
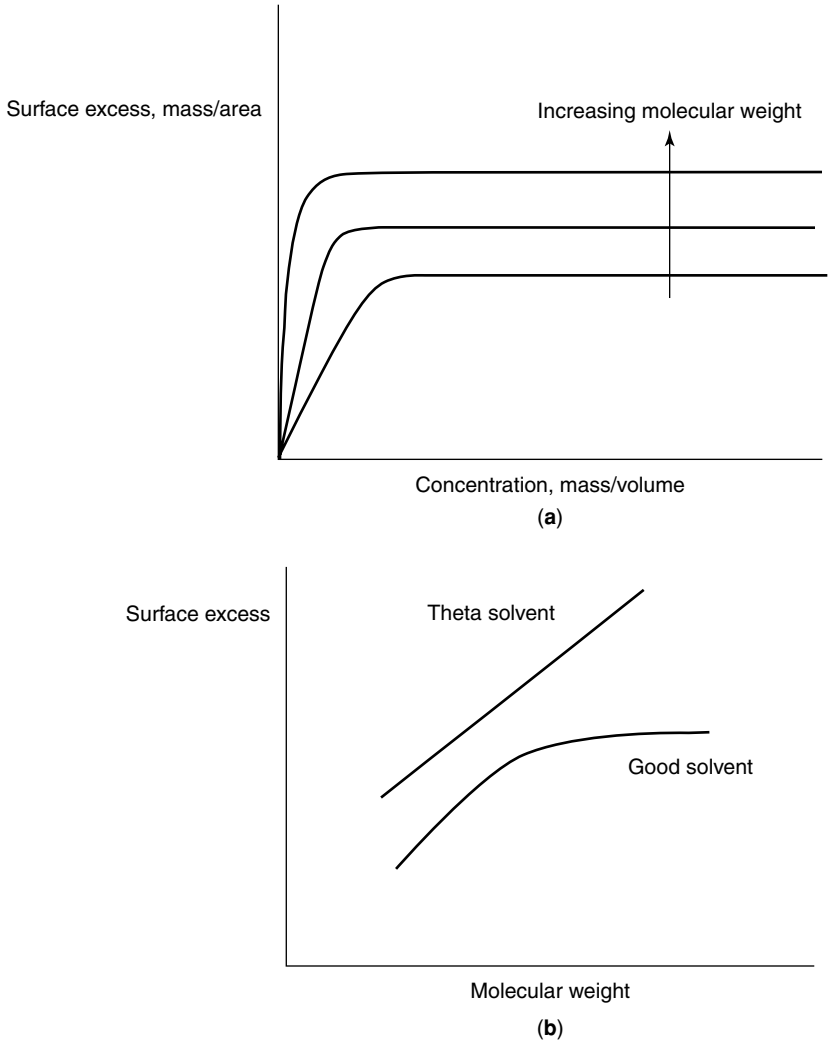

Fig. 3. (**a**) High affinity adsorption isotherm; (**b**) molecular weight dependence of surface excess.

saturates rapidly with increase in concentration of polymer chains in solution. Initially, the surface excess increases with an increase in molecular weight but at high enough molecular weights, the surface coverage becomes independent of molecular weight, as illustrated in Figure 3b. The adsorbed amount is higher in the case of a theta solvent as compared to a good solvent and it increases continuously as a function of molecular weight (19).

The shape of the isotherm is influenced by the average molecular weight as well as the molecular weight distribution of the adsorbing polymer. At low molecular weights and for polymers showing a broad molecular weight distribution, the isotherm displays a more rounded profile, while in the case of a narrow molecular weight distribution and large molecular weights a sharp profile is observed. In a solution containing polymers of two different molecular weights, the low molecular weight polymer will adsorb first because of faster diffusion constants in the solution. However, the higher molecular weight polymer will eventually displace the lower molecular weight polymer at the surface (20).

Adsorption from a solution containing chains of different sizes depends on the concentration of the polymer chains in the solution. If the adsorbing chains have a broad molecular weight distribution, the smaller chains will adsorb at the surface only when the bulk concentration is extremely small. Under these conditions the surface is not saturated and it can accommodate chains of all sizes. On increasing the bulk concentration the surface gets saturated and the smaller chains begin to be displaced by the larger chains. Thus, the larger chains will predominantly populate a completely covered surface. This is a consequence of the fact that the total loss of translational entropy per unit mass when high molecular weight chains adsorb is lower, as compared to shorter chains, while the change in the enthalpy per unit mass is the same. Thus, the change in total free energy upon adsorption is lower for longer chains in comparison to the shorter ones.

Structure of Adsorbed Polymers. As seen in Figure 2, the structure of the adsorbed chain can be described in terms of loops, tails, and trains (1). The relative fractions of loops, tails, and trains in an adsorbed chain depend upon the strength of interactions between the monomeric units and the interface, polymer concentration, and molecular weight.

Experimentally, it is not possible to distinguish between the segments that form loops and segments that form tails. However, theories such as the Scheutjens–Fleer theory (21) provide information regarding the structure of the adsorbed chains. According to this theory, train segments dominate the structure of adsorbed low molecular weight polymers. With increase in molecular weight, the fraction of segments forming loops and tails increases at the expense of the segments participating in trains. The fraction of the chain in loops increases continuously with the size of the chain; however, after an initial increase, the fraction of the chain in tails remains more or less constant.

The average length of the tail in an adsorbed polymer is predicted to increase with molecular weight and this dependence becomes stronger as the solution concentration increases. On increasing the bulk concentration, the fraction of the chain present in the tail is also predicted to increase at the expense of the fraction of monomers in loops.

The bound fraction, defined as $p = \Gamma_{tr}/\Gamma$ (Γ_{tr} is the surface excess of polymer in physical contact with the substrate), can be experimentally measured and has been known to vary from 0.2 to 0.8 (22). The bound fraction strongly depends on

the solvent quality, the polymer–surface interaction, and the surface coverage. In a good solvent the bound fraction remains constant when the surface is unsaturated. This corresponds to the adsorption from dilute solutions. However, in concentrated solutions when the surface is saturated, the bound fraction starts to decrease. This suggests that chains initially have a flat conformation but as the surface gets populated the chains begin to form loops and tails (23). The bound fraction also increases when the interaction between the chain and the surface increases or when the solvent quality decreases.

For adsorbed homopolymers the average density (or concentration of chain segments) decays monotonically with the distance (z) from the surface. Neutron reflectivity and small-angle neutron scattering have experimentally measured the segment density of the adsorbed layer. Scaling arguments suggest that the segment density scales as $z^{-4/3}$ (24) in good solvents, whereas mean field calculations predict that the segment density scales as z^{-2} (25). These predictions are valid only in the limit that the chains are extremely large. Experimental results obtained so far are in qualitative agreement with these predictions; however, there seems to be no agreement on the value of the exponent (26,27).

Thickness of Adsorbed Layers. Since the adsorbed layer is heterogeneous in the distribution of segments, the experimentally measured thickness will depend upon the structural aspect of the adsorbed chain that the technique measures. For example, hydrodynamic techniques are sensitive to the contributions from tail segments. On the other hand, ellipsometry is sensitive to the trains and loops of an adsorbed layer. As the tails are much longer than the loops, the hydrodynamic thickness is larger than those measured by optical techniques. The structure of the adsorbed layer changes with the solvent quality, surface coverage, and size of the adsorbing molecule; therefore, all of the above parameters will influence the value of the measured thickness. For example, since the tail length increases strongly with the chain size, the hydrodynamic thickness shows a stronger dependence on the molecular weight as compared to the thickness obtained by ellipsometry. Also because of the fact that chains adopt flat conformations at low surface coverage, the hydrodynamic thickness will be lower at low surface coverage, but will increase strongly with increasing surface coverage (21).

Thickness measurements on adsorbed layers have found that the thickness of the adsorbed layer exhibits a power law dependence on the molecular weight. However, the value of the exponent has been reported to vary from 0.4 to 0.7. The value of the exponent depends upon the technique and the polymer–solvent system being studied (28). In the case of adsorption from a theta solvent, the thickness of the adsorbed layer varies as $M^{0.5}$ (29).

Dynamics of Adsorbed Chains. In solution, conformation interconversions in a polymer chain occur in microsecond time scales. At a surface, because of adsorption of train segments the time frame for conformational rearrangements of adsorbed macromolecules is increased to hours. The nonequilibrium nature of the adsorbed layer is strongly evident in the exchange kinetics of adsorbed polystyrene molecules (30,31). The exchange time constants depend on the duration of time that the adsorbed chains are allowed to stay on the surface before being displaced. In order to explain this behavior, it is suggested that the adsorbed chains continuously relax toward an equilibrium state by increasing the bound fraction. The time required to reach an equilibrium conformation can be of the order of days. The direct IR measurements of bound fraction in poly(methyl methacrylate) and

poly(dimethyl siloxane) also suggest that the bound fraction increases with time (32,33).

An interesting feature of adsorbed polymers is that the chains do not desorb from the surface when exposed to the pure solvent. This apparent irreversibility of adsorption arises from the fact that the activation energy required to remove a chain from a surface is extremely high. However, it is possible to replace an adsorbed chain with a displacer molecule that has a higher affinity for the surface (34).

If the exchange is governed by surface energetics, the surface excess of the initially adsorbed polymer decays exponentially with time. The time constant for exchange of an equilibrated layer in this case increases exponentially with the molecular weight of the adsorbed molecules. However, this is true only for a chemically homogeneous surface. In the case of a chemically heterogeneous surface the exchange time constant shows a power law dependence on the molecular weight (30).

If the exchange is governed by diffusion away from the surface, then a stretched–exponential type of behavior $\Gamma(t) = \Gamma(0)\ \exp[-(t/\tau)^{\beta}]$ is observed for the decay in the surface excess of the initially adsorbed polymer. The value of the exponent β can vary between 0 and 1, depending on the rate of readsorption and the bulk diffusion rates (35,36). If diffusion is slow and the chain exhibits a strong tendency to readsorb, β will have a small value ($\beta < 1/2$). The time constant for exchange in this case scales as D^{-1}, where D is the diffusion coefficient of the polymer chain in the matrix of adsorbed chains.

Adsorption of Copolymers. In the case of adsorption of copolymers the structure and extent of adsorption depend on the type of copolymer involved. Figure 4a is a schematic of the type of structures that adsorbed copolymers might adopt.

In block copolymers (qv), the block that is preferentially adsorbed is called the anchor while the nonadsorbing block is called the buoy. In this case the adsorbed structure is affected by the nature of the solvent and the relative sizes of the blocks.

In a solvent that selectively solubilizes one of the blocks, when the chain adsorbs, the anchor collapses to form a dense layer, while the buoy stretches out to form a brush-like structure. Adsorption in this case is decided by the competition between van der Waals attraction between the anchor and the substrate and repulsive interactions between the buoys. This is referred to as the "van der Waals brush regime" (37).

If the solvent is nonselective, the anchor has a swollen structure similar to an adsorbed homopolymer. In the case of adsorption of an AB block copolymer from nonselective solvents there are two possible cases (38): The first is referred to as the "buoy" regime, in which the anchor are small and adsorption is dominated by repulsive interactions between the buoys. Increasing the length of the anchor will increase the amount adsorbed. The second case is called the "anchor" regime, in which the anchor layer is saturated and the buoys are small in size. Here, increasing the length of the anchor block will not increase the adsorbed amount.

A major difference between adsorption of homopolymers and block copolymers is that in the case of block copolymers, the proportion of trains and loops are small as compared to the tails. Consequently, the volume profile in block copolymers exhibits a parabolic decay with distance (39,40). In the case of random

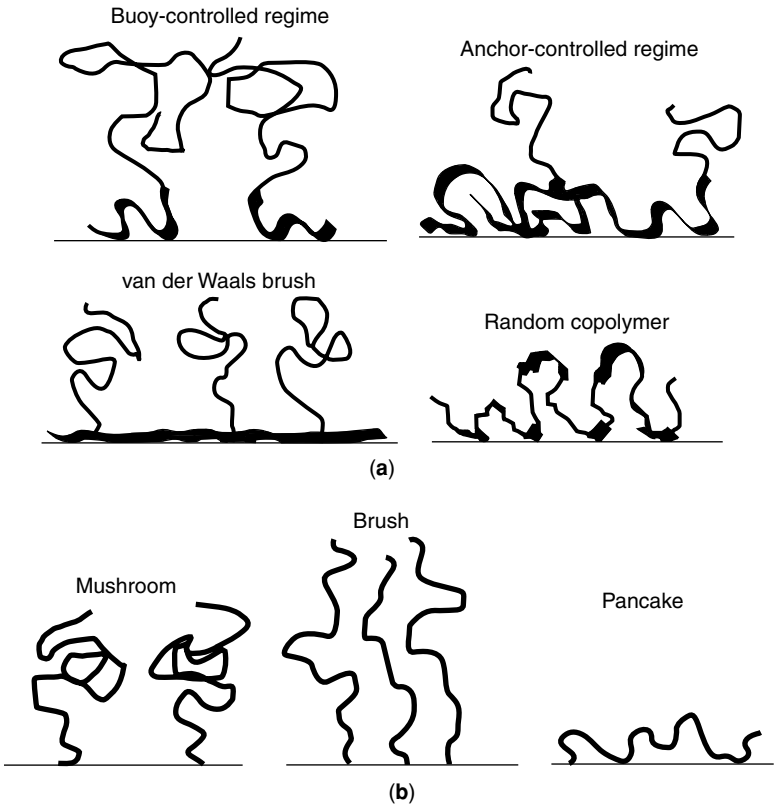

Fig. 4. (**a**) Adsorption of copolymers at a surface; (**b**) end functionalized polymers at a surface.

copolymers, in addition to the solvent quality and size, the adsorption behavior is determined by the composition and distribution of the monomers along the chain. For a truly statistical copolymer the adsorption behavior can be expected to be between the behaviors of the two homopolymers (41).

Adsorption of End Functionalized Chains. Terminally attached polymer chains (42) are a special case of adsorption because the end groups may be permanently grafted to the surface. The reason for this kind of behavior is the formation of strong bonds between the end group and the surface. If the bond is chemical in nature the adsorption is called chemisorption. In the case of physisorption, the interaction between the end group and the surface strongly outweighs the solvent–surface and solvent–end group interaction.

Figure 4b is a schematic of the various structures that terminally adsorbed chains can adopt at the interface. The structure of these attached chains depends on the surface coverage, solvent quality, and the polymer–surface interaction. If the latter interaction is extremely weak the chain gets repelled from the surface, forming a "mushroom" type structure at low surface coverages. If the polymer–surface interaction is strong enough then at low surface coverage the polymer adopts a flat conformation called a "pancake." At large surface coverages, the chains stretch to form a structure known as a "brush."

The degree to which the chains extend is controlled by the excluded volume interactions between the chains and the entropic penalty due to stretching. The extension of the mushroom structure normal to the surface is of the order of $2R_g$, where R_g is the size of the chain in the bulk, while in the case of an extended brush it is much longer. For a fixed surface coverage the thickness of the adsorbed layer increases linearly with chain length. If the chain length is fixed the thickness has a power law dependence on the grafting density (43).

Measurements of the structure of these chains when the polymer does not adsorb on the surface indicate that the volume fraction profile is parabolic at high surface coverages. Changing the solvent conditions causes a dramatic change in the volume profile, which changes from being parabolic in good solvents to being block-like in bad solvents (44).

Adsorption of Polyelectrolytes. The presence of charges on the surface or on the polymer chain affects the adsorption behavior of polymers. When the polymer is uncharged but the surface is charged, the surface attracts counterions that can prevent the polymer from adsorbing. This interaction can be screened by addition of salt, but the effect of the salt is not very significant.

In the adsorption of polyelectrolytes, columbic interactions play a significant role. These interactions can exist between the chain and the surface as well as between the ions on the chain. Addition of salt causes these interactions to be screened and therefore the salt concentration has a significant impact on the adsorption behavior. When adsorption occurs on an uncharged surface the adsorbed amount increases with an increase in salt concentration. When the salt concentration is low the adsorbed chains are predominantly flat and the adsorbed amount does not depend significantly on the length of the molecule. At high salt concentrations the polyelectrolyte adsorption is similar to the adsorption of uncharged homopolymers exhibiting similar structural features such as loops and tails. Under these conditions the adsorbed amount does increase as a function of molecular weight. Similarly, when the polyelectrolyte adsorbs on a surface having the same charge, no adsorption is seen until a critical salt concentration after which the adsorbed amount starts to increase. When the surface is oppositely charged and the polymer has a strong interaction with the surface, the polyelectrolyte adsorption increases with salt concentration provided that the chain is highly charged (45). However, if the chain is not highly charged, increasing the salt concentration reduces the electrostatic interaction between the chain and the surface, reducing adsorption. Increasing the salt concentration may also reduce the solvent quality and will result in an increase in adsorption. Also, if the counterions start adsorbing on the surface, they will displace the adsorbed polyelectrolyte chains (46). Using scaling arguments it has been shown that the thickness of the adsorbed layer is a nonmonotonic function of the surface charge density (47).

A sequential adsorption of anionic and cationic charged polyelectrolytes also leads to formation of stable multilayers (48). Upon adsorption, the charged groups present in the adsorbed chains may overcompensate the charges present on the surface, resulting in a change in its polarity. Now the surface can attract another oppositely charged polyelectrolyte molecule. By sequentially using anionic and cationic polyelectrolytes it is possible to form a multilayer whose stability can be controlled by the polymer charge and the ionic strength. It has been shown that very stable multilayers are formed with high charge content and in the presence of low ionic strength (49).

Adsorption at Liquid–Liquid Interfaces

An example of adsorption of this kind is the adsorption occurring at the oil–water interface. The driving force for adsorption in this case is the minimization of the interfacial tension between the two interfaces. Typically, random copolymers or block copolymers, in which the monomeric units are preferentially solvated in either of the two phases, adsorb readily at the interface. In the case of homopolymers, adsorption occurs either if the polymer is soluble in both the phases or if the polymer has functional groups that can reduce the interfacial tension. Thus, both poly(ethylene oxide) and poly(methyl methacrylate) readily adsorb at the toluene–water interface. The former is soluble in both the phases while the latter has polar side groups that effectively screen the interactions between toluene and water. However, because of its hydrophobic nature polystyrene does not adsorb at the same interface (50).

One of the simplest methods to study adsorption at the oil water interface is to measure the variation of interfacial tension as a function of concentration. If the polymer used for adsorption is monodisperse, then the Gibbs equation (51) may be used to estimate the surface excess. However, if the polymer is polydisperse, this method will give erroneous values of the surface excess because the larger molecules will tend to adsorb preferentially, and the equation is unable to account for this adsorption behavior. As a result, most of the data available in the literature report the change in the interfacial tension as a function of concentration without attempting to convert it into an adsorbed amount. Apart from interfacial tension measurements, other techniques such as total internal reflection fluorescence microscopy (52) and scintillation measurements from radiolabeled polymers (53) have also been used to measure the adsorption at the liquid–liquid interface.

The thickness of adsorbed layers at liquid interfaces has been experimentally studied using neutron reflectivity (54). The structure of the adsorbed polymer at the liquid–liquid interface depends on the nature of the polymer and the interaction of the segments with the two phases. For example, if a diblock copolymer adsorbs at an oil water interface, the chain will partition itself in the two phases such that the block that is preferentially solvated by water will be in the aqueous phase, while the block that is preferentially solvated by oil remains in the organic phase. This results in the chains stretching at the interface, and the adsorbed layer becomes thick. On the other hand, if a random copolymer having the same composition as the diblock copolymer were to be adsorbed at the same interface, the interfacial thickness would be smaller because the unfavorable interactions between the parts of the copolymer and the two phases would localize the chain at the interface.

Adsorption at Air–Liquid and Polymer–Polymer Interfaces

The structure of adsorbed chains at the air–liquid interface is similar to that at the solid–liquid interface. Adsorption at air–liquid interface has been studied by ellipsometry (54), X-ray and neutron reflectivity (55,56), surface tension measurements (57), X-ray evanescent wave-induced fluorescence (58), and Langmuir trough techniques (55). Neutron reflectivity measurements indicate that in the

case of homopolymers the segment density decreases as $z^{-4/3}$, which is consistent with scaling predictions for homopolymers at the solid–liquid interface (55).

Another interface of interest is the interface between two polymers. Adsorption at this interface is important from the point of compatibilization in blends. The structure of block copolymers at the interface can be studied using neutron reflectivity. By selective deuteration it is possible to distinguish between the blocks and the homopolymer chains. The measurements indicate that the block copolymer partitions itself in the two immiscible phases, and the segments joining the blocks are distributed over the interfacial region (59).

Applications of Polymer Adsorption

The phenomenon of polymer adsorption has applications in the areas of colloidal science, tribology, separation science, adhesion, nanotechnology, and medicine. Here, we summarize some recent applications of adsorbed polymers.

Flocculation and Stabilization of Colloids. When two surfaces covered with adsorbed polymers are brought in contact with each other they may experience strong repulsive or attractive forces. The interaction forces depend on solvent quality, surface coverage, and segment–surface interactions. In poor solvents or on sparsely coated surfaces the force can be attractive. For sparsely coated surfaces, chain segments from one surface get adsorbed onto the other surface, resulting in bridging. In the removal of suspended fine solids in wastewater treatment it is advantageous to bring particles together, and here bridging-induced flocculation or other attractive forces are useful. In a good solvent and in the case where the surface is completely saturated with adsorbing chains, the force is repulsive. This phenomenon is known as *steric repulsion*. Colloidal particles that tend to coagulate can be stabilized by addition of extremely small amounts of polymer as stabilizers. This technique is commonly used in stabilizing inks, cosmetics, processed food, lubricants, etc (60).

Friction and Lubrication. Steric repulsive forces also exist between two surfaces that are covered by polymer brushes. The onset of repulsive forces coincides with the touching of two brush-coated surfaces. This distance can be controlled by the molecular weight of the polymer chain. Interestingly, in the case of brushes the friction coefficient is very low. This offers an ideal situation where the surfaces can sustain a large normal force with very little resistance to sliding and may find applications as friction modifiers (61). The development of chemical grafting technique in the last five years offer possibilities to create micron-thick brush layers and may offer a more robust approach for practical applications (62).

Polymer Structure and Characterization. In separation science, the phenomenon of adsorption coupled with size-exclusion chromatography (SEC) has been applied to rapidly separate and characterize polymers. In this technique, called full adsorption–desorption/SEC coupling (FAD/SEC), all the components of a polymer blend are initially adsorbed onto an adsorbent. Then each component is displaced using a suitable small-molecule displacer and sent into the SEC column to characterize their size and mass distribution. This approach also finds application in characterizing copolymers having complex architecture (63).

Nanotechnology. In the past 10 years, layer-by-layer deposition has emerged as an important technique to prepare tailored polymer thin films. In this technique oppositely charged polyelectrolytes are adsorbed on a charged surface in a sequential manner. It is possible to incorporate a number of features in these films by varying the functional groups in the adsorbing polymers. For example, by incorporating electrooptical moieties in the multilayer it is possible to form nonlinear optical devices. Similarly, by incorporating silica and submicron-sized metallic spheres one can obtain arrays for photonic band gap applications. It is also possible to obtain two- or three-dimensional structures by the same technique, making it an attractive alternative to conventional photoresist-based lithography (64).

Biomaterials. Adsorbed polymers find many applications as surface modifiers in biomedical applications. By choosing a combination of hydrophobic and hydrophilic copolymers, surfaces can be modified to make them biocompatible (65) (see BIOMOLECULES AT INTERFACES). In the area of tissue engineering (qv), adsorbed layers with specific amino acid sequences can be used to promote cell adhesion and proliferation. The recent developments in the design of biochips to analyze specific DNA molecules also take advantage of this technology. Polymer adsorption on patterned surfaces can be used to mimic pattern recognition. This effect can be used to develop sensors and molecular-scale separation processes (66).

AMORPHOUS POLYMERS

Introduction

Amorphous materials are characterized by the absence of a regular three-dimensional arrangement of molecules; ie, there is no long-range order. However, a certain regularity of the structure exists on a local scale denoted as short-range order. For low molecular weight amorphous materials the structure is characterized with respect to the short-range order of the centers of the molecules as well as the orientational order of the molecular axes. For the case of long-chain amorphous materials it is necessary to specify an additional structural parameter, namely the conformation (1) of the chain which depends predominantly on the intramolecular interactions along the chain (see CONFORMATIONS AND CONFIGURATION).

The structure however is not static but changes continuously as a result of thermally driven orientational and translational molecular motions. The time scale of these motions may consist of a few nanoseconds up to several hundred years. The structure of the amorphous state as well as its time-dependent fluctuations can be analyzed by various scattering techniques such as x-ray, neutron, and light scattering. The static properties (structure) are probed by coherent elastic scattering methods, whereas the time-dependent fluctuations are investigated by inelastic and quasi-elastic neutron scattering, and dynamic light scattering.

Scattering Methods for the Study of Static and Dynamic Properties

X-ray experiments use radiation with a wavelength in the range $10^{-1} - 1$ nm (see X-RAY SCATTERING). The energy of x-rays is so high that all electrons are excited. The electric field of the incoming wave induces dipole oscillations in the atoms.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

The accelerated charges generate secondary waves that add up at large distances to the overall scattering amplitude. All secondary waves have the same frequency, but they may have different phases caused by the different path lengths. Because of the high frequency it is only possible to detect the scattering intensity, the square of the scattering amplitude, and its dependence on the scattering angle. Neutron scattering (qv) experiments allowed for measurements of polymer conformations at large scales, which were not feasible with x-rays. Neutrons interact with the nuclei of the atoms whereas x-rays interact with the electrons. The interaction with matter is different, but the problem of interfering secondary waves is the same. Instead of the electron density the scattering length density is dealt with. The essential fact in neutron scattering is the pronounced difference in the scattering amplitude between hydrogen and deuterium, which is important for the variation of the contrast between the particles and the matrix. Quasi-elastic neutron and light scattering experiments measure the correlation function of the conformational fluctuations of the macromolecules at a given length scale. Neutron scattering monitors the segmental mobility of a polymer chain in the nanometer and nanosecond region, whereas light scattering reflects translational diffusion of the whole polymer coil.

This article describes the present state of knowledge regarding the structure of amorphous polymers as obtained from scattering techniques and the corresponding dynamic properties from a structural point of view. A detailed knowledge of the structure is very important because the thermal, mechanical, viscoelastic, optical, and even electrical properties are strongly governed by the structure and its temporal fluctuations.

In order to describe the static structure of the amorphous state as well as its temporal fluctuations, correlation functions are introduced, which specify the manner in which atoms are distributed or the manner in which fluctuations in physical properties are correlated. The correlation functions are related to various macroscopic mechanical and thermodynamic properties. The pair correlation function $g(\boldsymbol{r})$ contains information on the thermal density fluctuations, which in turn are governed by the isothermal compressibility $\kappa_T(T)$ and the absolute temperature for an amorphous system in thermodynamic equilibrium. Thus the correlation function $g(\boldsymbol{r})$ relates to the static properties of the density fluctuations. The fluctuations can be separated into an isobaric and an adiabatic component, with respect to a thermodynamic as well as a dynamic point of view. The adiabatic part is due to propagating fluctuations (hypersonic sound waves) and the isobaric part consists of nonpropagating fluctuations (entropy fluctuations). By using inelastic light scattering it is possible to separate the total fluctuations into these components.

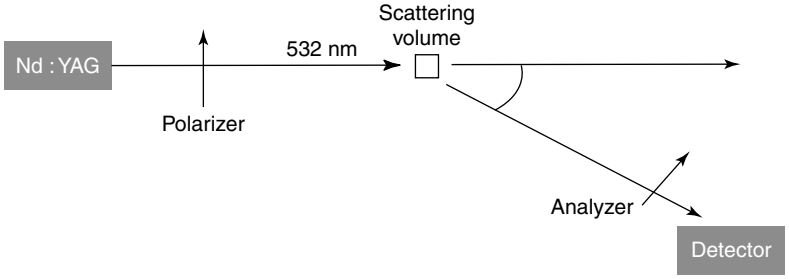
Knowledge of the density and orientational correlation functions is not sufficient to characterize the structure completely, since different structures can give rise to identical correlation functions. Therefore it is necessary to assume models. A complete description of the structure requires that the spatial arrangement of the chain elements, the chain conformation, be known. Usually, average values of the conformation (2) such as the mean square radius of gyration or the mean square end-to-end distance are determined. Direct structure measurements involve the interaction between electromagnetic radiation and the substance in question. A full description of the system will require information about both its

static and dynamic properties. Structure information about the time-averaged or static state is obtained from elastic scattering experiments; ie, the scattered intensity is integrated over all frequencies. Time-dependent or dynamic structures, on the other hand, can be studied with inelastic scattering techniques; ie, the scattered intensity is analyzed with respect to the frequency. The mathematical tool which is used to relate the scattering function $S(q, \omega)$ with properties of the system is a Fourier or Laplace transformation. The system in real space is characterized by correlations between various physical properties (eg, particle densities, distances between atoms, orientations, fluctuations in the local dielectric tensor, pressure and entropy fluctuations) in terms of the corresponding correlation functions.

The theoretical analysis of the scattered spectrum was first presented by Komarov and Fisher (3) and Pecora (4) independently in 1963. In 1964 the spectrum of laser light scattered by dilute solutions of polystyrene latex spheres was observed (5) and was found to exhibit a lineshape in good agreement with theory. In a typical scattering experiment (6) a monochromatic beam of radiation is incident on the material; the wave vector is denoted as $\boldsymbol{k}_0$ and the frequency by ω_0. The scattered radiation is recorded as a function of the scattering angle and frequency shift ω, where

$$\boldsymbol{q} = \boldsymbol{k}_1 - \boldsymbol{k}_0 \quad \text{with} \quad |\boldsymbol{q}| = \frac{4\pi n}{\lambda} \sin(\theta/2) \tag{1}$$

$\boldsymbol{k}_1$ is the wave vector of the scattered radiation, ω_1 the frequency, and λ the wavelength.



The distribution of the scattered radiation as a function of $\boldsymbol{q}$ contains information about the distribution of atoms or molecules on a molecular level, provided that the wavelength of the radiation used is of the order of magnitude of the interatomic spacings. This is the case for neutron and x-ray scattering, whereas in the case of light scattering only integral properties of the structure can be analyzed because of the large wavelength involved. It is worth mentioning that one characteristic property of elastic scattering is its coherence. Thus spatial information is contained in the phases, and the scattered intensity is determined by the interference of the scattered waves in front of the detector. Consequently, if q is a characteristic correlation length in a polymeric system, the obtained information is an ensemble average over distances of the order of q^{-1}. A polarized light scattering experiment with wavelengths 2–3 orders of magnitude longer than neutron wavelengths, observes averages over much longer correlation lengths. By correctly chosen q-range, local or global features of the polymers can be studied (7).

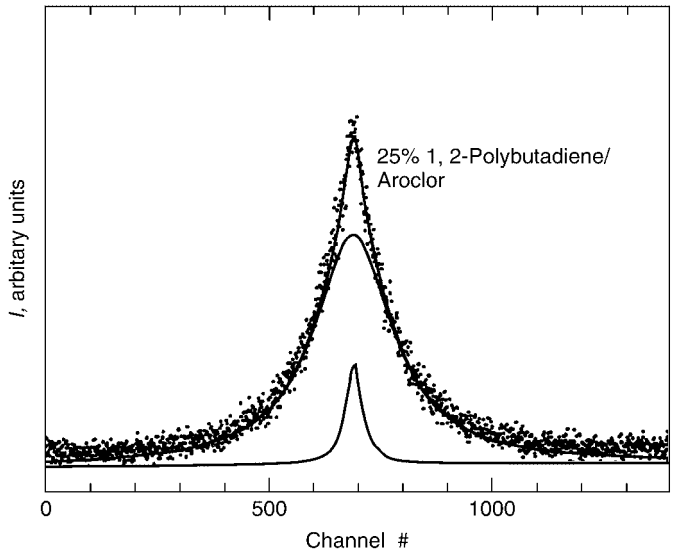


Fig. 1. Depolarized Rayleigh spectra of 1,2-polybutadiene in Aroclor at 353 K. The depolarized spectra were fit to either one or a sum of two Lorentzian functions plus a baseline, considering the overlap of neighboring orders. The integrated intensity is proportional to the effective optical anisotropy γ_{eff}^2.

The method of light scattering with different techniques (8) can cover a wide dynamic range from 10^5 up to 10^{-12} s. With Fabry–Perot interferometry the Rayleigh–Brillouin (9) and depolarized spectra (10,11) can be frequency analyzed to reveal the effects of segmental (12) and orientational (13) fluctuations between 10^{-8} and 10^{-12} s. At longer time scales the scattered light can be analyzed by the photon correlation spectroscopy (pcs) technique. The polarization of the scattered light and the scattering vector $\boldsymbol{q}$, which determines the wavelength of the observed fluctuations, selects and characterizes the observed motion. Figure 1 shows a typical depolarized Rayleigh spectrum (14) of 1,2-polybutadiene in Aroclor at 353 K. The depolarized spectra were fit to either one or a sum of two Lorentzian functions plus a baseline, considering the overlap of neighboring orders. The integrated intensity is proportional to the effective optical anisotropy γ_{eff}^2 and is given by following the expression:

$$I_{\text{VH}} = Af(n)\rho^*\gamma_{\text{eff}}^2 \tag{2}$$

where A is a constant, $f(n)$ is the product of the local field correction and the geometrical factor $1/n^2$, with n being the refractive index and ρ^* is the number density of the solute. Figure 2 shows depolarized intensity correlation functions for a poly(styrene-*b*-1,4-isoprene) block copolymer (15) in the disordered state. The total molecular weight M_n of the copolymer is 3930 and the molecular weight of the polystyrene (PS) block is 2830. The primary contribution to the spectra comes from the local segmental motion of the PS in the copolymer and the dispersion broadens with decreasing temperature, which is evident by inspection of the curves in Figure 2.

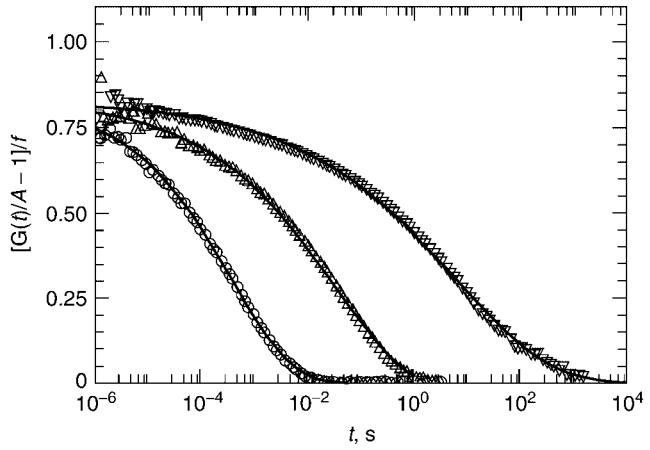

Fig. 2. Depolarized intensity correlation functions for the poly(styrene-*b*-1,4-isoprene) block copolymer. Solid curves are the KWW fits to the data and the β parameters used in the fits are given in the inset. The total molecular weight of the copolymer is $M_n = 3930$ and the molecular weight of the PS block is equal to 2830. The primary contribution to the spectra comes from the local segmental motion of the PS in the copolymer and the dispersion broadens with decreasing temperature. ○ $\beta = 0.38$ at 323 K; △ $\beta = 0.30$ at 303 K; ▽ $\beta = 0.25$ at 287 K.

The structure of the amorphous state is subjected to time-dependent variations, because of the existence of translational and/or orientational motions of both the individual segments and the chain as a whole (16). These motions couple to the light since they induce variations of the local dielectric constant $\varepsilon(\boldsymbol{r}, t)$ or the local polarizability $\alpha(\boldsymbol{r}, t)$. Inelastic and quasi-elastic scattering measurements allow the determination of the time laws according to which these motions occur (17). The particular motion detected by the light scattering technique depends on the polarization of the scattered light and on the scattering vector $\boldsymbol{q}$, which gives the wavelength of the observed fluctuations. Light scattering depends on the directions of the polarizations of the scattered radiation and the incident radiation. Provided that the incident and scattered light are polarized with the electric vector at right angles to the plane containing $\boldsymbol{k}_1$ and $\boldsymbol{k}_0$, VV scattering is observed. Frequency shifts are detectable in the case of light scattering, and thus, temporal fluctuations of the structure can be determined. Individual photons may be scattered with a slight frequency shift. The magnitude and sign of the frequency shift depend on the velocity and the direction with respect to the incident radiation in which an individual particle is moving. This frequency shift is referred to as the *Doppler effect*. The free motion of the particles (macromolecules) in solution is a thermal diffusion with no net transport and therefore no net exchange in energy between the system and the incident light. The scattered light thus consists of a narrow Lorentzian spectrum of frequencies symmetrically broadened because of the random Brownian motion of the particles, and centered at the incident frequency of the laser. The time-correlation function and the frequency-dependent power spectrum are related by Fourier transform. This is usually referred to as quasi-elastic light scattering (qels), a technique allowing one to extract dynamical information about the system, ie, the diffusion coefficient. Because of the large

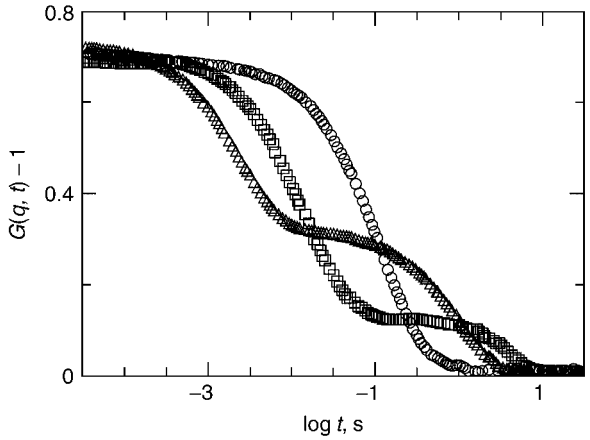

Fig. 3. Experimental intensity correlation functions in the VV configuration for a low molecular weight (PS/PI) polymer blend. Two diffusive decay rates are essentially observed in the VV configuration; however, close to the critical point the faster rate dominates. ○ 315 K (VV); □ 328 K (VV); △ 348 K (VV).

wavelength of the incident light, one sees only integral structural properties, averaged over long distances. The so-called depolarized (18) (VH) light scattering (dls), where V and H indicate a vertical and horizontal direction of the polarization of the incident and scattered light relative to the scattering plane, is related to fluctuations of the anisotropy of the polarizability tensor. Thus, reorientational motions of individual optically anisotropic molecules or collective motions of such molecules may be analyzed by dls (19).

The light scattering spectrum obtained in the VV configuration contains both the anisotropic component and an isotropic one, which is related to local density fluctuations, giving rise to fluctuations of the polarizability or the dielectric constant. In most cases the anisotropic contribution is much smaller than the isotropic one; therefore, the VV scattering measures the density fluctuations (isotropic part) directly. Figure 3 shows experimental correlation functions in the VV configuration for a low M_w polystyrene/polyisoprene (PS/PI) blend, and Figure 4 shows the corresponding depolarized experimental correlation functions (20). Two diffusive decay rates are essentially observed in the VV configuration (Fig. 3); however, close to the critical point the faster rate dominates. The relaxation mode that is shown in the VH scattering geometry is due to double scattering induced by composition fluctuations.

The quantities measured in light scattering spectroscopy are either the autocorrelation function of the electric field $C(t) = \langle \boldsymbol{E}(t) \cdot \boldsymbol{E}(0) \rangle$ or its Fourier transform, the spectrum of the scattered light $I(\omega)$, by using the Fabry–Perot interferometer.

$$I(\omega) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} \mathrm{e}^{-i\omega t} C(t)\, \mathrm{d}t \tag{3}$$

The correlation function $C_{\mathrm{aniso}}(\boldsymbol{q}, t)$ of the total scattered field from undiluted polymers is given by

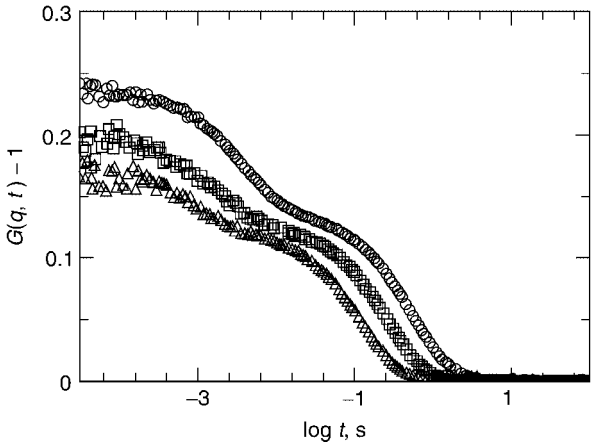

Fig. 4. Depolarized intensity correlation functions for the (PS/PI) polymer blend of Figure 3. The relaxation mode that is shown in the VH scattering geometry is due to double scattering induced by composition fluctuations. △ 353 K (VH); □ 343 K (VH); ○ 333 K (VH).

$$C_{\text{aniso}}(\boldsymbol{q},t)=\left\langle \sum_{m,n}^{N}\sum_{i,j}^{N_s}\alpha_{yz}^{(n)}(j,t)\alpha_{yz}^{(m)}(i,0)\exp\left\{i\boldsymbol{q}\cdot\left[\boldsymbol{r}_j^{(n)}(t)-\boldsymbol{r}_j^{(m)}(0)\right]\right\}\right\rangle \tag{4}$$

where N is the number density of the polymer, and N_s is the number of scatterers per molecule. The angular brackets denote an ensemble average. According to the above equation two mechanisms are generally responsible for VH scattering: segmental orientation combined in the subscript yz and segmental center of mass motion in the exponent term. Alternatively, these two modes are not always statistically independent and frequently even reflect other motions such as overall molecular orientation and coherent internal Rouse–Zimm modes for rigid and flexible coils respectively. On the other hand the correlation function of the isotropic component of the scattered light can be written in the form

$$C_{\text{iso}}(\boldsymbol{q},t)=\alpha^2\left\langle \sum_{m,n}^{N}\sum_{i,j}\exp\left\{i\boldsymbol{q}\cdot\left[\boldsymbol{r}_j^{(n)}(t)-r_j^{(m)}(0)\right]\right\}\right\rangle \tag{5}$$

In contrast to the correlation function of the anisotropic component, only the segment center of mass motion affects the isotropic scattering component. However, because of intra- and interchain interactions in bulk polymers there is no rigorous calculation of the general expressions in equations 4 and 5. Only the Rayleigh–Brillouin spectrum of a viscoelastic fluid, which is determined by the high frequency part of the density fluctuations in equation 5, has an analytical form (21). A spectrum has been computed using a generalized relaxation equation. The polarized scattering is governed by thermal density fluctuations, which, from a thermodynamic point of view, can be separated into an adiabatic and an isobaric component. The adiabatic component gives rise to longitudinal hypersonic waves. The isobaric component I_R causes a nonpropagating thermal diffusive mode. The

translational motion of the segments associated with the isotropic light scattering produces thermally induced longitudinal sonic waves, the nonpropagating thermal diffusive mode, and a localized motion. The first two fluctuations give rise to the shifted Brillouin doublet (22,23) I_B at frequencies $+\omega_s$ and $-\omega_s$ and to the central Rayleigh line. The line width of the unshifted central line, the Rayleigh line, is determined by the thermal conductivity. The intensity ratio, the so-called Landau–Placzek (LP) ratio, is given in the simplest case by the ratio of the specific heats C_P and C_V.

$$\frac{I_R}{2I_B} = \langle C_P/C_V \rangle - 1 \tag{6}$$

In viscous fluids, however, a coupling occurs between internal and external modes of freedom and translational motions. This structural relaxation process, characterized by a frequency ω_e, influences both the central line as well as the Brillouin doublet, depending on the frequency of this relaxation relative to the frequency of the hypersonic waves. In principal three different cases must be considered:

(1) The so-called fast relaxation limit in which $\omega_e \gg \omega_s$. In this case the structural relaxation gives rise to a broad background scattering in the frequency scale, leaving the Rayleigh–Brillouin spectrum nearly unchanged.

(2) The intermediate relaxation limit in which $\omega_e \cong \omega_s$. The two frequencies are of the same order of magnitude and the structural relaxation contributes heavily to the line width of the Brillouin lines. The relaxation processes can be resolved by means of the Fabry–Perot interferometry (24). Figure 5

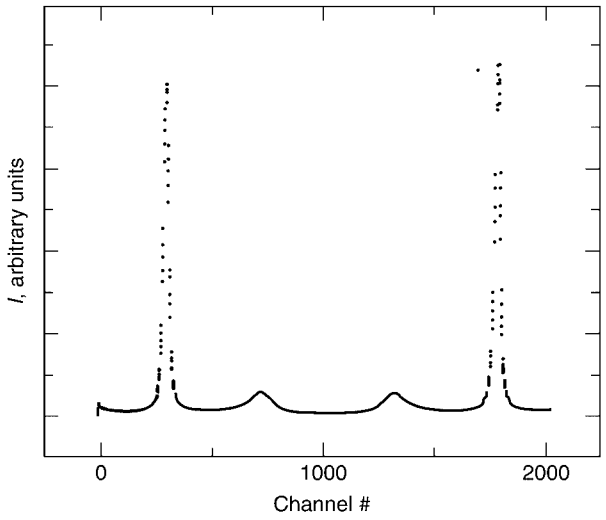

Fig. 5. Polarized Rayleigh–Brillouin spectrum of amorphous PnHMA taken with a Burleigh plane Fabry–Perot interferometer using a free spectral range of 12.4 GHz at 295 K. The two Brillouin peaks are shifted from the incident frequency by the product of the wave vector $\boldsymbol{q}$ and the sound velocity u. The line width of the Brillouin peaks is related to the attenuation of the sound waves. • PnHMA.

visualizes a polarized Rayleigh–Brillouin spectrum of amorphous poly(*n*-hexyl methacrylate) taken with a Burleigh plane Fabry–Perot interferometer using a free spectral range of 12.4 GHz at 295 K. The two Brillouin peaks are shifted from the incident frequency by the product of the wave vector $\boldsymbol{q}$ and the sound velocity u. The line width of the Brillouin peaks is related to the attenuation of the sound waves.

(3) The slow relaxation limit in which $\omega_e \ll \omega_s$. The structural relaxation leads to an additional central line, the so-called Mountain peak (25,26), the width of which can be determined by pcs (27). Thus, structural relaxation processes taking place close to the glass-transition temperature can be investigated by this technique.

The dynamics of slowly varying thermal density fluctuations has been studied by means of pcs (28,29) in the frequency range between 10^{-3} and 10^{7} Hz for several polymeric systems in the molten state as well as in the glassy state. The measured intensity autocorrelation function $C(\boldsymbol{q}, t)$ is related to the normalized time correlation function $g^{(1)}(\boldsymbol{q}, t)$ by

$$C(q,t) = A\left[1 + f\left|\alpha g^{(1)}(q,t)\right|^2\right] \tag{7}$$

where f is the instrumental factor, calculated by means of a standard, a is the fraction of the total scattered intensity associated with the process under investigation with correlation times longer than 10^{-7} s, and A is the baseline. For the pcs measurements near T_g, fluctuations in density and orientation are strongly coupled and hence the relaxation times obtained are indistinguishable. Experimentally only those components with relaxation times longer than 10^{-7} s (frequencies $<$ 0.1 MHz) will be observed by pcs. It was found that, in general, the observed correlation functions are highly nonexponential and have been fitted to the empirical Kohlraush–Williams–Watts (KWW) function

$$g^{(1)}(t) = \exp\left[-(t/\tau)^{\beta}\right] \quad \text{with} \quad 0 < \beta \leq 1 \tag{8}$$

and for concentration fluctuations it is written as

$$g^{(1)}(q,t) = \exp\left[-(t/\tau)^{\beta}\right] \quad \text{with} \quad 0 < \beta \leq 1 \tag{9}$$

Using the KWW function the mean relaxation time is given by

$$\langle\tau\rangle = \int_{-\infty}^{+\infty} g^{(1)}(t)\,\mathrm{d}t = \frac{\tau}{\beta}\Gamma(\beta^{-1}) \tag{10}$$

where $\Gamma(\beta^{-1})$ is the Gamma function. $g^{(1)}(t)$ is related to the longitudinal compliance (30,31) $D(t)$ by

$$\alpha g^{(1)}(t) = \left[D_0 - D(t)\right]/D_\infty \tag{11}$$

and

$$D(t) = D_\infty + (D_0 - D_\infty)\int_{-\infty}^{+\infty} L(\ln\tau)(1 - e^{-1/\tau})\, d\ln\tau \tag{12}$$

The depolarized spectrum is dominated by local fluctuations of the optical anisotropy owing to an overall orientation of stiff molecules, local motions of optically anisotropic segments or internal Rouse–Zimm modes for flexible chain molecules. The depolarized spectrum thus reflects dynamics of collective molecular orientation when the interaction between translation and rotation can be neglected.

Density Fluctuations—Excess Scattering at Low *q*

From statistical fluctuation theory (32), the static structure factor is given by

$$\lim_{q\to 0} S(q) = \langle \delta N^2 \rangle = V\rho^2 k_B T \beta_T(T) \tag{13}$$

where $\delta N\,(=N - \langle N\rangle)$ is the fluctuation in the number of particles in the scattering volume V, ρ is the average number density, and β_T is the isothermal compressibility $[-1/V(\partial V/\partial P)_T]$. The total density fluctuation in an arbitrary volume is given by

$$\Psi_T \frac{\langle \delta N^2 \rangle}{\langle N \rangle} = e k_B T \beta_T(T) \tag{14}$$

According to the above equation, the density fluctuations should have a temperature dependence similar to that of $\beta_T(T)$, which is discontinuous at T_g. However, it has been shown earlier (33–42) that it is only the temperature coefficient of the density fluctuations which is discontinuous at T_g.

The density fluctuations defined above can be obtained experimentally in two ways: (*1*) from the measured compressibility data using equation 14, or (*2*) from small-angle x-ray scattering (saxs), using the extrapolating intensity at $q = 0$ (33–42):

$$\lim_{q\to 0} I(q) = n^2 k_B T \beta_T(T) \tag{15}$$

where n is the average electron density. Then, the particle density fluctuation is given by

$$\frac{\langle \delta N^2 \rangle}{\langle N \rangle} = \frac{I(0)}{nZ} \tag{16}$$

where Z is the number of electrons per particle.

Two examples are discussed below where the measured density fluctuations are compared with the calculated ones from the compressibility data. In Figure 6,

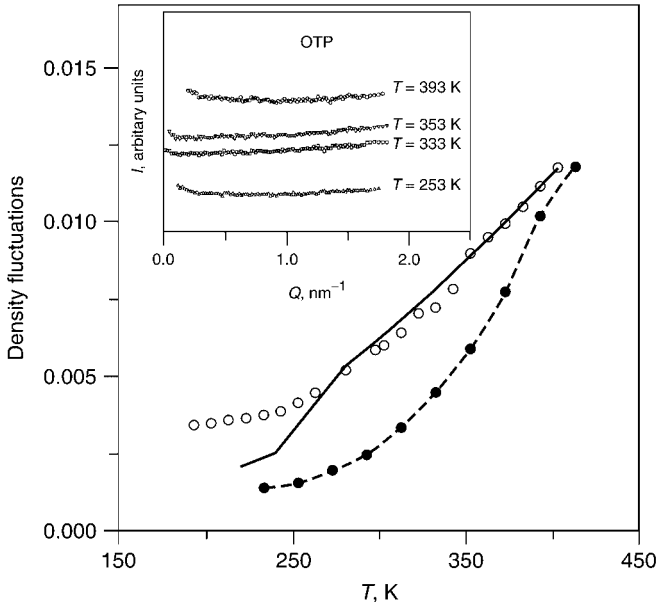

Fig. 6. Density fluctuation in OTP measured by saxs (○). The solid line gives the calculated density fluctuations from the measured isothermal compressibility. Filled symbols gives the propagating density fluctuations calculated from the Brillouin shift in a Rayleigh–Brillouin experiment. The inset shows typical saxs curves obtained with a conventional Kratky saxs camera.

the density fluctuations are shown for the glass-forming liquid *ortho*-terphenyl (OTP), and in Figure 7 for two polymers with slightly different backbone structures; bisphenol A polycarbonate (BPA-PC) and tetramethyl-bisphenol A polycarbonate (TMPC) (42). In both cases, at $T > T_g$, there is a good agreement between the measured and calculated density fluctuations but at $T < T_g$, the former exceed the latter by a factor of 2. Below T_g, the density fluctuation can be described as $\rho k_B T \beta_T(T_g)$, where $\beta_T(T_g)$ is the compressibility obtained from pressure–volume–temperature (PVT) measurements in a comparable time scale with $I(0)$, without, however, displaying a leveling-off to a constant value. The much higher density fluctuations below T_g result from the non-equilibrium nature of the glass and the contribution of frozen-in fluctuations (33–42).

