boundary (σ_{CR}), which is typically slightly lower ($\sim$5%) than the applied bulk stress (σ_B) (Fig. 17, after Reference 121—the data shown is for an isolated craze in an "infinite" sheet, points on the x-axis denoting the distance from the centerline of the craze and is of course symmetrical about that line). Eventually a failure criterion is reached and the fibrils fail. The loss of the load-bearing

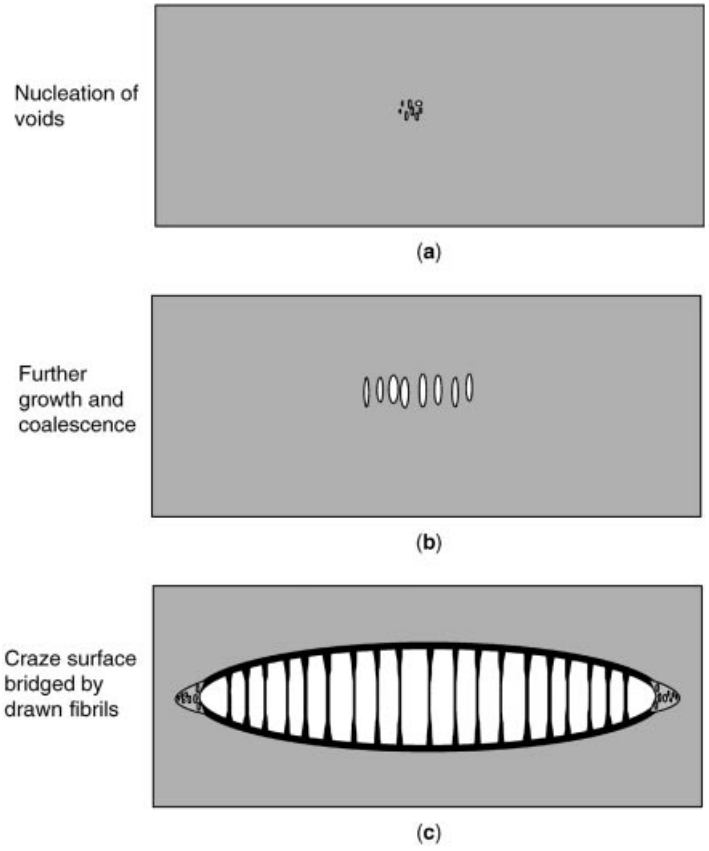

Fig. 15. Schematic of (**a**) void formation, (**b**) craze initiation, and (**c**) craze growth.

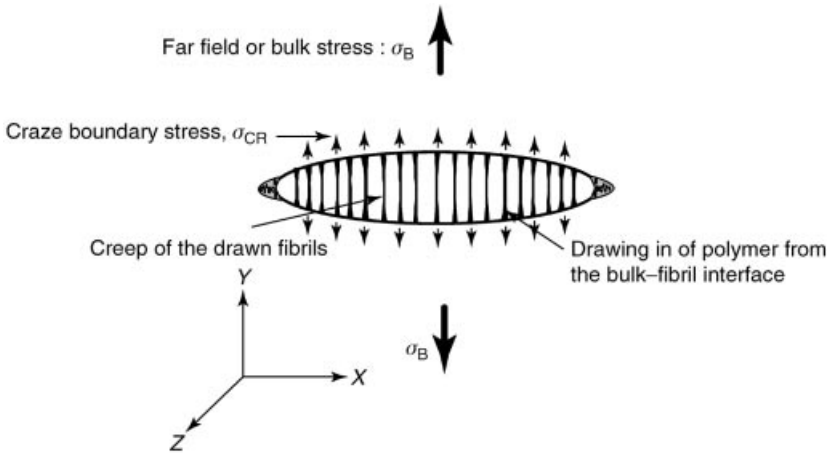

Fig. 16. Craze morphology and possible growth mechanisms.

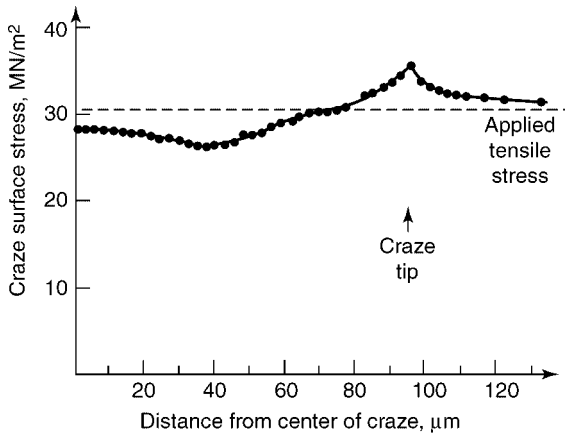

Fig. 17. Craze surface stress as a function of position from the craze centre for polystyrene. After Lauterwasser and Kramer (121), with permission of Taylor and Francis Ltd., http://www.tandf.cp.uk/journals.

capacity of the failed fibrils means the neighboring fibrils are subjected to an additional load and this can, under certain circumstances, lead to a runaway failure of the fibrils, true crack formation, and ultimately brittle failure.

Crazes also normally occur at surface crack tips. The presence of a crack causes a geometrically imposed increase in the local stress (stress concentration), which results in a dilatational stress field. This in turn leads to the formation of a local plastic zone and, in a manner similar to the above, to cavitation and the formation of a craze. The general features of a surface craze are the same as those of an internal craze (Fig. 15), though with the obvious lack of symmetry owing to the presence of the crack. Such crazes tend to stabilize a crack by blunting the crack tip, reducing the stress concentration while retaining a load-bearing capacity.

We now look in more detail at the individual stages of craze formation and subsequent growth.

Craze Initiation

Unlike the shear yield process, crazing is an inherently non-isovolume event. Cavitation of the material requires a dilatational component of the stress tensor, such as occurs in triaxial stress systems that may be found in samples subjected to plane strain conditions. In addition, it is found in practice that there is a time dependency on the appearance of crazing. That is, there is generally a time delay between application of the load and the first visible appearance of a craze. A number of models have been proposed which require either a critical cavitation stress, a critical strain, or the presence of inherent microvoids, which can grow under the applied local stress or strain.

Sternstein and Ongchin (1969). Considering that cavitation was required for craze nucleation, Sternstein and Ongchin (122) postulated that it is

the dilatational component of the stress tensor along with a stress bias σ_b (flow stress) that controls craze initiation:

$$\sigma_b = A + \frac{B}{I_1} \tag{43a}$$

where for plane stress, $\sigma_b = \sigma_1 - \sigma_2$, and

$$I_1 = \sigma_1 + \sigma_1 + \sigma_1 = 3p > 0 \tag{43b}$$

where I_1 is the first stress invariant ie the dilatational component of the stress tensor. A and B are temperature-dependent constants. We note that under this criterion, crazing will not occur under pure hydrostatic tension ($\sigma_1 = \sigma_2 = \sigma_3$), pure shear stress [$(\sigma_1 + \sigma_2 + \sigma_3)/3 = 0$, $I_1 = 0$], or compressive stress states ($I_1 < 0$). The model was extended beyond the specific case of plane (or biaxial) stress conditions to a general three-dimensional case by Sternstein and Meyers (123). Because they are essentially empirical, the Sternstein et al models have several shortcomings: (*1*) the stress bias, $\sigma_1 - \sigma_2$, is related to the shear stress and it is difficult to reconcile a shear stress component controlling initiation of a craze in a direction perpendicular to the principal stress component σ_1, (*2*) the parameters A and B have no direct or obvious physical interpretation, (*3*) no time dependency for the initiation of crazes.

Gent (1970). Gent (124) proposed a model in which the hydrostatic tensile stress at an inclusion or local heterogeneity increases the free volume and therefore effectively reduces the T_g of the material. At a sufficiently high stress concentration, the reduction in T_g is sufficient to reduce the local T_g to the test temperature. The reduced yield stress of the material in this rubber-like phase and the hydrostatic tensile stress then leads to cavitation and craze initiation. Implicit in this free-volume approach is that an imposed hydrostatic pressure will tend to prevent the formation of crazes in accordance with experimental observation. The criterion is summarized in the equation for the critical applied stress for initiation, σ_c:

$$\sigma_c = \frac{\beta(T_g - T) + P}{k} \tag{44}$$

where T_g is the glass temperature of the material, T is the test temperature, P is the bulk hydrostatic pressure, k is the stress concentration, and β is a constant related to the pressure dependence of T_g, and has a value of approximately 5 MPa/K. However, the inferred stress concentrations, k, required to induce crazing at room temperature were unrealistically large (of the order of 20) and the authors acknowledge it is a factor not easily accessible to experimental techniques. In addition, Lauterwasser and Kramer (121) calculated the reduction in T_g at the crack tip due to the imposed hydrostatic stress. Using the data in Figure 15 they calculated the hydrostatic pressure term to be one third of the bulk stress (σ_{bulk} = approximately 30 MPa) plus the additional surface stress at the craze tip of approximately 5 MPa, giving a total of 15 MPa. Using a value of 1°C/5 MPa for the

pressure dependence of T_g, they estimated the reduction in T_g at the crack tip to be a modest 3°C, certainly not enough to reduce the local T_g to the test temperature.

Oxborough and Bowden (1973). Addressing the lack of generality in terms of the usable stress states in the original Sternstein and Ongchin paper (122), which was limited to plane stress conditions, and concerns as to the physical interpretation of the critical stress (stress bias $\sigma_b = \sigma_1 - \sigma_2$) Oxborough and Bowden(125) proposed a criterion for craze initiation based on a critical strain. The form of the criterion is identical to that in the Sternstein and Ongchin paper, with the critical stress σ_b replaced by a critical strain ε_c:

$$\varepsilon_c = X' + \frac{Y'}{I_1} \tag{45}$$

where I_1 is again the first stress invariant and X' and Y' are time- and temperature-dependent variables. Noting that under a general stress state the maximum strain is in the direction of the principal stress and is given by

$$\varepsilon_1 = \frac{1}{E}(\sigma_1 - \nu\sigma_2 - \nu\sigma_3) \tag{46}$$

ν is the Poisson's ratio and assuming that crazing occurs at the critical strain given by equation 45, they derived a criterion for crazing that is written in terms of the principal stresses:

$$\sigma_1 - \nu\sigma_2 - \nu\sigma_3 = \frac{X}{\sigma_1 + \sigma_2 + \sigma_3} + Y \tag{47}$$

where $X = EX'$ and $Y = EY'$.

Using this criterion, Bowden and Oxborough could successfully fit the crazing data of Sternstein and Ongchin as well as their own data on four grades of polystyrene. Further, their data showed that the critical strain for crazing decreased with an increasing component of tensile hydrostatic stress and also decreased with increasing load time. Both the X and Y fitting parameters were shown to decrease with increasing temperature. The Y parameter also decreased with increasing load time, though the X parameter appeared to be relatively insensitive to loading time. Ultimately however, the X and Y parameters remain curve-fitting variables and offer little insight into the mechanisms or underlying structural parameters controlling craze initiation/growth.

Argon and Hannoosh (1977). The apparent time dependence for craze initiation after initial loading suggests the possibility that a thermally activated process may control initiation. Argon and co-workers (111,126,127) suggested a mechanism which considered that craze initiation occurs when a critical porosity is reached. The initial microscopic pores are formed when thermally activated micro-shear bands are blocked, the resulting local strain energy being sufficient to provide the surface energy for the formation of a microcrack. Allowing for additional free energy to form a stable pore, Argon and co-workers (111,126) derived

the following expression for the free energy required for pore formation:

$$\Delta G^*_{\text{pore}} = (0.15)^2 \pi (G/\tau)(\mu\phi^3) + \alpha L^3 \sigma_Y \tag{48}$$

where G is the shear modulus at the test temperature, τ the shear stress, φ a dimension related to the size of the sheared region (typically of the order of a molecular diameter), σ_Y the yield strength, L a length scale related to the spacing of molecular inhomogeneities, and α a factor of the order of 0.1. By considering the local stress field at an inclusion or groove and by taking the deviatoric stress, s, to be largest for a groove perpendicular to the maximum principal tensile stress, an expression was derived for the increase in the local porosity β as a function of time t, given by

$$\beta = \dot{\beta}_0 t \exp(-\Delta G^*_{\text{pore}}(s)/kT) \tag{49}$$

where $\dot{\beta}_0$ is a pre-factor characteristic of the vibrational frequency of the sheared region. Following these arguments, two criteria for the negative pressure p and the critical initial porosity β_i required for the expansion of the pores was determined (126):

$$p = \left(\frac{2\sigma_Y}{3}\right)\ln\left(\frac{1}{\beta}\right)Q \tag{50a}$$

$$\beta_i < \frac{1}{(1+2G/\sigma_Y)} \tag{50b}$$

where σ_Y is the yield stress, and Q a normalization factor. By further considering the negative pressure required to expand the porous region, an expression was derived for the initiation time, t_{in}, of craze nucleus formation (111):

$$t_{in} = \frac{1}{\dot{\beta}_0} \exp\left(\frac{\Delta G^*_{\text{pore}}}{kT} - \frac{\xi}{Q}\right) \tag{51}$$

where ξ is $(\sigma_1 + \sigma_2)/2\ \sigma_Y$, with σ_1 and σ_2 the principal stresses and σ_Y and Q are as before. The authors also recognized that while the craze may have initiated, it requires additional time for the craze to grow before it becomes visible (this is an inherent problem when discussing initiation times for crazes as it almost inevitably includes a period of craze growth for the crazes to be detectable). An estimate for the growth time, Δt_{growth} was derived based on a power law relationship between effective strain rate, $\dot{\varepsilon}_e$, and effective stress, σ_e:

$$\left(\frac{\dot{\varepsilon}_e}{\dot{\varepsilon}_{eo}}\right) = \left(\frac{\sigma_e}{\sigma_{e0}}\right)^m \tag{52}$$

where $\dot{\varepsilon}_e 0$, σ_{e0}, and m are temperature-dependent material constants.

Thus, the total time for craze nucleation is the sum of the time to initiation and the growth time to the point where the crazes are visible:

$$t_{\text{craze nucleation}} = t_{\text{in}} + \Delta t_{\text{growth}}$$

For small negative pressures, the growth time can be a significant proportion of the total time for nucleation. The model also predicts that under pure shear stress (an isovolume deformation), though considerable pore formation is present, no craze nucleation will occur because of the lack of a dilatational component of the stress. The authors went on to derive expressions to model the time dependence of the density of pore formation and subsequent craze saturation density (where the crazes have relieved the stress sufficiently that further craze nucleation is stopped) and expressions for biaxial craze nucleation. A set of such data from reference (111) is shown in Figure 18, where the surface density of crazes is plotted as a function of initiation time for polystyrene samples subjected to a combination of deviatoric stresses and negative pressures. The general features under each set of conditions are the same, with an increase in the craze density with time followed by saturation. It is also seen that the saturation density increases with increasing deviatoric stress and also with increasing negative pressure. The solid lines are the results from the model developed in reference (111). While the model captures the broad features of the material response, it should be noted that a number of parameters in the model cannot be easily determined from independent experiments. Consequently, a number of the parameters have been determined by optimizing the fit to experimental data such as that shown in Figure 18. These parameters, however, compare favorably with the expected ranges for such values. The reader is referred to the original paper for further discussions (111).

Kambour [1978]. Kambour, one of the pioneers in the area of crazing from as early as the mid-60's, has made significant contributions to the field and his thorough review article has already been mentioned (118). In 1978 Kambour and Gruner (128) reported a set of data for eight resins which showed a correlation between the critical strain for crazing in air, ε_c, and a combination of three factors, σ_y, the yield stress in tension, ΔT, the difference in the glass-transition temperature and the test temperature (T_g-T_{test}), and the solubility parameter (δ_p), [reported here in terms of the cohesive energy density, CED ($= \delta_p{}^2$)]:

$$e_c \propto \left[\frac{\text{CED} \cdot \Delta T}{\sigma_Y}\right] \tag{53}$$

In a follow-up paper in 1983 (129) it was shown that the correlation held for a further 29 polymers and copolymers, though in this case an additional correlation was used:

$$e_c \propto \left[\frac{\text{CED} \cdot \Delta T}{E}\right] \tag{54}$$

where E is the elastic modulus, and an implicit correlation between E and σ_Y is assumed. Figure 19 shows the data from the 1983 paper (129) and, while the correlations are shown to be satisfactory, the author acknowledges that the underlying

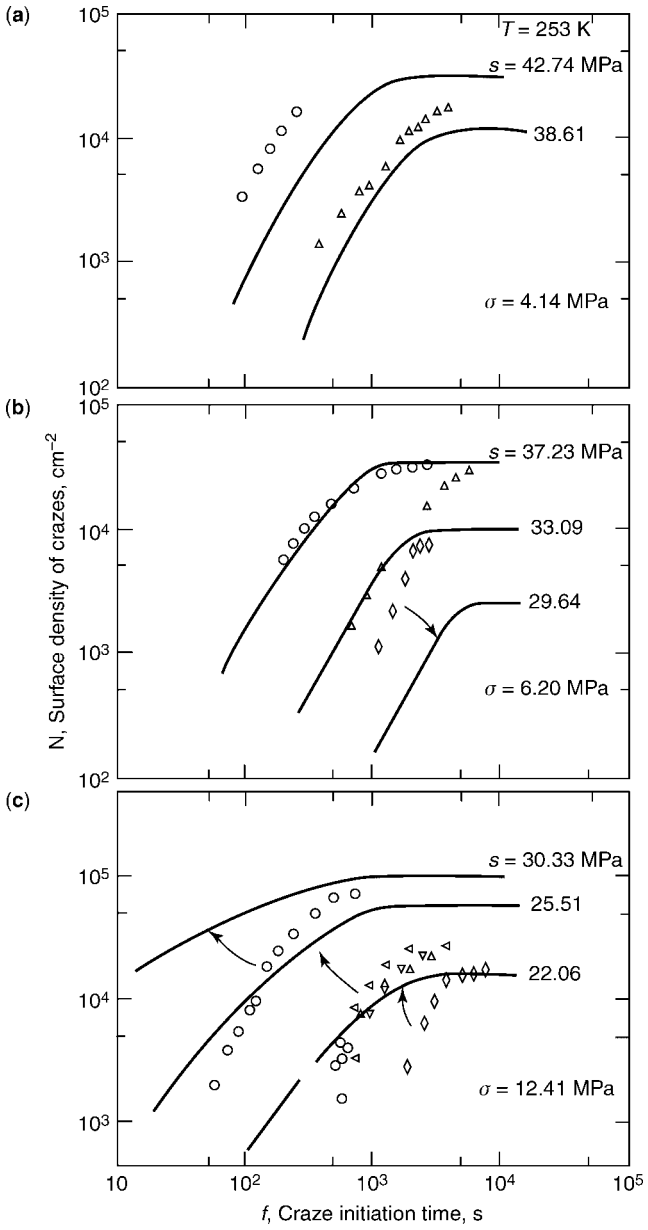

Fig. 18. Craze density as a function of initiation time for polystyrene subjected to a combination of deviatoric stresses (s) and negative pressures (σ). After Argon and Hannoosh (111), with permission of Taylor and Francis Ltd., http://www.tandf.cp.uk/journals.

source of the correlation is open to interpretation. [Note: In the 1983 paper (129), it appears that the abscissa labels have been inadvertently swapped between Figures 1 and 2, though the captions are correct. The abscissa has been corrected here.] Experimental craze growth studies as a function of temperature and aging

time are compared with the general predictions of this and two of the models discussed above (Sternstein et al and Argon et al) in Reference (130).

Craze Growth

After initiation the craze starts to grow. There are two aspects to consider when considering craze growth:

(1) Growth of the craze in the plane perpendicular to the load direction and in the direction of the craze tip (direction X in Fig. 16).
(2) Craze thickening, ie opening of the craze–bulk interfaces and extension of the fibrils in the Y direction (Fig. 16).

Craze Tip Advance. The earliest explanation for the advance of the craze tip was the continued nucleation of isolated voids ahead of the craze tip and their subsequent expansion (127).

However, experimentally it has been observed that craze growth occurs faster than craze initiation and so it is difficult to explain growth with such a model as it is essentially the same mechanism as initiation. Also, some of the features of the craze predicted from such a mechanism, such as a closed cell structure formed

from the formation of isolated voids, are inconsistent with experiments that clearly show that the craze has an open structure.

The currently accepted model for craze tip advance is that proposed by Argon and Salama (131) and based on the Taylor meniscus instability mechanism (132,133). This is the same phenomenon that is observed when two wetted plates are pulled apart and is shown schematically in Figure 20. In this scenario, the craze–bulk interface is treated as the solid boundary, and the plastically deformed, strain-softened matter at the craze tip is the liquid. As the boundary layers separate an instability is set up owing to a negative pressure gradient in the "fluid." Small fingers propagate into the craze tip at a characteristic spacing of λ_c. The fingers expand as shown in Figure 20, eventually joining up to leave isolated columns of polymer. It is possible to calculate the minimum spacing, λ_M, necessary for the

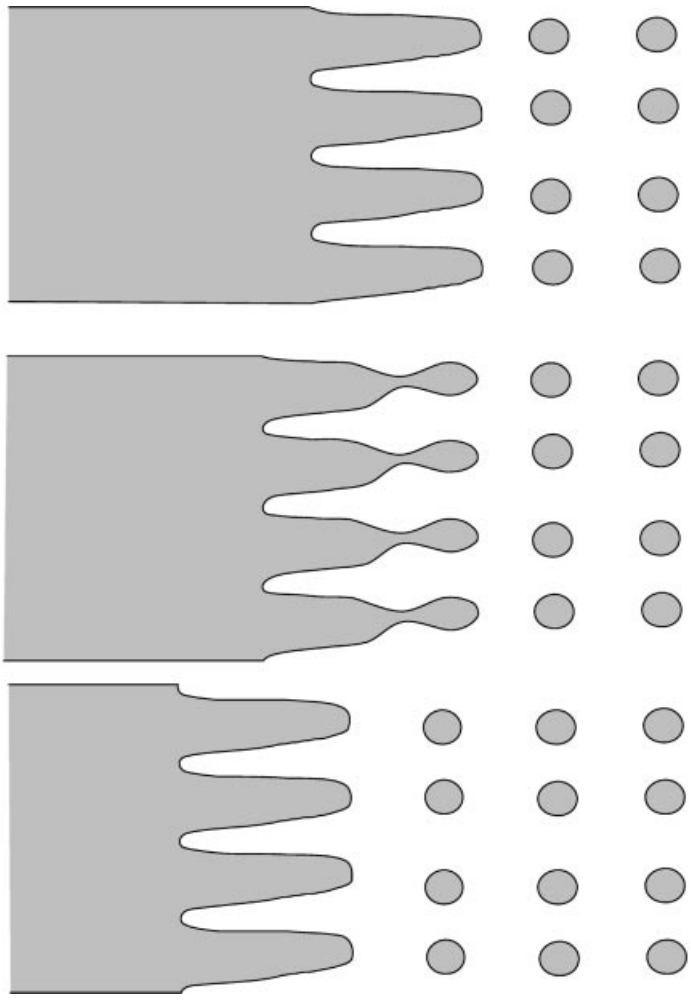

Fig. 20. Schematic for the Taylor meniscus instability mechanism for craze front advance. After Argon and Salama (131).

instability to grow (116):

$$\lambda_M = 2\pi\sqrt{\frac{\Gamma}{d\sigma_0/dx}} \tag{55}$$

where $d\sigma_0/dx$ is the hydrostatic stress gradient ahead of the craze and Γ is the surface energy. The fastest growing wavelength, λ_c, is given by (131,134)

$$\lambda_c = \sqrt{3}\lambda_M \tag{56}$$

Though a somewhat idealized picture of craze growth, the basic premise of the Taylor meniscus instability model has been verified by Donald and Kramer (135), who measured a critical wavelength in polystyrene crazes that was in close agreement with the interfibrillar distance. Further, following the procedure of Fields and Ashby (134) a steady-state craze tip velocity may be estimated by assuming a non-Newtonian fluid of the form

$$\left(\frac{\dot{\varepsilon}}{\dot{\varepsilon}_F}\right) = \left(\frac{\sigma}{\sigma_F}\right)^n \tag{57}$$

where $\dot{\varepsilon}_F$, σ_F, and n are material constants, leading to the expression for the tip velocity V_0:

$$V_0 = \frac{\sqrt{3}}{2}\frac{\dot{\varepsilon}_F h}{(n+2)}\left[\frac{\sqrt{3}h(\beta^* S_t)^2}{8\sigma_F\Gamma}\right]^n\left(1-\frac{2\Gamma}{\beta^* S_t h}\right)^{2n} \tag{58}$$

where h is the thickness of the craze at the crack front and $\beta^* S_t$ is the hydrostatic pressure between the void fingers.

The (relatively) simple form of equation 58 leading to a constant craze growth rate belies the complicated nature of craze growth in practice. While a linear growth in the craze length has been observed (136), equally a linear growth of the craze has been observed with logarithmic time (137–139). Undoubtedly the complicated, and possibly changing, nature of the stress field at the craze tip and even subtle differences in the morphology of the polymer can dramatically affect craze growth.

Craze Thickening. As indicated in Figure 16, two mechanisms exist for craze thickening:

(1) Drawing in of isotropic material from the bulk–craze interface
(2) Creep of the fibrillar material

Both processes can of course occur simultaneously, though it is generally accepted that it is the drawing in of fresh material that dominates the thickening of the craze in amorphous polymers. Evidence for this comes from a number of experiments aimed at examining either the volume fraction of craze material or the draw ratio of the fibrils as a function of position in the craze. If fibril creep

occurred to any significant extent, then the fibrils farther from the craze tip, which are naturally older and hence have been subjected to the interface stress for longer, would have a higher draw ratio. Evidence from crazes in PS (121) and poly-*tert*-butylstyrene (140) show an essentially constant draw ratio along the craze length, rising slightly at the craze tip owing to the locally high craze stresses present when they form (117)—this actually leads to a narrow band along the center line of the craze where the draw ratio is higher and volume fraction lower (127). Hence, the main mechanism of craze thickening is from material drawing in at the craze–fibril interface in a manner analogous with that of cold drawing under tensile loading. The material that is drawn in comes from what is termed the "active zone," a thin layer of material at the bulk–craze interface consisting of strain-softened material and which is typically of the order of a fibril diameter in size.

As noted, once the material has been drawn into the craze it appears to stabilize, and little, if any, further extension takes place. As with cold drawing, the fibrillar material is seen to take on a natural draw ratio, λ_N, the value of which is characteristic of the individual polymer. Kramer (116,141) found that the natural draw ratio correlated well with the maximum theoretical extension expected for an entangled network, λ_{max}:

$$\lambda_{max} = \frac{L_c}{k(M_e)^{1/2}} \text{ and } L_c = \frac{L_M M_e}{M_{m0}} \tag{59}$$

where M_e is the molecular weight between entanglements, L_M the monomer unit length, M_{m0} the monomer molecular weight, and k a constant. The molecular weight between entanglements, M_e, is a characteristic of any given polymer and can be determined experimentally from

$$M_e = \rho RT/G_N \tag{60}$$

where G_N is the measured rubbery plateau shear modulus, ρ the density, T the temperature, and R the gas constant. It is interesting to note that in polymers with a molecular weight less than approximately half the entanglement molecular weight, stable crazes are not seen to form and it seems then that entanglements are a necessary feature for stabilizing the craze–fibril structure.

During the surface drawing process in the active zone, it is inevitable that material that is destined to go into two neighboring fibrils can share a common molecule. Thus, as the fibrils form, the molecule must either disentangle such that the molecule flows into only one fibril or the chain must break. As we noted above, entanglements appear to be necessary for the formation of stable fibrils and, if the molecule is unable to disentangle, then it is inevitable that chain scission must occur during craze growth. On this basis Kramer (116,117) suggests that the energy required to create new surface (Γ) is given by the standard surface energy plus a component due to the energy required for chain scission:

$$\Gamma = \gamma + \frac{Uvd}{4} \tag{61}$$

where γ is the Van der Waals surface energy, U the polymer backbone bond energy, v the network strand density, and d is the root mean square end-to-end distance between entanglements. Kramer also estimated the force required to break a molecule, f_b, given approximately by

$$f_b = \frac{U}{2a} \tag{62}$$

where a is the bond length. If, during the fibril formation, the force should rise above this level breakage will obviously occur. If the force remains below this level then fibril formation can proceed via disentanglement.

Disentanglement of the polymer chains is generally accepted to occur by the mechanism of reptation as proposed by Doi and Edwards (142) and by deGennes (143). In this model, the movement of the chain is taken to be confined to a tube, the confinement coming from neighboring chains. The molecule moves through this tube in a snake-like motion by a series of cooperative steps. McLeish (144) has introduced the concept of "forced reptation" with regards to craze formation. Here, one end of the molecule is locked into a formed fibril and as material continues to be drawn in to the fibril, the molecule is pulled through its confining tube at a velocity v_f. From such considerations they determined that the maximum force acting on the molecule, f_d, is given by

$$f_d = v_f \xi \frac{M}{M_0} \tag{63}$$

where ξ is a monomeric friction coefficient, M the molecular weight, and M_0 the monomer molecular weight. Thus, if $f_d < f_b$ disentanglement will occur in preference to chain scission. It is worth noting also that if we assume that the velocity of the chain through the confining tube, v_f, is proportional to the applied strain rate and further that the monomeric friction coefficient is a thermally activated process (proportional to $e^{(1/T)}$) then equation 63 indicates that disentanglement is favored by low molecular weights, low strain rates, and high temperatures. However, while this approach correctly accounts for the dependence of craze growth on these parameters, in practice the majority of polymers are of a sufficiently high molecular weight (and hence chain length) that a single molecule will cross between the prefibril regions several times. Again, following the argument of McLeish this results in the polymer chain being pinned at several points along its length in what has been described as a 'block and tackle' arrangement (Fig. 21). This has the effect of increasing the velocity the chain must move at through the confining tube for a given macroscopic strain rate. On the basis of these concepts, Kramer (117) derived an expression for the maximum force on the chain (at its center) of

$$f_{max} = \xi v_f \frac{M^2}{16 M_0 M_e} \tag{64}$$

where M_e is the average molecular weight between the entanglements. It is seen then that the maximum force on the chain is proportional to the square of the

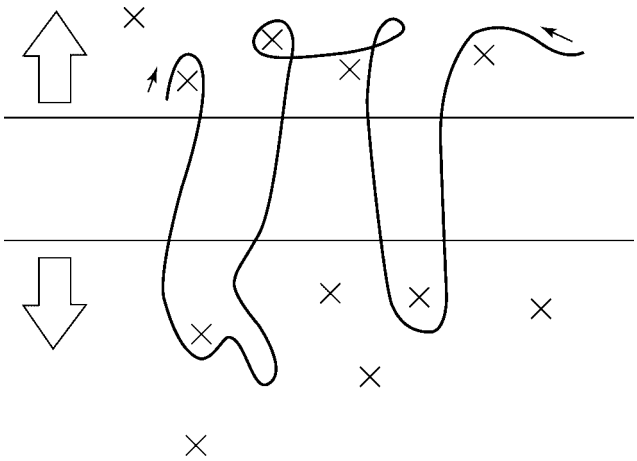

Fig. 21. Block-and-tackle arrangement for disentanglement at the craze boundary as proposed by McLeish and co-workers. Reprinted from Ref. 142 and 144, with permission from Elsevier.

molecular weight. During the formation of the fibril the chain is assumed to break randomly along its length, thereby reducing M, until the maximum force in the chain falls below the level required for scission. The concept of entangled molecules and the competition between chain scission and disentanglement is important not only for the growth kinetics but also, as we will see in the following section, for the ultimate failure of the fibrils/craze.

Craze Failure

Craze breakdown is obviously of fundamental importance since it is the mechanism by which the crack grows and so leads ultimately to failure. However, the mechanism of craze failure is still unclear. The two main mechanisms that have been proposed are

(1) Failure in the fibril, or
(2) Failure at the active zone

It is likely that both occur depending on the conditions and morphology of the material. The first step in considering the likelihood of fibril failure is to look at the stress levels within the fibril. Because of the reduced cross-sectional area in the craze region, the true stress on the fibrils (σ_{CT}) can be considerably higher than the stress at the craze boundary (σ_{CR}) by a factor given by the draw ratio of the fibril (λ):

$$\sigma_{CT} = \lambda \sigma_{CR} \tag{65}$$

λ is typically of the order of 2 to 4 for amorphous polymers and as noted above can be somewhat higher at the midrib of the fibril. Though at these stresses the creep contribution to the fibril length is minor, any small inhomogeneities in the local structure can lead to localized creep. Further, as discussed above, the material which forms the fibril has passed through the active zone at the craze–bulk boundary and has undergone chain scission. This results in the fibrillar material having a lower molecular weight and a reduced entanglement density. These conditions can then lead to chain disentanglement by essentially plastic flow. Such a mechanism can be facilitated by the small diameter of the fibrils leading to a reduction in the constraints that a polymer chain might otherwise see in the bulk. However, if fibril failure were the dominant mechanism in the breakdown of the craze, then it would be reasonable to expect failure to occur at the fibril midpoint where the fibril is oldest and has been subjected to the highest stresses for the longest length of time. While this has indeed been observed (145,146), it is more generally seen that the point of failure is at the craze–bulk interface, ie at the active zone. This in turn would imply that, for the majority of polymers, the reduction in entanglement density on traversing the active zone during fibril formation is not sufficient to destabilize the fibril.

We saw above that the material that flows into the active zone, and which may go on to form fibrils, has to undergo a degree of disentanglement or chain scission. This results in the material within the active zone having a lower entanglement density than the bulk material. Further the material in the active zone is in a strain-softened state, characterized by more liquid-like dynamics. If the entanglement density is low enough and the polymer strands dwell within the active zone for a sufficiently long period of time then the strands may fully disentangle. The material then loses its load-bearing capacity, and that particular fibril element will fail. In practice, because polymers generally have a broad distribution of molecular weights, there is a chance that the material destined to form a fibril will consist of relatively short chains with a low entanglement density. Thus, the likelihood of a given fibril failing is ultimately governed by a statistical distribution (note that, although not included in this analysis, the presence of inhomogeneities, inclusions, flaws etc can also lead to a breakdown in the active zone owing to a decreased load-bearing capacity). Kramer and Berger (117) developed such a statistical model and the reader is referred to the original paper for the full mathematical development. In brief, they based their calculations on the number of effectively entangled strands, n_e, that survive during the formation of the active zone, ie those which do not undergo chain scission. From this they formulated an expression for the probability that a given fibril would fail, P_F, given by the product of the probability that a strand survives fibril formation, $P_{survive}$, and the probability that it then disentangles, P_{dis}, summed over the total number of chains which go into fibril formation. The probability of a chain i surviving, $P_{survive}(i)$, is given by a normal distribution:

$$P_{survive}(i) = \frac{1}{\sqrt{2\pi n_e(1-q)}} \exp\left(\frac{(i-n_e)^2}{2(1-q)n_e}\right) \tag{66}$$

and where q is the fraction of originally entangled strands which do not undergo chain scission. The probability of disentanglement P_{dis} is given by

$$P_{\mathrm{dis}}(\mathrm{i}) \approx \exp\left(\frac{-t_{\mathrm{dis}}(\mathrm{i})}{\tau_{\mathrm{res}}}\right) \tag{67}$$

τ_{res} is a measure of the time the strand spends within the active zone and t_{dis} is the time for disentanglement, and is a function of strand molecular weight, the molecular weight between entanglements, the force on the strand, and the monomeric friction coefficient. Though the τ_{res} term is a fitting parameter, the model captures many of the features observed with craze stability such as the molecular weight dependence (117).

Other Considerations for Crazing

The preceding sections only touch upon the main characteristics of crazing and many of the additional factors that go into determining the initiation, growth, and failure of the craze have been omitted. Without elaboration, we mention several such factors and refer the reader to the relevant references.

The structure of the craze as discussed above has been idealized as a uniform array of isolated fibrils bridging the boundaries of the craze. In reality it is found that the main fibrils are connected to their neighbors by small "cross-tie" fibrils (117,147). The formation of these cross-tie fibrils has been modeled by Tijssens and van der Giessen (148), interestingly using many of the concepts presented in the section on yield. The presence of such cross-tie fibrils gives the craze some tangential load-bearing capacity, and a modeling of such a structure shows that their presence can lead to an increase in the stress on the main fibril, at times sufficient to cause failure of the polymer backbone (149,150).

A common, and potentially serious, drawback of polymers is their susceptibility to environmental factors, causing a greater likelihood to form crazes. Indeed, it has been estimated that environmental-stress cracking is responsible for as much as 30% of failures in engineering polymers in service (151). Environmental stress cracking (ESC), as the phenomenon is known, occurs predominately (though not exclusively) in amorphous polymers in contact with organic solvents. The other prerequisite for ESC is the presence of a stress since ESC is a result of the *physical* interaction of the polymer and solvent and is not due to a *chemical* interaction (ie no chemical degradation occurs).

One view of how the ESC agents act on the polymer is that they can diffuse into the polymer and cause it to swell. This in turn will increase the polymer chain mobility and so cause an effective decrease in the local T_{g}, leading to an increase in the propensity to craze ie crazing occurs at lower stresses or strain. An alternative view is that the liquid can wet the surface, reducing the energy required to create new surfaces and so aiding the formation of voids. This latter effect may be important in the early stages of craze initiation. The reviews by Kambour (118), Volynskii (152), Wright (153) and the work of, for example, Arnold (154–156) cover this area in detail and are briefly discussed in the chapter Fracture (qv) in this encyclopedia.

Just as crazing tends to be a precursor to failure under static loading, it is also seen to develop under cyclic loading conditions. The area of cyclic or fatigue failure of polymers has been extensively investigated, with much of the early work carried out by Hertzberg and co-workers (157–160) and Döll and co-workers (161–163). The reader is referred to the chapter Fatigue (qv) in this encyclopedia for a detailed review.

FLAMMABILITY

Introduction

Plastics (polymers) are a large and growing fraction of the fire load in homes, commercial environments, and transportation (1–5). Moreover, the plastics that are most widely used are those that are least expensive and these tend to be the most flammable. *Flammability*, which generally refers to the propensity of a substance to ignite easily and burn rapidly with a flame, is one indicator of fire hazard. Figure 1 shows the relationship between two measures of flammability—heat release capacity (see under Heat Release Rate) and flame resistance (see under Testing for Regulatory Compliance) versus the truckload price of commercial polymers. Flammability and cost span over 2 orders of magnitude but the commodity polymers costing less than about $1/pound comprise over 95% of the polymers in use and these will continue to burn after brief exposure to a small flame. Engineering and specialty plastics costing over $2/pound are typically polymers with aromatic backbones and fluoropolymers, and these will self-extinguish or resist ignition because of high thermal stability or low fuel value. Figure 1 shows that the flame resistance of polymers does not always correlate with cost but does correlate reasonably well with heat release capacity.

Regulations (1–5) governing the flammability of plastics (eg, see section Testing for Regulatory Compliance) used in consumer electronics, electrical equipment, building and construction, home furnishings, automobiles, and public transportation have created an annual worldwide market of tens of billions of pounds for flame-retardant plastics (1). The designation flame retardant, flame resistant, or ignition resistant as it applies to these plastics typically refers to the tendency of a thin (2–3 mm) strip of the material to withstand a brief exposure to a Bunsen burner flame or a hot wire without continuing to burn. Flame or ignition resistance is a low level of fire safety that is intrinsic to heat-resistant polymers but can be achieved with commodity polymers by adding flame-retardant chemicals (1–4). The economic incentive to add flame retardants to commodity polymers in order to pass flammability requirements (ie, the slope in Fig. 1) has focused polymer flammability research over the past few decades on the mechanisms and efficacy of flame-retardant additives (6–10), rather than on polymer flammability as an intrinsic material property. This trend in research combined with the fact that flaming combustion of solids is a highly coupled, multiphase process, and that fire test results depend on the apparatus, test conditions, and sample geometry, has limited the understanding of polymer flammability to a descriptive/qualitative nature.

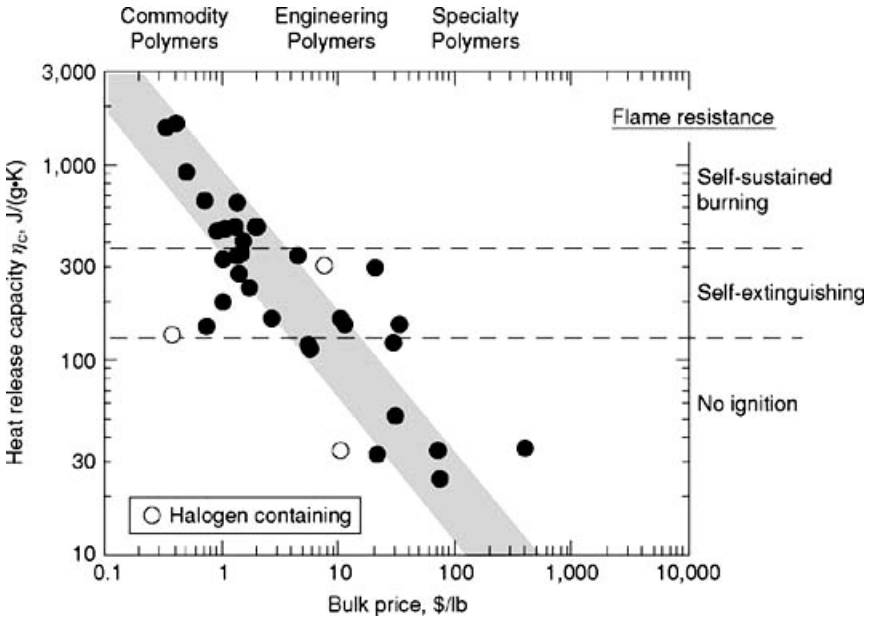

Fig. 1. Heat release capacity, cost, and flame resistance of commercial polymers.

In this article simplifying assumptions are made about the burning processes under well-defined (standardized) conditions in order to provide mathematical relationships between polymer chemical structure and flammability properties. Experimental data are used in lieu of, and in support of, analytic results drawn from the broad subject material that is referenced in the bibliography. The goal of this article is to provide a consistent, mechanistic interpretation of the burning process as it relates to synthetic polymers and to describe currently accepted test methods to quantify burning behavior.

The Burning Process

Gases and volatile liquids are small molecules that are held together by weak (<1 kJ/kg) secondary chemical bonds. These volatile compounds spontaneously form combustible mixtures with air that ignite easily and burn with a high velocity. Polymers are very large (macro) molecules with the same intermolecular and intramolecular forces as low molecular weight compounds, but their boiling temperature is essentially infinite because of their high molecular weight. Consequently, both intermolecular and intramolecular (backbone) chemical bonds of polymers must be broken to generate volatile fuel species, and this process requires a large (≈2 MJ/kg) and continuous supply of thermal energy for ignition and sustained burning.

Flaming combustion can be roughly divided into physical and chemical processes taking place in each of three separate phases: gas, mesophase, and condensed (liquid/solid) phase (6,7,10–16). The *mesophase* is the interface between

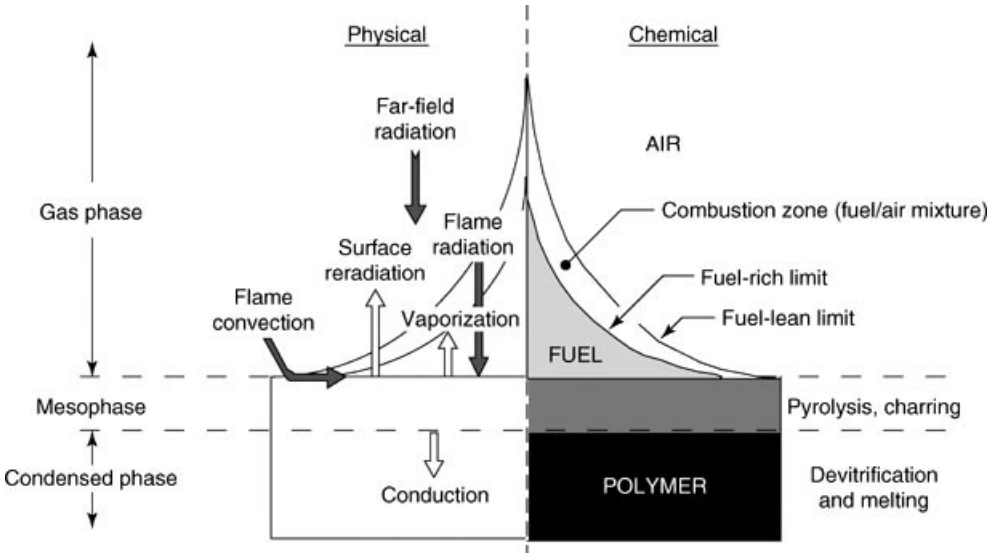

Fig. 2. Physical and chemical processes in the flaming combustion of polymers.

the gas and condensed phase during burning. Figure 2 is a schematic diagram of a horizontal polymer slab that is burning with a diffusion flame. Physical processes are shown on the left-hand side of Figure 2, and these include energy transport by radiation and convection between the gas phase (flame) and the mesophase; energy loss from the mesophase by mass transfer (vaporization of the pyrolysis gases); and conduction into the solid. At typical burning rates the polymer surface (mesophase) recedes at a velocity of about 10^{-6} m/s. Conservation of momentum at the gas–mesophase boundary shows that fuel gases evolve at a relatively low velocity ($\approx 10^{-3}$ m/s) compared to the burning velocity of these gases when mixed with air (≈ 1 m/s). Consequently, fuel generation is the rate-limiting step in polymer flaming combustion and it is governed primarily by the rate at which heat and mass are transported to and from the polymer, respectively.

The important chemical processes are shown on the right-hand side of Figure 2, and these are thermal degradation of the polymer in a thin surface layer (the mesophase) as a consequence of the physical (energy transport) processes; mixing of the volatile pyrolysis products with air by diffusion; and combustion of the fuel/air mixture in a combustion zone that produces radiant energy over a spectrum of wavelengths including visible. The combustion zone is bounded by a fuel-rich region on the inside and fuel-lean region on the outside. Increasing the concentration of oxygen in the environment is known to increase the flame heat flux, because of either a higher flame temperature, an increase in the volume of the combustion zone, or an increase in the soot concentration (luminosity) of the flame. The chemical and physical processes of flaming combustion particular to each of the gas, meso, and solid phase are treated separately below.

The Gas Phase.

Kinetics. Condensed phases (solids and liquids) of combustible compounds will only burn if they can be made to generate volatile fuel/air mixture, and so the

phenomena that lead to ignition and the release of heat are those of the gas phase (11–19). Although there are hundreds or thousands of chemical reactions going on in the flame that convert oxygen and fuel to stable combustion products, kinetic modeling and experimental data have shown that the burning velocity is most sensitive to the following reactions involving active radicals of fuel (R), hydroxyl (OH), hydrogen (H), and oxygen (O), and halogen or phosphorus (X):

$$\begin{aligned}
&\text{Initiation:} && \mathrm{RH} \xrightarrow{k_1} \mathrm{R^{\cdot}} + \mathrm{^{\cdot}H} \\
&\text{Branching:} && \mathrm{^{\cdot}H} + \mathrm{O_2} \xrightarrow{k_2} \mathrm{^{\cdot}OH} + \mathrm{^{\cdot}O} \\
&\text{Propagation (and primary heat producing reaction):} && \mathrm{^{\cdot}OH} + \mathrm{CO} \xrightarrow{k_3} \mathrm{CO_2} + \mathrm{^{\cdot}H} \\
&\text{Propagation:} && \mathrm{^{\cdot}OH} + \mathrm{H_2} \xrightarrow{k_4} \mathrm{H_2O} + \mathrm{^{\cdot}H} \\
&\text{Termination:} && \mathrm{^{\cdot}H} + \mathrm{O_2} \xrightarrow{k_5} \mathrm{^{\cdot}HO_2} \\
&\text{Inhibition:} && \mathrm{^{\cdot}H} + \mathrm{HX} \xrightarrow{k_6} \mathrm{H_2} + \mathrm{^{\cdot}X} \\
&\text{Inhibition:} && \mathrm{^{\cdot}OH} + \mathrm{HX} \xrightarrow{k_7} \mathrm{H_2O} + \mathrm{^{\cdot}X}
\end{aligned} \tag{1}$$

The set of seven radical reactions in equation 1 accounts for the key processes of initiation, branching, propagation, and termination typical of hydrocarbon fuels as well as the inhibition reactions that are important for polymers containing halogen or phosphorus in a low oxidation state. Because the concentrations of radicals are empirically related as $[\mathrm{H}] \approx [\mathrm{OH}] \approx 2[\mathrm{O}]$, the set of equations can be solved for the total concentration of active radicals, $[\mathrm{n}] = [\mathrm{H}] + [\mathrm{O}] + [\mathrm{OH}]$. Defining a rate of chain initiation, $\theta = k_1[\mathrm{RH}]$, a branching coefficient $f = (2/5)k_2[\mathrm{O_2}]$, and a linear termination coefficient $g = (2/5)\{k_5[\mathrm{O_2}] + (k_6+k_7)[\mathrm{HX}]\}$, the rate of change of radical concentration at time t is

$$\frac{\mathrm{d}[n]}{\mathrm{d}t} = \theta + f[\mathrm{n}] - g[\mathrm{n}] \tag{2}$$

The general solution of equation 2 for the total radical concentration at any time is

$$[\mathrm{n}] = \frac{\theta}{g-f}\{1 - e^{-(g-f)t}\} \tag{3}$$

Figure 3 is a schematic plot of equation 3 for three special cases:

(1) $f > g$: In this case the branching reactions dominate and the radical concentration increases exponentially as $[\mathrm{n}] = \{\theta \exp((f-g)t) - 1\}/(f-g)$, until the reactants are depleted.

(2) $g = f$: In this case the radical concentration increases steadily with time as $[\mathrm{n}] = \theta t$. It is the boundary between steady state and exponential growth.

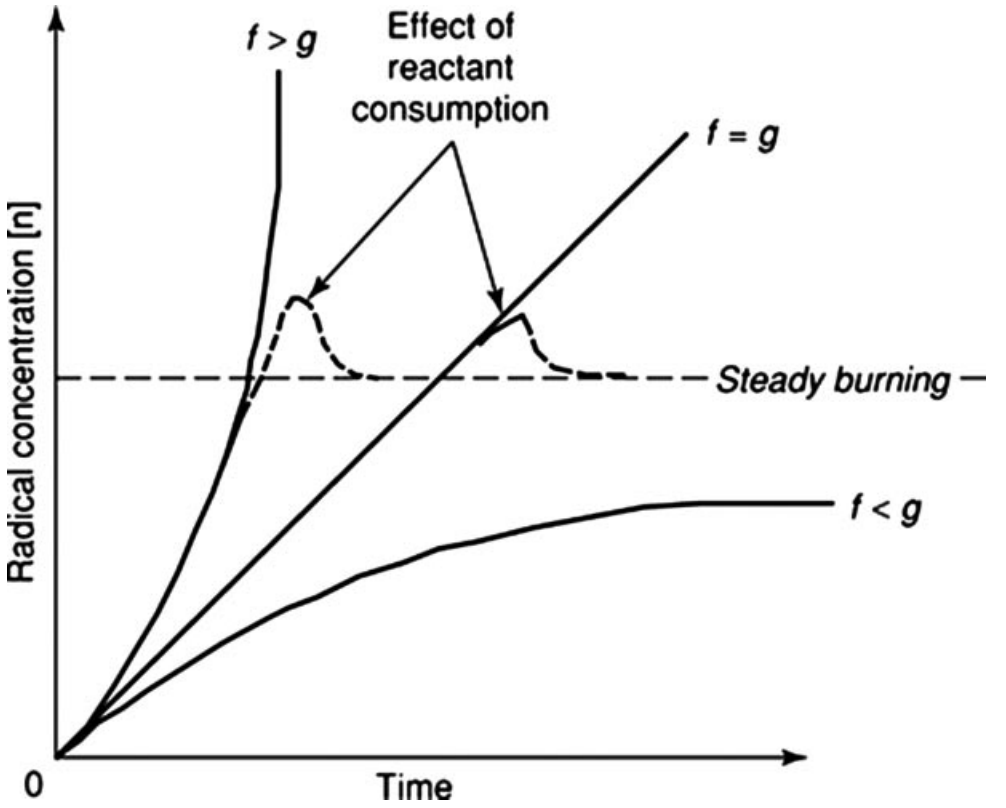

Fig. 3. Gas phase kinetics: accelerating ($f > g$), steady growth ($f = g$), and steady state ($f > g$) radical concentration histories at ignition.

(3) $g > f$: In this case the rate of chain termination is greater than branching and a steady-state concentration is reached at $[n] = \theta/(g - f)$. This steady state may be above or below the concentration for flame propagation.

The molar inhibition efficiency of the halogen atoms X = bromine (Br), chlorine (Cl), and fluorine (F) is found to be in the ratio Br/Cl/F = 10/2/1; ie, bromine is 10 times more efficient than fluorine and 5 times more efficient than chlorine on a mole basis. On a mass basis the inhibitor efficiency is Br/Cl/F = 2/1/1, which explains the widespread use of bromine-containing monomers and additives as flame retardants (4–10).

Thermochemistry. If the kinetics are such that the combustion reactions proceed to completion at a rate that sustains flaming combustion, the chemical reaction of a generic fuel with atmospheric oxygen yields carbon dioxide (CO_2), water (H_2O), nitrogen (N_2), and mineral acid (HX) in quantitative yield:

$$C_cH_hO_mN_nX_x + \left(c + \frac{h - x - 2m}{4}\right)O_2 \rightarrow c\ CO_2 + \frac{h - x}{2}H_2O + \frac{n}{2}\ N_2 + x\ HX \qquad (4)$$

Equation 4 assumes complete, 100% efficient, conversion of reactants (fuel gases, O_2) to products (CO_2, H_2O). Flaming combustion efficiency rarely exceeds 99% and typically ranges from 50 to 95%. Smoke is a combination of complete (CO_2, H_2O, acid gases) and incomplete (soot, carbon monoxide, partially oxidized fuel gases) combustion products that occurs when combustion inhibitors are present, oxygen concentration is low, or there is insufficient reaction time or temperature in the combustion zone. The composition of smoke is highly dependent on the chemical composition of the polymer and the ventilation conditions under which the polymer is burning. Acid gases are irritating to eyes and nasal passages which makes escape more difficult. Carbon monoxide is the primary toxic compound in smoke. Soot absorbs light which limits visibility and increases the luminosity or radiant power of the fire. Smoke is considered to be the main fire hazard but it depends on ventilation and the burning rate of the polymer, and so it is the latter quantity, ie, the burning or heat release rate, that is considered to be the primary indicator of fire hazard (4,11,12,20,21).

The chemical pathway to soot formation is recombination of aromatic radical fragments in the fuel-rich region inside the flame (see Fig. 2). Minute polycyclic aromatic hydrocarbon particles are formed that are 10–100 nm in diameter, and these elementary soot particles may oxidize in the combustion zone of the flame. However, the elementary soot particles will agglomerate and grow in size until they are large enough to interact with visible light (0.3–0.7 μm), ultimately reaching sizes of the order of a micron that absorb infrared radiation. Smoke is a combination of these soot particles in an aerosol with unburned liquid hydrocarbons, carbon dioxide/monoxide, water, and halogen acid gases, if present in the burning polymer (11–13).

Energetics. Regardless of the gas phase combustion kinetics and thermochemistry, burning will only be possible if the energy balance is favorable. The first law of thermodynamics for a constant pressure gas phase process in which all of the work is pressure–volume (P–V) work states that the internal energy change dU is related to the change in heat content dQ:

$$dU + P\,dV = dQ \tag{5}$$

If the volatile fuel and air are well-mixed and react to generate a power density $\dot{Q}'''$ (heat of combustion per unit volume per unit time, W/m^3), a portion of which accumulates in the reaction volume as a rise in the temperature of the fuel/air mixture and a portion of which is lost to the surroundings at ambient temperature T_a by convection and radiation, the first law energy balance for the fuel/air mixture during deflagration (burning) is

$$\rho c \frac{dT}{dt} + P\frac{dV}{V} = \dot{Q}''' - \frac{\bar{h}S}{V}(T - T_a) - \frac{\varepsilon\sigma S}{V}\left(T^4 - T_a^4\right) \tag{6}$$

where ρ, c, V, and T are the instantaneous density, heat capacity, volume, and temperature of the fuel/combustion products/air mixture, $\bar{h}$ is the average heat transfer coefficient at the boundary between the combustible mixture and the environment having surface area S at temperature T and pressure P. In equation 6, ε is the gas emissivity and σ is the Stefan–Boltzmann constant. Defining quantities

$\theta = T - T_a$ and $\tau = \rho c V/\overline{h}S$ and assuming a constant fraction ϕ of the power density is lost by radiation to the surroundings,

$$\frac{S}{V}\varepsilon\sigma\left(T^4 - T_a^4\right) \approx \phi\dot{Q}''' \tag{7}$$

Substituting equation 7 into equation 6, rearranging and separating variables

$$\frac{d\theta}{dt} - \frac{\theta}{\tau} = \frac{1}{\rho c}\{\dot{Q}'''(1-\phi) - P\,d\ln V\} \tag{8}$$

where $\dot{Q}'''$, ρ, and c are initial values for the mixture. If deflagration (burning) raises the temperature from T_a to T_f with a corresponding increase in volume from V_a to V_f at constant pressure over a short time interval (0, t_f) with $t_f \ll \tau$, and heat is transferred by radiation only, equation 8 becomes

$$T_f - T_a \approx \frac{1}{\rho c}\left\{Q'''(1-\phi) - P\ln\left(\frac{V_f}{V_a}\right)\right\} \tag{9}$$

where $Q''' = t_f\dot{Q}'''$ (J/m^3) is the energy density at ignition. If the moles of reactants (fuel and air) and combustion products (CO_2 and H_2O, principally) are equal and behave as ideal gases and T_f is the (quasi) adiabatic flame temperature, then

$$Q''' = \frac{\rho c(T_f - T_a) + P\ln(T_f/T_a)}{1-\phi} \tag{10}$$

The *lower flammability limit* (LFL), is the minimum volume (or mole) fraction of fuel in a fuel/air mixture that sustains ignition (11,12,18). The LFL has been measured for hundreds of gaseous and liquid hydrocarbon fuels including fuels that contain oxygen, nitrogen, sulfur, boron, phosphorus, and halogen (11). The average value of Q''' for 236 combustible compounds is

$$Q''' = \rho_f h_c^0 \mathrm{LFL} = 1864 \pm 278 \text{ kJ/m}^3 \tag{11}$$

where ρ_f and $h_c{}^0$ are the vapor density and heat of complete combustion of the fuel, respectively. If burning occurs at the lower flammability limit of the fuel, then equations 10 and 11 are equal and

$$\frac{\rho c(T_f - T_a) + P\ln(T_f/T_a)}{1-\phi} = 1.9 \text{ MJ/m}^3 \tag{12}$$

Equation 12 can be solved for the quasi-adiabatic flame temperature at standard temperature and pressure (STP). For $\phi < 0.2$, the flame temperatures calculated using equation 12 are in the range $T_f = 1720$–1420 K, compared to experimental values $T_f = 1600 \pm 100$ K (11,12). Equation 12 shows that the lower flammability limit corresponds to a temperature $T_f \approx 1600$ K at which the rate of heat losses from the flame equal the rate of heat production in the flame owing to the combustion reactions.

The Mesophase. The mesophase is the interface between the gas and condensed phases during burning. All of the thermal degradation chemistry that results in volatile fuel generation occurs in the mesophase (also known as the pyrolysis zone). A qualitative diagram of the mesophase properties is shown in Figure 4. The temperature distribution at the burning surface is primarily a consequence of the prevailing energy balance but the viscosity, density, and physical dimension of the mesophase shown qualitatively in Figure 4 is determined by the temperature field and thermal degradation chemistry. For polymers that thermally

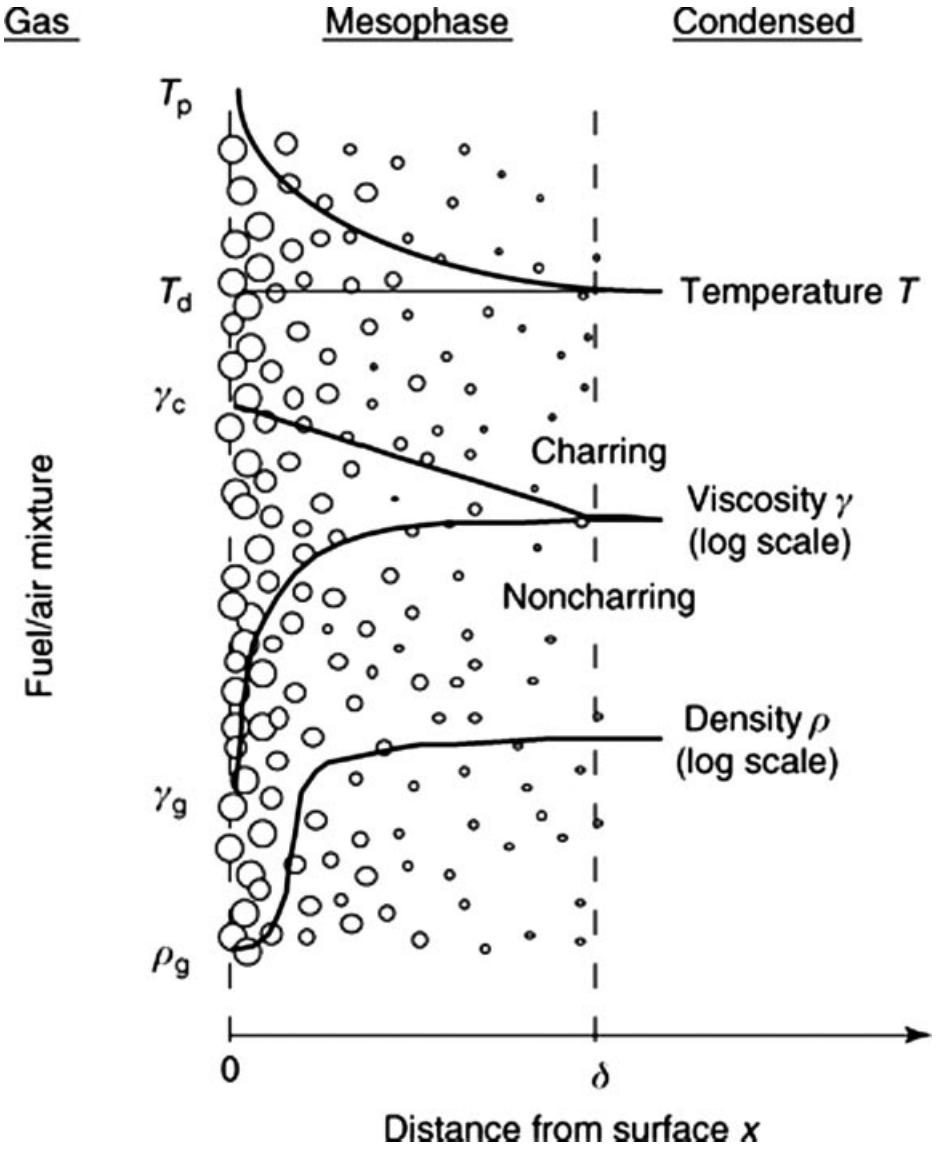

Fig. 4. Mesophase profiles of temperature, viscosity, and density during flaming combustion.

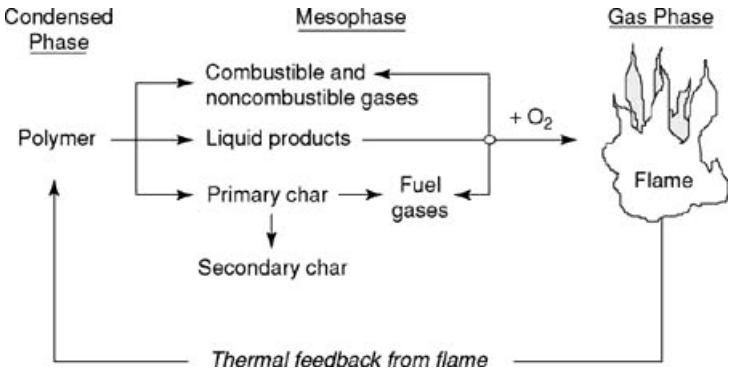

Fig. 5. Phenomenology of polymer burning.

degrade with the formation of a solid char the viscosity of the mesophase is higher than that of the molten polymer and probably comparable to that of the solid polymer. The mesophase is composed of thermal degradation products in a variety of phases including gas, liquid, and solid as indicated schematically in Figure 4 by the bubble density and in Figure 5 by a generic product distribution.

Figure 5 shows the phenomenology of polymer burning and illustrates the coupled nature of the flaming combustion of condensed phases. The sequence of events for self-sustained burning involves the application of heat sufficient to thermally degrade (pyrolyze) the solid polymer to low molecular weight volatile fuel species and possibly a nonvolatile/solid char depending on the polymer chemical structure. Mixing of the volatile thermal degradation products with atmospheric oxygen and ignition of this fuel/air mixture results in flaming combustion. Flaming combustion produces thermal energy in proportion to the heat of combustion of the volatile thermal degradation products and at a rate that is controlled by the fuel generation rate. The majority of the combustion energy from the flame is lost to the environment but a fraction is returned to the polymer surface by convection and radiation (see Fig. 2). If the feedback of thermal energy from the flame at the polymer surface is sufficient to generate fuel vapors, flaming combustion will continue after the ignition source is removed and burning will be self-sustained.

Kinetics. In Figure 5 the first stage of thermal degradation produces primary volatiles (gas and liquid products/tar) and possibly a primary char residue (see under Char Yield). If a primary char forms, further decomposition generates a secondary gas (principally hydrogen) and a thermally stable carbonaceous char. Figure 6 shows thermogravimetric data at a heating rate of 10 K/min for anaerobic pyrolysis of polybenzimidazole (2,2′-*m*-phenylene-5,5′-bibenzimidazole, PBI). Polybenzimidazole is a heat-resistant, char-forming polymer that thermally degrades by primary and secondary decomposition events as evidenced by distinct mass loss rate peaks for these processes. Models have been proposed that account for some or all of the pyrolysis products (gas, tar, primary char secondary char, secondary gas) as various combinations of sequential or simultaneous thermal degradation reactions. However, a detailed mechanism for the thermal degradation of most polymers, especially char-forming polymers, is unlikely and unnecessary for a phenomenological treatment of fuel generation chemistry.

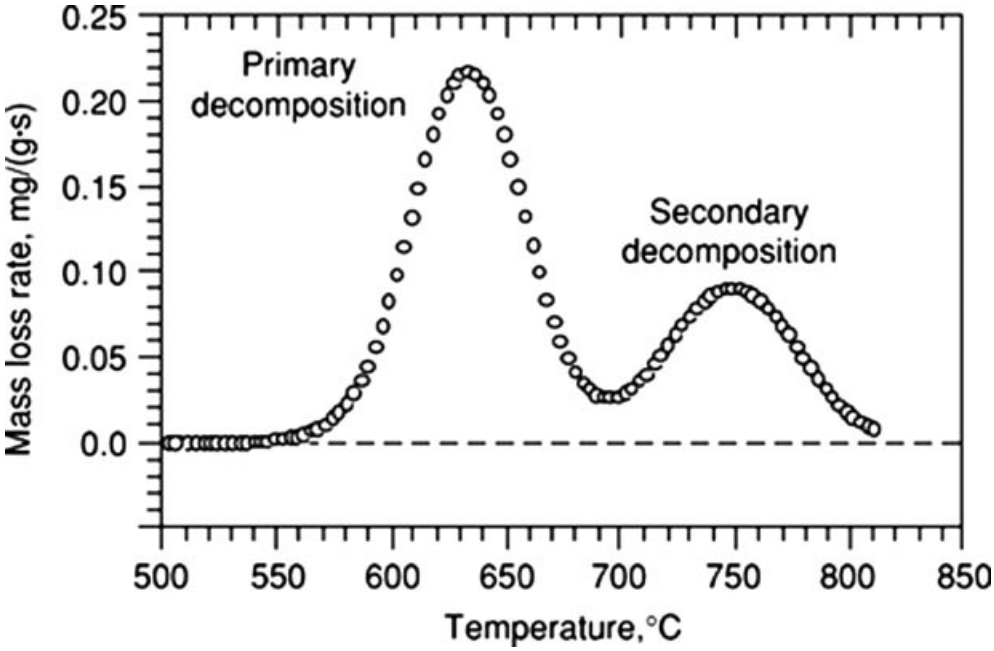

Fig. 6. Fractional mass loss rate versus temperature for polybenzimidazole in TGA ($\beta =$ 10 K/min).

Mechanistic reaction kinetics of polymer thermal degradation processes show that the overall mass loss (fuel generation) rate should be first order with respect to the instantaneous mass if the reactive intermediates (free radicals) maintain a steady-state concentration, regardless of whether thermal degradation occurs by random or end-chain scission. A first-order thermal degradation scheme that accounts for the main pyrolysis products is (4,7,10)

$$\text{Polymer (P)} \xrightarrow{k_d} \text{Intermediate (I*)} \tag{13}$$

$$\text{I*} \xrightarrow{k_g} \text{Gas (G)} \tag{14}$$

$$\text{I*} \xrightarrow{k_c} \text{Char (C)} \tag{15}$$

Equations 13–15 are a subset of the reactions shown in Figure 5 but they are sufficient to represent the mesophase fuel generation kinetics. In particular, polymer P thermally degrades to a reactive intermediate I^* with rate constant k_d. The intermediate produces gas G and/or char C, with rate constants k_g and k_c, respectively. Figure 7 shows data for a variety of pure, unfilled polymers plotted

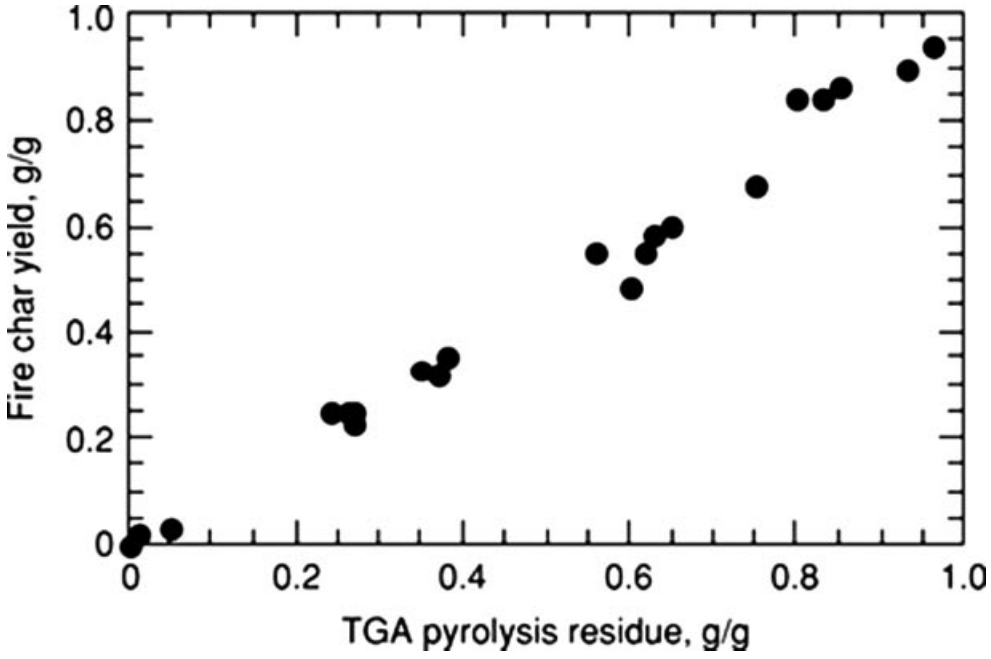

Fig. 7. Char mass fraction in fire versus anaerobic pyrolysis.

as the mass fraction of char measured immediately after flaming combustion has ceased in a fire calorimeter (see under Testing to Obtain Engineering Data) versus the char residue at 900 ± 100°C for the same material after anaerobic pyrolysis in a thermogravimetric analyzer at a heating rate of about 10 K/min. It is seen that the char yield of a material in a fire is essentially equal to its residual mass fraction after anaerobic pyrolysis at temperatures representative of the char temperature in a fire. Although oxidative degradation products have been identified at the surface of olefinic polymers after flaming combustion, the data in Figure 7 suggest that oxidation reactions in the solid *during* flaming combustion are not important to the overall fuel fraction. If the reactive intermediate I* in equations 13–15 is a stationary state then $dI^*/dt = 0$, and if thermal decomposition is an anaerobic process, the fuel generation rate is

$$-\frac{dm'}{dt} = k_p m' = A\, e^{-E_a/RT} m' \tag{16}$$

where m' is the mass of volatile fuel, k_p is the mass loss rate constant in terms of a global frequency factor A (1/s) and activation energy E_a (J/mol). Equation 16 is easily solved for the fuel generation rate at constant temperature (isothermal conditions). However, the polymer temperature changes rapidly from ambient to the pyrolysis temperature near the burning surface, and so a nonisothermal solution of equation 16 is required to capture the dynamics of the fuel generation process as it occurs in the mesophase. For an arbitrary temperature history $T(t)$

in the mesophase, the mass of fuel generated at any time t is

$$\ln\left\{\frac{m'(\tau)}{m'(0)}\right\} = -\int_0^t A\,\exp\left\{-\frac{E_a}{RT(t')}\right\}dt' \tag{17}$$

Equation 17 can be solved numerically for any specified temperature history. However, the mesophase temperature history is a function of both time and position (see Fig. 4), and so the transient temperature distribution $T(x, t)$ must be specified in order to obtain an analytic solution for equation 17. If the temperature distribution is static during steady burning of a thick sample as the surface $x = 0$ recedes at constant velocity $v = (dx/dt)_T$ and the mesophase is a thin surface layer, then the rate of temperature rise of the mesophase is constant, $(dT/dt)_{x=0} = -v(dT/dx)_t = \beta$. The assumption of a constant heating rate for the mesophase transforms the independent variable in equation 17 from time to temperature and allows for a solution in terms of the mass fraction of polymer remaining at temperature T

$$\frac{m(T)}{m_0} = \mu(T) + \{1 - \mu(T)\}\,e^{-y} \tag{18}$$

where

$$y = \frac{k_p R T^2}{\beta(E_a + 2RT)}$$

The equilibrium char fraction at temperature T is

$$\mu(T) = \frac{k_c}{k_c + k_g} = \left\{1 + \frac{A_g}{A_c}\,\exp\left(-\frac{E_g - E_c}{RT}\right)\right\}^{-1} \tag{19}$$

in terms of the frequency factors A_g, A_c and the activation energies E_g, E_c, for gas and char formation, respectively. A temperature-dependent equilibrium char fraction, which is the ratio of rate constants for gas and char formation, is consistent with the use of group contributions for the char-forming tendency of polymers (22) (see under Char Yield). The fractional mass loss rate at temperature T is obtained by differentiating equation 18 with respect to time. For $\mu\,(T) = \mu =$ constant, the result is

$$-\frac{1}{m_0}\frac{dm}{dt} = (1 - \mu)k_p\,e^{-y} \tag{20}$$

Setting the time derivative of equation 20 equal to zero shows that the maximum fuel generation rate occurs when

$$k_p(T_p) = A\,\exp\left(-\frac{E_a}{RT_p}\right) = \frac{\beta E_a}{RT_p^2} \tag{21}$$

Substituting k_p from equation 21 into equation 20 for $E_a \gg RT_p$ gives the maximum fuel generation rate

$$-\frac{1}{m_0}\frac{dm}{dt}\bigg|_{max} = (1-\mu)\frac{\beta E_a}{eRT_p^2} \tag{22}$$

The temperature T_p in equations 21 and 22 is the temperature at the maximum fuel generation rate during the course of the linear temperature history. Defining a characteristic heating rate $\beta^* = A\ \Delta T_p$, where $\Delta T_p = RT_p{}^2/E_a$ is the half-width of the pyrolysis temperature interval, equation 22 takes the form of a (statistical) thermodynamic phase transition temperature

$$T_p = \frac{E_a}{R\ln(\beta^*/\beta)} \tag{23}$$

Thermogravimetric analysis (TGA) is a common laboratory method for studying the thermal degradation kinetics of polymers at constant heating rate (6–10). The maximum fuel generation rate and T_p are readily obtained from these experiments as shown in Figure 8 for poly(methyl methacrylate) (PMMA) and polyamideimide (PAI). Figure 8 shows the onset thermal degradation temperature T_d, the temperature at peak mass loss rate T_p, and the char fraction μ for PAI. The range of temperatures over which pyrolysis takes place is of the order $eRT_p{}^2/(1-\mu)E_a$, which is seen to be very different for these two polymers of widely differing thermal stability and charring tendency. Table 1 contains T_d, T_p, and T_{ign} for a number of polymers.

Thermochemistry. The basic thermal degradation mechanism leading to volatile fuel generation in polymers involves primary and secondary decomposition events as illustrated in Figure 5. The primary decomposition step can be main-, end-, or side-chain scission of the polymer. Subsequent thermal degradation reactions depend largely on the chemical structure of the polymer but typically proceed by hydrogen transfer to α- or β-carbons, nitrogen or oxygen, intramolecular exchange (cyclization), side-chain reactions, small-molecule (SO_2, CO_2, S_2) elimination, molecular rearrangement, and/or unzipping to monomer (15). Unzipping or depolymerization of vinyl polymers is characterized by a *kinetic chain length or zip length* that is the average number of monomer units produced by a decomposing radical before the radical is deactivated by termination or transfer. Mathematically, the zip length is the ratio of the rate constants for initiation to termination.

Aromatic backbone polymers such as polycarbonate, polyimides, polyaramides, polyarylsulfones, and polyphenyleneethers tend to decompose in varying degrees to a carbonaceous char residue through a complex set of intramolecular rearrangements and side-chain reactions involving cross-linking and bond scission. The char yield is the mass fraction of carbonaceous char that remains after flaming combustion of the polymer. Charring competes with termination reactions that generate volatile species and thus reduces the amount of available fuel in a fire. In addition, char acts as a heat and mass transfer barrier that lowers the flaming heat release rate. Figure 7 demonstrated that the char yield in a fire is roughly equal to the anaerobic pyrolysis residue at high (flame) temperatures. Polymers

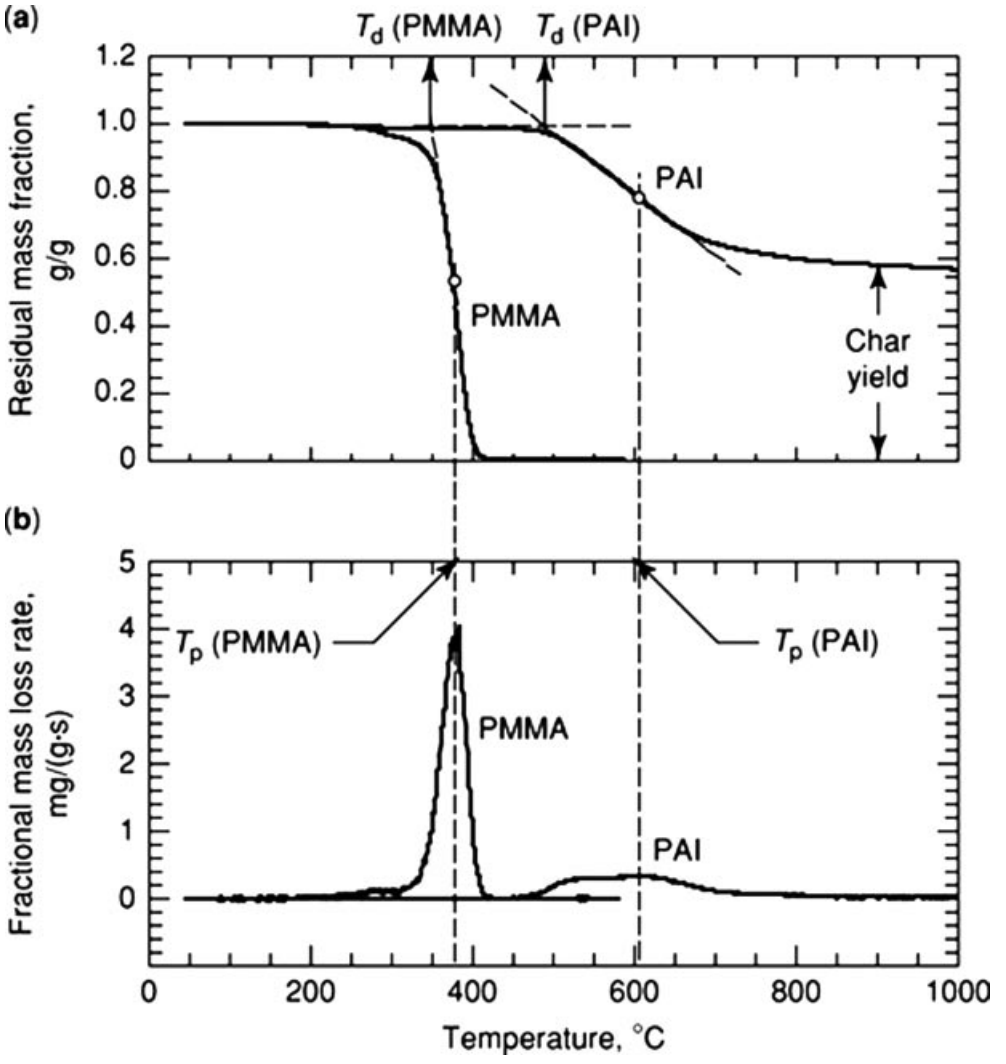

Fig. 8. Thermogravimetric analysis (TGA) data for poly(methyl methacrylate) (PMMA) and polyamideimide (PAI): (**a**) residual mass fraction versus temperature; (**b**) mass loss rate versus temperature.

that contain heterocyclic or aromatic structures in the backbone tend to form char during thermal decomposition in rough proportion to the carbon/hydrogen (C/H) ratio of the polymer. Figure 9 shows the mass fraction of char plotted versus the mole fraction of hydrogen in the polymer molecule. High C/H ratios favor termination by cross-linking between carbon radicals, and char is formed. Low C/H ratios favor termination of carbon radicals by hydrogen transfer, resulting in low molecular weight fuel species rather than char. The relative rates of intermolecular cross-linking and aromatization and intramolecular hydrogen transfer and cyclization reactions, ie, the ratio $k_c/(k_c + k_g)$ in equation 19, will determine the char yield at any particular hydrogen mole fraction.

Energetics. In principle, the heat (enthalpy) of gasification is the difference between the enthalpy of the solid in the initial state at ambient temperature and pressure, T_0, P_0, and the enthalpy of the volatile thermal decomposition products at T_p, P_0. If the stored heat is Δh_s, the enthalpy of fusion (melting) for semicrystalline polymers is Δh_f, the bond dissociation enthalpy is Δh_d, and the enthalpy of vaporization of the decomposition products is Δh_v, then the enthalpy of gasification per unit mass of fuel is (10)

$$L_g = \Delta h_s + \Delta h_f + \Delta h_d + \Delta h_v = \int_{T_0}^{T_p} c(T)\,dT + \Delta h_f + \Delta h_d + \Delta h_v \tag{24}$$

The symbol L_g derives from latent heat, ie, the recoverable heat in a reversible process. Thermolytic cleavage of primary chemical bonds in the polymer backbone to produce volatile fuel and char is obviously not a reversible process, but the symbol L_g will be used throughout to conform with the literature in the fire sciences. Table 2 illustrates the magnitude of these enthalpic terms for amorphous PMMA, polystyrene (PS), and semicrystalline polyethylene (PE). The stored heat Δh_s was obtained by numerical integration of heat capacity versus temperature from ambient to the dissociation temperature as per equation 24. The dissociation

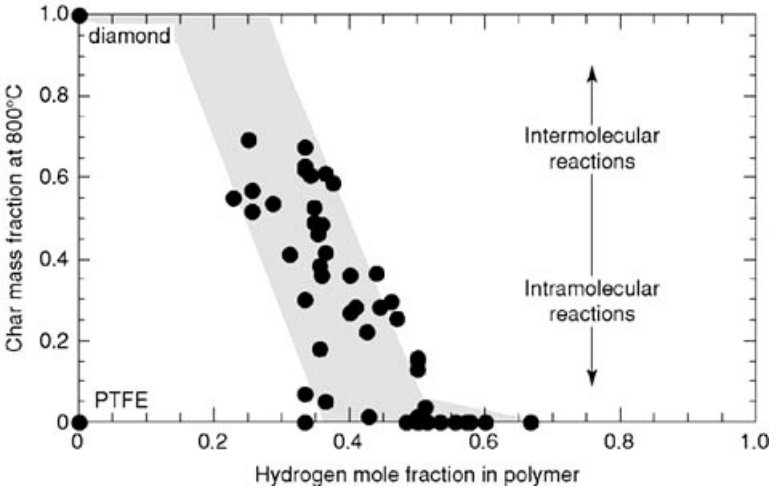

Fig. 9. Char mass fraction versus hydrogen mole fraction in polymer.

Table 2. Components of the Enthalpy of Gasification for poly(methyl methacrylate) (PMMA), polystyrene (PS), and polyethylene (PE)

	PMMA	PS	PE
Monomer molecular weight, g/mol	100	104	28

Δh_v, J/g	375	387	345
$L_g = \sum \Delta h_i$, J/g	1665	1850	2301
L_g(measured), J/g	1700	1800	2200

(bond breaking) enthalpy Δh_d is assumed to be equal to the heat of polymerization but opposite in sign for these polymers which thermally degrade by random or end-chain scission. The degradation product for PE is assumed to be a tetramer (ie, octane with $M_g = 112$ g/mol) for the purpose of calculating the heats of dissociation and vaporization on a mass basis for this polymer, and the degree of crystallinity of PE is taken to be 90%. All other enthalpies in Table 2 were obtained from handbooks using monomer molecular weights to convert the energies to a mass basis. The values for h_g in the second to last row were obtained by summing the individual enthalpies according to equation 24 for each polymer.

In practice, the enthalpy of gasification is rarely calculated because detailed and reliable thermodynamic data for the polymer and its decomposition products are generally unavailable. Direct laboratory measurement of L_g using differential thermal analysis and differential scanning calorimetry has been reported, but L_g is usually measured in a constant heat flux gasification device or fire calorimeter (see under Steady Burning). In these experiments a plot of mass loss rate per unit surface area (mass flux) versus external heat flux has slope $1/L_g$ where

$$L_g = \frac{h_g}{1 - \mu} \tag{25}$$

h_g is the heat of gasification per unit mass of solid and μ is the nonfuel fraction (char or inert filler). The last row in Table 2 lists the average of h_g values for these noncharring polymers. Agreement is seen to be quite good between experimental values and thermochemical calculations of h_g. Table 3 contains L_g, μ, and h_g for 53 polymers. Analysis of the data in Table 3 shows that L_g and μ vary widely with polymer chemical structure but that h_g is relatively independent of composition with an average value $h_g = 2.0 \pm 0.5$ kJ/g.

The Condensed Phase.

Thermal Properties. The rate at which heat is transported and stored in the condensed phase is of fundamental importance because these processes determine the time to ignition and burning rate of polymers. Table 4 lists generic thermophysical properties at ambient temperature (295 ± 3 K) gathered from the

literature for a number of common thermoplastics, thermoset resins, elastomers, and fiber-glass reinforced plastics (4). Entries are individual values, averages of values from different sources, or averages of a range of values from a single source and therefore represent in most cases a generic property value with an uncertainty of about 10–20%.

Neglecting changes in the slope or magnitude of thermal properties that occur at phase changes such as the glass transition, melting, and decomposition temperatures of polymers, the temperature dependence of κ, ρ, and c for an amorphous polymer can be roughly approximated

$$\kappa(T) = \kappa_0 \left(\frac{T}{T_0} \right)^{1/2} \tag{26}$$

$$\rho(T) = \rho_0 \left(\frac{T_0}{T} \right)^{1/2} \tag{27}$$

$$c(T) = c_0 \left(\frac{T}{T_0} \right) \tag{28}$$

These properties are plotted in reduced form in Figure 10 as $P(T)/P(T_0)$ versus T/T_0, where $P(T)$, $P(T_0)$ are the values of κ, ρ, or c at temperature T and standard temperature (298 K), respectively.

The product $\kappa\rho c$ is a quantity called the thermal inertia that emerges from the transient heat transfer analysis of ignition time (see eq. 40). The temperature dependence of κ, ρ, and c in equations 26–28 suggests that the product of these terms (ie, the thermal inertia) should have the approximate temperature dependence:

$$\kappa(T)\rho(T)c(T) \approx \kappa_0\rho_0 c_0 T/T_0 = (\kappa\rho c)_0 T/T_0 \tag{29}$$

where κ_0, ρ_0, c_0, are the room temperature (T_0) values listed in Table 4.

Another thermal parameter that emerges from unsteady heat transfer analyses is the thermal diffusivity $\alpha = \kappa/\rho c$, which, according to equations 26–28, should be relatively independent of temperature

$$\alpha(T) = \frac{\kappa(T)}{\rho(T)c(T)} = \alpha_0 \tag{30}$$

Room temperature values of polymer thermal diffusivity are listed in Table 4.

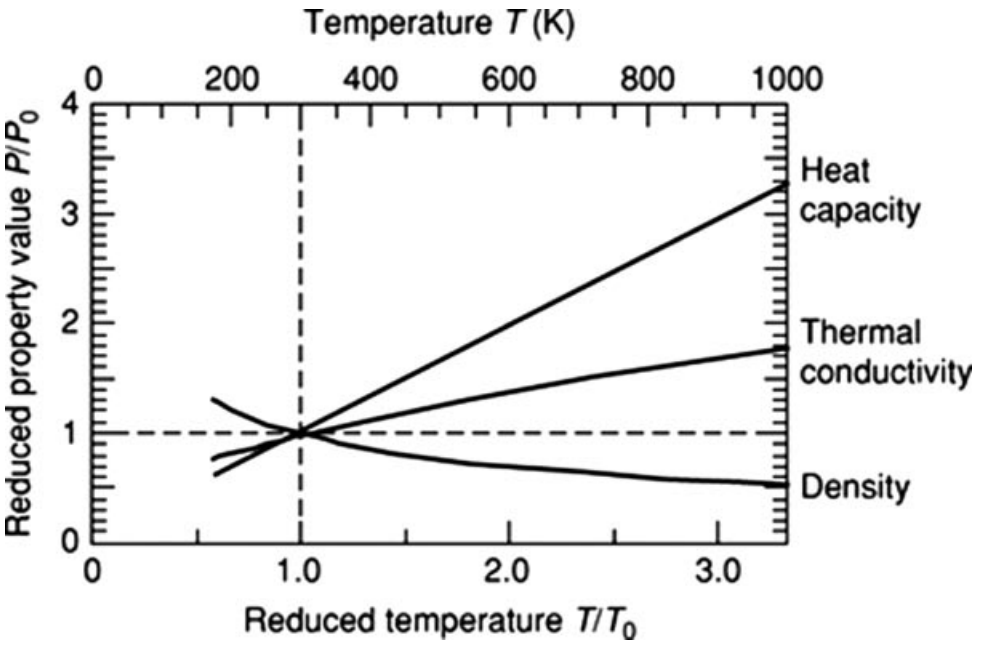

Fig. 10. Temperature dependence of polymer heat capacity, thermal conductivity, and density.

Another thermal property that affects the response of a polymer to the exposure from an external heat source is the surface absorptivity. It is generally assumed that polymers behave as gray surfaces, ie that the total hemispherical surface absorptivity is equal to the total hemispherical emissivity, ε. Hallman (23) measured ε for many polymers and different radiant heat sources. Some of Hallman's measurements are given in Table 5. These values are applicable prior

Table 5. Surface Absorptivity of Polymers

to ignition and it is reasonable to assume that $\varepsilon = 1$ for the flaming surface of a polymer.

Fire Behavior of Solid Polymers

The continuum level treatment of the fire behavior of polymers disregards the discrete (molecular) structure of matter so that the temperature distribution, and more importantly its derivatives, are continuous throughout the material. In addition, the polymer is assumed to be thermally thick and have identical properties at all points (homogeneous) and in all directions (isotropic). In this way analytic results for ignition and burning can be derived from unsteady and steady heat transfer analyses, respectively, using simplified mass and energy balances. The continuum level treatment provides scaling relationships between the properties of polymers and their fire response, but ignores many important characteristics of burning behavior such as the effect of char formation on heat and mass transfer, swelling (intumescence), and dripping that can only be captured empirically or through detailed numerical modeling and analyses.

Ignition. Ignition is the initiation of combustion of a fuel/air mixture that is uniformly heated (autoignition) or comes in contact with a flame, spark, or glowing wire (piloted ignition). The ignition of volatile liquid and gaseous fuels is fairly well understood because only the global or local thermodynamic state of the system need be considered (17–19). As shown in section The Gas Phase, the reaction of gaseous fuels with air will be self-sustaining if the combustion energy density of the mixture is above a minimum (critical) value of about 2 MJ/m^3. The burning of condensed phases is more complicated because there is dynamic coupling of heat and mass transfer between the gas phase and condensed (meso, solid) phase (11–13). Consequently, a variety of criteria have been proposed for piloted ignition of solids and these can be roughly divided into thermal (condensed phase) and chemical (gas phase) (11,24). The primary example of a thermal criterion is an ignition temperature for the solid, while chemical criteria extend to a critical mass flux or a critical heat release rate. Any of these criteria can be expressed in terms of an external heat flux at which the temperature or the flux of mass/energy reaches some critical value. The criteria for piloted ignition of polymer solids are examined separately below.

Chemical Criteria. Chemical criteria for ignition of condensed phases include a boundary layer reaction rate and a critical mass flux of fuel gases, both of which are equivalent to establishing a lower flammability limit at the ignition source for a fixed test geometry and ventilation rate. Table 6 lists mass fluxes at incipient piloted ignition and incipient burning/extinction for over 20 polymers measured in a fire calorimeter (see under Testing to Obtain Engineering Data) or similar device. Also listed is the effective heat of combustion (HOC) of the fuel gases and the product of the mass flux and HOC at ignition or extinction, ie, the heat release rate (HRR). The mass flux at ignition in Table 6 varies between polymers because of differences in the lower flammability limit of their pyrolysis products/fuel gases. If piloted ignition occurs when the concentration of pyrolysis gases in air reaches the LFL of the particular fuel species and $\dot{m}''_{\mathrm{f}}$ and $\dot{m}''_{\mathrm{a}}$ are the mass fluxes of fuel and air in a well-mixed volume at the igniter, then for

Average		1.0	21	3.2	66
Standard deviation		0.4	6	1.2	17

LFL $\ll 1$,

$$\frac{\dot{m}_{\mathrm{f}}''}{\dot{m}_{\mathrm{a}}''} = \frac{m_{\mathrm{f}}}{m_{\mathrm{a}}} = \frac{\rho_{\mathrm{f}}}{\rho_{\mathrm{a}}}\left(\frac{\mathrm{LFL}}{1-\mathrm{LFL}}\right) \approx \frac{\rho_{\mathrm{f}}}{\rho_{\mathrm{a}}}\mathrm{LFL} \tag{31}$$

The average convective heat transfer coefficient at the polymer surface at incipient ignition is

$$\bar{h} = c_{\mathrm{a}}\dot{m}_{\mathrm{a}}'' \tag{32}$$

The mass flux at ignition from equations 11, 31, and 32 is

$$\dot{m}_{\mathrm{f}}|_{\mathrm{LFL}} = \frac{\rho_{\mathrm{f}}}{\rho_{\mathrm{a}}}\frac{\bar{h}}{c_{\mathrm{a}}}\mathrm{LFL} = \frac{\bar{h}Q'''}{\rho_{\mathrm{a}}c_{\mathrm{a}}}\frac{1}{h_{\mathrm{c}}^0} = \frac{\mathrm{HRR}^*}{h_{\mathrm{c}}^0} \tag{33}$$

Equation 33 shows that there is a parameter with the units and significance of a virtual heat release rate $\mathrm{HRR}^* = \bar{h}Q'''/\rho_{\mathrm{a}}c_{\mathrm{a}}$ that is independent of the type of polymer but depends on the nature of the convective environment, ie, the test

conditions. Piloted ignition of a solid polymer will occur under a particular set of test conditions when

$$\dot{m}''_{\text{ign}} = \dot{m}''|_{\text{LFL}} \geq \frac{\text{HRR}^*}{h_c^0} \tag{34}$$

or when

$$h_c^0 \dot{m}''_{\text{ign}} \geq \text{HRR}^* \tag{35}$$

In fire calorimeters (see under Testing to Obtain Engineering Data) HRR* is of the order

$$\text{HRR}^* \frac{\bar{h}\bar{Q}'''}{\rho_a c_a} = \frac{(10\ \text{W/(m}^2 \cdot \text{K)})(1.9\ \text{MJ/kg})}{(1\ \text{kg/m}^3)(1\ \text{kJ/(kg} \cdot \text{K)})} \approx 20\ \text{kW/m}^2$$

Equations 34 and 35 are physically based criteria for ignition of polymers in typical (see under Testing to Obtain Engineering Data) convective environments where a spark is located 25 mm from the heated polymer surface. Equation 35 is a steady-state, two-dimensional analog of the combustion energy density criterion for gaseous ignition (eq. 11) and, like that criterion, is independent of the chemical composition of the fuel gases. Using HRR* = 20 kW/m^2 and the indicated HOCs in Table 6, equation 34 predicts $\dot{m}''_{\text{ign}} = 1.00 \pm 0.37$ g/(m^2·s) at the flashpoint, which is indistinguishable from the average experimental result. Equation 35 predicts that piloted ignition is imminent when $h_c{}^0\ \dot{m}''_{\text{ign}} = \text{HRR} \geq \text{HRR}^* = 20$ kW/m^2, which is also indistinguishable from the experimental result HRR = 21 ± 6 kW/m^2 at incipient ignition (the flashpoint). Table 6 also lists the mass flux and heat release rate for the majority of polymers at the firepoint when the flame is first established. It seems that the mass flux and HRR increase by a factor of 2–3 between the flashpoint and the firepoint as additional heat flux is imparted to the surface from the flame at incipient burning.

Thermal Criterion. A chemical criterion (eq. 34 or 35) is probably sufficient for ignition to occur but a surface temperature in the vicinity of the thermal decomposition temperature is necessary to begin the fuel generation process. The thermal theory of ignition assumes that the surface temperature at ignition is a characteristic property of the polymer. If fuel gasification obeys a simple energy balance such as equation 24 and the temperature dependence of the heat capacity is equation 28, ie, $c(T) = c_0 T/T_0$, then the enthalpy of gasification at ignition is

$$\frac{c_0}{T_0}\int_{T_0}^{T_{\text{ign}}} T\,\text{d}T + \Delta h_f + \Delta h_d + \Delta h_v = L_g \tag{36}$$

The heat capacity–temperature integral in equation 36 can be solved explicitly with the result

$$\frac{c_0 T_{\text{ign}}^2}{2T_0} + \left(\Delta h_f + \Delta h_d + \Delta h_v - \frac{c_0 T_0}{2}\right) = L_g \tag{37}$$

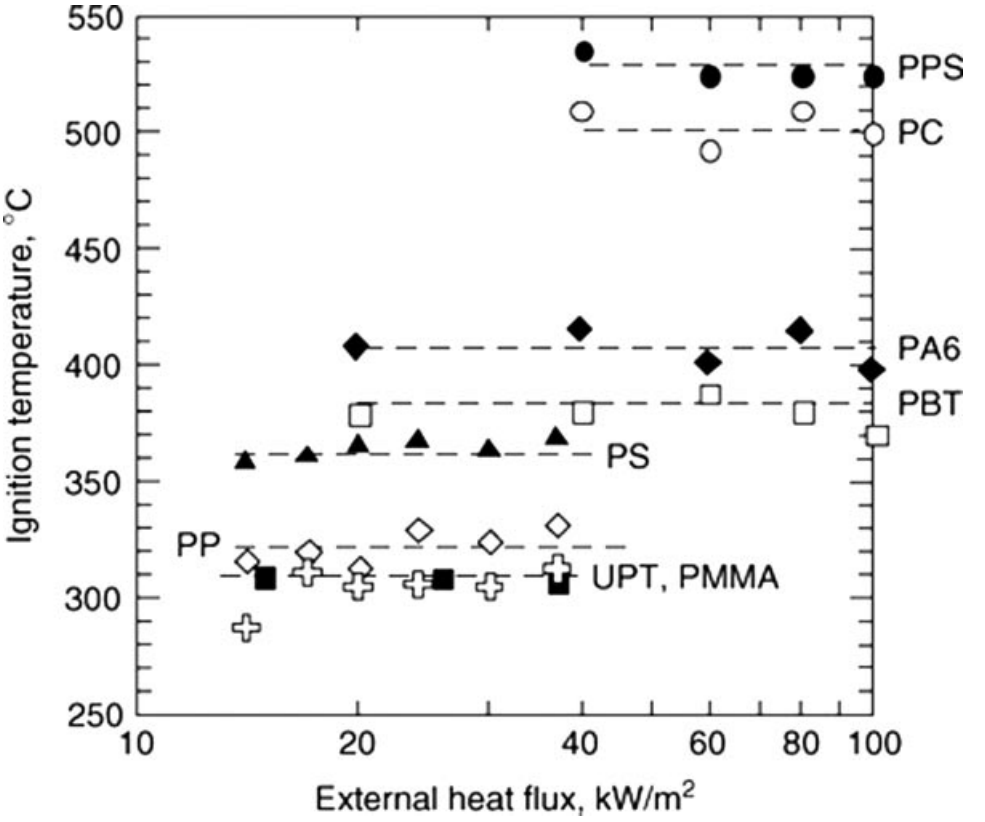

Fig. 11. Ignition temperature versus external heat flux for PPS (●), PC (○), PA6 (◆), PBT (□), PS (▲), PP (◇), UPT (■), and PMMA (✙).

The data in Table 2 suggest that $(\Delta h_f + \Delta h_d + \Delta h_v - c_0 T_0/2) \approx L_g/2$, which allows equation 37 to be solved for T_{ign}:

$$T_{ign} \approx \left(\frac{T_0 L_g}{c_0}\right)^{1/2} \tag{38}$$

Figure 11 is a plot of measured surface temperature at piloted ignition in a fire calorimeter (see under Testing to Obtain Engineering Data) or similar device over a range of external heat fluxes for polyphenylenesulfide (PPS), polycarbonate (PC), polycaprolactam (PA6), polystyrene (PS), polybutylene terephthalate (PBT), polypropylene (PP), unsaturated polyester thermoset (UPT), and PMMA. The ignition temperature of each polymer is relatively independent of heat flux as per equation 38, which also accounts for the large differences between polymers (see Table 1). Using typical properties for commodity and engineering polymers,

$$T_{ign} = \left(\frac{T_0 L_g}{c_0}\right)^{1/2} = \left\{\frac{(298\ \text{K})(2\ \text{MJ/kg})}{1.5\ \text{kJ/(kg}\cdot\text{K)}}\right\}^{1/2} = 630\ \text{K} = 357^\circ\text{C}$$

which approximates the ignition temperature of these materials in lower part of Figure 11. For a constant ignition temperature, unsteady heat transfer (4,11,12) gives the time to ignition, t_{ign}, for a thermally thick sample at a constant external heat flux $\dot{q}''_{ext}$

$$\frac{1}{\sqrt{t_{ign}}} = \frac{\dot{q}''_{ext} - \dot{q}''_{loss}}{TRP} \tag{39}$$

where

$$TRP = \frac{\sqrt{\pi \kappa \rho c}}{2}(T_{ign} - T_0) \tag{40}$$

is a quantity known as the thermal response parameter (TRP). Equation 39 states that a plot of the reciprocal square root of the time-to-ignition versus the external heat flux has a slope equal to average value of the thermal response parameter. The product $\kappa \rho c$ in equation 40 is an effective property called the thermal inertia that can be approximated using equation 29 and tabulated values for κ, ρ, and c (see Table 4) or from the thermal response parameter if T_{ign} is measured separately or calculated (see eq. 38 and section on Ignition Temperature). The intercept $\dot{q}''_{loss}$/TRP of equation 39 can also provide an estimate of T_{ign} if an additional expression is introduced to account for the surface heat losses at incipient ignition

$$\dot{q}''_{loss} = \bar{h}(T_{ign} - T_0) + \varepsilon\sigma\left(T_{ign}^4 - T_0^4\right) \tag{41}$$

For a thermally thin sample of thickness b and at low external heat fluxes near the critical value, the ignition time and external heat flux are related

$$\frac{1}{t_{ign}} = \frac{\dot{q}''_{ext} - \dot{q}''_{loss}}{\rho b c (T_{ign} - T_0)} \tag{42}$$

Equations 39 and 42 state that $t_{ign} \to \infty$ as $\dot{q}''_{ext} \to \dot{q}''_{loss}$ at the flashpoint. In other words, the minimum (critical) value of the external heat flux that can cause ignition is

$$CHF = \dot{q}''_{loss}(\text{ignition}) = \bar{h}(T_{ign} - T_0) + \varepsilon\sigma\left(T_{ign}^4 - T_0^4\right) \tag{43}$$

At the firepoint, flaming combustion is first established. If a flame covers a polymer surface having $\varepsilon \approx 1$ and heat losses are by reradiation only from a surface for which the burning and ignition temperatures are the same, then the first term on the right-hand side of equation 43 is zero and the critical heat flux (CHF) for burning is

$$CHF_b = \dot{q}''_{loss}(\text{burning}) \approx \dot{q}''_{rerad} = \sigma T_{ign}^4 \tag{44}$$

Equations 43 and 44 explain why thermally stable/heat-resistant polymers with high thermal decomposition/ignition/burning temperatures require a higher heat

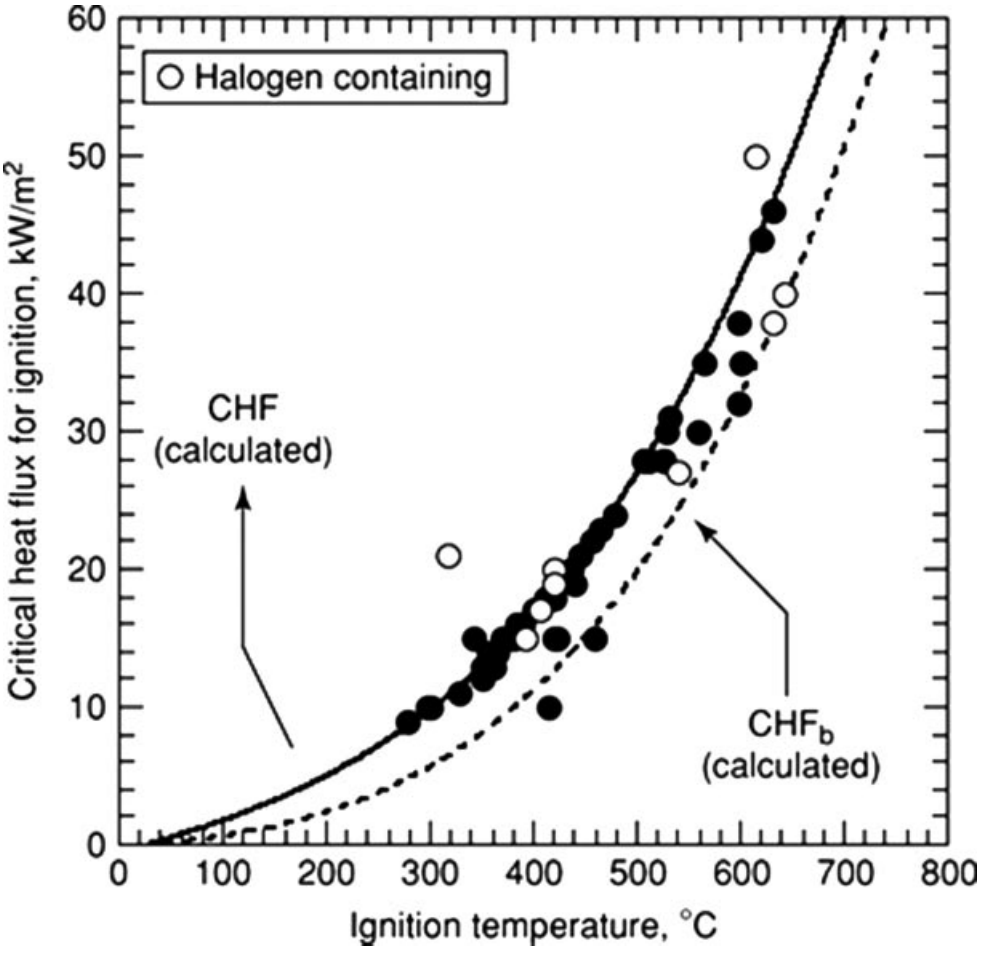

Fig. 12. Critical heat flux versus ignition temperature. Symbols are measurements at sustained ignition. Lines are calculated from abscissa for incipient ignition (solid) and incipient burning (dashed).

flux to ignite and burn. Figure 12 is a plot of the critical heat flux versus the ignition temperature of common polymers measured separately. The solid line is calculated from the abscissa using equation 43 and the dotted line using equation 44.

Steady Burning. Once ignition is sustained and the burning rate reaches a constant value, the HRR (W/m^2) of the polymer in steady flaming combustion is (4,11,12,20,21)

$$\mathrm{HRR} = \chi h_c^0 \dot{m}'' = \chi \frac{h_c^0}{L_g} \dot{q}''_{net} \tag{45}$$

where χ is the combustion efficiency in the flame and

$$\dot{q}''_{net} = \dot{q}''_{ext} + \dot{q}''_{flame} - \dot{q}''_{loss} \tag{46}$$

is the net heat flux for steady flaming combustion with $\dot{q}''_{\text{flame}}$ the total convective and radiative heat flux from the flame to the polymer surface (see Fig. 2). The dimensionless ratio of the heat of combustion to the heat of gasification in equation 45 is the heat release parameter (HRP)

$$\chi \frac{h_c^0}{L_g} = \chi(1-\mu)\frac{h_c^0}{h_g} = \text{HRP} \tag{47}$$

Fire calorimetry (4,11,20,25) (see under Testing to Obtain Engineering Data) is used to obtain HRP as the slope of heat release rate versus external heat flux or as the ratio $\chi {h_c}^0/L_g = \text{HOC}/L_g$, from individual measurements. Table 7 contains HOC and χ ($\equiv$HOC/${h_c}^0$) for common polymers while HRP are listed in Table 8. The heat of combustion of the fuel gases, ${h_c}^0$, was measured separately in a pyrolysis-combustion flow calorimeter (26) (see section on The Pyrolysis-Combustion Flow Calorimetry).

Figure 13 shows representative HRR histories for thermally thick and thin samples of polymers that gasify completely or form a char during burning. It is apparent that none of these heat release rate histories show a constant (steady-state) value of heat release rate over the burning interval as presumed in equation 45.

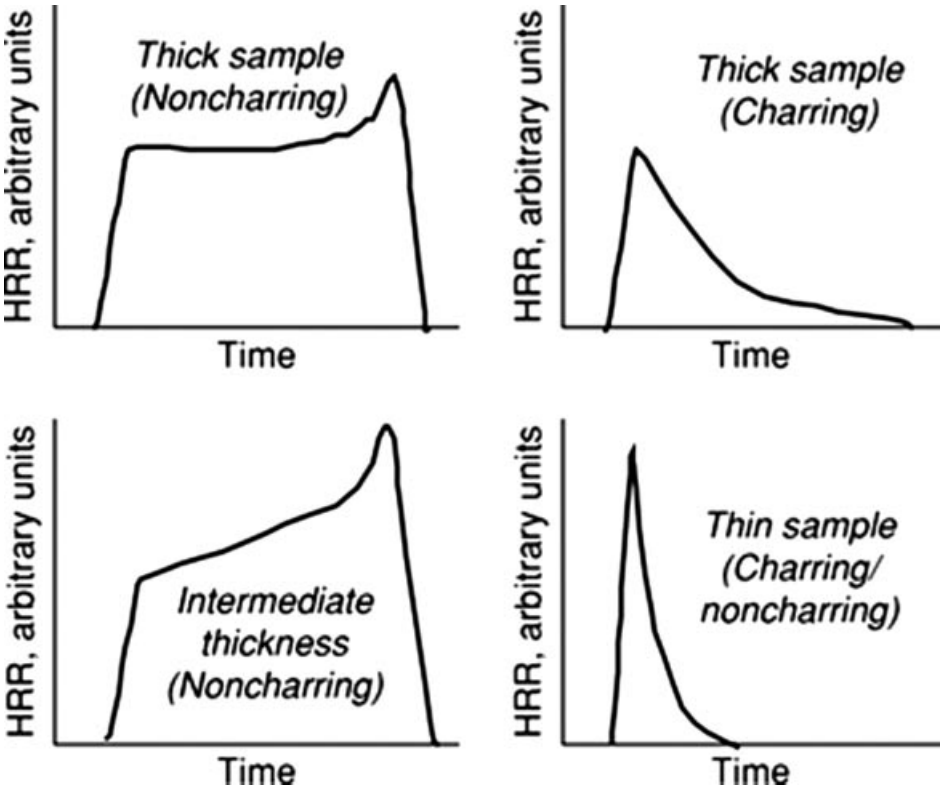

Fig. 13. Representative heat release rate histories in flaming combustion for thick and thin samples of charring and noncharring polymers.

Consequently, an average heat release rate for the entire test or over some time interval is typically used in place of a steady HRR. In fact, the interpretation of time varying heat release rate histories is a subject of active research in fire science. The curves on the left-hand side of Figure 13 are characteristic of noncharring ($\mu = 0$) plastics of different thickness. The heat release histories for the charring plastics on the right-hand side of Figure 13 show the typical peak in heat release rate soon after ignition followed by a depression in the heat release rate as the char layer forms and increases in thickness. The growing char layer insulates the underlying plastic from the surface heat flux so that the net heat flux at the in-depth pyrolysis front decreases with time. Char can also act as a mass diffusion barrier to the volatile fuel. Charring polymers can be linear, branched, or cross-linked thermoplastics, elastomers, or thermosets having amorphous or semicrystalline morphologies.

In all cases in Figure 13 the time integral (area under), the heat release rate history per unit mass of polymer consumed by burning, is the effective heat of flaming combustion, HOC (J/kg). The effective heat of combustion is determined primarily by the fuel chemistry, ventilation rate, and combustion efficiency in the flame. Combustion efficiency is low when halogens are present in the polymer molecule or added as flame- retardant chemicals, when soot or smoke is produced in large yield, or when there is insufficient oxygen for complete conversion of the organic fuel to carbon dioxide and water. Flaming combustion efficiency appears to be relatively independent of the charring tendency of a polymer (compare Tables 2 and 5).

Figure 14 shows fire calorimetry data for the average heat release rate of plastics versus their char yield after burning or pyrolysis. The nonlinear dependence of heat release rate on char yield in Figure 14 indicates that charring suppresses the HRR more than can be accounted for by the fuel fraction alone (eg, eq. 47). In fact, charring correlates with thermal stability (L_g) and acts as a barrier to the transfer of mass and heat during burning as illustrated schematically in Figure 13, all of which tend to reduce HRR.

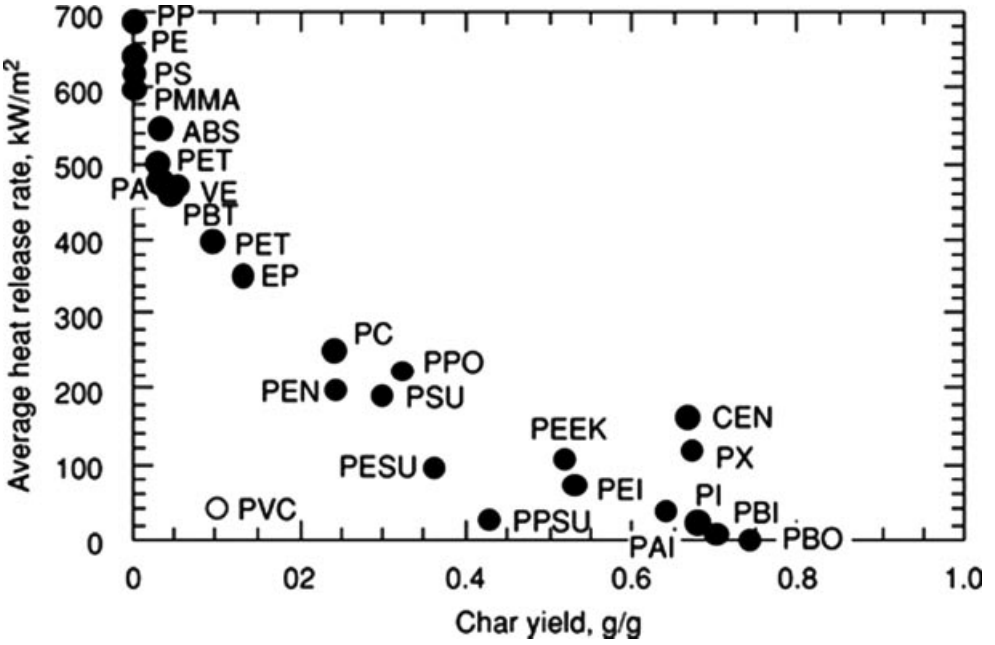

Fig. 14. Average heat release rate in flaming combustion versus char yield of polymers.

Unsteady Burning. Unsteady burning or transient ignition is the fire behavior that is most relevant to flammability tests (5,25,27). In flammability tests of flame resistance a thin strip of polymer is typically subjected to a Bunsen burner flame for several seconds to force ignition, after which the sample is removed from the flame and the duration, extent, and characteristics of burning are recorded. Polymers that continue to burn after removal from the ignition source are considered relatively flammable while polymers that self-extinguish are relatively flame resistant. Flame resistance is related to fire behavior by combining equations 45–47 and separating the heat release rate into unforced (HRR_0) and forced (HRP $\dot{q}''_{ext}$) components

$$HRR = HRR_0 + HRP\ \dot{q}''_{ext} \tag{48}$$

where the heat release rate in unforced flaming combustion, ie, in the absence of an external heat flux, is

$$HRR_0 = HRP(\dot{q}''_{flame} - \dot{q}''_{loss}) \tag{49}$$

Equation 49 states that the surface flame must provide all of the energy to sustain burning in unforced combustion. However, $\dot{q}''_{flame}$ contains convective and radiative components and will depend on the size and orientation of the sample with respect to its flaming surface while $\dot{q}''_{loss}$ depends on sample thickness and heat transfer boundary conditions for unsteady burning. Consequently, HRR_0 is generally apparatus- or test-specific. The fire parameters HRP and HRR_0 for a fire

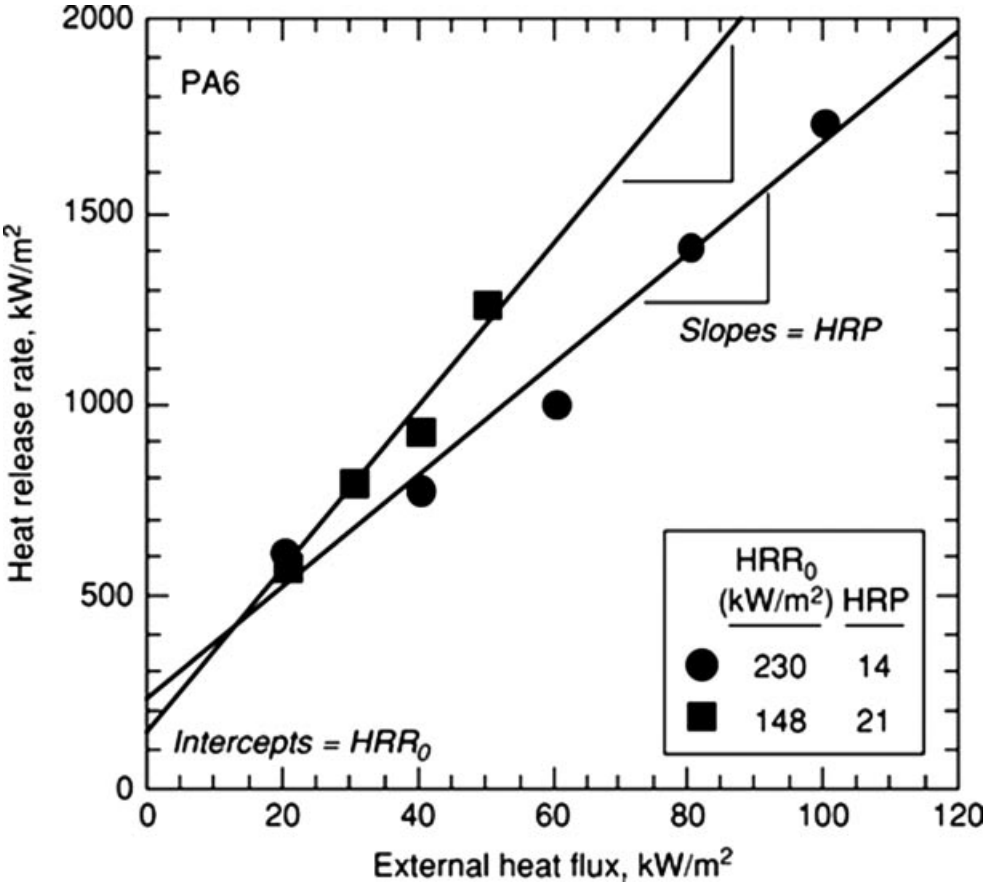

Fig. 15. Heat release rate versus external heat flux data for polycaprolactam (PA6) from different sources. Slopes are HRP. Intercepts are HRR_0.

calorimeter (see under Testing to Obtain Engineering Data) can be determined from the slope and intercept, respectively, of a plot of HRR versus external heat flux in a fire calorimeter as shown in Figure 15 for PA6 data from two different sources (4).

If extinction occurs when the gas phase combustion energy density falls below a minimum (critical) value, analogous to the phenomenon that governs ignition, then equations 38 and 48 provide a criterion for flame extinction in a flammability test. After the sample ignites and the flame is removed $\dot{q}''_{ext} = 0$, and the sample will self-extinguish if

$$HRR_0 < HOC\ \dot{m}''_b = HRR^*_b \tag{50}$$

where $\dot{m}''_b$ and $HRR_b{}^*$ are the critical mass flux and heat release rate for sustained burning, respectively, in the flammability test (see eqs. 36–38). From equations

49 and 50, the flame heat flux at the firepoint is

$$\dot{q}''_{\text{flame}}\,(\text{extinction}) \leq \frac{\text{HRR}^*_b}{\text{HRP}} + \dot{q}''_{\text{loss}} \tag{51}$$

Since $\text{HRR}_b{}^*$ is test-dependent, the same value that governs horizontal burning/extinction in fire calorimeters ($\text{HRR}_b* \approx 70$ kW/m^2; see Table 6) will not necessarily apply to extinction in an upward flame spread test of a thin strip of polymer. Table 8 lists HRR_0 for common polymers along with their flammability rating in the upward vertical (V) or horizontal (H) burning Underwriters Laboratory (UL) test for flammability of plastic materials (a Bunsen burner ignition test). Table 8 shows that when $\text{HRR}_0 < 50$ kW/m^2 as measured in a fire calorimeter, self-extinguishing behavior is observed exclusively in the vertical burning test. Equation 49 shows that HRR_0 decreases as the difference between the heat influx from the flame and the heat efflux by reradiation. Negative HRR_0 values toward the bottom of Table 8 are observed for halogen-containing/flame retarded (FR) plastics that may burn with a low flame heat flux. Negative HRR_0 values are also observed for heat-resistant/thermally stable polymers that have high losses and a thermally insulating char. In either case, $\dot{q}''_{\text{flame}}$ can be less than $\dot{q}''_{\text{loss}}$ and negative HRR_0 values are expected and observed.

Another widely used flammability test is the limiting oxygen index (LOI) (25) test (see section on The Limiting Oxygen Index Test). The LOI is a downward-burning test of a thin ($3 \times 6 \times 150$ mm) polymer strip in a flowing gas stream whose oxygen concentration is adjusted until the sample flame is on the verge of extinguishing. The dependent variable in the LOI test is the flame heat flux, which increases in rough proportion to the oxygen concentration in the combustion atmosphere (independent variable). The concentration of oxygen in the combustion atmosphere at incipient burning/extinction is the LOI, and this corresponds to a flame heat flux in equation 51:

$$\text{LOI} \propto \dot{q}''_{\text{flame}}(\text{extinction}) = \frac{\text{HRR}^*_b}{\text{HRP}} + \dot{q}''_{\text{loss}} \tag{52}$$

A value $\text{HRR}_b{}^* \approx 100$ kW/m^2 has been observed for the LOI test. This value is somewhat higher than the critical heat release rate for incipient burning/extinction of horizontal slabs ($\text{HRR}_b* \approx 70$ kW/m^2; see Table 6) and upward burning of vertical strips ($\text{HRR}_b* \approx 50$ kW/m^2) because heat transfer from the flame is less efficient in downward burning, and so a higher HRR is necessary for sustained ignition in the LOI test.

The equations for ignition, steady burning, and unsteady burning show that flammability tests measure the fire behavior of the polymer in unforced burning, whether as an afterflame time in a Bunsen burner test (see under Testing for Rugulatory Compliance) or as an oxygen concentration at incipient extinction (see under Testing for Quality Assurance and Research). Substituting equations 44 and 38 into equation 51 or 52 gives the efficiency of heat transfer from the

flame to the polymer surface in terms of the fire parameter HRP:

$$\frac{\dot{q}''_{\text{flame}}(\text{extinction})}{\text{HRR}_b^*} = \frac{\text{HRP}}{1+(\lambda/\text{HRP})} \tag{53}$$

where $\lambda = (\sigma/\text{HRR}_b{}^*)(\chi h_c{}^0\ T_0/c_0)^2$ is a dimensionless quantity that is test-dependent by virtue of χ and $\text{HRR}_b{}^*$. Table 8 shows that self-extinguishing behavior in the UL 94 V test and an LOI above 30 is observed exclusively for HRP $\leq$ 5 in these tests where $\text{HRR}_b{}^* = 75 \pm 25$ kW/m^2. Substituting HRP $= 4.5 \pm 0.5$ into equation 53 for typical $\lambda = 20 \pm 5$ (see Tables 3, 4, and 7) gives $\dot{q}''_{\text{flame}}/\text{HRR}_b{}^* \approx 0.8$ at incipient extinction in tests of flame resistance. Thus, at incipient extinction/burning when the combustion zone of the flame is in close proximity to the sample surface, a large fraction ($\approx$80%) of the heat released by combustion is used to sustain the burning process.

Chemical Structure and Fire Properties

A powerful tool to study the effect of chemical structure on the properties of polymers is the additivity principle. The additivity principle, pioneered by Van Krevelen (22), assumes that polymer properties when expressed per mole of substance can be calculated by summation of atomic, chemical group, or bond contributions:

$$\mathbf{P} = \sum_j n_i P_i$$

where $\mathbf{P}$ is a molar property, n_i is the number of moles of component i in the polymer repeat unit contributing to the property, and P_i is the numerical value of the contribution. In the study of fire behavior, the use of specific (mass-based) properties p is more convenient, and these are related to the molar properties and molecular weight M of the repeat unit

$$p = \frac{\mathbf{P}}{M}\frac{\sum_j n_i P_i}{\sum_j n_i M_i}$$

where M_i is the molar mass of component i. Additive molar contributions to polymer fire properties κ, ρ, c, $h^0{}_{c,p}$, T_p, and μ are well documented and their calculation from molar group contributions is straightforward. However, it is often the case that the molar group contributions are not available in the literature for new polymers with novel backbone and pendant structures. Recognizing this limitation of Van Krevelen's group contribution method, Bicerano generalized the additive scheme using graph theory to develop atomic connectivity indices which replace the larger chemical groups in the traditional additive approach as the principal descriptors of the topology of the polymer repeat unit (28). Bicerano's approach is still empirical in that the connectivity indices must be determined from experimental data or by correlation with known group contributions. However, once the connectivity indices are determined for a particular property, that

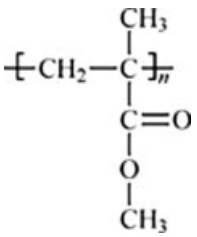
property may be predicted for any chemical structure for which the atomic (as opposed to group) composition is known. The connectivity index method of predicting polymer properties from atomic composition can be accomplished with a hand calculator but is more typically implemented using a stand-alone computer code or accessed as a module in molecular modeling software. Reactive molecular dynamics (RMD) simulations of thermal degradation is a semiempirical method that has recently been applied to the calculation of fuel species and fuel generation rates of polymers (10). RMD simulations are the most fundamental and powerful approach to understanding and predicting polymer flammability because, unlike the additive approaches, RMD has the potential to predict the products and rates of thermal decomposition, ie, the fuel generation chemistry.

Heat Transport. There are no good fundamental theories to predict the thermal conductivity κ (W/(m · K)), heat capacity c (kJ/(kg · K)), or density ρ (kg/m^3) of condensed phases (eg, solid or molten polymers) from chemical structure but empirical structure–property correlation allows calculation of these properties from additive atomic or chemical group contributions if the chemical structure of the polymer is known. Table 4 lists thermal properties of polymers, some of which were calculated from the chemical structure using additive contributions (22,28) when experimental values were not available.

Heat of Combustion. Thermodynamics allow calculation of the heat of combustion, $h_c{}^0$, as the difference between the free energy of the products and reactants in equation 4. Additive molar contributions to the free energy of gaseous, liquid, and solid fuels have been tabulated and used successfully to estimate heats of combustion. A simpler method for calculating or measuring combustion heat is based on the observation that the net heat of complete combustion of organic fuels per mole of oxygen consumed is independent of the chemical composition of the fuel (20),

$$C = h_c^0 \left(\frac{nM}{n_{O_2} M_{O_2}} \right) = \frac{h_c^0}{r_0} = 13.1 \pm 0.7 \text{ kJ/g } O_2 \tag{54}$$

where $h_c{}^0$ is the net heat of complete combustion of the fuel with all products in their gaseous state, n and M are the number of moles and molecular weight of the molecule or polymer repeat unit, respectively, n_{O_2} is the number of moles of O_2 consumed in the balanced thermochemical equation, and r_0 is the stoichiometric oxygen-to-fuel mass ratio. To illustrate the thermochemical calculation of the net heat of combustion, consider PMMA, which thermally degrades by end-chain scission/unzipping/depolymerization to monomer in quantitative yield. PMMA has the following chemical structure:



The methyl methacrylate (MMA) repeat unit in brackets is the volatile fuel species when PMMA burns and it has the atomic composition $C_5H_8O_2$; so the balanced chemical equation for complete combustion of PMMA is

$$C_5H_8O_2 + 6\ O_2 \rightarrow 5\ CO_2 + 4\ H_2O$$

Thus, 6 moles of O_2 are required to completely convert 1 mole of PMMA repeat unit to carbon dioxide and water. Inverting equation 54, the heat of combustion of the MMA fuel is

$$h_c^0 = C\left(\frac{n_{O_2}M_{O_2}}{nM}\right) = \frac{(13.1\ \text{kJ/g}\ O_2)(6\ \text{moles}\ O_2)(32\ \text{g}\ O_2/\text{mol})}{(1\ \text{mole MMA})(100\ \text{g MMA/mol})} = 25.15\ \text{kJ/g} \tag{55}$$

Net heats of complete combustion of polymers are available in the literature. If the mass fraction of char that remains after burning is μ, the fuel fraction is $(1 - \mu)$, and the heat of complete combustion of the fuel gases, ${h_c}^0$, is related to the heat of combustion of the char, ${h_{c,\mu}}^0$, and polymer, ${h_{c,p}}^0$,

$$h_c^0 = \frac{h_{c,p}^0 - \mu h_{c,\mu}^0}{1 - \mu} \tag{56}$$

Experimental values for ${h_c}^0$ determined by pyrolysis-combustion flow calorimetry (see below) are listed in Table 7. The elemental analysis of chars gives typical chemical formula C_5H_2 from which the heat of combustion of the char calculated from oxygen consumption is ${h_{c,\mu}}^0 \approx 37$ kJ/g, which can be used to estimate the heat of combustion of the fuel gases of charring polymers using equation 56 if μ is known.

Enthalpy of Gasification. In principle, the enthalpy of gasification, L_g, could be estimated from chemical structure using additive molar contributions or estimated from equation 25 if μ is known and h_g is taken to be 2 MJ/kg. Also relevant to the energetics of fuel generation is the observation that the activation energy for pyrolysis, E_a (J/mol), measured from laboratory TGAs approximates the molar enthalpy of gasification if M_g is the molecular weight of the fuel gases (10):

$$L_g = \frac{E_a}{M_g} \tag{57}$$

If M is the molar mass of the polymer repeat unit it follows from equation 57 that the ratio

$$\frac{M_g}{M} = \frac{E_a}{ML_g} \tag{58}$$

should be characteristic of the mode of thermal degradation. For example, polymers such as PMMA, polyoxymethylene (POM) and, to a first approximation, PS that thermally degrade by end-chain scission (depolymerize/unzip) produce monomer at near-quantitative yield. Consequently, these polymers should have

Table 9. Heats of Gasification, Pyrolysis Activation Energy, Char Yield, as well as Calculated and Measured Molecular Weights of Decomposition Products for Some Polymers

Polymer	M, g/mol	L_g, kJ/g	μ, g/g	h_g, kJ/g	E_a, kJ/mol	M_g/M	Pyrolysis products

PX	180	6.4	0.7	1.9	≈275	<1	

$M_g \approx M$, or $M_g/M \approx 1$. Polymers such as PE and PP that decompose by main chain scission (cracking) to multimonomer fragments will have $M_g/M > 1$. Conversely, polymers with complex molecular structures and high molar mass repeat units ($M \geq 200$ g/mol) such as polyamides (PA), cellulose, poly(ethylene terephthalate) (PET), or polycarbonate (PC) that degrade by random scission, cyclization, small-molecule splitting, or by chain stripping of pendant groups such as poly(vinyl chloride) (PVC) yield primarily low molar mass species (water, carbon dioxide, alkanes, mineral acids) relative to the repeat unit so that for these materials $M_g/M < 1$. Table 9 shows fuel/monomer molar mass ratios M_g/M calculated as E_a/ML_g according to equation 58 for some of the polymers in Table 3. Global pyrolysis activation energies for the thermally stable engineering plastics listed in the last four rows of Table 9 are estimated to be in the range $E_a = 275 \pm 25$ kJ/mol. Qualitative agreement is observed between the modes of pyrolysis (end-chain scission, random scission, chain stripping) and the calculated fragment molecular weight using equation 58, suggesting that the global pyrolysis activation energy determined from TGA experiments approximates the molar enthalpy of pyrolysis of the degradation products.

Ignition Temperature. Common sense and much experimental data suggest that the ignition temperature and thermal decomposition temperature of polymers should be related since mass loss/fuel generation begins in earnest at these temperatures. However, the heating rate in a fire is of the order of 10–20

Table 10. Thermokinetic Properties of PMMA, PE, and Phenolic Triazine

Polymer	$\ln(\beta^*)$, K/s	c_0, kJ/(kg · K)	E_a, kJ/mol	M_g, kg/mol
PMMA	30	1.4	160	0.10
PE	43	1.5	264	0.11
Phenolic triazine	36	1.5	178	0.12

times higher than the heating rates normally used to measure thermal decomposition temperatures in laboratory thermogravimetry experiments. Figure 11 and equation 38 show that the ignition temperature of polymers is not particularly sensitive to heat flux (heating rate) while equation 23 states that the thermal decomposition temperature of polymers in TGA experiments increases by about 45°C for each 10-fold increase in heating rate. Consequently, there should be a heating rate β_{ign} in a TGA experiment for which the ignition and decomposition temperatures of polymers are equal, ie, $T_{ign} = T_p(\beta_{ign})$. Substituting equation 57 into equation 38

$$T_{ign} = \left(\frac{T_0 L_g}{c_0}\right)^{1/2} = \left(\frac{T_0 E_a}{M_g c_0}\right)^{1/2} \tag{59}$$

Setting this result equal to T_p in equation 23

$$\left(\frac{T_0 E_a}{c_0 M_g}\right)^{1/2} = \frac{E_a}{R \ln(\beta^*/\beta_{ign})} \tag{60}$$

Equation 60 can be evaluated at $T_0 = 293$ K using the properties in Table 10, with the result that the heating rate for which $T_{ign} = T_p(\beta_{ign})$ is of the order

$$\beta_{ign} = \beta^* \exp\left(-\frac{E_a\, c_0 M_g}{R^2 T_0}\right)^{1/2} \approx 1 - 3 \text{ K/min} \tag{61}$$

which is at the lower range of heating rates typically used in nonisothermal TGA experiments, $\beta = 10$–20 K/min. From equations 59–61, the ignition and decomposition temperatures are related as

$$\frac{1}{T_{ign}} = \frac{1}{T_p} + \frac{R \ln(\beta/\beta_{ign})}{E_a}$$

Consequently, T_p measured in a TGA in an inert environment at heating rates $\beta/\beta_{ign} \approx 10$ can be 25–50 K higher than T_{ign} (see Table 1) for typical $E_a \approx 200$ kJ/mol. Figure 16 is a plot of the data in Table 1 for the measured ignition temperature of polymers versus their mean thermal decomposition temperature $(T_d + T_p)/2$. The use of a mean thermal decomposition temperature rather than T_p as an estimate of T_{ign} compensates for most of the heating rate effects described by equations 59–61. Also contained in Figure 16 are data for the incipient burning (firepoint) and incipient ignition (flashpoint) temperatures of hydrocarbon oils plotted on the ordinate and abscissa, respectively.

Because of its importance to flammability, Van Krevelen identified a number of experimental indices that can be used to characterize the short-term thermal

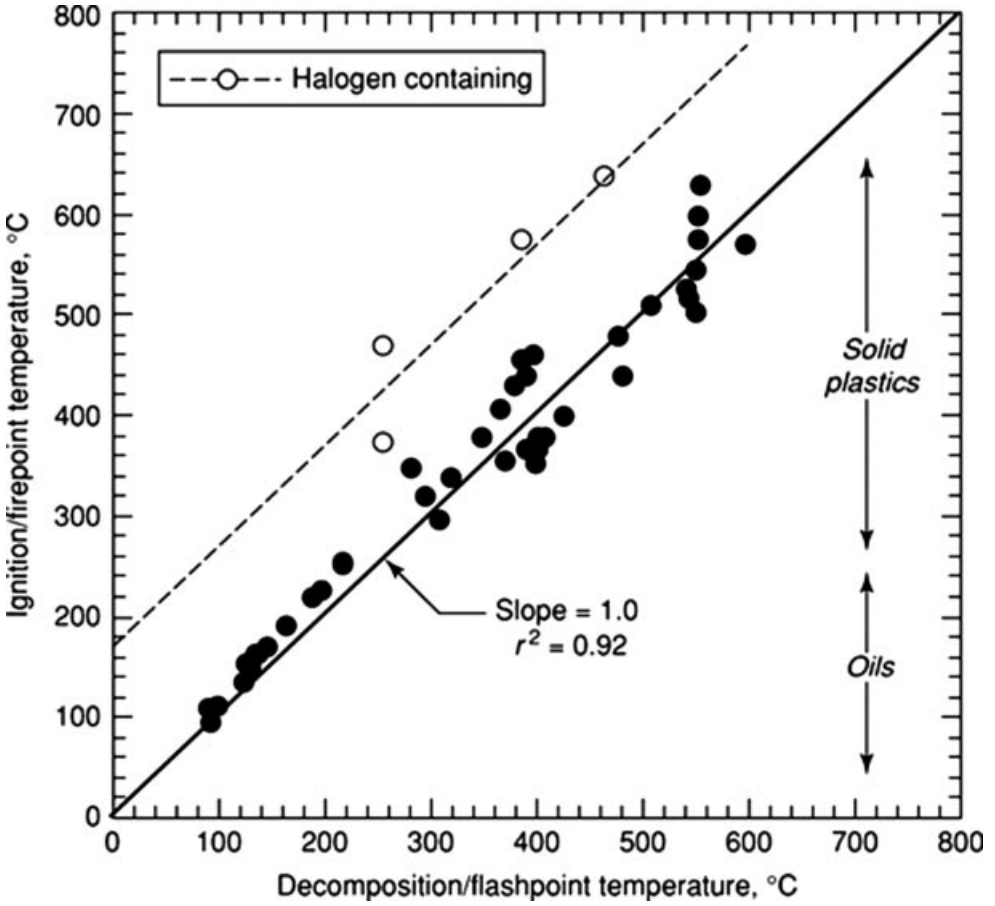

Fig. 16. Ignition/firepoint temperature versus decomposition/flashpoint temperature for solid/liquid fuels.

stability of a polymer (22). The indices, which are determined from temperature scanning thermogravimetry experiments at constant heating rates of 3–10 K/min, are T_d, the temperature (in Kelvin) at which the polymer weight loss is just measurable; $T_{d,1/2}$, the temperature at which the weight loss reaches 50% of its final value; $T_{d,max}$, the temperature at the maximum rate of weight loss; and E_a, the activation energy for pyrolysis. Noting that all of these temperatures depend on heating rate and that $T_{d,max}$ is identical to T_p in the present work, Van Krevelen proposed the following interrelationships based on tabulated data for 37 polymers (all temperatures are in Kelvin):

$$T_d = 0.9T_{d,1/2} \tag{62}$$

$$T_{d,max} = T_p \approx T_{d,1/2} \tag{63}$$

$$T_p \approx 423 + E_a \text{ (kJ/mol)} \tag{64}$$

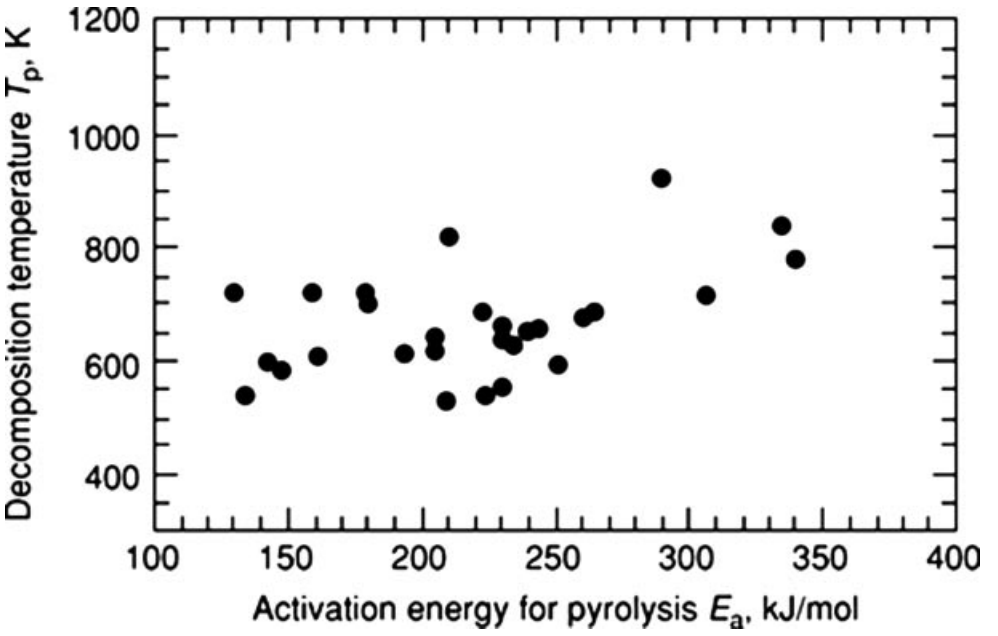

Fig. 17. Pyrolysis temperature versus activation energy of polymers.

Equation 64 can be cast in the form of equation 23 by defining a reference temperature $T_0 = E_a/R \ln(\beta*/\beta_0) = 423$ K. Equations 62–64 imply that T_p or $T_{d,1/2}$ can be used as the primary indicator of thermal stability with the other indices being roughly estimated from it. A plot of T_p versus E_a from thermogravimetric analyses of various polymers at heating rates of the order of 10 K/min is shown in Figure 17. The trend is in qualitative agreement with equation 64 but the correlation coefficient is too low (<0.5) for predictive purposes. For this reason, Van Krevelen extended the use of additive molar group contributions to the calculation of the thermal decomposition temperature. In Van Krevelen's method of calculating the thermal decomposition temperature, the molar thermal decomposition function $Y_{d,1/2}$ is related to the product of the polymer repeat unit molecular weight M and the decomposition temperature, viz.

$$MT_{d,1/2} = Y_{d,1/2} \tag{65}$$

The decomposition temperature is calculated by summing the individual molar decomposition functions $Y^i{}_{d,1/2}$ for each chemical group of molar mass M_i comprising the repeat unit:

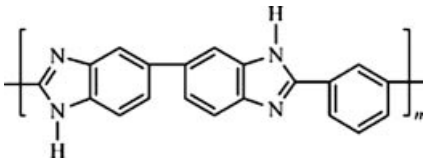
$$T_{d,1/2} = \frac{Y_{d,1/2}}{M} = \frac{\sum_j n_i Y^i_{d,1/2}}{\sum_j n_i M_i} \tag{66}$$

The molar group contribution $Y^i{}_{d,1/2}$ for each of the chemical groups comprising the polymer was determined for decomposition temperatures measured at

Table 11. Group Contributions to the Decomposition Temperature of Polybenzimidazole

Structural group, i	n_i	M_i, g/mol	$Y^i_{d,1/2}$, g · K/mol
	2	116.12	105
	1	76.09	65

a linear heating rate ≈ 3 K/min. For example, the decomposition temperature of PBI having the chemical repeat unit structure



is calculated from the $Y^i_{d,1/2}$ given in Table 11 and equation 66 as

$$T_p = \frac{(2)(105)+(1)(65)}{(2)(116.12)+(1)(76.09)} \times 1000 = 892\ \text{K} = 619^\circ\text{C}$$

which is in general agreement with the literature value $T_p \approx 903$ K and the data in Table 1 and Figure 6.

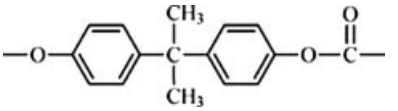
Char Yield. Pyrolysis/char residue has the character of a thermodynamic quantity since it depends only on temperature and the composition of the material through the enthalpy barriers to gas and char formation, E_g, E_c, in equation 19. The char-forming tendency of different groups is additive and roughly proportional to the aromatic (ie, nonhydrogen) character of the group (see Fig. 9). The char yield is calculated by summing the char-forming tendency per mole of carbon of the chemical groups, $C_{FT,i}$, and dividing by the molecular weight of the repeat unit (22)

$$Y_c = \frac{C_{FT}}{M} \times M_{carbon} = \frac{\sum_j n_i C_{FT,i}}{\sum_j n_i M_i} \times 12 \qquad (67)$$

The $C_{FT,i}$ are the moles of carbon remaining as char per mole of chemical group i in the polymer measured at 850°C. Negative corrections are made for aliphatic groups containing hydrogen atoms in proximity to char-forming groups because of the possibility for disproportionation and subsequent volatilization of hydrogen-terminated chain fragments that are no longer capable of recombining/cross-linking to make char. Table 12 lists the char-forming tendency of the structural units comprising bisphenol-A polycarbonate (PC) whose chemical structure is

Table 12. Group Contributions to the Char Yield of Bisphenol-A Polycarbonate

Structural group, i	n_i	M_i, g/mol	$C_{\mathrm{FT},i}$, mol · C/mol
	2	76.10	4
	1	42.08	−3
	1	44.01	0
—O—	1	16.00	0



From the data in Table 12 and equation 67 the char yield of PC is calculated to be

$$Y_c = \frac{(2)(4)+(1)(1-3)+(1)(0)+(1)(0)}{(2)(76)+(1)(42)+(1)(16)+(1)(44)} \times 12 = 0.24 = 24\%$$

which compares with the measured value $Y_c = 0.25$ in Table 3. The method is empirical and relatively simple to use and good agreement is obtained with other measured pyrolysis residues in Table 3. The char yield of polymers under anaerobic conditions is thus well described using the additive molar contributions of the individual structural groups comprising the polymer.

Heat Release Rate. Individually, the material and combustion properties κ, ρ, c, ${h_{c,p}}^0$, T_p, and μ have found limited success as descriptors of fire behavior because the coupling of gas and condensed phase burning processes is complex (eg, Fig. 2). Direct measurement of fire behavior or flammability requires about 1 kg of material from which to prepare samples and is therefore prohibitively expensive for research where only gram quantities are typically available. Separate determination of thermochemical and combustion properties using laboratory thermal analyses and combustion calorimetry requires only gram quantities of material but the process is time-consuming. Consequently, recent work has focused on identifying a flammability parameter that captures the chemical dynamics of flaming combustion in a single laboratory test using research (gram) quantities of material (10,26,29).

The heat release rate in flaming combustion, HRR, is the amount of heat Q released by gas phase combustion of unit mass of fuel m, released by pyrolysis per unit time t, and per unit area of burning surface, S. A simple dimensional analysis

gives

$$\mathrm{HRR} = \frac{1}{S}\frac{\mathrm{d}Q}{\mathrm{d}t} = \rho\delta\left(\frac{1}{m}\frac{\mathrm{d}Q}{\mathrm{d}t}\right) = \rho\delta\dot{Q}_\mathrm{c} \tag{68}$$

where ρ and δ are the average density and thickness of the mesophase, respectively. If a specific heat release rate is defined that is equation 22 multiplied by the heat of combustion of the pyrolysis/fuel gases, ${h_\mathrm{c}}^0$,

$$\dot{Q}_\mathrm{c} = \beta\left\{\frac{h_c^0(1-\mu)E_\mathrm{a}}{eRT_\mathrm{p}^2}\right\} = \beta\eta_\mathrm{c} \tag{69}$$

where

$$\eta_\mathrm{c} = \frac{h_\mathrm{c}^0(1-\mu)E_\mathrm{a}}{eRT_\mathrm{p}^2} \approx \frac{h_{\mathrm{c,p}}^0}{\Delta T_\mathrm{p}} \tag{70}$$

is a collection of thermal and combustion properties with the units [J/(kg · K)] and significance of a heat *release* capacity. The heat release capacity is the maximum amount of heat released by combustion per degree of temperature rise per unit mass of polymer in the mesophase. If the heating rate in the mesophase is β, then η_c is related to HRR

$$\mathrm{HRR} = \eta_\mathrm{c}(\chi\rho\delta\beta) = \eta_\mathrm{c} f(\dot{q}''_\mathrm{net}) \tag{71}$$

where $f(\dot{q}''_\mathrm{net}) = \chi\rho\delta\beta$ is an increasing function of the external heat flux with units of (kg · K)/(m^2 · s). Figure 18 is a plot of the average heat release rate at an external heat flux of about 50 ± 10 kW/m^2 versus η_c for the same or similar polymers. The proportionality between HRR and η_c in Figure 18 is reasonably good considering that the coefficient of proportionality $f(\dot{q}''_\mathrm{net}) = f(\dot{q}''_\mathrm{ext} + \dot{q}''_\mathrm{flame} - \dot{q}''_\mathrm{loss})$ varies with thermal stability, char-forming tendency, mesophase density, and flaming combustion efficiency in a complex way.

Equation 70 is an explicit result for a parameter, η_c, that contains most of the properties known to correlate with flammability. In particular, η_c is proportional to the fuel fraction and heat of combustion of the fuel, and inversely proportional to thermal stability (heat resistance). Because η_c is a combination of a material properties each of which is calculable from additive molar group contributions, η_c itself should be calculable from the same or similar molar groups if it is a material property.