The free-volume fluctuation model (43) which is based on the average free volume and its fluctuations has been successful in describing such differences in density fluctuations of different polymers as well as to explain the suppression of the intensity of sub-glass processes in polymer/additive systems. According to the model, the free volume is assumed to have a Gaussian distribution characterized by two parameters: (*1*) the average free volume $\langle V \rangle$ and (*2*) the distribution of free volume, which is given by the variance $\langle \delta V^2 \rangle^{1/2}$ of the distribution $P(\delta V)$. The saxs measurements allow the direct evaluation of the density fluctuation and the average free volume can be estimated from the position of the "amorphous halo" as obtained from wide angle x-ray scattering (waxs). Figure 8 gives a schematic of the distribution $P(\delta V)$ of the density fluctuations in glassy BPA-PC and TMPC

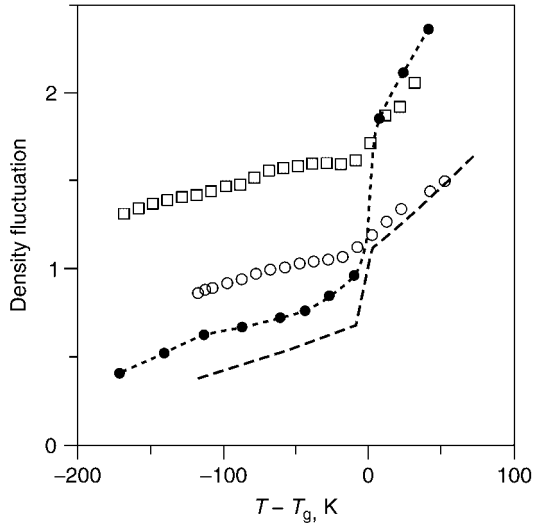

Fig. 7. Density fluctuations, measured by saxs, for BPA-PC (○) and TMPC (□) as a function of $T-T_g$. The dotted line is the calculated density fluctuation of TMPC from the isothermal compressibility data of this study obtained in a PVT experiment. The dashed line represents the calculated density fluctuation of BPA-PC from the literature compressibility data.

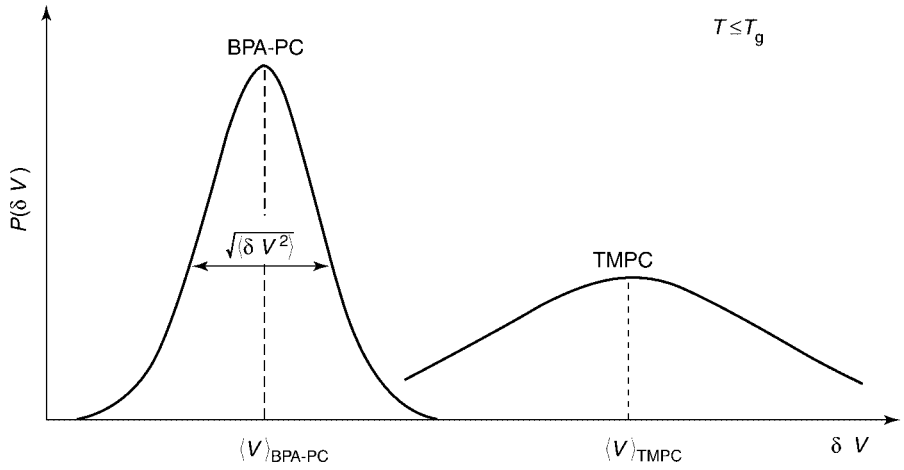

Fig. 8. Schematic of the distribution $P(\delta V)$ of the density fluctuations in glassy BPA-PC and TMPC, according to the free-volume fluctuation model.

according to the free-volume fluctuation model. Peak positions and widths are determined by the average free volume and by its fluctuations, respectively. This is a nice example of a system where $\langle V\rangle$ and $\langle \delta V\rangle$ are determined to be different against the assumed "universality." This variance reflects on the structural units; in TMPC the methyl substitution causes less efficient packing as compared to BPA-PC.

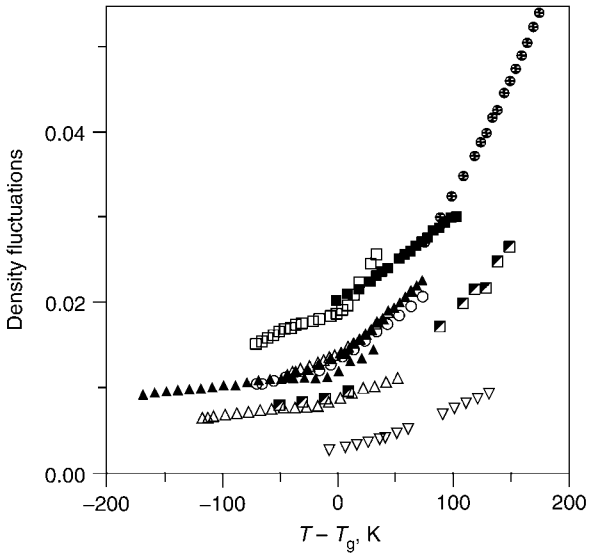

Fig. 9. Density fluctuations of some glass-forming liquids and polymers as a function of temperature difference from T_g. ▽ BKDE; △ BPA-PC; ▲ TMPC; □ OTP; ○ poly(cyclohexyl methacrylate) (PCHMA); ▲ poly(*n*-butyl methacryalte); ■ poly(*n*-hexyl methacrylate); □ poly(methyl methacrylate) (PMMA); • polybutadiene.

In Figure 9, the measured density fluctuations from a variety of polymers and glass-forming liquids are compared. The amount of density fluctuations at the glass transition is typically about 1%; however, the results shown (Fig. 9) indicate considerable variation among the different polymers and glass-forming liquids investigated. Typically, glass-forming liquids possess the lowest fluctuations and in some cases (mainly within the poly(*n*-alkyl metacrylate) series, ie, for poly(methyl methacrylate) (PMMA), poly(*n*-butyl methacryalate) (PnBMA), poly(*n*-hexyl methacrylate) (PnHMA), the measured density fluctuation above the glass transition exceeds the calculated one from the PVT measurements on identical samples. The higher contribution of density fluctuations can have different origins, such as "contamination" from concentration fluctuations (ie, additives) or contribution from short-range intersegmental density fluctuations. Additives alone, however, should be in high concentrations (44) to explain the observedbehavior.

The evaluation of density fluctuations using equation 14 or 16, conceals the relative contribution of propagating and static components in the measured total density fluctuations. To overcome this difficulty one can evaluate the contribution of the propagating density fluctuations from the temperature dependence of the phonon peak obtained in the Rayleigh–Brillouin experiment (44). This is based on the notion that the propagating density fluctuations are determined from the thermal-diffuse scattering (tds) near the origin of the reciprocal space, as in the case of crystalline solids. Then in the limit $q \to 0$, this contribution is given by

$$\Psi_S = \left.\frac{\langle \delta N^2 \rangle}{\langle N \rangle}\right|_{\text{phonon}} = \rho k_B T \beta_S(T) \tag{17}$$

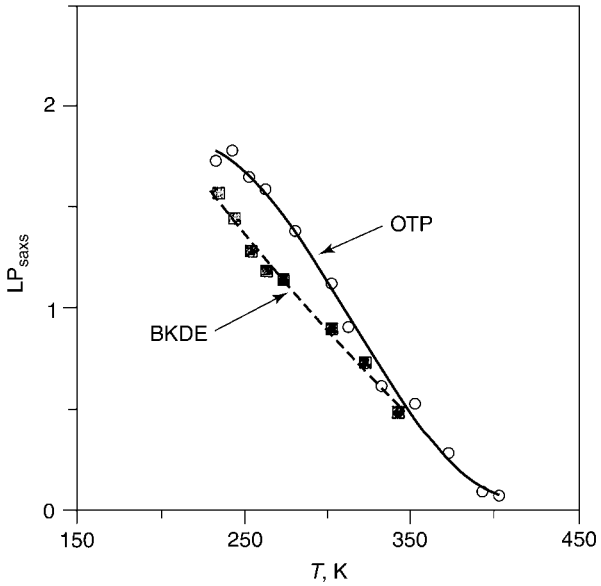

Fig. 10. LP intensity ratio obtained from the measured compressibilities of OTP (○) and BKDE (■).

where $\beta_S(T)$ is now the adiabatic compressibility ($\beta_S = 1/\rho^* u^2$, ρ^* is the mass density and u is the sound velocity) evaluated at the frequency ω_{phonon}. The ratio of the total to the propagating fluctuations defines an "x-ray" LP ratio (44):

$$R_{LP} = \frac{\Psi_T}{\Psi_S} - 1 = \frac{\beta_T}{\beta_S} - 1 \tag{18}$$

which is readily obtained in a Rayleigh–Brillouin experiment from the intensities of the central (I_C) and shifted Brillouin lines (I_B) as $I_C/2I_B$. The temperature dependence of the LP ratio for two glass-forming liquids, OTP and BKDE [1,1-di(4′-methoxy-5′ methyl-phenyl)cyclohexane] (45), is shown in Figure 10 and is in good agreement with the values predicted for relaxing liquids.

On the basis of the saxs results obtained within the shown q-range, one would assume that the density fluctuations of OTP and BKDE (equivalently called BMMPC) behave as one would expect from equilibrium statistical mechanics. However, one can notice a slight increase of $I(q)$ at low q, which finds its counterpart at the much higher $I(q)$ at the smaller q values accessible by light scattering (ls). In order to use both sets of data (ls and saxs) in a common plot, an effective compressibility $k_B T \beta_T$ is defined, which is obtained from saxs as I/n^2 and from ls by using (45):

$$\frac{R_i(q)}{\pi^2/\lambda^4(\rho * \partial\varepsilon/\partial\rho *)^2} = k_B T \beta_T \tag{19}$$

where $R_i(q)$ is the isotropic Rayleigh ratio [$R_i(q) = R_{VV}(q) - (4/3)R_{VH}$]. The results, in the form of relative density fluctuations, are shown in Figure 11 for BMMPC.

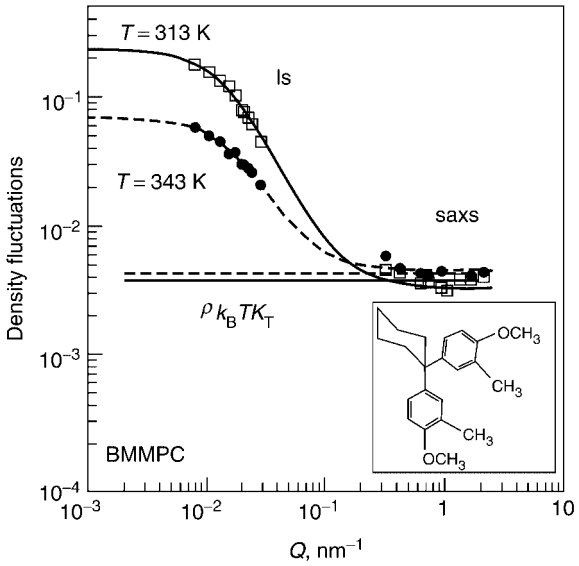

Fig. 11. Relative density fluctuations of BMMPC measured by light scattering (ls) and saxs at two temperatures: T_g + 52 K and T_g + 82 K. The curves are obtained by fitting with the Ornstein–Zernike function.

For the description of the shape of the static scattering function one can try to use the Ornstein-Zernike function:

$$S(q) = \frac{S(0)}{1 + \xi_{OD}^2 q^2} \tag{20}$$

where ξ_{OD} is the static correlation length. For OTP and BMMPC, very large correlation lengths up to 180 nm at temperatures T_g + 40 K are obtained. On the basis of the distinct scattering feature, which violates the thermodynamic law (eq. 13), these fluctuations are called long-range density fluctuations in contrast to the normal density fluctuations detected by conventional-laboratory saxs measurements.

The essential contribution of Fischer and co-workers was not only to show the existence of long-range density fluctuations in static experiments (46–48) (which was known from earlier static light scattering measurements), but also to demonstrate the existence of a new ultraslow hydrodynamic process (ie, $\Gamma \sim q^2$) in pcs, with relaxation rates Γ about $10^{-4} - 10^{-7}$ lower than those associated with the α-process at a given temperature (45,49), and to study the associated kinetics (50). These effects are caused by long-range density fluctuations indicating a nonhomogeneous distribution of free volume and the appearance of the ultraslow mode is a result of the redistribution of free volume in space. A model has been proposed (45,49), which describes the long-range density fluctuations as a result of the coexistence of molecules with two different dynamic states, and a particular molecule and its surrounding can pass over from the “solid-like” state into the “liquid-like” state on a time scale which is given by the ultraslow mode.

Order in Amorphous Polymers and the Associated Dynamics

It is well known (51–53) that the waxs spectra of semicrystalline samples display sharp diffraction peaks whose intensity and width reflect the frequency and periodicity, respectively, of some characteristic distances obtained using Bragg's law: $d = 2\pi/q^*$. Today, there is consensus that "amorphous" polymers are not completely amorphous but they possess a reasonable degree of local order. For example, the presence of a scattering peak in x-ray diffraction patterns (called *amorphous halo*) implies the existence of fluctuations in electron density distribution within the sample. Although there is not a known one-to-one correspondence between peak position and size of the corresponding density fluctuations, the Bragg equation, $\lambda = 2d \sin\theta$, may still be applied to an amorphous halo position to provide an equivalent Bragg size for the density fluctuation. Hence, in amorphous polymers the *equivalent* Bragg spacings are discussed. It has been shown that the position of the amorphous halo varies systematically within the same family of polymers and that it is correlated with the cross-sectional area of the polymer chain in the crystal (53).

As an example of regularity in the diffraction patterns, the waxs spectra for different polycarbonates of bisphenol A (54) are shown in Figure 12. The figure shows different diffraction patterns starting from the monomer ($x = 1$, which is crystalline), the pentamer ($x = 5$), and other oligomers up to the bulk. It is interesting to note that there is a correlation of the most intense reflection in the crystalline monomer with the amorphous halo in the BPA polymers and that the first sharp diffraction peak gets broader as one moves from the pentamer to the polymer.

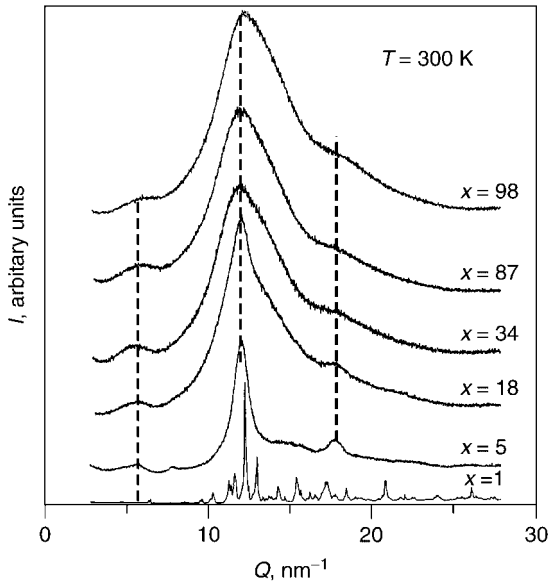

Fig. 12. Waxs spectra of different polycarbonates of bisphenol A starting from the monomer ($x = 1$), to the pentamer ($x = 5$), to the polymer. Notice the sharp diffraction maxima in the monomer (crystalline) and the broader patterns on the polymeric substances.

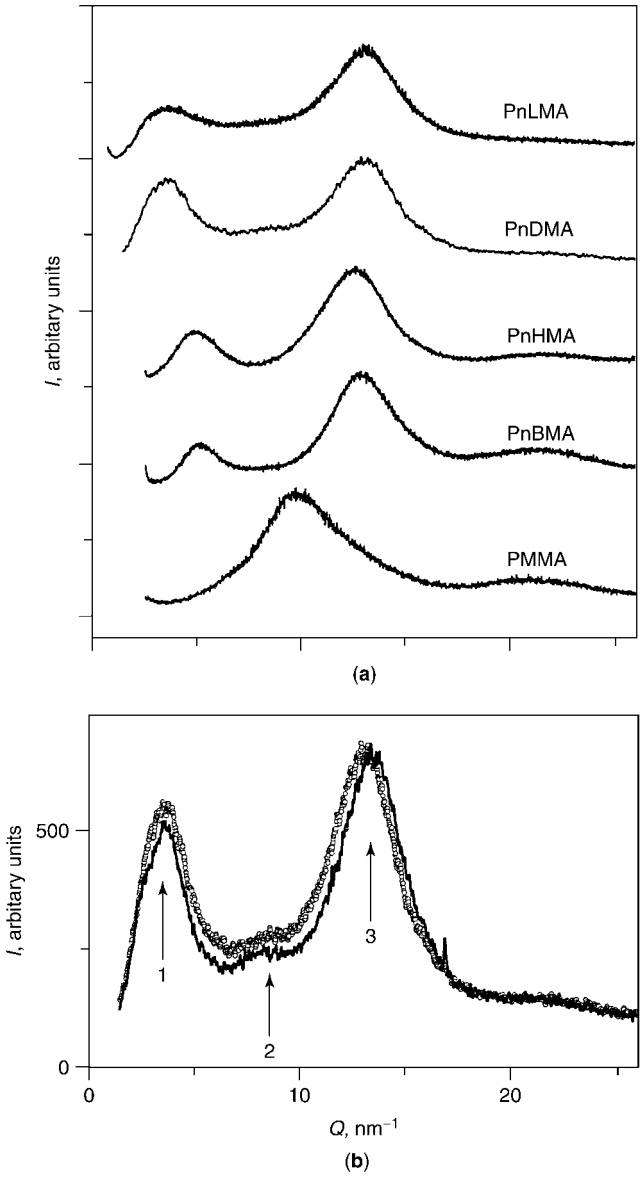

Fig. 13. (**a**) Waxs spectra of a series of poly(n-alkyl methacrylates) shown at 293 K. Notice the development of the LVDW peak which shifts to lower Q values with increasing alkyl side chain. (**b**) Waxs spectra for PnDMA shown at two temperatures as indicated. Arrows show the positions of the three main peaks in the spectra. ○ $T = 293$ K; —— $T = 223$ K.

Another class of polymers with interesting intersegmental structure and packing properties are the poly(n-alkyl methacrylates) (55,56). Figure 13 gives the waxs pattern of PMMA, PnBMA, PnHMA, PnDMA, and PnLMA. With the exception of PMMA, the waxs spectra for poly(n-alkyl methacrylates) show three peaks (arrows 1, 2, and 3 in Fig. 13b). The peak at high q, with an equivalent

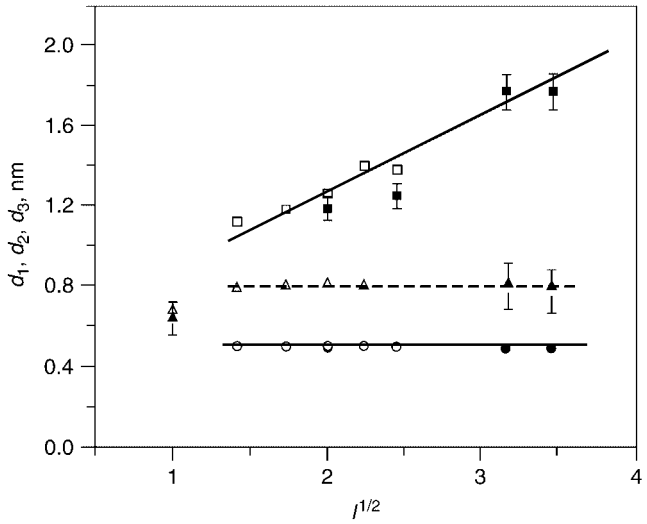

Fig. 14. Equivalent Bragg spacings as a function of the number of carbon atoms (l) on the alkyl chain. Lines are linear fits to the data. Notice the pronounced l-dependence of d_1. • d_3; ▲ d_2; ■ d_1.

Bragg spacing of about 0.5 nm, corresponds to the van der Waals (VDW) contacts of atoms and is known as the VDW peak. The temperature variation of this peak reflects mainly the thermal expansion of the system. The peak at low q, which is usually referred as the low van der Waals (LVDW) peak, is found to have a systematic dependence in the number (l) of carbon atoms on the alkyl side chain. Figure 14 displays the dependence of the three peaks on $l^{1/2}$ for a series of poly(n-alkyl methacrylates), with l in the range $1 \leq l \leq 12$ at 293 K. The LVDW peak, with corresponding distances from 1.0 to 1.8 nm, reflects mainly the average distance between adjacent backbones, which is an increasing function of the number of carbon atoms l on the alkyl side chain. The l-dependence of d_1 can be parameterized as $d_1 = d_0 + sl^{1/2}$, with $d_0 \approx 0.7$ nm and $s \approx 0.385$ nm/CH2. The intermediate peak (Peak #2), which is more difficult to obtain, is also plotted in Figure 14. Its position corresponds to the main peak in PMMA which, in contrast to the rest of the series, does not exhibit an LVDW peak. This feature of PMMA has been discussed in the literature earlier (51).

In the past, there has been a continuous effort to correlate specific dynamic properties, such as the boson peak, the separation of the segmental (α-) from the subglass (β-) process, and the fragility with the structure of amorphous polymers. More specifically, a correlation between the low frequency peak in the Raman spectra and the properties of the first sharp diffraction peak was shown to exist (57,58). Herein the relation of the structure factor with the dynamic property of fragility is recalled (55). The temperature dependence of the relaxation times of various members of the series of poly(n-alkyl methacrylates) is shown in Figure 15. Despite the fact that the "fragility" is usually defined for homogeneous systems, whereas here the monomer itself is intrinsically heterogeneous, one can still compare $\tau(T)$ from different samples. For this purpose one can employ the usual "fragility plot" where the relaxation times are plotted as a function of reduced temperature

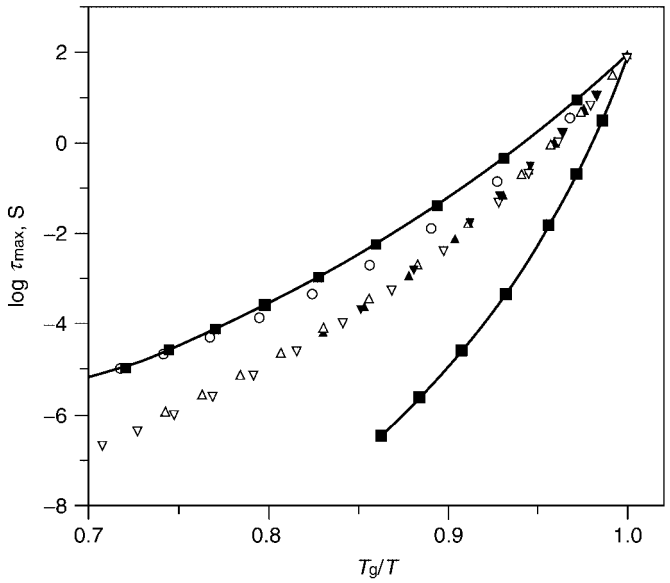

Fig. 15. T_g-scaled plot of the segmental relaxation times of PMMA (♦), PnEMA (▲), PnBMA (△), PnHMA (▼), PnNMA (▽), PnDMA (■), and PnLMA (○). The T_g is operationally defined here as the temperature at which the segmental relaxation time is 100 s. There is change in the nature of the glasses when going from PMMA to the higher member of the series, which reflects in the change from "fragile" to "strong" behavior.

(Fig. 15). Furthermore, to facilitate the comparison, the *glass-transition temperature* T_g is operationally defined as a temperature corresponding to the most probable relaxation time of 100 s. There is a pronounced variation of the curvature or the "steepness index" which is defined as

$$m = \frac{\mathrm{d}\log\tau}{\mathrm{d}(T_g/T)} \tag{21}$$

which is evaluated near T_g, in going from PMMA (with $m \sim 92$) to poly(n-decyl methacrylate) (PnDMA) ($m \sim 36$). The variation in m implies a change from "fragile" to "strong" liquids, which occurs within the same family of polymers only by increasing the length of the side chain with the addition of a CH_2 unit.

The dynamic behavior within the class of poly(n-alkyl methacrylates) possess the natural question as to whether this dynamic richness reflects on the structural changes, and if so, on what length scale. In other words, are the observed dynamic changes from "fragile" to "strong" reflected on the structural changes? Earlier studies already revealed a correlation between the monomer structure and the degree of intermolecular cooperativity (59). The correlation is shown in Figure 16, where both the steepness index m and the position of the LVDW peak is shown as a function of l. In doing so one is directly comparing a dynamic with a structural property. There is a nice correlation between the two quantities, which shows that the observed dynamic changes from "fragile" to "strong" occur by reorganizations at the intersegmental distances, which are enlarged by increasing l. The above is

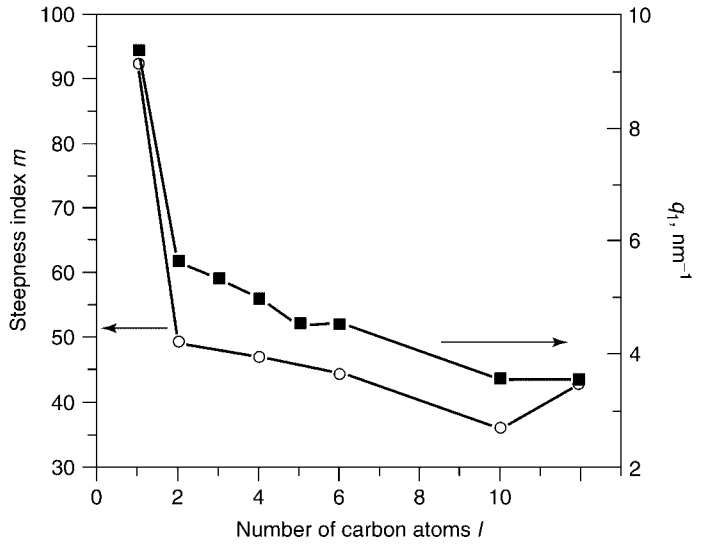

Fig. 16. Steepness index m [$=\mathrm{d}\log\,\tau/\mathrm{d}(T_g/T)$], extracted from the initial slopes in the previous figure, plotted as a function of the number of carbon atoms (l) on the side chain of poly(n-alkyl methacrylates). In the same plot the dependence of the LVDW peak in the waxs spectra Q_1 is shown. There is a one-to-one correspondence between the structural properties and the steepness index, which implies the relation of the fragility to the intersegmental correlations.

one example where the static structure factor influence the dynamic properties within a series of polymers.

Temperature Dependence of the Amorphous State

All linear and most branched amorphous polymers are liquids. In the realm of continuum mechanics a material is a liquid if it flows. Nonrecoverable deformation resulting from applied tractions are proportional to the time of the created stresses, which are also proportional to or functions of the strain rate. They are liquid-like flow deformations. Also stresses in liquids caused by applied shear strains decay to zero with time. Most amorphous polymers are highly viscous and markedly viscoelastic. This time- and frequency-dependent mechanical behavior is dependent on molecular structure and weight, temperature, pressure, and concentration. Many of these polymers have no crystalline solid state because there are stereochemical variations along their molecular chain-like backbones. This lack of long-range regularity in the molecular structure precludes an assembly with the long-range order, which is the essence of the crystalline state. In other words irregular molecules cannot crystallize. On the other hand even some polymers with stereoregular chains, such as polycarbonate, do not crystallize readily because of exceedingly low rates of nucleation.

Upon cooling with consequent molecular crowding the mobility of molecular segments diminishes. Ultimately the local mobility becomes so low that the short-range order that exists does not achieve its more compact equilibrium

structure in the time allowed by the imposed cooling rate. The rate of decrease of volume with temperature upon further cooling diminishes in a usually narrow temperature range in comparison to that due to the change in magnitude of anharmonic vibrations alone. The liquid structure is thus kinetically "frozen in" and the liquid is called a glass. The intersection of the equilibrium volume–temperature line with the glass line defines the glass temperature T_g. Most often T_g is called the glass-transition temperature implying a thermodynamic change in state. Below T_g the material is said to be in the glassy state. However no change in state occurs. The amorphous material is still in the liquid state albeit with an enormous viscosity (above 10^{11} Pa·s; 10^{12} P) and extremely long relaxation and retardation times. A glass is therefore a viscoelastic liquid with a specific volume which is greater than its equilibrium value. A volume–temperature cooling curve for high molecular weight polyisobutylene (NBS PIB) is shown in Figure 17, where the decrease in the thermal contraction coefficient α in the neighborhood of T_g is clearly seen (60). The dependence of $T_g(q)$ upon the rate of cooling q is illustrated in Figure 18, where cooling curves for polystyrene (PS) were obtained at rates ranging from 2°C/min to 1°C/day (61). When held isothermally and

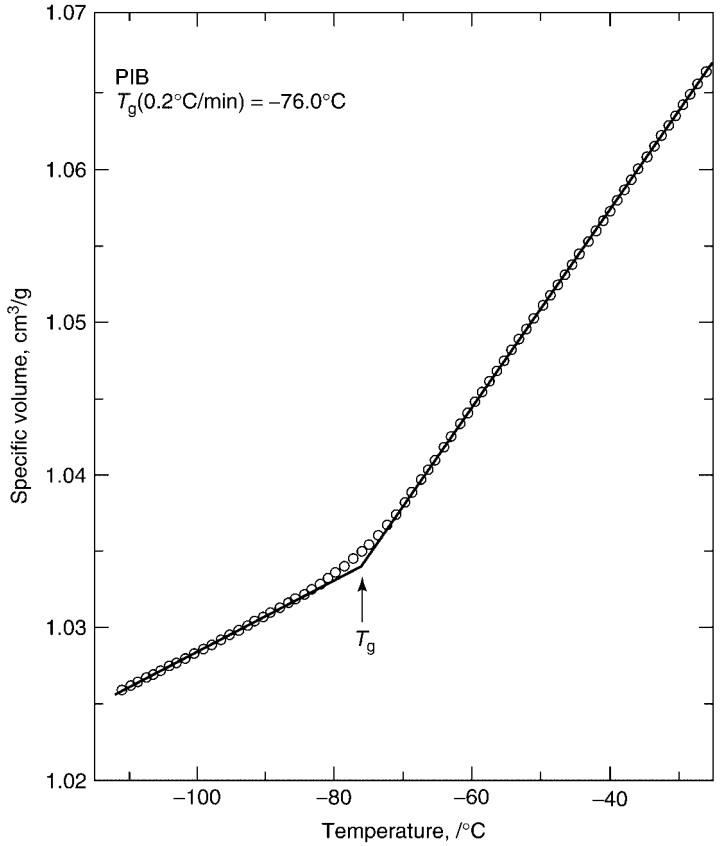

Fig. 17. Dilatometric cooling curve at 0.2°C/min for PIB obtained using the differential gas dilatometer (60).

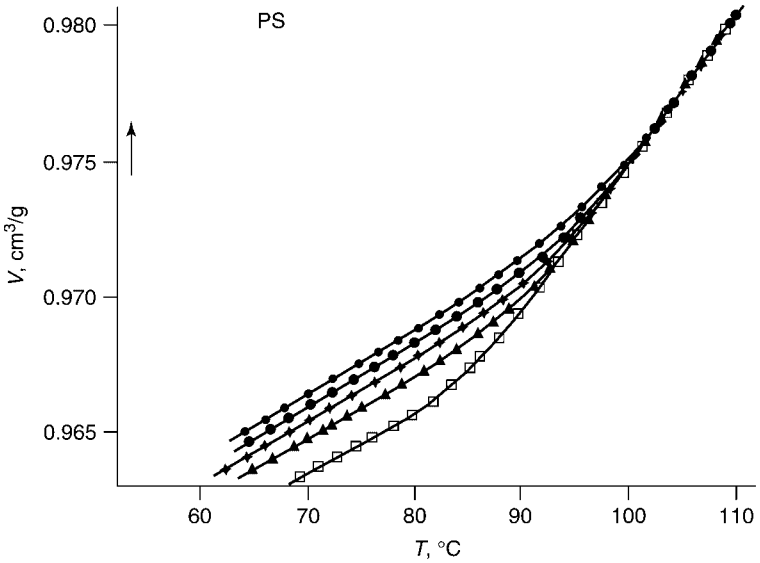

Fig. 18. Volume–temperature curves obtained at different rates of cooling q for PS encompassing the glass temperature $T_g(q)$ (61). – q, K/h: —●— 120; —○— 30; —◆— 6; —△— 1.2; —□— 0.042.

isobarically below T_g, the volume decreases with time toward its equilibrium value. This process is called physical aging, during which kinetic properties slow down enormously and brittleness increases. The above comments on T_g and glasses are not restricted to amorphous polymers, since all amorphous materials organic, inorganic, polymeric, and nonpolymeric will become glassy (rigid, highly viscous, and usually brittle) upon cooling if crystallization does not intervene.

Materials with molecular networks, such as cross-linked elastomers and crystalline polymers, do not flow and so are classified as viscoelastic solids. Shear stresses do not decay to zero with time, ie, equilibrium stresses can be supported. Above T_g, such amorphous materials are still classified as solids, but most of their physical properties such as thermal expansivity, thermal conductivity, and heat capacity are liquid-like.

Viscoelastic Behavior of Amorphous Materials

The stress σ in an ideally elastic materials is uniquely related to a specific strain γ, $\sigma = G\gamma$ (where G is the shear modulus), whereas the stress in a Newtonian fluid is uniquely related to the rate of strain, $\dot{\gamma} = d\gamma/dt$,

$$\sigma = \eta\dot{\gamma} \tag{22}$$

Such behavior is approximated over limited ranges. The energy input to deform an ideal elastic body is entirely recoverable. In other words, the mechanical energy is conserved. The energy input to deform a Newtonian fluid is completely dissipated into heat. None of the deformation is recoverable. Most materials are measurably

viscoelastic where the energy of deformation is partially dissipated into heat. Their mechanical response is consequently a function of time and frequency. Because of the time or frequency dependence, when mechanical measurements are made, it is necessary to hold one of the pertinent variables constant to obtain characterizing functions. The three most common measurements involve creep, stress relaxation, and dynamic (sinusoidal) deformation. Isothermal measurements are necessary, since although isochronal temperature scans may be considered easier, during such scans time-scale shifts and magnitudes of compliance or rigidity can change simultaneously. Isothermal results separate the two variables (62) (see VISCOELASTICITY).

Creep. In the creep experiment a constant stress σ_0 is created in a previously relaxed specimen at some starting time, and the resulting strain $\gamma(t)$ is followed as a function of the ensuing time. Given a sufficiently long time of creep, the velocity of creep will decelerate to zero if a viscoelastic solid is being measured or to a finite constant value if a viscoelastic liquid is being measured. Some time after an apparent constant velocity is reached, in the latter case, viscoelastic steady state is achieved. Then the stress can be made equal to zero by removing all tractions on the specimen and a portion of the deformation will be recovered; again, as a function of time. The portion that is permanent deformation reflects the contribution of viscous flow to the total deformation accumulated during creep. Since a viscoelastic solid does not flow, by definition, all of its creep deformation is recoverable. When the strains or the strain rates are sufficiently small, the creep response will be linear. In this case, when the time-dependent strain is divided by the constant stress, a unique creep compliance curve results; that is, at each time there is only one value for this ratio, which is the compliance; ie, $\gamma(t)/\sigma_0 \equiv J(t)$. Two sources of error that are most specifically deleterious to creep recovery is not reaching steady state before removing the stress (a nonunique curve results), and the presence of friction and other sources of residual stress. Ultimately, in recovery measurements, instrumental disturbances determine the longest time of valid measurement.

Stress Relaxation. The decaying stress is measured as a function of the time after a sudden "instantaneous" strain γ_0 is applied to a previously relaxed sample in the stress relaxation measurement. The stress $\sigma(t)$ eventually drops to an equilibrium finite value for a viscoelastic solid and to zero for a viscoelastic liquid. Sources of uncertainty that are particularly serious in stress relaxation are (*1*) the determination of applied small strains if the sample is glassy or crystalline, since the linear range of response may be exceeded even at a strain of 1% and (*2*) the difficulty in measuring the attendant stress over the required 4–6 orders of magnitude in the softening dispersion. Stress relaxation and creep often cover the same kind of time scale range, 0.1 s to 10 h or a day. Measurements extending for months to years have been carried out, but are not common. The stress relaxation modulus $G(t) \equiv \sigma(t)/\gamma_0$.

Dynamic Mechanical Measurements. Dynamic mechanical measurements yield either the complex modulus, $G^*(\omega) = G'(\omega) + iG''(\omega)$, or the complex compliance, $J^*(\omega) = J'(\omega) - iJ''(\omega)$.

Sinusoidal stresses or strains of constant frequency are applied to a sample until a steady sinusoidal strain or stress results, with a fixed phase angle between the input and the output. Most often only about two cycles are required

to establish steady conditions. The greatest errors are obtained when the system phase angle of measurement is near 0, 90, or 180°. In some forced oscillation measurements the uncertainty of the loss modulus G'' becomes great when phase angle of the system approaches 0 and 180°, and G', the storage modulus, usually cannot be accurately determined when the material phase angle is near 90°. Dynamic moduli or compliances can be calculated without ambiguity from most sinusoidal measurements, but to avoid confusion in an already cluttered nomenclature it has become traditional to only calculate compliances from creep and moduli from stress relaxation. Dynamic measurements are the measurement of choice if information at equivalently short times is desired, since such measurements are possible at a megacycle and higher, but creep or stress relaxation measurements at times shorter than a millisecond are not possible. The circular frequency ω (in radians per second) should be associated with the reciprocal of the time t.

Questions concerning further experimental details including many on linear and nonlinear flow measurements can often be answered in References 62–68.

Significant Variables

Temperature Dependences. Each and every group of molecular mechanisms contributing to viscoelastic behavior has its own temperature-dependent rate. This is usually recognized except for behavior observed high above the T_g of amorphous polymers, where a single temperature dependence of time or frequency shifts is usually reported. The temperature dependence of the terminal zone of response, reflecting viscous flow and long-range recoverable deformation, was first reported to be different from that observed in the softening dispersion (the glassy to rubbery zone) in PS (69) and later in PVAc [poly(vinyl acetate)] (70). Numerous other examples have since been recognized (71,72). An example from atatic polypropylene (aPP) is given in Figure 19 (30,71–75).

There is evidence that the softening dispersion which extends from the glassy level ($J_g \approx 10^{-9}$ Pa^{-1}) to the rubbery level (J_g 10^{-5} Pa^{-1}) of compliance has three contributions (segmental, sub-Rouse, and Rouse modes) (76–79). Reducing data to a common extended curve by shifting them along the time or frequency scale to obtain a wider range of characterization is only legitimate when all of the contributions from molecular mechanisms to deformations have the same temperature dependence. Therefore, curves of viscoelastic functions reflecting the presence of more than one mechanism cannot be validly superposed to yield accurate predictions. Such data is considered thermorheologically complex. The presence of multiple temperature dependences is also observed in permitivity and dynamic light scattering measurements. An example of the reduction of the recoverable compliance curves of PIB shown in Figure 20 is seen in Figure 21 (78). The apparent success of the reduction is shown to be illusory with data taken over a wider frequency range. This is seen in Figure 22, where loss tangent curves [$\tan \delta = J''/J' = G''/G'$ (1)] presented at four temperatures from −74.2 to −35.8°C (78,80) reveal the presence of two groups of viscoelastic mechanisms which shift along the time-scale differently with temperature.

In addition to temperature time-scale shifts, which are attributed to changes in the relative or fractional free volume (62), the magnitude of the compliance or

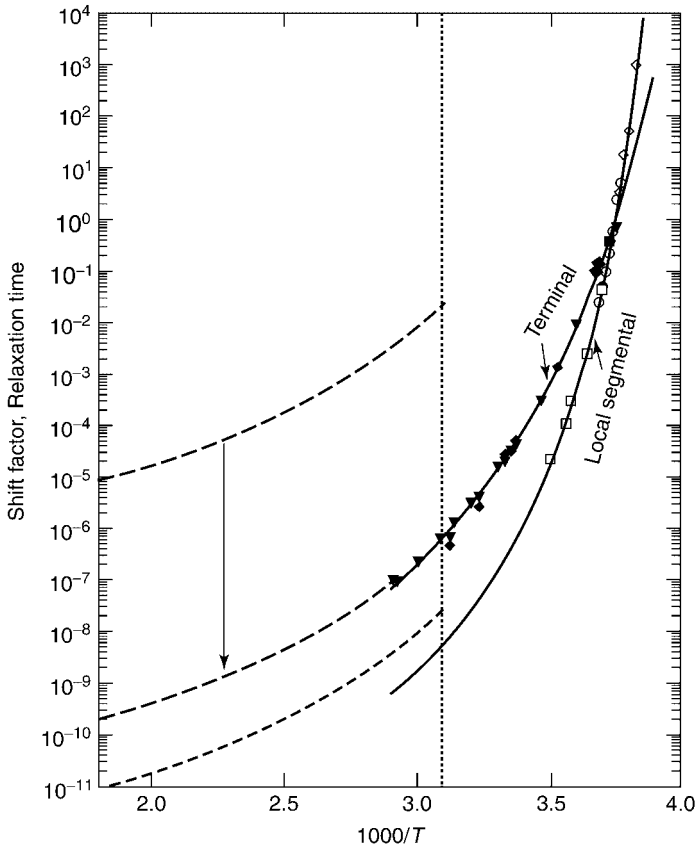

Fig. 19. Temperature dependence of the shift factors of the viscosity (▼), terminal dispersion (⧫), and softening dispersion (◊) of app from Ref. 73. The temperature dependence of the local segmental relaxation time determined by dynamic light scattering (□) (30) and by dynamic mechanical relaxation (○) (74). The two solid lines are separate fits to the terminal shift factor and local segmental relaxation by the Vogel–Fulcher–Tammann–Hesse equation. The uppermost dashed line is the global relaxation time τ_R, deduced from nmr relaxation data (75). The dashed curve in the middle is τ_R after a vertical shift indicated by the arrow to line up with the shift factor of viscosity (73). The lowest dashed curve is the local segmental relaxation time τ_{seg} deduced from nmr relaxation data (75).

modulus can change. The kinetic theory of rubber-like elasticity suggests that the entropically based modulus contribution to the viscoelastic response should increase in direct proportion to the absolute temperature. Correspondingly the reciprocal of the steady-state recoverable compliance should be directly proportional to the absolute temperature. In Figure 23 this can be seen to be true at temperatures that are greater than $2T_g$, but between $1.2T_g$ and $2T_g$; J_s (identified in the figure as J_e) is essentially independent of temperature. At still lower temperatures a strong decrease of J_s is seen (81).

Molecular Weight and Distribution Dependences. The influences of molecular weight and its distribution on the viscous flow (82) viscoelastic behavior

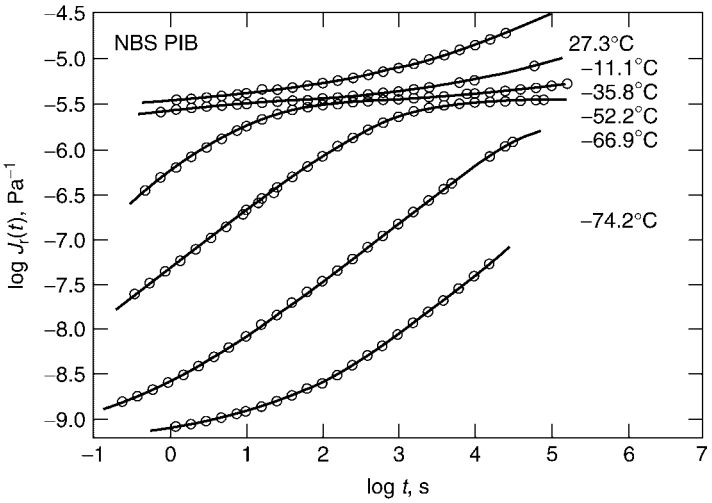

Fig. 20. Double-logarithmic plot of the recoverable compliance $J_r(t)$ of the National Bureau of Standards (NBS) PIB sample measured as a function of time at six temperatures as indicated.

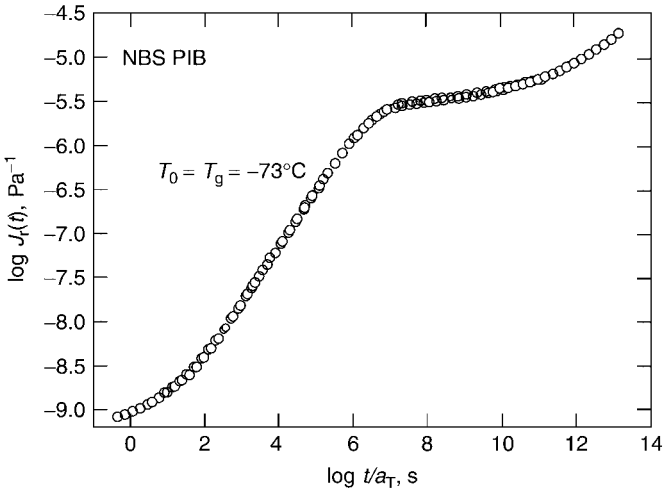

Fig. 21. Data from Figure 20 reduced to a common curve at the reference temperature T_0 of −73°C.

of amorphous polymers (83) have been reviewed. The flow behavior of bulk amorphous polymers and their concentrated solutions has been rationalized (82). Also, the basis for analyzing the viscosity as the product of two factors has been documented:

$$\gamma = F\zeta \tag{23}$$

where F is the structure factor, which depends on the polymer chain length (molecular weight) and branching, and ζ is the friction factor per chain atom,

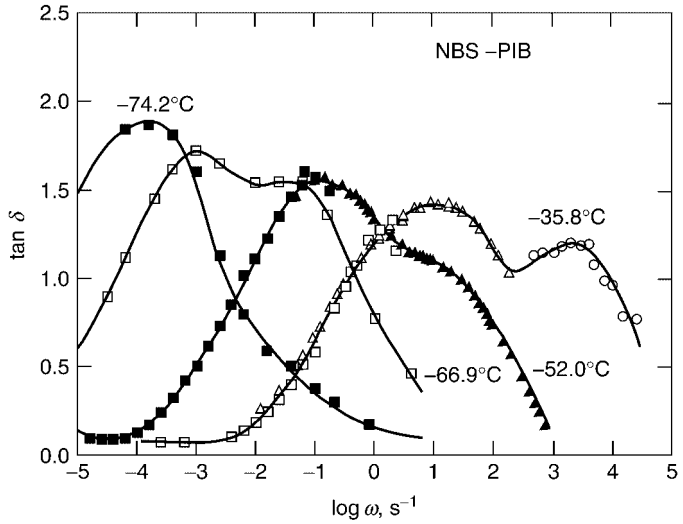

Fig. 22. tan δ as a function of actual frequencies at several temperatures for NBS PIB. The data were obtained by using several instruments spanning the frequency range as shown in the abscissa. The high frequency data at $-35.8°C$ (○) are from Ref. 80. The rest of the data were obtained by a combination of creep compliance and dynamic modulus measurements.

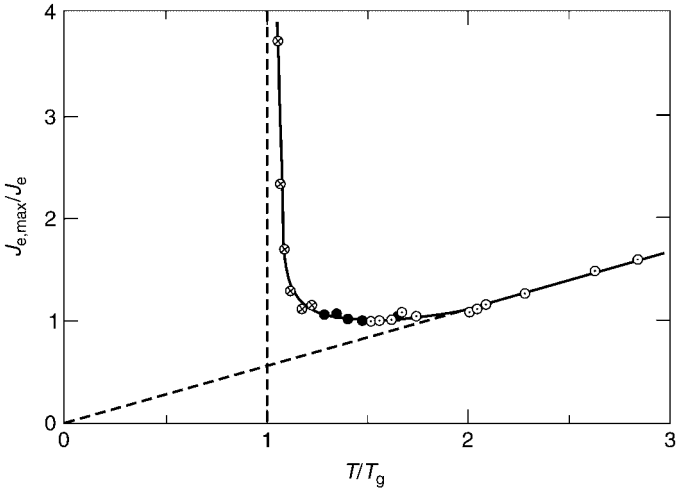

Fig. 23. Normalized reciprocal steady-state recoverable compliance $J_{e,max}/J_e$ for three polymers, poly(dimethyl siloxane), PIB, and PS, versus the reduced temperature T/T_g; T_g is the glass temperature and the normalized compliance $J_{e,max}$ is the largest experimentally indicated value which appears to occur at $T/T_g \approx 1.5$. which depends principally on temperature. The latter is influenced by the molecular weight through the variation of the glass temperature. Holding the number-average molecular weight M_n constant so that T_g does not change while varying the weight-average molecular weight M_w at constant temperature, as was

done in References 83 and 84, ζ can be held constant so that the molecular weight dependence can be determined. It was found that at low molecular weights, F is proportional to the molecular weight in accord with Bueche's theory (85). Above a critical molecular weight M_c, the dependence increases to a proportionality of $M^{3.4}$ (82,83,86). This behavior appears to be universal and independent of the chemical nature of the polymer.

For polymers with broad molecular weight distributions the viscosity appears to be a function of the weight-average molecular weight M_w. This relationship fails for extreme binary blends with molecular weight ratios of 8 (87), 27 (88), and 380 (89). The blend data fall substantially below the curve determined for narrow distribution polymers.

Viscoelastic Behavior of Narrow Molecular Weight Distribution Polymers

The variations of the viscoelastic behavior of narrow molecular weight distribution amorphous polymers can most readily be seen in the broadening of the retardation spectrum $L(\lambda)$, as shown in Figure 24 (90). $L(\lambda)$, where λ is the retardation time, characterizes the contribution to the creep compliance $J(t)$, the dynamic storage compliance $J'(\omega)$, and the dynamic loss compliance $J''(\omega)$ according to the following relations (62):

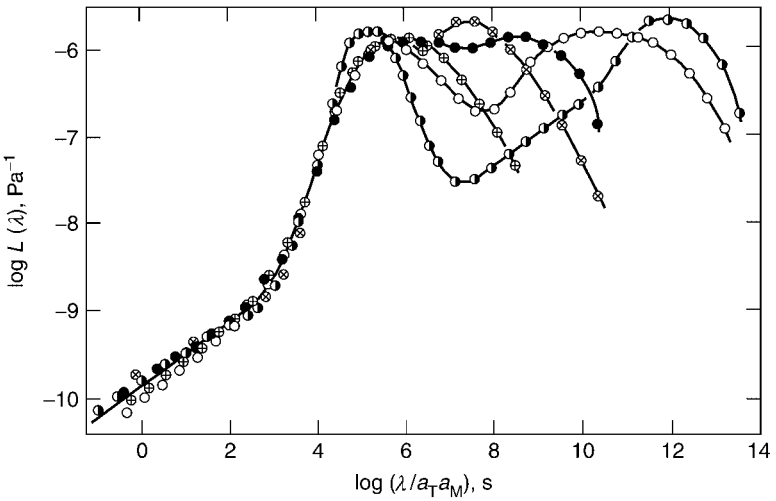

Fig. 24. Bilogarithmic plot of the retardation spectra $L(\lambda)$ of PS with narrow molecular weight distribution as functions of the reduced retardation time $\lambda_r = \lambda/a_T\, a_M$, where a_T is the temperature reduction factor and a_M is the molecular weight reduction factor [the latter reflects the change in $T_g(M)$]. The molecular weights and symbols for the various PSs are 4.7×10^4, A25, ⊕; 9.4×10^4, M102; ⊗; 1.9×10^5, L2, •; 6.0×10^5, A19, ○; and 3.8×10^6, F380, ◑. The reference temperature $T_0 = 100°C$ and the reference molecular weight $M_0 = 1.9 \times 10^5$.

$$J(t) = J_g + \int_{-\infty}^{\infty} L(1 - e^{-t/\lambda}) d\ln\lambda + \frac{t}{\eta} \tag{24}$$

$$J'(\omega) = J_g + \int_{-\infty}^{\infty} \left(\frac{L}{1+\omega^2\lambda^2}\right) d\ln\lambda \tag{25}$$

$$J''(\omega) = \int_{-\infty}^{\infty} \left(\frac{L\omega\lambda}{1+\omega^2\lambda^2}\right) d\ln\lambda + \frac{1}{\omega\eta} \tag{26}$$

The integrals involving L deal only with recoverable deformation, which for the most part reflects molecular orientation from various mechanisms. Permanent deformations are accounted for by the terms containing the viscosity coefficient η. From equation 24 it can be seen that the long-time limiting recoverable compliance is

$$J_s = J_r(\infty) \equiv \lim_{t\to\infty} \left[J(t) - t/\eta\right] = J_g + \int_{-\infty}^{\infty} L d\ln\lambda \tag{27}$$

Thus the steady-state recoverable compliance J_s is the sum of the glassy compliance and the limiting delayed compliance,

$$J_d = \int_{-\infty}^{+\infty} L d\ln\lambda \tag{28}$$

The recoverable shear creep compliance $J_r(t) = J(t) - t/\eta$, but to obtain $J_r(t)$ over an appreciable range of time-scale in the terminal (long-time) zone of response the recoverable deformation must be measured directly, after achieving steady state in a creep measurement, and subsequently setting the stress to zero. Since the measurement of recovery is a zero-stress experiment, extensive recovery cannot be determined with instruments that employ ball-bearing to support the moving element. Air-bearing instruments are also severely limited. With a magnetically levitated moving element an optimized range of measurement is achieved. The steady-state recoverable compliance of a viscoelastic liquid in elongation may not be measurable even under the weightless condition of outer space because of the interference of surface tension. In oscillatory measurements of dynamic compliances or moduli the interference of friction can be avoided with wire supports.

Equation 24 indicates that the strains arising from different molecular mechanisms add simply in the compliances and in principle can be separated. On the other hand, the stresses do not add and the different mechanisms cannot be easily resolved in modulus functions. In solution the solvent and the polymer contributions are also seen to be additive, as shown below. To understand the somewhat esoteric viscoelastic functions this additivity is helpful. It should also be noted that there are only two functions that do not contain contributions involving viscous flow, which obscure the recoverable responses which are largely, if not completely,

due to molecular orientations. They are the storage compliance J' and the recoverable creep compliance $J_r(t)$.

Near T_g, molecular mobilities are so small that the times required to achieve steady state become enormous. To avoid this dilemma, it has been proposed that steady-state could be achieved in creep at higher temperatures in a short time and would be maintained with cooling to the neighborhood of T_g so long as the stress was held constant (31). This tactic appears to work and is extremely useful.