From the additivity principle for polymer properties, a molar heat release capacity Ψ is defined (29) with units of J/(mol · K) whose functional form is equation 70 but with the thermal stability and combustion properties written as additive molar quantities **H, V, E**, and **Y/M** in place of ${h_\mathrm{c}}^0$, $(1-\mu)$, E_a, and T_p, respectively. If each chemical group i in the polymer adds to the component molar properties according to its mole fraction n_i in the repeat unit, then in terms of molar quantities

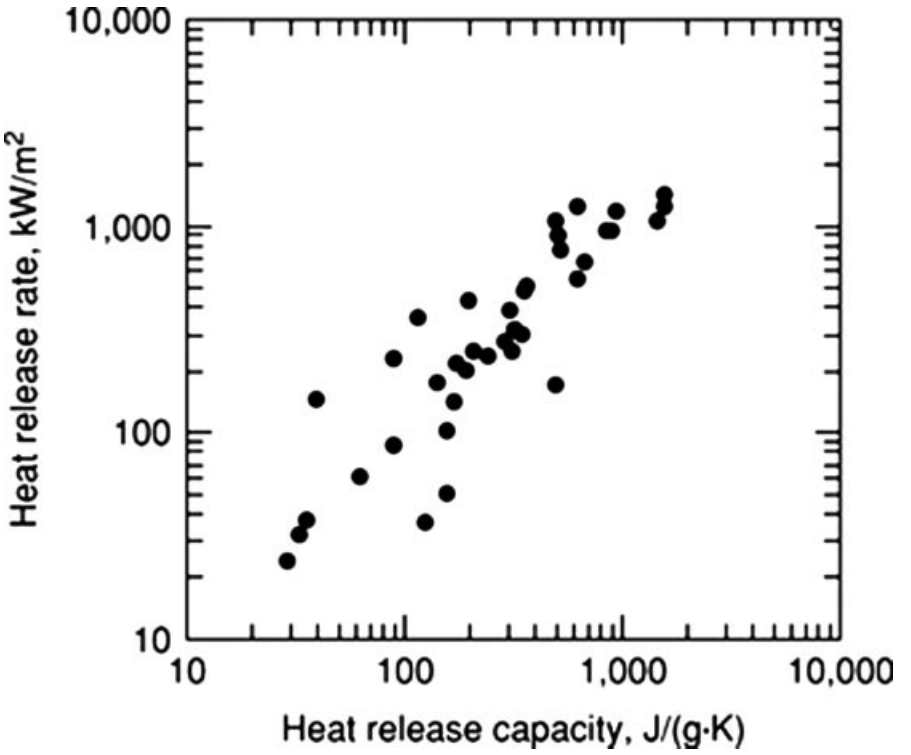


Fig. 18. Average heat release rate versus heat release capacity of polymers.

equation 70 becomes

$$\Psi = \frac{\text{HVE}}{eR(\mathbf{Y}/\mathbf{M})^2} = \frac{\left(\sum_i n_i H_i\right)\left(\sum_i n_i V_i\right)\left(\sum_i n_i E_i\right)}{eR\left(\sum_i n_i Y_i / M_i\right)} \tag{72}$$

with H_i, V_i, E_i, Y_i, and M_i being the molar heat of combustion, mole fraction of fuel, molar activation energy, molar thermal decomposition function, and molar mass of component i, respectively. Expanding the summations in equation 72 and retaining only the noninteracting terms for which $i = j = k \ldots$ (ie, neglecting terms containing products and quotients with mixed indices), the heat release capacity on a mass basis is

$$\eta_c = \frac{\Psi}{M} = \frac{\sum_j n_i \Psi_i}{\sum_j n_i M_i} = \frac{\sum_j N_i \Psi_i}{\sum_j N_i M_i} \tag{73}$$

Experimental heat release capacities η_c have been measured for over 200 polymers and the results are used to generate over 30 additive molar group contributions by treating the Ψ_i as adjustable parameters in equation 73 for polymers with known chemical structures (29). Table 8 contains η_c for a few dozen polymers. Figure 19 compares calculated and measured heat release capacities for 50 polymers using

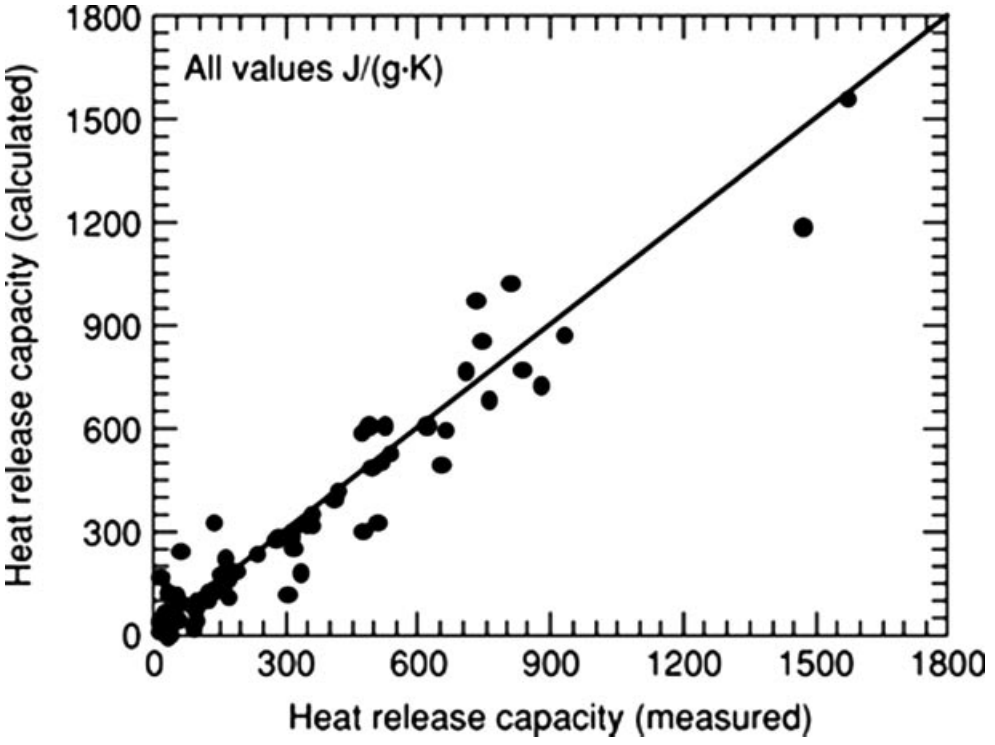

Fig. 19. Polymer heat release capacities: calculated versus measured values.

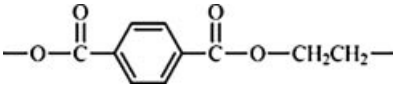
the 30 empirical Ψ_i determined by Walters and Lyon (2003). Overall agreement between measured and calculated values is about 15%, which is encouraging at this early stage of research. Additive contributions to the heat release capacity are being updated as more polymers are tested and the measurement technique improves. As an example of the additive procedure for calculating the heat release capacity, the chemical repeat unit for PET is



for which the most recent chemical group contributions are listed in Table 13. Combining the N_i, M_i, and Ψ_i for PET as per equation 73,

$$\eta_c = \frac{\sum N_i \Psi_i}{\sum N_i M_i} = \frac{(1)(28.8)+(2)(0)+(2)(16.7)}{(1)(76.10)+(2)(44.01)+(2)(14.03)} = \frac{62.2\ \text{kJ/(mol}\cdot\text{K)}}{192.18\ \text{g/mol}}$$

$$= 324\ \text{kJ/(kg}\cdot\text{K)}$$

The predicted heat release capacity for PET compares favorably with typical experimental values for this polymer, $\eta_c = 326 \pm 52$ kJ/(kg · K) (see Table 8),

Table 13. Group Contributions to the Heat Release Capacity of Poly(ethylene terephthalate)

Structural group, i	n_i	M_i, g/mol	Ψ_i, kJ/(mol · K)
	1	76.10	28.8
	2	44.01	0.0
	2	14.03	16.7

considering that the group contributions are average values derived from several different polymers.

Flame Resistance. *Flame resistance* is the ability to withstand flame impingement or give protection from it. Equation 53 shows that a critical heat release rate criterion for incipient burning/extinction gives a simple scaling relationship between flame resistance and fire behavior in terms of the heat release parameter. At the molecular level, HRR is governed by the heat release capacity (see under Heat Release Rate) which is proportional to HRR in steady burning (eq. 71) for a particular set of test conditions and material properties. Heat release capacity can be related to flame resistance in the same way that HRR was related to flame resistance (see Unsteady Burning). If the heat release rate is equation 71 and the criterion for flame extinction in flammability tests is equation 50, then flame extinction is related to heat release capacity

$$\mathrm{HRR} = \eta_c f(\dot{q}''_{\mathrm{flame}} - \dot{q}''_{\mathrm{loss}}) \leq \mathrm{HRR}^*_b \tag{74}$$

Equation 74 states that (analogous to HRR) there is a critical value of η_c below which flame extinction will occur in a flammability test:

$$\eta_c \leq \frac{\mathrm{HRR}^*_b}{f(\dot{q}''_{\mathrm{flame}} - \dot{q}''_{\mathrm{loss}})} \tag{75}$$

Figure 1 showed generic η_c and flame resistance results for commercial polymers. Figure 20 shows grouped ratings for 50 polymers in the Underwriters Laboratory vertical (V) and horizontal (H) test for flammability of plastics (27) (see section on Testing for Regulatory Compliance and Table 14). Three ranges of flammability are observed with respect to η_c in Figures 1 and 20: No ignition in a vertical test (UL 94 V0 rating or better) for $\eta_c < 200$ kJ/(kg · K); self-extinguishing (UL 94 V) behavior after 10–30 s of burning in a vertical test for $\eta_c = 200$–400 kJ/(kg · K); a self-propagating flame in a horizontal burning (HB) test for $\eta_c > 400$ kJ/(kg · K).

With regard to flammability as measured in the LOI test (25) (see section on The Limiting Oxygen Index Test), if Equation 52 applies and $\dot{q}''_{\mathrm{flame}}(\mathrm{extinction}) = \varphi \mathrm{LOI}$, then equation 74 gives the criterion for flame extinction

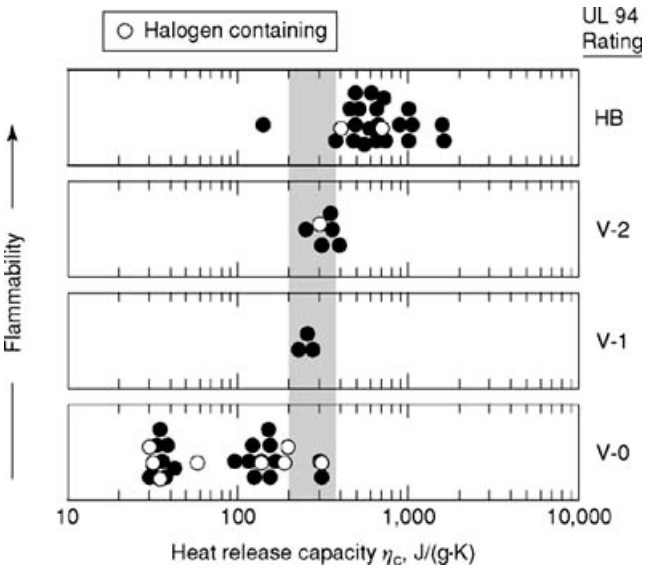


Fig. 20. Flammability rating in UL 94 test versus heat release capacity of 50 polymers.

in the LOI test:

$$\eta_c \leq \frac{\mathrm{HRR}_b^*}{f(\varphi \mathrm{LOI} - \dot{q}''_{\mathrm{loss}})} \tag{76}$$

Equation 76 suggests that LOI and η_c are inversely related. Figure 21 is a plot of generic values of LOI versus η_c (see Table 8). A power law $\mathrm{LOI} = 125/\eta_c^{1/4}$ can be fit to the data with reasonable accuracy (correlation coefficient = 0.84), confirming the inverse relationship between LOI and η_c suggested by equation 76.

Smoke. The *smoke extinction area* (SEA; m^2/kg) is a global measure of the condensed phase (liquid and solid) products of flaming combustion having units of square meters of particulate scattering surface per kilogram of material burned. The SEA is measured in a fire calorimeter under well-ventilated conditions from optical extinction of the combustion gas stream (25). Table 15 lists the specific SEA for a variety of polymers averaged from the literature. Figure 22 is a plot of SEA in Table 15 versus the flaming combustion efficiency of the same polymer

Table 14. UL 94 20-mm Vertical Burning Test Classification Criteria

	Classification		
Observation	V-0	V-1	V-2
t_1 or t_2 for any specimen	10 s	30 s	30 s
$t_1 + t_2$ for 5 specimens	50 s	250 s	250 s
$t_2 + t_3$ for any specimen	30 s	60 s	60 s
Afterflame or afterglow up to clamp, any specimen	No	No	No
Ignition of cotton	No	No	Yes

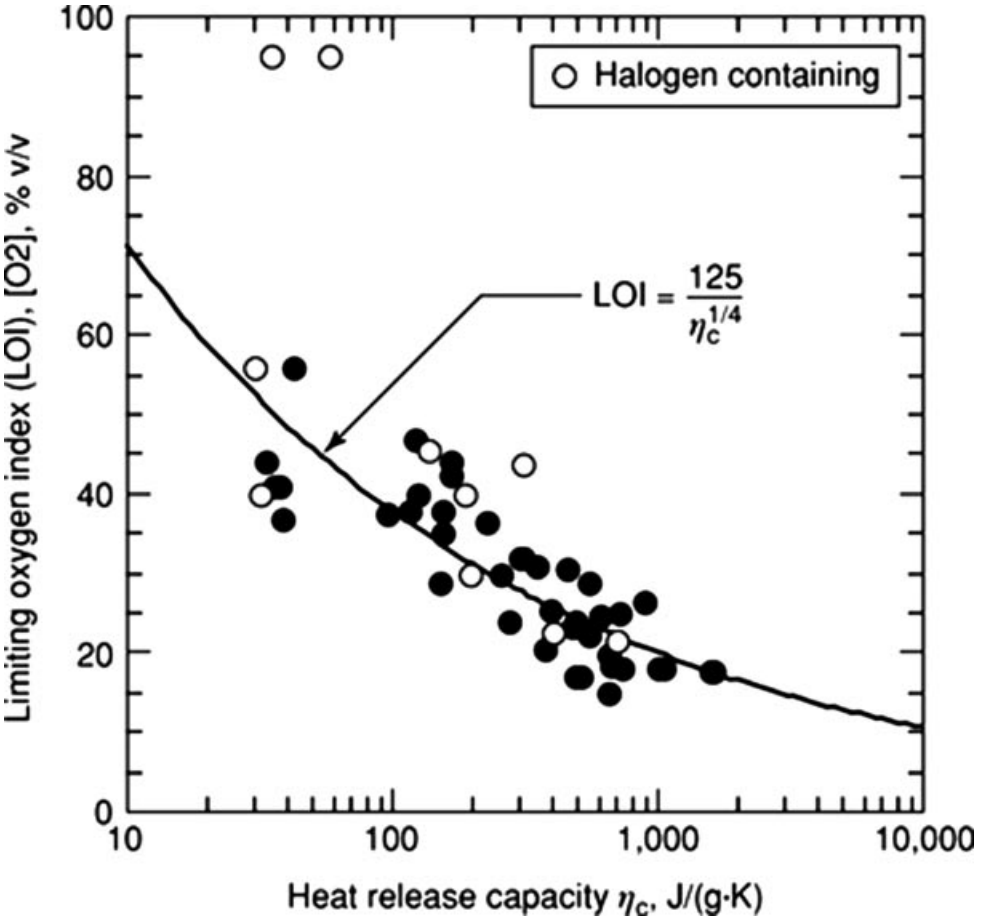

Fig. 21. Limiting oxygen index versus heat release capacity for 50 polymers.

listed in Table 7. It is seen that SEA varies by a factor of 100 between different polymers and is particularly sensitive to combustion efficiency in the range $\chi = 0.8–1.0$. Below $\chi = 0.8$, SEA is essentially independent of combustion efficiency.

The effect of chemical structure on smoke production can generally be described as follows. Aliphatic oxygenated fuels (POM, PMMA, PA) and those with high thermal stability (PBI, PAI, PEI, PES, PEEK, PAS) or extremely low burning rate (PTFE, CPVC, wood) tend to produce less smoke per unit mass of material burned than aliphatic (PE, PP), aromatic oxygen- and nitrogen-containing (PET, PBT, EP, PC, PU, BMI, VE, PPO) or aromatic sulfur-containing (PSU, PPS) polymers.

Polymers with low thermal stability and pendant (ABS, PS) or backbone (EP, UPT, VE, PPO) aromatic groups produce a large amount of smoke because their thermal degradation products (fuel gases) contain the aromatic nucleus for soot formation (see under The Gas Phase).

Low thermal stability aromatic polymers with high SEA (ABS, EP, PS) produce 50% more smoke per unit mass when brominated flame retardants are added

Table 15. Smoke Extinction Area of Polymers

Polymer	SEA, m^2/kg

to inhibit combustion. These materials, listed at the bottom of Table 15, produce 5–20 times more smoke per unit mass than the commodity and engineering polymers in the top half of the table. Silicones are anomalous with respect to SEA because the scattering particles are silica (SiO_2), which is a complete (rather than incomplete) combustion product of the backbone silicon.

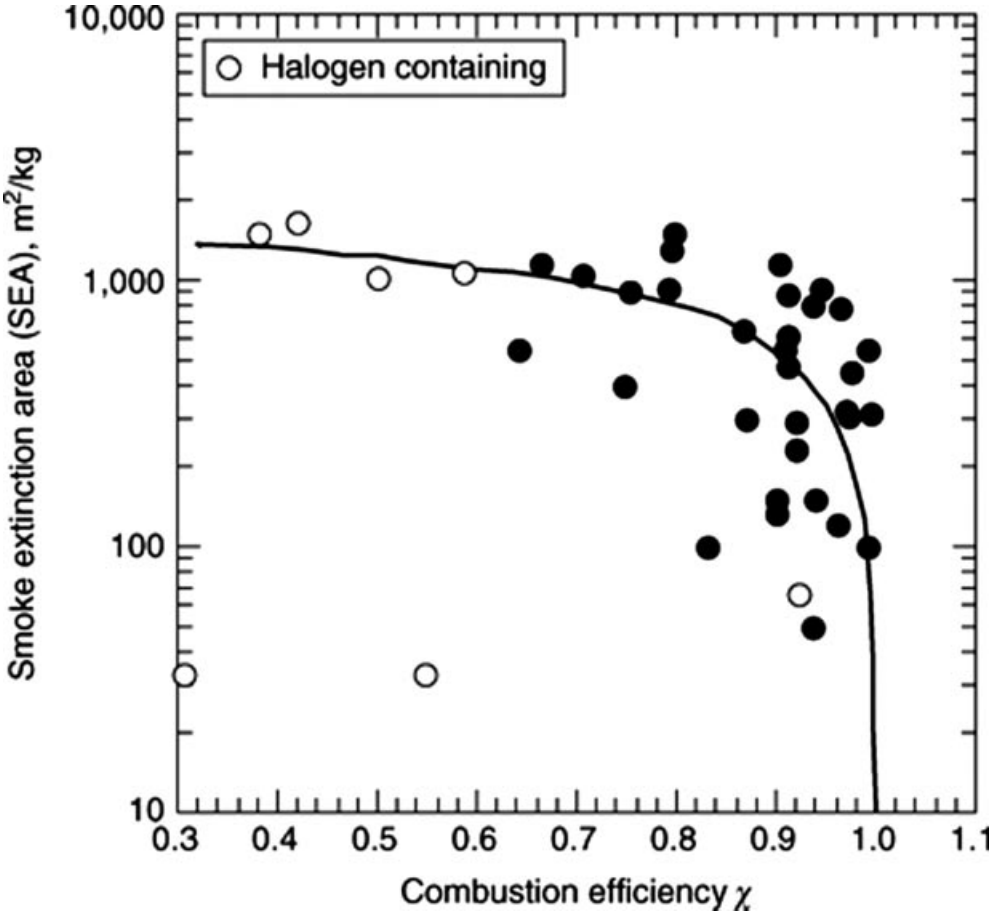

Fig. 22. Smoke extinction area (SEA) versus flaming combustion efficiency (χ) for 40 polymers.

The highest SEAs are associated with halogen-containing polymers (rigid and flexible PVC, PMMA/PVC alloy) apparently because of combustion inhibition by chlorine (see equations 1–3 and Fig. 22).

The smoke point is another measure of the tendency of a fuel to produce smoke and this quantity, like SEA, is related to the chemical composition and structure of the fuel. The *smoke point* is defined as the minimum fuel mass flow rate at which smoke first escapes from the tip of a laminar diffusion flame (see Fig. 2), ie, the residence time of the smoke in the combustion zone becomes too short to effect complete oxidation. The results of the smoke point test are qualitatively similar to the SEA data in Table 15 with respect to chemical structure and smoke-forming tendency. In particular, it is found that the smoke-forming tendency, as determined by smoke point measurements, is lowest for oxygenated fuels (alcohols, aldehydes, esters, ethers) and increases through the series alkanes, branched alkanes, alkenes, and aromatics.

Fire and Flammability Tests

Terminology: Fire versus Flammability. There is no universal agreement on the definition of flammability tests and how they are different from fire tests. A common application of fire and flammability tests is to obtain data for regulatory compliance, as will be discussed in the next section. Fire safety codes and regulations are generally based on two strategies. The first strategy involves preventing, or at least minimizing the likelihood of ignition. Since in practice it is not possible to completely eliminate ignition, the second strategy involves managing the impact of a subsequent fire.

Flammability tests are typically associated with the first strategy. A small specimen (linear dimensions of the order of centimeters or inches) of a polymer is exposed to a small heat source (Bunsen burner-type flame, hot wire, etc.) for a short duration (seconds). Pass/fail criteria are based on ignition of the specimen during exposure, formation of flaming droplets, and/or sustained flaming or smoldering after removal of the heat source.

For the purpose of this article, fire tests are associated with the second strategy and defined as experimental methods to characterize the behavior of polymers under more severe thermal exposure conditions that are representative of the growth phase of a compartment fire. These conditions are simulated with a gas-fired or electrical heater or a large gas burner turbulent diffusion flame (flame length of the order of a meter or several feet). The incident heat flux to the specimen is primarily radiative when heaters are used, and mainly convective for flame exposure. Total incident heat flux varies from approximately 1 kW/m^2 to more than 100 kW/m^2. Note that the maximum radiant heat flux from the sun on earth is approximately 1 kW/m^2. Polymers that are not treated with fire retardant chemicals typically ignite when exposed to heat fluxes of 10–20 kW/m^2 in the presence of a small pilot flame or hot spark.

The aforementioned definitions imply that flammability tests are concerned with a lower level of performance. Passing a flammability tests does not mean that a material will be less hazardous when involved in a fire. This is consistent with one definition of the term *flammable*, which in ASTM E176, *Terminology of Fire Standards*, is described as, subject to easy ignition and rapid flaming combustion (25).

The characteristics that are measured in a fire test are indicative of the performance of the material under the conditions of the test and are therefore referred to as fire-test-response characteristics. They may or may not be indicative of the hazard of a material under actual fire conditions. The most common fire-test-response characteristics that are measured in fire tests are the ease of ignition, flame spread, heat release, smoke generation and toxic potency of smoke (20,25).

Fire and Flammability Test Applications. There are three distinct applications of fire and flammability tests as discussed below.

Regulatory Compliance. Codes and regulations have been developed in many countries to ensure a level of public fire safety that is acceptable to society. The main objectives of these codes and regulations in terms of fire and flammability of materials are to limit the likelihood of ignition and to reduce the rate of fire growth to the critical stage of flashover in the compartment of fire origin. In addition, codes and regulations also limit the quantities of particulate matter

(affects visibility) and of toxic/corrosive products of combustion that can cause human casualties and excessive damage to equipment.

Codes and regulations are intended to provide a minimum level of safety based on loss objectives that are acceptable to society. Other stakeholders often specify additional requirements. For example, an insurance company might have more stringent requirements to reduce the risk of incurring excessive losses in the event of a fire. Building owners and operators might require a level of safety that exceeds the building code. Manufacturers of transportation vehicles might issue specifications for their product suppliers that go beyond the regulations.

Codes, regulations, and specifications specify acceptance criteria for the products that are used in specific areas of the environment that is regulated. These criteria are based on performance in one or more fire or flammability tests. This approach has been applied extensively to two environments where the potential exists for large life loss: buildings and transportation vehicles. Some important fire and flammability tests that are used in different parts of the world to ensure a specific level of safety in these two environments are summarized in subsequent sections of this article.

Quality Assurance and Research. Fire and flammability tests are also used in support of production control. The objective of a production control program is to ensure that a product that is sold in the marketplace is identical to the specimen that was originally tested for regulatory compliance. Often it is not practical or economically feasible to use the qualification test(s) in a follow-up production control program and a simple test is often adequate to verify consistency of the product. Relatively simple flammability tests are therefore most often used for the purpose of quality assurance. The same tests are then also used in research and development of new products.

Data for Fire Safety Engineering Design and Analysis. Fire safety codes and regulations are largely prescriptive. This means that they contain acceptance criteria for materials, products, and assemblies based on performance in one or several tests. The overall level of safety that is accomplished is not explicitly stated. Sometimes it is not possible to demonstrate that a material, product, or assembly meets the specified acceptance criteria. For example, it might not be possible to obtain a valid test result for a product that melts and shrinks away from the heat source in a fire test. Fire safety codes and regulations generally contain a clause that gives the enforcing official the authority to accept a variance from the specified acceptance criteria. To persuade the enforcing official it is necessary to demonstrate that the material, product, or assembly does not compromise the level of safety that is implicit in the code or regulation. This usually requires an engineering analysis and tests to obtain material properties that are needed in support of the analysis.

In recent years performance-based codes and regulations have become increasingly popular. Such codes and regulations explicitly state the minimum level of performance of the system (building, railcar, etc.) in case of fire. That a particular design meets the specified level of performance is again based on an engineering analysis. Similar analyses are performed in support of the investigation and reconstruction of actual fire incidents.

Fire and Flammability Test Standards. Regardless of the application, it is important that fire and flammability test methods be free of systematic error

(bias). It is also essential that consistent results can be obtained from experiments repeated at different times within one laboratory (repeatability) and that there is reasonable agreement between the results for the same material, product, or assembly tested in different laboratories (reproducibility). These are the reasons why fire safety codes, regulations, and specifications refer to standardized fire and flammability test methods and why test data needed in support of fire engineering are obtained with standardized experimental protocols.

Consensus-Based Test Standards. Most fire and flammability test standards are developed by consensusbased committees. The rules and procedures by which these committees operate ensure that the development cannot be dominated by a single interest group and that there is reasonable agreement between the different interest groups represented on the committee.

The primary consensus-based organizations in the United States developing and maintaining fire and flammability test standards are ASTM International (previously the American Society for Testing and Materials) and the National Fire Protection Association (NFPA). Committee E05 on Fire Tests is the primary committee in ASTM that develops fire and flammability test standards (25). Several material- or product-oriented Committees have subcommittees that develop fire and flammability test standards as well. For example, Committee D20 on Plastics has a subcommittee on thermal properties (D20.30) that develops and maintains some fire and flammability test standards for plastics. The Fire Test Committee is responsible for all fire and flammability test standards that are used by any of the fire safety codes and standards published by NFPA. A number of test laboratories in the United States, such as Underwriters Laboratories and FM Global, have established a consensus process that meets the requirements of the American National Standards Institute (ANSI) so that they now can publish American National Standards.

International fire and flammability test standards are developed by the International Organization for Standardization (ISO) and the International Electrotechnical Committee (IEC). The latter is concerned with electrical products only. Technical committees TC 92 and TC 89 are the primary committees that develop and maintain fire and flammability test standards in ISO and IEC respectively. As in ASTM, there are a number of product- or industry-specific committees in ISO that also develop fire and flammability test standards. For example, SC1 on Test Methods of ISO TC 136 on Furniture has published two ignition tests for upholstered seating. An important difference between ISO and IEC vs ASTM and NFPA is that the international committees establish consensus on a geographical basis. Each country that actively participates in the work can be a voting member on an ISO or IEC committee. Committees are composed in a similar manner in CEN and CENELEC, which are the European counterparts of ISO and IEC respectively. However, member countries can have multiple votes in CEN and CENELEC committees. The number of votes is a function of the population of the country.

Other Types of Test Standards. There are also many fire and flammability tests methods that are not developed by a consensus-based process. In the United States these types of test standards are typically promulgated by regional or federal government agencies. The latter are published as part of the regulations that refer to these test methods in the Code of Federal Regulations (CFR), although

many federal regulations rely on consensus-based test standards. Some federal fire and flammability test standards are also described in military specifications (MIL specs) issued by the different agencies of the Department of Defense. The U.S. government has recognized the advantages of using test standards that have been subjected to a review and are accepted by all interest groups and is now actively supporting the adoption of consensus-based tests standards. Examples of regional fire and flammability test standards that are not consensus-based are the California Technical Bulletins to assess the fire and flammability characteristics of upholstered furniture and mattresses. Finally, specifications for suppliers issued by manufacturers of passenger airplanes, railcars, etc., might also rely on fire and flammability test procedures that have not been developed by a consensus-based process. For example Airbus, Boeing, and Bombardier all have their own fire and flammability test standards.

Testing for Regulatory Compliance. There are literally hundreds of fire and flammability tests for polymers (5,25). It is not possible to provide an overview of these tests in this article. A few important tests have been selected to illustrate the key concepts. These tests include the ones that are referred to in the first four sections of this article: the UL 94 20-mm vertical burning test (27), the limiting oxygen index test (25), the cone calorimetry (25), and the pyrolysis combustion flow (29) calorimetry. For guidance on available fire and flammability test methods to evaluate polymers, the reader is referred to ASTM D3814, *Standard Guide for Locating Combustion Test Methods for Polymeric Materials* (25). A comprehensive review of fire and flammability tests used in support of codes and regulations in different parts of the world can be found in Troitzsch (5).

Typical Example of a Flammability Test. The UL 94 standard provides procedures for bench-scale tests to determine the acceptability of plastic materials for use in appliances or other devices with respect to flammability under controlled laboratory conditions. The standard includes several test methods that are employed depending upon the intended end use of the material and its orientation in the device. The standard outlines two horizontal burning tests, three vertical burning tests, and a radiant panel flame spread test. The most commonly used method is summarized below as a typical example of a flammability test.

The first vertical burning test described in the UL 94 standard is the "20-mm Vertical Burning Test; V-0, V-1, or V-2." A photograph of the test cabinet is shown in Figure 23. The V-0, V-1, or V-2 classification is based on the duration of afterflaming or afterglowing following the removal of the burner flame, as well as the ignition of cotton by dripping particles from the test specimen.

In this test, specimens measuring 125 mm in length and 13 mm in width are suspended vertically and clamped at the top end. A thin layer of cotton is positioned 300 mm below the test specimen to catch any molten material that may drop from the specimen. A 20-mm-long flame from a methane burner is applied to the center point on the bottom end of the specimen. The burner is positioned such that the burner barrel is located 10 mm below the bottom end of the material specimen. The flame is maintained for 10 s, and then removed to a distance of at least 150 mm. Upon flame removal, the specimen is observed for afterflaming and its duration time recorded (t_1). As soon as the afterflame ceases, the burner flame is reapplied for an additional 10 s, and then removed again. Durations of afterflaming (t_2) and/or afterglowing (t_3) are noted. On the basis of the results,

Fig. 23. UL 94 cabinet. Photo Courtesy of Fire Testing Technology © 2004.

the material is classified as either V-0, V-1, or V-2 based on the criteria outlined in Table 14.

Typical Examples of Fire Tests. The following two examples are commonly used tests that illustrate two distinct approaches to simulate the thermal exposure conditions in a pre-flashover compartment fire. The steiner tunnel test uses a gas burner to heat the specimen primarily by convection. The radiant flooring panel test relies on a gas-fired panel that exposes a flooring specimen to a radiant heat flux profile.

The Steiner Tunnel Test. The primary intent of the steiner tunnel test is to quantify the wind-aided flame spread propensity of the material tested. It is

Fig. 24. The steiner tunnel test. Photo Courtesy of Southwest Research Institute © 2004.

the most common reaction-to-fire test method prescribed by U.S. model building codes. The steiner tunnel test is described in ASTM E84, *Standard Test Method for Surface Burning Characteristics of Building Materials*, and NFPA 255, *Standard Method of Test of Surface Burning Characteristics of Building Material.* The apparatus, as shown in Figure 24, consists of a long tunnel-like enclosure measuring 8.7 × 0.45 × 0.31 m. The test specimen is 7.6 m long and 0.51 m wide, and is mounted in the ceiling position. It is exposed at one end, designated as the burner end, to a 79 kW gas burner. There is a forced draft through the tunnel from the burner end, with an average initial air velocity of 1.2 m/s. A smoke photometer is mounted on the exhaust duct. The photometer consists of a white light source on one side of the duct and a photocell on the opposite side of the duct.

The measurements consist of flame spread over the surface and light absorption in the exhaust duct of the tunnel. Test duration is 10 min. A flame-spread index (FSI) is calculated on the basis of the area under the curve of flame tip location versus time. The FSI is 0 for an inert board, and is normalized to approximately 100 for red oak flooring. The smoke developed index (SDI) is equal to 100 times the ratio of the area under the curve of light absorption versus time for the 10-min test duration to the area under the curve for red oak flooring. Thus, the SDI of red oak flooring is 100, by definition.

The classification of linings in the model building codes in the United States is based on the FSI. There are three classifications: Class A, or I, for products with FSI $\leq$ 25, Class B, or II, for products with 25 $<$ FSI $\leq$ 75, and Class C, or III, for products with 75 $<$ FSI $\leq$ 200. Class A, or I, products are generally permitted in

stairways. Class B, or II, products can be used in corridors, and Class C, or III, products are allowed in other rooms and areas. The model building codes do not permit interior finishes that produce excessive amounts of light-obscuring smoke. Products that have to be tested according to the tunnel test must have an SDI of 450 or less.

The Radiant Flooring Panel Test. The National Bureau of Standards (NBS; currently the National Institute of Standards and Technology, or NIST) conducted a series of full-scale fire tests in the 1970s to investigate the fire hazard of floor coverings. The main concern was flame spread from a fire room to a connected corridor. This work resulted in the development of the radiant flooring panel test. This test is described in ASTM E648, *Standard Test Method for Critical Radiant Flux of Floor Covering Systems Using a Radiant Heat Energy Source*, and NFPA 253*, Standard Method of Test for Critical Radiant Flux of Floor Covering Systems Using a Radiant Heat Energy Source*. The international version of this test method, ISO 9239-1*, Reaction to Fire Tests for Floor Coverings—Determination of the Burning Behavior Using a Radiant Heat Source*, includes a photometer in the exhaust stack to measure smoke optical density (see Fig. 25).

The Radiant Flooring Panel Test apparatus consists of an air–gas-fueled radiant heat panel inclined at 30° to and directed at a horizontally mounted floor covering system specimen. The radiant panel generates a heat flux distribution along the 1-m length of the test specimen from a nominal maximum of 10 kW/m^2 (1 W/cm^2) to a minimum of 1 kW/m^2 (0.1 W/cm^2). The test is initiated by open-flame ignition from a pilot burner. The heat flux at the location of maximum flame propagation is reported as the critical radiant flux.

Rate of Heat Release Test for Aircraft Cabin Materials. The Federal Aviation Administration requires (14 CFR 25.853) that large areas including interior ceiling and wall panels, partitions, galley structures, cabinets, and stowage compartments of commercial transport aircraft pass a rate of heat release test in addition to flammability and smoke tests. The rate of heat release apparatus (see Fig. 26) is a modified version of the ASTM E906, *Standard Test Method For Heat And Visible Smoke Release Rates of Materials and Products (configuration A)*. Samples are 150 × 150 mm and are cut from cabin components or tested in representative thickness. Samples are exposed to a radiant heat flux of 35 kW/m^2 in a vertical orientation and ignited by an impinging pilot flame. The rate of heat released by flaming combustion is deduced from the calibrated temperature rise of the air stream passing over the sample surface at a prescribed flow rate. The maximum rate of heat release cannot be greater than 65 kW/m^2 over the entire duration of the 5-min test and the heat released during the first 2-min of the test cannot be greater than 65 (kW · min)/m^2.

Testing for Quality Assurance and Research.

The Limiting Oxygen Index Test. The LOI test is a typical example of a method that is used to control the production of materials, products, and assemblies and in research to develop new products. This test is standardized in North America as ASTM D2863, *Standard Test Method for Measuring the Minimum Oxygen Concentration to Support the Candle-Like Combustion of Plastics (Oxygen Index)*, and internationally as ISO 4589-2 *Plastics—Determination of Burning Behavior by Oxygen Index—Part 2: Ambient-Temperature Test*. The test does not correlate well with other fire and flammability tests nor does it provide a reliable

Fig. 25. The radiant flooring panel test. Photo Courtesy of Fire Testing Technology © 2004.

indication of material performance in real fires. However, the results appear to be very sensitive to the composition of the material and the test is therefore ideally suited to serve as a quality assurance tool of fire-retardant-treated materials.

The LOI test apparatus consists of a glass tube of 75–100 mm in diameter and 450–500 mm in height. Figure 27 shows a photograph of the apparatus. A specimen with a height between 70 and 200 mm and a width of 10–20 mm is

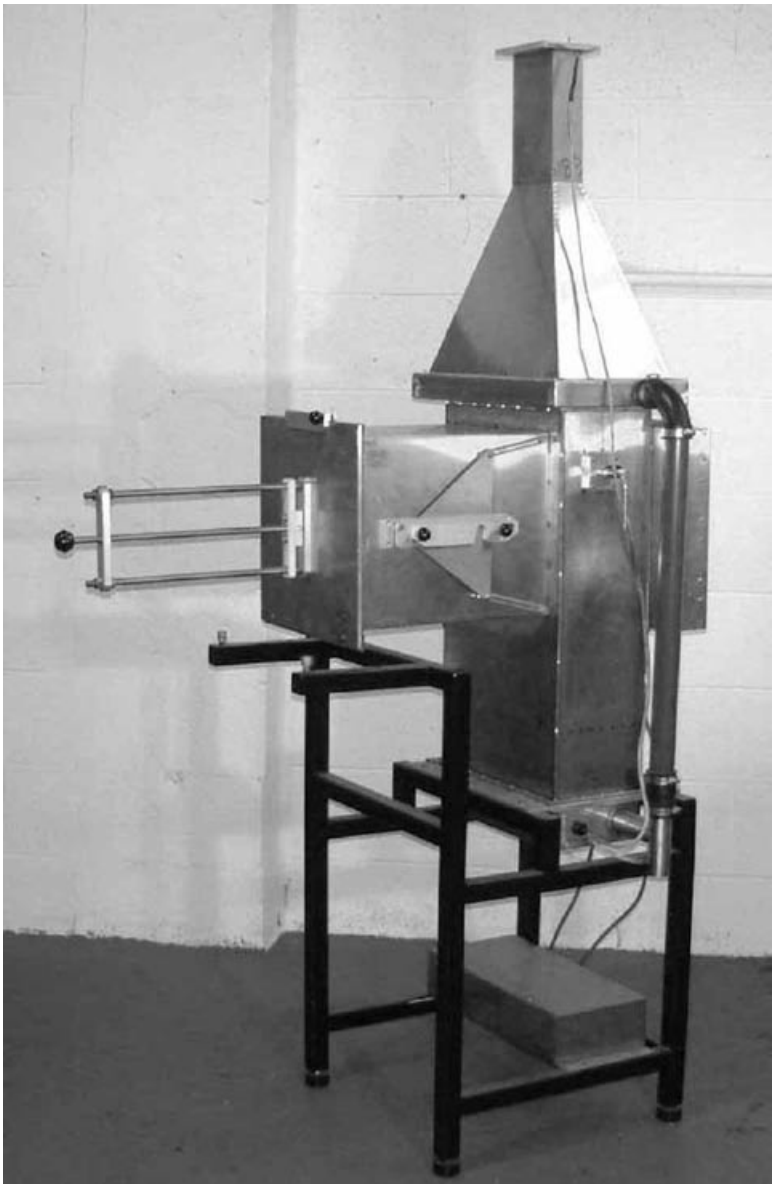

Fig. 26. Rate of heat release apparatus. Photo Courtesy of The Govmark Organization, Inc.

supported inside the glass tube. A gas mixture of oxygen and nitrogen is supplied at the bottom of the tube and a small candle-like flame is applied to the top of the specimen in an attempt to ignite it. The objective is to find the minimum oxygen concentration in nitrogen that will result in sustained combustion for at least 3 min or excessive flame propagation down the specimen. The dimensions of the specimen and the limit of excessive flame propagation depend on the type of material that is being tested.

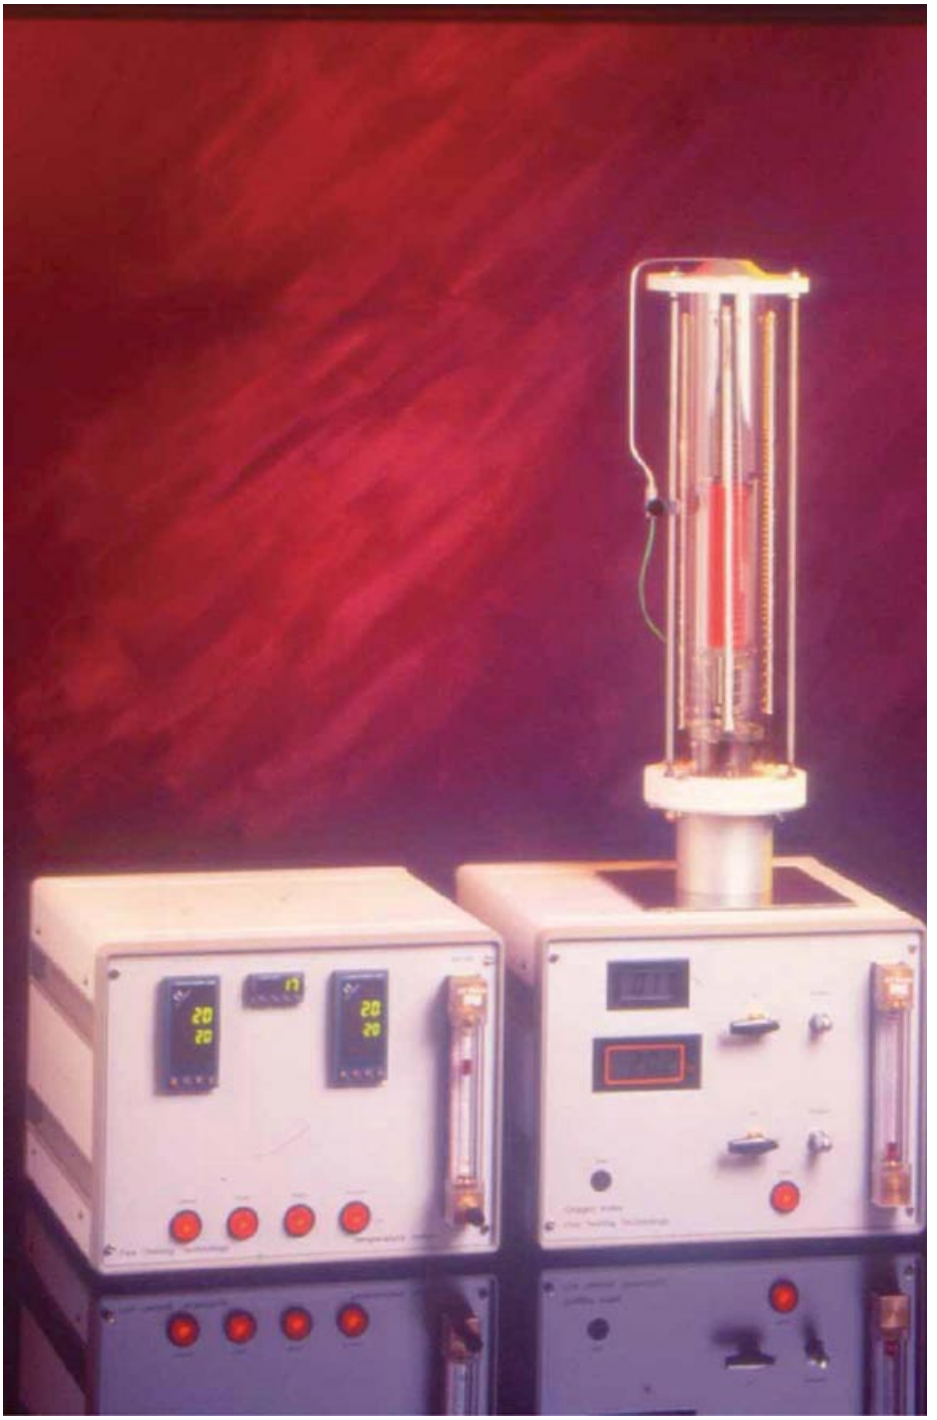

Fig. 27. The limiting oxygen index test. Photo Courtesy of Fire Testing Technology © 2004.

The Pyrolysis-Combustion Flow Calorimetry. Pyrolysis-combustion flow calorimetry (PCFC) is a method for measuring quantitative flammability parameters of combustible materials and is used in research to develop new polymers with improved fire performance (see Lyon and Walters). In PCFC the condensed-phase and gas-phase processes of flaming combustion are separately reproduced through controlled pyrolysis of milligram samples in an inert gas stream and high temperature thermal oxidation (combustion) of the pyrolyzate in excess oxygen. The rate of heat released by combustion per unit mass of sample during the test (specific heat release rate; see under Heat Release Rate) is measured by oxygen consumption calorimetry (see Enthalpy of Gasification). Time integration of the specific heat release rate gives the net heat of combustion of the fuel gases, $h_c{}^0$. The maximum value of the specific heat release rate, normalized for the sample heating rate, is a material flammability parameter with the units and significance of a heat (release) capacity that is a good predictor of flame test results and fire performance. The temperature at maximum specific heat release rate is a good approximation of the ignition temperature (see sections on Ignition; Ignition Temperature as well as Table 1).

Testing to Obtain Engineering Data. Heat release rate is the primary characteristic to quantify the fire hazard of a material. Most fire tests to obtain engineering data therefore measure heat release rate. The rate of heat release is generally determined using oxygen consumption calorimetry. In 1917, Thornton showed that for a large number of organic liquids and gases, a nearly constant net amount of heat is released per unit mass of oxygen consumed for complete combustion. Sixty years later, researchers at NBS also found this to be true for organic solids and obtained an average value for this constant of 13.1 MJ/kg of O_2. This value may be used for practical applications and is accurate with very few exceptions to within ±5%. Thornton's rule implies that it is sufficient to measure the oxygen consumed in a combustion system in order to determine the net heat released. This method, generally referred to as "oxygen consumption calorimetry," is now the most widely used and accurate method for measuring heat release rate in experimental fires. A summary of the most commonly used oxygen consumption calorimeters follows.

Bench-Scale Calorimeters.

The Cone Calorimeter. The cone calorimeter is standardized in North America as ASTM E1354, *Test Method for Heat and Visible Smoke Release Rates for Materials and Products Using an Oxygen Consumption Calorimeter*, and internationally as ISO 5660-1*, Fire Tests—Reaction to Fire—Part 1: Rate of Heat Release from Building Products (Cone Calorimeter Method)*. A photograph of a commercial version of the cone calorimeter is shown in Figure 28.

A square sample of 100 × 100 mm is exposed to the radiant flux of an electric heater. The heater has the shape of a truncated cone (hence the name of the instrument) and is capable of providing heat fluxes to the specimen up to 100 kW/m^2. An electric spark plug is used for piloted ignition. Heater temperature is measured as an average of the readings of three thermocouples in contact with the coil. It is set and maintained at a certain level by a three-term controller. Calibration of heat flux as a function of heater temperature is performed with a total heat flux meter of the Schmidt-Boelter type. Prior to testing, the heater temperature is set at the appropriate value resulting in the desired heat flux.

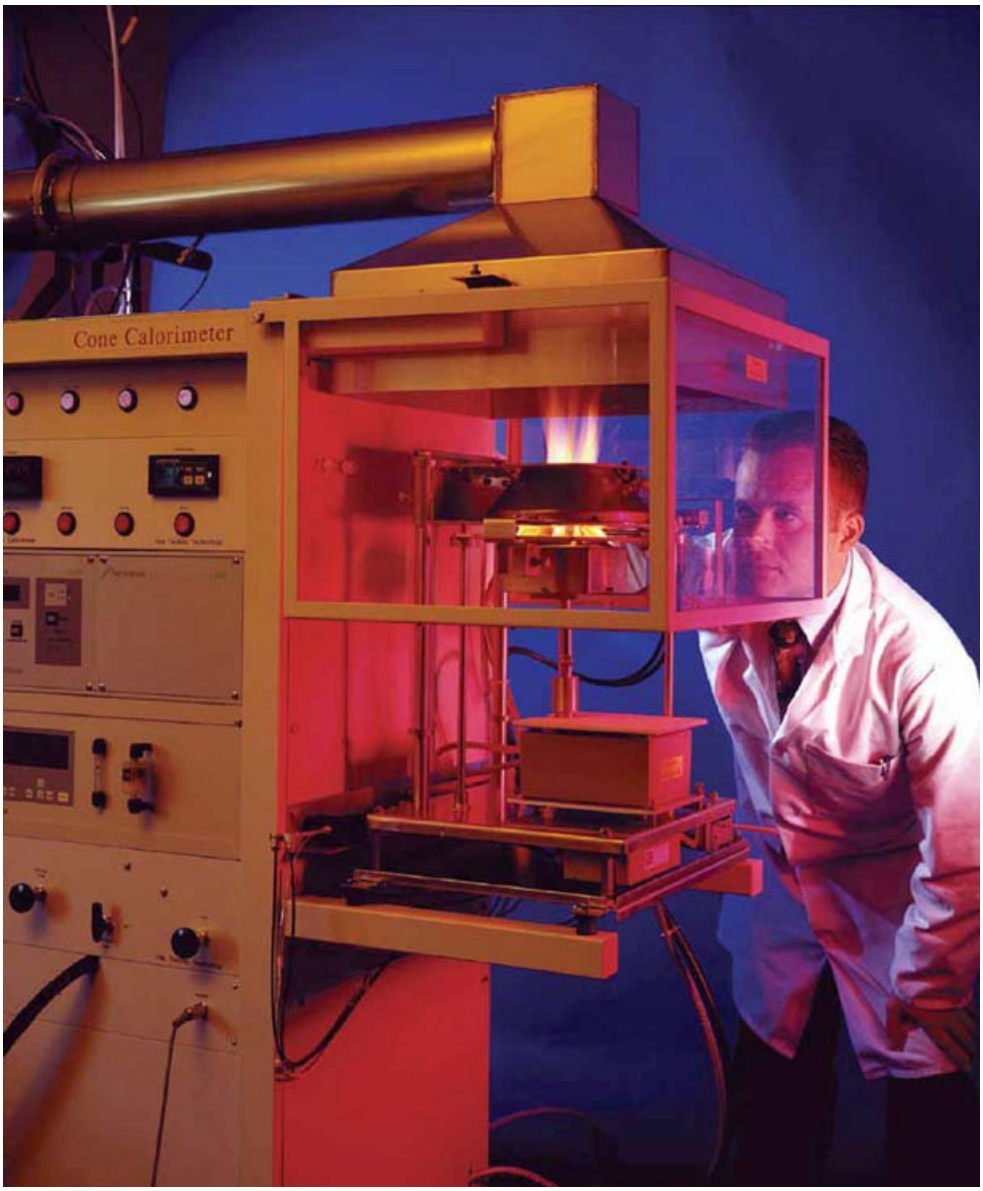

Fig. 28. Commercial version of the cone calorimeter. Photo Courtesy of Fire Testing Technology © 2004.

At the start of a test, the specimen in the appropriate holder is placed on the load cell, which is located below the heater. The load cell has a tare adjustment so that high accuracy mass loss measurements can be made, even if the mass of the holder and a possible substrate are much higher than that of the specimen. As soon as the pyrolysis products released by the specimen ignite, the electric spark plug is removed. All combustion products and entrained air are collected in the hood. An orifice plate at the entrance of the exhaust duct results in an almost uniform

gas mixture. At a sufficient distance downstream from the mixing orifice, a gas sample is taken and analyzed for O_2. A laser photometer is located close to the gas sampling point to measure light extinction by the smoke. The exhaust gases are removed by a high temperature blower. The flow rate can be adjusted between 0 and 50 L/s. For standard testing, the cone calorimeter is used in constant volume mode and the fan speed is set at 24 L/s. Downstream of the fan is a second orifice plate. Measurements of the differential pressure across and gas temperature at the orifice plate are used for calculating the mass flow of the exhaust gases.

The cone calorimeter can also be used to obtain other data in support of fire safety engineering analysis. For example, the instrument can be used to determine ignition characteristics of a material by measuring the time to ignition at different heat flux levels. A laser smoke photometer is mounted on the duct to determine the smoke production rate. A continuous gas sample can be taken from the exhaust duct and analyzed to determine the concentration of different toxic and corrosive products of combustion in the effluents. Fourier transform infrared spectroscopy is now a common method to measure the concentration of toxic and irritant gases in the exhaust duct of the cone calorimeter.

The Fire Propagation Apparatus. The fire propagation apparatus was developed by FM Global Research (previously Factory Mutual Research Corp.). The test is described in ASTM E2058, *Standard Test Methods for Measurement of Synthetic Polymer Material Flammability Using a Fire Propagation Apparatus (FPA)*. A photograph of a commercial version of the fire propagation apparatus is shown in Figure 29.

Fig. 29. Commercial version of the fire propagation apparatus. Photo Courtesy of Fire Testing Technology © 2004.

The fire propagation apparatus is similar to the cone calorimeter and can be used to obtain the same types of measurements. However, there are some significant differences that are briefly summarized below:

(1) The products of pyrolysis are ignited with a small hydrogen flame that is located 10 mm above the center of the specimen.
(2) The specimen is surrounded by a quartz tube. This makes it possible to conduct tests in a vitiated or oxygen-enriched atmosphere. The tube allows for a forced flow over the specimen surface and reduces the effect of external heat flux and specimen surface temperature on convective heat losses prior to ignition.
(3) Specimens are heated by high temperature (approximately 2300 K) tungsten filament lamps that are located outside the quartz tube. Since the spectral response of many materials is different for a radiant heat source at this temperature compared to heat fluxes in fires from sources at much lower temperatures, specimens have to be blackened. In addition, because of the type of heaters that is used and the quartz tube arrangement, the maximum incident heat flux that can be obtained is 70 kW/m^2.

Large-Scale Calorimeters.

The Room/Corner Test. The room/corner test is used to evaluate the fire growth characteristics of wall and ceiling linings. The walls and/or ceiling of a 2.4 $\times$ 3.6 $\times$ 2.4 m room are lined with the test material. A gas burner is placed in one of the rear corners of the room opposite the 0.8 $\times$ 2.0 m open doorway in the front wall. Products of combustion are collected in a hood located in front above the door opening and extracted by a high temperature blower through the exhaust duct. The instrumentation in the exhaust duct is similar to that in the cone calorimeter, except that flow rate is typically determined on the basis of bidirectional probe measurements of centerline velocity and the smoke photometer often uses a white light source instead of a He–Ne laser. Several room/corner test standards have been developed and are used for regulatory purposes. For example, NFPA 265, *Standard Methods of Fire Tests for Evaluating Room Fire Growth Contribution of Textile Wall Coverings*, is required in the United States to qualify textile wall coverings for use in unsprinklered spaces of certain types of buildings. ISO 9705, *Fire Tests—Full-Scale Room Test for Surface Products*, is more severe than NFPA 265 and is used to qualify materials as fire restricting for high speed craft (small passenger ferries operating with short distance from shore). Figure 30 shows an ISO 9705 test in progress.

The Furniture Calorimeter. Often it is very difficult to determine the burning behavior of complex objects on the basis of the fire performance of its individual components. For example, it is very hard to determine the burning behavior of upholstered furniture on the basis of the fire characteristics of the foam, fabric, and framing materials and to account for the geometry and configuration of the furniture and how it is ignited. It is much more practical to measure the heat release rate and related properties for the complete object. This can be done in a furniture calorimeter. The object is placed on a load platform to measure the mass loss rate during the test. It is ignited with a standardized ignition source and the products

Fig. 30. ISO 9705 room/corner test in progress. Photo Courtesy of Southwest Research Institute © 2004.

of combustion are collected in a hood and extracted through an exhaust duct. Measurements of oxygen concentration, flow rate and light transmission in the exhaust duct are used to determine the heat release rate and smoke production rate from the object as a function of time. Furniture calorimeter test standards have been developed in ASTM for chairs, mattresses and stacked chairs. The corresponding designations are ASTM E1537, ASTM E1590, and ASTM E1822 respectively.

The Intermediate-Scale Calorimeter (ICAL). One of the limitations of the Cone Calorimeter is that only relatively small samples can be evaluated. As a

result, products that have joints or layered materials with a thickness exceeding 50 mm can generally not be tested in the Cone Calorimeter in a representative manner. For those types of products or assemblies, a larger calorimeter is required. Such an intermediate scale calorimeter forms the subject of ASTM standard E1623, *Standard Test Method for Determination of Fire and Thermal Parameters of Materials, Products, and Systems Using an Intermediate Scale Calorimeter (ICAL)*.

The ICAL apparatus consists of an array of gas heaters, forming a vertical radiant panel with a height of approximately 1.33 m and width of approximately 1.54 m. The test specimen measures 1×1 m, and is positioned parallel to the radiant panel. The heat flux to the specimen is preset to a maximum of 60 kW/m^2 by adjusting the distance to the panel. Gas flow to the panel is controlled to maintain the temperature to the panel, and consequently the heat flux to the specimen. The products of pyrolysis from the specimen are ignited with hot wires located close to, but not in contact with, the specimen at its top and bottom. The specimen is placed in a holder that is put on a load cell to measure mass loss during testing. Panel and specimen are positioned beneath the hood of the standard ISO 9705 room/corner test. All products of combustion are collected in the hood and continuously extracted through the exhaust duct. Instrumentation is provided in the duct for measuring heat release rate on the basis of oxygen consumption. A smoke photometer is also included for measuring smoke obscuration in the duct.

The Fire Products Collector. The first industrial-size calorimeter for fires into the MW range was built at Factory Mutual (currently FM Global) around 1980. This calorimeter, also referred to as the FM fire products collector, was designed to measure heat and other fire products from test fires up to a size associated with sprinkler activation in commodity warehouse storage and other representative occupancies. Approximately 10 years later, a similar industrial-size calorimeter for heat release rate measurements up to 10 MW was constructed at the National Testing Laboratory (SP) in Sweden. Since then several other laboratories, such as the National Research Council of Canada, the Fire Research Station in the United Kingdom, Underwriters Laboratories and Southwest Research Institute in the United States developed the capability of measuring heat release rate from large fires into the MW range.

Glossary

A_i
: frequency factor for kinetic process, where i = initiation, branching, gasification, charring, etc

α
: thermal diffusivity, $= \kappa/\rho c$ (m^2/s)

$\beta*$
: kinetic heating rate (K/s)

β
: experimental heating rate (K/s)

c_i
: heat capacity of substance, where i = gas, air, polymer, etc ($J/(kg \cdot K)$)

C
: heat of combustion of oxygen, =13.1 kJ/g O_2

$C_{FT,i}$
: molar char-forming tendency of chemical group i in polymer (dimensionless)

χ
: combustion efficiency of fuel gases in flame (dimensionless)

δ
: mesophase dimension (m)

E_i
: activation energy for kinetic process, where i = initiation, branching, gasification, charring, pyrolysis, etc (J/mol)

ε
: emissivity (dimensionless)

ϕ
: radiative fraction of power density at ignition (dimensionless)

γ
: viscosity (Pa)

$\overline{h}$
: average surface convective heat transfer coefficient ($W/(m^2 \cdot K)$)

$h_c{}^0$
: heat of combustion of fuel gases (J/kg)

h_g
: enthalpy of gasification per unit mass of polymer (J/kg)

HOC
: heat released by flaming combustion of fuel gases (J/kg)

HRP
: heat release parameter, $= \chi h_c{}^0/L_g$ (dimensionless)

HRR
: heat release rate per unit area of burning surface in flaming combustion (W/m^2)

HRR^*
: apparatus-dependent ignition parameter (W/m^2)

$HRR_b{}^*$
: critical heat release rate for incipient burning/extinction (W/m^2)

HRR_0
: heat release rate in unforced burning (W/m^2)
η_c
: heat release capacity ($J/(kg \cdot K)$)
k_i
: rate constant for kinetic process, where i = initiation, branching, gasification, charring, etc (s^{-1})
κ
: thermal conductivity ($W/(m \cdot K)$)
L_g
: latent heat of gasification per unit mass of volatile fuel (J/kg)
LOI
: limiting oxygen index/concentration of oxygen at extinction (dimensionless)
$\dot{m}''_a$
: mass flux of air ($kg/(m^2 \cdot s)$)
$\dot{m}''_f$
: mass flux of fuel gases ($kg/(m^2 \cdot s)$)
M_i
: molar mass of substance, where i = fuel gases, oxygen, monomer, chemical group, etc (kg/mol)
μ
: mass fraction of char or inert residue after burning or pyrolysis (dimensionless)
n_i
: number of moles of substance i
$\dot{q}''_{ext}$
: external heat flux from fire or radiant heater (W/m^2)
$\dot{q}''_{flame}$
: heat flux to surface from flame by convection and radiation (W/m^2)
$\dot{q}''_{loss}$
: rate of heat loss from surface per unit area (W/m^2)
$\dot{q}''_{net}$
: net heat flux to surface (W/m^2)
$\dot{q}''_{rerad}$
: heat flux reradiated to environment from surface (W/m^2)
Q'''
: heat of combustion per unit volume (energy density) for ignition in air, =1.9 MJ/m^3
$\dot{Q}'''$
: heat of combustion per unit volume per unit time (power density) at ignition
R
: gas constant, =8.314 $J/(mol \cdot K)$
ρ
: mass density (kg/m^3)
σ
: stefan–boltzmann constant, $= 5.7 \times 10^{-8}$ $W/(m^2 \cdot K^4)$
SEA
: smoke extinction area (m^2/kg)

t_{ign}
: time to ignition (s)
T_{a}
: ambient temperature (K)
T_{f}
: flame temperature (K)
T_{ign}
: ignition temperature (K)
T_{p}
: pyrolysis temperature (K)
T_0
: standard temperature = 298 K ≈ room temperature
$Y_{\text{d},1/2}$
: molar thermal decomposition function ((kg · K)/mol)
Ψ_i
: molar group contribution to the heat release capacity (J/(mol · K))

IONIC LIQUIDS, POLYMERIZATION IN

Introduction

The first room temperature ionic liquid (RTIL), $[EtNH_3][NO_3]$ (mp 12°C), was reported in 1914 (1), and since then a great deal of research effort has been exerted to exploit possible applications of these compounds. Initially, RTILs were used mainly as electrolytes in batteries or for metal electrodeposition; however, nowadays they are finding an ever increasing range of applications.

Ionic liquids may be viewed as molten salts and are liquids containing only cations and anions at ambient or near ambient (<100°C) temperature. They exhibit a relatively wide electrochemical window, good electronic and ionic conductivities, a broad range of room temperature liquid compositions, and may have negligible vapor pressure, and excellent chemical, thermal, air and moisture stability (2–6). They are composed of weakly coordinating anions, for example, BF_4^- and PF_6^- and, hence, are highly polar yet noncoordinating solvents. Most imidazolium and pyridinium ionic liquids have polarities similar to those of small molecule alcohols (7,8). Their hydrophilicity/lipophilicity is tunable by varying the combination of cations and anions. Thus, RTILs have been referred to as "designer solvents" (9), and millions of different RTILs could potentially be synthesized and optimized for specific applications. Depending on their structures, RTILs are able to dissolve a variety of organic, inorganic, and organometallic compounds. Their ease of handling, low vapor pressures, and potential for recycling make them promising potentially environmentally benign reaction media to replace volatile molecular solvents in both the chemical industry and in academic research.

Furthermore, RTILs have limited miscibility with some common organic solvents but high compatibility with transition metals. As a consequence, a biphasic or phase-separable (organic/RTIL biphasic systems) catalysis concept can be developed in which a homogeneous catalyst is immobilized in one liquid phase (RTIL) and the reactants and/or products reside largely in another liquid phase (organic) (10), thus enabling easy product and catalyst separation with the retention of the transition metal catalyst in an ionic liquid phase. Various common organic reactions employing metal catalysts have been conducted by employing ionic liquids as alternative reaction media, including Diels-Alder reactions (11), Friedel-Crafts reactions (12), hydrogenations (13), hydroformylations (14), alkylations (15), dimerizations (16), Heck reactions (17), Suzuki couplings (18), Sonogashira couplings (19), ring-closing olefin metathesis reactions (20), alcohol oxidations (21), and nucleophilic substitutions (22).

			$^{+}NR_3R'$
Cl^-	Easy to synthesize, hydrophilic	Easy to synthesize, hydrophilic	Inexpensive, hydrophilic
NO_3^-	Anion can produce reactive RTIL	Hydrophilic	Inexpensive, hydrophilic
PF_6^-	High thermal stability	Less thermally stable	Dopant RTIL to decrease cost
$N(CF_3SO_2)_2^-$	Low viscosity, hydrophobic, expensive	Hydrophobic	Low viscosity

Fig. 1. Matrix of RTIL cations and anions.

Some typical RTILs and how structure affects properties are shown in Figure 1. Representative common cations and anions used to prepare RTILs are shown in Figure 2. RTILs are commercially available from ACROS Organic (Fisher Scientific, UK), Chemada Fine Chemicals (Israel), Covalent Associates (Boston, Mass.), C-TRI (Korea), CYTEC (Canada), Sigma-Aldrich (US), BASF (US), Merck KGaA (Germany), QUILL (UK), Sachem (Austin, Tex.), Scionix (UK), and Solvent-Innovation (Germany).

Ionic Liquids for Polymerization

One of the earliest examples of polymerization in RTILs was reported in 1990 in a Lewis acidic ionic liquid: $AlCl_3$-1-ethyl-3-methylimidazolium chloride [EMIM]Cl

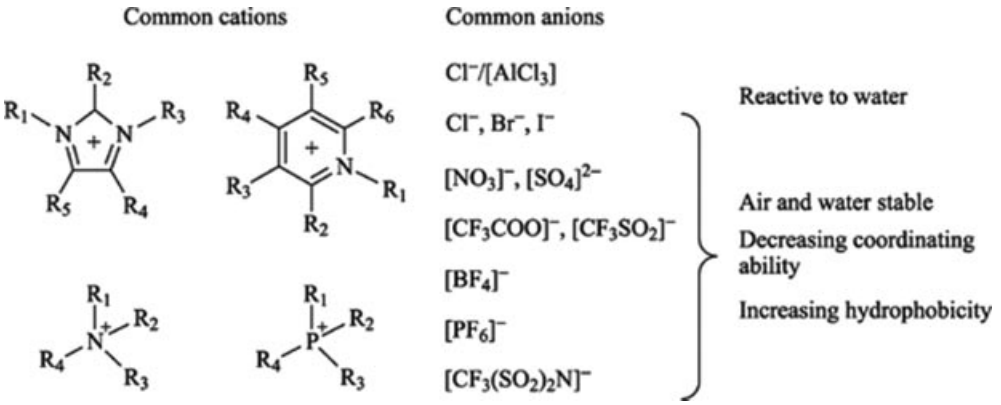

Fig. 2. Representative common cations and anions used to prepare room temperature ionic liquids.

(23). It was found that the combination of $TiCl_4$ and $AlEthylCl_2$ in $AlCl_3$/[EMIM]Cl can be catalytically active for ethylene polymerization, although the yield of polyethylene (PE) was low. This work opened a new route for making polymers using RTILs as alternative reaction media. Later, replacing $TiCl_4$ with Cp_2TiCl_2 was shown to give higher yields of PE using the same RTIL (24). More examples of related work on using ionic liquids for polymerization or oligomerization of olefins can be found in the literature and in patents (25,26). It was believed that the active sites are cationic alkyl–metal complex generated by the interaction of added transition metal catalyst with alkylaluminum moieties present in the ionic liquids via halogen abstraction and alkylation. The electrochemical polymerization of benzene in various ionic liquids has been described as a method for synthesis of poly(*p*-phenylene) (27). In these studies, ionic liquids were used mainly as convenient electrolytes. Carlin and Osteryoung produced a new electroactive material by electrochemical oxidation of triphenylsilyl chloride (Ph_3SiCl) in the acidic ionic liquid ($AlCl_3$-[EMIM]Cl) (28). The film formed exhibited reversible redox behavior and was electronically conducting in the oxidized state by incorporation of the cation of the ionic liquid into the film. However, most of the RTILs mentioned above are the 1st generation ionic liquids, which are haloaluminate-based ionic liquids and thus easily undergo hydrolysis to form undesirable HCl by-products.

Free Radical Polymerization

Free radical polymerization is extensively used for the synthesis of a variety of polymeric materials due to its versatility, synthetic ease, and compatibility with a wide variety of functional groups, which is also coupled with its tolerance to water and protic media. However, conventional free radical polymerization has a significant drawback, which is related to the reactivity of the propagating free radical chain ends and their propensity to undergo a variety of termination and chain transfer reactions. The materials obtained are therefore polydisperse with limited control over molecular weight and architecture. Ionic polymerizations (anionic or cationic) were for many years the only "living" polymerization techniques available that achieved efficient control over the structure and architecture of vinyl polymers. Although these techniques can generate polymers with low polydispersity, controlled molecular weight, and control over chain ends and macromolecular architectures, they are not suitable for the polymerization and copolymerization of many vinylic monomers. This limitation is due to the incompatibility of the growing polymer chain ends (carbanion or carbocation) with numerous functional groups and certain monomer families. In addition, stringent reaction conditions, including the use of ultrapure reagents and the need for total or near-total exclusion of water and oxygen, limit the widespread commercial use of these techniques. These challenges spurred polymer chemists to develop new concepts which allow a living or controlled polymerization using special free radical polymerization techniques. As a consequence, nitroxide-mediated polymerization (NMP), atom transfer radical polymerization (ATRP), and radical addition-fragmentation and transfer (RAFT) were developed. The general strategy behind these processes is the reversible termination of the growing polymeric chain with a mediating radical to reduce the overall concentration of the propagating radical chain ends.

In the absence of other reactions leading to initiation of new polymer chains (ie, no reaction of the mediating radical with the vinylic monomer), the concentration of reactive chain ends is extremely low, minimizing irreversible termination reactions, such as combination or disproportionation. All chains would thus be initiated only from the desired initiating species, and growth should occur in a living fashion, allowing a high degree of control over the entire polymerization process with well-defined polymers being obtained (29).

Although polymerization in moisture-sensitive ionic liquids has certain advantages when compared to traditional solvents, little polymerization work was done in RTILs until the introduction of the 2nd generation of air, moisture, and thermally stable, neutral ionic liquids, composed of dialkylimidazolium cations and PF_6 or BF_4 anions. In spite of the fact that these ionic liquids are anticipated to be potentially useful solvents for ionic polymerization due to their highly polar nature, the first report of polymerization in the new nonhygroscopic ionic liquids was based on a free radical polymerization process—atom transfer radical polymerization (ATRP). Carmichael and co-workers (30) observed first-order kinetic behavior over a wide range of reaction temperatures using ethyl-2-bromoisobutyrate initiator and CuBr/*N*-propyl-2-pyridylmethanimine as the catalyst pair in a 50/50 (V/V) MMA/[BMIM]PF_6 system. The reactions are faster as compared to those in common solvents, while the polydispersities (M_w/M_n, where M_w is weight-average molecular weight and M_n is number-average molecular weight) are narrow: 1.30–1.43. By extraction with toluene, the polymer can be separated from the solution while copper catalyst remains in the ionic liquid phase, which facilitates catalyst re-use by adding fresh monomer. The use of the RTIL medium also eliminated the need for postpurification to eliminate toxic copper salts, which entails passing the polymer solution through purification columns. Carmichael and co-workers attributed this polymerization behavior to the increased polarity of ionic liquids, because a similar increase in the rate has been observed with other polar/co-ordinating solvents. In a recent communication (31), Hong and co-workers reported large increases in both the rate of polymerization and the molecular weights that were obtained in the polymerizations of methyl methacrylate (MMA) in [BMIM]PF_6 as compared to identical polymerizations carried out in conventional organic solvents. These dramatic increases were believed to be at least in part because of the high viscosity of the polymerization media. Thus, a "diffusion-controlled termination" mechanism was proposed to explain the diminished chain terminations in such a viscous system, which would account for a simultaneous increase in both rate of polymerization and degree of polymerization. Very recently, Benton and Brazel (32) reported similar behavior, high molecular weights and rapid polymerization rates, for MMA in [BMIM]PF_6. Harrison and co-workers (33) used a pulse laser polymerization (PLP) technique to polymerize MMA in [BMIM]PF_6, which is the IUPAC-recommended standard procedure for measuring the rate constant of propagation (k_p). They found that both the propagation and termination rates were significantly affected by [BMIM]PF_6. They attributed the increase of the propagation rate to the increased polarity of the ionic liquid solution, which lowers the activation energy of propagation through charge-transfer interactions. The termination rate is decreased simply because of the increased viscosity of the polymerization medium. Both an increase of k_p and decrease of k_t contribute a roughly ten-fold increase of overall rate of polymerization. Quite

recently, Cheng and co-workers (34) reported free radical polymerization of acrylonitrile in [BMIM]BF_4 using AIBN as initiator. These workers also note that ionic liquids are excellent media for achieving high molecular weight polymers. They attribute this result to low chain transfer constants for RTILs and the ability of these solvents to stabilize the growing radical chain ends.

Clearly most of the early studies on polymerization in RTILs used [BMIM]PF_6 as the medium. This was largely due to the commercial availability and easy synthesis of this material. However, [BMIM]PF_6 can readily hydrolyze to release toxic HF as a by-product, and there is an ever increasing focus on the use of more benign RTILs in polymer systems. Zhang and co-workers (35) measured the polarity and viscosity of over a dozen RTILs based upon a wide range of cations and anions, and attempted to correlate these physical data with the *low conversion* conventional free radical polymerization behavior of styrene and MMA in these RTILs. This study revealed no obvious trends between polarity or viscosity of RTILs and polymerization rate or molecular weight of the formed polymer. At around the same time, Strehmel and co-workers (36) reported that the higher the viscosity of the RTIL, the higher the yields and molecular weights of the polymers. However, unlike in the work by Zhang and co-workers, these workers carried their polymerizations to high (near quantitative) conversions, where the Trommsdorff effect strongly impacts polymerization behavior. Clearly, the higher viscosities will affect polymerization behavior in this regime and make it difficult to ascertain polymerization behavior in the non-Trommsdorf regime. The RTILs employed in this latter study were composed of cations and anions of similar structures except the alkyl length and positions on the cation, while either cations or anions are structurally different in the former case. In our opinion, it is still too early to make a conclusion regarding the effects of polarity and viscosity of the RTIL on polymerization behavior. It would be very interesting to repeat the experiments of Strehmel and co-workers (36) but keep conversions low. The polarity of molecular solvents is a complex of many interactions including: H-bonding, π-interaction, or van der Waals forces. In RTILs, the situation is even more complicated since both cations and anions may have their own distinct interactions. Zhang and co-workers used solvatochromic dye (Nile red) to measure the polarities of RTILs and the results had similar trend as those in Reference (37). Since Nile red is a positively solvatochromic, it preferentially interacts with anions of RTILs. The apparent polarities deduced may be not reflect the real values, thus further experiments need to be carried out to address this problem. In addition, the polymers synthesized in RTILs all have similar glass transition temperatures and microstructures as compared to those obtained in benzene or in bulk, based upon thermal analysis and ^{13}C NMR experiments (38).

Biedroń and co-workers (39) reported heterogeneous ATRP in [BMIM]PF_6. Alkyl acrylates (methyl, butyl, hexyl, and dodecyl) are either soluble, partly soluble, or completely insoluble in this RTIL depending on the length of the alkyl substituent. For the heterogeneous systems, the alkyl acrylate formed an upper monomer phase while the CuBr/pentamethyldiethylenetriamine (PMDETA) catalyst remained in the lower RTIL phase. Methyl acrylate (MA) and poly(methyl acrylate) (PMA) are miscible with [BMIM]PF_6 and form a homogeneous polymerization system, therefore, all reactions proceed in one phase. For the three other acrylates, the growing macromolecular chains react with the monomer at the

interface but reside predominantly in the monomer phase. In all cases, the reactions were living radical polymerizations. The advantages of heterogeneous ATRP are easy separation of polyacrylate from the RTIL phase after reaction, with less copper catalyst contamination and reduction of side reactions due to the absence of catalyst in the upper monomer phase, as compared to bulk ATRP. It was found that using a chiral RTIL (1-(*R*-(+)-2′-methylbutyl)-3-methylimidazolium hexafluorophosphate) could impact the stereoregularity of polymer produced by ATRP (40).

Sarbu and co-workers (41) used different catalyst systems (iron or copper halides) to successfully carry out ATRP in a range of 1-butyl-3-methylimidazolium ionic liquids. In iron-mediated ATRP, no additional ligand was required to achieve a controlled polymerization of MMA although both initiation rates and rates of reaction were low. Systems without organic ligands were effective only in a phosphonate ionic liquid for copper-mediated ATRP of MMA, while a ligand was required in ionic liquids with halide or carbonate anions. ATRP in ionic liquids proceeds with low initiation efficiency. This has been attributed to the high concentration of the catalyst in the RTIL phase, into which the small initiators can easily diffuse and thus generate high concentration of free radicals. The free radical can undergo irreversible termination and cause the low initiation efficiency. However, initiator efficiency can be improved by employing macroinitiators, which have little tendency to diffuse into the RTIL phase. In addition, the catalyst can be regenerated after removal of polymer and unreacted monomer.

Reversible atom transfer radical polymerization of MMA in [BMIM]PF_6, [BMIM]BF_4, and [DMIM]BF_4 (1-dodecyl-3-methylimidazolium tetrafluoroborate) has been described (42). In [BMIM]PF_6, the reverse ATRP of MMA was achieved with 2,2′-azobisisobutyronitrile (AIBN)/$CuCl_2$/2,2′-bipyridine initiation system, in which the system is homogeneous throughout the reaction. Due to a cage effect with ionic liquids molecules, the termination of the primary radicals through decomposition of AIBN might occur before they can initiate polymerization, which accounts for the low initiation efficiency of AIBN. The Cu catalyst is also soluble in the ionic liquid. As a consequence of both factors, less catalyst is needed to effectively mediate the polymerization process in ionic liquids than in other reverse ATRPs. The ionic liquids and catalyst can be recovered and reused.

Zhang and co-workers (43) used both a bimolecular initiation system (benzoyl peroxide (BPO) + 2,2,6,6-tetramethylpiperidine 1-oxyl (TEMPO)) and a universal initiator system (2,2,5-trimethyl-3-(1-phenylethoxy)-4-phenyl-3-azahexane (TMPPAH)) for the attempted nitroxide-mediated polymerization of MMA and St. Polymers were produced but polymerizations were not living/controlled for either monomer. Possible reasons are the low diffusion rates of mediating radicals and slow degradation of free TEMPO at elevated temperatures in the presence of [BMIM]PF_6. Ryan and co-workers (44) demonstrated a controlled/living nitroxide-mediated polymerization of MA in 50% V/V of [HMIM]PF_6 initiated by the initiator pair AIBN + 4-oxo-2,2,6,6-tetramethyl-1-piperidinyl-*N*-oxyl (4-oxo-TEMPO) at 140°C–155°C. The reaction rates under these conditions were greater than for similar reactions conducted in anisole. In both of these studies, self-polymerization (thermal polymerization) was observed because of the high temperatures used. Other kinds of living free radical polymerization, such as RAFT and charge transfer polymerization, have also been reported in RTILs (45).

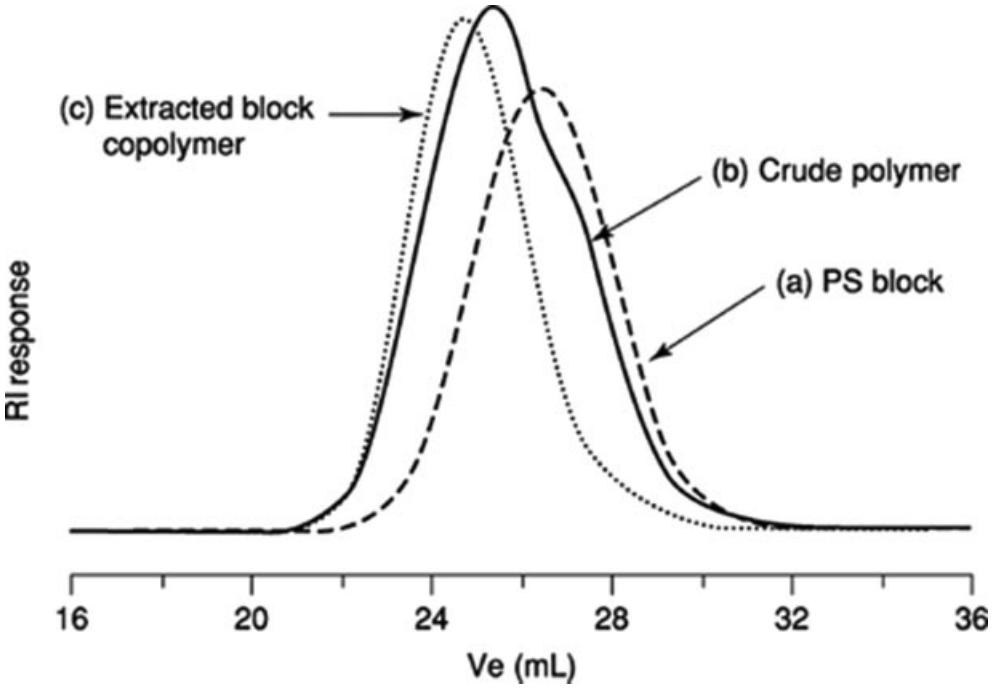

Fig. 3. SEC traces of (a) PS block from BPO in [BMIM]PF6, (b) PS-*b*-PMMA before extraction, and (c) PS-*b*-PMMA after extracting with cyclohexane and acetonitrile.

Combined with CuBr/PMDETA catalyst, dendritic polyarylether 2-bromoisobutyrates (G*n*-Br, n=1–3) can be used as effective macroinitiators for ATRP of *N*-hexylmaleimide and styrene in [BMIM]PF_6 at lower temperature than in anisole. The afforded polymers had well-defined molecular weights and low polydispersities ($1.18 < PDI < 1.36$) (46). The two monomers showed a stronger tendency to form alternating structures in RTILs as compared to polymerizations conducted in anisole.

Limited solubility of some monomers and polymers in ionic liquids presents opportunities to make diblock copolymers by sequential addition polymerization. Zhang and co-workers (47) demonstrated the formation of PSt-b-PMMA by sequential addition in [BMIM]PF_6 through conventional free radical polymerization using benzoyl peroxide (BPO) as initiator. St was polymerized first and the polymer gradually precipitated out when the conversion reached around 50% due to the insolubility of PSt in [BMIM]PF_6. The chain coils wrapped the macroradicals inside resulting in prolonged lifetimes because of diminished termination. Unreacted St monomer was pumped out on a high vacuum line. After adding the second monomer (MMA), diblock copolymers were formed at room temperature although the re-initiation was not 100% (see Figure 3). Reversal of the polymerization sequence only afforded homopolymer, PMMA. Kubisa and co-workers used a similar strategy to produce PBA-b-PMA and PMA-b-PBA block copolymers (PBA is poly(butyl acrylate) by different sequences of addition of monomers using the ATRP method in the same ionic liquid (48). They found that when conversion of

MA, used as first monomer, exceeded 70%, a significant percentage of dead PMA chains contaminated the final diblock copolymer. Conversely, when MA was added to the solution of PBA in [BMIM]PF_6, "clean" diblock was formed, essentially free of homopolymer, and BA can be polymerized to complete conversion. Ma and co-workers (42,49) also described successful synthesis of block copolymers, where St was polymerized by chlorine-end-capped PMMA as macroinitiator through reverse ATRP in [BMIM]PF_6, [BMIM]BF_4, and [C_{12}MIM]BF_4.

The effect of solvents on reactivity ratios and sequence length distributions for free radical polymerization has been extensively studied. The calculated reactivity ratios of St and MMA ($r_{St} = 0.381 \pm 0.02$ and $r_{MMA} = 0.464 \pm 0.02$) in [BMIM]PF_6 by nonlinear method (CONTOUR computer program (50)) are significantly different from those ($r_{St} = 0.54 \pm 0.04$ and $r_{MMA} = 0.50 \pm 0.04$) in benzene at 60°C (51). The "boot-strap" model (52), polarity of the solvents, interaction between solvent and monomers (eg solvent–monomer complex), viscosity and system heterogeneity all possibly contribute to the different reactivity ratios in RTILs and in benzene.

[BMIM]PF_6 was found to be an efficient plasticizer for PMMA, prepared by *in situ* radical polymerization in this ionic liquid (53). The polymers have physical characteristics comparable with those containing traditional plasticizers (phthalates, adipates, and trimellitates) and retain greater thermal stability. RTILs are normally used as inert solvents for polymerization. However, Mays and co-workers discovered that polymerization of MMA can be carried out at ambient temperature in the ionic liquid trihexyl-tetradecyl-phosphonium bis(2,4,4-trimethylpentyl)phosphinate ([H_3TDP] [$(PM_3)_2$P]) via a redox-initiated polymerization mechanism (54). The cation of [H_3TDP][$(PM_3)_2$P] apparently reacts with BPO in a redox reaction, with the cation as reductant and BPO as oxidant. The generated radical efficiently initiated polymerization at room temperature to produce PMMA with high yield and high molecular weight.

Ionic Polymerization

Living anionic polymerization usually gives narrower molecular weight distribution polymers as compared to those obtained by living free radical polymerizations. These polymerizations can proceed to complete conversion with far fewer side reactions such as termination and chain transfer. The ability to introduce terminal functional groups by using selective termination agents is an additional advantage of anionic polymerization. On the other hand, the stringent purification requirements for living anionic polymerization put some limits on the commercial synthesis of polymers using this method. Even though RTILs are in some ways ideal potential solvents for ionic polymerizations, because the RTIL can possibly help to stabilize the growing carbanions or carbocations due to their ionic nature, there are no reports in the literature on anionic polymerization in ionic liquids. This is primarily because it is very difficult to adequately purify ionic liquids to the standards required for anionic polymerizations. Our preliminary data (not yet published) indicate that termination occurs due to impurities in the RTIL. Vijayaraghavan and co-workers (55) reported the first case of cationic polymerization of styrene in *N*-butyl-*N*-methylpyrrolidinium bis(trifluoromethanesulfonyl)amide

([P_{14}][Tf_2N]). The cationic initiator used was a Brønsted acid: bis(oxalato)boric acid (HBOB). The polymerization proceeded in a living manner but the reaction temperature was high (60°C). PSt produced had low molecular weights (1300–1700) and moderate polydispersities (1.3–1.5). The author suggested that RTILs might promote the dissociation of the acid that can efficiently initiate polymerization. Biedron and Kubisa (56) conducted cationic polymerization of styrene in [BMIM]PF_6 with a 1-phenetyl chloride/$TiCl_4$ initiating system. Polymers were obtained but chain transfer was significant, resulting in a lack of control over molecular weight and molecular weight distribution.

Ring-Opening Polymerization

Ring-opening metathesis polymerization of norbornene using cationic allenylidene precatalys, [(*p*-cymene)RuCl(Pcy_3)(=C=C=CPh_2)][OTf], in a biphasic medium, (1-butyl-2,3-dimethylimidazolium hexafluorophosphate ([BDMIM]PF_6)/toluene), was carried out (57). The catalyst was in the ionic liquid phase, and the upper toluene phase dissolved the polymer that was formed. Both the ionic liquid and catalyst could be reused up to six times without significant loss of catalytic activity and with quantitative yields of polymer. After reloading of catalyst, the catalyst system can still be re-used up to five times. The enhanced recycling capabilities as compared to other alkylidene catalysts were attributed to the ionic character of the cationic allenylidene complex, while the other systems gradually lost their catalytic abilities within three successive runs.

Biedroń and co-workers (58) presented the results of the cationic ring opening polymerization of 3-ethyl-3-hydroxymethyloxetane in the most common hydrophilic ionic liquid, [BMIM]BF_4, using the BF_3-Et_2O initiation system. The advantage of carrying out this reaction in ionic liquids over solution or bulk polymerizations is the high reaction temperature that can be used (up to 180°C because intermolecular hydrogen bonding that leads to the formation of aggregates is reduced at the elevated temperature). The intramolecular H-bonding, facilitating intramolecular chain transfer, is not significantly affected. The multihydroxyl, branched structure was preserved, and the molecular weights of the polymers were in the same range as those made in organic solvents or in bulk. On the contrary, the application of ionic liquids can also help to reduce the reaction temperature. At higher temperatures, side reactions may be significant. Polycarbonate made by ring opening polymerization of ethylene carbonate experiences decarboxylation when the reaction is carried out at 180–200°C (59). In acidic ionic liquids such as [BMIM]Cl-$AlCl_3$ or [BMIM]Cl-$SnCl_2$, the reaction can take place at temperatures of 100–120°C depending on the ionic liquid used. The drawback of these new reaction systems is that decarboxylation was still not negligible, and low levels of ethylene carbonate polymers were formed.

Enzyme-Catalyzed Polymerization

Candida Antarctica lipase (lipase CA) catalyzed formation of biodegradable polyesters in [BMIM]PF_6 and [BMIM]BF_4 has been reported (60). Ring-opening

polymerization of ε-caprolactone and polycondensation of dicarboxylic acid diesters with 1,4-butanediol were examined. Higher molecular weight products and improved conversions suggest the potential for green polymer chemistry by the combination of nontoxic enzyme catalyst, mild reaction conditions with potentially environmentally benign solvents.

Condensation Polymerization

Polyimides and polyamides are important materials due to their attractive thermal, mechanical, and electrical properties. Usually, the synthesis of high molecular weight polyimides in organic solvents requires high temperatures and the presence of an acidic catalyst. Vygodskii and co-workers (61) studied the condensation polymerization behavior in RTILs composed of different anions and cations. High molecular weight polyimides and polyamides were obtained using RTILs as novel reaction media, without addition of catalyst.

Transition-Metal Catalyzed Polymerization

Poly(phenyl-acetylene) (PPA) is a conjugated polymer with interesting photoconductivity, photoluminescence, nonlinear optical, and membrane properties. It can be obtained by different polymerization methods including radical, cationic, metathesis catalyst or Ziegler–Natta polymerizations. High molecular weight PPA can also be obtained by Rh(I) catalyzed phenylacetylene polymerization in ionic liquids such as *n*-butylpyridinim tetrafluoroborate ([bupy]BF_4) or [BMIM]PF_4 (62). The catalyst used was either (diene)Rh(acac) or [(diene)$RhCl_2$]$_2$, and the cocatalyst used was triethylamine. The polymer was separated from the ionic liquid using either extraction with toluene or filtration by adding methanol into ionic liquids to form a suspension of PPA in the solvent mixture methanol/RTIL. Extraction usually facilitates catalyst recycling, but cannot permit the maximum product recovery. While more polymers can be recovered through the filtration method, the Rh(I) complex solution after filtration shows no catalytic activity. The molecular weights ranged from 55,000 to 200,000.

Rogers and co-workers (63) used 1-hexylpyridinium bis(trifluoromethanesulfonyl) imide ([C_6Pyr][NTf_2])/methanol as a solvent pair for palladium-catalyzed alternating copolymerization of styrene and carbon monoxide, in which the palladium catalyst was L$Pd(OAc)_2$ (L=2,2′-bipyridine and 1,10-phenanthroline). [C_6Pyr][NTf_2] and catalyst can be recycled, and the yields and molecular weights were higher as compared to those obtained when the polymerization was carried out in methanol alone. Furthermore, the catalyst stability and propagation rate were improved due to the inhibited chain transfer and catalyst decomposition in [C_6Pyr][NTf_2].

Electrochemical Polymerization

Electrochemical polymerization is a major method to synthesize conducting polymer for potential application in energy storage devices, electrochromic devices,

and light-emitting diodes. This process shows some advantages over chemical synthesis including faster reactions, simple procedures, generation of the polymer in the doped state, and easy control of the film thickness. Naudin and coworkers (64) have used ionic liquids for the electrochemical polymerization of poly(3-(4-fluorophenyl)thiophene) (PFPT). The electrochemical behavior was similar to that in common nonaqueous electrolyte. However, X-ray photoluminescence spectroscopy revealed the presence of some ionic liquid residue in the formed film. Other kinds of conjugated polymers such as polypyrrole, polyaniline, and unsubstituted polythiophene were also synthesized in ionic liquid (65).

Other Applications of Ionic Liquids in Polymers Systems

Polyaniline nanoparticles with diameters from about 30–80 nm can be fabricated by interfacial polymerization at the interface between aqueous media and RTILs (66). Electronic devices such as electrochemical mechanic actuators have improved cycle life and larger generated strain using [BMIM]PF_6, [BMIM]BF_4, or [BMIM][NTf_2] as electrolytes as compared to traditional organic or aqueous solvents, because ionic liquids have high ion conductivity, large electrochemical windows, and fast ion mobility (67). Single-ion conductive membrane material, made out of polymerizable ionic liquids by incorporating some ethylene oxide spacer cross-linkers, has high ionic conductivity (1.37×10^{-4} S cm^{-1}), and the film formed is transparent and free standing (68). In order to overcome migration of ions of RTILs along with potential gradient with target ions in membrane application, poly(VdF-co-HFP) containing zwitterionic ionic liquids was reported as a new polymer gel electrolyte which only transports target ions (69). RTILs have been used as porogens in cross-linked polymer systems formed by free radical polymerization of cross-linking monomers (70). RTILs are also effective solvents for regenerating cellulose via the aid of microwave irradiation (71). Forming hydrogen-bonding between hydroxyl functions on the polymer chains and anions of RTILs such as Cl^-, Br^-, and SCN^-, which are hydrogen bond acceptors, can break the intermolecular hydrogen bonding between linear glucose polymer chains. A recent review on application of ionic liquids in polymerization is available in the literature (72).

Conclusions

Room temperature ionic liquids have proved over recent years to be useful and unique reaction media for a variety of chemical reactions. Some potential benefits of working with RTILs as solvents for polymerization are wide and varied (Table 1):

Faster reaction rates and better selectivities are often observed in RTILs as compared to those in common organic solvents. In addition to these advantages, the nonvolatility, nonflammability, and recycling potential also help RTILs become a preferred alternative reaction medium to meet environmental and other requirements. Although polymerization in 1st generation RTILs was not very attractive when compared to similar reactions carried out in organic solvents, the 2nd generation RTILs are showing much greater promise. This is evidenced by

Table 1. Potential Benefits of Polymerization in RTILs

• Ability to rapidly generate high molecular weight polymers with low residual monomer
• Simplified methods to synthesize complex molecular architectures such as block- and graft copolymers, and copolymers with new monomer sequences, as compared with more complicated techniques such as anionic, cationic and living radical polymerization
• Ability to design reactions to be carried out at much higher temperatures, as RTIL volatility is much lower and thermal stability is much higher than traditional solvent
• Improvement in polymer physical properties, such as tensile strength, elastic modulus and impact strength, based on the reaction mechanism in RTILs
• Ability to work with biological components in a nondenaturing environment during reactions that incorporate enzymes, proteins, and other biologically active agents into polymer networks.

the increasing number of papers published in this area every year, and interesting and important discoveries. When conventional free radical polymerizations are carried out in RTILs, there is an increase in the propagation rate due to the high polarity of the RTIL and a decrease in the termination rate because of the high viscosity of the RTILs, and thus the overall reaction rate is greatly increased. For living/controlled polymerization such as ATRP, the reactions in RTILs are still controllable with faster reaction rates and easy separation of catalysts and/or ligands from the resulting polymers. Several other polymerization processes have been conducted in RTILs, with the notable exception of anionic polymerization, which needs careful work in order to find the right RTILs, purification techniques, and polymerization conditions.

MICROENCAPSULATION

Introduction

Microencapsulation is the coating of small solid particles, liquid droplets, or gas bubbles with a thin film of coating or shell material. In this article, the term *microcapsule* is used to describe particles with diameters between 1 and 1000 μm. Particles smaller than 1 μm are called *nanoparticles*; particles greater than 1000 μm can be called *microgranules* or *macrocapsules*.

Many terms have been used to describe the contents of a microcapsule: active agent, actives, core material, fill, internal phase (IP), nucleus, and payload. Many terms have also been used to describe the material from which the capsule is formed: carrier, coating, membrane, shell, or wall. In this article the material being encapsulated is called the *core material*; the material from which the capsule is formed is called the *shell material*.

Although virtually any coating material, conceptually, is a candidate microcapsule shell material, most commercial microcapsules produced to date utilize a relatively small number of different shell materials. Table 1 lists representative examples of these materials along with typical applications. Microcapsule shell material selection for a specific application is determined by a number of factors including cost, availability, processing ease, and inherent barrier properties. Shell materials for pharmaceutical, food, and personal care products are limited to materials that are approved by regulatory agencies responsible for such products. Defining an optimal shell material for a given application can be complex, since many interacting parameters determine success of a given capsule shell material. Fortunately, many suppliers of candidate shell materials provide valuable information concerning the use of their products in various encapsulation processes.

Microcapsules can have a wide range of geometries and structures. Figure 1 illustrates three possible capsule structures. Parameters used to characterize microcapsules include particle size, size distribution, geometry, actives content, storage stability, and core material release rate. Characterization studies provide valuable insight into the nature of various types of capsules and how they function in specific applications.

Throughout the world, research and development activity dedicated to advancing microcapsulation technology is producing a steadily increasing number of commercially successful products that utilize microcapsules. Many established encapsulation processes like spray drying and fluidized bed coating are being refined and improved while new processes continue to be developed. Various reviews of this subject exist (1–6). Pan coating, a well-established means of producing coated

Table 1. Shell Materials Used to Produce Commercially Significant Microcapsules

Shell material	Regulatory status	Chemical class	Encapsulation process	Applications
Gum arabic	Edible	Polysaccharide	Spray drying	Food flavors
Gelatin	Edible	Protein	Spray drying	Vitamins
Gelatin–gumarabic[a]	Nonedible[b]	Protein–polysaccharide complex	Complex coacervation	Carbonless paper
Ethylcellulose	Edible	Cellulose either	Wurster process or polymer–polymer incompatibility	Oral pharmaceuticals
Polyurea or polyamide	Nonedible	Cross-linked polymer	Interfacial polymerization *in situ* polymerization	Agrochemicals and carbonless paper
Aminoplasts	Nonedible	Cross-linked polymer		Carbonless paper, fragrances, and adhesives
Maltodextrins	Edible	Low molecular weight carbohydrate	Spray drying and desolvation	Food flavors
Hydrogenated vegetable oils	Edible	Glycerides	Fluidized bed	Assorted food ingredients

[a] Treated with glutaraldehyde.
[b] For intended application, ie, carbonless paper.

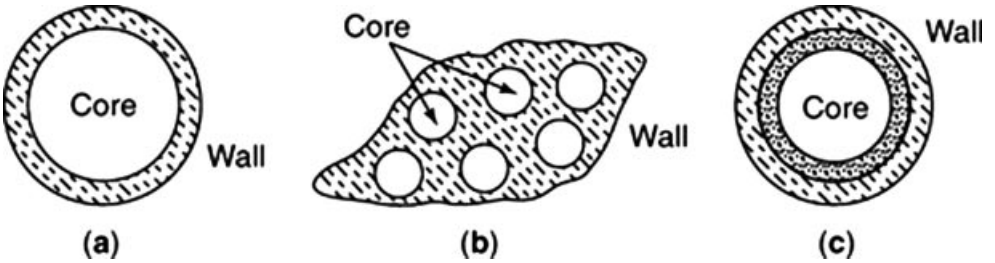

Fig. 1. Schematic diagrams of several possible capsule structures: (**a**) continuous core/shell microcapsule in which a single continuous shell surrounds a continuous region of core material; (**b**) multinuclear microcapsule in which a number of small domains of core material are distributed uniformly throughout a matrix of shell material; and (**c**) continuous core capsule with two different shells.

particles for the pharmaceutical industry, is not discussed because it produces particles larger than 1000 μm.

Encapsulation Processes

Because there are so many encapsulation processes, various schemes have been created in order to classify them. Some schemes classify encapsulation processes as chemical or physical even though so-called chemical processes may be based exclusively on physical phenomena, while physical processes may involve chemical reactions. This author prefers to simply classify encapsulation processes as type A or type B. Type A processes are defined as those in which capsule formation occurs entirely in a liquid-filled stirred tank or tubular reactor. Type B processes are processes in which capsule formation occurs because a coating is sprayed or deposited in some manner onto the surface of a liquid or solid core material dispersed in a gas phase or vacuum. This latter category includes processes in which liquid droplets containing core material are sprayed into a gas phase and subsequently solidified to produce microcapsules. Emulsion and dispersion stabilization play a key role in the success of both type A and B processes.

Differences in some type A and type B processes can be subtle, but significant. For example, solvent evaporation is a key step in spray dry encapsulation protocols (type B), and protocols involving solvent evaporation from an emulsion (type A). The difference in these protocols is that evaporation in the former case occurs directly from a liquid to a gas phase, whereas in the latter case evaporation involves transfer of a volatile liquid from a dispersed phase to a continuous liquid phase from which it is subsequently evaporated. Another example is encapsulation by gelation. In type A gelation processes, the droplets that are gelled and become microcapsules are formed by dispersion in a liquid phase and are gelled in this phase. In type B gelation processes, droplets formed by atomization or extrusion into a gas phase are subsequently gelled either in the gas phase or a liquid gelling bath.

Representative examples of both types of processes follow. Type B processes tend to be promoted by organizations that sell and service equipment for producing

microcapsules. Most type A processes are developed and used in-house by organizations that produce microcapsules.

Type A processes	Type B processes
Complex coacervation	Spray drying
Polymer–polymer incompatibility	Fluidized bed
Interfacial polymerization at liquid–liquid and solid–liquid interfaces	Interfacial polymerization at solid–gas or liquid–gas interfaces
In situ polymerization	Centrifugal extrusion
Solvent evaporation or in-liquid drying	Extrusion or spraying into a desolvation bath
Submerged nozzle extrusion	Rotational suspension separation (spinning disk)

Type A Processes

Complex Coacervation. This process occurs in aqueous media and is used primarily to encapsulate water-immiscible liquids or water-insoluble solids (4,5). In the complex coacervation of gelatin with gum arabic (Fig. 2), a water-insoluble core material is dispersed to a desired drop size in a warm gelatin solution. After gum arabic and water are added to this emulsion, pH of the aqueous phase is typically adjusted to 4.0–4.5. This causes a liquid complex coacervate of gelatin, gum arabic, and water to form. When the coacervate adsorbs on the surface of the core material, a liquid complex coacervate film surrounds the dispersed

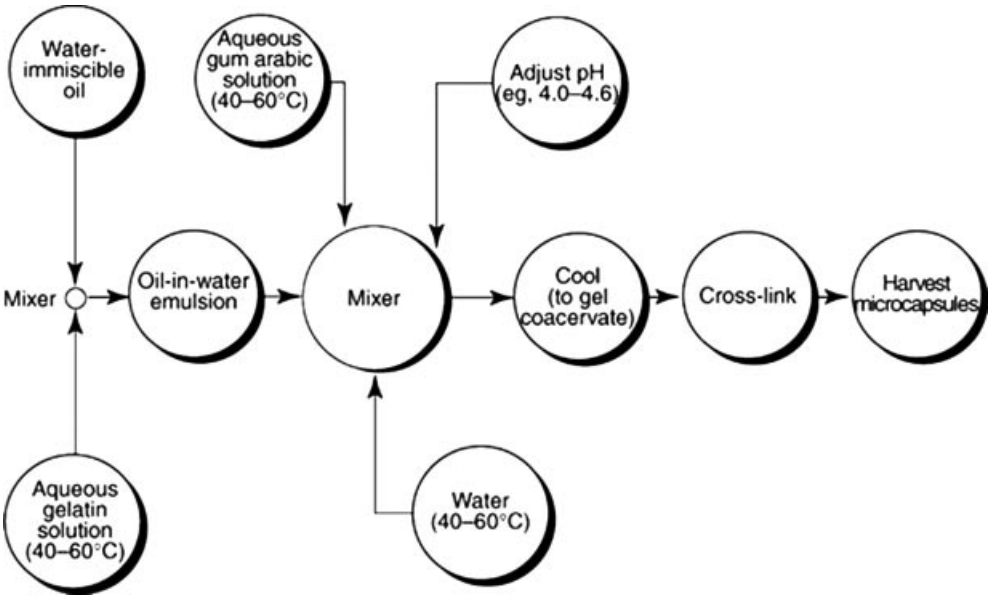

Fig. 2. Flow diagram of a typical encapsulation process based on the complex coacervation of gelatin with gum arabic.

core material, thereby forming embryo microcapsules. The system is subsequently cooled, often below 10°C, thereby gelling the liquid coacervate shell. After gelation, the coacervate gel typically is chemically cross-linked. For many years, glutaraldehyde was the preferred cross-linking agent, but an enzyme, transglutaminase, has now emerged as a candidate cross-linking agent, particularly when the capsules are for food or cosmetic applications.

Many pairs of oppositely charged Polyelectrolytes (qv) are able to form a liquid complex coacervate suitable for microcapsule formation. Normally, gelatin is the positively charged polyion, because it is readily available and forms suitable complex coacervates with a wide range of polyanions. Polyanions typically used include gum arabic, polyphosphate, poly(acrylic acid), and alginate.

Chemically cross-linked complex coacervate capsule shells generally are highly water-swollen, but can be dried in a spray dryer or fluidized bed dryer. If such capsule shells are treated with urea and formaldehyde under acidic conditions, these materials polymerize within the water-swollen complex coacervate capsule shell, thereby greatly, increasing the degree of chemical cross-linking, reducing water content of the shell, and enhancing ease of drying to a free-flow powder.

A wide variety of capsules loaded with water-immiscible or water-insoluble materials have been prepared by complex coacervation. Capsule size typically ranges from 20 to 1000 μm, but capsules outside this range can be prepared. Although core contents are often 80–95 wt%, capsules with lower loadings can be made. Complex coacervation processes are adversely affected by active agents that have finite water solubility, are surface-active, or are unstable at pH values of 4.0–5.0. The shell of dry complex coacervate capsules is sensitive to variations in atmospheric moisture content and becomes plasticized at elevated humidities.

Simple Coacervation. Aqueous solutions of water-soluble polymers are phase-separated in aqueous media when sufficient salt is added to such solutions. This phenomenon is called *simple coacervation*. As long as phase separation produces a liquid polymer-rich phase, simple coacervation can be used to produce microcapsules (5). Microcapsules with a gelatin or poly(vinyl alcohol) shell have been formed in this manner. The use of poly(vinyl alcohol) as a capsule shell material is of great interest in various applications because it is a widely available synthetic polymer with excellent oxygen and oil barrier properties (see BARRIER POLYMERS; VINYL ALCOHOL POLYMERS).

Polymer–polymer Incompatibility. Two chemically different polymers dissolved in a common solvent are usually incompatible. That is, they spontaneously separate into two liquid phases, with each phase containing predominately one polymer. When a core material insoluble in the solvent is dispersed in such systems, it is spontaneously coated by a thin film of the liquid phase that contains the polymer designed to be the capsule shell material; this polymer must be preferentially adsorbed by the core material which is not difficult to arrange. Microcapsules are harvested by desolvating this coating either by chemical cross-linking or addition of a nonsolvent (Fig. 3) (4,5). In the latter case, the embryonic capsule as slurry is often added to a very large excess of nonsolvent in order to minimize capsule agglomeration during isolation.

Polymer–polymer incompatibility encapsulation processes can be carried out in aqueous or nonaqueous media but, thus far, have primarily been carried out in

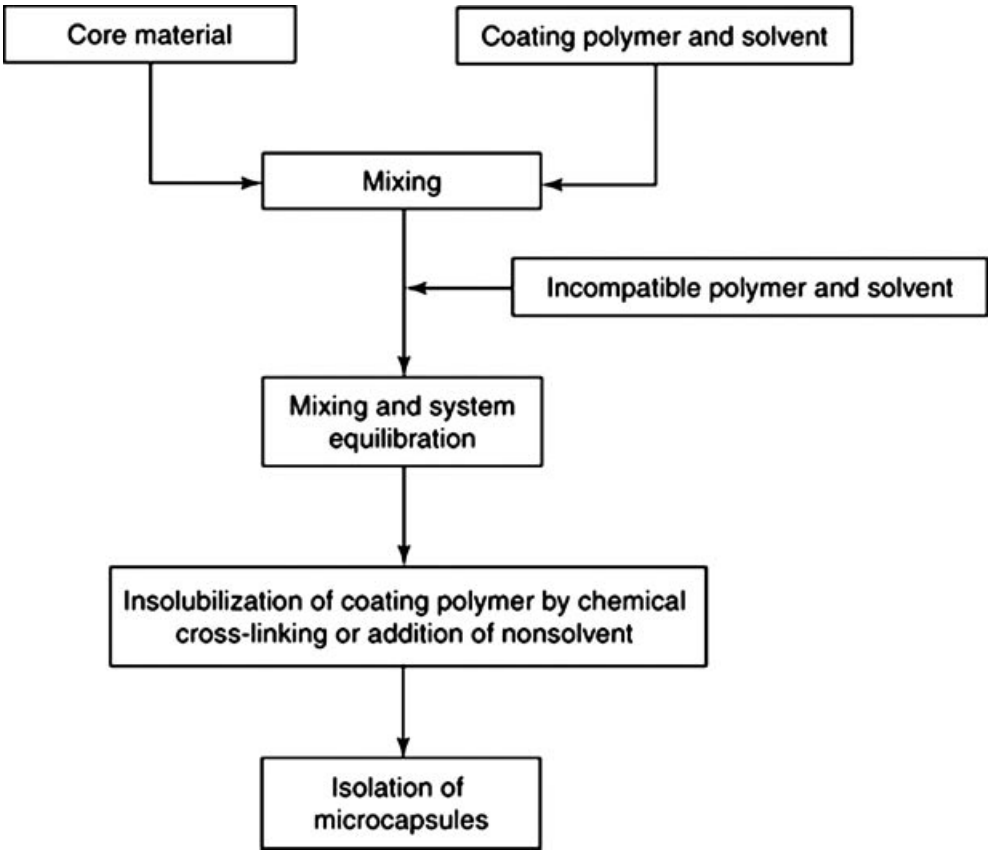

Fig. 3. Flow diagram of a typical encapsulation process based on polymer–polymer incompatibility.

organic media. Core materials encapsulated tend to be polar solids with a finite degree of water solubility. Historically, ethylcellulose has been the shell material used. Biodegradable shell materials such as poly(D,L-lactide) and lactide–glycolide copolymers have received much attention. In these latter cases, the object has been to produce biodegradable capsules that carry proteins or polypeptides. Such capsules tend to be below 100 μm in diameter and are for oral or parenteral administration (7).

Interfacial Polymerization. Many types of polymerization reactions can be made to occur at interfaces, or produce polymers that concentrate at interface, thereby producing microcapsules. Accordingly, this approach to encapsulation has steadily developed into a versatile family of encapsulation processes. Figure 4 schematically illustrates five types of encapsulation processes that utilize these types of reactions.

Figure 4**a** represents interfacial polymerization encapsulation processes in which shell formation occurs at the core material–continuous phase interface due to reactants in each phase diffusing and rapidly reacting there to produce a capsule shell (1,8). The continuous phase normally contains a dispersing agent in order

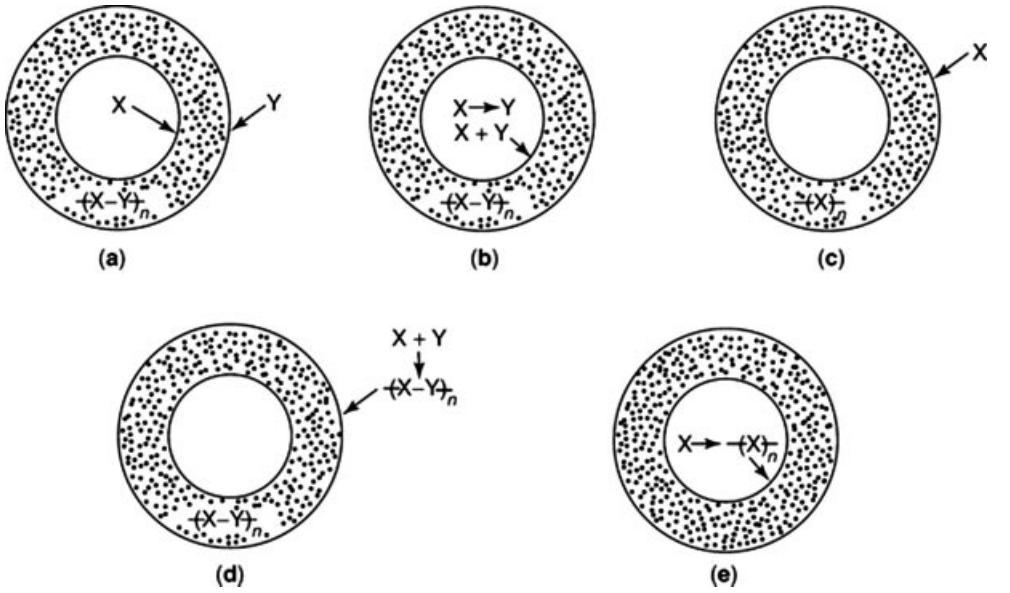

Fig. 4. Schematic diagrams that illustrate the different types of interfacial polymerization reactions used to form microcapsules. Reactants: X, Y; polymerization product: $(X{-}Y)_n$ or $-(X-)_n$. See text for descriptions of cases (**a**)–(**e**).

to facilitate formation of the dispersion. The dispersed core phase encapsulated can be water, or a water-immiscible solvent. The reactant(s) and coreactant(s) in such processes generally are various multifunctional acid chlorides, isocyanates, amines, and alcohols. For water-immiscible core materials, a multifunctional acid chloride, isocyanate, or a combination of these reactants is dissolved in the core, and a multifunctional amine(s) or alcohol(s) is dissolved in the aqueous phase used to disperse the core material. For water or water-miscible core materials, the multifunctional amine(s) or alcohol(s) is dissolved in the core, and a multifunctional acid chloride(s) or isocyanate(s) is dissolved in the continuous phase. Both cases have been used to produce capsules.

Figure 5 illustrates the type of encapsulation process, shown in Figure 4**a**, when the core material is a water-immiscible liquid. Reactant X, a multifunctional acid chloride, isocyanate, or a combination of these reactants, is dissolved in the core material. The resulting mixture is emulsified in an aqueous phase that contains an emulsifier such as partially hydrolyzed poly(vinyl alcohol) or a lignosulfonate. Reactant Y, a multifunctional amine or a combination of amines such as ethylenediamine, hexamethylenediamine, or triethylenetetramine, is added to the aqueous phase, thereby initiating interfacial polymerization and formation of a capsule shell. If reactant X is an acid chloride, a base is added to the aqueous phase in order to act as an acid scavenger.

A key feature of encapsulation processes (Figs. 4**a** and 5) is that the reagents for the interfacial polymerization reaction responsible for shell formation are present in two mutually immiscible liquids. They must diffuse to the interface in order to react. Once reaction is initiated, the capsule shell that forms becomes

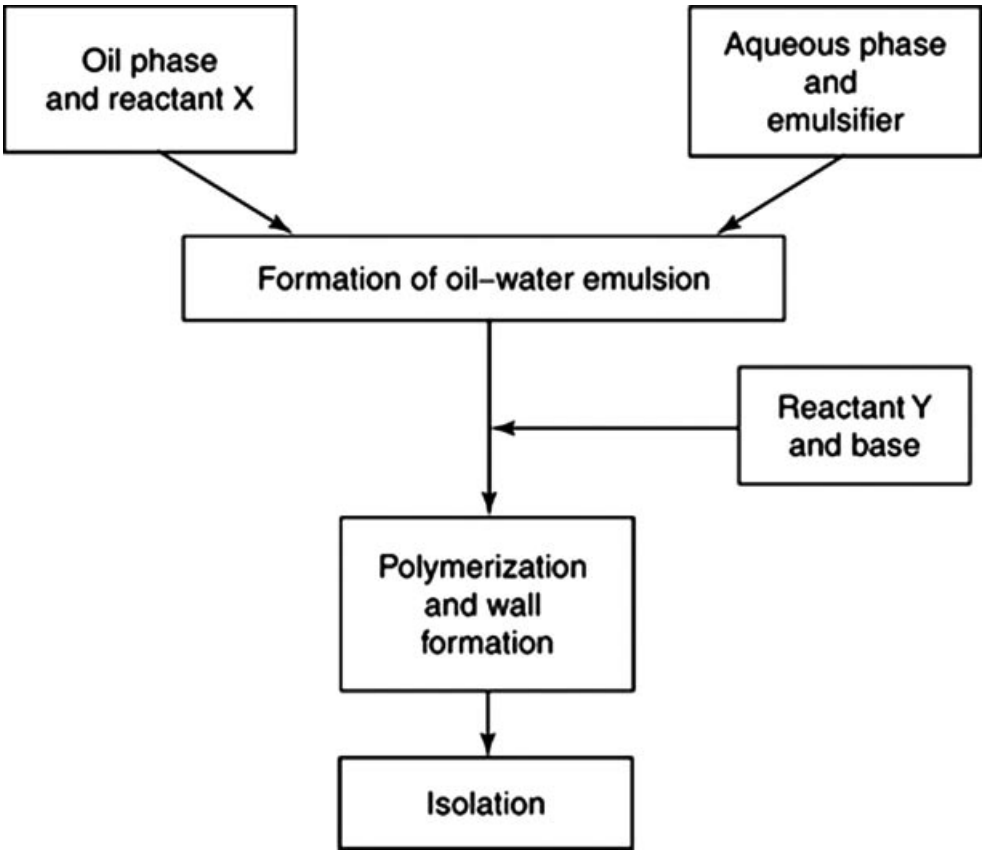

Fig. 5. Flow diagram of a typical interfacial polymerization encapsulation process in which reactants X and Y are dissolved in separate mutually immiscible phases (see Fig. 4**a**).

a barrier to diffusion and ultimately begins to limit the rate of the interfacial polymerization reaction. This, in turn, influences morphology and uniformity of thickness of the capsule shell. Kinetic analyses of the process have been published (8). A drawback to the technology for some applications is that aggressive or highly reactive molecules must be dissolved in the core material in order to produce microcapsules. Such molecules can react with sensitive core materials.

Figure 4**b** represents the case where a reactant dissolved in the dispersed phase reacts with the continuous phase to produce a co-reactant. The co-reactant and any unreacted original reactant left in the dispersed phase then proceed to react with each other at the dispersed phase side of the interface and produce a capsule shell. Capsule shell formation occurs entirely because of reaction of reactants present in the droplets of the dispersed phase. No reactant is added to the aqueous phase. As in the case of the process described by Figure 4**a**, a reactive species must be dissolved in the core material in order to produce a capsule shell.

A specific example of the process represented by Figure 4**b** occurs when a multifunctional isocyanate is dissolved in a liquid, water-immiscible core mate-

rial and the mixture produced is dispersed in an aqueous phase that contains a dispersing agent. The aqueous phase reacts with some of the isocyanate groups to produce primary amine functionalities. These amino groups react with unreacted isocyanate groups to produce a polyurea capsule shell (9).

Figure 4**c** illustrates interfacial polymerization encapsulation processes in which the reactant(s) that polymerizes to form the capsule shell is transported exclusively from the continuous phase of the system to the dispersed phase–continuous phase interface where polymerization occurs and a capsule shell is produced. This type of encapsulation process has been carried out at liquid–liquid and solid–liquid interfaces. An example of the liquid–liquid case is the spontaneous polymerization reaction of cyanoacrylate monomers at the water–solvent interface formed by dispersing water in a continuous solvent phase (10). The poly(alkyl cyanoacrylate) produced by this spontaneous reaction encapsulates the dispersed water droplets. An example of the solid–liquid process is where a core material is dispersed in aqueous media that contains a water-immiscible surfactant along with a controlled amount of surfactant. A water-immiscible monomer that polymerizes by free-radical polymerization is added to the system and free-radical polymerization localized at the core material–aqueous phase interface is initiated, thereby generating a capsule shell (11).

Figure 4**c** also describes the spontaneous polymerization of *para*-xylylene diradicals on the surface of solid particles dispersed in a gas phase that contains this reactive monomer (12) (see XYLYLENE POLYMERS). The poly(*p*-xylylene) polymer produced forms a continuous capsule shell that is highly impermeable to the transport of many penetrants, including water. This is an expensive encapsulation process, but it has produced capsules with impressive barrier properties. It is a type B encapsulation process, but is included here for the sake of completeness.

Figure 4**d** represents *in situ* encapsulation processes (13,14), an example of which is presented in more detail in Figure 6 (14). The first step is to disperse a water-immiscible liquid or solid core material in an aqueous phase that contains urea, melamine, water-soluble urea–formaldehyde condensate, or water-soluble urea–melamine condensate. In many cases, the aqueous phase also contains a system modifier that enhances deposition of the aminoplast capsule shell (14). This is an anionic polymer or copolymer (Fig. 6). Shell formation occurs once formaldehyde is added and the aqueous phase acidified, eg, pH 2–4.5. The system is heated for several hours at 40–60°C.

A unique feature of *in situ* encapsulation technology is that polymerization occurs in the aqueous phase, thereby producing a condensation product that deposits on the surface of the dispersed core material where polymerization continues. This ultimately produces a water-insoluble, highly cross-linked polymer capsule shell. The polymerization chemistry occurs entirely on the aqueous phase side of the interface, and so reactive agents do not have to be dissolved in the core material. The process has been commercialized and produces a range of commercial capsules.

Figure 4**e** represents interfacial polymerization processes in which a solution of water-immiscible vinyl monomer(s), vinyl monomer initiator, and core material is dispersed in an aqueous phase that contains a dispersing agent. Polymerization is then initiated, eg, by heating. The polymer produced within the droplets of the core material is designed to precipitate or deposit at the core material–aqueous

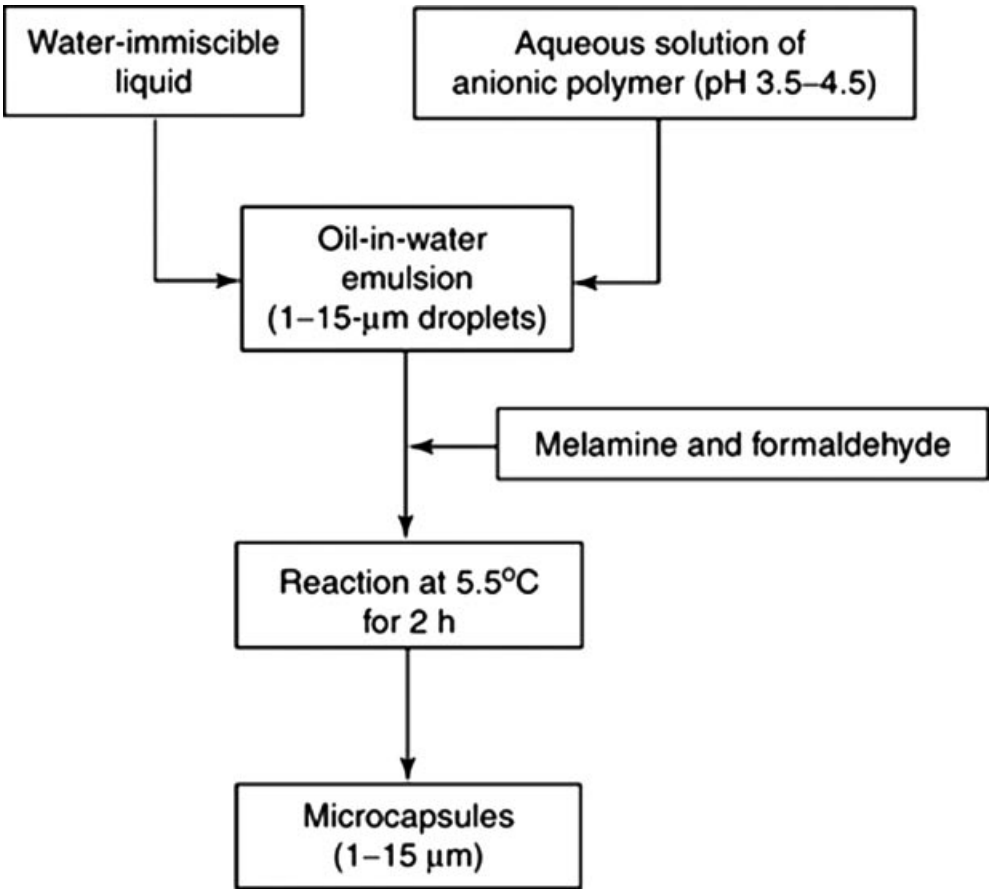

Fig. 6. Flow diagram of a microencapsulation process that utilizes acid-catalyzed *in situ* polymerization of melamine or urea with formaldehyde to form a capsule shell (see Fig. 4**d**).

phase interface, thereby producing a microcapsule shell. Although this technology was disclosed many years ago, it has not been much in use, presumably because the capsules produced do not have acceptable barrier properties.

Solvent Evaporation. This encapsulation technology involves removing a volatile solvent from an oil-in-water, oil-in-oil, or water-in-oil-in-water emulsion (4,15). In most cases, the shell material is dissolved in a volatile solvent, such as methylene chloride or ethyl acetate. The active agent to be encapsulated is dissolved, dispersed, or emulsified into this solution. Water-soluble core materials like hormonal polypeptides are dissolved in water that contains a thickening agent before dispersion in the volatile solvent phase that contains the shell material. This dispersed aqueous phase is gelled thermally to entrap the polypeptide in the dispersed aqueous phase before solvent evaporation occurs (16).

Once the active agent is dispersed in the volatile solvent phase, the dispersion produced is typically emulsified into an aqueous phase that contains a dispersing agent. The solvent used to dissolve the shell material is subsequently

removed from this emulsion at atmospheric or reduced pressure. Significantly, solvent evaporation processes can be based on nonaqueous media. In such cases, a volatile organic solvent is removed by evaporation from an organic solvent that has low volatility.

The microcapsules produced by solvent evaporation processes can range in size from below 1 μm to over several hundred micrometers. The technique is used often to form drug-loaded microparticles from biodegradable polymer shell materials (15,16). Significantly, solvent removal from the dispersed phase of a solvent evaporation process occurs by partitioning or extraction of a volatile solvent into the continuous phase of the emulsion, rather than by direct evaporation into a gas phase. The solvent is removed from the continuous phase by evaporation. Because of this, a range of mass-transfer events can occur during the solvent evaporation process. These may have a negative effect on microcapsule formation, such as causing loss of core material to the continuous phase. Because of this, solvent evaporation encapsulation processes have also been described as solvent removal, in-liquid drying, or emulsion solvent evaporation encapsulation processes.

Centrifugal Force and Submerged Nozzle Processes. A variety of type A encapsulation processes have used centrifugal force or submerged nozzles to produce microcapsules. For example, a device in which a perforated cup was immersed in an oil bath and spun at a fixed rate has been described (17). An emulsion of core and shell material fed into the spinning cup is thrown in droplet form into the oil outside the spinning cup by centrifugal force. Such droplets are gelled by cooling to thereby yield gel beads loaded with an oil that are subsequently dried.

Capsules have also been produced by extruding in droplet form a liquid core and liquid shell formulation through a submerged two- or three-fluid nozzle into a moving stream of carrier fluid. The liquid shell formulation is gelled, usually by cooling, to yield gel beads that can be dried (18). By using a three-fluid nozzle, capsules with unique multiple shell structures can be produced. To date, type A centrifugal force and submerged nozzle encapsulation processes have been used primarily for the encapsulation of various vitamin or flavor oils, and probiotics. The capsules tend to be relatively large and typically are formed from natural shell materials capable of being gelled thermally.

Type B Processes

Spray Drying. Spray-dry encapsulation processes (Fig. 7) consist of spraying an intimate mixture of core and shell material into a heated chamber where rapid desolvation occurs to thereby produce microcapsules (19,20). The first step in such processes is to form a solution of the carrier or shell material in the solvent from which spray drying is to be done. Water is the most common solvent for spray drying. Any film-forming shell material can, in principle, be used, but water-soluble polymers, such as gum arabic, modified starch, and hydrolyzed gelatin, are used most often. Solutions of these shell materials at 50 wt% solids have sufficiently low viscosities so that they can still be atomized without difficulty. It is not unusual to blend gum arabic and modified starch with maltodextrins, sucrose, or sorbitol.

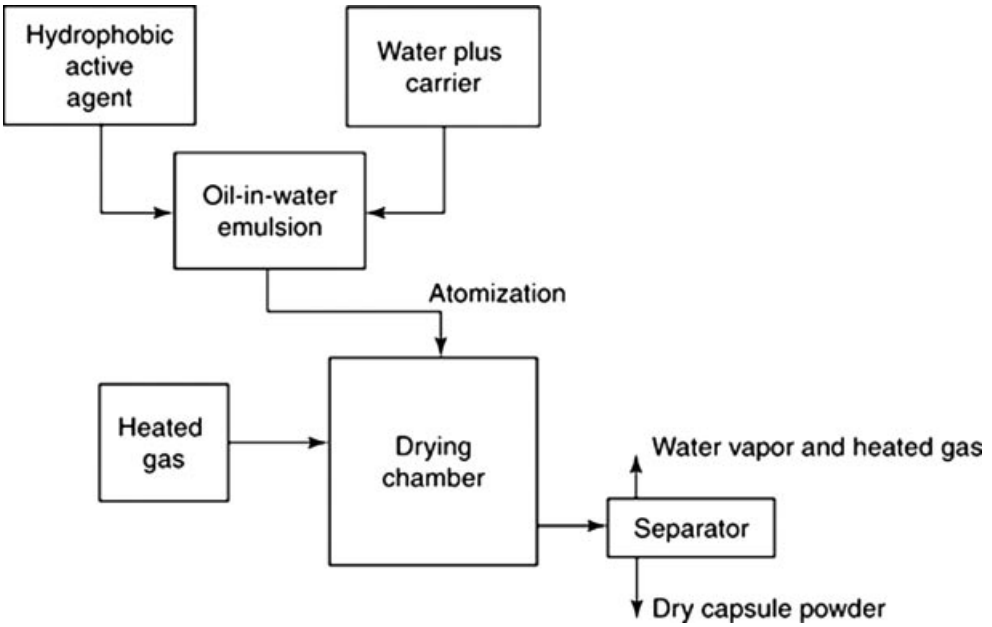

Fig. 7. Flow diagram of a typical spray-dry encapsulation process.

The second step is to disperse the core material being encapsulated in the solution of shell material. Usually, the core material is a hydrophobic or water-immiscible oil, although solid powders have been encapsulated. A suitable emulsifier is used to aid formation of the dispersion or emulsion. In the case of oil core materials, the oil phase is typically reduced to a drop size of 1–3 μm. This is done in order to minimize free oil on the surface of the dried capsules. Once a suitable dispersion or emulsion has been prepared, it is sprayed into a heated chamber. The small droplets produced have a high surface area and are rapidly converted to a fine powder by desolvation in the chamber. Residence time in the spray-drying chamber is 30 s or less. Inlet and outlet air temperatures are important process parameters, as is relative humidity of the inlet air stream.

Capsules produced by spray drying often have a diameter of 10–40 μm. They may be individual particles or aggregates. In either case, capsule geometry varies from irregular to spherical. Core material loadings of commercial spray-dried capsules are typically 20–30 wt%, although loadings as high as 60 wt% have been reported. The core material is dispersed as small droplets or particles throughout spray-dried capsules. Hydrocolloid carriers such as gum arabic and modified starch produce spray-dried capsules that are dispersible in cold water, but warm or hot water is needed to dissolve them completely. Maltodextrins and hydrolyzed gelatins give capsules soluble in cold and hot water.

Spray-dry encapsulation is a low cost process capable of producing a range of microcapsules in good yield. It is often used to produce commercial capsules loaded with fragrance or flavor oils. A number of research workers have prepared drug-loaded biodegradable capsules from nonaqueous media by spray drying (20). This technology has steadily improved over the years, but the capsules produced may

contain a small amount of free or unencapsulated active agent. If this active agent is an oil that contains components capable of oxidizing on storage, an objectionable odor or taste may be produced. Another problem is loss of volatiles during the atomization and drying steps if the active agent contains low boiling, polar active agents such as ethyl acetate and acetaldehyde. Such agents can be difficult to encapsulate by this technology. Their retention is favored by maximizing initial concentration of carrier material.

Spray chilling, cooling, and congealing are essentially variations of conventional spray drying. These processes use a chilled gas to solidify molten capsule shell material formulations rather than volatilize a solvent, as is done in the case of spray drying (21,22). Various fats, waxes, fatty alcohols, or fatty acids are used as shell materials. In such encapsulation procedures, the active agent is dispersed in a molten shell material with the aid of an emulsifier, if necessary (see EMULSIFIERS). This dispersion is atomized through heated nozzles into a cooling chamber analogous to that shown in Figure 7. The shell material is solidified by cooling and solid particles are isolated. If the chamber is at room temperature, the coating material has a melting point between 45 and 122°C. If the chamber is cooled, material melting at 32–43°C can be used. Particles produced by this method have water-insoluble shells. The influence of processing temperature on shell material polymorphism, a phenomenon characteristic of many fats, has been discussed (23).

Fluidized-Bed Coating. Fluidized-bed encapsulation technology involves spraying shell material in solution or hot melt form onto solid particles suspended in a stream of heated gas, usually air (2,6,24). Although several types of fluidized-bed units exist, the so-called top and bottom spray units have been used most often to produce microcapsules. In top-spray units, hot melt shell materials such as fats and waxes are sprayed onto the top of a fluidized bed of solid particles (25). The coated particles are subsequently cooled producing capsules with a solid shell. This technology is used to prepare a variety of encapsulated water-soluble food and pharmaceutical ingredients. Top-spray units are generally not recommended for applying solutions of shell material because the spray droplets move countercurrent to the gas stream that suspends the fluidized bed. This favors solvent evaporation and deposition of a poor coating of shell material.

In bottom-spray or Wurster units (Fig. 8), the coating material is sprayed as a solution into the bottom of a column of fluidized particles. The freshly coated particles are carried away from the nozzle by the airstream and up into the coating chamber where the coating solidifies due to evaporation of solvent. At the top of the column or spout, the particles settle. They ultimately fall back to the bottom of the chamber, where they are guided once again by the airstream past the spray nozzle and up into the coating chamber. The cycle is repeated until a desired capsule shell thickness is reached. Coating uniformity and final coated particle size are strongly influenced by the nozzle(s) used to apply the coating formulation. This technology is routinely used to encapsulate solids, especially pharmaceuticals (qv). It can coat a wide variety of particles, including irregularly shaped particles. The technology generally produces capsules larger than 100–150 μm, but can produce coated particles smaller than 100 μm. An important feature of the Wurster process is that it can be used to apply a wide range of coating materials and multiple layers of different coating materials. Candidate coating materials include various

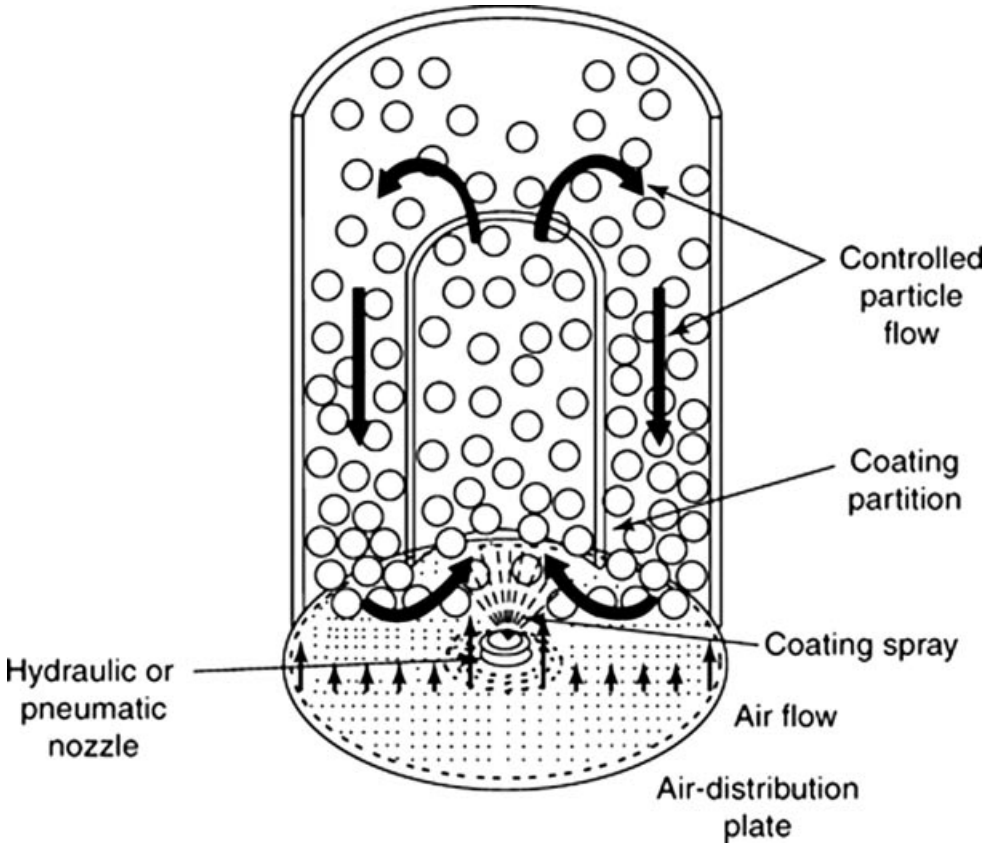

Fig. 8. Schematic diagram of a Wurster coating chamber. Courtesy of the Coating Place.

water-soluble polymers or hydrocolloids, solvent-soluble polymers, sugars, and pseudolatices. The latter are aqueous dispersions of small polymer particles which fuse together during desolvation to form a continuous capsule shell.

Centrifugal Force Processes. Several type B encapsulation processes utilize centrifugal force to form microcapsules. In one process, two mutually immiscible liquids, the core and shell material, are pumped through a two-fluid nozzle that is spun rapidly (26). The two-fluid column produced breaks up spontaneously into a series of droplets. Each droplet contains a core region surrounded by a continuous film of fluidized shell material. The shell is solidified either by cooling or by immersion in a gelling bath to produce microcapsules that can be harvested. In the former case, the shell material is typically a molten wax or fat that has relatively low melt viscosity and solidifies by cooling as it falls away from the nozzle. It may contain a small amount of polymer added in order to toughen the final capsule shell. The core material is, typically, water or an aqueous solution. In the latter case, the fluidized shell material, typically, is an aqueous sodium alginate solution. This solution is gelled ionically by immersion in an aqueous $CaCl_2$ solution to form a gel bead which can subsequently be dried and isolated. The core material is a water-immiscible liquid. This type of encapsulation technology tends

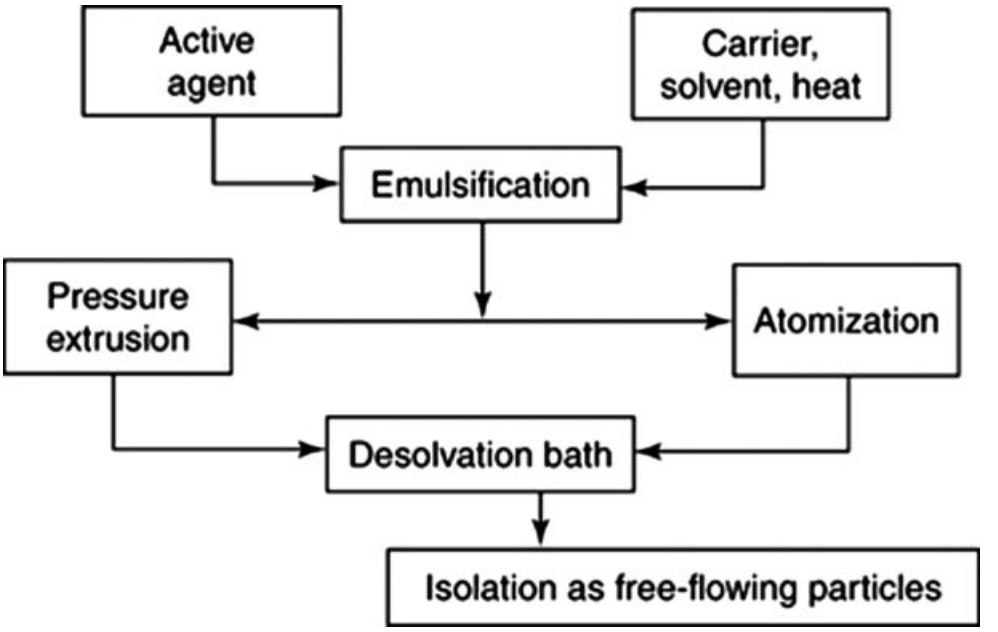

Fig. 9. Desolvation process.

to favor production of larger microcapsules. The lower particle size limit is approximately 250 μm; the upper particle size limit is several millimeters.

A second type B encapsulation process that uses centrifugal force is called *rotational suspension separation* (6). It utilizes a rapidly spinning disk to produce particles of core material surrounded by shell material. The fluidized shell material formulation, often a wax, fat, or a solution of a polymer in these materials, is mixed with particles of core material. The resulting dispersion is fed onto a rotating disk placed at the top of a chamber. Individual particles of liquid-coated droplets are flung off the edge of this disk into the chamber producing solid particles of core material enclosed in a thin film of liquid shell material. The shell formulation solidifies as the embryonic capsules fall to the bottom of the chamber producing solid microcapsules. Droplets of pure coating material are also flung off the edge of the disk, and fall in a circumferential area or zone below the disk at a closer distance to the disk than the capsules.

A number of hot-melt shell formulations have been applied in this manner to produce a range of capsules. It is claimed that the process is capable of rapidly producing capsules smaller than 100 μm in large amounts at low cost. Candidate core materials must act like solids on the rotating disk and should have a spherical geometry. Candidate coating formulations must solidify rapidly on cooling and not have high viscosities. For these reasons, preferred shell formulations, typically, are waxes and fats or polymer solutions in these materials.

Desolvation or Extractive Drying. This encapsulation technology (Fig. 9) has been used to produce commercial water-soluble capsules loaded with a range of flavor compounds (27,28). Water-soluble shell materials used are maltodextrins, sugars, and gums (qv). The shell material is dissolved in as little wa-

ter as possible and the core material is dispersed in this solution. Heat, up to 124°C, is used to reduce the viscosity of the shell formulation so that dispersion can be achieved readily. The dispersion of core material and shell formulation is either extruded or atomized into a desolvation solvent. Preferred desolvation solvents are water-miscible alcohols such as 2-propanol or polyglycols. This step solidifies the particles. Because the core materials used in this process are miscible with the desolvation solvents used, capsules with no free core material are produced. Such capsules have excellent storage stability properties. The problem with this approach to encapsulation has been that it uses solvents other than water which must be recycled. It also produces capsules with relatively low core loadings. Core loadings as high as 15% can be achieved, but forming stable emulsions in the concentrated hot aqueous core solutions used poses serious problems.

A steady stream of encapsulation technologies continues to appear in the patent literature. Some are simply modifications or improvements of established technologies, whereas others are new technologies such as very low temperature casting (29), deposition of coating material from a supercritical fluid (30), and polymer phase separation induced by evaporation of a volatile solvent from a two-component solvent mixture (31).

Applications

Microcapsules are incorporated in a number of products produced by the pharmaceutical, graphic arts, food, agrochemical, cosmetic, and adhesive industries. In order to illustrate the wide range of microcapsule applications, it is appropriate to describe briefly a number of commercial microcapsule-based products and the role that microcapsules play in these products.

Graphic Arts. Carbonless copy paper was the first large-scale commercial application of microcapsules. This product has consumed thousands of tons of capsules annually for many years, although the rate of usage has begun to decline significantly. Figure 10, a schematic diagram of a three-part business form, illustrates the concept of carbonless copy paper. The bottom surface of the top sheet of this form (sheet A) and the second sheet (sheet B) is coated with a layer of small microcapsules. The coating includes inert spacer particles, often starch particles, that are larger than the microcapsules. They protect the microcapsules from premature rupture. The capsules, filled with a colorless solution of 2–6% leuco dye dissolved in a high boiling organic solvent, rupture under pressures encountered in normal handwriting or impact printing. The dye solution released is transferred from the bottom surface of sheets A and B to the top surface of sheets B and C, respectively, where it reacts to form an image. The reactive coating on the top surface of sheets B and C contains acidic sites that activate leuco dyes. Reactive materials often used are attapulgite clay (see Clays) or phenolic resins. Sheet A in Figure 10 is called a coated back (CB) sheet; sheet B, a coated front back (CFB) sheet; and sheet C, a coated front (CF) sheet. The capsules and reactive coating can be coated on the same paper surface. In this case, the product is called self-contained carbonless copy paper.

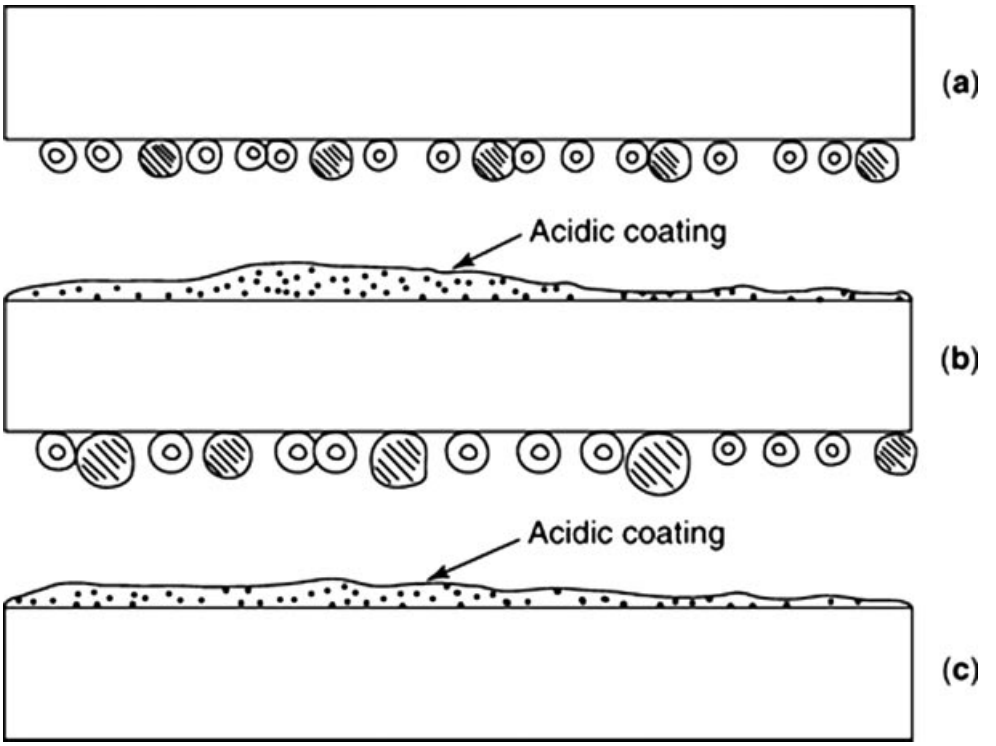

Fig. 10. Cross section of a three-part business form prepared from carbonless copy paper, where ◎ are microcapsules and ● are starch: (**a**), CB sheet; (**b**), CFB sheet; and (**c**), CF sheet.

Blythe and co-workers (32) discuss the industrial and commercial aspects of microcapsules for carbonless paper. Such capsules must be small enough to give a sharp image on the reactive coating of the transfer sheet and large enough to be broken by pressures encountered in normal writing and impact printing. The upper size limit is approximately 20 μm, since capsules larger than this produce a fuzzy image. The lower size limit is approximately 1–2 μm. Capsules smaller than this tend to fall into the crevices of the paper where they are protected from breakage. Capsules that meet these size requirements and are able to retain leuco dye solutions can be produced by complex coacervation, interfacial polymerization, or *in situ* polymerization. Solvents for dyes used in carbonless copy paper are high boiling ($>200^{\circ}$C) organic liquids that experience minimal solvent loss during product storage. Candidate solvents include benzylated ethylbenzene, benzyl butyl phthlate, isopropylbiphenyl, and diisopropylnaphthalene. Solvent choice is determined by cost, availability, toxicity, and the ability to dissolve the dye system, produce the desired color intensity on the transfer sheet, and form acceptable microcapsules.

Microcapsules have many imaging applications other than carbonless paper. They are used in toners for electrophotography, thermomsensitive printing

papers, various thermosensitice recording products, photosensitive recording materials, and thermofixing photosensitive paper (33). Encapsulated liquid crystal formulations coated on polyester film produce a variety of temperature-sensitive display products, while polyester film coated with capsules loaded with leuco dyes is used as a means of measuring line and force pressures.

So-called microencapsulated electronic inks have received much publicity in recent years. They consist of microencapsulated electrophoretic media that change color (eg, black to white) when an electric field is applied to thin microcapsule layers placed between thin electrodes. This color change occurs because the microcapsules contain a mixture of two color components dispersed in a dielectric fluid. The two color components can conceptually be two different colored particles (eg, white titanium dioxide and carbon black) or particles of one color (eg, titanium dioxide) dispersed in a dyed dielectric fluid. In either case, application of an external electrical field causes the color components to migrate or separate inside the microcapsules, thereby forming different colored images. Such inks make it possible to create flexible electronic paper displays that require low power and can receive and display information electronically (34–36).

Pharmaceuticals. The concept of microencapsulation has intrigued the pharmaceutical industry for many years, because it offers the possibility of providing a number of important new oral and parenteral dosage forms. Microcapsules in oral dosage forms can conceptually taste-mask bitter pharmaceuticals, provide extended release *in vivo*, provide enteric release, improve the stability of incompatible drug mixtures, provide resistance to oxidation, reduce volatility, and distribute a drug in many small carrier particles so that effects of the drug on the sensitive walls of the stomach are minimized. Microencapsulated parenteral formulations can provide prolonged delivery of drugs with short half-lives *in vivo* and perhaps even achieve targeted drug delivery. For these reasons, microencapsulation has received much attention by pharmaceutical scientists (37) and yielded a number of commercial pharmaceutical formulations. Initially, many of the microcapsules in these formulations had an ethylcellulose shell and were produced by a polymer–polymer phase-separation process carried out in hot cyclohexane (5). More recent formulations tend to have an acrylic copolymer coating and are prepared by using a fluidized bed coating process. Core materials encapsulated tend to be solids with finite water solubility. Encapsulated potassium chloride, KCl, has been used extensively because the KCl dispersed in many small capsules minimizes high localized KCl concentrations that can irritate the lining of the stomach and induce bleeding. Encapsulated aspirin for arthritic patients is an example of using microencapsulation to extend time of release of a drug in the gastrointestinal tract. In this case, the encapsulated aspirin formulation provides overnight relief. Finally, encapsulated oral acetaminophen formulations for children are used to provide taste-masking. One application that has received much attention in recent years is the development of microcapsules with a biodegradable poly(lactide–glycoilide) copolymer shell for delivery of vaccines (38,39) (see CONTROLLED RELEASE TECHNOLOGY).

Several commercial parenteral formulations utilize microcapsules. The core materials are polypeptides with hormonal activity. The shell materials are poly(lactide–glycolide) copolymers. The capsules are produced by solvent evaporation, polymer–polymer phase separation, or spray-dry encapsulation processes.

Core material release can occur over a 30–90 day period *in vivo*, although not at a constant rate.

Injectable encapsulated leuprolide acetate formulations (Lupron Depot) have developed into a major tool for treating cancer of the prostrate. Lupron Depot dosages that last 30 and 90 days *in vivo* are available. Biodegradable poly(lactide–glycolide) polymers are the shell materials used to form these microcapsules. The capsules are produced by removing volatile solvent from a water-in-oil-in-water emulsion. Okada reviewed their preparation and release behavior (16). An encapsulated formulation of bromocryptin [25614-03-3] is used to inhibit milk production in women after pregnancy. Injectable biodegradable microcapsules loaded with fertility control agents have been under development for a number of years and have been carried to various stages of clinical development (40) (see BIODEGRADABLE POLYMERS, MEDICAL APPLICATIONS).

The development of injectable microcapsules for delivery of chemotherapy agents remains an active area of research. The ultimate goal is to achieve targeted delivery of chemotherapy agents to specific sites in the body, ideally by injection of drug-loaded microcapsules that would seek out and destroy diseased cells. Intra-arterial infusion chemotherapy is a direct approach to targeted delivery. The clinical applications of microspheres and microcapsules in embolization and chemotherapy have been assessed (41).

Biomedical and Biotechnology. The use of microcapsules for a variety of biomedical and biological applications has been promoted for many years (42,43). Several biomedical microcapsule applications are in clinical use or have approached clinical use. One application is the use of liquid-filled microcapsules or microbubbles as ultrasound contrast agents. Such microcapsules can be formed in several different ways (44). Perfluorocarbon-gas-filled microbubbles with a human albumin shell (45) are FDA (U.S. Food and Drug Administration) approved.

Another biomedical application is the encapsulation of live mammalian cells for transplantation into humans. The purpose of encapsulation is to protect the transplanted cells or organisms from rejection by the host. The capsule shell must prevent entrance of harmful agents into the capsule, allow free transport of nutrients necessary for cell functioning into the capsule, and allow desirable cellular products to freely escape from the capsule. This type of encapsulation has been carried out with different types of live cells, but studies with encapsulated pancreatic islets or islets of Langerhans are most common. The alginate–poly(L-lysine) encapsulation process originally developed in 1981 (46) catalyzed much of the cell encapsulation work carried out since. In 1993, Vos and co-workers (47) reviewed the obstacles that must be overcome for successful application of microcapsules in islet transplantation. Work on this approach to islet transplantation has continued. Vos and co-workers (48) recently reported a study of the long-term biocompatibility, chemistry, and function of encapsulated pancreatic islets. These authors report that capsules prepared with purified alginate are biocompatible and stable *in vivo* up to two years after implantation. Yin and co-workers (49) describe microcapsules loaded with hepatocytes for use in a bioartificial liver assist device.

The microencapsulation or immobilization of a variety of live cells and organisms has been examined. The capsules prepared often are larger than 1000 μm and may not have a well-defined capsule shell, but they are designed to provide

many of the capabilities traditionally associated with microcapsules. Rokstad and co-workers (50) evaluated several different types of alginate microcapsules that contained endostatin secreting cells. Park and Chang (51) reviewed the microencapsulation of microbial cells. Goosen discussed animal cell encapsulation (52). A wide range of applications has been explored, including the use of alginate microcapsules gel beads to shorten the handling time for preparing champagne.

Other biomedical and biological applications of microcapsules exist. For example, the encapsulation of enzymes continues to attract interest even though loss of enzyme activity due to harshness of the encapsulation protocols used has been a persistent problem (53). Microencapsulated activated carbons can be used as sorbents to remove metabolic wastes and/or toxins from blood (54). The use of microcapsules in antibody hormone immunoassays has been reviewed (55). The encapsulation of hemoglobin as a red blood substitute has received much attention because of AIDS and blood transfusions (56).

Food Ingredients. A number of food ingredients or additives have been encapsulated and are available commercially. Solid ingredients encapsulated are typically water-soluble and are often encapsulated with a hydrophobic hot-melt coating material applied by a fluidized-bed coating process. Preferred hydrophobic coating materials are partially hydrogenated vegetable oils of varying melting points, monoglycerides, and diglycerides. If a hydrophilic coating is used, it tends to be gum arabic, modified starch, or mixtures of these materials with a maltodextrin. Such capsules typically are produced by spray drying. All coating materials used are well-accepted food-grade products.

Several reviews (57–59) and books (60,61) examine in some detail many aspects of the formation, properties, and uses of microencapsulated food ingredients. Encapsulation is designed to provide taste-masking, possibly a degree of prolonged release, stabilization of the core material against oxidation, and minimization of reaction with other ingredients in the final product. Dziezak discussed the function of a number of commercially available encapsulated solid food ingredients (62). Acidulants like citric and lactic acid encapsulated in partially hydrogenated vegetable oil are used in meat processing, where they provide direct acidification and shorten processing time. Sodium acid pyrophosphate encapsulated in hydrogenated vegetable oil is used in frozen cake batters in order to aid mixing and reduce gas release during batter make-up. In both types of applications, release of core material occurs during a heating cycle that melts the shell formulation and releases the core material. Figure 11 illustrates the nature of commercial NaCl-loaded microcapsules with a lipid coating produced by fluidized-bed coating.

Acidulants like citric, lactic, and fumaric acids encapsulated in a water-soluble maltodextrin shell formulation are used in dry mix beverages and desserts, as well as prepared premixes for the baking and dairy industries. The maltodextrin coating is designed to minimize hygroscopicity, reduce dusting, and minimize reactions with incompatible ingredients. It dissolves in the presence of liquid water to rapidly release the contents of the capsules during a mixing cycle. Figure 12 is a photomicrogrpah of commercial spray dried microcapsules that contain an oxygen-sensitive supplemen oil.

Various iron compounds have been encapsulated in order to provide food products with enhanced iron contents. Boccio and co-workers (63) studied the

Fig. 11. Scanning electron micrograph of commercial NaCl microcapsules with a lipid coating produced by fluidized-bed coating. Magnification: x.

bioavailability in mice and storage stability in milk of ferrous sulfate encapsulated with a lecithin shell. They report high bioavailability of the encapslated ferrous sulfate and found that the capsule-containing milk was stable to heat processing (100°C, 30 min) as well as 6-month storage at room temperature.

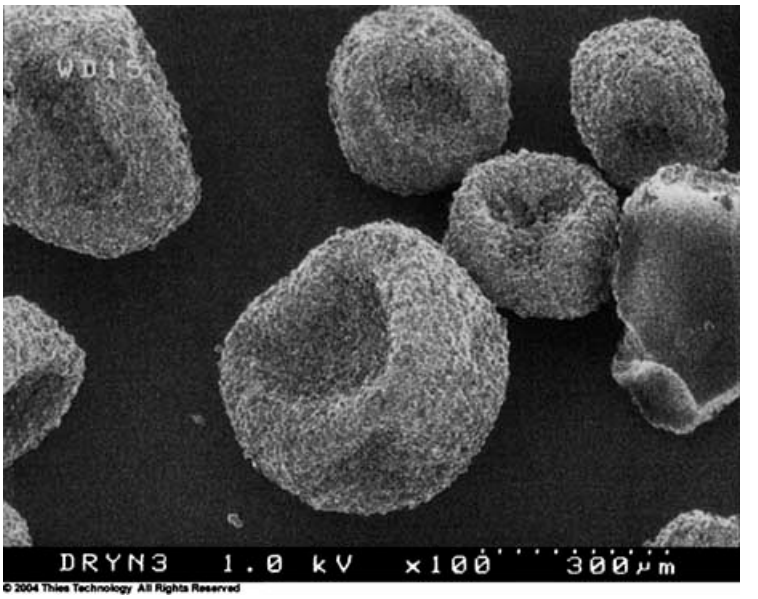

Fig. 12. Scanning electron photomicrograph of commercial PFUA-loaded microcapsules.

Calcium proprionate [4075-81-4] and sodium bicarbonate [144-55-8] encapsulated in hydrogenated vegetable oil are used in chemically leavened products. Release typically occurs during the baking cycle due to melting of the hydrogenated shell material. Sodium bicarbonate encapsulated with maltodextrin is used in dry mix baking and other chemically leavened products. In this case, release occurs during the mixing step. Sodium chloride [7647-14-5] encapsulated in a hydrogenated vegetable shell is used in various meat products, yeast-containing mixes, and assorted doughs. The capsules are designed to minimize inhibition of yeast activity, rancidity, and excessive salt binding during product storage.

Liquid food ingredients encapsulated traditionally have been oil-soluble flavors, spices, and vitamins. However, in recent years, the encapsulation of 3-*n* polyunsaturated fatty acids (PUFAs) for improved cardiovascular health has received much interest recently. Fish oils contain desired PUFAs and are microencapsulated in order to increase resistance of the PUFAs to oxidation. Encapsulation also provides taste-masking. A human feeding study established that the *n*-3 PUFAs in a microencapsulated fish oil have the same desired effect on platlet *n*-3 fatty acid profile as unencapsulated fish oil (64). Figure 12 is a photomicrograph of commercial capsules loaded with PUFAs.

Hydrophobic flavors, food oils, and fats are often encapsulated with a water-soluble shell material applied by spray drying from water (65), but gelatin-based shells formed by complex coacervation can also be used (66). Water-soluble shell materials applied by spray drying include milk protein (casein), modified starches, gum arabic, maltodextrins, or blends of these polysaccharide polymers with maltodextrins. Vitamins are encapsulated with zero bloom strength gelatin by spray drying.

A range of spray-dried flavor-filled capsules with water-soluble shell formulations are used in various dry beverage mixes and other dry food products. Flavors containing ethyl acetate and other low boiling point components pose problems for successful spray-dry encapsulation. Such components are either lost during the initial emulsification process or during the actual dewatering step as a result of azeotrope formation. Another problem with spray-dry encapsulation is the formation of free surface oil. The rapid desolvation that occurs in the drying chamber can produce blow holes in the capsules, essentially leaving a small amount of flavor oil or free or surface oil, which oxidizes on storage and detrimentally affects product quality. This effect generally limits the flavor content of capsules produced by spray drying to 20–30 wt%. Another approach to the encapsulation of food flavors is desolvation by pressure extrusion. The rod-like particles produced in this manner typically have a relatively low loading (8–10 wt%), although higher loadings (15%) have been reported. The advantage of this technology is that it yields essentially defect-free particles with superb shelf-life storage stability. Macrocapsules loaded with a flavor oil are produced by dropwise extrusion through a submerged multifluid nozzle. Figure 13**a** shows the outer surface of commercial capsules produced in this manner. Figure 13**b** is a photomicrograph of a cut capsule that shows the thickness of the capsule shell and lack of macrosopic defects in the shell. Another approach to the encapsulation of food flavors, spray chilling, should be particularly well suited to the encapsulation of aqueous flavor compositions. Release occurs during a product heating cycle, eg, bake or microwave.

Magnification: x. (**b**), Cut macrocapsule that shows uniformity and thickness of the capsule shell. Magnification: x.

The food industry has increasingly realized that microencapsulation offers much potential for the development of new products. For example, Talwlkar and Kailasapathy (67) discuss the effect of microencapsulation on oxygen toxicity in probiotic bacteria, another appplication area of current interest. Hagenbart gives a valuable discussion of the problems that must be overcome when an effort is made to develop microcapsule formulations for use in food products (68).

Agrochemicals. The microencapsulation of pesticides, herbicides, and other pest control agents has been an active area of development. Several books or book chapters (69–72) summarize much of these efforts. Wilkins (69, pp. 314–315) and Tsuji (71) list commercial microencapsulated formulations of pest control agents available in 1990 and 1999, respectively. Most of the microcapsules in these formulations are prepared by interfacial polymerization.

Pest control agents are microencapsulated in order to prolong activity while reducing mammalian toxicity, volatilization losses, phytotoxicity, environmental degradation, and movement in the soil. Ideally, encapsulation would also reduce the amount of agrochemical needed. Penncap-M was the first of several encapsulated pesticide formulations commercialized by Atochem North America (Pennwalt) (8). It is sold as an emulsifiable concentrate of encapsulated methyl parathion. The 30–50-μm capsules are prepared by interfacial polymerization. Encapsulation reduces mammalian toxicity of methyl parathion and prolongs its activity. Significantly, the use of highly toxic pesticides, including microencapsulated forms like Penncap-M, is declining. Microencapsulated chlorpyriphos is no longer sold in the United States.

A significant trend in current agrochemical development work is the on-going transition from highly toxic pesticides to pest control agents with markedly less mammalian toxicity. Examples of the latter include insect pheromones to disrupt mating, insect growth regulators, and pyrethins. Microencapsulation enhances the effectiveness of these compounds. For example, methoprene [40596-69-8],

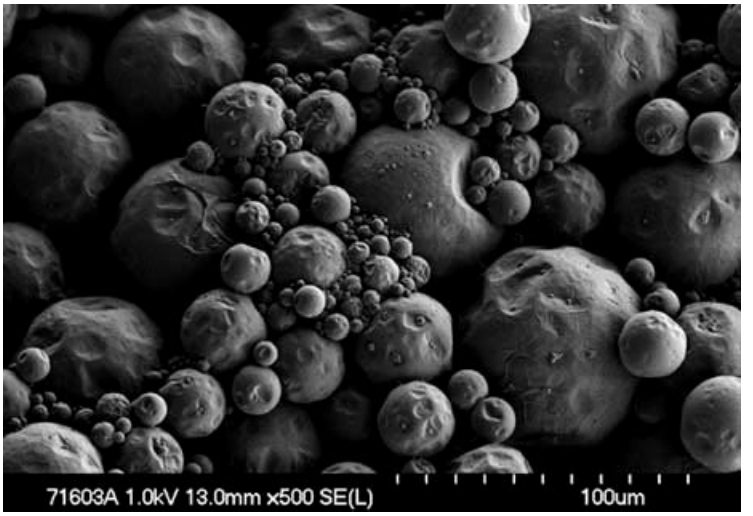

Fig. 14. Scanning electron photomicrograph of pheromone-loaded microcapsules produced by interfacial polymerization. Magnification: x.

a mosquito growth regulator, has been sold as an encapsulated formulation that provides release over a 5–7 day period in the field. A microencapsulated pyrethin formulation is used to control crawling insects such as cockroaches. The capsules are sold as an aqueous-based suspension that provides protection for at least 30 days. Field tests indicate that effectiveness of the encapsulated pyrethin compares favorably with several nonencapsulated pesticides although the capsule formulation leaves a visible residue. Encapsulated fenitrothion [122-14-5] is also available commercially. The capsules are 20 μm in diameter and have a polyurethane shell formed by interfacial polymerization (73). Commrcial microencapsulated pheromone formulations are available and provide pheromone release in the field for 14–28 days. Figure 14 is a photomicrograph of the outer surface of pheromone-loaded microcapsules produced by interfacial polymerization.

The encapsulation of biopesticides has been studied for many years, but the author is not aware of any commercialized encapsulated biopesticide formulations. Hunter-Fujita and co-workers (74) summarize the techniques and shell materials used to produce past encapsulated biopesticide formulations. More recently, Behle and co-workers (75) describe the storage stability and field activity of a spray-dried nucleopolyhedrovirus formulation. Cost and long-term stability of encapsulated biopesticides remain issues to be resolved.

Several encapsulated herbicide formulations exist. Encapsulated alachlor herbicide has been sold as a liquid or dry granule formulation. The capsules, produced by interfacial polymerization, are spherical with a diameter of 2–15 μm. Two thiocarbamate herbicides, EPTC and vernolate [1929-77-7], were encapsulated by interfacial polymerization because they are volatile compounds. When applied in unencapsulated form, they must be incorporated in the soil within 2 h in order to provide effective weed control. When applied as a microencapsulated formulation, the rate of volatilization is lower and soil incorporation can be

delayed by 24 h (76). Microencapsulation of clomazone reduces the risk of bleaching of nontargeted foilage (77).

Various workers have explored the use of microencapsulation as a means of preparing formulations for feeding fish at various stages of development (78). Encapsulated fish food is currently commercially available (79).

Consumer and Industrial Products. Many encapsulated consumer and industrial products exist. Advertising inserts that utilize encapsulated perfumes and flavors contain a coating of scent-filled capsules which break and release scent when the insert is torn open. This product is widely used as a marketing tool, primarily for new perfumes. Various paper products are coated with scent-filled capsules that break when the coated area is rubbed.

Microcapsules are present in a number of personal care and cosmetic products (80). For example, deodorants may contain capsules that release their core contents due to moisture developed because of sweating. Microcapsules are incorporated in various cosmetic creams, powders, and personal cleansing products. Kiyama (81) summarizes the preparation and use of poy(vinyl alcohol) microcapsules in cosmetic products. Miyazawa and co-workers (82) describe the formation of agar capsules designed for cosmetic use. They note that residual glutaraldehyde in capsules with gelatin shells formed by complex coacervation may be an issue for microcapsules intended for cosmetic applications.

Microcapsules are used in several film coatings other than carbonless paper. Encapsulated liquid crystal formulations coated on polyester film produce a variety of temperature-sensitive display products, including thermometers. Polyester film coated with capsules loaded with leuco dyes analogous to those used in carbonless copy paper is used as a means of measuring line and force pressures.

Microcapsules loaded with phase change materials (PCMs) have been incorporated into various textiles (83). They provide enhanced heat capacity not easily achieved in other ways. Nelson (84) discusses a variety of textile applications of microcapsules including encapsulated PCMs. Encapsulated PCMs offer much promise as a means of improving the thermal capacity of various heat-transfer fluids (85).

Several groups have described the fabrication of microcapsules loaded with a catalyst. Catalysts encapsulated include palladium(II) acetate (86) and osmium tetraoxide (87). Microencapsulated catalysts are described as effective, easily isolated from a reaction system by filtration, and reusable. Shchukin and co-workers (88) recognized that chemical processes can be performed within microcapsules to produce unique products that are retained within the microcapsules. They produced crystalline WO_3 nanoparticles inside microcapsules with a polyelectrolyte shell.

Pernot and co-workers (89) discussed a number of one- and two-component adhesive systems that utilize microencapsules. A majority of fasteners used in automobiles are coated with microcapsules loaded with an adhesive. When the fastener is installed, a fraction of the capsules in the coating rupture, releasing the adhesive payload. The adhesive essentially glues the fasteners in place, preventing them from becoming loose and causing rattles. The capsules are designed so that only a fraction of them break each time a fastener is taken off and put back. The on/off cycle can be repeated three or four times.

Encapsulated ammonium polyphosphate [10124-31-9] incorporated in plastics acts as a fire-retardant. In Japan, microcapsules loaded with naramycin are incorporated into poly(vinyl chloride) (PVC). The capsule-loaded PVC is used to coat a range of electrical cables. Rodents bite and gnaw on cables coated with PVC free of capsules, ultimately causing power interruptions; but when rodents bite into cables coated with capsule-loaded PVC coatings, they break the capsules in the coating, thereby releasing the naramycin [66-81-9], a taste-repellent to the rodents. The encapsulation of fillers and pigments for engineering plastics as well as inks and toners is an active area of development (90).

The oil industry uses microencapsulated oil-field chemicals. For example, microencapsulated breaker is delivered into a subterranean formation, where it breaks the fracturing liquid used to stimulate the recovery of fluids such as crude oil or natural gas. Examples of breakers encapsulated include oxidizers, enzymes, and various mineral or organic acids.

Microcapsules designed to serve as inertial confinement fusion targets represent an intriguing potential capsule application that is currently under active development. Schultz and co-workers (91) reviewed the status of this effort in the United States in 1999. Capsules for this application must meet strict spherical geometry and shell thickness uniformity requirements. Tsai and co-workers (92) note that desired properties of candidate shell materials include high gas permeability, high Young's modulus and tensile strength, and good optical transparency. They described the formation of candidate capsules with a polyimide shell by vapor deposition polymerization.

New Developments. Creation of novel microencapsulation technology and applications of microcapsules are goals that many research and development groups are pursuing globally. Technical deficiencies of current capsules, unanticipated problems in marketing, and poor product design are problems that handicapped past efforts. The growing number of products that utilize microcapsules indicates that these issues are increasingly resolved successfully.

NONDESTRUCTIVE TESTING

Introduction

Polymers are macromolecules that contain repetitive, regular or irregular arrangements of organic molecular groups, ie, carbon atoms covalently bonded with other carbon and/or heteroatoms. Technical polymers usually contain additives, fillers, and pigments. Polymer–matrix composites (PMC) contain at least a second, insoluble phase, frequently in the form of fibers or particles. The structure and morphology of polymers and PMC can be quite complex; see, eg, AMORPHOUS POLYMERS; SEMICRYSTALLINE POLYMERS; MORPHOLOGY, ADDITIVES, VISCOELASTICITY, PHASE TRANSFORMATION, and Reference 1. Properties of polymers and PMC that may be relevant for nondestructive testing (NDT) are as follows: (*1*) (pronounced) temperature dependence, viscoelastic behavior, and, in some cases, specific transition temperatures; (*2*) limited thermal stability, upper limit set by incipient decomposition or melting; (*3*) relatively low density; (*4*) transparency, semitransparency, or opaqueness with respect to the visible part of the electromagnetic spectrum; (*5*) electrical insulation and relatively low electrical conductivity for specially formulated compositions; and (*6*) possible changes in volume, properties, and, in some cases, even chemical reactions induced by absorption or diffusion of media.

The literature on NDT of polymers and PMC comprises the classes shown in Table 1. References illustrate the available range of literature or a specific topic. Omission or inclusion of a reference does not imply a rating by the authors. The amount of information available in electronic format only is steadily increasing, eg, References 2–8, and many journals feature electronic on-line editions. Electronic database searches are sensitive to spelling, eg, "non-destructive" yields 27, and "nondestructive" 384, active standards of the American Society for Testing and Materials International. Most NDT methods apply to various material classes. Those documents that explicitly mention polymers or PMC deal with effects specific to certain materials, eg, the Felicity effect in PMC (9), or with polymer products used in large quantities (10–14). Standards tend to lag behind technical developments, as discussed for acoustic emission (15), but similar arguments hold for other NDT methods.

Nondestructive testing (NDT) is the development and application of technical methods for the detection, location, measurement, and evaluation of discontinuities, defects and other imperfections, the assessment of integrity, the assessment of properties and composition, or the measurement of geometrical characters without impairing the intended use or application of the test object (31).

Table 1. Classes of Literature on NDT of Polymers and PMC

Source type	Sample references	Remarks
Handbooks	(16–26)	Some volumes available in 3rd edition, others in preparation; 3rd edition also available in electronic format on compact disc with supplemental information
Monographs	(27,28)	
Normative codes and standards	(9–14)	Few codes and standards are explicitly on NDT applied to polymers and PMC, but most NDT codes and standards are applicable to polymers and PMC, except when explicitly stating another class of materials; up-to-date information can be obtained on the Web sites of standards-issuing organizations, eg (2–5)
Guidelines (without normative character)	(29,30)	A few guidelines are explicitly on NDT applied to polymers and PMC, but most NDT guidelines apply to polymers and PMC, except when stating explicitly another class of materials
Journals	Electronic journals Class A (6,7) Class B (8)	Literature on NDT of polymers and PMC comprises two classes (see Bibliography for examples): A. journals dealing with NDT B. journals dealing with polymers and PMC
Conference proceedings	Class A Class B	Conferences again comprise two classes: A. general or topical (on specific NDT methods and/or applications) NDT conferences B. conferences on polymers and PMC Information on many conferences is available on the Internet, eg, through links on the Web sites of national NDT societies[a]
Technical documents	Equipment descriptions, technical manuals, application notes	Provided, eg, by equipment manufacturers or test agencies
Educational documents	Lecture notes, training manuals	Provided, eg, by lecturers, national NDT societies, NDT training and certification agencies

[a]Web sites of most national NDT societies can be found at www.icndt.org/directory.htm (however, some listings may not be up-to-date).

Composites are a combination of at least two materials, insoluble in one another, combined to yield a material with certain properties not possessed by the constituents (32). In PMC, polymers form a continuous constituent, called *matrix*, in which the other phase(s) are embedded (see COMPOSITE MATERIALS).

The distinction between "natural" and "synthetic" polymers or PMC (eg, natural versus synthetic rubber, plastics versus biopolymers, wood versus fiber-reinforced composites) is of limited relevance for the application of NDT methods.

Classes of Nondestructive Test Methods. NDT methods are classified according to the physical principle or effect that constitutes their base (26), corresponding to the probe-type or energy source (Table 2, the list of methods is incomplete). Each NDT method can be characterized by its type of (*1*) probe or energy source, (*2*) interaction with the test object, (*3*) signal detection, (*4*) signal recording, and (*5*) signal interpretation (26). Other categories for grouping NDT methods are, eg, (*1*) "imaging" versus "nonimaging" methods, (*2*) "volume" versus "local" method, (*3*) noncontact versus contacting methods, (*4*) *in situ* versus *ex situ* or "field" versus "laboratory" testing, (*5*) real-time versus post-test indication and (*6*) "small" or "specific" specimen size versus full-scale testing.

Mechanical Test Methods

Determination of mechanical properties is one, although indirect, way of finding indications of defects (see MECHANICAL PERFORMANCE OF PLASTICS). The elastic modulus of polymers and PMC depends, among others, on porosity or microcrack content. Quantitative evaluation requires comparison with specimens with known content from destructive analysis or others (33). Qualitative, relative comparison is feasible, but still requires careful conditioning, since mechanical properties depend on humidity content and temperature. The tensile elastic modulus of samples from one batch typically yields standard deviations of 3–5% for carbon fiber-reinforced polymers (CFRP) and of 5–7% for glass fiber-reinforced polymers (GFRP). Values around 2% have been obtained for high quality CFRP laminates.

Dynamic Mechanical Analysis (qv) (DMA) or dynamic thermal mechanical analysis (DTMA) indicate damage in polymers or PMC (34), and aging effects in polymers by a shift in the transition temperature (35). Limitations are the volume of the test chamber or the required specimen shape.

Compliance, ie, the displacement-to-load ratio, is used in fracture mechanics tests to determine crack length or to monitor crack growth (36).

Vibration or modal analysis yield indications of defects in structural elements or parts when excited by suitable loads (37) (also see SONIC AND ULTRASONIC TEST METHODS). The literature mainly describes applications to PMC laminates, aiming at detecting critical delaminations (38). A relative comparison for a specific element with time, loading, or exposure may be sufficient to find indications of a defect or of a change in the behavior of the structure. Comparison with finite element calculations is one approach for quantitative evaluation (39). Recent research on monitoring of PMC elements or structures also investigates the use of piezoelectric sensors for detection of delaminations by external excitation (40).

Table 2. Classes of NDT Methods

Class	Methods (examples)	Remarks
Mechanical	E-modulus measurement Vibration analysis Modal analysis Scanning probe microscopy	Mostly indirect indications of defects
Optical	Visual inspection Optical microscopy Brillouin scattering Photoelasticity Projection moiré Shearography Optical holography	Using visible part of electromagnetic spectrum (wavelength roughly between 400 and 700 nm)
Penetrating radiation	X-ray radiography X-ray tomography γ-ray radiography Neutron radiography Neutron scattering Electron microscopy	Electromagnetic (wavelengths below about 1 nm) and particle radiation
Electromagnetic	Dielectric spectroscopy Resistance measurement Eddy-current testing	X-ray and γ-ray classified among penetrating radiation
Sonic/ultrasonic	Tap testing Acoustic emission Acousto-ultrasonics Ultrasonics Acoustic microscopy	
Thermal/infrared	Thermography	Infrared spectrometry is classified among chemical/analytical
Chemical/analytical	Infrared spectrometry Raman spectrometry Ultraviolet spectrometry X-ray spectrometry Magnetic resonance imaging	

Scanning probe microscopy of polymers (listing of web sites on Atomic Force and Scanning Probe Microscopy, with images, is available at http://www.ou.edu/research/electron/www-vl/afm.shtml) and PMC (41,42), beside images indicating possible defects, yields mechanical properties, eg, force-stiffness relations (43), and quantitative surface roughness or corrugation relating to tribology (44), on a microscopic scale (see also MECHANICAL PERFORMANCE OF PLASTICS).

Optical Test Methods

Optical test methods use the visible part of the electromagnetic spectrum; ie, they comprise a subset of the electromagnetic test methods.

Visual inspection by eye is certainly the oldest method and is widely used, but subject to physiological limitations. Optical and electronic equipment, eg, endoscopes originally developed for medical applications, and electronic image recording and processing have become standard tools for visual inspection.

Composition and/or morphology of many polymers and PMC limit NDT visual inspection to surface and near-surface features. Transparent polymers and semitransparent PMC allow for the detection of inhomogeneities, such as voids, pores, or cracks, as well as qualitative or semiquantitative estimates of fiber volume fraction and/or fiber alignment. Light sources enhance sensitivity in visual through-thickness and surface inspection.

Standards for visual inspection of polymer products are in preparation (12). Evaluation requires experience and is operator-dependent. Indications can be documented with photography. Digital photography or digitization of photographs allow for image processing and automated image analysis.

Conventional dye penetrant testing for surface crack detection in PMC is described in older literature (45), but is now rarely used, except for highlighting cracks in PMC after destructive sectioning (46).

Optical microscopy has also profited from recent advances. Scanning near field optical microscopy (SNOM) (47) (SNOM images of polymers and other materials are available at, eg, http://wwwex.physik.uni-ulm.de/SNOMWeb/), eg, reaches spatial resolution at the molecular level when using fluorescent molecules, competing with the scanning probe methods (48). The limitations are typical specimen size and scanning area.

Using coherent or structured light to illuminate the test object can reveal information that is not accessible to visual inspection (25,49,50). Commonly, a film or camera is used to record this information.

Interferometric methods use laser illumination to measure surface deformations under thermal, mechanical, vibration, or pressure loading (51). By virtue of the high sensitivity of a few tens of nanometer, inhomogeneities in the interference fringe pattern due to cracks, delaminations, or material inhomogeneities can be revealed using small loads. Because the laser light is only used to record the information, care must be taken to set up the appropriate loading scheme that enhances the type of defect to be found. Well-known methods in composite testing, especially for aerospace and spacecraft applications, are electronic or digital speckle pattern (correlation) interferometry (ESPI or DSPI) (52–55) and shearography, also termed shearing speckle pattern interferometry (SSPI) (56). The methods are used to find indications of delaminations, voids, and cracks. Quantitative evaluation of deformation and strain is also important (57) and can be used to measure stress concentrations, vibration modes (58,59), or material parameters. By nature, the techniques discussed are surface techniques and therefore most appropriate for surface or close-to-surface defects. However, when combined with transient loads, some information on the depth of a flaw can be gained (60).

(Digital) holographic interferometry (61) basically yields the same information as DSPI, but is limited because it requires a development step (photographic processing or numerical reconstruction) before indicating the load effect on the object.

Limitations of the interferometric techniques are due to the required mechanical stability of the measurement head relative to the object of better than 1 μm. Safety regulations for using high power lasers also have to be observed.

Structured light methods comprise shadow moiré, projection moiré, and fringe projection (25,62). They use a structured intensity pattern, most commonly a set of parallel fringes, to illuminate the object. A camera records the fringes on the object surface from a triangulation angle. In moiré methods (63) fine pitch gratings can be used, because the imaged fringes are demodulated by a reference grating in front of the camera before recording. Moiré methods are usually used to measure deformations or to compare the shape of objects, eg, in production control, with a resolution of roughly 1/10,000 of the field of view (64–66). The physics of fringe projection is basically the same (67), but the fringes are directly recorded by the camera. Hence, the pitch of the grating is limited by the camera resolution.

By using a sequence of ever coarser gratings and a calibrated setup, the absolute shape of an object is acquired with a resolution of roughly 1/1,000 of the field of view (68).

Penetrating Radiation Test Methods

Penetrating radiation comprises electromagnetic radiation in the wavelength range below about 1 nm (roughly equivalent to 1 keV energy) or particle radiation. The former is generated in the electronic shell of atoms (X-rays) or by processes in the atomic nuclei (γ-rays). Particle radiation can be generated with particle accelerators, sometimes requiring special targets. Neutrons, eg, come from a spallation source (69) or a nuclear reactor. X-rays are produced by electron beam impact on targets in evacuated tubes or in accelerators by *Bremsstrahlung*, the "braking" radiation emitted by accelerated, charged particles. Ultraviolet and low energy X-ray radiation of high intensity from synchrotrons is used for analysis (70) and processing (71) of polymers and PMC. A list of currently operational synchrotron sources is available, eg, at http://www.src.wisc.edu/community/sr_sources.html (see SYNCHROTRON RADIATION).

Polymers and PMC are of relatively low density and hence do not absorb X-rays or γ-rays efficiently. "Low" energy radiation (typically 10–40 keV) yields enhanced contrast for X-ray radioscopy or radiography of polymers and PMC due to the nonlinear shape of the absorption versus energy curve (72). Higher energy γ- and X-ray sources are hence less suitable.

Contrast can be enhanced by X-ray contrast agents or X-ray dye penetrants (73). These consist of high density materials, eg, liquid halogen compounds (ZnI, methylenediiodide, or diiodobutane) and are different from the dye penetrants used in visual penetrant testing. Test objects are immersed or the contrast agent is injected into, eg, cracks or delaminations extending to the surface of the test object. Any pore, void, crack, or delamination not extending to the surface hence escapes detection. Sufficient wetting between contrast agent and material is important for complete penetration. Even then, a minimum amount of contrast agent is necessary to obtain detectable contrast. Many commercial contrast agents (*1*) are toxic or carcinogenic requiring appropriate safety measures, (*2*) are volatile to some degree, limiting immersion time and imaging duration, (*3*) are of limited

shelf live, and (*4*) raise concerns about inducing deleterious effects (73). There is at least one documented case of suspected dye penetrant induced microcracking in PMC (74).

Penetration and absorption of the electromagnetic or particle radiation results in energy deposition (heating) and implantation of beam particles. Energy deposition and particle irradiation may affect the microstructure and induce breaking or formation of new molecular bonds. Examples are gamma radiation effects (75) and cross-linking in polyethylene by electron irradiation (71). The intensity needed for cross-linking usually exceeds that obtained from NDT beam sources.

Conventional X-ray tubes with an energy range from 10 to 450 keV have a typical source diameter (focal spot) of a few millimeters. Microfocal X-ray sources (76) with a source diameter of about 5 to 10 μm allow for magnification in X-ray radiography by projection imaging (test object close to source, imaging system at a distance). The small source size limits the blur due to geometrical projection with conventional X-ray sources. Energy—microfocal X-ray sources operate up to about 200 keV—and intensity limit the maximum distance between source and imaging system. Magnification can be up to 100 times, but frequently the size of details to be imaged or the maximum size of the imaging system set lower limits.

At energies below 40 keV, X-ray absorption in air is a major limitation, and replacing air by low density helium has been recommended (77). This requires a special enclosure for X-ray source and imaging system, often limiting the size of the test object. *X-ray beam hardening* (78), ie, the preferential absorption of low energy X-rays in the test object, also occurs in polymers and PMC, but to a lesser extent than in denser materials.

Low X-ray intensity yields longer exposure times; for a 1-mm thick CFRP plate a G2 class X-ray film (79) (ie, a D4 class film at that time), 17–18 keV X-ray energy, 1000 mm imaging system–focus distance, and a focus–object distance of 150 mm, resulted in an exposure of about 600 s (80).

X-ray image intensifiers converting the incident X-rays into an image on a scintillating screen allow time-resolved X-ray imaging when recorded with a video camera. Crack initiation in PMC, eg, was investigated with a microfocal X-ray source and X-ray image intensifier with 25-Hz video imaging at magnifications between 5 and 10 times (81). Digitized frames of the video recording can be electronically processed and analyzed. Conventional or X-ray film still images can also be digitized for electronic processing (82).

X-ray radiography is moving from X-ray film to computed radiography (CR). Reusable imaging plates with 25 or 50 μm resolution are commercially available. Manufacturers data sheets indicate that up to 1000 record–erase cycles can be performed (83). Special electronic filters may improve detection of indications. Electronic image recording and storage allow for easy processing and electronic data transmission. However, long-term storage and readability of the records may pose problems in the future. Development of standards in CR is under way (84,85).

X-ray Compton back-scattering can yield indications of delaminations in PMC without the use of contrast agents, ie, including those that do not extend to the surface. The basis is a special source–detector arrangement (86).

X-ray laminography was developed for investigating specific layers of fiber-reinforced laminate sheets by multiple exposure on the same film. Recently, it has been developed into a computer tomography (CT) method (87), but is rarely used.

X-ray CT with commercial CT equipment or synchrotron radiation (70) is increasingly used in research and development, and industrial use is incipient. X-ray micro-CT yields spatial resolution of around 10–20 μm for microfocal (76) and down to 1–2 μm for synchrotron X-ray sources (88). These resolutions require "small" test objects, around a few cubic decimeters in the microfocal and a few cubic centimeters in the synchrotron X-ray source.

X-ray refraction, based on small angle X-ray scattering (SAXS), may prove useful in the detection of microdamage in PMC, such as crack growth (89) and fiber debonding (90). SAXS images of polymer nanocomposites are shown in Reference 91. Near-edge X-ray absorption fine structure (NEXAFS) and related X-ray techniques provide information on composition and morphology of polymers on a microscopic scale (see X-RAY MICROSCOPY).

Neutrons find various applications in the characterization of polymers and PMC (92). Neutron scattering experiments investigate structure and behavior of polymers at the atomic level (93). Neutron absorption as a function of the atomic number of the elements differs from that of X-rays, and the power of neutron radiography (94) for polymers and PMC, even combined with metals, is illustrated at, eg, http://neutra.web.psi.ch/gallery/index.html. Currently operational neutron radiography sources are listed at www.anlw.anl.gov/nr/oldindex.htm.

Positron annihilation spectroscopy (PAS) is used in research on free volume (95) or on aging effects in polymers (96), and muon spin resonance with muon beams (97) yields information on dynamic processes in polymers (98), but specimen size may be limited.

Electron microscopy is one example of electron beam analysis of polymers and PMC. Beam charging effects occur in most polymers and PMC (99), unless when coated with a thin conductive layer (carbon, gold, or platinum). Environmental scanning electron microscopes (ESEM) do not require such coatings (100). Size and shape of the test object and possible electron beam heating effects then decide whether the method is NDT.

Electromagnetic Test Methods

Many polymers and most PMC show no or only comparatively low electrical conductivity, which limits application of electromagnetic test methods. One of the main exceptions is CFRP. The continuous network of carbon fibers in CFRP allows for electrical resistance measurements, eg, based on the four-probe method. Electrical potential (101) or resistance methods are used in fracture mechanics to detect delaminations (102) and to monitor damage in CFRP (103). Whether the application of electrodes is nondestructive depends on the intended use.

Electrical conductivity measurements have also been developed as tomography (104). Eddy-current testing (ET) of CFRP laminates is feasible (105). ET is noncontact and NDT, as long as thermal effects from resistive heating and energy dissipation are sufficiently small. Superconducting quantum interference devices (SQUID) have been used for ET to detect damage in CFRP (106). However, SQUID

may soon be replaced by sensors based on giant magnetoresistance (GMR) or giant magnetoimpedance (GMI) effects (107).

Dielectric measurements are performed on polymers and PMC for research and industrial applications, specifically to find materials with low dielectric losses (108) (see DIELECTRIC RELAXATION).

Fractoluminescence (109), ie, the emission of visible light, and electromagnetic emission from fracture of polymers or PMC (110) have not yet been investigated as NDT tools. Microwave testing is applicable to nonconducting materials (111) and used, eg, for exciting ultrasonic waves in PMC (112) or the characterization of anisotropic materials, such as short fiber–reinforced injection molded parts (113). The energy deposition due to microwave radiation, on the other hand, is applied in processing of polymers and PMC (114).

Sonic and Ultrasonic Test Methods

Sonic and ultrasonic test methods use elastic waves propagating in solid or fluid media and are classified into "active" and "passive" methods. The former requires emission of waves into the test object; the latter, waves emitted by the material itself.

Tap testing a PMC structure by hand or by a suitable instrument, an experienced operator can tell whether the structure is sufficiently defect-free (115).

Acoustic emission (AE) analysis is an example of a passive method (21). Beside piezoceramic lead zirconate titanate (PZT) sensors, thin piezoelectric poly(vinylidene fluoride) (PVDF) films (116) and noncontact interferometry (117) also sense the rapid, transient elastic waves generated inside most materials. Composites (118) made from PZT fibers have recently been characterized as AE sensors (119). AE of polymers and PMC is affected by (*1*) relatively large signal attenuation limiting the maximum distance between sensor and signal source, and mainly in PMC; (*2*) anisotropy, limiting location accuracy; and (*3*) several source mechanisms that can act simultaneously. In PMC, the so-called Felicity effect ie, the appearance of AE activity at the same sensitivity but lower load levels than previously attained (31), forms the base of commercial AE applications in integrity assessment of PMC structures (9).

Quantitative AE analysis for characterizing damage accumulation in PMC is described in Reference 120, approaches for signal analysis and identification of mechanisms in Reference 121, and a practical AE application to automotive composites in Reference 122.

Ultrasonic waves (typically in the MHz range) can be excited by piezoelectric transducers coupled to the test object. Electromagnetic acoustic transducers (EMAT) (123) cannot be used for ultrasonics of polymers and PMC; alternatives are discussed in Reference 124. The waves propagate and are scattered and attenuated in the material. The signal can be detected in either reflection or transmission mode (by the transducer emitting the ultrasonic pulse for reflection or by additional transducers at other locations in transmission). Acousto-ultrasonics (AU) (11) records low frequency guided waves (typically 30–500 kHz) emitted at another location to detect changes in the test objects, eg, in carbon–carbon

composites (125). Recently developed stacked transducers look promising for low frequency applications (126).

Ultrasonic A-, B-, and C-scans (23) can be obtained from polymers and PMC. Isotropic or anisotropic elastic constants, attenuation, and phase transitions are detected in detailed A-scan data analysis (127,128). Ultrasonics is also used for process monitoring in manufacturing of polymeric or PMC parts (129).

Ultrasonic C-scan is standard for quality inspection of PMC plates (28), but the large signal attenuation with penetration depth limits this to "thin" plates. Lower frequency waves, eg, 0.5 MHz, yield larger penetration for equivalent attenuation, but the longer wavelengths limit the spatial resolution (eg, 6 mm for 0.5 MHz at 3000 m/s).

Another limitation is posed by the shadowing effect in PMC. The delamination closest to the transducer will reflect the ultrasonic pulse to such an extent that delaminations below will be masked, unless their lateral size is larger. Even C-scans taken on both sides do not necessarily guarantee detection of delaminations in all layers. In the reflection mode, repeat echoes from multiple reflections have to be distinguished from "real" indications, especially in relatively thin PMC shells.

The shape of certain structures, eg, shells or thin rods with small radii of curvature, limits the application of ultrasonics, but there is equipment that allows three-dimensional movement of the transducer (130).

The standard coupling via immersion in water or use of water jets may be prohibited, since many polymers and PMC change mechanical properties or chemical composition due to penetration of water (swelling, softening, leaching of components, hydrolysis). If immersion in water is used, formation of gas-bubbles from dissolved air has to be prevented. Gel-like coupling agents may leave stains on the surface, but now wheel array sensors for dry coupling (131,132) are available, eg, for the inspection of aerospace structures (133). Air-coupled ultrasonics also offer an alternative (131,134,135). Ultrasonic pulses in polymers and PMC can also be generated by laser (136,137), but this may lead to heating effects. Ultrasonic imaging is widely used for electronic components, where indications of defects (delaminations, cracks, pores) in the epoxy packaging have to be detected (138).

Ultrasonic computer tomography (CT) of polymers is feasible (139).

Recently, phased-array technology (140) has become a novel ultrasonic scanning technique. Multielement transducers in conjunction with high speed electronics allow for electronic focusing and steering of the ultrasonic beam. Since no mechanical movement is involved, the "scanning speed" can be enhanced, enabling imaging for on-line control of manufacturing (141,142).

Ultrasonic transducers can excite various wave modes, eg, guided Lamb waves that may be suitable for specific applications (143). Ultrasonic excitation is also used to detect the so-called acoustic nonlinearity associated with defects, eg, in PMC (144,145). The combination of recording guided ultrasonic waves with numerical back-calculation of wave propagation for detecting indications of defects in PMC pipes also looks promising (146). Surface-bonded fiber optics can detect ultrasonic waves via interferometric techniques (147). Beyond frequencies of 1 GHz, ultrasonics is called *acoustic microscopy*; for details, the reader is referred to Reference 148. This technique can be applied to polymers or PMC (149), specifically to polymeric microelectronics packaging (150).

Thermal and Infrared Test Methods

Thermal and infrared methods can also be classified as passive or active (see THERMAL ANALYSIS). *Passive thermography*, ie, recording the temperature distribution, is rarely used for detecting indications, but probably found useful in polymer and PMC process monitoring (151). The emissivity of the specimen and other factors have to be considered for accurate measurements (152).

Active thermography requires the application of a stimulus (thermal heat), either as single pulse (153) or continuously varying with time (154). The pulse, typically from flash lights, its duration, and intensity, as well as direction (surface or back side of test object) will affect the detectability of the indications (155). Surface finish or paint coats may affect the absorption of the pulse. In CFRP, excitation by short ultrasonic pulses (156) and noncontact eddy currents is also feasible.

In lock-in thermography (154), the selected frequency of the heat "wave" to which the detector is tuned (locked) is important. *Heat waves* are diffusion waves that yield a quadratic dependence on time for the observation of indications at a certain depth of the test object. For thin-walled PMC shells (a few millimeters) this does not constitute a severe limitation (157). Limited operating temperature, pronounced temperature-dependent properties, and thermal degradation may pose limits on the application of active thermography to polymers and PMC. A recent example of a possible application of active thermography in PMC is the determination of the fiber orientation of CFRP (158) that, in the future, may replace the conventional destructive methods.

Chemical and Analytical Test Methods

Chemical analysis of polymers typically deals with monomers or functional groups rather than constituent atoms. Thermal infrared and laser optical Raman spectrometry are the typical tools (36) (see TEST METHODS; VIBRATIONAL SPECTROSCOPY), but frequently, specific specimen size or form is required. For physical properties, mechanical and sonic/ultrasonic NDT methods are available (see above). Molecular mass distribution and related properties of polymers, or fiber or particle volume fraction and distribution for PMC, are usually determined destructively (see TEST METHODS).

Detection, Sizing, and Evaluation of Indications with Nondestructive Test Methods

Basic Approaches. The morphology of polymers and PMC comprises several levels, each with specific defects (see MORPHOLOGY). In NDT, a defect is an aggregate of or a single imperfection or discontinuity that exceeds specified acceptance criteria. These criteria may depend on and vary with location, size, or orientation of the indication. The indications can further be (*1*) relevant, (*2*) nonrelevant, or (*3*) false (31). Hence, not all detected indications are "defects."

Locating the indication is frequently performed with "imaging" methods that also image reference points on the test object. Some nonimaging methods also yield information on location, eg, from source location algorithms in acoustic emission analysis (21).

Locating is a prerequisite for *sizing*, ie, the determination of geometrical dimensions required by specified size criteria. This relates to the spatial resolution of the NDT method. For nonimaging methods, sizing may be replaced, eg, in acoustic emission by defect severity evaluation (159). Principles, limitations, and accuracy of defect location and sizing in polymers and PMC with specific NDT methods are described in (16–26).

Defect types frequently relate to the mechanism causing the indication. Many NDT methods have an intrinsic sensitivity for specific types of indications. Examples are (*1*) ultrasonic C-scans sensitive to boundaries between materials of different acoustic impedance (eg, voids, delaminations), (*2*) X-ray radiography sensitive to variations in density (eg, inclusion of foreign objects, voids), and (*3*) acoustic emission sensitive to microscopic stress release (eg, crack growth).

Determination of Structural Integrity with Nondestructive Test Methods. Some commercial NDT applications, mainly on PMC, do not aim at detection and evaluation of individual indications, but rather at the so-called structural integrity. Most technical structures contain flaws that may evolve into defects that accumulate and grow with time. Structural integrity analysis evaluates test objects with respect to critical defect accumulation, beyond which further use may lead to catastrophic failure. A prime method for determination of the integrity of PMC structures is acoustic emission analysis (9,21). Driven in part by economic considerations, predicting the remaining service-life is increasing in importance. NDT monitoring is hence expected to contribute to, or to be incorporated into, service-life engineering approaches to design.

Smart Monitoring of Polymer–Matrix Composites Elements. The increasing use of PMC in structural elements or as reinforcement or for repair may, at least in critical applications, require periodic inspection or even continuous monitoring. Intermittent or continuous, smart monitoring of PMC aims at automatic detection of specified defects. One research direction develops intelligent materials or structures that sense indications, assess their significance, eg, with computer-based evaluation or expert systems (160), and, if considered significant, take appropriate corrective measures. A full review of smart monitoring of PMC structures is beyond the scope of this article, but a few examples will illustrate this active research area.

Fiber optics based monitoring of PMC includes, eg, strain (161), temperature, acoustic emission signals, and other measurements (162). Electromagnetic resistance measurements yield information on strain changes and defect accumulation (101–104). Even carbon nanotubes are now investigated as strain sensors in PMC (163). Piezoelectric thin wafers or plates (164) or active fiber composites made from piezoelectric fibers (165) also yield, eg, strain and acoustic emission signals. The performance of fiber optics and piezoelectric sensors for detection of microdamage in CFRP is compared in Reference 166.

Another area receiving increasing attention recently is the application of electroactive polymers in actuators and sensors (167). Quite likely, this could lead

to new approaches for NDT of polymers and PMC in the context of smart monitoring of structural elements.

Special Applications of Nondestructive Test Methods

Determination of Geometry or Size and Reverse Engineering. So far, determination of geometrical characteristics has only been discussed with respect to defect location and sizing. However, NDT also comprises determining geometrical characteristics of test objects per se (31). Determination of size and shape, with calipers by hand, with gauges, or with computer-controlled tactile coordinate-measuring machines, is a routine quality assurance procedure, but noncontact methods are also used (168). Size and shape of the test object may pose some limitations. Another example is wall thickness measurements with dedicated ultrasonic thickness gauges (169). As discussed above, the maximum thickness is limited by the frequency-dependent, attenuating properties of polymers and PMC. Requirements on spatial resolution, eg, for test objects where the wall thickness varies over distances that are short compared with the size of the probe, pose another limitation. CT offers another approach for determining geometrical characteristics, X-ray CT being most widely used. CT based on other probe types (see Table 2), eg, ultrasonics (139), magnetic resonance imaging (MRI), also called Nuclear Magnetic Resonance (NMR) imaging (170) (see NUCLEAR MAGNETIC RESONANCE), optical coherence tomography (mainly applicable to GFRP but with limited penetration in CFRP and not suitable for aramide fiber–reinforced PMC) (171), thermal impedance tomography (172), and positron emission tomography (173) are feasible as well.

The driving force behind the development of industrial CT has been and still is the medical field; new methods and improvements are likely to originate there (174). Spatial resolution in X-ray CT depends on the type of X-ray source and on the size and shape of the test object (76,88). X-ray and MRI CT, however, yield more than geometrical characteristics; the data can be converted into distributions of, eg, density, elemental composition (175), or even velocity (176). Three-dimensional CT representations of the geometry, converted into computer-aided design (CAD)-compatible files (177), are used for quality control by comparing with CAD design data for deviations from specification and tolerances, or for computer-aided manufacturing, such as rapid prototyping or reverse engineering (178,179).

Nondestructive Testing of Adhesive Joints. Many commercially available adhesives are based on polymers. NDT of adhesive joints (180) poses challenges because of (*1*) the small size of possibly deleterious defects (eg, porosity), (*2*) the thinness of the adhesive layers, and (3) sometimes, the size, shape, and material of the adherends. Acousto-ultrasonics (181) and various types of ultrasonics (182,183) are applicable to adhesive joints. Ultrasonics can be combined with noncontact optical methods (184) and pulsed thermography (185). However, the assessment of the "quality" or of the quantitative strength of the adhesive bond based on the NDT data often proves difficult.

Process Monitoring and Process Control with Nondestructive Test Methods. NDT plays an important role in quality assurance for products from

all classes of materials and is increasingly used in process monitoring and control. NDT monitoring of polymers and PMC comprises, eg, cure monitoring of molding with thermography (151), infrared methods (186), fiber optics (187), dielectric spectroscopy (188), or ultrasonics (129). Phased-array ultrasonics may be used for on-line manufacturing control (142). NDT process control requires sufficiently fast data analysis and feedback into the process management or steering facility. Some approaches for smart monitoring of PMC, eg, AE, show potential for NDT process control.

Cost may limit process control to either crucial or most effective parameters, eg, pressure and temperature in extrusion (189). Process simulation for optimization of parameters (190) prior to process implementation is also a cost-effective tool (see PROCESSING, MODELING).

Summary and Outlook

Beside technical aspects mentioned above, there are additional considerations for selecting NDT methods for a specific purpose. Cost, frequently, is decisive and major cost factors are (*1*) test duration, including time used for setup and post-test analysis and assessment; (*2*) type of equipment, its sophistication, calibration, and maintenance (compatibility with previous records from periodic inspection may require costly maintenance of aging equipment); (*3*) equipment operator, specifically operator training and certification (191); (*4*) accreditation of test agency; (*5*) qualification or validation of the NDT method (192); and (*6*) accuracy and precision estimates required by test standards or quality management systems.

NDT may hence be effective and economic in scientific research, product or process development, manufacturing process control, quality assurance, and in-service monitoring of crucial or high performance rather than mass produced, low cost polymer and PMC products.

Size and shape of the test object relative to the required spatial and, sometimes, temporal resolution may significantly influence the choice of the NDT method. "Small" objects are readily tested with commercial equipment, while "large" objects may require portable equipment or robots, special test rigs, or several operators. "Single shot" imaging, if satisfying the specification, is to be preferred over scanning, where test duration mainly depends on scan time, ie, scan step to scan area ratio. The shape of test objects may preclude the use of imaging methods, eg, because of hidden areas or uneven spatial resolution. Large size combined with high spatial and/or temporal resolution increases the amount of data and duration of analysis.

Five trends seem to govern the development of NDT, namely, (*1*) increasing sensitivity, (*2*) increasing spatial resolution, (*3*) decreasing test and analysis duration, (*4*) increasing automation of testing, analysis, and evaluation, and (*5*) increasing use of so-called real-time NDT methods (80). The increase in computing power at constant or even lower cost, frequently projected to follow an exponential growth, called *Moore's law* (http://www.intel.com/research/silicon/mooreslaw.htm), is still defying predictions that computer technology will reach physical limits. Hence, the last three trends may continue, while the first two may reach physical or economic limits sooner.

Applying a combination of NDT methods is advisable in many cases. A useful guiding principle is to choose NDT methods that yield complementary information, eg, based on different probe types (Table 2). One example is acoustic emission monitoring with high sensitivity for potentially critical areas, followed by high spatial resolution inspection of such areas by, eg, ultrasonic or X-ray methods to quantitatively locate and size the indication.

The general problem of selecting the "optimum" NDT method for polymers and PMC requires consideration and balancing of several aspects. These are (*1*) requirements on type and size of indications that have to be detected with specified confidence compared to size and shape of the test object; (*2*) technical feasibility of the test method, including behavior of the material under the applied stimulus; (*3*) availability of the test method; (*4*) (eventually) formal requirements, eg, operator certification, test facility accreditation, test method validation; (*5*) (eventually) compatibility with previous measurements; and (*6*) overall cost. It would be of interest to have more quantitatively evaluated, comparative tests applying different NDT methods to specimens with simulated, known defects (80) or to real test objects. A comparative study of the cost of different NDT methods for polymer and PMC would also be welcome.

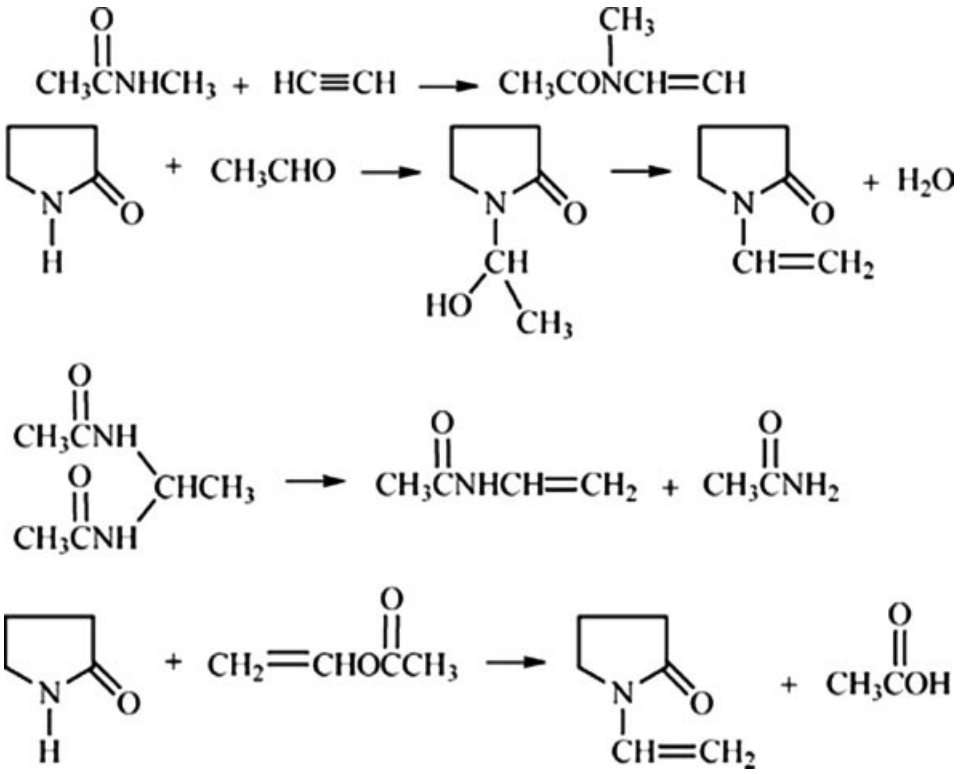
N-VINYLAMIDE POLYMERS

Introduction

N-Vinylamide-based polymers, especially the *N*-vinyllactams, such as poly(*N*-vinyl-2-pyrrolidinone) [9003-39-8] or simply polyvinylpyrrolidinone (PVP), continue to be of major importance to formulators of personal-care, pharmaceutical, agricultural, and industrial products because of desirable performance attributes and very low toxicity profiles. Because of hydrogen bonding of water to the amide group, many of the *N*-vinylamide homopolymers are water soluble or dispersible. Like proteins, they contain repeating (but pendant) amide (lactam) linkages and share several protein-like characteristics (1). Many studies have actually employed PVP as a substitute for proteins, eg, in simplifying the chemistry of the effects of radiation on polymers (2). Proteins are extremely complicated molecules with not only sequence distribution but tertiary bonding and structural complexity and it is an oversimplification to compare them to PVP, but the effects of radiation on PVP can be more readily studied. PVP can even be considered as a uniform synthetic protein-like analogue. By itself it does not enter into intermolecular hydrogen bonding, thus affording low viscosity concentrates, and also, unlike the proteins, PVP is soluble in polar solvents like alcohol. But even given these differences, the chemistry of PVP, the most commercially successful polymer of the class, is in many respects similar to that of proteins because of amide linkages sharing with them complexation to large anions such as polyphenols, anionic dyes, and surfactants. In addition to the ability to complex, PVP and its analogues along with a large assortment of copolymers are excellent film formers. They exhibit the ability to interact with a variety of surfaces by hydrogen or electrostatic bonding, resulting in protective coatings and adhesive applications of commercial significance such as hair-spray fixatives, tablet binders, disintegrants, iodophors, antidye redeposition agents in detergents, protective colloids, dispersants, and solubilizers, among many others.

Monomers

N-Vinylamides and *N*-vinylimides can be prepared by reaction of amides and imides with acetylene (3), by dehydration of hydroxyethyl derivatives (4), by pyrolysis of ethylidenebisamides (5), or by vinyl exchange (6), among other methods; the monomers are stable when properly stored.



Poly *N*-vinyl-2-pyrrolidinone (VP) [88-12-0] is of significant commercial importance and hence is the principal focus of this article. Vinylcaprolactam is available (BASF) and is growing in importance, and vinyl formamide is available as a developmental monomer (Air Products). Some physical properties are given in Table 1.

***N*-Vinyl-2-Pyrrolidinone.** Commonly called vinylpyrrolidinone or VP, *N*-vinyl-2-pyrrolidinone was developed in Germany at the beginning of World War II. It is a clear, colorless liquid that is miscible in all proportions with water and most organic solvents. It can polymerize slowly by itself but can be easily inhibited by small amounts of ammonia, sodium hydroxide (caustic pellets), or

Table 1. Physical Properties of Selected Vinylamides and Vinylimides

Compound	CAS Registry Number	Bp, °C$_{kPa}$[a]	Mp, °C
N-Vinylacetamide	[5202-78-8]	107–109	
N,*N*-Methylvinylacetamide	[3195-78-6]	$70_{3.3}$	
N-Vinylacetanilide	[4091-14-9]	$102–105_{0.13}$	52
N-Vinyl-2-piperidinone	[4370-23-4]	$125–126_{3.3}$	45
N-Vinylcaprolactam	[2235-00-9]	$129–130_{2.7}$	34.5
N-Vinylphthalimide	[3485-84-5]	$128–130_{3.3}$	86.5
N-Vinyl-2-oxazolidinone	[4271-26-5]	$77–78_{0.067}$	
N-Vinyl-5-methyl-2-oxazolidinone	[3395-98-0]	$105–108_{0.33}$	

[a] To convert kPa to mmHg, multiply by 7.5. Pressure = 101.3 kPa (760 mmHg) if not shown.

Table 2. Properties of *N*-Vinyl-2-Pyrrolidinone (Commercial Production)

Property	Value
Molecular wt.	111
Assay, %	98.5[a]
Moisture content, %	0.2[b]
Color (APHA)	100[b]
Vapor pressure, Pa[c] at

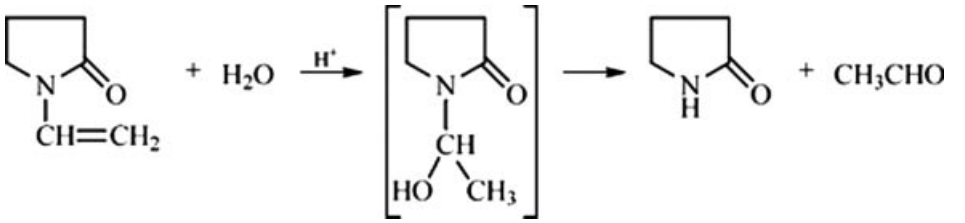
[c]To convert Pa to mmHg, multiply by 0.0075.

antioxidants such as *N,N′*-di-*sec*-butyl-*p*-phenylenediamine. It is stable in neutral or basic aqueous solution but readily hydrolyzed in the presence of acid to form 2-pyrrolidinone and acetaldehyde. Properties are given in Table 2.



Commercially available VP is usually over 99% pure but does contain several methyl-substituted homologues and 2-pyrrolidinone. Even at this high level of purity, further purification is required if reliable kinetic data concerning rates of polymerization are desired. This can be accomplished only by recrystallization, because distillation will not separate methyl-substituted isomers (7).

Manufacture. The principal manufacturers of *N*-vinyl-2-pyrrolidinone are ISP and BASF. Both consume most of their production captively as a monomer for the manufacture of PVP and copolymers. The vinylation of 2-pyrrolidinone is carried out under alkaline catalysis analogous to the vinylation of alcohols. 2-Pyrrolidinone is treated with ca 5% potassium hydroxide, then water and some pyrrolidinone are distilled at reduced pressure. A ca 1:1 mixture (by vol) of acetylene and nitrogen is heated at 150–160°C and ca 2 MPa (22 atm). Fresh 2-pyrrolidinone and catalyst are added continuously while product is withdrawn. Conversion is limited to ca 60% to avoid excessive formation of by-products. The *N*-vinyl-2-pyrrolidinone is distilled at 70–85°C at 670 Pa (5 mmHg) and the yield is 70–80% (8).

Shipment and Storage; Specifications. *N*-Vinyl-2-pyrrolidinone is available in tank cars and tank trailers and in drums of various sizes. Shipping containers are normally steel or stainless steel. Tank cars are provided with heating coils to facilitate unloading in cold weather. Rubber, epoxy, and epoxy–phenolic coatings are attacked and must be avoided. Carbon steel has been successfully used for storage tanks, but stainless steel preserves product quality better. Aluminum and certain phenolic coatings are also satisfactory.

Toxicity Data on N-Vinyl-2-Pyrrolidinone. Results of a chronic inhalation study in rats warrant a review of industrial hygiene practices to assure that VP vapor concentrations are maintained at a safe level. One of the manufacturers, ISP, recommends that an appropriate workplace exposure limit be set at 0.1 ppm (vapor) (9). Additionally, normal hygienic practices and precautions are recommended, such as prompt removal from skin and avoidance of ingestion. In case of accidental eye contact, immediately flush with water for at least 15 min and seek medical attention. Refer to the manufacturers' Material Safety Data Sheets for more detailed information. Table 3 provides some toxicity data.

Table 3. Summary of Toxicity Data for *N*-Vinyl-2-Pyrrolidinone

Test	Result
Acute oral LD_{50}	1.5 mL/kg (rats)
Acute dermal LD_{50}	0.56 g/kg (rabbits)
Acute inhalation LC_{50}	700 ± 100 ppm(rats)
Eye irritation	Severe (rabbits)
Primary irritation index (PII)	0.38 (rabbits)
Skin Repeated Insult Patch Test	Not a primary irritant or sensitizer (humans)
Subacute inhalation	No gross or clinical abnormal effects; subacute/chronic inflammation of respiratory tract at 16.5 and 66 ppm (rats)
Subchronic inhalation	Evidence of liver damage at 15, 45, and 120 ppm; no evidence of toxicity at 1 ppm (rats)
Chronic inhalation	Benign and malignant tumors of the nasal mucosa at the 10 and 20 ppm levels; liver tumors noted at 20 ppm
Mutagenicity	Negative in a battery of five assays

Homopolymerization of *N*-Vinyl-2-Pyrrolidinone

VP was originally polymerized in bulk by heating in the presence of small amounts of hydrogen peroxide. This neat polymerization was a difficult process to work-up, requiring crushing of the solidified polymer mass and extraction with ether to remove unreacted monomer and by-products. However, it was important to the original application as a blood substitute because it afforded low molecular weight (10,11). Low molecular weight is necessary for excretion from the kidneys (12). Bulk polymerization favors the tendency of VP to undergo chain transfer to monomer. Neat VP polymerized with di-*tert*-butyl peroxalate in the presence of a nitroxide scavenger that exclusively traps carbon centered radicals generates considerable nonvinyl radicals by chain transfer (13,14). VP (and presumably PVP) can, under the right circumstances, undergo chain transfer, and this route is more prevalent as the concentration of monomer is increased.

Because VP and PVP are soluble in water, early workers realized that polymerization could be more easily controlled in such a high heat capacity solvent. In the presence of acid, VP readily hydrolyzes, and when initiated with hydrogen peroxide, the pH drops quickly into the acidic range. The problem this presents was solved by buffering with bases. Of all of the bases tried by the early German chemists, ammonia not only prevented hydrolysis by neutralizing acidic by-products, it accelerated the polymerization. The early workers found that with an optimized concentration of monomer and ammonia level, the molecular weight was reproducibly controlled by the hydrogen peroxide level. Even relatively high molecular weight could be achieved by small amounts of hydrogen peroxide, but such levels might easily be compromised by unproductive side reactions. High molecular weight homopolymers are more reliably produced by initiation with organic peroxides and azo initiators.

Ammonia H_2O_2 Initiation. The lower molecular weight grades (K-15 and K-30) of PVP are prepared industrially with an ammonia/H_2O_2 initiation system. Such products are the standards for the pharmaceutical industry and conform to the various national pharmacopeias. Several papers have appeared concerning the mechanism of this polymerization (15).

The proposed rate expression for the ammonia/H_2O_2 process is as follows:

$$R_p = k[H_2O_2]^{1/2}[NH_3]^{1/4}[VP]^{3/2} \tag{1}$$

Comparing this to the theoretical expression based on the steady state approximation suggests that the mechanism is not straightforward:

$$R_p = k_p[M]\,\frac{(fkd[I])^{1/2}}{kt} \tag{2}$$

Higher than first order for monomer, such as the 3/2 power suggests that VP is involved in initiation (16). If the efficiency of initiation is a function of the monomer concentration, then $f = f^1[M]$, and substituting in equation 2 gives

$$R_p = k_p[M]^{3/2}\,\frac{(f^1kd[I])^{1/2}}{k_t} \tag{3}$$

The $[I]^{1/2}$ is reflected in $[H_2O_2]^{1/2}$ but $[NH_3]^{1/4}$ can be explained by the finding (17) that the rate of polymerization is proportional to $[NH_4^+]^{1/2}$. If the equilibrium expression for $NH_3/[NH_4^+]$ is solved for $[NH_4^+]$ and this expression substituted, the quarter power for ammonia is apparent.

Several papers (6,18) have appeared that attempt to reconcile the ability of H_2O_2 to act as a rather strong transfer agent (hydrogen donor), generating the weakly initiating species $HOO^\bullet$, with its ability to act as a source of $HO^\bullet$ hydroxy radicals that are known to be active vinyl initiators. Such studies demonstrate that $HO^\bullet$ generated by photolysis behaves classically as an initiator for PVP (the rate is, as expected, first order in VP and half order in H_2O_2). Polymerization with 2,2′-azobisisobutyronitrile (AIBN) in the presence of H_2O_2 demonstrates that H_2O_2 in this case acts as a proton donor, reducing molecular weight, suggesting it also functions similarly during NH_3/H_2O_2 initiation. Even with other water-soluble initiators, VP behaves classically, with the rate expression being first order in monomer and half order in initiator (19,20). This would indicate that VP is a vinyl monomer with normal behavior and hence the H_2O_2/NH_3 initiation system is unusual. The evidence clearly demonstrates that it is a redox initiator system requiring trace amounts of cuprous or ferrous salt (21). Other bases such as NaOH or KOH can be employed to replace NH_3 if precautions are taken to sequester these metal ions, preventing them from being deactivated in the redox complex (22).

In one of the few published studies of H_2O_2 initiation, it is shown that in the case of methacrylamide, the monomer participates in its own initiation by reacting with H_2O_2, forming an intermediate hydroperoxide (23). Subsequently, this hydroperoxide generates hydroxyl radicals capable of initiation. Like that of methacrylamide, VP polymerization is very sensitive to molecular oxygen reacting faster with it than propagation to polymer (18), and a similar reaction might be at work with VP that would be expected to generate an intermediate hydroperoxide capable of entering into a redox initiation system. The proposed mechanism would also explain the formation of 2-pyrrolidinone as a consequence of redox polymerization, dispelling the previous belief that 2-pyrrolidinone was a result of primary radical termination caused by reaction of hydroxyl radicals with the growing chain, followed by hydrolysis of the hemiacetal (24,25) subsequently formed. Hydroxyl radicals afford PVP with one hydroxyl per chain, correlating well with a mechanism that relies on hydroxyl radical initiation and strong H_2O_2 chain transfer (26). In this case, one end of the polymer is not an aldehyde but rather a hydroxyl group, and no evidence for other than proton termination could be found, producing a methylene terminus at the other end of the polymer chain. Figure 1 illustrates the proposed mechanism and explains the formation of acidic by-products responsible for the acidic pH drift during polymerization.

Organic Peroxides and Azo Initiation

The H_2O_2/ammonia initiation system is not employed commercially in the manufacture of higher molecular weight homologues; they are prepared with organic initiators. Such polymerizations follow simple chain theory and are usually performed in water commercially. The rate of polymerization is at a maximum in aqueous media at pH 8–10 and at 75 wt% monomer (27,28). Polymerization rates

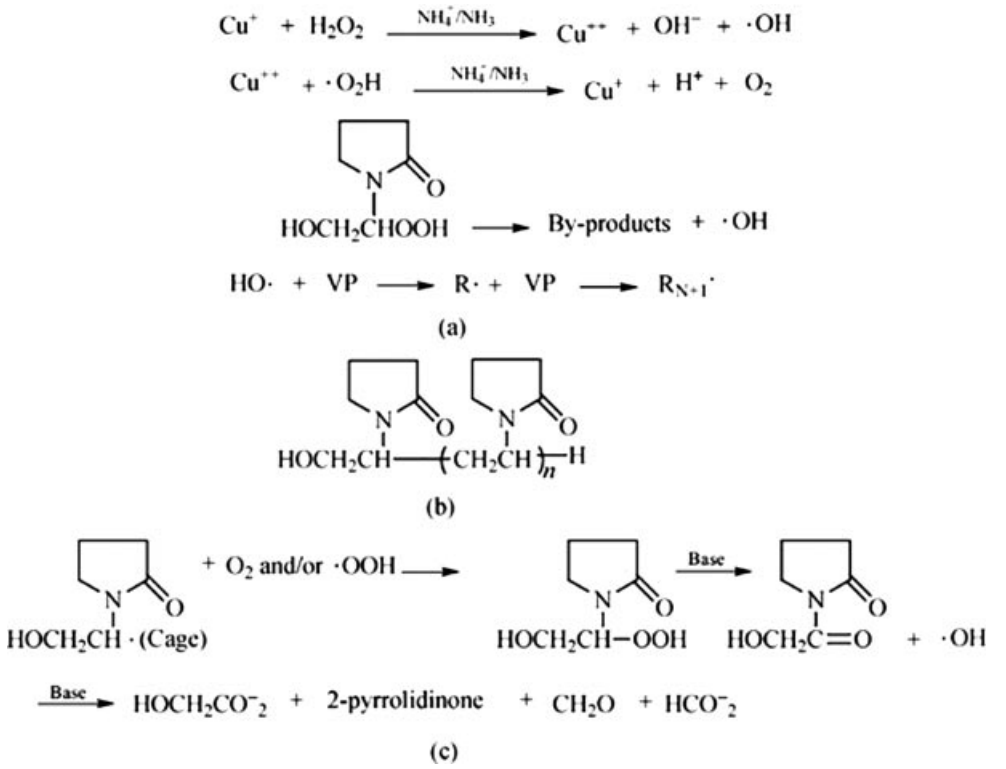


Fig. 1. Mechanism of NH_3/H_2O_2 polymerization of VP: (**a**) initiation; (**b**) end groups; (**c**) 2-pyrrolidinone generation.

follow the polarity and hydrogen bonding capability of the solvent (29). One possible explanation for this fact is that water is most capable of reducing the apparent negative charge on the beta carbon VP's vinyl group by hydrogen bonding to the pyrrolidinone carbonyl and polar interactions. Such a reduction permits the electron-rich radical terminus to more easily approach another VP and hence allows the acceleration (29). Alternatively, PVP may be somewhat more hydrophobic than VP forming associates ("micelles") capable of enhancing the rate of polymerization by concentrating monomer close to the reacting polymer terminus. This is the reason why even in relatively dilute aqueous solutions the rate can be substantial. The hydrophobic effect accounts for a higher VP concentration at the reactive polymer terminus (30).

Cationic Polymerization. VP polymerizes to low molecular weight (oligomers) with typical cationic initiators, such as boron trifloride etherate (31). This reaction requires high concentrations, if not neat, of monomer and scrupulously anhydrous conditions for high yields; VP will readily hydrolyze to 2-pyrrolidinone and acetaldehyde even in the presence of trace moisture when catalyzed by strongly acidic reagents. Pyrrolidinone derivatives apparently complex and deactivate cationic polymerization catalysts and generally present an unfavorable environment for polymerization (32). Thus, initiating species are relatively

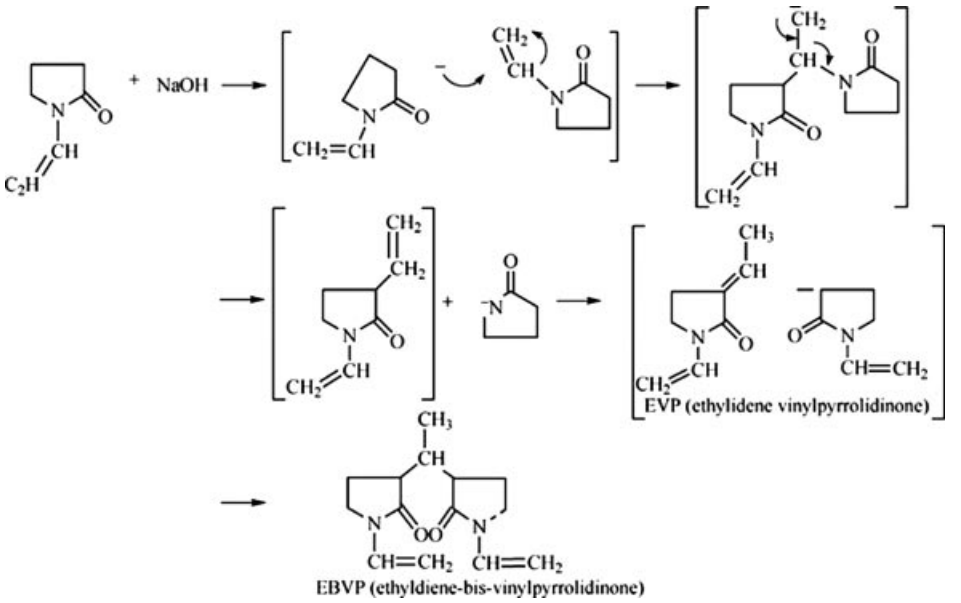
short-lived and readily deactivated, or undergo chain transfer; hence, more than catalytic amounts of initiator are required for high yields.

Interest has been rekindled in cationic polymerization by the discovery that carboxylic acid groups trapped in insoluble matrices like activated carbon or poly(glutamic acid) can generate higher mol wt. polymers (33–35). Additionally, oxoaminium salts (36) derived from 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) or anodic polymerization (37) on platinum electrode surfaces will also afford higher molecular weight polymers. Such cationically generated polymers would be expected to afford microstructure and greater tacticity because of the higher activation energy for inversion associated with a growing cationic terminus vs a growing free-radical terminus. Unfortunately, none of the above references present detailed polymer structural characterizations.

Microstructure. Interest in PVP microstructure and the potential for tacticity has been reviewed (38,39). PVP generated by free radicals has been shown to be atactic except when polymerization is conducted in water. In this case, some syndiotacticity is observed (39). In the presence of syndiotactic templates of poly(methacrylic acid) (or poly(MAA)), VP will apparently polymerize with syndiotactic microstructure, although proof is lacking (40–44). The reverse, polymerization of MAA in the presence of PVP, affords, as expected, atactic poly(MAA) (45,46).

Advances in VP cationic polymerization hold out the possibility of tacticity, and the study of this route to crystalline homologues continues to be of interest.

Proliferous Polymerization. Early attempts to polymerize VP anionically resulted in proliferous or "popcorn" polymerization (47). This was found to be a special form of free-radical addition polymerization, and not an example of anionic polymerization, as originally thought. VP contains a relatively acidic proton alpha to the pyrrolidinone carbonyl. In the presence of strong base such as sodium hydroxide, VP forms crosslinkers *in situ*, probably by the following mechanism:



Both ethylidene vinyl pyrrolidinone (EVP) and ethylidene-bis-vinylpyrrolidinone (EBVP) are generated in about a 10:1 ratio, respectively (24). At the temperature required to generate these cross-linkers and when their concentration reaches some minimum level, usually a few percent, proliferous polymerization begins (48). The same situation can be reached by the addition of a suitable cross-linker (49). Although no initiator is required, the polymerization can be prevented in the presence of typical free-radical inhibitors or initiated by very small amounts of AIBN. Reviews indicate that the rate of polymerization accelerates because the initially formed cross-linked seeds swell to generate active sites by bond homolysis and that growing chains resist termination because of the rigid cross-linked structure. Very high conversions can be achieved and the resulting product, a granular "popcorn" mass, can be freed of residual monomer/soluble polymer by careful washing. Drying results in a free-flowing white powder (50).

Crospovidones are produced commercially by these two processes, ie, *in situ* generation of cross-linker or addition of divinylimidazoline, and they are indistinguishable by ir. Both types exhibit a T_g of 190–195°C, which is not that much above the 175°C of high molecular weight, soluble PVP (24). Proliferous polymers prepared with easily hydrolyzed cross-linker containing an imine linkage do not further swell even when the cross-links are hydrolyzed (49). In order to reach the low swell volume typical of these resins with a typical VP/cross-linker polymerized with free-radical initiator, sizeable amounts of cross-linker are actually required, resulting in much higher (240°C) T_gs. The crospovidones are therefore unusually high molecular weight, highly chain-entangled polymers having covalent cross-links that most likely retard the termination reaction during polymerization and are not entirely responsible for the resulting mechanical properties, such as swell ratio. Even hydrolyzing such cross-links is not sufficient to cause dissolution.

The crospovidones are easily compressed when anhydrous but readily regain their form upon exposure to moisture. This is an ideal situation for use in pharmaceutical tablet disintegration and they have found commercial application in this technology. PVP strongly interacts with polyphenols, the crospovidones can readily remove them from beer, preventing subsequent interaction with beer proteins and the resulting formation of haze. The resin can be recovered and regenerated with dilute caustic.

PVP Hydrogels

Cross-linked versions of Water-Soluble Polymers (qv) swollen in aqueous media are broadly referred to as Hydrogels (qv) and have a growing commercial utility in such applications as oxygen-permeable soft contact lenses (Table 4) and controlled-release pharmaceutical drug delivery devices (51). Cross-linked PVP and selected copolymers fit this definition and are of interest because of the following structure/performance characteristics:

Structure	Performance	Benefit
Nonionic	Compatibility with other ingredients	Stable formulation
Pyrrolidinone	Low toxicity	Nonirritating/nonthrombogenic
	Complexation actives/O_2	Controlled release transport
	High T_g	Mechanical stability
	Hydrolytic stability	Storage stable
Ethylene backbone	Nonbiodegradable, hydrolytic stability	Resists biocontamination storage-stable
Cross-links	Swell volume/viscosity	Mechanical stability/diffusion control

Cross-linked PVP can be prepared by several routes other than proliferous polymerization PPVP (crospovidones). Although a hydrogel, the swell volume of this type of polymer cannot be controlled over a large increment because the granular particles cannot be formed into larger uniform assemblies. These limitations can be overcome by the polymerization of VP in the presence of a few percent of suitable cross-linker utilizing standard free-radical initiation by, for example, AIBN (52–54) or actinic radiation (gamma rays) (55,56). This results in a lightly cross-linked PVP. If the polymerization is carried out incorrectly, significant amounts of uncross-linked soluble polymer may be present that must be removed before a meaningful physical analysis such as swell ratio can be accomplished. The solution to this problem is to balance the reactivity ratios of the cross-linker and other comonomers with those of VP to obtain uniform copolymerization and cross-linking (57,58). Not only does this reduce the level of soluble uncross-linked polymer but affords crystal-clear hydrogels so important for use in contact lenses. Allyl-substituted sugars used to generate cross-linked polyacrylic acid gels,

Table 4. Generic Names of Polymeric Compositions Used in Soft Contact Lenses

USAN Generic Name	Polymer composition[a]	Water, %	Trademarks	Manufacturer

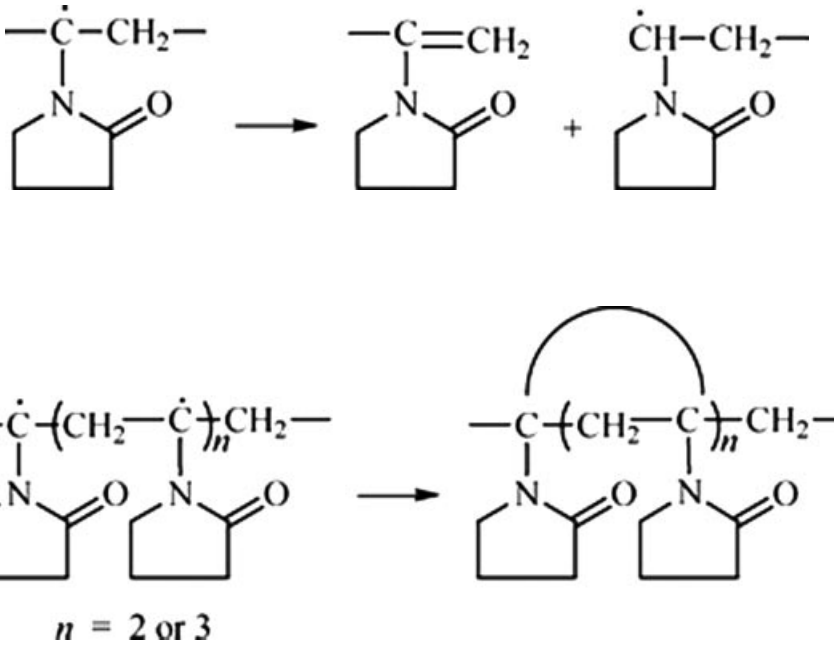
[a] HEMA, hydroxyethylmethacrylate; EGDM, ethyleneglycoldimethacrylate.

carbomers, employed as thickeners in pharmaceutical formulations, have been shown to work well with VP (59).

Cross-linked PVP can also be obtained by cross-linking the preformed polymer chemically (with persulfates, hydrazine, or peroxides) or with actinic radiation (60). This approach requires a source of free radicals capable of hydrogen abstraction from one or another of the labile hydrogens attached alpha to the pyrrolidone carbonyl or lactam nitrogen. The subsequently formed PVP radical can combine with another such radical to form a cross-link or undergo side reactions such as scission or cyclization (61,62), thus:



If the starting PVP homopolymer is too low in molecular weight or too dilute, cyclization or cleavage is preferred (62,63). However, because of the high T_g of PVP, the backbone is sufficiently rigid to avoid reorientation during bond homolysis so that the same bond has a good chance of reforming; hence, PVP yields cross-linked structures in preference to cleavage (64) and PVP hydrogels formed by e-beam have become commercially important for use as conductive electrodes for medical applications (65).

Poly(*N*-Vinyl-2-Pyrrolidinone)

Poly(*N*-vinyl-2-pyrrolidinone) (PVP) is undoubtedly the best characterized and most widely studied *N*-vinyl polymer. It derives its commercial success from its biological compatibility, low toxicity, film-forming and adhesive characteristics, unusual complexing ability, relatively inert behavior toward salts and acids, and thermal and hydrolytic stability.

First developed in Germany by I. G. Farben (W. Reppe) during the 1930s, PVP was subsequently widely used in Germany as a blood–plasma substitute and extender during World War II (66). In the United States, it has been manufactured since 1956 by ISP, and more recently by BASF.

Molecular Weight and *K* Value. Poly(*N*-vinyl-2-pyrrolidinone) is described in the *United States Pharmacopeia* (67) as consisting of linear *N*-vinyl-2-pyrrolidinone groups of varying degrees of polymerization. The molecular weights of PVP samples are determined by size-exclusion chromatography (sec), osmometry, ultracentrifugation, light scattering, and solution viscosity techniques. The most frequently employed method of determining and reporting the molecular weight of PVP samples utilizes the sec/low angle light-scattering (lalls) technique (68,69).

A frequently used and commonly recognized method of distinguishing between different molecular weight grades of PVP is the K value. Its nomenclature is accepted by the USP, FDA, and other authoritative bodies worldwide. The *Pharmacopeia* (USP) specifies that for very low molecular weight, a 5% solution whereas for very high molecular weight, a 0.1% solution be measured. All other molecular weights employ a 1% solution. The relative viscosity is obtained with an Ostwald–Fenske or Cannon–Fenske capillary viscometer, and the K value is derived from Fikentscher's equation (70).

$$\log \frac{\eta_{\text{rel}}}{c} = \frac{75K_{\text{o}}^2}{1 + 1.5K_{\text{o}}c} + K_{\text{o}}$$

where $K = 1000K_{\text{o}}\eta_{\text{rel}}$ = relative viscosity, and c = concentration of the solution in g/100 mL. Solving directly for K, the Fikentscher equation is converted to

$$K = [300c \log Z + (c + 1.5c \log Z)^2 + 1.5c \log Z - c]/(0.15c + 0.0003c^2)$$

where $Z = \eta_{\text{rel}}$. Table 5 illustrates a correlation chart where the K value is simply read off from a knowledge of η_{rel}.

The intrinsic viscosity $[\eta]$ may be approximated from the Fikentscher equation by

$$[\eta] = 2.303\ (0.001K + 0.000075K^2)$$

where $[\eta]$ = intrinsic viscosity and $K = K$ value of sample.

Table 5. K_{o} Value vs Relative Viscosity at 1% Concentration (wt/vol)[a]

K value	Relative viscosity	K value	Relative viscosity
20	1.120	60	2.031

65	508,600		

[a]Ref. 68.

Utilizing the Mark–Houwink equation (71)

$$[\eta] = K\bar{M}_v^a$$

it is possible to relate the viscosity-average molecular weight ($\bar{M}_v$) to the *K* value.

For commercial grades of unfractionated PVP prepared by similar means (presumed to exhibit similar molecular weight distribution (MWD) and degree of branching), the following regression formula can be employed (68):

$$\log \text{mol wt.} = 2.82 \log K + 0.594$$

Table 6 indicates mol wt. vs *K* value obtained by this technique. Table 7 lists M_n obtained by osmometry methods. The specifications for Technical and Pharmaceutical grades are given in Tables 8 and 9.

Glass-Transition Temperature. The T_g of PVP is sensitive to residual moisture (72) and unreacted monomer. It is even sensitive to how the polymer was prepared, suggesting that MWD, branching, and cross-linking may play a part (73). Polymers presumably with the same molecular weight prepared by bulk polymerization exhibit lower T_gs compared to samples prepared by aqueous solution polymerization, lending credence to an example, in this case, of branching caused by chain transfer to monomer.

Table 7. Osmometry Molecular Weights for PVP[a]

Sample	Technique	$\overline{M}_n$

[c] Calculated as acetaldehyde.

Molecular weight also plays a significant role in T_g, which increases to a limiting value of 180°C for high purity samples above K-90 in molecular weight. The following equation applies:

$$T_g(^\circ\mathrm{C}) = 175 - \frac{9685}{K^2}$$

and Table 10 illustrates this relationship with commercially available samples.

Solubility. One of PVP's more outstanding attributes is its solubility in both water and a variety of organic solvents. PVP is soluble in alcohols, acids, ethyl lactate, chlorinated hydrocarbons, amines, glycols, lactams, and nitroparaffins. Solubility means a minimum of 10 wt% PVP dissolves at room temperature (moisture content of PVP can influence solubility). PVP is insoluble in hydrocarbons, ethers, ethyl acetate, *sec*-butyl-4-acetate, 2-butanone, acetone, cyclohexanone, and chlorobenzene. Both solvent polarity and Hbonding strongly influence solubility (74).

Swelling Behavior. One way to visualize the interaction of solvents with PVP is to examine the effect the former have on lightly cross-linked PVP, as a model for the linear polymer (75).

Such gels can be prepared from a minimum of diallyl cross-linker and VP to afford products that are mechanically stable and easy to handle as hydrogels. Such samples must be extracted because soluble polymer competes for solvent, affording lower swell volumes than those expected. The extracted and dried samples are swollen to equilibrium in a variety of solvents (Table 11). Three groups of solvents can be distinguished: the first includes those in which the cross-linked polymer swells 15–25 times. VP, H_2O, CH_3OH, C_2H_5OH, benzylamine, and chloroform are examples. Swelling drops off with longer chain-length alcohols. Aromatic derivatives like benzyl alcohol and aniline afford similar swelling ratios to each other and to aliphatic analogues. This indicates that simple aromatic groups do not interact. When comparing volume instead of weight, water actually causes a 0.36% shrinkage of the gel. Water can therefore cross-link by hydrogen bonding to a limited but measurable extent. The second group consists of acetone, MEK, and dioxane solvents that not only increase the swell ratio (to a much lesser extent) but also increase the swell volume by 60–100%. The third group consists of hydrocarbons, benzene, carbon tetrachloride, isopropyl ether, and triethyl amine. In this case, they have little or no effect on swelling. The hallmark of this group is lack of hydrogen-bonding capability.

In water, the swell ratio actually decreases with temperature at a constant rate of $-0.12\%/^{\circ}C$. PVP gels therefore swell exothermically in water, and, as expected, heat reverses the process. Cooling back to a lower temperature results in the expected higher swell ratio being reestablished. Alcohols and other

Table 11. Swelling of Cross-linked Polyvinylpyrrolidone in Various Liquids at 20°C[a]

Liquid	Degree of swelling	Liquid	Degree of swelling

[a]Ref. 75.

hydrogen bonding solvents cause the same effect but to a lesser extent. Nonhydrogen-bonding solvents actually cause an increase in swelling with temperature (Table 12).

Rheology. PVP solubility in water is limited only by the viscosity of the resulting solution. The heat of solution is −16.61kJ/mol (−3.97 kcal/mol) (76); aqueous solutions are slightly acidic (pH 4–5). Figure 2 illustrates the kinematic

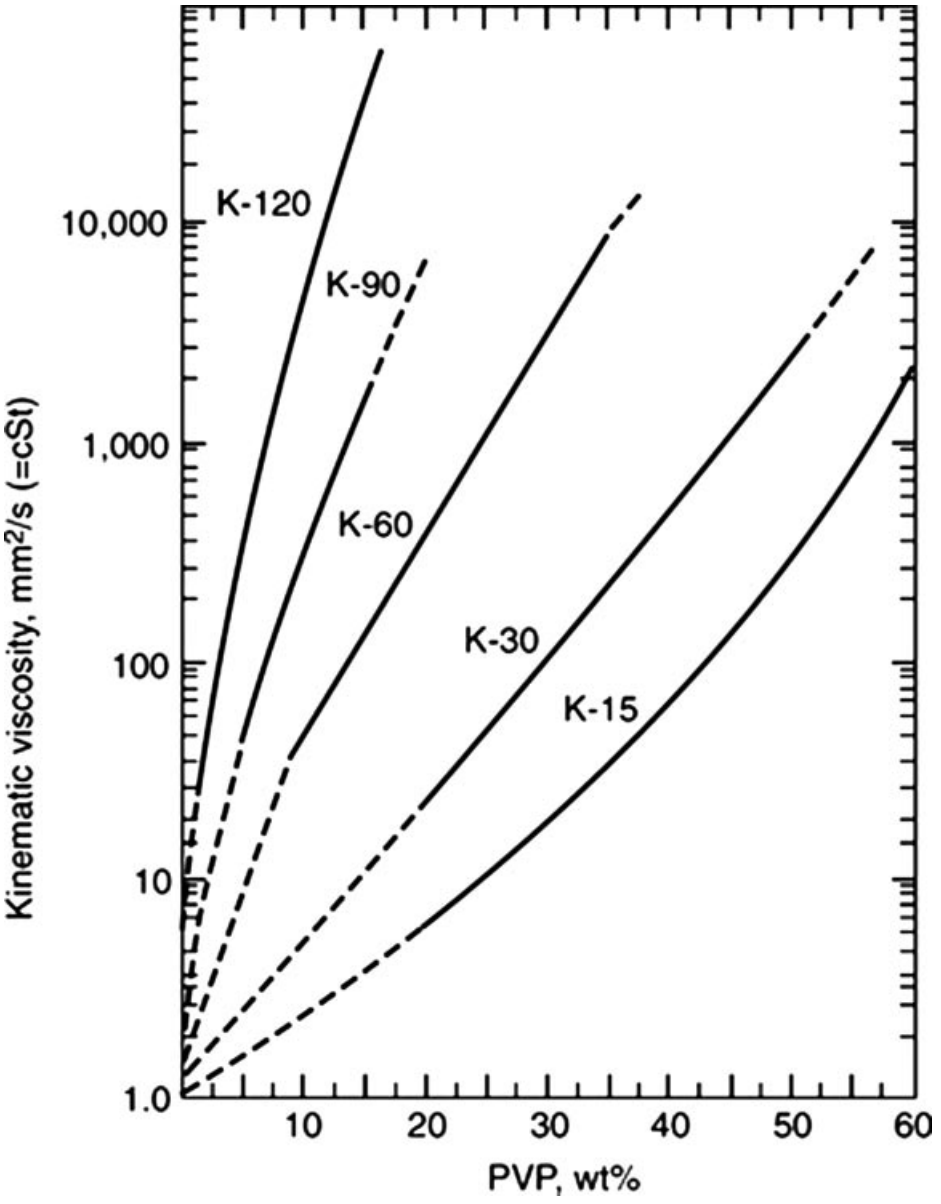

Fig. 2. Kinematic viscosity of PVP in aqueous solutions.

viscosity of PVP in aqueous solution. The kinematic viscosity of PVP K-30 in various organic solvents is given in Table 13.

Aqueous Solutions of PVP. Although it is soluble in a variety of polar solvents, PVP has generated significant interest because of its aqueous solubility. Water can readily hydrogen bond to the polar, negatively charged pyrrolidinone carbonyl oxygen because pyrrolidinone, a five-membered planar lactam, affords maximum π, π-orbital overlap. The canonical resonance forms highlight the

Table 13. Kinematic Viscosity of PVP K-30 in Organic Solvents

	Kinematic viscosity,[a] mm^2/s (=cSt)	
Solvent	2% PVP	10% PVP
Acetic acid (glacial)	2	12
1,4-Butanediol	101	425

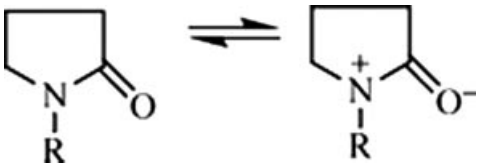
[a]Kinematic viscosity = absolute viscosity/density.

potential for a partial negative charge to form on oxygen:



The partial charge on nitrogen is sterically shielded by the polymer backbone and the surrounding pyrrolidinone methylenes. Because of high dipole moment and polarity, PVP has a noticeable effect on water structure and various methods have been proposed to measure bound water (77). One study even illustrates the different categories of water generated by freezing aqueous PVP solutions (78). The results are summarized in Figure 3, and, as can be seen, PVP is hydrated with

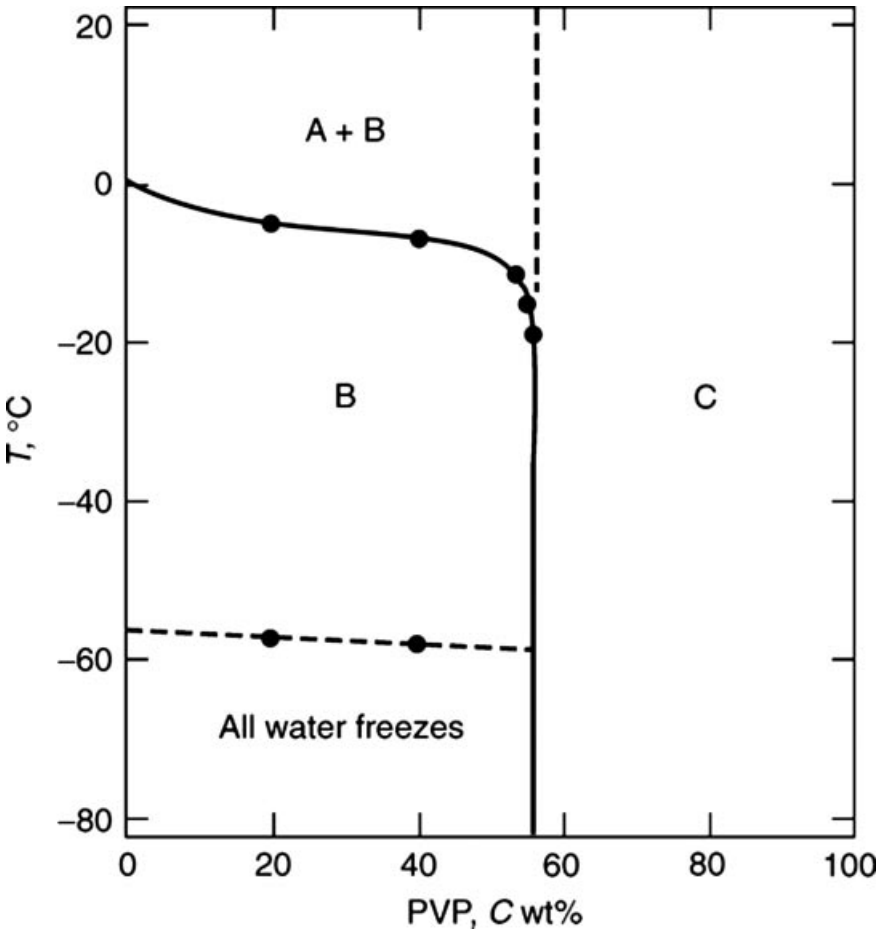


Fig. 3. Phase diagram for the three kinds of water in PVP aqueous solutions (78). A, freezable water; B, bound, nonfreezable water (six per repeat unit); C, nonfreezable water.

bound water that will not freeze (concentrated solutions >57% will not freeze). PVP is therefore used as a protectorate in cryobiology (79).

The actual amount and structure of this "bound" water have been the subject of debate (80), but the key factor is that in water, PVP and related polymers are water structure organizers, which is a lower entropy situation (81). Therefore, it is not unexpected that water would play a significant role in the homopolymerization of VP, because the polymer and its reactive terminus are more rigidly constrained in this solvent and termination k_t is reduced (82).

Complexation

The combination of electrostatic interaction (induced dipole–dipole interaction) with an increase in entropy resulting from the discharge of bound water is fundamental to PVP's ability to complex with a variety of large anions.

Other factors that can stabilize such a forming complex are hydrophobic bonding by a variety of mechanisms (van der Waals, Debye, ion dipole, charge transfer, etc). Such forces complement the stronger hydrogen bonding and electrostatic interactions.

Approximately a minimum $\bar{M}_n$ of 1–5000 is required before complexation is no longer dependent on molecular weight for small anions such as KI_3 and 1-anilinonaphthaline-8-sulfonate (ANS) (83,84). The latter anion is a fluorescent probe that, when bound in hydrophobic environments, will display increased fluorescence and, as expected, shows this effect in the presence of aqueous PVP. PVP, when complexed with HI_3, shrinks in size as it loses hydrodynamic volume, possibly because of interchain complexation. ANS, on the other hand, causes the polymer to swell by charge repulsion because it behaves like a typical polyelectrolyte (85).

Adsorption Isotherms. Equilibrium dialysis studies indicate around 10 repeat VP units (base moles) are required to form favorable complexes (86,87). This figure can rise to several hundred for methyl orange and other anions depending on structure (88,89).

Although hydrophobic bonding is well established as a significant force stabilizing such complexes, some work suggests that such generalizations do not apply to every case (89). However, a study of the complexes of PVP with tetraanionic porphyrins has shown that the reaction of porphyrin with cupric ion is slowed dramatically in the presence of PVP. This is interpreted as demonstrating the existence of hydrophobic pockets preventing a reaction that is clearly favored if both species are in aqueous environments (90). Hydrophobic bonding has been illustrated by comparing competitive binding of butyl orange (BO) with 1-amino-4-methylamino anthraquinone-2-sulfonate (AQ) (91). The thermodynamic data for BO show that the binding process is athermal and stabilized entirely by the entropy term. On the other hand, AQ exhibits a large enthalpy and small entropy value and its binding is by the stronger and energetic interaction caused by hydrogen bonding (NH groups of AQ) and hydrophobic interaction of the polynuclear aromatic AQ; both structural features are missing from BO (91).

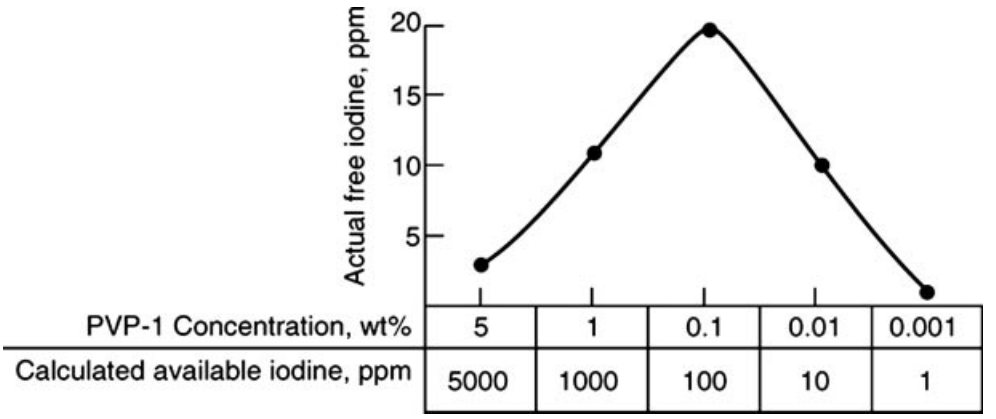

Fig. 4. Free iodine in povidone–iodine aqueous solutions (96).

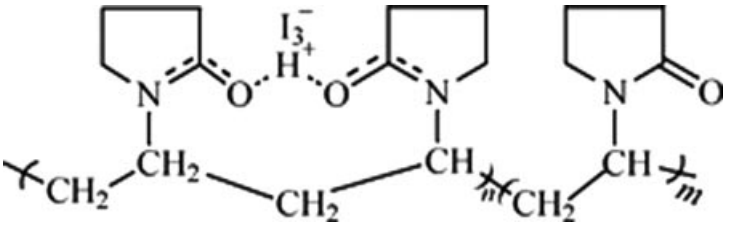
Iodine Complexes. The small molecule/PVP complex between iodine and PVP is probably the best-known example (92) and can be represented as follows:



It is widely employed as a disinfectant in medicine (povidone–iodine) because of its mildness, low toxicity, and water solubility. In actuality, the complex is based on HI_3 since HI is formed *in situ* from iodine during the manufacturing process (93). According to the *U.S. Pharmacopeia*, povidone–iodine is a free flowing, brown powder that contains from 9 to 12% available iodine. It is soluble in water and lower alcohols. When dissolved in water, the uncomplexed free-iodine level is very low (Fig. 4) (94); however, the complexed iodine acts as a reservoir and by equilibrium replenishes the free iodine to the equilibrium level. This prevents free iodine from being deactivated because the free form is continually available at effective biocidal levels from this large reservoir (95). The structure of the complex has been studied and in essence is similar to the representation above (95,96). PVP will interact with other small anions and resembles serum albumin and other proteins in this regard (97). It can be "salted in" with anions such as NaSCN or "out" with Na_2SO_4 much like water-soluble proteins (98).

Phenolics. PVP readily complexes phenolics of all types to some degree, the actual extent depending on structural features such as number and orientation of hydroxyls and electron density of the associated aromatic system. A model has been proposed (99). Complexation with phenolics can result in reduced PVP viscosity and even polymer-complex precipitation (100).

One practical result of this strong interaction is the employment of PVP to remove unwanted phenolics such as bitter tanins from beer and wine. This process is more easily carried out with insoluble crospovidone, which can be regenerated for reuse with dilute base (101). Soluble PVP has been employed to prevent photoyellowing of paper by complexing free-phenolic hydroxyl groups in lignin (102).

Dyes. PVP is currently (ca 1997) employed in a variety of antidye redeposition detergents as a result of its strong interaction with fugitive anionic dyes (103,104). This interaction depends on the structure of the dye. Cationic dyes complex only if they also contain hydrogen-bonding functionality. Anionic dyes complex more easily, depending on the number of anionic groups, size of the aromatic nucleolus, and number and orientation of phenolic hydroxyl groups, etc.

Anionic Surfactants. PVP also interacts with anionic detergents, another class of large anions (105). This interaction has generated considerable interest because addition of PVP results in the formation of micelles at lower concentration than the critical micelle concentration (CMC) of the free surfactant the mechanism is described as a "necklace" of hemimicelles along the polymer chain, the hemimicelles being surrounded to some extent with PVP (106). The effective lowering of the CMC increases the surfactant's apparent activity at interfaces. PVP will increase foaming of anionic surfactants for this reason.

Because of this interaction, PVP has found application in surfactant formulations, where it functions as a steric stabilizer for example to generate uniform particle-size polystyrene emulsions (107–109). In a variety of formulations, a surfactant's ability to emulsify is augmented by PVP's ability to stabilize colloids sterically and to control rheology.

Polymer/Polymer Complexes. PVP complexes with other polymers capable of interacting by hydrogen bonding, ion dipole, or dispersion forces. For example mixing of PVP with poly(acrylic acid) (PAA) in aqueous solution results in immediate precipitation of an insoluble complex (110). Addition of base results in disruption of hydrogen bonding and dissolution (111–113). Complexes with a variety of polyacids (114) and polyphenols (115) have been reported. The interest in compatibility on a molecular level, an interesting phenomenon rarely found to exist between dissimilar polymers, is favored by the ability of PVP to form polymer/polymer complexes.

Practical applications have been reported for PVP/cellulosics (105,116,117) and PVP/polysulfones (118,119) in membrane separation technology, eg, in the manufacture of dialysis membranes. Electrically conductive polymers of polyaniline are rendered more soluble and hence easier to process by complexation with PVP (120). Addition of small amounts of PVP to nylon 66 and 610 causes significant morphological changes, resulting in fewer but more regular spherulites (121).

Copolymerization

The Q and e values of VP are 0.088 and −1.62, respectively (122). This indicates resonance interaction of the double bond of the vinyl group with the electrons of the lactam nitrogen, whence the electronegative nature. With high $e+$ monomers such as maleic anhydride, VP forms alternating copolymers, much as expected

Table 14. VP Copolymerization Parameters[a]

Comonomer (M_2)	r_1	r_2	Reference
N-Vinyl caprolactam	2.80	1.70	125
Maleic anhydride	−0.027	0.074	126
Methyl methacrylate	0.01	4.04	127

Acrylic acid	0.100	0.880	129
Dimethylaminoethyl	0.07	4.7	130
Methacrylate	0.69	11.16	131

[a]Ref. 124.

(123). With other monomers between these Q and e extremes a wide variety of possibilities exist. Table 14 lists reactivity ratios for important comonomers.

Copolymerizations can be conveniently carried out in aqueous solution or in a variety of solvents, depending on monomer/polymer solubilities. Various strategies have been employed to compensate for the divergence in reactivity ratios in order to form uniform (statistical) copolymers such as semibatch or mixed monomer feeds, the goal being to add the more reactive monomer at the rate at which it is being consumed (132). Clearly, if the difference in reactivity is too great, then the amount of more reactive monomer that can be uniformly incorporated is significantly reduced. Of the monomers listed, styrene fits this category (133).

Poly(Vinylpyrrolidinone-co-Vinyl Acetate). The first commercially successful class of VP copolymers, poly(vinylpyrrolidinone-*co*-vinyl acetate) is currently manufactured in sizeable quantities by both ISP and BASF. A wide variety of compositions and molecular weights are available as powders or as solutions in ethanol, isopropanol, or water (if soluble). Properties of some examples of this class of copolymers are listed in Table 15.

Table 15. Properties of PVP/VA Copolymers[a]

	PVP–VA copolymer

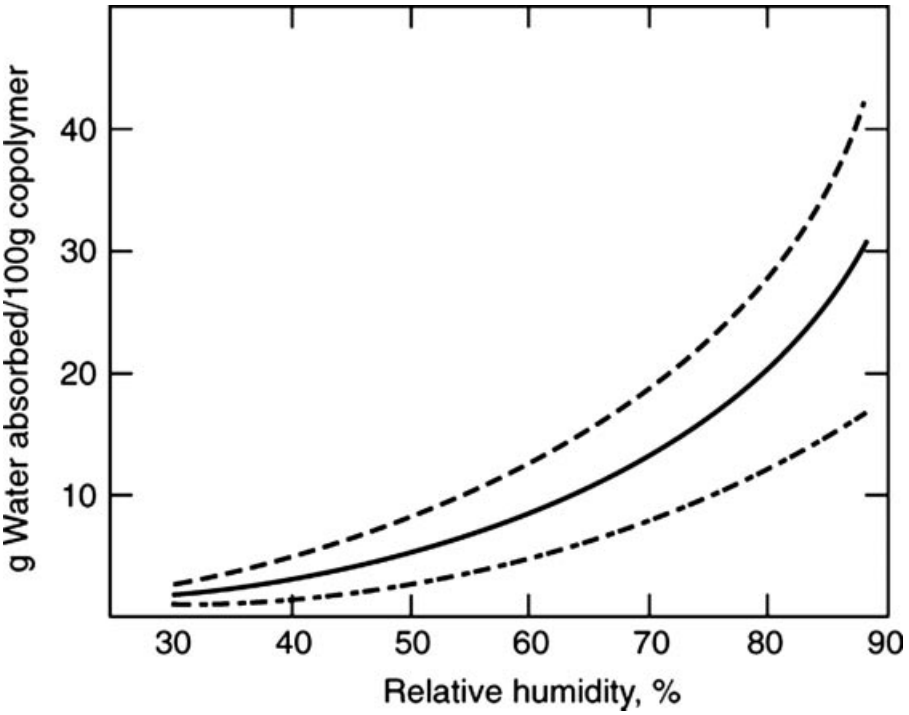

Fig. 5. Hydrophilicity of three wt% monomer ratios of PVP/VA: (– – –), 70/30; (—), 50/50; (—·—·), 30/70.

Although reactivity ratios indicate that VP is the more reactive monomer, reaction conditions such as solvent polarity, initiator type, percent conversion, and molecular weight of the growing radical can alter these ratios (135). Therefore, depending on polymerization conditions, copolymers produced by one manufacturer may not be identical to those of another, especially if the end use application of the resin is sensitive to monomer sequence distribution and MWD.

An important reason for the ongoing interest in these copolymers is that vinyl acetate reduces hydrophilicity so that applications that require less moisture-sensitive films such as those employed to set hair are less prone to plasticize and become tacky under high humidity conditions (136) (Fig. 5).

As shown in Figure 6, desirable fixative properties superior to PVP homopolymer can be specified by judicious selection of the amount of vinyl acetate. Hair sprays are limited in the molecular weight of the resin because if they are too high the resulting viscosity of the formulation will result in a poor (coarse) spray pattern. Increasing the VP/VA ratio causes properties to increase in the direction shown by the arrows.

Other applications for VP/VA copolymers are uses as water-soluble or remoistenable hot-melt adhesives (137), pharmaceutical tablet coatings, binders, and controlled-release substrates.

Tertiary Amine-Containing Copolymers. Copolymers based on dimethylaminoethyl methacrylate (DMAEMA) in either free-amine form or

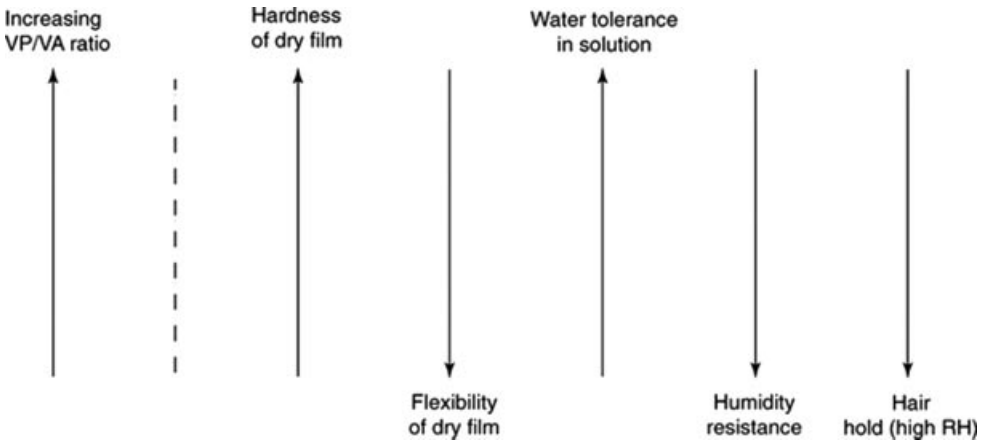

Fig. 6. Effect of VP/VA monomer ratio on properties of VP/VA copolymers.

quaternized with diethyl sulfate or methyl chloride have achieved commercial significance as fixatives in hair-styling formulations, especially in the well-publicized "mousses" or as hair-conditioning shampoo additives. This success has occurred because the cationic charge affords substantive resins that strongly adhere to the hair (138).

The most successful of these products contain high ratios of VP to DMAEMA and are partially quaternized with diethyl sulfate (Polyquaternium 11) (139–141). They afford very hard, clear, lustrous, nonflaking films on the hair that are easily removed by shampooing. More recently, copolymers with methylvinylimidazolium chloride (Polyquaternium 16) (142) or methacrylamidopropyltrimethyl ammonium chloride (MAPTAC) (Polyquaternium 28) have been introduced. Replacement of the ester group in DMAEMA with an amide analog as in Polyquaternium 28 results in a resin resistant to alkaline hydrolysis and hence greater utility in alkaline permanent wave and bleach formulations (see QUATERNARY AMMONIUM COMPOUNDS).

Unquaternized DMAEMA copolymers afford resins that are mildly cationic and less hydroscopic. They provide more moisture-resistant fixatives (143). Further refinements have been accomplished by adding a third comonomer such as *N*-vinylcaprolactam (VCl). In this case, replacement of VP with VCl results in a terpolymer (VP/VCl/DMAEMA) with even greater high humidity moisture resistance and curl retention.

Copolymers Containing Carboxylic Groups. A new line of VP/acrylic acid copolymers in powdered form prepared by precipitation polymerization (144) from heptane have been introduced commercially (145). A wide variety of compositions and molecular weights are available, from 75/25 to 25/75 wt% VP/AA and from 20×10^3 to 250×10^3 molecular weights.

The copolymers are insoluble in water unless they are neutralized to some extent with base. They are soluble, however, in various ratios of alcohol and water, suggesting applications where delivery from hydroalcoholic solutions (146) but subsequent insolubility in water is desired, such as in low volatile organic

Table 16. Properties and Applications of Commercial PVPs

Polymer	Mfr/Trade name	Grades	Properties/applications
		Homopolymers	
PVP	ISP/PVP, Plasdone BASF/Luviskol, Kollidon	K-15 to K-120 K-12 to K-90	Film former, adhesive, binder, com-plexant, stabilizer, crystallization inhibitor, dye scavenger, detoxi-cant, viscosity modifier
		Cross-linked	
Proliferous polymerization	ISP/Polyclar, Polyplasdone BASF/Divergan	Various (by particle size) various (by particle size)	Pharmaceutical tablet disintegrant, adsorbent for polyphenols (tanins), beverage clarification
		Copolymers	
PVP/VA	BASF/ISP/PVP–VA copolymers	Various monomer ratios in ethanol, IPA or water in ethanol, IPA or water	Film forming adhesives for hairsprays, mousses, gels, shampoos, styling lotions, bio-adhesives, water-remoist-enable or removable adhesives
PVP/DMAEMA	ISP/copolymer	845/937/958	Mildly cationic, hair styling aids and conditioners, with strong hold; sub-stantive, lustrous film-formers
PVP/DMAEMA DES quaternary	ISP/Gafquat BASF/Luviquat	755N/734PQ11	Strongly cationic, substantive, mousse and gel hair fixative ingredients

[a] Graft copolymers.

compound (VOC) hair-fixative formulations or tablet coatings. Unneutralized, their T_gs are higher than expected, indicating interchain hydrogen bonding (147).

Miscellaneous Copolymers. VP has been employed as a termonomer with various acrylic monomer–monomer combinations, especially to afford resins useful as hair fixatives. Because of major differences in reactivity, VP can be copolymerized with alpha-olefins, but the products are actually PVP grafted with olefin or olefin oligomers (148,149). Likewise styrene can be polymerized in the presence of PVP and the resulting dispersion is unusually stable, suggesting that this added resistance to separation is caused by some grafting of styrene onto PVP (150). The literature contains innumerable references to other copolymers but at present (ca 1997), those reviewed in this article are the only ones known to have commercial significance.

Applications

An overview of the various product categories is given in Table 16.

The Chemical Abstracts Services Registry Number and IUPAC nomenclature for PVP are [9003-39-8] and 1-ethenyl-2-pyrrolidinone homopolymer, respectively; however, it is known by a variety of approved names by foreign and domestic regulatory authorities. For example:

Name	Chemical name
Povidone	Poly(*N*-vinyl-2-pyrrolidinone)
Polyvidone	
Polyvidon	Poly(*N*-vinylbutyrolactam)
Polyvidonum	Poly(1-vinyl-2-pyrrolidinone)
	1-Vinyl-2-pyrrolidinone polymer
	Poly{1-(2-oxo-1-pyrrolinyl)ethylene}

Trade names for nonpharmaceutical grades are PVP, Peregal ST, Albigen A, and Luviskol; for pharmaceutical grades, Plasdone and Kollidon. The insoluble or crospovidones likewise exist as two grades: nonpharmaceutical are Polyclar and Divergan; pharmaceutical, Polyplasdone XL and Kollidon Cl.

PHOTOREFRACTION

Introduction

This article introduces the field of photorefraction and the photorefractive effect in polymer composites. The photorefractive effect is expected to play a significant role in the development of all-optical information processing techniques. Photorefractive materials, including polymers, have been proposed for use in high density optical data storage; associative image processing techniques, including dynamic holography, novelty filtering and image amplification; spatial light modulation, such as beam fanning, optical limiters, phase conjugators, self-induced optical resonators, programmable interconnections in integrated optics; and simulations of neural networks and associative memories with parallel signal processing (1–8).

The photorefractive effect requires a specific mechanism for the spatial modulation of the index of refraction of a material arising from an intensity modulation of the incident light (as in a diffraction pattern or hologram). The specific mechanism is the generation, transport, and trapping of charge through photoconduction in the illuminated regions to set up space-charge fields between the light and dark regions. These space-charge fields cause the modulation of the index of refraction acting through electro-optic and molecular orientation effects (9–11).

Scope of Article. The Photorefractive Process section describes the photorefractive process in detail, including theoretical models for photorefraction that are used to determine optimized material properties for applications using polymers. That section also describes how photorefraction can be distinguished from other photo-induced refractive index changes. Composition of Polymeric Photorefractive Materials section describes many of the ways polymeric composite materials have been formulated for their photorefractive properties, primarily by incorporating different functionalities via doping with electro-optic chromophores, photo-charge generation and transport agents, and plasticizers. Test Methods section briefly describes important experimental techniques for studying photorefraction, including four-wave mixing, two-beam coupling, and ellipsometry. Test Methods section also highlights several techniques for studying photoconductivity specifically for the photorefractive response. Finally, Applications section discusses recent progress in developing polymeric photorefractive devices.

Because of the extensive overlap with electro-optics and nonlinear optics, the reader is referred to separate articles on these topics in this encyclopedia. See ELECTROOPTICAL APPLICATIONS for a discussion of the changes in the optical response of polymers due to an applied AC or DC electric field from the so-called Pockels or Kerr effects. Also see, for an overview, NONLINEAR OPTICAL PROPERTIES.

Similarly, because photoconductivity is essential to photorefraction, readers may refer to CONDUCTIVE POLYMER COMPOSITES.

In addition to those cited above, many other helpful review articles have appeared in the archived research literature, for example, References 12–18.

History and Advantages of Polymeric Photorefractive Materials. The research literature on photorefraction dates back to its discovery as optical damage in the inorganic ferroelectric crystal, lithium niobate in 1966 (19). The first reports on photorefraction in an organic crystal appeared in 1990 (20) and in a polymeric material in 1991 (21). Application of crystalline photorefractive materials has been limited due to (1) the difficulty of crystal growth and processing and (2) fundamental limits on the maximum possible variation in the index of refraction of inorganic crystals in which large optical nonlinearities, measured by the electro-optic coefficient, r_e, are generally accompanied by large dielectric constants, ε_r, leading to screening of the space-charge distribution through polarization effects (1). For the linear electro-optic contribution, the relevant figure of merit is defined by $Q = n^3 r_e/\varepsilon_r$, where n is the index of refraction. Q values for organic photorefractive materials can exceed those of inorganic materials by more than an order of magnitude. The electro-optic mechanism in polymers is intrinsically different from that in inorganic crystals. In ferroelectric crystals, acoustic and optical phonons contribute significantly to the electro-optic effect, where the polarizability is largely ionic. The linear electro-optic response in organic polymers is primarily due to the electronic excitations of individual molecules and/or molecular units, thus yielding low dielectric constants and minimizing dispersion over DC to optical frequencies (22).

Because of these advantages as well as orientational enhancement effects and the superior compositional flexibility of polymers, the number of studies of polymers for photorefraction grew rapidly during the 1990s and into the current decade. It is now common to see a chapter on polymeric photorefraction in treatises that once emphasized only inorganic crystalline materials (for example, see References 23–27) and to see specific sections on photorefraction in overviews of nonlinear optical properties of polymers (for example, See references 28–31).

The Photorefractive Process

The essential property of photorefraction is the writing of a refractive index grating due to a nonuniform incident optical field, typically through interference and/or diffraction of the incident light beam(s). The photorefractive effect can be understood as four distinct sequential steps, shown schematically in Figure 1. (*1*) The incident light generates mobile charges, usually positively charged "holes" in polymeric materials, through the photoionization of light sensitive constituents called sensitizers or photocharge generation agents (32). (*2*) The photo-induced charge carriers (holes) drift away due to an applied electric field, E_B, separating the positive from the negative charges by the charge-transfer photoconducting properties of the material, while the negative charges generally remaining localized (33). Other transport mechanisms including diffusion and photovoltaic processes are possible and, though significant in inorganic materials, they have not been found significant in photorefractive polymers. These first two steps show the

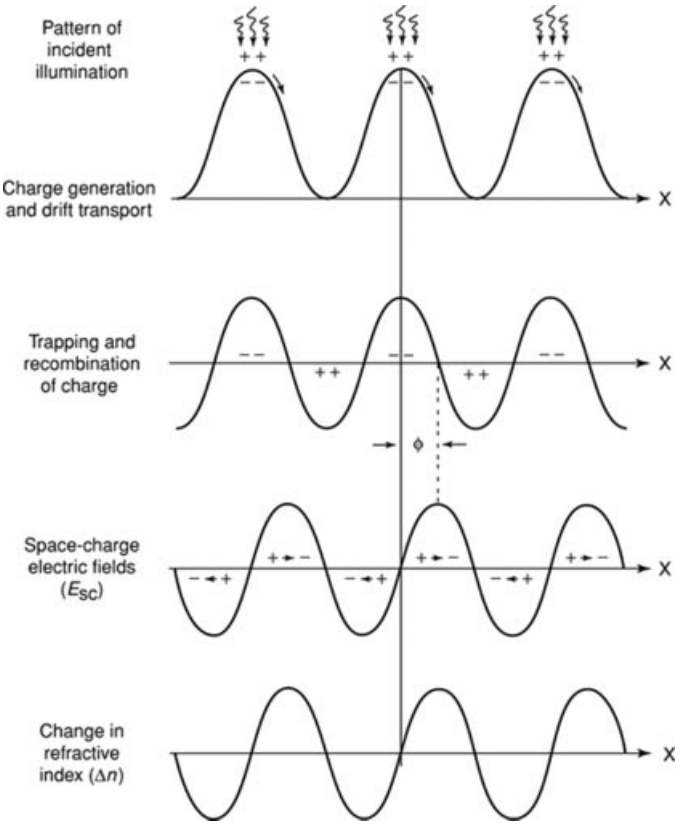

Fig. 1. Schematic of the photorefractive process. Note the phase shift, ϕ, between the incident intensity grating and the resulting photorefractive grating in the material. Depending upon the trapping depth and depth of modulation of the intensity of light incident on the material, the phase shift can vary between 0 and $\pi/2$. The absence of this phase shift indicates that mechanisms of photoinduced refractive index change other than photorefraction are involved. Many photorefractive applications require phase shifts approaching $\pi/2$.

importance of the photoconductivity of the material which must provide for the transport of the charge over distances many times greater than the wavelength of the illumination. (*3*) Because the photorefractive material does not generate mobile charge in dark regions (where destructive interference occurs), the third step in the process is the trapping of the mobile charges at suitable charge trapping sites. These trapped charges establish charge density gradients in the material that produce a patterned internal ("space-charge") electric field, shifted from the incident light pattern by the migration of the mobile charges into dark regions. (*4*) Lastly, the space-charge field arising between the dark and light regions modulates the index of refraction of the material via the electro-optic effect and reorientation of the molecular dipoles in the space-charge field (11,34–36). The resulting index-of-refraction pattern then stores the information in the original illumination pattern. This index-of-refraction grating will diffract an incoming reference beam to reproduce the pattern that created it as in a hologram.

Not surprisingly, different material functions are required for each of the steps in the formation of a photorefractive grating, leading to development of multifunctional composite materials and the search for optimal combinations of material properties as discussed in Composition of Polymeric Photorefractive Materials section.

One of the most important results of these processes is that a phase shift ϕ appears between the index of refraction grating and the incident light intensity pattern, ideally by as much as 90° when the centers of mobile and fixed charge density correspond to the regions of minimum and maximum light intensity, respectively (as shown in Fig. 1). As discussed further in Test Methods section and Applications section, this phase shift makes possible an energy exchange between two incident crossed beams (two-beam coupling) necessary for many optical data processing applications requiring optical gain, amplifying one beam at the expense of another.

Refractive Index Modulation by E_{sc}. Photorefractive behavior in polymers can be very roughly modeled by assuming a one-dimensional index of refraction change caused by the vector sum of the applied "bias" field E_B and a space-charge field resulting from separated, trapped charges within the material E_{sc}, $E_T(x) = E_{sc} + E_B$ (4,37),

$$\Delta n(x) \approx -\frac{n^3 r_e}{2} E_T(x) + \frac{3 r_K}{2n} E_T^2(x) \tag{1}$$

where n is the index of refraction, r_e is the effective Pockels (linear) electro-optic coefficient, and r_K is the effective Kerr (quadratic) coefficient due to chromophore reorientation. As further discussed below, E_{sc} is inversely proportional to the relative permittivity ε_r (as seen in eq. 3).

For a common alternate representation of the quadratic field dependence, see equation 2.

Refractive index modulations on the order of $\Delta n \sim 10^{-2}$ have been suggested with known materials at field strengths of only 28 V/μm (38).

Orientational Enhancement Effect. In addition to a strictly electronic and linear (Pockels) electro-optic response given by the first term on the right side of equation 1, the quasi-one-dimensional nonlinear optical chromophores incorporated into the polymer for their electro-optic response often exhibit large differences in the polarizability parallel versus perpendicular to the chromophore long axis (36,39–42). This so-called "polarization anisotropy" ($\Delta\alpha \approx \alpha_\parallel - \alpha_\perp$, where $\alpha_\parallel$ and $\alpha_\perp$ are the linear polarizabilities along and perpendicular, respectively, to the long molecular axis) typically arises from strong light absorption and a large ground state dipole moment μ_g (14) as found in highly colored nonlinear optical chromophores. In fact, reorientation of these chromophores in the space-charge field usually plays the dominant role in determining the depth of the index-of-refraction grating in polymeric composite materials (4). The orientational effect can be interpreted either in terms of the optical Kerr effect (4) as in the second term on the right in equation 1 or as a polarization anisotropy appearing with a quadratic dependence on the space-charge field (14,43). In the latter case, the quadratic dependence is often represented using the following expression based

upon an oriented gas model (14).

$$\Delta n_{\text{orient}}(x) \approx \frac{N(\alpha_{\parallel} - \alpha_{\perp})}{45n} \left(\frac{\mu_{\text{g}} E_{\text{T}}}{k_{\text{B}} T} \right)^2 \tag{2}$$

where N is the density of reorienting nonlinear optical molecules, k_{B} is the Boltzman constant and T is the temperature.

To understand the significance of the orientational enhancement effect and how it increases the depth of the refractive index change beyond that of the linear electro-optic effect found in crystalline materials, it is helpful to recall that the bulk linear electro-optic effect can only occur when the material lacks inversion symmetry (see ELECTROOPTICAL APPLICATIONS). To induce the asymmetric order in amorphous polymers, the polymer is typically subject to electric-field poling to align the dipoles. In this poling process (see NONLINEAR OPTICAL PROPERTIES), the polymer is heated above its glass-transition temperature (T_{g}) (see GLASS TRANSITION) and then cooled during the application of the poling field to freeze in polar order.

In room-temperature experiments with low T_{g} polymers ($<100^{\circ}$C), it is found that the polymers will not maintain the polar order needed for the linear electro-optic effect when the poling field is turned off. These materials must therefore be poled *in situ* for the requisite asymmetry to appear. At the same time, an external electric field (also called the bias or drift field) must be applied across the photorefractive polymer *in situ* to enable the mobile charges to move efficiently into the dark regions. Thus, the requisite external poling field is already present for polymeric photorefractive materials. This applied bias field serves two purposes: (*1*) The dominant mechanism for charge transport is drift of the holes in the direction of the applied field (as further discussed below). (*2*) The external field strengthens the alignment of the polymer polar order required for the linear electro-optic effect and for the electric-field-induced birefringence.

The applied bias field is not the only field experienced by the molecules, however. The creation of space-charge fields E_{sc} will also modulate the orientation of the nonlinear chromophores. This so-called orientational enhancement effect was discovered by Moerner and co-workers when they found that the measured diffraction efficiency of a low T_{g} photorefractive polymer required E_{sc} to be an order of magnitude larger than should have been permitted by the projection of E_{B}, using only the linear electro-optic effect (11). In effect, the sinusoidal space-charge grating produced a sinusoidal variation in the electro-optic r_{e} coefficients *and* a sinusoidal birefringence of the polymer. Additional enhancements were obtained upon adding a plasticizer to the composite in order to further reduce T_{g} (44).

A schematic of the typical oblique transmission experimental geometry used to measure the diffraction efficiency of a photorefractive polymer this way is shown in Figure 2. The sample must be tilted with respect to the bisector of the two beams because the applied field must have a component parallel to the grating wavevector in order to move charges along the grating. This experimental geometry complicates analysis of the relationship between the vector fields and the tensor elements of the resulting refractive index change. A more complete

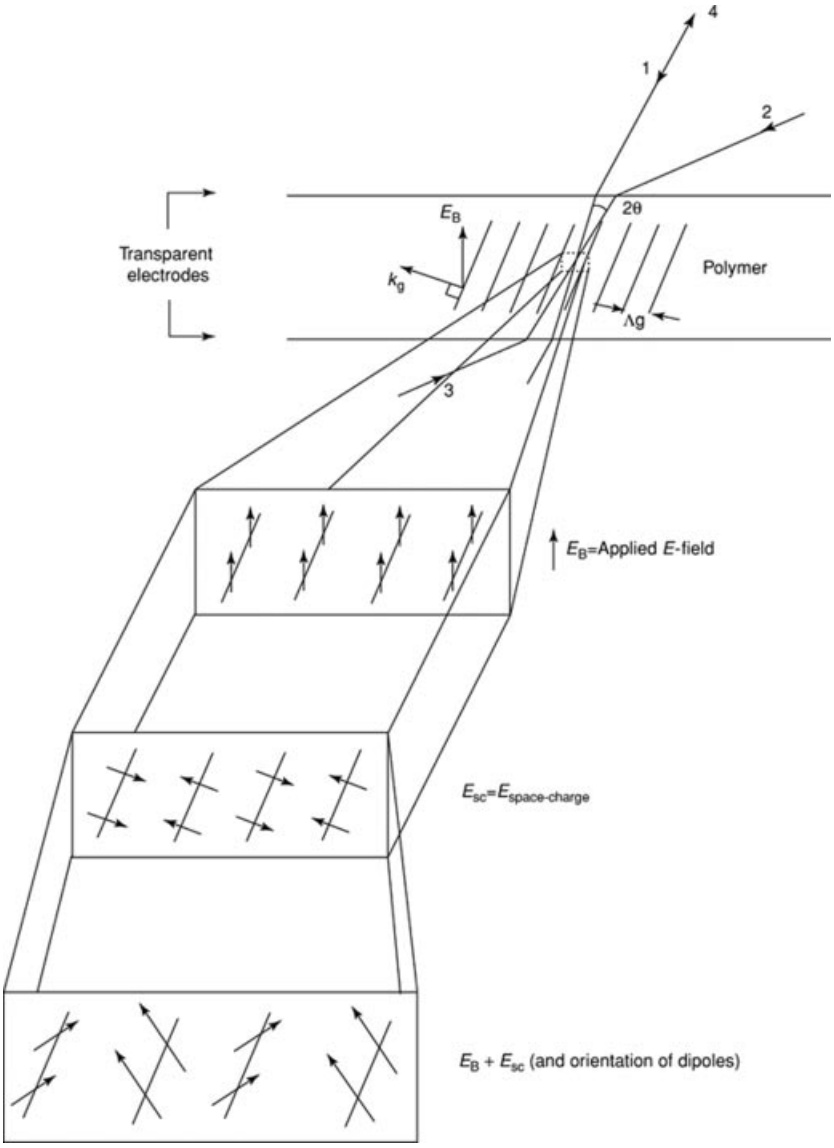

Fig. 2. Oblique geometry typically used for characterizing bulk photorefractive polymers. The magnified portion illustrates the orientational enhancement effect described in the text due to the modulated poling of the electro-optic chromophore in the combined $E_B + E_{sc}$ fields. The beam and grating geometry applies for both four-wave mixing (beams 1–4) and two-beam coupling (beams 1 and 2).

treatment, including the tensorial nature of the index of refraction modulation, as well as figures of merit, may be found in Reference 45.

Understanding the effects of orientational enhancements has been made more complex, however, by the need to account for supramolecular interactions such as dipolar aggregation, the tendency of dipoles to adopt align antiparallel

with their neighbors (38). Several studies have explored the effects of glass transition temperature on polymeric photorefractive properties (46–48).

Origin of the Space-Charge Field E_{sc}. For a photorefractive index grating, the space-charge field E_{sc} can be described approximately by (49)

$$E_{sc} \approx \left(\frac{\Phi}{h\nu}\right)(eL_{eff})\left(\frac{mI_0\alpha}{\varepsilon_0\varepsilon_r}\right) \tag{3}$$

where Φ is the photocarrier generation efficiency, $h\nu$ the photon energy, e the electronic charge, L_{eff} the effective transport length traveled by the mobile charge, α the absorption coefficient, and ε_0 the vacuum permittivity. The modulation index m is a function of the grating geometry and is given by $m = 2\sqrt{I_1 I_2}/I_0$, where the interference arises from two crossed beams of combined irradiance $I_0 = I_1 + I_2$. For this elementary hologram, the resulting irradiance distribution is

$$I(x) = I_0[1 + m\cos(k_g x)] \tag{4}$$

where k_g is the wavevector defined by the spacing Λ_g between adjacent irradiance maxima in the incident grating (the grating "wavelength"). Thus, $k_g = 2\pi/\Lambda_g = 4\pi n \sin\theta/\lambda_g$, where λ_g and θ are the incident optical wavelength (assuming the interfering beams are the same wavelength) and the crossing half-angle between those beams inside the sample. For visible wavelengths, Λ_g ranges from 0.3 to 20 μm, due to the limited range of accessible angles between the two beams (see Fig. 2).

Photoconduction. The generation, transport, and trapping of charge necessary to create E_{sc} and the resulting index-of-refraction modulation are each steps in the process of photoconduction in the photorefractive material (50). The literature on photoconductivity in polymers is voluminous and the variety of effects to be accounted for mirrors the variety of applications to which polymers may be adapted (see, for example, References 51–53). The original rate equations developed by Kukhtarev for inorganic materials (54) are inadequate for polymers due to the electric-field dependence of the charge photogeneration efficiency (55) and the complexities of charge trapping in the transport of charge (56). Unlike the photoconductive effects in inorganic materials, photoconduction in polymers is generally modeled using temperature-activated hopping mechanisms, not the standard band transport model used for inorganic ferroelectric crystals (57–59). In high-mobility polymers, however, the transport involves both traps associated with polymer transport and the conduction band associated with the ordered phase of the material. These combined effects require a hybrid model for the transport, and its dependence on field (60–62). The hopping model assumes conductivity is controlled not by the size and accessibility of the conduction band, but by the presence and location of suitable trapping and recombination centers between which charges move via electric-field dependent or thermally activated jumps. In polymeric photoconduction, the charge hopping is between traps which are sensitized by the presence of a drift (DC) electric field across the sample as in the Poole–Frankel model (21,33,63–66). Traps are parametrized by their "depth," ie, by the likelihood that charge may be released from the trap thermally as well as optically (a "shallow" trap) or may only be released, if at all, by absorption of a

photon (a "deep" trap, either active or inactive depending upon its photoionizability) (67). Traps may be shallow or deep based on their thermal ionizability and photoionizability and are distinguished from recombination centers by the relative likelihood of the charge either being released from a *trap* to participate further in conduction or being neutralized through *recombination* with a carrier of the opposite sign. Thus, photoconductivity is also an increasing function of incident photon energy.

The time evolution of the charge generation and trapping process has been the subject of particular study because of significant interest in the development of photorefractive materials with a faster response. Notable recent developments include the numerical simulation of the kinetics of E_{sc} as a function of the light intensity, grating vector, electric field and density of deep inactive traps (68), the introduction of both shallow and deep traps with different, nonzero, excitation rates into the theory (69), and the experimental study of rise, decay, and steady-state photocurrents with pulsed light (70). The rate limiting step in the photorefractive process varies between materials, primarily being due to either the photocarrier generation efficiency or the charge mobility (1,69). Preillumination of the sample has been shown to affect the timing of the response significantly (69–72).

Photocarrier Generation Efficiency. The photocarrier generation efficiency Φ_g depends upon the applied electric field, and is usually approximated as having a power-law dependence of $\Phi_g \sim E^p$, where p varies between 1.5 and 3.5, depending upon the material (1,50,73). The reason for this dependence is that even if the initial quantum yield from the incident photons is large, the photogeneration efficiency is limited by geminate recombination or back electron transfer due to the small thermalization radius of many polymers, ie, freed carriers cannot separate sufficiently so that the energy of their Coulombic attraction is less than $k_B T$ (55). A strong applied field will help to separate the charge carriers and so improve the effective carrier generation efficiency (34). Typically, the field dependence of the charge generation and the effects of geminate recombination are understood using the Onsager model (74,75). That model is inadequate, however, in accounting for the slow recombination rate of electron–hole pairs in polymeric materials and has been augmented by the Marcus theory of electron transfer in more recent treatments to model slow recombination rates found in photoconductive polymers (76).

Charge Transport, Mobility and Free Charge Lifetime. An important parameter for understanding charge transport in photorefractive polymers is the quantity L_{eff}, which describes the transport length of the generated photocarriers. L_{eff} depends on the presence of applied fields, the grating geometry, and the intrinsic mechanisms of carrier transport (77). It is important to maximize L_{eff}, which is defined so as to be always less than the inverse grating wavevector (on the order of 0.1–2.0 μm) (35). In its simplest form for one carrier and only drift transport, we can represent L_{eff} in terms of the grating wavevector k_g and the average drift length L_E

$$L_{eff} = \frac{L_E}{\left[1 + (k_g L_E)^2\right]^{\frac{1}{2}}} \tag{5}$$

where $L_E = \mu\tau|\boldsymbol{E}_B + \boldsymbol{E}_{sc}|$ is the transport length due to the combined fields. Here, μ is the effective carrier mobility (also a strongly increasing function of E_B) and τ is the effective free lifetime of the carrier over distances large compared to the distances between traps.

From equation 5, it can be seen that maximization of L_{eff} for a given grating spacing requires maximization of the μ–τ product or application of a large external field. Because of the dispersive nature of the transport, μ and τ are not easily defined quantities in polymers (78). The mobilities are field dependent, often in a highly nonlinear way, and the presence of significant trapping in a polymer complicates their determination (33,79). Furthermore, τ in many polymers may be effectively limited by the presence of "deep traps" from which further photoionization is inhibited.

A major trade-off in the development of poled polymers for photorefraction arises from the need both to maximize the mobility for photoconductive transport and yet to minimize the dark conductivity to allow poling and subsequent storage of the photorefractive grating (80). Unfortunately, because poling introduces charge carriers into the sample, if the mobility of carriers in the photoconducting polymer is appreciable, the sample will short-circuit in the presence of a large applied poling or drift field before the molecules have adequately aligned (4).

On the other hand, another advantage of polymers over inorganic photorefractives is that the space-charge fields attainable are not generally limited by the trap density, so that large diffraction efficiencies have been realized by the application of large external fields. Thin-film polymers are amenable to the application of large external field, which has led to large efficiencies by compensating for small values of the $\mu\tau$ product. Destruction of samples due to dielectric breakdown remains a problem and materials with large Δn in a relatively small applied field are of significant interest (38).

One potential benefit of using high mobility polymers is in reducing the response time of the materials in the cases when neither charge generation (69) nor rotational mobility (81) of the chromophores are the rate limiting factors in the PR process. Unlike diffraction efficiency, which can be increased by application of a stronger external field, the application of a strong external field cannot fully compensate for slow speed due to low mobility. While the mobility in some polymeric photorefractives has been found generally to be an increasing function of applied field, negative-field dependence has been predicted and observed in other cases (75,79).

Perhaps a better model for describing the disorder in charge generation and transport in molecularly doped polymers is the so-called "disorder formalism" proposed by Bässler for xerographic photoreceptors (82). In this model, transport occurs through hopping between localized states with a Gaussian distribution of energies and separation distances. A random distribution of permanent dipoles due to the nonlinear optical chromophores produces a local variation of the electrostatic potential and an increasing energy width, and position disorder appears with increasing dipolar molecule concentration. Increasing concentrations of molecules with large dipole moments led to increased disorder and reduced carrier mobility and photorefractive speed (79).

Distinguishing Photorefraction from Other Photoinduced Refractive Index Changes. A variety of photoinduced effects, such as photochromism,

thermochromism, thermorefraction, conventional electronic $\chi^{(3)}$ effects and photochemical changes, may lead to changes in the refractive indices of a polymer in ways other than photorefraction, or even so-called, pseudo-photorefraction (83–86). Each of these lacks the physical separation of internal space-charge that leads to a phase shift between the incident light intensity and the refractive index modulation. Though not always experimentally simple, there are many ways to distinguish true photorefraction from competing mechanisms, such as cis–trans isomerization, which lead to refractive index changes (75,87).

Two Beam Coupling via a Phase Shift of the Index Grating. The most unmistakable sign of photorefraction (and one of its most promising features) is asymmetric two-beam coupling (88). A critical element in this coupling is the nonzero phase shift between the phase grating and the incident interference pattern (indicated by ϕ in Fig. 1). For absorption gratings from photochemical or photochromic effects, the index and intensity gratings are in phase. Two-beam coupling techniques for measuring the grating phase are discussed in (88) and in Test Methods section. Two-beam coupling in the absence of a moving grating (89) or an AC applied field is the strongest evidence of photorefraction. Its absence, however, does not alone signify the absence of photorefraction (21,90).

Hologram Erasability. The photorefractive effect is reversible. The traps that lead to the space-charge fields in photorefractive materials must themselves be photoionizable. If so, the photorefractive diffraction grating is erased simply by bathing the material in a uniform field of the proper photon energies. For photochemical effects, reversibility generally requires heating or other chemical treatment. Photochromic gratings tend to be only partially erasable under uniform illumination.

Enhancement by External Fields. The photoconductive response generally increases at least as the square root of the applied drift field. Application of an external field enhances photocarrier generation both by reducing the barrier to charge release and, as previously discussed, by assisting the separation of photogenerated charges to lessen the effects of geminate recombination.

Correlation with Photoconductivity. To confirm that the refractive index grating is due to the photoconduction of mobile charges into dark regions, comparisons between the absorption spectrum and the wavelength dependence of the photoconductivity and photorefractivity of a material help identify the underlying photoconduction mechanism and resultant charge density gradients (33). These comparisons are complicated by the fact that the mobility and photocharge generation efficiency of photorefractive materials can be orders of magnitude lower than those properties appearing in materials developed solely for photoconduction. Some of the difficulties in quantifying relevant photoconductivity parameters in polymeric photorefractives are discussed in Reference 91 and in Test Methods section.

Polarization Anisotropy of the Grating Readout. The photorefractive response is dependent upon the polarization of the incident beam. If pure *s*- or *p*-polarized light is used in writing the grating, the depth of the index grating and thus the diffraction efficiency will be different depending upon whether the polarization of the beam has components parallel to the poling field (75). As discussed

in Test Methods section, the writing beams in a four-wave mixing configuration usually are *s*-polarized beams to limit the coupling between the illuminating interference pattern and the diffraction of one beam into the other, which is maximized when the reading beam is *p*-polarized to sample the refractive index change parallel to the applied poling field. In addition, the polarization of the writing beams will change the energy-transfer direction in two-beam coupling measurements due to the orientational enhancement effect (11).

Composition of Polymeric Photorefractive Materials

In this section, in addition to reviewing common ingredients for photorefractive polymeric materials, some of the problems that are being overcome in the formulation of useful multifunctionality in multicomponent polymers are explored. Current polymeric materials are limited in some cases by their slow response times and short wavelengths of operation (44,92) and in other cases by the need for large external electric fields and tendencies towards dielectric breakdown and other material instabilities. Typically, photorefractive polymers require the application of fields around 40–100 V/μm, severely limiting sample thicknesses to under 100 μm. Higher speed operation is required for data processing using these materials. Also, further work is needed to develop polymeric photorefractives with a longer wavelength response for compatibility with current optical communications standards (for example, typical near infrared telecommunications operate at 1550 μm).

Formulation of the ideal photorefractive polymer requires finding or mixing materials that combine necessary photogeneration, charge transport and trapping response with electro-optic and orientational anisotropy properties. With respect to the electro-optic response in organic materials, the largest nonlinearities have been in polymers that combine an extended system of highly mobile π-electrons with electron donor and acceptor groups at para positions. To make these materials photorefractive, it is necessary to include one or more additional functionalities, usually by doping after polymerization. Charge generation, transport and trapping properties can be tailored by attaching molecules to the polymer structure with the appropriate ionization energy or electron affinity (63). For instance, charge transfer complexing is accomplished by adding donor sensitizers to acceptor polymers, or vice versa, so that the charge released by the donor is taken by the acceptor to create an absorption band corresponding to the difference between the donor and acceptor energies. Also, because many otherwise appropriate polymers tend to absorb primarily in the ultraviolet spectrum, dye sensitization of these polymers leads to greater absorption of visible light or longer through the release of photocarriers in the dye (4,33).

When combining functions by adding plasticizers, sensitizers, charge transport agents, and other functional groups, one may be limited to having less than the optimum amount of the nonlinear response to accommodate these functionalities. Also, doping of materials often leads to an increase in phase segregation, which causes undesirable light scattering and can severely limit the useful lifetime of the polymer and/or its processability (21). In the trade-off between using

fully-functionalized polymers with better stability and the improved responsiveness of guest–host systems, guest–host systems currently lead in terms of the depth of the index grating, the achievable two-beam coupling gain, and, surprisingly, even in the speed of grating dynamics (4).