In Figure 24 (90) the lowest molecular weight, narrow distribution PS depicted as A25 ($M = 47{,}000$) has only two contributions, (*1*) at short times a common linear portion between log λ_r of -1 and 3 with a slope of 1/3 and it is followed by (*2*) a symmetrical peak centered at log $\lambda_r = 6$. The short-time region reflects the presence of Andrade creep in which the recoverable creep compliance is a linear function of $t^{1/3}$. An alternative description by a generalized Andrade creep with t^{β_α}, with β_α not necessarily equals to 1/3 and varies from one polymer to another, is possible. Actually such a generalized Andrade creep is the short-time part of the

$$J_\alpha(t) = J_g + (J_{e\alpha} - J_g)\left\{1 - \exp\left[1 - (t/\tau_\alpha)^{1-n_\alpha}\right]\right\} \tag{29}$$

where $0 < (1 - n_\alpha) \leq 1$ and $(1 - n_\alpha)$ is to be identified with β_α (72,91). The steady-state compliance $J_{e\alpha}$ is the part of J_d contributed by the local segmental motion, also called the α-relaxation. As to be discussed later in sections on Dielectric Spectroscopy and Photon Correlation Spectroscopy, the time correlation function of the α-relaxation of amorphous polymers can be analyzed to have the stretched exponential form $\exp[-(t/\tau_\alpha)^{\beta_\alpha}]$, similar to equation 8, and β_α varies from polymer to polymer. For example, PS and PIB have β_α equal to 0.36 and 0.55 respectively.

The retardation spectrum of $J_\alpha(t)$ from equation 29 has the τ^{β_α} dependence at a short retardation time τ (notice that λ has been used earlier to denote retardation times), and also exhibits the peak as exhibited by the nonpolymeric glass-formers (see Fig. 29 to be introduced later). $J_{e\alpha}$ has been determined only for low molecular weight polymers and is approximately $J_{e\alpha} \approx 4.0 J_g$ for PS (92) and $J_{e\alpha} \approx 5.0 J_g$ for poly(methylphenyl siloxane) (93).

The increase in the compliance contributed by the area under the symmetrical peak overwhelms the Andrade or the generalized Andrade contribution and increases until a rubbery level is reached at about 10^{-6} cm^2/dyn (10^{-5} Pa^{-1}). This increase in compliance is attributed to the polymer chain modes, first successfully described by Rouse (94). His theory was extended by Ferry, Landel, and Williams from a dilute solution theory to one dealing with the viscoelastic properties of undiluted polymers (95) (see VISCOELASTICITY). However, the extended Rouse model has limitations. It has been recognized (96) that by taking the short-time limit of the extended Rouse modes contribution to the modulus, one obtains $G(0) = \upsilon NkT = \upsilon \rho RT/M$, where N is the number of molecules per cm^3 and υ is the number of submolecules per chain (62). The number of monomers in a submolecule, z, is given by P/υ, where P is the number of monomers in a polymer chain. For a polymer of molecular weight 150,000 and a density of 1.5 g/cm^3 and by assuming that the smallest submolecule that can be still be Gaussian consists of five monomer units (ie, $z = 5$), it was found that $G(0) = 7.5 \times 10^6$ Pa [$J(0) = 1.3 \times 10^{-7}$ Pa^{-1}]. This value is about 2 orders of magnitude smaller (larger) than the experimentally determined value of

the glassy modulus G_g (glassy compliance J_g) which typically falls in the neighborhood of 10^9 Pa (10^{-9} Pa^{-1}). Thus the extended Rouse model cannot account for the short-time portion of the glass–rubber dispersion of entangled polymers because here the modulus (compliance) decreases (increases) continuously from about 10^9 Pa (10^{-9} Pa^{-1}) to the plateau modulus of about 10^5 Pa (10^{-5} Pa^{-1}). These deficiencies of the extended Rouse model are not surprising because, after all, according to the model the submolecule is the shortest length of chain which can undergo relaxation and the motions of shorter segments within the submolecules are ignored. The Gaussian submolecular model of Rouse can, at best, account only for viscoelastic behavior in the longer relaxation time portion of the glass–rubber softening dispersion. Thus the extended Rouse model has to be augmented by the molecular mechanisms involving chain units smaller than the submolecule but larger than the local segmental motion, which we called the sub-Rouse modes. Clear evidences of sub-Rouse modes were found by viscoelastic measurement (78,79) and by dynamic light scattering (27,29) in PIB. The high frequency peak or shoulder of tan δ as a function of frequency in Figure 6 is caused by the sub-Rouse modes. The softening dispersion thus has three contributions: (*1*) the local segmental motion responsible for $J(t)$ from $J_g \approx 10^{-9}$ Pa^{-1} up to about $J_{s\alpha} \approx 5 \times 10^{-9}$ Pa^{-1}, (*2*) the sub-Rouse modes from $J_{s\alpha}$ up to somewhere near $J_{sR} \approx 10^{-7}$ Pa^{-1}, and (*3*) the modified Rouse modes from $J_{sR} \approx 10^{-7}$ Pa^{-1} up to the plateau level. These estimates may vary for polymers with very different chemical structures.

Although the local segmental relaxation does not show up in Figure 22, other supplementary data indicate that all three groups of viscoelastic mechanism—local segmental, sub-Rouse, and Rouse modes—all have different temperature shift factors. For the Rouse and the sub-Rouse modes this fact was shown first by creep compliance measurements in PS in the softening dispersion (72,98) long before sub-Rouse modes were clearly resolved in PIB (Fig. 22) and the term used. It has been confirmed in PS by dynamic modulus measurements. Examples are the data on PS obtained (99) using an inverted forced oscillation pendulum and some unpublished data (72,100) on PS and TMPC (tetramethyl BPA polycarbonate) using a commercial instrument, and in PIB (101). These data are partly reproduced in a review (72). The lack of reduction of the data is clear from the dependence of the shape of the tan δ peak with temperature of measurement and occurs over a frequency region that corresponds to compliances in the range from 10^{-5} Pa^{-1} down to about 10^{-7} Pa^{-1}. Narrowing of the softening dispersion of PMMA and PVAc with decreasing temperature was found by comparing the data obtained (102) at higher temperature (higher frequency) with that obtained (103) at lower temperature (longer times). This behavior can be considered to be unusual because viscoelastic spectra usually are seen to broaden with falling temperature. All the abnormal behaviors described in this paragraph follow as consequences of the shift factors of local segmental relaxation, the sub-Rouse modes, and the Rouse modes having decreasing sensitivity to temperature in this order, as found directly in PIB (79,97). As temperature is decreased, time–temperature superposition fails because the separations between the three groups of viscoelastic mechanisms are decreased, a phenomenon which is appropriately called *encroachment* (72,79).

As the molecular weight increases a second long-time peak develops in $L(\lambda)$, reflecting a rubber-like plateau in $J_r(t)$ which increases in length. The spectrum

Fig. 25. seen in Figure 24 for the highest molecular weight PS sample F380 (3.8×10^6) has two additional long-time features 3) a second Andrade region and 4) a terminal symmetrical peak, centered at $\log \lambda_r \cong 12$. The length of the plateau seen in $\log J_r(t)$ is measured by the time separation of the two peaks in $L(\lambda_r)$, $\Delta \log \lambda_m$. The length of the plateau can be seen to increase with the 3.4 power of the molecular weight, just as the viscosity. In fact the length of the plateau goes to zero at the viscosity critical molecular weight ($M_c \approx 35{,}000$) as seen in Figure 25, where λ denotes the retardation time (89). Since the rubber-like plateau is attributed to the presence of a transient entanglement network of the polymer chains, it is clear that the entanglements manifest themselves at the same molecular weight in viscous and recoverable deformations with the same degrees of enhancement with increasing molecular weight. Although Figure 24 was derived from the reduced curve obtained by time–temperature superposition of isothermal recoverable creep compliance data, actually the two shift factors of terminal dispersion and the local segmental relaxation do not have the same temperature dependence in a common temperature range above T_g (Fig. 19). None of the three mechanisms in the softening dispersion have the same temperature dependence for their shift factors. Therefore, the shift factor a_T used to obtain master curve for polymers by time–temperature superposition, as given in Figures 21 and 24, is actually a combination of the individual shift factors of the several different viscoelastic mechanisms. At low temperatures, a_T is principally determined by the shift factor of the local segmental mode. With increasing temperature, in turn a_T is principally determined by the shift factors of the sub-Rouse modes, the Rouse modes, modes in the plateau, and the terminal modes. Hence, it is wrong to assume that a_T describes the temperature dependence of *any* or *all* of the viscoelastic mechanisms.

Applying the kinetic theory of rubber-like elasticity (62,109) to the entanglement network one can determine the molecular weight between entanglements M_e from the plateau compliance J_N or plateau modulus G_N (62);

$$J_N = G_N^{-1} = M_e/\rho RT \tag{30}$$

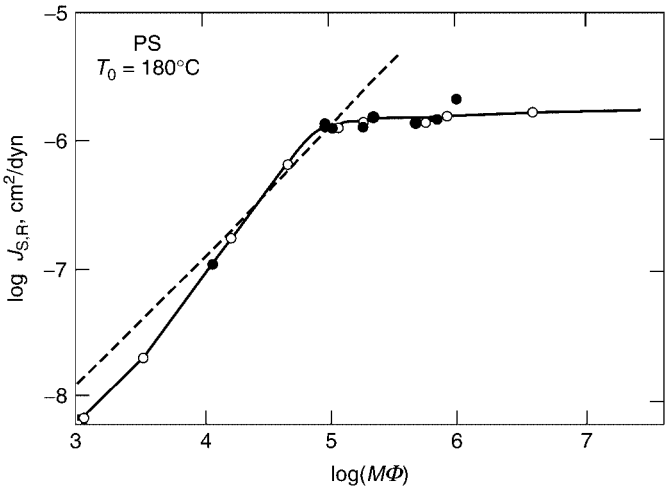

Fig. 26. Reduced steady-state compliances $J_{s,r}$ for PSs with narrow molecular weight distributions plotted logarithmically as a function of the product of the molecular weight M and the volume fraction of polymer, Φ. The dashed line represents the prediction of the modified Rouse theory. The solvent in the solutions is TCP. • $J_{s,r}$(solution) = $J_s\ \Phi^2\ T/T_0$; ○ $J_{s,r}$(bulk) = J_s.

where ρ is the density, T is the absolute temperature (K), and R is the gas constant. At high molecular weights $M \gg M_c$ the steady-state recoverable compliance J_s has been reported to be 2–10 times larger than J_N (83). Reported values for J_s have to be accepted with caution because the dependence of J_s is far more sensitive to the molecular weight distribution than to the molecular weight. The results for $J_s(M)$ reported in Reference 105 are shown in Figure 26, where at low molecular weights J_s is amazingly close to the first power dependence predicted by the modified Rouse theory (94,95) with no adjustable parameters. At higher molecular weights, $M > 3M_c$, and J_s becomes independent of molecular weight. This surprising behavior was first reported by Tobolsky and co-workers (110). Results from nine studies on PS show that the published values vary by up to a factor of 5 (111).

It has been shown (112) that molecular weight blends with low concentrations of high molecular components can exhibit J_s values that are nearly 20 times greater than those shown by any of the monodisperse components. Trace amounts of high molecular tails in low molecular weight polymers can enhance the J_s by more than a 1000-fold (105). The recoverable compliance of a polymer with close to a random molecular weight distribution can be more than 10 times higher than that of a narrow distribution sample with the same number-average molecular weight M_n (113).

Long-chain branching, in particular narrow distribution, star-branched polymers (chains joined at a common center) also enhances the steady-state recoverable compliance J_s. It has been shown (114) that four- and six-arm star PS do not show the molecular weight independence at high molecular weight as seen with linear polymers. J_s continues to increase with the first power of the molecular weight; ie, the Rouse prediction continues unabated at the highest molecular weights measured.

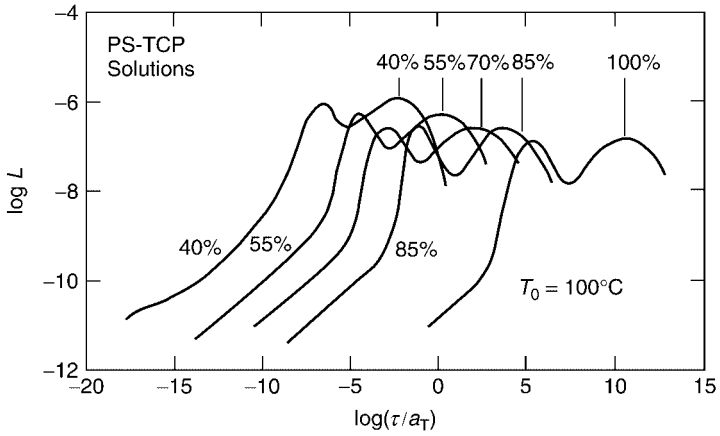

Fig. 27. Logarithmic plot of retardation spectra against reduced time for the more concentrated solutions (40% and above) of PS PC-6A (in TCP) and of the undiluted polymer. In all cases the reference temperature T_0 is 100°C.

Concentration Dependence. The effect of diluent on the viscoelastic behavior of a polymer is profound and complicated. The first and most dramatic effect is the usual strong decrease in the glass temperature T_g, which happens because the T_g of the solvent is usually much lower than that of the polymer, since T_g is tied to the local mobility of the molecules; ie, the local mobility determines when liquid structure rearrangements cannot keep up with the imposed *rate of cooling*. Thereafter the specific volume of the liquid is greater than its equilibrium value. The rearrangements needed to obtain the required local molecular packing are kinetically arrested. Contraction continues with cooling at a diminished rate only because of the reduction in the magnitude of the anharmonic molecular vibrations. Therefore, with increasing diluent concentration, at a given temperature, one obtains solutions that are further above their T_g. Hence molecular mobility is greater because of the larger relative free volume, and the viscoelastic functions $J(t)$, $G(t)$, and $G^*(\omega)$ are found at increasingly shorter times or higher frequencies. This shift toward shorter times with increasing diluent concentration can be seen in Figures 27 and 28 (107,108). The retardation spectra for a narrow molecular weight distribution PS ($M = 860{,}000$) and seven solutions in tricresyl phosphate (TCP) are presented. The spectrum for the bulk polymer is compared with those of the four most concentrated solutions (40, 55, 70, and 85 wt% of PS) at 100°C in Figure 27. The severe shifts to shorter reduced times t/a_T are due to the decrease of T_g. The four lowest concentrations 1, 25, 10, 25, and 40 wt% of PS are compared at −30°C in Figure 28, which shows the shift to shorter times, but the other two effects are most clearly seen at the lower concentrations, although they are present at all concentrations. The separation of the two major peaks diminishes with decreasing polymer concentration, reflecting the shortening rubber-like plateau. With dilution the overlap of the polymer chain coils diminishes and therefore the number of intermolecular entanglements per molecule decreases. With dilution the concentration of viscoelastic elements decreases and each element supports a greater observed compliance. Finally, it should be appreciated that the

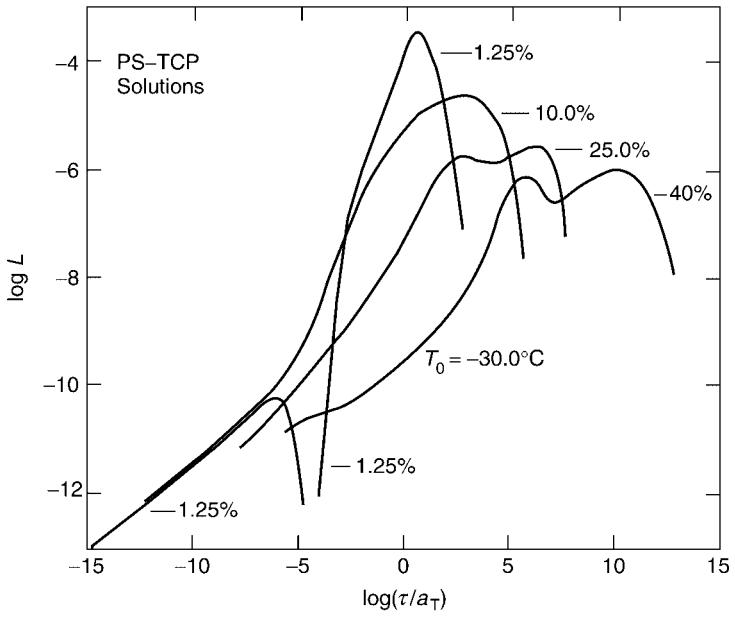

Fig. 28. Logarithmic plot of retardation spectra against reduced time for the less concentrated solutions (40% and less) of PS PC-6A (in TCP) and of the undiluted polymer. In all cases the reference temperature T_0 is −30°C.

solvent manifests its independent contribution to the deformation, especially at the lowest polymer concentrations. The spectrum for the 1.25% solution is split into two peaks. Measurements on the pure solvent identified the peak at short times to be due to the solvent. Hence the second sharp peak is the polymer peak. The fact that the polymer and solvent molecule motions influence one another, but contribute additively but separately to the deformation, is the reason for the manifestation of two observed T_g's in some of the solutions (107,108).

The Glass Temperature, A Material Characterizing Parameter

For the glass temperature to be a material characterizing parameter it must be determined by cooling from equilibrium (see GLASS TRANSITION). Heating measurements yield an approximation to the fictive temperature of the starting glassy materials, which is a function of its thermal history below T_g. The glass-transition temperature is therefore a specimen characterizing parameter and a unique function of the rate of cooling. It has been shown (115) that local segmental motions contribute both to the glassy Andrade creep region and to liquid structural relaxation. It is therefore reasonable to expect that for a given rate of cooling the local mobility which determines the T_g departure from an equilibrium liquid structure has to be the same for all amorphous materials. It has consequently been established that at T_g the retardation function, at short times, in the region of the time scale attributed to local segmental motions is the same functionally

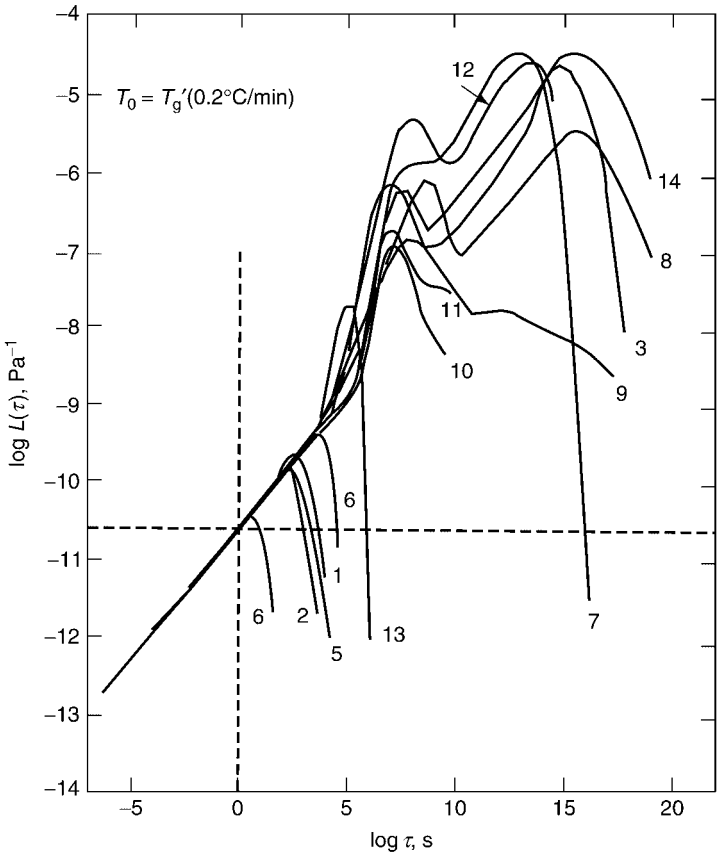

Fig. 29. Superposition of the retardation spectra at short times for 1) 6PE; 2) Aroclor 1248; 3) polypropylene; 4) TCP; 5) OTP; 6) $Tl_2SeAs_2Te_3$; 7) PS Dylene 8; 8) PIB; 9) Viton 10A; 10) EPON 1004/DDS; 11) EPON 1007/DDS; 12) PB/Aroclor 1248 Soln; 13) Se 14) PVAc.

and in position for many amorphous materials including nonpolymeric, organic glass-formers, inorganic glasses, and polymers. Figure 29 shows the common viscoelastic behavior between log τ of -6 to $+1$, where τ is the reduced retardation time. To obtain close superposition, T_g's measured at a cooling rate of 0.2°C/min were adjusted by up to 2°C, which is thought to reflect the usual magnitude of uncertainty (60). It is at longer times that the structural differences of the materials manifest themselves. In the region of Andrade creep dominance $L(\tau)$ was calculated by Thor Smith to be (116)

$$L(\tau) = 0.246\beta_A\tau^{1/3} \tag{31}$$

where β_A is the Andrade coefficient (117) in

$$J_r(t) = J_A + \beta_A t^{1/3} \tag{32}$$

In the short-time regime the constant J_A in equation 32 is equal to the glassy compliance J_g. From Figure 29, at $\tau = 1$ s, $L(\tau)$ is 2.24×10^{-12} cm^2/dyn (or is 2.24×10^{-11} Pa^{-1}). Therefore, the temperature at which $\beta_A = 9.10 \times 10^{-12}$ cm^2/(dyn·s$^{1/3}$) is T_g ($Q = 0.2^\circ$C/min, where Q is the rate of cooling).

Although the short-time compliance data of diverse amorphous materials can be represented by Andrade creep (eq. 32), the reason for such a "universal" behavior is unclear. The alternative description of the local segmental contribution by equation 29 with $(1-n_\alpha) \equiv \beta_\alpha$ not necessarily equal to 1/3 and its value dependent on the material itself offers a different possibility. The generalized Andrade creep

$$J_r(t) = J_g + Bt^{1-n_\alpha} \tag{33}$$

which is the short-time limit of equation 29, will replace equation 32 and be used to fit the data at short times and determine J_g in the process.

Dependence of Viscoelastic and Dynamic Properties on Chemical Structure

It was recognized already in the early days of viscoelastic measurements that the time or frequency dependence of the softening zone can vary considerably with the chemical structure of the polymer. As early as in 1956 it was found that the softening dispersions of PIB and PS contrast sharply (118,119). The glassy compliance (modulus) and the plateau compliance (modulus) are similar for PIB and PS, but the width of the glass–rubber softening dispersion of PIB is several decades broader in time or frequency than that of PS. In a 1991 review (120) it was remarked that the origin of this difference is still not clear. From the discussion in previous sessions and results summarized in a review (71,72), the other differences in viscoelastic properties of PIB and PS include the lesser differences between the temperature dependences of the three viscoelastic mechanisms in the softening dispersion of the former (71,72,79). The terminal dispersion as well as the $M^{3.4}$ molecular weight dependence of the viscosity of monodisperse entangled linear polymers does not depend on chemical structure of the repeat units. Nevertheless, the difference between the temperature dependences of the terminal dispersion (or the viscosity) and the local segmental motion is significantly less in PIB than in PS.

Dielectric relaxation and photon correlation spectroscopic measurements (to be discussed later) have found that the stretched exponential time correlation function of the α-relaxation of amorphous polymers, $\exp[-(t/\tau_\alpha)^{\beta_\alpha}]$, has β_α that varies from polymer to polymer. For example, PS and PIB have β_α equal to 0.36 and 0.55 respectively. It was recognized that this difference in the stretched exponent β_α of PIB and PS is the origin of their contrasting viscoelastic properties (72,79, 121,122).

Low Molecular Weight Amorphous Polymers. The most spectacular observations of breakdown in time–temperature superposition occur in low molecular weight polymers. The effect was first seen in PS by creep and recovery measurement (105). The recoverable compliance $J_r(t)$ for a 3400 Da molecular weight PS undergoes a dramatic change in shape of the recoverable compliance

curve as the temperature is lowered toward T_g. At the same time the steady-state recoverable compliance J_s decreases 30-fold down to a value which is only about five times J_g. This was confirmed by complex shear modulus measurements of Gray, Harrison and Lamb (123). The viscoelastic anomalies found in low molecular weight PSs are general phenomena because they are also found in other polymers. These include polypropylene glycol (124), poly(methylphenyl siloxane) (125), and selenium, a natural polymer (126,127). An example is shown by $J_r(t)$ data of a near monodisperse poly(methylphenyl siloxane) with molecular weight of 5000 Da plotted against the logarithm of the reduced time t/a_T. The origin of the effect has been traced (122) to the stronger temperature dependence of the shift factors of the local segmental modes, the sub-Rouse modes, and the Rouse modes in this order, ie, encroachment of the local segmental mode toward the two longer time mechanisms (122). Confirmation of this explanation was provided by dielectric relaxation in polypropylene glycol and in PI (126,128).

Dynamic Properties of Amorphous Polymers Probed by Other Techniques

Besides viscoelastic measurements described above, there are a variety of techniques that can probe the dynamic and viscoelastic properties of amorphous polymers. Their advantages and disadvantages as compared with shear viscoelastic measurements in elucidating the dynamic properties become clear in the following sections.

Dielectric Spectroscopy. Dielectric experiments obtain the permittivity $\varepsilon'(\omega)$ and loss $\varepsilon''(\omega)$ of materials that has a permanent dipole moments over a wide range of frequency (129,130). The complex dielectric permittivity $\varepsilon^*(\omega) = \varepsilon'(\omega) - i\varepsilon''(\omega)$ is given by the one-sided Fourier transform of the normalized dipole moment autocorrelation function $\phi(t) = \langle M(0) \cdot M(t)\rangle / \langle M^2(0)\rangle$ as

$$\left[\varepsilon^*(\omega) - \varepsilon_\infty\right] / (\varepsilon_0 - \varepsilon_\infty) = \int_0^\infty \exp(-i\omega t') \left[-\mathrm{d}\phi(t')/\mathrm{d}t'\right] \mathrm{d}t' \tag{34}$$

where ε_0 and ε_∞ are the low and high frequency limit of $\varepsilon'(\omega)$, respectively.

By a combination of commercial instruments, the wide frequency range $10^{-4} < f = \omega/2\pi < 10^{10}$ Hz is accessible to probe the molecular motions. The technique usually probes only the local segmental relaxation (often called the primary or α-relaxation in dielectric relaxation) and the secondary (β, γ, ...) relaxations exclusively. For a few polymers such as polypropylene glycol and PI that have a component of the dipole moment parallel to the polymer chain backbone, additional relaxation processes due to some normal modes that correspond to the mechanical terminal zone, are dielectrically active (126,128,131–133). The α-loss peak has an asymmetrically skewed shape with a width which can be much larger than a Debye peak given by $\varepsilon'' \propto \omega\tau/(\omega^2\tau^2 + 1)$. The degree of departure from the Debye peak varies from polymer to polymer. The two parameter Cole–Davidson (134) and the three parameter Havriliak–Negami (HN) (135) empirical functions have often been used to fit the experimental data because these two are empirical functions of the frequency and are very convenient for fitting experimental data.

An equally popular empirical function of frequency is obtained from equation 34 with $\phi(t)$ given by the KWW function (136,137)

$$\phi(t) = \exp\left[-(t/\tau)^{1-n_\alpha}\right] \tag{35}$$

with $0 < (1 - n_\alpha) \equiv \beta_\alpha < 1$. The KWW function has two parameters as compared with three parameters in the HN equation. As a consequence, the HN function always provides a better fit to the data than does the KWW function. Nevertheless the KWW function has been found to give an adequate fit (with ubiquitous deviation at high frequencies) to the dielectric data and is often used in current literature. It is also popular with theoreticians for the construction of models to explain the non-Debye behavior of the α-relaxation process. The popularity is probably due to the fact that it has only two parameters, the KWW exponent $1-n_\alpha$ that controls both the width and the degree of skewness and τ corresponds approximately to the most probable correlation time. Irrespective of the choice of the empirical function used to fit the dielectric dispersion, the frequency of the dielectric loss maximum determines the most probable frequency of the local segmental motion. In contrast to viscoelastic measurements, the Rouse modes and the modes in the terminal zone are usually not observed. Thus the α-relaxation is the dominant contribution to $\varepsilon^*(\omega)$ and its dispersion or $1-n_\alpha$ can be easily determined. The dielectric dispersions of small molecular glass-formers including salol, toluene, bromopentane, propylene carbonate, glycerol, propylene glycol are temperature-dependent (138), with $1-n_\alpha$ increasing with increasing temperature and in some cases approaches unity (ie, Debye relaxation) at high temperatures. There are also some evidences that the dielectric dispersion of the α-relaxation of amorphous polymers also narrows with increasing temperature; however, apparently $1-n_\alpha$ is not close to unity even at high temperatures where the α-relaxation time is of the order of 10^{-10} s. An example is PVAc (139,140). This difference between small molecular glass-former and amorphous polymers is due to the presence of bonded interaction between repeat units in the polymer chains (141,142). In fact, the local segmental mode of a polymer chain already has dispersion broader than the Debye relaxation as shown by dielectric relaxation measurement of dilute solution of PVAc in a solvent (143).

Photon Correlation Spectroscopy. Photon correlation spectroscopy (pcs) is one among several light scattering techniques reviewed in the beginning of this article. The technique is sensitive to density fluctuations as well as concentration fluctuations (125,144,145) and obtains directly the autocorrelation functions in the time domain. It has been suggested that pcs data correspond to the longitudinal compliance (146). The local segmental mode is the main contributor to density fluctuation and is featured exclusively in the data taken by pcs, although in addition the sub-Rouse modes have also been seen in PIB (27,31). Most pcs studies on bulk polymers as well as nonpolymeric glass-forming liquids have shown that the KWW functions are adequate representations of the experimental time-correlation functions for the density fluctuations. Thus the KWW function that fits the pcs data gives directly the dispersion of the α-relaxation. The KWW exponent $1-n_\alpha$ characterizing the dispersion varies from polymer to polymer. For example, PS has the smaller value of 0.36 (23,29), PIB has the larger value of 0.55 (27,31),

and poly(methylphenyl siloxane) has the intermediate value of 0.45 (125). Since pcs, dielectric relaxation, and shear mechanical relaxation or compliance measure different dynamic variables and different correlation functions, it is not surprising that dispersion parameter $1 - n_\alpha$ and the effective relaxation or retardation time τ_α determined by the three techniques can be different (147–150).

Besides pcs, other light scattering techniques including Brillouin scattering and Fabry–Perot interferometry described in previous sections have been applied to probe the dynamics of polymers at higher frequencies than the more conventional techniques. Interpretations of the results from these techniques are still subjects of controversy and are not discussed here.

Ultrasonic Attenuation. The frequency range of this technique is of the order of 1 MHz. The attenuation α of the longitudinal waves is related to the longitudinal loss modulus M'' by $M'' = 2\alpha\rho u^3/\omega$, and the longitudinal storage modulus M' by $M' = \rho u^2$, where ρ is the density and u is the ultrasonic velocity. For an example of the use of this techniques, see References 151 and 152.

Nuclear Magnetic Resonance Techniques. Several experimental techniques stemming from the basic principles of nuclear magnetic resonance (qv) were developed in the last decade, which probe relaxation as local as the primary local segmental motion and the secondary relaxation and as extensive as diffusion of the entire chain. Some of these techniques and representative data have been reviewed (153) and are not discussed further here. However, in Figure 30 the local segmental relaxation correlation time τ_c of high molecular weight PS is shown as a function of temperature obtained by two-dimensional exchange nmr (154,155) up to long times exceeding 100 s, and compared with the shift factor $a_{T,S}$ from time–temperature superposition of recoverable creep compliance $J_r(t)$ curves of another high molecular weight PS (PS-A25) in the glass–rubber softening region described earlier (105). Only the fits to the data of τ_c and $a_{T,S}$ by the William–Landel–Ferry (WLF) equation (156) are given. The nmr τ_c has the same temperature dependence as $a_{T,S}$ in the temperature range below 384 K, where $a_{T,S}$ is determined principally by measurements of $J_r(t) < 10^{-7}$ Pa^{-1} and reflects the shift factors of the local segmental motion, $a_{T,\alpha}$, and the sub-Rouse modes, $a_{T,sR}$. Above 384, τ_c starts to exhibit stronger temperature dependence than $a_{T,S}$. Between approximately 384 and 407 K, $a_{T,S}$ is determined by curves with $J_r(t)$ larger than 10^{-7} Pa^{-1} and consist of Rouse modes and possibly some shorter time modes in the plateau. Thus the nmr data gives another proof that the local segmental relaxation time has stronger temperature dependence than the Rouse modes (71,72). Above approximately 407 K, the creep compliance data is contributed entirely by the terminal viscoelastic mechanism, which has exactly the same temperature dependence as the viscosity shift factor $a_{T,\eta}$ shown also in Figure 30. It is unsurprising that the extrapolation of $a_{T,S}$ to this high temperature regime shows a different (weaker) temperature dependence than the actual shift factor for the viscosity. More important is that the nmr data τ_c of the local segmental relaxation time τ_α clearly has stronger temperature dependence than the viscosity in the *entire* temperature range shown in Figure 30.

Quasi-elastic Neutron Scattering. Coherent and incoherent inelastic neutron scattering are unique experimental techniques to characterize molecular motions on a time scale between 10^{-14} and 10^{-8} s. The continued development of high resolution inelastic scattering techniques in the past two decades (157–159) enables measurement of the dynamic structure factor $S(Q, \omega)$ and the

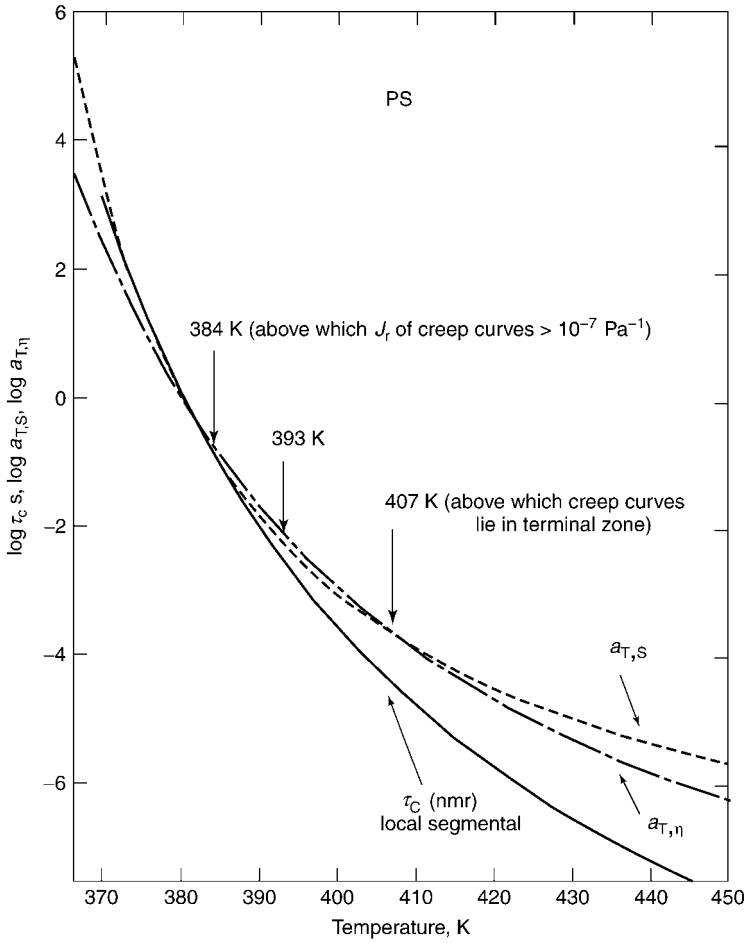

Fig. 30. The local segmental relaxation correlation time τ_c of high molecular weight PS as a function of temperature obtained by two-dimensional exchange nmr (154,155) up to long times exceeding 100 s, and compared with the shift factor $a_{T,S}$ from time–temperature superposition of recoverable creep compliance $J_r(t)$ curves of another high molecular weight PS (PS-A25) in the glass–rubber softening region (105). Only the fits to the data of τ_c (——) and $a_{T,S}$ (– – – –) by the WLF equation are given. The viscosity shift factor $a_{T,\eta}$ is also shown (– – – – –). The nmr τ_c clearly has stronger temperature dependence than the viscosity in the *entire* temperature range. There is also good agreement between the temperature dependence of τ_c and $a_{T,S}$ at temperatures below 384 K where $a_{T,S}$ becomes sequentially the shift factor of first the sub-Rouse modes and second the local segmental modes as temperature is decreased toward T_g.

intermediate scattering function $S(Q, t)$ in the typical Q (momentum transfer) range of $0.01\ nm^{-1} < Q < 0.5\ nm^{-1}$, suitable for the study of the local segmental motion in polymers. $S(Q, t)$ is related to the density–density correlation function. The advantage of quasi-elastic neutron scattering (QENS) is the information on the Q-dependence. Also partial replacement of hydrogen atoms by deuterons in the repeat units of the polymer let the experimenter select the location of the motion to be studied by the technique. The disadvantage is the presence of scattering by anharmonic vibrations and faster processes, which make the extraction of

the part of the data related to local segmental relaxation difficult. Consequently, at present interpretation of QENS data is unclear and controversial, and is not discussed here.

Enthalpy and Heat Capacity Relaxation. The conventional techniques based on differential scanning calorimetry by which enthalpy relaxation is measured at different cooling and heating rates is discussed elsewhere in the encyclopedia by others. Extensive review of the subject can be found in Reference 160. Measurements of heat capacity and entropy of polymers as a function of temperature are well documented and the data can be found in Reference 161. Frequency-dependent heat capacity spectroscopy has been developed (162,163) and application to study the local segmental dynamics of polymers has been made (163).

Positronium Annihilation Lifetime Spectroscopy. Positron annihilation lifetime spectroscopy (pals) is primarily viewed as technique to parameterize the unoccupied volume, or so-called free volume, of amorphous polymers. *In vacuo*, the ortho-positronium (o-Ps) has a well-defined lifetime τ_3 of 142 ns. This lifetime is cut short when o-Ps is embedded in condensed matter via the "pick-off" mechanism whereby o-Ps prematurely annihilates with one of the surrounding bound electrons. The quantum mechanical probability of o-Ps "pick-off" annihilation depends on the electron density of the medium, or the size of the heterogeneity. Typically the heterogeneity is assumed to be a spherical "cavity" (164,165) so that τ_3 can be easily related to an average radius R ($R_0 = R + \Delta R$) of the nanopore:

$$\tau_3 = \frac{1}{2}\left[1 - \frac{R}{R_0} + \frac{1}{2\pi}\sin\left(\frac{2\pi R}{R_0}\right)\right] \tag{36}$$

Novel studies on zeolites (165–167) confirm the validity of this approach and find ΔR, the o-Ps penetration depth into the electron cloud surrounding the cavity, to be nearly constant ($\Delta R \approx 0.161$ nm). For amorphous polymers, it is understood that spherical nanopores are a first-order approximation at best. Nevertheless, pals is widely used for the structural characterization of the unoccupied volume in glassy materials. There are many works on pals studies of amorphous polymers. Only some of the more recent works are cited here (168–170).

Pressure Dependence of Polymer Dynamics. Pressure is one of the essential thermodynamic variables that control the structure and the associated dynamics of polymers and glass-forming systems. The pressure dependence of the viscoelastic relaxation times is of paramount importance because hydrostatic pressure is encountered in polymer processing. Dielectric spectroscopy was among the first dynamic techniques to take advantage of pressure through the recognition of the fact that the dynamic state of a glass-forming system can only be completely defined if T and P are specified. This observation motivated studies of the effect of pressure on the dielectric α- and β-processes in a number of systems in the early 1960s (171–174). The main concern in these pioneering studies was to unravel the effect of pressure on separating mixed processes.

However, since then and until only recently, the lack of a versatile experimental setup has put a halt in these studies and made pressure, for a number of years, the "forgotten" variable. During the past 20 years, polymer chemistry has produced an unparalleled number of polymeric compounds with unmatched physical properties ranging from polymer blends with a well-defined thermodynamic

state to block copolymers with well-controlled nanostructures. Moreover, the interest in traditional fields such as polymer crystallization has been rejuvenated through the possibility of new experimental probes and novel synthesis. Pressure, however, was not applied up until recently in systems where the thermodynamic state of the system is of importance.

Herein an example of current interest is provided, where the thermodynamic state of the system play a dominant role in polymer dynamics. The example consists of studying the effect of pressure on the local and global chain dynamics (175,176).

The effect of pressure on the local segmental dynamics and on sub-T_g relaxations has been studied in detail (172–174). It was found that pressure exerts a stronger influence on the segmental as compared to the local sub-T_g relaxations and is the right variable if a separation of the two modes is needed. On the other hand, the effect of pressure on the global chain dynamics that control the flow regime and thus of interest in polymer processing only recently has started to be explored.

Herein the results of recent studies (175,176) are reviewed, treating the effect of pressure on the segmental and chain dynamics as a function of polymer molecular weight. The polymer is PI, which has been extensively studied before as a function of temperature for different molecular weights. Being a Type-A polymer (according to Stockmayers classification) it has components of the dipole moment both parallel and perpendicular to the chain, giving rise, respectively, to end-to-end vector and local segmental dynamics. The aim is to investigate the effect of P on M_e. This question is not only of fundamental importance but has industrial implications as well (ie, in polymer processing). For this purpose five *cis*-PIs have been used: PI-1200, PI-2500, PI-3500, PI-10600, and PI-26000, with the numbers indicating number-average molecular weights and with polydispersity of less than 1.1. The entanglement molecular weight of PI is 5400; thus the first three samples are not entangled.

The molecular weight dependence of the segmental and longest normal modes are shown in Figure 31 in the different samples as a function of pressure, at 320 K. Notice that the segmental modes (through the higher apparent activation volume) exhibit a stronger P-dependence than the corresponding normal modes. At any given P, the longest normal mode times exhibit a weak molecular weight dependence for $M < M_e$ ($\tau \sim M^2$) and a stronger dependence for $M > M_e$ ($\tau \sim M^{3.4}$). Notice the additional molecular weight dependence for the smaller molecular weights due to chain-end effects. Nevertheless, increasing pressure does not change significantly the picture from atmospheric pressure and this signifies that there is a minor, if any, dependence of M_e on P.

The main results can be summarized as follows. The spectral shape of the normal modes and of the segmental mode is invariant under variation of T and P. However, both time–temperature superposition and time–pressure superposition of the entire spectrum fails because of the higher sensitivity of the segmental mode to T and P variations, respectively. The former has been discussed in earlier sections (71,72,79,126,128). The latter results from the higher activation volume for the segmental mode. The activation volume of the segmental mode for the different molecular weights exhibits a strong T-dependence and scales as $T-T_g$. Lastly, M_e does not show a significant P-dependence.

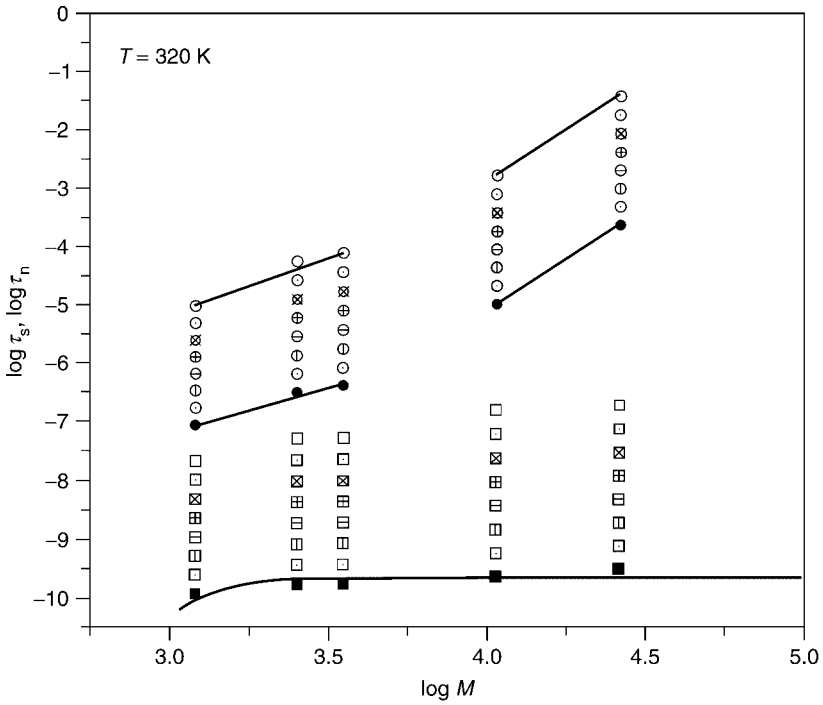

Fig. 31. Molecular weight dependence of the segmental (□) and longest normal mode (○) for the five PIs investigated, plotted for different pressures at 320 K. The shortest time corresponds to the data at 1 bar and the rest are interpolated data shown at intervals of 0.5 kbar. The line through the segmental times at atmospheric pressure is a guide for the eye.

ANIONIC POLYMERIZATION

Introduction

This article describes the general aspects of anionic polymerization of vinyl, carbonyl, and heterocyclic monomers. Polymerizations involving multicomponent catalyst systems (coordinated anionic polymerization) are not discussed. Anionic polymerization is a chain reaction polymerization in which the active species is formally an anion, ie, an atom or group with a negative charge and an unshared pair of electrons. Anions can be considered to be the conjugate bases of the corresponding acids, as shown in the following equation. The stability and reactivity of anionic species can be deduced from pK_a values for the equilibria depicted in this equation for the corresponding conjugate acid. The more acidic conjugate acids (lower pK_a values) are associated with a correspondingly more stable anionic species.

$$\mathrm{A{-}H} \overset{K_a}{\rightleftharpoons} \mathrm{A^-} + \mathrm{H^+} \qquad (1)$$

In general, these anions are associated with a counterion, typically an alkali metal cation. The exact nature of the anion can be quite varied depending on the structure of the anion, counterion, solvent, and temperature. The range of possible species is depicted in terms of a Winstein spectrum of structures as shown in equation 2 for a carbanionic chain end (R^-). In addition to the aggregated (**1**) and unassociated (**2**) species, it is necessary to consider the intervention of free ions (**5**) and the contact (**3**) and solvent-separated (**4**) ion pairs; Mt^+ represents a metallic counterion such as an alkali metal cation (1). In hydrocarbon media, species (**1–3**) would be expected to predominate. Polar solvents tend to shift the Winstein

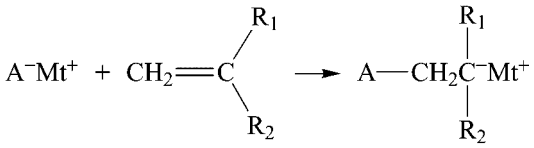
spectrum to the right, ie, toward more reactive, less associated, more ionic species. With respect to the nature of the bonding in organoalkali metal compounds, it is generally agreed that the carbon–alkali metal bond is ionic for sodium, potassium, rubidium, and cesium. For carbon–lithium bonds, however, there is disagreement regarding the relative amount of covalent versus ionic bonding (1–3). One unique aspect of anionic polymerization is that the reactive propagating species are not transient intermediates. Carbanions and organometallic species can be prepared and investigated independently of the polymerization process. These species can also be characterized during the polymerization.

$$\underset{1}{(RMt)_n} \rightleftharpoons \underset{2}{n\,RMt} \rightleftharpoons \underset{3}{R^-,Mt^+} \rightleftharpoons \underset{4}{R^-//\,Mt^+} \rightleftharpoons \underset{5}{R^-} + Mt^+ \qquad (2)$$

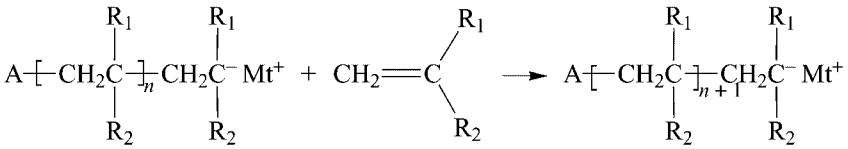
Living Anionic Polymerization

A *living polymerization* is a chain polymerization that proceeds in the absence of the kinetic steps of termination and chain transfer (4,5). For living anionic polymerization of vinyl monomers, the propagating species is a carbanion associated with the corresponding counterion, as shown in the scheme below. Living polymerizations provide versatile methodologies for the preparation of macromolecules with well-defined structures and low degrees of compositional heterogeneity. Using these methodologies it is possible to synthesize macromolecular compounds with control of a wide range of compositional and structural parameters including molecular weight, molecular weight distribution, copolymer composition and microstructure, stereochemistry, branching, and chain-end functionality. Anionic polymerization is the archetype of a living polymerization and it embodies the following defining characteristics of living polymerizations (6).

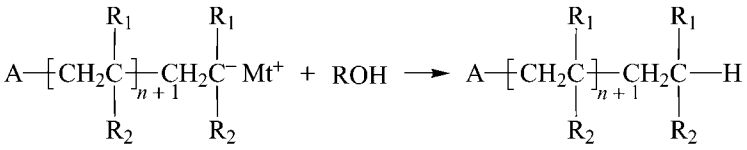
(1) *Initiation*



(2) *Propagation*



(3) *Deliberate termination* (no spontaneous termination)



Molecular Weight. The number-average molecular weight (M_n) in living anionic polymerization is a simple function of the stoichiometry and the degree of conversion of the reaction since one polymer is formed for each initiator molecule. The expected number-average molecular weight can be calculated, as shown in equation 3, as a function of conversion.

$$M_n = \text{grams of monomer consumed/moles of initiator} \tag{3}$$

From a practical point of view, polymers can be prepared with predictable molecular weights ranging from $\approx 10^3$ to $> 10^6$ g/mol using living anionic polymerizations. The ability to predict and control molecular weight depends critically on the absence of significant amounts of terminating species that react with the initiator, decrease the effective number of molecules of initiator, and thus increase the observed molecular weight relative to the calculated molecular weight.

Molecular Weight Distribution. In principle, it is possible to prepare a polymer with a narrow molecular weight distribution (Poisson distribution) by using living polymerization when the rate of initiation is competitive with or faster than the rate of propagation (5,7). This condition ensures that all of the chains grow for essentially the same period of time. The relationship between the polydispersity and the degree of polymerization for a living polymerization is shown in equation 4:

$$X_w/X_n = 1 + \left[X_n/(X_n+1)^2\right] \approx 1 + (1/X_n) \tag{4}$$

The second approximation is valid for high molecular weights. The Poisson distribution represents the ideal limit for termination-free polymerizations. Thus, it is predicted that the molecular weight distribution will become narrower with increasing molecular weight for a living polymerization system. Broader molecular weight distributions are obtained using less active initiators, with mixtures of initiators or with continuous addition of initiator as involved in a continuous flow, stirred tank reactor. Thus, living polymerizations can form polymers with broader molecular weight distributions. It has been proposed that a narrow molecular weight distribution (monodisperse) polymer should exhibit $M_w/M_n \leq 1.1$ (8).

Block Copolymers. One of the important aspects of living polymerizations is that since all chains retain their active centers when the monomer has been consumed, addition of a second monomer will form a diblock copolymer (9–11). Sequential addition of monomer charges can generate diblocks such as A—B, triblocks such as A—B—A, A—B—C, and even more complex multiblock structures. In principle, each block can be prepared with controlled molecular weight and narrow molecular weight distribution.

Chain-End Functionalized Polymers. In principle, the propagating carbanionic center that remains at the end of the polymerization can react with a variety of electrophilic species to incorporate functional groups (—X) at the chain end, as shown in equation 5 (12–14):

$$P^- + X—Y \text{ (electrophilic reagent)} \longrightarrow P—X + Y^- \quad (5)$$

Methods have been reported and tabulated for the synthesis of a diverse array of functional end groups.

An alternative methodology for the synthesis of functionalized polymers using living anionic polymerization is the use of functionalized initiators (15,16). If a functional group (or a suitably protected functional group) is incorporated into the initiator, then that functional group will be at the initiating end of every polymer molecule, as shown below:

(1) *Initiation*

$$X—I^- + M \longrightarrow X—I—M^-$$

(2) *Propagation*

$$X—I—M^- + n\,M \longrightarrow X—I—\left[M\right]_n—M^-$$

(3) *Termination*

$$X—I—\left[M\right]_n—M^- \longrightarrow X—P$$

where X is the functional group in the initiating species $X—I^-$ and X—P is the α-functionalized polymer. In principle, this method can quantitatively produce functionalized polymers with controlled molecular weights and narrow molecular weight distributions.

Star-Branched Polymers. An extension of the concept of controlled termination reactions is the ability to prepare star-branched polymers by post-polymerization reactions with multifunctional linking reagents as shown in equation 6, where L is a linking agent of functionality n (17–20):

$$n\,P^* + L \longrightarrow (P)_nL \quad (6)$$

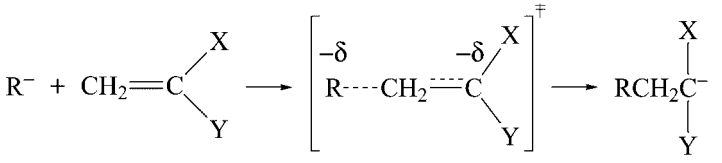
For example, termination of a living anionic polymerization with a tetrafunctional electrophile such as silicon tetrachloride will produce a four-armed star polymer as shown in equation 7. Given that PLi is a well-defined living polymer, a branched polymer with a predictable, well-defined structure will be formed from the linking reaction.

$$4\,PLi + SiCl_4 \longrightarrow (P)_4Li + 4\,LiCl \quad (7)$$

A variety of linking agents with variable functionalities have been described and tabulated in the literature (11,18,19).

General Considerations

Monomers. Two broad types of monomers can be polymerized anionically: vinyl, diene, and carbonyl-type monomers with difunctionality provided by one or more double bonds; and cyclic (eg, heterocyclic) monomers with difunctionality provided by a ring that can open by reaction with nucleophiles. For vinyl monomers, there must be substituents on the double bond that can stabilize the negative charge that develops in the transition state for monomer addition, as shown in equation 8:



(8)

These substituents must also be stable to the anionic chain ends; thus, relatively acidic, proton-donating groups (eg, amino, hydroxyl, carboxyl, acetylene functional groups) or strongly electrophilic functional groups that can react with bases and nucleophiles must not be present or must be protected by conversion to a suitable derivative. In general, substituents that stabilize the negative charge by anionic charge delocalization render vinyl monomers polymerizable by an anionic mechanism. Such substituents include aromatic rings, double bonds, as well as carbonyl, ester, cyano, sulfoxide, sulfone, and nitro groups. The general types of monomers that can be polymerized anionically without the incursion of termination and chain-transfer reactions include styrenes, dienes, methacrylates, vinylpyridines, aldehydes, epoxides, episulfides, cyclic siloxanes, lactones, and lactams. Monomers with polar substituents such as carbonyl, cyano, and nitro groups often undergo side reactions with initiators and propagating anions; therefore, controlled anionic polymerization to provide high molecular weight polymers is generally not possible. Many types of polar monomers can be polymerized anionically, but do not produce living, stable, carbanionic chain ends. These types of polar monomers include acrylonitriles, cyanoacrylates, propylene oxide, vinyl ketones, acrolein, vinyl sulfones, vinyl sulfoxides, vinyl silanes, halogenated monomers, ketenes, nitroalkenes, and isocyanates.

The simplest vinyl monomer, ethylene, although it has no stabilizing moiety, can be polymerized by an anionic mechanism using butyllithium complexed with *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA) as a complexing ligand. The conversion of a double bond to two single bonds provides the energetic driving force for this reaction. Because of the insolubility of the crystalline, high density polyethylene formed by anionic polymerization, the polymer precipitates from solution during the polymerization.

Solvents. The choice of suitable solvents for anionic polymerization is determined in part by the reactivity (basicity and nucleophilicity) of initiators and propagating anionic chain ends. For styrene and diene monomers, the solvents of

choice are alkanes and cycloalkanes, aromatic hydrocarbons, and ethers; the use of alkenes has also been described, although chain transfer can occur. Aromatic hydrocarbon solvents provide enhanced rates of initiation and propagation relative to the alkanes; however, chain transfer reactions can occur with alkylated aromatic solvents, eg, toluene.

Polar solvents such as ethers and amines react with organometallic initiators, as well as propagating polystyryl and polydienyl carbanions, to decrease the concentration of active centers (21–23). The rate of reaction with ethers decreases in the order Li > Na > K. For example, dilute solutions of poly(styryl)lithium in tetrahydrofuran (THF) at room temperature decompose at the rate of a few percent each minute. Alkyllithium initiators also react relatively rapidly with ethers; the order of reactivity of organolithium compounds with ethers is tertiary RLi > secondary RLi > primary RLi > phenyllithium > methyllithium > benzyllithium (21). An approximate order of reactivity of ethers toward alkylithium compounds is dimethoxyethane, THF > tetrahydropyran> diethyl ether> diisopropyl ether. Tertiary amines can also react with alkyllithium compounds. The importance of these reactions can be minimized by working at lower temperatures (eg, $<0^{\circ}$C); it is also advisable to use only the minimum amounts of ethers and other Lewis bases required as additives.

For less reactive anionic chain ends such as those involved in the propagation of heterocyclic monomers, a wider range of solvents can be utilized. For example, dipolar aprotic solvents such as dimethylsulfoxide (DMSO), *N*,*N*-dimethylformamide (DMF), and hexamethylphosphoramide (HMPA) can be used for polymerizations of epoxides.

Initiation

A useful guide to choose an appropriate initiator for anionic polymerization of a given monomer is that the initiator should have a reactivity (stability) similar to that of the propagating anionic species (23,24). If the initiator is too reactive, then side reactions are promoted. If the initiator is relatively unreactive, the initiation reaction may be slow or inefficient.

The stabilities of anionic initiators can be deduced from the pK_a values of the corresponding conjugate acids as shown in equation 1 (25). Monomer reactivity in anionic polymerization can be categorized in terms of the stability of the anions formed by nucleophilic addition or ring opening as deduced from the pK_a values for the conjugate acids of these anions. Thus, those monomers that form the least stable anions, ie, have the largest values of pK_a for the corresponding conjugate acids, are the least reactive monomers in anionic polymerization; in turn, these less reactive monomers require the use of the most reactive, organometallic initiators as shown in Table 1. Initiators can be classified in terms of their mechanisms of initiation: (*1*) initiation by electron transfer (alkali and alkaline-earth metals and radical anions) and (*2*) nucleophilic addition. The following sections discuss each of these initiator types.

Initiation by Electron Transfer.

Alkali Metals. The direct use of alkali metals and alkaline-earth metals as initiators for anionic polymerization of diene monomers as first reported in 1910

Table 1. Relationships between Monomer Reactivity, Carbanion Stability, and Suitable Initiators[a,b]

Monomer type	pK_a DMSO	pK_a H_2O	Initiators[c]
Ethylene	56		RLi
Dienes	44		NH_2^-, RLi, RMt
Styrenes	43		Naphthalene radical anions[d], cumyl K, Mt
Acrylonitrile	32		RMgX
Alkyl methacrylates	30–31	27–28	Fluorenyl$^-$, Ar_2RC^-, ketyl radical anions[e]
Vinyl ketones	26	19	
Oxiranes	29–32	16–18	RO^-
Thiiranes	17	12–13	
Nitroalkenes	17	10–14	
Siloxanes		10–14	RO^-, OH^-
Lactones	12	4–5	RCO_2^-
Cyanoacrylates	11		HCO_3^-, H_2O
Vinylidene cyanide	11	11	

[a] Ref. 24.
[b] pK_a of the conjugate acid of the anionic propagating intermediate.
[c] Mt refers generally to alkali metals (Li, Na, K, Rb, Cs).
[d] For example, naphthalene radical anion$^{\bullet -}$ $Li^+/Na^+/K^+$.
[e] $Ar_2CO^{\bullet -}$.

is primarily of historical interest because these are uncontrolled, heterogeneous processes (4). One of the most significant developments in anionic vinyl polymerization was the discovery reported in 1956 by Stavely and co-workers (26) at Firestone Tire and Rubber Co. that polymerization of neat isoprene with lithium dispersion produced high *cis*-1,4-polyisoprene, similar in structure and properties to *Hevea* natural rubber. This discovery led to the development of commercial anionic solution polymerization processes using alkyllithium initiators.

The mechanism of the anionic polymerization of styrenes and 1,3-dienes initiated by alkali metals has been described in detail (27). Initiation is a heterogeneous process occurring on the surface of the metal (Mt) by reversible transfer of an electron to adsorbed monomer (M), as shown in the following scheme:

$$\mathrm{Mt} + \mathrm{M} \rightleftharpoons \mathrm{Mt}^+, \mathrm{M}^{\cdot -}$$

$$2\ \mathrm{Mt}^+, \mathrm{M}^{\cdot -} \longrightarrow \mathrm{Mt}^+, {}^-\mathrm{M}\text{—}\mathrm{M}^-, \mathrm{Mt}^+$$

$$\mathrm{Mt}^+, {}^-\mathrm{M}\text{—}\mathrm{M}^-, \mathrm{Mt}^+ + n\ \mathrm{M} \longrightarrow \mathrm{Mt}^+, {}^-\mathrm{M}\text{—}\left[\mathrm{M}\right]_n\text{—}\mathrm{M}^-, \mathrm{Mt}^+$$

The initially formed radical anions ($M^{\bullet -}$) rapidly dimerize to form dianions. Monomer addition to these dianions forms adsorbed oligomers that desorb and continue chain growth in solution. Unlike homogeneous anionic initiation processes with organometallic compounds, this heterogeneous initiation reaction continues to generate new active chain ends during the course of the subsequent propagation reactions. Consequently, there is little control of molecular weight, and relatively broad molecular weight distributions have been reported for the

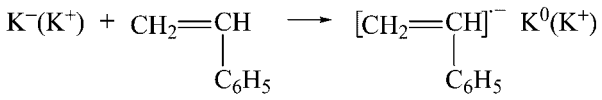
soluble polymer obtained from these bulk polymerizations (M_w/M_n = 3–10) (28); formation of a high degree of branching and gel content (45%) have also been reported for these processes (26,28).

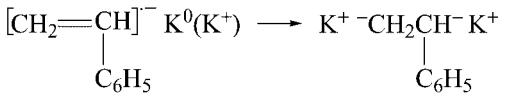
Alkali metals can dissolve in solvating media such as ethers and amines to form blue solutions of solvated electrons. In the presence of strongly complexing ligands such as crown ethers or cryptands, electrides (complexed alkali cation and electron) or nuclides (complexed alkali cation and alkali metal anion) can be formed as shown below (29):

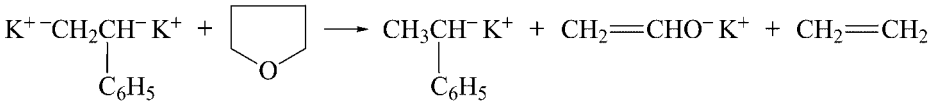
$$2\ Mt \overset{\text{crown ether or cryptand}}{\rightleftharpoons} [Mt^+]Mt^- \text{ (Nuclide)}$$

$$Mt \overset{\text{crown ether or cryptand}}{\rightleftharpoons} [Mt^+]e^- \text{ (Electride)}$$

Nuclides have been shown to react with monomers such as styrene and methyl methacrylate to form intermediate dianions that are rapidly protonated by the solvent THF to form the monoanion initiating species, as shown below (30,31):





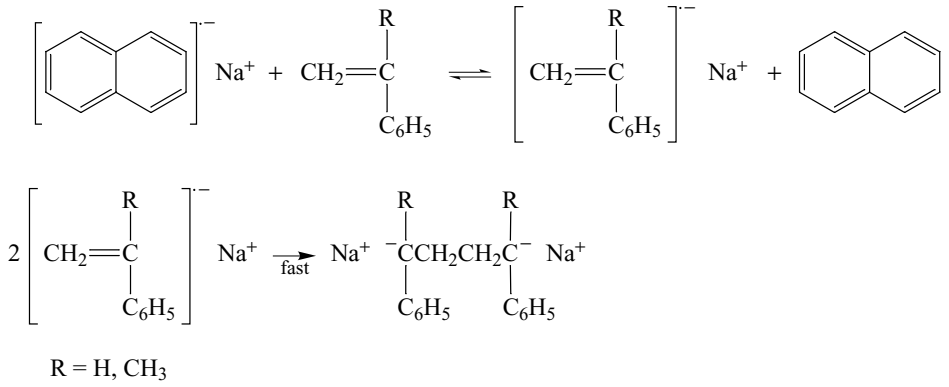


For the nuclide-initiated polymerization of methyl methacrylate, although there was good agreement between calculated and observed molecular weights, the molecular weight distributions were broad (M_w/M_n = 1.2–1.6) (31).

Radical Anions. Many aromatic hydrocarbons react reversibly with alkali metals in polar aprotic solvents to form stable, homogeneous solutions of the corresponding radical anions, as shown in equation 9 (4,27).

$$M + Ar \rightleftharpoons Ar^{\cdot -}Mt^+ \text{ (Mt = Li, Na, K, Rb, Cs)} \quad (9)$$

Radical anions can only be formed efficiently in polar aprotic solvents such as THF and glymes. Aromatic radical anions such as sodium naphthalene react with monomers such as styrene by reversible electron transfer to form the corresponding monomer radical anions, as shown in the following scheme (R = H):

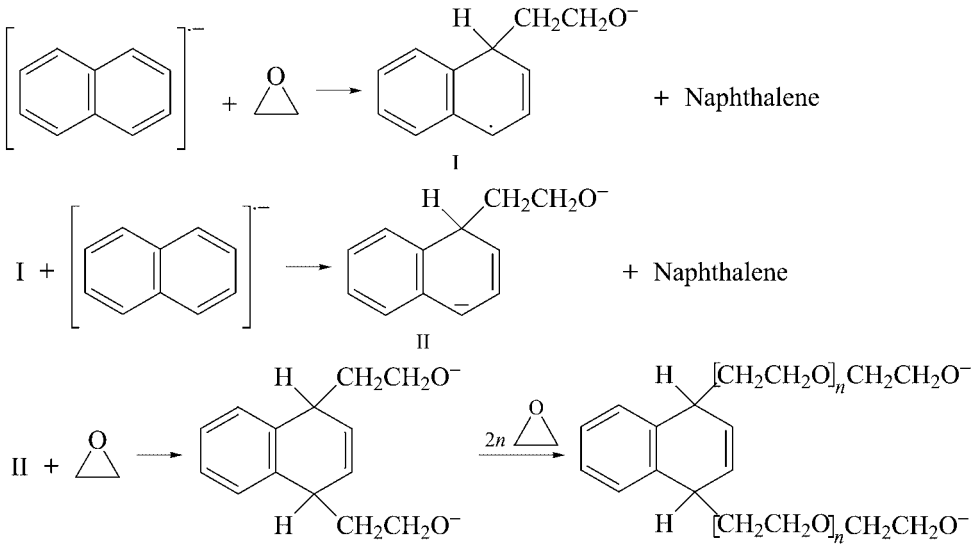


R = H, CH_3

Although the equilibrium between the radical anion of the monomer and the aromatic radical anion lies far to the left because of the low electron affinity of the monomer, this is an efficient initiation process because the resulting monomer radical anions rapidly undergo tail-to-tail dimerization reactions with rate constants that approach diffusion control.

The reactions of monomers with aromatic radical anions or directly with alkali metals can be used to prepare oligomeric dianionic initiators from monomers such as α-methylstyrene that have accessible ceiling temperatures ($T_c = 61^\circ C$) (32), as shown in the above scheme (R = CH_3). Dimers or tetramers can be formed depending on the alkali metal system, temperature, and concentration.

Monomers that can be polymerized with aromatic radical anions include styrenes, dienes, epoxides, and cyclosiloxanes. For epoxides and cyclosiloxanes, the mechanism of initiation involves nucleophilic addition of the radical anion to these monomers, as shown below, in contrast to the electron transfer mechanism occurring for hydrocarbon monomers (see previous scheme).



Initiation by Nucleophilic Addition.

Alkyllithium Compounds. Although anionic polymerization of vinyl monomers can be effected with a variety of organometallic compounds, alkyllithium compounds are the most useful class of initiators (1,21,24,33). A variety of simple alkyllithium compounds are readily available commercially in hydrocarbon solvents such as hexane and cyclohexane. They can be prepared by reaction of the corresponding alkyl chlorides with lithium metal.

Alkyllithium compounds are generally associated into dimers, tetramers, or hexamers in hydrocarbon solution (2,21). The degree of association is related to the steric requirements of the alkyl group; ie, the degree of association decreases as the steric requirements of the alkyl group increase.

The relative reactivities of alkyllithiums as polymerization initiators are intimately linked to their degree of association, as shown below, with the average degree of association in hydrocarbon solution, where known, indicated in brackets after the alkyllithium (2,23,33):

(1) *Styrene polymerization*:

Menthyllithium [2] > *s*-C_4H_9Li [4] > *i*-C_3H_7Li [4–6] > *i*-C_4H_9Li > *n*-C_4H_9Li [6] > *t*-C_4H_9Li [4]

(2) *Diene polymerization*:

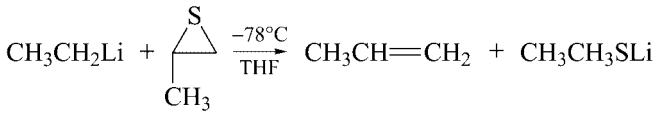
Menthyllithium [2] > *s*-C_4H_9Li [4] > *i*-C_3H_7Li [4–6] > *t*-C_4H_9Li [4] > *i*-C_4H_9Li > *n*-C_4H_9Li [6]

In general, the less associated alkyllithiums are more reactive as initiators than the more highly associated species.

Alkyllithium initiators are primarily used as initiators for polymerizations of styrenes and dienes (see Table 1). They effect quantitative, living polymerization of styrenes and dienes in hydrocarbon solution. In general, these alkyllithium initiators are too reactive for alkyl methacrylates and vinylpyridines (see Table 1). *n*-Butyllithium is used commercially to initiate anionic homopolymerization and copolymerization of butadiene, isoprene, and styrene with linear and branched structures. Because of its high degree of association (hexameric), *n*-butyllithium-initiated polymerizations are often effected at elevated temperatures (>50°C) to increase the rate of initiation relative to propagation and thus to obtain polymers with narrower molecular weight distributions (34).

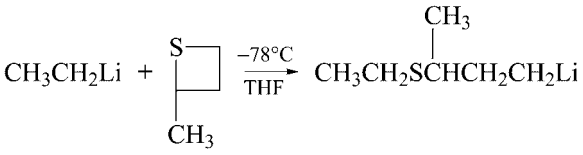
sec-Butyllithium is used commercially to prepare styrene—diene block copolymers because it can initiate styrene polymerization rapidly as compared to propagation so that even polystyrene blocks with relatively low molecular weights (10,000–15,000 g/mol) can be prepared with stoichiometric control and narrow molecular weight distributions.

Alkyllithiums react quite differently with cyclic sulfides compared to the normal nucleophilic ring-opening reaction with epoxides (35,36). Ethyllithium reacts with 2-methylthiacyclopropane to generate propylene and lithium ethanethiolate. The resulting lithium ethanethiolate is capable of initiating polymerization of 2-methylthiacyclopropane.



(10)

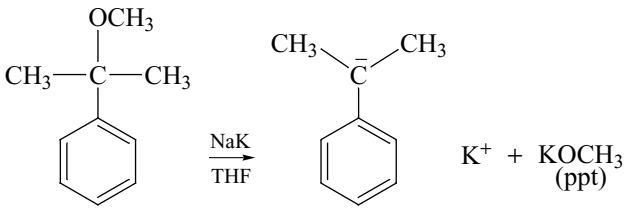
In contrast, ethyllithium reacts with 2-methylthiacyclobutane to form an alkyllithium product that is capable of initiating polymerization of styrene.



(11)

Organoalkali Initiators. In general, the simple organoalkali metal derivatives other than lithium are not soluble in hydrocarbon media. However, higher homologues of branched hydrocarbons are soluble in hydrocarbon media. The reaction of 2-ethylhexyl chloride and sodium metal in heptane produces soluble 2-ethylhexylsodium (37). This initiator copolymerizes mixtures of styrene and butadiene to form styrene—butadiene copolymers with high (55–60%) vinyl microstructure (38,39).

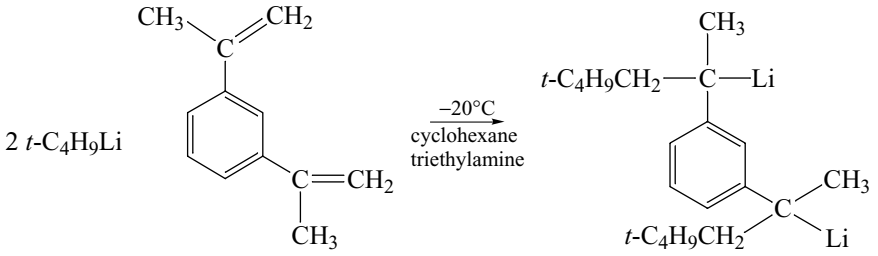
Cumyl potassium ($pK_a \approx 43$ based on toluene) is a useful initiator for anionic polymerization of a variety of monomers, including styrenes, dienes, methacrylates, and epoxides. This carbanion is readily prepared from cumyl methyl ether, as shown in equation 12, and is generally used at low temperatures in polar solvents such as THF.



(12)

Difunctional Initiators. Aromatic radical anions, such as lithium naphthalene or sodium naphthalene, are efficient difunctional initiators (see scheme under Radical Anions). However, the need to use polar solvents for their formation limits their utility for diene polymerization since the unique ability of lithium to provide high 1,4-polydiene microstructure is lost in polar media. The methodology for preparation of hydrocarbon-soluble, dilithium initiators is generally based on the reaction of an aromatic divinyl precursor with 2 moles of butyllithium. Unfortunately, because of the tendency of organolithium chain ends in hydrocarbon solution to associate and form electron-deficient dimeric, tetrameric, or hexameric aggregates, most attempts to prepare dilithium initiators in hydrocarbon media have generally resulted in the formation of insoluble, three-dimensionally associated species (40).

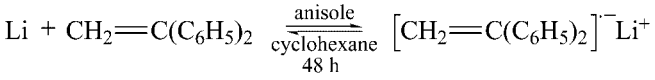
The reaction of *m*-diisoproprenylbenzene with 2 moles of *t*-butyllithium in the presence of 1 equiv of triethylamine in cyclohexane at −20°C has been reported to form pure diadduct without oligomerization (eq. 13) (41). This initiator in the presence of 5 vol% of diethyl ether for the butadiene block has been used to prepare well-defined poly(methyl methacrylate)-*block*-polybutadiene-*block*-poly(methyl methacrylate).



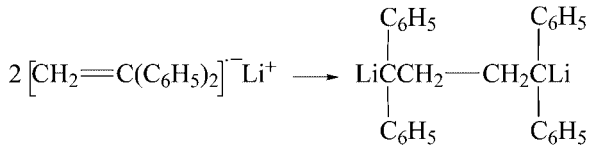
(13)

The reaction of pure *m*-divinylbenzene with *sec*-butyllithium in toluene at −49°C in the presence of triethylamine ($[(C_2H_5)_3N]/[Li] = 0.1$) has been reported to produce the corresponding dilithium initiator in quantitative yield (42). Polymerization of butadiene with this initiator in toluene at −78°C produced well-defined polybutadiene with high 1,4-microstructure (87%).

A useful, hydrocarbon-soluble, dilithium initiator has been prepared by the dimerization of 1,1-diphenylethylene with lithium in cyclohexane in the presence of anisole (15 vol%) as shown in equations 14 and 15 (43). Although the initiator was soluble in this mixture, it precipitated from solution when added to the polymerization solvent (cyclohexane or benzene). Therefore, the dilithium initiator was chain extended with approximately 30 units of isoprene to generate the corresponding soluble oligomer. This initiator was used to prepare well-defined polystyrene-*block*-polyisoprene-*block*-polystyrene and poly(α-methylstyrene)-*block*-polyisoprene-*block*-poly(α-methylstyrene) triblock copolymers with >90% 1,4-microstructure by sequential monomer addition.



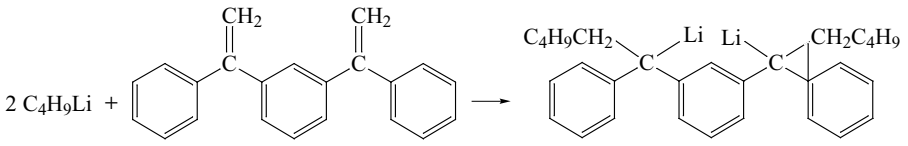
(14)



(15)

The addition reaction of 2 mol of *sec*-butyllithium with 1,3-bis(1-phenylethenyl)benzene (eq. 16) proceeds rapidly and efficiently to produce the corresponding dilithium species that is soluble in toluene or in cyclohexane (24,44). Although this dilithium initiator is useful for the preparation of homopolymers

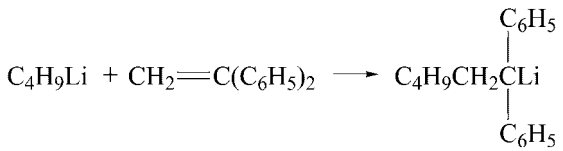
and triblock copolymers with relatively narrow molecular weight distributions, it is necessary to add a small amount of Lewis base or ≥2 equiv of lithium alkoxide (eg, lithium *sec*-butoxide) to produce narrow, monomodal molecular weight distributions.



(16)

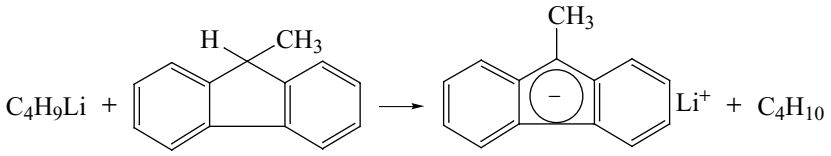
Functionalized Initiators. Alkyllithium initiators that contain functional groups provide versatile methods for the preparation of end-functionalized polymers and macromonomers (15,16). For a living anionic polymerization, each functionalized initiator molecule will produce one macromolecule, with the functional group from the initiator residue at one chain end and the active anionic propagating species at the other chain end. However, many functional groups such as hydroxyl, carboxyl, phenol, and primary amine are not stable in the presence of reactive dienyllithium and styryllithium chain ends. Therefore, it is necessary to convert these functional groups into suitable derivatives, ie, protected groups, that are stable to the carbanionic chain ends and that can be removed readily after the polymerization. Examples of protected functional initiators include the hydroxyl-protected initiators, 1-lithium-6-(1-ethoxyethoxy)hexane, 6-(*t*-butyldimethylsiloxy)hexyllithium, and 3-(*t*-butyldimethylsiloxy)propyllithium, as well as a primary amine-protected initiator, 4-*bis*(trimethylsily)aminophenyllithium (45).

1,1-Diphenylmethylcarbanions. The carbanions based on diphenylmethane ($pK_a = 32$) (see Table 1) are useful initiators for vinyl and heterocyclic monomers, especially alkyl methacrylates at low temperatures (46). 1,1-Diphenylalkyllithiums can also efficiently initiate the polymerization of styrene and diene monomers that form less stable carbanions. Diphenylmethyllithium can be prepared by the metalation reaction of diphenylmethane with butyllithium or by the addition of butyllithium to 1,1-diphenylethylene, as shown in equation 17. This reaction can also be utilized to prepare functionalized initiators by reacting butyllithium with a substituted 1,1-diphenylethylene derivative. Addition of lithium salts such as lithium chloride, lithium *t*-butoxide, or lithium 2-(2-methoxyethoxy)ethoxide with 1,1-diphenylmethylcarbanions and other organolithium initiators has been shown to narrow the molecular weight distribution and to improve the stability of active centers for anionic polymerization of both alkyl methacrylates and *t*-butyl acrylate (47,48).



(17)

Fluorenyl Carbanions. Salts of fluorene ($pK_a \approx 23$) are more hindered and less reactive than many other organometallic initiators. Fluorenyl carbanions can be readily formed by metalation of fluorenes with alkali metal derivatives, as shown in equation 18. Carbanion salts of 9-methylfluorene are preferable to fluorene, since the latter generate chain ends that contain reactive, acidic fluorenyl hydrogens that can participate in chain transfer reactions. Fluorenyl salts are useful initiators for the polymerization of alkyl methacrylates, epoxide, and thiirane monomers.



(18)

Styrene and Diene Monomers

Kinetics of Polymerization.

Initiation Kinetics. The mechanism of initiation of anionic polymerization of vinyl monomers with alkyllithium compounds and other organometallic compounds is complicated by association and cross-association phenomena in hydrocarbon solvents and by the presence of a variety of ionic species in polar media (4,27,33,49). The kinetics of initiation are complicated by competing propagation and the occurrence of cross-association of the alkyllithium initiator with the propagating organolithium (50). Thus, only the initial rates provide reliable kinetic data.

Typical kinetics of the initiation reaction of *n*-butyllithium with styrene in benzene exhibit a first-order dependence on styrene concentration and approximately a one-sixth-order dependence on *n*-butyllithium concentration, as shown in equation 19.

$$R_i = k_i(K_d/6)^{1/6}[C_4H_9Li]_o^{1/6}[M] \tag{19}$$

Since *n*-butyllithium is aggregated predominantly into hexamers in hydrocarbon solution, the fractional kinetic order dependency of the initiation process on the total concentration of initiator has been rationalized on the basis that unassociated *n*-butyllithium is the initiating species and that it is formed by the equilibrium dissociation of the hexamer as shown below:

$$(n\text{-}C_4H_9Li)_6 \overset{K_d}{\rightleftharpoons} 6\ n\text{-}C_4H_9Li \tag{20}$$

$$n\text{-}C_4H_9Li + CH_2{=}CH(C_6H_5) \xrightarrow{k_i} n\text{-}C_4H_9{-}CH_2CHLi(C_6H_5) \tag{21}$$

The kinetic order for *sec*-butyllithium-initiated polymerization of styrene is close to 0.25 in benzene solution; this result is also consistent with initiation by unassociated *sec*-butyllithium, since *sec*-butyllithium is associated predominantly into tetramers in benzene solution.

The frequent coincidence of the fractional order with the degree of association supports the postulate that the initiating species is a small amount of reactive monomeric alkyllithium in equilibrium with the much larger concentration of the unreactive aggregated species. However, the correctness of this interpretation, ie, direct dissociation to monomeric, unassociated species, has been questioned (33). The experimentally observed energies of activation, eg, 75 kJ/mol (18 kcal/mol) for *n*-butyllithium initiation of styrene polymerization (51), appear to be too low to include the enthalpy of complete dissociation of the aggregates, which is estimated to require approximately 452 kJ/mol (108 kcal/mol) (52). An alternative is the incomplete or stepwise dissociation of the aggregate, for example, as shown in equations 22–25 for hexamers; equation 25 plus equation 24 would apply for tetramers.

$$(RLi)_6 \rightleftharpoons (RLi)_5 + RLi \tag{22}$$

$$(RLi)_6 \rightleftharpoons (RLi)_4 + (RLi)_2 \tag{23}$$

$$(RLi)_2 \rightleftharpoons 2\,RLi \tag{24}$$

$$(RLi)_4 \rightleftharpoons 2\,(RLi)_2 \tag{25}$$

In aliphatic solvents the inverse correspondence between reaction order dependence for alkyllithium and degree of organolithium aggregation is not observed (49). In addition, the rates of initiation in aliphatic solvents are several orders of magnitude less than in aromatic solvents. Most reaction orders for alkyllithium initiators in aliphatic solvents are close to unity. These results suggest that in aliphatic solvents the initiation process may involve the direct addition of monomer with aggregated organolithium species (eq. 26) to form a cross-associated species.

$$(RLi)_n + M \longrightarrow [(RLi)_{n-1}(RMLi)] \tag{26}$$

The formation of cross-associated species would be expected to complicate the kinetics and lead to variable reaction orders as a function of conversion. The observation of pronounced induction periods has been ascribed to the enhanced reactivity of the mixed (ie, cross-associated) aggregated species. The effects of cross-association provide at least a partial explanation for the discrepancies reported in the literature for the kinetic order dependencies on alkyllithium initiator concentration; thus, only in the initial stages is it likely that a detailed interpretation of the mechanism is possible.

Lewis bases and alkali metal alkoxides have been used as additives to modify the initiation reaction with alkyllithium compounds. In the presence of THF, the

initiation reaction kinetics of styrene with *sec*-butyllithium exhibit a first-order dependence on alkyllithium concentration. Lewis bases such as ethers and amines, when present in amounts comparable to the initiator concentration, dramatically increase the relative rate of initiation of styrene and diene polymerizations relative to propagation.

The effect of lithium alkoxides on alkyllithium-initiated polymerizations is important because these salts are ubiquitously present to some extent as impurities formed by the reactions with oxygen (13) (eq. 27) and hydroxylic impurities (eq. 28). In fact, it is common practice to utilize excess butyllithium, ie, more than the stoichiometric amount required to generate the required molecular weight, to scavenge impurities in the solvent and monomer feed.

$$RLi + O_2 \longrightarrow R{-}R + RO_2R + ROOH + ROH \quad (27)$$

$$RLi + R'OH \longrightarrow R{-}H + R'OLi \quad (28)$$

The effects of lithium alkoxides on the rates of alkyllithium-initiation reactions depend on the solvent, the monomer, the alkoxide structure, the alkyllithium initiator, and the ratio of [RLi]/[LiOR′] (49,50). For *n*-butyllithium initiation of styrene in cyclohexane, the rate of initiation is increased at low relative concentrations of added lithium alkoxide [t-C_4H_9OLi]/[C_4H_9Li]< 0.5). At a ratio of 1/1, the rate is essentially the same as the control without alkoxide; beyond this ratio, the rate decreases continuously with increasing relative concentration of lithium alkoxide. In aromatic solvents, the initiation rate decreases with increasing relative concentrations of lithium alkoxide. Lithium alkoxides generally accelerate the rate of initiation by alkyllithiums (*n*-butyllithium and *sec*-butyllithium) for isoprene in hexane.

Propagation Kinetics. The kinetics of propagation for styrene and diene monomers in hydrocarbon solvents with lithium as the counterion is complicated by chain-end association (49,50,53). The kinetics of propagation can be investigated independently of initiation so that complications from cross-association with the initiator are absent. The reaction order dependence of the propagation rate on active center concentration is independent of the identity of the hydrocarbon solvent, aromatic or aliphatic, although the relative propagation rates, under equivalent conditions, are faster in aromatic versus aliphatic solvents.

Styrene Monomers. The anionic propagation kinetics for styrene (S) polymerization with lithium as counterion is relatively unambiguous. The reaction order in monomer concentration is first order as it is for polymerization of all styrene and diene monomers in heptane, cyclohexane, benzene, and toluene. The reaction order dependence on total chain-end concentration, $[PSLi]_o$, is one-half as shown in equation 29:

$$R_p = -d[S]/dt = k_{obs}[PSLi]_o^{1/2}[S] \quad (29)$$

The observed one-half kinetic order dependence on chain-end concentration is consistent with the fact that poly(styryl)lithium is predominantly associated into

dimers in hydrocarbon solution. If the unassociated poly(styryl)lithium is the reactive entity for monomer addition, a simple dissociative mechanism can be invoked (equations 30 and 31). This mechanism leads to the kinetic equation shown in equation 32.

$$(\mathrm{PSLi})_2 \overset{K_\mathrm{d}}{\rightleftharpoons} 2\ \mathrm{PSLi} \tag{30}$$

$$\mathrm{PSLi} + \mathrm{S} \xrightarrow{K_\mathrm{p}} (\mathrm{PS})\mathrm{SLi} \tag{31}$$

From equations 30 and 31, it can be seen that the observed rate constant for propagation, k_{obs}, is actually a composite of the propagation rate constant, k_p, and the equilibrium constant for dissociation of the dimeric aggregates, K_d, raised to the one-half power (eq. 32).

$$\begin{aligned} R_\mathrm{p} &= -\,\mathrm{d[S]}/\mathrm{d}t = k_\mathrm{p}[\mathrm{PSLi}][\mathrm{S}] \\ &= k_\mathrm{p}(K_\mathrm{d}/2)^{1/2}[\mathrm{PSLi}]_\mathrm{o}^{1/2}[\mathrm{S}] \\ &= k_\mathrm{obs}[\mathrm{PSLi}]_\mathrm{o}^{1/2}[\mathrm{S}] \end{aligned} \tag{32}$$

The measurement of the dissociation constants of the aggregates is difficult because of the low concentration of the unassociated species; thus, it is generally not possible to obtain directly a value for the propagation rate constant k_p (see, however, Refs. 54–56).

In contrast to this simple interpretation, the kinetic order dependence on chain-end concentration for propagation of styrene and *o*-methoxystyrene in toluene with alkyllithium initiators varies from 0.62 to 0.66 (56). Furthermore, recent neutron scattering data indicate that poly(styryl)lithium in benzene solution exhibits concentration-dependent degrees of aggregation involving predominantly dimers and tetramers, as well as small amounts of large-scale aggregates (57). These results suggest that the actual mechanism of propagation may be much more complicated than that depicted in equations 30 and 31 (see, however, Ref. 58).

A comparison of the observed propagation rate constants for styrene polymerization with different alkali metal counterions is shown in Table 2. Poly(styryl)sodium was presumably associated into dimers since kinetic orders of one-half were observed for the rate dependence on the active chain-end concentration. Poly(styryl)potassium exhibits intermediate behavior; dependence on chain-end concentration was one-half order at higher concentrations, but first order at low concentrations. Poly(styryl)rubidium and poly(styryl)cesium exhibit first-order dependencies on chain-end concentrations which is consistent with unassociated chain ends in cyclohexane. The counterion dependence is $K^+ > Rb^+ > Cs^+ \gg Li^+$ in cyclohexane and $K^+ > Na^+ > Li^+$ in benzene. The interpretation of these results is complicated by the fact that the complex observed rate constants (k_{obs}) reflect both the fact that the dissociation constant for the dimers increases with increasing cation size (no association for rubidium and cesium) and also the fact that the requisite energy associated with charge separation in the transition state would be less for the larger counterions.

Table 2. Kinetic Parameters for Styrene Propagation in Hydrocarbon Solvents[a]

Counterion	Solvent	Temperature, °C	$[k_p(K_D/n)^{1/n}]$ (k_{obs}), $L^{1/n}/(mol^{1/n}\cdot s)$
Lithium	Benzene	30	1.55×10^{-2}
Lithium	Cyclohexane	40	2.4×10^{-2}
Sodium	Benzene	30	17×10^{-2}
Potassium	Benzene	30	180×10^{-2}
Potassium	Cyclohexane	40	30
Rubidium	Cyclohexane	40	22.5[b]
Cesium	Cyclohexane	40	19[b]

[b]Propagation rate constant presumably for the unassociated species (see eq. 32); first-order dependence on active chain-end concentration observed.

Diene Monomers. The delineation of the mechanism of propagation of isoprene and butadiene in hydrocarbon solution with lithium as counterion is complicated by disagreement in the literature, regarding both the kinetic order dependence on chain-end concentration and the degree of association of the chain ends, as well as by apparent changes in kinetic reaction orders with chain-end concentration (53). For butadiene and isoprene propagation, reported reaction order dependencies on the concentration of poly(dienyl)lithium chain ends include 0.5, 0.33, 0.25, and 0.167. Kinetic studies of isoprene propagation with lithium as counterion in hydrocarbon solvents showed that the kinetic order dependence on chain-end concentration changed from 0.5 to either 0.25 or 0.17 as the chain-end concentration was varied from 10^{-2} to 10^{-6} mol/L (53,59,60). Comparison of these kinetic orders with the degrees of association of the poly(dienyl)lithium chain ends is complicated by the lack of agreement regarding the predominant degree of association of these species in hydrocarbon solution. Predominant degrees of association of both 2 and 4 have been reported by different research groups using the same techniques, ie, concentrated solution viscometry and light scattering (61–64). Recent evaluation of the association states of poly(butadienyl)lithium chain ends in benzene by small-angle neutron scattering, as well as both dynamic and static light scattering, indicates that dimeric and tetrameric aggregates are in equilibrium with higher order aggregates ($n > 100$) (65,66).

Relative Reactivities of Styrene and Dienes. The relative reactivities of dienes *versus* styrenes depend on the chain-end concentrations because of the differences in kinetic order dependencies on chain-end concentration. The relative rates of propagation at [PLi] $= \approx 10^{-3}$ M are in the order styrene > isoprene > butadiene. However at [PLi] $\leq \approx 10^{-4}$ M, isoprene propagates faster than styrene (53).

Effects of Lewis Bases. The addition of small amounts of Lewis bases such as ethers and tertiary amines generally increases the rate of propagation in alkyllithium-initiated polymerizations. These Lewis bases decrease the average degree of association of the polymeric organolithium aggregates as determined by concentration solution viscosity measurements. In contrast, addition of strongly coordinating Lewis bases such as N,N,N',N'-tetramethylethylenediamine and pentamethyldiethylenetriamine can either increase or decrease the reaction rate for alkyllithium propagation of isoprene relative to hydrocarbon solution, depending on the chain-end concentration (67). This situation arises from the

different reaction order dependencies on chain-end concentration, ie, 0.3 in hydrocarbon solution compared to 1.1 for the stoichiometric Lewis base complexes. The addition of lithium alkoxides generally decreases the rate of propagation, while addition of other alkali metal alkoxides increases the rate of polymerization in hydrocarbon solution.

Polar Solvents. A change in the reaction medium from hydrocarbon to polar solvent causes changes in the nature of the alkali metal carbanions that can be interpreted in terms of the Winstein spectrum of ionic species, as shown below (68,69). Thus, in addition to the aggregated (**1**) and unassociated (**2**) species that can exist in hydrocarbon solution, in polar solvents it is necessary to consider the intervention of free ions (**5**) and the contact (**3**) and solvent-separated (**4**) ion-paired carbanion species, as shown below:

$$\begin{array}{ccccccccc} (RMt)_n & \rightleftharpoons & n\,RMt & \rightleftharpoons & R^-,Mt^+ & \rightleftharpoons & R^- \,//\, Mt^+ & \rightleftharpoons & R^- + Mt^+ \\ \mathbf{1} & & \mathbf{2} & & \mathbf{3} & & \mathbf{4} & & \mathbf{5} \\ \downarrow k_1[M] & & \downarrow k_2[M] & & \downarrow k_3[M] & & \downarrow k_4[M] & & \downarrow k_5[M] \end{array} \qquad (33)$$

In general, as the polarity and solvating ability of the medium increases, more ionic species (a shift in the Winstein spectrum from left to right) are formed. In addition, each different chain-end species can react with monomer with its own unique rate constant.

In weakly polar solvents such as dioxane ($\varepsilon = 2.21$), the kinetics of styrene propagation exhibit pseudo-first-order kinetics as illustrated in equation 34, where k_{obs} is the observed pseudo-first-order rate constant, k_p is the propagation rate constant, and $[PS^-Mt^+]$ represents the concentration of carbanionic chain ends that does not change for a living polymerization.

$$-d[S]/dt = k_{obs}[S] = k_p[PS^-Mt^+][S] \qquad (34)$$

The values of k_p can be obtained by plotting k_{obs} versus $[PS^-Mt^+]$. The order of reactivity [rate constants in brackets are in units of L/(mol·s)] of alkali metal counterions is Li [0.9] < Na [3.4–6.5] < K [20–34] < Cs [5–24] (27). The trend of increasing reactivity with increasing ionic radius, as also observed in hydrocarbon solution, has been taken as evidence for contact ion pairs as the reactive propagating species. Similar behavior has been observed for isoprene polymerization in diethyl ether ($\varepsilon = 4.34$); the propagation rate constant assigned to the lithium contact ion pair is 3.2 L/(mol·s) (70).

In more polar solvents such as THF ($\varepsilon = 7.6$), a concentration dependence was observed for the plots of k_{obs} versus $[PS^-Mt^+]$; ie, k_p exhibits a linear dependence of $1/[PS^-Mt^+]^{1/2}$ (27). This dependence has been interpreted in terms of the participation of both ion pairs and free ions as active propagating species, as shown below:

$$\begin{array}{ccccc} R^-,Mt^+ & \overset{K_{diss}}{\rightleftharpoons} & R^- & + & Mt^+ \\ \downarrow k_{\pm}[M] & & \downarrow k_-[M] & & \end{array} \qquad (35)$$

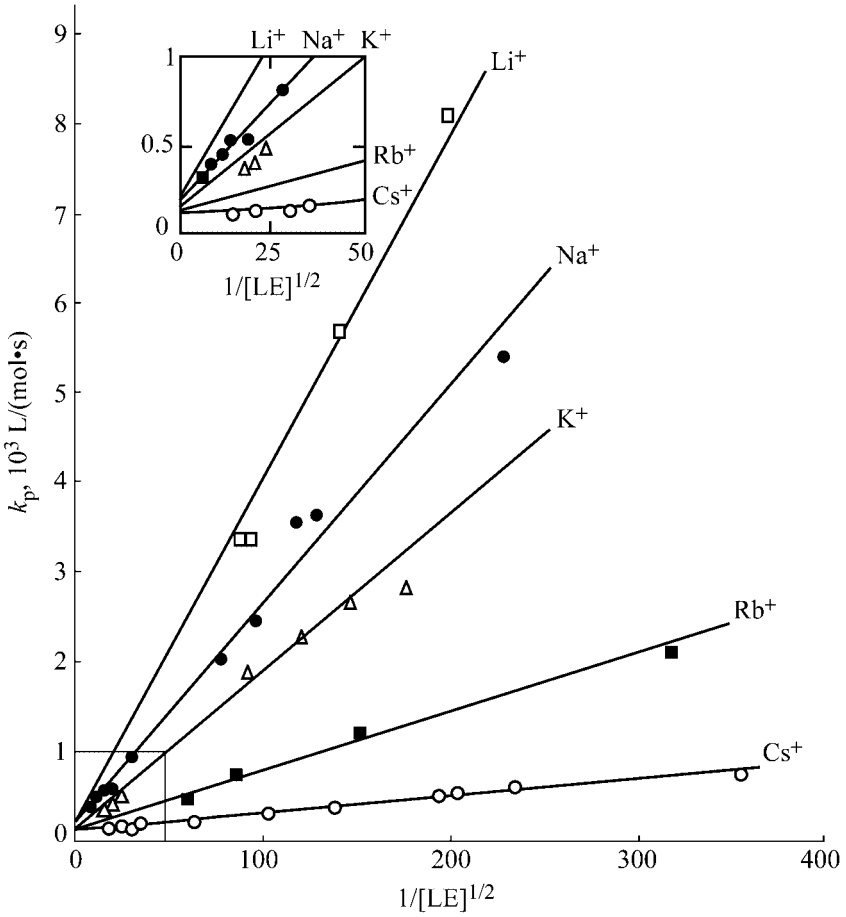

Fig. 1. Plots of the propagation constant k_p for salts of living polystyrene in THF vs $1/[LE]^{1/2}$. □ Li^+; ● Na^+; △ K^+; ■ Rb^+; ○ Cs^+. $T = 25°C$. From Ref. 27; reprinted by permission of Springer-Verlag.

where $k_\pm$ is the propagation rate constant for the ion pair species, k_- is the propagation rate constant for the free ion, and K_{diss} is the equilibrium constant for dissociation of ion pairs to free ions. The corresponding expression for k_p is shown below, recognizing that this k_p is only an apparent propagation rate constant.

$$k_p = k_\pm + k_- K_{diss}^{1/2}/[P^- Mt^+]^{1/2} \tag{36}$$

Plots of the apparent propagation rate constant versus $1/[P^- Mt^+]^{1/2}$ are shown in Figure 1. From this figure it can be deduced that the slopes of the lines decrease as the cation size increases from lithium to cesium. Since k_- is independent of the cation, the variation of the slope with counterion reflects a decrease in K_{diss} as the counterion size increases. This is consistent with independent measures of the dissociation constants for free ion formation from both conductometric and

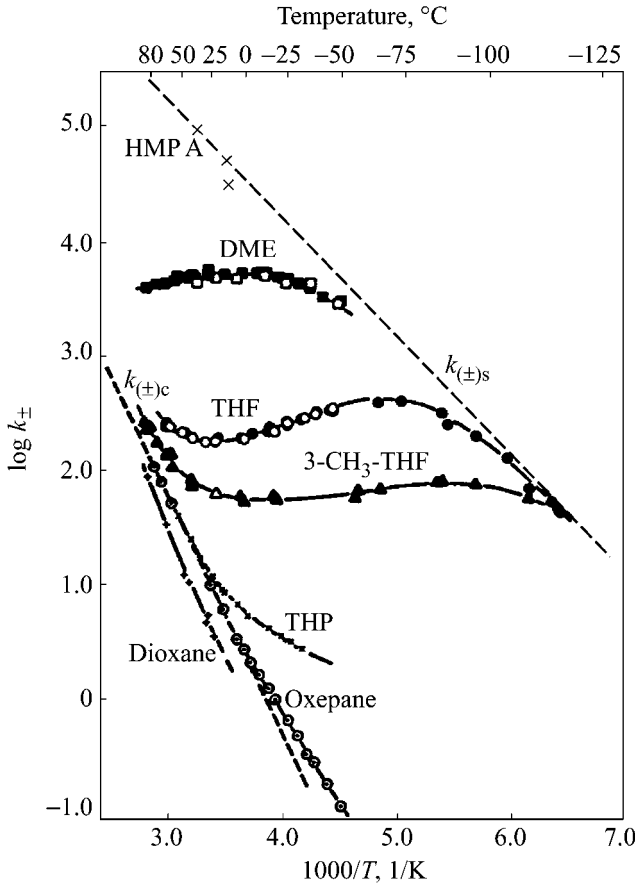

Fig. 2. Arrhenius plots of the propagation constants of ion pairs of poly(styryl)sodium in various solvents. The curves approach a common assymptote at low temperatures, interpreted as a linear Arrhenius plot referring to the propagation constant of solvent-separated ion pairs, and the curves approach again a common assymptote at high temperatures, interpreted as a linear Arrhenius plot referring to the propagation constant of tight ion pairs. From Ref. 27; reprinted by permission of Springer-Verlag.

kinetic studies. Figure 1 also shows that the intercepts, that represent $k_{\pm}$, also decrease with increasing cation size. Values of the propagation rate constant for free styryl anions are relatively insensitive to solvent; values for k_{-} of 0.65×10^5 and 1.3×10^5 L/(mol·s) have been reported at 25°C in THF (27). Corresponding values of $k_{\pm}$ vary from 160 L/(mol·s) for lithium to 22 L/(mol·s) for cesium ion in THF at 25°C. Similar results have been obtained for cumyl potassium-initiated polymerization of butadiene in THF; k_{-} had a value of 4.8×10^4 L/(mol·s) and $k_{\pm}$ was <1 L/(mol·s) at 0°C (71).

Although normal Arrhenius behavior was observed for k_{-}, anomolous increases of $k_{\pm}$ with decreasing temperature were observed in polar solvents such as THF and dimethoxyethane (glyme), as shown in Figure 2 (27). These results have been explained in terms of a temperature-dependent equilibrium between contact and solvent-separated ion pairs, as shown below:

Table 3. Ion Pair Rate Constants for Anionic Polymerization of Poly(styryl)sodium in Ethereal Solvents and the Equilibrium Constant and Thermodynamic Parameters for Ion Pair Equilibrium

Solvent	k_c, L/(mol·s)	k_s, 10^4 L/(mol·s)	$K_{c/s}$ (25°C)	ΔH, kJ/mol[a]	ΔS, J/(mol·K)[a]
DME[b]	12.5	5.5	0.13	−23	−94
THF	34	2.4	2.25×10^{-3}	−27	−142
3-CH_3-THF[c]	20	12.4	5.8×10^{-4}	−21	−134
THP[d]	10.7	5.3	1.3×10^{-4}	−12.6	−117
Dioxane	5.5	—	$<10^{-5}$	—	—

[a]To convert J to cal, divide by 4.184.

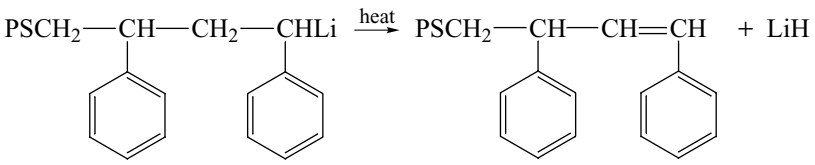
$$\underset{\text{contact}}{R^-,Mt^+} \underset{}{\overset{K_{c/s}}{\rightleftharpoons}} \underset{\text{solvent-separated}}{R^-//\ Mt^+}$$

$$\downarrow k_c[M] \qquad \downarrow k_s[M]$$

This equilibrium shifts from the less reactive contact ion pair to the more reactive solvent-separated ion pair as temperature is decreased because the contribution from the unfavorable (negative) entropy of dissociation ($T\Delta S$) decreases and the enthalpy of dissociation is negative. As shown in Table 3, the values of k_c and k_s are not much dependent upon solvent, but the equilibrium constants $K_{c/s}$ are very dependent on the polarity of the solvent. These results also provide a rationalization for the effect of counterion on $k_\pm$ shown in Figure 1. Smaller cations such as lithium interact more strongly with solvent and form significant amounts of more reactive solvent-separated ion pairs.

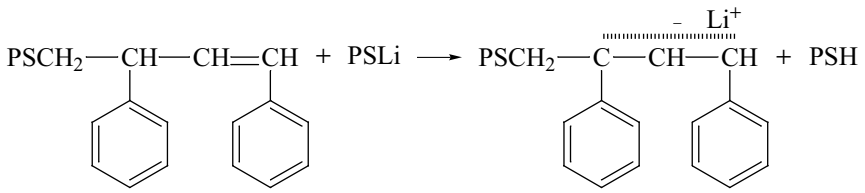
Termination Reactions. The categorization of a given polymerization system as living is based on results obtained on the laboratory time scale, ie, the absence of chain-termination or chain-transfer reactions occurring within the normal time required to complete the polymerization and carry out any subsequent chemical reactions with the active carbanionic polymer chain ends (6). In fact, the amount of spontaneous termination reactions in typical alkyllithium-initiated polymerizations of styrene and diene monomers depends on time, temperature, and whether polar additives are present (22,72,73).

Polymeric organolithium compounds exhibit good stability in hydrocarbon solution at ambient temperatures and for short periods of time at elevated temperatures (22,72). The principal mode of decomposition is loss of lithium hydride (β-hydride elimination) to form a double bond at the chain end, as illustrated below for poly(styryl)lithium.



(37)

Poly(styryl)lithium exhibits good stability over the duration of the polymerizations and beyond, ie, days, at ambient temperatures in hydrocarbon media. However, at elevated temperatures, it is observed that the initial uv absorption at 334 nm decreases and a new absorption is observed at 450 nm, assigned to a 1,3-diphenylallyllithium species as shown below (22):



(38)

The rate constant for spontaneous decomposition was reported to be 4×10^{-5} s^{-1} at 65°C in cyclohexane (22,74). Analogous decomposition reactions have been observed for poly(styryl)sodium. The thermal stability of poly(α-methylstyryl)lithium is much lower than that of poly(styryl)lithium. The observed half-lives for spontaneous termination are 5 h and a few minutes at 25 and 60°C, respectively (75). However, the chain ends were stabilized with respect to spontaneous decomposition by the addition of TMEDA. The relative thermal stability of styryl carbanionic chain ends follows the order K $\gg$ Na $>$ Li for the alkali metal counterions.