Electro-Optic and Electric-Field-Induced Birefringent Materials. As can be seen from the analysis of The Photorefractive Process section, one material parameter to be optimized is the electro-optic and orientational response. This can be accomplished either by finding compatible materials with large linear electro-optic coefficients or by optimizing the orientational effects using materials with large birefringence (polarization anisotropy). One major difference in these approaches is the response speed of the photorefractive effect in that the orientational approach is expected to be slower, but submillisecond responses of low T_g materials have been demonstrated (93–96).

Optimizing the nonlinear response of the polymer usually requires saturating the polymer with the appropriate chromophore, typically 25–35 wt% (38). The most common electro-optic molecules used with these polymers are azo-dyes, such as ethyl-hexyloxy-dimenthyl-nitrophenylazo benzene (EHDNPB) (61,97–102), and dimethyl-*p*-nitrophenylazo anisole (DMNPAA) (103–105), and dicyanostyrene (DCST) derivatives, such as diethylaminodicyanostyrene and (DDCST) (106), though the range of molecules used includes simple donor–acceptor units and complex oligomers (107). The chromophore unit is the most common distinguishing factor among demonstrably photorefractive materials. The photorefractive response tends to decrease with an increase in the size of the chromophore (5,108).

Plasticizers. To optimize the reorientational effects, either polymers with low glass transition temperature (T_g) values (after incorporating other material properties, as discussed below) are used or a plasticizer is added to depress the T_g value and enable molecular rotations (109), which may or may not be desirable depending upon the need to better fix the grating in the polymer with a high T_g or to deepen the index-of-refraction modulation through orientation of the chromophores in the space-charge field (11,48).

The most common plasticizer used is ethylcarbazole (ECZ), typically added at 15–30 wt% (110–114). One trade-off in the use of inert plasticizers is the accompanying decreased concentration of other active ingredients. Thus, the use of functionalized plasticizers or materials that fulfill dual roles is preferred (115). However, others used include benzyl butyl phthalate (BBP) (40,110,112,116), polybutylacrylate (PBA) (117), and diphenyl phthalate (DPP) (118), and several systems have been developed in which the amount of plasticizer needed is either decreased significantly (119) or eliminated entirely (59,60,106,120,121), using triphenylamine units.

Photogeneration Sensitizers. As discussed in Origin of the Space-Charge Field E_{sc} section, charge generation is often the rate limiting step in achieving the fastest photorefractive response. Though only a small amount is required, typically from 0.1 to 1 wt%, the sensitizer's role is critical. When adding a photogeneration sensitizer, it is important that it absorbs at a longer wavelength than the nonlinear optical chromophore so that attenuation of the beam by the sensitizer is minimized. Obviously, this requires careful balancing of functions that compete for absorbance within the polymer. Sensitizers for photogeneration

are available throughout the visible and near infrared spectra that may permit tuning of the photorefractive effect for an otherwise identical polymer (4,58,65).

Charge-generation agents are typically variations on C60 (see, for example, References 116,122–125) or trinitrofluorenone (TNF) derivatives (see, for example, References 126–130), although squaraines, phthalocyanines (131), difluorobenzontrile (FTCN) (113), and others have also been used. TNF is a charge-transporting molecule/sensitizer, long wavelength photosensitizer. Addition of this charge-generating agent increases the absorption of the material at wavelengths larger than 550 nm as well as increasing the shallow trap concentration. The absorption coefficient increases approximately linearly as a function of concentration of charge-generation agent.

Also, in order to increase the sensitivity of polymer photorefractives, researchers have also investigated the effects of incorporation of nanoparticles (99,132,133). For example, CdSe quantum dots (99,102,133) have come into favor as sensitizers because of their nanoscale and ability to be made to suit specific applications with wavelength sensitivity.

Charge-Transport Agents. The charge-transport agents in a photorefractive polymer must provide a closely-spaced network or oxidizable molecules for charge hopping. For the backbone of the photorefractive composite material, poly(*N*-vinylcarbazole) (PVK) is the most common polymer used because of its excellent charge-transport properties and because the photocharge generation efficiency can be improved by adding acceptor molecules that form a charge transfer complex with the carbazole moiety (16,134). Other common transport agents include hydrozanes, such as diethylaminobenzaldehyde-diphenylhydrazone (DEH), polyphenylvinylene (PPV), and arylamines, such as tritolylamine (TTA) (1,71). Typically, the photoconductive polymer requires 40–60 wt% to provide sufficient density of transport sites (1).

The most common reasons for not using polyvinylcarbazole (PVK) are phase separation and higher glass transition temperature (T_g), and therefore the need for high amounts of plasticizer, as discussed above. As previously mentioned, the use of a fully-functionalized polymer helps to minimize phase separation while significantly reducing orientational enhancement effects and requiring higher temperature electric field poling. In a fully-functionalized polymer, a polymer main chain or side chains are linked to the chromophore, charge generator, and sensitizer, thereby providing all the necessary photorefractive components in one polymer (17,135–144). Another recent technique to overcome the limitations of PVK systems is to dope polyimides with dyes that form nanocrystalline J-aggregates. Such systems exhibit high third-order macroscopic polarizability (145,146). Sol-gel glasses with low T_g have also been used (147,148). For any of these materials, the highest occupied energy level of the transporting agent must be higher than that of the photogenerating agent (1).

Combinations with Liquid Crystals. Because polymeric photorefraction is greatly enhanced by the fast reorientation of the nonlinear optical component, many researchers have investigated the use of liquid crystals as ingredients in polymer-composite photorefractives (149–152). Readers looking for a more detailed understanding of liquid crystalline polymers should also see Liquid Crystalline Polymers, Side-Chain. A major advantage with these materials is that

the liquid crystal alignment can be accomplished with very low fields, on the order of $\sim$1 V/μm (153). One of the most common liquid crystals used as the nonlinear optical material is pentylcyanobiphenyl (5CB) (154). It has been used either doped with a photoionizable dye sensitizer, but without a photoconducting polymer or mixed into either polymer-disperse liquid crystal form (155) or a homogeneous photorefractive polymer/nematogen composite (120) to take advantage of photoconducting properties of the polymer.

The resolution of gratings in bulk nematic liquid crystals is too low for most applications leading researchers to develop polymer-dispersed liquid crystal (PDLC) photorefractives. In these materials, liquid crystal domains are dispersed throughout a solid polymer matrix (156). One of the largest two-beam coupling gains recorded, 3700 cm^{-1}, was obtained from a mixture of a commercial liquid crystal mixture in a PVK/TNF complex (157). For many liquid crystal polymer composites, the use of PVK is not as common; other polymers such as poly(methyl methacrylate) (PMMA) (89,158–161), poly(vinyl alcohol) (PVA) (162–164), photocross-linkable polymers (PCP) (165), and phenylenevinylene (PPV) (166) are more commonly used than PVK, often requiring additional photoconducting agents (122,149,163). The polymer PMMA is also used in a number of related holographic data storage applications (103,158,167) because of its ease of fabrication and thus low cost, as well as its low index of refraction and high melting point.

Test Methods

The two most common techniques for characterizing the photorefractive efficiency of a material are degenerate four-wave mixing (DFWM) and two-beam coupling (2BC), both of which use similar configurations, as shown in Figure 3. Ellipsometric techniques are used to measure the electric-field-induced birefringence. Standard time-of-flight and xerographic discharge methods are used to measure photoconductivity, as well as specialized techniques that take advantage of the holographic gratings in photorefractive materials.

Four Wave Mixing. In a DFWM experiment, a refractive index grating is recorded by two interfering writing beams (beams 1 and 2 in Fig. 3), which is then read by a weaker third beam (beam 3, which diffracts as beam 4). A maximum index change is obtained when the writing beams are *s*-polarized and the reading beam is *p*-polarized (158). This technique is particularly useful in evaluating the rise time or decay time of hologram formation (168). Different times may be seen, however, depending upon whether or how long the bias electric field is applied before the beams are incident on the sample or whether one of the two writing beams is applied well before the other. Theoretical evaluation of the rise time or the decay time is also complicated by the use of different analytical functions to fit the time dependence of the diffraction efficiency (1,4).

One figure of merit in DFWM is given by the energy required to achieve a specified diffraction efficiency in a given thickness of material. The diffraction efficiency is the ratio of the diffracted beam intensity $I_{\text{diffracted}}$ to the incident reading beam intensity I_{reading}. This criterion may be difficult to compare for different device structures such as waveguide versus bulk materials. The theoretical

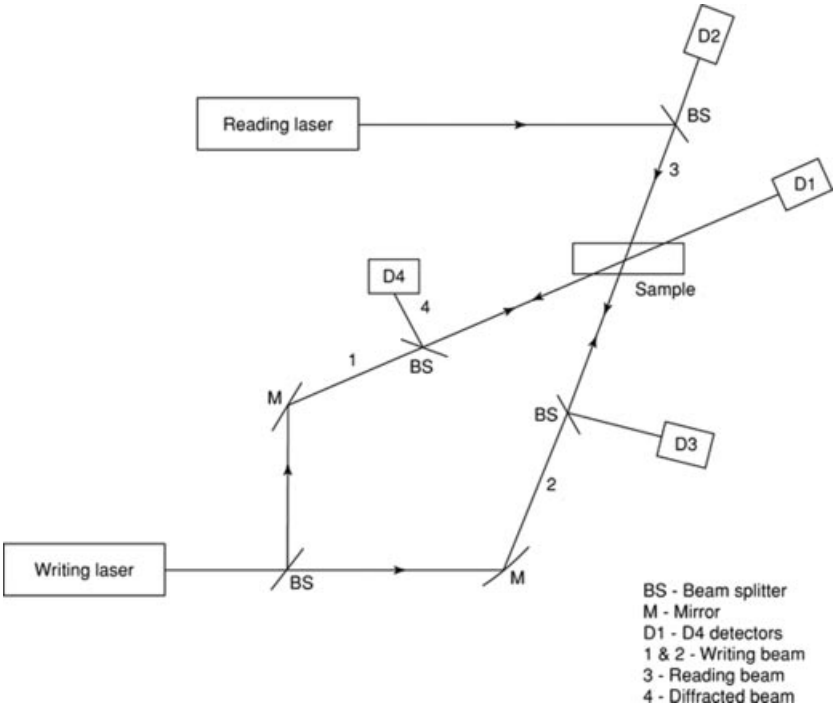

Fig. 3. Experimental schematic for four-wave mixing. The diffraction grating is written by beams 1 and 2 and read by beam 3, which need not be of the same wavelength as the writing beams. In the absence of a reading beam, the same geometry may be used to measure two-beam coupling between the writing beams.

diffraction efficiency can be expressed as (35)

$$\eta = \frac{I_{\text{diffracted}}}{I_{\text{reading}}} = \mathrm{e}^{-\alpha d/\cos\theta} \sin^2\left(\frac{\pi G d \Delta n}{\lambda}\right) \tag{6}$$

where α is the absorption coefficient, d is the interaction length of the beams and G is function of the geometry and polarization of the incident and reading beams on the material (for example, $G = 1/\sqrt{\cos\theta_1 \cos\theta_2}$ in a simplified quasi-one-dimensional model, where θ_1 and θ_2 are the internal angles of the intersecting beams (37,75). For thin films or materials where the absorption is small, it is usually sufficiently accurate to drop the exponential decay factor and even to approximate the sine function by its argument (35). Using the measured diffraction efficiency to determine Δn and combining with equation 1, one can determine the magnitude of the space-charge field E_{sc} in the material. Diffraction efficiencies of nearly 100% have been reported at applied electric fields as low as 58 V/μm in polymeric photorefractives (44,161,169) or even lower fields for polymer-dispersed liquid crystals (170).

In some cases it is important to also compare diffraction efficiency to the diffraction sensitivity of the sample. Sensitivity is a measure of the depth of the refractive index change as a function of the incident power. A material may be

sensitive for very low intensities yet not diffract sufficient power for device needs. The sensitivity may be important in that the change in the index of refraction may saturate at a specific laser power density (49).

Two-Beam Coupling. In a 2BC experiment, the additional reading beam is not used. Instead, the transmitted intensities of the two writing beams are monitored as a function of the applied external electric field. The writing beams will be deflected or diffracted with respect to the original beams, interfering constructively with one, destructively with the other. Sometimes a piezo transducer is used to measure the phase shift by causing a time-varying energy transfer between beams. These energy shift oscillations depend on the spatial phase shift ϕ of the incident diffraction pattern and the refractive-index grating (171–173).

One important figure of merit in the case of 2BC is the optical gain coefficient Γ, which can be determined by comparing the energies of the two beams when the other is momentarily blocked. If γ_i represents the ratio of the incident powers in front of the sample and γ_f the ratio behind the sample, then the gain is given by

$$\Gamma = \frac{1}{L}[\ln(\gamma_i\gamma_f) - \ln(\gamma_i + 1 - \gamma_f)] \approx \frac{4\pi n_1}{\lambda\cos\theta}\sin\phi \tag{7}$$

where L is the interaction length within the sample, θ is the half-angle between the beams, ϕ is the phase shift, and n_1 is the nonlinear refractive index (4,174). Gains in polymer photorefractives as large as $\sim$400 cm^{-1} have been reported, a factor of 10 larger than seen in inorganic crystals (175,176). The actual transferred power, given by $\exp(\Gamma d)$, is limited in polymers due to the small sample thickness d required to attain large applied fields. The 2BC experiment is also used to characterize the response time of the photorefractive polymer, with the fastest responses being around 5 ms at relatively high powers of 1 W/cm^2 (177).

Two beam coupling measurements can be complicated by the presence of beam fanning, by which additional coupling to randomly scattered light in the sample leads to loss of energy to the scattered light (178). Though not a measurement technique, it is a potentially important application of photorefractive polymers and is discussed further in Applications section.

Ellipsometry. Because of the importance of the orientational enhancement effect, the electric-field-induced birefringence is independently measured using a transmission ellipsometry technique. In this experiment, the photorefractive polymer is placed between two crossed polarizers with the normal to the sample tilted 45° from the x-axis of the propagating laser beam, as shown in Figure 4. Any change in the refractive index of the sample will result in a change of the polarization state of the laser beam, allowing light to emerge through the polarizers. The index change is then measured by observing the transmittance of the plane-polarized light after passing through both polarizers and the sample (179). Use of ellipsometry is further discussed in Reference 180. Transient ellipsometry techniques are discussed in Reference 46.

Photoconductivity. As outlined in Introduction section, the first three steps of the photorefractive process are related to photoconduction, which controls the rate of grating formation and the amplitude of the charge grating, as well as the rate of erasure under uniform illumination. Therefore, to understand and optimize the physical processes involved in photorefractive polymers, it is

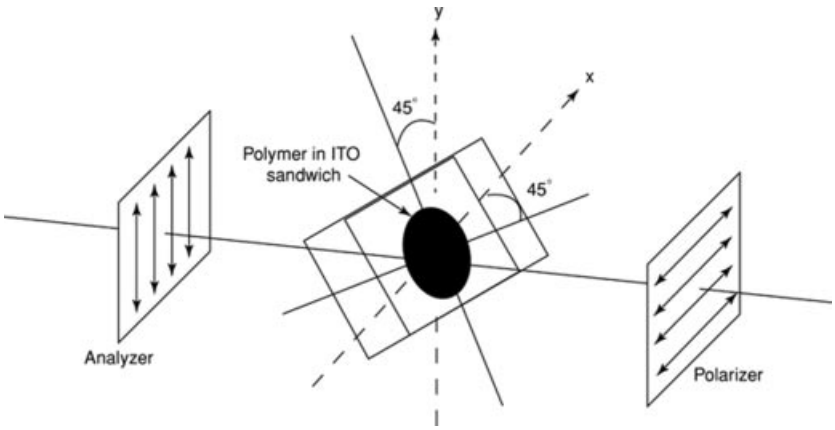

Fig. 4. Schematic for ellipsometry measurements.

important to measure their photoconductivity. The most common methods for characterizing the photoconductivity and the hole mobility and effective trapping of photorefractive polymers are conventional DC techniques, xerographic discharge, and time-of-flight mobility measurements (65,181,182).

In the conventional DC technique, a direct comparison is made between the current through the sample under the drift field both in the dark and under uniform illumination. The photoconductivity σ_{ph} is related to the charge mobility μ when the absorption is low by $\sigma_{\mathrm{ph}} = pe\mu = [\Phi\ \alpha\ I\ \tau_{\mathrm{eff}} / h\nu]\ e\mu$, where p is the density of mobile holes produced at intensity I, e the elementary charge, $h\nu$ the photon energy, Φ the quantum efficiency of charge generation, and α the absorption coefficient. Recall that the mobility, together with the effective carrier lifetime, determine the speed of response of the material (the effective carrier lifetime τ is then controlled by recombination and trapping processes).

The photoconduction sensitivity is usually determined by using a xerographic discharge technique that is applicable to thin films under low intensity illumination, because the measurement of small magnitudes might be confused by sample heating effects. In this experiment one charges the sample using a corona poling apparatus similar to that used for poling, then views the thin film sample as a discharging capacitor and measures the rate of decay of the surface potential with an electrometer and transparent probe under a high light source, using filters or the monochrometer to control the range of wavelengths illuminating the sample. This method can be used with even very low conductivity samples by monitoring the decay rate over long times (91).

One difficulty with bulk photoconductivity measurements is the analysis of the effects of different electrode materials. Comparisons are needed to determine the effects of Ohmic (free supply of charges) versus blocking electrodes (1). To determine the carrier mobilities and the effects of trapping, a relatively unusual approach used for photorefractive polymers is to supplement conventional time-of-flight mobility measurements, during which the flow of photoinduced charge across the bulk sample is monitored on an oscilloscope, with holographic time-of-flight (HTOF) measurements (183). In these measurements, an interference

pattern from two short laser pulses in a four-wave mixing geometry creates a sinusoidal distribution of charge carriers that can drift in the presence of an external field (66). As the charge separation advances, the space-charge field is probed with a cw laser through the electro-optic effect. The diffraction efficiency is a function then of the coincidence and anti-coincidence of the mobile carriers with the stationary charge. From the plot of the diffraction efficiency versus time one can determine the drift mobility and the degree of charge transport disorder due to the highly dispersive transport that appears in amorphous polymeric materials. Dispersive transport leads to a length-dependent mobility in these materials (66). A significant advantage of HTOF over conventional time-of-flight measurements is the ability to vary the drift length by varying the angle between the writing beams and between the beams and the applied field and to monitor the motion of charge internally, rather than across the bulk sample (184).

Applications

Data Storage. When a reference beam intersects with the scattered light from an object in a photorefractive material, a hologram is recorded, stored in the form of a refractive index pattern in the material. The image can then be reconstructed by diffracting a third beam on this hologram (in the same manner as DFWM as shown in Figure 3, except that the reading beam need not be of the same wavelength). The use of a photorefractive material in the recording of a hologram eliminates the need for chemical processing in the development of the hologram. Digital data storage is one of the earliest applications of photorefractive polymers (4,185,186).

The high optical damage threshold, low dielectric constants, high photosensitivity, and low cost of photorefractive polymers make them more efficient than inorganic materials (129). Optical data storage in PMMA-based photorefractive polymers has been demonstrated as a cheap and compact way improve data storage on compact discs and digital versatile discs (103). Polysiloxane-based photorefractive polymers have demonstrated the highest optical clarity and lowest optical scattering to date (105).

A significant drawback to the use of photorefractive polymers for data storage is the lack of easy fixing mechanisms and the resulting volatility of the recording. Dark lifetimes and the grating growth rate tend to be inversely proportional to each other (4). Using high T_g materials, the grating can be written above the glass transition temperature and frozen-in by cooling the sample during writing, but this scheme has not yet proved practical (187). Other photoinduced refractive index change mechanisms may be preferable for long-term holographic storage where optical gain is not required.

Another drawback of many photorefractive polymer composites is the need to use a thin film geometry that is not as amenable to high storage density as a bulk crystalline material. Multiple holograms have many applications including parallel holographic memory, template matching, and optical neural networks, interconnects, and correlators (188). Additionally, various types of multiplexing including angular and rotation (189,190) multiplexing allow for the storage of many holograms on the same material A nonmechanical angular multiplexed

holographic memory system has been demonstrated in liquid crystalline materials using a moving LCD window that is controlled electronically (191). Using these techniques, each hologram is recorded in the photorefractive polymer using a uniquely oriented setup; the individual holograms can be similarly read using a unique read setup. In this manner, several thousand data pages may be stored in the same element. Polymers are advantageous because large samples can be fabricated, allowing a larger recording volume to hold more holograms.

Materials combining photopolymers with liquid crystals are ideal for wavelength tunable storage devices. Such polymer-dispersed liquid crystal composites (PDLCCs) provide a medium for switchable holograms; when the refractive index of the polymer is matched to one of two principal refractive indices of the liquid crystal (LC) an applied electric field alters the orientation of the LC molecules, turning the recorded grating on or off (3,104). As previously mentioned, liquid crystals have the advantage of only requiring a few volts to induce an index grating because of their high nonlinearities (192).

To overcome volatility problems, two-photon absorption (TPA) is the most promising long-term data storage technique to date. TPA can be observed in all materials and lacks the noncentrosymmetric symmetry requirements of even-order nonlinear optical effects. Nevertheless, in centrosymmetric polymers two-photon absorption is allowed between states that have the same parity according to parity selection rules (112). Such a system has been demonstrated with nondestructive readout (113). Additionally, use of two-photon absorption on photorefractive polymer dispersed liquid crystals has been used to record a high 3D data density of 204.8 Gbits/cm^3 (158).

The formation of thick phase holograms has been demonstrated by fabricating photorefractive polymers by injection molding (193).

Adding fluorescent molecules to photopolymers also provides a method for optical data storage. In such a system, the fluorescent molecules bond to the polymer matrix and become more concentrated in the polymerized regions causing the required refractive index pattern (194).

Optical Correlation, Imaging through Scattering Media, and Novelty Filtering. Using a photorefractive polymer, optical correlation can be made all-optical, eliminating the need for a computer or any other such devices. Such a device was demonstrated in a 100-μm-thick photorefractive polymer using a low power laser. The document is optically encoded and authenticity is validated by correlating the encoded information with a master copy. Such a setup is used in such applications as the identification of individual pupils and fingerprints, searching of large databases and navigation. Spatial correlation is accomplished by creating a hologram by recording the interference pattern of the optical wavefront of the object with a reference beam in the material. Optical correlation is performed by overlapping the Fourier transform of the master copy with the hologram in the polymer. If the two optical codes match, a correlation peak can be observed and the document under test may be considered valid (4,195,196).

One common application of optical correlation in photorefractive polymers is in edge enhancement, a form of high pass image filtering which uses a Fourier transform holographic operation with a photorefractive composite. Two beams, the more intense one containing the image, interfere in a photorefractive material. The resulting interference pattern is stronger at the edges due to a closer matching of

intensities at the edges. Thus, the refractive index change is greatest at the edges and more of the readout beam is deflected or diffracted. A third beam recovers the reconstructed image with enhanced edges. The reconstructed image is an exact copy of the object only if the signal beam intensity is less than that of the reference beam. Violating this condition produces an image only at the edges of the object where the largest index modulation occurs (149,192).

Time-gated holographic imaging through scattered media has been demonstrated at wavelengths appropriate for medical imaging. In these demonstrations, the hologram is formed by the temporal overlap of direct light from the object that has been temporally stretched (without scattering) and a reference pulse (197).

In vibration analysis, or novelty filtering, the hologram acts as an adaptive beam splitter with exact wavefront matching: a plane-wave reference beam is diffracted into the signal beam that is reflected from the surface of the object. The applied field is reversed so that the exponential gain coefficient becomes negative, thus transferring energy from the signal beam to the reference beam, reducing the signal intensity. Only objects moving faster than approximately the inverse of the response time of the photorefractive material are observed. The fast moving parts are constantly changing in time and do not interact long enough with the reference beam to lead to the recording of a hologram. An image amplification configuration may be used build a device to observe an object under low light levels (116,198). This technique can also be used to visualize the mode patterns of a vibrating object; the mode patterns can reveal defects and areas under particular stress. Such devices have typically been made with PVK (199). Applications include remote sensing and inspection, especially in hazardous environments.

Beam Fanning. Beam fanning is the spontaneous amplification of scattered light in a photorefractive material arising from an energy exchange between the incident beam and light randomly scattered from impurities or defects (178). It results from a redistribution of charges in the nonlinear material and can complicate two-beam coupling measurements or provide promise for novel applications, such as self-pumped phase conjugation (200) and some forms of optical limiting (201,202). The effect of beam fanning is the depletion of the pump beam and the appearance of a fanned beam that is swept to one side of the material.

Waveguides. Utility in waveguides generally imposes additional restrictions on the polymer composition. The geometry required to couple an external static drift field to the optical field in the waveguide dictates the use of channel waveguides to reach maximum efficiency so that the poling direction has a component along the space-charge field. The bias field is then applied across the width of the channel. Narrow channels are preferred although coupling into the channels becomes more difficult in this case. Problems with the use of waveguides in the study of photorefractive effects also include the presence of thermo-optic changes in the guide and/or coupling mechanism, whereby small temperature changes may significantly change the coupling angles. Thus, temperature control may be imperative in practical applications. All polymer dopants, of course, should be soluble in an appropriate spin-coating solvent for making thin films ($\approx 1\ \mu$m) and of sufficiently high molecular weight so as not to evaporate with the solvent. Waveguides may be utilized in optical data storage applications (203–206).

To summarize, the benefits from the development of photorefractive polymers are many but there are still significant problems to overcome before these benefits

can be realized (1). Foremost among the problems may be balancing the competing needs for both steady-state performance and fast response speed, as well as the often competing factors of stability, high mobility and fast orientational response to attain fast, highly sensitive, and efficient response. It will be necessary to better understand the trade-off between dark and photoconductivity and the effects of preillumination history (207). Better understanding is also needed of the nature and depth of charge trapping sites in polymers to optimize the dark lifetimes of the gratings.

POLYMER BLENDS

Polymer Blends

Mixing of two or more different polymers together makes it possible to achieve various property combinations of the final material—usually in a more cost-effective way than in the case of synthesis of new polymers. Therefore, great attention has been paid to the investigation of these systems, as well as to the development of specific materials. Recently, the problem of polymer blends has also become important for recycling industrial and/or municipal plastics scrap. A considerable amount of information has been collected during more than three decades, summarized in dozens of monographs (see General References).

Basic problems associated with the equilibrium and interfacial behavior of polymers, compatibilization of immiscible components, phase structure development, and the methods of its investigation are described herein. Special attention is paid to mechanical properties of heterogeneous blends and their prediction. Commercially important types of polymer blends as well as the recycling of commingled plastic waste are briefly discussed.

Equilibrium Phase Behavior

Mixing of two amorphous polymers can produce either a homogeneous mixture at the molecular level or a heterogeneous phase-separated blend. Demixing of polymer chains produces two totally separated phases, and hence leads to macrophase separation in polymer blends. Some specific types of organized structures may be formed in block copolymers due to microphase separation of block chains within one block copolymer molecule.

Two terms for blends are commonly used in literature—miscible blend and compatible blend. The terminology recommended by Utracki (1) will be used in this article. By the *miscible polymer blend*, we mean a blend of two or more amorphous polymers homogeneous down to the molecular level and fulfilling the thermodynamic conditions for a miscible multicomponent system. An *immiscible polymer blend* is the blend that does not comply with the thermodynamic conditions of phase stability. The term *compatible polymer blend* indicates a commercially attractive polymer mixture that is visibly homogeneous, frequently with improved physical properties compared with the constituent polymers.

2 POLYMER BLENDS

Equilibrium phase behavior of polymer blends complies with the general thermodynamic rules (2–6)

$$\Delta G_{\text{mix}} = \Delta H_{\text{mix}} - T\Delta S_{\text{mix}} < 0 \tag{1}$$

and

$$\mu_i^{'} = \mu_i^{''}\ i = 1,2,\ldots,n \tag{2}$$

where ΔG_{mix}, ΔH_{mix}, and ΔS_{mix} are the Gibbs energy, enthalpy, and entropy of mixing of a system consisting of i components, respectively, $\mu_i{}'$ and $\mu_i{}''$ are the chemical potentials of the component i in the phase μ' and μ''. The condition given in equation 1 is necessary but it is not sufficient. Equation 2 must be also fulfilled.

Generally for a compressible polymer blend the following requirement must be satisfied (5–7):

$$\left(\frac{\partial^2 \Delta G_{\text{mix}}}{\partial v_i^2}\right)_{T,P} = \left(\frac{\partial^2 \Delta G_{\text{mix}}}{\partial v_i^2}\right)_V + \left(\frac{\partial V}{\partial P}\right)_{T,v_i}\left(\frac{\partial^2 \Delta G_{\text{mix}}}{\partial v_i \partial V}\right) > 0 \tag{3}$$

where v_i is the volume fraction of component i, V molar volume of blend, P and T are pressure and temperature of the system. If we consider an incompressible system with $\Delta V_{\text{mix}} = 0$, the application of equation 3 to the simple Flory–Huggins relationship for ΔG_{mix} (4) leads to the condition of these stability

$$\frac{1}{N_1 v_1} + \frac{1}{N_2 v_2} - 2\chi_{12} \geq 0 \tag{4}$$

where N_1, N_2 are the numbers of segments of polymer 1 or 2, and χ_{12} is the interaction parameter between polymers 1 and 2. The entropy contribution (the first and second terms on the left-hand side of equation 4 supporting miscibility of polymers is practically zero ($N_1, N_2 \gg 1$). In this case, the miscibility is controlled by the enthalpy of mixing (interaction parameter χ_{12}). For nonpolar polymers without strong interactions, the temperature dependence of χ_{12} (Fig. 1, curve 1) is given as

$$\chi_{12} = A + \frac{B}{T} \tag{5}$$

where A and B are positive constants characterizing enthalpy and entropy parts of interaction parameter χ_{12}, respectively. Its positive value indicates a very poor miscibility of high molecular weight nonpolar polymers.

Relationships describing the compressibility of polymer blends are based on the equations-of-state theories (5,6,8–16). These relationships include contributions to the entropy and enthalpy of mixing resulting from volume changes during mixing. The temperature dependence of free-volume interaction is schematically presented as curve 2 in Fig. 1. This value plays a decisive role in determining phase behavior of a polymer blend at high temperature range.

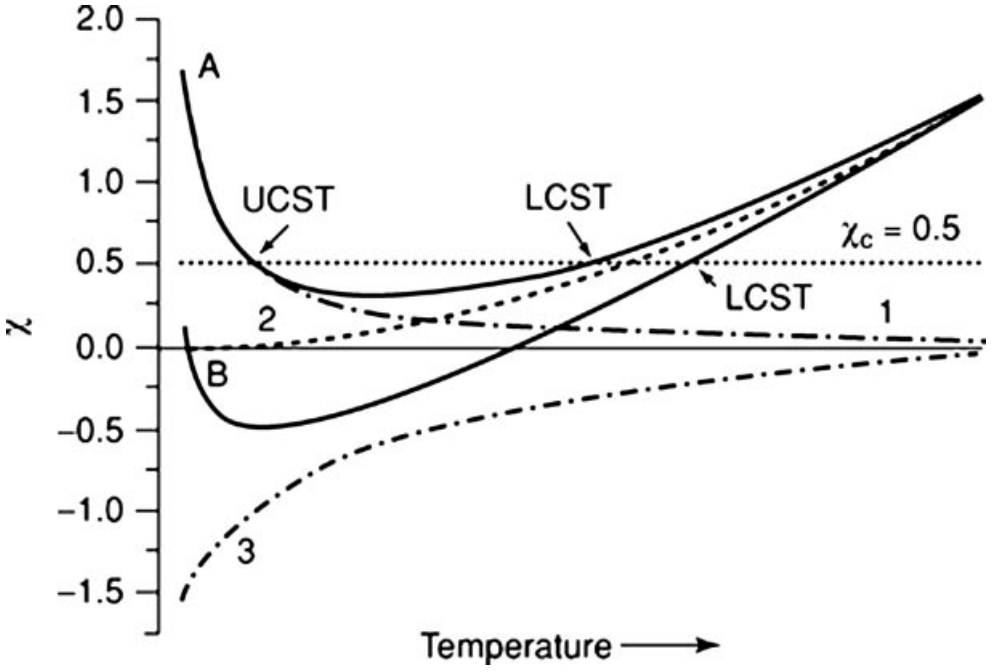

Fig. 1. Schematic temperature dependence of interaction parameters resulting from different types of interactions in a polymer blend. (1-dispersive interactions, 2-free-volume interactions, 3-specific interactions, A-sum of 1+2, B-sum of 1+2+3).

From the equation 4 it follows that the negative value of parameter χ_{12} is necessary to obtain a stable homogeneous polymer blend. The negative value of χ_{12} is characteristic of systems with specific interactions such as dipole–dipole or hydrogen bond interactions (1,5,6,17). A schematic representation of the temperature dependence of a specific interaction parameter, according (13), is given in Figure 1, curve 3.

The critical value of interaction parameter χ_c for "symmetric" polymer blends of polymers 1 and 2 ($N_1 = N_2 = N$, N-number of segments in polymer chain) is $\chi_c = 2/N$. When χ_{12} value crosses the critical value, a polymer blend separates into two macrophases. The character of the temperature dependence of χ_{12} determines the shape of the phase diagram (Fig. 1). Figure 2 shows schematic binodal and spinodal curves corresponding to the different types of interaction parameters presented in Figure 1. Binodal curves (Fig. 2, curves 1–4), defining the two-phase region, are calculated from equation 2 (2,4–6,18). A spinodal curve is obtained by solving of equation 4. The spinodal curve defines the region of absolute instability of the polymer blend. The point common to the binodal and spinodal curves is the critical point. The position of the critical point of a blend of monodisperse polymers coincides with the maximum (UCST-upper critical solution temperature) or minimum (LCST-lower critical solution temperature) of a binodal curve (18) (Fig. 2). If only dispersive interactions among polymer molecules are effective in a blend (Fig. 1, curve 1), partial miscibility can be expected at low temperatures. Above the UCST, the polymer blend is homogeneous (Fig. 2 curve 1) (4–6). Values

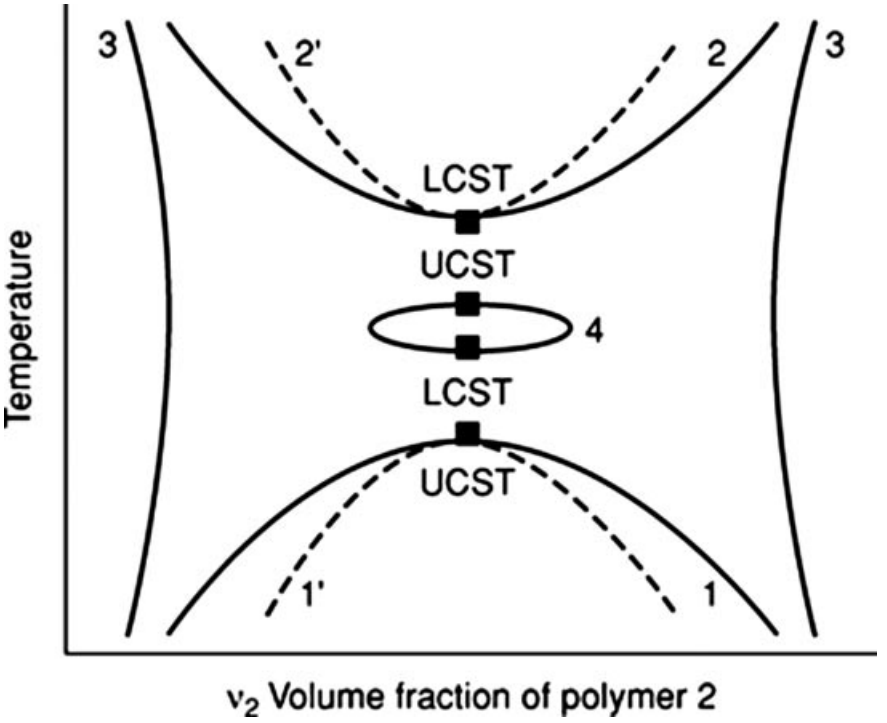

Fig. 2. Possible types of phase diagrams corresponding to interactions in Figure 1 (—— ——binodal curves, ———- spinodal curves, UCST—upper critical solution temperature, LCST—lower critical solution temperature).

of interaction parameters of nonpolar polymers can be found in literature (1,5,6) or estimated from the solubility parameters, δ_1 and δ_2, of the neat components

$$\chi \approx (\delta_1 - \delta_2)^2 \tag{6}$$

The χ parameter of disperse interactions is always positive, and miscibility is driven only by combinatorial entropy of mixing. In general, nonpolar polymers are rarely miscible with each other. Considerable data relevant to interaction energies obtained by different techniques can be found in the literature (5,6,19,20).

The area below the spinodal curve is the region of absolute instability of a polymer blend. The phase separation in this region is controlled by a spinodal mechanism. The region between spinodal and binodal curves is called the metastable region. Phase separation in this region is controlled by a nucleation mechanism.

Phase structure at an initial stage of phase decomposition depends on the type of decomposition mechanisms. The characteristic trait of the spinodal decomposition in an absolutely unstable region is phase separation in the whole volume of a blend. Initially, the resulting structure is very fine, but gradually gets coarse (5,21), and the final stage of separation is full macrophase separation. If the phase separation takes place in the metastable region, the decomposition of a blend

depends on the formation of a nucleus of a new phase. The resulting structure at the initial stage is grainy. The critical sizes of existing nuclei increase by Ostwald ripening mechanism (16)—small grains dissolve and large grains grow due to the dependence of the concentration gradient of dissolved molecules of the nucleating component, which are in turn dependent on grain radius. At the final stage, when the separation is finished, the full phase-separated structure is again obtained (5).

In unstable region, appearing fluctuations increase. The fluctuations can be considered as a set of sinusoidal waves with a constant length (6,16). The amplitude of the fluctuations appearing in the initial stage of the phase separation increases with time, as described by Kwei and Wang in Reference 6. The phase structure of the system is co-continuous for a broad range of blend compositions. At the end of the process, separated phases are identical to the blend components. Theories describing various stages of spinodal decomposition (using various approximations) have been developed (16). Scattering methods have been used for many experimental studies of phase structure decomposition in polymer blends. The initial, intermediate, and late stages of phase structure separation, differing in the time dependence of the domain size of individual phases were identified. The individual stages of the phase structure development are described by different time dependences of the phase domain size. The development of spatial concentration fluctuation is generally described by Ginsburg–Landau equation, considering chemical potential as a function of the order parameter, contribution of the random forces, and the hydrodynamic interaction between polymer molecules (16). Similar equations also describe polymer dissolution if, due to a change in thermodynamics parameters, an immiscible blend passes to a miscible one. The phase separation is affected by the presence of a copolymer and by a shear flow (16). A more detailed description of the kinetics of phase decomposition in polymer blends can be found in Reference 16.

If we have a system with free-volume or specific interactions, an increase in temperature causes phase separation at LCST. In real systems, where several types of interactions are effective, phase behavior with two regions of partial miscibility of components with UCST and LCST (Fig. 2, binodals 1 and 2) or hourglass-shaped binodal and spinodal curves (Fig. 2, binodal 3) can be expected (5,6,9,13–16). In some cases, a closed loop of immiscibility with LCST and UCST (Fig. 2, binodal 4) or a closed loop and region of partial immiscibility at high temperatures with LCST (Fig. 2, binodals 2 and 4) are observed. This pattern of phase behavior is caused by a diminishing intensity of specific interactions with increasing temperature.

Whether polymers are miscible or not depends on a delicate balance of interactions among all components in a system (6). Any favorable gain in the energy of mixing is accompanied by an unfavorable noncombinatorial entropy effect (22,23).

The effective value of the interaction parameter χ_{eff} of a multicomponent polymer blend is controlled by its composition. Blends containing statistical copolymers of A and B monomers can be used as examples. Using the mean field-theory leads to the following relation for χ_{eff}

$$\chi_{\text{eff}} = \sum_i \sum_{j>i} \chi_{ij} \left(v_i^{\text{A}} - v_j^{\text{B}}\right)\left(v_i^{\text{B}} - v_j^{\text{A}}\right) \tag{7}$$

where χ_{ij} is the interaction parameter between segments i and j. For the identical type of segments, its value is zero. It follows from equation 7 that at a proper composition of copolymers, the value of χ_{ij} can be negative, and the resulting blend is homogeneous.

The former discussion deals with liquid–liquid phase behavior; however, one or both components of the blend can sometimes crystallize. For a polymer pair that is miscible in the melt, cooling well below the melting point of pure crystallizable component leads to a pure crystalline phase of that component. Far below the melting point, the free energy of crystallization is considerably larger than that of mixing. Because polymers never become 100% crystalline, the pure crystals coexist with a mixed amorphous phase consisting of the material that did not crystallize (6,7).

The morphology of heterogeneous polymer blends is controlled by interfacial tension. The interfacial tension, σ, is intrinsically positive and can be defined as the change in the Gibbs free energy when the interfacial area A is reversibly increased at constant temperature and pressure at closed system (24).

$$\sigma = \left(\frac{\partial G}{\partial A}\right)_{T,P} \tag{8}$$

In a multicomponent system, the tendency to minimize the system Gibbs free energy leads to migration of the minor component on the interface. The resulting increase in concentration of this component at the interface (compared to its concentration in the bulk) (24) decreases the interfacial tension, as follows from equation 9

$$\frac{\partial \sigma}{\partial \ln c_2} = -RT\left(\frac{\Delta N_2}{VN_1}\right) \tag{9}$$

where c_2 is the molar concentration of the component 2, ΔN_2 is the excess number of molecules of the component 2 on the interface, N_1 is the number of molecules of the component 1, and V is volume of the system. Therefore low energy additives can greatly reduce the interfacial tension between polymers, and hence are expected to increase the degree of dispersion in blends. Block and graft copolymers are the most effective interfacial agents. They show considerable surface activity of the low energy components, and their emulsifying property depends on their structure.

Compatibilization

As it follows from thermodynamics, the blends of immiscible polymers obtained by simple mixing show a strong separation tendency, leading to a coarse structure and low interfacial adhesion. The final material then shows poor mechanical properties. On the other hand, the immiscibility or limited miscibility of polymers enables formation of a wide range structures, some of which, if stabilized, can impart excellent end-use properties to the final material. To obtain such a stabilized structure, it is necessary to ensure a proper phase dispersion by decreasing interfacial tension to suppress phase separation and improve adhesion. This can

be achieved by modification of the interface by the formation of bonds (physical or chemical) between the polymers. This procedure is known as compatibilization, and the active component creating the bonding as the compatibilizer (1,6,7). Two general methods are used for compatibilization of immiscible polymers: (i) incorporation of suitable block or graft copolymers, or (ii) reactive compatibilization.

Incorporation of Copolymers (Nonreactive Compatibilization). Block or graft copolymers with segments that are miscible with their respective polymer components show a tendency to be localized at the interface between immiscible blend phases. The copolymers anchor their segments in the relevant polymer, reducing interfacial tension and stabilizing dispersion against coalescence (24–52). Random copolymers, sometimes also used as compatibilizers, reduce interfacial tension, but their ability to stabilize the phase structure is limited (53). Finer morphology and higher adhesion of the blend lead to improved mechanical properties. The morphology of the resulting two-phase (multiphase) material, and consequently its properties, depend on a number of factors, such as copolymer architecture (type, number, and molecular parameters of segments), blend composition, blending conditions, and the like (25,38,39). Creton and co-workers (54) have reviewed the molecular criteria for copolymers linking two immiscible homopolymers that must be fulfilled to achieve a good stress-transfer ability of the interface. In Figure 3, the conformation of different block, graft, or random copolymers at the interface is schematically drawn.

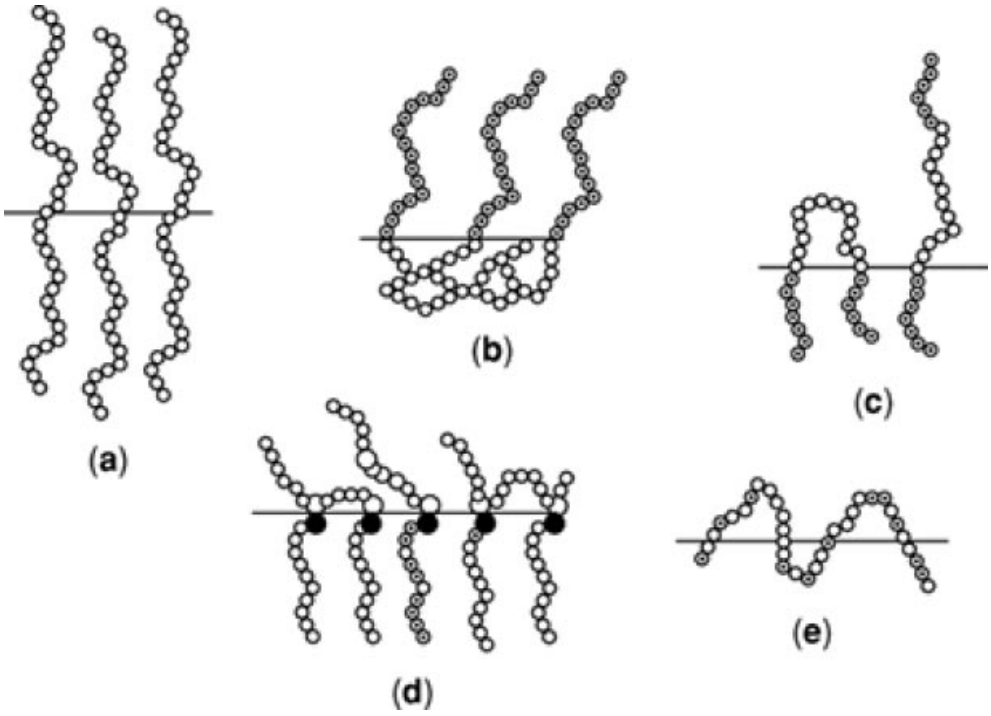

Fig. 3. Possible localization of A-B copolymer at the A/B interface. Schematic of connecting chains at an interface, a-diblock copolymers, b-end-grafted chains, c-triblock copolymers,d-multiply grafted chain, and e-random copolymer.

Besides copolymers synthesized specially for compatibilization of immiscible polymers, commercial products (typically used as impact modifiers) are utilized as compatibilizers in research as well as in practice. Typical examples are styrene-butadiene block copolymers and their styrene-hydrogenated butadiene analogues used for compatibilization of styrene polymers (PS, HIPS, SAN, ABS), with polyolefins (49), or ethylene–propylene copolymers for compatibilization of various polyolefins (50).

Mechanical properties that are sensitive to stress transfer (impact strength, tensile strength, elongation) are usually considered as criteria of compatibilization efficiency because they indirectly characterize interface adhesion (1,7,45). Morphological characteristics, such as particle size of the dispersed phase, structure homogeneity, character of interfacial layer, existence of micelles, or mesophases, also give evidence on the compatibilization efficiency (25,29,40–44).

This process, however, inherently bears two practical limitations. Blending of an immiscible polymer pair requires a specific block or graft copolymer. Consequently, a specific synthetic procedure is necessary to obtain the desired copolymer. This can be costly, and sometimes there is no feasible technology at manufacturer's disposal. Moreover, the amount of the copolymer to be added is often significantly higher than that for saturation of the interface. A part of the copolymer may be trapped in the bulk phase during blending and never reach the interface. This fact can negatively affect the blend morphology and may lead to a higher compatibilizer consumption.

During more than three decades, much information on nonreactive compatibilization has been obtained and successfully applied in the development of new multiphase materials. Moreover, the prove efficiency of block or graft copolymers in the controlling of the phase structure development has led to new, more effective approaches to producing these copolymers directly during the blending. This process is known as reactive compatibilization.

Reactive Compatibilization. Reactive compatibilization is the process that allows generating graft or block copolymers acting as compatibilizers *in situ* during melt blending (46,55). These copolymers are formed by reactions at the interfaces between suitably functionalized polymers, and they link the immiscible phases by covalent or ionic bonds. In this process, the copolymers are formed directly at the interfaces, where they act like preformed copolymers, ie, they reduce the size of the dispersed phase and improve adhesion. For this reason, the problem with transport of the compatibilizer to interface is not relevant and structure control is easier than in the case of adding preformed copolymers. In order to achieve efficient compatibilization of polymer blends, the reactions between the functional groups should be selective and fast, and the mixing conditions should minimize the limitation of mass transfer in the course of the reaction.

There are several types of reactive compatibilization. If the mixed polymers contain reactive groups, the reaction is straightforward. The polymers without reactive groups have to be functionalized or a miscible polymer containing proper reactive groups is added to the respective component. Therefore, reactive groups such as anhydride, hydroxy, amine, or carboxy are incorporated, into one or both of the polymers to be compatibilized. Maleic anhydride-grafted polymers, such as PP, PE, EPR, EPDM, SEBS, or ABS (46,55), which can react with polymers

containing amino group can serve as examples:

Reactive compatibilization of polymers through copolymer formation is also possible with the help of low molecular weight compounds (56), eg by combination of a peroxide with an oligomer coagent for preparation of PE/PP blends (57) or bis-maleic imide for PE/PBT (58). Special cases of reactive compatibilization can be considered radical-initiated reactions of monomers forming homopolymers and grafts on the chains of dissolved polymers. This process is used for manufacture of such important polymers as HIPS or ABS (59).

Preparation and Phase Structure Development

Methods of Blend Preparation. Most polymer pairs are immiscible, and therefore, their blends are not formed spontaneously. Moreover, the phase structure of polymer blends is not equilibrium and depends on the process of their preparation. Five different methods are used for the preparation of polymer blends (60,61): melt mixing, solution blending, latex mixing, partial block or graft copolymerization, and preparation of interpenetrating polymer networks. It should be mentioned that due to high viscosity of polymer melts, one of these methods is required for size reduction of the components (to the order of μm), even for miscible blends.

Melt mixing is the most widespread method of polymer blend preparation in practice. The blend components are mixed in the molten state in extruders or batch mixers. Advantages of the method are well-defined components and universality of mixing devices—the same extruders or batch mixers can be used for a wide range of polymer blends. Disadvantages of the method are high energy consumption and possible unfavorable chemical changes of blend components. Evolution of the phase structure in polymer blends during melt mixing and rules for prediction of the structure of the formed phases are discussed in the next section.

During several past years, novel solid state processing methods, such as shear pulverization or cryogenic mechanical alloying, have been developed to provide efficient mixing of polymer blends (62). The polymers are disintegrated in pulverizers at cryogenic temperatures, and nanoscale blend morphologies are achieved. Since the blends are prepared as solid powders, they must be consequently processed in the melt for concrete manufacture. Mechanochemistry of this process makes it possible to obtain block or graft copolymers acting as compatibilizers. In spite of these advantageous results, this procedure has not been used so far in industrial practice because of large energy consumption.

Solution blending is frequently used for preparation of polymer blends on a laboratory scale. The blend components are dissolved in a common solvent and intensively stirred. The blend is separated by precipitation or evaporation of the

solvent. The phase structure formed in the process is a function of blend composition, interaction parameters of the blend components, type of the solvent, and history of its separation. Advantages of the process are rapid mixing of the system without large energy consumption and the potential to avoid unfavorable chemical reactions. On the other hand, the method is limited by the necessity to find a common solvent for the blend components, and in particular, to remove huge amounts of organic (frequently toxic) solvent. Therefore, in industry, the method is used only for preparation of thin membranes, surface layers, and paints.

A blend with heterogeneities on the order of 10 μm can be prepared by mixing of latexes without using organic solvents or large energy consumption. Significant energy is needed only for removing water and eventually achievement of finer dispersion by melt mixing. The whole energetic balance of the process is usually better than that for melt mixing. The necessity to have all components in latex form limits the use of the process. Because this is not the case for most synthetic polymers, the application of the process in industrial practice is limited.

In partial block or graft copolymerization, homopolymers are the primary product. But, an amount of a copolymer sufficient for achieving good adhesion between immiscible phases is formed (59). In most cases, materials with better properties are prepared by this procedure than those formed by pure melt mixing of the corresponding homopolymers. The disadvantage of this process is the complicated and expensive startup of the production in comparison with other methods, eg, melt mixing.

Another procedure for synthesis of polymer blends is by formation of interpenetrating polymer networks. A network of one polymer is swollen with the other monomer or prepolymer; after that, the monomer or prepolymer is crosslinked (63). In contrast to the preceding methods used for thermoplastics and uncrosslinked elastomers, blends of reactoplastics are prepared by this method.

Phase Structure Development in Molten State.

Starting Period of Melt Mixing. Most polymer blends are prepared by melt mixing and processed in the molten state. Therefore, the phase structure of a blend is formed during melt flow and is petrified by solidification. Formation of the phase structure at the initial stage of the mixing was intensively studied by Macosko's group (64–68). It was found that sheets of minor phase are formed after the start of mixing. Quite rapidly, holes are formed in these sheets that coalesce. Further, the sheets transform to fibers or co-continuous structures, which can pass (depending on blend composition and properties of the components) to a dispersed structure (see Figs. 4**a**–4**e**). If the softening or melting transition temperature of the minor phase is lower than that of the major phase, switching of phase continuity occurs at this stage of mixing (67). It was found that the reduction of characteristic size of phase domains from millimeters (characteristic size of polymer pellets) to micrometers is rapid. This reduction has been achieved during the first 2 min in batch mixers and in the first mixing zones in extruders.

Type of Phase Structure. For application of polymer blends, type and fineness of their phase structure are important. In blends of immiscible polymers 1 and 2 with low content of 2, particles of component 2 are dispersed in the matrix of component 1. With rising fraction of 2, partially continuous structure of 2 appears. With further increase in the amount of 2, fully co-continuous structure is formed (see Fig. 5). After that, phase inversion occurs, where 2 forms the matrix and 1

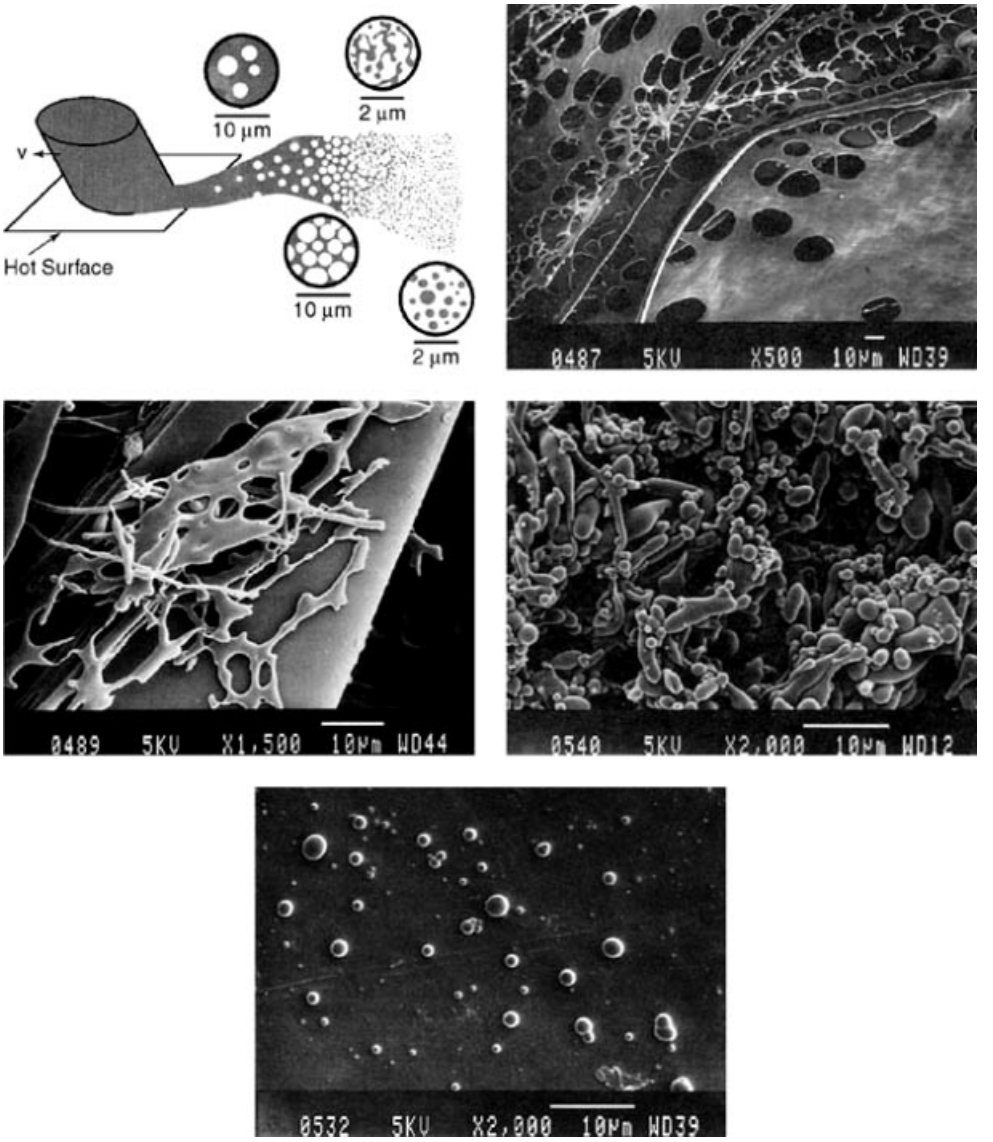

Fig. 4. (**a**) Scheme of initial morphology development. (**b**) Holes and lace structure observed in ribbons at 1.0 min mixing. (**c**) Broken lace structure and small spherical particles at 1.0 min mixing. (**d**) Morphology of the dispersed phase particles at 1.5 min mixing. the dispersed phase (69,70). Dependencies of continuity indexes or percentages of continuity (the continuous fraction of a component, determined as a fraction of the component that can be dissolved with a selective solvent) on volume fraction of component 2 are schematically shown on Figure 15. In contrast to low molecular weight emulsions, where phase inversion occurs in one point or in a very narrow

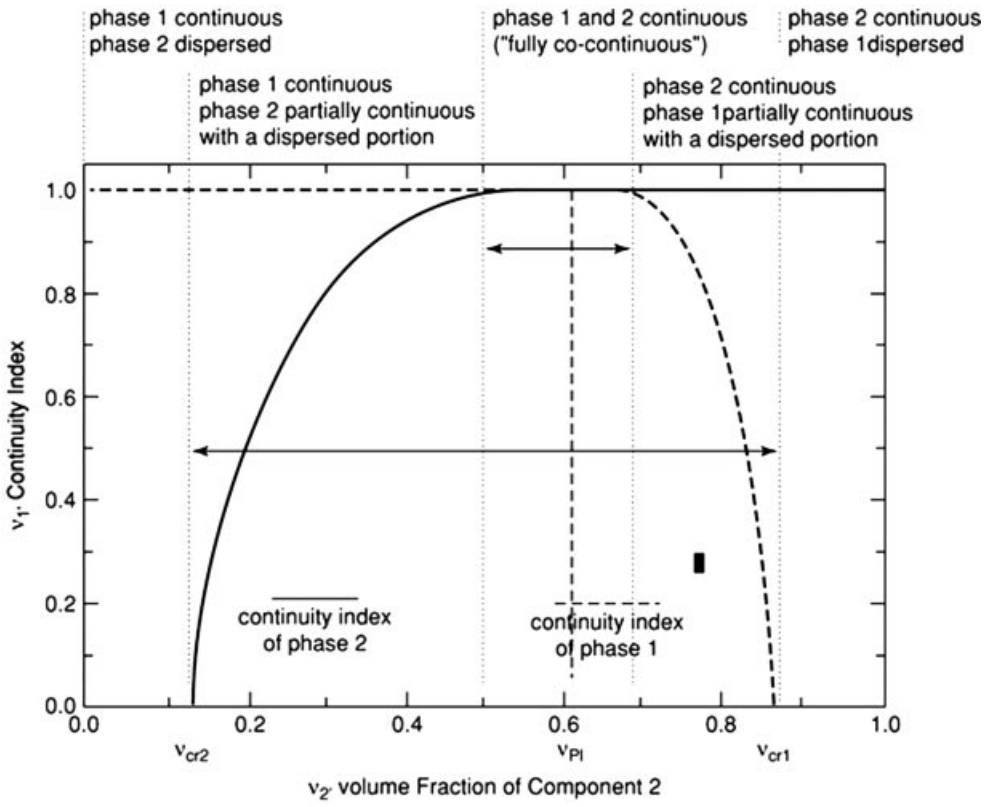

Fig. 5. Composition range of co-continuous structure. Full line continuity index of phase 2, broken line continuity index of phase 1. v_{cr1}, v_{cr2}, v_{f1} a v_{f2} are volume fractions of phase 1 or 2 at which partial or full co-continuity of the related phase start. v_{PI} designate phase inversion composition. Reproduced with permission from Reference 69.

interval of composition, co-continuous range for polymer blends is frequently quite wide. Phase inversion points calculated as the center of the interval with full co-continuity of both the components and of the interval between critical volume fractions, v_{cr1} and v_{cr2} for starting continuity of components 1 and 2, need not be the same. The interval of volume fractions of the components in which the blend structure is co-continuous depends on rheological properties of the components, interfacial tension, and mixing conditions. There have been several attempts to formulate a rule for prediction of the phase inversion point from the knowledge of viscosity of the components (69,71–74). They qualitatively describe the experimentally verified tendency of a less viscous component to be continuous down to low volume fractions. However, all fail in quantitative evaluation of a substantial portion of experimental data (69). The proposed rules for prediction of the phase inversion from the knowledge of elastic properties of the components (75–77) contain unknown parameters or have limited validity.

Utracki and Lyngaae-Jørgensen (78) proposed a theory based on the assumption that the critical volume fractions relate to the percolation thresholds of droplets, and phase inversion appears at the composition at which the blend

with dispersed component 1 and matrix 2 has the same viscosity as the blend with dispersed component 2 and matrix 1. The theory qualitatively describes dependencies of the continuity indexes on the blend composition found experimentally. However, for some blends, v_{cr} does not relate to the percolation threshold for spheres, and the predicted point of phase inversion does not agree with the experimental one for a number of systems.

A model for formation of fully co-continuous morphology based on material properties and processing conditions was proposed (79). It is based on the assumption that full co-continuity is achieved when randomly oriented cylindrical particles, formed by deformation of droplets of a minor component, are closely packed. For the volume fraction of a minor component, v_{dl}, at which co-continuous structure is formed, the following equation was derived

$$\frac{1}{v_{dl}} = 1.38 + 0.0213\left(\eta_m \dot{\gamma} \frac{R_0}{\sigma}\right)^{4.2} \tag{10}$$

where η_m is viscosity of the matrix, $\dot{\gamma}$ is the shear rate, σ is the interfacial tension, and R_0 is the radius of equivalent sphere related to a droplet of the minor phase. The model qualitatively describes the fact found experimentally that the width of the co-continuity interval increases with decreasing interfacial tension. Unfortunately, the model cannot be used in a predictive manner because R_0 has to be determined afterwards.

Recent studies (80,81) showed that at long mixing in batch mixers, transition from co-continuous to dispersed morphology appears. The mixing time, at which the transition was determined, is about one order of magnitude longer than the time necessary for reduction of the characteristic size of phase domains from millimeters to micrometers. At present, it is not clear whether co-continuous structure is only transient, or in some cases, steady (relating to certain steady mixing conditions) morphology. Elucidation of this problem is complicated by the fact that transitions between co-continuous and dispersed structures frequently occur after a long time of mixing, where it is very difficult to avoid strong degradation of the blend components.

In addition to co-continuous morphology, droplet-within-droplet (composite droplets, subinclusion, salami-like) morphologies are sometimes formed in blends with a higher content of minor component (see Fig. 6) (70,82). In some systems, ribbon like or stratified morphology was detected instead of classic co-continuous one (75). Rules for formation of individual types of morphology have not been formulated so far.

Prediction of the type of morphology in polymer blends containing three and more components is a more difficult task than for binary blends. Generally, properties of the components, interfacial tensions between them, and mixing conditions should be considered. A quite successful predictive scheme was proposed for blends with matrix component 2 and two minor dispersed components 1 and 3. It was proposed (70,83) that component 3 encapsulates the component 1 if the spreading coefficient λ_{31} is positive. λ_{31} is defined as

$$\lambda_{31} = \sigma_{12} - \sigma_{32} - \sigma_{13} \tag{11}$$

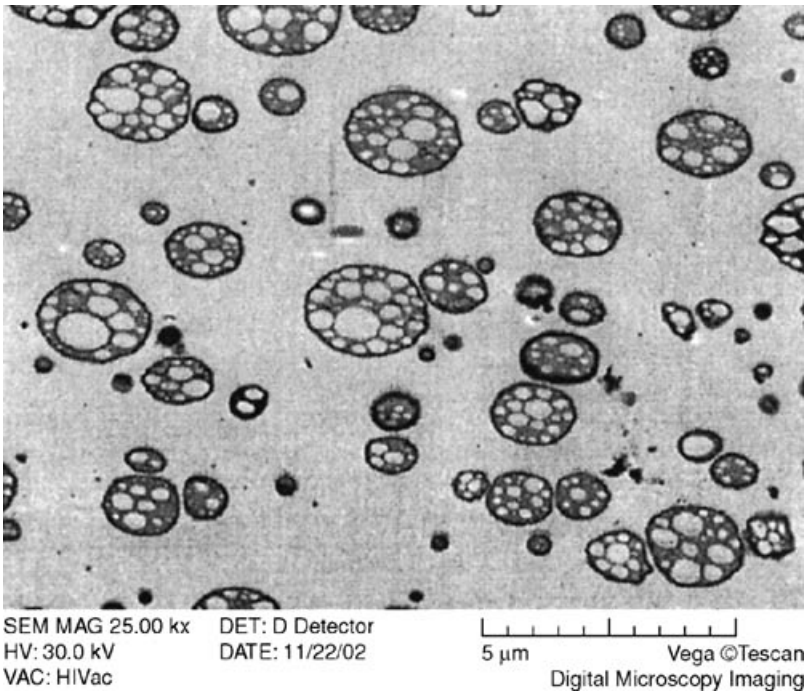

Fig. 6. Micrograph of droplet-within-droplet (composite droplets, subinclusion, salami-like) morphology.

where σ_{12}, σ_{32}, and σ_{13} are the interfacial tensions for each component pair. If spreading coefficient λ_{13} is positive, the component 1 encapsulates component 3. For both λ_{31} and λ_{13} negative, separated droplets of 1 and 3 are formed. The concept of spreading coefficients was extended taking into account the overall interface Gibbs free energy by including interfacial area of each component (84). Predictions of these schemes agree with a substantial number of experimental results (70,83–86), but the effect of rheological properties of the components on the type of phase structure was reported in some papers (87–89). The results of Reference 89 were plausibly explained if effective interfacial tensions, relating to flow, considering elasticity of the components were used in the predictive schemes. No rule for prediction of the continuity degree of the components is available for ternary blends.

Binary Polymer Blends.

Size of Dispersed Droplets in Flow. The effects of the properties of blend components and mixing conditions on fineness of the phase structure are well understood qualitatively for binary polymer blends with dispersed structure. It is broadly accepted that the size of dispersed droplets in flowing blends is controlled by the competition between the droplet breakup and coalescence (70,90–94). On the other hand, the droplet breakup and coalescence in blends with viscoelastic components are complex events described only approximately. Moreover, the flow field in mixing devices is also complex, which further complicates correct description of the phase structure development (70,92–94).

Deformation of a droplet in a flow field is controlled by the competition of the deforming stress, τ, setting on the droplet by external flow field and the shape conserving interfacial stress, σ/R, where R is the droplet radius (70,90–96). For characterization of the deformation, the dimensionless capillary number, Ca, defined as $Ca = \tau R/\sigma$, is used. Above a critical value, Ca_c, the external stress overrules the interfacial stress, the droplet is stretched and finally breaks into fragments. For Newtonian droplets in a Newtonian matrix, Ca_c is a function of the ratio, $p = \eta_d/\eta_m$, of the viscosities of the dispersed phase and matrix. For blends with viscoelastic components, Ca_c is also a function of their elasticity parameters. A minimum Ca_c was found for η_d/η_m between 0.1 and 1 for shear and extensional flows. At shear flow, Ca_c gradually increases with decreasing p for $p < 0.1$. For $p > 1$, Ca_c steeply increases with increasing p and goes to infinity for $p \approx 3$–4. At extensional flow, the minimum is flat and an increase in Ca_c for high and low p is weak. For flow in mixing devices, the dependence of Ca_c on p lies between those for shear and extensional flow (94). Two main breakup mechanisms were recognized: stepwise, ie, a repeated droplet breakup into two fragments, and transient, where the droplet is stretched into a long fiber that bursts into a chain of small droplets (70,90,92–94,97). It seems that the stepwise mechanism operates for Ca only slightly higher than Ca_c and the transient one for $Ca \gg Ca_c$. Other breakup mechanisms such as tip streaming (or erosion) of small droplets from the surface of deformed droplets and breakup into two main and several satellite droplets were detected (70,94–96). So far, the role of individual breakup mechanisms in complex flow fields generated in mixing devices has not been fully understood, and it is the object of intensive investigation.

Flow-induced coalescence is caused by droplet collisions due to the difference in their velocities (91–94,98–100) (see Fig. 7). The coalescence is usually described in "ballistic approximation," ie, the number of fusions of droplets in a time period is expressed as a product of the number of collisions of noninteracting

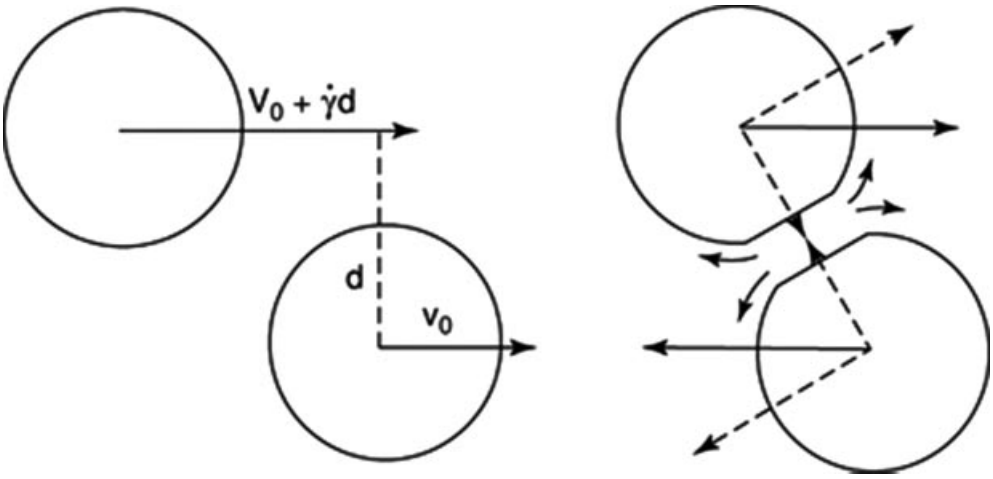

Fig. 7. Shear flow induced coalescence of droplets with the same coordinate in neutral direction. Forces causing droplet approach and rotation in coordinate system moving with the center of inertia are indicating.

droplets and probability, P_c, that the collision will be followed by droplet fusion (91,92,94,100,101). A more or less intensive flattening of the droplets appears during their collision in dependence on properties of the blend components and flow field (100,102). Most calculations of P_c were focused on the case where droplets keep spherical shape during coalescence (102,103) or where the radius of flattened area is substantially larger than interdroplet distance (91,92,100). Unfortunately, the dependences of P_c on system parameters are quite different in these cases. In the former case, P_c is a decreasing function of p and the ratio of radii of large and small droplets and is independent of the average droplet size and deformation rate. On the other hand, in the latter case, P_c is independent of the ratio of droplet radii and depends on average R and the deformation rate. Therefore, inadequate application of any of these extreme cases can lead to a serious misinterpretation of experimental results. Recent calculations (104,105) have shown that for deformable droplets, P_c is given by the value for the spherical particles in the region of small R and steeply decreases at a certain R where a substantial flattening appears (for the shape of P_c, see Fig. 8). It should be mentioned that the so far developed theories describe dilute systems (simultaneous collisions of three and more droplets are not considered) of Newtonian droplets in a Newtonian matrix.

Generally, the distribution of droplet sizes in flow can be obtained as a solution of the generalized Smoluchowski (balance population) equation describing the competition between the droplet breakup and coalescence. Various approximate approaches to the solution of the equation with various expressions for breakup and coalescence frequencies have been used in the literature (101,105–115). For rather long mixing in batch mixers, achievement of a steady state in the droplet size distribution is assumed. For mixing in extruders, development of the droplet

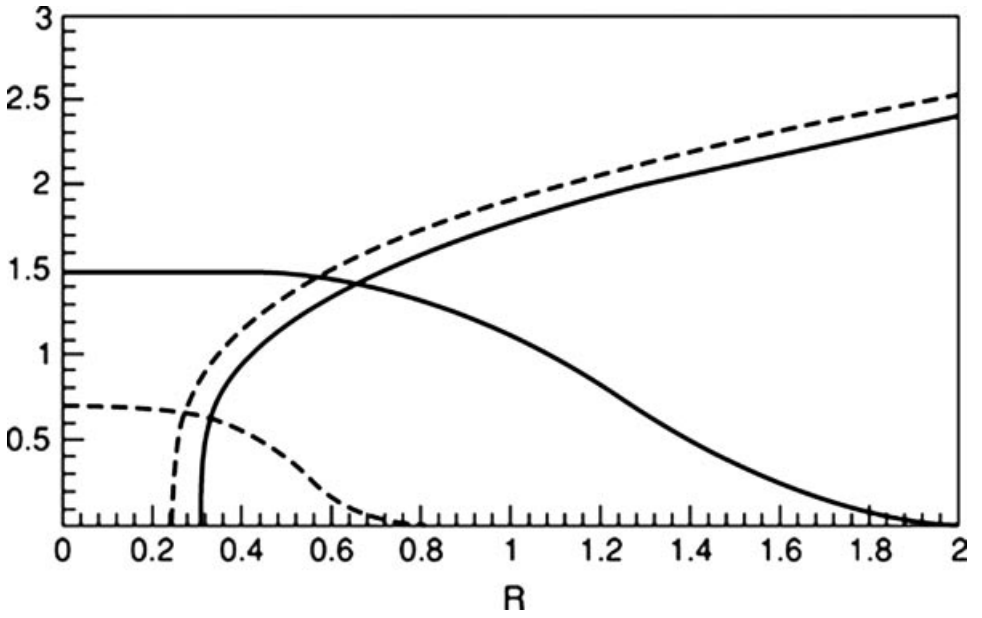

Fig. 8. Scheme of graphic solution of equation 12. Full and broken lines relate to blends with and without a compatibilizer. Y-axis shows $F(R)$ and $(4/\pi)\dot{\gamma}vP_c(R)$ in arbitrary units.

size distribution during throughput in individual zones of the extruders should be studied. A simplified model, where a system of droplets is still monodisperse and breakup leads to a decrease and coalescence to an increase in droplet size, can be helpful in understanding the dependence of average droplet size on parameters of a system (116). The steady droplet radius for this model in shear flow can be calculated from the equation (116)

$$\left(\frac{\mathrm{d}n}{\mathrm{d}t}\right)_{\mathrm{B}} = \left(\frac{\mathrm{d}n}{\mathrm{d}t}\right)_{\mathrm{C}} \Rightarrow F(R) = \left(\frac{4}{\pi}\right)\dot{\gamma} v P_{\mathrm{c}}(R) \tag{12}$$

where $(\mathrm{d}n/\mathrm{d}t)_{\mathrm{B}}$ and $(\mathrm{d}n/\mathrm{d}t)_{\mathrm{C}}$ are changes in the droplet number in a time unit due to their breakup and coalescence, respectively, and the breakup frequency $F(R) = 0$ for $R < R_{\mathrm{c}} = \sigma Ca_{\mathrm{c}}/(\eta_{\mathrm{m}}\dot{\gamma})$. The dependence of F on R for $R > R_{\mathrm{c}}$ has not been well established, and very different expressions have been used in literature (116). It seems, based on recent results, that F increases with R slower than linearly (96, 117). This assumption is in agreement with experiments showing a steeper than linear increase in R with increasing v in a certain blend under constant mixing conditions (70,90,93,94,116). In spite of the approximations used in calculation of P_{c}, the shape of the dependence P_{c} on R is always similar to that in Figure 8. It follows from graphic solution of equation 12, shown in Figure 8, that for R_{c} smaller than R, at which P_{c} falls to very low value, steady state can be achieved during reasonable time. In the opposite case, regions of R exist where only coalescence or practically only breakup occurs.

Under constant mixing conditions, an increase in average droplet radius with increasing volume fraction of the dispersed phase has been observed (70,93,94,99,106,118). The increase is a consequence of the fact that the breakup frequency is in first approximation independent of v, but the frequency of coalescence is an increasing function of v. An increase in interfacial tension leads to an increase in R (118) due to a decrease in Ca. The effect of viscosity ratio, p, can be directly studied by changing η_{d} while keeping η_{m} constant. For a system containing a low v, the effect of p on droplet breakup is decisive and the dependence of R on p for stepwise breakup is controlled by the dependence of Ca_{c} versus p. For a transient breakup mechanism, the situation is different and an increase in p can lead to smaller R also for $p > 1$ (91,92,112). Generally, P_{c} decreases with increasing p. Therefore, a lower R at $v \to 0$ and a steeper increase in R with v should appear for lower p if the stepwise breakup mechanism is decisive. This type of dependency was observed for polypropylene/ethylene-propylene elastomer blends mixed in the chamber of a Plasticorder (94,119). For the transient breakup mechanism, R should be smaller for larger p for all volume fractions of the dispersed phase. If η_{m} is changed at a constant η_{d}, p and Ca are changed simultaneously. In most cases, an increase in η_{m} at constant η_{d} and mixing conditions leads to a decrease in the droplet size in the whole concentration range (94,119). The effect of elasticity of the components has not been fully understood so far. Available experimental results show that the deformation and breakup of droplets more elastic than the matrix are more difficult than in the related Newtonian system (70,120,121). Generally, the dependence of the droplet size on shear stress (mixing intensity) is affected by the concentration of the dispersed phase because R_{c} (R for $v \to 0$) depends on stress (deformation rate) in a different way than P_{c}.

While R in dilute blends typically decreases with increasing stress applied during mixing (94,122–124), in concentrated systems, R is a complex function of system parameters and it can be a decreasing, increasing, or nonmonotonic function of the applied stress (70,94,125,126). Only a weak dependence of R on processing parameters was frequently observed (70,127–129), apparently due to a non-Newtonian character of the matrix, increase in temperature in a mixer at growing mixing rate, and increasing P_c with decreasing R. Usually, quite fine morphology is achieved after a short time of mixing in batch mixers or in first zones of extruders (64–68,70,128–130). On the other hand, large particles of dispersed phase with high viscosity surrounded by material with fine phase structure were found in blends with low interfacial tension (94,131–133). Uniform fine morphology was achieved in these systems only after long and intensive mixing.

Phase Structure Evolution During Annealing. Substantial changes in the phase structure of molten blends of immiscible polymers appear at rest, and are driven by the tendency to achieve a minimum interfacial area. Deformed (elongated) droplets either retract to spheres or break up into smaller fragments. Relaxation occurs by one of several mechanisms, depending on initial deformation (the ratio of long and short semiaxes a/b) and the viscosity ratio (96,134,135). A droplet with the a/b less than approximately 9 retracts to a single sphere. Very elongated droplets (about $a/b > 60$) break up by the capillary wave (Rayleigh) instability, ie, by the transient breakup mechanism mentioned above, into a chain of small droplets. In this case, the amplitude of the perturbation wave grows exponentially with time and the growth rate increases with interfacial tension and decreases with viscosity of both the components and fibril radius (70,91–94,96). For droplets with intermediate deformation, the breakup is dominated by end pinching (96,134,135). Co-continuous structures stay either co-continuous and show increase in the phase size with time or break up into droplet/matrix morphologies (136,137). The breakup of fibers between crossing points of the structure is controlled by the capillary wave mechanism and it can occur if the length of fibers between the crossing points is substantially larger than the fiber thickness. Therefore, the coarsening of co-continuous structures is typical of blends with compositions near 1/1 and their breakup appears for blends with asymmetric compositions. The coarsening rate increases with interfacial tension and decreases with the viscosity of blend components (137). A substantial increase in the size of dispersed particles after annealing in the molten state was found for many polymer blends with particulate morphology (138). Two main mechanisms were suggested: coalescence driven by molecular forces and Brownian motion (139), and Ostwald ripening (140,141). Analysis of these mechanisms showed that the rate of coarsening should increase for coalescence and decrease for Ostwald ripening with increasing interfacial tension (138). A clear increase in the coarsening rate with interfacial tension was found experimentally (138). Moreover, coalescing droplets were detected in some experiments (142,143). Therefore, it seems that the coalescence induced by molecular forces and Brownian motion is the main mechanism of droplet coarsening, at least for blends with moderate or high interfacial tension.

Blends Containing a Compatibilizer.

The Effect of Compatibilizer on a Blend Microrheology. The presence of a compatibilizer at the interface substantially affects the development of the phase structure of molten blends in the flow and quiescent state. The position

and width of the concentration region related to co-continuous morphology are affected by two competing mechanisms. A decrease in interfacial tension caused by a compatibilizer favors the formation and stability of co-continuous structures. On the other hand, the compatibilizer suppresses the coalescence, which is assumed to be a reason for the co-continuity formation (69). Experimentally, narrowing of the concentration region with co-continuous structure was observed for some systems (69,144,145), but no change was found in other systems (69,146,147). Fixation of co-continuous structure in a blend containing 20% of minor component by the addition of a compatibilizer was also observed (148).

The effect of a compatibilizer on fineness of the phase structure can be understood through its effects on droplet breakup and coalescence. The decrease in interfacial tension mentioned above leads to a decrease in the critical droplet radius, R_c, at a constant Ca_c. Generally, Ca_c of a compatibilized blend differs from that of the related binary blend without compatibilizer (149,150). The bulk flow convects the compatibilizer towards the ends of the droplets causing a gradient in interfacial tension along the droplet surface. The lower interfacial tension on the tips promotes tip streaming, tending to reduce Ca_c. On the other hand, Marangoni stresses oppose deformation. An increase in the droplet surface due to deformation leads to compatibilizer dilution and, therefore, to an increase in interfacial tension. The last two effects tend to increase Ca_c (149,150). At breakup by the transient mechanism, a compatibilizer causes an increase in the breakup time due to a decrease in interfacial tension and existence of interfacial tension gradients (149–151). A decrease in interfacial tension due to the presence of a compatibilizer decreases the droplet radius, R, at which the probability of coalescence, P_c, falls to a negligible value. Two other mechanisms contributing to coalescence suppression were proposed (149,152). The first involves immobilization of the interface (suppression of liquid circulation in droplet) due to the Marangoni stress. The Marangoni stress is induced by convection of a compatibilizer out of the gap between approaching droplets, which leads to a gradient of interfacial tension (149,150). The immobilization of the interface decreases P_c for small R. The other mechanism, repulsion of the droplets arises mainly from the compression of the compatibilizer block extending into the matrix phase (149,152). This mechanism is applied only if the dilution of a compatibilizer in the gap between droplets is not large. The effect of a compatibilizer on the breakup frequency and P_c (decrease in interfacial tension and the Marangoni effect are considered) is schematically illustrated in Figure 8. Figure 8 shows that the situation when steady state is not achieved is more probable for blends with a compatibilizer. In the calculation of steady R, changes in interfacial tension induced by changing interfacial area in droplet breakup and coalescence should be considered (153). The above effect can be quantified if the distribution of a copolymer between the interface and bulk phases, relationship between copolymer concentration at the interface and interfacial tension, and the rate of copolymer migration along the interface and between the interface and bulk phases are known.

Effect of the Compatibilizer Architecture. Compatibilization efficiency of various copolymers follows from their thermodynamic and microrheological effects. It has been generally accepted that the total molecular weight of the copolymer, molecular weight of its blocks and their number are the main structural compatibilizer characteristics affecting the phase structure of the final blend.

Contradictory results have been published on the effect of block copolymers with different numbers of blocks. In some papers, diblock copolymers have been found more efficient compatibilizers than triblock copolymers (51,154,155), whereas in several other studies, the opposite results have been obtained (156–158). Still others state that there is no difference between diblocks and triblocks (159). Some more recent articles show the compatibilizing efficiency of multiblock (tetrablock, pentablock, heptablock) copolymers (160–162), which seems to be supported also by some theoretical studies (163,164).

It has been believed that proper molecular weight of the copolymer blocks should be close to that of the relevant homopolymer. However, some results show that copolymers with differing lengths can be efficient compatibilizers. A complex situation also occurs when the copolymer blocks are not chemically identical with homopolymer chains, but only similar, and thus they exhibit limited miscibility. The complexity of these issues have been shown in a number of studies.

Thus Xu and Lin (154) successfully compatibilized a high molecular weight blend of *i*PS and *i*PP with a *i*PS-*i*PP diblock copolymer, where the molecular weight of both blocks amounted to 150,000. Feng (165) has shown that for PS/polyolefin blends, even PE-*g*-PS graft copolymers can be suitable compatibilizers.

Cavanaugh and co-workers (166) have studied the compatibilization efficiency of various styrene-butadiene copolymers in polystyrene (PS, M_w = 202,000)/polybutadiene (PB, M_w = 320,000) blends. The most effective compatibilizer proved to be a long, asymmetric diblock (M_w = 182,000; PS content 30%), which could entangle in both homopolymer phases. Short diblock copolymers and most of the random copolymers were inadequate as interfacial agents. Moderate improvement in impact strength was observed for a S-B multiblock.

The effects of the block length and block number in linear S-B block copolymers on compatibilization efficiency in low molecular weight PS/PB blends were studied also by Horák and co-workers (167). For this detailed stucture study, PS (M_w = 40,000), PB (M_w = 60,000), and di-, tri-, and pentablock S-B copolymers, having M_w of the PS block either 10,000 or 40,000, were prepared. Besides standard slow cooling, also quenched samples, having the structure close to that of the molten state, were prepared. It shows that in quenched samples, all block copolymers, with an exception of large 40S–60B–40S, are molecularly dispersed (probably at the PS/PB interface). Escape of the S-B copolymers from the interface is observed for the copolymers having short PS blocks, while the copolymers with long PS blocks remain a part of the PS/PB interfacial layer, and this phenomenon manifests itself by the formation of a finer morphology and better stress-transfer properties than in blends containing S-B copolymers with short PS blocks.

Segregation of a poly(2-vinylpyrrolidone-*block*-styrene-d_8-*block*-2-vinylpyrrolidone) (PVP-dPS-PVP) triblock and dPS-PVP diblock copolymers between the PS and PVP homopolymers was studied by Dai and co-workers (169). Both the block copolymers show an increase in the interfacial excess beyond the saturation plateau, due to condensation of copolymer micelles adjacent to the PS/PVP interface in the PS phase (Fig. 9). A significantly lower critical micelle condensation (CMC) was determined for the triblock copolymer when compared with the diblock. While the condensation of the diblock copolymer micelles at the PS/PVP surface occurs above the CMC, no such preferential segregation is observed for the triblock copolymer.

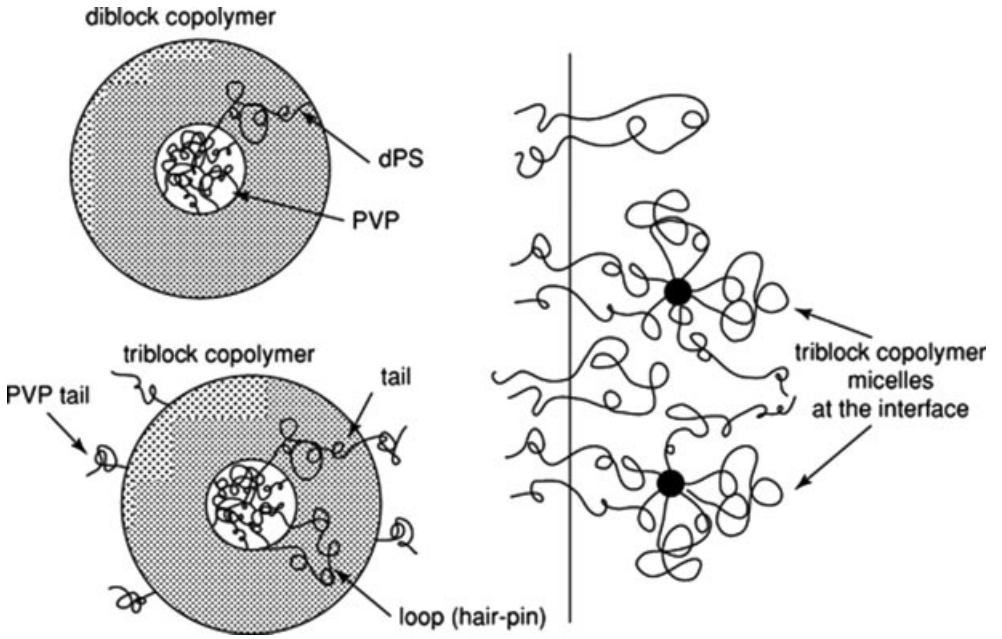

Fig. 9. Condensation of PVP-dPS-PVP triblock copolymer micelles adjacent to the PS/PVP interface in the PS phase. Schematics of (left) the isolated micelle structure for diblock and triblock copolymers and (right) triblock copolymer micelles adsorbed onto an interfacial brush of triblock copolymers.

The compatibilization process becomes more complicated when one of the copolymer blocks is not completely miscible with the corresponding blend component, ie, interaction parameter $\chi > 0$. This problem has been studied in polystyrene (PS)/polyolefin (PO) blends compatibilized with various block copolymers, consisting of styrene and aliphatic hydrocarbon sequences different from the used polyolefin (161,162,168,170–173). It was found that in these blends, the most important factor controlling localization of the block copolymers at the PS/PO interface is the length of the styrene block in the block copolymers. Copolymers having the styrene blocks long enough to form entanglements with the styrene homopolymer in the blend, are entrapped in the final compatibilized blends in this phase. Hence, their transport to the PS/PO interface is difficult and their compatibilization efficiency is low. Critical molecular weight for the formation of the entanglements of PS chains, $M*$, cca 18,000 was determined (174,175). Surprisingly, in these blends, block copolymers with "long" styrene blocks are less efficient compatibilizers than those with "short" blocks.

Also the interfacial layer between the homopolymers differs in A/B + A-*block*-B' blends from that in A/B + A-*block*-B blends. In blends compatibilized with block copolymers having the corresponding blocks miscible with the blend components, they are supposed to be molecularly dispersed to a high degree at the A/B interface (Figs. 9, 3). In A/B/A-*block*-B′ blends, block copolymers with "short" A blocks are localized at the A/B interface as well, but they do not lose their ordered supermolecular structure (Fig. 10). Block copolymers having "long" A blocks are

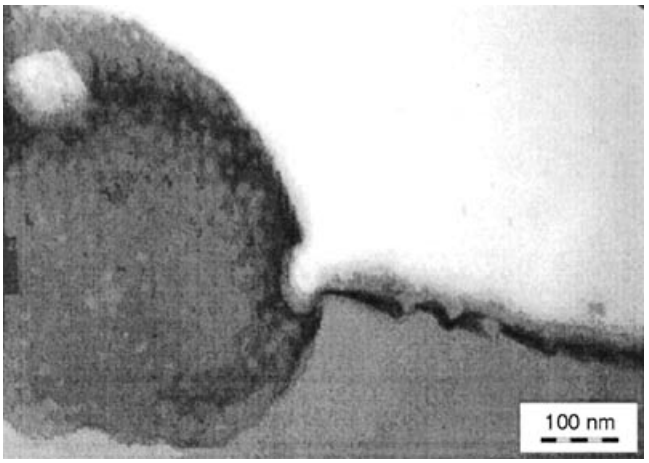

Fig. 10. TEM micrographs of the interface in PS/PP (4/1) blend with addition of 10S-60B-10S block copolymer.

entrapped in the A homopolymer in the form of micelles or small particles, swollen by homopolymer chains (Fig. 11**a**). Additional annealing of these blends leads to pronounced migration of the entrapped copolymers to the A/B interface (Fig. 11**b**) and improvement of mechanical properties. On the other hand, coalescence and worsening of the A/B interface coverage were observed in annealed blends on addition of copolymers having "short" styrene blocks (168). In general, morphology of the A/B/A-*block*-B′ blends depends on the conditions of blend mixing and processing, and cannot be predicted using only the rules of equilibrium thermodynamics. This dependence on the processing conditions is more pronounced in blends with an excess of the A phase, ie, of the homopolymer that is fully miscible with one block of the block copolymer used (168).

Different behavior of block copolymers having blocks miscible with the corresponding homopolymers and those where one block differs chemically from the

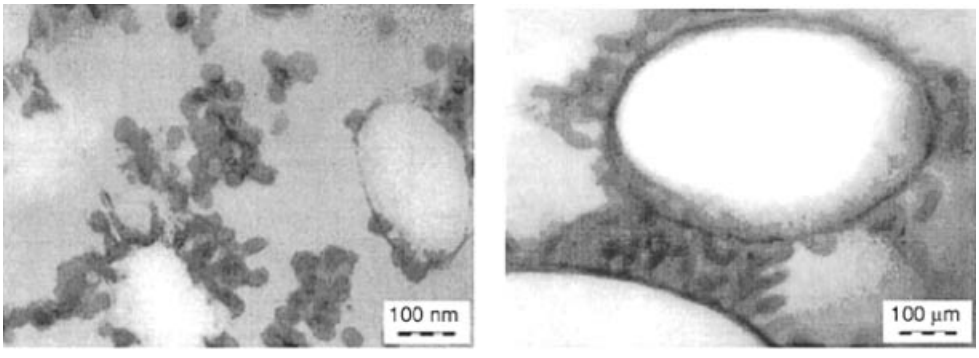

Fig. 11. TEM micrographs of the interface in PS/PP (4/1) blend with addition of 40S-60B-40S block copolymer: (**a**) as prepared sample; (**b**) annealed sample.

homopolymer was observed also by other authors. Barlow and Paul (176) and Appleby and coworkers (157) reported remarkable improvement of ductility and impact or tensile strength in PS/PP blends compatibilized by the commercial material Kraton G1652. This poly(styrene-*block*-ethene-*co*-butene-*block*-styrene) (S-EB-S) triblock copolymer has an M_n value of one PS block approximately equal to 8,000, that is, considerably below the critical value $M*$ necessary for the entanglement formation. Tjong and Xu (177) found that the presence of this BC in PS/high density polyethylene blends leads to increased adhesion between the two phases as well as decreased particle dispersion. Cigana and co-workers (178) observed improvement of mechanical properties in PS/ethene-*co*-propene rubber blends (PS/EPR) with Kraton G1652, unlike with the S-EB-S triblock copolymer, where the molecular weight of the S block was about 24,000 (Kraton G1651).

In the PS/EPR blends, Radonjič and co-workers (179) found the S-B-S triblock copolymer with M_n of the PS blocks of 7,000, to be localized at the PS/EPR interface. The compatibilization efficiency of this block copolymer was further confirmed by finer dispersion in the resulting PS/EPR/S-B-S blends, as well as by improved PS/EPR adhesion. This short triblock copolymer appears to be a good compatibilizer also in *i*PP/*a*PS blends. According to Šmit and Radonjič (180), S-B-S forms an interfacial layer between dispersed honeycomb-like PS/S-B-S particles and PP matrix and influences also crystallization in *i*PP.

Hence, the compatibilization efficiency of block and graft copolymers is influenced by many factors, such as their chemical composition with respect to the character of the corresponding blend components, the number of the blocks, their molecular weights, and consequently, the total molecular weight. Also, in blends where one block of a compatibilizer is not miscible, but only compatible with, the corresponding blend component, achievement of thermodynamic equilibrium can be difficult, as it depends on the processing conditions. However, it seems that triblock copolymers can be considered the most efficient compatibilizers for most of the blends studied.

We can conclude that despite extensive studies performed during more than three decades, no reliable rules for the prediction of the effect of molecular characteristics of block copolymers on the structure and properties of polymer blends have been formulated to date.

Effect of Compatibilizer Concentration. The compatibilizing efficiency of the copolymers is, besides the architecture, a function of their concentration. The effect of a compatibilizer concentration has been quantitatively characterized by the emulsification curve—the dependence of the average particle diameter of the minor dispersed phase on copolymer concentration (70). The particle diameter decreases with increase of copolymer concentration until a constant value is obtained. For most systems, this value is achieved if the copolymer amount is 15–25% of the dispersed phase. There are systems where saturation was detected only at substantially higher concentration of a copolymer (181).

Structure Determination of Polymer Blends. Properties of polymer blends are closely associated with their structure on several scale levels, such as crystallinity and supermolecular structure of the blend components, and, of course, morphology of the final blend. Thus, a series of methods that enable one to characterize these different structure parameters should be employed, including WAXS, SAXS, SANS, SEM, TEM, LS, and DSC.

Wide angle X-ray scattering (WAXS) affords information on the level of interatomic distances, ie, this method can be used for determination of crystalline modification in partially crystalline polymers, degree of crystallinity. Also, dimensions of the crystallites can be estimated from the width of the crystalline reflections (182). Small-angle X-ray scattering (SAXS) experiments lead to determination of supermolecular structure, such as ordered two-phase separation in block copolymers (183,184), long period in semicrystalline polymers (185), or micellar structure (186,187). Classic experimental techniques used in SAXS have been reviewed by Stein (188). Small-angle neutron scattering (SANS), a related and often complementary method to SAXS, is also a very useful tool for determination of supermolecular structure in polymer blends (189). Moreover, by using SANS, interactions in polymer blends can be studied if one of the blend components is deuterated in order to obtain scattering contrast (190). Recently an ultrasmall-angle neutron scattering spectrometer (USANS) was developed (191), lifting the upper resolution limit of SAXS and SANS instruments by an order of magnitude, and thus permitting an overlap with light scattering techniques.

The most suitable and comparatively rapid method used for determination of the morphology of polymer blends appears to be electron microscopy. Techniques employed in scanning electron microscopy (SEM) have been reviewed by Shaw (192). In addition to the use of SEM for determination of particle size and shape in a blend, and adhesion between the blend components (193, Fig. 12), evolution of the structure based on the processing conditions and blend homogeneity can be quickly studied (194, Figs. 13, 14). Transmission electron microscopy (TEM) is a much more time-consuming method. Polymer samples need to be stained with OsO_4 or RuO_4 in order to obtain sufficient contrast, and in addition, very thin sections are necessary (195,196). The simplest result obtained by means of TEM is, similarly to SEM, description of the blend morphology. However, there is a wider scale of possibilities, such as localization of a block copolymer used as a compatibilizer in blends of immiscible polymers (197). Chi-An Dai and co-workers (198) published a study of the morphology development of poly(2-vinyl pyrrolidone)-*block*-(deuterated polystyrene)-*block*-poly(2-vinyl pyrrolidone

Light scattering can be used for determination of the blend morphology, not only in the solid, but also in the molten state (199,200). This method was successfully used in detection of phase transitions in polymer blends, and in determination of changes in droplet size in immiscible polymer blends due to breakup and/or coalescence. In comparison with microscopic methods, scattering methods can easily examine larger blend volume, and therefore, give more reliable average values of morphological parameters. On the other hand, microscopic methods provide more straightforward and complex information (201).

Differential scanning calorimetry (DSC) is used especially for discrimination between miscible and immiscible polymer blends (202). One T_g depending on blend composition indicates a miscible system, two T_g coinciding with related T_g of the components indicate an immiscible blend, and two T_g shifted to the direction of their average is typical of partially miscible systems.

As polymer blends are very complex systems, a combination of different methods for complete description of their structure is of great importance. Several examples of typical combinations are described below.

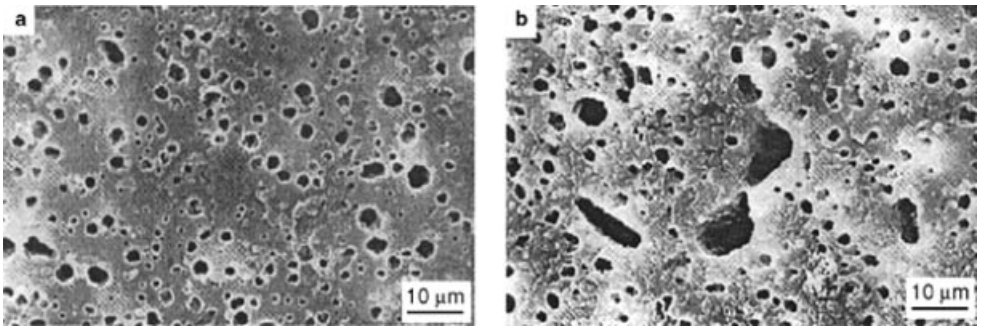

Fig. 14. Phase structure of PP/PS/SBS (71/24/5) blends mixed in microextruder at 250°C for 20 min: (**a**) smaller particles; (**b**) larger particles.

Note that disordered lamellae are found for $\Sigma > 0.6$ chains/nm^2. The bar scale denotes 100 nm.

Combination of WAXS and SAXS is a very efficient way of detailed description of crystallization in blends of semicrystalline polymers. Baldrian and co-workers (203,204) has studied isothermal melt crystallization of blends of low molecular weight poly(ethylene oxide) (PEO) and poly(methyl methacrylate) (PMMA) using time resolved SAXS/WAXS measurements on the ELETTRA synchrotron (205). He has reported the formation of unstable PEO lamellae of nonintegrally folded

chains at the very beginning of crystallization and subsequent transformation of these lamellae into stable PEO crystals with one-folded or extended chains. Amorphous PMMA plays a decisive role in structure development. A similar study was performed by Campoy and co-workers (205) with polyamide (PA6) and the liquid-crystalline copolyester Vectra using calorimetric data and X-ray diffraction.

Structure development in blends of polyaniline doped with camphor sulfonic acid (PANI-HCSA) and PA was studied by Hopkins and co-workers (206) using SAXS and SANS. At 3 vol% PANI loading concentration, salt domains with characteristic length of 22 nm are expected to be present in the blend with PA12. This differs from the blend of PA6 where a fractal geometry was found. For higher salt concentrations, no simple structural model was found.

Wignal and co-workers (207) investigated phase separation of linear (high density) and short-chain branched (linear low density) polyethylenes (HDPE/LLDPE) by of combination of SAXS, SANS, DSC, and TEM. According to SANS, this blend is homogeneous in the melt when the ethyl branch content in LLDPE is low, but due to the structural and melting point differences between HDPE and LLDPE, the components may phase-separate in the solid state.

Block copolymers, usually used as compatibilizers in additive compatibilization, are very often organized in an ordered supermolecular structure, which manifests itself by an interference maximum in the region of SAXS (183,184). The compatibilization efficiency of a block copolymer is associated with its interaction with the blend components, and consequently, with the changes of its supermolecular structure. Hence it is convenient to begin the study of its structure in compatibilized blends using SAXS. Additionally, SAXS gives information on a comparatively large sample volume, even if the information concerns the reciprocal space. Microscopic methods show the real structure, but of a very small part of the sample, which can be inhomogeneous. Thus, combination of scattering and microscopic methods appears to be a very useful for investigation of the compatibilization process. Moreover, TEM and SEM experiments are relatively time consuming, while measurement of one SAXS curve takes several minutes. Thus, it is possible to check samples obtained under preparation conditions, when the steady state is achieved by comparison of SAX curves. Then, several selected samples can be studied by electron microscopic methods (168). Kinning shows in his study (208) a very instructive comparison of different orderings of a styrene-butadiene block copolymer in a styrene homopolymer, obtained by TEM together with corresponding SAXS curves (Figs. 16, 17)

Physical Properties of Polymer Blends

Preparation of heterogeneous polymer blends ranks among the effective ways of upgrading polymers and preparing new cost-effective materials. Tensile modulus, E_b, or shear modulus, G_b, tensile yield strength, σ_{yb}, tensile strength (stress at break), σ_{ub}, fracture resistance, permeability, P_b, to gases and vapors, etc. are viewed as very important physical properties that simultaneously predetermine possible applications of the blends of industrially useful polymers. Phase structure (morphology), which depends on blend composition, relative viscosities of components, interfacial energy, mixing machine and adopted conditions of the mixing

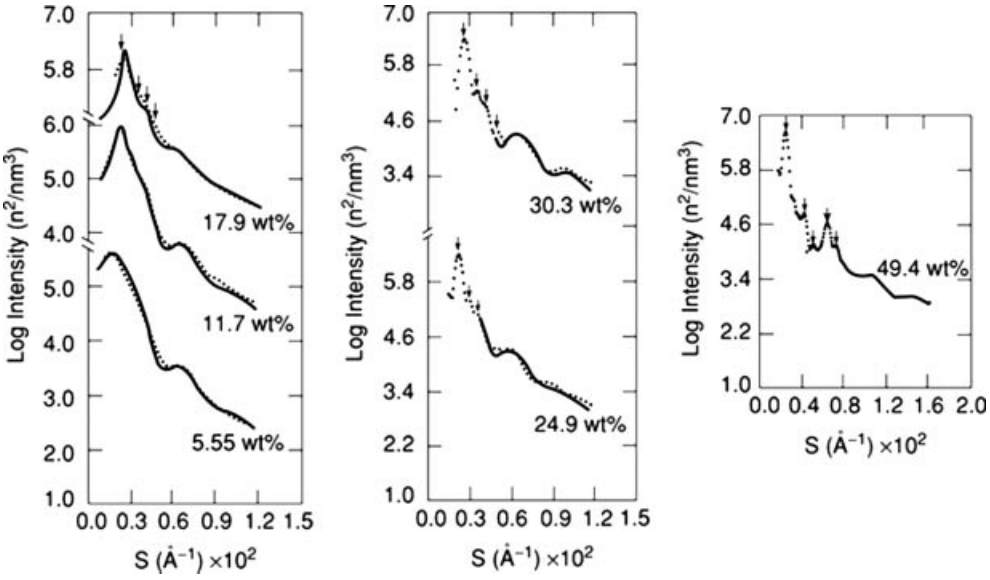

Fig. 16. SAXS curves of blends consisting of copolymer SB 20/20 in 3900 PS homopolymer at various copolymer concentrations.

process, annealing, reprocessing, etc., is essential for the properties of heterogeneous melt-mixed blends consisting of immiscible or partly miscible polymers (209,210). As the phase structure of a blend formed in a mixing machine does not correspond to a state with the lowest Gibbs free energy, the phase structure

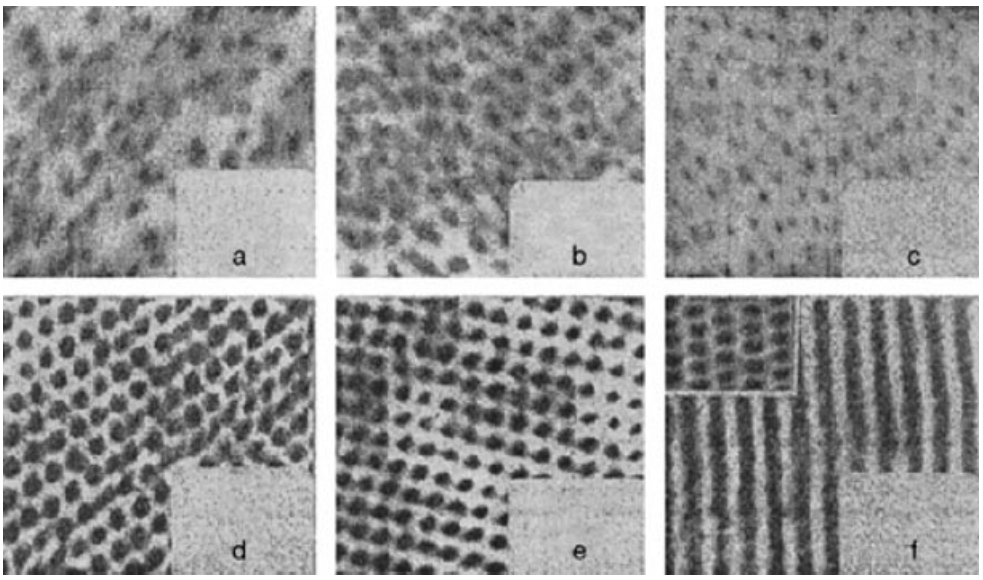

Fig. 17. Transmission electron micrographs of blends containing copolymer SB 20/20 in 3900 PS homopolymer. Copolymer concentrations are (**a**) 5.55 wt%, (**b**) 11.7 wt.%, (**c**) 17.9 wt%, (**d**) 24.9 wt%, (**e**) 30.3 wt%, and (**f**) 49.4 wt%. The bar scale denotes 100 nm.

coarsening begins to take place immediately after completion of the mixing process and is stopped only by freezing-in the melt. The coarsening process is reinitiated whenever blends are heated to processing temperatures in the course of following operations, such as injection or compression molding, reprocessing, and quiescent annealing. In practice, the coarsening is undesirable phenomenon because it usually accounts for deterioration of physical (mechanical) properties of annealed or reprocessed blends.

Heterogeneous blends of immiscible or partially miscible polymers are isotropic heterogeneous materials with three-dimensional spatial continuity of one or more components (69,211). In binary blends, the co-continuity (duality) of constituents occurs in the central composition interval delimited by the critical fractions, v_{1cr} and v_{2cr}, of the components (69,78,212,213). From the viewpoint of mechanical properties, blends can be divided into two basic categories: (1) at $v_1 < v_{1cr}$ or $v_2 < v_{2cr}$, the minority component is dispersed as spherical particles in the continuous majority component (matrix); (2) at $v_1 > v_{1cr}$ and $v_2 > v_{2cr}$, both components become partially continuous. As soon as the volume fraction of a component exceeds v_{cr}, continuous entities are formed in the mixed blend, but a spectrum of particles still coexists. With increasing volume fraction, the degree of continuity (continuity index) of the component increases, so that in a narrower interval delimited by the volume fractions $v_{1dl} > v_{1cr}$ and $v_{2dl} > v_{2cr}$, both components are fully co-continuous (213–215). The coarsening process manifests itself by narrowing the interval of the phase duality and/or by an increase in the particle size of the minority component. Physical properties of solid heterogeneous blends primarily depend on respective properties of the components, frozen-in phase structure, and interfacial adhesion. Typical dependencies of physical properties on the blend composition are schematically visualized in Figure 18.

Predictive Formats for Selected Physical Properties of Polymer Blends. Tailoring of heterogeneous polymer blends with balanced physical properties for specific applications is a frequent task of materials engineering. A great number of heterogeneous polymer blends have been studied and reported in available literature. A review of empirical knowledge gathered so far is beyond the scope of this basic treatment. Instead, the existing means applicable in projecting polymer blends will be outlined. To reduce experimental time and costs of a blend development, it is highly desirable to have reliable formats for the prediction of considered physical properties, eg, E_b, σ_{yb}, σ_{ub}, P_b. Although modeling and simulations cannot fully replace experimental investigation, their role in the designing and structural analysis of blends is ever increasing.

Physical properties of blends consisting of a continuous matrix and one or more dispersed (discrete) components can be predicted by using adapted models proposed for particulate composite systems (216–220). Most of these models do not consider effects of the particle size, but only of volume fractions of components in the system. Thus, the increase in particle size due to particle coalescence is not presumed to perceptibly affect mechanical properties, except for fracture resistance, which is controlled by particle size and properties of dispersed rubbers. As polymer blends with three-dimensional continuity of two or more components are isotropic materials, simple parallel or series models or models for orthotropic or quasi-isotropic materials are not applicable. Physical properties of blends with partially co-continuous constituents can be calculated by means of a predictive

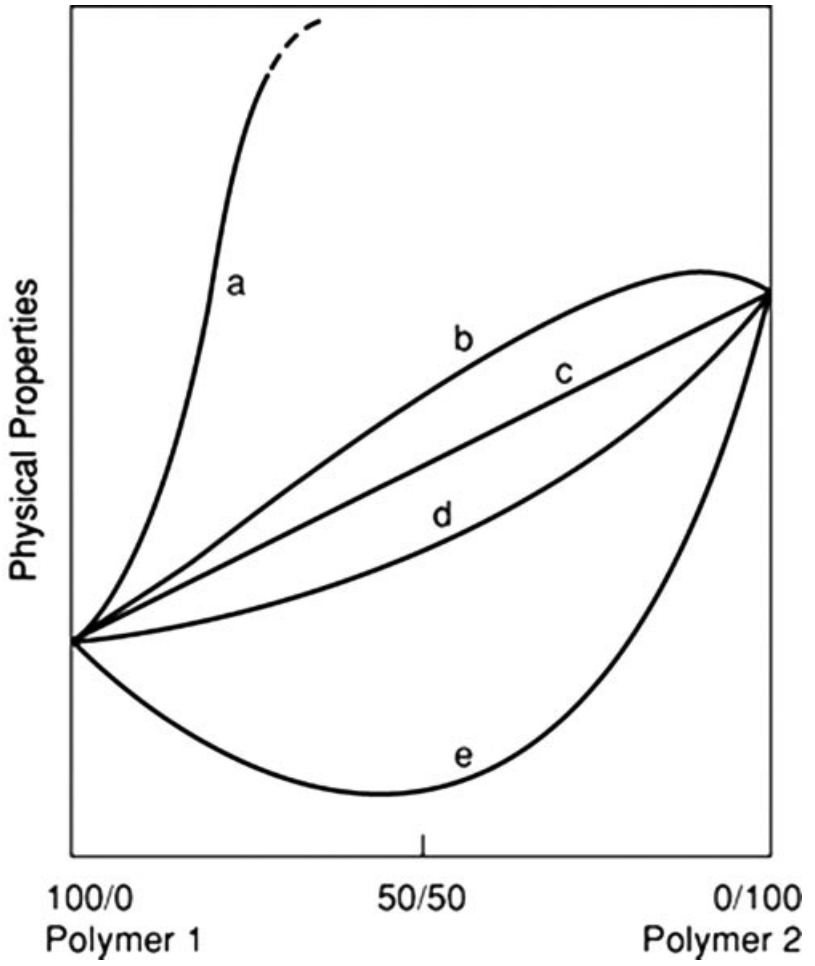

Fig. 18. Effect of the composition of heterogeneous binary blends on their physical properties (schematically). (**a**) Fracture resistance, toughness and impact resistance of commercial rubber-toughened polymers; (**b**) modulus and tensile (yield) strength of blends consisting of partially miscible polymers; (**c**) density (straight line corresponds to the rule of mixtures); (**d**) modulus, compliance, tensile yield strength, stress at break, permeability to gases, thermal conductivity of compatible blends with good interfacial adhesion; (**e**) tensile yield strength and stress at break of blends with poor interfacial adhesion; fracture and/or impact resistance of nontoughened blends.

format (221–223) based on a two-parameter equivalent box model (EBM) (Fig. 19) and modified equations rendered by the percolation theory for two-component systems (78,212,224–227). This combination is necessitated by the fact that the EBMs are not self-consistent models. The EBM assumes that either component consists of a fraction continuous in the direction of the acting force (v_{1p} or v_{2p}) and a fraction discontinuous in that direction (v_{1s} or v_{2s}). In this concept, the lines of force do not cross any interface in the fractions v_{1p} and v_{2p}, while the phase continuity is completely disrupted in the fractions v_{1s} and v_{2s}, where all

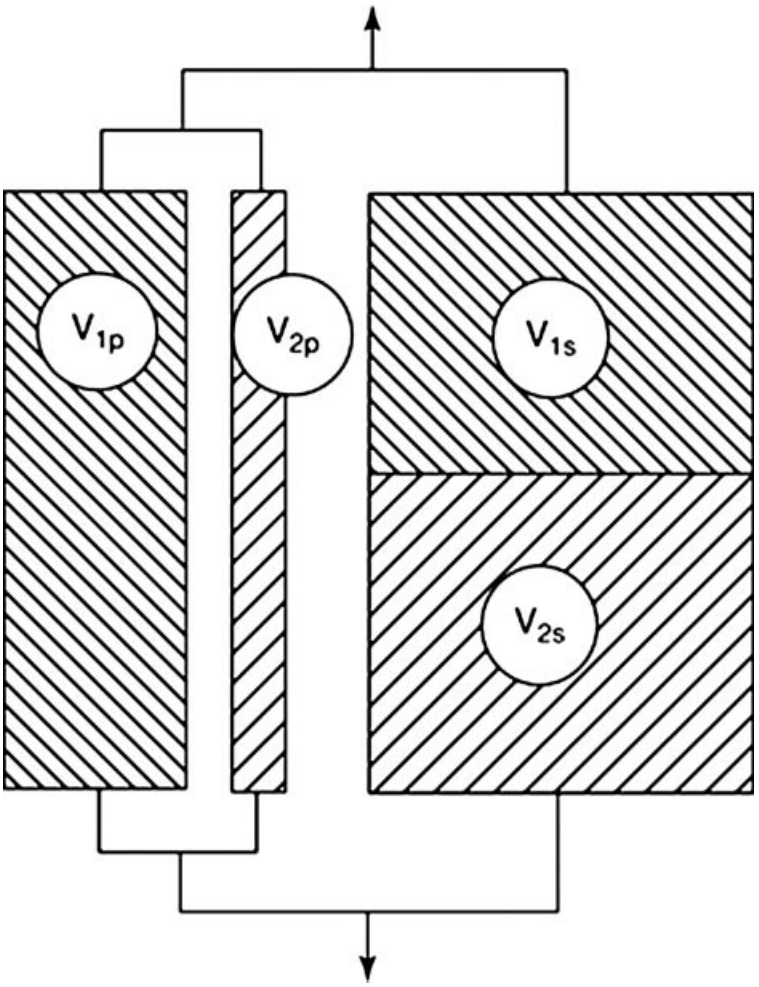

Fig. 19. Equivalent box model for a heterogeneous binary blend (schematically).

stress is transmitted through the present interfaces. (Obviously, the continuity of blend components evaluated by means of extraction methods (69,210,228) has a different meaning). The predictive format takes into account (i) the respective properties of components, (ii) the co-continuity interval of components, (iii) interfacial adhesion and (iv) partial miscibility (if any) of components. Application of the EBM to the prediction of physical properties of blends requires (1) calculation the volume fractions v_{ij} and (2) derivation of equations for the properties under consideration in terms of the EBM. Simultaneously predicted physical properties of blends are interrelated because they are calculated by using an identical set of input parameters characterizing a certain phase structure. The model is likely to fail if the blending process produces a significant change in the structure (eg, in crystallinity), and consequently, in the considered properties of one or both constituents.

Calculation of the Volume Fractions in the EBM. The EBM is a two-parameter model because out of four volume fractions v_{ij}, only two are independent; the volume fractions visualized in Figure 19 are interrelated as follows:

$$\nu_1 = \nu_{1p} + \nu_{1s}; \nu_2 = \nu_{2p} + \nu_{2s}; \nu_1 + \nu_2 = \nu_p + \nu_s = 1 \tag{13}$$

The percolation theory (224–227) provides a universal formula for some physical properties of binary systems (modulus, permeability) where the contribution of the second component is negligible. The formula has been experimentally shown (212,229) to plausibly fit the modulus of model blends with $E_1 \gg E_2$ in the range $v_{1cr} \leq v_1 \leq 1$. Modifying this approach for binary blends, the following equations were derived (221–223):

$$\nu_{1p} = [(\nu_1 - \nu_{1cr})/(1 - \nu_{1cr})]^q, \tag{14a}$$

$$\nu_{2p} = [(\nu_2 - \nu_{2cr})/(1 - \nu_{2cr})]^q \tag{14b}$$

where q is the critical exponent. The remaining v_{1s} and v_{2s} are evaluated by using equation 13. The theoretical critical volume fraction (percolation threshold) $v_{cr} = 0.156$ was calculated (78,219,226,227) for random spatial array of discrete spherical domains. Most reported values of q are located in the interval 1.6–2.0, which complies well with the theoretical prediction (224,227) or $q = 1.8$. In a first approximation, "universal" values $v_{1cr} = v_{2cr} = 0.156$ and $q = 1.8$ can be employed in the EBM, which may provide a good prediction for blends whose components show similar viscosity and elasticity under mixing conditions. Experimental values of v_{1cr} and/or v_{2cr} have usually been found in the interval 0.15–0.25; however, extreme values around 0.03 or 0.46 have also been observed (230). Any considerable change in viscosity of one component influences both v_{1cr} and v_{2cr} (230,231), wherein the component with lower viscosity exhibits a stronger tendency to continuity, which manifests itself in a lower v_{cr} and an asymmetric interval of the phase duality. Owing to enormous complexity, only recently has a quantitative prediction of v_{cr} been attempted (213), which operates with rheological characteristics of components and of the blending equipment. Despite a number of simplifying assumptions, it provides useful guidelines for minimizing v_{cr} of one component in binary blends. In the marginal zone, $0 < v_1 < v_{1cr}$ (or $0 < v_2 < v_{2cr}$), where only component 2 (or 1) is continuous, simplified relations can be used for the minority component in the EBM, ie, $v_{1p} = 0$, $v_{1s} = v_1$ (or $v_{2p} = 0$, $v_{2s} = v_2$), to obtain an approximate prediction of physical properties.

Moduli of Binary Heterogeneous Blends. A linear stress–strain relationship, indispensable for modulus measurements, is granted only at very low strains, typically below 1%, where virtually all blends show interfacial adhesion sufficient for transmission of acting stress. At strains exceeding the linearity limit, blend modulus (or compliance) decreases (or rises) with the strain. The tensile modulus of a two-component blend (Fig. 19) is given as (222)

$$E_b = E_1\nu_{1p} + E_2\nu_{2p} + \nu_s^2/[(\nu_{1s}/E_1) + (\nu_{2s}/E_2)] \tag{15}$$

where $v_s = v_{1s} + v_{2s}$. Along with the tensile modulus from stress–strain measurements (Fig. 18, curve d), the storage modulus E_b' and the loss modulus E_b'' are frequently used. Dynamic mechanical thermal analysis (DMTA) at a constant frequency is the case of steady state harmonic conditions to which the elastic-viscoelastic correspondence principle is applicable (232). Thus, isochronous DMTA is a method allowing the use of the models for elastic materials also for viscoelastic materials by replacing elastic constants by complex (viscoelastic) counterparts (233,234). Introducing $E_1* = E_1' + iE_1''$, $E_2* = E_2' + iE_2''$ and $E_b* = E_b' + iE_b''$ into equation 15 and separating real and imaginary terms, one obtains

$$E_b' = E_1' v_{1p} + E_2' v_{2p} + v_s^2 N'/M \tag{16a}$$

$$E_b'' = E_1'' \nu_{1p} + E_2'' \nu_{2p} + \nu_s^2 N''/M \tag{16b}$$

where

$$N' = \nu_{1s} E_1' \left(E_2'^2 + E_2''^2\right) + \nu_{2s} E_2' \left(E_1'^2 + E_1''^2\right) \tag{17a}$$

$$N'' = \nu_{1s} E_1'' \left(E_2'^2 + E_2''^2\right) + \nu_{2s} E_2'' \left(E_1'^2 + E_1''^2\right) \tag{17b}$$

$$M = \left(\nu_{1s} E_2' + \nu_{2s} E_1'\right)^2 + \left(\nu_{1s} E_2'' + \nu_{2s} E_1''\right)^2 \tag{17c}$$

A possible occurrence of an additional mechanical transition (loss peak) in the dynamic mechanical spectrum of polymer blends was ascribed to the geometrical arrangement of phases, rather than to a molecular relaxation process within the interfacial area (235).

In boundary regions, ie, $v_1 < v_{1cr}$ or $v_2 < v_{2cr}$, the blend modulus can be calculated from the Kerner – Nielsen equation (216,217,219), which for dispersed component 2 with $E_2 > E_1$ reads

$$E_{b1} = E_1(1 + A_1 B_1 v_2)/(1 - B_1 \psi_2 v_2). \tag{18a}$$

The quantities A_1, B_1, ψ_2 are defined as follows:

(1) $A_1 = (7 - 5\mu_1)/(8 - 10\mu_1)$, where μ_1 is the Poisson ratio of the (glassy) matrix;
(2) $B_1 = (E_2/E_1 - 1)/(E_2/E_1 + A_1)$; $\psi_2 = 1 + [(1 - \nu_{2max})/(\nu_{2max})^2]\nu_2$, where v_{2max} is the maximum packing fraction of the dispersed particles (the value $v_{2max} = 0.63$ for random close packing of monodisperse spheres is usually used (217).

If component 1 with lower modulus E_1 is dispersed in a stiffer matrix 2, eg, in rubber-toughened plastics, then inverted relations can be employed (216,217):

$$E_{b2} = E_2(1 - B_2 \Psi_1 \nu_1)(1 + A_2 B_2 \nu_1) \tag{18b}$$

where $A_2 = (8 - 10\mu_2)/(7 - 5\mu_2)$; $B_2 = (E_2/E_1 - 1)/(E_2/E_1 + A_2)$; the formulas for ψ_1 and ψ_2 are analogous. Alternatively, similar equations derived by other

authors (218,219,236) for particulate systems can be used; the differences in moduli predicted by existing theories are not significant.

Compliance of Heterogeneous Binary Blends. As end products made of thermoplastics and their blends are frequently exposed to a long-lasting dead load, their resistance to creep becomes a significant characteristic of their dimensional stability. By introducing a co-continuous creep-resistant component, the creep of blends can be substantially reduced. To anticipate the time-dependent compliance $D_b(t)$ of a blend, the corresponding functions $D_1(t)$ and $D_2(t)$ of the components are to be experimentally evaluated. In analogy to the blend modulus (Fig. 18, curve d), the compliance of heterogeneous binary blends with co-continuous components reads (237–239):

$$D_b(t) = \left\{v_{1p}/D_1(t) + v_{2p}/D_2(t) + (v_{1s} + v_{2s})^2/[D_1(t)v_{1s} + D_2(t)v_{2s}]\right\}^{-1} \tag{19}$$

To describe the compliance of blends with one continuous component and one discontinuous component, equation 19 can provide a first approximation by using $v_{1p} = 0$, $v_{1s} = v_1$ or $v_{2p} = 0$, $v_{2s} = v_2$. More accurate equations can be obtained by modifying existing equations (213). If the minority polymer 2 of the volume fraction v_2 having a lower compliance $D_2(t) < D_1(t)$ is dispersed in polymer 1, the compliance $D_{b1}(t)$ of the blend is (237)

$$D_{b1}(t) = D_1(t)[1 - B_1(t)\psi_2 v_2]/[1 + A_1 B_1(t) v_2] \tag{20a}$$

where $B_1(t) = [D_1(t)/D_2(t) - 1]/[D_1(t)/D_2(t) + A_1]$; A_1 and ψ_2 are defined for equation 18a. If the component 1 is dispersed in the component 2, then the inverted relation applies:

$$D_{b2}(t) = D_2(t)[1 + A_2 B_2(t) v_1]/[1 - B_2(t)\psi_1 v_1] \tag{20b}$$

where $B_2(t) = [D_1(t)/D_2(t) - 1]/[D_1(t)/D_2(t) + A_2]$; A_2 and ψ_1 are defined for equation 18b.

As the stress–strain linearity limit of most thermoplastics and their blends is very low, nonlinear viscoelastic behavior of heterogeneous blends needs to be considered in most cases. The nonlinearity is at least partly ascribed to the fact that the strain-induced expansion of materials with Poisson's ratio smaller than 0.5 markedly enhances the fractional free volume (240). Consequently, the retardation times are perpetually shortened in the course of a tensile creep in proportion to the achieved strain. Thus, knowledge of creep behavior over appropriate intervals of time and stress is of great practical importance. The handling and storage of the compliance curves $D(t,\sigma)$ in a graphical form is impractical, so numerous empirical functions have been proposed (241), eg,

$$D(t,\sigma) = W(\sigma)(t/\tau_{rm})^n \tag{21}$$

where $W(\sigma)$ is a function of the stress, τ_{rm} is the mean retardation time, and $0 \leq n \leq 1$ is the creep curve shape parameter reflecting the distribution of retardation times. Parameters characterizing the nonlinear compliance of the parent polymers

can be extracted from generalized creep dependencies obtained by means of time-strain superposition. The predictive format based on equations 14a, 14b, 19 and 21 allows the prediction of corresponding parameters for blends and the construction of the creep curves of blends for selected stresses in the region of recoverable stress-strain behavior (238,239).

Yield and/or Tensile Strength of Heterogeneous Binary Blends. If blend components show yielding (usually at a strain of 3–6%), the yield strength in tension σ_{yb} of the resulting blend obeys the following equation, derived in terms of the EBM in Fig. (19) (221,242):

$$\sigma_{yb} = \sigma_{y1}\nu_{1p} + \sigma_{y2}\nu_{2p} + A\sigma_{y1}\nu_s, \tag{22}$$

where $\sigma_{y1} < \sigma_{y2}$ characterize the parent polymers and $0 \leq A \leq 1$ the extent of interfacial debonding. Two limiting values of σ_{yb}, identified with the lower or upper bound, can be distinguished by means of equation 22: (i) Interfacial adhesion is so weak that complete debonding occurs before yielding between the fractions of constituents coupled in series ($A = 0$ at the yield stress). As a function of blend composition, the lower bound of σ_{yb} passes through a minimum (Fig. 18, curve e). (ii) Interfacial adhesion is strong enough to transmit the acting stress between constituents so that no debonding ($A = 1$) appears in the course of yielding; then the contribution of the series branch in the EBM is added to that of the parallel branch (the effect of different strain rates in the parallel and series branches on σ_{y1} and σ_{y2} is neglected). However, if two components differing in the yield strength are coupled in series, then this branch yields at σ_{y1} or σ_{y2}, whichever is lower. The upper bound of σ_{yb} is a monotonic function of the blend composition (Fig. 18, curve d). Whenever a partial or complete debonding occurs before yielding, then σ_{yb} passes through a minimum as a function of blend composition (211). A good correlation was found between the partial miscibility of blend components and their interfacial adhesion (243).

The yield strength σ_{yb1} of particulate systems, where dispersed particles do not yield and have a good adhesion to the matrix, is approximately equal to that of the matrix σ_{y1} (244). In the case of "zero" adhesion, the yield strength σ_{yb2} drops with the volume fraction of particles (219,245):

$$\sigma_{yb2} = \sigma_{y2}\left[1 - (\nu_1/\nu_{1max})^{2/3}\right] \tag{23}$$

The latter formula also holds for glassy matrices with rubber-like inclusions, because yield strength of the dispersed component is negligible (219).

With regard to the experience that equation 23 is suitable for the evaluation of the yield as well as tensile strength of particulate systems, equation 22 can also be tentatively applied (221–223) for the tensile strength σ_{ub} of blends by replacing the yield strengths σ_{y1} and σ_{y2} by the tensile strengths σ_{u1} and σ_{u2}, respectively. If fracture mechanisms in the blend components are very different, the format may not fit the σ_{ub} versus v_2 dependence.

Application of the Predictive Formats. In addition to the prediction of selected physical properties of envisaged blends, subsequent comparison of model calculations with experimental data allows the experimentalists (i) to analyze the phase structure of prepared blends, (ii) to evaluate interfacial adhesion or the

extent of interfacial debonding, and (iii) to assess to which extent the potential of a material has been exploited, etc. A great advantage of the EBM approach is that several physical properties can be simultaneously evaluated, eg, modulus, yield, or tensile strength, and permeability to gases (222,223,246). If no information is available about the phase structure of blends, the properties can be predicted by using the "universal" values $v_{1cr} = v_{2cr} = 0.16$ and $q = 1.8$. However, this should be regarded as a first approximation that may not well approximate experimental data due to the fact that v_{1cr} and v_{2cr} of a studied system may be different, being affected by the relative viscosities of components, conditions of blend mixing, phase structure coarsening, etc. Conversely, as soon as some experimental data for a specific system are available, it is possible to determine actual v_{1cr} and v_{2cr} by a fitting procedure; thus the formats can be alternatively viewed as an efficient tool for analysis of the phase structure of blends. In a similar way, the phase structure of ternary blends (242,247) and/or the extent of interfacial debonding (248) can be evaluated. The outlined format for the modulus was successfully used in the structure analysis of interpenetrating epoxy and silica networks (249). Blends consisting of partially miscible polymers often show positive deviations (Fig. 18, curve b) of the moduli and yield strength, (250,251) which are ascribed to two effects: (i) respective properties of one or both conjugate phases are higher than those of parent polymers; (ii) molecular mobility in conjugate phases is reduced due to associative interactions (heterocontacts) between the chains of components. The properties of these blends can be modeled by combining the predictive formats with an empirical equation expressing the composition of conjugate phases as a function of blend composition (251). The predictive format was also used for manifestation of the effects of the phase structure coarsening (narrowing of the co-continuity interval) on the modulus, yield or tensile strength, and gas permeability of heterogeneous polymer blends characterized by good or poor interfacial adhesion (252). If postmixing treatments (quiescent annealing before freezing-in the melt, molding, reprocessing) account for a more profound drop in blend properties, then it is likely that—in addition to phase structure coarsening of the blend—the respective properties of constituents have deteriorated due to changes in their structure or due to chemical degradation.

Toughness of Polymer Blends. Toughness (fracture resistance) ranks among the most closely watched properties of polymer materials because it is an important prerequisite in most applications. It is commonly defined as the ability to resist fracture by absorbing mechanical energy (253–256). In general, toughness is an extremely complex phenomenon, depending on polymer composition (molar mass, chain flexibility, chain-entanglement density), surface energy, density, crystallinity, modulus, and yield strength as well as on testing conditions (specimen geometry and dimensions, mode of loading, strain rate, temperature, presence of notches, etc.). Only parameters based on fracture mechanics can separate the effects of testing conditions from the effects of intrinsic material properties. Relevant material characteristics can be derived from either the energy balance approach or the stress intensity approach. Linear elastic fracture mechanics (LEFM), which is appropriate for (semi)brittle materials, operates with the strain energy release rate and the stress intensity factor. Nonlinear fracture mechanics (257,258) developed for ductile materials—including toughened polymers and blends—has introduced the J-integral fracture toughness, which can be

considered as a nonlinear elastic energy release rate. A widely used method is that of the essential work of fracture (EWF), which is a material property related to the J-integral (255). Despite an enormous amount of empirical knowledge gathered so far, there are no quantitative means for anticipating the toughness of new materials.

Amorphous glassy polymers show two types of localized deformation mechanisms, ie, crazing and shear yielding (256,259–261). A craze can be described as a microcrack bridged by polymer fibrils (5 – 20 nm in diameter) partially bearing the load. Crazes initiated by pre-existing defects or flaws typically develop in a plane perpendicular to a maximum principal stress in polymers, whose crazing stress is lower than yield stress (under the conditions of testing) (262–264). Crazing involves formation of microvoids that account for an increase in volume. Crazes grow through drawing of fibrils formed from the bulk polymer, and at the final stage give rise to cracks at a stress below that necessary to cause bulk shear yielding. The energy absorption per unit volume is relatively high within the craze deformation zone, but the amount of material involved in that absorption is very limited, so ensuing brittle fracture requires a very low mechanical energy. Brittle polymers have a low crack initiation energy (unnotched toughness) as well as a low crack propagation energy (notched toughness) (265). Brittle fracture is typical of PS, SAN, PMMA and highly crosslinked glassy polymers (256,259,260).

Shear yielding involves localized or homogeneous plastic deformation occurring without any volume change. A number of glassy polymers possess some degree of ductility (at room temperature) at moderate rates of straining, eg, polycarbonate (PC), polysulfone, and polyethersulfone (260). Ductile fracture requires sufficient molecular (segmental) mobility for shear yielding (plastic flow) to occur. Yielding localized in planar zones with high shear strains gives rise to "shear bands" at an angle of about 45° to the acting force, ie, in the direction of maximum shear stress. The strain hardening due to chain orientation eventually imposes a limit of the achievable plastic deformation. Ductile behavior is favored by uniaxial stress conditions, low strain rates, elevated temperature and smaller specimen cross-section (256,260). Ductile polymers have high crack initiation energy and low crack propagation energy (265,266). The transition between crazing and shear yielding is mainly predetermined by the entanglement and/or crosslinking density, because an increasing network density hampers the void formation in the process of crazing. Thus, the craze initiation stress is lower than the shear band initiation stress, and crazing prevails in polymers with a network density lower than a critical value. Shear yielding is typical of highly entangled thermoplastics with flexible chains.

In semicrystalline polymers, the main energy-absorbing mechanism is shear yielding (261,267,268). Local crazing may take place as a part of the fracture process ahead of a running crack without being an important energy-absorbing mechanism. Semicrystalline polymers usually have high toughness at temperatures above their T_g. Their toughness decreases with increasing crystallinity and perfection of the crystallites because shear yielding is impeded. Rising spherulite size has negative effects on toughness because larger defects and voids are created, and cracks propagate more easily along the interfaces between coarser spherulites. Higher molar mass accounts for the enhanced number of tie molecules between crystallites and spherulites, which improve the fracture resistance (260).

Molecular mobility, crazing, and shear yielding are thermally activated rate processes that follow the Eyring equation (256,264). For this reason, all plastics are brittle under extreme testing conditions (low temperatures and high strain rates permit only crazing because the yield stress is higher than the craze initiation stress). The brittle/ductile transition temperature $T_{b/d}$ of a polymer means that at $T < T_{b/d}$ the fracture is brittle, while at $T > T_{b/d}$ the fracture is ductile. The transition is a consequence of the fact that the yield strength decreases faster with rising temperature than the brittle strength so that yielding starts to be a dominating deformation mechanism at $T > T_{b/d}$. This temperature, which is of major engineering importance, always lies below T_g. However, it increases with the strain rate, crosslinking density, presence of notches, etc. (264).

Advanced characterization of the fracture processes in polymers and their blends is provided by the methods of fracture mechanics. Comprehensive reviews of this topic can be found in References 253, 255–259. Despite the achieved progress in this field, the plastics industry traditionally employs standard empirical tests for evaluating toughness (259,269). The Charpy or Izod impact test and falling-weight impact tests are widely used, although they provide only a semiquantitative basis for selection of materials. The impact resistance is a measure of the ability of a material to withstand the application of a sudden load without failure (259); however, it is not a material property because it depends on testing method and conditions, specimen geometry, and other factors. The obtained values are suitable for simple ranking of available materials or for evaluation of achieved improvements in material formulations. It should be noted that it is extremely difficult to correlate the impact strength found for a type of specimen with the impact performance of the manufactured article (260). In practice, it is advisable to select a method and testing conditions resembling the service conditions. Instrumented impact devices, which register the load-displacement curves in the course of impact, provide a deeper insight into the fracture mechanisms.

Toughening of rigid polymers consists of the involvement of their large fractions in energy absorption processes. To achieve this goal, a suitable amount of rubbery particles (of proper size, modulus, crosslinking density, and interfacial adhesion) is to be evenly dispersed in the brittle matrix to function as stress concentrators and to initiate multiple energy-absorbing plastic microdeformations. A good dispersal of rubbery component and formation of an optimum size of particles are often aided by suitable compatibilization. During initial deformation, cavitation (formation of voids of the order of 10 nm) occurs within or around the rubber particles, which triggers either multiple crazing, in polymers prone to crazing, or shear deformations (bands) in shear-yielding matrices (256). Cavitation is an essential step in the toughening process because it relieves the triaxial tension built up in the proximity of the crack tip. After cavitation, only biaxial tension remains, which is more favorable to shear yielding. A spectacular upswing in the toughness occurs at a certain rubber volume fraction, which indicates a percolation character of the underlying process. In this way, the toughness can routinely exceed by 1–2 orders of magnitude the value characterizing a neat rigid matrix (Fig. 18, curve a). However, in practice there is always a need to balance fracture resistance against other properties, eg, stiffness, resistance to creep, and dimensional stability.

As the optimum fraction of the rubber component is rather low (0.05–0.30), the term “rubber-toughened polymers” (instead of “blends”) is commonly used.

Almost any engineering plastic can be made tougher in its rubber-modified version, but at the expense of modulus and yield strength. Although the mechanism of plastic deformation in such materials depends on the properties of matrix (molecular weight, crystallinity, entanglement density, cohesive energy), dispersed rubber (modulus, cohesive energy, particle size, crosslinking), and adopted test conditions (test specimen dimensions, test speed, test temperature, notch dimensions), the fracture resistance of toughened polymers is primarily derived from the deformation and failure behavior of the rigid matrix, where most of the mechanical energy is absorbed via multiple crazing and/or shear yielding during straining and fracture. Semicrystalline polymers usually fracture in a ductile manner due to high resistance to crack initiation; however, in the presence of a sharp defect (notch) they show brittle fracture, because their resistance to crack propagation is low (255). For this reason, impact resistance of the notched test specimens is an important criterion of the achieved toughening. The quantitative theory of toughening based on the energy balance model (270) correctly predicts trends in the deformation and fracture behavior of toughened plastics with various structures. However, due to extreme complexity of the toughening phenomenon, there has been no format for the prediction of fracture resistance of rubber-modified plastics to date.

Rubber particle cavitation and subsequent multiple matrix crazing is the dominant mechanism of toughening in rubber-modified brittle matrices such as HIPS, SAN, PMMA, and ABS polymer (260,271,272). In less brittle matrices, such as SAN and PMMA, mixed crazing and shear yielding can occur (265). In the beginning, application of external stress causes the biggest rubber particles to cavitate and initiate the first series of crazes, which grow by increasing their area and thickness. The rising deformation initiates secondary cavitation of smaller rubber particles and further crazing. Thus, crazes lying close to a craze plane begin to connect together; a rapid craze thickening follows, involving the drawing of fresh polymer from the walls of rising crazes. The latter stage can be identified with an effective energy-consuming process. Fibrillation occurs in an increasing fraction of rubber particles, which stretch in parallel with the crazes up to a saturation point. The rupture of a blend deformed by multiple crazing is assumed to be associated with failure in the fibrillated rubber particles when the local tensile strain exceeds their limiting value. The light scattering from microvoids formed in the matrix crazes and/or in the rubber particle cavities accounts for the stress whitening (273).

In HIPS, where the "salami" rubber particles consist of hard polystyrene subinclusions embedded in the matrix of crosslinked rubber, a specific type of cavitation was revealed (256). Cavitation in the rubber "membranes" results in a craze-like structure where rubber fibrils form bridges between the PS subinclusions and between the subinclusions and the PS matrix. Yielding in the matrix allows the rubber fibrils to stretch and the rubber particles to expand until strain hardening stops the process. PVC and poly (oxymethylene) (POM) also show very high values of the notched Izod toughness when the incorporated rubber forms an intermeshed (network) structure (265) instead of discrete particles. A higher effectivity of intermeshed rubber phase morphology was ascribed to a lower percolation threshold in comparison with that for an assembly of spherical particles. The toughening mechanism of ABS consists in the formation of numerous shear

bands in addition to massive crazing (259). A similar effect can be produced in SAN by bimodal-sized rubber particles (265).

Shear yielding is the process by which most intrinsically ductile polymers achieve high strains. The incorporation of a rubbery component still enhances the toughness so that supertough materials can be produced (260,265,274), but the main purpose of the modification is to improve the resistance to crack propagation (notch sensitivity) (259). The high stress concentrations generated in the matrix by rubber particles bring about a spectacular rise in the rate of plastic deformation, because the adjacent matrix is free to yield and stretch in the way that was not possible in the neat matrix. The main factors controlling the shear yield stress of toughened plastics are the yield behavior of the rigid matrix and the volume fraction, shear modulus, and particle size of the dispersed rubber. Essential gains in toughness are achieved only when the cohesive failure within the rubber particles induces accelerated shear yielding in the matrix, which is then followed by strain hardening of the yield zone due to stretching of both rubber and rigid matrix. In this plastic deformation process, chain segments slip past each other, so that the material in the yield zone changes its shape, while only minor changes in density are due to disturbed molecular packing. Yielding localized in planar zones with high shear strains gives rise to pronounced shear bands; strain hardening due to the chain orientation eventually imposes a limit of the achievable plastic deformation. Toughening is particularly effective in the case of an array of closely spaced rubber particles, which assures that the ligaments between particles become fully yielded (256). The maximum degree of macroscopic toughness can be achieved if the local ligament thickness (surface-to-surface interparticle distance) decreases below its critical value (261,266), which is related to the experimental finding that brittle polymers become ductile below a critical specimen thickness (less than 1 μm). The critical ligament thickness is characteristic of the matrix for a given loading mode, temperature, and rate of deformation (266).

Toughness of semicrystalline polymers is enhanced by means of techniques similar to those developed for glassy polymers (260,267,275). Rubbery particles usually initiate both massive crazing and shear banding, which depend on blend composition, morphology, rubber particle size, and interfacial adhesion. An additional positive effect of the rubber component may consist in that its nucleating effect leads to finer spherulitic structure, thus improving the inherent toughness of the crystalline phase. Specific nucleating agents can markedly increase the toughness of the PP matrix by modifying crystalline structure and increasing the concentration of tie molecules (276,277).

Because of profound differences in the deformation and fracture behavior of polymer matrices, the optimum size of toughening rubber particles depends on the inherent fracture mechanism of a matrix. On the other hand, these optimum dimensions are affected by some properties of the rubber used, eg, modulus, viscosity, and crosslinking density. Rubber particles of improper size are ineffective in the toughening process. The existence of a minimum particle size for efficient toughening corresponds to the minimum particle size required for cavitation (256). Extensive experimental work has established that the particle size of a toughener should lie within an optimum range. The optimum diameter of rubber particles for efficient toughening of brittle glassy polymers tending to craze decreases with their entanglement density; the values reported (265) for PS, SAN, and PMMA

are 2.5, 0.75, and 0.25 μm, respectively. On the other hand, matrices absorbing fracture energy via shear yielding (polycarbonate, polyamides, PET, PBT, PVC) are commonly toughened with particles of 0.5 μm or less, eg, 0.2–0.3 μm for polyamides, added in the amounts necessary for the critical interparticle distance. The critical ligament thickness in a matrix depends on temperature, strain rate, loading mode, and other factors (265). Thermoset resins are routinely toughened by liquid carboxy-terminated butadiene rubbers (CTBN) dissolved in the resin mixture, and after curing, form separate domains 0.2 – 0.5 μm in diameter (253).

A fine dispersion of rubber in a polymer matrix is facilitated by a low interfacial tension between blended components in the molten state. Under these conditions, the rubber particles may not be well bonded to the matrix for efficient stress transfer (54). At any rate, the final particle size strongly depends on the rubber relative viscosity and blending conditions. The goal of concurrently optimizing dispersion and adhesion of a rubbery modifier is rather difficult to achieve. An elegant solution is offered by core-shell impact modifiers with a well-defined size and a narrow particle-size distribution (278). A major advantage of core-shell particles is that their size is set during their synthesis (emulsion polymerization) and remains the same after the dispersal in a host matrix. A soft core, made up of a rubbery polymer, is surrounded by a shell of grafted rigid polymer. The core of the particles provides the soft component that induces toughening mechanisms. The shell of a much higher T_g than the core has two primary functions: (i) to facilitate isolation of the particles from emulsion and to keep the cores from adhering to one another; (ii) to act as the interlayer binding the matrix to the core. Core-shell particles of acrylate rubber-PMMA, polybutadiene-PMMA, or polybutadiene-SAN are used for PA, PET, and PBT; ABS core-shell materials are effective in toughening PBT and PC. The amount of incorporated modifier particles varies from 5 to 30% by weight of the matrix.

A key factor in the performance of core-shell particles as impact modifiers is their adhesion to the host matrix, determined by the composition of both shell and matrix (278). If the latter polymers are compatible (miscible or partly miscible), the toughener will be effective. However, in most cases, the matrix and shell consist of dissimilar polymers. Also in this situation, solubilization of the matrix polymer into the grafted shell needs to be ensured to develop proper interfacial adhesion. High degrees of solubilization are favored by negative values of the interaction energy density, high molecular weight of the shell relative to the matrix, and a low shell thickness. If the matrix and shell are highly incompatible, introduction of a suitable compatibilizer can enhance the efficiency of core-shell impact modifiers. Alternatively, the matrix/shell adhesion can be enhanced by employing possible reactions between functional groups introduced in the shell and reactive sites of the matrix. Recent advances in polymerization techniques permit synthesis of various types of modified polyolefins (279), eg, polypropylene toughened with evenly distributed particles of ethylene-propylene rubber bound to the matrix.

The transition of dispersed particles from the rubbery to glassy state defines the lowest temperature at which the incorporated rubber is able to reduce the matrix yield stress and account for significant toughening (280,281). The effect of added rubber usually fades away at temperatures 10–20 K above its T_g, which is manifested as a sharp drop in the fracture energy (256). An equation was derived for the brittle-ductile transition temperature as a function of the particle

volume fraction, size, distribution, and matrix ligament thickness (282). However, this critical temperature is also affected by testing conditions. In proportion to their fraction, rubbery impact modifiers reduce the modulus and yield strength of toughened polymers as quantified by equations 18b and 22, respectively.

Impact resistance of ductile polymers was also improved by blending with 5–15% of a brittle component, eg, polycarbonate with SAN (283) or polyamide 6 with poly(styrene-*co*-maleic anhydride) (SMA) (284). Although the enhancement of impact resistance is lower than in the ductile matrix/rubber systems, the advantage of rigid particles is a simultaneous increase in toughness and stiffness. To achieve these effects, brittle inclusions should be small and interfacial adhesion should be high. Then, the brittle inclusions having a sufficiently higher modulus and a lower Poisson's ratio than the matrix become ductile under the action of the compressive component of stress (285,286) and absorb mechanical energy. To prevent formation of a co-continuous brittle component at higher volume fractions, it is convenient to add two brittle and incompatible minority components. To achieve their separate dispersion, the surface energy of one minority component should be higher than that of the matrix, while the reverse relation holds for the other minority component (242). Ternary blends of polyamide 6 containing rigid particles of SMA (about 5%) and particles of maleated ethylene-propylene rubber (about 5%) are an example of blends with balanced mechanical properties (286,287). In these blends, the losses in stiffness and tensile strength caused by rubbery component are (more than) compensated by the action of the brittle component, while both minority components contribute to the toughness enhancement.

Recently, specific conditions have been elucidated under which isometric filler particles (calcium carbonate) can account for a considerable toughening of PE (288) and PP (289). The notched Izod impact energy of PE/$CaCO_3$ materials rose by one order of magnitude when the mean interparticle ligament thickness of the PE matrix dropped to values below 0.6 μm. Under these conditions, the stiff filler brought about a substantial increase in both the modulus and toughness. The achieved improvements of the toughness of PP/$CaCO_3$ were smaller, while polyamide 6/$CaCO_3$ (290) showed brittle behavior, probably due to a high plastic resistance of the matrix. In all cases, dispersal of fine filler particles and elimination of their agglomerates were critical for enhancing the toughness.

Rheological Properties of Molten Blends. The dependence of shear viscosity, first normal stress difference or storage modulus on blend composition varies very substantially from system to system. According to the type of relation between the logarithm of viscosity and concentration, blends were classified into four categories (291–293). Additive blends fulfill the log-additivity rule:

$$\log\eta = \sum_i v_i \log \eta_i \tag{24}$$

where v_i and η_i denote, respectively, volume fraction and viscosity of the component i. Other categories are blends showing a positive deviation from log-additivity, blends with a negative deviation, and blends where both the positive and negative deviation have been observed. Because polymer blends are non-Newtonian liquids with η dependent on $\dot{\gamma}$, dependences of η on the blend composition determined at a constant shear rate and at a constant shear stress can be different. Dependences

at a constant stress are more plausible, because the stress is continuous at the interface in contrast with the deformation rate. Different types of the dependence of η on v at different shear stresses were found for some systems (291). Therefore, the above classification does not characterize polymer pairs only, but it is also a function of flow conditions. Dependences of the first normal stress difference and storage modulus on blend composition are similar to those for viscosity (291).