The carbanionic active centers based on 1,3-butadiene and isoprene, with lithium as counterion, generally possess good stability in hydrocarbon solvents at ambient temperatures. However, poly(dienyl)lithiums undergo complex decomposition reactions upon prolonged storage or heating at elevated temperatures. Poly(butadienyl)lithium in ethylbenzene exhibits an absorption maximum at 300 nm, which gradually decreases in intensity with the formation of absorption tails between 350 and 500 nm (22). Approximately 20% of the active centers were destroyed in less than 3 h at 100°C in ethylbenzene (76). The apparent first-order rate constant for decomposition of poly(butadienyl)lithium in hexane was estimated to be 1.9×10^{-5} s^{-1} at 93°C and a chain-end concentration of 2.2 mequiv of poly(butadienyl)lithium per 100 g of solution (25 wt% polymer) (74). The corresponding first-order rate constant for chain-end decomposition of poly(isoprenyl)lithium at 93°C was estimated to be 6.7×10^{-5} s^{-1} (74). Although the differences are not large, the relative order of increasing stabilities of chain ends toward thermal degradation is poly(α-methylstyryl)lithium $\ll$ poly(styryl)lithium $<$ poly(isoprenyl)lithium $<$ poly(butadienyl)lithium as estimated by chain-end titration data.

Size exclusion chromatography (sec) analyses of the thermal decomposition products of poly(dienyl)lithiums in heptane at 80°C have shown that the chain-end decomposition is accompanied by formation of species which have double and triple the molecular weight of the original living polymer (77). After heating for 46 h at 80°C in heptane, a 12 wt% yield of coupled products was observed for poly(isoprenyl)lithium; after heating for 27 h at 80°C in heptane, a 19wt% yield of coupled products was observed for poly(butadienyl)lithium. The following reactions illustrate the type of reactions proposed to explain the formation of dimeric products:

$$\underset{\text{Active, uncoupled}}{PCH_2{-}CH{=}CH{-}CH_2Li} \xrightarrow{\text{heat}} \underset{\text{Inactive, uncoupled}}{PCH{=}CH{-}CH{=}CH_2} + LiH \tag{39}$$

$$P'Li + PCH{=}CH{-}CH{=}CH_2 \longrightarrow \underset{\text{Active, coupled}}{PCH(Li){-}CH{=}CH{-}CH_2{-}P'} \tag{40}$$

$$\underset{\text{Li}}{PCH(Li){-}CH{=}CH{-}CH_2{-}P'} \xrightarrow{\text{heat}} LiH + \underset{\text{Inactive, coupled}}{PCH{=}CH{-}CH{=}CH{-}P'} \tag{41}$$

Evidence also suggests that athermal metalation of the backbone can occur as shown below:

$$PBDLi + P{-}CH_2{-}CH{=}CH{-}CH_2{-}P \longrightarrow PBDH + \underset{\text{Li}}{P{-}CH(Li){-}CH{=}CH{-}CH_2{-}P} \tag{42}$$

It would be expected that this in-chain metalation coupled with elimination of lithium hydride would lead to in-chain diene units which would have even more reactive allylic hydrogens for further metalation–elimination–coupling sequences that would promote thermal decomposition, branching, and ultimately gel formation.

Polymeric organolithium compounds exhibit limited stability in ether solvents analogous to alkyllithium compounds. Living carbanionic polymers react with ether solvents such as THF in a pseudo-first-order decay process and the rate decreases in the order Li > Na > K. For example, a 10^{-5} M solution of poly(styryl)lithium in THF at 25°C exhibited a rate of decay of a few percent per minute, but poly(styryl)cesium was found to be exceptionally stable (78). Metalation and decomposition reactions can also occur in the presence of amines such as TMEDA.

Chain-Transfer Reactions. Chain-transfer reactions to polymeric organoalkali compounds can occur from solvents, monomers, and additives that have pK_a values lower or similar to those of the conjugate acid of the carbanionic chain end (72). Relatively few monomers that undergo anionic polymerization exhibit chain transfer to monomer. Chain transfer has been well documented for the anionic polymerization of 1,3-cyclohexadiene. The chain-transfer constant (k_{tr}/k_p) was calculated to be 2.9×10^{-2} at 20°C and 9.5×10^{-3} at 5°C in cyclohexane (79). Although chain transfer would be expected for *p*-methylstyrene, controlled polymerizations can be effected when the temperature is maintained at room temperature or below. The observations of broad molecular weight distributions and a low molecular weight tail by sec analysis have provided evidence for chain transfer during the anionic polymerization of *p*-isopropyl-α-methylstyrene (80).

The kinetics of chain transfer to ammonia have been investigated for potassium amide-initiated polymerization of styrene in liquid ammonia at −33.5°C.

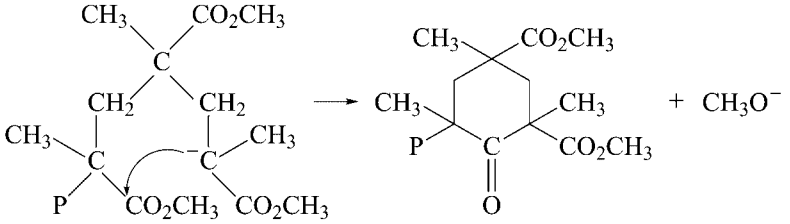
The calculated chain-transfer constant (k_{tr}/k_p) was 2.34×10^{-4} (81). The chain-transfer reaction of poly(styryl)lithium with toluene at 60°C was investigated during the polymerization of styrene with the use of ^{14}C-labeled toluene. The calculated chain-transfer constant (k_{tr}/k_p) was 5×10^{-6} (82). A much larger chain-transfer constant ($k_{tr}/k_p = 1.28 \times 10^{-4}$) was found for analogous transfer from toluene to poly(styryl)sodium. Chain-transfer reactions are promoted by Lewis bases. A chain-transfer constant of 0.2 was reported for the telomerization of butadiene initiated by metallic sodium in a toluene/tetrahydrofuran mixture at 40°C (83). Significant chain-transfer effects have also been reported for alkyllithium-initiated polymerizations using alkenes as solvents. Allenes and alkynes act as modifiers in alkyllithium-initiated polymerizations that have the effects of lowering rates of reaction and polymer molecular weights. Although these carbon acids can terminate chain growth, the ability of the resulting metalated chain-transfer product to reinitiate chain growth has only been demonstrated for 1,2-butadiene (84).

Polar Monomers

Polar Vinyl Monomers. The anionic polymerization of polar vinyl monomers is often complicated by side reactions of the monomer with both anionic initiators and growing carbanionic chain ends, as well as chain-termination and chain-transfer reactions. However, synthesis of polymers with well-defined structures can be effected under carefully controlled conditions. The anionic polymerizations of alkyl methacrylates and 2-vinylpyridine exhibit the characteristics of living polymerizations under carefully controlled reaction conditions and low polymerization temperatures to minimize or eliminate chain-termination and chain-transfer reactions. The proper choice of initiator for anionic polymerization of polar vinyl monomers is of critical importance to obtain polymers with predictable, well-defined structures. As an example of an initiator that is too reactive, the reaction of methyl methacrylate (MMA) with *n*-butyllithium in toluene at −78°C produces approximately 51% of lithium methoxide by attack at the carbonyl carbon (85).

Methyl Methacrylate. The most generally useful initiator for anionic polymerization of MMA and related compounds is 1,1-diphenylhexyllithium which is formed by the quantitative and facile addition of butyllithium with 1,1-diphenylethylene (DPE) (eq. 17) (46). Using this initiator in THF at −78°C, it is possible to polymerize MMA to obtain polymers and block copolymers with predictable molecular weights and narrow molecular weight distributions. Controlled polymerizations are not effected in nonpolar solvents such as toluene, even at low temperatures. Other useful initiators for polymerization of MMA are oligomers of (α-methylstyryl)lithium whose steric requirements minimize attack at the ester carbonyl group in the monomer. These initiators are also useful for the polymerization of 2-vinylpyridine (see METHACRYLIC ESTER POLYMERS).

The principal termination reaction in the anionic polymerization of MMA is a unimolecular backbiting reaction with the prepenultimate ester group to form a six-membered ring, β-keto ester group at the chain end, as shown below:



The rate of this backbiting reaction decreases with increasing size of the counterion.

A dramatic development in the anionic polymerization of acrylate and methacrylate monomers was the discovery that by addition of lithium chloride it was possible to effect the controlled polymerization of *t*-butyl acrylate (86). Thus, using oligomeric (α-methylstyryl)lithium as initiator in THF at -78°C, the molecular weight distribution (M_w/M_n) of the polymer was 3.61 in the absence of lithium chloride but 1.2 in the presence of lithium chloride ([LiCl]/[RLi] = 5). In the presence of 10 equiv of LiCl, *t*-butyl acrylate was polymerized with 100% conversion and 95% initiator efficiency to provide a polymer with a quite narrow molecular weight distribution ($M_w/M_n = 1.05$). More controlled anionic polymerizations of alkyl methacrylates are also obtained in the presence of lithium chloride. Other additives, which promote controlled polymerization of acylates and methacrylates, include lithium *t*-butoxide, lithium (2-methoxy)ethoxide, and crown ethers (47,48). The addition of lithium chloride also promotes the controlled anionic polymerization of 2-vinylpyridine.

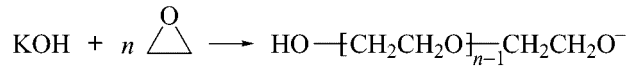
The kinetics of anionic polymerization of MMA are complicated by chain-end association effects and the involvement of both free ions and ion pairs as propagating species. Lithium ester enolates are highly aggregated even in THF; association numbers range from 2.3 to 3.5 (87). Because of chain-end association, a dependence of propagation rate constants on chain-end concentration has been observed for lithium and sodium counterions. The propagation rate constant for the free ions at -75°C in THF is 4.8×10^5 L/(mol·s) (88). The propagation rate constants for ion pairs vary in the order Cs $\approx$ K $\approx$ Na $\gg$ Li. This is consistent with the conclusion that contact ion pairs are the predominant propagating species. The ion pair rate constants for lithium and potassium as counterions in THF at -40°C are 100 and 750 L/(mol·s), respectively (89).

The kinetic effects of lithium chloride on anionic polymerization of alkyl acrylates and methacrylates have been carefully examined (47,48,90,91). Added lithium chloride decreases the rate of propagation but has little effect on the rate of termination. In the absence of lithium chloride, free ions as well as associated and unassociated species can participate in the propagation event. By a common ion effect, the role of free ions is minimized by addition of lithium chloride. In the absence of lithium chloride, the rate of interconversion between tetameric aggregates, dimeric aggregates, and unassociated ion pairs is slow relative to propagation resulting in broader molecular weight distributions. Lithium chloride decreases the amount of aggregated species and forms cross-associated complexes with the lithium ester enolate ion pairs. Most important, the equilibration among these lithium chloride cross-aggregated species is fast relative to propagation so that narrow molecular weight distributions can be obtained.

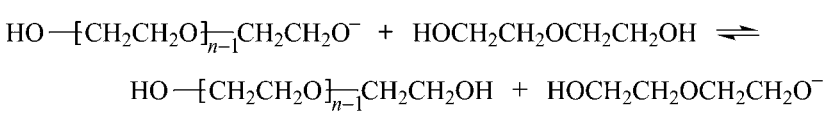
Heterocyclic Monomers. A variety of heterocyclic monomers can be polymerized by anionic ring-opening polymerizations. The types of anionically polymerizable heterocyclic monomers include oxiranes (epoxides), thiacyclopropanes, thiacyclobutanes, lactones, lactides, lactams, anhydrides, carbonates, and siloxanes (92). Among these heterocyclic monomers, the anionic polymerizations of epoxides have been examined most extensively.

Ethylene Oxide. The anionic polymerization of ethylene oxide is complicated by association phenomena and the participation of ion pair and free ion intermediates in the propagation reactions (see POLYETHERS). Simple lithium alkoxides are strongly associated into hexamers and tetramers even in polar media such as THF and pyridine (93). As a consequence, lithium alkoxides are unreactive as initiators for the anionic polymerization of oxiranes. Association effects can be minimized by effecting polymerizations in alcohol media or in dipolar aprotic solvents.

The potassium hydroxide-initiated polymerization of ethylene oxide in alcoholic solvents such as diethylene glycol produces low molecular weight polyols ($M_w \approx 600$–700) with broad molecular weight distributions because of chain-transfer reactions with alcohol that occur throughout the polymerization, as shown below (98):



(43)



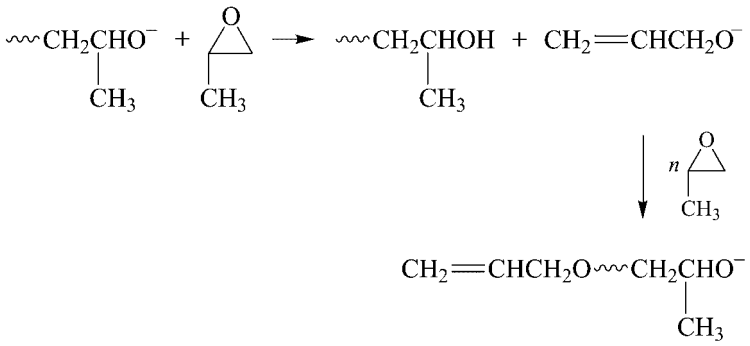
(44)

"Living polymerizations with reversible chain transfer" (6) can be effected for alkoxide-initiated polymerizations of ethylene oxide in the presence of alcohol ([ROH]/[NaOR] $\approx$ 10) in solvents such as dioxane (95,96). Narrow molecular weight distributions are obtained because, although there is formally a chain-transfer reaction between OH-ended polymers and alkoxide-ended polymers, the equilibrium between these two types of chain ends is rapid and reversible such that all chains participate uniformly in chain growth as described in Reference 97.

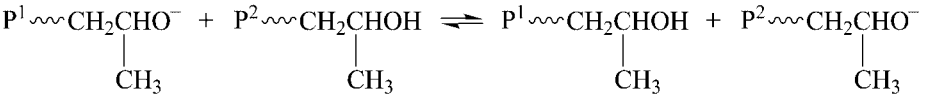
Association phenomena and the presence of both ion pairs and free ions as propagating species complicate the kinetics of sodium alkoxide-initiated polymerizations of ethylene oxide even in dipolar aprotic solvents such as HMPA ($\varepsilon = 26$). However, living polymerizations occur in dipolar aprotic solvents and in ethers such as THF, although the rates are much slower in ethers. The rates of propagation increase with increasing radius of the cation. The rates of propagation of ethylene oxide are also accelerated in the presence of cation complexing agents such as crown ethers and cryptands. Although the cryptated ion pairs are somewhat less reactive than the uncomplexed ion pairs, cryptands promote dissociation of the ion pairs to form free ions that are 70 times more reactive than the ion pairs (98). Because of the concentrated charge on oxygen, contact ion pairs predominate. The propagation rate constants in THF at 20°C for the cesium ion pair and

the free ion are 7.3 and 100 L/(mol·s) (98). An optimized, living polymerization procedure utilized *N*-carbazolylpotassium as initiator in THF at 20°C in the presence of crown ether (4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane); narrow molecular weight distribution polymers with controlled molecular weights as high as 266,000 g/mol could be obtained (99).

Propylene Oxide. The anionic ring-opening polymerizaton of propylene oxide is much slower than the analogous polymerization of ethylene oxide (see POLYETHERS). The propagation rate constant at 40°C in neat propylene oxide is 1.9×10^{-4} L/(mol·s) (100). The anionic ring-opening polymerization of propylene oxide using hydroxide or alkoxide initiators is not a living polymerization. Chain transfer to monomer competes with propagation to limit the maximum molecular weight attainable and to broaden the molecular weight distribution, as shown below.



Thus, chains are formed that have the unsaturated allyloxy end group. The chain-transfer constant (k_{tr}/k_p) is approximately 0.01; thus, the molecular weight attainable is theoretically limited to approximately 6×10^3 g/mol (101). However, molecular weights as high as 13,000 g/mol have been obtained for polymerization of neat propylene oxide with potassium as counterion in the presence of 18-crown-6 ether. Under these conditions, chain-transfer constants as low as 8×10^{-4} have been reported (102). This is due to the rapid equilibration between hydroxyl-ended chains and alkoxide-ended chains, that ensures uniform growth of all chains even after chain transfer, as shown below:



However, chain transfer to monomer will still broaden the molecular weight distribution and prevent molecular weight control even when reversible chain transfer among growing species occurs. This rapid and reversible chain transfer is used to prepare branched polypropylene oxide polymers. Initiation of propylene oxide polymerization with an alkali metal alkoxide and a triol such as glycerol will produce the corresponding polypropylene oxide with an average functionality of three.

The anionic polymerization of propylene oxide initiated by potassium alkoxide or hydroxide occurs predominantly (95%) by cleavage of the O—CH_2 bond. For bulk polymerization at 80°C, approximately 4% head-to-head placements occur.

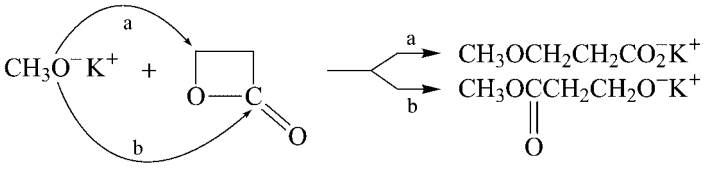
However, there is no stereocontrol in this alkoxide-initiated ring opening and the resulting polymer is nontactic (103).

Chain-transfer reactions to monomer occur with other homologues of propylene oxide. The reactivity of higher epoxides decreases as expected on the basis of steric hindrance effects on nucleophilic attack at the oxirane carbons.

Propylene Sulfide. The anionic polymerization of propylene sulfide is a living polymerization that proceeds in the absence of termination and chain transfer (96) (see POLY(ALKYLENE SULFIDE)S). The regiochemistry of addition corresponds to regular head-to-tail addition without detectable amounts of head-to-head or tail-to-tail additions. The polymer stereochemistry is nontactic. The kinetics of propagation of propylene sulfide initiated by carbazylsodium in THF at chain-end concentrations $<10^{-3}\ M$ are not complicated by chain-end association effects. The reported propagation rate constants for contact ion pairs and free ions at -40°C were 1×10^{-3} and 1.7 L/(mol·s), respectively (96). The ion pair rate constants for the corresponding [2.2.2]cryptate-solvated sodium thiolate were more than two times larger than the corresponding free ion rate constants in THF at -39°C (98).

Lactones.

β-Propiolactone. The anionic polymerizations of the β-lactones and ε-lactones have been extensively investigated (104). Living characteristics are observed for the polymerization of β-propiolactone using a dibenzo-18-crown-6 ether complex of sodium acetate as the initiator in dichloromethane (105). Depending on the reactivity of the initiator, either acyl–oxygen cleavage or alkyl–oxygen cleavage can occur to form the corresponding alkoxide or carboxylate anions, respectively, as illustrated below for initiation with potassium methoxide that results in both modes of ring opening.

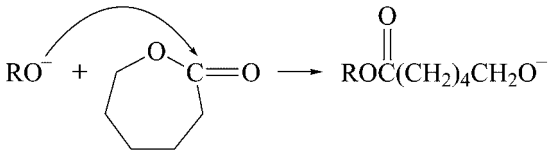


(45)

Only alkyl–oxygen cleavage is observed for initiation with potassium acetate. Regardless of the initiator, all propagating species eventually become carboxylate anions because in each subsequent propagation step a fraction of the alkoxide anions are converted to carboxylate anions. The kinetics of these polymerizations are complex. Both complexed ion pairs and free ions are involved in the propagation reactions and the free ion rate constants depend on monomer concentration. The relative reactivity of complexed ion pairs and free ions is temperature-dependent. Above the inversion temperature of -35°C, free ions are more reactive than ion pairs, but below this temperature, the ion pairs are more reactive. At 30°C in DMF, the observed (average) propagation rate constant is 0.13 L/(mol·s) (106). The anionic polymerization of α,α-dialkyl-β-propiolactones such as pivalolactone (α,α-dimethyl-β-propiolactone) initiated with carboxylate anions exhibits the main characteristics of living polymerizations.

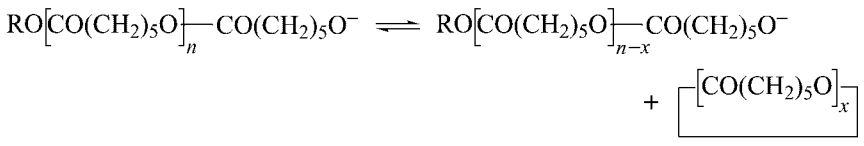
ε-Caprolactone. The anionic polymerization of ε-lactones, especially ε-caprolactone, is generally complicated by intramolecular cyclization reactions and redistribution reactions that prevent control of molecular weight and lead to

broader molecular weight distributions (104). Alkoxides and not carboxylates are active initiators for polymerization of ε-caprolactone consistent with the identification of the alkoxide anion as the propagating species, as shown below:



(46)

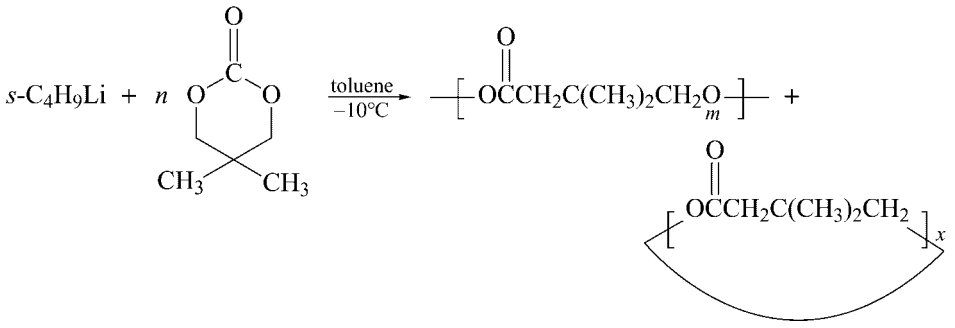
Chain-end association complicates the kinetics of polymerization. Evidence for aggregation of lithium and sodium alkoxides, but not for potassium alkoxides, in THF has been found. The propagation rate constants in THF at 20°C for the free ions and ion pairs are 3.5×10^2 and 4.8 L/(mol·s) (107). The anionic polymerization of ε-caprolactone leads to the formation of considerable amounts of oligomers as by-products. In dilute solution no high polymer is formed. In bulk polymerization, more than one-third of the equilibrium distribution of products are oligomers that have been identified to be cyclic (see eq. 47). The intermolecular analogue of this reaction (transesterification) leads to scrambling of the polymer molecular weights and a molecular weight distribution that broadens with time.



(47)

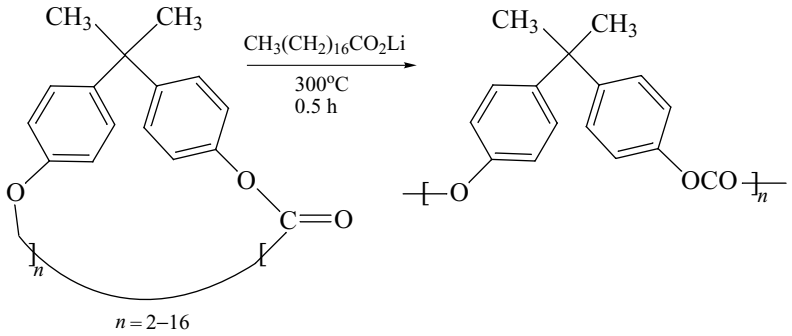
Polymerizations with lithium as counterion minimize backbiting reactions at short reaction times.

Cyclic Carbonates. Aliphatic, cyclic carbonates such as 5,5-dimethyl-1,3-diox-2-one can be polymerized using alkyllithium compounds as initiators in hydrocarbon solution to high molecular weight polymers (108,109). Ring-chain equilibration is promoted at long reaction times and in THF as solvent. At −10°C in toluene, *sec*-butyllithium-initiated polymerization of 5,5-dimethyl-1,3-diox-2-one proceeds via a lithium alkoxide-propagating species to form high molecular weight polymer ($M_n \approx 100{,}000$ g/mol) with only small amounts of a cyclic oligomer fraction after 1 h.



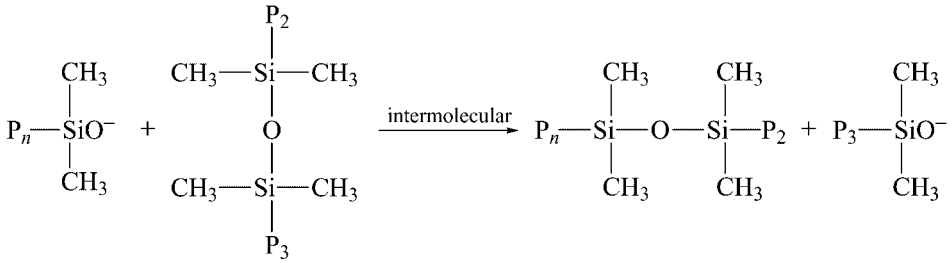
(48)

Efficient methods for the synthesis of cyclic bisphenol-A polycarbonates have provided a practical technology for the rapid synthesis of high molecular weight bisphenol-A polycarbonates by anionic ring-opening polymerization, as shown below (108). A mixture of cyclic oligomers ($M_w \approx 1300$) was polymerized with lithium stearate for 0.5 h at 300°C to yield the corresponding linear polymer with M_w = 300,000 and M_w/M_n = 2.4 (110). Rapid chain–chain equilibration occurs under these conditions. Other useful anionic polymerization initiators include lithium phenoxide, lithium phenylacetate, and sodium benzoate. Diphenylcarbonate can be used as a chain-transfer agent to control the molecular weight.

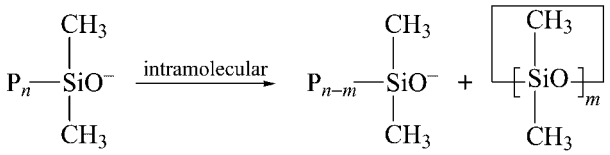


(49)

Siloxanes. A variety of bases, eg, hydroxides, alkoxides, phenolates, and silanolates, are effective initiators for the anionic polymerization of hexamethyl cyclotrisiloxane (D_3) and octamethyl cyclotetrasiloxane (D_4) (111). The heat of polymerization for the cyclic oligomers in the series from the tetramer (D_4) to the decamer (D_{10}) is approximately zero and the only driving force is a small positive entropy [approx 5.8 J/(mol SiO groups·K)] (112). The trimer D_3 is unique in having a slightly exothermic heat of polymerization of 19.6 kJ/mol (3.5 kcal/mol) (113). The growing polymer for D_4 polymerization is in equilibrium with the monomer (2% at 140°C) as well as with various kinds of oligomers and cyclic polymers (10–15%); a Gaussian distribution of linear polymers is obtained. The concentrations of each of the various cyclics ($n > 15$) are in accord with the Jacobsen–Stockmayer cyclization theory (114). The mechanism of polymerization can be described as an equilibration among these various components; in addition to reaction with the monomer, the growing silanolate chain ends react with all siloxane bonds via intramolecular cyclization and intermolecular chain transfer, as shown below:

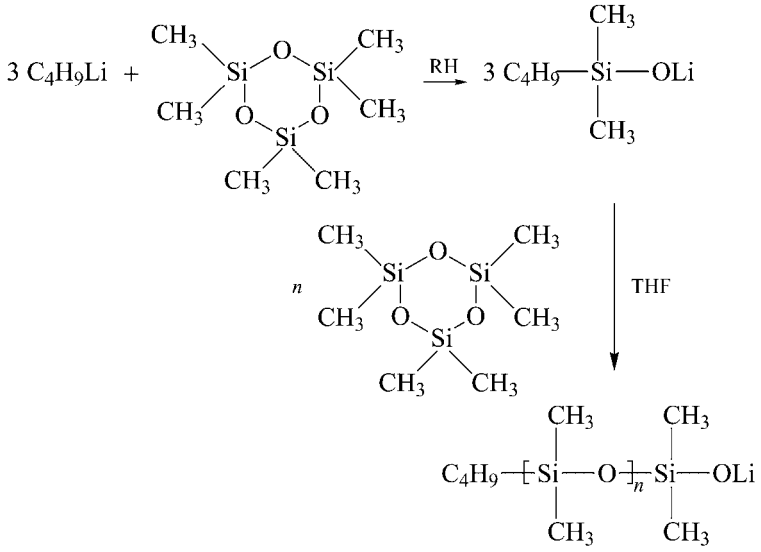


(50)



(51)

In contrast to the polymerization of D_4, the anionic polymerization of D_3 with lithium as counterion is a living polymerization which produces polydimethylsiloxanes with well-defined structures. Useful initiators include lithium silanolates or the product from the reaction of 3 moles of butyllithium with D_3 in hydrocarbon solvent, as shown below. It is noteworthy that no polymerization occurs in the absence of a Lewis base promoter such as THF, glymes, DMSO, or HMPA.



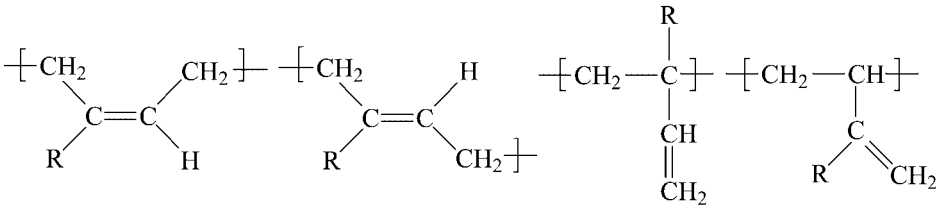
The kinetics of polymerization of cyclosiloxanes are complicated by chain-end association. Complexation of counterions with cryptands disrupts the aggregates. For the lithium [2.1.1]cryptand complex in aromatic solvent at 20°C, the propagation rate constants for D_3 and D_4 are 1.4 and 4×10^{-3} L/(mol·s), respectively (98) (see SILICONES).

Stereochemistry

Polydienes.

Polydienes in Hydrocarbon Solvents. One of the most important synthetic and commercial aspects of anionic polymerization is the ability to prepare polydienes with high 1,4-microstructure using lithium as the counterion in hydrocarbon solution (115,116). The key discovery was reported in 1956 by scientists at the Firestone Tire and Rubber Co., that polyisoprene produced by lithium metal-initiated anionic polymerization had a high (>90%) *cis*-1,4 microstructure analagous to

natural rubber (26). In general, conjugated 1,3-dienes [CH_2=C(R)–CH=CH_2] can polymerize to form four isomeric microstructures as shown below:



cis-1,4 *trans*-1,4 1,2 3,4

R = H (butadiene; 1,2 = 3,4); R = CH_3 (isoprene)

The stereochemistry of the anionic polymerization of isoprene and butadiene depends on the counterion, monomer concentration, chain-end concentration, solvent, temperature, and the presence of Lewis base additives (see BUTADIENE POLYMERS; ISOPRENE POLYMERS). The effect of counterion on polybutadiene stereochemistry is illustrated by the data in Table 4, which shows that lithium is unique among alkali metal counterions in producing polybutadiene with high 1,4 microstructure. Similar results have been reported for the stereochemistry of the anionic polymerization of isoprene (see Table 5) except that the stereochemistry with lithium as the counterion in neat isoprene is 94% *cis*-1,4 and 6% 3,4 compared with 35% *cis*-1,4, 52% *trans*-1,4, and 13% 1,2 for analogous polymerization of butadiene. From the data in Table 6, it is possible to delineate the effects of monomer concentration, chain-end concentration, monomer concentration, and solvent. The highest *cis*-1,4 microstructures are obtained in the absence of solvent, ie, with neat monomer, at low concentrations of initiator ($\approx 10^{-6}$ *M*). High *cis*-1,4 enchainment is also favored by the use of aliphatic versus aromatic solvents at low concentrations of initiator; however, the total amount of 1,4 microstructure (cis + trans) is relatively insensitive to solvent and chain-end concentration. In general, temperature is not an important variable for polydienes prepared in hydrocarbon solution, with lithium as the counterion; however, relatively large effects of pressure have been reported.

A comprehensive hypothesis has been proposed to explain the effects of the concentrations of active chain ends and monomer on polydiene microstructure

(123). Based on studies with model compounds and the known dependence of polydiene microstructure on diene monomer (D) and chain-end concentrations as shown in Table 6, the mechanistic hypothesis shown below was advanced.

$$\sim\sim\text{cis}^* + \text{D} \xrightarrow{k_p^{cis}} \sim\sim\text{cis,cis}^*$$

$$k_1 \rightleftharpoons k_{-1}$$

$$\sim\sim\text{trans}^* + \text{D} \xrightarrow{k_p^{trans}} \sim\sim\text{trans,cis}^*$$

It was proposed that isomerization of the initially formed cis form of the active chain end occurs competitively with monomer addition at each step of the reaction (123,124). Thus, when the concentration of monomer is high relative to the chain-end concentration, the first-order isomerization of the cis form does not compete effectively with monomer addition. However, at low concentrations of monomer relative to chain ends, the isomerization does compete and significant amounts of the trans form will be in equilibrium with the cis form.

The kinetic order dependence on the active chain-end concentration is approximately 0.25 for diene propagation, while the kinetic order dependence on the active chain end concentration is approximately one for cis–trans isomerization of the chains ends (53,116). Thus, while the unassociated chain ends add monomer, isomerization of the chain ends occurs in the aggregated state. Since aggregation is favored by increasing chain-end concentrations, high 1,2 microstructure is observed (47% for butadiene) for high chain-end concentrations ([PBDLi] = $\approx 0.1\,M$) and high *cis*-1,4 microstructure (86% for butadiene) is obtained at low chain-end concentrations ($\approx 10^{-6}\,M$).

The microstructure of anionic polymerization of other poly(1,3-diene)s with lithium as counterion in hydrocarbon media is also predominantly 1,4 (115). However, higher amounts of *cis*-1,4 microstructures are obtained with more sterically hindered diene monomers. Thus, using conditions which provide polyisoprene with 70% *cis*-1,4, 22% *trans*-1,4, and 7% 3,4 microstructure, 2-*i*-propyl-1,3-butadiene and 2-*n*-propyl-1,3-butadiene provide 86% and 91% *cis*-1,4 enchainment, respectively. Both 2-phenyl-1,3-butadiene (92% *cis*-1,4) and 2-(triethylsilyl)-1,3-butadiene (100% *cis*-1,4) also exhibit high *cis*-1,4 enchainment.

Polydienes Polar Solvents. In polar media, the unique, high 1,4 stereospecificity, with lithium as counterion, that is observed in hydrocarbon media is lost and large amounts of 1,2-poly(butadiene) and 3,4-poly(isoprene) enchainments are obtained (see Tables 7 and 8). Tables 7 and 8 show that there is a tendency toward higher 1,4 content with increasing size of the counterion in polar media. The highest 1,2 content in polybutadiene and the highest amounts of 1,2 and 3,4 enchainments in polyisoprene are obtained with lithium and sodium. The highest 1,4 enchainments are observed for cesium as counterion in polar media. Higher 1,4 contents are also obtained in less polar solvents such as dioxane.

There are several important structural differences for polydienyl anions in polar media versus hydrocarbon solvents: (*1*) chain ends are generally not associated into higher aggregates in polar media compared to hydrocarbon; (*2*) the charge distribution of unsymmetrical allylic anions is a function of solvent, counterion, and temperature; (*3*) the kinetic and equilibrium distribution of chain-end configurations can vary with solvent and counterion; (*4*) the distribution of contact ion pairs, solvent-separated ion pairs, and free ions can vary with solvent, counterion, and temperature.

Using the relationship that the chemical shift per electron corresponds to 114 ppm/electron, the calculated charge distributions for neopentylallyl-alkali metal **I** and neopentylmethylallyl-alkali metal **II** compounds have been calculated and the results are shown in Table 9 (131).

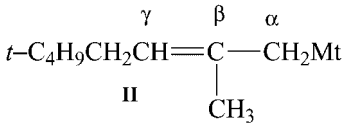
I



II

Compounds **I** and **II** can be regarded as models for butadienyl and isoprenyl carbanionic chain ends, respectively. The data in Table 9 show that while the negative charge is more localized on the alpha (α) carbon in hydrocarbon solution for the lithium derivatives, in polar media there is less charge on the alpha (α) carbon

Table 9. Calculated Charges on Allyl Carbon Atoms of Neopentylallyl- and Neopentylmethylallyl-alkali Metal Compound[a]

Counterion	Solvent	Calculated charges on allylic carbon atoms			∑(total)
		α	β	γ

[a]Ref. 131.

and more charge on the gamma (γ) carbon in all allyl organoalkali compounds. The presence of more negative charge on the gamma (γ) carbon provides a partial explanation for the formation of predominantly side-chain vinyl microstructure in polar media; however, lithium with the least charge on the gamma carbon gives the highest 1,2 enchainment and cesium with high charge on the gamma carbon gives the highest 1,4 enchainment. It has been suggested that a highly solvated lithium cation in ether solvents, which is situated closer to the alpha carbon in the allylic anion, may block reaction with monomer at this position and lead to preferential attack at the less hindered gamma position to form 1,2-butadiene units (132).

Sterically hindered, 2-alkyl-substituted dienes form high 1,4 microstructure in polar media as well as in hydrocarbon media (115). Butyllithium-initiated polymerization of 2-isopropyl-1,3-butadiene in diethyl ether produces a polymer with 81% *cis*-1,4 and 19% *trans*-1,4 microstructure. Similarly, >90% 1,4 microstructure is observed in THF for butyllithium-initiated polymerization of 2-triethylsilyl-1,3-butadiene, 2-trimethoxysilyl-1,3-butadiene, 1-phenyl-1,3-butadiene,1-pyridyl-1,3-butadiene, and 2-phenyl-1,3-butadiene.

Polar Modifier Effects. Small amounts of Lewis base additives in hydrocarbon media can exert dramatic effects on polydiene microstructure as shown by the data in Table 10. Lewis bases which interact most strongly with lithium produce the highest amount of 1,2 microstructure. For example, there is a correlation between the enthalpies of interaction of Lewis bases with polymeric organolithium compounds and the ability of these bases to promote 1,2 enchainment (136). The highest vinyl contents for polybutadiene are obtained with the most strongly coordinating ligands such as the bidentate bases, TMEDA and DIPIP (bispiperidinoethane). To obtain significant amounts of vinyl microstructure with

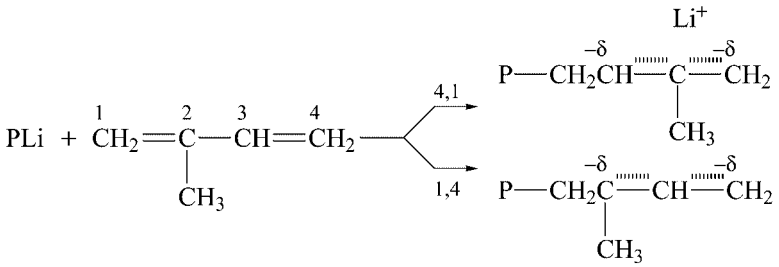
weak donor-type bases such as diethyl ether and triethylamine, they must be present in large amounts relative to lithium. In contrast, the strongly coordinating bases produce high vinyl polybutadiene microstructure at low base to lithium atom ratios (R = [Base]/[Li] = 1–2).

An interesting effect of Lewis bases on diene microstructure is the fact that in the presence of strongly coordinating bases such as TMEDA, 1,2 units are observed for polyisoprene. For example, the microstructure of polyisoprene formed in the presence of TMEDA ([TMEDA]/[Li] = 1) in cyclohexane corresponds to 21% 1,4, 12% 1,2, and 67% 3,4 (137). The formation of 1,2 units requires the formation of the less stable 1,4 chain ends versus 4,1 chain ends as shown in equation 52:

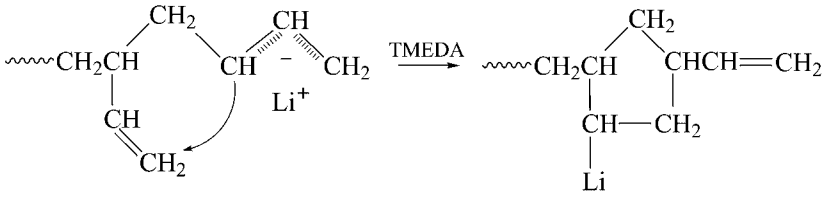


(52)

With lithium as counterion in neat monomer or in hydrocarbon solvent, no 1,2 enchainment is detected (see Tables 5 and 6).

Another interesting and surprising phenomenon observed in alkyllithium-initiated polymerization of butadiene in the presence of TMEDA is that cyclization to form in-chain vinylcyclopentane units (up to 60%) is observed

when the butadiene monomer is introduced into the reactor at low rates (eq. 53) (138).



(53)

Under such conditions, propagation does not effectively compete with cyclization; similar results are obtained with bispiperidinoethane. With respect to the mechanistic requirements for this type of cyclization, it was reported that batch polymerization in THF/TMEDA (92/2, v/v) at 0°C showed no evidence of these cyclic units although the vinyl content was almost 90%. This reaction forms a relatively unstable 2° alkyllithium from a resonance-stabilized allylic lithium, which would appear to be energetically unfavorable. However, it should be noted that this process also converts a π bond into a more stable σ bond as in any vinyl polymerization. The generality of this cyclization process in monomer-starved systems was demonstrated by showing that significant amounts of cyclization are observed using sodium as counterion in the presence of TMEDA and also with lithium complexed only with THF.

The ability to prepare polydienes with variable microstructures is an important aspect of alkyllithium-initiated anionic polymerization. The main consequence of the change in microstructure is that the glass-transition temperatures of the corresponding polymers are higher for polymers with more side-chain vinyl microstructure. For example, the glass-transition temperature of polybutadiene is an almost linear function of the % 1,2 configuration in the chain as shown in Figure 3 (139). Thus, while *cis*-1,4-polybutadiene has a glass-transition temperature of −113°C, 1,2-polybutadiene has a glass-transition temperature of −5°C (140). This has practical consequences because polybutadienes with medium vinyl contents (eg, 50%) have glass-transition temperatures ($\approx$ −60°C) and properties which are analogous to styrene–butadiene rubber. Analogously, the glass-transition temperature of *cis*-1,4-polyisoprene is approx −71°C, a polyisoprene with 49% 3,4 enchainment exhibited a T_g of −36°C (141).

Methacrylate Stereochemistry. Like the anionic polymerization of dienes, the anionic polymerization of alkyl methacrylates, especially MMA, is dependent on the counterion, solvent, and to a certain extent temperature (116,142,143). In general, the stereochemistry of the anionic polymerization of alkyl methacrylates in toluene solution with lithium as the counterion is highly isotactic (68–99%) and the isotacticity increases with the steric requirements of the alkyl ester group as shown in Table 11. Isospecificity for polymerizations in toluene is also observed for alkyl sodium initiators (67% mm), but not for potassium or cesium alkyls in toluene. Sterically hindered Grignard reagents, in particular *t*-butylmagnesium bromide or isobutylmagnesium bromide prepared in ether, provide controlled, living polymerizations and highly isotactic polymers (86.7 and 92.5% mm, respectively), provided that excess magnesium bromide is present to shift the Schlenk

equilibrium (eq. 54) in favor of RMgBr.

$$R_2Mg + MgX_2 \rightleftharpoons 2\ RMgX \tag{54}$$

In contrast, using di-*t*-butylmagnesium, prepared in ether, PMMA was obtained with predominantly syndiotactacity (79% rr). Highly isotactic PMMA is obtained for ether-free dibenzylmagnesium-initiated polymerization in toluene. Ate-type complexes of *t*-butyllithium with trialkylaluminums ([Al]/[Li] $\geq$ 2) effect living and highly syndiotactic ($\geq$90% rr) polymerization of MMA in toluene. Analogous complexes of *t*-butyllithium with (2,6-di-*t*-butyl-4-methylphenoxy)diisobutylaluminum ([Al]/[Li] $\geq$ 1) at 0°C in toluene generate PMMA with predominantly syndiotactic placements (71–75% rr). In contrast, the ate complex of *t*-butyllithium with bis(2,6-di-*t*-butylphenoxy)methylaluminum forms predominantly heterotactic PMMA (67.8% mr) and poly(ethyl methacrylate) (87.2% mr at −78°C; 91.6% mr at −95°C).

As shown in Table 12, in polar media highly syndiotactic PMMA is formed for free ions and with lithium and sodium as counterions; for sodium, syndiospecificity is observed only in more polar solvents such as dimethyoxyethane or in the presence of strongly solvating ligands such as cryptands. Lithium is the smallest alkali metal cation and the most strongly solvated; the equilibrium constants for formation of free ions and solvent-separated ion pairs are largest for lithium and

smallest for cesium. Since cesium and potassium have a tendency to form heterotactic placements, it is proposed that contact ion pairs result in predominantly heterotactic placements while solvent-separated ion pairs and free ions form predominantly syndiotactic placements in polar media. These results are general for a variety of alkyl methacrylates; even diphenylmethyl methacrylate gives 87% syndiotactic triads in THF with lithium as counterion at −78°C. However, the exception is trityl methacrylate which forms 94% isotactic triads under the same conditions and also in toluene.

A variety of stereoregulating mechanisms have been invoked to explain the stereochemistry of anionic polymerization of alkyl methacrylates (158–160). As discussed earlier (161), although syndiotactic diads are thermodynamically slightly favored over isotactic diads, the free-energy differences are so small that the formation of stereoregular chains must be kinetically controlled. The kinetic control arises from the differences in free energies of activation ($\Delta\Delta G^{\neq} = \Delta G_{iso}{}^{\neq} - \Delta G_{syndio}{}^{\neq}$) with respect to addition of a monomer unit to form an isotactic versus a syndiotactic diad. Relatively small activation energy differences can lead to large differences in the stereochemistry of propagation. Thus, a change in free energy of activation difference of only 5.4 kJ/mol (1.3 kcal/mol) can change the stereochemistry from 50/50 = iso/syndio to 90/10 = iso/syndio. Since only limited tools are available to predict or understand the physical and chemical basis of such factors as solvation, particularly those associated with small energy differences of

this order of magnitude, it is prudent to limit phenomenological interpretations of these stereochemical effects. Thus, any explanation of the predominantly syndiotactic polymerization stereochemistry in THF with lithium as the counterion (84% rr at −85°C) is tempered by the fact that the stereochemistry for the free-radical polymerization of MMA is also highly syndiotactic (78.5% at −55°C) (139). Many factors such as polar monomer coordination and interaction of the counterion with the chain end and with the penultimate groups have been invoked to explain the formation of isotactic polymers in non-polar media. The coordination of the penultimate ester group with the lithium ester enolate group at the chain end would dictate a meso placement. This simple picture, however, does not take into account the fact that these lithium ester enolates are highly associated in hydrocarbon solution and in polar media such as THF (87).

The control of PMMA stereochemistry is important because the glass-transition temperature of PMMA strongly depends on the microstructure (143). The measured T_g for 99% mm PMMA is reported to be 50°C, and the T_g for PMMA with 96–98% rr triads is 135°C. To obtain a PMMA with higher upper use temperature, polymers with the highest syndiotactic microstructure are required.

Styrene Stereochemistry. The effect of counterion, solvent, and temperature on the stereochemistry of anionic polymerization of polystyrene is shown in Table 13. The principal conclusion is that the stereoregularity of polystyrenes

prepared by anionic polymerization is predominantly syndiotactic and that the stereoregularity is surprisingly independent of the nature of the cation, the solvent and the temperature, in contrast to the sensitivity of diene stereochemistry to these variables.

When small amounts of water were deliberately added to butyllithium in hydrocarbon solution, it was possible to prepare polystyrene with as much as 85% polymer that was insoluble in refluxing methyl ethyl ketone and identified as isotactic polystyrene by x-ray crystallography (164). Isotactic polystyrene (10–22% crystalline) can be prepared when lithium *t*-butoxide is added to *n*-C_4H_9Li initiator and the polymerization in hexane (styrene/hexane = 1) is effected at −30°C (165). This polymerization becomes heterogeneous and is quite slow (after 2–5 days, 50% monomer conversion; 20–30% conversion to isotactic polymer).

Vinylpyridines. The stereochemistry of anionic polymerization of 2-vinylpyridine is predominantly isotactic for most polymerization conditions as shown by the data in Table 14 (166). The coordination of the penultimate pyridyl nitrogen with the magnesium ester enolate at the chain end has been invoked to

explain the high meso triad content for initiation by Grignard-type reagents in hydrocarbon solution. The absence of this interaction for 4-vinylpyridine results in almost atactic polymer stereochemistry.

Copolymerization

Relatively few comonomer pairs undergo anionic copolymerization to incorporate significant amounts of both monomers into the polymer chains (167). In general, the comonomer that is most reactive (lowest pK_a value for the conjugate acid of the propagating anion; see Table 1) will be incorporated to the practical exclusion of the other comonomer. Comonomer pairs that can be effectively copolymerized include styrenes with dienes and methacrylates with acrylates, ie, comonomer pairs with similar reactivity.

Anionic copolymerizations have been investigated by applying the classical Mayo–Lewis treatment that was originally developed for free-radical chain reaction polymerization (168). The copolymerization of two monomers (M_1 and M_2) can be uniquely defined by the following four elementary kinetic steps, assuming that the reactivity of the chain end (M_1^- or M_2^-) depends only on the last unit added to the chain end; ie, there are no penultimate effects.

$$\sim\sim M_1^- + M_1 \xrightarrow{k_{11}} \sim\sim M_1 — M_1^- \tag{55}$$

$$\sim\sim M_1^- + M_2 \xrightarrow{k_{12}} \sim\sim M_1 — M_2^- \tag{56}$$

$$\sim\sim M_2^- + M_2 \xrightarrow{k_{22}} \sim\sim M_2 — M_2^- \tag{57}$$

$$\sim\sim M_2^- + M_1 \xrightarrow{k_{21}} \sim\sim M_2 — M_1^- \tag{58}$$

From these four basic kinetic equations, the Mayo–Lewis instantaneous copolymerization equation can be derived as shown below:

$$\frac{d[M_1]}{d[M_2]} = \frac{[M_1](r_1[M_1]+[M_2])}{[M_2](r_2[M_2]+[M_1])} \tag{59}$$

where $r_1 = k_{11}/k_{12}$ and $r_2 = k_{22}/k_{21}$ and $d[M_1]/d[M_2]$ represents the instantaneous copolymer composition. The monomer reactivity ratios r_1 and r_2 represent the relative reactivity of each growing chain end for addition of the same monomer compared to crossover to the other monomer. Representative monomer reactivity ratios for anionic copolymerizations are listed in Table 15. The applicability of standard copolymerization theory to anionic polymerization has been considered in detail. Equations 55–58 represent an oversimplification since the chain ends are aggregated in hydrocarbon solution and there is a spectrum of ion pairs and free ions in polar media.

In most copolymerizations, $r_1 \neq r_2$ and one monomer is preferentially incorporated into the initially growing polymer. This leads to a depletion of the

		THF	30	0.13	∼0	

preferentially incorporated monomer in the feed and the composition of the copolymer formed changes with conversion. For systems undergoing continuous initiation, propagation, and termination, the resulting compositional heterogeneity is intermolecular; ie, the copolymer formed initially is different from the copolymer formed at the end of the reaction. However, in living anionic copolymerization, all of the compositional heterogeneity arising from the disparity in monomer reactivity ratios is incorporated into each growing polymer chain.

Tapered Block Copolymers. The alkyllithium-initiated copolymerizations of styrene with dienes, especially isoprene and butadiene, have been extensively investigated and illustrate the important aspects of anionic copolymerization. As shown in Table 15, monomer reactivity ratios for dienes copolymerizing with styrene in hydrocarbon solution range from approximately 8 to 17, while the corresponding monomer reactivity ratios for styrene vary from 0.04 to 0.25. Thus, butadiene and isoprene are preferentially incorporated into the copolymer initially. This type of copolymer composition is described as either a *tapered block copolymer* or a *graded block copolymer*. The monomer sequence distribution can be described by the structures below:

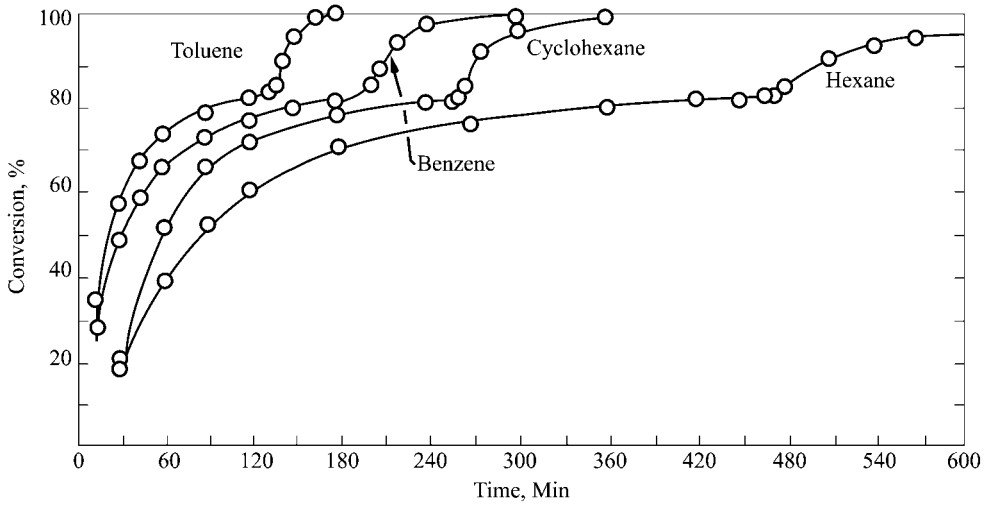

Fig. 4. Copolymerization of butadiene and styrene in different solvents at 50°C. Parts of butadiene/styrene/solvent/*n*-butyllithium = 75/25/1000/0.13 (2.0 mmol). From Ref. 50; reprinted by permission of the Rubber Division of the American Chemical Society.