Generally, there is interrelation between rheological properties and morphology of flowing blends. Therefore, the morphology must be assumed in calculation of rheological properties or both characteristics must be calculated simultaneously. Great attention has been paid to the development of the theory of viscosity for blends containing a small amount of a dispersed component (96,291,292). A number of expressions for viscosity were derived using various approximations for these blends. For blends containing a very small volume fraction, v, of Newtonian droplets in the Newtonian matrix, the following equation was derived for $C_a \ll 1$.

$$\eta = \eta_m\left(1 + \frac{5p+2}{2p+2}v\right) \tag{25}$$

Equations considering somewhat higher contents of dispersed droplets, higher C_a and viscoelasticity of the components were derived. Also, these expressions predict for blends containing dispersed droplets that viscosity of a blend is higher than that of its matrix also for $p \ll 1$. This is a general feature of all theories describing rheological properties of dispersed droplets in matrix and assuming stick condition at the interface.

The Palierne model (294,295) describes a linear viscoelastic response of a dispersion of droplets that are spherical in stress-free state. The model may account for viscoelastic properties of both matrix and droplets, effects of finite concentration, distribution of size and composition of the droplets, and interfacial tension effects (also for compatibilized blends). The agreement of its predictions with experimental results is good (295). Description of rheological properties of blends with co-continuous structure is more complicated. In this case, it is useful to characterize the interface. The interfacial area per unit volume Q and specific anisotropy tensor q, characterizing anisotropy of the microstructure are used as proper characteristics for blends with a general shape of the interface (96). Development of theories for prediction of time evolution of Q and q and average stress tensor, which would serve for prediction of rheological properties, is in progress (96).

A reasonable explanation of negative deviation of η from log-additivity rule (eq. 24) was proposed by Utracki (293). It is assumed that the interlayer slip at the interface should be considered in immiscible polymer blends. A semiempirical theory considering the emulsion behavior and interlayer slip factor can predict all the above-mentioned categories of blend behavior with respect to log-additivity rule depending upon the system parameters. More recently, the origin of the slip at the interface was discussed in more detail (296). Suppression of the slip at the interface by the presence of a compatibilizer can explain the typically observed higher viscosity of compatibilized blends than that of the related blends without compatibilizer (297). Most polymer blends have the dependence of shear viscosity on the shear rate similar to that of homopolymers only with a somewhat shorter

Newtonian plateaus due to the effect of the interface (291,295). In contrast, dynamically vulcanized blends show yield stress, ie, a strong increase in η with decreasing shear rate in the region of low $\dot{\gamma}$ (298–300). It seems that the yield stress is induced by long-living entanglements between crosslinked domains of characteristic size of about 1 μm.

Permeability of Blends to Gases and Vapors. The permeation of gases, vapors, and liquids through films (layers, walls) of blends is of primary importance in many applications (packaging, pipes, tanks, etc.). The permeability of polymers is mainly determined by their polarity and crystallinity. Polyolefins are good barriers to moisture, but are highly permeable to hydrocarbons. On the other hand, aliphatic polyamides have outstanding resistance to hydrocarbons, but poor resistance to moisture. Thus, there are many reasons for blending various polymers to tailor materials with balanced and acceptable physical properties (301).

For a miscible polymer pair, the blend permeability P_b was empirically found to approximately obey the semilogarithmic additivity rule (302):

$$1nP_b = \nu_1 1nP_1 + \nu_2 1nP_2 \tag{26}$$

where P_1 and P_2 are the permeabilities of components. In the free volume approach (303,304), it is assumed that the free volume of the mixture consists of the additive contributions from each component, which leads to the following equation:

$$\ln(P_b/Q) = [\nu_1/\ln(P_1/Q) + \nu_2/\ln(P_2/Q)]^{-1} \tag{27}$$

where Q is a characteristic constant for the gas. The transport through blends consisting of miscible polymers is comprehensively reviewed in References 301–303.

Heterogeneous blends of immiscible or partially miscible polymers are much more important engineering materials than homogeneous blends. The permeability of blends consisting of a continuous matrix and dispersed particles of another polymer can be approximated by models developed for particulate systems (301,302). However, these models (assuming dispersed components in the form of spheres, cylinders, cubes, lamellar structures of random orientation, etc.) were found inadequate for the prediction of the blend permeability throughout the composition range (225,305–307), a part of which necessarily corresponds to blends with co-continuous components. Thus, the EBM (Fig. 19) combined with the percolation approach was found (301) to be the most convenient predictive model for the permeability of heterogeneous blends. The permeability of binary blends consisting of partially continuous components can be predicted (223,230,308) using the format formally analogous to that for tensile modulus given in the previous section on mechanical properties (Fig. 18, curve d):

$$P_b = (P_1 v_{1p} + P_2 v_{2p}) + v_s^2/[(v_{1s}/P_1) + (v_{2s}/P_2)] \tag{28}$$

The data are usually presented as the relative permeability $P_{br} = P_b/P_1$ (relative to the component 1 with a lower permeability) versus blend composition. The "basic" curve calculated for $v_{1cr} = v_{2cr} = 0.16$ and $q = 1.8$ by means of equations

14 and 28 may deviate from experimental data if component 2 with a higher permeability, which controls P_{br}, is characterized by v_{2cr} different from 0.16. *Vice versa*, it is possible to evaluate realistic values of v_{1cr} and v_{2cr} in individual series of blends by fitting experimental data. For blends consisting of components that differ by 2–4 orders of magnitude in their permeability, the semilogarithmic plot is more instructive (308); moreover, it indicates v_{2cr} as a break (discontinuity), so that v_{2cr} can be adjusted with an accuracy of about 0.01. In this way, the format becomes an efficient tool for the analysis of the phase structure of polymer blends. In marginal regions $0 < v_1 < v_{1cr}$ (or $0 < v_2 < v_{2cr}$), simplified relations can be used for the EBM, ie, $v_{1p} = 0$, $v_{1s} = v_1$ (or $v_{2p} = 0$, $v_{2s} = v_2$), to obtain an approximate prediction of permeability. The permeability of layered materials can be modeled as the series coupling of components.

The outlined format was found to match up well the permeability of a number of permeant-blend systems, eg, water–HDPE/LDPE, toluene–HDPE/polyamide 6, methanol–polyethylene/silicone rubber, oxygen–PVC/chlorinated PE (230); oxygen–PMMA/siloxane copolymer, oxygen–PE/poly (vinylidene chloride), oxygen–poly(ethylene-*co*-vinyl alcohol)/poly(ethylene-*co*-vinyl acetate) (308). The agreement with experimental data was very good throughout the composition range. Moreover, the format is suitable for simultaneous prediction or fitting of several physical properties, such as modulus and permeability (246) or modulus, tensile strength, and permeability (223).

Commercially Important Polymer Blends

There are three practical reasons for blending of polymers: (i) developing materials with desired properties, (ii) extending performance of expensive polymers by diluting it with a low cost polymer and (iii) utilizing plastic scrap by mechanical recycling. It is estimated that about one third of all commercially produced polymer materials are blends of two or more polymers. These multicomponent and largely multiphase materials show various combinations of properties unattainable in any one polymer alone. Major concern is focused on increasing impact strength, processability, tensile strength, stiffness, and heat resistance (309). It should be emphasized that an improvement in one property leads usually to deterioration of another property, and therefore the main efforts have been devoted to attaining well balanced properties of the final material required for the pertinent applications. Commercially produced polymer blends are the subject of several excellent monographs (1,55,56,310–312). Thus, only several examples of technically important polymer blends prepared by different compatibilization procedures are briefly presented in this chapter together with basic information on the recycling of mixed plastic waste.

High Impact Polystyrene (HIPS). Polystyrene shows excellent processability, good appearance, tensile strength, and thermal and electrical characteristics; however, its brittleness considerably limits its use in high performance products. Therefore, modification of its toughness made possible rapid growth of high impact polystyrene grades (60,272,313). Polystyrene whose impact strength is modified by the incorporation of rubber can be manufactured either by

mechanical blending of components under controlled conditions or by grafting of the polymerizing styrene onto the rubber.

Mechanical blending of PS with PB is not very effective, and in its classic form is a matter of the past. Blending technology is still used for modification of polystyrenes with special rubber components such as thermoplastic elastomers, eg, SBS or SEBS. HIPS is also sometimes blended with styrene homopolymer to yield material with reduced cost but intermediate properties still acceptable for some applications.

At the present time, HIPS is produced by polymerization of styrene containing 5–10% of dissolved polybutadiene. The process yields both the styrene homopolymer and the polybutadiene-*graft*-polystyrene, where PS side chains are grafted onto the main polybutadiene chain. The process can be carried out technologically as mass (bulk) polymerization or as a mass suspension process, either batchwise or continuously. It is initiated thermally or by suitable initiator (such as dibenzoyl peroxide). As conversion reaches 2–3%, phase separation occurs as a result of immiscibility of PS and PB. The system forms so called polymeric oil-in-oil emulsion, in which the dispersed phase is a solution of PS in styrene, and the continuous phase is a solution of PB in styrene. Grafted copolymer is formed at the interface and acts as an emulsion stabilizer. As the volume ratio of PS and PB in styrene approaches one, and the mixture is subjected to sufficiently strong shearing agitation—phase inversion takes place. Sufficient agitation of the reaction mixture in the phase inversion region is essential for morphology control of the final polymer blend. Particles of newly formed dispersed phase still contain permanently included residues of the original dispersed styrene phase as isolated particles. The presence of polystyrene subinclusions in polybutadiene particles is characteristic of HIPS, increasing its impact strength due to an increase in the "effective volume" of the PB phase. Near the completion of polymerization, crosslinking of the rubber component takes place. Rubber crosslinking must be sufficient to prevent disintegration during processing.

The HIPS performance is controlled by the amount and type of rubber, particle size distribution, rubber-phase volume, degree of grafting and crosslinking, as well as by molecular characteristics of the PS matrix. Most HIPS grades contain 5–7% of rubber, which covers the total volume fraction from 20 to 30%. For optimum toughening, the rubber particles of several micrometers are required. For good surface appearance a bimodal particle size distribution of rubber phase (eg, 2 and 0.2 μm) is desirable. The presence of rubber phase in the PS matrix substantially improves not only impact strength but affects also other properties compared with styrene homopolymer. Thus elasticity modulus, tensile strength, and hardness somewhat decrease while elongation and melt viscosity increase. All things considered, HIPS shows balanced complex end-use properties, which is advantageous in a broad application sphere.

HIPS is currently processed by procedures such as injection molding, extrusion, blow-molding, and thermoforming. HIPS properties can be further modified by incorporation of special additives such as flame retardants, stabilizers, antistatic agents, etc. The main production fraction of HIPS is consumed in the manufacture of packaging materials, technical products, toys, and various consumer goods.

Acrylonitrile-Butadiene-Styrene Polymer. The name acrylonitrile–butadiene–styrene (ABS) polymer is reserved for a family of thermoplastics with the SAN matrix containing dispersed elastomer particles.The oldest approach to the ABS preparation, similarly as in the case of HIPS, is mechanical blending of individual components. At present the graft polymerization of a mixture of styrene with acrylonitrile in the presence of a suitable rubber component is the current process of ABS polymer manufacture. Most producers employ some form of emulsion technology, but the mass or mass-emulsion polymerization is also technologically feasible (60,272).

Common types of ABS have an average composition of 21–27% acrylonitrile, 12–25% butadiene, and 54–63% styrene. The styrene component contributes good processability and stiffness to the final ABS, butadiene increases the impact strength, and acrylonitrile improves chemical and heat deformation resistance. The two-phase system where rubber particles are dispersed in the matrix of SAN shows a morphology similar to HIPS, but the particle size is smaller with fewer SAN subinclusions than those in HIPS. ABS polymer shows excellent toughness combined with good thermal and chemical resistance, high elastic modulus, and good appearance.

ABS can be processed by all common molding technologies. The main consumption of this polymer is for household appliances, automotive parts, business machine and telephone components, electrical devices, pipes and fittings, and leisure-time equipment.

Poly(2,6-dimethyl-1,4 phenylene oxide)/High Impact Polystyrene (PPO/HIPS). Poly (phenylene oxide) is a polymer with high heat deformation resistance, excellent electrical properties, and high resistance to acids and bases. Because of high melt viscosity, PPO is blended with styrene polymers to achieve rheological properties necessary for processing by current technologies. Improvement in PPO toughness is obtained simultaneously with viscosity decrease if HIPS is used as a modifier. Rubber particles distributed uniformly throughout the new matrix are responsible for an increase in toughness, and polystyrene improves its processability. Unlimited PPO/PS miscibility enables preparation of blends of broad composition scale with well-balanced end-use properties. For high performance applications in electrotechnical and automotive industries, high impact blends of PPO with ABS, PA, or PC are manufactured.

Polypropylene/Rubber. Polypropylene (PP) is a versatile polymer with good resistance to heat, chemicals and solvents, and good electrical properties. Other properties can be improved by compounding with various nonpolymeric additives as well as with polymers. Blending with elastomers and copolymerizing with other monomers are used for toughening of this polymer (314,315). Synthetic elastomers as EPM, SEBS, PIB, and natural rubber are incorporated into PP matrix by mechanical blending. Especially PP/EPM blends are of considerable practical importance. These blends with a low EPM content are used as high impact polypropylene, the blends with high content of this elastomer can be used as thermoplastic elastomers. Phase structure control of modified PP depends strongly on molecular characteristics of the matrix (crystallinity, crosslinked part etc.) and therefore it is relatively difficult to achieve the desired and sufficiently stabile blend morphology. The presence of rubber particles in PP matrix increases the

impact strength, but leads to lower tensile strength, stiffness, and heat deformation resistance. The set of end-use properties is convenient mainly for application in automotive industry.

Poly(vinylchloride)/Rubber. PVC is an important commodity polymer with good chemical resistance and low flammability. Without modification, however, it is not practically processable, and its mechanical properties and heat resistance are very poor. Therefore, various additives as lubricants, stabilizers, and impact modifiers are incorporated to PVC grains to obtain versatile polymer.

To achieve good toughness, required for many applications, impact modifiers are added to PVC. Chlorinated polyethylenes, ethylene-vinyl acetate copolymers, styrene-methyl methacrylate grafted elastomers, vinyl rubbers, and polyacrylates are the most frequently used (316). These polymers are blended together with other additives. Blending conditions are extraordinarly important for morphology control and consequently for final properties of the blends.

Most of high impact PVC blend production is consumed in civil engineering applications. Because of low price and ability to be properly modified, this oldest commercially produced polymer remains one of the most important synthetic materials.

Polyamide/Rubber Blends. The family of polyamides (PA) encompasses polymers with a variety of chemical compositions. A characteristic feature of these polymers is poor toughness at low temperature and/or in the presence of notches. Multi-year efforts to improve their toughness has resulted in numerous modification procedures (317). Most are based on melt blending of acid or anhydride-containing elastomers with PA. At present, producers of toughened PA typically use rubbers containing small amount of maleic anhydride (up to 2%). During blending, reactive compatibilization takes place. The maleic-anhydride groups react with amino groups of PA giving rise to graft copolymers at the interface. Saturated rubbers, eg, EPDM, SEBS, or BR are used. The obtained morphology shows the dispersed rubber particles of size between 0.001–0.1 μm. Compatibilization based on the reaction of anhydride and amino groups is also utilized for preparation of engineering materials as PA/PP, PA/ABS, or PA/PPO blends.

Polycarbonate Blends. Polycarbonates (PC) are classified as construction plastics because of their high heat deformation temperature, electric properties, and mechanical characteristics including impact strength. Similarly, as in the case of polyamides, they do not achieve the required toughness if notched or if exposed to low temperature. Therefore, polycarbonates are blended with ABS polymer to combine their properties with the toughness of ABS. No compatibilizer is needed in the blending of both the components as SAN and PC are partly miscible (313).

PC/ABS blends are materials with an excellent combination of end-use properties, improved processability and, moreover, an acceptable cost. A broad scale of PC/ABS types is used in the automotive industry and other engineering applications.

Recyclates of Polymers. Blending of polymers is an important aspect of the recycling technologies that aim to overcome the problem of separation (sorting) mixed polymeric waste into pure feedstock streams by direct processing of mixed materials with or without compatibilizers (318,319). Mechanical recycling of commingled plastic waste may be viewed as a compromise between conflicting

requirements. That is, sorting of the waste is expensive, but can give recyclates of higher quality; on the other hand, reprocessing of commingled plastics is relatively inexpensive, but the resulting product shows lower mechanical and aesthetic properties. In any case, under certain circumstances, the mechanical blending of mixed plastics waste can be advantageous from both the economical and ecological viewpoints.

For reprocessing of mixed plastics, either current processing machines or special machinery for manufacturing large profiles are used. The recyclates, called plastic lumber, suffer from inferior mechanical performance due to immiscibility, and thus poor adhesion of components. Moreover, the presence of heterogeneities and particulate contamination restricts application of the products. Therefore, commingled plastics are often processed into large profiles which can rather fulfill requirements for strength characteristics. For manufacture of such profiles, specific procedures have been developed. Thus, the intrusion process combines extrusion of mixed plastics with melt filling to a large mold without using screenpack or an extrusion nozzle (Klobbie process) (319). Continuous extrusion produces linear profiles with large cross-sections of molten polymer materials that are then extruded into cooled dies.

For more demanding applications, the commingled plastic wastes as well as partially sorted plastics mixture can be processed using compatibilizers. Recyclates with good mechanical properties as well as appearance have been reported. Thus, a mixture of polyolefins blended with organic peroxides or with a combination of peroxides and liquid PB gives materials of the same or higher impact resistance than the virgin HDPE (57). A mixture of polyolefins and styrene plastics blended with a multicomponent compatibilizer (combination of SB and EPDM copolymers) shows excellent impact strength and acceptable mechanical properties. Still better results have been obtained with a compatibilization system containing, besides copolymers, stabilizers based on aromatic amines. This combination shows even a synergistic effect (320). It seems that in case, the mixed polymers are not seriously damaged during their life cycle the compatibilization and restabilization can be an advantageous way of material recycling.

POLYMER VESICLES

Introduction

Vesicles (latin: *vesicula* = small bubble) are self-supported closed bilayer assemblies of several thousand amphiphiles that enclose an aqueous interior volume. The bilayer is a two-dimensional fluid composed of amphiphiles with their hydrophilic head groups exposed to the aqueous solutions and their hydrophobic tails aggregated to exclude water (Fig. 1). The bilayer structure is highly ordered yet dynamic because of the rapid lateral motion of the amphiphiles within the plane of each half of the bilayer.

Cells exploit bilayer structures to create anatomical boundaries, eg in the case of cell membranes which are composed of lipids, proteins, and carbohydrates. During the early 1960s researchers demonstrated that certain classes of lipids, especially phospholipids, could be used to form protein- and carbohydrate-free *model membranes*. Methods were developed for the preparation of supported bilayer lipid *membranes* (1), and it was discovered that dried thin films of phospholipids spontaneously hydrate to yield lipid *vesicles* (2). Vesicles have since then been used as model systems for fluid interfaces and biomembranes (3). Practical applications involving vesicles are in the area of cosmetics and pharmaceutics.

The term *liposome* is frequently interchanged with the term *vesicle* and is usually reserved for vesicles of glycerophospholipids or other natural lipids. *Lipids* (greek: *lipos* = fat) are amphiphiles consisting of two hydrophobic hydrocarbon chains and a polar hydrophilic head group. The most important classes of lipids are phospho- and glycolipids, which contain a phosphate group or a sugar group as head groups. Head groups may in general be ionic, zwitterionic, or dipolar. The typical chemical structures of phospho- and glycolipids are shown in Figure 2.

Since Bangham's 1960s description of lipid vesicles as *liposomes* (4), many other *somes* have been created such as *virosomes* by integrating a cell-binding HIV protein into liposomes (5), *niosomes* made from nonionic amphiphiles similar in size to lipids (6), *polymersomes* formed by amphiphilic block copolymers (7), *peptosomes* made of block copolymers containing polypeptide chains (8,9), and *novasomes*, multilamellar niosomes developed for topical and cosmetic application (10).

In recent years the number of studies on polymer vesicles or polymersomes has strongly increased after first reports by the groups of Eisenberg (11,12), and Bates and Discher (7,13). Since then, amphiphilic block copolymers, rod-coil polymers (14–16), dendrimers (17), and amphiphilic fullerene derivatives (18) have been reported to form vesicular structures. Vesicles can now be made from various polymers, from modified biological to wholly synthetic, from diblock, triblock,

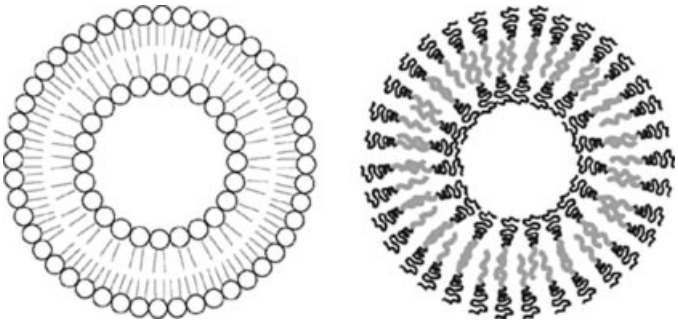

Fig. 1. Lipid and block copolymer vesicles with their typical bilayer structure.

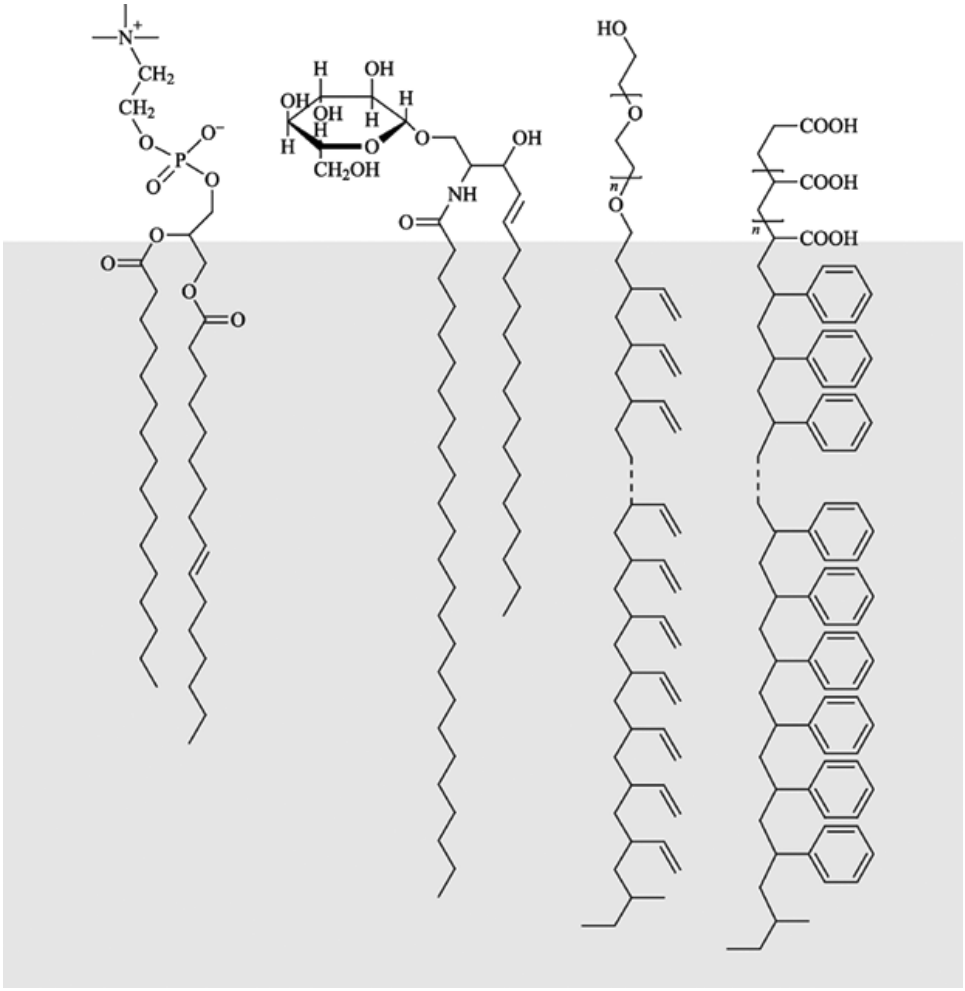

Fig. 2. Chemical structures of a typical phospholipid (phosphatidylcholine), a glycolipid (galactocerebroside), and two vesicle-forming block copolymers, poly(butadiene-*b*-ethylene oxide) and poly(styrene-*b*-acrylic acid.) The grey region indicates the hydrophobic interior of the bilayer.

multiblock, and even statistical copolymers in media ranging from complex to neat organics and water (19–21). A summary of vesicle-forming block copolymers is given in Table 1.

Bilayer and Vesicle Formation

The formation of vesicles can be viewed as a two-step self-assembly process where first the amphiphile forms a bilayer which in a second step closes to form a vesicle (Fig. 3). In the following we will first discuss conditions that lead to the formation of bilayers and then consider their closure to form vesicles.

Energy and Kinetic Aspects.

Thermodynamics of Bilayer Formation. The free energy of a bilayer is mainly determined by the interfacial energy F_{int} of the hydrophobic/hydrophilic interface and the repulsive energy F_{rep} of adjacent amphiphiles (96):

$$F = 2F_{\text{int}} + 2F_{\text{rep}} = 2\gamma a + \frac{2k}{a} = 4\gamma a_0 + \frac{2\gamma}{a}(a - a_0)^2 \tag{1}$$

where γ is the interfacial tension, k is a constant describing the repulsion between the hydrophilic part of the amphiphiles, and a is the interfacial area per amphiphile. The factors 2 arise from the contribution of the two monolayers of the bilayer. A further contribution arises from the elastic stretching energy for the molecules to fit into the planar assembly. The minimum free energy can be obtained by setting $\partial F/\partial a = 0$, which yields an equilibrium interfacial area per chain

$$a_0 = \sqrt{\frac{k}{\gamma}} \tag{2}$$

which allows to recast the expression for the free energy in equation 1 in terms of γ and a_0. The last term in equation 2 then corresponds to a harmonic potential with an area elasticity modulus γ/a, which will be considered in more detail below. Typical values for the interfacial area per chain are $a_0 \approx 0.5$ nm^2 for phospholipids and $a_0 \approx$ 1–50 nm^2 for block copolymers (37,46).

Closure to Vesicles. A flat bilayer disk has a rim energy $F_{\text{disk}} = 2\pi\gamma R_{\text{disk}}$ (Fig. 3), which can be prevented by bending and closing the bilayer to form a

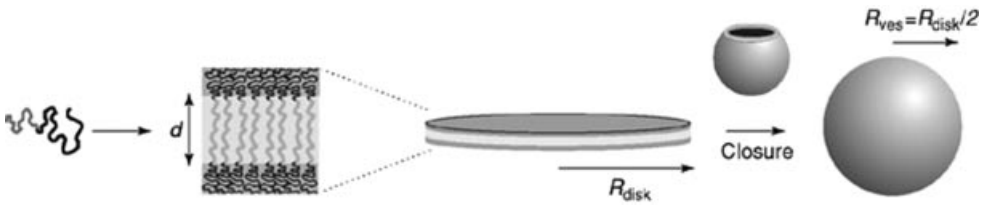

Fig. 3. Scheme of the formation of bilayers and their closure to form a vesicle. From Ref. 20, with permission from John Wiley & Sons, Inc.

Table 1. Overview of Vesicle-Forming Di- and Triblock Copolymers with Corresponding Solvents and Co-solvents

Polymer	Solvent	Co-solvent	Reference
Diblock copolymers			
Poly(dimethylsiloxane-*b*-ethylene oxide), PDMS-PEO	Water		22,23

vesicle. The corresponding bending energy is given by $F_{\mathrm{bend}} = 8\pi\kappa$ (eq. 9), where κ is the bending elastic constant. For a fixed bilayer area $A = \pi R^2{}_{\mathrm{disk}} = 4\pi R^2{}_{\mathrm{ves}}$, a flat bilayer will bend to form vesicles if $F_{\mathrm{bend}} < F_{\mathrm{disk}}$, or if the vesicle radius R_{ves} is larger than

$$R_{\mathrm{ves}} > R_{\mathrm{min}} \approx \frac{2\kappa}{\gamma} \tag{3}$$

The minimal vesicle radius R_{min} is increasing with increasing bending modulus and decreasing interfacial tension. Rigid amphiphiles with in-plane order have large bending moduli and therefore form large vesicles. In the case of fluorosurfactants the crystallinity of the bilayers leads to high values of the bending moduli such that rigid bilayer sheets are formed which are unable to bend into vesicles (97). At a given bending modulus an increase of the interfacial tension can induce a transition from planar bilayers to closed vesicles as has been shown for PS-PAA (39). If the interfacial tension is the dominant contribution to the free energy, the bending modulus is $\kappa \sim \gamma\, d^2$ (eq. 17), and the minimal radius is just dependent on the bilayer thickness $R_{\mathrm{min}} \sim d^2$.

Since the bending energy $F_{\mathrm{bend}} = 8\pi\kappa$ is independent of R, there is no distinguished equilibrium radius for $R_{\mathrm{ves}} > R_{\mathrm{min}}$. After preparation one mostly obtains polydisperse vesicle samples. The increase in translational entropy will slightly favor the formation of small vesicles. As will be outlined below, a control of the vesicle radius is possible by inducing an asymmetry between the outer and the inner monolayer.

Energy Scales. The interfacial energy is in nearly all cases the dominant contribution to the free energy. It is related to the interaction energy ε between the hydrophilic and hydrophobic domains, where typical values are $\varepsilon \approx 5$–10 kJ/mol ($\varepsilon \approx 2 - 4$ k_{B}T) per repeat unit, ie CH_2— or monomer. ε is related to the Flory-Huggins interaction parameter $\chi = z\varepsilon/k_{\mathrm{B}}\,T$, where z is the coordination number. For a typical value of $z = 6$ the interaction parameter is $\chi \approx 12$–24. The interfacial tension is given by $\gamma = \varepsilon/a$, which for $a \approx 0.5$ nm^2 has values in the range $\gamma \approx$ 17–34 mN/m ($\gamma \approx 4$–$8 k_{\mathrm{B}}$T/nm^2).

The key parameter for block copolymer thermodynamics is the segregation parameter $\chi\, N$, where $N = N_{\mathrm{A}} + N_{\mathrm{B}}$ is the degree of polymerization of the block copolymer given by the degrees of polymerization of block A and block B, N_{A} and N_{B}, respectively. Throughout the article, "A" will denote the hydrophobic block and "B" the hydrophilic block, respectively. The molar fraction of the hydrophilic block is given by $f = N_{\mathrm{B}}/N$. For typical values of $N \approx 10$–1000, the segregation parameter is $\chi N \gg 100$, which corresponds to the limit of strong segregation. The segregation parameter χN together with the relative block length f dictates the phase behavior of block copolymers, eg the formation of micelles (98), lyotropic phases (99,100) and bulk phases (101,102).

A characteristic parameter for amphiphiles is the critical micelle concentration (CMC), which is related to the interaction energy as $c_{\mathrm{CMC}} \sim \mathrm{e}^{-N\varepsilon/KT}$. The CMC corresponds to the number of free chains in equilibrium with micelles. For single chain surfactants, typical values are in the range of $c_{\mathrm{CMC}} \approx 10^{-2}$–$10^{-4}\,M$, whereas for double chain lipids typical values are in the range of $c_{\mathrm{CMC}} \approx 10^{-9}\,M$. For block copolymers the CMC is expected to be much smaller. Luo and co-workers

(123) estimated the fraction of free chains to be between 10^{-14} and 10^{-32} M depending on segregation strength. For most vesicle forming systems, the fraction of single free chains is negligibly small.

Exchange Kinetics and Freezing. There are two processes that lead to exchange of amphiphiles between micelles or vesicles (103):

(1) Exit/insertion of single free amphiphiles: This is the classical mechanism for low molecular weight surfactants; the exchange rate is practically independent of concentration
(2) Merger/splitting of two micelles or vesicles upon contact with exchange of amphiphiles: The exchange rate increases with concentration because the number of collisions is increasing

The exchange of amphiphiles for both processes is a thermally activated process. As such, the average exchange time (residence time in a micelle or vesicle) is of the order $\tau \sim e^{N\varepsilon/kT}$. With increasing interaction energy ε or interfacial tension γ, and as the alkyl or polymer chain becomes longer, the exit rate of a chain becomes appreciably lower. Exchange times for single chain surfactants are $\tau \approx 10^{-5}$–10^{-3} s, whereas typical values for lipids are $\tau \approx 10^5$ s, ie of the order of several hours to days. For polymeric amphiphiles the exchange times are still orders of magnitude larger.

The small fraction of single free chains together with slow exchange kinetics essentially freezes the exchange process. A sufficiently fast exchange of amphiphiles is, however, necessary to sustain thermodynamic equilibrium. Therefore vesicles, once formed, are in a metastable, trapped, or quenched thermodynamic state. The number of amphiphiles and therefore their bilayer area is essentially constant on timescales of most experiments. An extreme case is glassy polymers with very slow lateral mobility which can even impede shape changes of polymer vesicles ("frozen" vesicles).

The presence of co-solvents can fluidize and activate polymer exchange rates. The influence of solvent composition on vesicle exchange kinetics has been investigated for PS-PAA in DMF/water mixtures (30). When the water content was <6.5 wt%, the formation of the aggregates was reversible. When the water content was >7.5 wt%, the morphology of the aggregates depended on the method of sample preparation and the morphological reversibility decreased significantly. Shape transitions such as spheres → cylinders → bilayers were not achievable within a period of several days. The kinetics could be accelerated by increasing the efficiency of adhesive collisions through addition of ions or increase of the polymer concentration.

Packing and Geometry.

Packing parameter and Curvature. An important factor determining the shape of self-assembled amphiphilic structures is the size of the hydrophobic part of the amphiphile relative to the hydrophilic part. The shape can be parameterized in terms of the packing parameter Δ, which is given by

$$\Delta = \frac{v}{al_c} = 1 - Hl_c + \frac{Kl_c^2}{3} \tag{4}$$

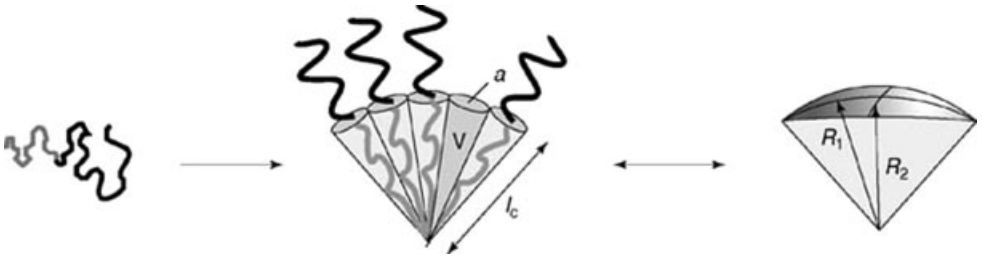

Fig. 4. Packing of amphiphiles at curved interfaces. The volume v, the surface area a, and the chain length l_c determine the interfacial curvature, which is characterized by the two principal radii R_1 and R_2.

where v is the volume of the hydrophobic chain, l_c is the contour length of the hydrophobic chain, and a is the interfacial area, as shown in Figure 4. The packing parameter is related to the curvature of the hydrophobic/hydrophilic interface as described by its mean curvature H and its Gaussian curvature K (104,105), which are given by the two principal radii of curvature, R_1 and R_2

$$H = \frac{1}{2}\left(\frac{1}{R_1} + \frac{1}{R_2}\right)$$
$$K = \frac{1}{R_1 R_2} \tag{5}$$

The simplest shapes are spheres, cylinders, and bilayers which have values of the packing parameter and curvature as shown in Table 2.

Conditions for Bilayer Formation. In order to obtain bilayers or vesicles for an amphiphile of length l_c, one needs to adjust the interfacial area until the surfactant parameter Δ approaches unity. With the optimum head group area a_0 from equation 2 and the definition of the packing parameter (eq. 4), one obtains a simple expression that can serve to rationalize the influence of different parameters on the packing parameter

$$\Delta \sim \frac{\gamma^{1/2} v}{k^{1/2} l_c} \tag{6}$$

Thus, for fixed length l_c, the packing parameter can be increased by

(1) increasing the interfacial tension γ, eg by working in aqueous solutions or adding water to organic solvents;

Table 2. Values for the Packing Parameter, the Principal Radii of Curvature, Mean and Gaussian Curvature for Different Amphiphile Aggregate Shapes

Shape	Δ	R_1	R_2	H	K
Sphere	1/3	R	R	$1/R$	$1/R^2$

$v \uparrow$	Core-swelling, screening of PAA	PS-PAA; Dioxane, THF, DMF	38,117

(2) decreasing the chain repulsion, k, eg by decreasing the hydrophilic block length (decreasing hydrophilic fraction f), screening of electrostatic repulsion via the addition of ions, or screening adjacent chain repulsion by increasing the polymer concentration;

(3) increasing the volume, v, eg by swelling with organic solvents.

By variation of these factors it is possible to drive amphiphile association in the direction spheres → cylinders → bilayers/vesicles. Detailed theoretical investigations have recently been performed by molecular dynamics simulations (106). Further factors involve temperature and added homopolymer, which affects the stretching energy of the core chains. The variation of these factors and their effects on aggregate morphology have been reviewed (29,32–36,107–110) and are summarized in Table 3.

Shape Transitions. The influence of the hydrophilic block length on the micellar shape has been systematically investigated for PS-PAA in DMF/water mixtures (10). As the length of the PAA block decreased, the morphology of the aggregates changed progressively from spheres for PS_{200}-PAA_{21} → cylinders for PS_{200}-PAA_{15} → bilayers (vesicles and lamellae) for PS_{200}-PAA_8. It was noted that for block copolymers of similar hydrophobic block length, the values of the interfacial area per chain a_0 decrease as the morphology changes from sphere → cylinder → vesicle, which is in accord with the reduced chain repulsion (eq. 2) leading to larger packing parameters for shorter hydrophilic chains (37).

As another example, Figure 5 shows the morphologies for a series of PB-PEO block copolymers in aqueous solutions, where a decrease of the hydrophilic block ratio f leads to shape changes from sphere → cylinder → vesicle (102). Similarly,

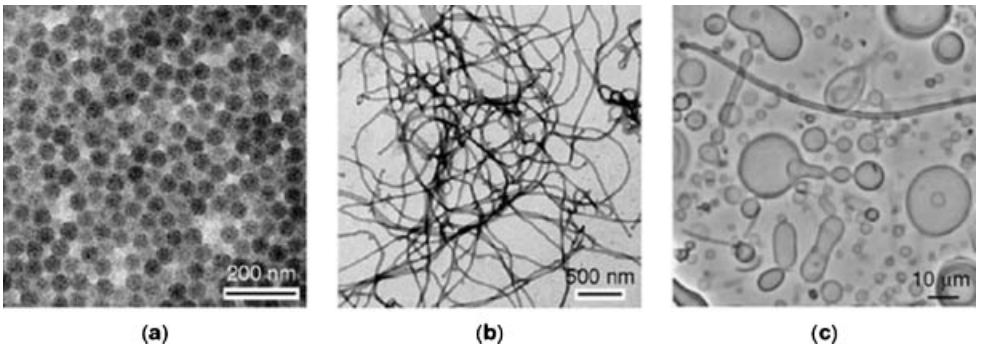

Fig. 5. TEM (**a**, **b**) and optical micrographs (**c**) of different shapes for a series of PB-PEO block copolymers, ranging from spherical micelles (PB_{202}-PEO_{360}, $f = 0.64$), cylindrical micelles (PB_{125}-PEO_{155}, $f = 0.55$) to vesicles (PB_{25}-PEO_{40}, $f = 0.38$). It illustrates the influence of the hydrophilic block fraction f on the self-assembly structure. From Ref. 20, with permission from John Wiley & Sons, Inc.

an increase of the size of the hydrophobic part at a given hydrophilic block length decreases f, leading to the same series of shape transition as shown for dendron-block copolymers with increasing dendron generation (17). This sequence of shape transitions induced by changes in block length is well known for low molecular weight nonionic surfactants (C_xE_y- series) (118).

Phase Diagrams. A phase diagram with the boundaries for the micellar shape transitions as a function of block copolymer composition has been determined for PEO block copolymers (Fig. 6**a**). The vertical lines are the boundaries separating different micellar shapes. As a rule of thumb, the hydrophilic fraction

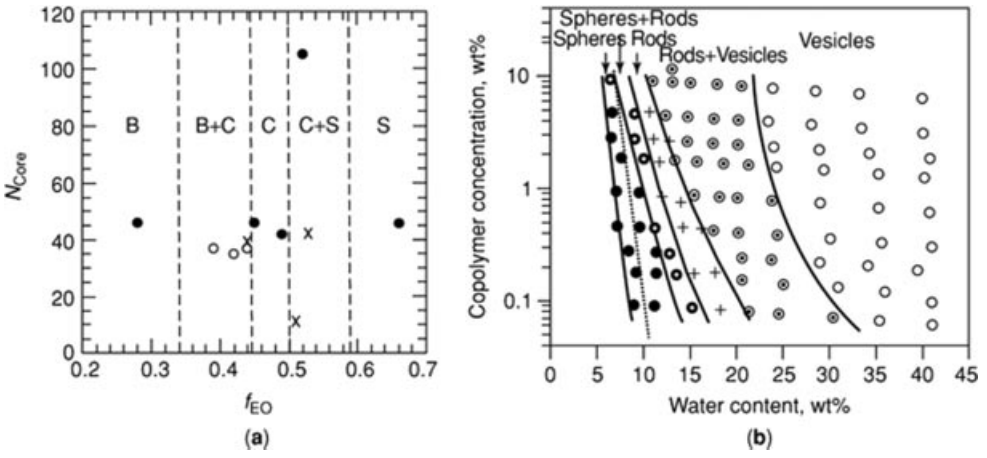

Fig. 6. Phase diagrams with shape transition boundaries for block copolymers as a function of (**a**) hydrophilic fraction f (from Ref. 46, with permission from ACS Publication Division) and (**b**) water content in dioxane/water solutions (from Ref. 39, with permission from ACS Publication Division). B: bilayers/vesicles; C: cylindrical micelles; S: spherical micelles.

of the block copolymer should be in a range $f \approx 30$–40%, a range which is similar to that for phospholipids, to obtain vesicles (46).

The influence of the interfacial tension γ on the micellar shape has been investigated for PS-PAA block copolymers in dioxane/water mixtures. With increasing water content the expected sequence of morphologies, sphere → cylinder → bilayer, is observed (115). Bilayers include vesicles, lamellae, and more complicated structures. The addition of water to dioxane solutions induces aggregation of the polystyrene segments and increases the interfacial tension γ. Figure 6**b** shows the corresponding phase diagram (39).

Not only the water content but also the polymer concentration affects the morphologies and the sizes of the aggregates. It was found that the boundaries of the morphological transitions shift to lower water contents with increasing total block length and with decreasing PAA block length. Further it was found that long core-forming blocks and high water contents favor the formation of vesicles and that short core-forming blocks and low water contents favor the formation of open bilayers. The addition of homopolystyrene changed the morphologies from bilayers or cylinders to spheres (37).

Intermediate Shapes. Details of the cylinder → vesicle shape transition have been investigated for PS-PAA block copolymers in dioxane/water mixtures (119). Accordingly, the morphological transition proceeds through a flattening of the rods via a lamellar intermediate state and their closing to form vesicles. The reverse shape transition proceeds via a collapse of the vesicle followed by a rearrangement to form dumbbell aggregates and finally smooth cylinders (40). For amphiphilic block copolymers with compositions f that are intermediate between cylinders and vesicles, Y-junctions and three-dimensional networks leading to a considerable morphological complexity were reported (120). Other complex structures involve the formation of filaments in polyelectrolyte bilayers as a consequence of the balance of long-range repulsive Coulomb interactions and short-range attractive hydrophobic interactions (59,121,122).

Segregation and Localization.

Strong Segregation Limit. So far flexible chain amphiphiles have been considered where a balance of chain repulsion, chain stretching, and interfacial tension together with the hydrophilic/hydrophobic ratio of the amphiphile dictates the aggregate shape. Vesicle formation is generally observed if the hydrophilic fraction of the amphiphiles is in a range $f \approx 30$–40%. This range can be much larger if the bilayer structure is further stabilized. This is typically the case for systems with

(1) large interfacial energy F_{int}: high energy interfaces in order of increasing interfacial tension are water/oil < water/silicone < water/fluorinated hydrocarbon;

(2) small stretching energy F_{el}, which is the case for polymers with small conformational entropy which are typically stiff polymer chains with low internal degrees of freedom or chains with highly localized segments;

(3) small repulsive energy F_{rep}, where the repulsion between adjacent polymer chains at the interface is screened, eg by addition of ions or increasing polymer concentrations to high volume fractions.

Under these conditions the interfacial energy is the most dominant thermodynamic contribution and hydrophobic and hydrophilic domains are highly segregated (strong segregation limit). The system globally minimizes the interfacial area per unit volume, which is given by

$$A_V = d\frac{\phi}{l} \tag{7}$$

where ϕ is the volume fraction of the hydrophobic domains and d is the dimensionality. Since for planar structures the dimensionality has the lowest value of $d = 1$, such interfaces are preferred compared to cylindrical ($d = 2$) or spherical ($d = 3$) domains. In this regime bilayer structures are preferred irrespective of the shape of the amphiphiles.

Secondary Valence Interactions. Under these conditions, the range of stability of planar bilayer structures and vesicles can be quite extended. Low entropy chains include fullerenes, rod-like polymers, and polymers carrying mesogens as well as polymer chains with highly localized chain segments such as branch points in dendrimers (covalent binding) or segments involved in strong functional or complementary interactions including H-bonds, Coulombic, dipolar or π–π interactions, ligand binding, α-helix/β-sheet formation, or other secondary valence interactions. These structures are schematically shown in Figure 7.

A well-known case where Coulombic interactions stabilize bilayer structures are mixtures of cationic and anionic surfactants, so-called catanionics (123). A related single component surfactant system which forms equilibrium vesicles over the whole range of volume fractions is single chain sulfonium surfactants (124). Here, the polarizability of the sulfur head group and H-bridges stabilize the bilayer morphology. Vesicle formation was described by Chu and co-workers (18) for pentaphenylfullerene anions, which form small vesicles of 17 nm diameter. Kukula and co-workers described vesicle formation of polybutadiene-*b*-poly(L)glutamates (7), where the hydrophilic glutamic acid blocks form α-helices. Schlaad and co-workers used polyelectrolyte ionic complex formation of double hydrophilic

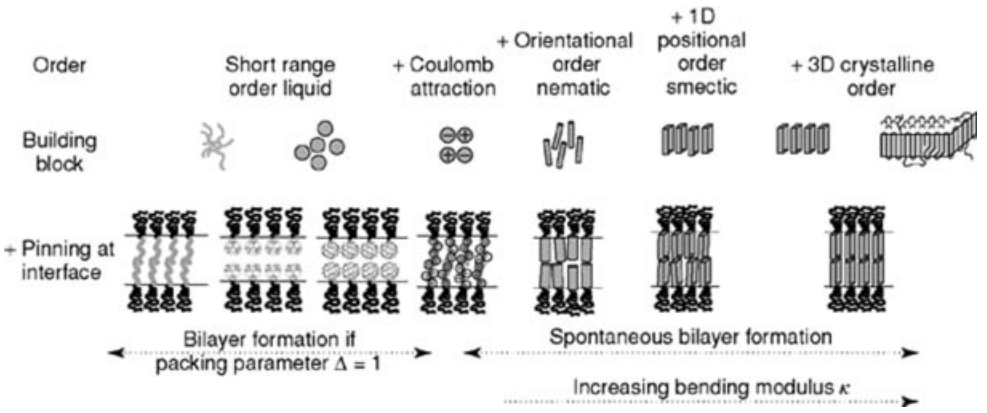

Fig. 7. Different amphiphile structures arranged, from left to right, with increasing in-plane order, which is an additional driving force for bilayer and vesicle formation. From Ref. 20, with permission from John Wiley & Sons, Inc.

block copolymers to form asymmetric equilibrium vesicles (125). Complexes of block ionomers and surfactants have also been reported to form vesicles (126,127). Even statistical copolymers can form well-defined vesicles by complementary functionalization with diaminopyridine and thymine groups, which are DNA-binding motives (128).

Liquid Crystalline Packing. A further factor that stabilizes bilayer structures is a hydrophobic part of the amphiphile, which is shape persistent and has a tendency to form ordered structures. One distinguishes *liquid-like* structures with short-range order (eg dendrimers, flexible polymer chains) from *nematics* with additional orientational order (eg rod-like polymers), *smectics* with additional one-dimensional positional order, and *crystalline materials* with three-dimensional positional order. Increasing in-plane order leads to an increase of the bending modulus of the bilayer resulting in large vesicles. For example, Jenekhe and coworkers (15,16) described giant vesicles that spontaneously formed from rod-coil block copolymers even in organic solvents.

The factors leading to bilayer or vesicle formation are schematically summarized in Figure 7, where amphiphiles are arranged according to their in-plane state of order. The pinning of hydrophobic mesogens to an interface is sufficient for the formation of stable bilayer structures. In summary, amphiphiles can be made to assemble into bilayers by adjusting the packing parameter toward unity, for high energy interfaces, or by using amphiphiles with low conformational entropy or using mesogenic amphiphiles.

Vesicle Preparation and Size Control. As outlined, the size and shape of vesicles depend to a large extent on preparation conditions. Several procedures are available for the formation of lipid vesicles (129,130), which are in most cases also suitable for the preparation of polymer vesicles.

Direct hydration. The simplest procedure is to hydrate a thin film or a solid piece of lipid or block copolymer with an aqueous solution, which leads to the spontaneous formation of vesicles. For film rehydration the amphiphile is dissolved in an organic solvent, which then is evaporated under vacuum or using a nitrogen stream to yield a thin film on a glass or Teflon substrate (131). Upon addition of water, the film swells under formation of a lamellar bilayer phase with vesicles budding or separating at lamellar defects from the film surface (Fig. 8). This method often yields multilamellar vesicles with a broad size distribution. For bulk rehydration stirring, vortexing or sonication is required for a complete hydration of the sample.

Electroformation. For electroformation (132), a thin film is deposited on adjacent electrodes (Pt, Au, ITO-coated glass) and the budding process is induced by an alternating current at typically 10 Hz (10 V) (7). The electric field decreases the membrane tension and thereby facilitates vesicle formation. This method yields the largest vesicles (giant vesicles) with diameters up to 100 μm.

Hydrating under shear, eg by vigorous stirring, reduces the vesicle size to the submicron range. Details of the shear-induced formation of vesicles from swollen lamellar phases have been investigated (92).

Organic Co-solvents. In this method the amphiphile is dissolved in an organic solvent and then mixed with an aqueous solution where it forms vesicles. It is a convenient way for the large-scale preparation of vesicles. Vesicle size and size distribution depends on the details of the mixing process, ie dropwise addition/

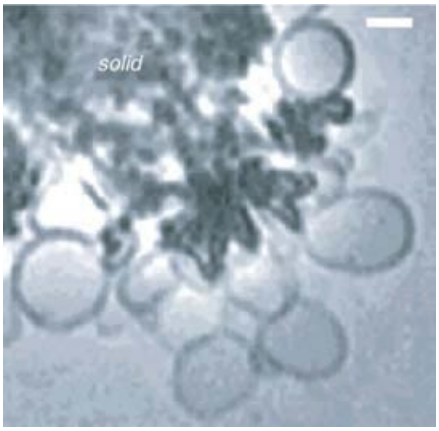

Fig. 8. Block copolymer vesicles budding-off from a swollen lamellar phase. After separation, there is no further exchange of block copolymers between vesicles. from Ref. 50, with permission from ACS Publications Division.

injection of the organic solution into water or addition/injection of water into the organic solution both with or without agitation by stirring or sonication. The organic solvent can subsequently be removed by reduced pressure, dialysis, gel filtration, or ultrafiltration.

Size Control. Once the vesicles are formed, they will keep their size and size distribution. In order to reduce their size one has to disrupt the vesicle membrane, which is done by strong shear forces, eg by ultrasonic irradiation, ball milling, and high-pressure extrusion through membranes or slits ("French press"). Extrusion through polycarbonate membranes, which are available with pore diameters between 50 and 800 nm, allows a reduction and control in vesicle size and polydispersity to obtain small unilamellar vesicles with size distributions within 10–20%. Fast and direct preparation of small monodisperse vesicles in the size range of 50–200 nm is possible using inkjet printers (133). By appropriate choice of sample preparation method, it is thus possible to tailor the size of the vesicle between 50 nm and 10 μm with narrow size distribution.

Glassy Polymers. Vesicle preparation for high molecular weight or glassy block copolymers requires the use of co-solvents. First, the block copolymer is dissolved in a water-miscible common solvent for both blocks (eg dioxane, THF, DMF). Then water is added, which induces the aggregation into micelles. Further addition of water increases the interfacial tension and drives shape transitions to cylindrical micelles, bilayers, and vesicles. Under optimal conditions, it is possible to obtain small, uniform unilamellar vesicles as is shown in Figure 9. In another method, the polymers are dissolved at high temperatures close to their glass-transition temperature. In case of low-boiling solvents, confinement under pressure is required. The formation of vesicles is subsequently induced by cooling (31).

Vesicle Shapes

Lipid and polymer vesicles can possess numerous shapes that can be systematically categorized and their energy described by concepts derived from differential geometry.

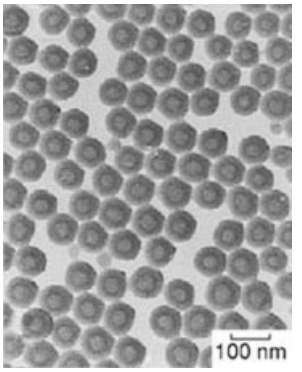

Fig. 9. Small, narrow disperse block copolymer vesicles prepared using organic cosolvents. From Ref. 115, with permission from ACS Publications Division.

Curvature Energy.

Membrane Energy. Any three-dimensional geometrical object can be characterized by its volume V, surface area A, and its mean and Gaussian curvature H and K, respectively. For bilayer membranes, a further contribution arises from the difference ΔA of the area of the outer and inner monolayer. This leads to five contributions to the free energy (134), which are obtained by integrating over the volume and the surface area of the vesicle as

$$\begin{aligned} F &= F_{\mathrm{V}} + F_{\mathrm{A}} + F_{\mathrm{H}} + F_{\mathrm{K}} + F_{\Delta \mathrm{A}} \\ &= \int \Pi \mathrm{d}V + \frac{k_{\mathrm{A}}}{2} \oint \bar{\rho}^2 \mathrm{d}A + \frac{\kappa}{2} \oint (2H)^2 \mathrm{d}A + \kappa_{\mathrm{G}} \oint K \mathrm{d}A + \frac{k_{\mathrm{A}}}{2} \oint (\rho - \mathrm{d}H)^2 \mathrm{d}A \end{aligned} \tag{8}$$

where Π is the osmotic pressure, V is the volume of the vesicle, k_{A} is the area elastic modulus, $\overline{\rho}$ is the deviation from the equilibrium area per chain a_0 (eq. 2), κ is the elastic bending modulus, H is the mean curvature (eq. 4), κ_{G} is the Gaussian bending modulus, K is the Gaussian curvature (eq. 4), ρ is the area difference between outer and inner bilayer, and d is the bilayer thickness. Integration of the osmotic pressure $\Pi = RT(n_{\mathrm{in}}/V - c)$ over the volume of the vesicle, and of the mean curvature H and area differences $\overline{\rho}$ and ρ over the area of the vesicle yields (134)

$$F = \frac{RTc}{2V_0}(V - V_0)^2 + \frac{k_{\mathrm{A}}}{2A}(A - A_0)^2 + 8\pi\kappa + \kappa_{\mathrm{G}} \oint K \mathrm{d}A + \frac{k_{\mathrm{A}}}{8A}(\Delta A - \Delta A_0) \tag{9}$$

where c is the concentration of solute outside the vesicle, n_{in} is the moles of solute inside the vesicle, $V_0 = n_{\mathrm{in}}/c$ is the volume for which the osmotic pressure vanishes, A_0 is the area of the relaxed bilayer, and ΔA and ΔA_0 are the actual area difference and the relaxed area difference between the outer and the inner monolayer.

Osmotic Pressure. The osmotic contribution to the free energy, F_{V}, arises from the presence of molecules in the solution to which the membrane is impermeable on the timescale of the experiment. This leads to an osmotic pressure $\Pi = RT\Delta c$, where Δc is the concentration difference between the solutions outside and inside the vesicle. The concentration difference that can be sustained by a curved membrane can be estimated by comparing the osmotic energy to the bending energy $F_{\mathrm{H}} = 8\pi\kappa$. For typical values of the bending modulus $\kappa \approx 1.5 \times 10^{-19}$

J (7,53) one finds at room temperature $\Delta c \approx 1$ mmol/L. Thus, only minute concentration differences between interior and exterior solution can be balanced by the curvature energy. Large osmotic pressure differences will instead lead to the inward/outward permeation of water and concomitantly an increase/decrease of the vesicle volume until the concentration difference is $\Delta c = 0$ and thus $V = V_0$. In practice, this allows one to control the vesicle volume by the molar concentration ("osmolarity") difference of the inner and outer solutions.

Membrane Area. Similar to the osmotic energy, the energy F_A involving the total area of the vesicle vastly exceeds the energy of the bending elasticity. Thus the vesicle will adapt an area $A = A_0 = \overline{N}a_0$ that is given by the number $\overline{N}$ of amphiphiles in the bilayer. The average area of the vesicles is in most cases fixed after sample preparation and may slightly depend on temperature or pH.

Genus. As a consequence of the Gauss–Bonnet theorem

$$\oint K \mathrm{d}A = 2\pi(2 - 2g) \tag{10}$$

the energy due to the Gaussian curvature F_K is related to a topological invariant of the vesicle, its genus g. The genus of a surface is given by its number of "holes" or "handles" (see Fig. 10). Therefore, local variations in the Gaussian curvature K have no effect on the global Gaussian curvature as long as the topology is fixed. For any fixed topology or genus, the energy F_K is thus constant and can be neglected by setting $\kappa_G = 0$.

Membrane Elasticity. For a vesicle with fixed volume $V = V_0$, area $A = A_0$, and genus the curvature energy of the bilayer membrane reduces to the sum of the remaining two terms of equation 9

$$F = F_H + F_{\Delta A} = \frac{\kappa}{2}\oint (2H - C_0)^2 \, \mathrm{d}A + \frac{k_A}{2A}(\Delta A - \Delta A_0)^2 \tag{11}$$

which correspond to the two modes of membrane deformation shown in Figure 11. C_0 is the spontaneous curvature, which has been introduced to account for a locally preferred curvature of the membrane due to the molecular structure of the amphiphile.

Area Difference. ΔA is the area difference between the inner and outer monolayer, which is related to the radius of the vesicle and the bilayer thickness d (see Fig. 12) via

$$\Delta A = A_{\mathrm{out}} - A_{\mathrm{in}} = 8\pi \, \mathrm{d}R \tag{12}$$

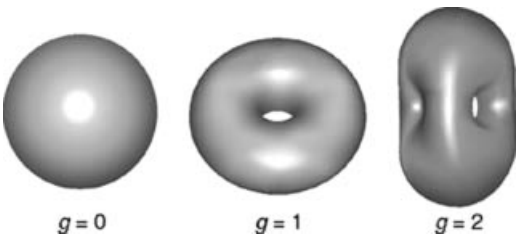

Fig. 10. Closed surfaces with genus (number of holes) of zero, one, and two.

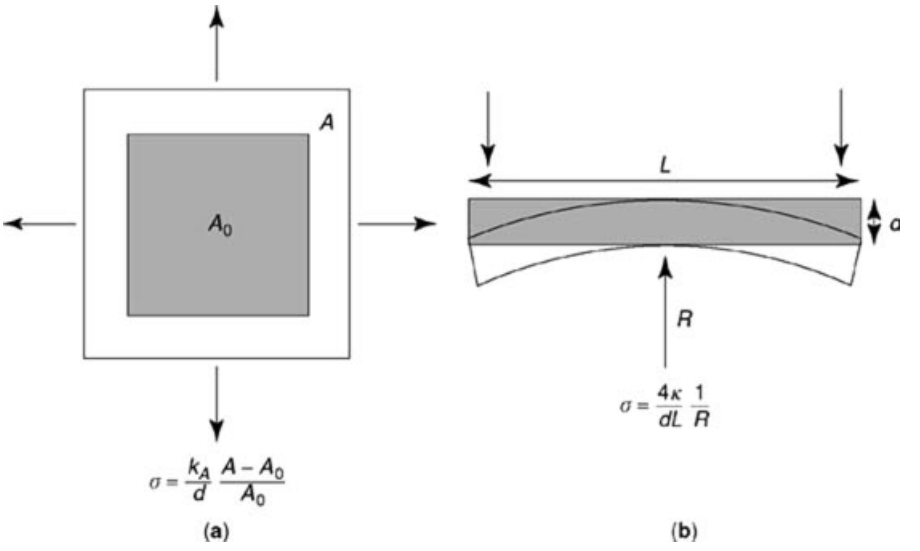

Fig. 11. Stretching (**a**) and bending (**b**) of a membrane with the corresponding elastic stretching modulus k_A and elastic bending modulus κ. In case of stretching, the stress σ is the force per unit area $A = L^2$, whereas in the case of bending, the stress is the force per unit cross-sectional area dL. According to simple elasticity theory for thin plates, the two moduli are related by $4\kappa = k_A d^2/12$ (135).

The actual area difference will, in general, differ from the optimal area difference ΔA_0

$$\Delta A_0 = (N_{out} - N_{in})a_0 = \Delta N a_0 \tag{13}$$

which is determined by the number of amphiphiles in each monolayer and the equilibrium area per amphiphile a_0. If the interfacial area per amphiphile is the

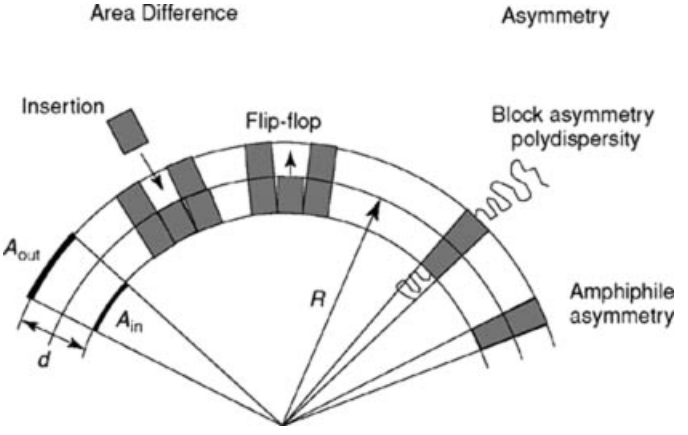

Fig. 12. Sources of area difference curvature ΔA (insertion, flip-flop) and spontaneous curvature C (block and amphiphile asymmetry, polydispersity) for bilayer structures. The vesicle will adapt a curvature that is a compromise between the two, depending on the related energy.

same in the outer and inner monolayer, ie $a_{out} = a_{in} = a$, then the relative area difference $\Delta A/A$ is related to the relative difference in the number of amphiphiles $\Delta N/N$ by

$$\frac{\Delta A}{A} = \frac{\Delta N}{N} = \frac{d}{2R} \tag{14}$$

with the mean bilayer area $A = Na$. Thus, for small lipid vesicles with a bilayer thickness $d = 3$ nm and a radius eg, $R = 20$ nm, there is a large ($\Delta N/N = 30\%$) difference in the number of lipids in the inner compared to the outer bilayer. This leads to a large free energy contribution related to ΔA, and so small vesicles are often relatively unstable. The area difference ΔA can change by the exchange of lipids between the inner and outer monolayer ("flip-flop"), or the addition (insertion, adsorption, anchoring) of amphiphiles to one monolayer (136) (Fig. 12).

Spontaneous Curvature. A different chemical environment on both sides of the membrane (eg different surface charge density, different electrolyte concentrations), an asymmetric molecular shape of the amphiphile, or a different chemical composition of the two monolayers tends to locally curve the membrane (Fig. 12). This membrane-asymmetry-related curvature is described by the spontaneous curvature

$$C_0 = \frac{1}{R} \tag{15}$$

of the bilayer. Different chemical environments on both sides of the membrane will in general also lead to differences in the interfacial area per amphiphile $a_{out} \neq a_{in}$ and thus in the area difference ΔA.

Bilayer asymmetry can already be caused by chain length segregation of polydisperse polymeric amphiphiles between the two monolayers. To reduce steric repulsion, short hydrophilic chains will tend to segregate to the inner monolayer, whereas long chains will preferentially segregate to the outer monolayer as schematically shown in Figure 12. The segregation of block copolymers of different length across the bilayer has been demonstrated by Luo and Eisenberg (41) using pyrene-labeled PS-PAA. Upon addition of a fluorescence quencher (Tl^+), vesicles prepared with the labeled short hydrophilic blocks experience minimum quenching, since these chains preferably segregate to the inside of the vesicles and are thus largely inaccessible to the quencher. Pyrene residues in the vesicles prepared from the longest labeled hydrophilic chains are 12 times more accessible to the quencher than the pyrene in the vesicles prepared from the shortest labeled hydrophilic chains (Fig. 13). This asymmetry leads to a certain spontaneous curvature C_0. If there is sufficient flip-flop of amphiphiles to adjust the corresponding area difference ΔA, there will be a thermodynamically preferred average radius $R \approx {C_0}^{-1}$ of the vesicles. As expected, the spontaneous curvature increased, and thus the size of the vesicles decreased with increasing PAA polydispersity, ie increasing bilayer asymmetry (137). This allows to asymmetrically localize two different types of polymer chains if the corona blocks are of sufficiently different length (138). In a further study (42,139), fluorescence quenching

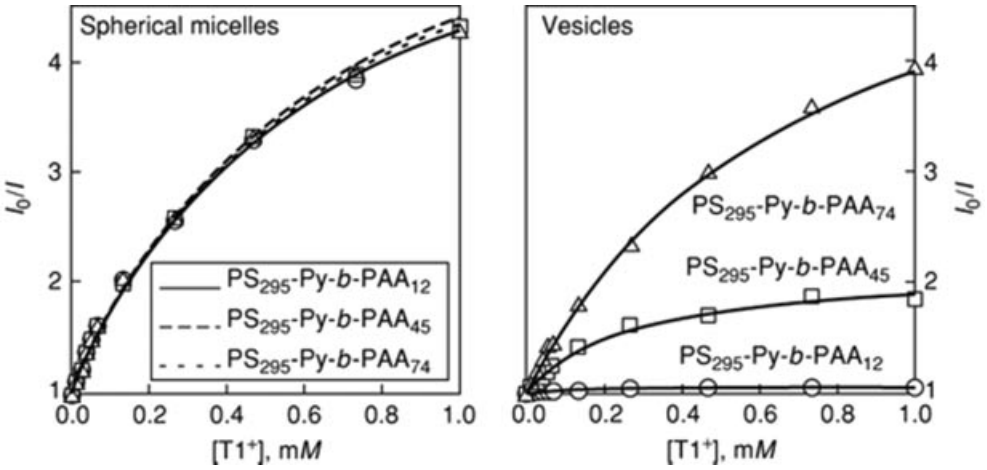

Fig. 13. Experiments showing preferential quenching of long, fluorescently labeled chains due to their accumulation in the outer monolayer of vesicles. In case of spherical micelles, preferential quenching is neither expected nor observed. From Ref. 41, with permission from the ACS Publications Division.

experiments have shown that this segregation is size dependent. The larger the vesicles, the lower the degree of segregation becomes.

The average radius of PS-PAA vesicles could also be changed in solvent mixtures of dioxane/THF/water or DMF/THF/water by changing the water content (11,42,43,111,139). An increase in vesicle size from $R \sim 45$ nm to $R \sim 100$ nm could be induced by increasing the water content from 25 to 70%, while a decrease in vesicle size could be induced by decreasing the water content by addition of THF/dioxane. The observed change has been attributed to minimization of the interfacial energy, but may also be related to changes in membrane diameter d. The addition of water extracts DMF/THF from the bilayer thereby decreases d, which according to equation 12 leads to an increase of the radius for a given area difference ΔA. The addition of DMF/THF will then lead to the reverse effect. The effect of block lengths, solvent composition, and additives on the vesicle size has been summarized in Reference (45).

Equilibrium Curvature. The two sources of curvature (ΔA, C_0) correspond to two different radii R. In general, a vesicle will thus be in a stressed state, its radius and shape minimizing the bending energy for a given difference ΔN of the number of amphiphiles in the inner and outer monolayer. The compromise between changes in area difference ΔA and local curvature C_0 in equilibrium depends on the relative magnitude of the two bending energies F_{H} and $F_{\Delta A}$. Only if the area difference is $\Delta A = \Delta A_0$, so that the corresponding radius $R = (\Delta A/8\pi d) = (1/C_0)$, then $H = C_0/2$ and the corresponding free energy of the membrane (eq. 11) is equal to zero. Under these conditions the vesicle is said to be in its "relaxed" thermodynamic state.

An illustrative example for the introduction of spontaneous curvature is bolaamphiphiles. *Bolaamphiphiles* are membrane-spanning bipolar amphiphiles. They are the most important lipid fraction from archebacteria that exhibit unusual

stability at extreme conditions of pH and heat. Single chain bolaamphiphiles form extended single-molecule-thick membranes. They are unable to form small vesicles because their vanishing spontaneous curvature requires a large difference ΔN of lipids in the outer and inner monolayer, which leads to a large free energy contribution related to ΔA. If the spontaneous curvature is increased by addition of cholesterol, small vesicles can be formed by sonication (140). The cholesterol is preferentially incorporated into the outer monolayer of the vesicle bilayer. Bolaamphiphiles with one large and one small head group form asymmetric vesicles with the larger group on the outside surface (141).

Chemically Asymmetric Bilayers. Vesicles from the asymmetric triblock copolymer PAA-PS-P4VP have been prepared in DMF/THF/water mixtures (86). Since the ionization of the two hydrophilic P4VP and PAA chains occurs in different pH ranges (for PAA at high pH, P4VP at low pH), a pH-induced flip-flop of the hydrophilic chains could be observed. Vesicles prepared at low pH contained P4VP chains on the outside and PAA chains on the inside membrane to minimize Coulombic repulsion, whereas vesicles prepared from the same triblock at high pH contained PAA outside and P4VP inside. This could be shown by measurements of the ς potential, which changed characteristically when changing the pH of the outside solution. A similar concept has been used for a one-step preparation of block copolymer vesicles with preferentially segregated acidic and basic corona chains (138). Asymmetric PEO-PDMS-PMOX vesicles have been prepared with a preferred orientation of the shorter hydrophilic blocks to the inside of the vesicles (142). The asymmetry was demonstrated by fluorescence quenching experiments similar as in Reference (41).

Vesicle Shapes and Shape Transitions.

Phase Diagram. As the surface area A is usually fixed for a vesicle after its preparation, it is useful to consider an area-equivalent radius $\overline{R} = (A/4\pi)^{1/2}$, which is defined via the radius of a spherical vesicle with the same surface area A. Using the radius $\overline{R}$ the reduced spontaneous curvature c_0, the reduced volume v, the reduced optimal area difference Δa_0, and the effective reduced area difference $\Delta \hat{a}_0$ are introduced which are given in Table 4. Reduced quantities are convenient measures of vesicles shapes irrespective of vesicle size.

The effective spontaneous curvature $\Delta \hat{a}_0$ is reflecting the different sources of membrane curvature. The constant $\alpha = \overline{\kappa}/\kappa$ gives the relative importance of the two bending moduli with the non-local bending rigidity given by $\overline{\kappa} = 2k_{\mathrm{A}}\, d^2/\pi$.

Table 4. Parameters Describing the Shape of Vesicles

		Spherical vesicle	
Reduced volume	$v = 3V/4\pi\ \overline{R}^3$	$v = 1$	$v < 1$: deflated vesicle
Reduced spontaneous curvature	$c_0 = \overline{R}C_0$	$c_0 = 1$	
Reduced relaxed area difference	$\Delta a_0 = \Delta A_0/8\pi\ d\overline{R}$	$\Delta a_0 = 1$	
Effective reduced relaxed area difference	$\Delta \hat{a}_0 = \Delta a_0 + (c_0/2\pi\ \alpha)$	$\Delta \hat{a}_0 = 1 + (1/2\pi\ \alpha)$	$\Delta \hat{a}_0 > 1$: prolate vesicles $\Delta \hat{a}_0 < 1$: oblate vesicles

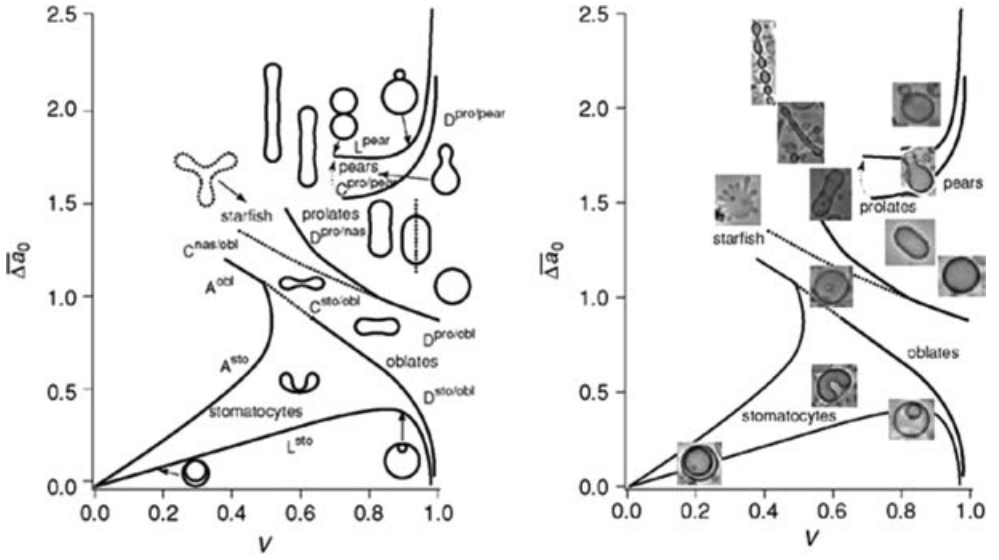

Fig. 14. (**a**) Theoretical phase diagram of vesicle shapes. From Ref. 3, with permission from Elsevier BV. (**b**) Experimentally observed vesicle shapes of PB-PEO block copolymer vesicles. From Ref. 144. Lipid and block copolymer vesicles show the same structural polymorphism.

For most bilayer systems the constant has values of $\alpha \approx 1$. A large area difference $\Delta\hat{a}_0 > 1$ tends to curve the membrane outward, whereas a smaller or negative value leads to inward curvature or invaginated vesicle shapes.

For a fixed value of α, the two parameters v and $\Delta\hat{a}_0$ determine the shape of vesicles which can be placed in a two-dimensional phase diagram as shown in Figure 14**a** (143). There are numerous shapes including spherical, tubular, oblate, and starfish vesicles. Vesicles with outwardly curved shapes and prolate vesicles are in the upper part of the diagram for $\Delta\hat{a}_0 > 1$, and inwardly curved shapes and oblate vesicles are in the lower part for $\Delta\hat{a}_0 > 1$. In this phase diagram, all the shapes are drawn to scale, have the same area, and differ only in their values of v and $\Delta\hat{a}_0$. Lipid and block copolymers exhibit a similar multitude of shapes as shown for PB-PEO block copolymer vesicles in Figure 14**b** (144).

Polymorphism. As during vesicle preparation the number of amphiphiles in the outer and inner monolayer and thus ΔN is fixed for each vesicle, each vesicle carries its own value of $\Delta\hat{a}_0$ and thus its own shape. This often leads to a zoo of different vesicle shapes within the same vesicle preparation. From the definition of Δa_0 and equation 12, it follows that

$$\Delta a_0 = \frac{\bar{R}}{2\mathrm{d}} \frac{\Delta N}{N} \tag{16}$$

which means that for a given relative difference $\Delta N/N$ between the number of amphiphiles in each monolayer, changes in Δa_0 and thus of vesicle shapes are particularly pronounced for large vesicles ($>1\ \mu$m) because of the large prefactor

$(\overline{R}/2d) \approx 10^3$. The polymorphism of vesicle shapes is quite commonly observed for large, micron-sized vesicles.

Shape Transitions. Shape transitions can be induced by changes in the reduced volume v and the effective spontaneous curvature $\Delta\hat{a}_0$ and can be mapped as a trajectory in the phase diagram in Figure 14. Changes in v can be induced by osmotic swelling or deswelling of vesicles, eg by changing the concentration ("osmolarity") of solutes outside the vesicles. Changes in $\Delta\hat{a}_0$ can occur via changes in area difference ΔA and spontaneous curvature C_0. Changes in temperatures can affect the membrane area and therefore the reduced volume v, but also $\Delta\hat{a}_0$ which leads to oblique trajectories in the phase diagram. For large reduced volumes, ie quasi-spherical vesicles, there is hardly any membrane area available for shape changes. For $v \leq 0.97$ required changes in $\Delta\hat{a}_0$ for shape transitions are of the order of unity or less, so that shape transitions become achievable. If, on the other hand, by permeation of solvent into the vesicle interior the reduced volume is adjusted to approach unity, all vesicles will become spherical.

Common shape transitions include

(1) the "pearling" transition, a sequential beading of tubular vesicles;
(2) the "budding" transition, where a small vesicle is expelled from the "parent" vesicle; and
(3) the vesicle-tubule transition.

Pearling Transition. The pearling transition has been investigated for giant tubular PB-PEO block copolymer vesicles. Thermal quenches lead to pearling of the tubes starting symmetrically from the two ends (see Fig. 15) (52). The pearling transition is slow because of the high membrane surface viscosity. The necks close one by one with velocities of the order of a few tens of nanometers per minute, and so complete pearling takes about 2 h.

The pearling transition of giant tubular lipid vesicles has also been induced by insertion of *O*-palmitoyl dextrans into the outside monolayer of the membrane. The insertion leads to an increase in the membrane curvature, which induces the

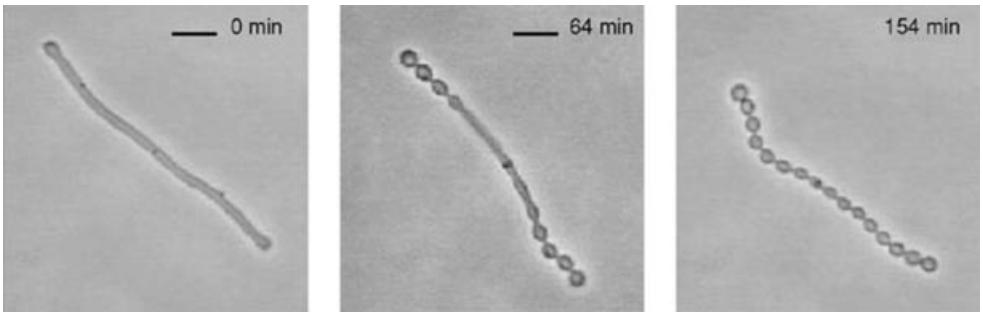

Fig. 15. Different stages of the pearling transition for a tubular PB-PEO block copolymer vesicle after a thermal quench from 38 to 25°C. Compared to lipid vesicles, the transition is extremely slow. The necks close one by one with effective velocities of a few tens of narometers per minute. From Ref. 52, with permission from ACS Publications Division.

pearling transition (145,146). The concentration critical for the shape transition depends on both the palmitoyl substitution frequency along the dextran and the size of the dextran.

Budding Transition. In cells, the budding of vesicles from internal organellae or the plasma membrane is an ubiquitous process and a key process for cellular traffic. In case of giant lipid vesicles, asymmetric insertion of fluorescently labeled PEO with cholesteryl anchor groups into the outer monolayer lead to an increase of the spontaneous curvature and induced budding of starfish vesicles (136). The addition of the cholesteryl anchor increases both components of the effective spontaneous curvature $\Delta\hat{a}_0$, the area difference, and the local spontaneous curvature as locally the membrane curves away from the polymer (147).

The budding transition is directly related to the fission and fusion process of vesicles. In case of block copolymer vesicles, details of this process have been investigated for PS-PAA using transmission electron microscopy of quenched intermediate states (13,42,139). Accordingly, the fusion proceeds via contact, adhesion, coalescence, and formation of a central, connecting wall. Destabilization of the wall leads to its asymmetric detachment and retraction with final formation of a uniform outer wall. The fission process starts with the elongation of the vesicle, formation of an internal waist, narrowing of the external waist, and final complete separation (Fig. 16). Vesicle fusion and fission kinetics have been followed by turbidity changes after jumps in water content and are found to have relaxation times as fast as seconds.

Vesicle-Tubule Transition. Transitions between spherical and tubular vesicles have been reported for a glycopolymer-containing amphiphilic block copolymer by varying the ratio of the co-solvents THF and DMF in aqueous solutions, and by changing the temperature at which the aggregates were prepared (62). Shape transitions involving tubular and starfish vesicles as well as connected tubules have been observed for PS-PEO as a function of water content, polymer concentration, and added ions (25).

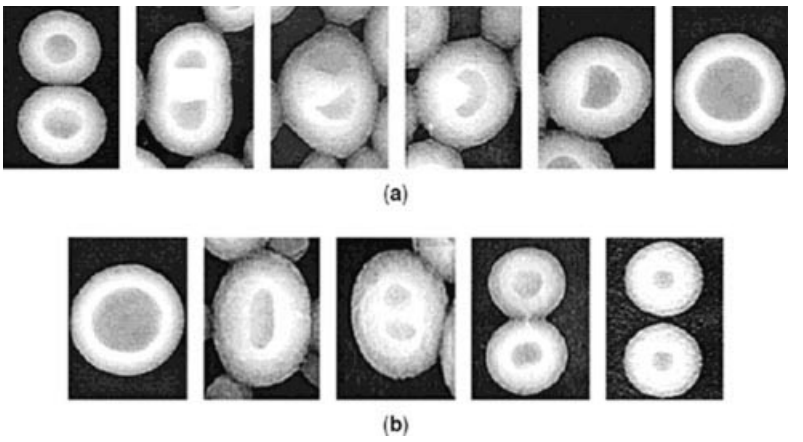

Fig. 16. Reconstruction of different stages of the fusion (a) and fission process (b) of block copolymer vesicles. From Ref. 42, with permission from the ACS Publications Division.

Shape transitions from vesicles to inverted hexagonally packed (hollow) rods were studied for PS-PEO in THF/water mixtures by increasing the water content. The transition proceeds via the formation of hollow regions in the walls of the vesicles, thickening of the walls, and alignment of the rods in a hexagonal pattern leading to the formation of quasihexagonal structures and eventually to the full development of inverted hexagonally packed rods. This mechanism is different from the usually observed fusion of vesicles (25,26). Fascinating intermediate structures such as undulating tubules (44) and ordered toroids (27,148) have been reported for transitions between cylinders and vesicles.

High Genus Vesicles. Block copolymer vesicles can also exhibit shapes, which are unknown for lipid vesicles such as stable high genus vesicles (51). Block copolymer vesicles can easily have a genus $g > 100$, as shown in Figure 17. The local membrane shape indicates that the bilayer has nonzero spontaneous curvature. Experimentally found shapes include vesicles with small and large passages, budded vertices, connected tubes, and spindles, which are stable for different values of the reduced volume and spontaneous curvature $\Delta\hat{a}_0$. The range of stability of these shapes can be depicted in a phase diagram similar to Figure 14.

The development and stability of holes or pores in bilayer membranes have been studied by poration experiments. These experiments show that pore stability depends strongly on the thickness d of the bilayer (149). For small d, poration leads to large unstable pores and the resulting membrane fragments reassemble into vesicles within minutes. For large d, submicron pores form and are extremely long-lived.

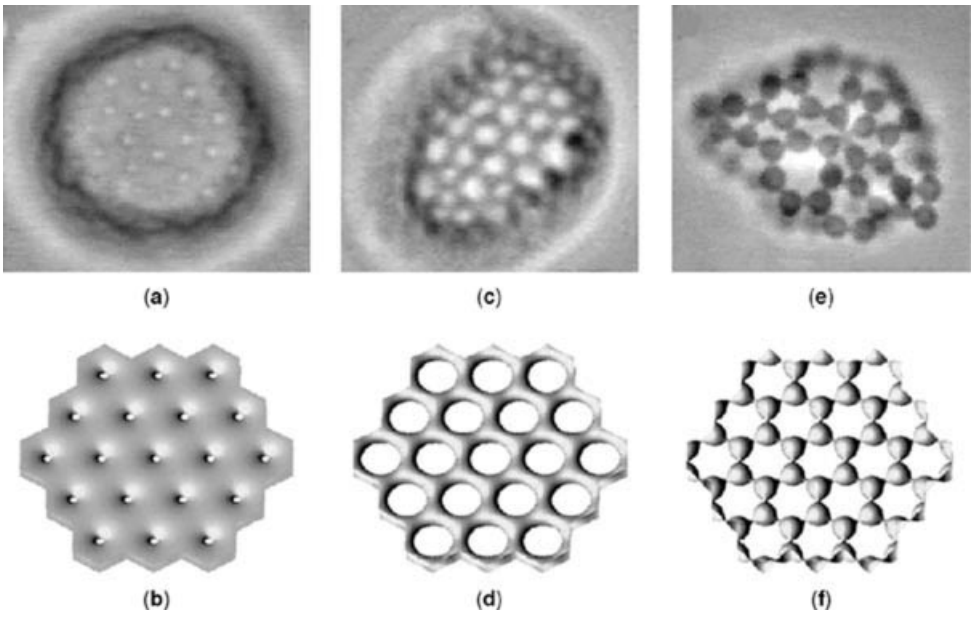

Fig. 17. Comparison of experimental and theoretical shapes for giant high genus PB-PEO vesicles with small passages (**a**, **b**), large passages (**c**, **d**), and budded vertices (**e**, **f**). The scale bar is 10 μm. From Ref. 51, with permission from the APS Associate Publisher.

Bilayer Properties

Physical properties of the vesicle membranes such as elasticity, toughness, stability, and permeability determine to a large extent the performance of vesicles in applications. These properties are largely determined by the interfacial tension and membrane thickness, the latter being adjustable via the chain length of the membrane forming block copolymer. This allows one to tailor membrane characteristics within a range outlined in the following sections.

Mechanical Properties. The mechanical properties of bilayers such as their bending elasticity (Fig. 11) can be understood by a rather simple model. If the bilayer is assumed to be a thin, solid-like film, there is a simple relation between the area elasticity modulus k_A and the bending modulus κ (19,135,150) (Fig. 11), ie

$$\kappa = \frac{1}{48} k_A d^2 \tag{17}$$

where d is the bilayer thickness. If the interfacial tension is the dominant contribution to the elastic properties of the membrane, then a comparison of the coefficients of the area elastic energy terms in equations 2 and 9 implies (96)

$$k_A = 4\gamma \tag{18}$$

Thus, both the bending modulus and area elasticity are directly related and are determined by the interfacial tension.

Thickness. The thickness of polymersome bilayers is several times greater than that of typical phospholipid bilayers in natural membranes. Lipid bilayers have a hydrophobic core thickness that is in a very narrow range of $d \approx 3$–4 nm to be compatible with integral membrane proteins. For self-assembled bilayers of PEE-PEO vesicles, the hydrophobic core thickness increases with increasing molecular weight from $d \approx 8$–21 nm (see Fig. 18) to more than 100 nm (53,151–153). The observed $d \sim M^{0.5}$ scaling is typical for random coil polymers and agrees with molecular dynamics simulations of block copolymer bilayers (106).

Elasticity. The elastic behavior of membranes has been studied using micropipette techniques on giant vesicles (>5 μm). These techniques allow one to simultaneously measure membrane stretching and bending moduli. The experiments show an interface-dominated elasticity. Membrane stretching moduli are found to be independent of chain length (Fig. 19**a**). A value of $k_A \approx 120$ mN/m is reported for PEE-PEO vesicles, which is in good agreement with $\gamma = k_A/4 \approx 30$ mN/m consistent with an oil/water interface (eq. 18). Bending and stretching elastic constants are in a range of values typical for lipid membranes (53). The well-investigated unsaturated lipid DPPC (dipalmitoyl phosphatidylcholine) mixed with cholesterol (1:1) has a value of $k_A = 102$ mN/m corresponding to $\gamma \approx 25$ mN/m (155). For polymersomes, the bending elastic constant κ is reported to be ~35 kT (7), which is in good agreement with equation 17. Data confirm the expected square dependence of the bending modulus on membrane thickness (Fig. 19**b**) (154).

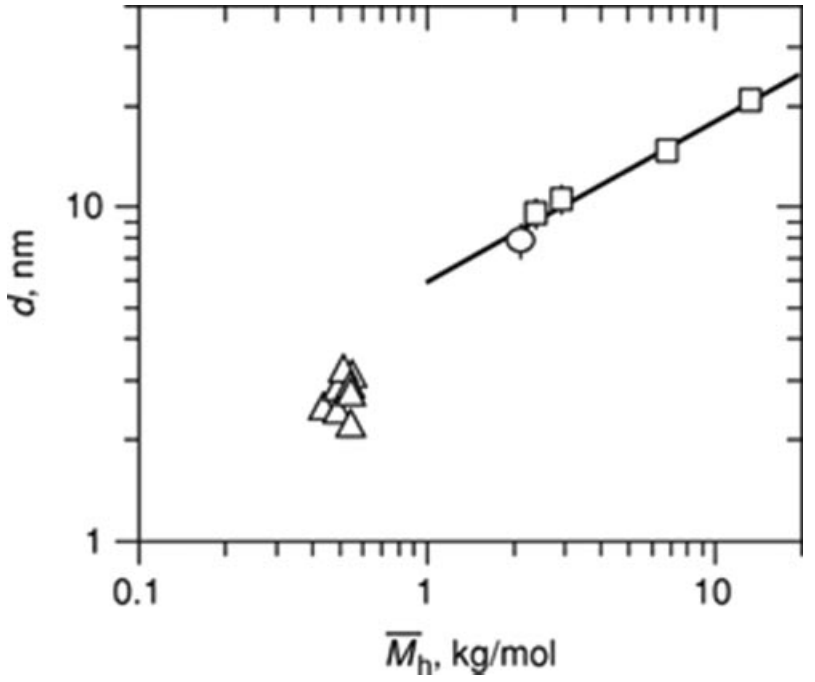

Fig. 18. Increase of the membrane thickness d with the hydrophobic molecular weight for PEE-PEO vesicles. Data (triangles) are also shown for membranes of various phospholipids. Block copolymer vesicle bilayers can be more than an order of magnitude thicker compared to phospholipid vesicles. From Ref. 151, with permission from the ACS Publications Division.

Toughness. Membrane stability as defined by the maximal area strain $\alpha_c = (A_c - A_0)/A_0$ increases with increasing molecular weight, approaching a universal limit set by the interfacial tension. The sustainable critical strain is $\alpha_c \approx 0.19$, which considerably exceeds the range of $\alpha_c = 0.03$–0.06 typical of natural lipid membranes (Fig. 20); lipid membranes cannot be strained without rupture, osmotically or otherwise, by more than about 5% in surface area. Polymersomes are almost an order of magnitude tougher and sustain far greater area strain before rupture compared to lipids. From the data, a critical yield stress of $\sigma_c = \frac{k_A \alpha_c}{d} \approx 1$ MPa can be estimated. One expects that both critical yield tensions and strains increase linearly with the bilayer thickness. Nonlinear responses and memory effects emerge with increasing molecular weight, indicating the onset of chain entanglements at higher molecular weight (151).

Dynamics. For polymersomes, measurements of the lateral diffusivity (47) and the membrane viscosity (152) indicate that membrane fluidity decreases strongly with increasing molecular weight. The decreases are most drastic when the chains are long enough to entangle.

Fluorescence recovery after photobleaching has been used to determine lateral diffusion in block copolymer bilayers (Fig. 21). The experiments yield a time constant τ from which the lateral diffusion coefficient $D = l^2/2\tau$ is calculated. In the fluid L_α phase, lipid molecules have lateral diffusion coefficients of

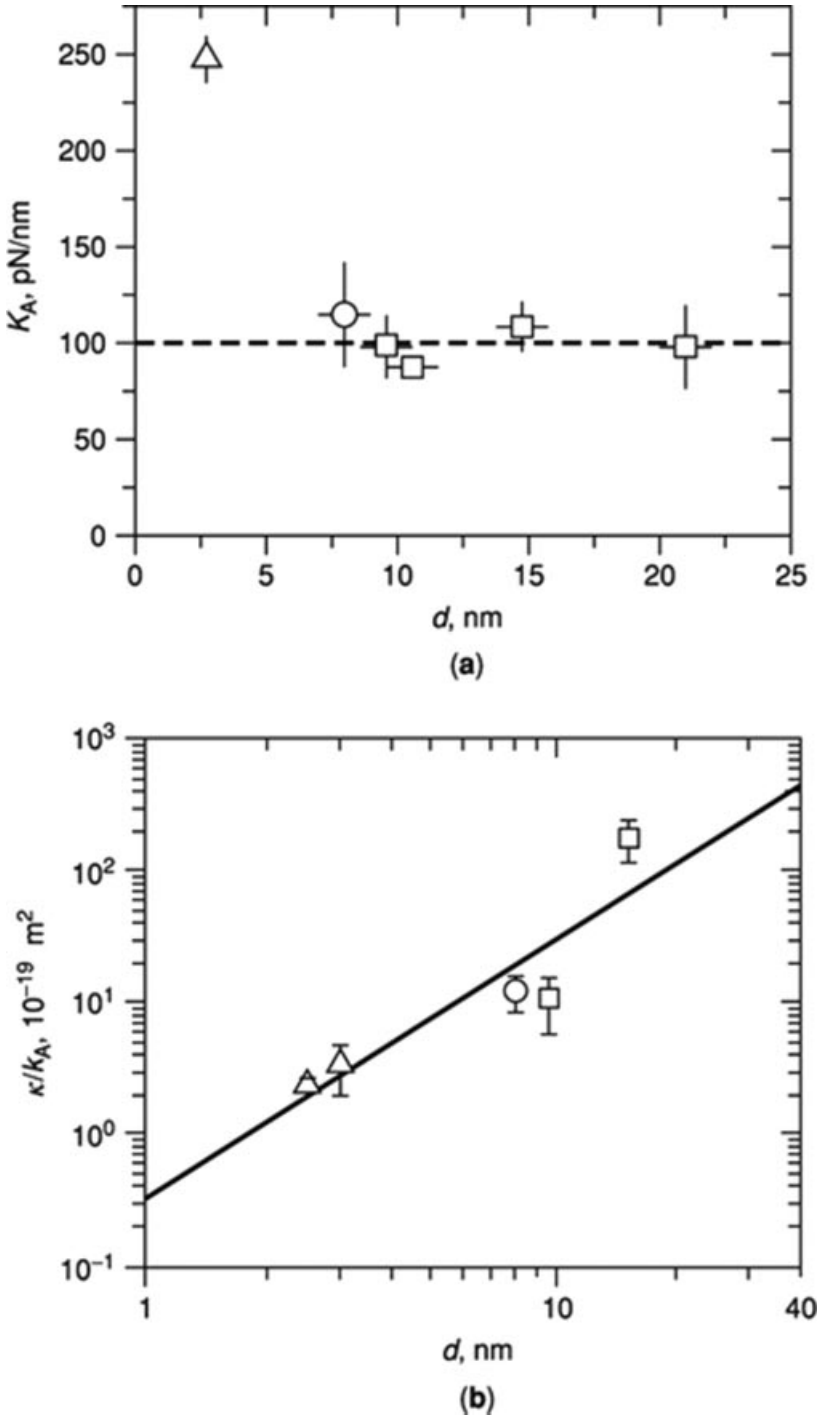

Fig. 19. (**a**) Area elasticity modulus k_A and (**b**) bending modulus κ as a function of the bilayer thickness d. The experiments are in agreement with equations 17 and 18. From Refs. 151 and 154, with permission from the ACS Publications Division.

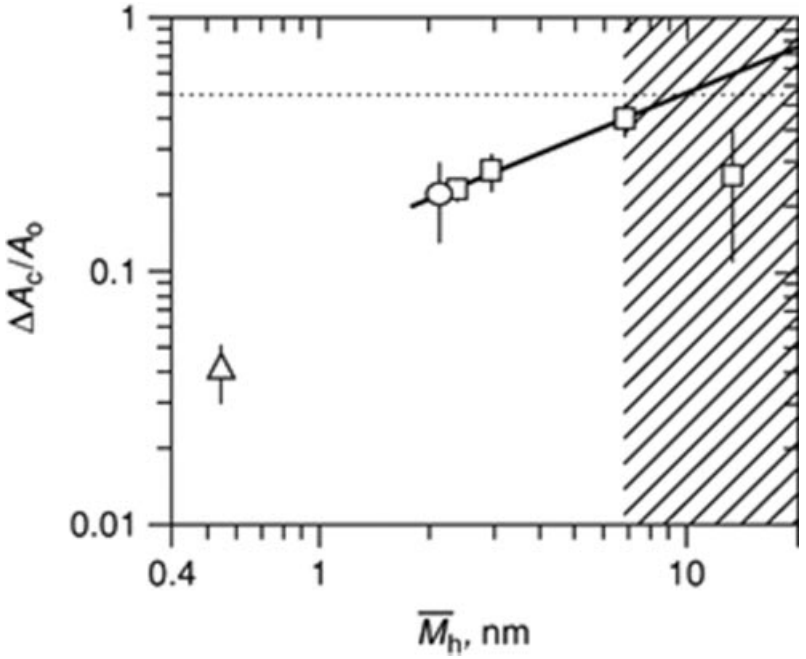

Fig. 20. Maximum area strain for lipid and block copolymer bilayers as function of molecular weight. This experiment demonstrates the increased toughness of block copolymer vesicles compared to lipid vesicles. From Ref. 151, with permission from the ACS Publications Division.

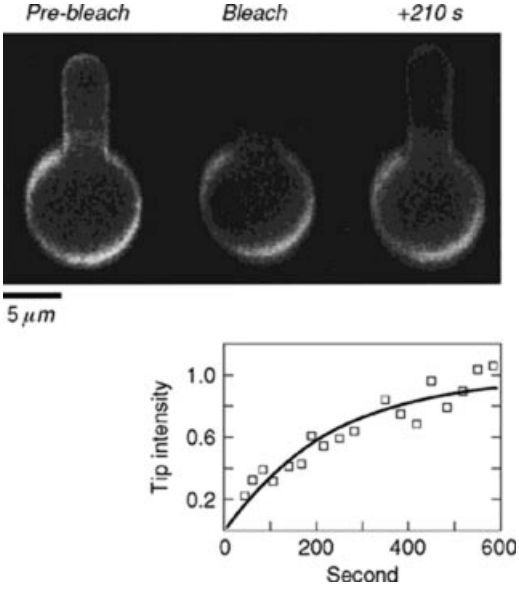

Fig. 21. Fluorescence recovery after photobleaching for a polymersome tip pulled into a glass micropipette. The recovery of the tip intensity can be monitored by fluorescence imaging showing the lateral diffusivity in the bilayer. From Ref. 47, with permission from the ACS Publications Division).

$D \approx 10^{-7}$–10^{-8} cm^2/s. Depending on molecular weight, block copolymers have much lower values of $D \approx 10^{-9}$–10^{-11} cm^2/s for molecular weights between 4000 and 10,000 g/mol (47).

The surface shear viscosity of block copolymer vesicles is about 500 times higher than those found in common phospholipid bilayers (53). The experiments involve pulling out a tether from an immobilized polymersome and following its relaxation back to the vesicle body. This provides an estimate of the viscous coupling between the two monolayers composing the polymer membrane. For giant vesicles of approx. 100 μm diameter, typical relaxation times for thin tethers of 50 μm length and 0.1 μm diameter are of the order of 30–90 s. The detected intermonolayer friction is about an order of magnitude higher than for phospholipid membranes.

Stability. Because of their increased toughness and bending elastisticity, block copolymer vesicles are more stable compared to lipid vesicles. Block copolymer vesicles have been reported to be stable over several years with no changes in size or size distribution (156).

Electromechanical Stability. The electromechanical stability of diblock copolymer membranes is several times larger compared to lipid membranes (152). At zero mechanical tension, the breakdown potential V_c for polymersomes with a membrane thickness of $d = 15$ μm is $V_c = 9$ V, compared to 1 V for liposomes with $d = 3$ nm. The breakdown potential increases with membrane thickness up to a limit set by the interfacial tension (53,152). The electromechanical stresses at breakdown universally exhibit a V_c^2 dependence. The membrane capacitance shows the expected strong d dependence.

Thermal Stability. The thermal expansion coefficient for lipid membranes far from phase transitions is generally in the range $\alpha_T = 0.001$–0.01 K^{-1} (157), which is similar for polymersomes with values of $\alpha_T \approx 0.002$ K^{-1} (49), albeit with no thermal transitions. The thermal stability of vesicles is of importance, if autoclaving is needed for sterilizing vesicles that are too large for filtration through 0.22 μm filters. When polymersomes are autoclaved in dilute suspension for 15 min at a maximum cycle temperature of 121°C (2 atm), about 10% of the vesicles have retained their contents (sucrose solution). Interestingly, the distribution of vesicle sizes shifts to smaller and tighter distribution. It is speculated that because of area expansion, small vesicles have budded off (49).

Stability to Lysis. The addition of surfactants eventually leads to lysis of vesicles. In general, the stability of polymer vesicles against lysis is expected to be higher compared to lipid vesicles, because of the reduced entropy of mixing of polymer and surfactant chains which leads to a reduced partition of surfactants in the polymer membrane. When using Triton-X as a nonionic surfactant, it was found that the concentration of surfactant required for dissolution after a fixed amount of time increases nearly linearly with membrane thickness (158). Because of low partition of hydrocarbon surfactants, vesicles formed by siloxane and fluorinated polymers are expected to have relatively high stability.

The incorporation of PEO-PPO-PEO (Pluronic L31) surfactants into preformed giant PEE-PEO vesicles has been investigated and was found to be weak and reversible (159). The incorporation reduced the area expansion modulus k_A by almost a factor of 2, while dramatically increasing the vesicles susceptibility to lysis. Additionally, water permeability was increased by a factor

of 2. Surfactant incorporation rates were proportional to the free surfactant concentration.

Permeability.

Permeation Coefficient. Vesicles will slowly release encapsulated molecules by permeation through the vesicle bilayer. The release rate is determined by the permeation coefficient P (in m^2/s), which is related to the solubility or the partition coefficient S of the compound between the aqueous phase and the bilayer, and to the rate of diffusion or diffusivity D of the compound in the bilayer, ie

$$P = S\mathrm{D} \tag{19}$$

In a fluid membrane, diffusion coefficients of small molecules have the same magnitude as in bulk solvents. Therefore, the factor determining the permeability is the partition coefficient. Small ions whose low solubility in hydrophobic environment leads to very small values of the partition coefficient exhibit very low permeabilities.

The permeability of small polar solutes across a bilayer or membrane can be greatly enhanced by introducing specific carriers. A small solute X can be transported by a carrier C such that the complex CX has a much higher partition coefficient compared to the bare solute X. Common ion carriers, or ionophores, are valinomycin for K^+ and crown ethers for alkali ions. Solutes can also cross the membrane through channel proteins, eg gramicidin.

If the permeation occurs via Fickian diffusion driven by the concentration gradient across the bilayer, the permeation time τ is related to the permeation coefficient as

$$\tau = \frac{R}{3}\frac{\mathrm{d}}{P} = \frac{V}{A}\frac{\mathrm{d}}{P} \tag{20}$$

where R is the radius, V the volume, A the surface area of the vesicles, and d is the bilayer thickness. Smaller vesicles exhibit a faster release because of the larger surface/volume ratio compared to larger vesicles. Often, the permeation of molecules is compared in terms of their permeability $p = Pd$ (in m/s), since most lipid bilayers have a similar bilayer thickness of $d \approx 3$ nm. For practical applications, equation 20 allows one to tailor release rates τ^{-1} via bilayer thickness and vesicle radius, which themselves can be controlled via polymer block length and vesicle preparation method. Because of the larger thickness of polymer bilayers compared to lipid bilayers, the permeability of molecules can be adjusted to be much slower.

Permeation Experiments. Encapsulated fluorescent and radiochemical labels are commonly used to evaluate permeabilities. Three different types of experiments allow to determine the permeation coefficient.

(1) In one experiment the release of labeled molecules into the exterior solution is monitored in a closed cell. If the initial concentration of the label inside the vesicle is c_0, and in the exterior solution is equal to zero, and if the volume encapsulated by the vesicles is much smaller than the volume of

the sample cell, $V_{ves} \ll V_{cell}$, then the concentration of the labeled molecule in the exterior solution is increasing with time t as

$$c(t) = c_\infty(1 - e^{-t/\tau}) \tag{21}$$

where $c_\infty = V_{ves}c_0/V_{cell}$ is the saturation concentration in the exterior solution for $t \to \infty$. For short times ($t \ll \tau$), $c(t) = c_\infty t/\tau$, which allows to obtain the permeation time and thus the permeation coefficient from the initial linear increase of the concentration with time. The concentration c_∞ can be obtained after lysing the vesicles via addition of a surfactant, where all labeled molecules are released into the exterior solution.
Conveniently, one monitors the increase of the fluorescence intensity of an encapsulated self-quenched dye, eg 50 m*M* 6-carboxyfluorescein (6-CF) (160) or calcein (161), as it permeates the vesicles. [^{3}H]Glucose is more generally applicable because it does not interact with charged lipid membrane surfaces and can be used at low ionic strength. Alternatively, a dilute solution of 6-CF (10 μm) is encapsulated and Co^{2+} (500 μm) is added to the external solution which quenches the fluorescence. Permeation of either Co^{2+} ions or the dye across the membranes causes a reduction in fluorescence intensity.

(2) In the second type of experiment the vesicle with encapsulated solute is placed in an ultrafiltration cell which is continuously flushed with solvent at a rate v_1 (in mL/min) (162,163)

$$c_1(t) = \frac{V_{ves}}{v_1\tau} c_0\, e^{-t/\tau} \tag{22}$$

The permeation coefficient can be obtained from the exponential decay, provided that the elution rate is faster than the permeation rate of the vesicles, $v_1 \gg V_{ves}/\tau$. This method does not rely on fluorescence labels and can be used for any solute. In addition, this method more closely resembles the *in vivo* situation where vesicles release solutes that are instantaneously carried away by the blood stream.

(3) In a third type of experiment the vesicles are investigated under equilibrium with free exchange between encapsulated and nonencapsulated solute. The exchange rate and fraction of encapsulated solute can be determined with pulsed field gradient nuclear magnetic resonance (PFG-NMR). Using this technique, the permeability of polyethylene oxide PEO through P2VP-PEO vesicle bilayers has been determined as a function of molecular weight of PEO (55). The analysis yielded a nearly linear dependence of the logarithmic transmembrane exchange rate on the hydrodynamic radius of the polyethylene glycol (PEG) molecules. The method does not require to separate encapsulated from nonencapsulated molecules. It allows to estimate the encapsulated molar fraction of PEO chains, which was in the range of 2%.

Barrier Properties. The water permeability p of lipid bilayers is reported to be in a range of $p = (5–100) \times 10^{-6}$ m/s. In comparison, polar solutes such as

glucose, glycerol, and urea have much smaller values of $p = (5–300) \times 10^{-10}$ m/s. Small ions such as Na^+, K^+, and Cl^- have the lowest permeabilities, in the range of $p = (1–100) \times 10^{-14}$ m/s (164). Even though the bilayers are only 3 nm thick, they provide an effective barrier to ions and other polar compounds.

The permeability of polymersome membranes for a given solute has been reported to be at least 10 times smaller compared to common phospholipid membranes (8). Retention of encapsulants (eg dextrans, sucrose, physiological saline) over periods of months has been observed for small ∼100 nm polymersomes prepared by liposome-type extrusion techniques (49) as well as with ∼10 μm giant vesicles. Permeability and membrane hydration have been shown to be inversely related to the bending modulus (165). It is suggested that membrane permeability and membrane hydration are related to the ability of the membrane to locally bend so as to create holes for solute permeation.

Cross-Linking, Anchoring, and Templating of Membranes

A major problem of lipid vesicles in pharmaceutical applications has always been their minor stability. Stabilization of vesicles can be achieved by introduction of covalent cross-links or the attachment of stabilizing polymers (87,166–168). The most common methods involve the

(1) formation of vesicles with polymerizable amphiphiles and subsequent polymerization (166,167,169);
(2) solubilization or association of polymerizable monomers to the amphiphile or vesicle bilayer with subsequent polymerization;
(3) association or anchoring of polymers for vesicle bilayer stabilization.

The polymerization of lipid assemblies was first demonstrated in monolayers, vesicles, and extended bilayers and subsequently in cast multilayers, black lipid membranes, and tubules. During the 1970s several groups demonstrated that fatty acids with an incorporated reactive group, eg photopolymerizable diacetylenes, could be polymerized in a monolayer (170,171). The introduction of synthetic double-tail amphiphiles, coupled with the successful demonstration of polymerization of fatty acid monolayers, led directly to the next step in the early 1980s. Vesicles of a polymerizable double-chain ammonium salt have been described with a methacrylate at the end of one hydrocarbon chain (**1**) (Fig. 22) (172). In short order three additional groups (173–175) reported the synthesis and polymerization of lipid diacetylenes (**2, 3**) in bilayer membranes. Within a year, the synthesis and polymerization of dienoyl lipids (**4**) (176,177), methyacroyl lipids and other diacetylenes (178), and styryl lipids (179) were reported.

Polymerizable Amphiphiles. Polymerization of amphiphiles with only one reactive group per lipid such as **1–3** yield vesicles that contain several polymer chains, termed polymerized vesicles. The presence of a second polymerizable group per molecule (**4**) allows cross-linking of the polymer chains and thus cross-linking of the bilayer structure. Such reactive groups include diacetylene, acryloyl, methacryloyl, itaconyl, dienoyl, muconyl, styryl, vinyl, thiol, and isocyanates. The

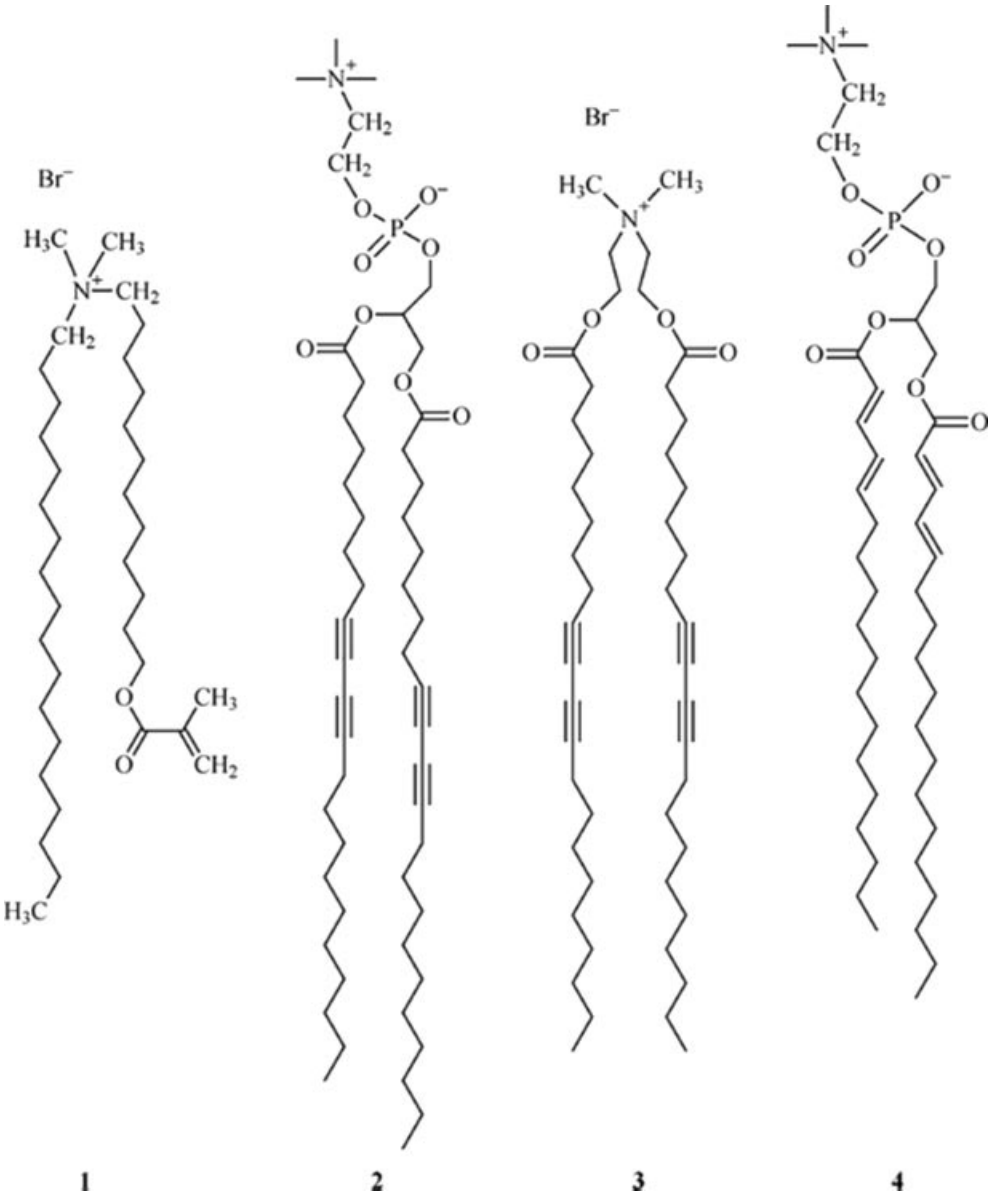

Fig. 22. Chemical structure of polymerizable and cross-linkable lipids.

use of carotene side chains for the preparation of cross-linked vesicles has also been demonstrated (180). Polymerization can be induced by photo, thermal, or redox initiation. In most cases, the vesicle size and shape are not significantly changed by the polymerization reaction.

Cross-Linking. Cross-linking increases membrane stability to detergents and organic solvents. The polymerization of monosubstituted lipids **1–3** in vesicles leads to moderate changes in stability, whereas more significant changes are

found only after polymerization of bis-substituted lipids. For example, polymerized vesicles from mono-methacryloyl lipids may still be disrupted by detergents and organic solvents, albeit at somewhat higher concentrations than required for unpolymerized vesicles. In contrast, polymerized vesicles from the bisdienoyl PC (**4**) are quite stable to detergents and organic solvents (181). The polymerization of **4** yields vesicles that are stable enough to maintain their spherical shape in the vacuum chamber of a scanning electron microscope (182). Polybisdienoyl PC vesicles are not solubilized by 2 m*M* sodium dodecyl sulfate (183).

Measurements of the release rate of encapsulated [^{3}H]glucose through vesicles before and after polymerization show that the permeabilities of vesicles of mono-methacryloyl lipids are reduced upon complete polymerization to 30–50% of the unpolymerized control vesicles (181). A much larger reduction (2 orders of magnitude) in membrane permeability is observed on photopolymerization of the bis-methacryloyl lipid **4**, which allows cross-linking of the vesicle bilayer. Thus the formation of linear chain polymers in vesicles does not significantly alter the physical properties, whereas polymerization of disubstituted lipids can lead to cross-linked polymer networks with a corresponding large change in vesicle properties.

Polymerizable Counterions. Ion exchange of the counterions of ionic lipids vs polymerizable counterions such as choline methacrylate presents an additional route for vesicle stabilization much like the formation of the actin network of natural membranes. Photopolymerization yields vesicles with surface-associated polyelectrolytes. These vesicles were reported to have a similarly reduced permeability as polymerized mono-methacryloyl lipid vesicles (184).

Polymerizable Block Copolymers. Unsaturated hydrocarbon polymers with a large number of polymerizable double bonds can be used to prepare fully cross-linked vesicle membranes. This has been demonstrated for polybutadiene block copolymers (23,168) and methacroyl-functionalized block copolymers (87) using free-radical polymerization, and for polycinnamoylethylmethacrylate block copolymers using a [2+2] photoaddition (68). Poly(ethylene oxide-*b*-3-(trimethoxysilyl)propyl methacrylate) vesicles could be efficiently cross-linked with triethylamine (79,80). PLA-PNIPAM block copolymer vesicles were cross-linked by chain extension of the PNIPAM block using hexamethylene diacrylate (77).

In case of the polybutadiene vesicles, the membrane transformation from liquid to solid state is directly observable upon osmotic deflation of the originally spherical vesicle as creases, folds, wrinkles, and dents proliferate like the deflation of a micron-sized rubber ball (Fig. 23). The cross-linked vesicles do not dissolve in chloroform, a common solvent for both blocks. Encapsulated sucrose was not lost in chloroform, indicating membrane stability on a molecular scale. The results imply defect-free membranes many microns-squared in area. Surface elastic moduli as well as sustainable wall stresses are orders of magnitude greater than any natural lipid membrane. Cross-linked vesicles could be dried, stored at room temperature for days, and then rehydrated to their original average diameter and volume (87). Mixing of saturated (PEE) and unsaturated (PB) block copolymers allows to tune the bilayer elastic constants as well as the rupture strength over a broad range (168). Preblending with a non-cross-linkable diblock copolymer of PEO-polylactic acid undermines vesicle stability in chloroform/water solutions (185). The results prove miscibility and stable integration of a binary block

copolymer mixture in a membrane, and allow to realize a first-order scheme for controlled release of encapsulants.

Solubilization of Monomers. Hydrophobic monomers such as methacrylates (186) and styrene (187) can be solubilized into the bilayers of lipid vesicles. These monomers can subsequently be polymerized within the membranes by an UV-induced free-radical polymerization, which leads to the formation of a quasi-two-dimensional polymer entanglement network. The polymerized vesicles are stable to addition of surfactant (bare liposomes are not), can be isolated by lyophilization, and subsequently redispersed in aqueous media by sonification. Depending on the dimensions of the templating vesicles, polymer hollow spheres can be produced with diameters ranging from several tens of nanometers up to hundreds of micrometers (188–191). After extraction of the surfactant matrix, the polymer particles contract considerably without loss of their spherical shape. By the same method, water-soluble polyelectrolyte nanocapsules have been prepared (192–194). These particles show a reversible pH- and ionic strength-dependent swelling transition, causing a considerable increase (decrease) of their radius together with a change of the permeability of the polyelectrolyte walls, which can be used to trigger the release of encapsulated materials.

Adsorption of Polyelectrolytes. Some water-soluble polymers adsorb to neutral or charged membrane surfaces by hydrophilic or ionic interactions which can stabilize or destabilize vesicles. Polyelectrolytes such as polyionene-6,6 (195,196) and poly(L-lysine) (197,198) have been adsorbed to negatively charged lipid vesicles and effects on bilayer thickness and polymer conformation have been investigated. Studies of the adsorption of polyanions to positively charged lipid vesicles are of importance for gene transfection of plasmid-DNA in gene therapy. The adsorption of poly(α-ethylacrylic acid) (PEAA) has been used to make lipid vesicles pH-sensitive. Acidification induces conformational changes of PEAA, leading to disruption of the vesicles (199,200).

Anchoring of Polymers. Synthetic polymers with hydrophobic side groups interact with membranes by insertion of these so-called anchors into the bilayer. Polysaccharides such as pullulan and amylopectin, which were derivatized with palmitoyl groups, are sufficiently hydrophobic to insert into lipid bilayers (201). If a sufficient amount of polysaccharide is added after vesicle formation, the

vesicles are coated only on the exterior surface. The bound polysaccharide reduces the vesicle permeability to water-soluble markers and decreases the sensitivity of the vesicle lipids to enzymatic hydrolysis by phospholipases (201). The surface characteristics of such polysaccharide vesicles are sufficiently different from those of uncoated vesicles in that they display an unusual distribution of vesicles in the body. The lung uptake of vesicle-encapsulated label is five times greater for *O*-palmitoyl amylopectin-coated vesicles than for uncoated vesicles. Monoclonal antibody fragments attached to polysaccharide-coated vesicles bind to specific cells with a higher frequency than those attached to antibody-free coated vesicles (202).

Pluronic-type PEO-PPO-PEO triblock copolymers were anchored into bilayers of soybean lecithin to prepare sterically stabilized vesicles (203–205). Vesicles with anchored polymer are reported to have an increased stability with respect to cation (Na^+, Mn^{2+})-induced flocculation. Also the addition of other hydrophobically modified polymers to lipid vesicles lead to a stabilization of the vesicles (206).

Templating. Solutions of multilamellar block copolymer vesicles could be used as templates for the preparation of vesicular structured monolithic silica using a sol/gel process (57). This method can be used to freeze vesicular structure for analysis, and also for the preparation of mesoporous silica with slit pores. Thin films of templated multi-bilayer vesicular structures of PS-PEO could also be prepared using sol/gel chemistry (28). The films were prepared from dilute PS-PEO/THF/water/silica precursor mixtures via solvent evaporation. For the silica/diblock copolymer films with regular mesophases, copolymer removal produced also mesoporous structures.

Biomedical Applications

Vesicles are intensely investigated with respect to their use as transportation systems for pharmaceutical and cosmetic applications (207,208). The potential of lipid vesicles is rooted in the notion that natural lipids will be at least partially biocompatible (209). Via conjugation with biological ligands different biomedical functions can be implemented into the vesicle (Fig. 24), including

(1) actuator functions for temperature-, pH-, salt-, and light-triggered release;
(2) the incorporation of adhesion sites, eg RGD sequence, sialyl-Lewis^x, HIV-TAT sequence;
(3) the conjugation of recognition sites, eg antibodies like anti-PECAM to target lung endothelia or anti-CD3 to peripheral blood cells (210);
(4) a "stealth" layer to prevent unspecific recognition; and
(5) integral proteins that provide channel and transport functions.

Conjugation can be achieved by covalently attaching a ligand to the end group of the peripheral polymer block, eg via activated ester synthesis, or by reconstitution of a protein or ligand into the vesicle bilayer. By using a mixture of functionalized and unfunctionalized block copolymers, vesicles with optimal ligand spacing can be prepared for efficient binding to cell surfaces.

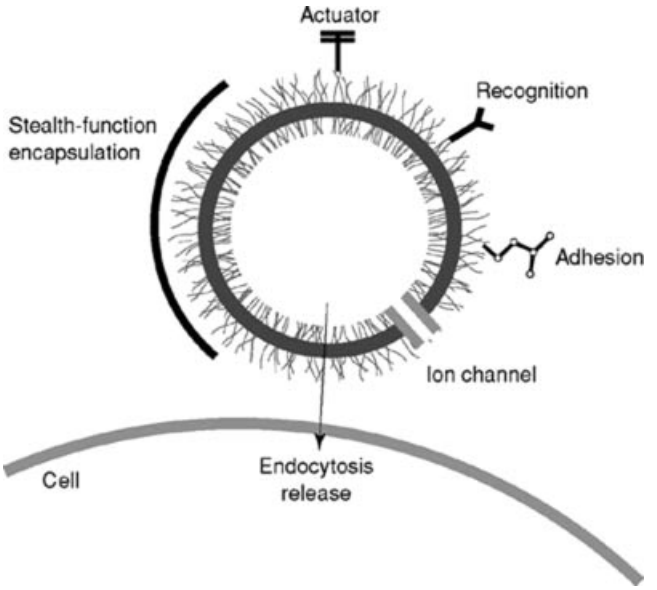

Fig. 24. Biomedical functions that can be implemented into vesicles. From Ref. 20, with permission from John Wiley & Sons, Inc.

Problems can consist in the chemical and colloidal stability, eg upon oral administration, and in the low permeation through cellular membranes. For this reason vesicles are mostly administered parenterally, ie intravenously, subcutaneously, or intramuscularly. Their tissue specificity is first confined to the cells of the reticuloendothelial system which recognizes them as foreign microparticles and transports them to liver and spleen. Their biodistribution can be regulated by surface modification, eg by placing PEO (*stealth* systems) or monoclonal antibodies (*site-specific targeting*) to the vesicle surface. By this means their residence time and bioavailablity can be increased (211).

Biocompatibility. The biocompatibility of materials is influenced predominantly by the material surface. Materials with hydrophilic surfaces are often well-suited, because hydrophilic, noninteracting surfaces are difficult to recognize by living systems and have low cytotoxicity.

Stealth Layers. It is known that PEO (or PEG, which is chemically the same) enhances the biocompatibility of polymeric materials. PEO is water soluble, chemically stable under physiological conditions, and shows low unspecific binding of proteins. Liposomes containing lipid-conjugated PEO as a hydrophilic layer do not interact with and are difficult to be recognized by living systems and have been called "stealth" liposomes. Blood plasma proteins, which generally adsorb to artificial surfaces and mediate clearance by immune system cells, are sterically delayed in deposition into or onto "stealth" membranes. After intravenous injection stealth liposomes are cleared more slowly from the blood circulation than are conventional liposomes. PEO chains can prolong circulation half-lives from a few hours to tens of hours. The extended circulation time allows stealth vesicles loaded with anticancer drugs (eg doxorubicin) to be distributed to distant and well-hidden

tumors (212). Eventually, liposomes are engulfed by phagocytic cells of the liver and spleen.

For optimal stealth properties, liposomes would have to be densely covered by a PEO layer. However, PEO liposomes are limited in their ability to integrate high molar ratios of PEO lipid because of shape transitions to micellar structure as a result of the increasing interfacial curvature and lower packing parameter. Polymersomes have the advantage that vesicles are entirely composed of PEO-based block copolymer amphiphiles and are not limited by PEO-driven micellization.

Blood Plasma Stability. Polymer vesicles are found to be stable for at least 5 days in plasma when suspended at room temperature and kept well-mixed (49). Under quiescent conditions vesicles are stable for almost 60 h. At longer times, aggregation of settled-out vesicles is observed. Within the aggregates, no vesicle fusion is observed because of the steric stabilization of the PEO chains.

Phagocyte Stability. Of particular importance is the assessment of the interaction of vesicles with the cellular components of blood, particularly granulocytes, which are the predominant circulating phagocytes. Neither adhesion nor stimulation of phagocytes are apparent when giant polymersomes are held in direct contact. When placed in contact with a white cell (Fig. 25**b**), vesicles do not exhibit any adhesion or other cellular response for up to 30 min, despite the presence of 20% plasma. In comparison, 1–2 min of contact between a yeast particle and a white cell (neutrophil leukocyte) leads to strong adhesion (49).

Proliferating cells are unaffected when cultured for an extended time with an excess of polymersomes. Similar *in vitro* tests with macrophages, endothelial cells, and myoblasts further indicate the inertness of the polymersome surface. The dense PEO layer prevents the deposition of phagocytic ligands such as plasma C3b on the vesicle surface, thereby repelling phagocyte adhesion. The lack of polymersome recognition by phagocytes is important for prolonged circulation upon intravital injection.

In Vivo Performance. Polymersomes are found to have *in vivo* circulation times of $\tau_{1/2} \approx 18$ h, which is about twofold longer than PEGylated or stealth

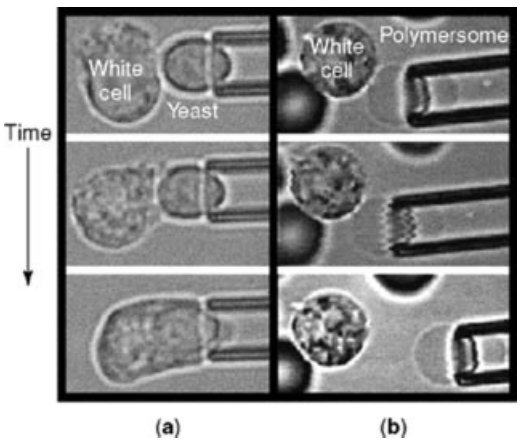

Fig. 25. Exposure of a yeast cell (**a**) and a polymersome (**b**) to a white cell. The yeast cell is rapidly engulfed, whereas there is no response upon contact with the polymersome. From Ref. 49, with permission from John Wiley & Sons, Inc.

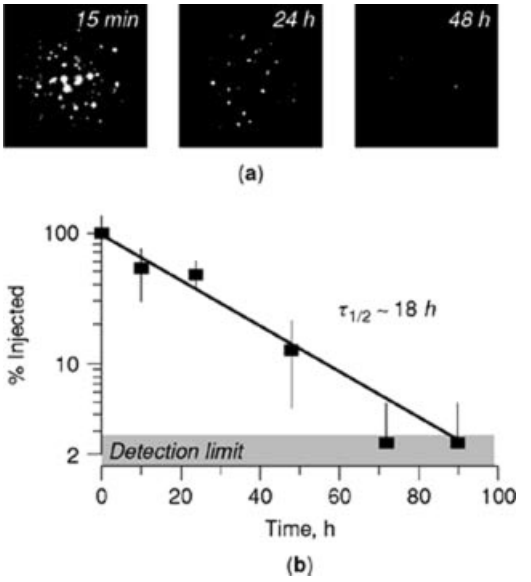

Fig. 26. Fluorescence images (**a**) and number of polymersomes (**b**) after different circulation times in rats. The experiment shows the delayed clearance of polymersomes from the blood stream. From Ref. 213, with permission from Elsevier B.V.

liposomes. Fluorescently labeled vesicles were injected into rat tail veins with subsequent bleeds taken to monitor vesicle clearance from the circulation (213) by taking a fluorescence image of centrifuged platelet-poor plasma (Fig. 26). From image analysis, the decay of the number of vesicles with time is obtained, which is fitted to an exponential to derive the circulation half time $\tau_{1/2}$.

As with lipid vesicles, the circulation time is limited by uptake into the liver and spleen. *In vitro* incubations of polymersomes in plasma indicate plasma protein adsorption during circulation, which leads to engulfment of the vesicles by phagocytes.

Toxicity. Toxicity is found to be a minor problem and many vesicle systems have passed standard toxicity tests. The hydrophilic PEO block effectively screens the influence of the hydrophobic cores on timescales of the measured circulation half-life $\tau_{1/2}$. With respect to long-time applications, PEE is structurally similar to low-density polyethylene, which is commonly used in implants and is generally considered bioinert (214). PB is also understood to be bioinert as it is commonly chosen for the hydrophobic block in triblock copolymers (215,216). In a more prolonged model test of biocompatibility, nondifferentiated C_2C_{12} cells were incubated with polymersomes. The cells remained well spread with no evidence of cytotoxicity. As shown by the Trypan blue exclusion assay, polymersomes had no significant effect on cell survival.

Encapsulation and Release.

Encapsulation Methods. Vesicles can solubilize and encapsulate hydrophilic as well as hydrophobic compounds. Hydrophobic compounds (eg carotene, vitamin E, Taxol, CdTe-quantum dots (20)) are solubilized into the hydrophobic interior of the bilayer. Solubilization can be achieved by stirring the

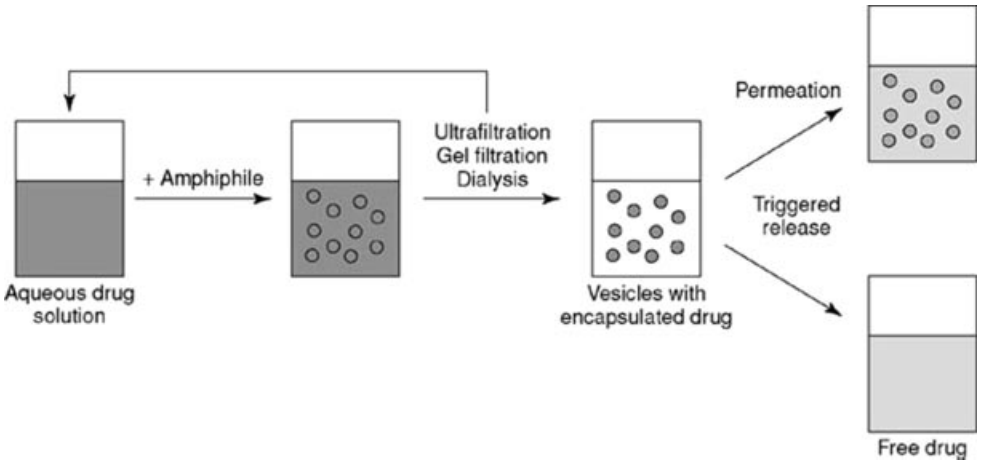

Fig. 27. Methods for encapsulation and release of hydrophilic drugs using vesicles. From Ref. 20, with permission from John Wiley & Sons, Inc.

hydrophobe in the aqueous vesicle solution or by dissolving the vesicle-forming amphiphile and the hydrophobe in an organic co-solvent with subsequent transfer into water. Because of the small mixing entropy, polymer vesicles have a higher selectivity for the solubilization of hydrophic compounds compared to lipid vesicles.

Hydrophilic drugs can be encapsulated by dissolving the vesicle-forming amphiphile in the aqueous drug solution (Fig. 27). Removal and recycling of nonencapsulated molecules is possible by ultrafiltration, gel filtration, dialysis, or centrifugation. Polymer vesicles can retain encapsulated molecules over periods of days to weeks. Encapsulated substances include fluorescein (7,102), rhodamin (68), eosin, myoglobin, hemoglobin (7), BSA (7), dextrans (7), PEG (55), sucrose (7), physiological saline, doxorubicin (78,217), β-lactamase (218), and cylindrical micelles (219). As has been shown, encapsulation of enzymes into liposomes or polymer nanocapsules protects them against proteases and denaturation (218). Particularly interesting is the integration of channel proteins into bilayers, which is discussed below.

Sustained Release. Depending on permeation coefficient, vesicle radius, and bilayer thickness, encapsulated low molecular weight solutes will be released on timescales of minutes to days. This can be used for the controlled release of drugs, where the dose can be predicted from the encapsulated volume and the initial drug concentration in the vesicle using equation 21. Large ionic solutes, in particular proteins, will have low release rates and are practically permanently encapsulated until the vesicle is ruptured.

Triggered Release. By triggering solution conditions vesicles can be spontaneously dissolved with a concomitant release of the encapsulated substance. This can be achieved with vesicles containing polymer blocks with solubilities responding to changes in pH, temperature, and ionic strength. Other stimuli include UV, light, enzymes, and reducing agents which degrade the polymer block.

pH-Triggered Release. The pH-induced release is of relevance for the delivery of drugs and genes into the cytosol via endolysosomal acidification and

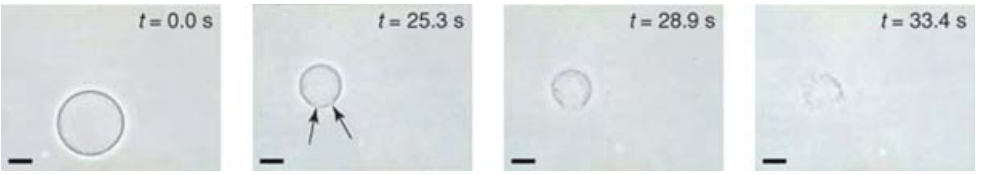

Fig. 28. Shrinking and lysis of P2VP-PEO vesicles by addition of dilute acetic acid. The arrows indicate the formation of holes in the membrane. From Ref. 224.

escape for applications in chemo- and gene therapy. The acid-catalyzed and thus pH-dependent hydrolysis of plasmenylcholine vesicles has been used to release encapsulated calcein (220). With the pH decreasing from 6.3 to 2.3, the time to release 50% of the calcein decreased by 3 orders of magnitude from 50 h down to 3 min. The acid-catalyzed hydrolysis of the vinylether linkage of PEG-DOPC lipids has been used to trigger the release of calcein from lipid vesicles at pH <4.5 (221–223). A pH response can also be realized by using polybase blocks which can be rendered water soluble by protonation at low pH (224). A pH-induced lysis is shown in Figure 28 for P2VP-PEO vesicles upon addition of acetic acid. A protonation of L-lysine residues in the hydrophobic domain of polypeptide diblock copolymer bilayers was used to destabilize vesicles to release encapsulated Fura-2 dye (82,83).

Reducing Agents. The release of eosin induced by addition of a reducing agent has been demonstrated for polymerized lipid vesicles. Immiscible lipid mixtures can laterally phase separate within the membrane to form domains. This can be achieved by using a mixture of hydrocarbon and fluorocarbon lipids, eg, a polymerizable dienoyl lipid and a labile fluorocarbon disulfide lipid in the ratio 9:1 (146), or a polymerizable fluorinated lipid together with a labile bolaamphiphile in the same ratio 9:1 (146). Photopolymerization of the lipid domains stabilizes the vesicles, which can efficiently entrap the fluorescent dye eosin. Exposure of the vesicles to dithiothreitol reduces the disulfide over several minutes and divides the lipid in half at the head group. The reduction product, a single-chain cysteine, prefers a micellar rather than a lamellar structure; therefore, the polymerized vesicles become leaky by the formation of holes, accompanied by release of the eosin (50% loss over 10 min) from the vesicle.

Oxidizing Agents. In case of PEO-PPS block copolymers, the thioether groups of the hydrophobic PPS blocks can be converted into the more hydrophilic sulfoxides and sulfones by exposure to an oxidative environment. This changes the hydrophilic–hydrophobic balance and can be used to destabilize PEO-PPS vesicles. In a study by Napoli and co-workers, hydrogen peroxide was used as the oxidizing agent, which was produced by glucose oxidase (GOx) upon reaction with glucose (73,74). When using PEO-PPS-PEO vesicles with encapsulated GOx, addition of glucose triggers the oxidation with a concomitant destabilization and dissolution of the vesicles.

Enzymatic. Another method of lipid cleavage involves the enzymatic hydrolysis of phospholipids. The enzyme phospholipase A_2 catalyzes the hydrolytic cleavage of phospholipids into fatty acids and lysolecithins, which disrupts the vesicle bilayer (225,226). However, it does not attack the polymerizable bisdienoyl

4. Therefore the selective hydrolysis of DPPC in mixed lipid membranes is possible (146) as shown by the release of 6-CF that had been encapsulated in vesicles of DPPC and **4** (1:1).

Hydrolysis. PLA-PEO and PCL-PEO block copolymers have been investigated for the release of doxorubicin (78). The release is induced by the hydrolysis of the PLA- and PCL-polyester blocks. PCL has a smaller degradation rate compared to PLA. The block copolymers were blended with PB-PEO prior to formation of the vesicles to increase the release times τ by a factor of 10, ie from 21 to 208 h.

Polymerization-Induced. Two-component vesicles of a polymerizable PC and a PE form stable vesicles. Photopolymerization induces a lateral phase separation of polymerized PC domains and unpolymerized PE domains. As pure PE does not form bilayers, this leads to a destabilization of the vesicles as shown by the release of calcein or other water-soluble self-quenched fluorescent markers (227).

Photo- and UV-Induced. The bacteriochlorophyll-sensitized photooxidation of plasmenylcholine vesicles was used to trigger the dissolution and release of Ca^{2+} ions (228). The photorelease of Ca^{2+} ions subsequently activated calcium-dependent phospholipase A2, leading to the enzymatic cleavage of DPPC phospholipid vesicles containing calcein. In effect, this lead to a light-induced release of encapsulated calcein via a two-step cascade process. Block copolymer vesicles (PMPS-PEO) containing encapsulated fluorescent dye can be broken up using UV irradiation, which photolytically cleaves the PMPS segments (229).

Conjugation with Membrane Proteins.

Reconstitution. The reconstitution of membranes from purified protein and lipid components is a well-known method for the study of membrane protein functionality. Membrane proteins that have been reconstituted into liposomes of polymerizable lipids include ATP synthetase (230), bacteriorhodopsin (231,232), rhodopsin (233,234), and porins.

ATP Synthetase. Membrane-bound proteins that utilize the proton gradient across the membrane to form ATP from ADP and phosphate are known as ATP synthetases. The synthetase complex, composed of a hydrophobic part (F0) and a water-soluble domain (F1, catalytic center) from Rhodospirillum rubrum, was incorporated into liposomes of a polymerizable sulfolipid (235). Lipid-free synthetase has a very low enzymatic activity. If the sulfolipid liposome is partially photopolymerized and the protein complex is incorporated into the liposome, the observed enzymatic activity is comparable to that of the natural lipid membranes.

Rhodopsin. Rhodopsin is the principal membrane protein of the light-harvesting and energy-transducing rod outer segment (ROS) cell. Light absorption by the chromophore of the transmembrane rhodopsin initiates spectral and structural changes in the protein that enable it to interact with several peripheral membrane enzymes, a G protein (transducin), and a phosphodiesterase. Recombination of these ROS enzymes with rhodopsin-lipid bilayers yields a system that displays the native activation sequence. Light stimulation (a millisecond flash) of the rhodopsin results in the activation of both peripheral proteins and a rapid hydrolysis of the cyclic GMP to decrease the pH of the aqueous buffer. These rhodopsin membranes are functional, with a high yield (10^5) of protons produced per photon.

Porins. In natural cell walls the rate and selectivity of substrate permeation is controlled by porins. Porins are transmembrane proteins that form trimeric water-filled channels that allow passive diffusion of small solutes, such as ions,

nutrients, or antibiotics, across the membrane. The most prominent of these porins is OmpF (outer membrane protein F). Molecules with a molecular weight above 400 g/mol are sterically excluded from the OmpF channels. In addition, it has stereospecific binding sites for maltooligosaccharides inside the aqueous channels, which enhance the diffusion of sugars across membranes. It is also the pathway of β-lactam antibiotics intrusion into the bacteria. OmpF has further the interesting property of being closed if a transmembrane voltage above a certain threshold is applied. Porins are quite stable and are not denatured at temperatures up to 70°C or in 2% SDS. They can be produced on large scales in Escherichia coli using recombinant technology.

OmpF was successfully reconstituted into lipid vesicles (186,218), which could be demonstrated using an encapsulated enzyme, β-lactamase, which is able to hydrolyze the antibiotic ampicillin. The hydrolysis product, ampicillinoic acid, can reduce iodine to iodide, which can be monitored by iodometry, ie via the decolorization of a starch/iodine complex in the exterior solution. The enzyme and the membrane channel have been shown to preserve their activity in the presence of hydrophobic methacrylate monomers before and after their cross-linking polymerization. Polymerization of hydrophobic *N*-butylmethacrylate and ethylene glycol dimethacrylate (186) lead to partial expulsion of some reconstituted channels during the cross-linking reaction, thereby decreasing the enzymatic activity.

OmpF has also been reconstituted into the membrane of PMOX-PDMS-PMOX triblock copolymer vesicles carrying polymerizable end groups (236). The triblock copolymer membrane had a thickness of 10 nm, which is two to three times thicker than a conventional lipid bilayer (237). Nevertheless, the channel-forming OmpF could be reconstituted and remained functional, showing similar activities as in lipid membranes, despite the extreme thickness of the membranes. The functionality even remained after polymerization of the reactive end groups, which was demonstrated by monitoring the ampicillin hydrolysis of encapsulated β-lactamase (156,218,237–240).

The maltooligosaccharide-specific channel LamB, or maltoporin, of E. coli forms trimeric channels in the outer cell wall of Gram-negative bacteria that allow a specific transport of maltose and maltodextrins. Simultaneously, it serves as a receptor for phage-λ. Because during infection the phages transfer their genome into the host cells, it has been proposed that the channels of LamB could be a major intrusion path for the viral DNA.

For this purpose LamB was reconstituted into membranes of PMOX-PDMS-PMOX vesicles and the binding to phage λ was studied (156). It was demonstrated that the functionality of the LamB protein is fully preserved, in particular its binding to phage λ (Fig. 29). The transfer of DNA into the vesicles was quantified by labeling the viral DNA with the fluorescent dye YO-PRO-1. After injection of the phage, the intensity is increasing because of partial capsoid lysis. The further increase of the intensity after lysis of the vesicles demonstrates the injection of DNA (156).

Generally, integral membrane proteins are vectorial molecules with distinct cytoplasmic and extracellular parts. They insert into cell membranes with a specific orientation. A reconstitution of aquaporin 0 with preferred orientation has been achieved by using vesicles consisting of an asymmetric PEO-PDMS-PMOX bilayer (94). The amino terminus of the porin orients to the cytoplasmatic side

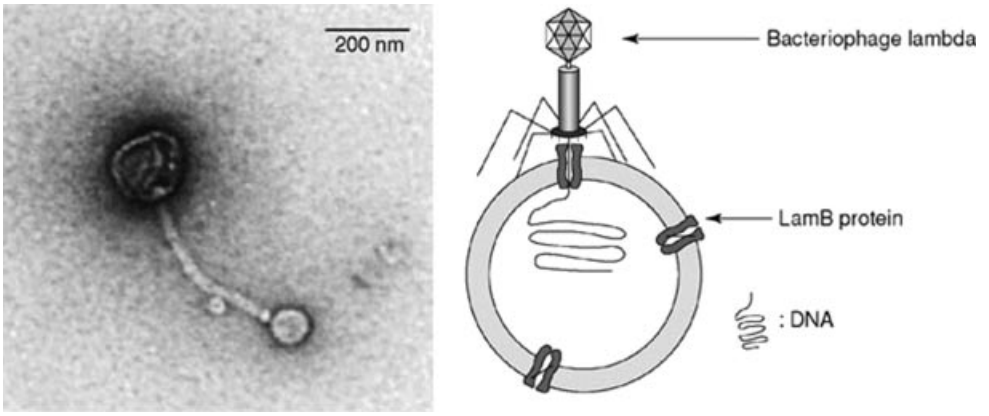

Fig. 29. Injection of virus-DNA through reconstituted LamB protein. The λ-capsid is icosahedral with an outer diameter at 63 nm and the inner diameter at 55 nm. From Ref. 156, with permission from the The National Academy of Sciences, USA.

of cell membranes and was labeled with a His tag to monitor its orientation by immunolabeling with nanogold-labeled antibodies.

Ionophores. Ionophores have been inserted into the bilayers of PMOX-PDMS-PMOX vesicles with encapsulated K_3PO_4 solution (241). The ionophore-assisted metal-ion transport across the block copolymer membranes was studied for Ca^{2+}, which without ionophores does not permeate the triblock copolymer membrane from the external solution. The incorporation of ionophores such as Lasalocid A, ETH5234, or alamethicin into the vesicle membrane led to permeation of Ca^{2+} as shown by the precipitation of calcium phosphate inside the vesicles (241).

Leukocyte Adhesion. A future challenge is the integration of adhesive sites into vesicle membranes to mimic leukocyte adhesion, allowing vesicles to target and exploit the same pathways that cells use to traffic throughout the body. To traffic from blood into tissues, cells adhere to blood vessel walls via specific receptor-ligand binding. The adhesion is initiated through proteins (selectins) that bind to carbohydrates, in particular to sialylated-fucosylated carbohydrate ligands such as sialyl-Lewis^x. Thus, sialyl-Lewis^x or closely related carbohydrates can be viewed as the minimum functional binding element. For this purpose, vesicle surface groups may be derivatized with specific ligands such as streptavidin, allowing the attachment of a wide array of adhesive functions such as biotinylated forms of sialyl-Lewis^x. First steps in this direction have been the investigation of the adhesion between biotinylated polymersomes and avidin-coated microspheres (242).

Outlook

In recent years there has been significant progress in the preparation of stable polymer vesicles over a size range of tens of nanometers to tens of micrometers by either polymerization of lipid vesicles or self-assembly of amphiphilic block

copolymers. The molecular parameters governing the formation of vesicles have been elucidated, enabling the preparation of a variety of chemically different vesicles in different solvents with specific physical, chemical, and biological functions. In particular the use of block copolymers has provided stability, a means to tailor membrane properties like thickness, bending elasticity, and permeability, and to attach biofunctional groups via appropriate choice of block length and block chemistry. Different functions can be implemented into a vesicle either by implementing them into a single block copolymer chain, or by assembling differently functionalized block copolymers into a vesicle.

An important use of vesicles will be the encapsulation and controlled release of hydrophilic compounds for pharmaceutical and cosmetic applications. Different release modes such as first-order release via membrane permeation, zero-order release using channel proteins, and instantaneous release triggered by environmental stimuli have already been realized. The encapsulation of enzymes for protection against proteases and detergents, of hemoglobin for use in erythrocyte mimics, of magnetic particles for application in diagnostics and therapy, of plasmid DNA for gene transfection in gene therapy, of vitamins in body care products, and of fertilizers in agro-chemistry are being discussed. In some cases stealth and conventional liposomes loaded with anticancer agents have recently overcome cost, scale-up, sterility, toxicity, and stability hurdles, and have demonstrated clinical efficacy (209).

The use of vesicles and membranes in nature is a constant source of challenge and inspiration. In cells, vesicles and membranes are used to separate metabolistic pathways, as intracellular transport systems, and for electrophysiological signaling, eg in neurons. The realization of such functions by using self-assembling, functionalized polymers may provide further understanding and use of nature's efficient self-organization principles (243,244). This also includes the assembly of photosynthetic centers into membranes for efficient light harvesting and separation of photogenerated charge carriers. Further, polymer bilayers are discussed as stable alternatives for lipid bilayer systems for use in biosensors. Reconstituted ion channels or encapsulated enzymes provide substrate selectivity necessary for selective detection of small amounts of solutes.

After some years of consolidation in vesicle and liposome research, the field is currently rapidly expanding, particularly in the field of block copolymer vesicles. It brings together scientists from many disciplines such as physics, chemistry, biology, pharmacy, medicine, materials science and engineering. New approaches and solutions to current challenges in biomedical, pharmacological, and cosmetic research are investigated with new and promising materials and methodology.

POLYPEPTIDE SYNTHESIS, RING-OPENING POLYMERIZATION OF α-AMINO ACID *N*-CARBOXYANHYDRIDES

Introduction

α-Amino acid *N*-carboxyanhydrides (NCAs) were first described in 1906 by Hermann Leuchs (1). Leuchs discovered that heating *N*-ethoxycarbonyl and *N*-methoxycarbonyl α-amino acid chlorides under reduced pressure resulted in the formation of the corresponding NCAs. Upon exposure to water, he observed that these NCAs reacted and were transformed into an insoluble mass. The concept of polymers not being established at that time, Leuchs described this product as cyclic oligopeptides. It was not until the 1920s, when the existence of macromolecules became widely accepted, that systematic studies on the synthesis and polymerization of NCAs were started (2–3). Since then, the NCA polymerization has matured and has become the most commonly applied technique for the large-scale (ie, multigram) synthesis of high molecular weight polypeptides and polypeptide-based block copolymers. A survey of the number of publications describing polypeptide synthesis via NCA ring-opening polymerization reveals that after a strong increase in the 1960s and 1970s, the interest in this technique decreased until the mid 1990s (Fig. 1). The renewed interest in the NCA ring-opening polymerization since then may be attributed to two factors, which are closely related to each other: (*1*) the development of novel methods for the polymerization of NCAs and (*2*) the notion that polypeptides and polypeptide-based hybrid block copolymers may be potentially interesting materials for a variety of applications in biomedicine and biomineralization, and analysis.

Much of the interest in the development of novel materials based on polypeptides is driven by their ability to fold in a variety of stable secondary, tertiary, and quaternary structures (see PROTEIN FOLDING). Polypeptides can self-assemble into complex, hierarchically organized nanoscale morphologies, which cannot be produced from conventional nonbiological polymers. These characteristics may allow the preparation of ordered films or organic/inorganic composites that could be of interest for a multitude of advanced applications. Since the folding properties of natural peptide polymers (proteins) are, amongst others, due to their uniform chain lengths and well-defined monomer sequences, synthetic methods that allow the polymerization of NCAs with precise control of molecular weight, molecular weight distribution, and composition are important to explore the full potential of novel synthetic polypeptide materials. This article provides an overview of the

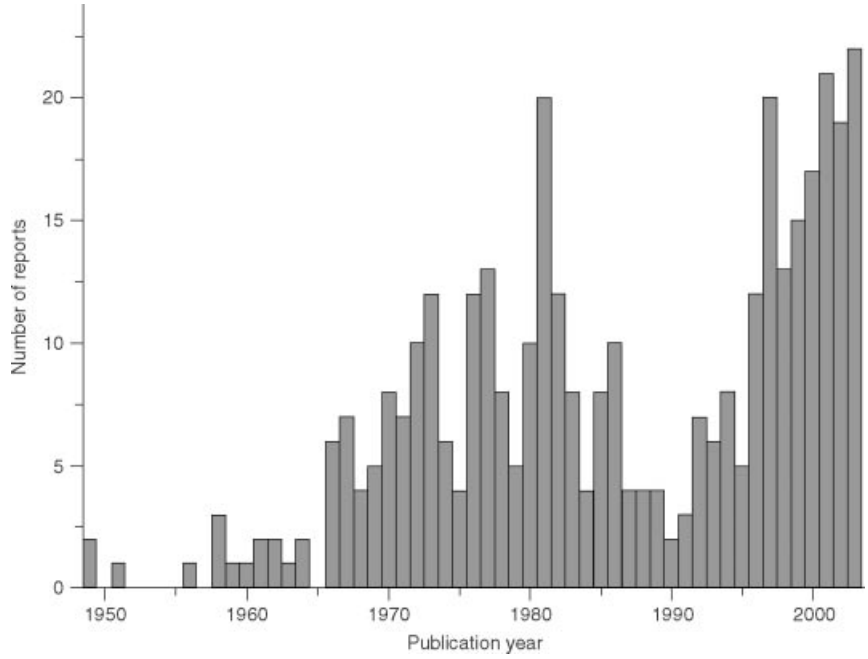

Fig. 1. Survey of the number of reports describing polypeptide synthesis via NCA ring-opening polymerization. *Source*: SciFinder Scholar, Dec. 2003.

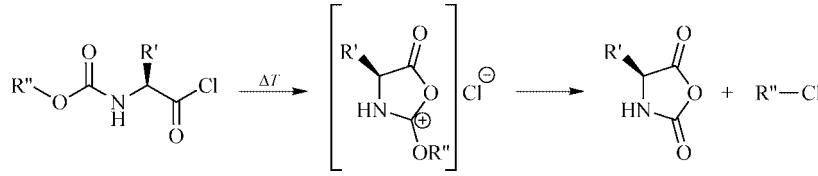
different methodologies that have been developed for the polymerization of NCAs and discusses the scope and limitations of each of these techniques for the preparation of polypeptides with controlled molecular weights and narrow molecular weight distributions.

NCA Synthesis

One obvious method for the preparation of NCAs is of course by cyclization of *N*-alkoxycarbonyl amino acid chlorides, as originally discovered by Leuchs (eq. 1) (1). Over the years, various improvements of this so-called Leuchs method have been made. While the original procedure used thionylchloride for the chlorination of *N*-alkoxycarbonyl α-amino acids, it was found that phosphorus bromide is more convenient, allowing cyclization to take place at lower temperatures (4). The rate of cyclization depends on the nature of the alkoxycarbonyl group and decreases in the following order: ethyl < methyl < allyl < benzyl. Equation 1 shows a mechanism that is in line with these observations.



(1)

One of the most widely applied methods for the preparation of NCAs involves the direct phosgenation of free α-amino acids (5). This synthesis, which is referred to as the Fuchs–Farthing method, is usually carried out in inert, low boiling solvents such as tetrahydrofuran, dioxane, or ethyl acetate. Mixtures of these solvents with methylene chloride have also been reported and have the advantage of a lower solubility for the hydrochloric acid that is released during the reaction. A low concentration of hydrochloric acid is important in order to prevent cleavage of the NCA ring. The liberated hydrochloric acid may also lead to problems in the synthesis of NCAs derived from trifunctional amino acids that carry acid-sensitive protective groups. To avoid premature cleavage of such protective groups, hydrochloric acid scavengers such as AgCN (6) or triethylamine (7) are added. Another method that prevents the formation of hydrochloric acid and allows the synthesis of NCAs carrying acid-sensitive protective groups starts with the preparation of the corresponding silylated amino acid derivatives. Upon treatment with phosgene, thionylchloride, or phosphorous trihalides, silylated amino acids react to produce the NCA and trimethylsilylchloride (8). The original Fuchs–Farthing procedure used phosgene, but modifications of this method have been developed in which phosgene is replaced by diphosgene (trichloromethyl chloroformate) (9) or triphosgene (bis(trichloromethyl)carbonate) (10). Instead of the gaseous phosgene, which can be difficult to handle, diphosgene and triphosgene are liquid and solid, respectively, which makes them much easier to handle and allows the use of stoichiometric quantities.

Monomer purity is of critical importance for the success of the NCA polymerization; the presence of traces of hydrochloric acid or other contaminants can lead to premature termination of chain growth and result in broadening of the molecular weight distribution. Advanced procedures have been developed, which allow the preparation of NCAs in high purities (11). These procedures involve washing an organic solution containing the NCA with chilled, aqueous bicarbonate. Polymerization of NCAs purified following this method by primary amine functionalized polystyrene macroinitiators was found to result in synthetic-peptide hybrid block copolymers with polydispersities that were smaller than those obtained using NCAs prepared and isolated according to the traditional procedures (12).

Traditional NCA Polymerization Methods

Traditionally, the most important classes of initiators for the NCA ring-opening polymerization included a broad range of nucleophiles and bases, such as primary amines, tertiary amines, and alkoxide and hydroxide ions (4,13). Other initiating systems, such as temperature, metal salts, and organometallic compounds, have also been used, but these have not found widespread application (4). Polymerization of NCAs using nucleophilic or basic initiators is thought to proceed along two main pathways, the amine mechanism (eq. 2) and the activated-monomer mechanism (Fig. 2) (4,13). The amine mechanism is a nucleophilic ring-opening chain growth process. The activated-monomer mechanism, on the other hand, starts with deprotonation of an NCA, which subsequently acts as the nucleophile that initiates chain growth. If decarboxylation is slow, chain growth may proceed

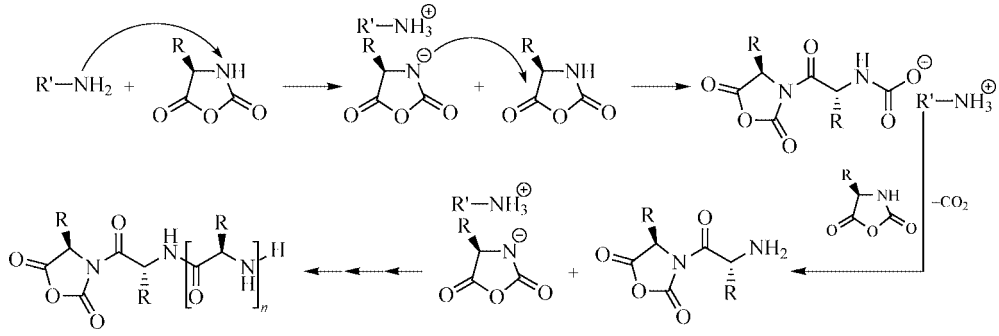


Fig. 2. NCA polymerization via the activated monomer mechanism.

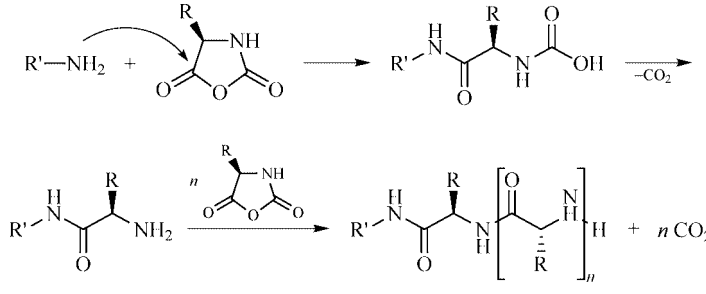
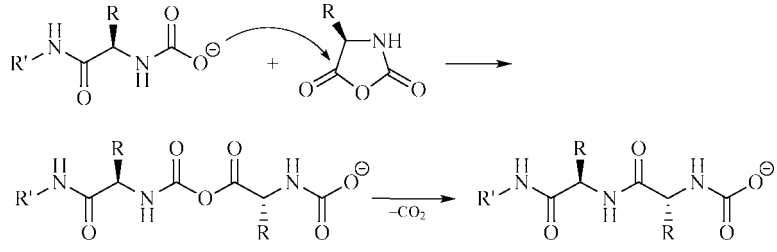
along a third pathway, the carbamate mechanism (eq. 3). The preferred pathway of polymerization for a given initiator is determined by its nucleophilicity/basicity ratio. Generally, NCA polymerizations initiated by primary amines, which have a high nucleophilicity/basicity ratio, predominantly follow the primary amine mechanism. NCA polymerizations initiated by tertiary amines or alkoxide/hydroxide ions, which are more basic than nucleophilic, mainly proceed along the activated monomer mechanism. This classification, however, is by no means unambiguous, and it is important to note that a given polymerization can switch back and forth many times between the different mechanisms during the course of the reaction. In other words, a propagation step for one mechanism is a side reaction for the other, and vice versa.



(2)



(3)

The existence of multiple, competitive mechanisms, which may act simultaneously during the course of a polymerization reaction, restricts control over the molecular weight and the molecular weight distribution of the resulting

polypeptide and also hampers the formation of well-defined block copolymers. Using very nucleophilic or basic initiators, the NCA polymerization can be biased toward the amine and activated-monomer mechanism, respectively. These initiators allow a certain level of control over the polymerization and can produce polypeptides with molecular weights which roughly correlate with the monomer-to-initiator ratio.

Especially primary amines and primary amine functionalized macroinitiators have been extensively used for the preparation of a broad range of polypeptides and polypeptide-containing hybrid polymers. In addition to simple polypeptide homopolymers, random copolymers have been prepared by co- or terpolymerization of different NCAs. Polypeptide copolymers have attracted attention, eg, as polymeric drug carriers (14). Furthermore, random copolypeptides have been used to study the conformational properties of amino acids (15). Polypeptides and polypeptide-containing block copolymers have been obtained by sequential copolymerization of different NCAs and by using primary amine end-functionalized nonpeptidic macroinitiators for the NCA ring-opening polymerization, respectively. Amongst other, triblock copolypeptides have been used to investigate the helix-forming propensities of amino acids (16). The solid-state structures of synthetic-peptide hybrid block copolymers have been studied in considerable detail (17). Most of these block copolymers form lamellar superstructures, with the polypeptide chains folded and arranged in an hexagonal array. Furthermore, peptide-synthetic hybrid block copolymers can possess good antithrombogenic properties, which make them of interest for medical applications.

In addition to simple, linear polypeptides, the NCA polymerization has also been used to prepare branched macromolecular architectures. Star polypeptides, probably the simplest example of branched polypeptides, can be obtained via NCA polymerization using multiple, primary amine functionalized initiators. Examples of multifunctional initiators include hexakisamines derived from 1,3,5-tris(bromomethyl)benzene (18), tetra-amino functionalized perylene chromophores (19) and cyclotriphosphazenes (20). Interestingly, Teflon-supported films of hexaarmed, ethylene glycol substituted polyglutamic acid star polymers based on a cyclotriphosphazene core were found to be excellent enantioselective membranes for amino acids (21). A further class of initiators that has been frequently used to prepare star-shaped polypeptides are poly(amido amine) (PAMAM) dendrimers (22-23). PAMAM dendrimers have been used as initiators for the ring-opening polymerization of sugar-substituted NCAs (eg, *O*-(tetra-*O*-acetyl-β-D-glucopyranosyl)-L-serine *N*-carboxyanhydride and *O*-(2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosyl)-L-serine *N*-carboxyanhydride) (23) as well as γ-benzyl-L-glutamate *N*-carboxyanhydride (23). It was found that the helicity of the PAMAM-based star polypeptides was significantly enhanced compared to their linear analogues. This effect was attributed to the aggregation of peptide segments on the dendrimer surface.

More complex branched polypeptides can be obtained following iterative reaction schemes involving several NCA ring-opening polymerization steps. Graft copolypeptides, which have also been termed multichain polypeptides, have been prepared using a linear poly(L-lysine) as initiator for the NCA ring-opening polymerization (24). These graft polypeptides were designed with the aim of developing polymer–drug and polymer–epitope conjugates (25–26). This synthetic

approach can be further extended by utilizing these graft copolymers as initiators for a next NCA ring-opening polymerization step. Repetition of this graft-on-graft strategy leads to highly branched, so-called dendritic-graft, polypeptides (27). In addition to the graft-on-graft strategy, branched polypeptides can also be prepared by end-functionalization of a peptide chain with an appropriate N^{α},N^{ε}-diprotected lysine derivative (28). Deprotection of the lysine amino groups doubles the number of end groups that can be used to initiate a subsequent NCA ring-opening polymerization step. Repetition of this NCA ring-opening polymerization–end-functionalization–deprotection sequence has been successfully used to prepare highly branched poly(L-lysine)s with molecular weights up to 33 kDa in small number of reaction steps.

Primary amine initiated NCA polymerizations have not only been carried out in homogeneous solution but also under heterogeneous conditions. The use of primary amine functionalized surfaces allows the preparation of thin, directionally aligned polypeptide films (29). If the density of the peptide chains at the surface is sufficiently high, the chains are mainly oriented normal to the surface. Such polypeptide films have been grown from a variety of surfaces, including silicon, aluminum, gold, indium-tin-oxide, quartz, and polytetrafluoroethylene (Teflon). Surface-initiated NCA polymerizations can be carried out either by exposing the amino-functionalized substrate to a solution containing the appropriate NCA monomer or by vapor phase deposition of the NCA monomer (30). Sequential addition of two different NCA monomers allows the preparation of surface-grafted polypeptide block copolymers (31). Surface-grafted polypeptide films obtained via NCA polymerization have been found to possess piezoelectric properties, (32) indicative for the parallel alignment of the peptide helices. Furthermore, the water permeability of porous Teflon membranes, which were modified with a surface-grafted layer of poly(L-glutamic acid) could be modulated by pH-induced variations in the secondary structure of the peptide chains (33).

Transition-Metal-Mediated NCA Polymerization

Transition-metal complexes have already been explored as initiators for the NCA ring-opening polymerization since the 1960s (34–35). Unfortunately, most of these complexes were characterized by relatively low initiator efficiencies and did not permit the synthesis of polypeptides with precise control of molecular weight and narrow molecular weight distributions in high yields. This situation changed dramatically, however, with the discovery of zero-valent nickel and cobalt complexes, which were found to be able to promote very efficient "living" polymerization of NCAs (36–37). The putative mechanism for the polymerization of NCAs using these initators, bipyNi(COD) and $(PMe_3)_4Co$, is outlined in Figure 3 (35). These transition-metal initiators were found to offer unprecedented control over molecular weight and allowed the high yield synthesis of polypeptides with molecular weights between 500 and 500,000 Da and polydispersities <1.20. Sequential addition of two different NCA monomers allowed the formation of well-defined block copolypeptides.

Peptide block copolymers prepared via transition-metal-mediated NCA polymerization have been investigated, eg, to direct the biomimetic synthesis of

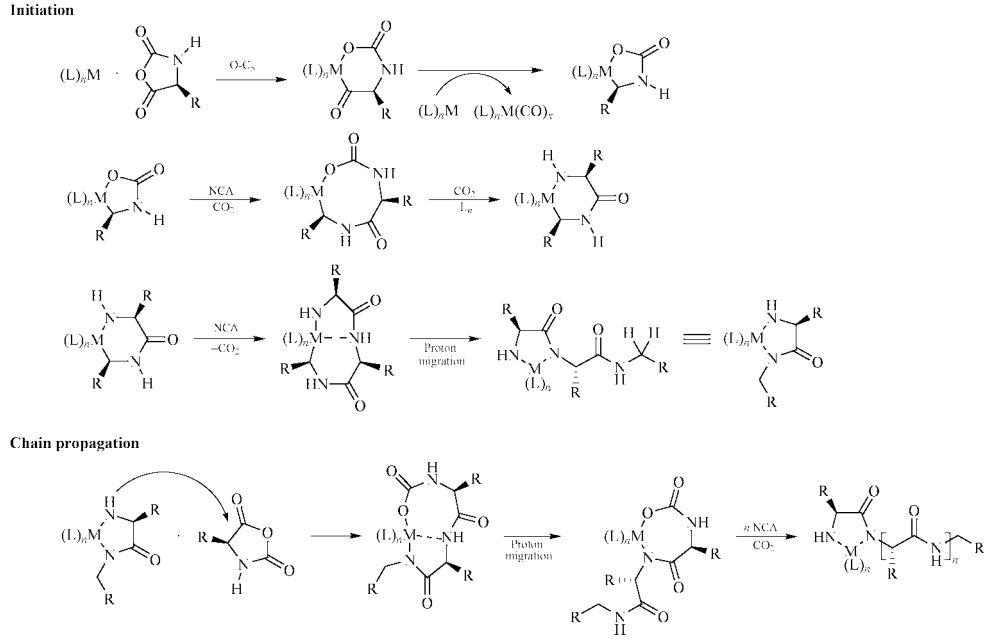


Fig. 3. Proposed mechanism for NCA polymerization using the initiators bipyNi(COD) and $(PMe_3)_4$ Co.

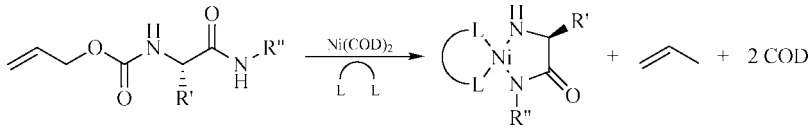
ordered silica structures (38) or to prepare self-assembled polypeptide hydrogels (39). Furthermore, such block copolypeptides have found application to generate hollow, organic/inorganic hybrid microspheres, which are composed of a thin inner layer of gold nanoparticles surrounded by a thick layer of silica nanoparticles (40). Alternatively, hollow spheres could be prepared that consisted of a thick inner layer of core–shell CdSe/CdS nanoparticles that are surrounded by a thicker silica nanoparticle layer (41). The latter spheres allow for microcavity lasing without the use of additional mirrors, substrate spheres, or gratings.

Initially, a major drawback of the transition-metal-mediated NCA polymerization, as it is outlined in Fig. 3, was the lack of control over the chain end functionality of the polypeptide chains. This is in great contrast to, eg, primary amine initiated NCA polymerizations, which are widely explored for the preparation of synthetic-peptide block copolymers and other peptide-hybrid architectures. This limitation could be overcome by the direct synthesis of the amido amidate metallacycle propagating species (eq. 4) (42).



(4)

These complexes allowed controlled polymerization of NCAs, which also provided additional support for their validity as polymerization intermediates. The initiating ligand was found to be quantitatively incorporated as a C-terminal

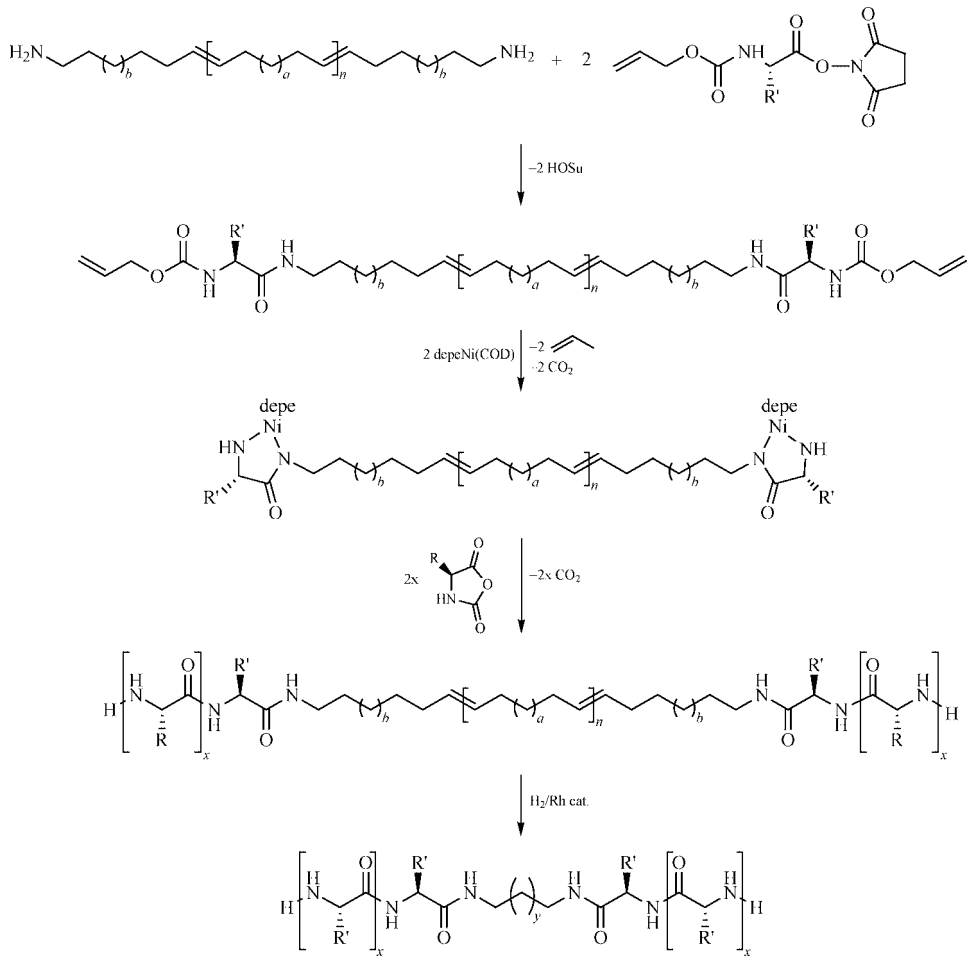


Fig. 4. Synthesis of poly(γ-benzyl-L-glutamate)-polyethylene-poly(γ-benzyl-L-glutamate) triblock copolymers from metallacyle-substituted macroinitiators.

group, which would allow the introduction of a broad variety of functional end groups. Interestingly, the direct synthesis of functional amido amidate metallacycles is not restricted to low molecular weight substituents, but can also be extended to polymeric macroinitiators (43). This is outlined in Fig. 4, which shows the transformation of α,ω-amino polyoctenamers obtained via ADMET into metallacycle-substituted macroinitiators. These macroinitiators were used to polymerize γ-benzyl-L-glutamate *N*-carboxyanhydride (Bn-Glu NCA). Selective hydrogenation of the polyoctenamer double bonds subsequently afforded poly(γ-benzyl-L-glutamate)–polyethylene–poly(γ-benzyl-L-glutamate) triblock copolymers. Transition-metal-mediated NCA polymerization is not restricted to homogeneous solutions, but can also be adapted to allow controlled polymerization of NCAs from surfaces (44).

Replacement of the achiral bipyridyl ligand in bipyNi(COD) by an optically active 2-pyridinyloxazoline ligand results in a metal complex (**1**) that can act

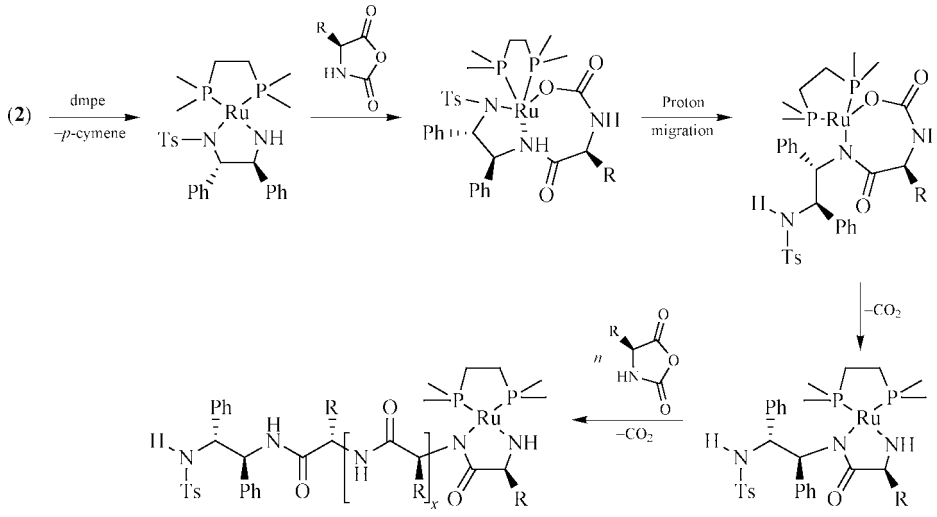

Fig. 5. Proposed mechanism for the polymerization of Bn-Glu NCA by **2**.

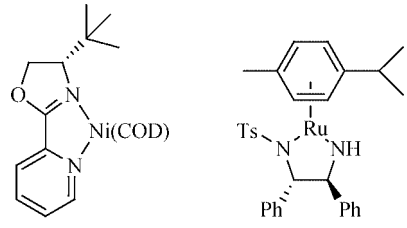
as an initiator for the stereoselective polymerization of Bn-Glu NCA (45). Complex **1** has polymerization properties identical to bipyNi(COD), ie, it can produce narrow polydispersity polypeptides with molecular weights corresponding to the monomer–initiator ratio in high yields. For the chiral 2-pyridinyloxazoline complexes, however, the polymerization rate constant for the D enantiomer (k_D) was found to be five times larger than that of the L enantiomer. These enantioselectivities are higher than those reported for many other chiral initiators and catalysts that have been explored for the stereoselective polymerization of NCAs (46). Even better results were obtained with chiral ruthenium initiators derived from the Noyori complex (**2**) (47).



1 **2**

The presence of 1 equiv 1,2-bis(dimethylphosphino)ethane (dmpe) resulted in an initiator that can promote living NCA polymerization of Bn-Glu NCA with a rate constant (k) that was found to be eight times larger for the L enantiomer in comparison with the D antipode. A putative model for the polymerization of Bn-Glu NCA by ruthenium complex (**2**) is shown in Fig. 5. It has been proposed that the observed enantioselectivity is due to the rigid, chiral coordination geometry at the metal center, which is located at the propagating chain end.

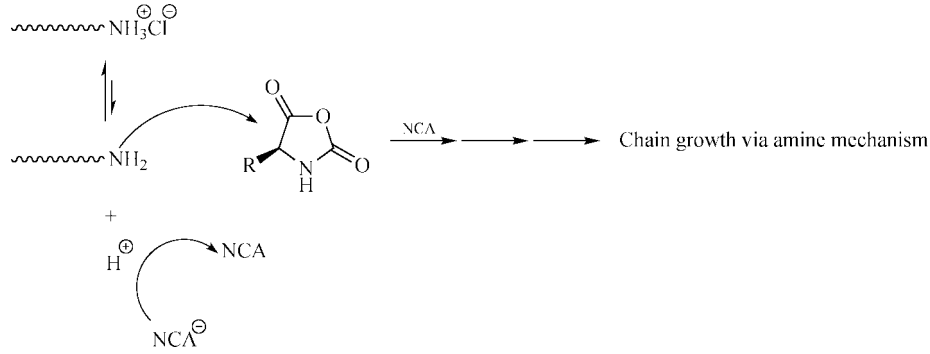


Fig. 6. Proposed mechanism for NCA polymerization in the presence of primary amine hydrochlorides.

Polymerization of NCAs Using Primary Amine Hydrochlorides

The inherent problem of the use of any of the traditional initiators for the NCA ring-opening polymerization is that the amino group at the growing peptide's *N*-terminus can act as both a nucleophile and a base. As a result, chain growth may proceed via both the amine and the activated-monomer mechanism. In the previous paragraph, the use of transition-metal complexes to control the reactivity of the growing polymer chain end has been described. An interesting alternative approach, which allows chain growth to take place preferentially via the amine mechanism and suppresses the activated-monomer pathway is to use primary amine hydrochlorides as initiators for the NCA ring-opening polymerization (48). The use of primary amine hydrochlorides is based on early work by Knobler and co-workers (49) who investigated stoichiometric reactions between primary amine hydrochlorides and NCAs. Their investigations revealed that this reaction proceeds smoothly and without the formation of polypeptides. When anionically prepared polystyrene macroinitiators with a primary amine end group were used for the ring-opening polymerization of ε-benzyloxycarbonyl-L-lysine NCA, hybrid block copolymers with very narrow polydispersities (<1.03) were obtained (48). These narrow polydispersities, which are close to a Poisson distribution, suggest that primary amines promote polymerization of NCAs in a well-controlled fashion. The mechanism proposed for the polymerization of NCAs in the presence of primary amine hydrochlorides is outlined in Figure (6). As illustrated in the figure, the primary amine hydrochloride is regarded as a dormant species, which is in equilibrium with the corresponding free amine and $H^+(Cl^-)$. While the primary amine end group is responsible for chain growth via the amine mechanism, the liberated $H^+(Cl^-)$ serves to protonate any NCA anion that may be present, thereby preventing polymerization via the activated monomer mechanism.

Polymerization of NCAs under High Vacuum Conditions

The two approaches that have been discussed so far, viz transition-metal-mediated and primary amine hydrochloride initiated NCA ring-opening polymerization,

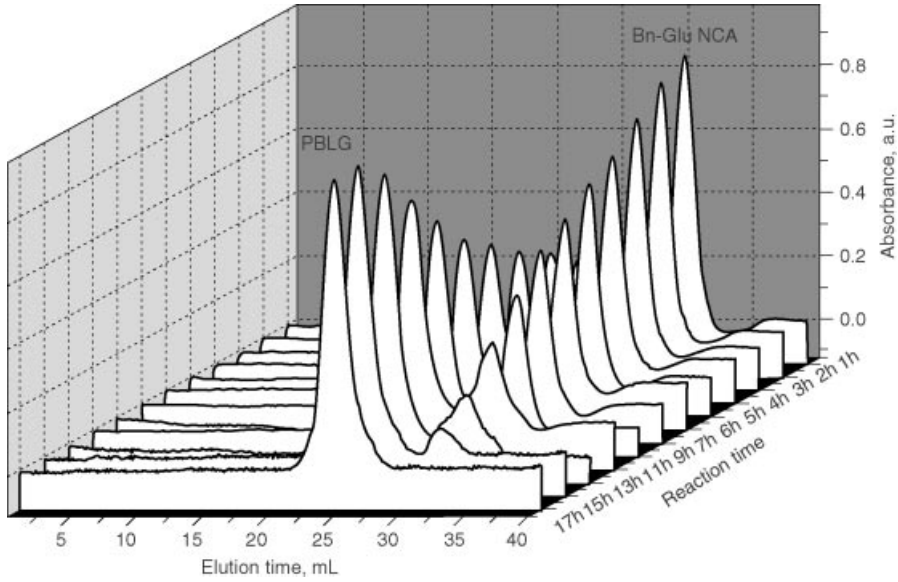

Fig. 7. GPC traces illustrating the evolution of polypeptide molecular weight and monomer consumption during the polymerization of γ-benzyl-L-glutamate *N*-carboxyanhydride (Bn-Glu NCA). Targeted number-average degree of polymerization was ~440. After 17 h, monomer consumption is >99%.

suggest that the limited control over molecular weight and molecular weight distribution of polypeptides produced from NCAs using traditional initiators such as primary amines is due to the polymerization mechanism. However, polypeptide homopolymers and block copolypeptides with molecular weights corresponding to the monomer–initiator ratio and with narrow molecular weight distributions can also be prepared using high vacuum techniques, which have traditionally been used for the anionic polymerization of vinyl monomers (50). High vacuum techniques allow careful purification of all reagents and can provide a reaction environment that is virtually free of any impurities that can interfere with polymerization. Under these conditions, using monomers purified via high vacuum techniques and thoroughly dried solvents, primary amine initiated NCA polymerizations can produce polypeptide homo and block copolymers with precise control of molecular weight and composition and narrow polydispersities (51). These primary amine initiated NCA ring-opening polymerizations fulfill all the requirements to be considered truly living polymerizations. For example, poly(benzyl-L-glutamate) homopolymers with a number-average degree of polymerization of ~440 ($M_n \approx 100{,}000$ Da) could be produced with a polydispersity of 1.18. Monomer consumption could be monitored using gel-permeation chromatography and was found to be quantitative after 17 h (Fig. 7).

Summary and Conclusions

Since its initial discovery by Leuchs in the early twentieth century, the NCA ring-opening polymerization has grown to become the most convenient strategy

for the large-scale preparation of polypeptides and synthetic-polypeptide hybrid materials. Traditionally, initiators for the NCA ring-opening polymerization were nucleophiles and bases, such as primary amines and KOtBu, which, however, only provided limited control over the molecular weight and molecular weight distribution of the resulting polypeptides. This is due to the existence of multiple, competing reaction pathways, which may act simultaneously during polymerization. To overcome these problems and enhance control over molecular weight, molecular weight distribution, and polymer composition, which is required for the preparation of advanced, complex macromolecular architectures, several alternative strategies have been developed. One approach involves the use of transition-metal complexes to control the reactivity of the growing polymer chain end. An alternative strategy, which has been successfully used to bias the NCA ring-opening polymerization to proceed exclusively via one pathway relies on the use of primary amine hydrochlorides as initiators. While these two examples suggest that the limited control over molecular weight, molecular weight distribution, and composition of polypeptides produced via NCA ring-opening polymerization using traditional nucleophilic or basic initiators can be solely attributed to the polymerization mechanism, the picture may be more complex. When high vacuum techniques are used to purify the NCA monomer and to conduct the polymerization, primary amines can also generate polypeptide homopolymers and block copolypeptides with narrow polydispersities and predictable molecular weights. These primary amine initiated NCA ring-opening polymerizations were shown to fulfill all the requirements to be characterized as truly living polymerizations. This last example underlines the importance of monomer purity and the absence of other contaminants that can interfere with the polymerization. Almost 100 years after its discovery, the mechanistic details of the NCA polymerization have not yet been fully unravelled. Nevertheless, great advances have been made in the development of novel synthetic methodologies, which allow controlled polymerization of NCAs, ie, the production of peptide polymers with controlled architecture, predictable molecular weight, and narrow molecular weight distributions. These advanced synthetic methodologies will prove useful to further exploit the potential of these materials, in particular for applications in biomedicine and biomineralization.

RADIATION CHEMISTRY OF POLYMERS

Introduction

The fundamental property of polymeric materials which sets them apart from other materials is their very large molecular weight. The arrangement of a large number of structurally similar chemical units into linear or branched chains provides polymers with their unique viscoelastic properties. This large molecular weight necessarily leads to both transient and permanent molecular entanglements, which determine the response of the polymer to applied loads. It is essentially this property which is altered, or deliberately manipulated, when a polymer is subjected to ionizing radiation.

High energy radiation leads to a succession of chemical reactions which ultimately lead to either an increase or a decrease in the molecular weight of a polymer. As will be discussed below, either result may be desirable. The initial processes which occur when a high energy photon interacts with an organic polymer are reasonably well established and do not depend essentially on the chemical structure of the material. However, these primary processes lead to a cascade of further reactions, the nature of which depends sensitively on the nature of the polymeric material; for example, the ability to dissipate excess energy, the relative bond energies within various structures, and the presence of oxygen, radical scavengers, and other moderating factors.

This article approaches the field of radiation chemistry of polymers from a mechanistic viewpoint, and does not describe in detail the growing list of applications of high energy radiation in polymer science. The basic principles of radiation chemistry are described, and subsequently the interaction of radiation with specific classes of polymers. The mechanisms of reaction are described by reference to specific materials. Furthermore, the means by which these mechanisms have been determined, ie, the methods of analysis, are described in detail. Finally, an attempt is made to draw overall conclusions about the radiation sensitivity of the constituent units of synthetic polymers.

Interaction of High Energy Radiation with Organic Matter. The passage of a high energy photon or particle through matter leads to a complex cascade of processes which results in the dissipation of the initial energy, ultimately as thermal energy and chemical reactions (1–5). If the source of radiation consists of high energy photons, the energy is deposited in a highly nonuniform manner via a number of processes. In organic polymers the most important mechanism of energy loss is *Compton scattering*, in which a photon interacts with an electron resulting in ejection of the electron and deflection of the photon with reduced

energy. The probability of the photon undergoing Compton scattering and the resultant energy of the ejected electron and scattered photon depend on the incident energy of the photon and the electron density of the material through which it is traversing.

Of less importance for high energy photons is the *photoelectron effect*, in which the entire energy of the photon is transferred to a single electron, which is ejected with energy equal to the incident photon energy minus the binding energy of the electron. Also of less importance for most commercial sources of ionization radiation is the mechanism of *pair production*. This also involves complete absorption of the incident photon energy, and results in the formation of an electron–positron pair. The combination of the two particles results in emission of two 0.51-MeV γ-rays, which may undergo further interaction with the material as described above. Pair production is only of importance when the incident photons have energies greater than 1.02 MeV.

If on the other hand the source of ionization is high energy electrons, the initial steps toward loss of the energy to the material involves *inelastic collisions* resulting in ionization and excitation of the material and loss of energy of the incident particle. On ejection of the secondary electrons, the resultant processes occurring are identical to those occurring on irradiation with high energy photons. These can be summarized as follows.

Initial interaction with photons:

$$\mathrm{R}\sim\sim\sim\sim\sim\sim\rightarrow\mathrm{R}^{+}+\mathrm{e}^{-} \tag{1}$$

Interaction of primary electrons with other structures:

$$\mathrm{R}+\mathrm{e}^{-}\rightarrow\mathrm{R}^{+}+2\,\mathrm{e}^{-} \tag{2}$$

As the energy of the electrons is reduced, there is increased probability of recombination of the cations and secondary electrons to form excited states:

$$\mathrm{R}^{+}+\mathrm{e}^{-}\rightarrow\mathrm{R}^{*} \tag{3}$$

The excited-state molecules may return to the ground state through radiationless decay, or undergo homolytic dissociation reactions to form free radicals, which are believed to be the main protagonists in subsequent radiochemical reactions. Heterolytic bond cleavage may in addition result in the formation of charged species.

Linear Energy Transfer and Recombination Reactions. The vast majority of studies on the radiation stability of polymeric systems have been concerned with either incident γ photons or electrons. This clearly reflects the greater availability of γ sources or electron accelerators. However, there has been a smaller but increasing interest in the effects of heavier charged particles on polymers, either because of interest in ion implantation or concern for the effects of heavy ions on materials in, for example, the space environment, or indeed processing of polymers using ion beams. Of most interest is the effect of the increased linear energy transfer (LET) of heavier charged particles on the mechanism of the

radiation chemistry. The results presented so far are conflicting. For example, While Parkinson and co-workers (6) and Boyett and Becker (7) did report differences between neutron and γ irradiation, others have indicated identical changes in properties (8). The effect of proton irradiation was found to be identical to electron irradiation for aliphatic polymers; however, some differences were observed for aromatic materials (9,10). However, Hill and Hopewell (11) found no difference between the mechanical properties of polyimides irradiated with γ rays or photons. A survey of several studies of the effects of ion beam irradiation on various polymers (12–17) again does not present a clear picture. This is clearly an area for further investigation.

Energy Transfer and Dissipation. From early times it was recognized that the presence of small concentrations of certain structures in a material can lead to a pronounced decrease in the radiation sensitivity of the material as a whole. The earliest observations of this type were of the evolution of gases from mixtures of small aromatic and aliphatic molecules. For example, Manion and Burton (18) reported in 1952 that the yields of reactions in irradiated mixtures of cyclohexane and benzene were reduced significantly compared to the yield expected from the linear addition of the yields of the pure individual molecules. This led to the concept of *protection effect*, in which the introduction of aromatic groups results in significant protection of the surrounding aliphatic structures. The mechanism of "protection" afforded by the aromatic molecules has been a subject of considerable discussion.

Since these early studies of mixtures of aromatic and aliphatic liquids (18,19), the phenomenon of radiation protection has been observed in copolymers of styrene with other monomers (20–25), in a range of alkylbenzenes (26), and in miscible polymer blends (27). The description of the mechanism of radiation protection has often in the past relied upon the assumption that the amount of energy deposited in each molecule or molecular segment within a polymer is proportional to its electron fraction. As a consequence the decrease in radiation sensitivity of one component must be due to either transfer of energy or charge prior to dissociation, or scavenging of intermediates in systems where significant mobility is present. It has been reported, however, that the assumption that the cross section is proportional to electron density is not at all times obeyed (28). Therefore the assignment of protection effects wholly to transfer processes must be made with caution, although the relative stabililizing effect of aromatic structures is not in question.

Yields and Units. The unit of radiation dose used in this text is the Gray (Gy); 1 Gy corresponds to an energy absorption of 1 J/kg of material. Typical applied doses in the field of radiation modification of polymers are in the range of tens of kGy; however, in some cases irradiation up to 10 MGy has been required to induce sufficiently large yields of new molecular structures. The yield of radiochemical events is expressed as the *G value* [written, for example, G(X) for the G value of cross-linking]. The G-value is defined as the number of products formed for every 100 eV, or 16 aJ, of energy absorbed by the material. Thus, 1 kGy of radiation will produce $G \times 1.036 \times 10^{-7}$ moles of product per gram of irradiated polymer (4). The SI unit for radiation yield is μmol/J, which is equivalent to 10 Gy (29).

Summary of Radiation-Induced Reactions in Polymers

The preceding section has described briefly the primary reactions occurring on interaction of high energy radiation with organic molecules in general. Following the succession of reactions detailed above, a number of subsequent combination and bond-breaking reactions lead to permanent changes in the properties of the material. Much experimental evidence exists to support the contention that most of these reactions are initiated by free radicals. The observation, by electron spin resonance (ESR) spectroscopy, of relatively large concentrations of radicals in polymers irradiated at low temperatures is one example of this.

In the vast majority of experimental studies of the radiation chemistry of polymers, we observe usually the final products of the passage of the high energy photons. Attempts to trap radical and charged species at low temperatures usually succeed in revealing part of the radiochemical history of the material. An indication of this can be obtained by consideration of the relative yields of products on radiolysis of simple alkane molecules. The respective bond energies of C—H and C—C bonds in linear alkanes are 4.3 and 3.4 eV (415 and 328 kJ/mol) (1). On consideration of these numbers alone, one would expect that the predominant products of radiolysis of linear alkanes would be due to rupture of C—C bonds. However, the main product of the radiolysis of linear alkanes, and indeed of polyethylene, is hydrogen gas. Furthermore, there is some debate as to whether permanent cleavage of the main-chain C—C bond actually occurs at all on irradiation of polyethylene. The origin of these results is of course the "cage" effect. The larger radical fragments formed on cleavage of C—C bonds are unlikely to escape from the reaction cage, and recombination reactions tend to occur. The smaller, perhaps thermally excited, hydrogen radicals formed by cleavage of C—H bonds have a much greater probability of escaping and undergoing recombination and other reactions. This simple and important observation also helps us understand the differences in the radiation chemistry of hydrocarbon polymers and perfluorocarbon polymers, as discussed below. In addition the unusual temperature dependence of the radiochemical yields of a number of materials can be explained by the cage effect. For example, the radiochemical G-values for formation of *stable* free radicals in γ-irradiated fluorinated ethylene–propylene copolymers (FEP) are 0.22 at 77 K, and 2.0 at 298 K (30), since at low temperatures cage recombination of the primary radicals is very effective, while at higher temperatures sufficient thermal energy is available to remove the radical fragments from the reactive cage.

Additional evidence of the very large number of nonpermanent bond cleavages initiated by ionizing radiation is the observation of large changes in the stereochemistry of initially highly stereoregular polymers, such as isotactic poly(methyl methacrylate) (iPMMA) and related polymers (31–34), as well as isotactic polypropylene (iPP) (35–38). The loss of stereoregularity arises from a racemization reaction occurring as a result of temporary scission of either the main chain or the side chain. The latter mechanism is favored for syndiotactic PMMA. The yield of temporary chain scissions is approximately 10 times greater than the yield of permanent chain scissions determined by measurement of gel fraction or molecular weight of the soluble polymers.

Cross-Linking and Chain Scission. The most important reactions occurring during radiolysis of polymers are those that lead to permanent changes in their molecular weight. The reactions leading to either increases or decreases in molecular weight are referred to as cross-linking and chain scission, respectively. End-linking, ie, reaction between a polymer main-chain species and a polymer chain end, is regarded as a cross-linking reaction of lower functionality. In general cross-linking and scission processes can occur simultaneously in any irradiated material; however, it is often observed that one tends to dominate over the other, and thus polymers can be broadly placed into the categories *cross-linking* or *degrading*. Over the past 50 years a solid understanding of the relationship between polymer structure and the relative yields of cross-linking and chain scission has been acquired. Thus, for linear polyolefins, the proportion of chain scission reactions increases as the number of tertiary and especially quaternary carbons along the backbone is increased. Polyethylene undergoes primarily cross-linking reactions, polypropylene undergoes approximately equal amounts of scission and cross-linking, which ultimately leads to an increase in molecular weight, and finally polyisobutylene undergoes chain-scission reactions exclusively. However, it must be clearly stated here that respective and absolute yields of the two types of reactions depend also on a number of extrinsic factors, such as the presence of a crystalline phase, the temperature, the presence of chain-end unsaturation, and perhaps most profoundly the presence of oxygen gas. In Table 1 below, we attempt to classify the various polymer types as either cross-linking or degrading on exposure to ionizing radiation in the absence of oxygen. Specific examples are discussed later in this article.

Evolution of Gases. When polymers are exposed to high energy radiation, the reactions induced will lead to the formation of low molecular weight gaseous molecules. A study of the structure and yields of the gaseous products

Table 1. Cross-Linking vs Chain Scission for the Polymer Classes on Exposure to Ionizing Radiation in Vacuum

Cross-linking dominates	Chain scission dominates
Polyethylene	Polyisobutylene
Polypropylene	
Polydienes	
Polystyrene	Poly(α-methyl styrene)
Polyacrylates	Polymethacrylates
Polyacrylamide	Polymethacrylamide
Fully fluorinated elastomers	Fully fluorinated thermoplastics
Poly(vinyl chloride)	Poly(vinylidene chloride)
	Polychlorotrifluoroethylene
Polyamides	Cellulosics
Polyesters	
Polysiloxanes	
Poly(vinyl alcohol)	
Poly(*N*-vinylpyrollidinone)	
Main-chain aromatic polymers	

can provide great insight into the mechanisms of the reactions occurring on radiolysis. In general, gaseous products can arise either from primary cleavage of the main-chain bonds or from cleavage at the side chains.

Polymers that fall into the class of degrading polymers can, on irradiation at elevated temperatures (more specifically at temperatures approaching their ceiling temperature), yield high concentrations of monomers among the gaseous products. The *ceiling temperature* is the temperature at which the reversible addition of monomers to a radical chain end is balanced by the tendency of the monomers to depolymerize. Thus, it was noted as early as 1953 (39) that poly(methyl methacrylate) foams on irradiation due to the formation of gaseous products, including methyl methacrylate monomer. Subsequently, it was reported that the yield of methyl methacrylate monomer increased substantially to a limiting yield around 180°C (40,41). Related to this is the pronounced tendency of these materials to undergo depolymerization after exposure to high energy radiation.

The most important commercial exploitation of this phenomenon has been the development of positive radiation resists for use in the semiconductor industry. A number of methacrylates and butene sulfones have been developed for these applications (42–44). Another important class of materials which undergo large-scale degradation of the main chain are the aliphatic polysulfones. For example, in 1981 Bowmer and O'Donnell (45) examined the yields of a number of aliphatic polysulfones as a function of temperature and discussed these results in terms of the change in the equilibrium between polymerization and depolymerization as the ceiling temperature is approached. This aspect of radiation chemistry has had far-reaching consequences for our modern society.

The second major mechanism leading to the formation of volatile products on irradiation of polymers is cleavage of the side-chain groups. In the case of linear polymers, such as polyethylene, scission of the C—H bond leads to the formation of thermally activated hydrogen atoms. As discussed above, these small entities are able to escape the reactive cage and undergo subsequent reaction. These include addition reactions to double bonds, and also abstraction of hydrogen atoms and recombination with hydrogen atoms to form molecular hydrogen gas. Thus, the main gaseous product formed on radiolysis of hydrocarbons is hydrogen gas. The yield of hydrogen gas in polymers of the cross-linking type is often in excess of that expected from consideration of the yield of alkyl radicals leading to the formation of cross-links. As early as 1954, Dole and co-workers (46) determined that up to 80% of the hydrogen gas measured after irradiation of polyethylene arose from the formation of vinylene unsaturation, with cross-linking reactions accounting for the remainder. The presence of hydrogen gas has an important influence on the kinetics of radical reactions, and in principle on the overall product distribution in irradiated polymers. It has been suggested (47,48) that hydrogen gas is capable of enhancing the rate of diffusion of free radical species via reaction with alkyl radicals as depicted below:

$$R'\bullet + H{-}H + H{-}R \rightarrow R' \cdots H \cdots H \cdots H \cdots R \rightarrow R'H + H{-}H + \bullet R \qquad (4)$$

The importance of the presence of hydrogen gas was first demonstrated by Dole and Cracco in 1961 (49–51) by measuring the rate of hydrogen exchange from irradiated high density polyethylene to gaseous D_2, and explored more completely

by Dole and co-workers over the next decade (47). Clough (48) much later provided a detailed analysis of the mechanism of migration of radicals through the solid state in aliphatic hydrocarbon polymers, including an analysis of the number of these "hydrogen-hopping" reactions expected on the production of main-chain radicals. The calculations accounted for localized hydrogen–deuterium exchange reactions in linear alkanes irradiated in the presence of D_2 gas. It should also be noted that in aromatic polymers, hydrogen atom addition to aromatic rings results in the formation of cyclohexadienyl radicals and, potentially, initiation of cross-linking reactions (22,24,52–54).

The great importance of the hydrogen-hopping reaction can be appreciated by considering the differences in the radiation chemistry of polyhydrocarbons and polyfluorocarbons. In the latter materials, reaction 4 is of course not operative, and the corresponding reaction involving fluorine radicals is believed to be unimportant after consideration of the respective C—F and F—F bond energies (approximately 510 and 155 kJ/mol, respectively). Thus, the reactivity of fluorocarbon radicals in irradiated fluoropolymers is much more dependent on the inherent mobility of the polymer chains than in hydrogenated polymers. Thus, cross-linking reactions, which require two alkyl radicals to meet each other, are unlikely to occur in fluoropolymers irradiated at normal temperatures. Thus, polytetrafluoroethylene (PTFE) undergoes chain scission at all temperatures below the melting temperature (55,56). On the other hand the fluoroelastomer Kalrez (DuPont), a copolymer of tetrafluoroethylene and perfluorinated methyl vinyl ether, can be readily cross-linked by exposure to γ radiation, because of the mobility of the polymer chains and related higher probability of radical recombination reactions (57). A corollary to this is the marked long-term stability of free radicals in irradiated fluoropolymers. Indeed, Judeikis and co-workers (58) and others have proposed the use of PTFE as a radiation dosimeter. Of more practical concern is the propensity of these stable radicals to react slowly with dissolved oxygen, a phenomenon leading to the well-known poor radiation stability of fluoropolymers.

Finally, examination of the volatile products of irradiation of branched polymers reveals the importance of loss of the side chains. For example, irradiation of branched copolymers of ethylene and α-olefins results in volatile products characteristic of both the frequency and structure of the side chain (59,60). In this work the authors also highlight the influence of radiation temperature and morphology of the irradiated semicrystalline polymer.

Formation of Unsaturated Groups. As indicated above, an important result of the radiolysis of polymer is the formation of unsaturated groups. In 1954, Dole and co-workers (46) reported the formation of main-chain unsaturation in irradiated polyethylene and demonstrated that the yield of these groups was proportional to the yield of hydrogen gas. In these materials the mechanism of formation of unsaturation was thus established at an early time. In this and a subsequent article (46,61), Dole and co-workers also indicated that other types of unsaturated groups, for example vinyl and vinylidene groups, are rather consumed in the radiation-induced reactions. Later, this same group deduced from measurements of gel fractions that the terminal unsaturation was reacting via an end-linking reaction, a result confirmed much later by Randall and co-workers (62–64) and Horii and co-workers (65,66).

Perhaps the most well-known system in which large amounts of unsaturated groups are formed is poly(vinyl chloride). It is well established that irradiation leads to the formation of alkyl radicals, which are the locus for subsequent dehydrochlorination reactions. This results in characteristic changes in the infrared and visible absorption spectra (67–69), as well as the formation of stable polyenyl radicals (67,68).

Color Centers. An obvious corollary of the formation of polyenyl radicals and conjugated double bonds in irradiated poly(vinyl chloride) is a marked changed in the visible appearance of the polymer (67–70). Color changes on irradiation of polymers may have important implications for a number of commercial applications, for example when the appearance of the material is of importance, as in medical applications, or when the optical properties of the material must be maintained in a high dose environment, for example in polymeric fiber optics in particle physics detectors. On the other hand, color development for radiation dosimeters has been exploited by a number of workers, most notably the group of McLaughlin (71–74).

Until recently the phenomenon of color changes in irradiated polymers has not received detailed attention. Clough and co-workers (75–77), however, have recently reviewed studies of color changes in a number of important synthetic polymers. They report that there are two classes of color centers in polymers, annealable and permanent. The former class of color center appears to be associated with free radicals trapped within the polymer matrix, whereas permanent color centers are stable chromophores formed as a result of radiochemical reactions. The free radicals can be destroyed by the application of heat, or often through reaction with atmospheric oxygen. Clough and coworkers (77) also reported that whereas the incorporation of aromatic groups provides a degree of protection against radiochemical damage to polymers, it does not necessarily protect against color formation, because presumably the products of reaction in aromatic polymers tend to have high extinction coefficients.

Changes in Molecular Weight of Polymers on Exposure to Radiation

The effects of cross-linking and main-chain scission on the molecular weight and the molecular weight distribution of polymers have been examined in great detail by a number of authors (78–89). The exact method of treatment of the problems depends on the molecular weight distribution of the polymer prior to irradiation, and on whether it can be described by a most-probable distribution or recourse must be made to a higher-order distribution. For simplicity, in this article we shall consider the effects of cross-linking and scission on polymer having an initial most-probable distribution; however, reference will be made to more complete analyses where appropriate.

Effects of Chain Scission. In the early 1950s, Charlesby and co-workers were considering theoretical approaches to the description of the changes in molecular weight of polymers during irradiation. In 1954 they reported that the molecular weight of PMMA, measured by solution viscometry, was inversely proportional to the radiation dose (80,90). Since that time a number of

refinements to these initial observation and theoretical expression have been made (81,91–94).

In summary, the number- and weight-average molecular weights change as described below:

$$\frac{1}{M_n(D)} = \frac{1}{M_n(0)} + 2k_1 G(S)D \tag{5}$$

$$\frac{1}{M_w(D)} = \frac{1}{M_w(0)} + k_1 G(S)D \tag{6}$$

In these expressions the constant k_1 is equal to 5.18×10^{-8} if the dose D is expressed in units of kGy. Most importantly, equations 5 and 6 are applicable to any initial molecular weight distribution, because in the case of degrading polymers, the molecular weight distribution will approach the most-probable distribution.

Effects of Simultaneous Cross-Linking. Charlesby (78) was also the first to describe the relationship between the molecular weight of a polymer and the radiation-induced chain cross-linking. He reported in 1954 that the dose required to produce incipient gel formation, known as the gel dose D_g, was inversely proportional to the initial molecular weight of the irradiated siloxane.

$$\frac{1}{M_n(D)} = \frac{1}{M_n(0)} + 2k_1[G(S) - G(X)]D \tag{7}$$

$$\frac{1}{M_w(D)} = \frac{1}{M_w(0)} + k_1[G(S) - 4G(X)]D \tag{8}$$

In this case, equation 7 applies to all initial molecular weight distributions, whereas equation 8 applies only to polymers having an initial most-probable distribution undergoing H-linking reactions. Expressions for changes in molecular weight in polymers having other initial molecular weight distributions, and also for the case of cross-linking via a Y-linking mechanism, have been developed, and these have been summarized by various authors (86–88,93).

The above expressions have been derived for the first two moments of the molecular weight distribution, M_n and M_w. However, the third moment, the z-average molecular weight, M_z, is experimentally accessible through measurement of sedimentation velocity of polymer chains. O'Donnell and co-workers (85,86) have reported the respective relationships between M_z and the radiochemical yields for scission and cross-linking. The results of analysis of the changes in M_z and M_w of irradiated poly(acrylic acid) and poly(methacrylic acid) (85) and polystyrene have also been reported (86).

Soluble Fractions. The above descriptions of the change in molecular weight on irradiation presuppose the ability to accurately measure the molecular weight distribution of the polymer after irradiation. A number of authors have pointed out that for polymers for which cross-linking dominates chain scission, measurement of molecular weight is limited to doses well below 50% of the gel

dose. More conveniently measured parameters are therefore the gel dose, that is, the dose to achieve incipient gel formation, and the residual soluble fraction beyond the gel dose.

The most widely used expression for analysis of the soluble fraction is also due to Charlesby and Pinner (95).

$$S + S^{0.5} = \frac{G(\mathrm{S})}{2G(\mathrm{X})} + k_2/[G(\mathrm{X})M_\mathrm{n}(0)D] \tag{9}$$

The constant k_2 is equal to 4.82×10^6 if the dose is expressed in kGy. Equation 9 assumes a post-probable initial molecular weight distribution, random scission and cross-linking reactions, and cross-linking by an H-linking mechanism. If cross-linking occurs by a Y-linking mechanism, the relationship between soluble fraction and dose is given by (96)

$$S + S^{0.5} = \frac{2G(\mathrm{S})}{G(\mathrm{X})} + k_3/[G(\mathrm{X})M_\mathrm{n}(0)D] \tag{10}$$

The constant k_3 is equal to 1.93×10^4 if the dose is expressed in kGy. Clearly, the choice of application of either equation 9 or equation 10 must be directed by additional evidence of the mechanism of cross-linking. Finally, a number of workers have derived expressions for the relationship between the soluble fraction and radiation dose for more general initial molecular weight distributions (81,88, 91–93,97).

The Radiation Chemistry of Specific Polymers

The radiation chemistry of polymers has attracted enormous interest since the initial studies by Charlesby, Dole, and Chapiro in the early 1950s. This interest has been a result of the recognition of the tremendous commercial importance of the radiation chemistry of polymers, and of the importance of an understanding of radiation chemistry to other fields. A number of excellent reviews have appeared over the past 45 years, including the seminal texts by Charlesby (1) and Chapiro (2), and the comprehensive review texts edited by Dole (98,99). Since then, a number of broad reviews of the effects of radiation have been published. For example, the *Polymer Handbook* has previously tabulated lists of the radiochemical yields reported elsewhere (100). The American Chemical Society has published a number of collections of papers presented at radiation chemistry meetings (101,102), and the two journals *Radiation Physics and Chemistry* and *Polymer Degradation and Stability* are of much interest. The 11 international meetings on radiation processing, which have been published in *Radiation Physics and Chemistry* (103–113), and the text by Singh and Silverman (114), provide an excellent overview of the field.

A number of more specific reviews have also been published. For example, Reichmanis has written about the use of radiation chemistry for electronics applications (43,115). Clough (116,117) has written a number of excellent reviews with

an emphasis on commercial applications of radiation chemistry, and the effects of oxygen on radiochemical events. The radiation chemistry of fluoropolymers has been reviewed recently by Lyons (118) and Forsythe and Hill (119). Burillo and co-workers (120) have addressed the use of radiation in the polymer recycling industry. Rosiak (121,122) has reviewed the emerging field of the radiation processing of biomedical polymers. More recently, Pruitt (123) has reviewed the major changes induced in medical polymers on irradiation, and given specific case studies of a number of materials. Hill and Whittaker (124) have detailed the importance of NMR spectroscopy in this field.

Polyethylene. It has been known for many years that polyethylene undergoes cross-linking on exposure to high energy radiation. In 1952 Charlesby (125) reported that exposure of polyethylene to pile radiation resulted in chemical changes consistent with cross-linking reactions. This initial observation prompted extensive work by him and others, most notably Dole, which has laid the foundations for the modern field of radiation chemistry of materials. The main findings of these and subsequent workers are summarized below (see Ethylene Polymers).

Free-Radical Intermediates. From an early time the participation of free radicals in the radiation chemistry of polymers has been well understood. Charlesby (125) in 1952 invoked a free-radical mechanism of cross-linking of polyethylene, although for other materials the participation of ionic species has also been suggested (126–137). The primary radicals observed at 77 K, at which temperature a significant proportion of the radicals are assumed to be trapped and prevented from further reaction, are the secondary alkyl radicals **I** (49,138–148).

I **II**

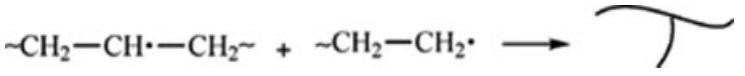
Dole and co-workers have reported yields of alkyl free radicals in polyethylene irradiated at 77 K ranging from 2.7 to 3.7 (141,145,149). Furthermore, Cracco, Arvia, and Dole (49) reported that on warming, alkyl radicals decay by a first-order process, and they attributed this to reactions between alkyl radicals within isolated spurs. The persistent free radicals on warming to room temperature are the allyl radicals **II**. The impact of long-term stability of radical species on the stability of polyethylene has been underlined by studies of Jahan and co-workers (150–157) of ultrahigh molecular weight polymer used in medical implants.

Cross-Linking. In addition to conversion of alkyl radicals to more thermally stable allyl radicals, a significant proportion can undergo radical–radical recombination reactions (eq. 11).

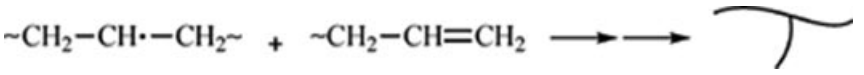
(11)

The product shown on the right of equation 11 is called an H-type cross-link. A number of alternative mechanisms of cross-linking have been proposed,

the most important being the formation of Y-type cross-links through either radical recombination reactions (eq. 12) or end-linking to terminal vinyl groups (eq. 13).



(12)



(13)

In the case of polyethylene the initial cleavage of carbon–carbon main-chain bonds is believed to be relatively unimportant compared with end-linking reactions. Evidence for this includes the absence of a contribution from chain-end free radicals in the ESR spectra of polyethylene irradiated at low temperatures, and careful analysis of the residual soluble fractions formed on irradiation at higher temperatures. Dole and Katsuura (158) suggested that if main-chain scission does occur, the cage effect is responsible for an overwhelming proportion undergoing recombination reactions. Not long after this, Kang, Saito, and Dole (159) measured the yields of cross-linking and main-chain scission in high density polyethylene at a range of temperatures by analyzing the residual soluble fractions with a Charlesby–Pinner equation modified for a Wesslau molecular weight distribution. They found that at each temperature over 308–393 K, the ratio of scission to cross-linking reactions was significant (ca 0.2) and decreased slightly at higher doses, an effect they ascribed to the reactions of vinylene double bonds to form cross-links. Similar results were reported by Dole and co-workers (149,160). In contrast to these articles, Lyons and Fox (161) reported negligible dose-dependence of $G(X)$ and 0.03 as the ratio of the yield of scission to that of cross-linking reactions.

The yields of cross-linking reactions in polyethylene have been reported extensively (97,149,159,160,162) and generally fall in the range $G(X) = 0.8–2.5$ for samples irradiated at ambient temperatures. The principle reason for this wide range of values of cross-link yields is the variation in crystallinity in the materials studied. It is reasonably well accepted that cross-linking reactions do not occur within the crystalline lamellae of polyethylene; Patel and Keller (163) confirmed this by analyzing the residual molecular weights of the chains within the crystalline regions of irradiated high density polyethylene after the amorphous regions had been removed by exposure to ozone. There was no evidence for cross-linking reactions between the chains previously within the crystalline regions. To further underline this relationship, O'Donnell and Whittaker (164) have reported that the value of $G(X)$ decreases progressively with increasing crystalline content for a range of materials having a similar initial molecular weight distribution.

In this same article, O'Donnell and Whittaker (164) compared the yields of cross-linking and scission, and other radiochemical products, in fully amorphous ethylene–propylene rubber (EPR) with the yields measured by them and reported by other workers for semicrystalline polyethylene and polypropylene. The yields of cross-linking and scission were significantly lower than those expected from extrapolation of the G-values for the homopolymers to zero crystalline content. In

other words, the yields for the fully amorphous materials were much lower than expected from considering yields within the amorphous regions of the semicrystalline polymers. It was concluded that the radiation-induced reactions must be favored at the crystalline–amorphous interface and that this might be a result of the stabilization of free-radical intermediates at the interface.

The relative importance of reactions 11–13 in the radiation cross-linking of polyethylene has been resolved to a large extent through a number of elegant studies of the structures of polymer irradiated to doses below the gelation dose, using high resolution solution-state ^{13}C NMR spectroscopy. The initial use of ^{13}C NMR to study radiochemical reactions was by Bennett and co-workers (165), who reported structural changes in irradiated liquid model compounds of polyethylene, *n*-hexadecane, and *n*-eicosane. These authors reported the formation of H-link structures apparently via recombination of two secondary main-chain alkyl radicals. Not long after this, Bovey and co-workers (166) reported the identification of both H- and Y-type links in *n*-$C_{44}H_{90}$ irradiated in the melt using solution-state ^{13}C NMR. Irradiation in the crystalline state produced only linear dimers, apparently through the end-linking of molecules at the crystal surfaces.

Several years after this, Randall and co-workers (62–64) studied irradiated high density polyethylenes using ^{13}C NMR, and identified a number of new structures, including internal double bonds and Y-type cross-links. The materials under consideration initially contained a high concentration of vinyl end groups, which react readily with secondary alkyl radicals (reaction 12 above) to form Y-links. The authors were unable to identify H-links in their irradiated HDPE samples, and suggested that for these materials irradiated to low doses, the H-linking mechanism is relatively unimportant.

More recently, Horii and co-workers (65,66) examined changes in the solution-state ^{13}C NMR spectra of relatively low molecular weight PE samples irradiated under a range of experimental conditions. The lower viscosity of the solutions as a result of the low molecular weight was manifested in narrow line widths in the NMR spectra, and thus the authors were able to observe resonances in the spectra due to H-type cross-links in all samples. The yields of H-links and Y-links were measured as a function of temperature (66), and it was found that H-links were the dominant product when PE was irradiated in the molten state, whereas Y-links were more commonly formed on irradiation at ambient temperatures. It was suggested that at higher temperatures the probability of reaction of the primary radicals (in reaction 12 above) with hydrogen radicals is higher in the molten state, and thus recombination of the longer-lived secondary radicals (reaction 11) dominates. These conclusions are supported by the study of O'Donnell and Whittaker (167) in which the formation of H-type cross-links in fully saturated ethylene–propylene rubber (EPR) irradiated well above T_g was confirmed. In addition, O'Donnell and Whittaker (168) have reported the observation of resonances due to H-type cross-links in LLDPE irradiated to very high doses.

Volatile Products. As discussed above, Dole and co-workers were the first to observe that hydrogen gas was a major product formed on the irradiation of polyethylene (46). Gaseous hydrogen was formed by recombination of hydrogen atoms formed by cleavage of C—H bonds, as illustrated in reaction 4 above, or by abstraction of hydrogen atom from the polymer main-chain by this ejected,

perhaps thermally activated, hydrogen atom itself. The role of the hydrogen gas so formed in radical migration was fully described by Dole and Cracco in 1961 and 1962 (50,51), and later through observation of the catalytic effect of hydrogen gas on the kinetics of decay of alkyl free radicals by Waterman and Dole (169) and Johnson and co-workers (145).

The yield of hydrogen gas in irradiated polyethylene has been reported by a number of workers to fall in the range of $G(H_2) = 3–4$, and shown by Kang and co-workers (159) to increase with increasing irradiation temperature. There is also evidence that the yield does depend to some extent on radiation dose (159) and polymer crystallinity (164).

In addition to hydrogen gas, small quantities of hydrocarbon gas reflective of the concentration and identity of side chains are produced on irradiation of polyethylene containing short chain branches. Bowmer and co-workers in 1983 (59) reported that the primary scission process leading to the formation of these small alkanes must occur at the tertiary carbon on the main chain. They also reported that the relative yields of volatile saturated products were essentially constant with increasing temperature, but that the total overall yield of gases did increase. On the other hand the formation of unsaturated products, principally ethylene and butylene, attributed to thermal depolymerization, increased markedly at elevated temperatures.

Unsaturation. The formation and reaction of unsaturated groups in polyethylene has been extensively studied by Dole and co-workers over a number of years, with a particular emphasis on the relationship between the rate of formation and decay of unsaturation with other radiochemical reactions. The main unsaturated product formed on irradiation of polyethylene is internal vinylene unsaturation. Dole and co-workers (46) suggested that up to 80% of the hydrogen gas evolved on irradiation resulted from processes leading to formation of vinylene groups. Dole and co-workers (61) further reported that the rate of formation of vinylene unsaturation was scarcely affected by irradiation at 77 K, at which temperature migration reactions are presumably retarded. This led them to suggest that molecular detachment of hydrogen molecules may be involved. Later, this group (159) reported that the *G*-value for the formation of vinylene groups was close to 2.4 at all temperatures in the solid state.

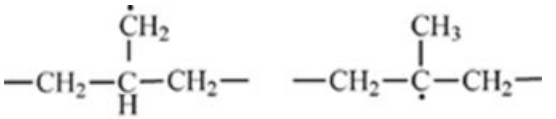
In addition to the formation of vinylene unsaturation, evidence for the formation of conjugated double bonds can be found in the appearance of new absorption bands in the UV spectrum of irradiated polyethylene (170–172). The rate of formation of dienes is significantly higher than that expected from consideration of the statistics of formation of vinylene unsaturation; Fallgatter and Dole (170) speculate on possible cooperative mechanisms of formation. The formation of more highly conjugated species is suggested to result from secondary reaction (171,172).

The kinetics of decay of double bonds initially present in the material have also been studied in detail. Dole and co-workers (61) reported that the decay of terminal vinyl or vinylene groups follows first-order kinetics until the formation of vinylene groups, mentioned immediately above, becomes significant. The exact mechanism of reaction of the vinyl end groups remains unclear; however, the participation of these groups in end-linking reactions (reaction 12) has been confirmed by Randall and co-workers (62–64) and Horii and co-workers (65,66).

Polypropylene. Polypropylene undergoes net cross-linking when exposed to ionizing radiation in the absence of oxygen. However, the radiation chemistry of polypropylene differs markedly from that of polyethylene as a consequence of the presence of tertiary carbons along the polymer backbone. Therefore, polypropylene undergoes significant levels of main-chain scission on irradiation (see PROPYLENE POLYMERS (PP)).

Initial studies of this polymer were mainly concerned with understanding the changes in molecular weight and the rate of gel formation on irradiation. Much of this work was concerned with the development of fundamental relationships between the radiochemical yields and molecular weights. The reported yields of chain scission and cross-linking fall in the ranges $G(S) = 0.198–0.62$ and $G(X) = 0.0645–0.272$, respectively (81,82,95,173–176). The apparent large variation in values of $G(S)$ and $G(X)$ are in part due to the difficulty in analysis of molecular weight or solubility changes in materials having broad molecular weight distributions, and also possibly due to a dose dependence of the G-value for chain scission (81,175,176).

Despite the increased probability of main-chain scission in polypropylene compared with polyethylene, there is no evidence of the formation of stable scission radicals on irradiation at low temperatures. Rather extensive ESR evidence has been accumulated that the stable free-radical intermediates are those listed below:



III **IV**

On irradiation at low temperatures, alkyl radicals (**III** and **IV**) are formed with a radiochemical yield $G(R)$ of 2.4–2.6, depending on the crystallinity of the material (99,164).

A particularly informative set of experiments which reveal the extent of initial bond cleavage has been conducted by Busfield and co-workers (35–38). They have studied the radiation-induced changes in the stereochemistry of isotactic polypropylene (iPP). The changes in the stereochemistry are a result of initial chain scission, isomerization, and rehealing of the broken bond, as shown below in Figure 1.

Studies of irradiated iPP (35–38,177) have provided evidence that the racemization reactions do not occur as isolated events, but rather that they may occur in clusters. The methyl region of the solution-state ^{13}C NMR spectrum of iPP can be resolved to the pentad level. The changes in the pentad distribution on irradiation are not consistent with random reactions occurring along the polymer backbone (35–38). A number of mechanisms have been suggested to account for the observed changes in tacticity, involving for example an increased probability of reaction after initial reaction, but all schemes have in common the observation that the proportion of syndiotactic sequences formed on irradiation is high and that the rate of equilibration of these sequences is low. It was also found that

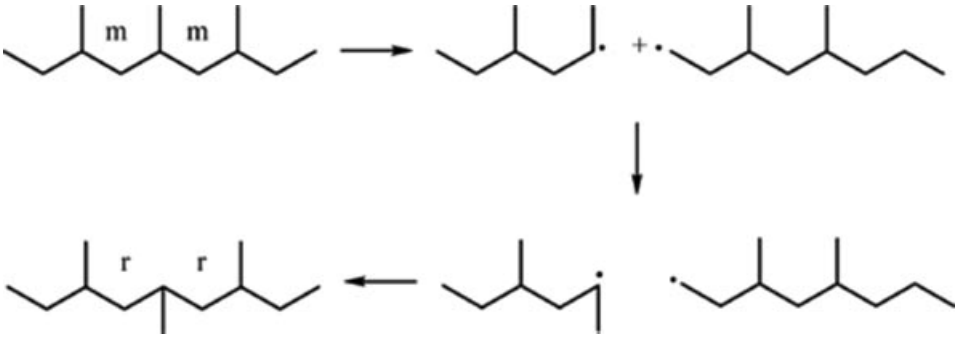


Fig. 1. The racemization of an initially isotactic polymer through chain scission, isomerization, and bond reforming.

electron-beam irradiation at high dose rates was much more effective in promoting changes in tacticity than γ irradiation to comparable doses (37).

Polyisobutylene. In 1954 Charlesby (80) noted that the molecular weight of polyisobutylene (PIB) decreased rapidly on exposure to high energy radiation. It has since been well understood that the presence of quaternary carbons in the main chain of polymers predisposes such a material to degradation (see BUTYL RUBBER). In the case of PIB, the primary reactions during radiolysis have been suggested by Alexander and co-workers (178) and Chapiro (179) to be those described in Figure 2. On the other hand Miller and co-workers (180) suggested that the initial chemical changes involve loss of a methyl hydrogen to form radical **VII**, followed by spontaneous β-cleavage (Fig. 3). In addition, Il'icheva and Slovokhotova (181) have suggested that the energetically favoured radical **VIII** can also undergo β-cleavage, as in Figure 4.

The ESR spectra of PIB irradiated at low temperature consists of a broad doublet with a hyperfine coupling constant of 2 mT, attributed to either radical **VIII** (182) or a combination of contributions from radicals **VII** and **VIII** (183, 184). The primary radicals **V** and **VI** (Fig. 2) have not been observed by ESR spectroscopy. Despite extensive studies of the radiochemical changes in PIB by ESR, volatile product analysis, and UV and IR spectroscopy, the mechanism of degradation had been uncertain until the advent of high resolution ^{13}C NMR methods. In a comprehensive study, Bremner and co-workers (185) and Hill and

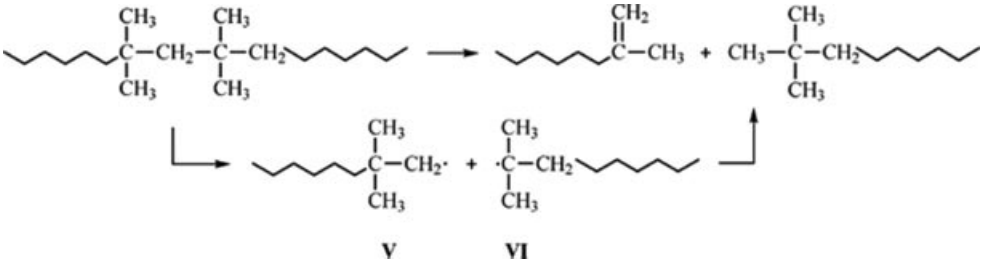

Fig. 2. Proposed mechanism of degradation of PIB via initial main-chain cleavage.

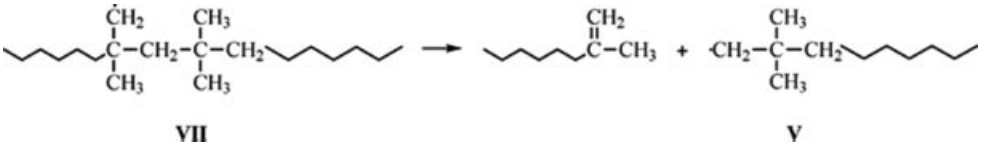


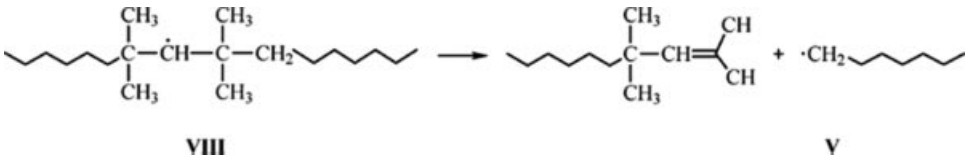
VII V

Fig. 3. Proposed mechanism of degradation of PIB via β scission of the side-chain methylene radical.

co-workers (186) identified the major products of degradation by NMR and other methods. They concluded that the schemes shown in Figures 2–4 are all possible degradation pathways, and that the major products are structures formed through the reaction scheme shown in Figure 2.

Polyethers. The radiation chemistry of the polyethers has received relatively little attention. It is known, however, that all of this class of materials undergoes net cross-linking reactions. A comprehensive study of the radiation chemistry of polyoxymethylene (POM) has been reported by Fischer and Langbein (187). These authors reported that irradiation at the high dose rates of 150 kGy/min with 1-MeV electrons at 287 K resulted in a reduction in the total mass of the sample of approximately 1% per 100 kGy absorbed dose. There was a corresponding increase in the yield of new acetate chain ends determined by IR spectroscopy. The evolved gases consisted of many products, however the main products were hydrogen ($G = 1.7$), methane ($G = 0.14$), and CO ($G = 0.013$). The gases also included formaldehyde and higher molecular weight molecules. These results were combined with ^{1}H NMR analysis of the polymer after irradiation. Peaks due to new acetate and methoxy chain ends, and H-type cross-links, were observed. The yields of products obtained from the NMR spectra appear to be high, perhaps reflecting the difficulty in obtaining quantitative NMR spectra of irradiated materials. Despite this, they were able to confirm that this polymer does crosslink on irradiation.

The effects of irradiation on the properties of poly(ethylene oxide) (PEO) have been examined by a number of workers (see ETHYLENE OXIDE POLYMERS). A number of these studies have been concerned with irradiation cross-linking of PEO in solution (188–201). When irradiated in the solid state, PEO undergoes net cross-linking with the reported gel doses of 3.5 and 1.1 kGy, respectively, for highly crystalline, lower molecular weight and more highly disordered, high molecular weight materials (202). King reported earlier changes in solution viscosity of PEO irradiated in air and in vacuum (203). Other studies have been concerned with changes in the crystalline structure on irradiation; the crystalline order is reduced at moderate radiation doses consistent with cross-linking reactions (202,204,205).



VIII V

Fig. 4. Proposed mechanism of degradation of PIB via β scission of the main-chain methine radical.

Finally, the effects of radiation cross-linking on the chain dynamics have been examined by Schilling and co-workers (206) using solid-state ^{13}C NMR techniques.

Poly(propylene oxide) (PPO) has also been observed to form a gel on irradiation (207). Roberts and co-workers (207) reported G(S) values of 0.22 and 0.55 and G(X) values of 0.15 and 0.31 for atactic and isotactic PPO, respectively. In this article the products of degradation are compared with previous reports of products of irradiation of PP and POM. It was found that the radiation chemistry is broadly consistent with that expected from previous studies.

Poly(vinyl alcohol). The radiation chemistry of poly(vinyl alcohol) (PVA) is similar in many respects to the degradation of PVC, described below (see VINYL ALCOHOL POLYMERS). PVA undergoes a progressive darkening on irradiation at elevated temperatures or gets heated subsequent to irradiation due to the formation of sequences of conjugated double bonds (208). The mechanism of degradation proposed by Zhao and co-workers (208), and shown in Figure 5 below, involves the participation of radical cations. Previous studies have indicated that hydrogen gas is a primary product of the degradation of PVA (209,210), leading to the formation of the α-carbon radicals, as shown in Figure 5. More recently, using ESR spectroscopy, Zainuddin and co-workers (211) have examined in detail the radical species formed on irradiation of PVA. They identified contributions for three radical species at low temperatures: the α-carbon radical (triplet ESR spectrum), a radical anion (doublet spectrum), and an unidentified neutral species (doublet radical). The latter two species contribute 62% of the total radical concentration at 77 K. These results are broadly consistent with the mechanism proposed in Figure 5; however, neither article comments on the expected changes in molecular weight on irradiation. Lu and co-workers (212) have shown that the molecular weight of PVA decreases on irradiation, with the polymer remaining soluble up

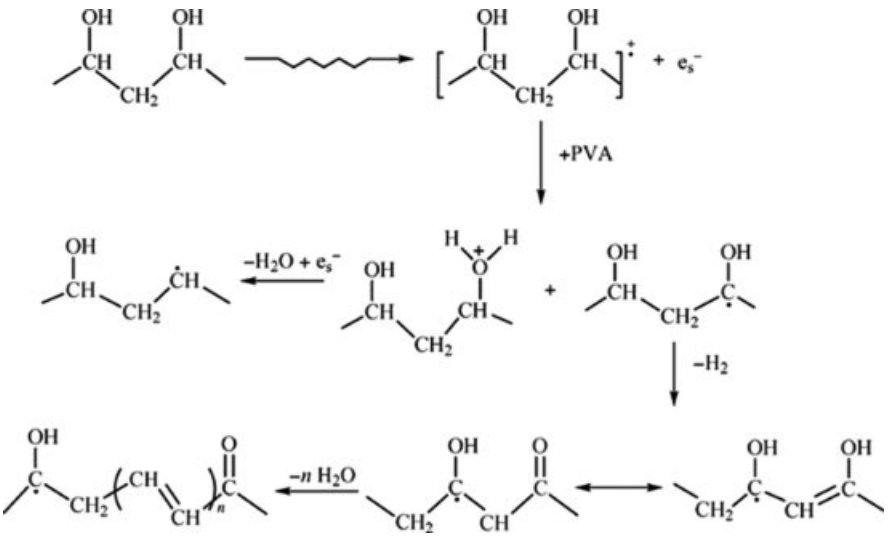


Fig. 5. Proposed mechanism of formation of conjugated structures during the radiolysis of poly(vinyl alcohol).

to doses greater than 1000 kGy. It is apparent that chain scission reactions must dominate over cross-linking reactions.

Poly(vinyl chloride). The mechanism of radiation chemistry of poly(vinyl chloride) (PVC) in many ways resembles the well-known thermal degradation of this polymer (see VINYL CHLORIDE POLYMERS). The principal results of exposure of PVC to ionizing radiation are evolution of hydrochloric acid and development of intense absorption bands in the UV and visible regions of the electromagnetic spectrum (67–69,213). The result of dehydrochlorination is the formation of polyene radicals. For example, absorption peaks at 252, 291, and 330 nm were assigned to allyl, dienyl, and trienyl radicals, respectively. The dehydrochlorination reactions dominate the radiation chemistry; the yield of cross-linking reactions is very low, as reported by Chapiro (69). Salovey and Gebauer (214) later reported from the changes in the polydispersity of irradiated PVC that chain scission and cross-linking are occuring simultaneously on irradiation in air.

Aliphatic Polyesters. Over the past 10 years the linear aliphatic polyesters, the polyalkanoates, and the copolymers of lactic and glycolic acids have attracted enormous interest as a result of their widespread use as biomedical materials. The radiation stability of these materials is of importance because of the potential to effect sterilization through exposure to ionizing radiation (215–225).

Polyhydroxybutyrate. Copolymers of hydroxybutyrate and hydroxyvalerate possess many mechanical properties in common with synthetic polyolefins, and so have attracted much attention as replacements for these materials in environments where biodegradability is an important parameter (see POLY(3-HYDROXYALKANOATES)). Carswell-Pomerantz and co-workers (217,218) have reported a detailed study of the radicals formed on irradiation of such materials. They found that the yield of radicals at 77 K was $G(\mathrm{R}) = 1.7 \pm 0.2$, independent of copolymer composition, but that on irradiation at 300 K, the yield of radicals was reduced for the copolymers because of their lower glass-transition temperatures compared with the homopolymer. At low temperatures a significant contribution to the ESR spectra from radical anions was noted. These radicals were observed to decay on warming to produce scission radicals. At still higher temperatures, radicals produced by abstraction of a methylene proton adjacent to the carbonyl group were detected.

The predominant reaction on radiolysis of polyalkanoates is chain scission. Carswell-Pomerantz and co-workers (218) have shown that the main volatile products of radiolysis are CO, CO_2, and H_2. Scission at the ester unit results in a reduction in the molecular weight of these materials, and the G-value for scission $G(\mathrm{S})$ for PHB was calculated to be 1.3. Using solution NMR, a very similar yield of reactions was determined from measurement of the yield of new chain ends. Cross-linking is not important in the radiation chemistry of PHB; however, analysis of the changes in molecular weights of irradiated PHBV copolymers provided evidence of some cross-linking, with the ratio of scission to cross-linking being 9 and 6.8 for materials having valerate mole fractions of 0.184 and 0.263, respectively.

Poly(lactic acid-co-glycolic acid). The degradation of the homopolymers and copolymers of lactic and glycolic acids (PLGA) has been reported by a number of authors (220–223). Babanalbandi and co-workers (220) have measured the G-radical values at 77 K for poly(L-lactic acid) (L-PLA) and poly(D,L-lactic acid)

(D,L-PLA) and reported these to be 2.0 and 2.4, respectively. They also reported $G(S) = 2.3$ and $G(X) = 0.0$ for D,L-PLA and $G(S) = 2.4$ and $G(X) = 0.28$ for L-PLA. These results are in contrast to the values of Collett and co-workers, who suggested that rather than chain scission dominating the radiation chemistry, these polymers form a gel on irradiation.

The results of Babanalbandi and co-workers (221), in which new aliphatic chains ends formed by cleavage of the main chain at the ester unit are observed, are in support of a mechanism in which chain scission dominates cross-linking. These authors reported *G*-values for the formation of chain end structures comparable with earlier study. Furthermore, the main volatile products of radiolysis of PLA and poly(glycolic acid) (GPA) are CO_2 and CO, consistent with chain scission being the most important reaction. In addition, small amounts of hydrogen and ethane gas were observed on the radiolysis of PLA. Finally, Montanari and co-workers (226) have examined the effects of radiation sterilization on the stability of PLGA microparticles used for drug delivery.

Aliphatic Polysulfones. The class of copolymers of olefins and sulfur dioxide are well known for undergoing extensive degradation on exposure to high energy radiation. In 1965 Ayscough and co-workers (227) reported an ESR study of the degradation products of sulfones and poly(olefin sulfone)s. They were able to confirm that the relatively weak C—S bonds are more susceptible to rupture compared with the C—H bonds. Later, Brown and O'Donnell (228,229) confirmed that this initial chain breakage leads to loss of SO_2 and permanent chain scission and reduction of molecular weight. The yield of scission reactions was found to increase progressively up to the ceiling temperature for the propagation–depropagation equilibrium, at which temperature rapid depropagation occurred. The yield of olefin gas evolved on radiolysis was observed to be lower than the yield of sulfur dioxide, because of the cationic homopolymerization of the olefins initiated by a polymeric carbonium ion (45,230). Isomerization of the olefin via a carbonium ion intermediate was also confirmed. The mechanisms of these reactions are summarized in Figure 6.

Polymethacrylates and Polyacrylates. The high energy radiation chemistries of polyacrylates and polymethacrylates were some of the first studied in detail for any polymer (see ACRYLIC ESTER POLYMERS; METHACRYLIC ESTER POLYMERS). For example, in the 1950s, Charlesby and co-workers reported extensively on the breakdown of poly(methyl methacrylate) (PMMA) on exposure to high energy radiation, and also on studies of coloration and gas formation associated with the loss of the side chains (20,39,80). The molecular weight of PMMA was shown to decrease on irradiation (80,231), with the decrease inversely proportional to the irradiation dose. The latter observation was later rationalized through the famous Charlesby–Pinner relationship (95), which allowed *G*-values of chain scission and cross-linking to be evaluated. Shultz and co-workers (232) reported that for 1-MeV electron irradiation of PMMA under vacuum, $G(S) = 0$ and $G(X) = 1.65$, and Wall and Brown (231) examined the yields for the principal gases formed on γ radiolysis under vacuum: H_2, CH_4, CO, and CO_2, for which the *G*-values were 0.21, 0.54, 0.45, and 0.32, respectively [$G(\text{gas}) = 1.6$].

ESR studies by Ovenall and co-workers (233–236) during the same period identified the natures of the spectra of the radicals formed in PMMA on radiolysis over a temperature range from ambient to 77 K. They identified the multiline

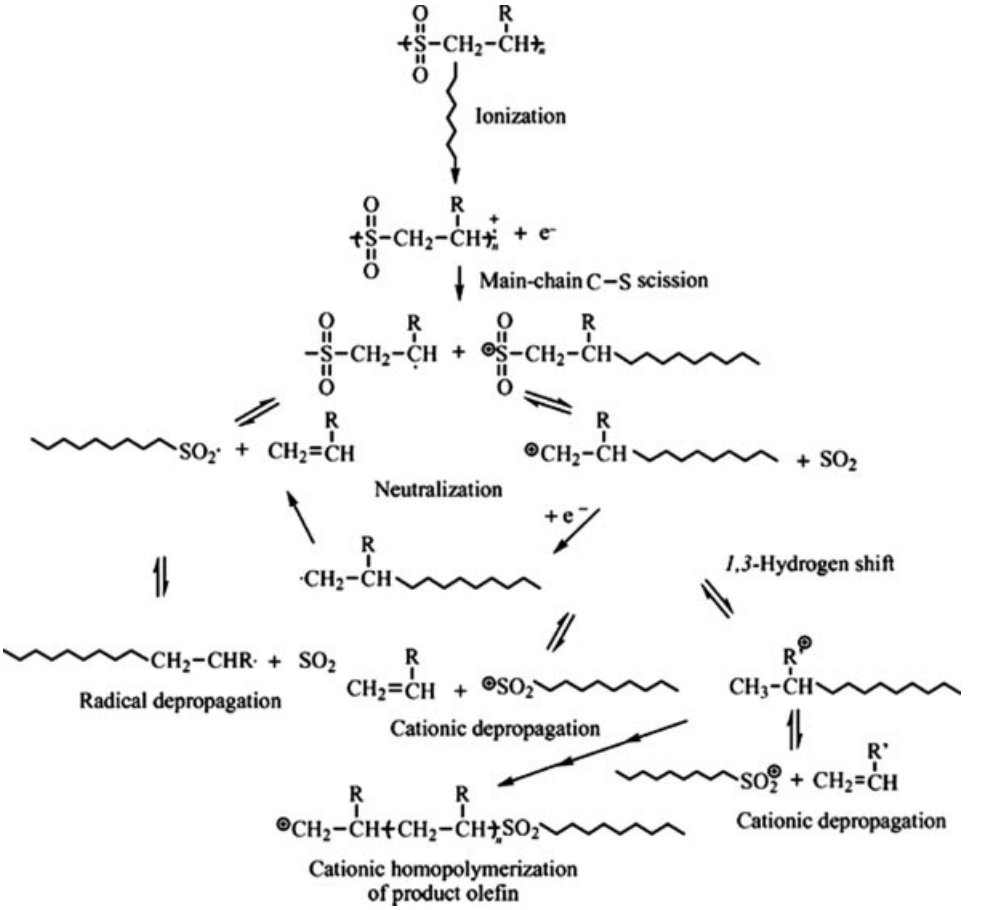

Fig. 6. Proposed mechanism of degradation of poly(olefin sulfone)s.

spectra observed at room temperature as being principally associated with chain-end radicals, which were characterized by a nine-line spectrum at room temperature, with $G(\mathrm{R}) = 2.5$. Later, O'Donnell and co-workers (237) were able to account for the nine lines in terms of two overlapping spectra, one consisting of five and the other of four lines, arising from two conformations of the chain-end radicals. Bowden and O'Donnell (238) later showed that the relative contributions of the two conformations varied with the observation temperature.

A consideration of the molecular weight changes and the natures and yields of the gaseous and radical products formed on radiolysis at room temperature allowed a mechanism for the radiolysis of PMMA to be formulated. The principal process associated with the degradation was scission of the ester side chain, forming the principal gaseous products and a main-chain radical which can further undergo β-scission to form the propagating radical and a chain-end double bond. It was also thought that some direct main-chain scission may occur at the α-carbon. The coloration of PMMA on radiolysis was believed to arise from the formation of oxygen and temperature-sensitive radical and charged species.

David and co-workers (32) confirmed the occurrence of direct main-chain scission and reported that racemization also occurred during radiolysis of syndiotactic PMMA. In the presence of a radical scavenger, no racemization was found to take place, suggesting that radical processes are involved in the racemization process (33). These results therefore indicate that irradiation must induce some temporary main-chain scission, which is followed by recombination of the scission radicals within the cage leading to a concomitant change in the stereochemistry of the polymer. The extent of the racemization observed for a γ-ray dose of 8 MGy was reported to be approximately 24%.

Because PMMA has a low ceiling temperature, the formation of propagating radicals on radiolysis at 453 K, with $G(S) = 10$, Charlesby and Moore (40) found spontaneous depolymerization of the polymer to monomer at this temperature. In a later article, David and co-workers (239) showed that depolymerization also occurred when PMMA was irradiated at ambient temperature and then heated to 433 K, and that the yield of monomer was independent of the absorbed dose and the initial molecular weight of the PMMA.

By contrast with PMMA, poly(methyl acrylate), PMA, and several other aliphatic polyacrylates were found by Shultz and Bovey (240) to undergo cross-linking and gel formation on irradiation with 1-MeV electron beams. They reported $G(S) = 0.15$ and $G(X) = 0.52$ for PMA. Graham (241,242) reported that the phenyl, benzyl, and 2-phenyl ethyl acrylate polymers also undergo cross-linking on γ radiolysis under vacuum. There was evidence of side-chain scission also, and according to Fox and co-workers (243,244) the major volatile products were similar to those observed for PMMA.

In these early years, the high energy radiation induced reactions of PMA and PMMA were not the only polyacrylates and polymethacrylates investigated, but they were found to be representative of the radiation chemistries of the two polymer families with different ester side-chains.

With improvements in the sensitivities of NMR and ESR spectrometers during the 1970s and the growing importance of microlithography in the production of solid-state devices, extra interest was directed to studies of the radiation-induced reactions of both polymethacrylates and polyacrylates. Because the methacrylate polymers almost entirely undergo scission on exposure to radiation under vacuum and the acrylates undergo cross-linking, they can be utilized as the basis for positive and negative resists, respectively. Thompson and co-workers (42) and Bowden (245) reported studies of the applications of PMMA in resist development, and examined the effect of incorporation of heavy atoms to enhance the sensitivity of PMMA to X-rays. Bowden (245) found that the sensitivity of a resist depends not only on the nature of the polymer but also on its molecular weight and molecular weight distribution, and that it increases with deceasing polydispersity. The development dose was found to decrease with increasing $G(S)$ for positive resists such as the polymethacrylates.

In a series of articles, Busfield, O'Donnell and co-workers reexamined the radical yields, gaseous products, molecular weight, and material property changes on γ radiolysis of PMMA and PMA (22,23,27,246–248).

O'Donnell and co-workers (22,248) have reevaluated radical formation on irradiation of PMMA at 77 K and room temperature. At 77 K the spectrum was analyzed in terms of the presence of $CHO\bullet$, $CH_3\bullet$, $\bullet COOCH_3$, and $-COOCH_2\bullet$,

as well as the propagation radical. At room temperature, only the propagating radical spectrum was observed. The *G*-value for overall radical formation at 77 K was 0.58, which is lower than that found at room temperature, 2.2, indicating the importance of radical recombination within the cage at 77 K. On annealing of the radicals produced at 77 K to room temperature and above, the radical decay is not linear, but reflects the onset of thermal transitions in PMMA (249).

A wide range of gaseous products have been identified by Busfield and co-workers (246) on γ radiolysis of PMMA at room temperature, which arise principally from a breakdown of the ester side-chains. The principal products and their yields G are respectively H_2, 0.34; CH_4, 0.66; CO, 1.08; CO_2 0.68; CH_3OH, 0.36; HCO_2CH_3, 0.69; dimethoxymethane, 0.11; and CH_3Ac, 0.02. Kudoh and co-workers (250) have measured the yields of H_2, CH_4, CO, and CO_2 on radiolysis at 77 K and report that whereas the hydrogen yields are the same at 77 K and room temperature, those for the other gases are lower at 77 K. This is in accord with the temperature dependence of the observed radical yields (248) and with the mechanical properties (251).

Busfield and co-workers (246) have examined the molecular weight dependence for γ radiolysis of PMMA in vacuum at room temperature, and Kudoh and co-workers (250) have also reported the dependence at 77 K. The values of G(S) at room temperature were 1.3 (246) and 1.7 (250) and at 77 K, 0.24 (250). These reflect the reported radical yields at the two temperatures. The variation of the molecular weight distribution with dose for e-beam irradiation of PMMA has been studied by Viswanathan (83). He has modeled the dependence of the distributions for use in predicting the sensitivities of positive resists in terms of product solubilities for development following exposure.

Busfield and O'Donnell (23) have examined the correlations between the changes in the molecular weight and the tensile properties of PMMA following radiolysis at room temperature. Both the flexural and compressive strengths decrease with increasing dose, reflecting the falling molecular weight of the polymer. Kudoh and co-workers have drawn similar conclusions for radiolysis at 77 K and ambient temperature (251).

The racemization of PMMA on radiolysis has been studied by Luo and co-workers (34), Dong and co-workers (31), and Thominette and Verdu (252) by use of NMR. Luo and co-workers (34) reported that for radiolysis of isotactic PMMA in solution, the yield of scission was greater than that for racemization, but the order was reversed for radiolysis in the solid state, indicating an important role for molecular motion of the scissioned chains. Dong and co-workers (31) investigated the γ radiolysis of both highly isotactic and highly syndiotactic PMMA. They found that their results were consistent with a temporary chain scission G-value of 18.6 at 353 K, and the polymers tended to approach a common average tacticity with increasing absorbed dose, which was the same as that found for PMMA prepared by free-radical polymerization.

By comparison with PMMA, the radiolysis of PMA has received much less recent attention. Busfield and co-workers (247) have measured the G-values for gaseous product formation at room temperature and 423 K, and they have also measured the dose to gel. The major volatile products were the same as those observed for the radiolysis of PMMA, but the total gas yield was much smaller: $G(\text{gas}) = 1.6$ compared with 3.9 for PMMA. However, the gas yield increased with

temperature, reaching 3.9 at 423 K. At 195 K the dose to gel was approximately 0.25 MGy, and decreased with increasing temperature.

The sensitivities of a wide range of other acrylate and methacrylate polymers to γ radiation have also been investigated, including poly(acrylic acid) (85,253), poly(methacrylic acid) (85,254–263), poly(hydroxyethyl methacrylate) (264,265), polymethacrylates with longer ester side-chains (266,267), and poly(ethylene glycol dimethacrylate) (268). In general, the behaviors of these polymers mirror the behaviors of the related methyl ester polymers, but some observations are worthy of special mention.

Hill and co-workers (85) have reported a study of the scission and cross-linking yields on γ radiolysis of poly(acrylic acid) and poly(methacrylic acid) using sedimentation equilibrium to obtain the weight- and Z-average molecular weights as a function of absorbed dose. The values $G(\mathrm{S}) = 0$, $G(\mathrm{X}) = 0.44$ and $G(\mathrm{S}) = 6.0$, $G(\mathrm{X}) = 0$, respectively, were obtained for the two polymers, highlighting the significant role of the substituent methyl group in determining the outcome of the radiolysis. Kudoh and co-workers (259) have investigated LET effects for electron radiolysis of PMMA. A comparison of the scission probabilities for γ radiation (0.5 Gy/s) and high energy electron beams (up to 4×10^{10} Gy/s) showed no evidence for dose rate effects; thus they found no evidence for spur overlapping at the high electron beam dose rates. Dong and co-workers (267) studied the role of the length of the aliphatic side chains in a series of highly syndiotactic polymethacrylates and found that poly(heptyl methacrylate) indeed undergoes gelation on γ radiolysis, via the heptyl side chain.

Heavy ion irradiation of PMMA has also received some attention, particularly by researchers at the Japan Atomic Energy Research Institute. Kudoh and co-workers (269–273) have compared the effects of γ radiation and electron beams with those for 30 and 45 MeV protons and heavier ion beams on the tensile and molecular weight properties of PMMA. They have found no difference between the sensitivities of the tensile properties of PMMA to γ-rays and electron and proton beams as a function of dose. However, the molecular weight dependence for PMMA showed a clear LET dependence for heavy ions above a critical LET, indicating overlapping between spurs. For low LET radiation the scission probability remains constant, but the scission probability decreases with increasing LET for high LET radiation. The critical LET level for PMMA is a few hundred $\mathrm{MeV} \cdot \mathrm{cm}^2/\mathrm{g}$.

Esters of Other Acids. Poly(*tert*-butyl crotonate) (PtBC) is an analogue of poly(*tert*-butyl methacrylate) (PtBMA) but it does not have the disubstituted main-chain carbon atom. Thus, on these grounds, PtBC might potentially undergo cross-linking, but this process may potentially be hampered by the severe steric hindrance involved in the formation of a cross-link at the main-chain ester–carbon atom. O'Donnell and co-workers (274,275) have reported studies of the yields for radical formation, cross-linking and scission, and the gaseous products on radiolysis of PtBC. Three major radicals were observed on radiolysis at 77 K: tertiary butyl radicals, oxygen centred radicals formed by loss of the tertiary butyl groups, and a third unidentified radical. The value of $G(\mathrm{R})$ was 1.28. The major gaseous radiolysis products were the same as those observed by Ungar and co-workers (276) for PtBMA, and the yield of CO_2 ($G = 1.0$) was greater than that for CO ($G = 0.26$), in contrast to the observations for PMMA and PMA. This is consistent

with the preferential loss of the labile *t*-butyl ester group. The values of $G(S) = 0.59$ and $G(X) = 0.66$ for PtBC can be compared with those for PtBMA, $G(S) = 0.21$ and $G(X) = 0.17$, reported by Shultz and Bovey (240). These values indicate that PtBC indeed undergoes cross-linking, while PtBMA undergoes net scission. However, the nature of the cross-links formed in PtBC have not been identified.

Polysiloxanes. Poly(dimethyl siloxane) (PDMS) undergoes cross-linking on exposure to ionizing radiation. As early as 1954, Charlesby (78,277,278) had reported that PDMS can be cross-linked to form a transparent rubbery material, and that the dose to achieve a cross-linked network was inversely proportional to the initial polymer molecular weight (see SILICONES). Early work also reported that the main volatile products of irradiation are hydrogen, methane, and ethane gases (277,279,280). Other chemical changes observed with IR spectroscopy were Si—H structures and new, unidentified —Si-O— structures (280,281). ESR studies have revealed that on irradiation at 77 K $CH_3\cdot$, $—CH_2\cdot$, —Si·, and —O· radicals are produced, and that, as expected, the radicals react on warming above the glass-transition temperature (127,282,283). *G*-values between 2.3 and 2.7 for cross-linking have been reported (279,284,285).

Whereas some evidence for chain-scission structures has been obtained from these previous studies, not until recently have conclusive measurements of the yields of scission reactions been reported (286–288). Hill and co-workers (286,287) have identified new structures formed in PDMS using solid-state ^{29}Si and ^{13}C NMR. They were able to measure the rate of formation of a number of chain-end, side-chain, and cross-link structures. The mechanism of cross-linking is dominated by Y-linking, although two minor H-linking products were also observed. On irradiation at 303 K, the radiochemical yields were $G(S) = 1.3$, $G(H) = 0.34$, and $G(Y) = 1.7$.

Fluorinated Polymers.

Fully Fluorinated Polymers. The radiation chemistry of fully fluorinated polymers shows remarkable temperature dependence, with all of the fluorinated thermoplastics undergoing degradation, ie, chain scission, at ambient temperatures, but with an increasing yield of cross-linking reactions at elevated temperatures. Over the past 10 years, this has led to renewed interest in the radiation chemistry and applications of these materials (see PERFLUORINATED POLYMERS, POLYTETRAFLUOROETHYLENE).

As discussed in a number of reviews (1,2,289), the parent of the fluoropolymer family, polytetrafluoroethylene (PTFE), undergoes degradation on irradiation. Over a number of years, this process has been exploited commercially to reduce the molecular weight of PTFE resins. Despite this recognition, the details of the mechanism of reaction have remained unclear, in part due to the paucity of experimental techniques available to study these materials. The inherent insolubility of PTFE has until recently restricted studies of radiation chemistry of PTFE to measurements of mechanical and thermal properties, and melt viscosity. For example, Bro and co-workers (290) reported in 1963 that the melt viscosity of PTFE decreased on irradiation followed by heating. This effect was more pronounced in the presence of air. In another example, Hedvig (291) in 1969 showed that the mechanical strength and in particular the elongation at break of irradiated PTFE dropped dramatically on irradiation, but that these properties disappeared on irradiation in air.

As mentioned above, the mechanism of degradation of PTFE is unclear, particularly the location of radiation-induced chemical reactions. However, ESR spectroscopy (290–293) has confirmed that the stable free-radical species at low temperatures are the chain-end radicals **IX** (shown below) and that at higher temperatures the secondary radicals **X** dominate the spectrum. Hedvig (291) has suggested that chain-end radicals terminate by abstraction to form the more stable secondary radical. These radicals persist for very long times, and this leads some authors (58) to suggest the suitability of PTFE as a radiation dosimeter.

IX **X**

The effect of irradiation at elevated temperatures was initially investigated by Lovejoy and co-workers (294), who found that irradiation of PTFE above the glass-transition temperature resulted in a decrease in the molecular weight of the material, as evidenced by a decrease in melt viscosity. In a later series of articles Tutiya (295–299) studied the effect of various irradiation conditions on the broad-line ^{19}F NMR spectra of PTFE. He reported in 1972 (295) that on irradiation above the melting temperature there was a significant decrease in the crystalline content, ascribed in part to the increased melt viscosity of the irradiated polymer. It was not until about 20 years later that these observations were pursued. In 1994 and the early 1990s, Sun and co-workers (55,300) and Oshima and co-workers (56) reported the radiation-cross-linking of PTFE above its melting temperature. Since then, Oshima and co-workers (56,301–310) have examined in detail the mechanism of formation and properties of radiation-cross-linked PTFE. It was found that cross-linked PTFE had significantly enhanced radiation stability compared with the uncross-linked resin despite the radical yield at low temperatures being significantly higher (304,308,309).

PTFE undergoes cross-linking via a Y-type mechanism (reaction 12 above). This has been confirmed by solid-state ^{19}F NMR measurements both by Katoh and co-workers (307,310) and Fuchs and co-workers (311,312). Initially, the Y-linking mechanism was favored over the H-linking mechanism after considering steric effects. However, it has been conclusively shown that branch points are formed and that the yield of branch points is superior to the yield of new chain ends (312), whereas Oshima (310) has suggested that double bond structures may also participate in the branching reactions.

In an early article Lovejoy and co-workers (294,313) reported that the copolymer of tetrafluoroethylene and hexafluoropropylene (FEP) would undergo degradation on irradiation at room temperature, but that it cross-links at higher temperatures. In 1985 Seguchi and co-workers (8) confirmed that FEP indeed undergoes cross-linking reactions through measurements of the soluble fractions after irradiation. The primary free radicals have been identified by Hill and co-workers (30) to be radicals **IX** and **X** above. In addition the yield of free radicals is significantly enhanced at room temperature compared with irradiation at 77 K. This is a consequence of the lower probability of cage recombination of the primary species at higher temperatures. In a later series of articles

(314–316) these authors have measured the yields of new structures by solid-state ^{19}F NMR spectroscopy and found that, as with PTFE, irradiation below the melting temperature resulted in predominately new chain ends due to chain scission. On the other hand, upon irradiation at 523 K, just above the melting temperature, new branch or cross-link structures were formed in significant quantities.

Similar conclusions have been reached for the third commercially important fully fluorinated polymer, namely the copolymer of tetrafluoroethylene and perfluoropropyl vinyl ether (317–320). This is not unexpected, because this material typically contains approximately 2 mol% of the vinyl ether. Irradiation at elevated temperatures by electron beam or with γ-rays resulted in increased yields of cross-links. Finally, Forsythe and co-workers (321) have also reported the radiation chemistry of members of the Teflon AF DuPont family of thermoplastics, and found that degradation proceeded through loss of hexafluoroacetone of the dioxole ring, leading to chain-scission reactions.

Fluoroelastomers. The above discussion has highlighted the importance of molecular motion on the ultimate radio-chemical products formed in fluorinated polymers. This is a consequence of the limited number of mechanisms of termination of radicals in fluorinated polymers when compared with protonated polymers. Specifically, in fluoropolymers there is no mechanism of radical migration equivalent to the hydrogen-hopping mechanism at work in irradiated hydrogen-containing polymers. The three-body intermediate suggested to participate in the hydrogen-hopping mechanism (eq. 4) is unlikely to form on radiolysis of fluorocarbons, on purely energetic grounds. Thus, the radicals produced in fluoropolymers are particularly long-lived, and when they do react it is usually through combination reactions. This means that the radicals must have sufficient mobility to be able encounter one another; hence the probability of chain cross-linking increases with increasing temperature, and in the semicrystalline materials discussed above, sufficient mobility is only achieved above the crystalline melting temperature.

The situation is somewhat similar for fluorinated elastomers (see FLUOROCARBON ELASTOMERS). The radiation chemistry of the copolymer of tetrafluoroethylene (TFE) and perfluoro-methyl vinyl ether (PFMVE), known commercially as Kalrez, has been studied in detail by Hill and co-workers (57,322–327) This material is a random copolymer of these two monomers with a TFE to PFMVE molar ratio of 2:1. It is a fully amorphous polymer with a glass-transition temperature close to 273 K. On irradiation at room temperature it undergoes cross-linking, as confirmed by measurement of structural changes by NMR spectroscopy (57), and changes in mechanical and solubility properties (327). When this material is irradiated below its glass transition temperature, chain scission tends to dominate over cross-linking reactions (326).

Partially Fluorinated Polymers. The radiation chemistry of fluoropolymers is very sensitive to the presence of hydrogen in the chemical structure. The introduction of hydrogen to the backbone generally results in a marked increase in the probability of cross-linking reactions occurring. Presumably, this is a result of the increased mobility of radicals as discussed immediately above. In addition, as pointed out by Wall and co-workers (328), the introduction of hydrogen leads to the formation of HF on irradiation, with concomitant formation of main-chain

Table 2. Radiochemical Yields of Cross-Linking and Scission for Several Partially Fluorinated Polymers

Polymer[a]	G(X)	G(S)	p_0/q_0	Ref.
PVDF	1.0	0.3	0.15	319
PVDF	0.95–1.05	0.2–0.4	0.18–0.21	317
PVF	3–8	1.8–4.0	0.28–0.35	317
PTrFE	1.1	0.4	0.18	319
PTrFE	1.1–1.2	0.3–0.5	0.16–0.21	317
ECTFE			0.3	322

[a]PVDF, poly(vinylidene fluoride); PVF, poly(vinyl fluoride); PtrFE, poly(trifluoroethylene); ECTFE, poly(ethylene-*co*-trifluoroethylene).

double bonds. These double bonds act as efficient sites for subsequent cross-linking reactions.

Of this class of polymers, the radiation chemistry of poly(vinylidene fluoride) (PVDF) has been examined in most detail. In 1962, Timmerman and Greyson (329) compared the mechanical properties of PVDF with PTFE and found that overall PVDF was more resilient to exposure to radiation. Not long after this, Yoshida and co-workers (330) reported the yields of cross-linking and scission reactions in irradiated PVDF, and that cross-linking dominated. The radiochemical yields of scission and cross-linking of PVDF and a number of other materials are listed in Table 2. The identity of the radical species formed on irradiation has been confirmed by Seguchi and co-workers (331). They found that the chain-end radical **XI** dominated the ESR spectrum at low temperatures, but that the main-chain radical **XII** became more important on warming. On long standing the polyenyl radical **XIII** came to dominate the ESR spectrum, highlighting the importance of loss of HF, and the increased radical mobility compared with fully fluorinated polymers.

XI **XII** **XIII**

As mentioned above, all of this class of polymers undergoes cross-linking on irradiation in vacuum. The yields of cross-linking and scission for these polymers are listed in Table 2. Of note also are the reports of cross-linking predominating in the copolymers of ethylene with TFE (332) and of ethylene with chlorotrifluoroethylene (333).

Polychlorotrifluoroethylene. In contrast to the above materials, the homopolymer of polychlorotrifluoroethylene (PCTFE) undergoes radiation degradation on exposure to ionizing radiation. Florin and Wall reported in 1961 that PCTFE undergoes chain scission, and calculated a G-value of 0.67 for scission from the dose to achieve zero strength. A relatively low yield of volatile products was reported: G(volatiles) = 0.11. Very recently, Hill and co-workers reexamined the radiation chemistry of this polymer (334,335). They measured the yields of free radicals to be 1.55 at 77 K decreasing to 0.32 at room temperature (335). The

ESR spectra were difficult to identify because of the large anisotropic hyperfine coupling to the fluorine nuclei. These authors also examined the radio-chemical products using solid-state ^{19}F NMR and FTIR spectroscopies (334). On irradiation below the melting temperature, there was no evidence of branch/cross-link formation. However, the yields of chain ends, double bonds, and branch points on irradiation at 493 K were 3.6, 0.2, and 0.5, respectively. The structure of the branches could not be confirmed; however, the respective yields of chain ends and branches indicate that scission dominates for this polymer.

Polydienes. The polydienes undergo cross-linking on radiolysis in vacuum. The principle reactions occurring are cross-linking, consumption of double bonds, isomerization of double bonds, and evolution of hydrogen gas. There is considerable variation in the reported *G*-values for these reactions, arising primarily from differences in the experimental techniques used in their determination. For example, physical measurements, usually of soluble fraction or swelling ratio, used to determine yields of cross-linking and scission reactions are particularly susceptible to errors in the case of polydienes. These techniques assume a random distribution of cross-linking and scission reactions; as will be seen below, this assumption may break down in the case of radiolysis of polydienes.

Polybutadiene. The primary products of irradiation of polybutadiene (PBD) are allyl free radicals. The yield of radicals has been reported to range from 0.19 to 0.44 (336,337). On heating the radicals decay in a monotonic fashion to low concentrations just above the glass-transition temperature of the polymer (337) (see BUTADIENE POLYMERS).

As mentioned above, the net result of irradiation of PBD is cross-linking. *G*-values for cross-linking, determined as described immediately above, range from 3.2 to 6.7 (338–343). In one case a *G*(S) value of 0.52 has been reported, although it is more generally accepted that the *G*-value for scission in irradiated PBD is much smaller than this (343).

As will be discussed below, these *G*-values contrast with the very high yield of reactions which consume double bonds in these polymers. The reason for this is the highly nonuniform cross-linking reactions in polydienes. The advent of solid-state ^{13}C NMR allowed direct observation and quantitation of the cross-link structures in irradiated polymers. In the case of poly(1,4-butadiene), O'Donnell and Whittaker (344,345) have reported very high *G*-values for consumption of double bonds, and formation of cross-link structures. The authors have suggested a chain reaction through successive double bonds to form a highly nonuniform network structure. As a result, the effective cross-link density is much lower than the measured chemical cross-link density. Similar results were reported for materials having different initial microstructure.

A number of workers have reported a very high rate of disappearance of double bonds on irradiation of PBD. Using IR spectroscopy, Parkinson and Sears (346) determined *G*(cis) to be 15, G(-trans) 11–22, and G(cis–trans) 7. The last reaction is the isomerization of a cis double bond to a trans double bond via an allylic radical intermediate. The rate of consumption of 1,2-vinyl groups was found to depend on the initial vinyl content; values from 0.2 to 40 were reported. Similarly, Golub (347,348) reported a *G*-value of 7.9 for consumption of double bonds, and 7.2 for isomerization. He suggested the formation of cyclic structures. O'Donnell and Whittaker (344) have reported the yields of these reactions for a number

of polybutadienes. The calculated G-value for loss of double bonds was initially 41.8 over a dose range of 0–1 MGy and decreased to 6.3 at higher doses (4–10 MGy). For poly(1,2-butadiene) the G-value for loss of double bonds was 237 (0–0.5 MGy), because of, it was suggested, an intramolecular chain reaction of the vinyl groups.

Polyisoprene. As with polybutadiene, polyisoprene (PIP) and natural rubber are cross-linking polymers. The radical intermediates have been identified as allyl radicals (336,337,342). Radical yields at 77 K ranging from 0.28 to 0.73 have been reported. It is also clear that the mechanism of reaction of these radicals is similar to that discussed above for polybutadiene. A G-value of 6.7 for the decrease in unsaturation has been reported by Golub and Danon (347). Much later, using solid-state NMR, Whittaker (349) obtained a G(d.b.) value of 45.8 (0–1 MGy). Significantly lower yields of cross-links have been reported; Boehm (350) has compiled a list of G(X) values ranging from 0.4 to 3.5 as determined by measurement of physical properties.

Polychloroprene. In contrast to PBD and PIP, the radiation cross-linking of polychloroprene does not appear to proceed by a chain-reaction mechanism (see CHLOROPRENE POLYMERS). The yields of cross-links [G(X)] were measured by a number of methods and determined to be 3.9 (NMR), 4.8 (swelling ratio), and 3.2 (sol. fraction) (351). This close correlation, and the observation of a narrow resonance in the ^{13}C NMR spectrum assigned to cross-link structures, indicated that cross-linking in this material occurs randomly throughout the material. Peaks are observed in the NMR spectra because of new chain structures formed on irradiation.

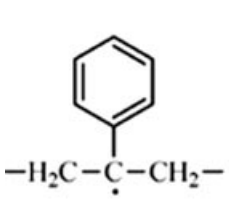
Aromatic Polymers.

Polystyrene. Polystyrene undergoes net cross-linking on irradiation (see STYRENE POLYMERS). In 1953 Charlesby (352) reported that the polymer undergoes gelation on irradiation, and that the yield of permanent chain scission reactions is small or negligible. Furthermore, he reported that despite cross-link reactions dominating the radiation chemistry, the overall yield of cross-linking is very small compared with nonaromatic polymers, because of the presence of the benzene ring. A major study of the changes in molecular weight (viscosity) and formation of volatile products was subsequently undertaken by Wall and Brown in 1957 (231). The major volatile product, hydrogen gas, is produced in low yields [$G(H_2) = 0.022–0.026$] compared with nonaromatic polymers.

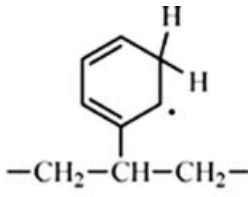
Since these early reports, a number of further studies have appeared (6,231,339) and these have been summarized in 1973 by Parkinson and Keyser (353). Since that date, efforts have been made to understand the relatively wide discrepancies in reported yields of radiochemical reactions, and also the effect of temperature on the radiolysis products. For example, values of the yield of radicals, G(R), measured at 77 K after irradiation at that temperature range from 0.04 to 0.50 (22,100,354–357). O'Donnell and co-workers (358) have proposed that the variation in reported yields of radical formation, and of chain scission and cross-linking, may be in part due to the presence of trace amounts of residual oxygen.

Using ESR spectroscopy, the mechanism of radiation-induced cross-linking of polystyrene has been revealed to a large extent by careful studies of radical intermediates. The major free-radical products formed on irradiation are the

α-carbon radical **XIV** and the cyclohexadienyl radical **XV** shown below. The contribution of radical anions to the ESR spectra was confirmed by Garrett (357) and Hill and co-workers (24). On heating these samples toward the glass-transition temperature (ca. 373 K), free-radical reactions occur until at room temperature the ESR spectrum resembles that observed for a sample irradiated at the elevated temperature. The radical concentration has decayed to negligible values at the glass-transition temperature. The mechanism of cross-linking has not been confirmed, but is suggested to involve recombination reactions between radicals **X** and **XI**. Measurements of gel doses for materials having different initial molecular weight distributions have suggested that H-linking rather than end-linking is the major mechanism of cross-linking (359).



XIV



XV

The effect of irradiation temperature has been examined in some detail. A number of workers have reported that the yield of cross-links decreases progressively above room temperature with a corresponding increase in the yield of chain-scission reactions (302,360–362). Burlant and co-workers (363) initially suggested that as the temperature increases, an increasing proportion of main-chain radicals **XIV** undergo a β-cleavage reaction to form terminal unsaturation and chain-end radical. On the other hand, from analysis of changes in molecular weights, Bowmer and co-workers (360) reported that the ratio of yields of scission to cross-linking reactions, $G(S)/G(X)$, increases from 0.02 at 303 K to 2.8 at 423 K. These authors suggest that competition between combination and disproportionation reactions between temporary scission radicals is responsible for this trend, with disproportionation, and hence permanent chain scission, becoming more likely at higher temperatures. A comparison was made with the mechanism of termination in the free-radical polymerization of styrene. Seguchi and co-workers (302,362) have also examined in detail the effects of temperature and tacticity on the relative yields of cross-linking and scission reactions in irradiated polystyrene, and have arrived at similar conclusions.

Poly(α-methyl styrene). Poly(α-methyl styrene) (PαMSTY) is one of the class of degrading polymers, having along its backbone a quaternary carbon, at which a stable scission radical can be formed. In addition to this, PαMSTY has a low polymerization ceiling temperature of 334 K (364). At and above this temperature, the polymer will undergo depolymerization to its monomers. Garrett and co-workers (365) measured the yield of chain scission $G(S)$ and the rate of depolymerization at temperatures of 298, 353, and 536 K. At the two lower temperatures the weight loss due to depropagation was negligible and the authors were able to calculate yields of chain scission from changes in the number-average molecular

weights (see eq. 5 above). The values of $G(S)$ were 0.29 ± 0.01 and 0.48 ± 0.06 at 298 K and 353 K, respectively. However, at the highest temperature, extensive and rapid first-order weight loss occurred. The G-value for depolymerization $[G(-M)]$ was found to be 320 ± 45. The results of a Monte Carlo simulation of this process resulted in an estimate of the yield of chain scission $[G(S)]$ of 1.8 and the average unzipping length of 400 (365).

This same group has also reported an ESR study of the radicals formed on irradiation at 77 K and room temperature (54). The authors identified a number of radical species including a propagation radical formed by direct chain scission, and radicals associated with the side chain and the aromatic ring.

Main-Chain Aromatic Polymers. The above discussion highlights the relative stability of polymers containing aromatic rings, due to the ability of these structures to dissipate excess energy through resonance effects (1). For example the yields of cross-links and free radicals in irradiated polystyrene are approximately 50 times lower in polyethylene. It has also been noted from comparisons of the radiation sensitivity of polymers having similar structures that those in which the structures are incorporated into the main chain are less sensitive to degradation than those with similar side-chain structures. This is partly due to the more effective cage effect in main-chain polymers, which tend to have higher glass-transition temperatures than those of side-chain polymers, but also due to more effective resonance coupling to the aromatic rings. It follows therefore that main-chain aromatic polymers represent some of the most radiation-resistant organic materials discovered so far.

Aromatic Polysulfones. The presence of the relatively labile sulfone linkage in Polysulfones (qv) results in these materials having a tendency to undergo degradation reactions. Under many conditions, however, aromatic sulfones are relatively stable and undergo net cross-linking. Brown and O'Donnell (366) initially reported the radiation chemistry of copolymers of bisphenol A and 4,4′-dichlorodiphenyl (Table 3). They found that on irradiation in vacuum at ambient temperatures, this material undergoes cross-linking with relative yields of cross-linking and scission reactions being respectively 0.051 and 0.012. These studies lead to a large body of work considering the effect of chemical structure on the radiation sensitivity of aromatic polymers. In general for all aromatic polysulfones, on irradiation at ambient temperature, cross-linking predominates. In addition, as aliphatic groups are introduced into the main chain, the radiation sensitivity is increased.

Lewis and co-workers (367) have reported a detailed study of the effect of polymer structure on the yields of chemical reactions for a series of polysulfone terpolymers containing varying amounts of bisphenol A and biphenyl units. They found a close to linear relationship between the yields of radicals and volatile sulfur dioxide with the ratio of the bisphenol A and biphenyl units. They report that the biphenyl unit imparts significantly higher radiation stability. As with other polymers, the details of the radiation chemistry are affected by the irradiation temperature, with Hill and co-workers (368) providing evidence of enhanced chain scission on irradiation of polysulfone copolymers (Table 3) at temperatures approaching the glass-transition temperature.

The ESR spectra of irradiated aromatic polysulfones, and aromatic polymers in general, are often poorly resolved, because of the effect of delocalization of

Table 3. Radiochemical Yields[a] of Formation of Free Radicals in Aromatic Main-Chain Polymers

Unit 1	Unit 2	Name	Radical Yield 10^{20} spins/kg	Ref.
		PEEK	1.0	379
		PEEKK	1.1	379
		Kapton	1.7	371
		Ultem	2.2	371

Table 3. (Continued)

Unit 1	Unit 2	Name	Radical Yield 10^{20} spins/kg	Ref.
		Bis-A PEPO	2.5	371
		Bis-A PSO	2.8	371
		Kevlar	5.6	371
		Nomex	5.6	371
		PPO	5.7	371

[a]The yield of free radicals is expressed in the units of spins/kg after irradiation to a dose of 10 kGy, rather than a G value, since the increase in radical concentration with dose is highly nonlinear with dose in the initial stages. To obtain a single-point G value at 10 kGy, divide the radical yield by 6.24×10^{20}.

the electron spin across aromatic structures, and the contribution from radical anions to the spectra at low temperatures. For example, Lewis and co-workers (367) reported that up to 75% of the total area of the ESR spectra of bisphenol A polysulfone irradiated to 10 kGy arose from radical anions, which were susceptible to photobleaching with UV radiation. These relatively uninformative spectra offer little information to assign reaction mechanisms. On the other hand, Hill and co-workers (96) have deduced, from measurements of changes in molecular weights and the formation of new structures detected on irradiation using solution-state ^{13}C NMR, that the main cross-linking mechanism involves Y-linking.

Polyimides. The two most important commercial Polyimides (qv) are Kapton and Ultem (structures shown in Table 3). Whereas Kapton is insoluble in most convenient solvents, Ultem is soluble and hence amenable to detailed study by standard methods. In 1985 Basheer and Dole (369) reported the yields of cross-linking and scission in irradiated Ultem to be respectively 0.014 and 0.005 on irradiation at room temperature. The gel dose of commercial Ultem film is of the order of 10 MGy. Devasahayam and co-workers (370) have reported a more detailed analysis of the changes in molecular weights on irradiation, and calculated *G*-values for scission and cross-linking for either H- or Y-linking mechanisms.

Basheer and Dole (369) reported that the ESR spectrum of irradiated Ultem was composed of contributions from radicals from scission at the isopropylidene unit and aromatic ether group. Recently, Devasahayam and co-workers (370) reported a detailed study of the free-radical yields and radical reactions in irradiated Ultem. At 77 K, the spectra contain significant contributions from radical anions, which were susceptible to thermal or photolytic annealing. Potential scission sites were identified from the radical products. Similarly, the formation of methylene radicals through loss of hydrogen atoms from the isopropylidene unit was suggested as a precursor to cross-linking reactions. Associated NMR analysis (371) of the radiolysis products identified a large number of products, the majority of which were identified with chain-scission products.

Kapton polyimide is an intractable material under usual conditions, and hence studies of its radiation chemistry are confined to measurements of volatile and free-radical products. The ESR spectrum of irradiated Kapton is a featureless singlet, and the yield of free radicals (1.7×10^{20} spins/kg after 10 kGy irradiation) was the one of the lowest of a large number of aromatic polymers compared in this study (372). Earlier, Hegazy and colleagues (373,374) confirmed the very high radiation stability of Kapton by measurement of the yields of volatile products of this polymer and other aromatic materials, including several aromatic polyimides. For Kapton, the evolved gases, in decreasing yields, were CO_2, CO, nitrogen, and hydrogen. Again Kapton was the most stable material studied.

A number of other polyimides have been studied by Hill and co-workers Devasahayam and co-workers (375) reported changes in the optical properties, and formation of free radicals in a series of fluorinated polyimides, and found that all materials were less stable than Kapton film. The fluorinated groups are incorporated in the polyimides to reduce coloration, and to provide oxygen atom resistance for space applications. Alexander and co-workers (376) have measured the radical yields for two fluorinated polyimide containing phosphine oxide groups attached to the aromatic main chain. The phosphine oxide unit also provides protection for the polymer against degradation from atomic oxygen. The relatively

high yields of radicals at 77 K, $G(R) = 0.50$ and 0.42 indicate, however, that this protection has been gained at the expense of radiation stability. Prior to this, Hopewell and co-workers (129) measured the radical yields and the solution viscosity of a number of phosphine oxide containing polyimides, and found that for these materials chain scission and cross-linking occur simultaneously on irradiation, but that scission is predominant on irradiation at room temperature.

Polyarylene Ether Ketones. The polyarylene ether ketone, known commercially as PEEK, is a semicrystalline thermoplastic of high melting temperature, and is insoluble in common organic solvent. The fully aromatic structure of PEEK imparts very high radiation resistance to this material. In a series of articles, Sasuga and co-workers (377,378) and Hegazy and co-workers (373,374,379) have measured a number of properties of PEEK and compared its radiation stability to a number of materials. The main volatile products, in decreasing yields at 15 MGy, are methane, hydrogen, CO, and CO_2. The source of the methane is not discussed. However, the overall yield of gases is very low compared to other aromatic polymers. The effect of crystallinity on the radiation chemistry is also demonstrated through the significantly higher yields of gases obtained from irradiation of a fully amorphous polymer.

In a related study, Hegazy and co-workers (379) examined the changes in the thermal properties of irradiated PEEK. An increase in glass-transition temperature and a small decrease in the heat of crystallization are both evidence of cross-linking formation. Similarly, the decrease and broadening of the recrystallization transition is due to cross-links.

Heiland and co-workers (380) have examined the radiation sensitivity of a series of polyarylene ether ketones using ESR spectroscopy and gas chromatography. The yields of radicals formed in all materials at 77 K were very low (approximately $1–2 \times 10^{20}$ spins/kg after 10 kGy irradiation). Introduction of methyl groups on the main-chain aromatic rings decreased the radiation stability, and further substitution of isopropylidene units into the main chain reduced the radiation stability even further.

Polycarbonates. The most commercially important Polycarbonates (qv) is bisphenol A polycarbonate (Bis-A PC). The effects of radiation on this material have been studied for a number of years, with a particular interest in the identity of the species responsible for a pronounced color change in Bis-A PC after irradiation. The radiation-induced green coloration has been assigned variously to trapped electrons (381) or a combination of trapped electron and radical ions (382,383). Golden and co-workers (384–386) have also in some detail examined the evolution of gases on irradiation (386), and found that the major volatile products are carbon dioxide and oxygen, with small amounts of hydrogen, methane, and benzene.

Bis-A PC undergoes net chain scission during irradiation in vacuum, presumably because of the high sensitivity of the carbonate group to chain scission. Evidence for this is the decrease in limiting viscosity after irradiation (384,386,387). More recently, further insight into the radiation degradation of Bis-A PC has been gained in a study by Babanalbandi and co-workers (388). In this the authors were able to confirm that the G-value for radical formation at 77 K is 0.5 ± 0.02, and that approximately 50% of the observed radicals are able to be photobleached with visible light, and hence are radical anions. NMR analysis of the soluble polymer after irradiation revealed new peaks, assigned to phenol-type chain end structures,

with a G-value for formation of 0.7. This observation confirmed that the main site of radiation degradation of Bis-A PC is the carbonate unit.

Aromatic Polyesters. The degradation of aromatic polyester has been investigated by a number of authors (7,53,389–398). The most commercially important material of this class is poly(ethylene terephthalate), a semicrystalline material of high melting temperature ($T_m \sim 538$ K) and moderate glass-transition temperature ($T_g \sim 343$ K) (see POLYESTERS, THERMOPLASTIC). On irradiation at low temperatures the observed ESR signal is primarily attributed to the secondary alkyl radicals formed by loss of a hydrogen atom from ethylene segments (53,391,394). The yield of radicals at room temperature was 0.025 (394). Since then, Choi and co-workers (132,398–401) have reported the radical yields of a number of allied main-chain aromatic polyesters. They found that for series of polymers containing fluorinated isopropylidene units the radiation stability was enhanced with higher content of the fluorinated residues (400). The yields of free radicals at 77 K were found to fall in the range 0.38–0.46. Later, this same group reported the radical yields for a number of linear halogenated aromatic polyesters [$G(R) = 0.41$–0.81] (401), terephthalate-based polyesters [$G(R) = 0.19$–0.41] (398), and naphthalene-containing polyesters [$G(R) = 0.08$–0.12] (132,399). In the last study the yield of radicals was found to increase, as expected, with the length of the aliphatic chain in the polyester, with, for example, $G(R)$ at 77 K increasing from 0.19 to 0.27 to 0.41 for terephthalate polyesters with the increasing length of the alkyl chain (n) of 2, 4, and 10, respectively (394).

Limited data is available on the respective rates of cross-linking and scission of the aromatic polyesters under radiolysis. Turner (394) has collected the data available from measurements of residual soluble fractions of irradiated poly(ethylene terephthalate), and reported values of $G(S)$ and $G(X)$ ranging from 0.07 to 0.17 and 0.07 to 0.14, respectively. The large range reflects the experimental difficulties and the range of irradiation conditions employed.

Babanalbandi and co-workers (388) have used ESR and NMR to determine the yields of radical intermediates and final products in irradiated U-polymer, a polyester of bisphenol A and terephthalic acid. The radical yield $G(R) = 0.5$ at 77 K was consistent with previous studies of similar polyesters. The NMR spectra of polymer irradiated to very high doses at room temperature revealed that phenol-type chain ends were the main stable products. The results are consistent with the observation of CO and CO_2 being the main gaseous products of the degradation of polyesters. For this material no evidence of cross-linking reactions was found.

Copolymers. The properties of polymers can be enhanced extensively through Copolymerization (qv) or blending of homopolymers. The effects of radiation on copolymers and blends might be expected to show behaviors that are related to the behaviors of the homopolymer constituents, modified by the polymer mole fraction composition and the electron densities of the components. For simple polymers, eg, those composed of carbon, hydrogen, and oxygen, random copolymers show a linear relationship between the properties of the homopolymers and the weight fraction of the components, eg, for copolymers of aliphatic esters (402). Although this behavior has been found to apply for many copolymer and blend systems, major differences from linear relationships are also common.

Aromatic components in mixtures of low molecular weight materials have long been known (18) to exhibit a protective effect on other components. This

protective effect is also found in random copolymers, such as the copolymers of styrene and methyl methacrylate, which have been studied by Busfield and co-workers (246), where the presence of styrene lowers the yields for radical intermediates, volatile products, and chain scission below those expected from the linear additivity rule. Similar observations have been made for radical formation in copolymers of glutamic acid and tyrosine (403), and several other systems.

On the other hand, positive deviations from the additivity rule for copolymers have also been reported. For example, Fox and co-workers (404) have reported that the radical yields at 77 K for γ radiolysis of the copolymers of methacrylic acid and acrylonitrile exhibit a positive deviation from the rule. They have attributed this to the breakup of the hydrogen bonding between methacrylic acid units by the acrylonitrile units in the copolymer.

Polymer Blends (qv) can be classified as being either compatible or incompatible. Most blends fall into the latter category. If this is the case, the additivity rule might be expected to apply, even for blends of homopolymers such as PS and PMMA, because the two components are phase separated. Garrett (357) has shown that this is indeed the case when homopolymers of comparable molecular weight are blended. However, if PS of low molecular weight is blended with PMMA of high molecular weight, a level of compatibility is achieved, and the PS then provides protection of the PMMA against degradation (357).

Many other instances of deviations from the additive rule and of protective effects in copolymers and blends have been reported in some of the studies discussed elsewhere in this article. The use of aromatic groups to provide protection against degradation has been utilized in some commercial materials. One example of this has been the incorporation of aromatic groups into polyester medical sutures (405) in order to protect the sutures against damage during radiation sterilization.

The Influence of Oxygen

Oxygen is a diradical, and so it can readily react at diffusion-controlled rates with free radicals formed in a polymer during radiolysis. This process has been well researched because it also occurs as a result of the thermal degradation of polymers, and consequently occurs during polymer processing. The mechanisms of these oxidation processes have been well documented in the literature and involve propagation, termination, and branching steps as part of a chain reaction. These mechanisms are summarized in Figure 7 (P = polymer).

Methods for stabilizing polymers by the addition of antioxidants and hydroperoxide decomposers are also well known, and are generally used with polymers which undergo radiolysis. For example, so called antirads are added to polypropylene to allow medical goods manufactured from it to be radiation-sterilized without discoloration or degradation.

The mechanism and kinetics of the reactions of oxygen with polymer radicals produced during radiolysis have been studied and extensively reviewed by Gillen, Clough, and co-workers (117,406–409), who have contributed greatly to this field. The roles of added polymer antioxidants and stabilizers have also been reviewed

Fig. 7. A summary of the reaction pathways in the oxidative degradation of polymers.

in a treatise edited by Clough, Billingham, and Gillen (410). Therefore, a detailed review will not be presented herein, and only some recent developments will be discussed.

In many polymers, radicals can have very long lifetimes, particularly if they are located in crystalline regions where they are protected from any added stabilizer. Jahan and co-workers (153), for example, have reported that long-lived radicals formed during sterilization of PE artificial joint components are at least partially responsible for their long-term deterioration. In addition, Young and

Slemp (411) have found that polymers exposed to space irradiation can exhibit a slow deterioration of properties on their return to earth atmosphere. These processes are just two examples of slow polymer aging due to polymer oxidation in air.

Clough and co-workers (409,412,413) have recently studied the structural changes induced in polymers and model compounds by oxidation through the use of ^{17}O-labeled oxygen and by the analysis of the polymer using ^{17}O NMR. This approach has provided a new insight of the oxidation and subsequent aging of irradiated polymers.

The Influence of Irradiation Temperature

The chemical changes that occur when polymers are irradiated include the formation of free-radical intermediates, the scission of main-chain bonds, the loss or modification of side-chains, the cross-linking of chains, the formation of new polymer structures, and the production low molecular weight products. One of the most important factors determining the extent to which these processes can occur is the prevailing temperature. For example, the crystalline melting and the α-transition temperatures, along with the temperatures of other secondary transitions in a polymer, play an important role in controlling chain motions, and hence the rates of reactions. In addition, the ceiling temperature determines the overall thermodynamic stability of a polymer chain when propagating radicals are present.

The temperature dependences of the rates of radiolysis reactions are determined by their activation energies, and can be predicted through the Arrhenius equation. In polymers, the activation energies for radiolysis reactions are positive, so that the rates of these reactions show a positive dependence on temperature. However, the activation energies for radiolysis reactions can show a considerable variation depending on both chemical and physical factors. For example, the activation energies for reactions can be quite different in the crystalline and amorphous regions of a polymer. Thus, the overall rates for formation of radiolysis products depend on the morphology of the polymer, which can vary from sample to sample. In addition, the rates of radiolysis reactions are likely to exhibit discontinuities at any first- and second-order polymer transition temperatures, which are characteristic of a polymer.

Thermodynamic considerations must also be considered. Negative enthalpies and negative entropies of reaction characterize free-radical polymerization reactions. Thus, whereas the free energy change for polymerization of a vinyl monomer may be negative at a low temperature, it will become zero at a higher temperature, the ceiling temperature. Above this temperature, spontaneous depolymerization of the polymer is thus thermodynamically possible.

Some representative examples of the effects of temperature drawn from reported work are presented below.

Secondary Transitions. The secondary transitions in polymers characterize the onset chiefly of side-chain motions and the motions of chain ends. The secondary transitions for PMMA and PS are given in Table 4. In these polymers, the β transitions occur below room temperature, and are associated with the

Table 4. Transition Temperatures for PMMA and PS

Transition	PMMA, K	PS, K
T_α	378 K	370 K
T_β	270 K	300 K
T_γ	103 K	138 K
T_δ	4 K	48 K

large-scale motions of the side chains. The γ and δ transitions occur at much lower temperatures.

At 77 K the polymer chain motions in PMMA and PS are very restricted, but as the temperature is increased to room temperature, the side chains become mobile. Thus, the polymer radicals formed in PMMA and PS on radiolysis at 77 K are relatively stable, but they decompose on annealing to higher temperatures.

Garrett (357) has reported a careful study of the reactions of the radicals formed on irradiation of PMMA and PS at 77 K when they are annealed to higher temperatures. For PS a small decrease in the radical concentration was observed at approximately 140 K and a further decrease occurs at about 270 K. The temperatures at which these changes occur coincide closely with the δ- and β-transition temperatures, respectively, for PS.

The radical concentration for PMMA decreased by approximately 45% at about 190 K and is associated chiefly with the loss of the anion formed on radiolysis (357). The temperature of 190 K corresponds to the temperature at which a change in the spin-lattice relaxation time has been reported to occur in s-PMMA (414), which is believed to be associated with the superposition of the motions of the α-methyl group and rapid fluctuations of the adjacent main chain.

Wundrich and co-workers (415) has examined the variation in G(S) for PMMA following radiolysis from 77 K to room temperature. From 77 K to approximately 140 K, G(S) was found to be constant, but above 140 K the values increased with temperature. He observed a second discontinuity at approximately 268 K. His reported values of G(S) in these regions are as follows: 0.3, 77–140 K; 0.3–0.9, 140–268 K; and 0.9–1.15, 268–293 K. Although there is no reported chain transition at 140 K, 268 K corresponds to the β transition in PMMA.

It has been proposed that the loss of the ester side group is the precursor for main-chain scission in PMMA, and so the lower G-values for scission below the β-transition temperature should be associated with lower G-values of volatile side-chain products. Kudoh and co-workers (250) found that the yield for hydrogen for PMMA was not sensitive to the radiolysis temperature. However, the yields of the products of ester side-chain scission and decomposition, principally CO and CO_2, were depressed by a factor of about 5 to 10 times when compared with those found for room temperature radiolysis. Kudoh and co-workers (260) also found a large difference in the tensile properties consistent with less chain scission at 77 K.

α Transition. The α transition in polymers, T_g, is associated with the onset of significant main-chain motion spread over several adjacent carbon atoms. Above T_g the free volume of the polymer increases, and so the rates of radical and other reactions may increase significantly. The effect of the glass-transition temperature

on radical reactions was clearly demonstrated by the work of Hill and co-workers (186) on polyisobutene (PIB). Annealing of PIB beyond its glass-transition temperature, 203 K, results in a rapid decrease in the radical concentration. At room temperature the radical concentration is very small and cannot be measured effectively by ESR spectroscopy. Many other polymers have been reported to behave similarly. However, Garrett and co-workers (416) found no evidence for a discontinuity in G(S) of PMMA at its α transition, 378 K. They reported that the value of G(S) increases continuously with temperature between 268 and 400 K and rises smoothly from 1.3 at 303 K to 3.9 at 413 K.

A similar observation has been reported by Bowmer and co-workers (360) for PS, which undergoes cross-linking on radiolysis at room temperature, $G(\mathrm{S}) = 0.0086$ and $G(\mathrm{X}) = 0.043$. However, as the temperature increases, G(S) increases and G(X) decreases. As a result, although no significant discontinuity was observed in the scission and cross-linking yields, in the neighborhood of the α transition, the behavior of PS changes, and it becomes a polymer which undergoes net scission on radiolysis [at 423 K $G(\mathrm{S}) = 0.074$, $G(\mathrm{X}) = 0.027$].

So, although the α transition does not appear to have a significant influence on the scission and cross-linking in PMMA or PS, it does play an important role in PIB and several other polymers. For example, the temperature dependence of G(S) has been found to increase significantly above this transition temperature for PIB (186), and for Kalrez, Forsythe and co-workers (57,383) have demonstrated that cross-linking only occurs on radiolysis above T_g.

Although no discontinuity has been found for G(S) at the α-transition in PMMA, Dong and co-workers (31) have shown conclusively that tacticity changes do occur in i-PMMA and s-PMMA with high yield above T_g. Similar changes in the tacticity of isotactic polypropylene have also been observed by Busfield and co-workers (35) for radiolysis at room temperature, which is above its α-transition temperature. The G-value for the loss of isotactic triads was estimated to be 64 at 298 K.

Crystalline Melting. Many of the radiolysis reactions of polymers are believed to occur principally in the amorphous regions or interphase regions at the crystalline boundaries. A strong influence of morphology has been reported by Busfield and Hanna (38) for the radiolysis of i-PP. They found that above the crystalline melting temperature the values of G(S) and G(X) at low dose are 11.6 and 3.5, respectively, whereas below the crystalline melting temperature the values are approximately equal and fall in the range 0.1–0.9. They also report that in the molten state the G-values for inversion of isotactic sequences in i-PP are also much higher: $G(\text{inversion}) = 106$.

Another recently reported difference in radiation chemistry above the crystalline melting temperature has been for polytetrafluoroethylene (PTFE). In the solid state PTFE is known to undergo scission readily. However, Oshima and co-workers (56) have found that just above the melting temperature of 600 K, PTFE undergoes cross-linking on e-beam irradiation, with a concomitant enhancement in the mechanical and chemical properties of the polymer.

Ceiling Temperature. For some polymers, for example PTFE, the ceiling temperature, T_c, is very high (693 K), whereas for others it may be below room temperature. Polymers with quaternary carbon atoms in the main chain, such as PMMA, PIB, and poly(α-methyl styrene), PαMS, are particularly susceptible

Table 5. The Temperature Dependence for $G(-M)$ for Poly(α-methyl styrene)

T, K	$G(-M)$

373	95
383	153
393	182
453	529

to radiation-induced depolymerization at elevated temperatures, because they have relatively low ceiling temperatures. For example, the ceiling temperature for PαMS is only slightly above room temperature, 339 K (for the pure liquid monomer standard state). Hill and co-workers (417) have reported the G-values for loss of monomer, $G(-M)$, on radiolysis of PαMS over a range of temperatures (see Table 5). Clearly, $G(-M)$ increases significantly for radiolysis above T_c where spontaneous depolymerization can occur.

Property discontinuities which can be associated with temperature transitions in many polymers have been observed, and the cases discussed above serve only as a few examples. Attention has been drawn to many other cases elsewhere in the article.

Summary and Major Conclusions

The radiation chemistry of polymers is an extremely rich field of study, both from an intellectual and a practical viewpoint. The very large body of research devoted to this field is testament to this fact. The overall outcome of this work is a clear understanding of the effect of radiation on this class of materials, and the factors which influence the rates of reaction and the product distribution. These include factors intrinsic to the polymers, and extrinsic factors more readily under the control of the experimental scientist or engineer. These are summarized below.

Intrinsic Factors.

Aliphatic Polymers. The main reactions occurring on radiolysis of aliphatic polymers are cross-linking, chain scission, evolution of gaseous molecules, formation of unsaturation, and reaction of unsaturated groups. Changes in physical properties of polymers on irradiation depend on the balance and overall yields of cross-linking and chain-scission reactions. For polyolefins, the presence of secondary, tertiary, and quaternary carbons in the main-chain leads to a progressively higher probability of chain scission. The presence of main-chain units such as sulfone, ester, and amide groups results in a higher probability of main-chain scission. Cross-linking can proceed through H- or Y-type linking. The rate of gel formation depends on the mechanism of cross-linking. The introduction of double bonds, either as terminal double bonds, or main-chain double bonds in polydienes, results in an increased probability of cross-linking reactions. Fully fluorinated thermoplastics tend to undergo chain scission reactions on irradiation at ambient temperature.

Aromatic Polymers. The introduction of aromatic groups results in significantly higher stability to radiation due to the resonant structure of the aromatic rings. Main-chain aromatic groups provide the highest stability to degradation.

Morphology. In semicrystalline polymers, chemical reaction is largely confined to the disordered, amorphous regions. Chemical reactions appear to be enhanced by the presence of an interface between crystalline and amorphous phases.

Extrinsic Factors. The temperature of irradiation can dramatically affect the radiation stability of a polymer. Irradiation of degrading polymers above their ceiling temperatures leads to extensive depolymerization. Unsaturated polyolefins tend to undergo increasing amounts of H-linking as opposed to Y-linking as the temperature is raised. Irradiation of fluoroplastics immediately above their melting temperature, or of fluoroelastomers above T_g, increases the probability of cross-linking reactions. Irradiation in the presence of oxygen increases the probability of long-term degradation reactions.

STARCH

Introduction

In nature, starch represents a link with the energy of the sun, which is partially captured during photosynthesis. Starch serves as a food reserve for plants and provides a mechanism by which nonphotosynthesizing organisms, such as man, can utilize the energy supplied by the sun.

Today, starch is inexpensive and is available annually from corn and other crops, and is produced in excess of current market needs in the United States and Europe (1). Starch is totally biodegradable in a wide variety of environments and could permit the development of totally degradable products for specific market demands. Degradation or incineration of starch products would recycle atmospheric CO_2 trapped by starch-producing plants and would not increase potential global warming (2) (see also ENVIRONMENTALLY DEGRADABLE PLASTICS).

For these reasons there has been renewed interest in starch-based plastics in recent years. Earlier studies of starch esters and ethers (3–10) indicated that they had inadequate properties in comparison with cellulose derivatives for most applications. More recently, starch graft copolymers (2), starch plastic composites (11,12), and starch itself (13–17) have been proposed as plastic materials.

Starch consists of two major components: amylose, a mostly linear α-D(1-4)-glucan and amylopectin, an α-D-(1-4)-glucan which has α-D(16) linkages at the branch point. The linear amylose molecules of starch have a molecular weight of 0.2–2 million, whereas the branched amylopectin molecules have molecular weights as high as 100–400 million (18,19) (see POLYSACCHARIDES AND CARBOHYDRATE POLYMERS).

In nature, starch is found as crystalline beads of about 15–100 μm in diameter, in three crystalline modifications designated A (cereal), B (tuber), and C (smooth pea and various beans), all characterized by double helices: almost perfect left-handed, six-fold structures, as elucidated by X-ray diffraction experiments (18,20,21). Starch beads may also show V crystallinity, characterized by a single helix when starch is in presence of fatty acids (22).