First there is a diene-rich block; a middle block follows, which is initially richer in butadiene with a gradual change in composition until eventually it becomes richer in styrene; a final block of styrene completes the structure. For a typical copolymerization of styrene and butadiene (25/75, wt/wt), the solution is initially almost colorless, corresponding to the dienyllithium chain ends and the rate of polymerization is slower than the hompolymerization rate of styrene, as shown in Figure 4. The homopolymerization rate constants for styrene, isoprene, and butadiene are 1.6×10^{-2} $L^{1/2}/(mol^{1/2}\cdot s)$, 1.0×10^{-3} $L^{1/4}/(mol^{1/4}\cdot s)$, and 2.3×10^{-4} $L^{1/4}/(mol^{1/4}\cdot s)$, respectively (49). After approximately 70–80% conversion, the solution changes to orange-yellow, which is characteristic of styryllithium chain ends. At the same time, the overall rate of polymerization increases (inflection point). Although the percent conversion at which the inflection point is observed does not appear to depend on solvent, the time to reach this percent conversion is quite solvent-dependent, as shown in Figure 4. Analysis of the copolymer composition indicates that the total % styrene in the copolymer is less than 5% up to approximately 75% conversion (see Fig. 5) (50). When these samples are analyzed by oxidative degradation by ozonolysis, polystyrene segments (corresponding to polystyrene blocks in the copolymer) are recovered only after the inflection point is reached as shown in Figure 5. For a 75/25 (wt/wt) feed mixture of butadiene/styrene, 80% of the styrene is incorporated into the tapered block copolymer as block styrene.

The kinetics of copolymerization provide an explanation for the copolymerization behavior of styrenes with dienes. One useful aspect of living anionic copolymerizations is that stable carbanionic chain ends can be generated and the rates of their crossover reactions with other monomers measured independently of the copolymerization reaction. Two of the four rate constants involved in copolymerization correspond at least superficially to the two homopolymerization reactions

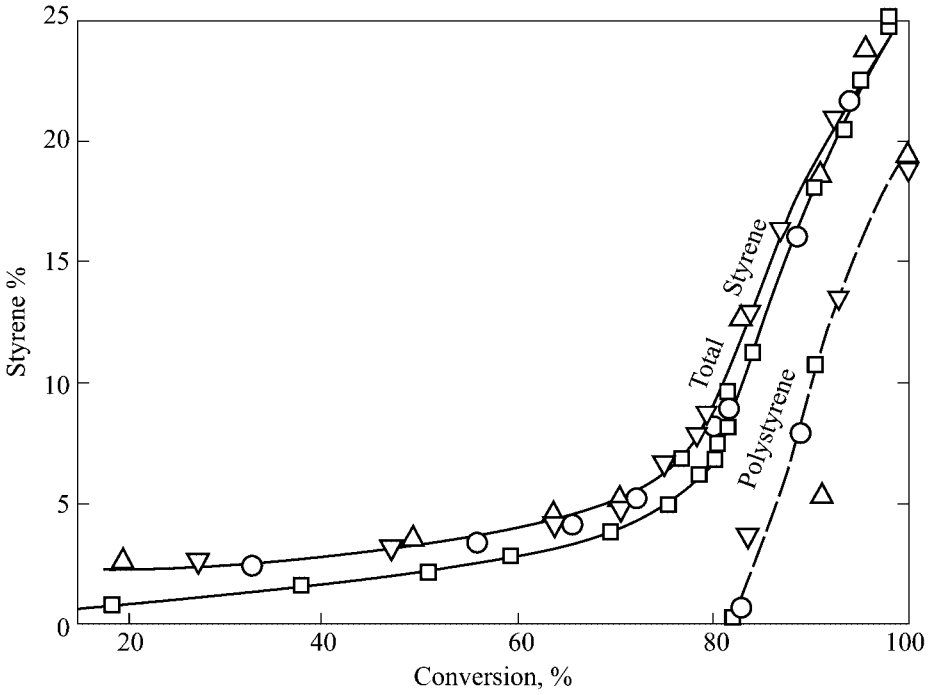

Fig. 5. Copolymerization of styrene from butadiene–styrene (75/25) at 50°C. □ Hexane; Δ cyclohexane; ∇ benzene; ○ toluene. From Ref. 50; reprinted by permission of the Rubber Division of the American Chemical Society.

of butadiene and styrene, eg, k_{BB} and k_{SS}, respectively. The other two rate constants can be measured independently as shown in equations 60 and 61:

$$\text{PSLi} + \text{Butadiene} \xrightarrow{k_{SB}} \text{PS—BDLi} \tag{60}$$

$$\text{PBDLi} + \text{Styrene} \xrightarrow{k_{BS}} \text{PBD—SLi} \tag{61}$$

Kinetic results of a number of independent kinetic studies can be summarized as follows for styrene–butadiene copolymerization (49,178):

$$\underset{[1.1 \times 10^{2}\text{L/(mol·s)}]}{k_{SB}} \gg \underset{[4.5 \times 10^{-1}\text{L/(mol·s)}]}{k_{SS}} > \underset{[8.4 \times 10^{-2}\text{L/(mol·s)}]}{k_{BB}} > \underset{[6.6 \times 10^{-3}\text{L/(mol·s)}]}{k_{BS}}$$

This kinetic order contains the expected order of homopolymerization rates, ie, $k_{SS} > k_{BB}$. The surprising result is that the fastest rate constant is associated with the crossover reaction of the poly(styryl)lithium chain ends with butadiene monomer (k_{SB}); conversely, the slowest reaction rate is associated with the crossover reaction of the poly(butadienyl)lithium chain ends with styrene monomer (k_{BS}). Similar kinetic results have been obtained for styrene–isoprene copolymerization.

In polar media, the preference for diene incorporation is reduced as shown by the monomer reactivity ratios in Table 15. In THF, the order of monomer reactivity ratios is reversed compared to that in hydrocarbon media. The monomer reactivity ratios for styrene are much larger than the monomer reactivity ratio for dienes.

The counterion also has a dramatic effect on copolymerization behavior for styrene and dienes (38). It is particularly noteworthy that the monomer reactivity ratios for styrene ($r_S = 0.42$) and butadiene ($r_B = 0.30$) are almost equal for copolymerization in hydrocarbon at 30°C using an organosodium initiator; however, butadiene is incorporated predominantly as vinyl units (60% 1,2). In contrast, initial styrene incorporation is observed for analogous organopotassium initiators ($r_S = 3.3$) and butadiene ($r_B = 0.12$).

Tapered butadiene–styrene copolymers are important commercial materials because of their outstanding extrusion characteristics, low water absorption, good abrasion resistance, and good electrical properties. Tapered block copolymers are used for wire insulation and shoe soles (after vulcanization) as well as for asphalt modification (179).

Random Styrene–Diene Copolymers. Random copolymers of butadiene (SBR) or isoprene (SIR) with styrene can be prepared by addition of small amounts of ethers, amines, or alkali metal alkoxides with alkyllithium initiators. Random copolymers are characterized as having only small amounts of block styrene content. The amount of block styrene can be determined by ozonolysis or, more simply, by integration of the ^{1}H nmr region corresponding to block polystyrene segments (δ = 6.5–6.94 ppm) (180). Monomers reactivity ratios of $r_B = 0.86$ and $r_S = 0.91$ have been reported for copolymerization of butadiene and styrene in the presence of 1 equiv of TMEDA ([TMEDA]/[RLi] = 1) (181). However, the random SBR produced in the presence of TMEDA will incorporate the butadiene predominantly as 1,2 units. At 66°C, 50% 1,2-butadiene microstructure will be obtained for copolymerization in the presence of 1equiv of TMEDA (134). In the presence of Lewis bases, the amounts of 1,2-polybutadiene enchainment decreases with increasing temperature.

In general, random SBR with a low amount of block styrene and low amounts of 1,2-butadiene enchainment (<20%) can be prepared in the presence of small amounts of added potassium or sodium metal alkoxides. Using 0.2 equiv of sodium 2,3-dimethyl-2-pentoxide, the monomer reactivity ratios for alkyllithium-initiated SBR were found to be $r_B = 1.1$ and $r_S = 0.1$ (182). The resulting copolymer had only 5% block styrene and 18% 1,2-vinyl microstructure. The unique copolymerization behavior in these mixed alkali metal alkoxide/organolithium systems may be due to the formation of cross-associated adducts.

Commercial anionically prepared, random SBR polymers (solution SBR) prepared by alkyllithium-initiated polymerization typically have 23% *cis*-1,4, 49% *trans*-1,4, and 28% vinyl microstructure compared to 10% *cis*-1,4, 70% *trans*-1,4, and 20% vinyl microstructure for emulsion SBR with the same comonomer composition. Solution SBRs typically have branched architectures to eliminate cold flow. Compared to emulsion SBR, solution random SBRs require less accelerator and give higher compounded Mooney viscosity, lower heat buildup, increased resilience, and better retread abrasion index (179). Terpolymers of styrene, isoprene, and butadiene have been prepared using a chain of single-stirred reactors, whereby the steady-state concentration of each monomer and Lewis base

modifier at any degree of conversion can be controlled along the reactor chain (183).

ANTIFOAMING AGENTS. See VOLUME 1.

ANTIOXIDANTS

Introduction

Antioxidants are used to retard the reaction of organic materials, such as synthetic polymers, with atmospheric oxygen. Such reaction can cause degradation of the mechanical, aesthetic, and electrical properties of polymers; loss of flavor and development of rancidity in foods; and an increase in the viscosity, acidity, and formation of insolubles in lubricants. The need for antioxidants depends upon the chemical composition of the substrate and the conditions of exposure. Relatively high concentrations of antioxidants are used to stabilize polymers such as natural rubber and polyunsaturated oils. Saturated polymers have greater oxidative stability and require relatively low concentrations of stabilizers. Specialized antioxidants which have been commercialized meet the needs of the industry by extending the useful lives of the many substrates produced under anticipated conditions of exposure. In 2000, approximately 227,000 t (500 million pounds) of antioxidants were sold in polymer applications, with a value of $1.3 billion (1). On average, the growth rate of antioxidants is around 4%, roughly tracking the growth of the global polymer markets (2).

Mechanism of Uninhibited Autoxidation

The mechanism by which an organic material (RH) undergoes autoxidation involves a free-radical chain reaction is shown below (3–5):

Initiation

$$RH \rightarrow \text{Free radicals, eg, } R\cdot, ROO\cdot, RO\cdot, HO\cdot \quad (1)$$

$$ROOH \rightarrow RO\cdot + OH\cdot \quad (2)$$

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

$$2\,ROOH \rightarrow RO\cdot + ROO\cdot + H_2O \quad (3)$$

$$ROOR \rightarrow 2\,RO\cdot \quad (4)$$

Propagation

$$R\cdot + O_2 \rightarrow ROO\cdot \quad (5)$$

$$ROO\cdot + RH \rightarrow ROOH + R\cdot \quad (6)$$

Termination

$$2\,R\cdot \rightarrow R{-}R \quad (7)$$

$$ROO\cdot + R\cdot \rightarrow ROOR \quad (8)$$

$$2\,ROO\cdot \rightarrow \text{Nonradical products} \quad (9)$$

Initiation. Free-radical initiators are produced by several processes. The high temperatures and shearing stresses required for compounding, extrusion, and molding of polymeric materials can produce alkyl radicals by homolytic chain cleavage. Oxidatively sensitive substrates can react directly with oxygen, particularly at elevated temperatures, to yield radicals.

It is virtually impossible to manufacture commercial polymers that do not contain traces of hydroperoxides. The peroxide bond is relatively weak and cleaves homolytically to yield radicals (eqs. 2 and 3). Once oxidation has started, the concentration of hydroperoxides becomes appreciable. The decomposition of hydroperoxides becomes the main source of radical initiators.

The absorption of (uv) light produces radicals by cleavage of hydroperoxides and carbonyl compounds (eqs. 10–12)

$$ROOH \xrightarrow{h\nu} RO\cdot + OH\cdot \quad (10)$$

$$R{-}\overset{\overset{O}{\|}}{C}{-}R \xrightarrow{h\nu} R{-}\overset{\overset{O}{\|}}{C}\cdot + R\cdot \quad (11)$$

$$R{-}\overset{\overset{O}{\|}}{C}\cdot \rightarrow R\cdot + CO \quad (12)$$

Most polymer degradation caused by the absorption of uv light results from radical-initiated autoxidation.

Direct reaction of oxygen with most organic materials to produce radicals (eq. 13) is very slow at moderate temperatures. Hydrogen-donating antioxidants

Table 1. Dissociation Energies of Carbon–Hydrogen Bonds[a]

R—H	D_{R-H}, kJ/mol[b]	Bond type
$CH_2{=}CHCH_2{-}H$	356	Allylic
$(CH_3)_3C{-}H$	381	Tertiary
$(CH_3)_2CH{-}H$	395	Secondary

(AH), particularly those with low oxidation–reduction potentials, can react with oxygen (eq. 14), especially at elevated temperatures (6).

$$RH + O_2 \longrightarrow R\cdot + HO_2\cdot \quad (13)$$

$$AH + O_2 \longrightarrow A\cdot + HO_2\cdot \quad (14)$$

Propagation. Propagation reactions (eqs. 5 and 6) can be repeated many times before termination by conversion of an alkyl or peroxy radical to a nonradical species (7). Homolytic decomposition of hydroperoxides produced by propagation reactions increases the rate of initiation by the production of radicals.

The rate of reaction of molecular oxygen with alkyl radicals to form peroxy radicals (eq. 5) is much higher than the rate of reaction of peroxy radicals with a hydrogen atom of the substrate (eq. 6). The rate of the latter depends on the dissociation energies (Table 1) and the steric accessibility of the various carbon–hydrogen bonds; it is an important factor in determining oxidative stability (8).

Polybutadiene and polyunsaturated fats, which contain allylic hydrogen atoms, oxidize more readily than polypropylene, which contains tertiary hydrogen atoms. A linear hydrocarbon such as polyethylene, which has secondary hydrogens, is the most stable of these substrates.

Autocatalysis. The oxidation rate at the start of aging is usually low and increases with time. Radicals, produced by the homolytic decomposition of hydroperoxides and peroxides (eqs. 2–4) accumulated during the propagation and termination steps, initiate new oxidative chain reactions, thereby increasing the oxidation rate.

Metal-Catalyzed Oxidation. Trace quantities of transition metal ions catalyze the decomposition of hydroperoxides to radical species and greatly accelerate the rate of oxidation. Most effective are those metal ions that undergo one-electron transfer reactions, eg, copper, iron, cobalt, and manganese ions (9). The metal catalyst is an active hydroperoxide decomposer in both its higher and its lower oxidation states. In the overall reaction, two molecules of hydroperoxide decompose to peroxy and alkoxy radicals (eq. 5).

$$ROOH + M^n \longrightarrow ROO\cdot + M^{(n-1)+} + H^+ \quad (15)$$

$$ROOH + M^{(n-1)+} \longrightarrow RO\cdot + M^{n+} + OH^- \quad (16)$$

$$2\,ROOH \longrightarrow ROO\cdot + RO\cdot + H_2O$$

Termination. The conversion of peroxy and alkyl radicals to nonradical species terminates the propagation reactions, thus decreasing the kinetic chain length. Termination reactions (eqs. 7 and 8) are significant when the oxygen concentration is very low, as in polymers with thick cross sections where the oxidation rate is controlled by the diffusion of oxygen, or in a closed extruder. The combination of alkyl radicals (eq. 7) leads to cross-linking, which causes an undesirable increase in melt viscosity and molecular weight.

Radical Scavengers

Hydrogen-donating antioxidants (AH), such as hindered phenols and secondary aromatic amines, inhibit oxidation by competing with the organic substrate (RH) for peroxy radicals. This shortens the kinetic chain length of the propagation reactions.

$$\mathrm{ROO\cdot} + \mathrm{AH} \xrightarrow{k_{17}} \mathrm{ROOH} + \mathrm{A\cdot} \qquad (17)$$

$$\mathrm{ROO\cdot} + \mathrm{RH} \xrightarrow{k_{6}} \mathrm{ROOH} + \mathrm{R\cdot}$$

Because k_{17} is much larger than k_6, hydrogen-donating antioxidants generally can be used at low concentrations. The usual concentrations in saturated thermoplastic polymers range from 0.01 to 0.05%, based on the weight of the polymer. Higher concentrations, ie, ca 0.5–2%, are required in substrates that are highly sensitive to oxidation, such as unsaturated elastomers and acrylonitrile-butadiene-styrene (ABS).

Hindered Phenols. Even a simple monophenolic antioxidant, such as 2,6-di-*tert*-butyl-*p*-cresol [128-37-0] (**1**), has a complex chemistry in an autooxidizing substrate as seen in Figure 1 (10).

Stilbenequinones such as compound **5** absorb visible light and cause some discoloration. However, upon oxidation phenolic antioxidants impart much less color than aromatic amine antioxidants and are considered to be nondiscoloring and nonstaining.

The effect substitution on the phenolic ring has on activity has been the subject of several studies (11–13). Hindering the phenolic hydroxyl group with at least one bulky alkyl group in the ortho position appears necessary for high antioxidant activity. Nearly all commercial antioxidants are hindered in this manner. Steric hindrance decreases the ability of a phenoxyl radical to abstract a hydrogen atom from the substrate and thus produces an alkyl radical (14) capable of initiating oxidation (eq. 17).

$$\mathrm{A\cdot} + \mathrm{RH} \longrightarrow \mathrm{AH} + \mathrm{R\cdot} \qquad (18)$$

Replacing a methyl with a tertiary alkyl group in the para position usually decreases antioxidant effectiveness. The formation of antioxidants such as compound (**4**) by dimerization is precluded because all benzylic hydrogen atoms are replaced by methyl groups. A strong electron-withdrawing group on the aromatic ring, such

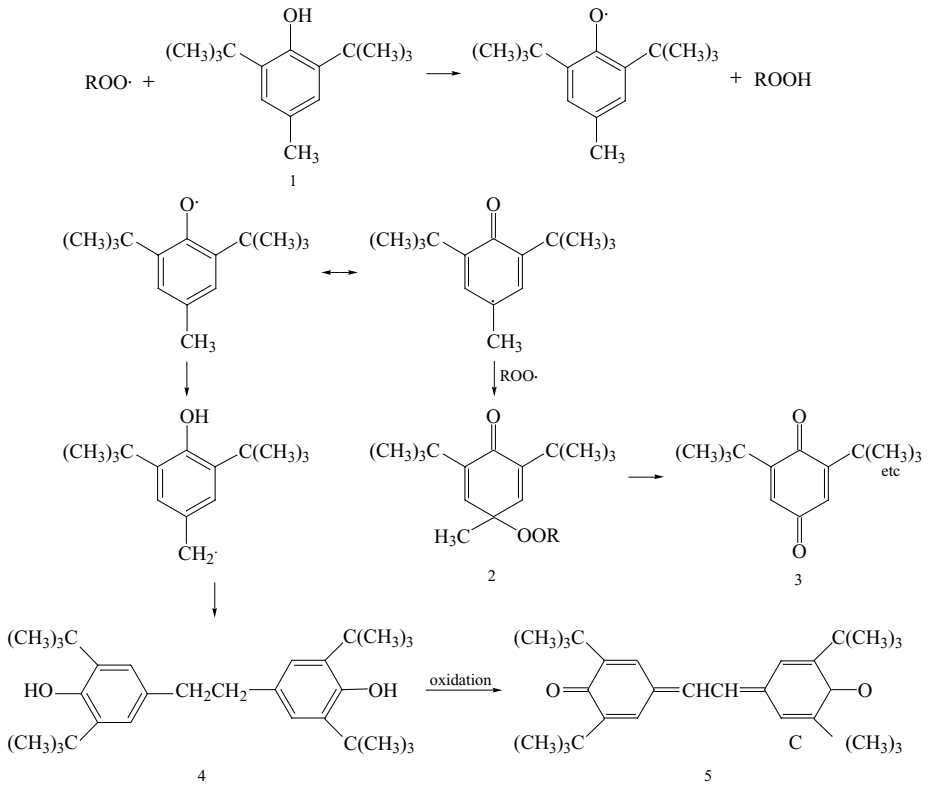

Fig. 1. Chemical transformations of 2,6-di-*tert*-butyl-*p*-cresol in an oxidizing medium (10).

as cyano or carboxy, decreases the ability of the phenol to donate its hydrogen atom to a peroxy radical of the substrate and reduces antioxidant effectiveness.

The usefulness of a hindered phenol for a specific application depends on its radical-trapping ability, its solubility in the substrate, and its volatility under test conditions. Table 2 shows the importance of volatility to stabilizer performance. Equimolar quantities of alkyl esters (**6**) of 3,5-di-*tert*-butyl-4-hydroxyhydrocinnamic acid were evaluated in polypropylene at 140°C, using two different procedures (15). When tested in an airstream, only the octadecyl ester(**6**) (where $n = 18$) was effective in stabilizing the polymer. Under these conditions, the lower homologues were lost by volatilization. The oxygen-uptake test, carried out in a closed system that minimizes evaporative loss, showed that homologues were effective to varying degrees. The differences in effectiveness can probably be attributed to differences in the solubility of various homologues in the amorphous phase of the polypropylene. When dodecane, a liquid in which all the compounds are soluble, was used as a substrate instead of polypropylene, the antioxidant activities were relatively close.

Introducing long aliphatic chains into a stabilizer molecule decreases volatility and increases solubility in hydrocarbon polymers. This improves performance; however, it also increases the equivalent weight of the active

Table 2. Influence of Antioxidant (6) Volatility on Effectiveness at 140°C

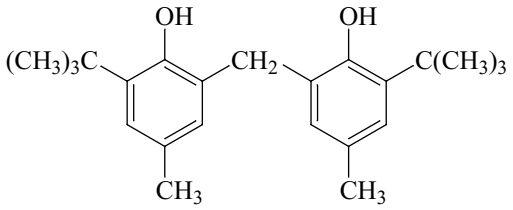
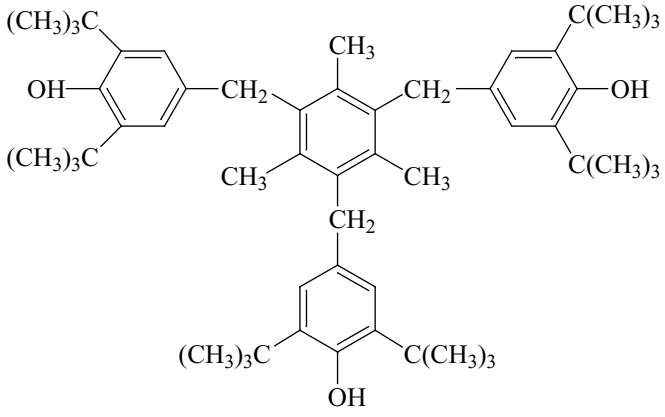
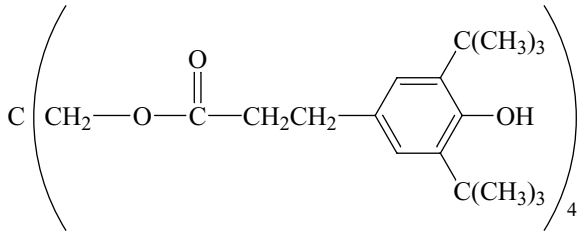
moiety. Di-, tri-, and polyphenolic antioxidants combine relatively low equivalent weights with low volatility. Commercially important di-, tri-, and polyphenolic stabilizers include 2,2′-methylenebis(6-*tert*-butyl-*p*-cresol) [85-60-9] (**7**), 1,3,5-trimethyl-2,4,6-tris(3′5′-di-*tert*-butyl-4-hydroxybenzyl)benzene [1709-70-2] (**8**), and tetrakis[methylene(3,5-di-*tert*-butyl-4-hydroxyhydrocinnamate)]methane [6683-19-8] (**9**).



(**7**)



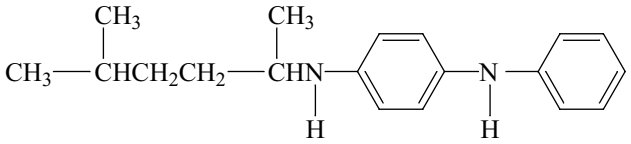
(**8**)



(**9**)

Aromatic Amines. Antioxidants derived from *p*-phenylenediamine and diphenylamine are highly effective peroxy radical scavengers. They are more effective than phenolic antioxidants for the stabilization of easily oxidized organic materials, such as unsaturated elastomers. Because of their intense staining effect, derivatives of *p*-phenylenediamine are used primarily for elastomers containing carbon black (qv).

N,*N*′-Disubstituted-*p*-phenylenediamines, such as *N*-phenyl-*N*′-(1,3-dimethylbutyl)-*p*-phenylenediamine [793-24-8] (**10**), are used in greater quantities than other classes of antioxidants. These products protect unsaturated elastomers against oxidation as well as ozone degradation (see RUBBER CHEMICALS).

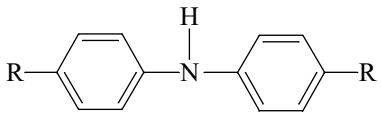


(**10**)

Low concentrations of alkylated paraphenylenediamines, such as *N*,*N*′-di-*sec*- butyl-*p*- phenylenediamine [69796-47-0], are added to gasoline to inhibit oxidation.

Figure 2 shows some of the reactions of aromatic amines that contribute to their activity as antioxidants and to their tendency to form highly colored polyconjugated systems.

Alkylated diphenylamines **11** and derivatives of both dihydroquinoline (**12**) and polymerized 2,2,4-trimethyl-1,2-dihydroquinoline [26780-96-1] (**13**) develop less color than the *p*-phenylenediamines and are classified as semistaining antioxidants. Derivatives of dihydroquinoline are used for the stabilization of animal feed and spices.



(**11**)

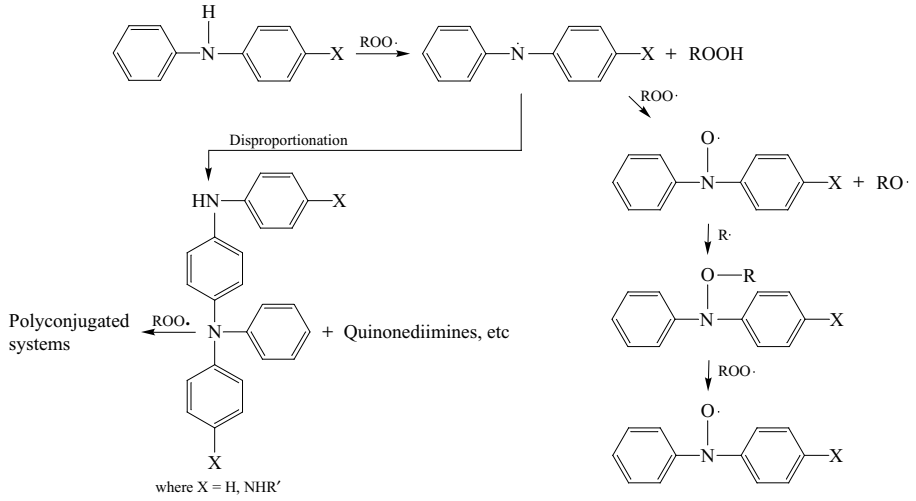


Fig. 2. Oxidation of aromatic amine antioxidants (**10**).

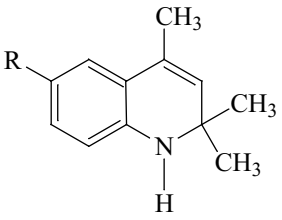
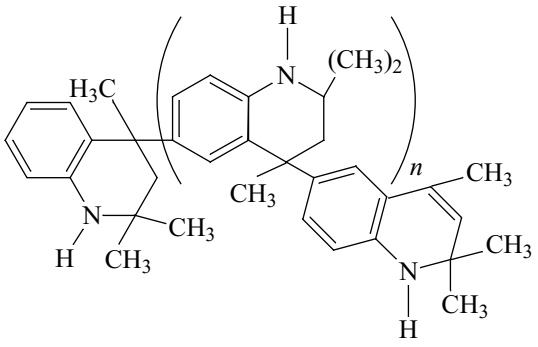
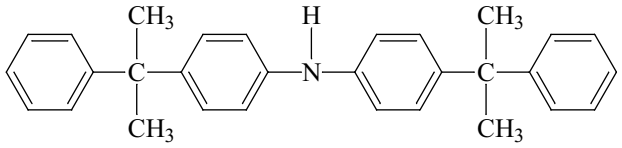


(**12**)



(**13**)

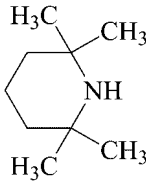
4,4′-Bis(α,α-dimethylbenzyl)diphenylamine [1008-67-1] (**14**) has only a slight tendency to stain and has been recommended for use in plastics as well as elastomers.



(**14**)

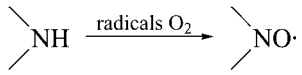
Hindered Amines. Hindered amines are extremely effective in protecting polyolefins and other polymeric materials against photodegradation. They usually are classified as light stabilizers rather than antioxidants.

Most of the commercial hindered-amine light stabilizers (HALS) are derivatives of 2,2,6,6-tetramethylpiperidine [768-66-1] (**15**) (16).

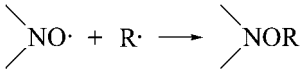


(**15**)

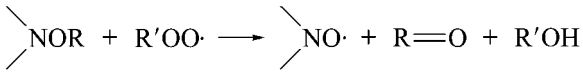
These stabilizers function as light-stable antioxidants to protect polymers. Their antioxidant activity is explained by the following sequence (17):



(19)



(20)



(21)

According to this mechanism, hindered-amine derivatives terminate propagating reactions (eqs. 5 and 6) by trapping both the alkyl and peroxy radicals. In effect, NO competes with O_2, and NOR competes with RH. Since the nitroxyl radicals are not consumed in the overall reactions, they are effective at low concentrations.

Hydroxylamines. A relatively new stabilizer chemistry, commercially introduced in 1996, (18) based on the hydroxylamine functionality, can serve as a very powerful hydrogen-atom donor and free-radical scavenger (19), as illustrated in Figure 3.

This hydroxylamine chemistry is extremely powerful on an equivalent weight basis in comparison with conventional phenolic antioxidants and phosphite melt-processing stabilizers. In terms of its free-radical scavenger capability, however, it is more effective during melt-processing of the polymer, but not during long-term thermal stability (ie, below the melting point of the polymer). This is quite interesting because of the similarity between the type of free-radical scavenging chemistry that hydroxylamines and phenols are both capable of providing. However, the temperature range is different. This is discussed further below.

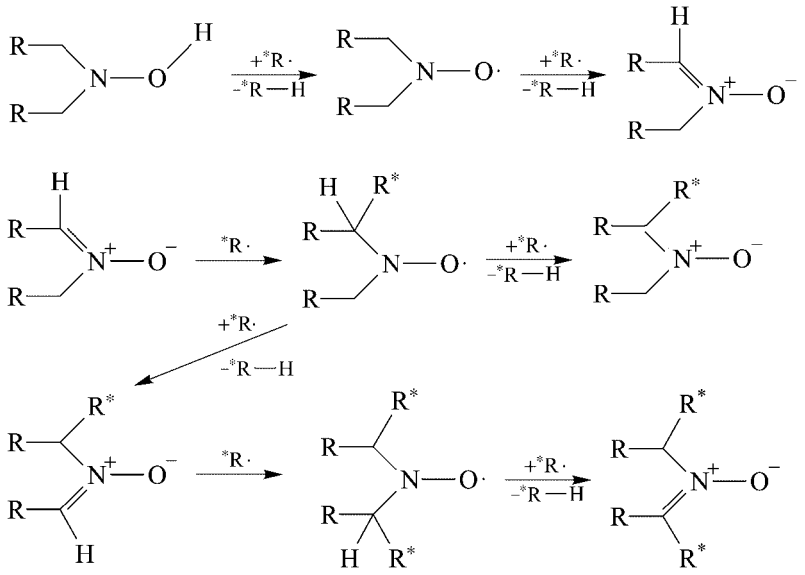


Fig. 3. Free Radical Decomposition Mechanism for Hydroxylamines. $*R^{\bullet}$= alkyl ($R^{\bullet}$), alkoxy ($RO^{\bullet}$), or peroxy ($ROO^{\bullet}$) type radicals.

The only commercial hydroxylamine product used in polyolefins and other selected polymers is a product of a process based on the oxidation of bis-tallow amine [14325-92-2].

There is a similar commercially available product based on related chemistry. It is a product of a process based on the oxidation of methyl-bis-tallow amine [204933-93-7]. The oxidation product of methyl-bis-tallow amine is a trialkylamineoxide, a precursor to hydroxylamine stabilization chemistry. The trialkylamineoxide is converted to a hydroxylamine and a long-chain olefin during the initial melt compounding of the polymer by a Cope elimination reaction, as shown below.

$$R_2(CH_3)N^+—O^- + \text{Heat} \longrightarrow R(CH_3)N—OH + R—CH{=}CH2$$

Benzofuranones. In 1997, a fundamentally new type of chemistry was introduced, which not only inhibits the autoxidation cycle, but attempts to shut it down as soon as it starts (20). The exceptional stabilizer activity of this class of benzofuranones is due to the ready formation of a stable benzofuranyl radical by donation of the weakly bonded benzylic hydrogen atom (see Fig. 4).

The resonance stabilized benzofuranyl (lactone) radicals can either reversibly dimerize or react with other free radicals. Model experiments have demonstrated that this class of chemistry behaves as a powerful hydrogen atom donor and are also effective scavengers of carbon-centered and oxygen-centered free radicals (21) (see Fig. 5).

While the sterically hindered phenols react preferentially with oxygen-centered radicals such as peroxy and alkoxy, rather than with carbon-centered radicals, benzofuranones can scavenge both types of radicals. Accordingly, a benzofuranone can be repeatedly positioned at key locations around the autoxidation

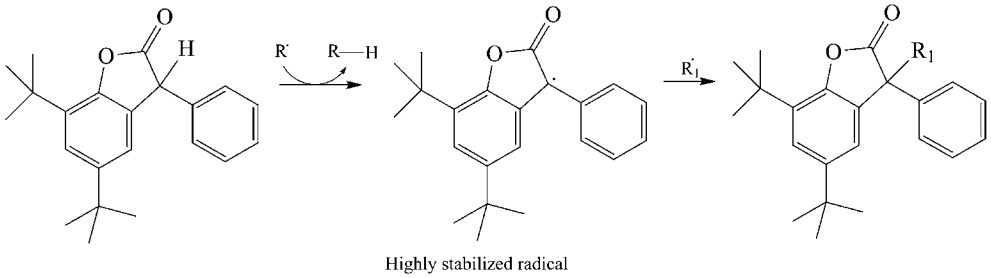

Fig. 4. Proposed Stabilization Mechanism of Arylbenzofuranones. R• = Carbon- or Oxygen-Centered Radical.

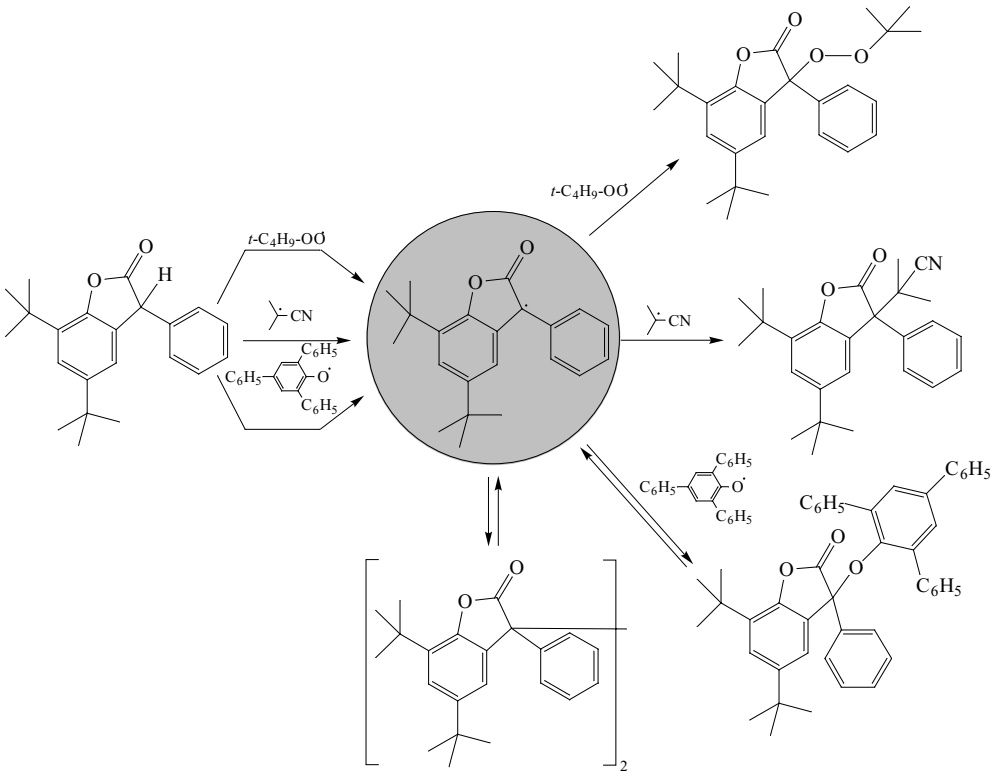

Fig. 5. Carbon-centered free-radical trapping reactions with benzofuranones.

cycle to inhibit the proliferation of free radicals. In addition, the scavenging of carbon-centered radicals is representative of a mode of stabilization that is more like "preventive maintenance," compared with more traditional stabilizers such as phenols and phosphites, which operate in something more like a "damage control" mode.

Benzofuranones are similar to hydroxylamines in that on an equivalent weight basis, they are more powerful than conventional phenolic antioxidants or phosphite-based melt-processing stabilizers. Once again it should be noted

that even though benzofuranones are capable of providing free-radical scavenging chemistry similar to phenolic antioxidants, the effective temperature domain is typically above the melting point of the polymer, eg, during melt-processing (similar to hydroxylamines). This will be discussed further below.

Peroxide Decomposers

Thermally induced homolytic decomposition of peroxides and hydroperoxides to free radicals (eqs. 2–4) increases the rate of oxidation. Decomposition to nonradical species removes hydroperoxides as potential sources of oxidation initiators. Most peroxide decomposers are derived from divalent sulfur and trivalent phosphorus.

Divalent Sulfur Derivatives. A dialkyl ester of thiodipropionic acid (**16**) is capable of decomposing at least 20 mol of hydroperoxide (22). Some of the reactions contributing to the antioxidant activity of these compounds are shown in Figure 6 (23,24).

According to Figure 6, hydroperoxides are reduced to alcohols, and the sulfide group is oxidized to protonic and Lewis acids by a series of stoichiometric reactions.

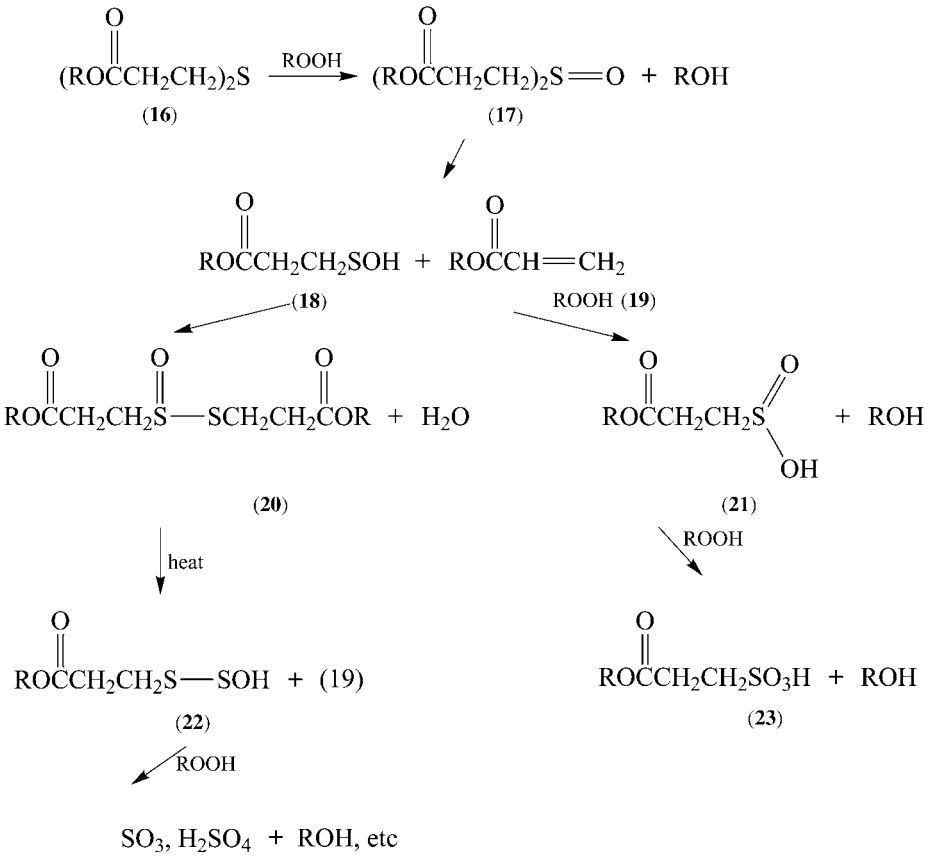

Fig. 6. Decomposition of hydroperoxides by esters of thiodipropionic acid (18).

The sulfinic acid (**21**), sulfonic acid (**23**), sulfur trioxide, and sulfuric acid are capable of catalyzing the decomposition of hydroperoxides to nonradical species.

When used alone at low temperatures, dialkyl thiodipropionates are rather weak antioxidants. Synergistic mixtures with hindered phenols, however, are highly effective at elevated temperatures and are used extensively to stabilize polyolefins, ABS, impact polystyrene, and other plastics.

Esters of thiopropionic acid tend to decompose at high processing temperatures, and their odor makes them unsuitable for some food-packaging applications.

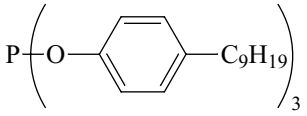
Trivalent Phosphorus Compounds. Trivalent phosphorus compounds reduce hydroperoxide to alcohols:

$$\mathrm{ROOH} + \mathrm{PR'_3} \longrightarrow \mathrm{ROH} + \mathrm{O{=}PR'_3} \qquad (22)$$

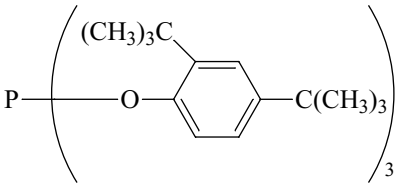
These compounds are used most frequently in combination with hindered phenols for a broad range of applications in rubber and plastics. They are also able to suppress color development caused by oxidation of the substrate and the phenolic antioxidant. Unlike phenols and secondary aromatic amines, phosphorus-based stabilizers generally do not develop colored oxidation products.

Esters of phosphorous acid derived from aliphatic alcohols and unhindered phenols, eg, tris-nonylphenylphosphite (**24**), hydrolyze readily and special care must be taken to minimize decomposition by exposure to water or high humidity. The phosphorous acid formed by hydrolysis is corrosive to processing equipment, particularly at high temperatures.

The hydrolysis of phosphites is retarded by the addition of a small amount of a base such as triethanolamine. A more effective approach is the use of hindered phenols for esterification. Relatively good resistance to hydrolysis is shown by two esters derived from hindered phenols: tris(2,4-di-*tert*-butylphenyl)phosphite [31570-04-4] (**25**) and tetrakis(2,4-di-*tert*-butylphenyl)4,4′-biphenylenediphosphonite [38613-77-3] (**26**). A substantial research effort over the last decade to develop hydrolytically stable phosphites while retaining the excellent hydroperoxide decomposing activity has resulted in the introduction of a number of new commercial products such as the dicumyl phosphite [154862-43-8].



(**24**)



(**25**)

(**26**)

Hydroxylamines. As mentioned above, hydroxylamines are very effective as free-radical scavengers. They are also noted for their ability to decompose hydroperoxides (25); this is shown in equation 21 and illustrated in Figure 7.

(23)

Hydroxylamines serve as a sequential source of hydrogen atoms, reducing hydroperoxides to their corresponding alcohol. In the course of this reaction, the hydroxylamine is converted to a nitrone.

Metal Deactivators

The ability of metal ions to catalyze oxidation can be inhibited by metal deactivators (26). These additives chelate metal ions and increase the potential difference between their oxidized and reduced states. This decreases the ability of the metal to produce radicals from hydroperoxides by oxidation and reduction (eqs. 15 and 16). Complexation of the metal by the metal deactivator also blocks its ability to associate with a hydroperoxide, a requirement for catalysis (27).

Examples of commercial metal deactivators used in polymers are oxalyl bis(benzylidene)hydrazide [6629-10-3] (**27**), *N*,*N*′-bis-(3,5-di-*tert*-butyl-4-hydroxyhydrocinnamoyl)hydrazine [32687-78-8] (**28**), 2,2′-oxamidobisethyl (3,5-di-*tert*-butyl-4-hydroxyhydrocinnamate) [70331-94-1] (**29**), *N*,*N*′-(disalicylidene)-1,2-propanediamine [94-91-7] (**30**), ethylenediaminetetraacetic acid [60-00-4] (**31**) and its salts, and critic acid (**32**) (Fig. 8).

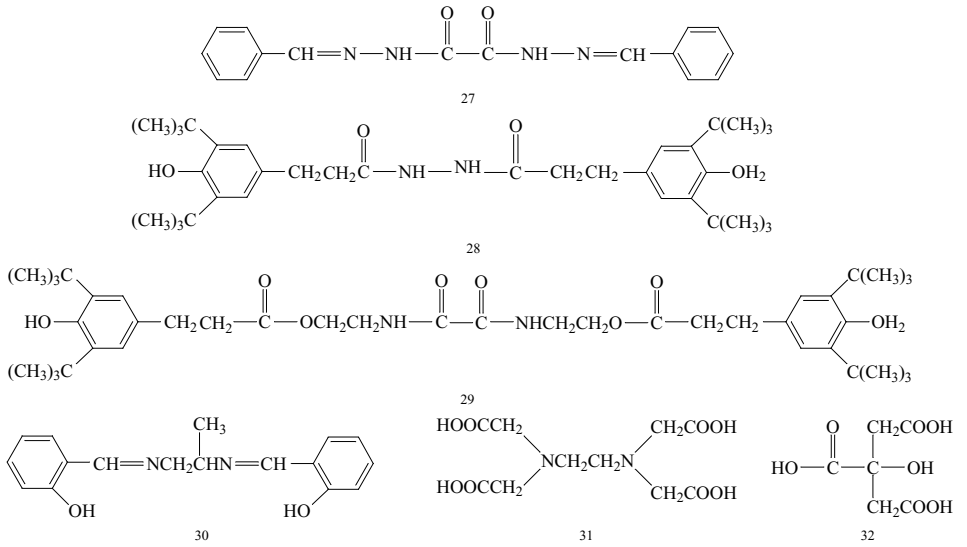

Fig. 8. Commercial metal deactivators.

Effective Temperatures for Antioxidants

As mentioned above, certain types of antioxidants provide free-radical scavenging capability, albeit over different temperature ranges. Figure 9 illustrates this in a general fashion for representative classes of antioxidants, over the temperature range of 0–300°C.

As a representative example, hindered phenols are capable of providing long-term thermal stability below the melting point of the polymer, as well as melt-processing stability above the melting point of the polymer. Most (if not all) hindered phenols are useful across the entire temperature range.

Thiosynergists, in combination with a hindered phenol, contribute to long-term thermal stability, primarily below the melting point of the polymer. In extreme cases where peroxides have built up in the polymer, thiosynergist can be shown to have a positive impact during melt processing. This, however, is not the norm, and this type of melt-processing efficacy has been left out of the figure.

Hindered amines, commonly thought of as being useful for uv stabilization, are also useful for long-term thermal stability below the melting point of the polymer. This effectiveness is due to the fact that hindered amines work by a free-radical scavenging mechanism, but they are virtually ineffective at temperatures higher than 150°C. Therefore, hindered amines, when used as a reagent for providing long-term thermal stability, should always be used in combination with an effective melt-processing stabilizer.

Phosphites, hydroxylamines, and lactones are most effective during melt-processing, either through free-radical scavenging or hydroperoxide decomposition. They are not effective as long-term thermal stabilizers. These type of stabilizers also help with long-term thermal stability. By sacrificing themselves during melt processing, they lessen the workload on the phenolic

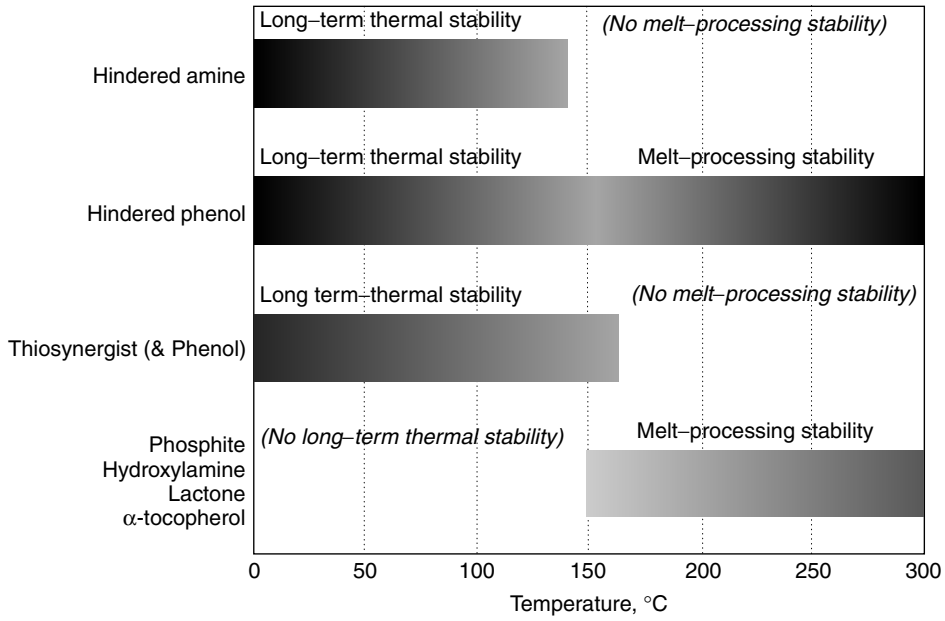

Fig. 9. General representation of effective temperature ranges for selected types of antioxidants.

antioxidant, allowing more to remain intact to help with long-term thermal stability.

One anomaly that should be pointed out is the hindered phenols based on tocopherols. Even though tocopherols, such as Vitamin E [10191-41-01], fall into the general class of hindered phenols, they behave more as melt-processing stabilizers, and less as reagents for providing long-term thermal stability, at least with regard to polymer stabilization.

Antioxidant Blends

In practical application, it is reasonable to use more than one type of antioxidant in order to meet the requirements of the application, such as melt-processing stability as well as long-term thermal stability. The most common combination of stabilizers used, particularly in polyolefins, are blends of a phenolic antioxidant and a phosphite melt-processing stabilizer. Another common combination is a blend of a phenolic antioxidant and a thioester, especially for applications that require long-term thermal stability. These common phenol-based blends have been used successfully in many different types of end-use applications. The combination of phenolic, phosphite, and lactone moieties represents an extremely efficient stabilization system since all three components provide a specific function.

For color-critical applications requiring "phenol-free" stabilization, synergistic mixtures of hindered amines (for both uv stability as well as long-term thermal

stability) with a hydroxylamine or benzofuranone (for melt processing), with or without a phosphite, can be used to avoid discoloration typically associated with the overoxidation of the phenolic antioxidant (28). The use of "phenol-free" stabilization systems is very effective in color-critical products, such as polyolefin films and fibers, as well as selected thermoplastic olefin (TPO) applications.

Synergist Mixtures of Antioxidants

A mixture of antioxidants that function by different mechanisms might be synergistic and provide a higher degree of protection than the sum of the stabilizing activities of each component. The most frequently used synergistic mixtures are combinations of radical scavengers and hydroperoxide decomposers.

Typically, blend titration experiments are performed at a set loading of additives, starting with 100% of Component A and 0% of Component B. A series of formulations are designed to shift to the other extreme with 0% Component A and 100% Component B. By measuring a series of performance parameters, the optimum ratio of A to B can be determined. This type of work is time consuming, but in the end, the optimum ratio is identified with real data. If three or more components are being assessed at the same time, statistically designed experiments are often useful in terms of sorting out the data.

Antagonistic Mixtures of Antioxidants

Mixtures of antioxidants can also work against each other. Chemistries that interfere with each other may not necessarily be obvious until the evidence is presented. For example, to ensure long-term thermal stability and good light stability, one might use a combination of a phenolic antioxidant and a divalent sulfur compound for thermal stability and a hindered amine for light stability.

Unfortunately, the oxidation products of the sulfur compound can be quite acidic and can complex the hindered amine as a salt, preventing the hindered amine from entering into its free-radical scavenging cycle. This antagonism has been generally known for quite a while (29) and has been discussed (30).

Other types of antagonistic chemistry often involve relatively strong acids or bases (either Bronstead or Lewis) that can interact with the antioxidants in such a way as to divert them into transformation chemistries that have nothing to do with polymer stabilization.