Crystalline starch beads in plastics can be used as Fillers (qv) or can be transformed into thermoplastic starch, which can be processed alone or in combination with specific synthetic polymers. To make starch thermoplastic, its crystalline structure has to be destroyed by pressure, heat, mechanical work, and Plasticizers (qv) such as water, glycerol, or other polyols.

This article reviews the main results obtained in the fields of starch-filled plastics and thermoplastic starch, with particular attention to the concepts of gelatinization, destructurization, extrusion cooking, and the complexation of

amylose by means of polymeric complexing agents with the formation of specific supramolecular structures. The behaviors of products now in the market are considered in terms of processability, physical-chemical and physical-mechanical properties, and biodegradation rates.

Starch-Filled Plastics

Starch can be used as a natural filler in traditional plastics (11,23–33) and particularly in polyolefins. When blended with starch beads, polyethylene films (34) biodeteriorate on exposure to a soil environment. The microbial consumption of the starch component, in fact, leads to increased porosity, void formation, and the loss of integrity of the plastic matrix. Generally (32,35–38), starch is added at fairly low concentrations (6–15%); the overall disintegration of these materials is achieved by the use of transition-metal compounds, soluble in the thermoplastic matrix, as pro-oxidant additives which catalyze the photo- and thermooxidative process (39–44).

Starch-filled polyethylenes containing pro-oxidants are commonly used in agricultural mulch film, in bags, and in six-pack yoke packaging. Commercial products based on this technology have been sold first by Ecostar and Archer Daniels Midland Cos. (45,46). In the St. Lawrence Starch (47,48) technology, bought by Ecostar, regular corn starch was treated with a Silane Coupling Agents (qv) to make it compatible with hydrophobic polymers, and dried to less than 1% of water content. It was then mixed with the other additives such as an unsaturated fat or fatty acid autoxidant to form a master batch, which is added to a commodity polymer. The polymer can then be processed by convenient methods, including film blowing, Injection Molding (qv) and Blow Molding (qv).

The temperature had to be kept below 230°C to prevent decomposition of the starch, and exposure of the master batch to air had to be minimized to avoid water absorption. Direct addition of starch and autoxidant without the master batch step can also be used; as this requires some specific equipment, it is only practical for large volumes (42). It was claimed that under appropriate conditions, the disintegration time of a buried carrier bag, containing an Ecostar additive to reach 6% starch, will be reduced from hundreds of years to 3–6 years (38). However there is no evidence of a compliance of such materials with the norms of biodegradability and compostability already in place at the international level. Moreover, the destabilization of polyethylene induced by the pro-oxidants may significantly affect its in-use performance as a function of time.

Within the field of starch-filled materials other systems were studied, some of which were completely biodegradable, such as starch/poly(ε-caprolactone) (49), and others partially biodegradable, such as starch/PVC/poly (ε-caprolactone) and its derivatives (50) or starch/modified polyesters (51). ln all these cases starch granules are used to increase the surface area available for attack by microorganisms.

Thermoplastic Starch

Starch can be gelatinized by extrusion cooking technology (52–66). As described by Conway in 1971, extrusion cooking and forming is characterized by sufficient work

and heat being applied to a cereal-based product to cook or gelatinize completely all the ingredients. In general the main components of high pressure cooking extruders are feeders, compression screws, barrels, dies, and heating systems (52). The effects of processing conditions on the gelatinization of starch and on the texture of the extruded product have been studied by several researchers (53–70). Gelatinized materials with different starch viscosity, water solubility, and water absorption have been prepared by altering the moisture content of the raw product and the temperature or the pressure in the extruder. It has been demonstrated that an extrusion-cooked starch can be solubilized without any formation of maltodextrins, and that the extent of solubilization depends on extrusion temperature, moisture content of the starch before extrusion, and the amylose/amylopectin ratio. Mercier (69) analyzed the properties of different types of starch and considered the influence of the following parameters: moisture content between 10.5 and 28%, barrel temperature between 70 and 250°C, residence time between 20 s and 2 min, in a twin-screw extruder. Corn starch, after extrusion cooking, gave a solubility lower than 35%, whereas potato starch solubility was up to 80% (Fig. 1).

Starch gelatinization is a difficult term to clearly define and it was used in the past to describe loss of crystallinity of starch granules, notwithstanding the process conditions applied (18), namely, extrusion cooking, spray drying, or heating of diluted starch slurries. The work carried out by Donovan in 1979 (71) and by Colonna and Mercier in 1985 (72) gave, however, a clear explanation of two different conditions for the loss of crystallinity of starch. Colonna reported that all starches exhibit a pure gelatinization phenomenon, which is the disorganization of the semicrystalline structure of the starch granules during heating in the presence of a water fraction >0.9. For normal genotypes, gelatinization occurs in two stages. The first step, at around 60–70°C, corresponds mainly to swelling of the granules, with limited leaching. Loss of birefringence, demonstrating that macromolecules are no longer oriented, occurs prior to any appreciable increase in viscosity. By contrast, differential scanning calorimetry (DSC) permits the determination of the gelatinization temperature more easily and precisely than microscopy and, additionally, the energy input needed to disorganize the crystalline structure of the granules. The second step, above 90°C, implies the complete disappearance of granular integrity by excessive swelling and solubilization. Nevertheless this last transition is not detectable by DSC. Only at this stage the swollen granules can be destroyed by shear.

As observed by Donovan (71) and Colonna (72), at low water volume fractions ($V_1 < 0.45$) loss of crystallinity occurred by two (pea and high amylose maize) or three (standard maize) crystalline melting steps, according to the Flory equation (Fig. 2):

$$1/T_m - 1/T_{m_o} = (R/\Delta H_u)(V_u/V_1)(V_1 - X_1 V_1)$$

where R is the gas constant, ΔH_u the fusion enthalpy per repeating unit (anhydroglucose), V_u/V_1 the ratio of the molar volume of the repeating unit to the molar volume of the diluent (water), T_m (K) the melting point of the crystalline polymer plus diluent, T_{m_o} (K) the true melting point of undiluted polymer crystallites, V_1 the volume fraction of the diluent, and X_1 the Flory–Huggins interaction parameter. At high water volume fractions, melting of crystallites and swelling are cooperative processes. According to Colonna, during extrusion cooking and

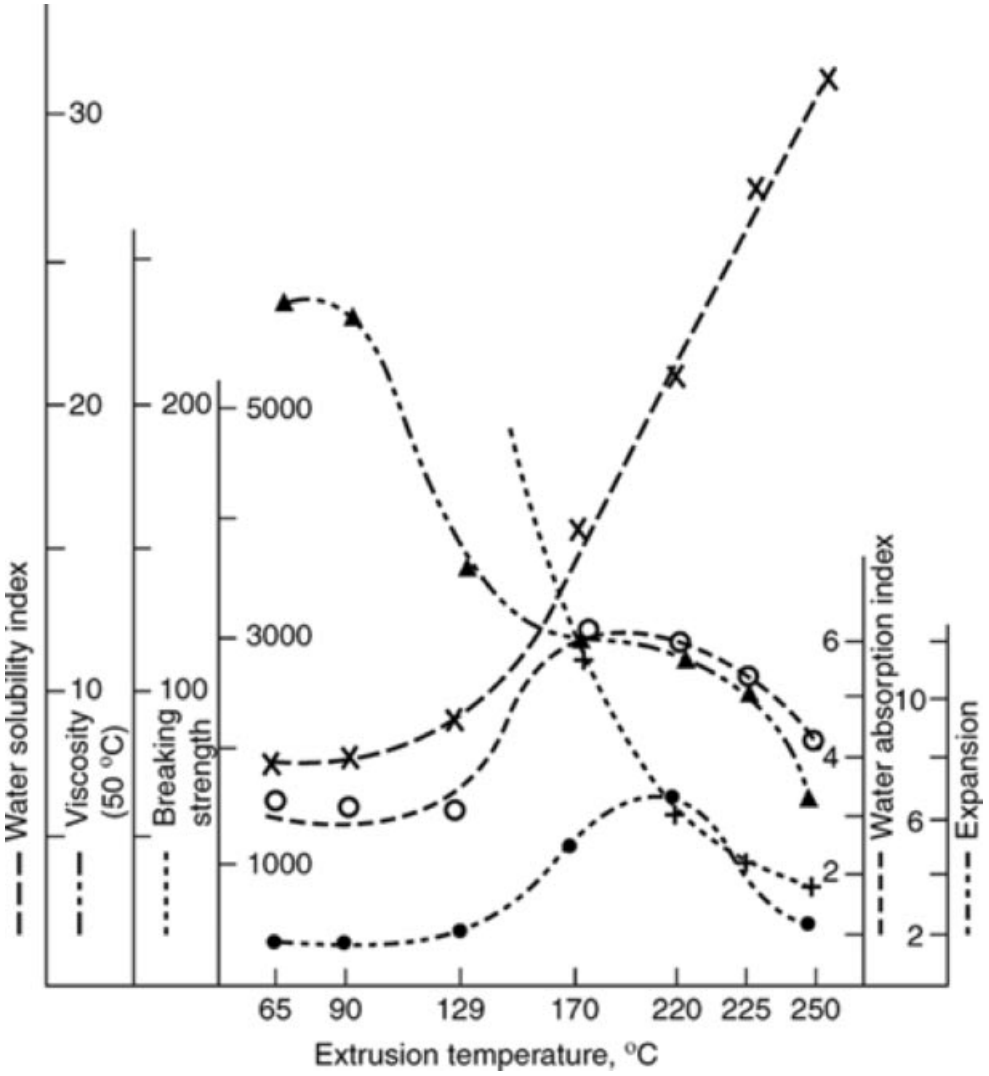

Fig. 1. Effects of extrusion temperature on expansion (●), breaking strength (+), viscosity at 50°C (▲), water absorption index (○), and water-solubility index (x) of extruded products from corn grits. Initial moisture content before extrusion was 18.2% by weight (69).

mainly under the conditions described by Mercier (water volume fraction <0.28) (68) starch undergoes a real melting.

In the patent literature the term *destructurized starch* (73–91) refers to a form of thermoplastic starch described as molecularly dispersed in water (92). Destructurization of starch is defined as melting and disordering of the molecular structure of the starch granules and as a molecular dispersion (75,92). The molecular structure of the starch granules is molten and consequently the granular structure disappears. This is achieved by heating the starch above the glass-transition and the melting temperature of its components until they undergo endothermic

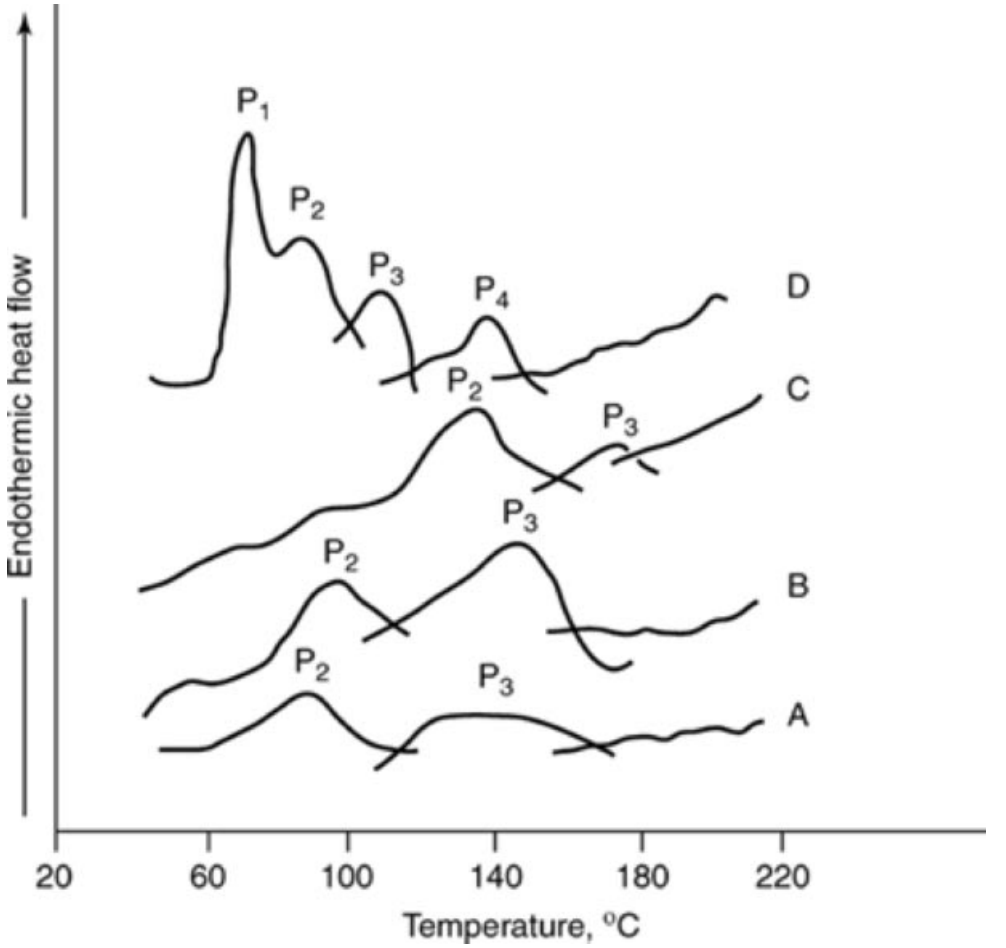

Fig. 2. Typical DSC curves for pea and maize starch. Water volume fractions (V_1): wrinkled pea (A), $V_1 = 0.35$; smooth pea (B) $V_1 = 0.29$; high amylose maize (C), $V_1 = 0.20$; and normal maize (D), $V_1 = 0.55$. Reprinted from Ref. 72, copyright 1985, with kind permission from Elsevier Science.

transitions. In the melt stage both the crystalline and the granular structure of the starch are destroyed and the starch–water system forms a single phase in which no structure is discernible microscopically. The disappearance of the molecular structure of the starch granule may be determined using conventional light microscopy techniques (93).

If starch is heated above the glass-transition and melting temperatures in presence of plasticizers, the endothermic transition can be replaced by an exothermic transition. Destructurized starch, in simple terms, is a form of thermoplastic starch suitable for applications in the sector of plastics, with minimized defects tied to the granular structure of native starch (17,94,98).

Thermoplastic starch alone can be processed as a traditional plastic (69, 92,99); its sensitivity to humidity, however, makes it unsuitable for most of the

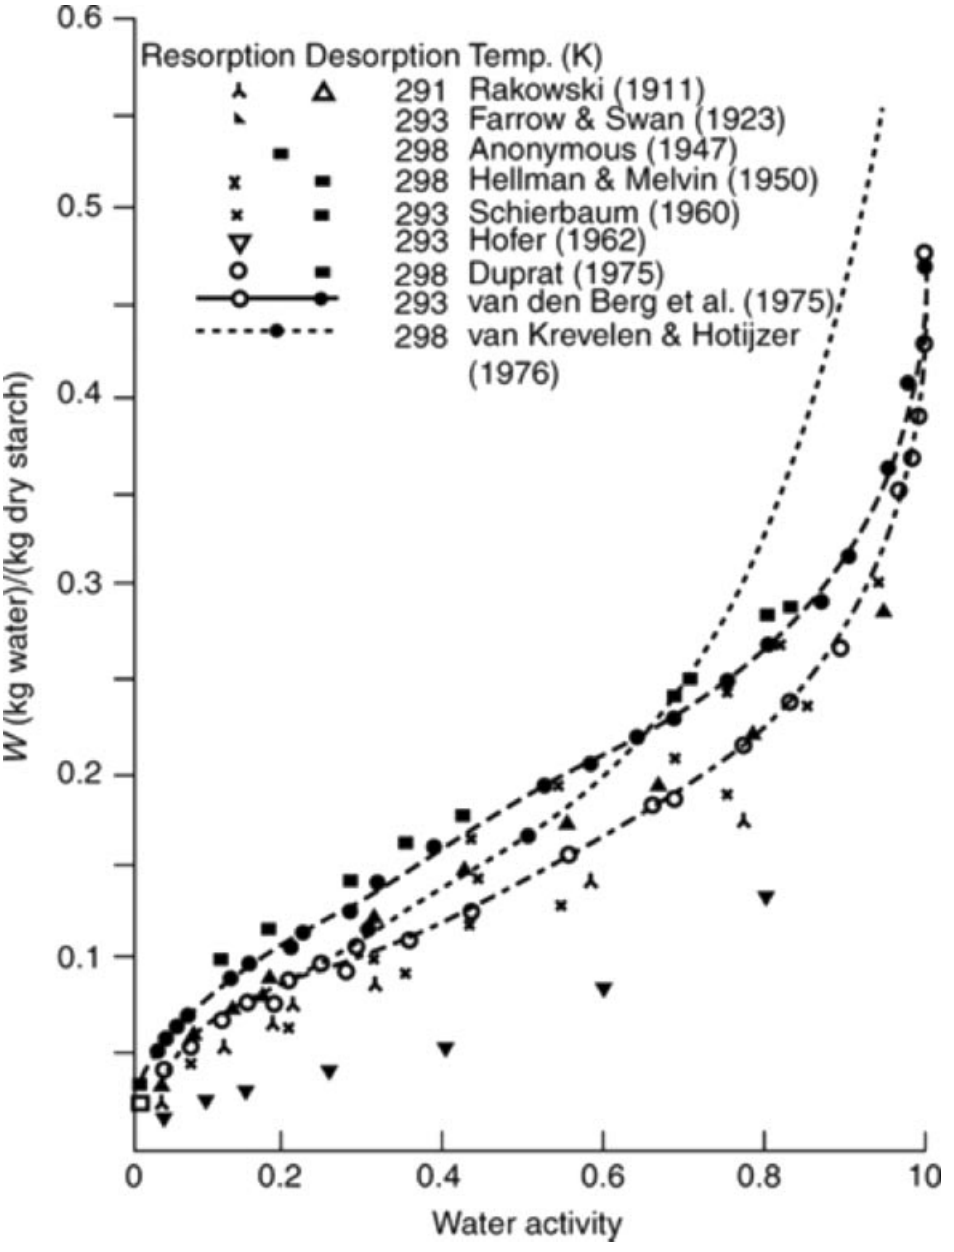

Fig. 3. Some sorption isotherms of water vapor on native potato starch as reported in the literature (100).

applications (Fig. 3). Starch can be also made thermoplastic at water contents lower than 10%, in the presence of high boiling point plasticizers (14,17), to avoid expansion phenomena at the die.

Another term which can be found in the literature is *thermoplastically processable starch* (TPS), defined as a thermoplastic starch substantially water-free.

40	40	—	20	59	39.7

[a]From Refs. 112 and 118.
[b]Ultimate tensile strength.

Thermoplastically processable starch is a modified native starch which is obtained without water, since instead of water, use is made of a plasticizer or additive. The starch is thermoplastically processed together with the additive, and the thermal transition taking place here is exothermic (101–106).

Starch can be destructured in combination with different synthetic polymers to satisfy a broad spectrum of needs for the market. In this case it is possible to reach starch contents higher than 50%. Otey has studied EAA (ethylene–acrylic acid copolymer)/thermoplastic starch composites since 1977 (107–117) and has demonstrated that the addition of ammonium hydroxide to EAA makes it compatible with starch. Urea, in these formulations, enhances the film tear propagation resistance and reduces aging phenomena due to segmental motions in amorphous starch (118,119). The films obtained with a content of plasticized starch of about 50% showed good tensile properties (Table 1) (112). The sensitivity to environmental changes and in particular the susceptibility to tear propagation precluded their use in most packaging applications (118); moreover, EAA is not biodegradable at all.

In 1989 studies on EAA–thermoplastic starch films, containing 40% by weight of EAA, processed at water contents lower than 2%, led to improved processability and film properties with elongation at break up to 200% (93). By microscopic analysis it was possible to observe at least three different phases: one consisting of destructured starch, one consisting of the synthetic polymer alone, and a third one described as "interpenetrated," characterized by a strong interaction between the two components. As a confirmation, phase changes observed by DSC, nuclear magnetic resonance (NMR) (113,117,120–124), for starch–EAA–PE films showed at least four phases. DSC endotherms and extraction of free starch with hot water demonstrated the existence of a starch phase. DSC showed melting of an EAA phase and a low density polyethylene (LDPE) phase but did not indicate the presence of EAA in amorphous regions of the PE. NMR, X-ray diffraction, and extraction indicated the presence of an insoluble starch–EAA complex (124). It was demonstrated that a portion of the starch forms complexes (122,123) with EAA when EAA is salified by ammonium hydroxide or other salts during extrusion cooking, providing partial miscibility between the two polymers.

Rheological studies were performed on a product consisting of 60% starch and natural additives and 40% of an EAA copolymer, containing 20 mol % of

acrylic acid (125). A strong non-Newtonian behavior was shown by the viscosity curves at high shear rates; at intermediate shear rates the material seemed to approach a Newtonian plateau, whereas at low shear rates a viscosity upturn was observed, suggesting the presence of yield stress. Breaking-stretching data for the same material are also reported in the literature, together with those of LDPE (125).

Starch/vinyl alcohol copolymer systems (126–131) can generate a wide variety of morphologies and properties, depending on the processing conditions, the starch type, and the copolymer composition. Different microstructures have been observed, from droplet-like to layered, as a function of different hydrophilicity of the synthetic copolymer. Furthermore, for this type of composite, materials containing starch with an amylose–amylopectin ratio >20/80 wt/wt do not dissolve even with stirring in boiling water. Under these conditions a microdispersion, consisting of microsphere aggregates is produced; individual particle diameters are under 1 μm (Fig. 4). A droplet-like structure is also confirmed by transmission electron microscopic (TEM) analysis of film slices (127). The droplet size is comparable with that of the microdispersion obtained by boiling.

For these products, high melt elasticity is monitored by exit pressure data, whereas its recoverable fraction is almost negligible (low die swell) (129,130). The morphology of materials in film form, containing starch with an amylose–amylopectin ratio lower than 20/80 wt/wt, gradually loses the droplet-like form, generating layered structures (Fig. 5). In this case no microspheres are produced by boiling and the starch component becomes partially soluble. Fourier transform infrared (FTIR) second derivative spectra of materials with droplet-like structure, in the range of starch ring vibrations between 960 and 920 cm^{-1}, gives an absorption peak at about 947 cm^{-1} (Fig. 6). This peak, observed also when starch is

[b]Dry starch plus EVOH = 100%.

complexed with butanol, is attributed (21) to ring vibrations, which result when amylose assumes a conformation known as the V form (a left-handed single helix). Therefore, the absorption at 947 cm^{-1} does not correspond to crystalline or gelatinized amylose, but to a complexed one (V-type complex), as in the presence of low molecular weight molecules such as butanol and fatty acid (21,129). Starch-based materials with an amylose content close to zero, even in the presence of vinyl alcohol copolymers, do not show any peak at 947 cm^{-1}, demonstrating that vinyl alcohol copolymers, as well as butanol, leave the amylopectin conformation unchanged.

On the other hand, the V complex formed by starch, having an amylose–amylopectin ratio higher than 20 wt%, with ethylene–vinyl alcohol (EVOH) copolymers makes even amylopectin insoluble in boiling water (Table 2). The experimental evidence was accounted for by a model considering large invididual amylopectin molecules interconnected at several points per molecule as a result of hydrogen bonds and entanglements by chains of amylose–vinyl alcohol copolymer V complexes (129). The biodegradation rate of starch in these materials is inversely proportional to the content of amylose–vinyl alcohol complex. Furthermore FTIR second derivative spectra show the 947 cm^{-1} peak increasing with biodegradation, which means a delayed microbial attack of complexed amylose relative to amylopectin (129). In addition, water permeability of starch/EVOH films is a function of the V-type complex and can range from about 2.46–1 $g \cdot cm/m^2 \cdot day$ 820–334 $g \cdot 30\ \mu m/m^2 \cdot 24h$ (130) (see BARRIER POLYMERS for units).

A general study of shear flow characteristics was performed on a material containing about 60% of starch and natural additives and 40% of ethylene–vinyl alcohol copolymer 40/60 mol/mol (131). A strong pseudoplastic behavior at high shear stresses as well as yield stress at lower ones was detected (Fig. 7). The nonlinear Bingham fluid model (132) well described its viscous behavior over a wide range of shear rates. High levels of melt elasticity were detected from steady shearing tests, whereas its recoverable fraction was almost negligible, at least for a reasonable time scale. The peculiar viscous and elastic behavior has been explained on the basis of the droplet-like morphology generated by the ability of starch to form V complexes in the presence of EVOH. Notwithstanding the peculiar rheological behavior shown by starch/EVOH systems, traditional processing techniques such as film blowing can be easily applied.

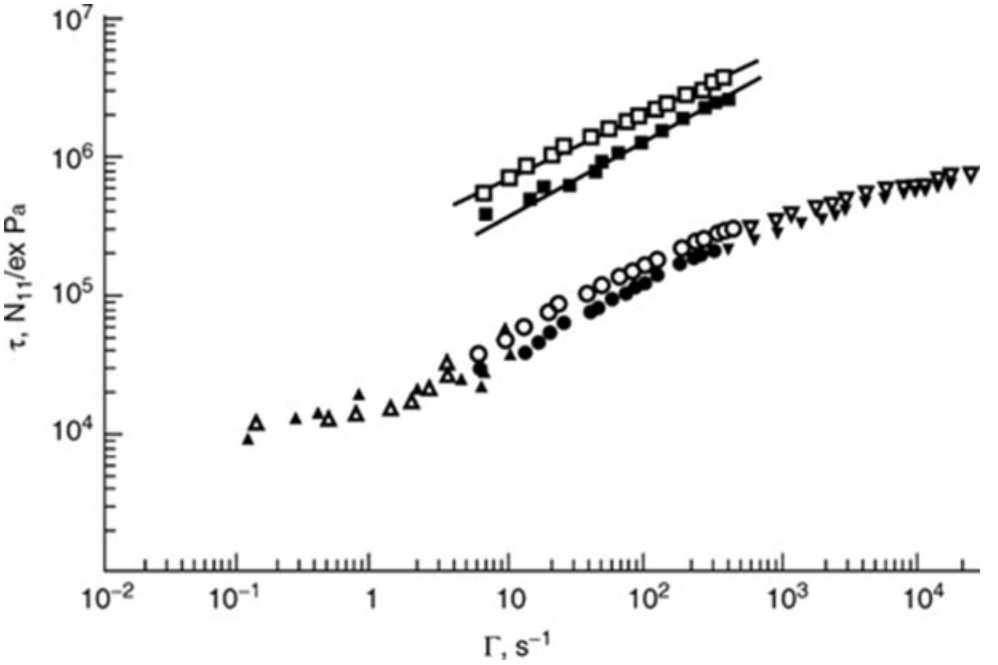

Fig. 7. Shear stress (○,●) and normal stress difference (N_{11}/ex) (□,■) versus wall shear rate of a thermoplastic starch/EVOH blend at 140 (open circles/squares) and 150°C (filled circles/squares) (131).

The products based on starch/EVOH show mechanical properties good enough to meet the needs of specific industrial applications (133). Their moldability is comparable with that of traditional plastics such as polystyrene (PS) and acrylonitrile–butadiene–styrene copolymer (ABS). Nevertheless, they continue to be highly sensitive to low humidities, especially when in film form, with evident embrittlement.

In terms of biodegradation, 10 months of aerobic biological treatment, performed by a high sensitivity respirometric test, provoked the degradation of more than 90% wt/wt of a product constituted by 60% of maize starch and natural additives and by 40% of EVOH copolymer at 40% mol/mol of ethylene. Furthermore, it has also been demonstrated that the synthetic component was degraded to about 80% wt/wt, notwithstanding interrupting the test when CO_2 evolution was still relevant (127,128). A material with the same composition, containing an EVOH copolymer, characterized by a lower ethylene content (29% instead of 40% mol/mol) and, therefore, by a reduced ability to generate interpenetrated structures, showed, in the Sturm test, an initial biodegradation rate significantly higher (127). The semicontinuous activated sludge (SCAS) test and biodegradation in lake water of a product constituted of 70% maize starch and natural additives and 30% EVOH support the hypothesis of substantially different biodegradation mechanisms for the two components (128):

(1) the natural component, even if significantly shielded by the interpenetrated structure, appeared to be initially hydrolyzed by extracellular enzymes;

(2) the synthetic component appeared to be biodegraded through surface adsorption of microorganisms, assisted by the increase of available surface area during the hydrolysis of the natural component.

Other evidences for disappearance of ethylene–vinyl alcohol copolymers have been produced to a limited extent by Roemesser (134) and Kaplan and co-workers (135). The presence of starch improves the biodegradation rate of these synthetic polymers; a fundamental role is also played by size and distribution of ethylene blocks. The degradation rate is too slow to consider these materials as compostable (128).

Specific types of plasticizers were selected in order to avoid migration phenomena and physical aging (133). The possibility of speeding up the biodegradation process was considered by modifying the ethylene–vinyl alcohol copolymer by introducing carbonyl groups, making it more sensitive to photodegradation (136). The transparency of the material was also improved by adding additives such as boric acid, borax, and other saline compounds (137). Surface treatment by wax lamination or coextrusion was also considered (138). With this kind of material it is possible to obtain finished parts by film blowing, injection molding, blow molding, thermoforming, etc. It is also possible to make foamed parts (139), particularly by an expansion process based on injection molding technology. The technology consists of a breathable mold connected with a vacuum pump, applied to an ordinary injection molding madrine (140). Cushioning characteristics of these materials are close to expanded polystyrene (EPS-55) (Fig. 8); moreover, the foam density is of 0.040 g/mL.

Starch can also be destructured in the presence of more hydrophobic polymers such as aliphatic polyesters (141). It is known that aliphatic polyesters with low melting points are difficult to process by conventional techniques for thermoplastic materials, such as film blowing and blow molding. With reference particularly to poly(ε-caprolactone) and its copolymers, films produced thereby are tacky as extruded, and rigid, and have low melt strength over 130°C; moreover, because of the slow crystallization rate of such polymers, the crystallization process proceeds for a long time after production of the finished articles with an undesirable change of properties with time.

Novamont's Mater-Bi starch-based technology implies processing conditions able to almost completely destroy the crystallinity of amylose and amylopectin, in the presence of macromolecules which are able to form a complex with amylose such as specific polyesters. They can be of natural or synthetic origin and are biodegradable. The complex formed by amylose with the complexing agent is generally crystalline, and it is characterized by a single helix of amylose formed around the complexing agent. Unlike amylose, amylopectin does not interact with the complexing agent and remains in its amorphous state. The specification of the starch, ie, the ratio between amylose and amylopectin, the nature of the additives, the processing conditions, and the nature of the complexing agents, allows engineering of various supramolecular structures with very different properties.

The scheme of a "droplet-like" and a "layered" structure which can be produced as a result of Mater-Bi technology is reported in Figures 9 and 10. The droplet-like structure (Fig. 9) is constituted by a core of an almost amorphous

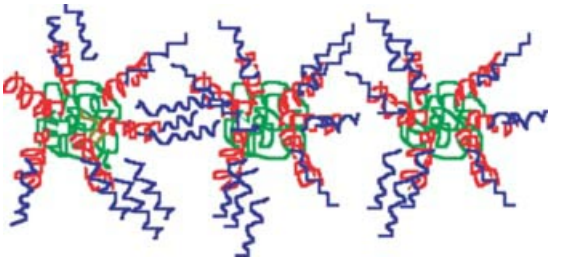

Fig. 9. Mater-Bi technology: droplet-like structure. Green, amylopectin; red, amylose; blue, complexing agent.

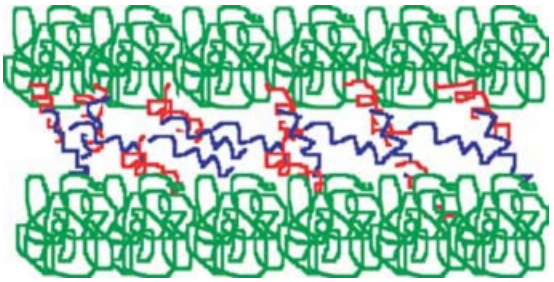

Fig. 10. Mater-Bi technology: layered structure. Green, amylopectin; red, amylose; blue, complexing agent.

amylopectin molecule screened by complexed amylose molecules which render amylopectin insoluble (142–144).

The layered structure is constituted by submicronic layers of amylopectin molecules intercalated by layers of complexing agent; such layers are compatibilized by complexed amylose (Fig. 10). The two structures and the many others derived from them explain the wide range of mechanical, physical-chemical, and rheological properties and the different biodegradation rates of Mater-Bi products.

Blending of starch with aliphatic polyesters improves their processability and biodegradability. Particularly suitable polyesters are poly(ε caprolactone) and its copolymers, or polymers of higher melting point formed by the reaction of 1,4-butandiol with succinic acid or with sebacic acid, azelaic acid, or poly(lactic acid), poly(hydroxyalkanoates), and aliphatic–aromatic polyesters.

The compatibilization between starch and aliphatic polyesters can be promoted either by the processing conditions and or by the presence of compatibilizers between starch and aliphatic polyesters such as amylose/EVOH V-type complexes (129) and starch-grafted polyesters. Chain extenders like diisocyanates, epoxides, etc. are preferred. These types of materials are characterized by excellent compostability and mechanical properties and reduced sensitivity to water.

Thermoplastic starch can also be blended with polyolefins (145). In this case, about 50% of thermoplastically processable starch is mixed with 40% of polyethylene and 10% of ethyl acrylate–maleic anhydride copolymer. During this mixing process an esterification reaction takes place between the maleic anhydride groups in the copolymer and the free hydroxyl groups in starch. Other studies have been performed on polyamide/high amylose (75,146,147) and acrylic copolymers/high amylose starch systems (75,147,148). The problem of partial biodegradability and a too high sensitivity to humidity persists.

Starch/cellulose derivative systems are also reported in other publications (137,141,149,150), particularly, cellulose acetate and butyrate/starch blends in presence of glycerol and epoxidized soybean oil (149).

The combination of starch with a water-soluble polymer such as poly(vinyl alcohol) (PVOH) and/or polyalkylene glycols has been widely considered since 1970 (151). More recently, the thermoplastic starch/PVOH system has been mainly studied for producing starch-based loose fillers as a substitute for expanded polystyrene (152–158). As an example, Altieri and Lacourse developed a technology based on hydroxy propylated high amylose starch containing small amounts of

PVOH for improving foam resiliency and density (152–156). In this case loose fill was produced directly by a twin-screw extruder. More advanced processes and alloys have been developed which have resulted in foams with lower foam densities (8–6 kg/m^3) and better performance (159–161).

Starch-Based Materials on the Market

The market of destructurized and complexed starch-based bioplastics accounts for about 25,000 ton/year, 75% of which is for packaging applications, including soluble foams for industrial packaging and films for bags and sacks. The market share of these products accounts for about 75–80% of the global market of bioplastics (162).

Leading producers with well-established products in the market are Novamont, National Starch, main Novamont partner and licensee in the sector of loose-fills and of foamed sheets, and, finally, Biotec with a capacity of about 2000 ton/year.

Following the recent start-up of its third line dedicated to the production of Mater-Bi film grades in Terni, Novamont's internal production capacity is of 20,000 ton/year. The total capacity, including the network of licensees in the sector of loose fills, is about 35,000 ton/year. The technology for the production of starch-based loose fills is licensed together with National Starch and Chemical Co.

The wide patent portfolio of Novamont covers the technologies of complexed starch developed by Novamont and of destructurized starch developed by Warner Lambert and acquired by Novamont in 1997 after the exit of Warner Lambert from the market in 1993. Moreover, on August 2001 Novamont acquired the film technology of Biotec which included an exclusive license of the Biotec's patents on TPS in the sector of film (162).

In recent years companies such as Earthshell, Apack, and Avebe dedicated significant efforts to the development of food containers through the "baking technology." Market tests are in place in the United States and Europe to check their performances (163). Moreover, very recently in the Netherlands, Rodemburg built up a plant for the transformation of potato wastes generated by the industry of fried potatoes in a granulate to be used for the injection molding of slow release devices. The claimed capacity is 40,000 ton/year.

The price of starch-based bioplastics ranges from 1.25 to 4 Euro/kg, with possibilities to compete even with traditional materials in some limited areas (163).

The properties achieved by starch-based bioplastics in certain applications and the commitment of the companies today dealing with this family of bioplastics give more confidence in the future possibilities of this market sector. Bioplastics from renewable origin, either biodegradable or nonbiodegradable, still constitute a niche market which requires high efforts in the areas of material and application development; the technical and economical breakthroughs achieved in the last three years, however, open new possibilities for such products in the mass markets. Novamont today boasts a diversified portfolio of industrial tailor-made materials for a wide range of applications, which explains its position as market leader (162).

After more than 12 years of research and development, Mater-Bi products are able to fulfil specific in-use performances in different application sectors, and offer original solutions both from the technical and the environmental point of view.

Under the Mater-Bi trademark today, Novamont produces a wide range of materials, divided into five families, according to the processing technologies: film, extrusion/thermoforming, injection molding, foaming, and tires technology. Mater-Bi products are mainly used in specific applications where biodegradability is required; examples include composting bags and sacks, fast food tableware (cups, cutlery, plates, straws, etc), packaging (soluble and insoluble foams for industrial packaging), film wrapping, laminated paper, food containers, agricultural film products (mulch film, nursery pots, plant labels, slow release devices, etc.), and hygiene (diaper backsheet, cotton swabs).

New sectors are also growing outside biodegradability, driven by the unique technical performance of some Mater-Bi products versus traditional materials, as in the case of breathable films with silky hand for diapers, chewable items for pets, or biofillers for tires. The new tire Biotred GT3, launched by Goodyear in 2001 and recently adopted by BMW and Ford, is an example of the high tech performances reached by Mater-Bi products (164).

Mater-Bi starch-based materials are characterized by the following properties:

(1) complete biodegradability and compostability according to existing standards (Fig. 11) (165–167)
(2) significant reduction of environmental impact, particularly with respect to CO_2 emissions and energy consumption, in comparison with traditional materials in specific uses (168,169)
(3) in-use performances similar to traditional plastics
(4) processability similar or improved in comparison with traditional plastic materials (162).

[c] To convert MPa to psi, multiply by 145.
[d] To convert N/mm to ppi, divide by 0.175.

Other properties of Mater-Bi films of the last generation can be summarized as follows:

(1) soft, silky handle
(2) wide range of permeability to water vapor from 0.75 to 3 $g \cdot cm/m^2 \cdot day$ (250 to 1000 $g \cdot 30\mu m/m^2 \cdot 24h$)
(3) wide range of mechanical properties from soft and tough materials to rigid ones, with no significant aging after one year of storage, (163) (Table 3 and 4)
(4) antistatic behavior
(5) colorability with food contact approved pigments
(6) compostability in a wide range of composting conditions: from home composting and static windrows to rotary fermenting reactors

They are biodegradable and compostable according to the present European standards and are certified by AIB Vincotte in Belgium, by DINCERTCO in Germany, and by IIP in Italy, according to CEN EN13432, DIN 54900, and

Table 4. Some Physical Properties of Mater-Bi Grades for Injection Molding, in Comparison with Traditional Plastics

Test	Procedure	Unit	Mater-Bi[a]	PP[b]	PS[c]
MFI	ASTM D1238	g/10 min	20–10	0.3–40	1.2–25
Strength at break	ASTM D638	MPa[d]	20–30	23	30–60
Elongation at break	ASTM D638	%	20–500	400–900	1–4.5
Young's modulus	ASTM D638	MPa	200–2000	1400–1800	3000–3500
IZOD (notched impact)	ASTM D256	kJ/m^2[e]	1–80	3–10	2–3

[a] 170°C, 5 kg.
[b] 23°C, 2.16 kg.
[c] 200°C, 5 kg.
[d] To convert MPa to psi, multiply by 145.

UNI 10785 standards, respectively (see DEGRADABLE POLYMERS AND PLASTICS IN LANDFILL SITES).

After the acquisition of Enpac in 1998 and the subsequent agreement with Novamont, National Starch is licensing two technologies for the production of loose fills: one from hydroxypropilated high amylose starch and a second from almost unmodified starch. The loose fills' densities range from 6 to 10 kg/m^3. The main licensees are Unisource, American Excelsior, Storopack, and Flow Pack in the United States.

Biotec, the German company which acquired in 1994 the patents of Fluntera, was acquired by EKI (Essem Kashoggi Industries) in 1998. Biotec, after the sale of the film business to Novamont in 2000 is concentrated on foodserviceware products and on pharmaceutical products.

Conclusions

Starch-based bioplastics constitute a new generation of materials able to significantly reduce the environmental impact in terms of energy consumption and green-house effect in specific applications, to perform as traditional plastics when in use, and to completely biodegrade within a composting cycle through the action of living organisms when engineered to be biodegradable. They offer a possible alternative to traditional materials when recycling is inpractical or not economical, or when environmental impact has to be minimized.

After more than 12 years of research and development, starch-based materials have begun to fulfil specific in-use performances in different application sectors. They are able to offer original solutions both from the technical and the environmental point of view.

Today some of the bioplastics available in the market are used in specific applications where biodegradability is required, such as the sectors of composting (bags and sacks), fast food tableware (cups, cutlery, plates, straws etc), packaging (soluble foams for industrial packaging, film wrapping, laminated paper, food containers), agriculture (mulch film, nursery pots, plant labels), hygiene (diaper back sheet, cotton swabs) and slow release devices in agricultural and pharmaceutical sectors. Moreover, new sectors are growing outside biodegradability, driven by improved technical performances versus traditional materials, as in the case of biofillers for tires and chewable items for pets.

The price of bioplastics from renewable origin is decreasing and ranges from 1.25 to 4 Euro/kg, with possibilities to compete even with traditional materials in some limited areas.

The world market for biodegradable plastics is still small, but it has grown significantly in the last few years, reaching about 33000 ton/year in the year 2000; products totally or partially from renewable resources represent nearly 85–90% of this market (170).

THERMAL ANALYSIS OF POLYMERS

Introduction

Thermal analysis is defined by the International Confederation of Thermal Analysis and Calorimetry (ICTAC) (1,2) as "a group of techniques in which a property of a sample is monitored against time or temperature while the temperature of the sample, in a specified atmosphere, is programmed." In practice, the temperature of the oven that contains the sample actually is programmed, while the temperature of the sample in some cases may differ from the programmed temperature. Exothermic or endothermic reactions or phase transitions in the sample subjected to the programmed temperature variation may cause variations in the temperature between the sample and oven up to several degrees.

The more common thermal analysis (TA) methods are listed in Table 1 (3). Acronyms used for the techniques are included in the right-hand column. The present discussion will be limited to the major techniques that are used to characterize polymer samples. These are differential thermal analysis (DTA), differential scanning calorimetry (DSC), thermogravimetry (TGA), thermomechanical analysis (TMA), dynamic mechanical analysis (DMA), and dielectric analysis (DEA). The most popular technique for polymer applications is DSC followed by TGA (along with its derivative, DTGA). The use of the other methods is not as widespread as DSC and TGA but is gaining in popularity. The realization of the potential for TMA as a valuable tool for polymer characterization is comparatively recent. DMA and DEA were originally developed by rheologists over 50 years ago and have been adopted by thermal analysts more recently.

In addition to the individual techniques cited above, there are situations where individual samples are subjected to a common atmosphere and thermal environment. This is referred to as a *concurrent analysis*. An example of this is the combined DTA and TGA measurement, where two separate measurement devices share the same oven. In some cases two or more measurements are performed on the same sample. There is also the possibility of interfacing several techniques, such as TGA combined with some form of evolved gas analysis such as gas chromatography, Mass Spectrometry (qv), or infrared spectroscopy (or some combination of these) (see CHROMATOGRAPHY, AFFINITY; VIBRATIONAL SPECTROSCOPY). This situation is referred to as '*coupling*' or a *coupled technique*. Since the possibilities for interfacing several analytical techniques are quite large, concurrent or coupled techniques will not be considered further in this presentation.

Prior to the advent of DSC (ca 1964–65), DTA was first used in the field of geology to study clay mineralogy and pyrometry. The evolution of DSC has its

origins in DTA, driven by applications in polymers and the timely development of techniques, instruments, and advanced software. In recent years, DSC has largely supplanted DTA for use in polymers, except for applications at high temperatures. Most commercial DSC instruments have a temperature range from -150°C up to 750°C, which is quite adequate for most polymer applications.

Differential Thermal Analysis

Description of the Method. As shown in Table 1 and Figure 1, DTA measures the differential temperature between a sample and a reference pan, which are closely matched thermally and arranged symmetrically within the oven. As the sample goes through the programmed dynamic temperature change, there is no temperature difference until the sample undergoes an exothermic or endothermic chemical reaction or change of physical state. In the case of an exotherm, the sample's temperature will increase, while in the case of an endotherm, it will decrease. In either case, the thermal event will be recorded as the sample temperature departs from the baseline and then returns to the base line when the

reaction or transformation is complete. Also, a change in the heat capacity of the sample will show as a change in slope (eg, Glass Transition (qv)) in the ΔT versus time or temperature plot. Modern DTA instruments generally use matched thermocouples as sensors, one each in contact with the sample or its container and the reference material or its container. The output of the differential signal is amplified and sent to a data acquisition system. Further details about DTA instrumentation and the appropriate experimental parameters can be found in several references by Wendlandt (4), Gallagher (Ref 5, Chapt. 1), and Wunderlich (Ref. 5, Chapt. 2). Some consideration of sample preparation, the effect of experimental parameters (eg, rate of heating and cooling), and methods for enthalpy and temperature calibration will be considered in the subsequent discussion of DSC.

Applications of DTA for Polymers. Table 2 (Ref. 5, Chapt. 1) describes some of the many applications of DTA and DSC. Both DTA and DSC can be used to determine the temperature of the transitions, cited in Table 2. However, the DSC peak area, in addition, gives quantitative calorimetric information (heat of reaction, transition, or heat capacity). DTA can only do so when calibration with a standard material allows the quantitative conversion of ΔT to heat flow and, ultimately, heat of transition (ΔH) or heat capacity (C_p). Also, the response of DTA with increasing temperature may be affected by poor heat transfer in the system, detector sensitivity, etc (4). For these reasons, when there is a choice between DSC and DTA, DSC is the preferred method. The illustrations shown below for applications of DSC in characterization of polymers also generally apply for DTA, with the limitations mentioned above. Therefore, DTA applications will not be considered here. Illustrations of polymer applications for DTA can be found in the Thermal Analysis section by Bacon Ke (6) in the previous edition of this encyclopedia.

Differential Scanning Calorimetry

Instrumentation. The development and introduction of DSC in 1964 (7) was a major innovation in thermal analysis. Several competitive commercial instruments were developed shortly afterward. Basically, there are two types of DSC instruments. The Perkin-Elmer version is called the "power compensation" DSC.

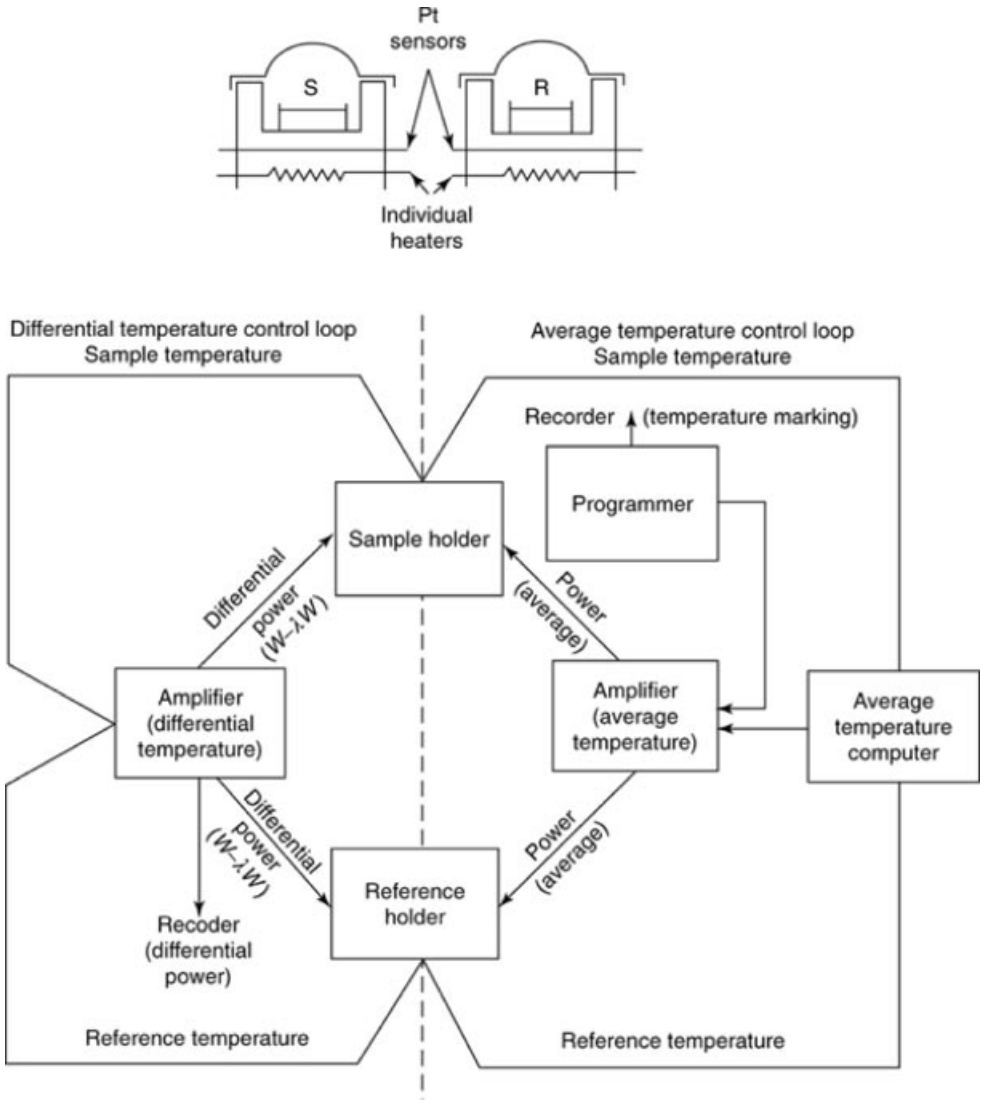

Fig. 2. A schematic representation of a power compensation DSC instrument and its operation (7).

Zahra and Zahra (8) reviewed a recent version of this type of DSC instrumentation. Figure 2 provides a schematic representation of the power compensation DSC.

The concept of operation of this instrument is based on keeping the temperature of R and S the same. This is achieved by placing the temperature sensors (platinum resistance thermometers) in a bridge circuit. Any change in temperature in either the sample or in the reference (by virtue of any exo- or endothermic event) is immediately compensated for by an equivalent amount of current flow required to drive a heater to keep them at the same temperature. Thus, the

integral of the power input during the transition (or the heat capacity change) is equal to the energy difference (ΔH) supplied to the sample or the reference during the particular event. The event would be endothermic or exothermic depending on whether the current travels to the sample or the reference pan, respectively. This results in an exothermic peak pointing downward and an endothermic peak pointing upward. This is in conformity with the thermodynamic convention, but differs with the sign convention for the DTA and the DSC "heat flux" for instruments made by other manufacturers, as discussed below. For DTA, ICTAC (2) recommends plotting "an upward deflection as a positive temperature differential and a downward deflection as a negative temperature differential with respect to the reference." In other words, exo is upward and endo is downward.

The second type of DSC unit operates in a "heat flux" mode. This type of instrument is offered by TA Instruments, Mettler-Toledo, Setaram, Netszch, and other manufacturers. Its operation is similar to that of DTA (ie, it generates a ΔT signal). However, the associated hardware and software, carefully integrated into the system, quantitatively converts ΔT to ΔH and compensates for other deficiencies, such as the temperature dependence of thermal transport and sensor sensitivity. Figure 3 shows two types of heat-flux calorimeters along with a schematic diagram taken from Boerio-Goates and Callanan (9). Figure 3**a** represents the Boersma-type instrument used by TA Instruments. In this unit, single thermocouples are in good thermal contact with the sample and the reference holders. In the Tian–Calvet-type calorimeter, shown in Figure 3**b**, a thermopile is used. The latter tends to give greater temperature sensitivity and better temperature averaging over the entire sample and reference containers. The schematic representation in Figure 3**c** notes the temperatures and thermal resistances that are necessary for mathematical analysis of the heat-flux DSC. The analysis is described by Wunderlich (5). Each type of DSC gives satisfactory enthalpy data (10) with an accuracy of around 1–2%. Some heat-flux DSC instruments can operate at temperatures up to 1500°C, while the power-compensation instrument operation is limited to 725°C.

Calibration and Standards. Thermal analysis methods are not absolute and calibration is needed to record the correct abscissa value of temperature T (in Kelvin) and time t (in seconds or minutes). On the ordinate, calibration is necessary for the amplitude of deflection, ΔT, expressed as the difference in temperature (in Kelvin) for DTA or as heat flux, dQ/dT (in joules per second or watts) for DSC. Each instrument manufacturer provides methods and standard materials for these calibrations. In addition, ICTAC, in collaboration with the National Institute of Standards and Technology (NIST), has developed a series of materials as calibration standards for DSC/DTA. These reference materials can be used to calibrate both the temperature scale (K, abscissa) and heat flow (J/g, ordinate) on the basis of the integrated area under the curve. Figure 4 shows the heat flow–temperature relationship for various solid–solid and solid–liquid melting standards. Table 3 lists the solid_1-to-solid_2 transitions, melting points, and Curie temperatures of various pure metals, and also their transition enthalpies (J/g) (11).

Figure 5 illustrates temperature calibration curves for both DTA/DSC and TGA using high purity nickel as a magnetic material (Curie point = 358.4°C). Unlike T_m, the Curie point temperature is practically unaffected by the changing of the heating rate between 1 to 20°C/min.

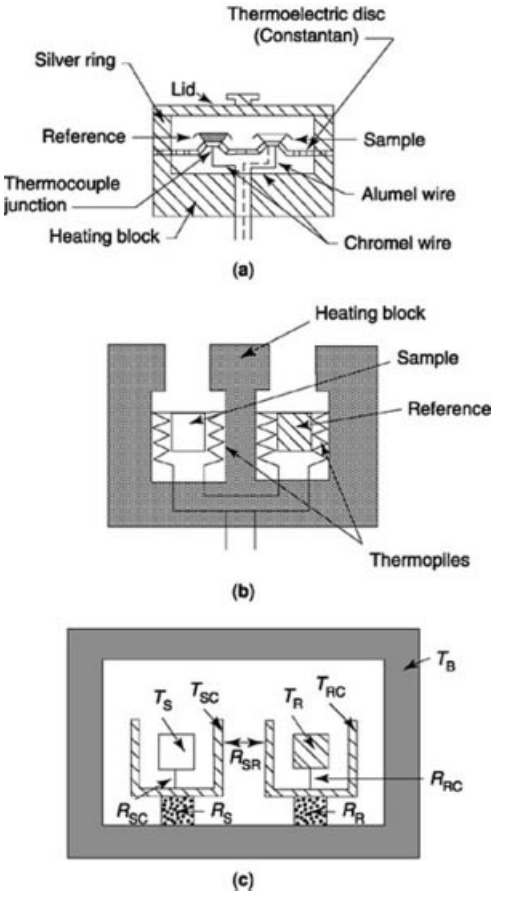

Fig. 3. Representation of a two heat-flux calorimeter showing (**a**) Boersma thermocouple placement and (**b**) the Tian–Calvet design. The schematic diagram (**c**) is appropriate for analysis of the response of both types of calorimeters. Symbols in (**c**) are: subscript T refers to temperature, R refers to reference; the temperatures of the block, sample, container, reference, and reference containers given by T_B, T_{SC}, T_R, T_{RC}, respectively; capital R refers to heat transfer resistance in the instrument (9).

Hakvoort (16) and also Della Gatta and Barczynska (17) advocate certain solid-state first-order transitions for use as subambient temperature standards. For relatively low temperature ranges, such as the glass transitions (T_g) for elastomers, Tan and Sabbah (18) have proposed the melting transitions of various organic compounds. Certified reference materials for heat capacity calibration, which are recommended by International Union of Pure and Applied Chemistry (IUPAC), are also available (Ref. 5, pp. 46 and 353–356). Two ASTM standards document procedures for temperature (ASTM E967) and heat-flow (ASTM E968) calibration in DSC.

Operating Parameters for DSC/DTA.

Sample Size. In order to avoid temperature gradients inside a sample, a small sample size is preferred. A small sample size also gives better resolution.

On the other hand, sensitivity of the instrument increases with increasing sample size. The choice of sample size for DSC/DTA depends on the composition of the sample. For pure polymers, 3–10 mg is sufficient. For heterogeneous materials, such as blends and filled polymers or those containing several other compounding ingredients (such as elastomer vulcanizates), larger samples in the range of 10–20 mg may be necessary. However, for characterization of all materials in an air or oxygen environment, thin samples weighing only 0.2–0.5 mg are recommended in order to minimize diffusional effects with respect to oxygen or air, inhibit secondary reactions, and improve reproducibility. In the case of heterogeneous materials it is advisable to run multiple samples in order to verify that the data are representative of the composition.

Sample History. A factor that is characteristic of polymers is the dependence of morphology on thermal history. Significant variations in the degree of crystallinity as well as temperatures for glass transition (T_g), crystallization (T_c), and crystalline melting (T_m) can be obtained by varying the crystallization and annealing temperatures, or by changing cooling and heating rates. Additional types of sample history may be due to the viscoelastic character of the polymer. Elastomer samples that have been pressed, molded, or extruded may exhibit appreciable elastic "memory," which eventually may result in severe distortion of the sample during the TGA, DSC, and DMA experiments. This would result in anomalous data. Another type of time-dependent sample history variation can be encountered with thermoplastic block copolymers. Here changes in dimensional stability and/or polymer transition temperature may occur because of changes in the morphology of the material during the thermal measurement. This might

result from changes in the phase distribution resulting from aggregation of the hard or soft block segments. A further complication is physical aging or enthalpy relaxation that occurs in the amorphous phase due to the tendency of a polymer in a nonequilibrium state to spontaneously shift toward the equilibrium state. This is a complex subject that is not considered here but is covered in some detail by Chartoff in Reference 5.

In order to obtain a representative DSC curve for the polymer sample that is consistent and reproducible, it is necessary to destroy the prehistory. This is achieved by preheating the sample above the crystalline melting temperature in an inert atmosphere, holding it there for a few minutes (generally, 5 min) and then cooling slowly to the start temperature. If the crystallization rate is slow, it may be necessary to hold the polymer (ie, anneal) at a temperature below the melting point for some time in order for crystallization to go to completion.

In certain cases, whenever a special kind of prehistory is imparted to a polymer (eg, either through processing or aging, such as in fiber and film processing from the melt), it is important to study the prehistory. Here it may be desirable *not* to destroy the prehistory because the DSC response of the material may be correlated with a process parameter, thus extending the usefulness of the DSC curve. In this case, one should always record the first heat DSC/DTA curve followed by a second run using the reheat procedure noted above.

Base Line. Selecting a proper base line for integrating the area under the curve is essential for enthalpy determinations. In the absence of detailed information about overall error in different alternative modes, a simple straight-line approach is adequate. However, for partial area measurements in kinetics, a more accurate base line may be needed. The following texts may be consulted for further information on this topic: Wendlandt (4), Brown (19), and Wunderlich (11). Many modern instruments have the ability to manipulate the base line. In the case of irreversible transformations without any weight loss, a simple rerun of a sample (after the transformation), under the same conditions should give a suitable base line. All current computerized instruments can subtract one base line from another that is generated under identical experimental conditions.

Thermal Transport. Heat transfer to the sample can be affected by the following factors: (*1*) physical arrangement of the sample and reference relative to the furnace; (*2*) the choice of sensor, its size and position; and (*3*) the type of construction materials. These factors determine the thermal coupling. They also influence the shape and size of the peak for a thermal event. The better the thermal coupling between the sample and the reference, the smaller the original ΔT signal and the faster the return to the base line, thus improving resolution. A higher thermal conductivity environmental gas, such as helium, will result in better thermal coupling. Placing a metal lid on the sample pan also markedly improves the thermal properties of the system by helping to press the sample into good contact with the pan and reducing heat flow to the environment.

Effect of Heating Rate. The thermal lag between the sample and the sensor increases as the heating rate increases and, generally, the resolution of a transition (or other thermal event) decreases. However, the amplitude of the ΔT signal increases with heating rate because the transition takes place in a shorter period of time and the rate of change is greater. With modern instruments, amplification of the ΔT signal at a lower heating rate is not a problem, but it increases

Table 4. Compromises in Operation and Construction for DTA and DSC

Parameter	Maximum resolution	Maximum sensitivity
Sample size	Small	Large
Heating rate	Slow	Fast
Sample–reference	Linked	Isolated
Particle size	Small	Large
Atmosphere[a]	High conductivity	Low conductivity

[a] In the absence of any reaction.

the signal-to-noise ratio. Therefore, compromises must be made. Typical heating rates for DSC experiments are in the 10–20°C/min range. For unknown polymer samples, a range of heating rates with different amounts of sample should be explored. This should provide information on the optimum conditions for detection and resolution of minor thermal events and would be a background study for establishing a routine procedure for subsequent analyses. The effects of different parameters on resolution and sensitivity are summarized in Table 4 (Ref. 5, p. 87).

DSC Applications in Polymers

The numerous applications of DSC in characterizing polymeric materials are quite varied. Therefore, it is only possible to cast a glimpse on the subject. Figure 6 shows a schematic DSC curve (20) for a pure polymer as it is progressively heated from a low temperature to a high temperature in an oxidative (A) or inert (B) atmosphere. The actual temperature, for a given polymer to undergo all of the thermal events shown in Figure 6, depends on the structure of the polymer. For an elastomer, a low temperature transition (glass-transition temperature T_g) may be as low as −140°C, whereas for a thermoplastic polymer, T_g values of room temperature or higher may be more common. As noted before, the DSC experiment should be started at a temperature at least 20–50°C lower than the region of interest and continued to at least 20°C higher than the highest transition temperature. The elevated temperature at which most carbon-chain polymers degrade is usually less than 500°C.

Starting from the lowest temperature, the first discontinuity observed is the glass transition, which appears as a shift of the base line corresponding to the heat capacity difference of the sample before and after the transition. There are various methods to mark the exact location in the curve where the glass-transition temperature T_g is recorded. This will be discussed below. The magnitude of base line shift (ΔC_p) during the glass transition is related to the concentration of amorphous chains in the sample and is affected by other factors such as molecular mobility and free volume.

As the temperature increases, there may be a cold crystallization peak (T_c, exotherm), followed by a crystalline melting peak (T_m, endotherm). The intensity of the cold crystallization peak depends on the prehistory of the sample. It will not be present at all if the sample were cooled under controlled conditions from the melt state or if it were annealed at a fixed temperature below T_m so as to complete

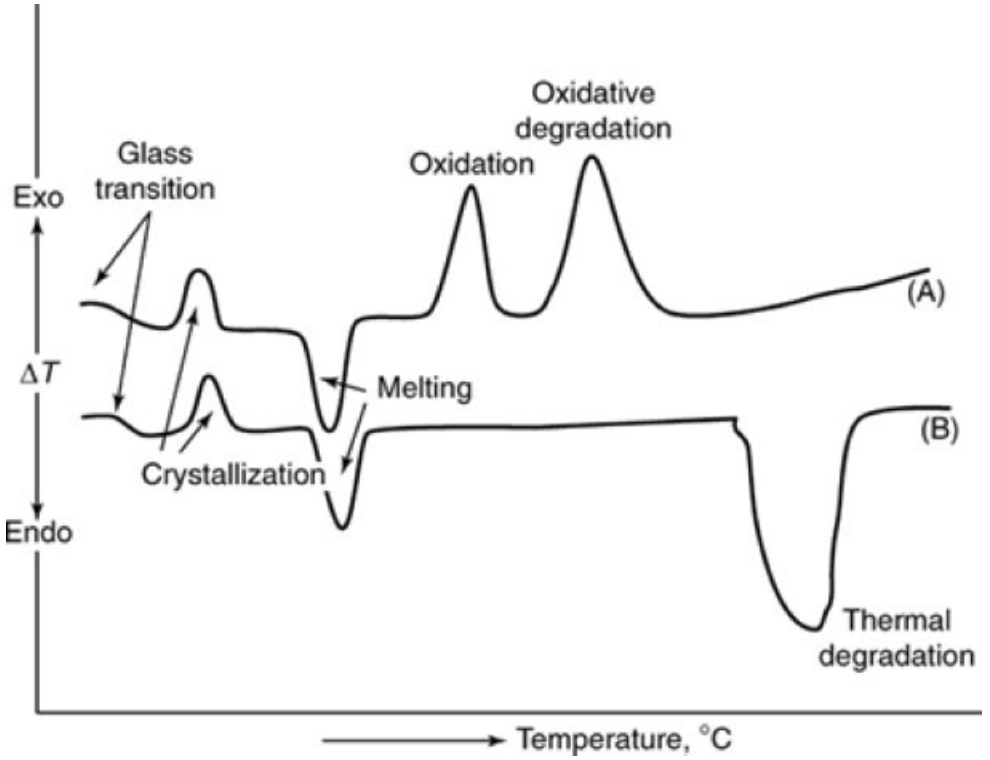

Fig. 6. Schematic DSC curves showing different transitions and reactions of a polymer, ranging from low temperatures to progressively higher temperatures. A, in oxygen; B, in nitrogen (20).

the crystallization process. If the sample is heated above T_m and then cooled slowly to a low temperature, and scanned again, the enthalpy or the area under the melting curve will relate directly to the amount of crystalline material in the polymer or the degree of crystallinity. Up to this point, the transitions mentioned are due to physical changes and they are reversible. Physical transitions are not accompanied by any weight change and are not affected by the environment (nitrogen or oxygen). Thus, they cannot be monitored using TGA, since there is no weight loss involved.

At a still higher temperature (150–220°C), if the polymer is an elastomer, formulated with all the vulcanizing ingredients or uncured thermosetting type monomer, an exotherm should occur indicating the curing reaction (not shown in Figure 6). DSC enthalpy determination (from the area under the exotherm) is one of the methods for determining the degree of cure of an elastomer formulation or a thermoset and can be used as a quality control tool.

At still higher temperatures (250–500°), the polymer undergoes degradation, resulting in main-chain scission, cross-linking, cyclization, and loss of volatile fragments. In an inert atmosphere, the degradation pattern may be endothermic, exothermic, or both, whereas in oxygen or air, it is always exothermic. As expected, degradation occurs at a much lower temperature in oxygen than in nitrogen. The

DSC degradation patterns in nitrogen and oxygen have been used to identify many polymers (21). Many authors, including Goh (22) and Savasçi and Baysal (23) have attempted to use oxidation exotherms to characterize the oxidative stability of elastomers, and, subsequently, to evaluate the effectiveness of added antioxidants. DSC curves in the degradation regime may tend to be erratic because of the loss of mass that may occur during the degradation event.

Glass-Transition Temperature.

Specifying T_g by DSC. All Amorphous Polymers (qv) become stiff and ultimately brittle like a glass, if sufficiently cooled. The temperature region where the physical transition from a rubbery to a glassy state takes place is called the "Glass Transition (qv)." It is characterized by a step change in C_p. As shown in Figure 7, the glass transition covers a wide range of temperature (10–15°C for pure, uncross-linked polymers and wider for blends, filled, and cross-linked polymers). A defined point in this temperature range is called the glass-transition temperature or T_g.

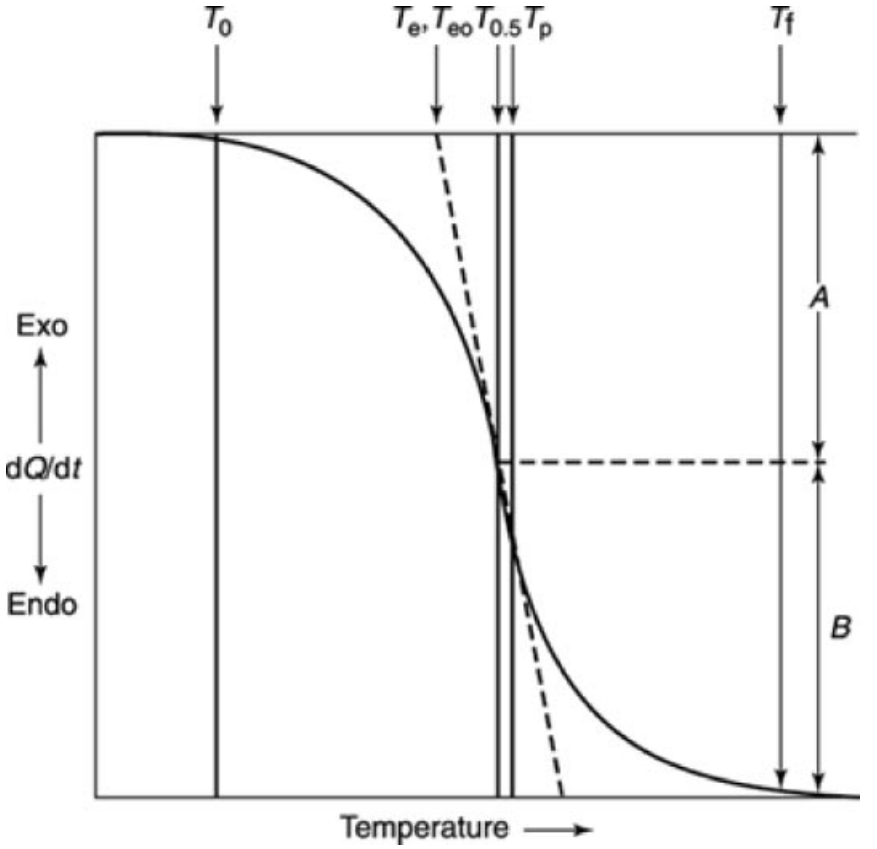

Fig. 7. Representative curve of heat flow versus temperature in the region of the T_g of a polymer: T_o, temperature of departure from the base line; T_e or T_{eo}, temperature of intercept of extrapolated base line and tangent to steepest slope; $T_{0.5}$, temperature of 50% transition (A = B); T_p, temperature of maximum slope (peak of derivative plot); T_f, temperature at completion of the transition (24).

Figure 7 shows five characteristic temperatures associated with a glass transition on the DSC curve. All five have been cited in various places in the literature as T_g, often without mention of the specific location actually picked (24). The assignment of T_g by thermal analysis methods was the topic of a recent ASTM symposium (25). T_o, the "onset" temperature, defines the point at which the first deviation from the base line on the low temperature side is observed. T_o is very subjective and often difficult to determine because of the base line slope; and it is not reproducible. T_e or T_{eo} (extrapolated onset, also called the fictive temperature) is the temperature at the intersection of the extrapolated base line and tangent taken at the point of maximum slope. It is generally reproducible and is the most quoted value in many early publications on thermal methods. $T_{0.5}$, the endotherm half-height (also called half-vitrification) is the temperature preferred in recent years for specifying T_g. The autoanalysis feature available with all modern thermal analysis equipment makes this determination easy and reproducible. It has better reproducibility than the extrapolation method and locates a temperature where the thermal transition has approximately reached the inflection point. ASTM E1356 and ASTM D3418 recommend either T_e or $T_{0.5}$ for specifying T_g.

Wunderlich (Ref. 5, p. 278) advises that T_g should be measured as the sample is progressively cooled, rather than heated. The advantage here is that the sample is in thermal equilibrium at the start of the measurement and enthalpy relaxation, often encountered in T_g measurements, is avoided. However, instrumental drawbacks, such as precise control of the cooling rates in some DSC models, preclude general use of cooling curves for determining T_g. If T_g is obtained by progressive heating of a cooled sample, it is advisable to cool the sample somewhat faster than the subsequent heating rate to avoid enthalpy relaxation. This is also discussed by Wunderlich (5). The heating or cooling rate and the location on the DSC curve where T_g is taken always should be specified along with the reported T_g value.

Another method for locating T_g is by taking the derivative of the DSC glass-transition curve. (The acronym DerDSC for "derivative DSC" is used here.) The derivative curves exhibit a peak corresponding to the maximum slope of the endothermic step in C_p accompanying T_g. In Figure 7, T_p is very close to $T_{0.5}$, the midpoint value. This is illustrated in Figure 8 for natural rubber (26). Note the small endotherm at the high temperature end, presumably due to enthalpy relaxation. The derivative curves may also be helpful in locating multiple transitions close in temperature and not resolved by the T_g curve (Ref. 25, p. 229). The disadvantage of this method is the high signal-to-noise ratio for the DerDSC curves.

For amorphous thermoplastic polymers, T_g at the extrapolated onset is technically more significant, since it defines the initial temperature for the loss of structural properties (eg, modulus) as the polymer softens through the glass-transition region. Thus, it defines both a low temperature limit for the processing of amorphous thermoplastic polymers and an upper use temperature. For elastomers, the temperature for useful elastomeric properties lies above the glass-transition region, (to the right of the T_g curve) shown in Figure 7. Therefore, T_f, the temperature at the completion of the glass transition, should be technically more significant (26). If the elastomer is cooled beyond this point it enters the glass-transition region and starts losing its elastic properties, becoming progressively stiffer as the temperature decreases. As noted above, ASTM E1356 describes the test method for determining the glass-transition temperature by DSC or DTA.

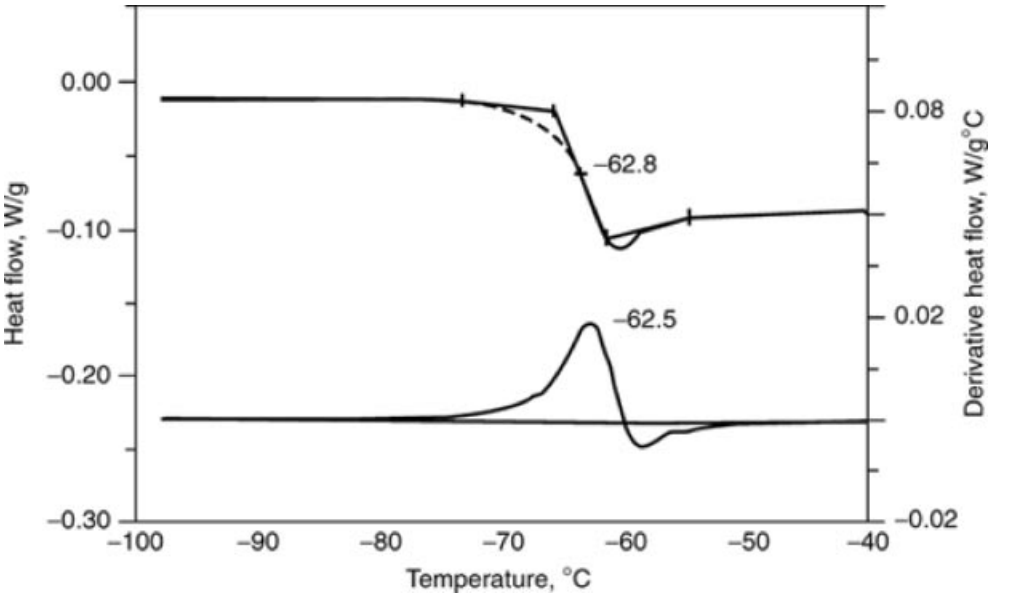

Fig. 8. DSC glass transition of natural rubber showing $T_{0.5}$ and T_p; heating rate 10°C/min (26).

Degree of Cure Using T_g. For many thermosets, T_g can be correlated with the conversion or degree of cure (Ref. 5, Chapt. 6). Therefore, simultaneously with the heat of reaction, measured by enthalpy, T_g can be used as a measure of the degree of cure. In the final stages of cure, where T_g is actually the more sensitive measure, it may be preferred to the residual heat of reaction, ΔH_1, as a measure of the degree of cure. This may happen when the glass transition immediately precedes the small residual exotherm. This is illustrated in Figure 9 (27) for epoxy–anhydride samples, previously cured to *apparent* completion at different temperatures. Note that the exotherms are facing downward, as would be expected for a power compensation DSC instrument; ΔH_c is the exothermic heat of reaction for 100% conversion, expressed as heat per mole of reacting groups (kcal/mole or kJ/mole) or per mass of material (cal/g or J/g) at the time t. The fractional degree of conversion is given by

$$\alpha_1 = \Delta H_1 / \Delta H_c \tag{1}$$

where α_1 is the fractional conversion or extent of reaction and ΔH_1 the heat generated up to time t_1.

The measurement of the degree of conversion by enthalpy measurement applies to elastomer cure also, since the vulcanization reaction is highly exothermic. Unlike for thermosets, T_g is not a measure of degree of cure for elastomers. Sircar discusses this and numerous other aspects of the characterization of elastomeric materials using thermal analysis in chapter 5 of Reference 5.

Melting in Semicrystalline Polymers.

Traditional DSC Methods. Many commercially available thermoplastics [eg, polyethylene (PE), polypropylene (PP), poly(ethylene terephthalate) (PET),

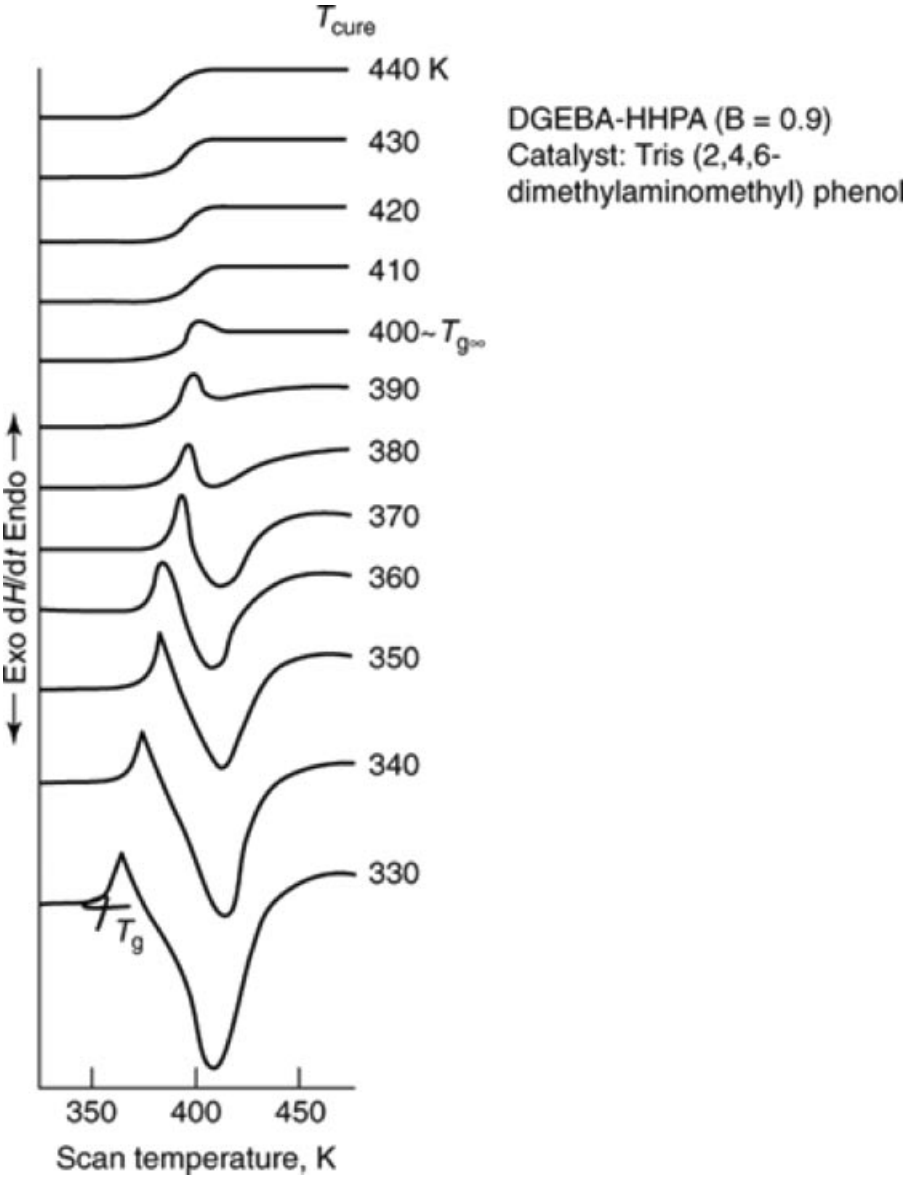

Fig. 9. DSC scans at 8°C/min on epoxy–anhydride samples previously reacted to apparent completion at indicated temperatures. Note increasing T_g followed by residual exotherm for samples cured below $T_{g\infty}$. Diminishing T_g at highest cure temperature suggests possible degradation (27).

various nylons, and numerous others] and some elastomers [eg, polychloroprene, known commercially as neoprene (CR), *cis*-1,4 -poly(butadiene) (BR), ethylene–propylene–diene polymer (EPDM)] are morphologically semicrystalline. These are virtually two-phase systems where a crystalline phase and an amorphous phase coexist. However, the crystalline phase and the amorphous phase are not

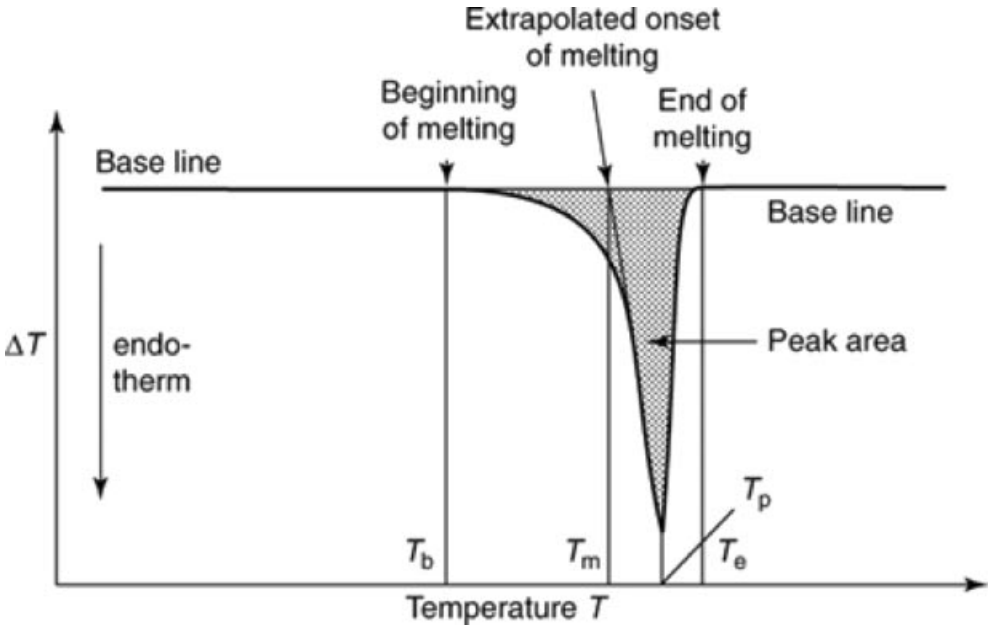

Fig. 10. Four characteristic temperatures for melting transitions. In addition, the peak area (heat of transition) and the time scale of the experiment should be recorded (11).

completely homogeneous. The crystals generally are of different sizes and forms and the amorphous phase near the crystallite interfaces is constrained and less mobile than the amorphous chains far from the crystallite boundaries. DSC is a useful tool for characterizing these semicrystalline materials.

Other important characteristics of Semicrystalline Polymers (qv) are that melting takes place over a range of temperatures (in some cases, over a range of 100°C or more) and supercooling always occurs, so that there is a hysteresis between the melting and crystallization cooling curves. Semicrystalline polymers melt at characteristic temperatures when heated in DSC. Wunderlich (Ref. 5, p. 277) describes reasons for designating the melting temperature T_m at different locations of the melting curve (Fig. 10). If there is a large temperature gradient within the sample, it has been observed empirically that the peak temperature often represents the actual melting temperature. Also, a sample with a broad melting range and a small melting rate (as are the semicrystalline polymers with crystals of different perfection, shape, and size) should be better characterized by its melting peak temperature, since T_p represents the temperature where the largest fraction of the sample melts. This is the most frequently quoted T_m for semicrystalline polymers. Lastly, the temperature for recovery of the base line, T_e, is a function of the design of the instrument. For a polymer with a very broad melting range, the instrument lag becomes negligible and T_e would indicate the melting temperature of the most perfect, highest melting crystals of the sample.

Another important characteristic of melting for semicrystalline polymers using DSC is the enthalpy or the value of the heat of fusion, ΔH_f. It should be noted that the value of ΔH_f, determined by DSC, denotes only the amount of crystallinity

present in the sample and not the inherent value of the enthalpy of fusion of a fully crystalline polymer, ΔH_u. Methods for determining ΔH_u are described by Starkweather and co-workers (28). If the enthalpy of fusion of the fully crystalline polymer is known, the degree of crystallinity of an unknown polymer sample can be determined as follows:

$$\text{Degree of crystallinity } (\%) = (\Delta H_f / \Delta H_u) \times 100 \tag{2}$$

As in the case of the glass transition, another important item to be reported is the heating or cooling rate. Equilibrium melting should be independent of heating rate, but rarely do polymer crystals represent equilibrium crystals, nor do they melt in DTA or DSC under equilibrium conditions. Under such nonequilibrium conditions, the time scale of a first-order transition (such as melting) is an important experimental parameter. It should be noted again that the magnitude of the step change in the base line during the glass transition relates to the amorphous content of the polymer. Similarly, the magnitude (area) of the melting transition enthalpy relates to the degree of crystallinity of the polymer. The degree of crystallinity of a semicrystalline polymer is an important parameter that correlates with most major engineering mechanical properties including elastic modulus, strength, and elongation to break. DSC is the most efficient method for accurately measuring the degree of crystallinity.

Modulated Differential Scanning Calorimetry. A relatively recent development in DSC instrumentation allows heating or cooling a sample under a constant underlying rate while simultaneously superimposing a sinusoidally varying time–temperature wave. This is shown in Figure 11 for the modulated differential scanning calorimetry [MDSC, TA Instruments; Sauerbrunn and co-workers (29)]. As described below, the accepted name for this method has since been changed to modulated temperature DSC, or MTDSC, after this term was introduced in 1996. A similar technology [dynamic DSC or step scan DSC (SCDSC) developed by Perkin-Elmer] is based on a series of isothermal holds, each followed by a linear heating segment (ramp) instead of the sinusoidal cycle of MTDSC. Schawe (30) compares the two methods (MTDSC versus DDSC) using the glass transition as an example. The results are virtually identical.

A major advantage of the MTDSC technique and analysis is that the total heat flow rate can be separated into two other signals by deconvolution of the raw data (Fig. 11**b**). One of these is a reversible signal, in phase with the modulated heating rate, and the other a nonreversible signal out of phase with the modulated heating but dependent on the rate of heat flow. Examples of polymer thermal events that are nonreversible are molecular relaxation, cold crystallization, evaporation, thermoset cure, elastomer vulcanization, and decomposition. The utility of having two response components is demonstrated in Figure 11**c** for PET, where the glass transition and the melting endotherm are reversible but the endothermic enthalpy relaxation at T_g and the exothermic cold crystallization are not. Another advantage of MTDSC is that once the instrument is calibrated for the amplitude and period, heat capacity data can be obtained directly in the same run by measuring the modulated heat flow signal, and dividing by the amplitude of the heating rate.

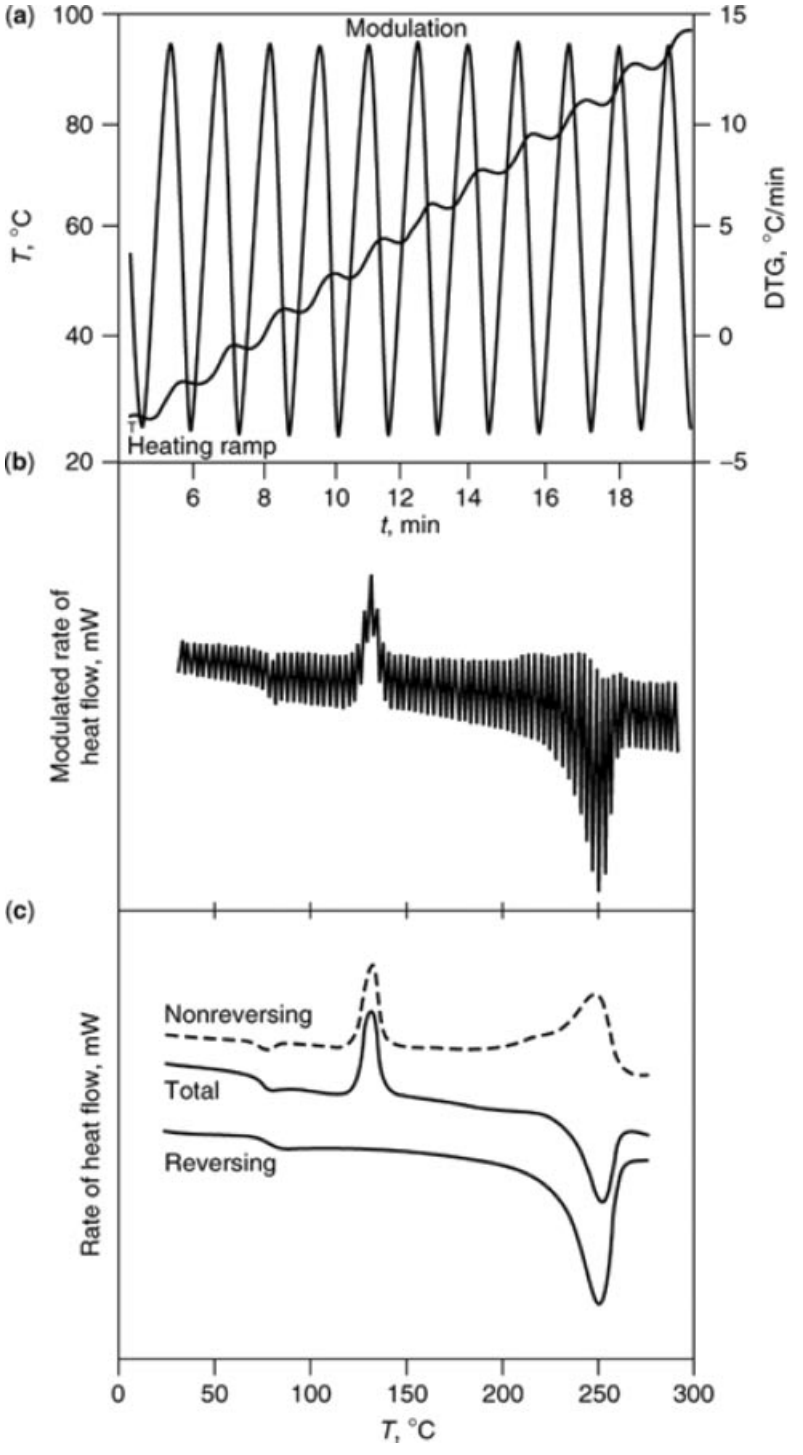

Fig. 11. Examples of MDSC data: (**a**) typical temperature–time profile; (**b**) raw data for an MDSC scan of quenched PET; (**c**) Deconvolution and analysis of the curve (29).

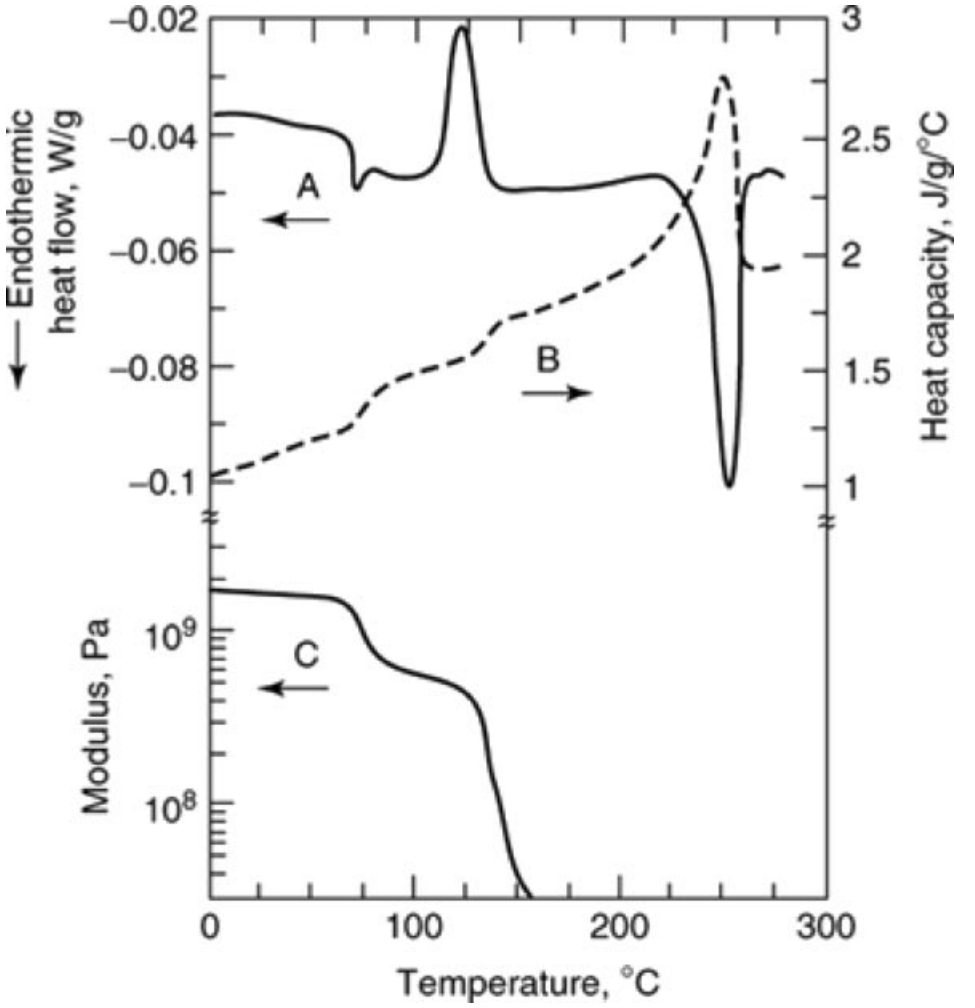

Fig. 12. Modulated DSC curve for Makroblend UT-400, an impact-modified polycarbonate/poly(ethylene terephthalate) blend. Curve A shows the conventional DSC curve; curve B shows the heat capacity extracted from the reversing component of the signal; curve C shows the modulus of the same material measured by DMA (Hale and Bair, in Ref. 5).

An interesting analysis of a blend of PET/polycarbonate (PC), using MTDSC, was reported by Hale and Bair (Ref. 5, p. 804) (Fig. 12). The conventional DSC curve (A) has all the indications of PET, but PC cannot be detected without the deconvoluted reversing curve (B) that indicates PC is present by virtue of its T_g that occurs in the same temperature range as the cold crystallization of PET. Further confirmation of the presence of PC is obtained from the dynamic mechanical storage modulus (curve C). The dynamic modulus technique will be discussed later in this article.

In the MTDSC technique, C_p (heat capacity) data from the convoluted MDSC is replaced with the term C_p^*, called a complex heat capacity. C_p^* can then be

further deconvoluted into an out-of-phase C_p'', and an in-phase (C_p'), component relative to the imposed temperature modulation. The vector sum of these components is equal to complex heat capacity, the data traditionally generated by MDSC. For most polymers, C_p'' is very small. In those cases, C_p and C_p^* will be virtually identical. However, a phase correction in MDSC should be relevant for time-dependent heat capacity phenomena. Aubochon and Gill (31) present a good comparison of MDSC and MTDSC with illustrations. The attention of interested readers is also directed to the papers on MDSC and MTDSC presented at the 11th ICTAC conference (1996), and later published in three volumes of the *Journal of Thermal Analysis* (1997). NATAS, the North American Thermal Analysis Society, has sponsored symposia on MDSC at each of its meetings for the past several years.

DSC Modifications and Simultaneous Techniques. DSC and other thermal analysis instrumentation have undergone many modifications and developments in recent years. Among these innovations is the coupling of various methods. In this context the terms *parallel*, *concurrent*, and *simultaneous* should be defined. Parallel techniques use separate samples, each in its own unique thermal environment. Concurrent or combined techniques also use separate samples, but the experiment is carried out in a common atmosphere and thermal environment. Simultaneous techniques use the same sample in the same atmospheric and thermal environment. Such methods are increasing in popularity. While a detailed treatment of this topic is outside the scope of this discussion, a brief list will be presented in order to provide input for those new to the subject area. Interested readers should consult the chapter by Gallagher (5) and the additional references mentioned therein.

Some of the simultaneous instruments available commercially are as follows: TGA/DTA/DSC, TGA/DTA/FTIR, DTA(DSC)/EGA(EGD), and DSC/FTIR. Also, high pressure DSC and photo-DSC instruments are available commercially. In addition, individual researchers have used simultaneous DSC/XRD (X-ray diffraction), DSC/EGA/XRD, and DSC/TRXRD (time-resolved X-ray diffraction). Experiments with parallel, combined, and simultaneous techniques help to affirm the conclusions drawn from a single technique and very often offer definitive clues to the actual mechanisms taking place during thermal analysis.

Thermal conductivities can be measured using DSC. Chiu and Fair (32) irreversibly modified a DSC cell to determine thermal conductivity. Sircar and Wells (33) developed a modification of this approach, which allowed the use of the same cell for conventional DSC work as well as for the measurement of thermal conductivity. Marcus and Blaine (34) discuss the possibilities for using MTDSC for measuring thermal conductivity.

Thermogravimetry

The terms, *thermogravimetry* (TG) and *thermogravimetric analysis* (TGA) are synonymous. Both ICTAC and International Union of Pure and Applied Chemistry (IUPAC) accept either of them. This is because of the early use and popularity of the term TGA, as well as an interest in avoiding verbal confusion with the glass transition T_g. There may also be potential problems with computer searching.

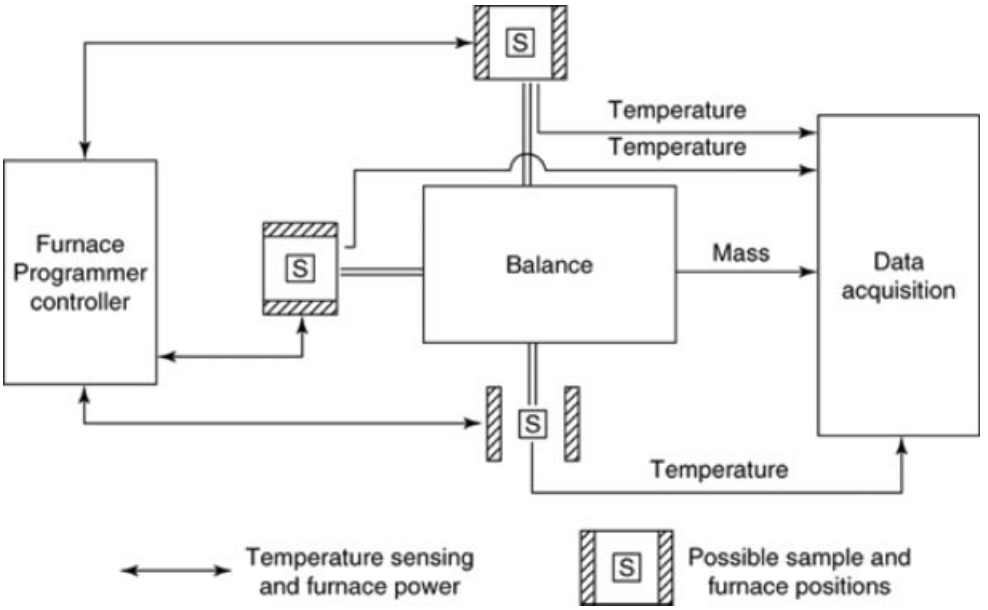

Fig. 13. Typical arrangement for the components of a TGA instrument (3).

Thermogravimetry involves the continuous recording of mass versus temperature or time as a sample is heated in a furnace with a controlled environment. The sample may be heated at a constant rate or held at an isothermal temperature. Madorsky (35) and Jellinek (36) authored major books dealing with thermogravimetry of polymers. The era of modern automated thermogravimetry started with the introduction of the electrobalance by Cahn and Schultz (37). Other competitors, such as DuPont, Mettler, and Perkin-Elmer, introduced their products in rapid succession.

Description of a TGA Instrument. The components of the instrument are the microbalance, the furnace, the programmer controller, and a computer or data acquisition system. Typical arrangements of the components for TGA are shown in Figure 13. The sample can be linked to the balance in three different ways: (*1*) above the balance, (*2*) below the balance, and (*3*) beside the balance as a horizontal extension to the beam.

Arrangement 1 is the most common. However, arrangement 3 is actually preferred because it minimizes the heat effects of the furnace that may be encountered in arrangement 2 and is less influenced by the flow patterns of the gases within the balance and furnace chamber. It also lengthens the balance lever arm, increasing sensitivity, and minimizes the problem of condensation of volatiles on the sample support. In order to minimize thermal expansion of the balance lever arm, quartz is frequently the beam material of choice.

The Balance. Figure 14 shows a schematic of the Cahn electrobalance (38) most frequently used in thermogravimetry work (arrangement 1). A photodetection system monitors the beam position. If the beam moves from the horizontal, enough current flows to the torque motor to move the beam back to its original

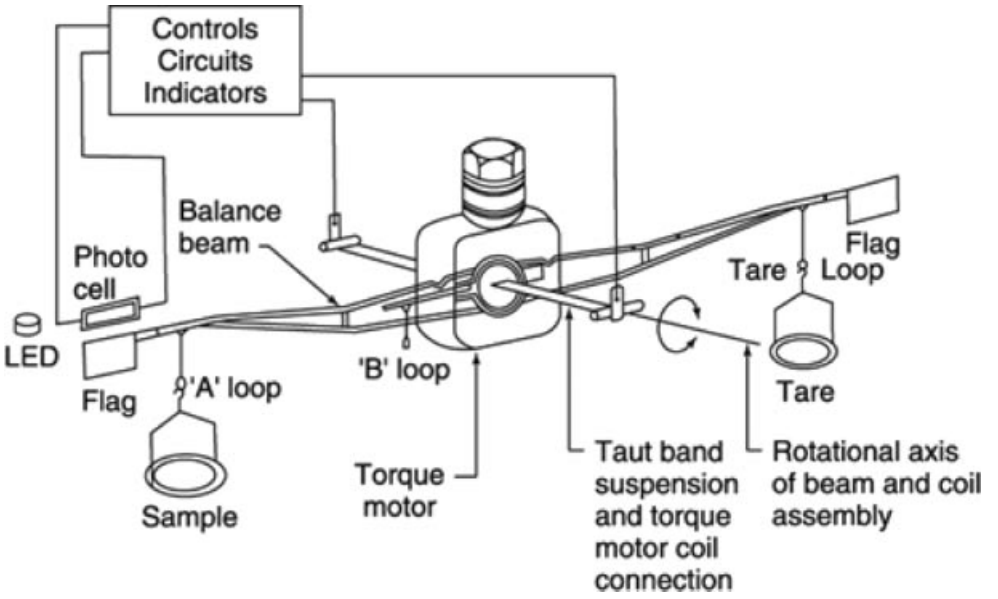

Fig. 14. The Cahn electrobalance (19).

position. The restoring force generated by the current is proportional to the change in mass. A sensitivity of 1 μg is easily achieved. The sensitivity and total capacity of the balance have an inverse relationship. A commercial instrument with high sensitivity (ELCHEMA of Potsdam, New York) has a sensitivity of 0.1 μg and an operating range of up to 100 μg.

The Furnace and Controller. The heating elements of the furnace are most often resistance heaters. Nichrome and Kanthal elements are used for the temperature range up to 1000–1200°C. This range is sufficient for most polymer applications. Aluminum sample pans are often used for low temperatures up to 600°C. For higher temperatures, platinum pans are frequently used as sample containers. For higher temperatures in the range up to 1500–1700°C, molybdenum disilicide (Super Kanthal) or silicon carbide (Globar) is used for heating elements, and platinum or platinum alloys for sample pans. Ceramic refractories such as mullite or alumina are needed to contain the controlled atmosphere. Only a few manufacturers, such as Linseis, Netzsch, and Setaram, market instruments for use above 1700°C. They are expensive and perform poorly below 300°C. Such high temperatures usually are unnecessary for polymers.

Most instrument manufacturers offer several furnace options in interchangeable modules to cover a broad range of temperatures. Thermal shock, oxidation, and vaporization shorten the life span of the resistance elements and refractories so that they may need occasional replacement. The higher the temperature of operation, the more severe this problem is. To enhance TGA instrument lifetime, Gallagher (5) recommends current limiting devices, thermocouple protection circuits and conservative ratings. Also, short times at elevated temperatures and less cycling to high temperatures will help. The use of dedicated computers and microprocessor chips has markedly improved the effective sensitivity and temperature

control of modern instruments. Speyer (39) describes many of the fundamental considerations for the proper design of TGA equipment.

For checking uniform heating rates, the temperature (T) versus time plot (t) is suggested. Wendlandt (40) found that replacing T in the above plot with the derivative dT/dt shows temperature fluctuations better than those of the temperature versus time plot. For further details, refer to the chapter by Gallagher (5).

Major Factors Affecting Thermogravimetry. Mass and temperature are the two most important parameters that must be determined accurately for proper characterization of a material by TGA. Table 5 (Ref. 5, p. 24) shows all of the factors that need to be taken into account for accurate determination of either mass (left-hand side) or temperature (right-hand side). However, it is easier to deal with corrections for mass than it is for temperature. The following discussion summarizes these factors.

Mass. The factors that may affect mass determination are buoyancy, atmospheric turbulence, condensation and reaction, electrostatic and magnetic forces, and electronic drift. Buoyancy corrections arise because the sample is in a lighter gas environment as the temperature of the environment increases. This shows up as a greater weight for the sample. The correction for this is minimal and, except for most accurate or demanding work, it can be neglected. If needed, there are suggestions for both instrumental and software adjustments that will take care of the correction. Atmospheric turbulence depends on the specific gas, its flow rate and pressure, as well as geometrical considerations. Wendlandt (4) discusses these factors in detail and suggests necessary compromises.

Evolved volatile products may condense on the cooler parts of the sample suspension system, thus altering the measured mass loss. The direction of flow of the evolved gases must be manipulated to protect the vulnerable parts of the balance mechanism, temperature sensor, and furnace windings from chemical attack. Also, in case the TGA system becomes contaminated from the products of the high temperature decomposition, subsequent experiments (particularly at high temperature) may be affected. An easy solution for this is to heat the system to around 600°C in an oxidizing atmosphere. This will eliminate most organic condensation products. If there is a chemical reaction with a component in the environment, there may be specific effects on the reversibility and the chemical equilibrium involved. Examples of this are the decomposition of carbonates, sulfates, hydroxides, and hydrates in the presence of CO_2, SO_3 and water, respectively. The partial pressure of the gases present will determine the extent of the respective reactions. Consequently, the degree of decomposition will be determined by the ability to sweep away the decomposition products.

Table 5. Major Factors Affecting Thermogravimetry

Mass	Temperature
Buoyancy	Heating rate
Atmospheric turbulence	Thermal conductivity
Condensation and reaction	Enthalpy of the process
Electrostatic and magnetic forces	Sample, furnace, and sensor arrangement
Electronic drift	Electronic drift

Catalytic reaction of the sample pan with the environment can also affect the environment. Moreover, potential reactions of a sample with the sample holder must be considered. For example, a silica crucible will lower the decomposition temperature of $CaCO_3$ by about 600°C in the presence of the self-generated atmosphere of CO_2. There is potential for reactions of materials such as alkalis and alkaline earth carbonates to react with ceramic or metal parts of the sample holder.

The form or packing of the sample is another factor that will determine excess of the degree of contact with gaseous environment and the rate of escape of the volatile products. Thus, decomposition may be diffusion controlled and dependent on the sample geometry instead of chemically controlled and dependent only on the sample composition. Packing will also affect the thermal gradients in the sample. Thus, results for a single "lump" of a sample, rather than a powder, may differ.

Low humidity of the surroundings and purge gases can generate electrostatic forces that can cause the sample holder to be attracted to or even stick to the nearest wall, thus disturbing the mass signal. This effect tends to be seasonal (dry winter) and there are simple remedies, such as wiping glass surfaces with conducting liquids or surfactants and providing a ground connection through thin metallic film on the glass surface. If moisture can be tolerated, the gas stream can be humidified to eliminate electrostatic charges or, if it is not too hot, the outer wall surface can be wrapped with a moist covering. The electronic drift problem usually is relatively minor and only becomes a problem for experiments lasting for several hours.

Temperature. As mentioned above, accurate temperature control is more of a problem in TGA than is weighing mass accurately. Referring again to the five factors affecting accurate temperature measurement as listed on the right-hand side of Table 5, geometrical placement of the sensor, the sample, and the furnace are particularly important. The sample should be as near to the thermocouple as possible in order to sense accurately the temperature of the sample, but should not affect the measurement of weight. It should not undermine effective control of the programmed rate of heating and cooling by virtue of the heating or cooling generated by any exothermic and endothermic reactions that take place. Also, the products of decomposition may have a corrosive effect on the thermocouple and balance parts. Thus, these volatile products should not come in contact with system components. Some of these requirements are contradictory, and compromises must be made.

The most common configurations for the placement of the sample and the thermocouple are shown in Figure 15 (Ref. 5, p. 30). This emphasizes the contradictions in the above requirements and the uncertainty in measuring the actual temperature of a sample. Very often, thermal runaway reactions caused by highly exothermic processes (e. g., oxidative decomposition of polymers) show as foldback curves (where the temperature increases and then decreases as heat is released) in the mass or weight % versus temperature plot. There is no completely satisfactory remedy for this. Using a high thermal conductivity atmosphere (helium) reduces the response time for temperature control and permits better heat dissipation or absorption by the sample but cannot completely alleviate the problem. Also, at a high flow rate, the high thermal conductivity gas will increase the heat loss from the furnace causing an increase in the power level necessary to obtain the same temperature.

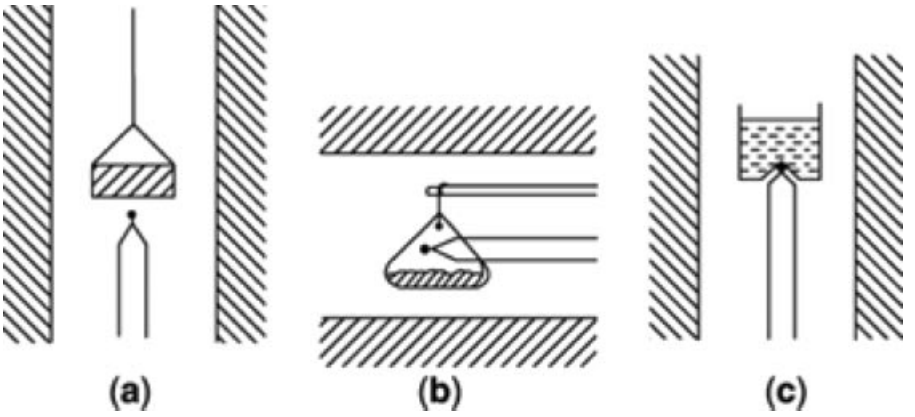

Fig. 15. Possible placements of the thermocouple relative to the sample in TGA (Gallagher, in Ref. 5).

Sartorius-Werke GmbH developed a clever solution (41). Here the balance and the sample chamber are completely separate, linked magnetically with a simple suspension (Fig. 16), thus alleviating the problem of corrosive gases coming in contact with the balance mechanism. A modern version of this "Thermosuspension balance" is available from Netzsch.

A number of manufacturers supply TGA instruments capable of operation in high vacuum or high pressure. A TGA with a magnetic suspension system is available from Rubotherm (Bochum, Germany). The magnetic suspension separates the high pressure sample environment from the delicate balance. The system can operate up to 1000°C or 450 atm. The readers should note that the pressure and temperature limits cited throughout this article represent the manufacturers' specifications, rather than any practical limits determined and recommended by the editor or the authors. Operation at reduced pressure is particularly valuable for determining the adsorption or absorption characteristics of materials. High pressure instruments may be used for studies of combustion, pyrolysis, catalysis, or nonstoichiometry.

Mass and Temperature Calibrations and Standards.

Calibration of Mass. Calibration of mass is conducted by weighing a standard mass (over 1 μg) at a controlled temperature. Room temperature is preferable, since buoyancy and aerodynamics add to the uncertainty when the experiment is conducted over a wide range of temperatures. Any changes due to these factors go into a blank or background correction.

For experiments over an extended period of time, such minor factors as fluctuations in room heating and air conditioning, exposure to sunlight, drafts, and other sources of temperature, and variable heat transfer from the furnace should be taken into consideration. These factors, along with vibration stability, should be considered when choosing a location for a TGA instrument. Generally, all TGA equipment gives precise data with only infrequent checks of the calibration with a standard mass. The starting mass for a TGA experiment is generally larger than that for DTA/DSC and is in the range of 6–10 mg for pure polymers and around 15 mg for filled or blended polymers.

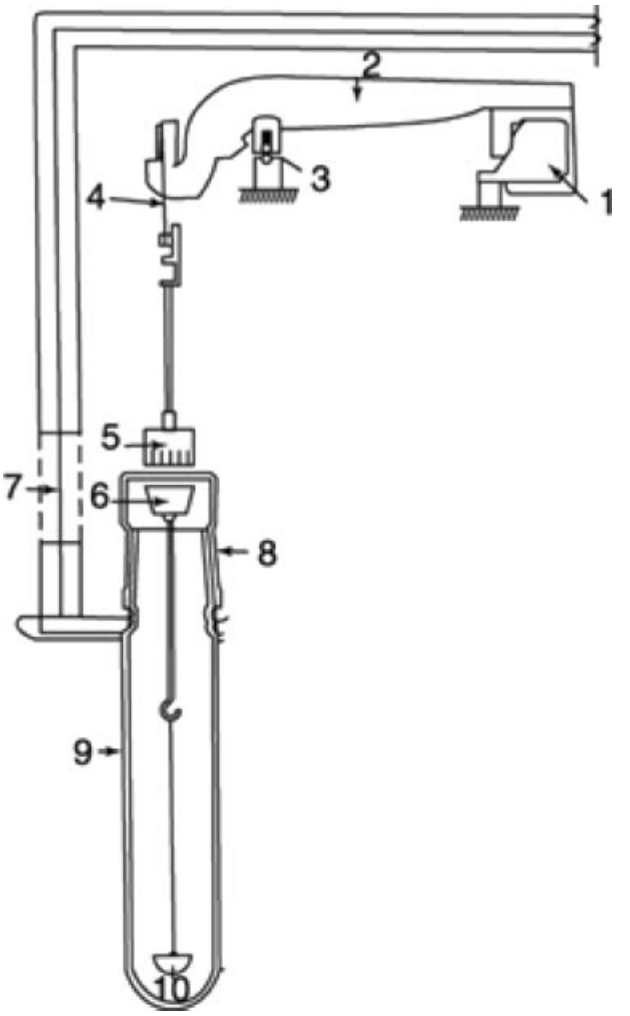

Fig. 16. Sartorius Model 4201 magnetic suspension balance. 1, Magnet and coil; 2, beam; 3, beam fulcrum; 4, suspension ribbon; 5, beam magnet; 6, suspension magnet; 7, observation window; 8, upper glass body; 9, lower glass body; 10, sample pan (41).

For a simple calibration of weight loss, the weight loss of a standard material can be checked under reproducible conditions of sample mass, packing, heating rate, sample holder configuration and atmosphere type, flow, and pressure. The TGA of calcium oxalate monohydrate ($CaC_2O_4 \cdot H_2O$) is often used as a standard for the calibration of mass loss in thermogravimetry. This is due to three well-resolved steps in its thermal decomposition.

The three steps in Figure 17 are (*1*) the loss of H_2O to form anhydrous oxalate, (*2*) the loss of CO to form the carbonate, and (*3*) the loss of CO_2 to form CaO. The observed weight losses, determined from the integral curve (TGA), may be compared with the theoretical values obtained from the known stoichiometry of the process. Potential differences in the sample temperatures indicated by the

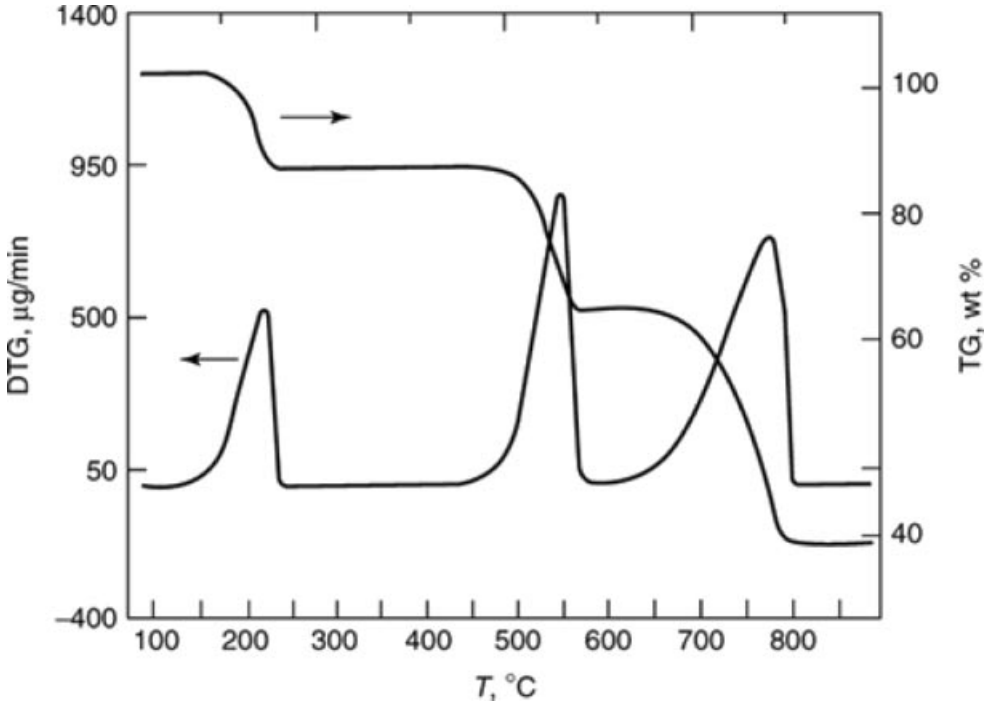

Fig. 17. TGA and DTGA curves for the thermal decomposition of calcium oxalate (CaC_2O_4, H_2O) in argon at 20°C/min (3).

TGA curve can arise when the starting masses differ significantly among the experiments. Plots of weight versus time should reveal the linearity of the heating rate in the range of the experiments. The derivative TGA curve (DTGA), shown in Figure 17, enhances resolution and gives a "fingerprint" of the decomposition process. DTGA curves always should accompany a TGA analysis. Such curves also are important for kinetic studies, since they are related to the actual rate of the reaction. Weight loss is, however, more readily evaluated from the integral curve. There is no international standard method for TGA, because all of the instrumental and experimental variables noted above cannot be fixed for different instruments and different laboratories. However, for a given instrument, standards for mass loss under carefully controlled conditions can be adopted for routine checks of reproducibility.

Temperature Calibration. As mentioned, temperature control and calibration of TGA equipment is more difficult. Not only are the sample and the thermocouple a finite distance apart, so as not to interfere with the weight measurement, but also the heat transfer between sample and oven in TGA is usually across an air or an inert gas gap. In addition, sample masses are often larger than those in DTA/DSC. There may be a large temperature gradient inside the sample. There are also other factors noted in the right-hand side of Table 5 that would affect temperature control.

Wunderlich (5) recommends that the actual sample temperature should be measured by using an external thermocouple in contact with the sample in the

crucible and then running a heating scan. The thermocouple adds additional weight to the balance pan. Therefore, the mass information is lost. Two methods commonly used to measure sample temperature in relation to the sensor temperature are (*1*) magnetic standards and (*2*) "fusible links." They have been found to work equally well in a comparison study (42).

In the "fusible link" method a small weight hangs at the end of a metal link. The link takes the normal position of the sample. When the link melts, there is a sharp break in the TGA curve. The temperature at the break point is the T_m of the metal, which should be known beforehand. The second method uses the Curie temperature (T_c) of a ferromagnetic material. A pellet of the reference material is placed in the field of a magnet, placed outside the balance. Because of the effect of the magnet, the actual weight measured by the thermobalance is either less or more than the true weight. As the Curie temperature of the standard material is reached, the magnetic effect vanishes and an equivalent increase or decrease of weight is recorded. A nice feature of using magnetic materials is that there is no interaction between different samples and multimetal sandwiches of magnetic standards can be used in a single experiment to obtain several calibration points. Representative curves for a series of magnetic standards are shown in Figure 18 (43). The heating and flow rates used for calibration should be the same as those chosen for subsequent experiments.

A series of magnetic reference metals are available from NIST. Gallagher (5) lists the selected metals and alloys for potential use as magnetic standards. The ICTAC Committee for Standardization has conducted an extensive round-robin study to establish the calibration procedures and recommended temperatures for various standards (44). An inert gas (N_2, Ar) whose thermal conductivity approximates that of the gas to be used in subsequent experiments should be used instead of oxygen, since these metals are liable to be oxidized. An ASTM method describes the practice for evaluating the temperature scale for thermogravimetry (ASTM E914). A recent proposal (Ref. 5, p. 48) is to use the ignition temperature of selected organometallic compounds for temperature calibration. There is an abrupt weight loss at the ignition temperature of these compounds. The temperature of ignition can be previously calibrated using DSC or DTA, which again has been calibrated using metallic standards to conform to the International Temperature Scale. ICTAC recommendations should be followed in reporting TGA data.

The present trend in thermal analysis is toward smaller samples and furnaces, as well as faster heating and cooling rates in order to obtain minimum turnaround times. As these trends continue, temperature calibration will remain a major consideration and probably increase in importance. For recommendations on the presentation of data, the reader should consult ICTA recommendations (2).

Application of TGA/DTGA in Polymers

The principal applications of TGA/DTGA in polymers are (*1*) determination of the thermal stability of polymers, (*2*) compositional analysis, and (*3*) identification of polymers from their decomposition pattern. Also, TGA curves are used to determine the kinetics of thermal decomposition of polymers and the kinetics of cure

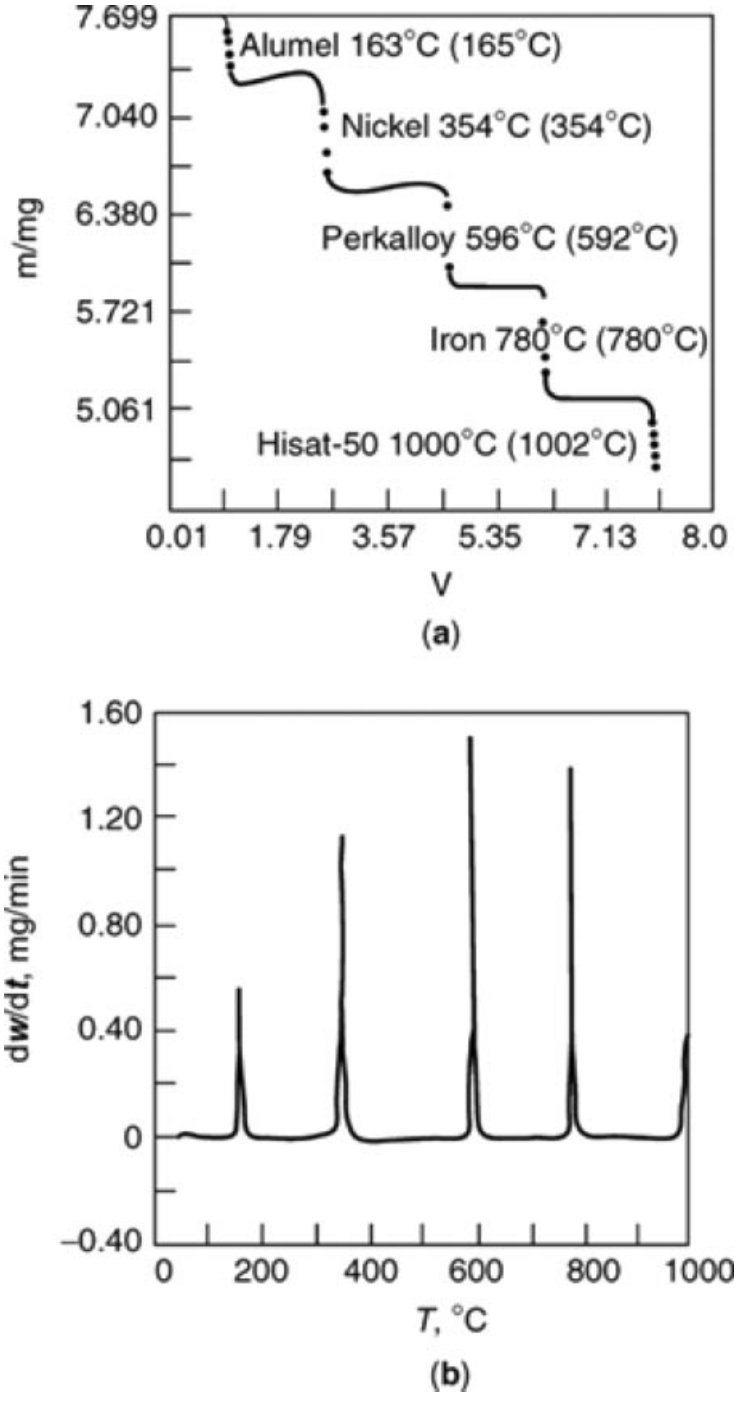

Fig. 18. Representative curves for a series of magnetic standards: (**a**) Thermomagnetometry (TM) curves using Perkin-Elmer TGS-1 and their materials and recommended temperatures. The values in parentheses were the observed values prior to calibration. (**b**) DTM (derivative) curves after conversion of the sensor voltage to actual temperature (43).

where weight loss accompanies the cure reaction (eg, as in condensation polymerizations, such as cure of phenolic resins). The latter will not be discussed here.

Thermal Stability of Polymers. Thermogravimetry has become a general method for comparing the thermal stability of polymers. In comparing thermal stability, it should be remembered that TGA measurements only record the loss of volatile fragments of polymers, caused by decomposition. TGA/DTGA cannot detect any chemical changes or degradation of properties caused by cross-linking. Examples of Degradation (qv) involving cross-linking without weight loss are the degradation of styrene-*co*-butadiene rubber (SBR) and butadiene rubber (BR) or their blends, although at high temperature they decompose into fragments with loss of weight that can be detected by TGA/DTGA. Small sample sizes and low heating rates prevent any dramatic influence of reaction heat that accumulates faster at high heating rates. However, there are some exceptions when small sample size and low heating rate do not yield satisfactory results.

A strict comparison of thermal stability can only be made when the samples are evaluated under identical conditions. Figure 19 shows an example of the stability determination of poly(vinyl chloride) (PVC) and polystyrene (PS) and a

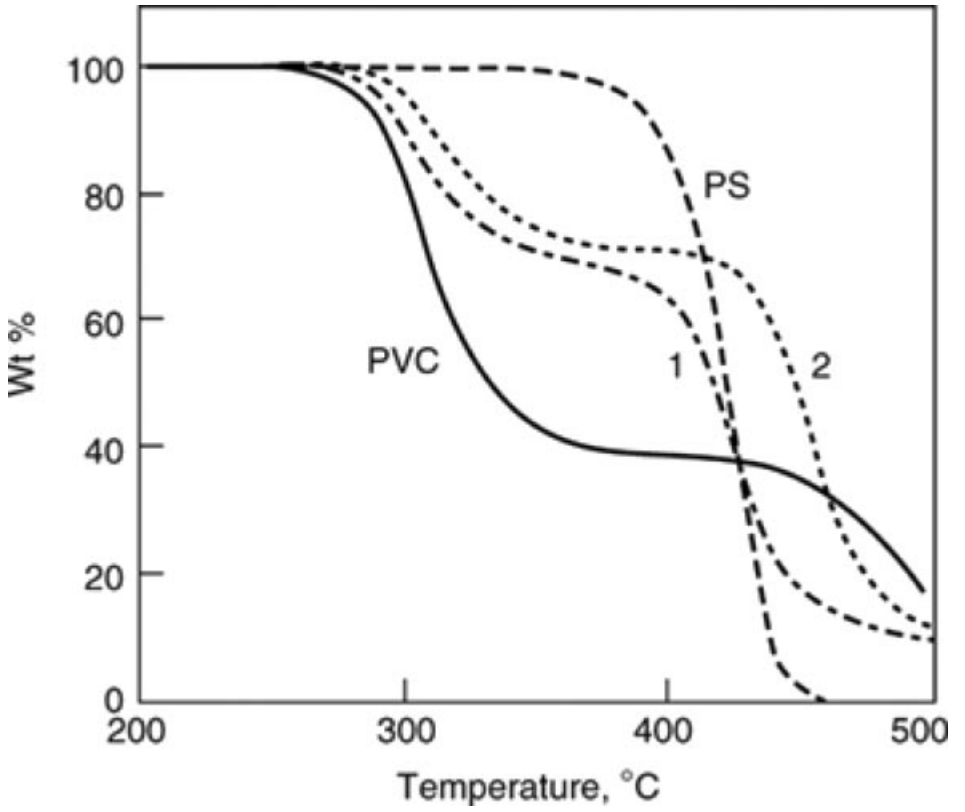

Fig. 19. TGA curves for PVC and PS films for 1:1 (by weight) blend of PVC and PS: 1, predicted behavior for the blend based upon the PVC and PS curves; 2, behavior observed experimentally for the blend (45).

50:50 blend of the two polymers by weight (45). The two inside curves are for (*1*) the predicted behavior for the blend, based on the neat PVC and PS curves, and (*2*) the actual experimental curve for the blend. Under thermal decomposition conditions, there is some possibility that any of the components or their degradation products can interact with one another causing either (*1*) greater stability for the blend, (*2*) less stability for the blend, or (*3*) no change in stability. The case of PVC and PS seems to be one where the blend is more stable than the individual pure polymers (Fig. 19). The shift of curve 2 to higher temperatures as compared to curve 1 indicates that some interaction between the components is taking place leading to mutual stabilization. This may be due to reducing the kinetic chain length (and rate) for dehydrohalogenation of HCl in the PVC component. It will also be dependent on the degree of mixing of PVC and PS in the blend. Examples of polymer blends that are less stable than the pure polymers, to name a few, are PVC/PMMA poly(methyl methacrylate) and (PVC)/PVA poly(vinyl acetate). PS and PMMA blends show no evidence of interaction; thus the thermal stability of their blends neither increases nor decreases.

Compositional Analysis of TGA/DTGA.

Copolymers. If different segments of the copolymer chain have different thermal stabilities, it is possible to quantitatively analyze certain polymers by TGA. The classical example is the polyethylene-*co*-(vinyl acetate) polymer or EVA. When EVA is thermally degraded in an inert atmosphere, the first product emitted at about 350°C is acetic acid. The rest of the hydrocarbon chain decomposes at a higher temperature (430°C). This is shown in Figure 20 (Ref. 5, p. 870). The weight loss at 350°C corresponds to the amount of vinyl acetate present in the copolymer.

The amount of vinyl acetate can be calculated from the weight loss as follows:

$$\%\text{vinyl acetate} = \%\text{weight loss} \times (1.43) \tag{3}$$

Rubber Vulcanizates. One of the common uses of TGA/DTGA analysis in the rubber industry is to determine the composition of a rubber formulation, either cured or uncured. The general TGA/DTGA procedure for elastomer vulcanizate analysis is illustrated in Figure 21 (46). The standard test method for compositional analysis by TGA (47) provides a method for determining four arbitrarily defined components: (*1*) highly volatile matter, (*2*) matter of medium volatility, (*3*) combustible material, and (*4*) ash, left after oxidative decomposition of inorganic components. The materials fitting this description in the case of elastomer vulcanizates are depicted in Figure 21 and described in Table 6. The definition of each component is based on its relative volatility. The success of the method depends on each component having a different thermal stability range in an inert atmosphere and in an oxidizing atmosphere. The standard method for compositional analysis by thermogravimetry is described in ASTM E1131.

The analysis is performed by first taring the microbalance and then introducing the sample. The initial weight is set after establishing an inert atmosphere. Next the desired heating program is started and the specimen weight continuously monitored in the recorder. The ordinate setting can be either weight in milligrams or percentage of the original sample weight. As noted in Table 6, the first weight loss (~150–350°C) is due to highly volatile matter. For a vulcanized rubber, this

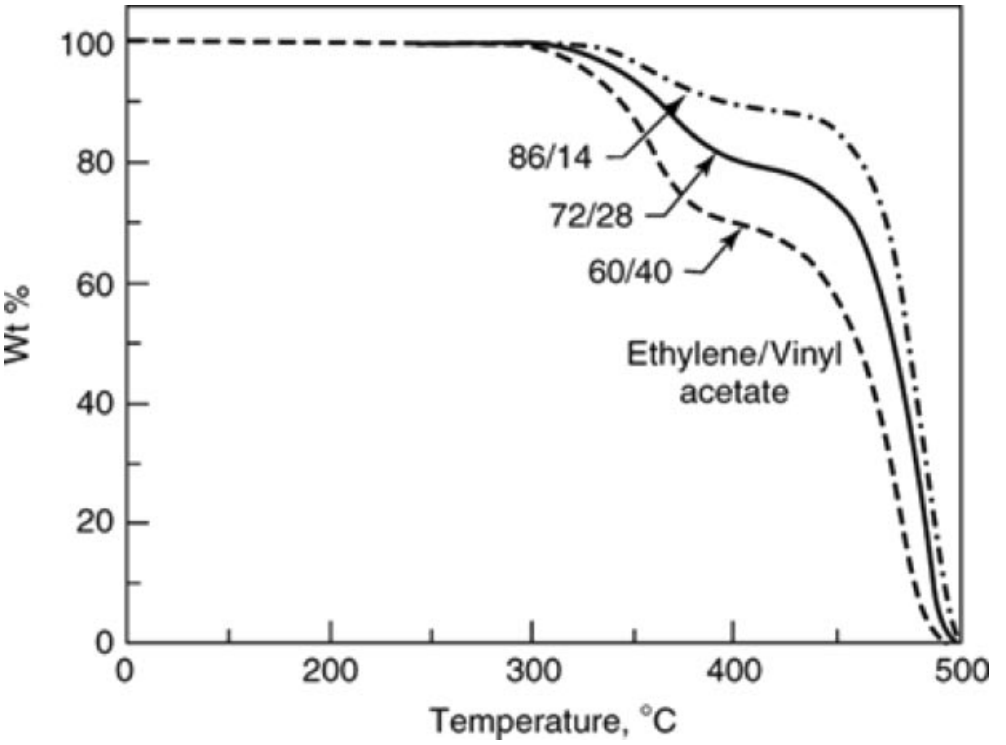

Fig. 20. Weight loss curves of several ethylene/vinyl acetate copolymers. The ethylene/vinyl acetate composition is shown next to each curve. The heating rate was 10°C/min (Hale and Bair, in Ref. 5).

generally consists of the amount of oil added as a processing agent and a small amount (∼1–2%) of decomposed fragments of the vulcanizing agent (sulfur peroxide), vulcanization accelerators and antioxidants, emulsifiers, etc. Moisture, if present, evolves at a lower temperature. The second fraction (∼350–550 or 600°C) represents the amount of polymer decomposed. After the plateau of the second or "medium volatile matter" weight loss has been established (∼600°C), the atmosphere is changed from inert to oxidative.

In the case of an elastomer vulcanizate that contains Carbon Black (qv), the sample is first cooled to ∼300 to 400°C before changing to air or oxygen. This is to ensure that the initial oxidation atmosphere is at a lower temperature than the carbon black oxidation temperature. The modified procedure often permits the identification of carbon blacks from the weight-loss profile (48). The combustible material refers to oxidizable material (eg, carbon black, graphite), which is not volatile in an inert atmosphere at temperatures up to 750°C. In the absence of nonblack fillers, the ash is mostly composed of zinc oxide, which is a component in most vulcanization recopies. The analysis is complete when a weight-loss plateau, corresponding to the residual sample mass, is established. Several reviewers have stressed the use of smaller sample sizes (for better resolution, lower heating rate) and an inert atmosphere of high thermal conductivity (eg, helium). In using small

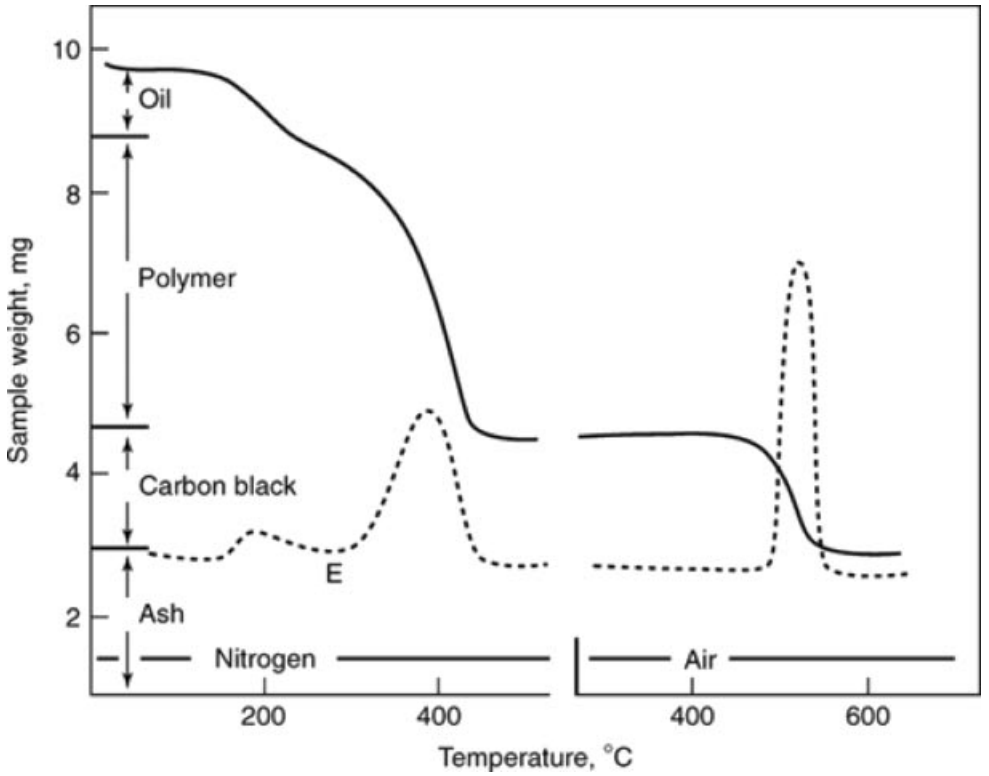

Fig. 21. Schematic TGA and DTGA curve for compositional analysis of a rubber vulcanizate (46).

Table 6. Definitions of Different Fractions in Thermogravimetric Analysis of Elastomers[a]

Highly volatile matter	Refers to moisture, polymer, diluent, oil, plasticizer, emulsifiers (eg, in styrene–butadiene rubbers), curatives (sulfur, accelerator), antioxidants, antiozonants, and other low boiling components (approx. 300°C or lower)
Medium volatile matter	Refers to medium volatility material such as processing oil, processing aid, elastomer, resin (used as curing agent), etc. In general, these materials degrade at 300 to 750°C.
Combustible material	Refers to oxidizable material, not volatile (in the unoxidized form) at 750°C or some stipulated temperature dependent on the material (eg, carbon black, graphite, etc).
Ash	Refers to nonvolatile residues in an oxidizing atmosphere which may include metallic oxides, filler or inert reinforcing material (eg silica). In the absence of nonblack fillers, the ash is composed of zinc oxide which is a component in most vulcanizates. A small amount of ash (<1%) may be due to elastomer residue.

[a]From Ref. 47.

samples it may be useful to characterize multiples to ensure that the results are representative of bulk material. The residue may be analyzed to determine the nature and amount of inorganic components by using X-ray fluorescence.

Factors that influence the accuracy of the component analysis procedure are the following. The above discussion assumes that there is no high boiling oil present as a processing aid that can interfere with detecting clearly the initial breakdown point of the polymer and no mineral filler (which may have water of crystallization or other constituents that escape around the temperature of the "highly volatile matter"). Also, it is important to note that the determination of carbon black by the suggested method is accurate only for hydrocarbon elastomers, which degrade cleanly in an inert atmosphere at temperatures below 500°C Elastomers with a heteroatom in the molecule leave a char residue, which volatilizes along with carbon black during the oxidation stage. Resin curing agents also will interfere with polymer determination. Graphite, if present, can be determined by oxidation at a higher temperature (~800°C). These and numerous other considerations, as well as possible remedies, have been discussed in considerable detail by Sircar (49).

Despite the above-cited difficulties, TGA-DTGA analysis remains a useful tool for the compositional analysis of rubber vulcanizates. It is a straightforward, reasonably accurate process and is much faster than classical extraction methods. Also, it is an excellent quality control tool for determining possible weighing errors and reproducibility for elastomer batches in a production setting. Thus, TGA-DTGA is the method of choice for compositional determinations for cured and uncured elastomer compounds, as well as for many other polymer compositions.

Identification of Elastomers. Sircar and co-workers (Ref. 5, p. 1278) developed a unique and very useful DSC and TGA/DTGA protocol for identifying elastomers. It involves using the measurement of T_g and the degradation patterns for many elastomers and their blends in both nitrogen and oxygen. On the basis of this, they classified elastomers into three principal groups according to their degradation characteristics in nitrogen: (*1*) those exhibiting an endotherm (eg, polyethylene, EPDM, butyl rubber); (*2*) those exhibiting an exotherm (eg, SBR, BR, NBR); and (*3*) those exhibiting multiple peaks, both exotherm and endotherm (eg, NR, IR). For details on using the protocol, the reader is referred to the above reference.

Controlled Rate Thermogravimetry. Gallagher (5) describes controlled rate thermal analysis. In the case of mass loss, the rate of change of temperature is controlled by a preset rate of weight loss or change in partial pressure. Gallagher describes three different modes of controlled rate TGA and also dynamic TGA with isothermal rest periods. In the first mode, the operator chooses a fixed rate of weight loss (eg, X%/min) and the temperature programmer maintains that rate of change, sometimes by both heating and cooling at different times. The second mode is similar to the first mode, except that the sample is always dynamically heated. TA Instruments, Inc. (50) markets a commercial software package called "Hi-Res TGA." It operates so that the heating rate approaches a preset maximum during periods of no mass loss. As the mass change is sensed, however, the heating rate automatically slows depending upon two parameters set by the operator (resolution and sensitivity). The aim is to improve resolution while minimizing the total time for the experiment. The third controlled rate option is called stepwise

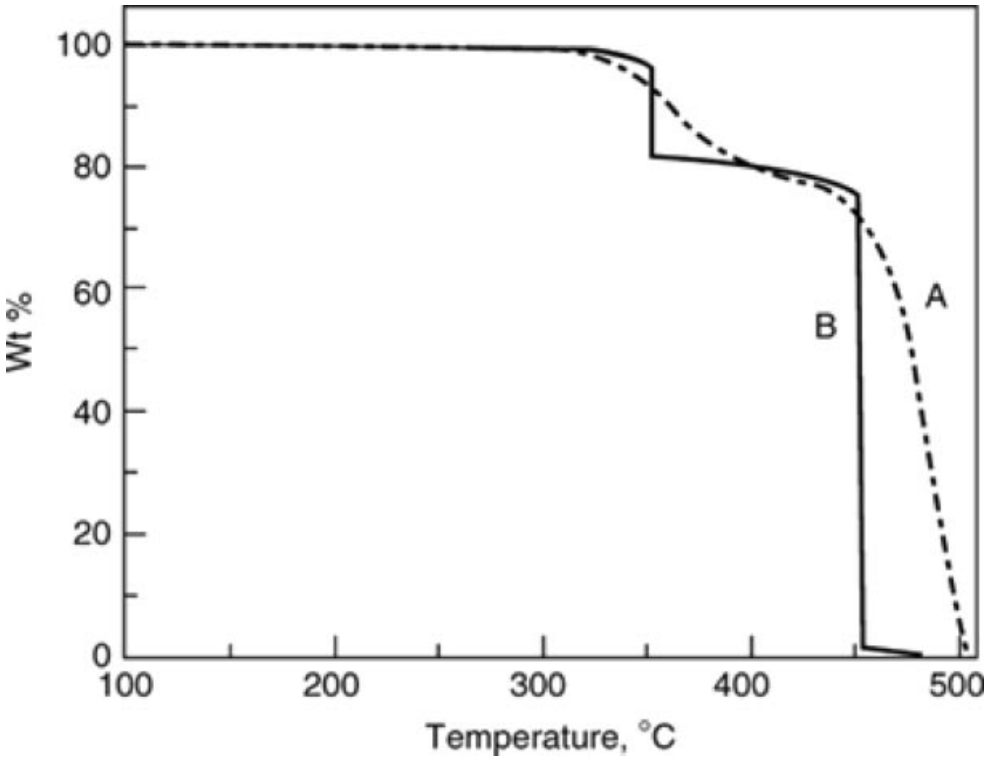

Fig. 22. Weight loss curves for a 72:28 ethylene/vinyl acetate copolymer. Curve **A** was obtained at 10°C/min rate of heating. Curve **B** was obtained using Autostepwise software, which automatically slows down the heating rate when a sharp change in weight loss is detected, and increases the rate when little change in weight loss is observed (from Hale and Bair, in Ref. 5).

(or autostepwise) isothermal measurement and involves one or more isothermal steps as the weight loss reaches a threshold level. The necessary software and instrumentation are available through Seiko Instruments (currently marketed by Mettler-Toledo) (51).

An example of autostepwise TGA shows an improvement in resolution for weight-loss curves of EVA samples. Without the autostepwise rate control it is evident (Fig. 20) that the end point for the acetic acid evolution is not distinct. The acetic acid weight loss curves are not completely level before the residual polymer fraction starts decomposing. As shown in Figure 22, the resolution can be much improved by using the High-Res or autostepwise TGA technique enabling more quantitative information. The figure shows an initial weight loss of 18.4%, corresponding to a vinyl acetate content of 26.3% versus the known value (supplied by the manufacturer) of 28%.

Simultaneous or Combined Techniques. Many of the simultaneous or combined techniques that include TGA as a component have been described while discussing DSC/DTA techniques. Others with TGA as a component are TGA-EGA or EGD, TGA-MS, TGA-FTIR, TGA-GC-MS, TGA-MS-MS, and TGA-APCI-MS. APCI stands for atmospheric pressure chemical ionization. More details are

available in the reference by Gallagher (5). The other acronyms, not mentioned in Table 1, are as follows: mass spectrometry (MS), Fourier transform infrared spectrometry (FTIR).

Thermomechanical Analysis

Thermomechanical analysis (TMA) measures the deformation of a material contacted by a mechanical probe, as a function of a controlled temperature program, or time at constant temperature. TMA experiments are generally conducted under static loading with a variety of probe configurations in expansion, compression, penetration, tension, or flexure. In addition, various attachments are available to allow the instrument to operate in special modes, such as stress relaxation, creep, tensile loading of films and fibers, flexural loading, parallel-plate rheometry, and volume dilatometry. The type of probe used determines the mode of operation of the instrument, the manner in which stress is applied to the sample, and the amount of that stress.

TMA Instrumentation. For accurate measurements of the change in dimension of small samples, the device generally used by most manufacturers of TMA is called a linear voltage differential transformer (LVDT). This device, as configured in a Perkin-Elmer TMA module, is shown in Figure 23. For distinguishing between expansion and contraction, the sign of the output voltage changes with the direction of motion. The device can readily detect changes of the order of 0.1 μm. Testing for linearity of the range of output voltage of an LVDT (mV/μm) is frequently performed by measuring gauge blocks of a sheet metal. For accurate work, it is necessary to provide compensation for the dependence of the output on temperature. The instrument shown in Figure 23 is typical of a single rod module, based on LVDT. Contemporary TMA instruments use closed loop electromagnetic circuits to accomplish constant loading and positioning of the probe as compared to older instruments where mechanical placement of the weights was used. The instrument in Figure 23 is reported to be capable of detecting changes as small as 3 nm and can operate in the temperature range -170 to 1000°C. The resolution is around 0.1 μm, when the instrument is operated carefully over a range of temperatures. Temperature-sensitive components such as the LVDT generally are isolated from the high temperature environment of the sample.

Optical instruments that use laser interferometry have much greater sensitivity with an accuracy of 0.02 μm or 1/32nd of the laser wavelength used. The surfaces for the sample and the reference specimens need to be polished for this kind of accuracy. Also, the high temperature limit is governed by the loss of reflection from the mirrored surfaces and is around 700°C, as compared to a maximum of 2000°C for the LVDT-based instruments.

For determining the coefficient of linear expansion, it is a common practice to generate $\Delta L/L_0$ curves with and without the sample. The two curves are subsequently subtracted to compensate for the expansion of the sample holder. For convenience, it is best to use a standard reference material, eg, an isotropic metal such as aluminum or platinum (52), as the sample holder. In Figure 24, we see that, compared to other isotropic materials, quartz (fused silica) has a very low thermal expansion coefficient (0.6×10^{-6}/°C). It is also easily formed. If the upper

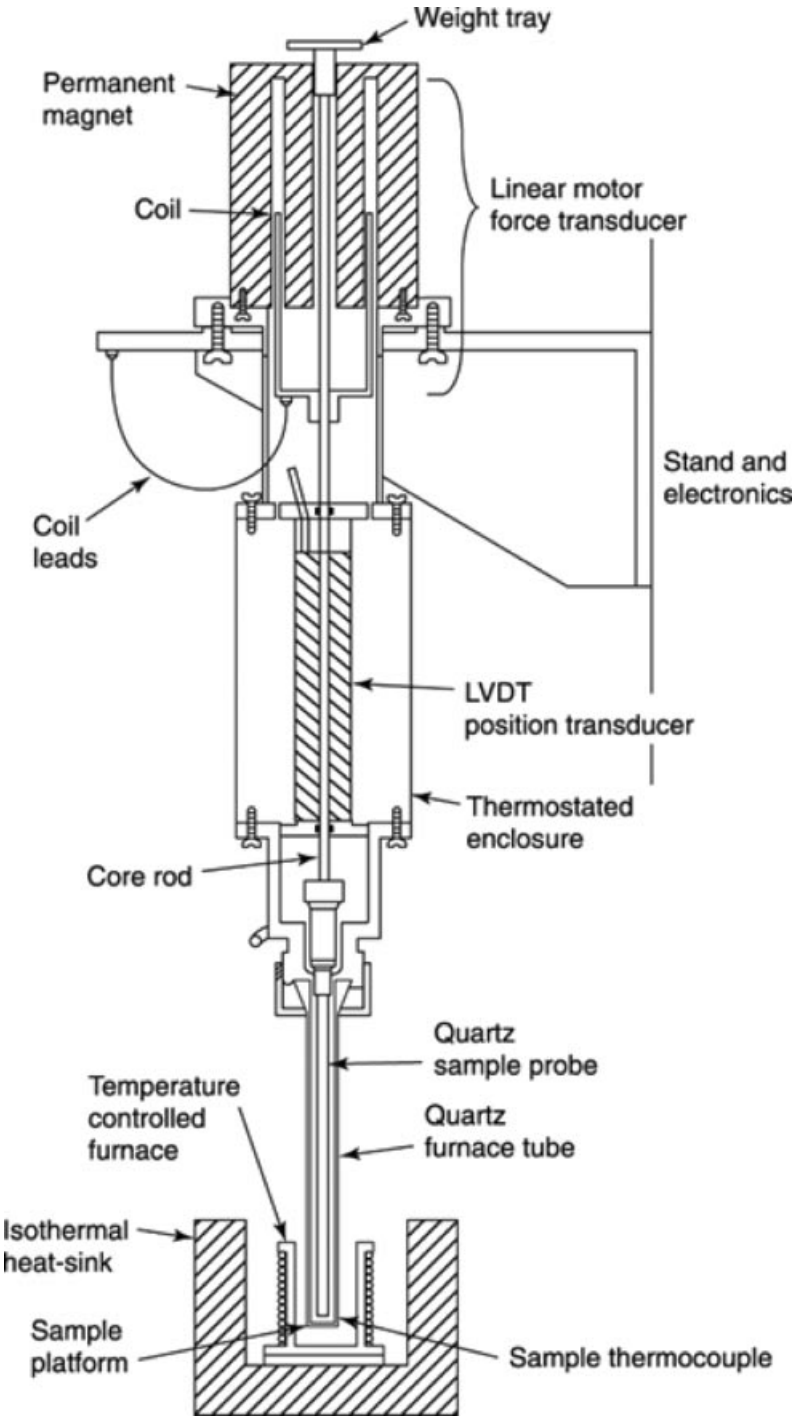

Fig. 23. Schematic representation of a typical thermomechanical analyzer (TMA), Perkin-Elmer Model TMA 7, based on an LVDT (3).