Application of Antioxidants in Polymers

Nearly all polymeric materials require the addition of antioxidants to retain physical properties and to ensure an adequate service life. The selection of an antioxidant system is dependent upon the polymer and the anticipated end use.

Polyolefins. Low concentrations of stabilizers ($<0.01\%$) are often added immediately to polyethylene and polypropylene after synthesis and prior to isolation so as to retard oxidation of the polymer before they are exposed to sources

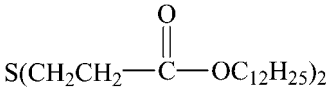
of oxygen or air (see ETHYLENE POLYMERS; PROPYLENE POLYMERS). Higher concentrations are added downstream during the conversion of the reactor product to a pelletized form. The antioxidant components and concentrations are selected by the manufacturer to yield general-purpose grades, or can be optimized to meet a specific end-use application.

In downstream applications, these polymers can be subjected to temperatures as high as 300°C, during cast film extrusion and thin-wall injection molding. In these type of demanding applications, processing stabilizers are used to decrease both the change in viscosity (molecular weight) of the polymer melt and the development of color. A phosphite, such as tris(2,4-di-*tert*-butylphenyl)phosphite (**25**) or bis(2,4-di-*tert*-butylphenyl)pentaerythritol diphosphite [26741-53-7], in combination with a phenolic antioxidant such as octadecyl 3,5-di-*tert*-butyl-4-hydroxyhydrocinnamate (**6**), may be used. Concentrations usually range from 0.01 to 0.5% depending on the polymer and the severity of the processing conditions. For long-term exposure, a persistent antioxidant such as tetrakis[methylene(3,5-di-*tert*-butyl-4-hydroxyhydrocinnamate)]methane (**9**), at a concentration of 0.1–0.5%, may be added to the base stabilization package.

A sulfur-containing synergistic mixture can be used to obtain an extended service life at a decreased cost.

The synergistic effect of a hydroperoxide decomposer, eg, dilauryl thiodipropionate [123-28-4] (**33**), and a radical scavenger, eg, compound **9**, in protecting polypropylene during an oxygen-uptake test at 140°C is shown in Table 3.



(**33**)

The sum of the individual activities of these antioxidants was 20 days, whereas a mixture of the two stabilizers protected the polymer for 45 days (31).

Oligomeric-HALS are effective thermal antioxidants for polypropylene. Thus 0.1% of *N*,*N*′-bis(2,2,6,6-tetramethyl-4-piperadinyl)-1,6-hexanediamine polymer, with 2,4,6-trichloro-1,3,5-triazine and 2,4,4-trimethyl-2-pentaneamine [70624-18-9] (**34**) (Fig. 10 & Table 4), protects polypropylene multifilaments against oxidation when exposed at 120°C in a forced-air oven for 47 days (32). The simple hindered phenol 3,5-di-*tert*-butyl-4-hydroxytoluene [128-37-0] (0.1%) affords protection for only 14 days.

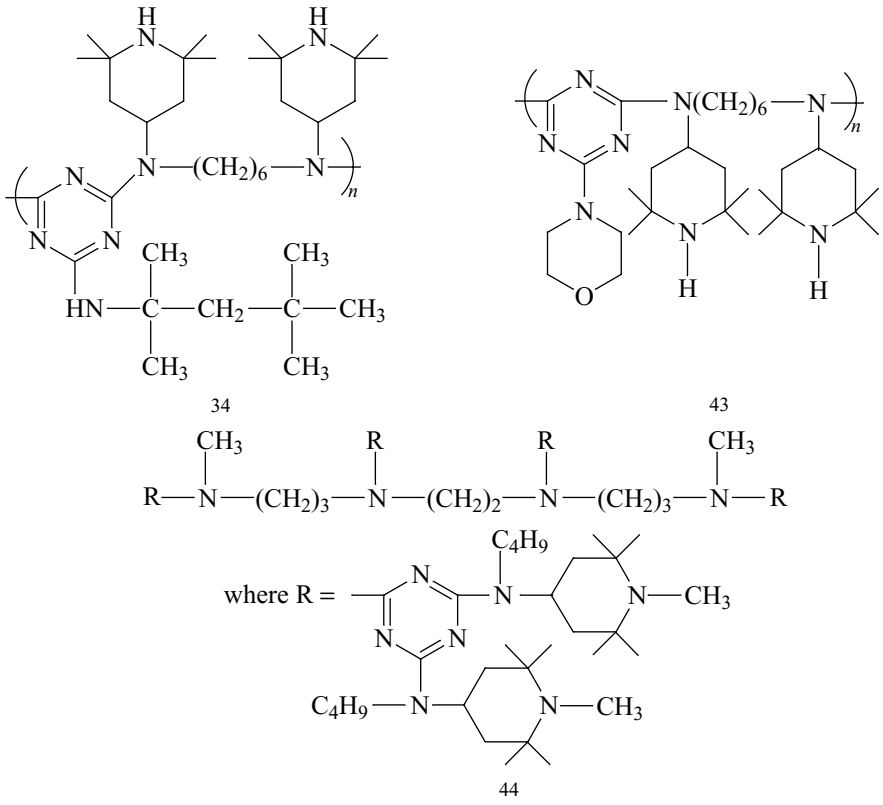


Fig. 10. Hindered 1,6-hexanediamine antioxidants.

The stabilization of polyolefins used to insulate copper conductors requires the use of a long-term antioxidant plus a copper deactivator. Both compounds **28** and **29** are bifunctional antioxidants that have built-in metal deactivators. Compound **27** is an effective copper deactivator as part of an additive package that includes an antioxidant.

Polyamides. Because of their excellent mechanical properties at high temperatures, polyamides, particularly mineral and glass-filled grades, are finding increased usage in demanding applications such as automotive (under-the-hood) applications (see POLYAMIDES, PLASTIC). Only a few publications dealing with stabilization of polyamides are found in the literature (33). The aliphatic polyamides differ in their structure, PA 6,6, PA 6, PA 4,6, PA 11, and PA 12 being the most common types. The oxidative stability of the various types is dependent on the density of the amorphous phase and the degree of crystallinity because these two factors control oxygen migration into the polymer matrix (34). Aromatic polyamides are rather insensitive to oxidative degradation.

The traditional stabilization system for aliphatic polyamides are copper salts. Typical systems are based on low levels of copper (<50 ppm) and iodide or bromide salts (35). The mechanism of stabilization is not well understood but may be due to hydroperoxide decomposition initiated by metal ions (36). These systems

[a]FDA regulated unless otherwise indicated. Regulated by the U.S. Food and Drug Administration as an indirect food additive under Title 21 of the U.S. Code of Federal Regulations (21 CFR), Part 175 (Adhesives and Coatings) and/or Part 177 (Polymers).
[b]CE: cellulosics; EVA: ethylene–vinyl acetate copolymers; PA: polyamides; PES: polyesters; PO: polyolefins; POM: polyoxymethylenes; PUR: polyurethanes, polyols; RU: rubber; PS: polystyrenes; PVC: poly(vinyl chloride).
[c]Not FDA regulated.

are effective in polyamides whereas in other polymers, such as polyolefins, small amounts of oxidized copper can often act as prodegradants. Good dispersion of the copper is critical to good performance. Since copper salts are water soluble, they can be leached from the polymer in certain applications (eg aqueous dye baths), leading to reduced efficacy and environmental issues. Aromatic amines are effective long-term stabilizers, but because of their discoloring nature, their use is limited to carbon black-filled systems. Phenolic antioxidants when added during the polycondensation reaction, contribute to improved initial color and long-term thermal stability, particularly at lower end-use temperatures. The relative merits of the various stabilization systems are shown in the following table:

Antioxidant system	Advantages	Disadvantages
Copper/halogen salts	Best performance at elevated temperatures (>150°C)	Discoloration
	Very low levels required	Leaching in aqueous environment Must be well dispersed
Aromatic amines	Good long-term thermal stabilizer performance	Discoloration
		Needs high concentration
Phenolics	Best performance at lower temperatures when copper salts cannot be used	Less effective at high temperature conditions such as under-the-hood
	Good initial and long-term color performance	

Styrenics. Unmodified styrenics such as crystal polystyrene are relatively stable, and under most end-use conditions it is not necessary to add antioxidants (see STYRENE POLYMERS). Low levels (0.1%) of a hindered phenolic antioxidant are added to protect the polymer during repeated processing of scrap. Styrene-acrylonitrile (SAN) copolymers discolor during processing above 220°C (see ACRYLONITRILE POLYMERS). While this is primarily a nonoxidative process related to the acrylonitrile comonomer, the color can be suppressed to some extent through the addition of a combination of a phenolic antioxidant and a phosphite (37). High impact polystyrene (HIPS) is more susceptible to oxidative degradation because of the presence of an unsaturated butadiene rubber phase. Antioxidants can be added either during the manufacturing process to protect the rubber phase during polymerization and monomer stripping or postpolymerization. Color and impact properties are typically better if the antioxidant is added during polymerization, but care must be taken to avoid adverse effects on the kinetics through interaction with the peroxide catalysts. This is particularly problematic if phosphites are added. Acrylonitrile–butadiene–styrene (ABS) is a graft copolymer produced primarily in an emulsion process followed by a compounding step in which the high rubber content polymer is blended with SAN in various ratios to achieve the desired end-use properties. Antioxidants are required during the coagulation and drying steps to protect the high rubber content particles. The best performance is achieved through the use of a combination of hindered phenol (0.25%) and thioester synergist (0.5%) (38). The stability of the finished ABS is directly related to the butadiene content (39).

Polyesters. Poly(ethylene terephthalate), PET, requires little to no antioxidant during thermal processing. In some cases, phosphites are added to improve the color of regrind. During polycondensation, pentavalent phosphorus compounds such as triphenylphosphate or trimethylphosphate may be added. These additives form complexes with the transesterification catalyst residues (manganese, tin, zinc), yielding a polymer with reduced hydroxyl end groups. This affords better hydrolytic stability during end use and reduced discoloration prior to the condensation reaction (40). Poly(butylene terephthalate), PBT, because of its higher hydrocarbon content, is more susceptible to oxidative degradation than PET. The combination of a phenolic antioxidant (0.05–0.10%) and a phosphite (0.1%) is typically used to stabilize PBT (see POLYESTERS, THERMOPLASTIC).

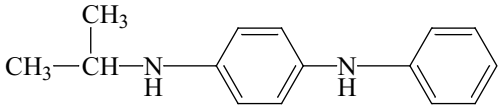
Polycarbonate. Polycarbonate, PC, is susceptible to photo-oxidation, and antioxidants are necessary to maintain the low color and high transparency critical to its end-use applications (see POLYCARBONATES). Phosphites (0.1%) are used to minimized color development during processing. It has been shown that the inherent stability of PC is related to the level of phenolic end groups (41). These levels can increase as a result of humidity-induced hydrolysis catalyzed by acid. The phosphite chosen must be very stable to avoid the generation of catalytic amounts of phosphorus acids.

Polyacetal. Polyacetals thermally decompose by an acid-catalyzed depolymerization process starting at the chain ends (see ACETAL RESINS). The polymer structure is stabilized by end capping and introducing comonomers to interrupt the unzipping. The process is autocatalytic since the liberated formaldehyde is easily oxidized to formic acid, which is a prodegradant. Formaldehyde scavengers and phenolic antioxidants are typically used in polyacetal formulations (42).

Polyurethanes. The oxidative stability of polyurethanes (PURs) is highly dependent on the chemical nature of both the polyol component and the isocyanate. Thus, PUR derived from a polyester polyol is typically more stable than one derived from a polyether polyol (see POLYURETHANES). The methylene group adjacent to the ether linkage in polyether polyols is easily oxidized to hydroperoxides during storage. If not inhibited, decomposition of these built-up hydroperoxides can occur catastrophically during the highly exothermic reaction of the polyol and the isocyanate. Blends of a hindered phenol (0.2%) and an aromatic amine (0.1%) are typically used as storage stabilizers in polyether systems providing PUR foams with excellent color. Similar systems are used in polyester polyols, but at lower use levels (43).

Elastomers. Polyunsaturated elastomers are sensitive to oxidation. Stabilizers are added to the elastomers prior to vulcanization to protect the rubber during drying and storage. Nonstaining antioxidants such as butylated hydroxytoluene (**1**), 2,4-bis(octylthiomethyl)-6-methylphenol [110553-27-0], 4,4′-bis(α,α-dimethylbenzyl)diphenylamine (**14**), or a phosphite such as tris(nonylphenyl)phosphite (**24**) may be used in concentrations ranging from 0.01 to 0.5%.

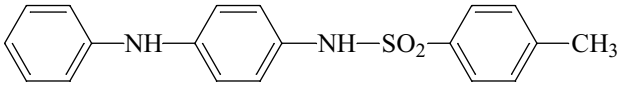
Staining antioxidants such as *N*-isopropyl-*N*′-phenyl-*p*-phenylenediamine [101-72-4] (**35**) are preferred for the manufacture of tires. These potent antioxidants also have antiozonant activity and retard stress cracking of the vulcanized rubber. Carbon black, used in tires for reinforcement, hides the color developed by the antioxidant. According to use requirements, up to 3% of an amine antioxidant having antiozonant activity is added prior to vulcanization.



(**35**)

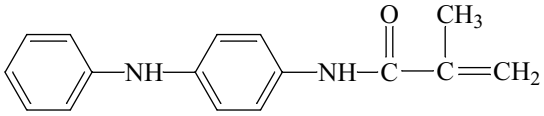
When staining tendencies of the substituted paraphenylene diamines cannot be tolerated, semistaining amine antioxidants are used to provide some protection to the elastomers. The semistaining antioxidants include polymerized compounds **13** and compound **14**. These compounds, however, provide no protection against ozone.

Antioxidants resistant to extraction by lubricants and gasoline are preferred for the stabilization of elastomers used in automotive applications such as gaskets and tubing. Aromatic amine antioxidants such as *N*-phenyl-*N*′-(*p*-toluenesulfonyl)-*p*-phenylenediamine [100-93-6] (**36**), with low solubility in hydrocarbons, are extracted slowly from elastomers and are used for these applications.



(**36**)

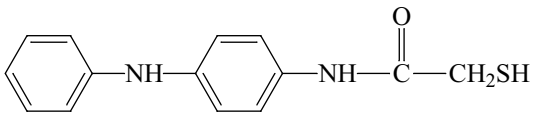
Binding the antioxidant chemically to the elastomer chain by copolymerization or grafting is a better solution to this problem. The addition of *N*-(4-anilinophenyl)methacrylamide [22325-96-8] (**37**) to a polymerization recipe for nitrile butadiene rubber (NBR) produces a polymer with a built-in antioxidant resistant to extraction (44).



(**37**)

Raw NBR containing 1.5% of the built-in antioxidant retained 92% of its original resistance to oxidation after exhaustive extraction with methanol. NBR containing a conventional aromatic amine antioxidant (octylated diphenylamine) retained only 4% of its original oxidative stability after similar extraction.

It is also possible to graft an aromatic amine antioxidant bearing a sulfhydryl group on to the backbone of an elastomer.



(**38**)

When 4-(mercaptoacetamido)diphenylamine [60766-26-9] (**38**) is added to EPDM rubber and mixed in a torque rheometer for 15 min at 150°C, 87% of it

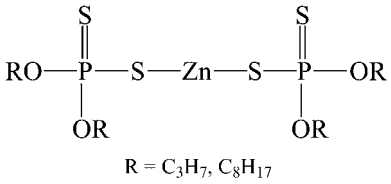
chemically binds to the elastomer (45). The mechanical and thermal stress placed on the polymer during mixing ruptures the polymer chain, producing free radicals that initiate the grafting process.

Poly(vinyl chloride). While reasonably stable with respect to oxidative degradation, PVC is very susceptible to thermal degradation. Protection of PVC from thermal degradation leading primarily to dehydrohalogenation reactions is out of the scope of this article. Some additives, used primarily as HCl scavengers, also have antioxidant properties. Aralkylphosphites, in particular, are used as components of thermal stabilizing mixtures which also exhibit antioxidant properties, leading to improved resin color.

Fuels and Lubricants. Gasoline and jet-engine fuels contain unsaturated compounds that oxidize on storage, darken, and form gums and deposits. Radical scavengers such as 2,4-dimethyl-6-*tert*-butylphenol [1879-09-0], 2,6-di-*tert*-butyl-*p*-cresol (**1**), 2,6-di-*tert*-butylphenol [128-39-2], and alkylated paraphenylene diamines are used in concentrations of about 5–10 ppm as stabilizers.

The catalytic activity of copper as an oxidant in fuels and lubricants can be inhibited by the use of a metal deactivator such as *N*,*N*′-disalicylidene-1,2-diaminopropane (**30**) at a concentration of 5–10 ppm.

Lubricants for gasoline engines are required to withstand harsh conditions. The thin films of lubricants' coating on piston walls are exposed to heat, oxygen, oxides of nitrogen, and shearing stress. Relatively high concentrations of primary antioxidants and synergists are used to stabilize lubricating oils. Up to 1% of a mixture of hindered phenols, of the type used for gasoline, and secondary aromatic amines, such as alkylated diphenylamine and alkylated phenyl-α-napththylamine, are used as the primary antioxidants. About 1% of a synergist, zinc dialkyldithiophosphonate, is added as a peroxide decomposer. Zinc dialkyldithiophosphates (**39**) are cost-effective multifunctional additives. They interrupt oxidative chains by trapping radicals by electron donation, decompose peroxides, and serve as a corrosion and wear inhibitors.



R = C_3H_7, C_8H_{17}

(**39**)

Both zinc and phosphorus deactivate the catalysts used to control emissions and governmental regulations limit their concentrations to below 0.1%.

Test Methods

Polymers. There are a variety of test methods available for monitoring the oxidative stability in the polymer as it is exposed to different types of stresses. These changes can be physical or aesthetic. Physical transformations of

the polymer might involve changes in molecular weight, molecular weight distribution, or crystallinity. Aesthetic transformations of the polymer might involve changes such as discoloration or changes in the surface appearance due to microscopic cracks which affect gloss.

These changes can be measured using simple testing equipment and procedures described in ASTM methods (eg, tensile strength, impact resistance, color development, oxidative induction time, oven aging).

Estimation of oxidative stability under conditions of use is more difficult to measure. To decrease the time required for oxidative failure, specimens are exposed at temperatures higher than those anticipated in use. Oven aging the polymer at temperatures below the melting point of the polymer is a method for assessing the long-term thermal stability of a given substrate. A range of test temperatures can be used to create an Arrhenius plot as test temperature (°C or K) vs time to failure (eg, embrittlement, or 50% retention of tensile strength or elongation). If the apparent activation energy remains constant, a plot of the logarithm of failure time against the reciprocal of the absolute temperature results in a straight line. Extrapolation to temperature of use provides an estimate of failure time.

Because of different reactions and the raw materials used, the apparent activation energy of the overall process can deviate considerably from linearity, and an extrapolation can lead to serious errors in estimating failure time (46).

Representative measures of aesthetic properties would include color development, loss of gloss, increase in haze, chalking, loss of surface smoothness, exudation and/or blooming of additives or low molecular weight polymer, and staining.

To assess the retention of physical or aesthetic properties, it is important to understand that increasing surface area-to-volume ratio increases susceptibility to oxidation as does the rate of loss of the antioxidant by volatilization (47).

In the past, oxygen-uptake measurements at elevated temperatures were used to determine oxidation resistance. Today, other types of testing, such as oxidative induction time (OIT), by differential scanning calorimetry or chemiluminescence, are used.

For oxygen-uptake experiments, the time required to absorb a specified volume of oxygen is an indication of failure when the change in the rate of oxygen absorption is not sufficient to permit an accurate measurement of the induction period. However, the amount of oxygen absorbed and the loss of desired properties must be correlated. This type of test is not reliable for estimating service life under conditions in which the polymer is exposed to air movement.

Oxidative induction time or oxidative induction temperature experiments are used to assess the relative oxidative stability of the polymer. The experiments are typically conducted under severe testing conditions, typically at elevated temperatures (significantly above the melting point of the polymer) using oxygen as the oxidant. It should be noted that this method is not useful for predicting long-term thermal stability; however, these methods can be useful for quickly assessing the relative potency of different types of stabilizer systems (48).

For chemiluminescence experiments, the procedure is similar to the aforementioned OIT experiments, in that the time to catastrophic oxidation of the

polymer is measured; in this case, below the melting point of the polymer. During this catastrophic oxidation, there are certain chemistries that take place which result in chemiluminescence. The amount of light that is given off during this process is measured by a charge-coupled device. This method, developed over the last decade, can provide useful information about the oxidative stability of the polymer in much shorter time period than conventional oven aging, but under more realistic oxidative environment in comparison with oxidative induction time (49).

Lubricants. A sequence of tests has been devised to evaluate antioxidants for use in automotive crankcase lubricants. The Indiana Stirring Oxidation Test (ISOT) JISK2514 is an example of a laboratory screening test. The oil is stirred at 165.5°C in the presence of air. Copper and iron strips are used as metal catalysts. The development of sludge, viscosity, and acidity are determined periodically. Failure time is determined when the development of acidity requires 0.4 mg KOH/g for neutralization. Formulated lubricants are then evaluated for performance in engines (see Oldsmobile Sequence III D) (50). Candidate lubricants containing the antioxidants are tested in fleets of automobiles for thousands of miles. As described above for polymers, modified oxygen uptake tests can also be used with lubricants to measure oxidative stability (51).

The effectiveness of antioxidants as preservatives for fats and oils is evaluated by determining the rate of peroxide development using the active oxygen method (52). The development of a rancid odor is used to evaluate the stability of food items (Schaal oven stability test) (53).

Ancillary Properties

In reality, there is more to antioxidants than providing stability to the polymer by quenching free radicals and decomposing hydroperoxides. Other key issues besides rates of reactivity and efficiency include performance parameters such as volatility, compatibility, color stability, physical form, taste or odor, regulatory issues associated with food contact applications, and polymer performance vs cost (54).

Volatility. Most additives are melt compounded into the polymer after the polymerization stage. The melt compounding and downstream conversion (into shaped articles) processing steps represent significant heat histories. Storage of the product can also be quite warm in certain climates. It is important that the antioxidant, as well as its transformation products that may also provide stability, does not volatilize from the polymer. Many commercial antioxidants have been designed with higher molecular weights to address this issue.

Compatibility. Antioxidants should be soluble in the polymeric matrix. If they are not soluble, they should at least migrate or diffuse slowly. If the solubility limit of the antioxidant in the polymer is exceeded, exudation will occur. Exudation or blooming involves the migration of the additive out of the polymer matrix onto the surface as a very thin film. Blooming of the antioxidant can diminish surface gloss, create stickiness, eliminate blocking (cling) of film surfaces to one another and negatively affect printability.

Color Stability. It is important that antioxidants do not provide unwanted color because of the transformation chemistries associated with preventing oxidation. Some antioxidants are prone to forming color by their very nature, while other antioxidants discolor only when they have been overoxidized. Pigments can be used to mask the subtle changes in the base color of the polymer.

Physical Form. Because of hazards associated with dusting, many antioxidants are now being offered commercially in dust-free forms, such as granules or pellets. Liquid or molten antioxidants are another interesting alternative, as long as they are compatible in the polymer matrix. Still, some polymer manufactures need the additives as fine powders in order to achieve good premixing with their reactor product before melt compounding into the traditional pellet form.

Taste and Odor. For applications that involve food contact, home or personal use, taste and odor are key issues. The human nose is very sensitive, more so than some analytical instruments, able to detect some compounds at the parts per billion (ppb) level.

Health and Safety Factors

Safety is assessed by subjecting the antioxidant to a series of animal toxicity tests, eg, oral, inhalation, eye, and skin tests. Mutagenicity tests are also carried out to determine possible or potential carcinogenicity. Granulated and liquid forms of antioxidants are receiving greater acceptance to minimize the inhalation of dust and to improve flow characteristics.

A number of antioxidants are regulated by the U.S. Food and Drug Administration (FDA) as indirect additives for polymers used in food contact applications (primarily food packaging) under Title 21 of the U.S. Code of Federal Regulations (21CFR), Part 175 (Adhesives and Coatings) and/or Part 177 (Polymers). Acceptance is determined by subchronic or chronic toxicity in more than one animal species and by the concentration expected in the diet, based on the amount of the additive extracted from the polymer by solvents that simulate food in their extractive effects. Materials are regulated by the FDA for use in plastics contacted by food stuffs to ensure a minimum risk to the consumer. Broad FDA regulation is increasingly a requirement for the successful introduction of a new antioxidant.

Cost Effectiveness

The point in using an antioxidant is to choose the appropriate type and level to adequately stabilize the polymer for a particular end-use application.

For example, if the material is a nondurable good, such as bags and food wrap, the type and concentration of antioxidant is chosen to minimize unnecessary costs associated with stabilizing the polymer. The antioxidant should be able to provide stabilization for the initial melt compounding and processing into the finished article. It is important to consider that scrap from the melt compounding needs to be recycled, and unexpected shutdowns and start-ups may occur.

On the other hand, if the material is a durable good, such as geomembranes, insulation for wire and cable, or gas and water transmission pipes, the type and concentration of the phenolic antioxidant is chosen to meet the long service-life criteria. The costs associated with this type or level of antioxidant is worth the additional value of the final product.

Commercial Antioxidants. Table 4 includes the main classes of antioxidants sold in the United States and the supplier's suggested applications. Some of these are mixtures rather than single components. This is especially true of alkylated amines and alkylated phenols. The extent of alkylation and the olefins used for alkylation can vary among manufacturers. Table 4 is not a complete listing of available antioxidants in the United States.

BARRIER POLYMERS

Introduction

Barrier polymers can be broadly defined as macromolecules having the ability to significantly restrict the passage of gases, vapors, and liquids. Since all polymers restrict the transport of penetrants to some degree and the barrier performance of polymers to different penetrants depends on a variety of factors, it is difficult to provide a concise, objective definition. In a practical sense, however, the definition of a barrier polymer depends upon the end-use requirements, and a material that provides sufficient barrier for a particular application can be considered to be a barrier polymer for that purpose. In the present discussion, polymers that have resistance to transport of gases, vapors, and liquids as one of their key attributes will be considered to be barrier polymers.

Polymers have found wide acceptance as alternatives to traditional materials such as glass, paper, and metals, in food, beverage, and other packaging industries. A key characteristic of glass and metals as packaging materials is their total barrier to transport of gases and vapors. While polymers can provide an attractive balance of properties such as flexibility, toughness, light weight, formability, and printability, they do allow the transport of gases and vapors to some extent. Unfortunately, an inexpensive, recyclable polymeric material possessing high barrier properties to every gas or vapor in addition to good mechanical, thermal, and optical properties is not available. For this reason, the selection of a barrier polymer for a particular application typically involves tradeoffs between permeation, mechanical, and aesthetic properties as well as economic and recycling considerations. Additionally, there is an ongoing interest in optimizing property sets of barrier polymers to provide an efficient and economical method for packaging and for extending the shelf life of packaged foods and beverages.

This article discusses various types of barrier polymers and structures, their permeability characteristics and the underlying phenomena involved, measurement techniques, ways to predict and improve barrier properties, and current as well as potential future applications for barrier polymers.

Fundamentals of Permeation in Polymers

The permeability coefficient, or simply permeability, characterizes the steady-state rate of mass transport of penetrant molecules through polymers. In a dense polymer film, the permeability P is defined as the molar flux of penetrant through the polymer relative to a fixed coordinate system N_A normalized by the film thickness L and the difference between the upstream (p_2) and downstream (p_1) partial pressures (1):

$$P = \frac{N_A L}{(p_2 - p_1)} \tag{1}$$

Accordingly, permeability has dimensions of quantity of penetrant (either mass or moles) times thickness divided by area, time, and pressure. Several units have been used to report permeability of gases and water vapor in the literature. In the United States, a commonly used unit for permeability of gases in barrier polymers is $(cm^3(STP)\cdot mil)/(100\ in.^2\cdot day\cdot atm)$. Table 1 provides conversion factors for several permeability units, including the SI unit $(mol\cdot m)/(m^2\cdot s\cdot Pa)$, which is commonly preferred in technical encyclopedias.

The steady-state transport properties of water vapor in barrier polymers are characterized by water vapor transmission rate (WVTR). The dimensions of WVTR are quantity of water transmitted through a film times thickness divided by area and time, and a common unit for WVTR is $(g\cdot mil)/(100\ in.^2\cdot day)$. Table 2 provides conversion factors for some WVTR units, including the SI unit $(mol\cdot m)/(m^2\cdot s)$. WVTR can be converted to water vapor permeability by dividing by the water partial pressure difference (which can be calculated from the specified relative humidity and temperature).

Penetrant transport through polymers is described by the so-called solution-diffusion model (1). According to this model, permeation through a flat sheet or film occurs in three steps: penetrant dissolves into the upstream (ie, the high partial pressure or high thermodynamic activity) side of the film, diffuses through the film, and desorbs from the downstream (ie, the low partial pressure or low thermodynamic activity) side of the film. The rate-limiting step in this process is diffusion through the film. In one dimension, penetrant diffusion through a polymer typically follows Fick's law:

$$N_A = -D\frac{dC}{dx} \tag{2}$$

where D is the effective diffusion coefficient for the penetrant in the polymer and dC/dx is the local concentration gradient of the penetrant.

When the downstream side penetrant partial pressure and concentration are negligible relative to those on the upstream face of the film, using Fick's law of

[a]Given permeability in the units shown in one element of the first column, convert it to the units shown in one element of the first row by multiplying the original permeability by the factor at the intersection of the row and column of interest. For example, a value of 2 (cc·20 μm)/(m^2·day·atm) is equal to (2 × 0.0508) or 0.1 (cc·mil)/(100 in.^{2}·day·atm). In this table and throughout the article cc (or cm^3) has been used to denote cubic centimeters of gas as measured at standard temperature and pressure (STP) conditions, which are 0°C and 1 atm.

Table 2. Table of Common WVTR Units with Conversion Factors[a]

Given	To obtain		
	$\frac{\text{mol·m}}{\text{m}^2\text{·s}}$	$\frac{\text{g·mil}}{100\ \text{in.}^2\text{·day}}$	$\frac{\text{g·cm}}{\text{m}^2\text{·day}}$
$\frac{\text{mol·m}}{\text{m}^2\text{·s}}$	1	3.95×10^{9}	1.55×10^{8}

$\frac{\text{g·cm}}{\text{m}^2\text{·day}}$	6.45×10^{-9}	25.4	1

[a]Given a WVTR value in units shown in one element of the first column, convert it to the units shown in one element of the first row by multiplying the original WVTR value by the factor at the intersection of the row and column of interest. For example, a value of 2 (g·cm)/(m^2·day) is equal to (2 × 25.4) or 50.8 (g·mil)/(100 $in.^2$·day).

diffusion (eq. 2), permeability can be expressed as product of the effective diffusion coefficient D and the solubility coefficient S, which is the ratio of the equilibrium penetrant concentration in the polymer at the upstream side of the film divided by the penetrant partial pressure or activity in the contiguous phase (1):

$$P = D \times S \tag{3}$$

According to equation 2, the diffusion coefficient is a kinetic term characterizing the mass flux of penetrant through a polymer film in response to a concentration gradient (1). Diffusion coefficients have units of (length)^2/time, and are often expressed in cm^2/s. The solubility or partition coefficient is a thermodynamic factor that links the equilibrium penetrant concentration in the polymer, C, with the penetrant partial pressure contiguous to the polymer surface, p (1):

$$C = S \times p \tag{4}$$

When the penetrants of interest are vapors, liquids, or solids, the partial pressure is often replaced by penetrant activity. For an ideal gas, penetrant activity is equal to the ratio of penetrant partial pressure to its saturation vapor pressure (1). For nonideal systems thermodynamic models must be used to estimate penetrant activity (2).

The diffusion process of penetrants in polymers can be broadly classified into two categories: Fickian (which obeys the Fick's law of diffusion) and non-Fickian. Penetrants in rubbery polymers and at low activities in glassy polymers typically exhibit Fickian behavior (3). The signature of Fickian diffusion in a thin polymer film contacted on both faces with a constant partial pressure (or activity) of penetrant is a weight increase due to penetrant absorption that is initially a linear function of the square root of the contact time and then asymptotically approaches a fixed equilibrium value (3). For Fickian diffusion-controlled kinetics of penetrant transport in a plane film whose thickness (L) is much smaller than its width or length, the time required to reach steady state in a permeation experiment, t_{SS}, is given by (3):

$$t_{ss} = \frac{L^2}{D} \tag{5}$$

The diffusion coefficients of large penetrants (eg, flavor and aroma compounds) in barrier polymers, which can be of the order of 10^{-14} cm^2/s or less, coupled with a typical film thickness of 10 μm result in extremely large time scales (over 3 years) to reach steady-state transport. Hence, over the shelf life of packaged products (typically of the order of several months), flavor and aroma compounds may never achieve equilibrium or steady-state conditions. In such cases, the steady-state permeability does not provide sufficient information to predict package shelf life. As discussed later, more detailed knowledge of penetrant solubility and diffusivity is required to accurately predict migration of such compounds.

In glassy polymers, deviations from Fickian behavior can occur. These deviations are generally believed to arise as a consequence of the finite rate of polymer structure reorganization in response to penetrant-induced swelling during the sorption–diffusion process (4). An example of so-called non-Fickian diffusion behavior is the penetrant sorbing into the polymer in two stages, an initial Fickian-like stage followed by a protracted, slow drift toward the final equilibrium sorption value (5). In such cases, the time required to achieve steady-state transport may be much higher than that predicted based on equation 5. This type of diffusion behavior is often observed when organic vapors at relatively high activity sorb into amorphous glassy polymers (6). For example, toluene vapors exhibit Fickian diffusion behavior in amorphous poly(vinyl chloride) (PVC) films at activities up to 0.4 and show increasingly non-Fickian behavior at higher activities (7).

Mechanism of Penetrant Transport in Dense Polymers

The rate-limiting step for penetrant diffusion is the creation of transient "gaps" in the polymer matrix via local scale polymer segmental dynamics involving several polymer chains (8). Penetrant molecules vibrate inside local cavities in the polymer matrix at frequencies much higher than the frequency of polymer chain motion required to open a gap of sufficient size to accommodate the penetrant. These steps are shown schematically in Figure 1. In Figure 1a, a penetrant molecule is shown dissolved in a polymer matrix. The penetrant vibrates inside a gap or molecular scale cavity in the polymer matrix at very high frequency (ca 10^{12} vibrations/s or 1 vibration/ps) (8). The polymer molecules do not occupy the entire volume of the polymer sample. Because of packing inefficiencies and polymer chain molecular motion, some of the volume in the polymer matrix is empty or "free" and this so-called free volume is redistributed continuously as a result of the random, thermally stimulated molecular motion of the polymer segments (1).

In Figure 1b, local polymer segmental motion has opened a connecting channel between two free-volume elements in the polymer matrix and the penetrant molecule can, as a result of its own Brownian motion, explore the entire corridor between the initial free-volume element which it occupied and the second free-volume element which is connected to it via the opening of a transient gap in the polymer matrix. Eventually, local segmental motion of the polymer segments closes the connection between the two free-volume elements and if the penetrant happens to be away from its original position, as shown in Figure 1c, when the gap in the polymer matrix is closed, the penetrant will be trapped in another free-volume element in the polymer matrix and will have executed a diffusion step. The

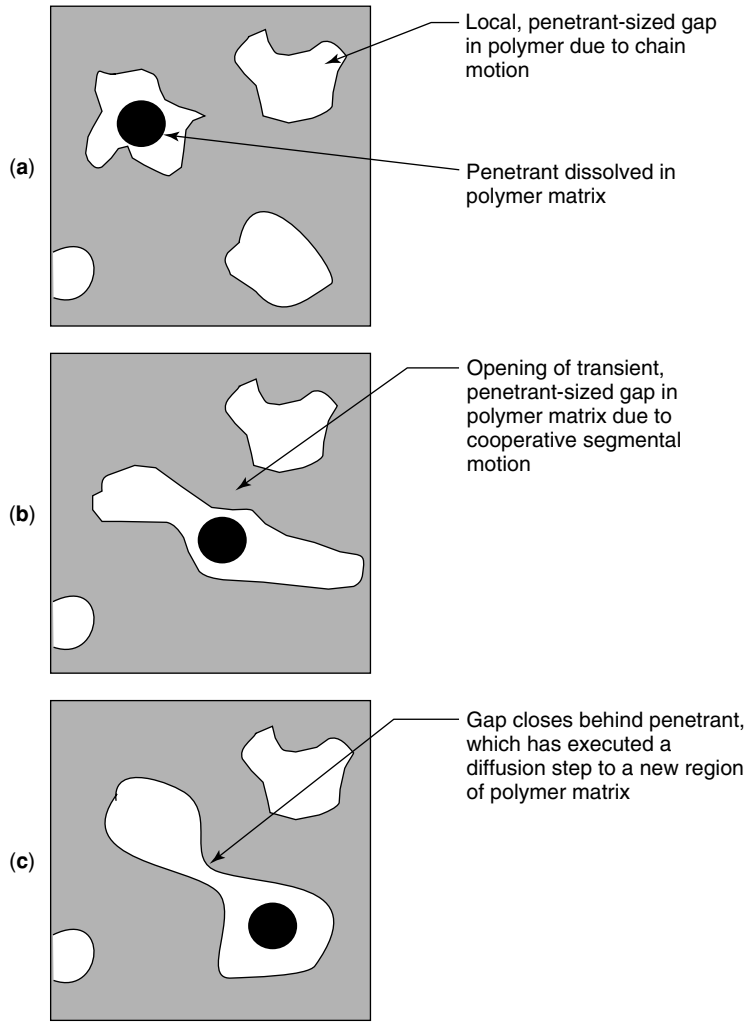

Fig. 1. Schematic depicting mechanism of penetrant transport in polymers (8).

process shown in Figure 1 has been called the "Red Sea" mechanism of penetrant transport in polymers (8).

Figure 2 shows a schematic of two polymer chains undergoing coordinated local segmental motion as a result of random, thermally stimulated movements of the polymer chains to open a gap between the polymer chains of sufficient size to permit passage of a penetrant molecule from one free-volume element to another (9). This schematic emphasizes that the polymer segmental motion is the rate-controlling step in penetrant diffusion.

Figure 3 provides a very simplistic schematic of the molecular processes involved in the local segmental motions of polymers that contribute to the formation of transient gaps in the polymer matrix important for penetrant diffusion. This figure shows what is believed to be a typical example of intramolecular cooperative local segmental motion of the polymer backbone of a polyethylene chain. This

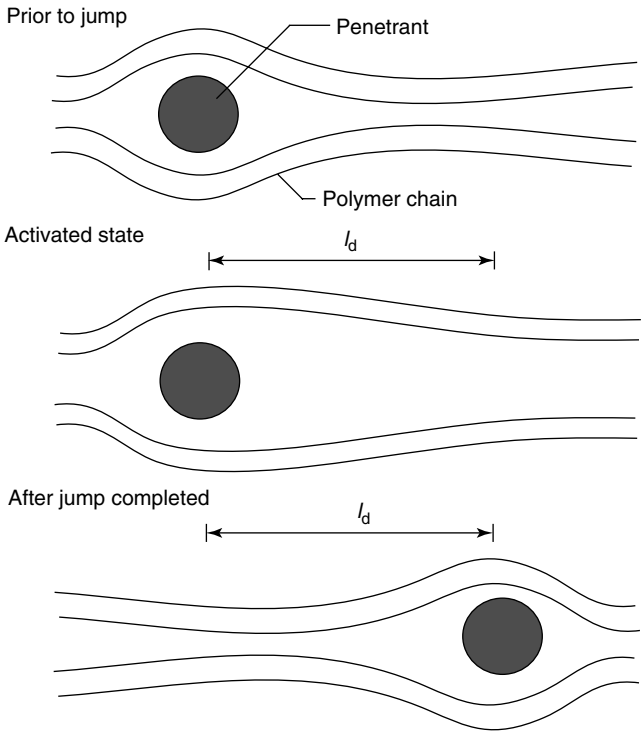

Fig. 2. Schematic depicting polymer chain position before, during, and after a diffusion step by a penetrant molecule (9).

so-called crankshaft motion requires the cooperation of several adjacent ethylene units and can act to create gaps in the polymer matrix of sufficient size to accommodate small penetrant molecules. It should be emphasized that the detailed understanding of the molecular level motions in polymers that contribute to diffusion is evolving rapidly as a result of more detailed atomistic simulation of penetrant transport in polymers. As a result, more realistic descriptions of the important molecular processes for penetrant diffusion in polymers should be expected in the near future.

The motion of polymer segments to produce a gap of sufficient size to accommodate a penetrant molecule is much slower than the vibration of the penetrant in a gap in the polymer matrix. For example, computer simulations of oxygen diffusion in a polyimide reveal that the oxygen molecules execute a diffusion step approximately once every nanosecond (1 ns = 1000 ps) (10). The rate of production of gaps of sufficient size to accommodate penetrant molecules decreases with increasing size of the penetrant. That is, there are fewer gaps produced per unit time in a polymer matrix of sufficient size to accommodate methane (kinetic diameter = 0.38 nm), for example, than there are for hydrogen (kinetic diameter = 0.289 nm).

Computer simulation results of diffusion in poly(2,6-dimethyl-1,4-phenylene oxide) (PPO) have been reported (11). Figures 4 and 5 present the results for the displacement of an oxygen molecule and a nitrogen molecule, respectively, as a

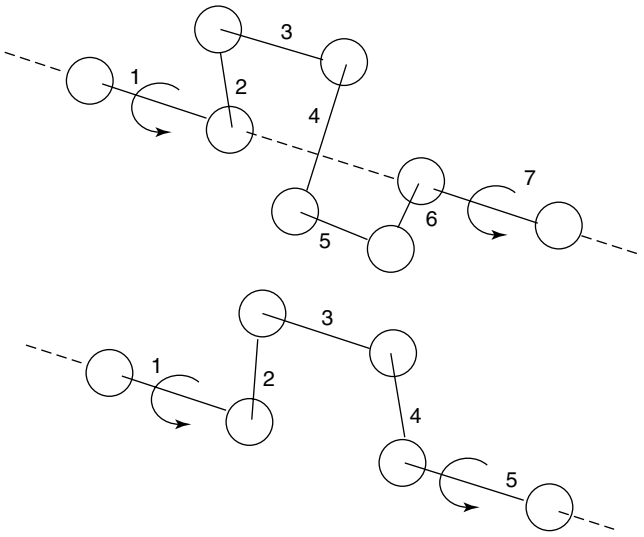

Fig. 3. Crankshaft motion—An example of local segmental dynamics in polyolefins. Each ball represents, for example, a methylene (ie, CH_2) unit in PE and the solid lines represent the covalent chemical bonds between neighboring CH_2 groups. Such molecular motions are believed to be important in providing pathways for diffusion of small molecules in polymers. The crankshaft motion requires the simultaneous rotation of several contiguous methylene units about bonds 1 and 7 or bonds 1 and 5 (9).

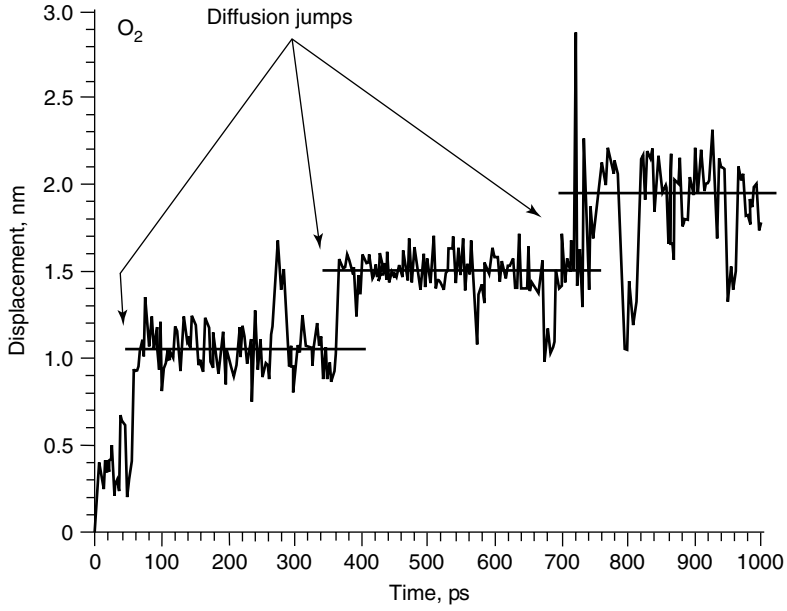

Fig. 4. Computer simulation of the displacement of an oxygen molecule in poly(2,6-dimethyl-1,4-phenylene oxide) as a function of time (11).

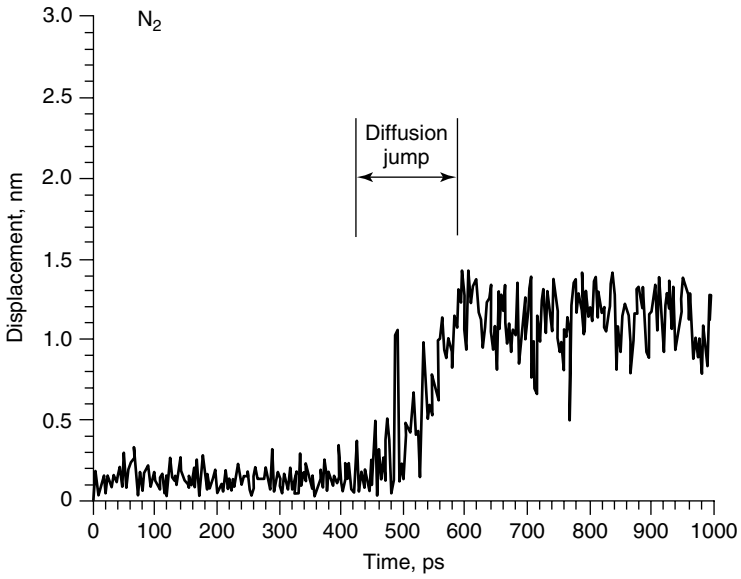

Fig. 5. Computer simulation of the displacement of a nitrogen molecule in poly(2,6-dimethyl-1,4-phenylene oxide) as a function of time (11).

function of time. There is about one diffusion jump for oxygen (kinetic diameter = 0.346 nm) every 300–350 ps but only one diffusion step for nitrogen (kinetic diameter = 0.364 nm) over the entire 1000 ps duration of the computer simulation (11). The oxygen molecule spends most of its time rattling within a small cage (or free-volume element) with average displacements of the order of 0.2 nm or so. The diffusion jumps occurring approximately every 300–350 ps involve displacements of the oxygen atom of the order of 0.4–0.5 nm. As shown in Figure 5, the diffusion jump length for nitrogen is longer (approximately 1 nm) and the jumps occur less frequently. However, these results are obtained for very short periods of time owing to computational limitations, and very long simulations would be required to generate precise estimates of jump lengths and jump frequencies. Because of the extremely demanding computational resources required for such molecular-level simulations, they are only now becoming possible for small molecule migration in relatively permeable polymers. As yet, computers are not fast enough to provide realistic simulations of phenomena such as migration of large flavor molecules in high barrier polymers.

Factors Affecting Permeability, Diffusivity, and Solubility

Free Volume. The dependence of penetrant transport properties on chain packing in polymers is often described using correlations involving the *fractional free volume* (FFV) of polymers. FFV is the fraction of volume in a polymer that is available to assist in penetrant transport, and does not include volume occupied by polymer molecules and volume in the polymer matrix that is otherwise unavailable

for penetrant transport. It is often estimated using group contribution methods. One popular method for estimating FFV is based on the following expression (1):

$$\mathrm{FFV} = \frac{V - V_0}{V} \tag{6}$$

where V is the polymer specific molar volume and V_0 is the so-called occupied volume that is not available to assist in penetrant transport. The occupied volume is usually estimated by Bondi's method as follows (12):

$$V_0 = 1.3V_\mathrm{w} \tag{7}$$

where V_w is van der Waals volume of the molecule. A good estimate of V_w can be obtained from bond radii, van der Waals radii of constituent atoms, and geometric factors. Bond radii are nearly constant from one molecule to another since the same chemical bond will always have the same radius. The most complete list of V_w values is available in the compilation given in Reference 13. The dependence of diffusion coefficients on FFV can be expressed as (14):

$$D = A \exp\left(\frac{-B}{\mathrm{FFV}}\right) \tag{8}$$

where A and B are empirical constants. The higher the FFV, the larger the diffusion coefficient. Figure 6 shows the effect of free volume on gas diffusion coefficients in a series of substituted polysulfones (15).

The dependence of solubility on FFV is usually weaker than that of diffusivity, especially in amorphous polymers (16). Therefore, permeability often follows a similar dependence on free volume as penetrant diffusivity. Attempts have been made to correlate FFV of polymers with gas permeability (17,18). As shown in Figure 7 (17), a nearly linear correlation was found to exist between the logarithm of oxygen permeability coefficients and the inverse of FFV in several families of amorphous, glassy polymers and high barrier liquid crystalline polymers. Many barrier polymers are glassy materials, since their use temperature is below their glass-transition temperature. In glassy polymers, which are nonequilibrium materials, free volume can be altered to some extent by the processing history of the sample (19). For instance, higher rates of cooling create higher free volume in the glassy state, and vice versa. A more effective way to alter free volume is to vary the chemical structure by, for example, adding or removing pendant groups on the polymer backbone (19). The presence of polar groups with low specific volumes can reduce the free volume (and hence, penetrant diffusion coefficients) by facilitating more efficient packing of the polymer chains due to stronger interactions between them (19). For example, barrier polymers such as polyacrylonitrile (PAN) and poly(vinyl alcohol) (PVOH) have polar pendant groups, which lead to strong energetic interactions between the polymer chains, efficient polymer chain packing, low free volume, and, in turn, low permeability coefficients.

Free volume in polymers can be measured using probes such as electrochromic, photochromic, and fluoroscent probes, as well as xenon nuclear magnetic resonance, small-angle x-ray scattering, density measurements, and positron

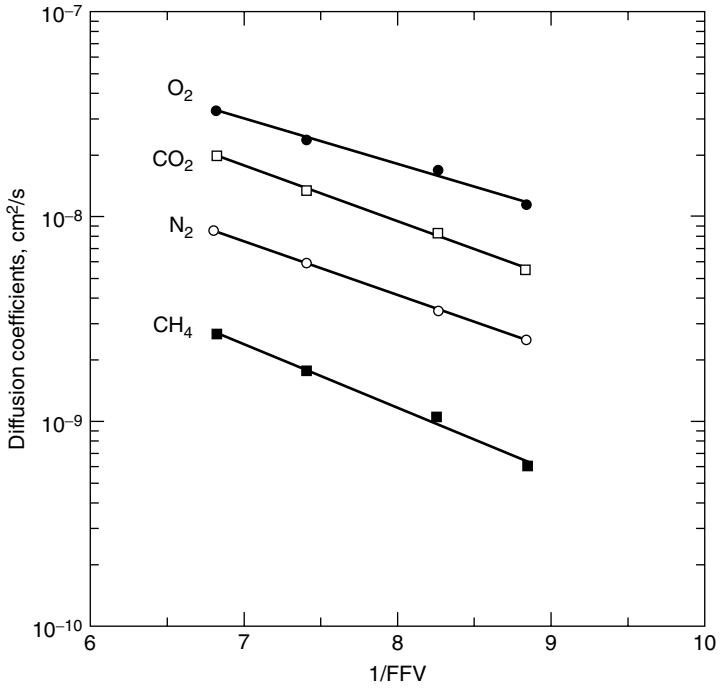

Fig. 6. Correlation of gas diffusion coefficients with inverse of polymer fractional free volume in a series of substituted polysulfones (15).

annihilation lifetime spectroscopy (pals) (20). Each method has its strengths and limitations, and a simple, direct measure of FFV is not available. The pals technique has, however, emerged in the past several years as a valuable nondestructive probe of free volume in polymers (20,21). PALS uses orthoPositronium (oPs) as a probe of free volume in the polymer matrix. oPs resides in regions of reduced electron density, such as free-volume elements, that typically range in radius from 0.2 to 0.4 nm. This range of cavity radii compares well with nonbonded interatomic distances in polymers and molecular radii of diffusing penetrants (20). PALS permits an estimate of both the size and concentration of free-volume elements in the polymer matrix. Transport properties of barrier polymers, copolymers, and polymer blends have been well correlated with FFV as measured by pals (20–26).