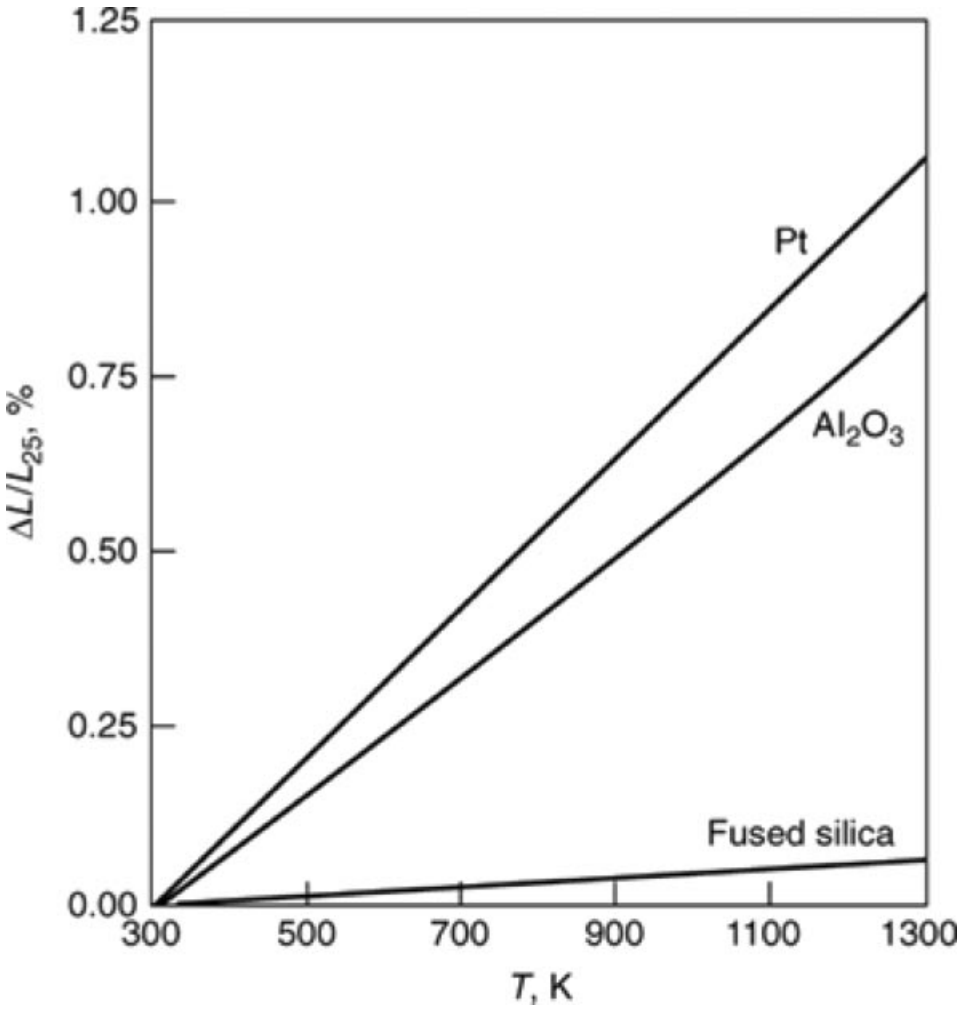

Fig. 24. TMA thermal expansion curves for platinum, alumina, and fused quartz (52).

temperature limit ($<1100^{\circ}$C) is acceptable, then use of a quartz sample holder may permit ignoring the small correction for the linear thermal expansion of the sample holder, with very little effect on accuracy. If the upper temperature limit is over 1100°C, a high temperature material such as alumina or platinum is the material of choice and the correction is substantial. Another way to reduce the correction is to use the instrument in a differential fashion. Both the optical and the LVDT instruments can be used in this fashion with the reference (a standard material) pushrod connected to the coil and the sample rod to the core. To obtain the correction accurately, the sample and the reference should have the same length. It is also necessary to maintain thermal equilibrium by keeping the heating and cooling rate low. This also avoids a thermal gradient inside the larger-sized samples typically used for TMA. It is necessary to allow sufficient time to equilibrate if programming several isothermal steps is the temperature profile followed.

A temperature calibration procedure for TMA has been proposed (53–55) and subsequently included as an ASTM method (Test Method for Temperature Calibration of Thermomechanical Analyzers, E1363-90). It uses a penetration probe and the melting temperature of one or more standard materials. Pure metals with sharp melting points are the standards often used. An open DSC pan may be used to contain the calibrant material. Another potential material would be the selected shape memory alloy, reported to be reproducible to $\pm 1^{\circ}$C (56). Several reviews on temperature calibration for TMA have been published based on ASTM efforts in this area (54,55). Sircar (26) suggests that, when used for elastomer evaluation, temperature calibration for TMA should be conducted with low melting liquids as in DSC. For calibration of the expansion, one manufacturer's manual (TA Instruments) recommends aluminum for calibrating the linear expansion parameter. Other calibration standards suggested for the linear coefficient of thermal expansion (CTE) are lead (57) and copper (58).

Sample Preparation and Procedure. Sample preparation for CTE measurement is somewhat more rigorous for TMA than for either DSC or TGA. Samples with flat parallel faces ($\sim$7 mm^2 $\times$ 1 to 2.5 mm in thickness) may be used. The larger the sample thickness, the greater will be the possibility of thermal gradients developing within the sample. ASTM D696 describes a recommended procedure for determining the coefficient of linear expansion of plastics. A general test method for solids (Test Method for Linear Expansion of Solid Materials by Thermomechanical Analysis, E831-86) is also available. Not all polymers and, particularly some elastomers, are amenable to TMA study. For example, a flat surface, to allow intimate contact of the sample and the probe, cannot be cut from a gum elastomer of high molecular weight. Maurer (59) has recommended hot pressing, which works for lower molecular weight gum rubbers. Silica powder also has been used to level the surface of gum elastomers (60). For penetration measurements the surface does not need to be smooth.

For Thermosets (qv), a flat surface can be achieved by molding, machining, or melt-pressing the sample. If the sample is punched, the burred edges must be removed or the sample placed burred edge up. Prime (Ref. 5, p. 1447) advises that the sample be conditioned in the TMA apparatus by heating to just above T_g and cooling with the loaded probe in place. This helps in relieving the internal stress, removes thermal history (eg, the effects of physical aging), and allows the sample to conform to the probe. For samples that are not fully cured, care must be taken not to advance the degree of cure while following this procedure.

For T_g studies in elastomers, the ASTM E831-86 procedure must to be modified (26). After the probe is zeroed at room temperature, the sample is placed on the TMA platform and cooled to -120°C under liquid nitrogen purge at 50 mL/min. After equilibration at -120°C for 10 min, a 0.5–1-g weight (10 mN) or equivalent force is placed on the top of the pan. This places the probe in contact with the hardened elastomer sample. The thickness of the sample is measured and the probe zeroed. The sample is ramped at a low rate of heating (2–5°C/min) under 50 mL/min of nitrogen purge from -120°C to 100°C. For presentation of data, the ICTAC recommendations (2) are followed.

The above procedure differs from ASTM E831 in two important ways. First, the weight should be added only after the elastomer sample is rigid (below T_g) to avoid compression; and second, a small weight of only around 0.5 g or less is

necessary to ensure intimate contact. Larger weights (1–3 g, as recommended for plastics by ASTM E831) may again compress the elastomer as it reaches temperatures above T_g. A static weight of 10 g or more or the equivalent force is generally used with a penetration probe.

Probe Configuration for TMA. Typical probe configurations for TMA have been described by Maurer (59) and Earnest (25). Figures 25**a** to 25**e** are from Earnest (25), whereas 25**f** and 25**g** are from Wendlandt (4). The coefficient of linear expansion uses a probe of greater surface area and is operated under negligible load (Fig. 25**a**). A high loading converts it to a compression probe for elastomeric materials and the results differ with load. Figures 25**b**, 25**c**, and 25**f** show various penetration probes. The hemispherical probe can also be used as an expansion probe. Ennis and Williams (61) used the hemispherical probe to determine linear

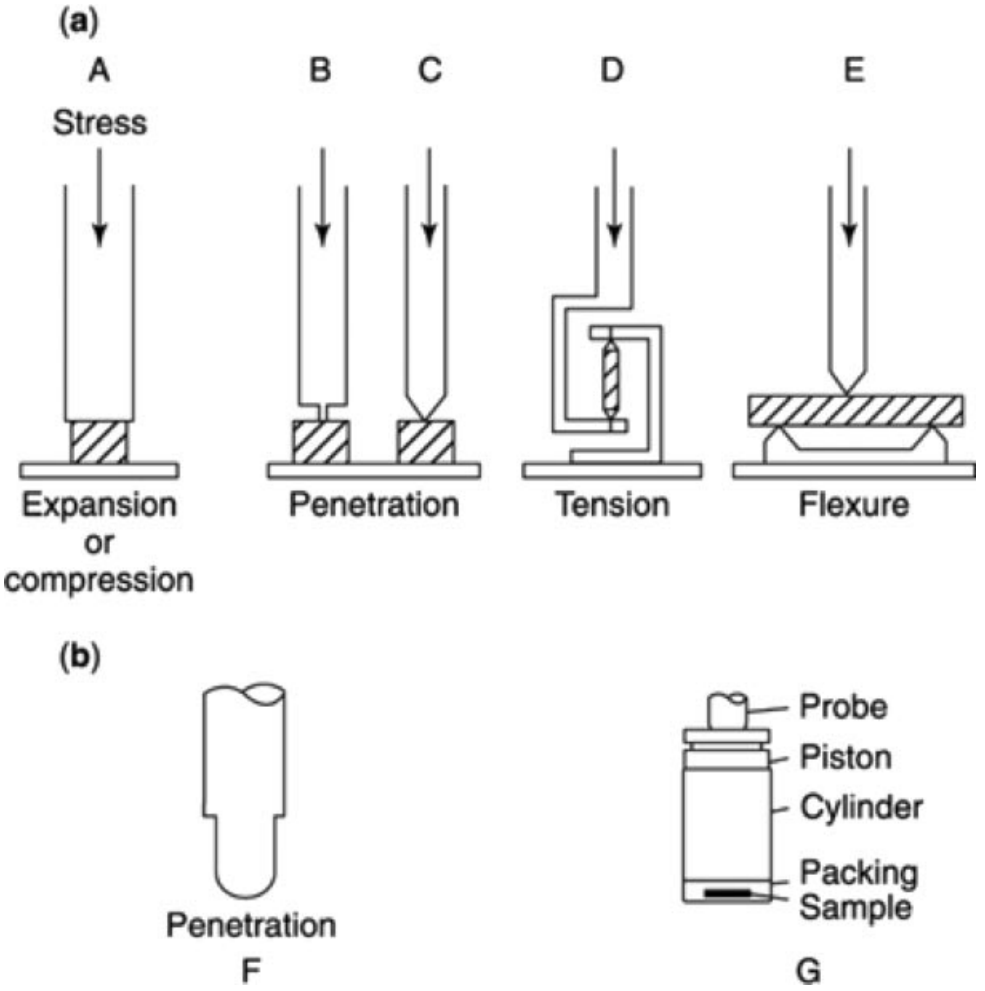

Fig. 25. Examples of probe geometry or operation modes for TMA: (**a**) from Neag (62); two Perkin-Elmer TMA sample probes for penetration and dilatometry (**b**) from Wendlant (4).

expansion of thermosets and claim better accommodation of probe misalignment with this type of probe. Figures 25**d** and 25**e** are for tensile and flexure modes, respectively. For anisotropic materials, the determination of linear expansion does not give the volume expansion by a simple calculation. However, TMA also can be used to determine volume expansion by using a fluid to surround the sample in a cylinder and piston arrangement, as shown in Figure 25**g**. This is similar to a dilatometer. Another method uses a vitreous silica dilatometer (ASTM E228). Special instrumentation has been designed to determine the coefficient of thermal expansion of fibers using TMA (Ref. 5, p. 1974). For "fingerprinting" of fibers, TMA offers more detail than either DSC or DTA. Therefore, TMA is the preferred technique if the study is limited to only a single method.

Derivative TMA. An example illustrating the use of different probe configurations for determining linear expansion in both the glassy and the rubbery states, as well as T_g of chloroprene rubber (neoprene, CR) (62), is presented in Figure 26. Note the use of the derivative signal (DTMA) for both the loaded expansion (penetration) and tension measurements. The derivative plot aids in locating the transitions or relaxations, which are not prominent, and also defines a reproducible transition point in cases where a diffuse transition is encountered. DTMA of tension measurements is a sensitive technique for evaluating polymer blends. Several transitions are reproducibly detected by this method when other modes may fail. The T_{go} values are the glass-transition temperatures reported in the literature. They correspond to the inflection point of the DSC curves (T_{eo}) in Figure 7. T_{gd} is slightly different and corresponds to the peak of the derivative DSC curve (see T_p in Figs. 7 and 8). Sircar (26) determined T_g values for eight elastomers using TMA (expansion and penetration probes), DSC, and DMA. He found that T_g(expansion) and T_g(penetration) have somewhat different values and the latter is closer to that determined by DSC. The differences in the T_g values are due to the differences in the temperature dependence of the different thermal properties being measured by different techniques: specific heat capacity in the case of DSC, linear expansion with the TMA expansion probe, and modulus in the case of the TMA penetration probe.

Illustrative Examples for TMA.

Expansion Mode. Figure 27 (64) illustrates the calculation of the CTE from the slope of the TMA curve of an epoxy printed circuit board and the use of the derivative (DTMA) to directly record the coefficient of linear expansion (α). Thermosetting polymers, especially when highly filled, can absorb moisture from the atmosphere. Moisture acts as a plasticizer and has the effect increasing α and lowering T_g. The process is reversible. While moisture in polar polymers is often tightly bound, desorption may occur on heating during the measurement. This will be discussed at greater length below. In this case the measurement will reflect the sum of thermal expansion and hygroscopic contraction. Purely thermal expansion then can be measured in a second run after the sample has been thoroughly dried.

Penetration Mode. TMA in the penetration mode can be used to evaluate the degree of cure of thermoset materials (64). A large load (typically, 10–100 g or 0.1–1.0 N) is employed for these experiments. The probe measures the softening associated with the large decrease in modulus as the temperature approaches T_g. The softening point correlates well with T_g (65,66). The penetration probe referred to in Figure 28 is a small-radius (0.48 mm) hemispherical probe. The

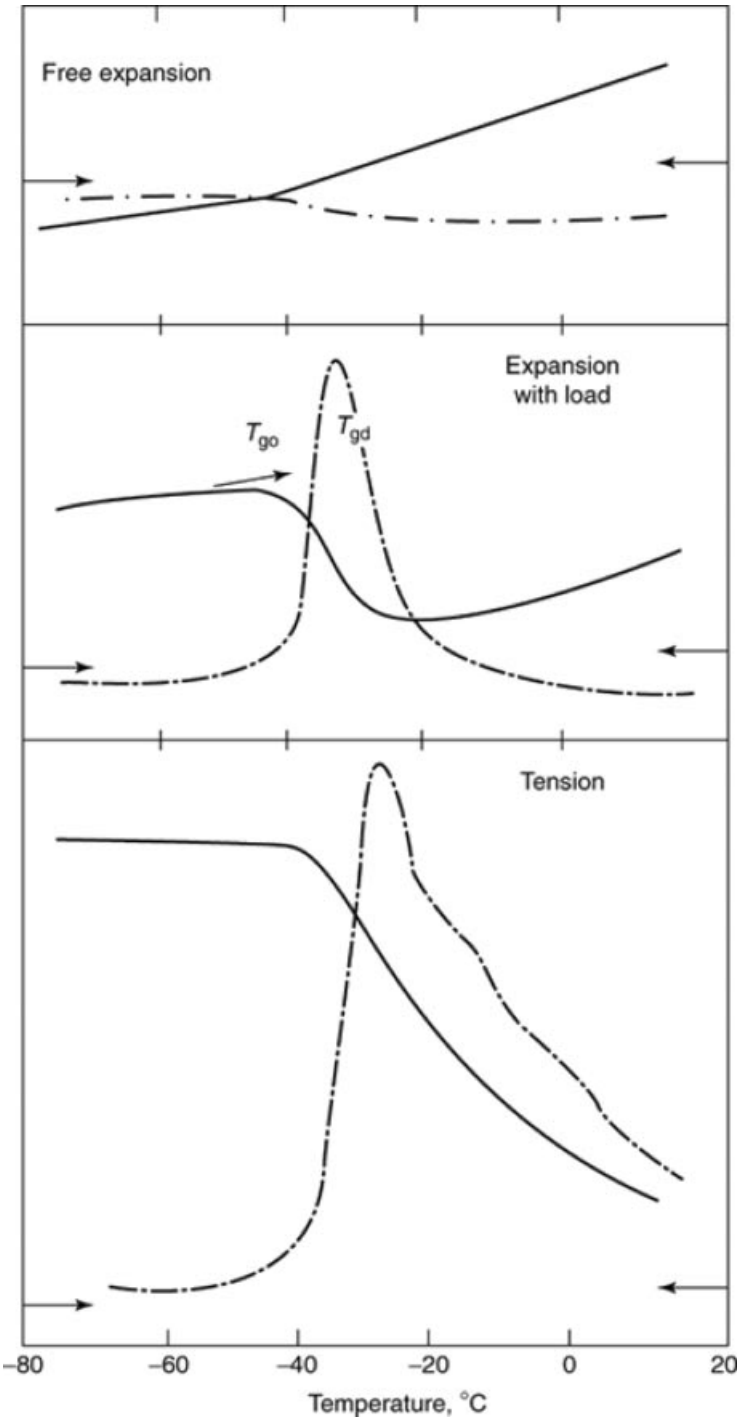

Fig. 26. TMA free expansion, indentation, and tension curves for polychloroprene (neoprene) vulcanizates; 5°C/min, 50-*g* load in indentation and tension.—, Δl versus temperature; -˙-˙-, $d(\Delta l/dT)$ versus temperature (63).

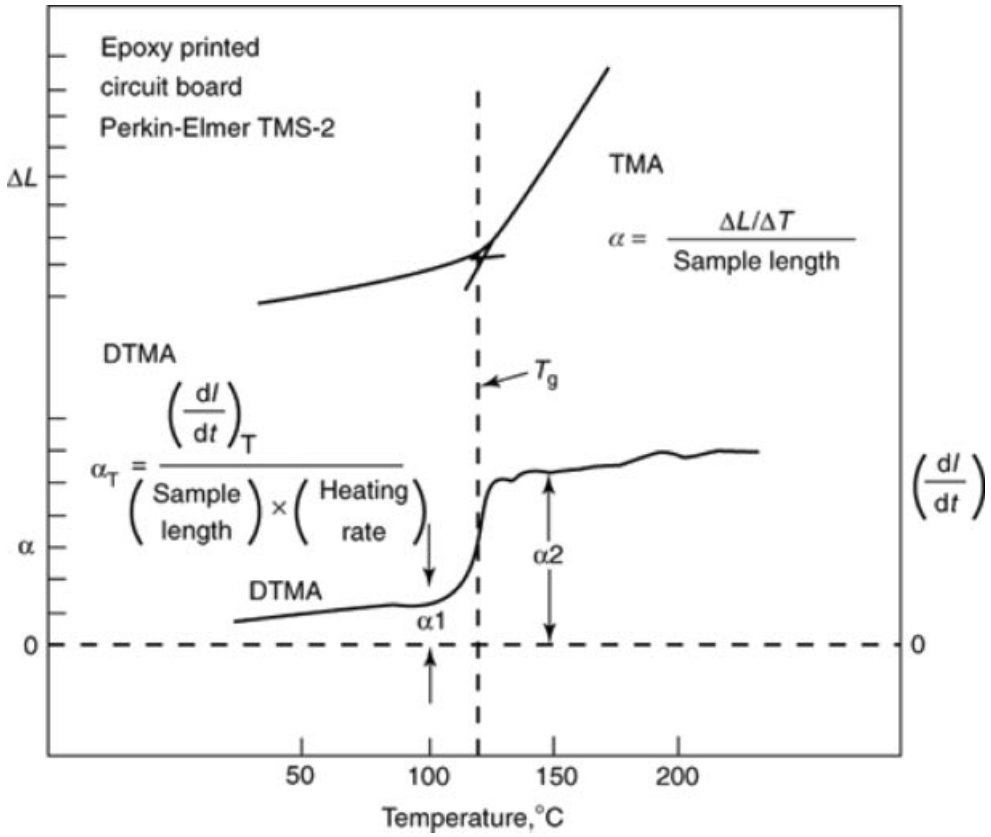

Fig. 27. Linear expansion before and after the glass-transition range using TMA-DTMA. Linear expansion coefficient α from TMA trace requires measurement of the slope; DTMA allows direct recording of α (64).

smaller amount of penetration for sample A indicates that this is more highly cross-linked of the two samples.

Flexure Mode. Figure 29 illustrates TMA data for a two-layer insulation wire coating. Using the knife-edged three-point bend flexure probe (67) accentuates the softening that occurs at the glass-transition temperature. It is remarkable that the softening of both the outer layer of polyester and the inner layer of poly(amide–imide) were easily detected.

Degree of Cure. As shown in Figure 27, the T_g is taken as the extrapolated intersection for the glassy and rubbery state curves. Typically, thermal expansion in the rubbery state is about three times that in the glassy state. The T_g determined by TMA (using either an expansion or penetration probe), is often related to the degree of cure for thermosetting polymers, as was mentioned in the discussion of DSC and illustrated in Figure 9. As the degree of cure increases, T_g increases and the coefficient of linear expansion (α) decreases. Thus, a relationship between T_g and conversion, independent of the temperature of cure, exists for most thermosetting systems. This will be discussed further later in this presentation. Also, a direct proportionality exists between the deflection temperature under load (ASTM D648) and the TMA T_g determined in either the expansion or

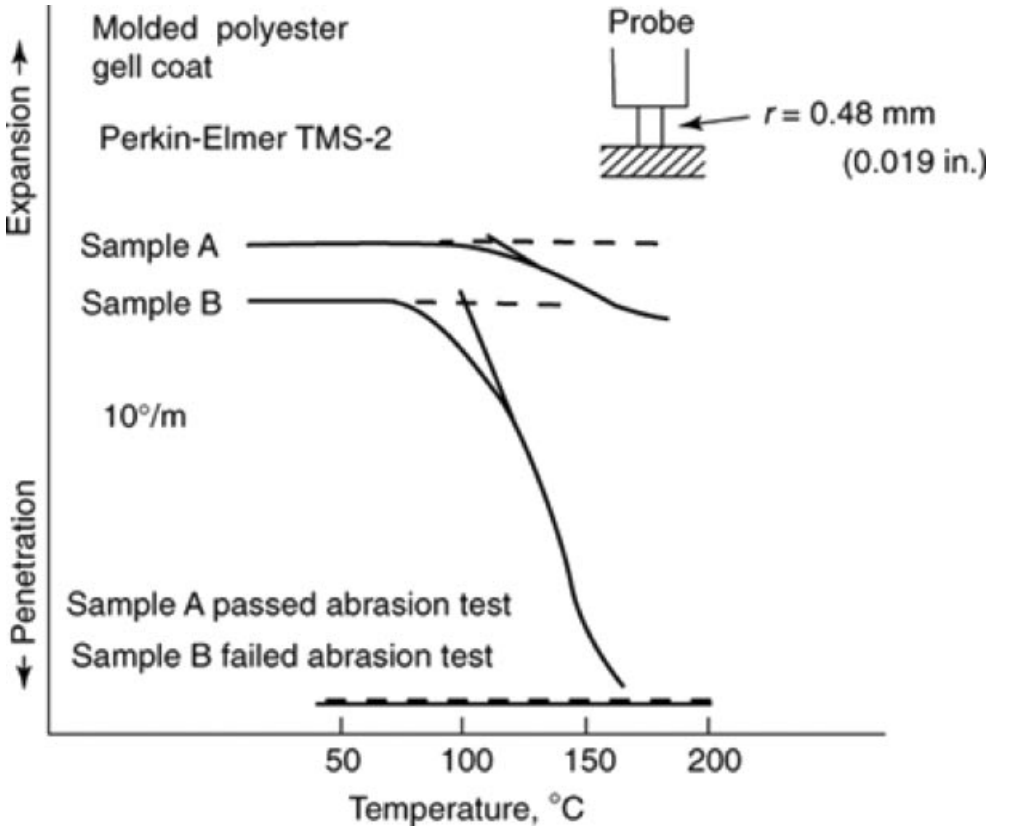

Fig. 28. TMA penetration tests to detect relative states of cure of a thermoset polyester. The more highly cross-linked material softens at a higher temperature, undergoes less penetration, and is more abrasion-resistant. – – – No load; ——— 50-g load (64).

the penetration mode. Sykes and co-workers (68) describe a fixture to measure a TMA heat distortion temperature (HDT) as defined in ASTM D648. For printed circuit board materials, Lamoureux (66) observed a correlation between T_g by TMA expansion and softening temperature determined by TMA penetration (as described above by Sykes and co-workers). For an elastomer compound, Brazier and Nickel (63) found a correlation between T_g, determined by TMA (expansion and penetration mode) and Gehman rigidity temperature.

Unlike thermosetting materials, the T_g of elastomers does not increase significantly with the degree of cure. However, the penetration temperature under a fixed load will increase with cure and can be used as a measure of the degree of cure of an elastomer compound. This is illustrated in Figure 30 (69) and is based on the fact that the elastomer modulus increases with cure.

Dynamic Mechanical and Dielectric Analysis

Dynamic mechanical (DMA) and dielectric analysis (DEA) methods are used both to study molecular relaxation processes in polymers and to determine inherent

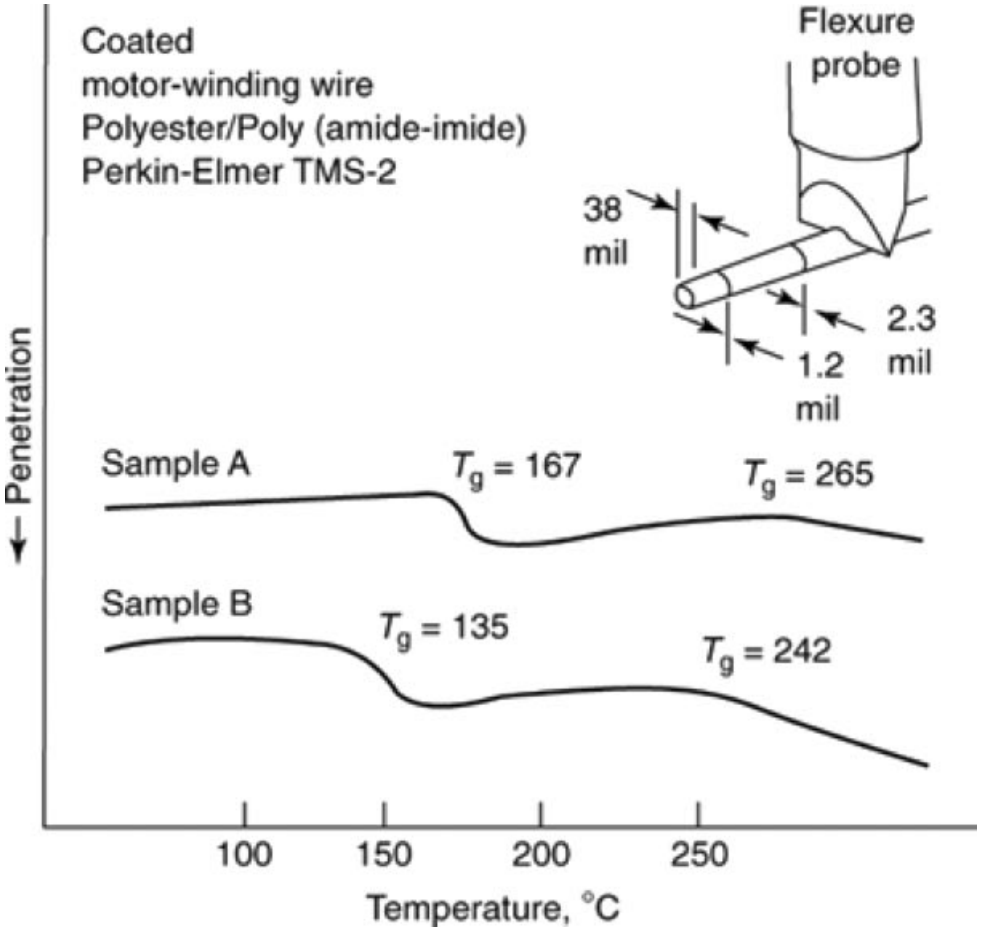

Fig. 29. Use of the TMA knife-edged flexure probe to determine the softening point of both the outer and inner coatings of a motor-winding wire (67).

mechanical and dielectric properties. DMA measurements involve mechanical excitation by imposing a small cyclic deformation to a sample and measuring the stress response. DEA involves imposing a cyclic (or alternating) electric field to a sample and observing the electric polarization or current induced in the sample (see DYNAMIC MECHANICAL ANALYSIS; DIELECTRIC RELAXATION).

DMA methods are widely used by thermal analysts to determine the viscoelastic properties of polymers for a number of purposes (see VISCOELASTICITY). The primary application of these techniques to the study of polymeric solids and melts is well documented. Excellent general discussions covering the subject are provided in References 70–72. Linear Amorphous Polymers (qv) exist in a number of characteristic physical states depending on the time scale and temperature of measurement. These are illustrated in Figure 31 in terms of an arbitrary modulus function and are classified as glassy, leathery, rubbery, rubbery flow, and viscous (73). All linear amorphous polymers exhibit these five physical states when they

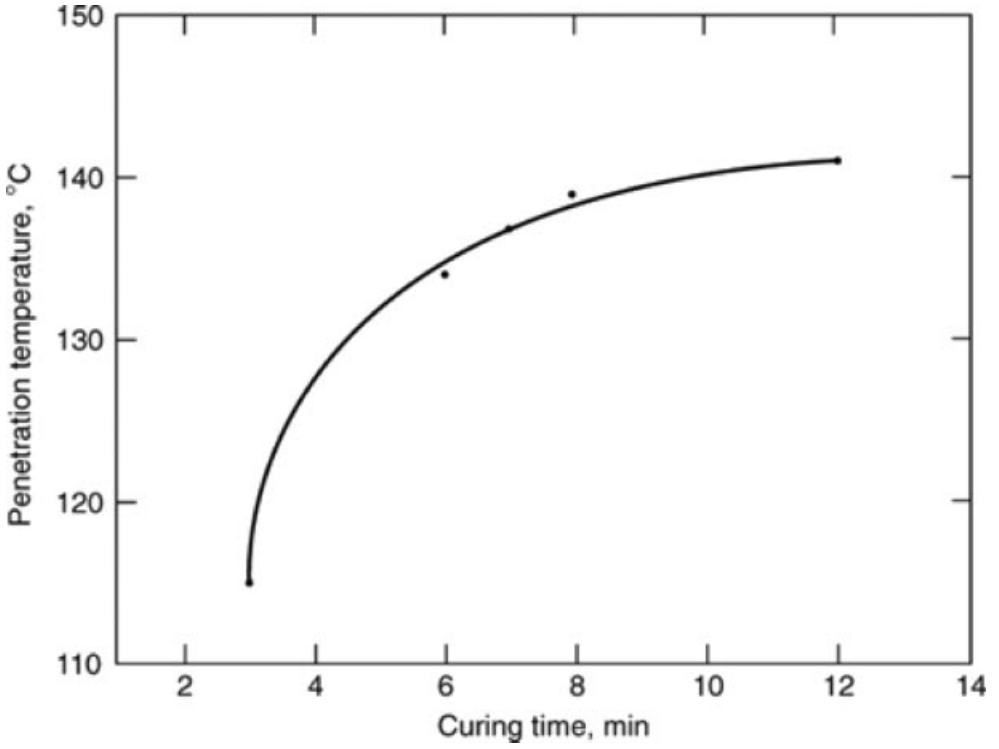

Fig. 30. Evaluation of the degree of cure of an elastomer by TMA penetration probe; sample is a carbon black filled rubber stopper (69).

are observed over a wide range of time or temperature. Polymers that are either cross-linked or crystalline do not exhibit the rubbery flow and viscous responses as illustrated.

Region 2 in Figure 31 corresponds to the Glass Transition (qv), which serves as an important benchmark or corresponding state for viscoelastic response. The particular physical state that the polymer exhibits during a DMA measurement reflects the extent to which the rate of molecular motion or relaxation compares to the test rate at a given temperature. In general, the modulus decreases either with decreasing test rate or increasing temperature. In fact, there is a strong relationship between time and temperature.

In most commercial dynamic mechanical instruments a steady-state alternating strain is applied such that

$$\varepsilon\,(u) = \varepsilon_0\, \mathrm{e}^{i\omega u} \tag{4}$$

is the generalized sinusoidal strain function in complex notation, where ε_0 is the strain amplitude, ω is the radian angular frequency of the sine wave (rad/s), and u is the historical time, $u \leq t$ ($u = 0$ at $t = 0$). An analysis of the cyclic stress and strain provides that the steady-state ratio of stress to strain is (70,73) a complex quantity having both in-phase and out-of-phase components.

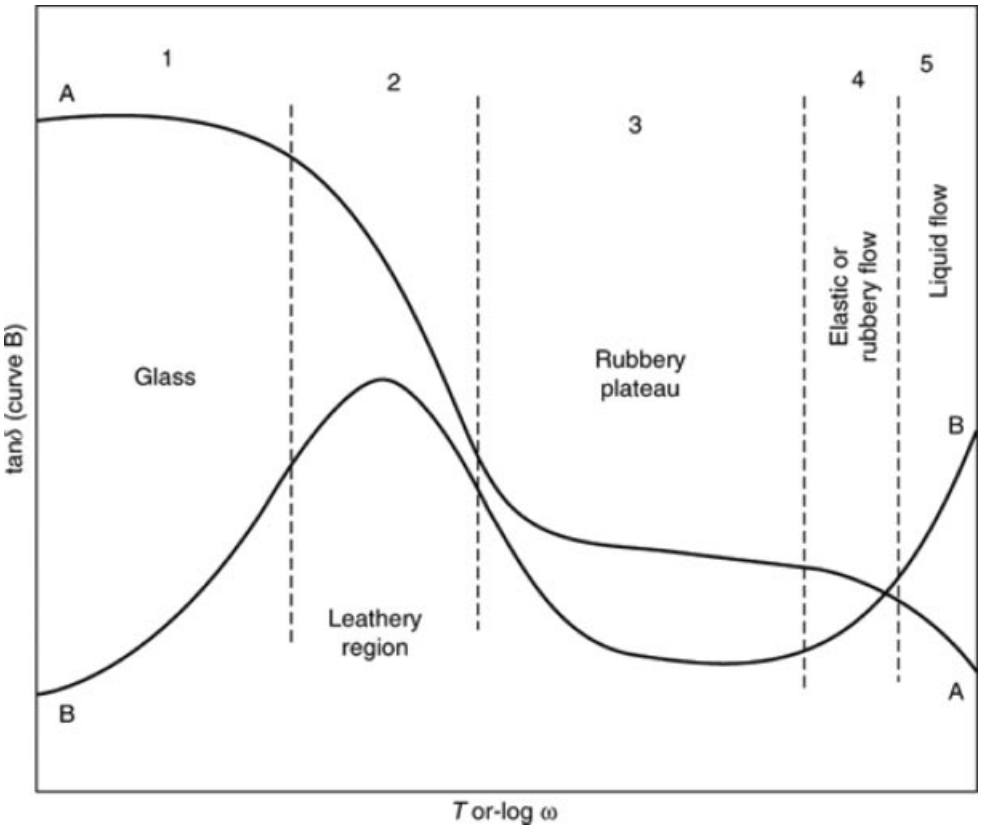

Fig. 31. Diagram of master curves for modulus and loss tangent for a typical amorphous polymer showing five characteristic physical states (73).

$$\frac{\sigma\ (t)}{\varepsilon\ (t)} = E^* = E^{'} + iE^{''} \tag{5}$$

Here $\sigma(t)$ is the stress at time t and ε is the strain; E^* is the complex dynamic mechanical modulus, E' is the ratio of in-phase stress to the applied strain, and E'' is the ratio of out-of-phase stress to strain. The out-of-phase stress leads the strain by 90°. Further, it can be shown that E' is related to the mechanical energy stored per cycle and E'' is related to the energy converted to heat through viscous dissipation. As a result, E' is referred to as the storage modulus and E'' is called the loss modulus. The material loss factor or loss tangent is

$$\tan\delta = E^{''}/E^{'} \tag{6}$$

representing the ratio of energy dissipated to energy stored per cycle of deformation. In a physical sense the storage modulus is related to the stiffness of the material and the loss modulus is reflected in the damping capacity of the material.

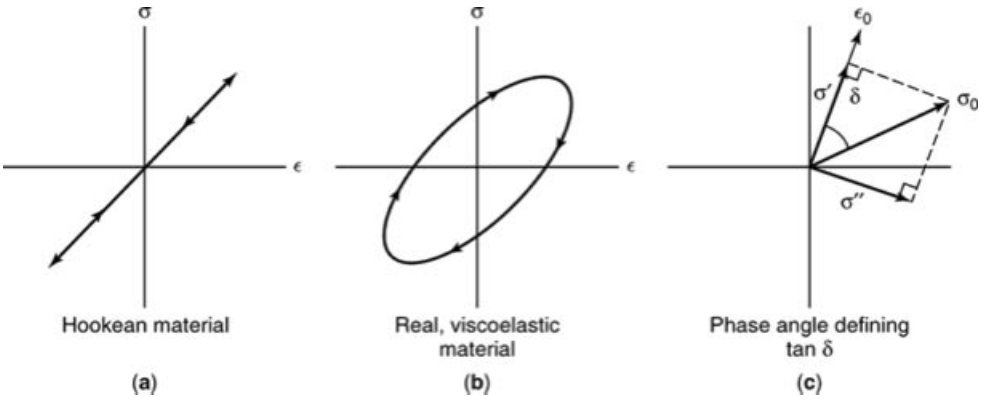

Fig. 32. Simple relationship between stress (σ) and strain (ε) in dynamic mechanical tests illustrating the role of the phase angle, showing (**a**) Hookian elastic response, (**b**) viscoelastic response, and (**c**) vectorial representations of complex oscillatory stress/strain response (74).

On the basis of the complex representation for the dynamic mechanical modulus, the relationships between stress and strain can be considered on a complex plane in terms of vectors (74), as shown in Figure 32**c**. The applied strain of magnitude ε_0 is out of phase with the resulting stress of magnitude σ_0 by an amount represented by angle δ. The stress components of σ^* are resolved as σ', in-phase, and σ'', 90° out-of-phase with $\varepsilon^* = \varepsilon_0$.

Further, Figure 32**b** illustrates that the phase shift between the cyclic stress and strain for a viscoelastic material results in a hysteresis loop, the size of which reflects the rate of viscous dissipation or heat generation during the cyclic deformation. For an ideal Hookean material, there is a zero-area loop (Fig. 32**a**). But as tan δ increases, so does the size of the hysteresis loop. This notion is particularly important in applications such as the damping of vibration and sound.

DMA experiments are performed under conditions of very small strain so that the material response is in the "linear viscoelastic" range. This means that the magnitude of stress and strain are linearly related and the deformation behavior is completely described by the complex modulus function, which is a function of time only. The theory applies both for the case of a tensile deformation or simple extension and for shear. In the latter case the comparable modulus is $G^*(t)$, with components $G'(\omega)$ and $G''(\omega)$. As a first-order approximation, $E = 3G$. The theory is developed assuming deformation under isothermal conditions, and temperature does not appear (nor is implicit) as a variable.

Dielectric analysis (DEA) measures changes in the properties of a polymer as it is subjected to a periodic (or alternating) electric field. In DEA a sample is placed between two electrodes. The traditional electrode geometry used for thermoplastics is a parallel-plate capacitor. The parallel-plate electrode measures the bulk dielectric response of the material subjected to a sinusoidal voltage applied to the electrodes. The electrodes typically are formed by vapor deposition or sputtering of a metal onto the polymer surfaces. A more contemporary dielectric electrode geometry is the interdigitated comb type of electrode which is particularly well

suited for *in situ* process monitoring. This will be discussed in more detail in a later section.

In DEA the applied voltage establishes an electric field in the sample. In response to this field, the sample becomes electrically polarized and conducts a net charge from one electrode to the other. This gives rise to a current whose amplitude is dependent on the frequency of the measurement as well as the temperature and structural properties of the polymer (or dielectric) being tested. The measured current is at the same frequency as that of the field (voltage) but shifted in phase and amplitude. The phase angle δ and the relative difference in amplitude between current and voltage provide data on dielectric properties.

In the following discussion it should be noted that we use the same symbol, ε, to represent both mechanical strain and the electrical dielectric constant. This is based on common terminology from the literature and should not cause the reader any difficulty, since both are used in differing contexts. ε^* represents the complex dielectric constant, ε' the in-phase component or permittivity, and ε'' the out-of-phase component or dielectric loss factor. It is also important to note that the dielectric "constant" is not a constant but is strongly dependent on both frequency and temperature.

A dielectric experiment is analogous to a DMA experiment where the charge is mathematically comparable to the strain and the voltage is comparable to the stress. The mathematical analysis is similar and, assuming a single relaxation time model for simplicity, it can be shown that the complex dielectric constant ε^* has the form $\varepsilon^* = \varepsilon' - i\varepsilon''$ with

$$\varepsilon' = \left[\varepsilon_u + \frac{(\varepsilon_r - \varepsilon_u)}{1 + (\omega\tau)^2}\right] \times E'_p \tag{7}$$

$$\varepsilon'' = \left[\frac{\sigma}{\omega\varepsilon_0} + \frac{(\varepsilon_r - \varepsilon_u)\omega\tau}{1 + (\omega\tau)^2}\right] \times E''_p \tag{8}$$

Here σ is the bulk ionic or dc conductivity; ω is the angular frequency ($2\pi f$); τ is the dipole relaxation time; ε_r is the relaxed dielectric constant or low frequency/high temperature dielectric constant (relative permittivity due to induced plus static dipoles); ε_u is the unrelaxed dielectric constant or high frequency/low temperature dielectric constant (relative permittivity due to induced dipoles only); ε_0 is the permitivity of free space; E'_p is the electrode polarization term for permittivity; and E''_p is the electrode polarization term for loss factor. The value of E'_p and E''_p is usually unity, except when ionic conduction is very high (75).

Many polymeric materials consist of dipoles (chemical bonds which have an unbalanced distribution of charge in a molecule) and traces of ionic impurities. If a polymer containing polar groups is heated so that an immobile dipole becomes mobile, an increase in permittivity is observed as the dipole starts to oscillate in the alternating electric field. This effect is referred to as a dipole transition and has a characteristic relaxation time (τ) associated with it (76). When exposed to an electric field, the dipoles tend to orient parallel to the field direction and the ions move toward the electrodes, where they form layers. The dipole relaxation time

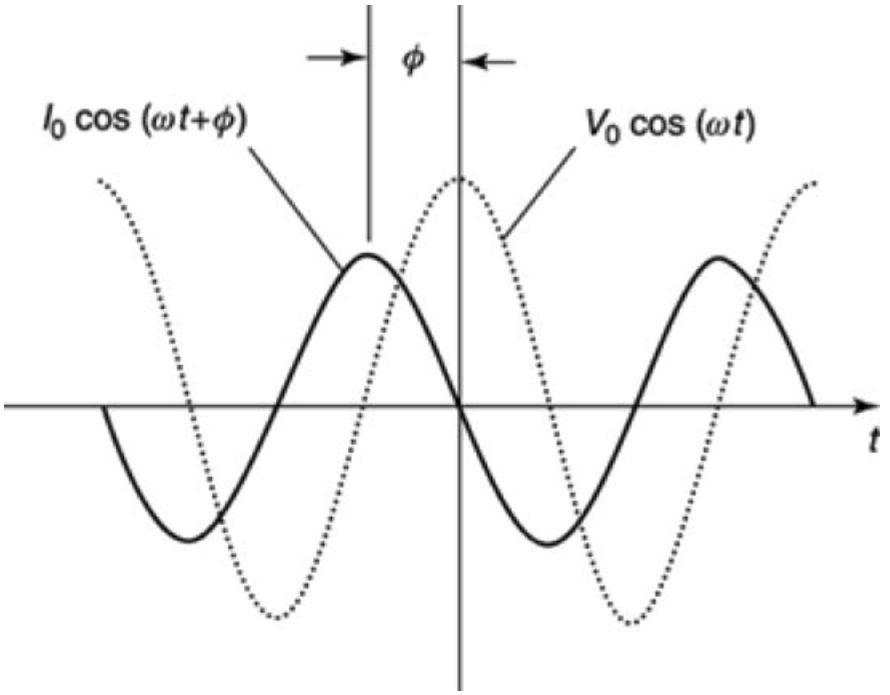

Fig. 33. Diagram of the phase shift between the current I and voltage V in a dielectric experiment that results from the lag in dipole response to the applied electric field.

is the time required for the dipoles to fully align, and the cycle time (reciprocal of frequency) is the time required for the electric field to change polarity.

The permittivity is a measure of the alignment of the dipoles in the applied electric field, while the loss factor represents the energy required to align the dipoles and to move the free ionic impurities. Both of these dielectric parameters depend on the temperature and the structure or composition of the material. The loss tangent

$$\tan \delta = \varepsilon'' / \varepsilon' \tag{9}$$

relates to the phase shift between the current, $I(t)$, and voltage $V(t)$, which results from the lag in dipole response with respect to the applied field, as indicated in Figure 33. Tan δ is often referred to as the dissipation factor. The functional forms of ε', ε'', and tan δ are shown in Figure 34, which represents the mathematical relationships for the dielectric functions calculated for a simple single relaxation model (71).

Most organic materials have permittivities ranging from 2 to 10. Polymers at temperatures well below the T_g generally have loss factors less than 0.1. When heated to T_g and above, they can have loss factors as high as 10^9 (71). Because of its large variation with the physical state of a material, the loss factor is a most useful function for the cure monitoring of thermosets.

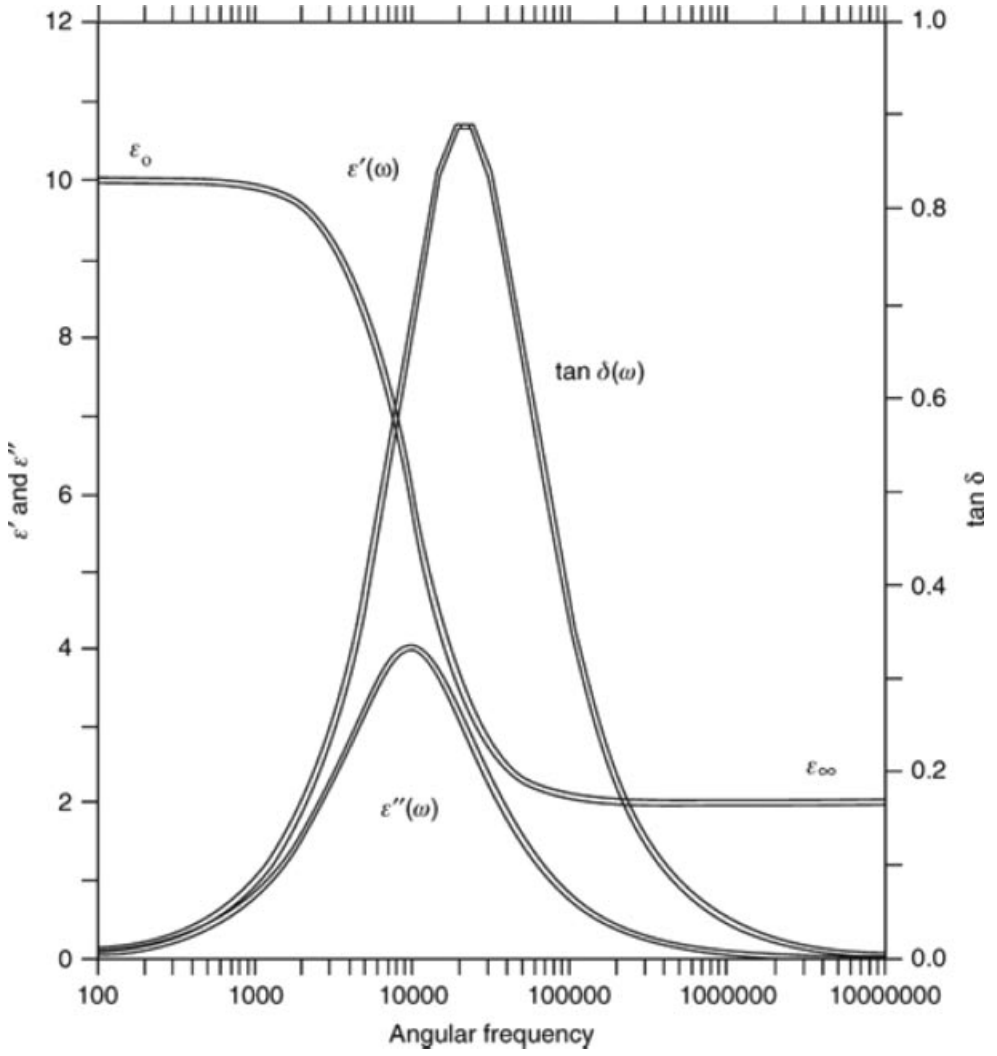

Fig. 34. Single relaxation time model curves for dielectric parameters ε', ε'', and tan δ. The curves were calculated using $\varepsilon_0 = 10$, $\varepsilon_\infty = 2$ and a relaxation time of 10^{-4} sec. (discussed in McCrum and co-workers, Ref. 69).

Dielectric analysis is used most frequently with thermoplastics to provide information on and an understanding of the molecular basis for relaxations. This is a more traditional context for DEA and ample information with numerous interesting examples is available in the literature, particularly in the text by McCrum (71) and the review by Chartoff (77). The reader is referred to these references for further insights. More recently, DEA has had extensive applications in the characterization and *in situ* process monitoring of the cure of thermosets, particularly in the manufacturing of composites. Since this topic is not as well known, we summarize in a subsequent section some of the more salient aspects of the use of DEA for the cure characterization of thermosets.

Applications of DMA in Characterization of Thermoplastics

Determining T_g by Dynamic Mechanical Analysis. Dynamic mechanical methods are popular among thermal analysts for measuring thermomechanical properties. Identifying the glass transition and how various system modifications affect T_g is a major application for DMA. Generally, the glass transition is easily identified from dynamic mechanical data because of the sharp decrease in storage modulus E' (or shear storage modulus G'), and the corresponding loss dispersion in E'' (shear loss G'') or tan δ that occur at T_g, as shown in Figure 35. These data are for a typical amorphous polymer (78). It is evident that there is latitude in how the exact value of T_g is chosen from a set of dynamic data, and this often leads to confusion in the literature. The criterion for selection of T_g from DMA data is usually either the peak in loss modulus E'' or peak in tan δ. While the peak tan δ is often used in the literature, the T_g value obtained is several degrees higher than peak E''. The tan δ peak corresponds more closely to the transition midpoint of the decreasing log E' curve, while the loss modulus peak more closely denotes the initial drop from the glassy state into the transition. In this respect the E'' peak T_g value is generally close to the intersection of the two tangents to the log storage modulus curve originating from both the glassy region and the transition region, the so-called "onset" temperature.

In general, the maximum loss modulus is the most appropriate value. This is the method prescribed by ASTM D4065. It is a reasonable criterion from a practical point of view because the upper use temperature of many amorphous polymers is the "softening" point. It is clear that by the transition midpoint (peak tan δ) the softening point has been exceeded.

For most linear amorphous polymers the transition region is rather narrow, covering around 15°C. In these cases the distinction between peak E'' and tan δ is not substantial. There are cases such as in crystalline polymers or cross-linked thermosets where the T_g region is broad and neither peak E'' or tan δ may be appropriate. Also in the case of both highly crystalline polymers and cross-linked polymers, T_g is a less prominent event and may be difficult to observe because the loss dispersion is not distinct. This is illustrated in Figure 36 (79). These data will be discussed further in a subsequent section. However, in general, the glass transition in crystalline and cross-linked polymers may be observed more clearly in DMA than by DSC, because the base line deflection ($\Delta E'$) at T_g is much larger than the ΔC_p measured in DSC. The change in modulus at T_g is often of the order of 10 to 10^3, while the ΔC_p change will be of the order of 10–30%.

Viscoelastic Relaxation Processes. There are several relaxation processes that are observed in polymers at temperatures below T_g. These relaxations, in addition to the major glass–rubber relaxation, are of continuing scientific interest and engineering importance. They are intimately associated with the stiffness of engineering thermoplastics, impact toughness, diffusion rates of low molecular weight vapors and liquids, and the effectiveness of plasticization, among others. A more detailed review of these is presented by Chartoff (77).

For isochronal (constant frequency) experiments on Semicrystalline Polymers (qv) in the temperature range between the crystalline melting point and liquid nitrogen temperature (−196°C or 77 K), at least three relaxation processes are often found. The high temperature α process is often related to the crystalline

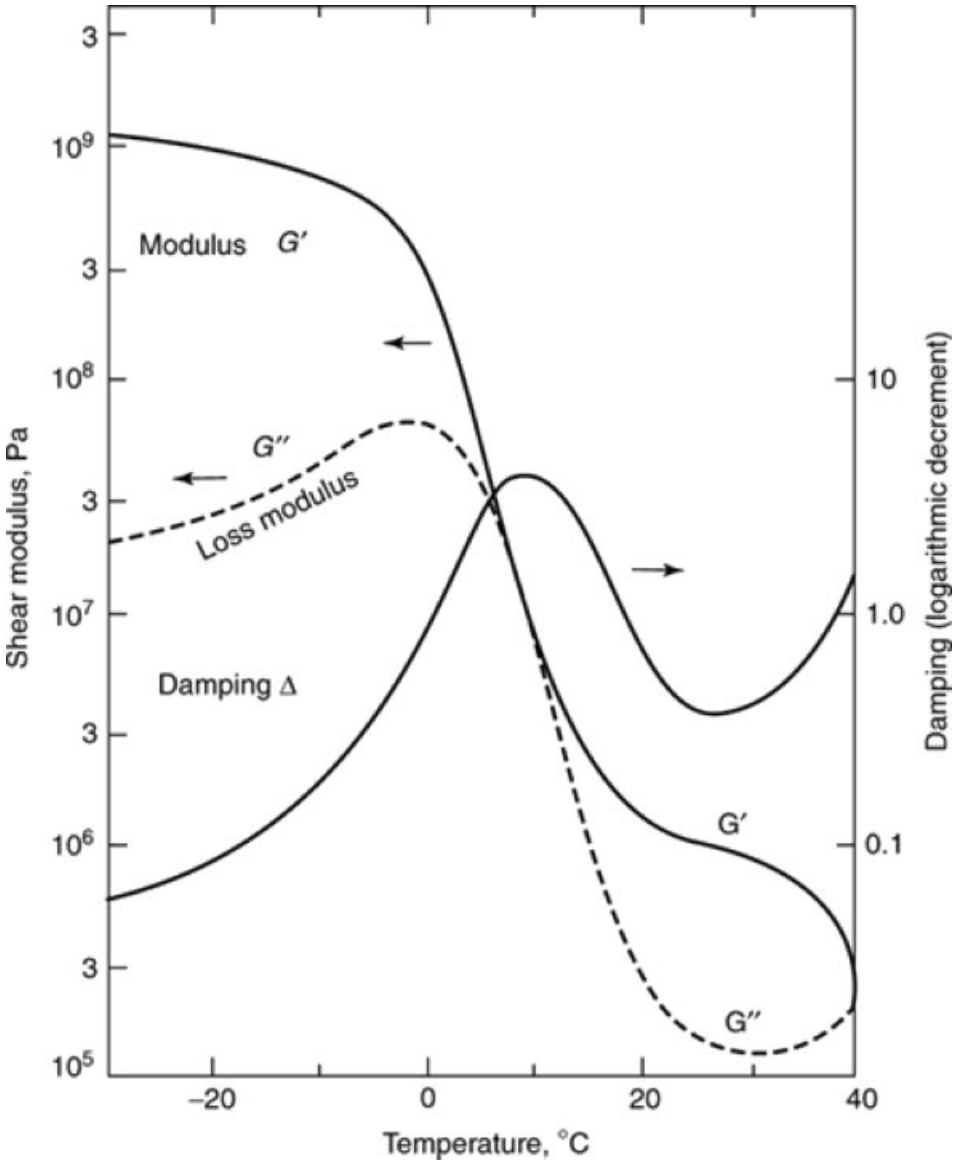

Fig. 35. Typical dynamic mechanical behavior for viscoelastic functions and G' and G'' and log damping decrement $= \pi \tan \delta$ (isochronal plot, constant frequency = 1 Hz) for a styrene–butadiene copolymer (78). To convert Pa to dynes/cm^2, multiply by 10.

fraction. The β process in these polymers is related to the amorphous phase and usually represents the glass transition. The low temperature γ process is generally considered to originate in the amorphous phase but may also have an important component associated with the crystalline phase. In amorphous polymers the highest temperature relaxation is the glass transition, also referred to as α, while β and γ relaxations also are commonly observed. Of course, in this case these are all associated with the amorphous phase.

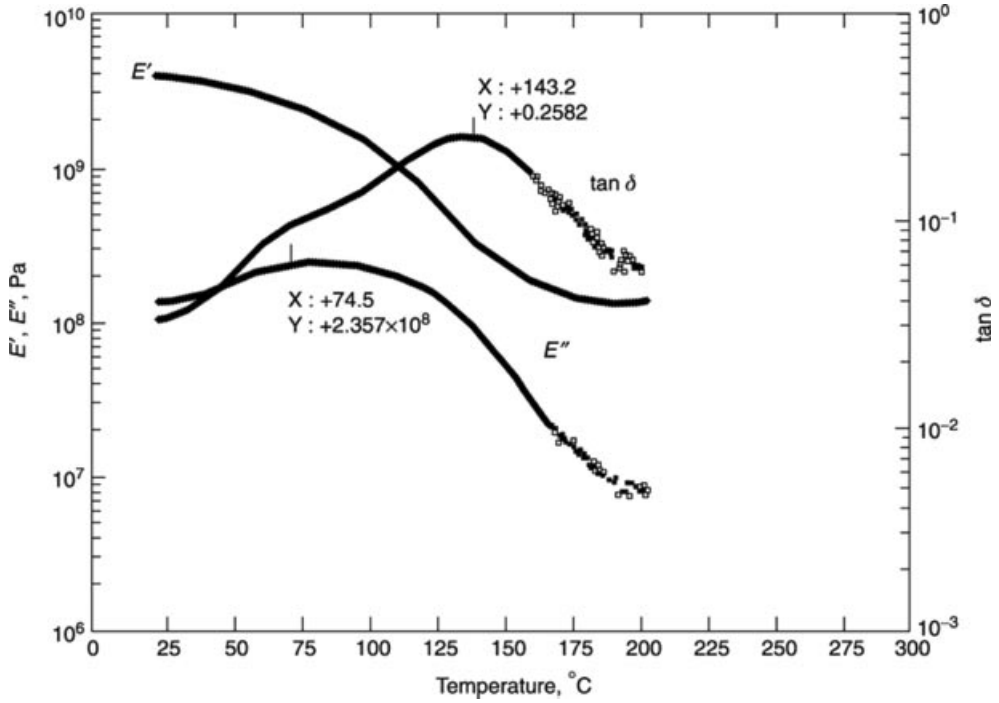

Fig. 36. DMA data at 1 Hz for a UV-cured acrylate polymer which is representative of a highly cross-linked system (79). The highly cross-linked acrylate represented has a very broad transition region that illustrates the problem involved in assigning T_g in such cases; the broad transition is due to multiple phases formed during cure. Δ, E'; $\diamond$, E''; ◘ tan δ.

The three points of greatest interest in relation to characterizing relaxation processes are (*1*) determining in what phase they originate, (*2*) describing the molecular processes underlying them, and (*3*) relating relaxation behavior to engineering properties and practical applications. DMA and DEA have proved most useful in helping to address these issues. DEA has been used extensively for studying the origin and mechanisms of relaxation processes. However, it is restricted to systems with active dipoles. As a result some relaxation processes that are active mechanically are not active dielectrically (the converse is also true), for example, the β relaxations in polyethylene and polytetrafluoroethylene.

Relaxations That Occur in Amorphous and Crystalline Polymers. In isochronal experiments on amorphous polymers, for the temperature interval between the melt and liquid nitrogen temperature, commonly each of the relaxation processes has distinct characteristics related to the specific motions associated with the relaxation processes. The highest temperature or α process is the glass transition involving the cooperative motion of several molecular segments or subunits (between 5 and 10). The glassy-state β and γ relaxations take place in polymers either with or without flexible side groups and are believed to be due to local rotational motions of the main chain and/or motions of side groups with differing degrees of cooperativity, and a distribution of relaxation times. The sub-T_g relaxations are characterized by an Arrhenius-type temperature dependence

of relaxation times. The more complex the cooperative motions associated with a relaxation process, the greater the activation energies. Thus each relaxation process has a different activation energy. This will be discussed further below.

In crystalline polymers there are at least two, and often three, processes observed below the melting point. In polymers that show all three, the high temperature α process commonly is connected with the crystal fraction in the semicrystalline material. The β process in such polymers is connected with the amorphous fraction and is the glass–rubber relaxation. In polymers where the α process is not of the above type, it is the glass transition. The low temperature process, γ(or β where α is missing), is generally agreed to originate in the amorphous phase but may also be affected by the crystalline phase.

There are some generalizations that can be made about the relaxation behavior of the above types (80). Inherently low crystallinity polymers show no crystalline high temperature process but do possess a well-developed amorphous fraction glass–rubber relaxation (α). Inherently easily crystallizable, high crystallinity polymers show both α and β relaxations where the α relaxation is associated with the crystalline phase. However, the β process tends to be less prominent than the amorphous phase α relaxation in the less easily crystallizable polymers. All crystalline polymers show the low temperature γ (referred to as β when α is missing) process.

The study of relaxation processes in Semicrystalline Polymers (qv) is a subject of continuing technological interest because of its practical importance. This is based on the observation that the stiffness of typical crystalline engineering thermoplastics at room temperature may be only one-third to one-fifth that of the same material at a low temperature. The drop in stiffness or modulus takes place in regions of temperature associated with a relaxation process.

Similarly, in Amorphous Polymers (qv) the drop in modulus accompanying sub–glass relaxations can have an important effect on engineering properties, particularly brittleness and impact resistance. This is discussed below in a section on impact behavior.

Effects of Plasticizers and Moisture. In amorphous polymers the glass transition and the relaxation behavior associated with it are very sensitive to the addition of small amounts of diluents. The relaxation is shifted to lower temperature isochronally or higher frequency isothermally. The usual explanation is that since the diluent molecules are small and mobile, they act to effectively increase the available free volume for segmental motion and hence speed it up. Similar plasticizing effects on the glass–rubber relaxation in crystalline polymers are observed. One example is the case of polyvinyl alcohol (PVOH), which is water-soluble. As shown in Figure 37 (81), PVOH can absorb large amounts of water, which shifts the glass transition to lower temperatures. As the relaxation shifts to lower temperatures, it also narrows. The shift to lower temperatures (as noted above) reflects the improved segmental mobility due to additional free volume imparted by the addition of moisture dispersed into the molecular network. The narrowing is likely due to a more uniform distribution of free volume, so that the formerly less-mobile amorphous phase fraction residing near the crystalline interface has become more mobile due to moisture plasticization.

These effects of moisture are also observed in aliphatic polyamides such as nylon-6,6 (82), nylon-6,10 (83,84), and nylon-12 (85), among others. There are

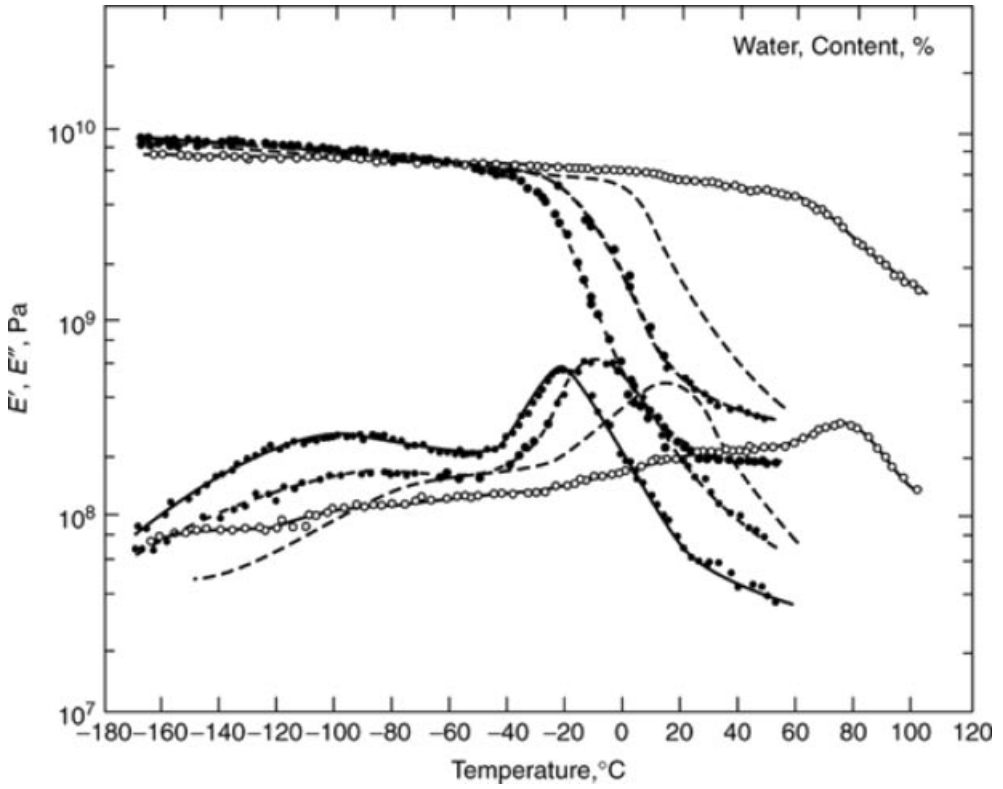

Fig. 37. Effect of moisture content on DMA glass transition of poly(vinyl alcohol) (81); E' and E'' vs temperature at 138 Hz with water contents indicated (T_g ~70°C for dry sample). ○, 0; – – – –, 8; ●, 20; ●, 30.

three major relaxations in nylon-6,6 (71,82,86,87). The α relaxation is the glass transition reflecting motion in fairly long chain segments in amorphous regions. The β relaxation has been attributed to the motion of labile amide groups and may be absent in dry, annealed specimens. The γ relaxation has been assigned to motion of short polymethylene segments with some involvement of adjacent amide groups. The addition of small amounts of water or alcohols (which readily dissolve in the amorphous fraction by virtue of hydrogen bonding) moves the α loss peak to lower temperatures (or higher frequencies isothermally) and narrows it, a result similar to that described above for PVOH. Moisture also reduces the temperatures of the β and γ relaxations to a lesser degree than the α relaxation.

The sorption of water by nylon has a major effect on major mechanical properties of engineering importance. For example, in molded nylon-6,6 at room temperature, the modulus decreases by about a factor of 5, the yield stress decreases by more than half, and there are major increases in the elongation and energy to break as the water content is increased from dryness to saturation (82,88). The reported properties of nylon are frequently those of nylon containing some amount of absorbed water. Thus, it is important to specify the water content or the relative humidity with which the polymer is in equilibrium.

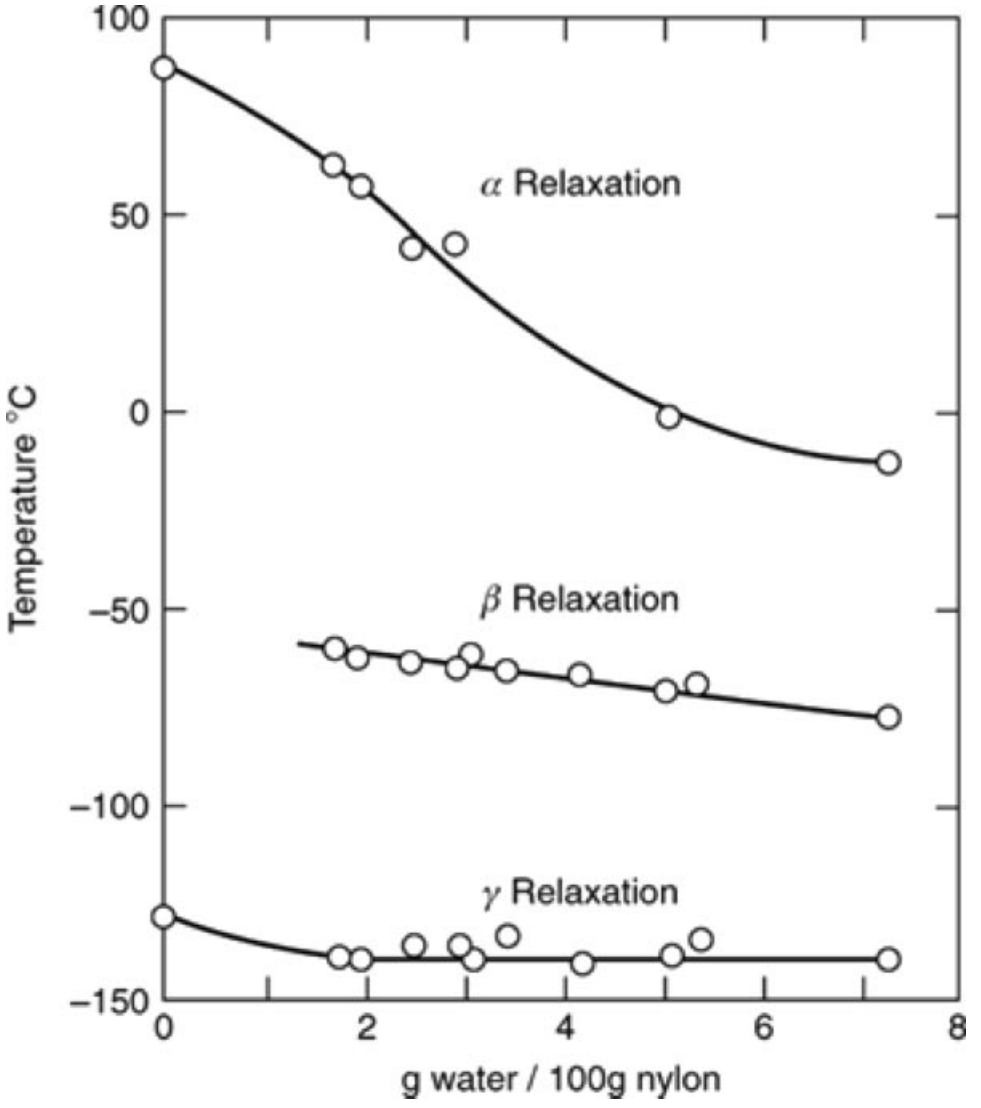

Fig. 38. Temperature position of loss modulus peaks in nylon-6,6 vs moisture content (1 Hz) (82).

The dependence of the relaxation temperatures on the level of absorbed water is known from dynamic mechanical studies (82,87,89) as well as dielectric studies (90). The temperature variations with sorbed moisture of the loss modulus peaks for the three relaxations are shown in Figure 38 (82). The test frequency for the three relaxations varies slightly but is around 1 Hz. The data indicate that the temperature of the α relaxation at a given frequency decreases by about 100°C between dryness and saturation. The β relaxation is also shifted to lower temperatures and higher frequencies by absorbed water, while the temperature of the γ relaxation is only slightly affected, shifting somewhat to lower temperatures and higher frequencies.

In addition, it is found that moisture increases the intensity of the β relaxation and reduces its activation energy, as well as decreases the peak height of the γ relaxation with little change in activation energy. The decrease in γ intensity has been referred to as an "antiplasticization" effect, since it is associated with an increase in modulus and decrease in impact strength. This is discussed further below in reference to impact behavior. The increase in β intensity has been associated with the motion of water molecules H-bonded with carbonyl and amide groups about the H-bond axis (84,90).

Moisture is an effective plasticizer for highly polar, phenylene polymers with α relaxations in excess of the 100°C boiling point of water. This is particularly noted in polyamides where strong hydrogen bonding prevents the loss of moisture even at high temperatures up to T_g. The polyamide derived from hexamethylenediamine and a 70/30 mixture of isophthalic and terephthalic acids (nylon 6I/T, 70/30) is quite hydrophillic. A considerable reduction in the dielectric α loss peak temperature (at frequency of 1 kHz) with increasing moisture content has been documented for this polymer (91). The α peak temperature is a linear function of relative humidity decreasing from 154°C at 0% RH to 60°C at 100% RH. The DSC T_g at 10°C/min decreased from 128°C for a dry sample to 48°C for one conditioned at 97% RH.

The hydrophilic character of nylon 6I/T (70/30) combined with a relatively low permeability to oxygen makes it an attractive candidate as a food-packaging material. The low permeability to O_2 is related to the antiplasticization of nylon 6I/T (70/30) by moisture. Moisture in this material decreases the γ relaxation strength as in other nylons, reducing the activation entropy for the γ process to zero. It is thought that water forms bridges between amide groups that are stable at low temperatures. These bridges serve as effective constraints, reducing the mobility of the adjacent aliphatic segments. Avakian and co-workers (91) contend that the permeability of O_2 is associated with the mobility of the aliphatic segments and will therefore decrease with suppression of the γ relaxation.

DMA data for samples of an aromatic poly(amide–imide) polymer containing various amounts of moisture are shown in Figures 39 and 40 (92). These data indicate a decrease in T_g of over 100°C at 4.25% moisture sorption. The dry T_g value is around 285°C. Each α loss dispersion has the same shape, indicating that moisture was not lost during the measurement (if moisture were lost, the loss dispersion would broaden because of a gradual shift in the relaxation to higher temperatures during the measurement). Since the α relaxation in this polymer occurs at temperatures well in excess of 100°C, the data show that water is indeed tightly bound in such systems. A broad β relaxation at around 100°C is seen to sharpen, increase in intensity, and shift upward to around 140°C in the wet specimens.

The effect of moisture on the β relaxations in amorphous phenylene polymers is well documented (93–95) for many of the systems cited previously. For example, Allen and co-workers (93) determined that both the dielectric and mechanical β relaxations in polysulfone, polycarbonate, polyphenylene oxide, and polyether sulfone were dependent on the water content of the samples. In addition, the amount of water absorbed depended on the polarity of the molecule. The effect of moisture on the dielectric β process in these polymers appears to be greater than for the mechanical loss process, as illustrated in Figures 41 and 42 (93).

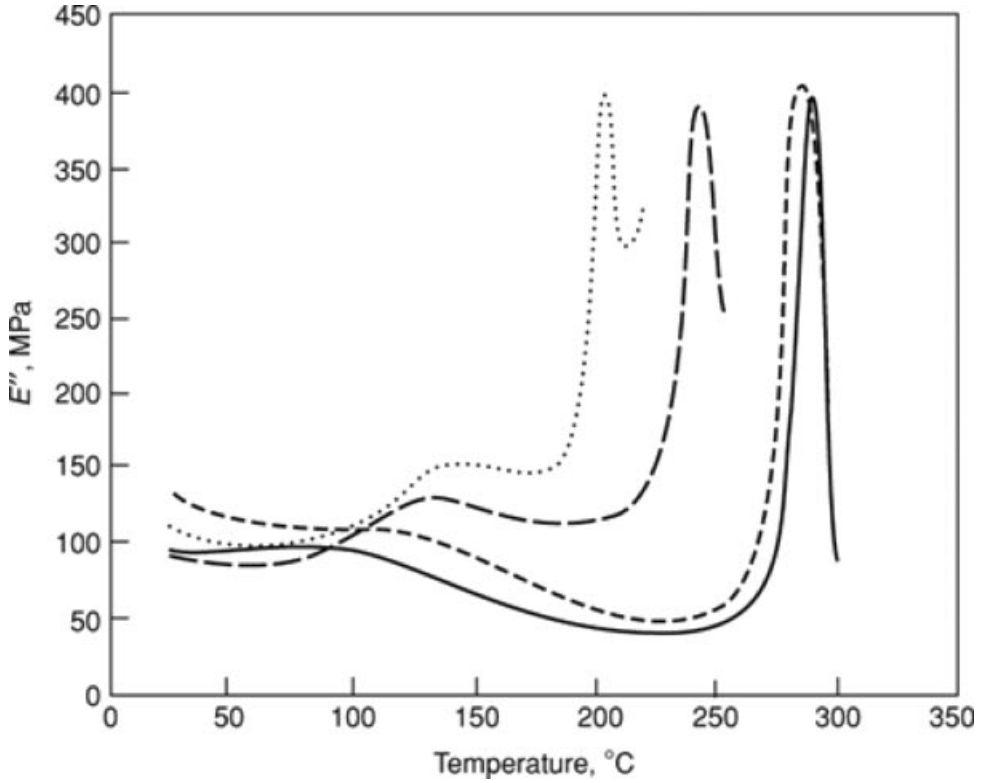

Fig. 39. Effect of moisture content on DMA glass transition of an aromatic poly(amide–imide). Note that a large moisture effect is noted even though T_g is well above the bp of water. ———, 0.90% water; – –, 0.85% water; —, 2.80% water; ●●●, 4.25% water (92).

These results indicate that the absorbed water hydrogen bonds to polar groups along the polymer chain and, as such, takes part in the molecular processes which give rise to the β relaxation. This is consistent with the other examples cited previously.

The polymers studied by Allen and co-workers (93) are modestly polar with maximum moisture uptakes of less than 1%. In more polar phenylene polymers such as polyimides (94) and poly(amide–imide)s (92), the mechanical β relaxation shows a more significant effect because of the larger amounts (1.5 to >4%) of moisture absorbed.

As in other crystalline polymers the glass–rubber (β) relaxation in linear or high density polyethylene (HDPE) is sensitive to plasticizing diluents. CCl_4 is effective in this regard (96–98). Loss data for HDPE containing absorbed CCl_4 such as those of Figure 43 (96) show a prominent E'' β peak in the -60 to -80°C range compared to a very weak (or nonexistent) relaxation peak in the -30 to -50°C range for the unplasticized material. It is evident that the diluent is effective in removing constraints on the amorphous segments, thus increasing their mobility (reduction in T_β), and in making more conformations available to reorientation (increase in β intensity).

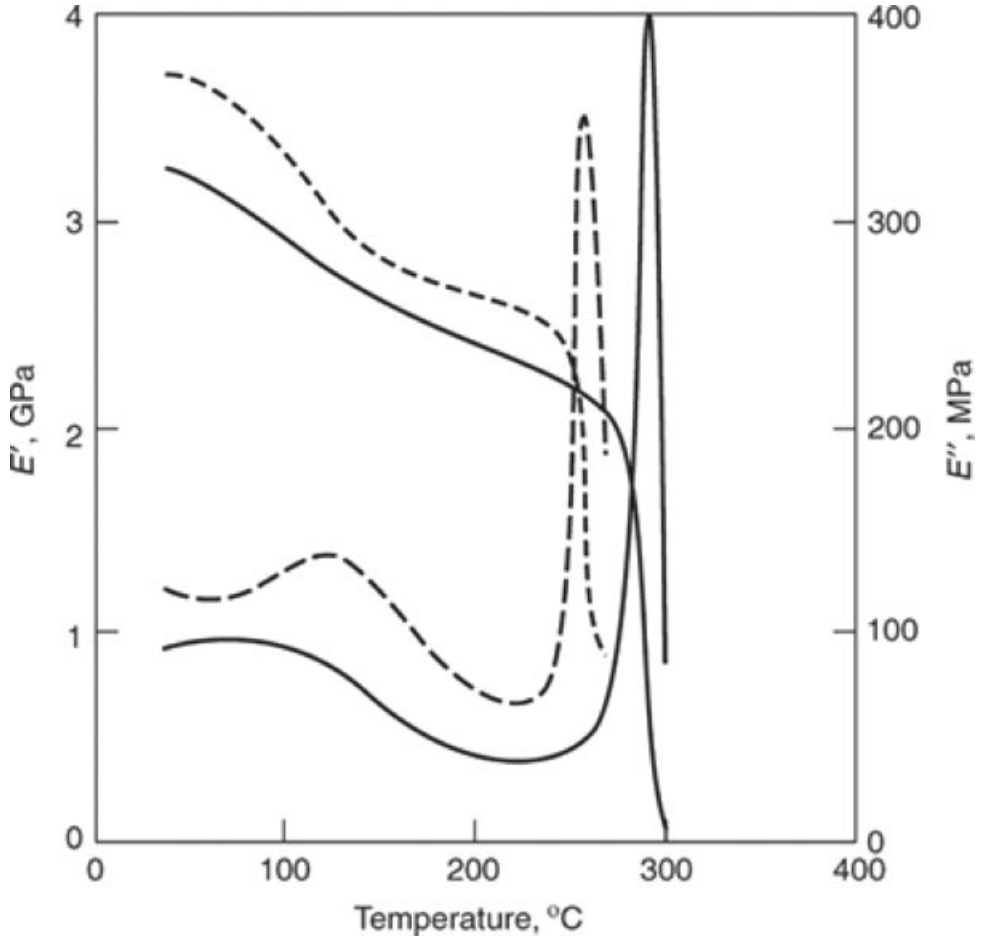

Fig. 40. Storage and loss moduli for a sample of dry poly(amide–imide) compared with one stored under ambient conditions of temperature and humidity. –, Ambient; —, dried (92).

Impact Behavior. The Fracture (qv) behavior of polymers under large-scale deformations is of considerable interest for engineering applications of polymers. It is important for material selection to have some practical criteria for decision making. Such criteria are discussed by Menges and Boden (99), who indicate how linear viscoelastic DMA data can be of benefit as a decision-making aid.

The cause of brittle fracture in polymers is the inability of the material to quickly dissipate by molecular relaxation processes the internal stresses generated as a result of the imposed deformation. Brittle fracture occurs when the time to failure is the same order of magnitude (or faster) than the speed of the relaxation process that dominates the mechanical behavior in the temperature range of interest. The relevant relaxation processes are the first $T < T_g$ secondary relaxation (β or γ). A qualitative criterion for determining whether the relaxation

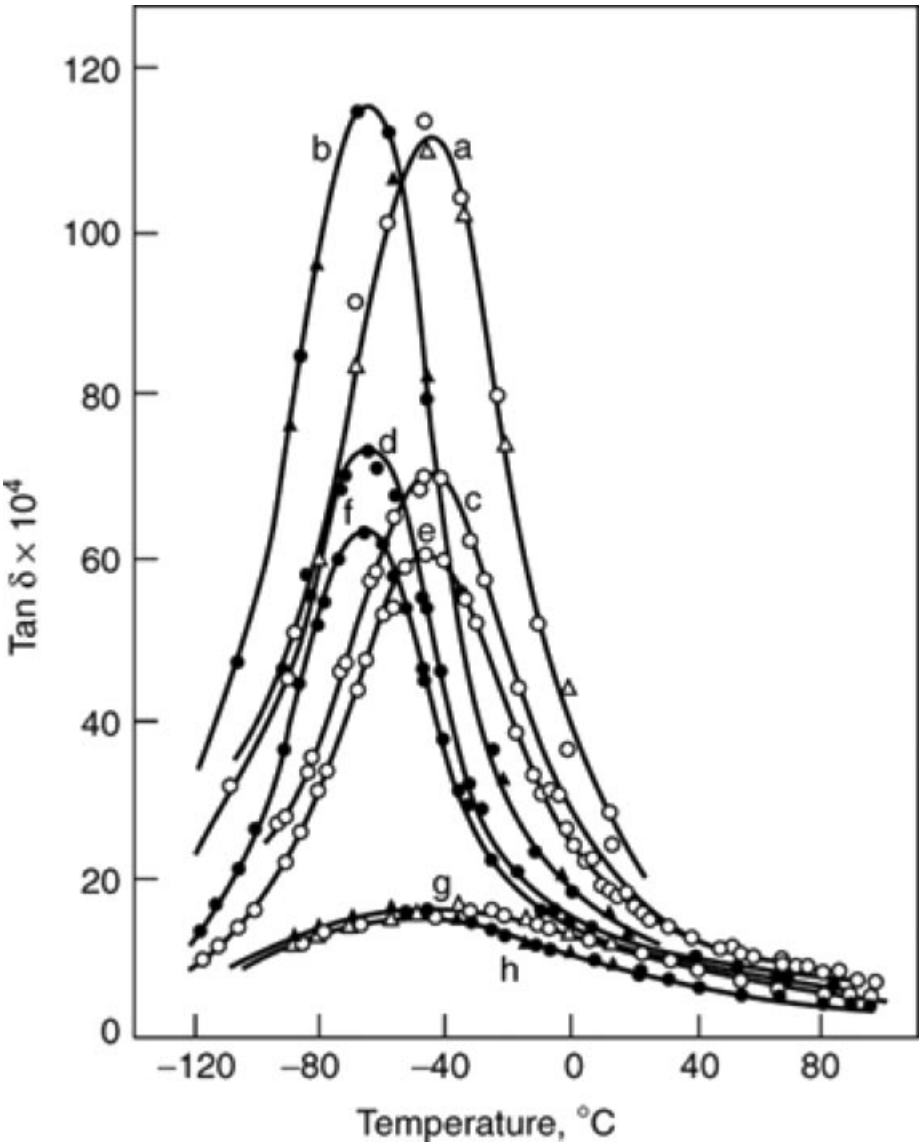

Fig. 41. Effect of H_2O and D_2O on the low temperature dielectric β relaxation in polysulfone at 1 and 10 KHz (93); circles, H_2O; triangles, D_2O; closed symbols, 1 KHz; open symbols, 10 KHz. The β peak intensity increases as absorbed moisture level increases.

will significantly influence the impact properties is whether the isochronal storage modulus (on a log modulus vs T plot) exhibits a distinct step at the damping maximum. The size of the step is related to the relaxation intensity. It has been known for some time that polymers with relatively intense low temperature relaxations may be expected to be "tough" at room temperature (100–102).

The occurrence of a secondary relaxation loss peak by itself is not a necessary and sufficient condition for improved impact strength (99,100). Additional

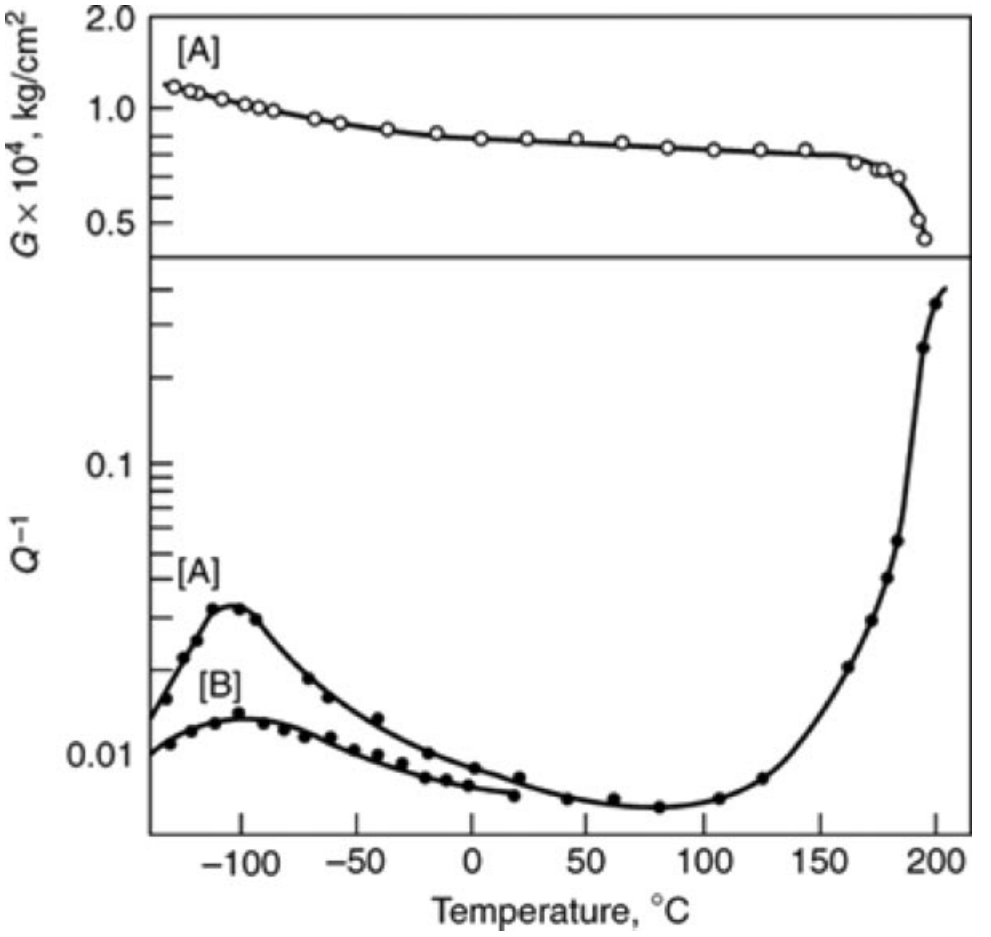

Fig. 42. Effect of H_2O on mechanical damping behavior of polysulfone at 1 Hz; (**A**) 0.31% H_2O, (**B**) 0.07% H_2O (93).

information such as actual impact test data, at temperatures above and below the relaxation, should be used to verify whether a given relaxation process has a significant influence on the impact behavior (see IMPACT RESISTANCE).

Evidence of the importance of secondary ($T < T_g$) relaxations in determining the impact strength of polymers is provided by numerous examples of changes in these relaxations by the addition of certain diluents that act as "antiplasticizers." The term *antiplasticizer* relates to the fact that, while these diluents lower T_g, they also cause increases in storage (and tensile) modulus and tensile strength but lower impact strength and elongation-at-break. Figures 44**a** and 44**b** (103) show storage modulus and tan δ curves for antiplasticized polysulfone and polycarbonate. As noted previously, both polymers in the pure state have well-defined β relaxations at about -100°C (173 K). It is readily apparent that at high diluent levels these relaxations are greatly reduced and virtually eliminated.

The presence of an antiplasticizer in these systems and the resulting near elimination of the β relaxation leads to a higher modulus value at temperatures

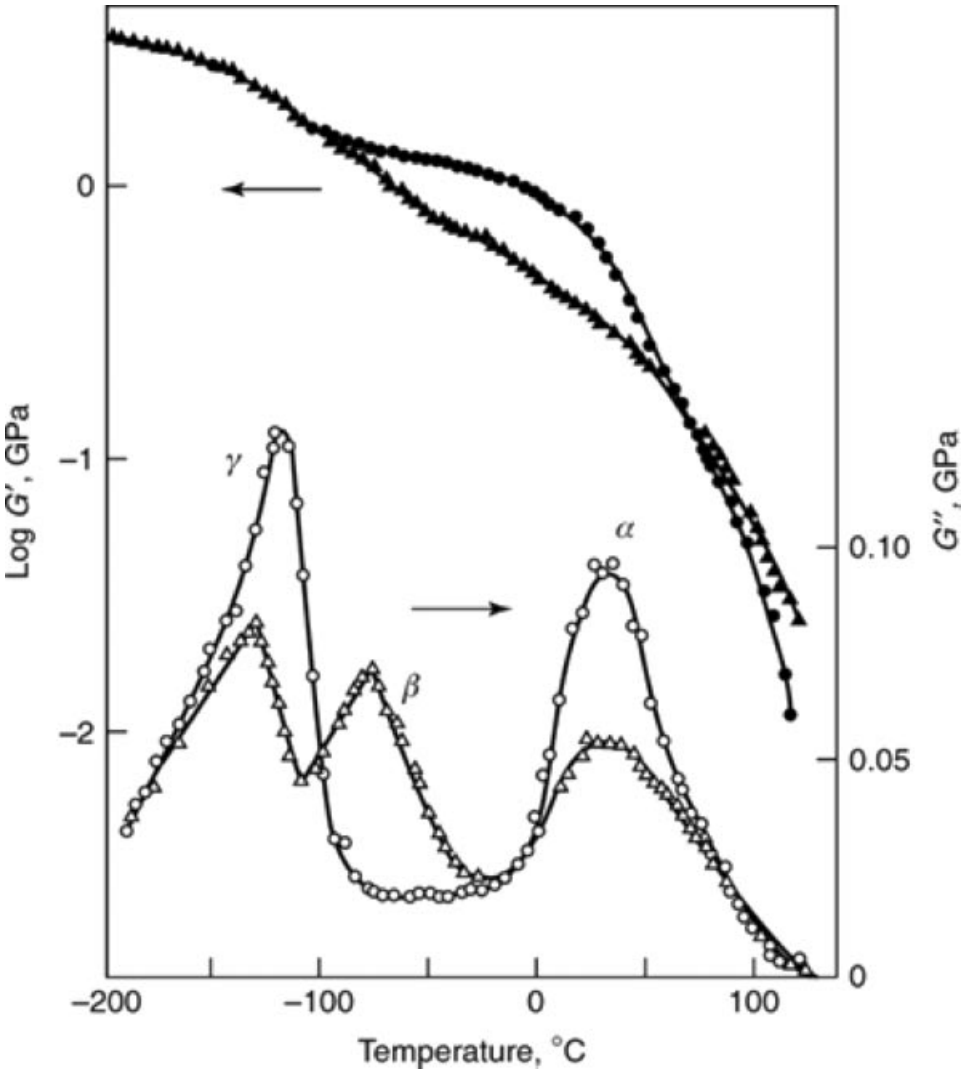

Fig. 43. DMA shear storage and loss moduli for linear polyethylene (LPE) unswollen (○,●) compared to LPE swollen with CCl_4 (11 wt%) (△,▲) (97).

above the relaxation range up through room temperature. This also results in higher tensile strength, lower elongation at break, and reduced impact strength, as noted in Table 7. Specific volume data suggest a qualitative explanation of antiplasticization in these systems, where the antiplasticizer molecules fill polymer free volume and restrict the local mode relaxations associated with the β relaxation.

Similar observations are found in the case of PVC (104,105), where the addition of normal plasticizers actually results in antiplasticization until the 15–20% plasticizer level is reached. At this point modulus and tensile strength begin to decrease because the T_g has been reduced to below room temperature. Pezzin

and co-workers (105) show that this antiplasticization effect is closely related to a reduction in the intensity of the β relaxation centered around -40°C.

We noted previously that various workers (82,85,89,95) have reported similar effects for nylons including nylon-6,6, an amorphous nylon 6I/T (70/30) based on iso- and terephthalic acids, and nylon-12. It was noted that at temperatures below the α relaxation, water is an antiplasticizer for nylon, increasing the modulus and tensile strength and reducing the intensity of the γ relaxation. Absorbed water reduces the activation entropy for the γ relaxation from a substantial positive value in the dry state to zero at saturation (91,106). It was suggested that this is explained by water forming bridges between amide groups and that these bridges reduce the mobility of the aliphatic segments adjacent to the amide groups. It is known that local mode relaxations of the aliphatic groups in cooperation with the amide groups give rise to the γ relaxation in nylon.

One further note on antiplasticization is that the ability of polymers to be antiplasticized will be related to the strength of their secondary relaxations. Thus, polymers with small relaxations should be unaffected by antiplasticizers (103).

Finally, we consider the question: What determines whether a given polymer will have a secondary relaxation strong enough to impart toughness as described above? This is discussed by Tanaka and co-workers (107), who examined the temperature/frequency dependence of α and β dielectric relaxations in a series of polyarylates with respect to Matsuoka's cooperative domain model for relaxation (108–110).

The cooperative domain model specifies that when a stress is applied to a polymer, the free energy of the system momentarily increases. As a result, conformers will readjust themselves and shift back to the lower free-energy state. In

general, for a conformer to complete a rotational relaxation its nearest neighbors must also rotate in cooperation. However, below the glass transition, polymer segments are pinned in place, making it very difficult for motions to take place. While intermolecular cooperative motions are locked in place during the stress application period, some intramolecular rearrangements are possible between the points along the chain that are pinned by their neighbors. The β relaxation process (or γ in certain cases) involves such motions. Tanaka and co-workers (107) noted that the size of a conformer in the β process is usually equal to the α conformer, such as for polycarbonate and PET. But in the arylates, with 2,2′-dicarboxy biphenyl groups, the rotation of conformers within a repeat unit becomes nearly impossible when one of the conformers is pinned. Thus, their β conformers are often several times larger than their α conformers. Such polymers exhibit very low β relaxation intensities and small values for the activation energy. As a result they have low impact strengths and a tendency for brittle behavior.

DMA Characterization of Cross-Linked Polymers

The Glass Transition. Highly cross-linked polymers are an important class of materials used as adhesives, coatings, and matrices for composites, to name just a few applications. Many of this class are referred to as *thermosets* and almost all are completely amorphous (an exception is the case of liquid crystal thermosets). The glass transition is a most significant parameter for this group and the difficulty in specifying T_g arises from the effect of crosslinking on relaxation in the transition region (79). The general effect on the glass transition by increasing crosslink density is shown in Figure 45. The transition loss dispersion decreases in intensity, broadens, and shifts to higher temperatures. Also, the transition slope of the storage modulus decreases. The broadening of the relaxation spectrum is further enhanced by network heterogeneity and microphase separation introduced into systems formed from the mixtures of reactive monomers that have different functionalities. The data of Figure 36 for a UV-cured acrylate polymer are representative of such a system.

The highly cross-linked acrylic represented in Figure 36 has a very broad transition region that well illustrates the problem involved in assigning T_g in such cases. The question to consider is: What criterion do we use for specifying T_g? The loss dispersion in Figure 36 covers a span of approximately 100°C and is very flat, with no well-defined maximum value. The E'' maximum which was determined numerically is 70°C lower than the peak tan δ. Furthermore, the E'' peak appears to occur in the transition region above the temperature where E' begins to decrease gradually from the glassy-state value. Our recommendation in such cases, where the T_g range is unusually broad, is based on practical considerations. Since network polymers are frequently used in structural applications as adhesives and composite matrix materials, the point where E' begins to drop from its glassy value is the most appropriate T_g assignment based primarily on the criterion of retention of structural integrity. This is most easily specified by the onset point, defined by intersection of the tangents to the storage modulus glassy-state curve and transition-region curve.

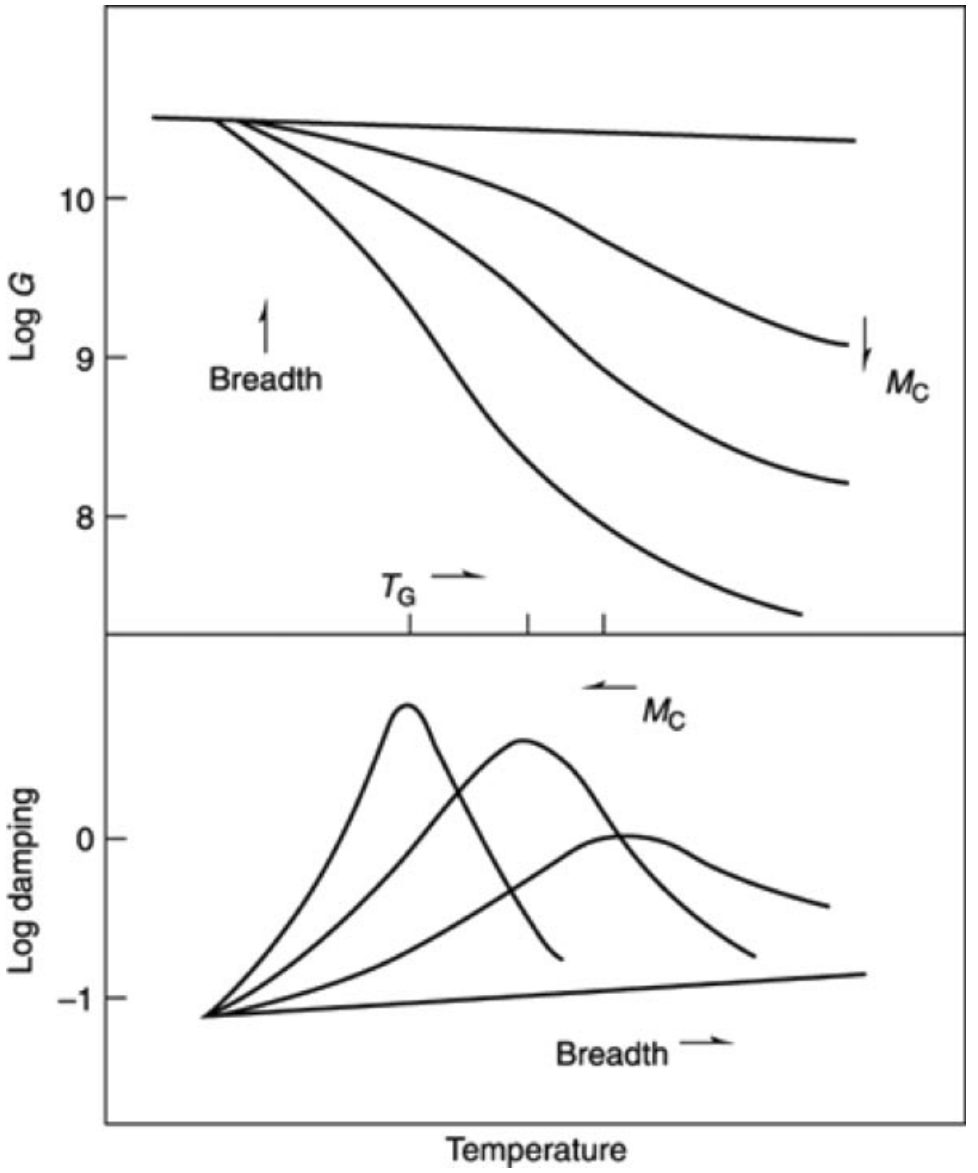

Fig. 45. Schematic diagram showing the effects of cross-linking on modulus and damping (loss tangent) vs temperature behavior at T_g.

Thermoset Cure Chracterization by DMA. On the basis of the information on crosslinking and T_g noted above, DMA can be used for the cure characterization of Thermosets (qv). There are two aspects of this. First, as the chemical conversion (extent of cure) and the degree of crosslinking advance, T_g increases. Thus the T_g measured by DMA correlates with the cure state of the material. In cases where T_g is not overly broad and a well-defined maximum in the loss modulus is evident, the T_g value obtained is related to crosslink density. Second,

the magnitude of the plateau modulus above T_g increases with crosslink density. This can be used to estimate the average crosslink density (or molecular weight between crosslinks) of the network. We present a brief review of these issues in the following paragraphs.

It has been shown that in many cases for thermoset systems, there is a quantitative relationship between the chemical conversion of the thermoset and its T_g value, independent of the time–temperature cure history (111). This is very convenient from an applications standpoint because measurement of T_g is equivalent to a direct measurement of conversion. It implies that either the molecular structure at a given degree of conversion is the same, regardless of the reaction path, or that differences in the structures produced for different reaction paths do not affect T_g. While a T_g–degree of cure relationship has been found valid for many epoxy–amine and other thermoset materials, it has been observed not to hold in some cases, which include some epoxy–DICY, cyanate–ester, and phenolic systems. It has also been found not to hold for a given resin system cured by two different methods such as thermal and microwave (112) or thermal and electron beam cures (113).

The reasons why a T_g–conversion relationship is not valid in some instances are not fully understood. One explanation is that the relationship is not likely to hold under conditions where the cured molecular network has a significant degree of heterogeneity due to composition or molecular weight heterogeneities in the initial monomer, or resulting from phase separation, or even the partial formation of a liquid crystal phase during polymerization. In the case of the epoxy–DICY and cyanate–ester systems, composition heterogeneity may arise, since the crosslinking agents are catalysts that are added initially as crystalline powders. In such cases there is always some degree of incomplete mixing of the catalyst so that the cross-linked network is heterogeneous, with multiple phases having different crosslink densities occurring on a microscale (114). These phase differences will correspond to local variations in catalyst concentration resulting in local "hot spots." In the phenolic systems the starting material is generally a mixture of oligomers, with a range of chemical functionalities. This also leads to a heterogeneous cross-linked phase distribution. For practical reasons, in dealing with thermoset cure, it is recommended that T_g–conversion data be generated as part of any cure characterization study. This will be useful even if there is not a direct correlation between T_g and conversion. The easiest way to develop a T_g–conversion relationship is via DSC. Where degree of conversion cannot be measured directly, T_g is a good means for evaluating cure advancement.

DMA also has been used to determine thermoset vitrification times by running the DMA in an isothermal or temperature-programmed mode that simulates actual processing conditions. The methodology for this is discussed in detail by Prime (115). In general, when thermoset reactions proceed at a given temperature, the uncured thermoset (which may be a solid) is initially converted to a liquid phase before reaction begins. Once the sample is in the liquid phase, crosslinking continues until the viscosity of the system becomes extremely high and the sample passes into the glassy state or vitrifies. At this point the reaction is inhibited due to restrictions on diffusion of reactive groups. So the reaction slows down drastically and, in most instances, essentially stops even though the chemical reaction is not complete. The increase in storage modulus (which parallels the rise in viscosity) of

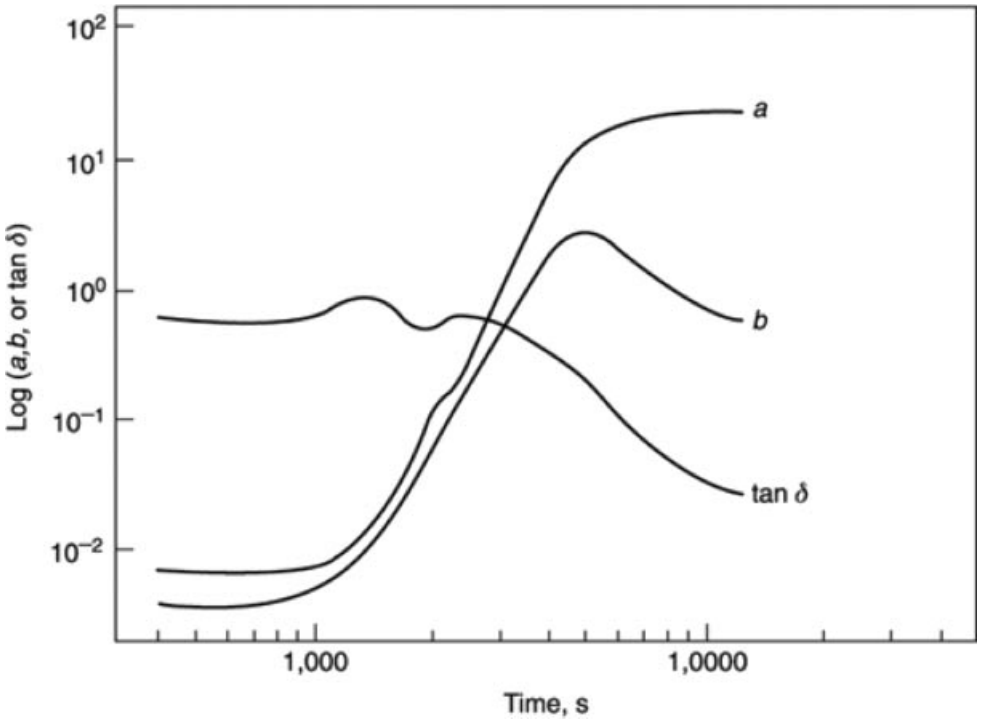

Fig. 46. DMA isothermal modulus and tan δ vs cure time plot for a supported epoxy resin sample (resin coated onto an inert fiber glass substrate); (**a**) storage modulus, (**b**) loss modulus (116).

the system from the onset of reaction can be mapped by DMA either for supported samples (resin coated onto an inert substrate) or unsupported samples. As shown in Figure 46, an isothermal modulus vs cure time plot (116), the storage modulus rises and then levels off at a high value characteristic of the glassy state.

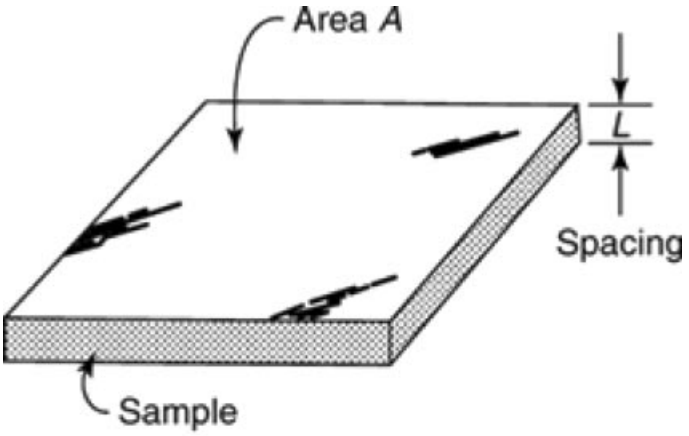
When the modulus reaches its plateau, the polymer has vitrified or attained the glassy state due to the advance of the crosslinking reaction. If the cure reaction is carried out at a temperature T_i , the cure reaction continues until the sample vitrifies (becomes glassy) at T_i . The effective T_g of the partially cross-linked, vitrified polymer will be equal to or slightly greater than the cure temperature T_i because the reaction rate slows down gradually upon vitrification. If the temperature is then raised above T_g , the curing reaction will continue and T_g will gradually increase until the reaction is completed, or T_g again increases to the reaction temperature. If an isochronal DMA scan is run for a partially cured sample, the storage modulus will decrease with temperature at T_g in the usual manner until the reaction starts again. Then the modulus will increase with temperature.

Dielectric Measurement Methods Applied to Thermoset Cure

Dielectric analysis (DEA) has the capability for following the transformation of a thermoset from a low molecular weight liquid resin to a solid cross-linked network.

In this respect it provides some detail beyond that from a DMA run with supported samples, because it more accurately follows changes that occur in the low viscosity state, as well as during the large viscosity increase leading up to vitrification. Using disposable microdielectric sensors (117), dielectric data can be obtained in the laboratory as well as *in situ* during reactive manufacturing processes with minimal disturbance of the process. Thus, DEA is well suited for process monitoring and process control in real time. DEA can provide information on key characteristics of thermosetting materials, including molecular relaxations, thermal transitions, onset of flow and viscosity minima, rate of cure, and degree of cure. Some of the topics of interest concerning the dielectrometry of thermosets are as follows: (*1*) ionic conductivity often dominating the observed dielectric properties; (*2*) the correlation between viscosity and conductivity early in cure; (*3*) the contribution of dipoles and sample heterogeneities to the measured dielectric properties; and (*4*) the importance of electrode polarization at low frequencies (118).

We noted previously that in DEA, a sample is placed between two electrodes and a sinusoidal voltage is applied to one of the electrodes. The traditional electrode is a parallel-plate capacitor, as illustrated in Figure 47. The applied voltage establishes an electric field in the sample. In response to this field, the sample becomes electrically polarized and also can conduct a net charge from one electrode to the other. Both the electric polarization and ionic conduction give rise to a current whose amplitude is dependent on the frequency of the measurement and



$$C_x = \frac{\epsilon'_x \epsilon_0 A}{L}$$

$$R_x = \frac{L}{\omega A \epsilon''_x \epsilon_0}$$

Fig. 47. Parallel-plate electrode geometry for dielectric measurements; capacitance is related to permitivity and resistance is related to loss factor.

the temperature and structural properties of the medium being tested. The DEA electrode assembly both transmits the applied voltage to the sample and senses the response signals.

Most thermosetting materials possess both permanent and induced dipoles. Static or permanent dipoles consist of inherently polar moieties (not induced by the electric field) within the material, such as amine or hydroxyl groups. The static dipoles, if sufficiently mobile, may rotate in an alternating electric field, thus also storing energy and contributing to the capacitive nature of a material. Even nonpolar polymers can be dielectrically active. In the presence of an electric field, electron clouds may be slightly shifted, inducing a small polarization that is aligned with the electric field. This acts to store energy and contributes to the capacitive nature of a material. These induced dipoles are responsible for nonpolar or symmetrically polar materials having permittivities greater than 2.

Static dipoles also contribute to the loss factor, as can be seen from equation 8. This contribution arises from viscous drag as the dipole rotates through the surrounding medium. As a result of this drag, there can be a significant phase lag between the maximum applied field and maximum dipole deflection. The energy lost because of this phase lag reaches a peak as ω approaches τ^{-1}. At higher frequencies the dipole hardly moves, because it is not able to keep pace with the changing field, and so little energy is lost, while at lower frequencies the dipole can keep up with the field more easily and, as a result, less energy is expended.

Ionic conduction is the result of current flow due to the motion of mobile ions within the material under test. It has been demonstrated that concentrations well below 1 ppm are sufficient to cause significant ionic conduction levels (118). From equations 7 and 8, it is evident that ionic conduction contributes only to the loss factor and does not affect the permittivity. Epoxy resins typically contain sodium and chloride ions, which are residuals from their manufacture. These impurities are quite sufficient to cause ionic charge transport. Thus, it is common to observe large loss factors in such thermosetting materials when the temperature is above T_g, because of the ionic conduction contribution to the loss factor.

An artifact that affects the dielectric properties when ionic conductivity is high is known as electrode polarization. This results from the thermosetting resin acting in combination with the electrodes used to introduce the electric field. Electrode polarization occurs when ionic conduction is extremely high, causing ions to collect at the material–electrode interface during a half-cycle of the oscillating electric field. As ions build up at the interface, they accumulate in a thin boundary layer and build up a considerable charge density, and therefore a large capacitance is formed. This has the effect of artificially decreasing the measured values of loss factor and increasing the measured values of permittivity. The measured permittivities attained through electrode polarization are usually large enough (greater than 100) to render electrode polarization easy to identify. A detailed discussion of the electrode polarization effect is given in Reference 75.

There are two electrode sensor geometries that are common in dielectric analysis. As noted previously, the traditional electrode is a parallel-plate capacitor (Fig. 47). However, this geometry is not well suited for thermoset cure monitoring. In order to obtain high signal levels with the classical parallel-plate technique, thin specimens with large areas are required, and the dielectric properties are an average of the bulk. In addition, low frequency measurements, which can reveal

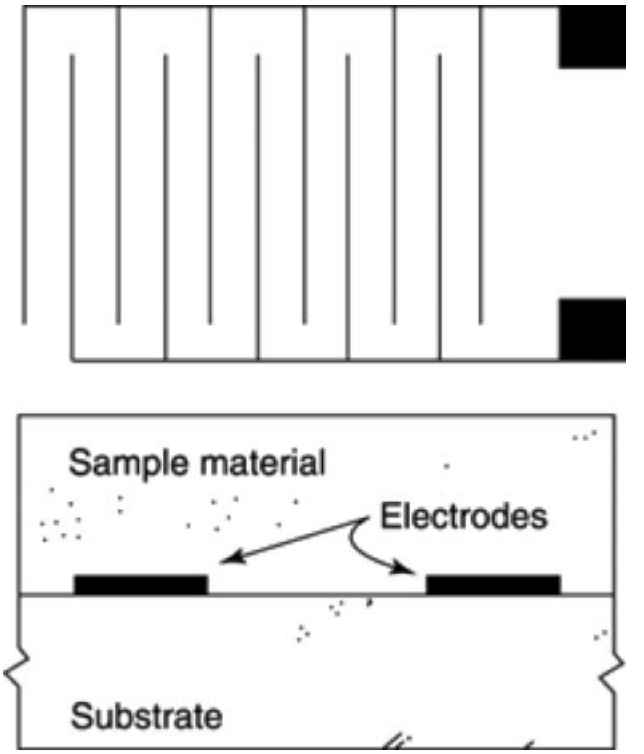


Fig. 48. Interdigitated or comb electrode geometry for contemporary microdielectric sensors (117,118).

much about glass transitions and the mechanical properties of the material, are often difficult to obtain using the parallel-plate technique, since the signal current is proportional to the test frequency. The principal disadvantage, however, is the need to accurately control or measure the plate spacing. Thermosets during cure frequently undergo dimensional changes due to temperature, reaction-induced shrinkage, or pressure. In order to obtain quantitative values for the dielectric properties, the plate spacing must be known throughout the experiment.

The interdigitated or comb electrode (117) is a contemporary, alternative geometry, as illustrated in Figure 48. For this type of sensor, metal electrodes are fabricated on an insulating substrate by photopatterning. The substrate is typically a ceramic or a silicon integrated circuit. Sampling is simplified. Either a small amount of sample is placed over the electrode sensor, or the sensor may be embedded in the test medium. The comb electrode has been miniaturized as a microdielectric sensor, which combines the electrode with a pair of field-effect transistors in a silicon, integrated microcircuit. For thermosets these microsensors circumvent the problems associated with parallel-plate capacitors while achieving comparable sensitivities. The microsensor is small, around 0.5 in. in size. This design permits a one-sided, very localized measurement of dielectric properties, is particularly well suited for thin films, and can be inserted directly into a part being cured. The modern measurement circuitry also circumvents the traditional

lower frequency limits, thus permitting dielectric analysis at frequencies as low as 0.001 Hz. Very fast response times of considerably less than 1 s are possible so that the microsensors can monitor very fast reactions.

Dielectric Analysis of Thermoset Glass Transitions. As a polymer is heated through its glass transition, static dipoles gain mobility and start to oscillate in the electric field. This causes an increase in permittivity, with a corresponding loss factor peak. At the low temperature side of the glass transition, dipoles are able to respond only to low frequency excitation, because their mobility is low. Dipole mobility increases as the polymer is heated through T_g and above. Charged ions also gain mobility as a material is heated through T_g and will start to contribute to conductive losses above T_g. The contribution of ion conductive loss to the measured loss factor may be large and can often overshadow the smaller dipole loss contributions. The loss dispersion observed in dielectric measurements is analogous to that observed for mechanical measurements. Low frequency dipole loss peaks (less than 1 Hz) correspond well to other thermal analysis measurements of T_g.

Figure 49 shows temperature-dependent data for the permittivity and loss factor of a diglycidal ether of bisphenol A (DGEBA) epoxy resin in the vicinity of its glass transition ($T_g = -17^\circ$C), measured at frequencies between 0.1 and 10,000 Hz (118). At temperatures well below T_g, the permittivity at all frequencies has a value of 4.2 (the unrelaxed permittivity, ε_u) and the loss factor is less than 0.1. As the temperature approaches T_g, the dipoles gain sufficient mobility to contribute to the permittivity, with evidence of this mobility increase occurring first at the lowest frequency. With a further increase in temperature, the permittivity for each given frequency levels off at the relaxed permittivity ε_r, and then decreases because of increasing temperature (118). This is then followed by an abrupt increase in ε' as a result of ionic conductivity and electrode polarization. At each frequency, a dipole peak is observed in the loss factor at T_g. ε'' then rises continuously with temperature because of an increase in ionic conductivity. The frequency at which the dipole loss peak occurs is proportional to the ionic mobility. Both the frequency of the loss factor maximum and the ionic conductivity increase by many orders of magnitude over a narrow temperature range, a characteristic of relaxation processes very close to the glass-transition temperature. Note in Figure 49, that the 0.1-Hz loss peak temperature is similar to the T_g as measured by DSC (-17°C). A similar correlation was observed between the onset of the modulus decrease by DMA at 0.1 Hz and the T_g as measured by DSC (119).

Cure Characterization. With considerations concerning the DEA observations related to T_g in mind, it is apparent that dielectric properties can be particularly useful in following chemical and physical changes in real time during thermoset cure. At the beginning of cure, the dipole relaxation time is much shorter than the cycle time, and the dipoles and ions move easily and align themselves with the field as the polarity changes, as illustrated in Figure 50**a**. Hence, both the permittivity and the loss factor have high values initially. As cure proceeds, crosslinking produces larger and more complex molecules and the viscosity of the medium increases. This restricts the motion of the dipoles and ions and causes an increase in the relaxation time. If the frequency of the electric field is fixed, then the relaxation time will approach the cycle time, and there will be less alignment of dipoles and less ion transport, as shown in Figure 50**b**. Eventually,

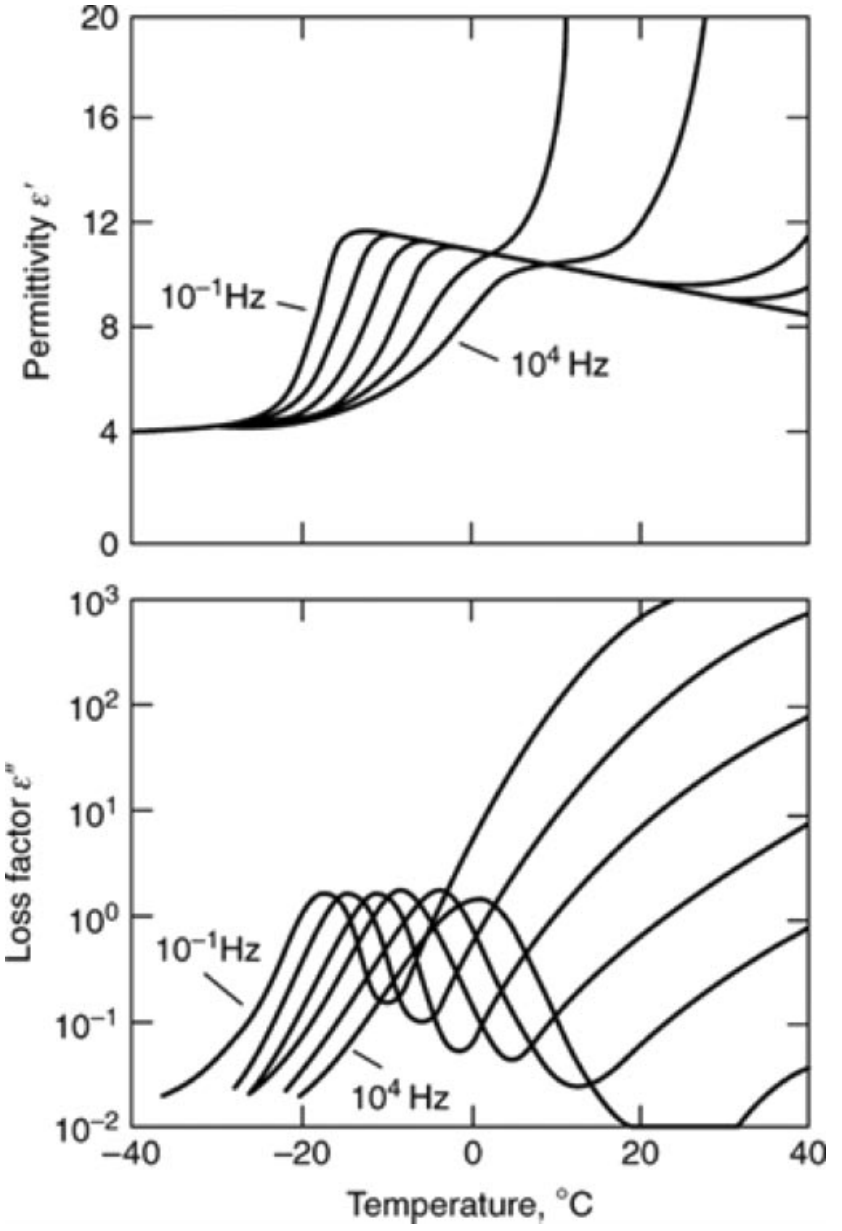

Fig. 49. Temperature-dependent data for the permittivity and loss factor of an uncured DGEBA epoxy resin (Epon 825) in the vicinity of its glass transition ($T_g = -17^\circ$C), measured at frequencies between 0.1 and 10,000 Hz (118).

as the relaxation time becomes large relative to the cycle time, the dipoles will be randomly oriented, as illustrated in Figure 50**c**. Concomitantly, as the curing polymer becomes more viscous and/or glassy, it offers increasing resistance to the motion of free ions, and ion mobility decreases. This results in both a low permittivity and a low loss factor.

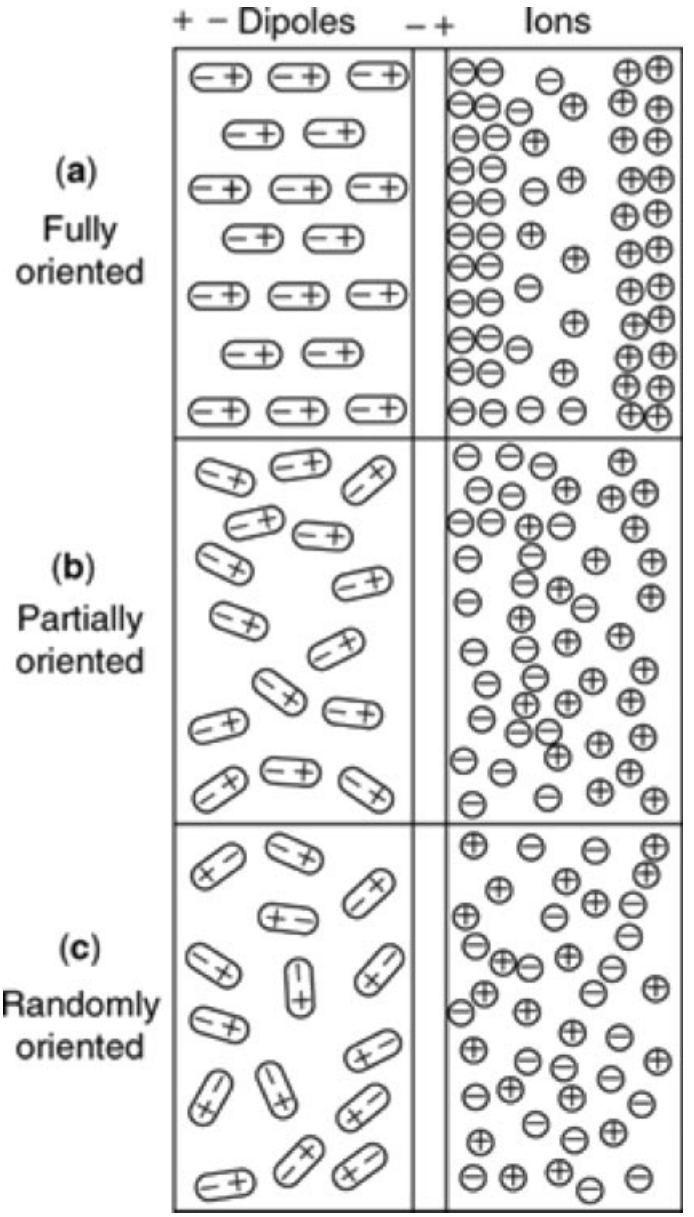

Fig. 50. Schematic representation of ion and dipole behavior at various stages of thermoset cure: (**a**) beginning of cure in liquid state, (**b**) during cure as viscosity begins to increase, and (**c**) after sharp rise in viscosity severely restricts dipole mobility (75).

During cure, ε'' generally will change by several orders of magnitude. As a result, ε'' is a particularly useful function for evaluating the progression of cure. The loss factor can be expressed as

$$\varepsilon'' = \varepsilon''_{\mathrm{d}} + \frac{\sigma}{\omega \varepsilon_0} \tag{10}$$

where ε''_d is the energy loss arising from dipole orientation, and σ, ω, and ε_0 are as previously defined in equations 7 and 8. At low frequencies, the conductivity term will usually be considerably larger than the dipole term, and the value for conductivity, σ, then can be extracted from the loss factor by equating σ to $\varepsilon''\omega\varepsilon_0$. The ionic conductivity is very useful for distinguishing frequency-dependent dipolar phenomena, such as the glass transition, from frequency-independent phenomena, such as the onset of flow and the viscosity minimum.

Examples and Applications of DEA in Curing of Thermosets

Valuable information about the molecular and rheological behavior of thermosets during processing can be obtained from DEA, particularly for on-line cure monitoring and process control. This is illustrated in the following example representing the cure of a DGEBA/diaminodiphenylsulfone, epoxy–amine system (DGEBA/DDS).

The permittivity change measured over a range of frequencies during the isothermal cure of a DGEBA/DDS resin is shown in Figure 51 (120). The cure temperature is 137°C. To a first approximation, these data are the mirror image of those in Figure 49, consistent with the idea that the change in dielectric properties due to crosslinking during isothermal cure is similar to the effect of a decrease in temperature at fixed T_g. Examination of Figure 51 shows an important difference between the temperature and cure time dependencies, namely, that the relaxed permittivity continues to decrease with cure time under isothermal conditions. This is a direct result of the changing chemistry. The permittivity decreases during cure because of the decreasing ability of the molecules (dipoles) to completely align during the cycle time. Early in the cure at long cycle times (ie, at low frequencies), the measured permittivity is high because of electrode polarization (121). The relaxed permittivity ε_r (ie, the maximum dipole alignment that can be achieved, assuming no electrode polarization) is indicated by the shoulder early in the polymerization at high frequencies. The relaxed permittivity for this system is ~14. As cure proceeds, the dipoles find it more difficult to align themselves with the periodic field and an unrelaxed permittivity, ε_u, of ~4 is achieved. The loss factor during cure is also illustrated in Figure 51. ε'' is a function of the energy required for both dipole orientation and ionic conduction. Early in the cure, ε'' is inversely proportional to the frequency ω (see eq. 10), indicating that ion mobility dominates the loss factor. In Figure 51, the conductivity σ can be seen to decrease (eq. 11) with cure because of the increasing viscosity of the resin. This decrease is followed by a peak in ε''. Here the highest frequency peak occurs at the shortest time. This loss peak is due to the restriction of dipole rotation in the cross-linked resin, and its maximum has been correlated with vitrification (120,122). Similar dielectric relaxation results during isothermal cure have been reported for a DGEBA/DDM (diaminodiphenyl methane) resin (121). Corresponding measurements may be made by dynamic mechanical analysis (see Figs. 52 and 53).

From equation 11, the ionic conductivity (σ) can be calculated from the frequency-independent portion of the loss factor data, that is, where a log–log plot of loss factor versus frequency has a slope of −1, using the relation

$$\varepsilon'' = \frac{\sigma}{\omega\varepsilon_0} \tag{11}$$

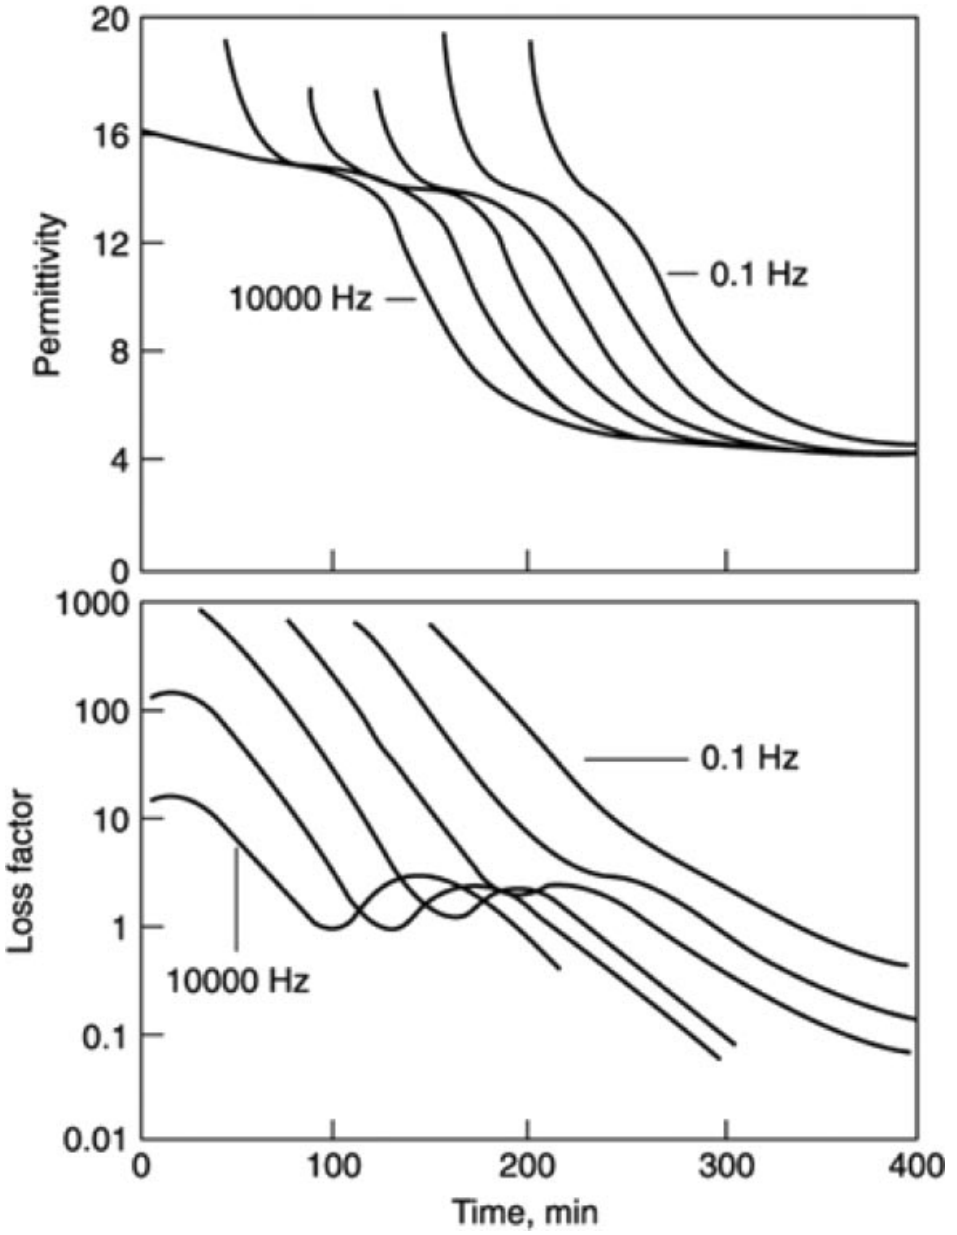

Fig. 51. Permittivity change measured over a range of frequencies during the isothermal cure at 137°C of an epoxy–amine system (DGEBA/DDS) (120).

Conductivity versus reaction time data for the isothermal cure of the DGEBA/DDS epoxy at six different cure temperatures are shown in Figure 54 (123). If the ion concentration does not change during cure, then σ is directly proportional to ion mobility. Early in the reaction, the ionic impurities move freely in the system and the ionic conductivity is high. The ionic conductivity decreases as

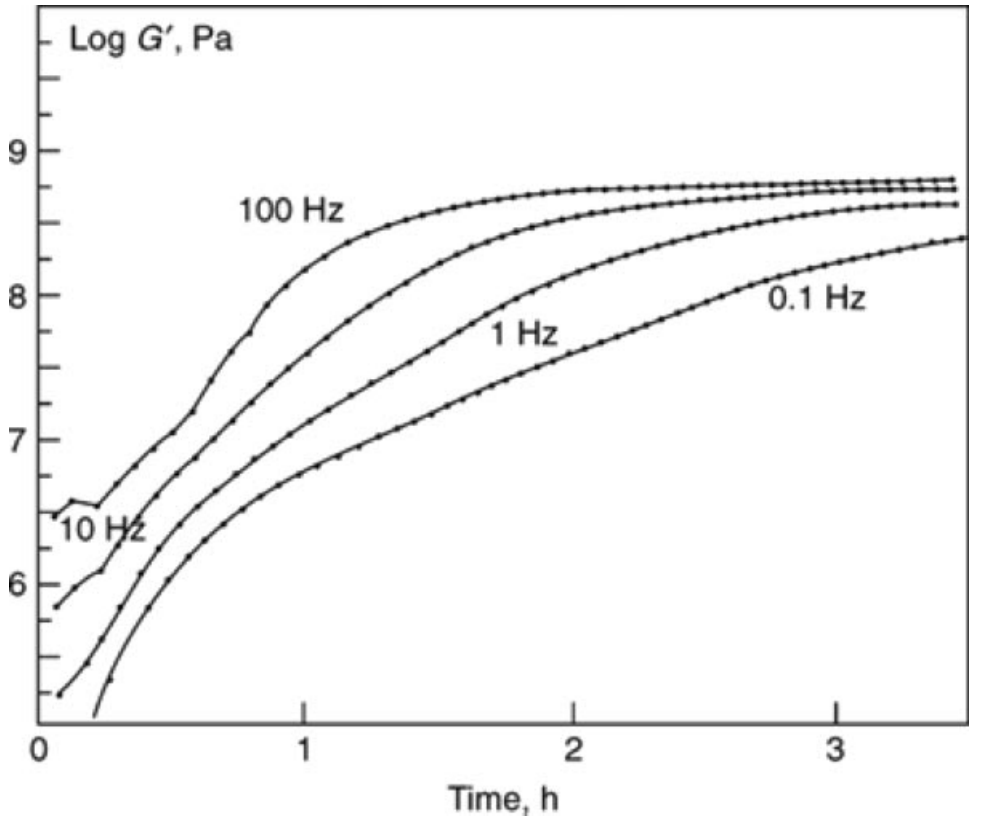

Fig. 52. Dynamic mechanical storage modulus data measured over a range of frequencies during the isothermal cure (137°C) of the same epoxy–amine system (DGEBA/DDS) as in Figure 51 (120).

the cure proceeds and viscosity increases, offering more resistance to the transport of ions. Hence, conductivity is related to the viscosity of the polymer system (124) and the density or "tightness" of the crosslink network. Eventually, there is an inflection in the conductivity versus cure time curve that marks the slowing of the reaction. When there is no further change in conductivity with cure time (ie, $d\sigma/dt \rightarrow 0$), the reaction is considered to be complete (125).

As noted above the ionic conductivity is related to the viscosity of the system prior to up to vitrification, where the reaction becomes diffusion-controlled (126). This is demonstrated by observing conductivity and viscosity changes during dynamic curing at a constant heating rate. Figure 55 illustrates the dynamic cure of a brominated epoxy–phenolic system at a heating rate of 7°C/min (125). Superimposed on the dielectric loss factor plot are dynamic viscosity data taken in a rheometrics rheometer specially adapted to simultaneously measure both dielectric and flow properties of a curing resin. At short times (corresponding to low temperatures), where the reaction is insignificant, the loss factor increases with temperature because of decreasing viscosity. After ∼18 min of ramped heating, the reaction rate becomes significant, resulting in a viscosity increase, while

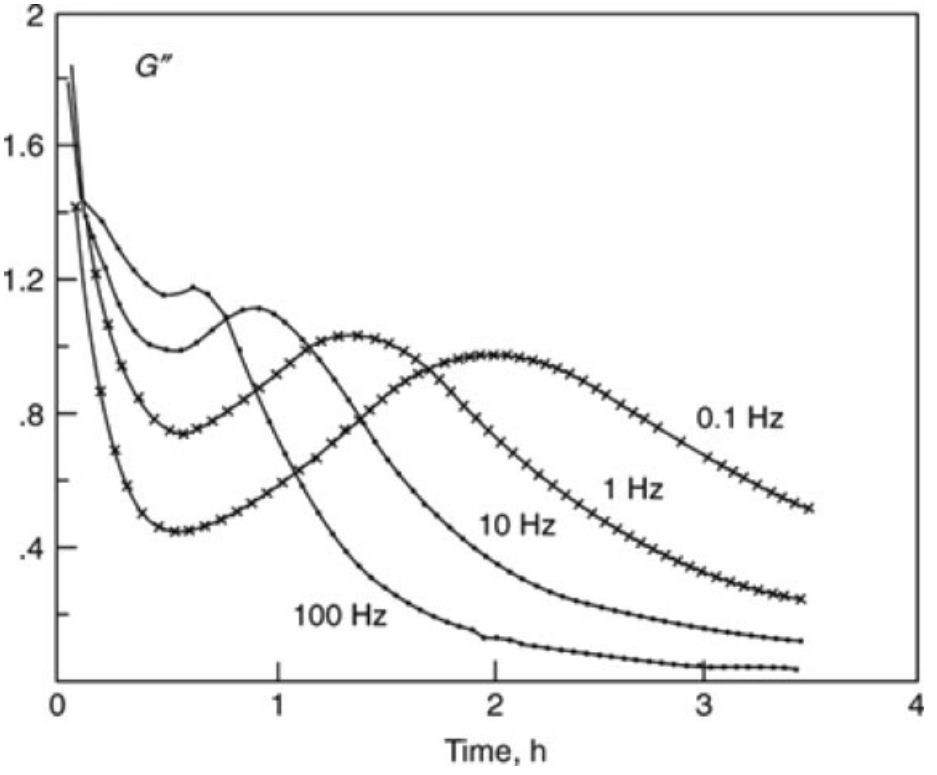

Fig. 53. Dynamic mechanical loss modulus data measured over a range of frequencies during the isothermal cure (137°C) of the same epoxy–amine system (DGEBA/DDS) as in Figure 51 (120).

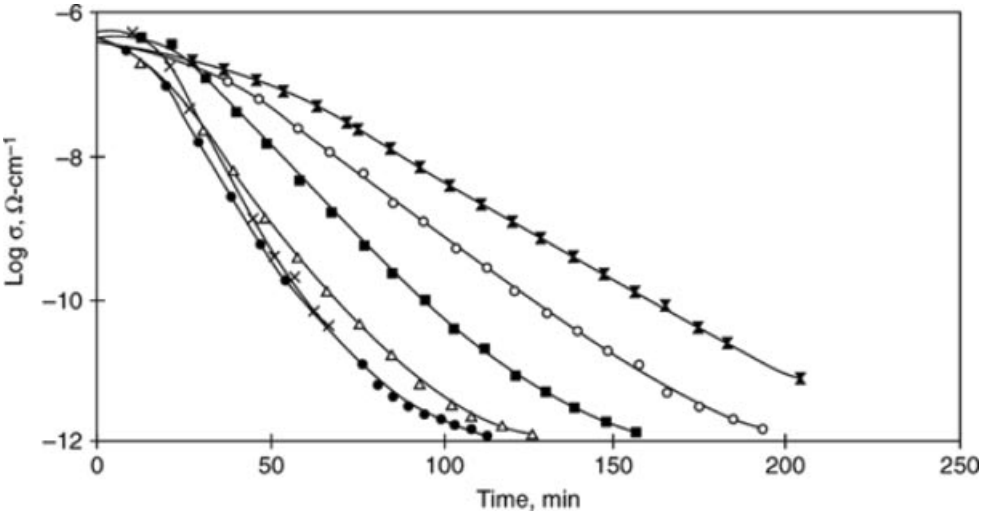

Fig. 54. Isothermal ionic conductivity data for the DGEBA/DDS resin of Figure 51 at various cure temperatures (76,120). ⧗, 135°C; ○, 145°C; ■, 162°C; △, 167°C; ●, 173°C; ×, 188°C.

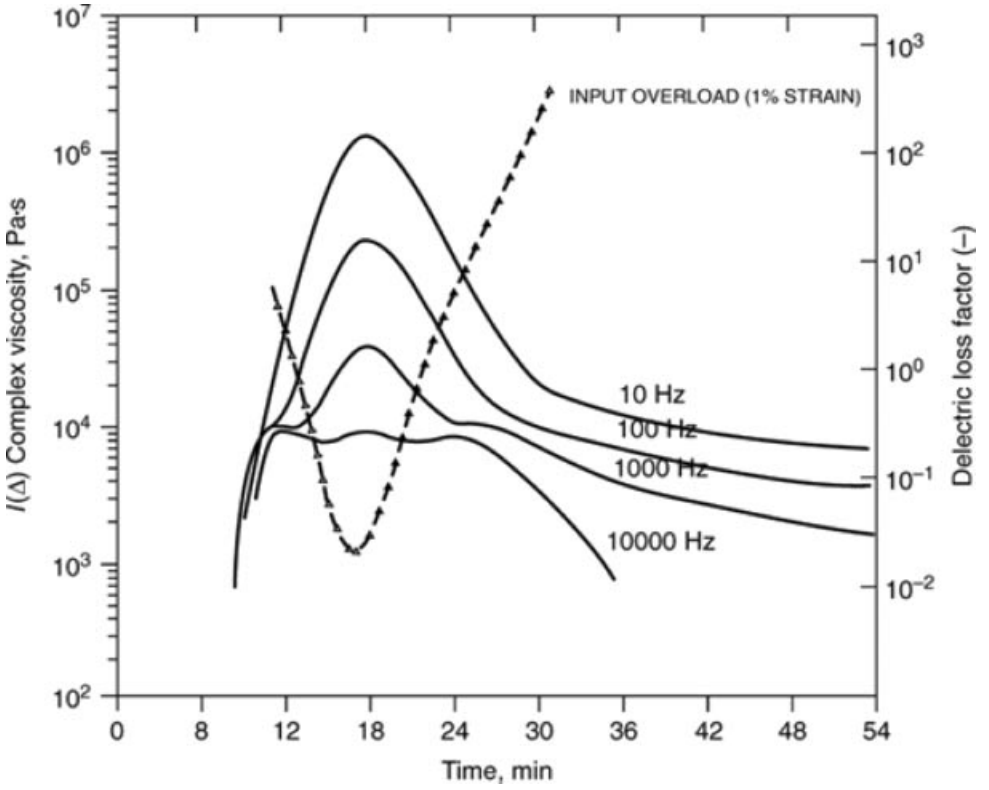

Fig. 55. Dynamic cure of a brominated epoxy–phenolic system at a heating rate of 7°C/min (125); superimposed on the dielectric loss factor plot are dynamic viscosity data taken with a rheometrics rheometer. 1 Pa · s = 10 P.

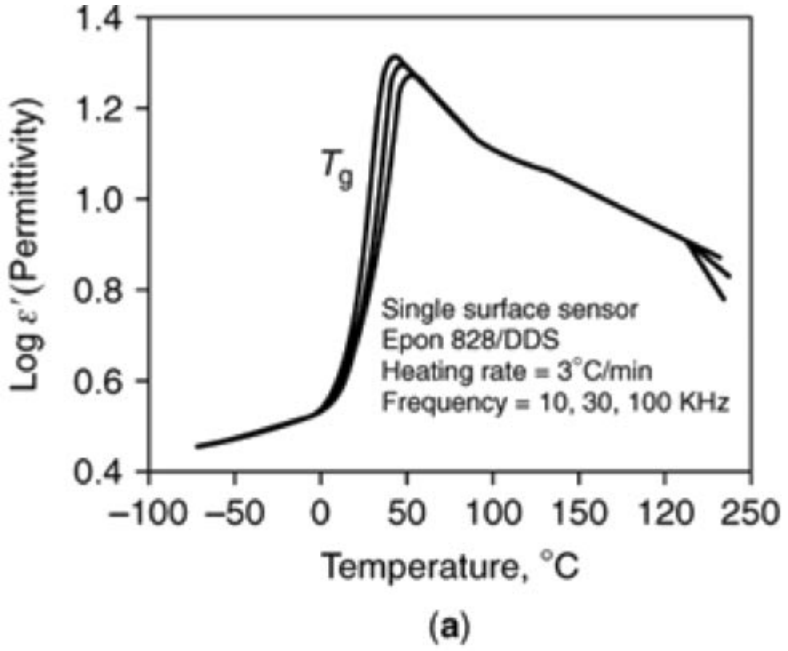
conductivity decreases. The loss factor maximum peak is frequency-independent and occurs in the same time range as the minimum viscosity. In addition, frequency-dependent dipole peaks preceding the loss factor maximum correspond to the softening of the resin system upon heating as the neat resin passes through the glass transition. The dipole peaks observed following the loss factor maximum occur near the time at which the torque input overloads on the rheometer, indicating that they correspond to vitrification (127,128). Similar studies were reported for a bismaleimide–triazine resin system (129).

Figure 56 shows the results of dielectric analysis for the DGEBA/DDS system at a heating rate of 3°C/min, presented as log ε'' versus temperature. The glass transition is detected by the frequency-dependent dipole peaks (Fig. 56**b**) between 0 and 50°C (T_g by DSC would be more typical of values at 0.1–1 Hz, perhaps 20–30°C lower than these data) (76). The frequency-independent viscosity minimum is also evident near 150°C.

For more detail on DEA characterization of thermoset cure as well as other aspects of thermosets, the reader is referred to the excellent presentation by Prime (115) and the entry on thermosets by Prime and Gotro in this encyclopedia.



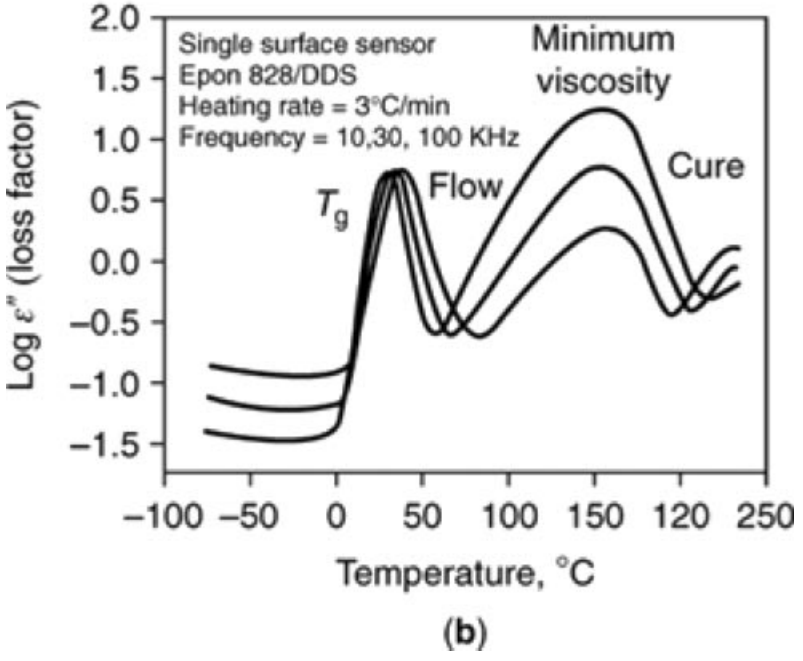


Fig. 56. Dielectric analysis data for the DGEBA/DDS system at a heating rate of 3°C/min, presented as log (ε'') vs temperature. The glass transition is indicated by the frequency-dependent dipole peaks between 0 and 50°C (76).