Temperature. The temperature dependence of permeability and diffusivity are usually modeled using Arrhenius equations of the following forms (1):

$$P = P_0 \exp\left(\frac{-E_p}{RT}\right) \tag{9}$$

$$D = D_0 \exp\left(\frac{-E_D}{RT}\right) \tag{10}$$

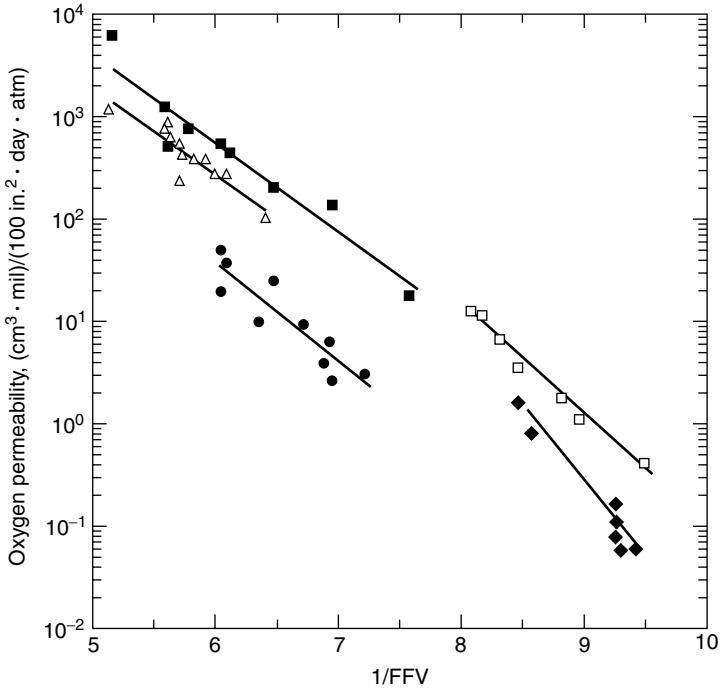

Fig. 7. Correlation of oxygen permeability with inverse of polymer fractional free volume for several families of amorphous, glassy, and liquid crystalline polymers (17). ■ Polystyrene (35°C), △ polycarbonates (35°C), ● polyesters (30°C), □ polyamides (25°C), ◇ liquid crystalline polymers (35°C).

where E_p and E_D are activation energies for permeation and diffusion, and P_0 and D_0 are preexponential factors. The effect of temperature on solubility is usually expressed by a van't Hoff relationship (1):

$$S = S_0 \exp\left(\frac{-\Delta H_S}{RT}\right) \tag{11}$$

where S_0 is a preexponential factor and ΔH_s is the heat of sorption of penetrant in the polymer. Since steady-state permeability is the product of diffusivity and solubility, the activation energy of permeation can be defined as the sum of activation energy of diffusion and the heat of sorption (1):

$$E_p = E_d + \Delta H_S \tag{12}$$

E_d is always positive; ΔH_s is often positive for light gases (such as H_2, O_2, and N_2), but can be negative for larger, more soluble penetrants (such as C_3H_8 and C_4H_{10}). For polymers such as low density polyethylene (LDPE) and poly(vinyl chloride) (PVC), E_p is always positive (1). Therefore, permeability increases with increasing temperature. To illustrate this behavior, Figure 8 shows the effect of temperature on oxygen permeability of four widely used barrier polymers (27).

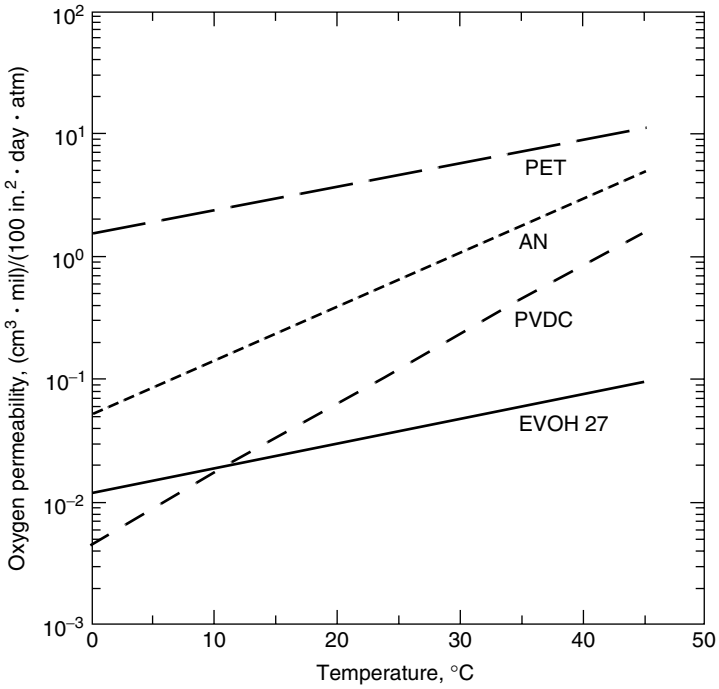

Fig. 8. Effect of temperature on oxygen permeability at 75% RH. PET is poly(ethylene terephthalate), AN is an acrylonitrile–styrene copolymer, PVDC is vinylidene chloride–vinyl chloride copolymer (coextrusion resin grade), and EVOH 27 is ethylene vinyl alcohol copolymer containing 27 mol% ethylene (27).

At temperatures far from the transition temperatures (eg, glass-transition temperature and melting point) the Arrhenius relationship (eq. 10) is obeyed, and with a known activation energy of diffusion, E_D, the diffusion coefficient of a penetrant in a polymer can be estimated at any temperature. In cases where E_D is not reported, it can be estimated using a known correlation (28,29) between D_0 and E_D:

$$\ln D_0 = a\frac{E_D}{RT} - b \tag{13}$$

where a and b are independent of penetrant type. The parameter a is independent of polymer type and has a universal value of 0.64 (30). b has a value of 9.2 [$-\ln(10^{-4}$ cm^2/s)] for rubbery polymers (ie, polymers above their T_g) and 11.5 [$-\ln(10^{-5}$ cm^2/s)] for glassy polymers (ie, polymers below their T_g) (13). Equation 13 is often referred to as a "linear free-energy" relation. Similar relations between D_0 and E_D are observed for viscosity of organic liquids, molten salts, and metals (31) and for first-order chemical reaction kinetics (32), which are also activated processes described by the Arrhenius equation. Additionally, common barrier polymers such as poly(ethylene terephthalate) (PET) and polycarbonate

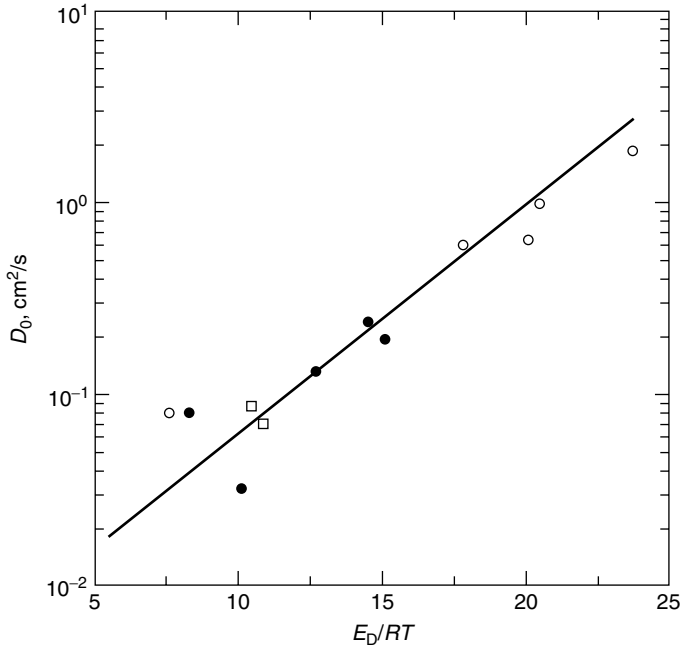

Fig. 9. Correlation of D_0 with E_D/RT for various penetrants in glassy polymers (33). ○ Poly(ethylene terephthalate), ● bisphenol-A polycarbonate, □ tetramethyl bisphenol-A PC.

(PC) are known to follow this relation both above and below the glass-transition temperature, as shown in Figure 9 (33). Combining equations 10 and 13 gives

$$D = \exp\left[-b - \left(1 - \alpha\right) \frac{E_D}{RT} \right] \tag{14}$$

On the basis of a single value of the diffusion coefficient at one temperature, E_D can be estimated from equation 14. This equation can then be used to estimate the diffusion coefficient at other temperatures, provided that the two temperatures do not traverse thermal transitions (such as glass transition) and the polymer morphology is otherwise unchanged.

Chemical Structure. The presence of polar groups on or in polymer chains often increases chain rigidity, which can increase glass-transition temperature and improve mechanical properties, and increases packing density (1). Conventional barrier polymers, such as PAN, have very low gas permeability as a result, in part, of restricted chain mobility due to the presence of polar groups. Polymer chain interactions can be quantified in terms of cohesive energy density (CED), and CED has a strong influence on penetrant diffusion. CED of a polymer is the square of its solubility parameter and characterizes the strength of attraction (or interactions) between the polymer chains. It can be estimated using group contribution techniques (13). In a simple model of penetrant diffusion in polymers, the activation energy for diffusion is directly proportional to the CED of a polymer

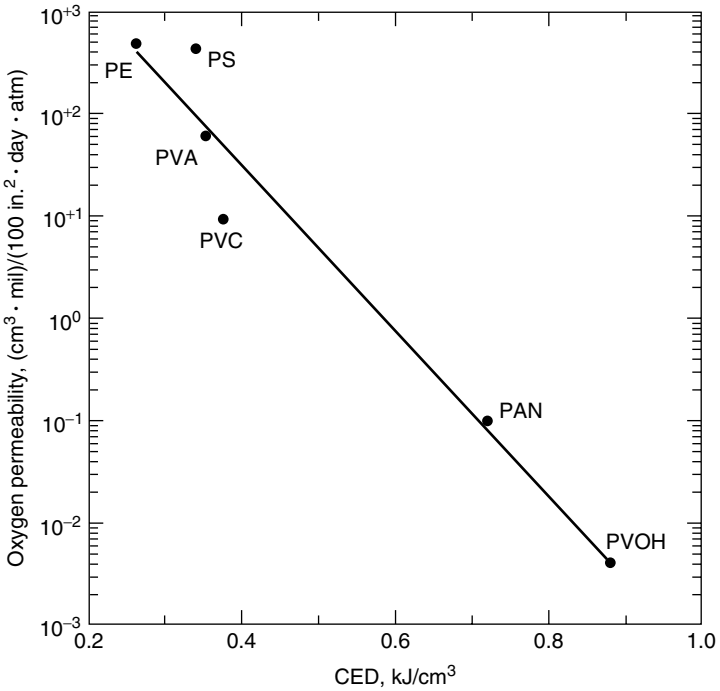

Fig. 10. Correlation of oxygen permeability (23°C, 0% RH) with CED for six barrier polymers: PE, PS, PVA, PVC, PAN, PVOH (36,37).

(34). On the basis of this model and the linear free-energy relation (35), the logarithm of penetrant diffusion coefficients should decrease linearly with increasing CED. Solubility of relatively nonpolar penetrants usually has a weaker dependence on CED than diffusivity, and hence, the logarithm of permeability should decrease linearly with increasing CED. As shown in Figure 10, a nearly linear correlation was found between oxygen permeability and CED of barrier polymers with permeability values ranging over 5 orders of magnitude (36,37).

Penetrant diffusivity, and hence permeability, can also be decreased by adding substituents to the polymer chain that reduce chain flexibility. Bulky side groups or rigid linkages such as aromatic groups decrease chain flexibility and hence reduce penetrant diffusion coefficients. Flexible linkages, such as ether or methylene groups, produce the opposite effect (1). Several methods are used to characterize chain flexibility (1). The glass-transition temperature is a measure of long range or bulk molecular motion, and high T_g materials are usually rigid and inflexible. Sub-T_g relaxations are another indication of molecular motion, and correlations of O_2 and CO_2 permeability with sub-T_g relaxations have been observed within a family of amorphous polyesters and copolyesters (38). However, the exact nature of molecular motions which control penetrant diffusion are complex and unclear, and hence T_g and sub-T_g relaxations do not, in general, provide predictive correlations with penetrant diffusivity (1).

Changes in molecular structure of the polymer often affect more than one factor influencing permeability and the net effect can be difficult to anticipate.

For example, addition of bulky side groups can stiffen the polymer chains, which is expected to reduce the diffusion coefficients. However, the same modification could also decrease chain packing in the amorphous phase and reduce the level of crystallinity in the polymer, which are expected to increase the diffusion coefficients (39). The net result of these competing effects can be difficult to predict a priori.

Crystallinity. Increasing crystallinity in a polymer generally decreases gas permeability (16) (see SEMICRYSTALLINE POLYMERS). Crystallinity influences both solubility and diffusion coefficients. For most polymers and penetrants of interest, crystalline regions, which are much more dense and well ordered than amorphous regions, preclude penetrant sorption, thereby reducing penetrant solubility. Additionally, the presence of impermeable crystallites in a polymer matrix acts as barriers to diffusion, increasing the path length for diffusion and, in some cases, increasing chain rigidity, which also reduces diffusion coefficients (16). Although crystallite size, shape, and orientation do not usually influence solubility in polymers significantly, these factors can be important in penetrant diffusion. The effect of crystallinity on penetrant diffusion can be expressed using the following model (39):

$$D = \frac{D_a}{\tau\beta} \tag{15}$$

where D_a is the penetrant diffusion coefficient in the amorphous polymer, τ is a geometric impedance (ie, tortuosity) factor, and β is a chain immobilization factor. Impermeable crystalline regions force penetrants to follow a tortuous pathway through the permeable amorphous regions. This effect is captured by the factor τ, which is the ratio of the average distance traveled by a penetrant molecule to the thickness of the sample (39). τ can be a complex function of crystalline content as well as crystallite size, shape, and orientation (16,40). Crystallites can also restrict segmental mobility by acting as physical cross-links. This effect is taken into account by the factor β and is generally more pronounced in flexible rubbery polymers such as polyethylene (PE). In glassy polymers such as PET, the inherent rigidity of the chain backbone imposes more impedance to chain mobility than the crystallites and hence, β is one (16) (see AMORPHOUS POLYMERS).

A two-phase model is often used to describe penetrant solubility in a semicrystalline polymer (41):

$$S = S_a\phi_a \tag{16}$$

where S_a is solubility coefficient in the amorphous regions of the polymer and ϕ_a is amorphous phase volume fraction. This model assumes that the solubility of the crystalline regions is zero, and that the presence of crystallites does not change the amorphous phase solubility coefficient. For polymers used in barrier packaging applications, the assumption of zero solubility in the crystalline regions is generally accurate (42). The second assumption that the amorphous phase solubility is independent of crystalline content is not necessarily obeyed, particularly in glassy polymers, whose state of amorphous phase structural organization may be influenced significantly by common processing protocols (eg, orientation, stretching,

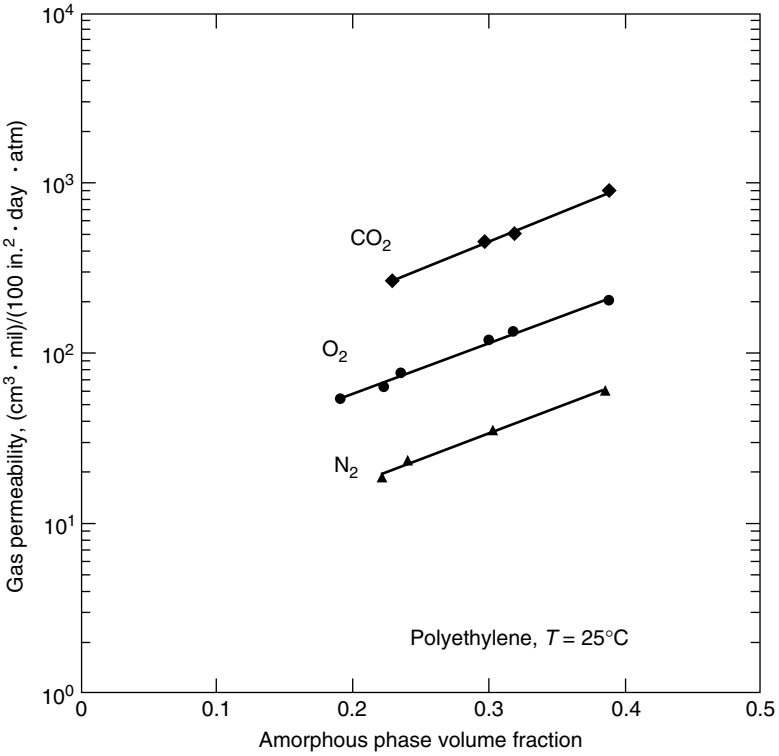

Fig. 11. Effect of crystalline content on gas permeability in PE at 25°C and 0% RH (47).

annealing, and contact with crystallization-inducing agents) (43–46). Nevertheless, the simplest and most commonly used model for the effect of crystallinity on steady-state permeability is based on these assumptions and is expressed by the following relationship:

$$P = (S_a \phi_a)\left(\frac{D_a}{\tau\beta}\right) \tag{17}$$

Figure 11 shows the effect of crystallinity on gas permeability in PE at 25°C. Permeability decreases with increasing crystallinity primarily because of decreasing diffusion coefficients. The effect of crystallinity is more pronounced on tortuosity factor τ than the chain immobilization factor β (47). In glassy polymers, the most widely used approximations for τ and β are $\tau = {\phi_a}^{-1}$ and $\beta = 1$. Introducing these values into the above equation yields $P = P_a {\phi_a}^2$, where P_a is the amorphous phase permeability.

In certain polymers, the simple assumptions of the two-phase model do not hold. For example, poly(4-methyl-1-pentene) (PMP), which is a highly permeable polymer, has a very low density crystal structure, and hence, penetrant molecules can sorb into its crystalline phase (42). In PET, it has been observed that the presence of crystalline regions increased the concentration of sorption sites in the

amorphous regions remaining in the polymer after crystallization (41). Others have recently examined this phenomenon in PET in more detail (48,49). It has been reported (43) that exposing amorphous PET to a strongly sorbing penetrant at high activity results in penetrant-induced crystallization. This process affects the amorphous phase penetrant solubility of PET, resulting in a marked increase in overall solubility with increasing crystallinity. For example, acetaldehyde solubility in PET increased by more than 300% as a result of penetrant-induced crystallinity of about 36 wt% (43). This effect was attributed to the creation of microvoids in the polymer as a by-product of penetrant-induced crystallization (43). Evidence for microvoid formation in PET due to exposure to strongly sorbing penetrants has been presented in studies investigating solvent treatments to improve the dyeability of PET yarns (44), and in studies investigating the effect of crystallizing liquids on the morphology of PET (45,46). For example, it has been reported that dye uptake in PET fibers exposed to dimethylformamide (DMF) was four to five times higher than in unexposed fibers (44). The dye diffusion coefficient was also more than 2 orders of magnitude higher in the DMF-exposed samples than in the unexposed samples (50).

Chain Orientation. Stretching or drawing of polymer films can improve mechanical properties, and under certain conditions, barrier properties (see FILMS, ORIENTATION). The degree of chain orientation achieved is dependent on the draw ratio and other process conditions (16). Orientation is usually characterized by birefringence and quantified by the Herman's orientation function f (51):

$$f = \frac{1}{2}(3\cos^2\theta - 1) \tag{18}$$

where θ is the average angle between the polymer chain axis and the draw direction.

Depending on the mode of deformation and the physical processes that occur during orientation, permeability may either increase or decrease with increasing orientation (16). Impermeable polymer crystallites may become oriented into plate-like structures during deformation, and this process generally decreases penetrant diffusivity by increasing tortuosity (16). In addition, drawing of semicrystalline polymers can improve barrier properties through stress-induced crystallization and orientation of the remaining amorphous phase. Hence, the reduction in permeability caused by orientation of crystallizable polymers can be greater than that in noncrystallizable polymers (16). The dramatic effect of orientation is supported by oxygen permeability data for PET in the literature. A 4 $\times$ biaxial orientation (ie, draw ratio = 4 in each axis) decreased the permeability of oxygen in PET by a factor of about 2 (52). For other systems, however, increases in permeability upon biaxial orientation have also been reported. A vinylidene chloride (VDC)–vinyl chloride copolymer, for example, showed an increase in oxygen permeability from 0.2 (cm^3·mil)/(100 $in.^2$·day·atm) to 0.3 (cm^3·mil)/(100 $in.^2$·day·atm) upon 2.5 $\times$ biaxial orientation (53). The permeability increase was attributed to microvoid development during orientation of the polymer chains after crystallinity was fully developed. Table 3 shows the effect of orientation on oxygen permeability of semicrystalline and amorphous barrier polymers (53). In semicrystalline VDC copolymer and nylon MXD-6 polymers, under the conditions studied, the orientation process results in a slight increase in oxygen permeability

Table 3. Effect of Orientation on Oxygen Permeability Characteristics of Semicrystalline and Amorphous Barrier Resins[a]

with chain orientation, whereas the reverse is true for amorphous Selar 3426 and polyacrylic-imide barrier polymers.

Penetrant Concentration (or Partial Pressure). The influence of penetrant concentration on solubility, diffusivity, and, in turn, permeability varies, depending on the penetrant–polymer system. Rubbery and glassy polymers typically show little or no concentration dependence for solubility, diffusivity, and permeability of light gases such as H_2, N_2, and O_2. Consistent with this notion, Figure 12a shows essentially no influence of pressure on H_2 permeability in PE (19). Gases such as CO_2, which are more soluble than light gases, typically have a permeability–presssure response in glassy polymers similar to that shown in Figure 12b. Permeability decreases monotonically with increasing pressure as predicted by the dual-mode sorption model (54). The magnitude of the permeability decrease depends upon the amount of so-called nonequilibrium excess volume in the polymer, which can increase with increasing T_g, the affinity of the penetrant for the nonequilibrium excess volume, and the mobility of the penetrant in the nonequilibrium excess volume relative to its mobility in the equilibrium free volume (1). The permeability of a rubbery polymer to an organic vapor often exhibits the behavior shown in Figure 12c. The monotonic increase in permeability is often due to increases in penetrant solubility with increasing pressure coupled with increases in diffusivity with increasing pressure (1). The response shown in

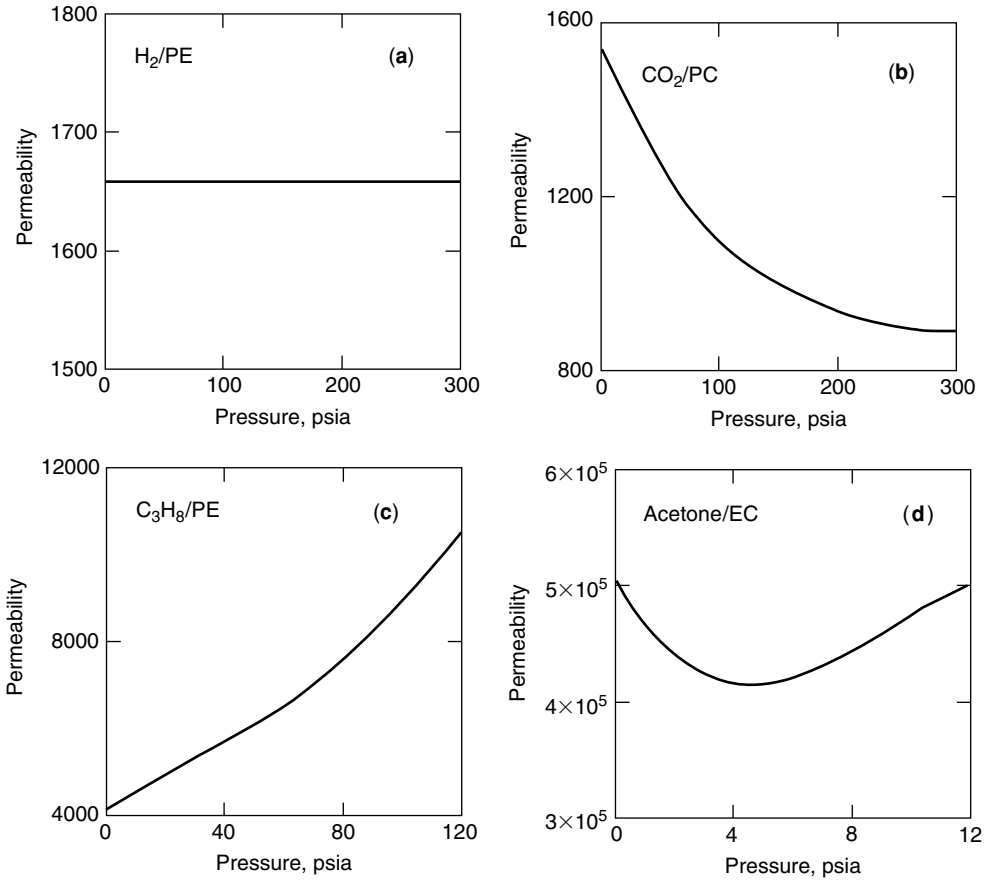

Fig. 12. Typical permeability–pressure dependence in rubbery and glassy polymers. (**a**) Hydrogen in PE at 30°C, (**b**) carbon dioxide in PC at 35°C, (**c**) propane in PE at 20°C, (**d**) acetone in ethyl cellulose (EC) at 40°C (19). The permeability values have units of $(cm^3 \cdot mil)/(100\ in.^2 day \cdot atm)$.

Figure 12d is typical for strongly interacting penetrants (eg, organic vapors) in glassy polymers at sufficiently high penetrant partial pressures. It can be viewed as a superposition of the behaviors in Figures 12b and 12c (1). The sharp increase in permeability begins as the penetrant plasticizes the polymer. Plasticization occurs when penetrant molecules dissolve in the polymer matrix at sufficient concentration to force polymer chain segment separation, thereby increasing the free volume, and in turn, facilitating polymer segmental motion. This increase in segmental mobility, which may be observed by the depression in T_g, results in an increase in penetrant diffusion coefficients and, in turn, permeability (1).

Humidity. The absorption of water can increase, decrease, or have no effect on gas permeability of barrier polymers (27). Increasing the relative humidity (RH) from 0 to 50% increases the oxygen permeability of cellophane (regenerated cellulose) by an order of magnitude, and exposure to 90% RH removes it from the class of high barriers by further increasing the permeability by more than an

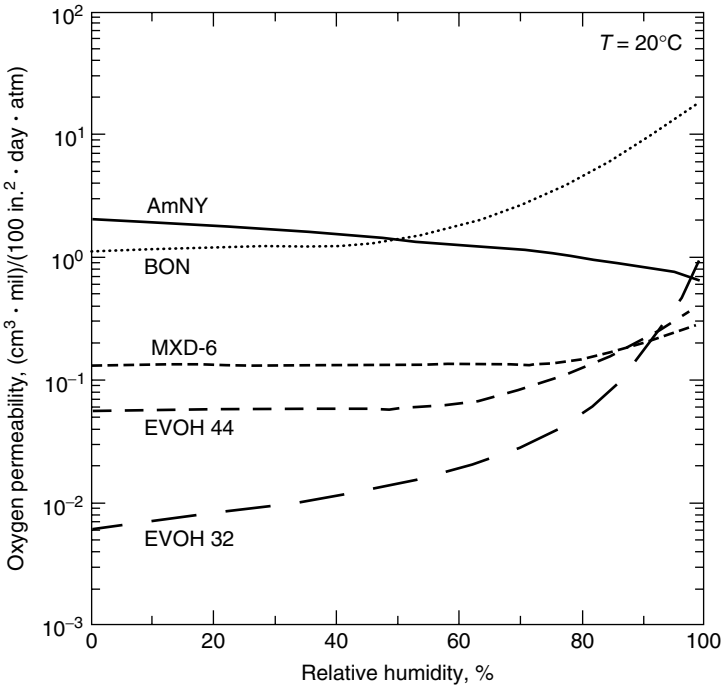

Fig. 13. Effect of relative humidity on oxygen permeability of hydrophilic barrier polymers. AmNY is amorphous nylon (Selar), BON is biaxially oriented nylon-6, MXD-6 is oriented poly(metaxylylenediamine–adipic acid), EVOH 44 and 32 are ethylene vinyl alcohol copolymers containing 44 and 32 mol% ethylene (27).

order of magnitude (27). For packaging of foods that require protection against oxygen ingress, cellophane is coated or laminated with water barriers such as polyolefins (27). Other hydrophilic barrier polymers, with the exception of certain amorphous polyamides, also lose their barrier properties with increasing RH, as shown in Figure 13. This is because water acts as a plasticizer and increases the free volume of the polymer (55). However, at low to moderate RH, amorphous polyamides and PET show slightly improved barrier properties with increasing RH (27). This behavior has been explained as the water molecules not swelling the polymer, but occupying some of the polymer free-volume sites instead, resulting in reduction in permeability of other gases (56). VDC copolymers, acrylonitrile copolymers, and polyolefins show essentially no effect of RH on gas permeability (57).

Techniques for Measuring Transport Properties

The determination of permeability, solubility, and diffusivity requires direct or indirect measurement of mass transfer under controlled conditions. The permeability of barrier polymers can be determined directly by measuring the pressure change or other physical evidence of transfer or indirectly by using an indicator of permeation, such as chemical reaction of the transferring gas with another

substance. The preferred methods of measurement differ for different classes of penetrants: light gases, water vapor, condensable vapors, and food flavor and aroma compounds.

There are two basic methods for measuring permeability: isostatic and quasi-isostatic (55). Isostatic methods employ a continuous flow on both sides of the polymer film to provide constant penetrant concentrations. Quasi-isostatic methods use a continuous flow to maintain constant penetrant concentration only on the upstream side and allow penetrant accumulation on the downstream side of the film. However, this accumulation is limited to a very low concentration, and hence the penetrant partial pressure difference can be approximated as a constant (55). Figure 14a typically shows the course of an isostatic permeability experiment for a barrier polymer film of uniform thickness exposed to constant penetrant partial pressure p on the upstream side and constant removal of penetrant that has permeated through the film to the downstream side. Using a specified initial condition (concentration in the film uniformly equal to zero) and boundary conditions (constant penetrant concentration C at the upstream side and zero penetrant concentration at the downstream side), this situation can be described by the following mathematical expression (58):

$$q = \frac{DC}{L}\left(t - \frac{L^2}{6D}\right) - \frac{2LC}{\pi^2}\sum_{n=1}^{\infty}\frac{(-1)^n}{n^2}\exp\left(\frac{-Dn^2\pi^2 t}{L^2}\right) \tag{19}$$

where q is the total mass of penetrant permeating per unit film area in time t, D is the diffusion coefficient, L is film thickness, and C is penetrant concentration at the upstream side in equilibrium with the upstream penetrant partial pressure p. When steady state is reached, t becomes large enough to make the exponential term negligibly small, and the above equation reduces to

$$q = \frac{DC}{L}\left(t - \frac{L^2}{6D}\right) \tag{20}$$

A plot of q vs t yields a straight line whose slope is the steady-state penetrant flux ($N_A = DC/L$) and whose x-axis intercept is called the time lag (t_L).

$$t_L = \frac{L^2}{6D} \tag{21}$$

The time lag can be related to the time required to achieve steady state ($t_{SS} \sim 2.7t_L$) (27). The diffusion coefficient can be calculated by rearranging the above equation (58):

$$D = \frac{L^2}{6t_L} \tag{22}$$

Permeability can be calculated from equation 1 and the steady-state flux value ($P = N_A\, L/p = DC/p$). It should be noted that for concentration-dependent diffusion coefficients, t_L will vary with the pressure difference across the polymer film, and as a result, this simple time lag analysis may yield significant

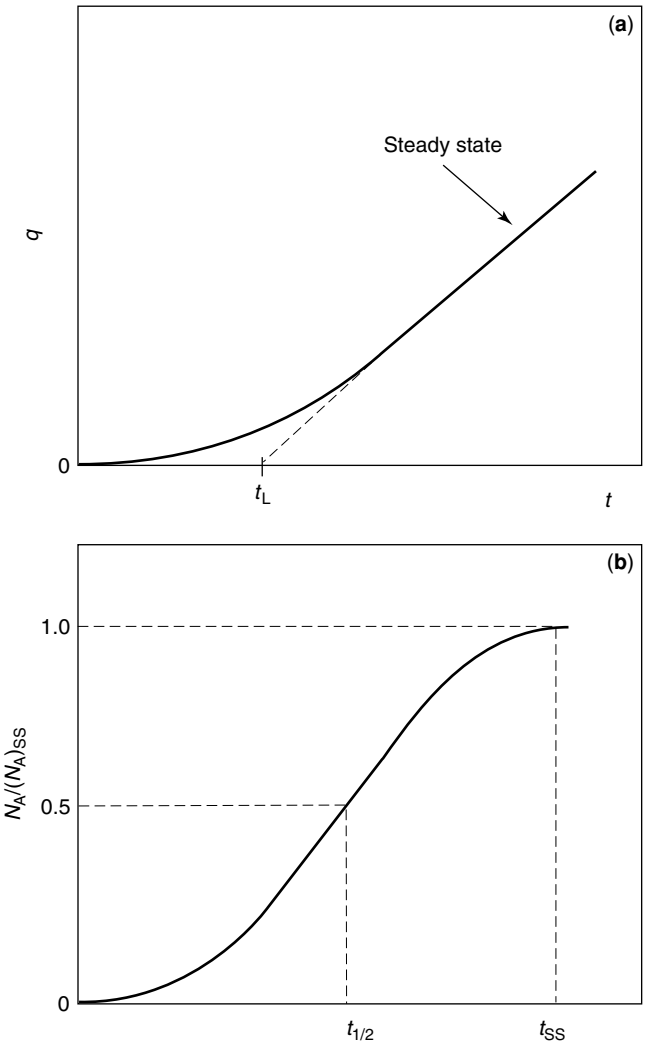

Fig. 14. (**a**) Mass of permeating penetrant per unit film area (q) as a function of time (providing a measure of time lag t_L). (**b**) Normalized penetrant flux (N_A) as a function of time (providing a measure of halftime $t_{1/2}$). t_{SS} is time required to achieve steady state.

errors in the diffusion coefficients estimated using equation 22 (58). More general expressions for the time lag have been developed by including the concentration dependence of D (59). Alternatively, a 'concentration-averaged' diffusion coefficient can be obtained by plotting normalized penetrant flux (ie, flux at any time t divided by the steady-state flux) as a function of time (Fig. 14b). The diffusion coefficient can be estimated using the following relationship (60):

$$D = \frac{L^2}{7.2t_{1/2}} \tag{23}$$

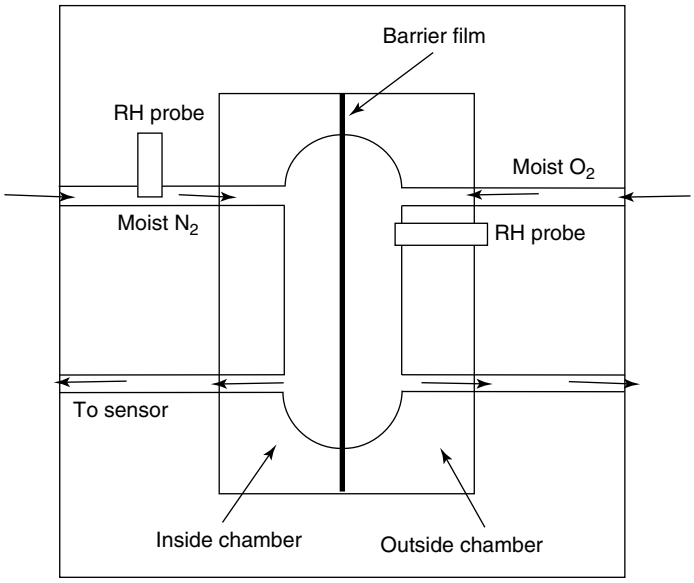

Fig. 15. A schematic of a permeation cell in the Ox-Tran (MOCON, Inc.) oxygen transmission rate measurement system (62).

where $t_{1/2}$ is the halftime (ie, time required for the penetrant flux to reach half of its steady-state value). Thus, permeability, diffusivity, and hence solubility ($S = P/D$) can be determined from a single experiment. Given the ready availability of computing power, it is now possible to use any of a variety of numerical techniques to fit the entire response and extract the desired parameters and, when applicable, their concentration dependence.

Oxygen and Carbon Dioxide Permeation. The most widely used commercial instrument for measuring oxygen transmission rates of flat films and packages is the Ox-Tran (Modern Controls Inc., Minneapolis, Minn.), and measurements are made in accordance with ASTM method D3985 (61). In this isostatic coulometric method, flat film samples are clamped into a diffusion cell, which is then purged of residual oxygen using an oxygen-free carrier gas such as N_2. The carrier gas is routed to the instrument sensor until a stable zero has been established. Pure oxygen is then introduced into the outside chamber of the diffusion cell (see Fig. 15) (62). Oxygen molecules diffusing through the film to the inside chamber are conveyed to the sensor by the carrier gas. The Ox-Tran system uses a patented coulometric sensor (Coulox) to detect oxygen transmission through both flat films and packages. This sensor provides parts-per-billion sensitivity to oxygen even in the presence of water vapor. Digital pressure and flow controls allow for RH control. Alternative instruments for measuring oxygen transmission rates include Oxygen Permeation Analyzers from Illinois Instruments Inc. (Ingleside, Ill.).

Modern Controls, Inc. (MOCON) also makes instruments for measuring carbon dioxide permeation. Their Permatran-C line of instruments uses an infrared detector to detect carbon dioxide that permeates through the test film.

Water Vapor Permeation. WVTRs can either be measured by the traditional gravimetric "cup" method (63) or by newer electronic instruments. The newer method (eg, ASTM method F1249 (64)) uses infrared detection to measure water vapor transmission through barrier films. One of the most widely used commercial WVTR systems is Permatran-W (Modern Controls Inc., Minneapolis, Minn.). The newest model of this system (Permatran-W 3/31) uses a patented modulated infrared sensor to detect water vapor transmission through flat films and packages. It provides a sensitivity in the range of parts per million. Various models are available with different temperature and RH capabilities.

Lyssy AG (Zollikon, Switzerland) also manufactures automatic water vapor permeability testers designated as the L80 line of instruments. The L80-5000 is the newest member and the fifth generation in this series.

In the traditional method (ASTM method E96) (27), a sample cell containing either a desiccant or distilled water is covered with the sample film and placed in a controlled atmosphere. Typical conditions for the desiccant method are 100°F (37.8°C) and an external RH of 90%, although the standard also allows for temperatures between 70 and 90°F (21 and 32°C) at (50 ± 2)% RH. The cell assembly is weighed periodically until steady state is reached. WVTR can be calculated from the steady-state rate of change in the weight of the cell.

Flavor and Aroma Compounds. Measurement of transport rates of flavor and aroma vapors in plastics is more complicated than that of either water vapor or light gases. Elaborate equipment and sensitive analytical devices are required to obtain reliable results. Since the transport behavior of these compounds is often strongly concentration dependent, measurements must be made in the activity range in which the compounds are present in practice. Thus, some of the major complexities include providing precisely mixed quantities of the condensable vapor in an inert carrier such as nitrogen or argon at very low concentrations, typically a few parts per million, and assuring that the concentration is maintained. Temperature must also be carefully controlled to prevent condensation on equipment surfaces (27).

As such, no single instrument has gained the widespread acceptance noted above for instruments for O_2, CO_2, and water vapor, though several methods have been used to measure transport properties of flavor and aroma compounds in barrier polymers. These include isostatic permeation techniques and gravimetric techniques (65). The permeation techniques directly yield permeability and diffusivity of flavors in barrier polymers. Solubility can then be calculated indirectly using the relation $P = D \times S$. The MAS 2000 Organic Vapor Permeation Test System (MAS Technologies Inc., Zumbrota, Minn.) is an example of a system that was commercially available for flavor permeation measurements. Mass spectrometry and flame ionization detection have also been successfully used as vapor concentration detectors (65). In contrast, gravimetric techniques permit direct and independent measurements of both solubility and diffusivity (66). It is possible to measure sorption and desorption of organic flavors in barrier polymers using sensitive gravimetric sorption instruments such as the McBain spring balance and the Rubotherm magnetic suspension balance (67–70). A schematic of a McBain spring balance assembly is shown in Figure 16. The polymer sample is suspended from a sensitive helical quartz spring inside the sorption chamber. After introducing the penetrant, the spring position relative to a fixed reference

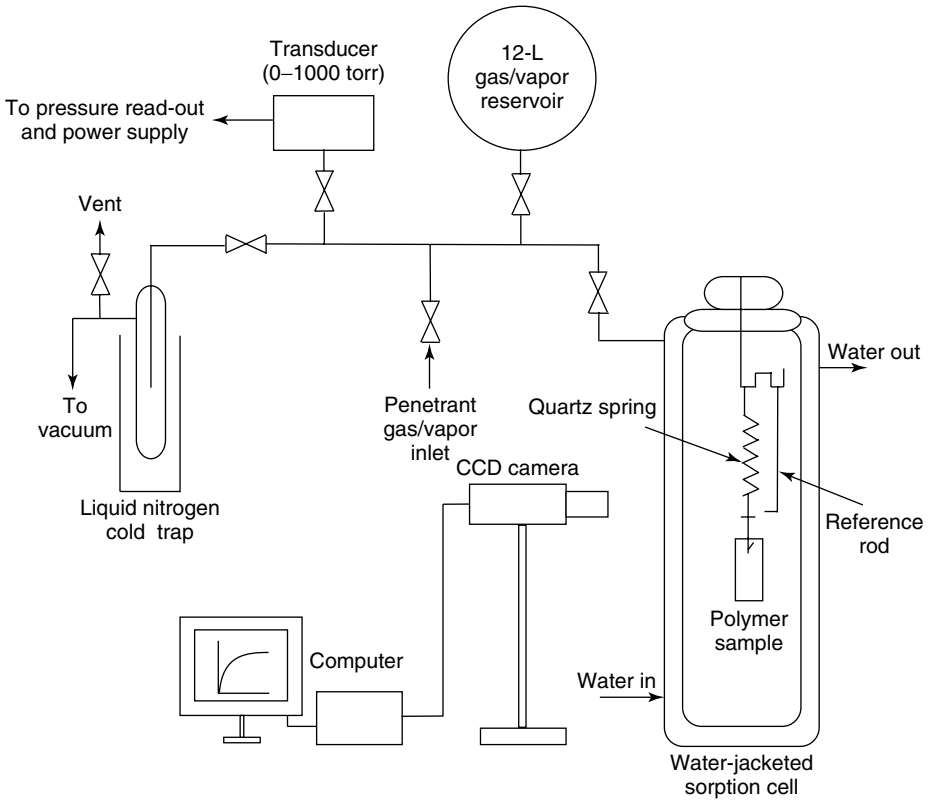

Fig. 16. A schematic of a McBain spring balance apparatus for measuring sorption and desorption of organic vapors in barrier polymers (66).

rod hanging inside the chamber is recorded using a CCD camera. From the kinetic uptake data, solubility and diffusivity values are estimated (71). Acceptable levels of agreement have been reported for solubility coefficients of ethyl acetate in LDPE, linear LDPE (LLDPE), and ionomer films obtained from gravimetric and isostatic permeation techniques (65).

Techniques for Predicting Transport Properties

Modeling Transport Properties of Gases and Condensable Vapors in Polymers. The permeation of low molecular weight gases such as O_2, N_2, CO_2 as well as large flavor and aroma compounds is an essential consideration in the selection and schematic of food packages and containers. Predictive models for permeation would minimize the number of experiments required in package material selection and development. Perhaps, more importantly, they also provide an insight into the underlying factors controlling permeation in barrier polymers.

The permachor method has been used to predict permeabilities of low molecular weight penetrants in barrier polymers (72). Although originally developed

for O_2, N_2, and CO_2, this method can be extended to other gases and vapors, provided there is no specific interaction between the penetrant and the polymer. It has been successfully used for over 60 different polymers (72). In this method, numerical values (ie, group contributions) are assigned to polymer segments. An average numerical value can then be obtained for the polymer, which is referred to as the permachor value of the polymer. A simple equation is used to relate gas permeability P to polymer permachor value π:

$$P = A\,\mathrm{e}^{-s\pi} \tag{24}$$

where A and s are temperature-dependent constants. This method also takes into account the reduction in permeability caused by the orientation of crystalline polymers using the following expressions:

$$P = \left(\frac{A}{\tau_0}\right) e^{-s\pi} \tag{25}$$

$$\tau_0 \approx \frac{1.13}{\sqrt{\phi_a}} \tag{26}$$

where τ_0 is tortuosity related to crystallite orientation and ϕ_a is the amorphous phase volume fraction. A good agreement has been reported between experimental and model predictions of O_2, N_2, and CO_2 permeability values in a variety of polymers (72). This method has also been modified for predicting liquid permeation through polymers (63). The permachor method works well for polymers and copolymers, but is not applicable to polymer blends (27). As with any group contribution method, caution should be exercised when attempting to perform predictions which are outside the data set used to generate the correlation.

Other methods for correlating gas permeability in barrier polymers with polymer molecular structure have been developed using free-volume theory (17,18,73). Group contribution techniques can be used to estimate polymer free volume from densities and intrinsic volumes of various polymer components. In the method proposed in Reference 18, polymer-specific free volume was used, which was defined as $(V-V_0)/M$, where V is specific volume, V_0 is specific occupied volume, and M is polymer molecular weight. V_0 can be calculated according to Bondi's method from van der Waals volumes of the various groups in the polymer structure (18). In this model, free volume was defined on a unit weight basis so that various molecular structures could be compared on the same weight basis. The model predicts a linear relationship between logarithm of gas permeability and the reciprocal of polymer-specific free volume. Other improvements to this model have been suggested (17,73). Gas permeability has often been correlated with FFV (as defined in eq. 6) using the following relation (73):

$$P = A\exp\left(\frac{-B}{\mathrm{FFV}}\right) \tag{27}$$

where A and B are constants for a particular gas. It has been observed that when this model is limited to a specific family of polymers, eg, polyesters and polyamides

(17), a reasonably good correlation can be obtained. However, when the correlation is broadened to include a wider range of polymer types, there is considerable scatter in the data, particularly at low values of gas permeabilities. Even though these free-volume-based models have some fundamental basis for correlating transport properties, they have the following limitations (18,73): (*1*) the assumption of solubility being independent of free volume and polymer structure is clearly an approximation, (*2*) the concept of free volume cannot capture all the factors affecting gas permeability (such as chain flexibility and CED), and (*3*) there may be errors in values of van der Waals volumes available in the literature. Attempts have been made to refine these models by introducing more empirical parameters and making them more predictive, and these efforts have resulted in significant improvements in the accuracy of the correlations (73).

Larger and more condensable penetrants, eg, flavor and aroma compounds, can have extremely low diffusion coefficients in common barrier polymers, resulting in extremely large time scales to achieve steady state. For example, *d*-limonene has diffusion coefficients of the order of 10^{-14} cm^2/s in PET (74). When coupled with a typical film thickness of 10 μm, this leads to time scale to reach steady state of more than 3 years. Hence, as noted before, over the shelf life of the packaged product (typically of the order of several months), flavor and aroma compounds may never reach steady-state transport. Therefore, independent predictions of their diffusion and solubility coefficients become necessary. Several methods have been proposed for predicting solubility coefficients. A widely used method is based on a thermodynamic approach that relates penetrant sorption to solubility parameters of the penetrant and the polymer (75). This dependence can be expressed as follows:

$$\begin{aligned} S &= S_0 \exp[(\Delta H_{vap} - \Delta H_{mix})/RT] \\ \Delta H_{mix} &= \nu_1 \phi_2 (\delta_1 - \delta_2)^2 \end{aligned} \tag{28}$$

where S_0 is a constant for a particular polymer, ν_1 is partial molar volume of the penetrant, ϕ_2 is volume fraction of polymer in the mixture, δ_1 and δ_2 are solubility parameters of penetrant and polymer respectively, and ΔH_{mix} is enthalpy change on mixing of penetrant molecules with polymer segments. The values of ν_1, δ_1, and δ_2 can be obtained from the literature (36). The enthalpy change on vaporization of the penetrant (ΔH_{vap}) can be calculated from the penetrant boiling point by using available correlations (2). Reasonably good agreements have been reported between model-predicted and experimentally observed solubility coefficients of several penetrants in vinylidene chloride–vinyl chloride copolymers and LDPE at 85 and 30°C respectively (76).

For penetrants that interact with the polymer matrix primarily via dispersion (ie, van der Waals) forces, penetrant solubility scales with measures of penetrant condensability such as penetrant boiling point, critical temperature, or the force constant in the Lennard–Jones potential model (43). The following relation between penetrant critical temperature and penetrant solubility has been derived using a classical thermodynamics model (13,77):

$$\ln S_a = N + MT_c \tag{29}$$

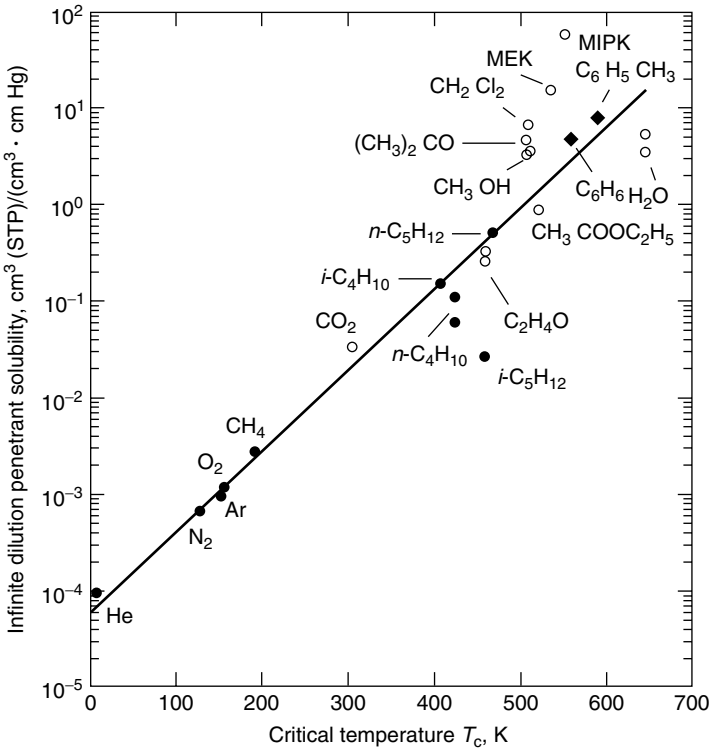

Fig. 17. Correlation of infinite dilution penetrant solubility with penetrant critical temperature in PET ((71) and unpublished data). ● Nonpolar penetrants, ○ polar and quadrupolar penetrants, ◇ aromatic penetrants. MEK is methyl ethyl ketone and MIPK is methyl isopropyl ketone. The slope $M = 0.019 \pm 0.001\ K^{-1}$ and intercept $N = -9.6 \pm 0.4$.

In this expression, N is a parameter that depends primarily on polymer–penetrant interactions and polymer free volume. T_c is the penetrant critical temperature, which is widely tabulated for many penetrants of interest (2). M is constant and has a value of approximately $0.016\ K^{-1}$ for gas dissolution in liquids and in rubbery and glassy polymers (13). While N varies from polymer to polymer, average values of -9.7 and -8.7 for rubbery and glassy polymers at 35°C, respectively, when solubility is expressed in $cm^3(STP)/(cm^3 \cdot cm\ Hg)$ have been recommended (13). Penetrants with strong dipole or quadrupole moments may be more soluble in a polar polymer matrix, such as PET, than predicted based on equation 29 (71). Although equation 29 is strictly valid for penetrant sorption in equilibrium matrixes, such as liquids or rubbery polymers, it also provides an excellent description of equilibrium solubility in glassy polymers (71). Figure 17 shows the correlation of penetrant solubility in PET with penetrant critical temperature (71). Nonpolar penetrants show excellent agreement with the model presented in equation 29 and polar or quadrupolar penetrants exhibit significant scatter around the correlation line.

Over wider ranges of critical temperature, it has been suggested that penetrant solubility coefficients may be better correlated with the square of reciprocal reduced temperature $(T_c/T)^2$ (78):

$$\ln S_a = n + m\left(\frac{T_c}{T}\right)^2 \tag{30}$$

where T is the temperature of the experiment, and m and n are the slope and intercept of the correlation line, respectively. This equation may also be derived from fundamental thermodynamic considerations (43). Other semiempirical methods, eg, UNIFAC group contribution model, have also been proposed for predicting penetrant solubility in polymers (79,80).

Several predictive and correlative methods have been developed for diffusion coefficients of penetrants in polymers. An empirical relationship has been developed for correlating diffusion coefficients with penetrant critical volume (81):

$$D_a = \frac{\tau}{V_c^{\eta}} \tag{31}$$

where D_a is amorphous phase diffusion coefficient, V_c is penetrant critical volume, and τ, η are adjustable constants. This equation has been proposed based on analogy with correlations of diffusion coefficients with critical volume of small molecules in liquids. For larger penetrants (eg, long-chain hydrocarbons), diffusion steps may occur via motion of only part of the molecule, and critical volume is not expected to capture the effective size of a penetrant unit participating in a diffusion step (43). In such cases, diffusion coefficients would be less sensitive to penetrant size than indicated in the above equation. Also, critical volume fails to capture the effect of penetrant shape on diffusion coefficients (71). Figure 18 shows a plot of D vs. V_c for PET at 25°C. Diffusion coefficients of penetrants (up to molecular weights of 100 Da) in PVC, PS (polystyrene), and PMMA [poly(methyl methacrylate)] have been correlated empirically with other measures of penetrant size, such as molecular diameter (82).

A theoretical model based on polymer free volume, temperature, and penetrant size and shape has been developed (83). According to this model, diffusion coefficients of large penetrants in amorphous rubbery polymers are given by

$$D = \frac{V_f^2}{6}\left(\frac{eRT}{M}\right)^{1/2}\left(\frac{1}{\ell_1 \mathrm{Ac}_1^2} + \frac{1}{\ell_2 \mathrm{Ac}_2^2} + \frac{1}{\ell_3 \mathrm{Ac}_3^2}\right)\exp\left(\frac{-E_D}{RT}\right) \tag{32}$$

where V_f is average free volume per polymer chain segment, e is the base of natural logarithm, M is penetrant molecular weight, ℓ_i is length of penetrant molecule along a given direction i (taken as the principal axis of inertia), Ac_i is effective penetrant molecular cross-sectional area perpendicular to the direction i, and E_D is the activation energy of diffusion. V_f can be calculated from the following equation (83):

$$V_f = V\left[0.025 + \alpha_f(T - T_{g2} + kw_1)\right] \tag{33}$$

where V is the total volume per mole of the polymer repeat unit, α_f is temperature coefficient of free-volume expansion, T_{g2} is glass-transition temperature of the polymer, k is plasticizing efficiency of the penetrant for the polymer, and w_1 is

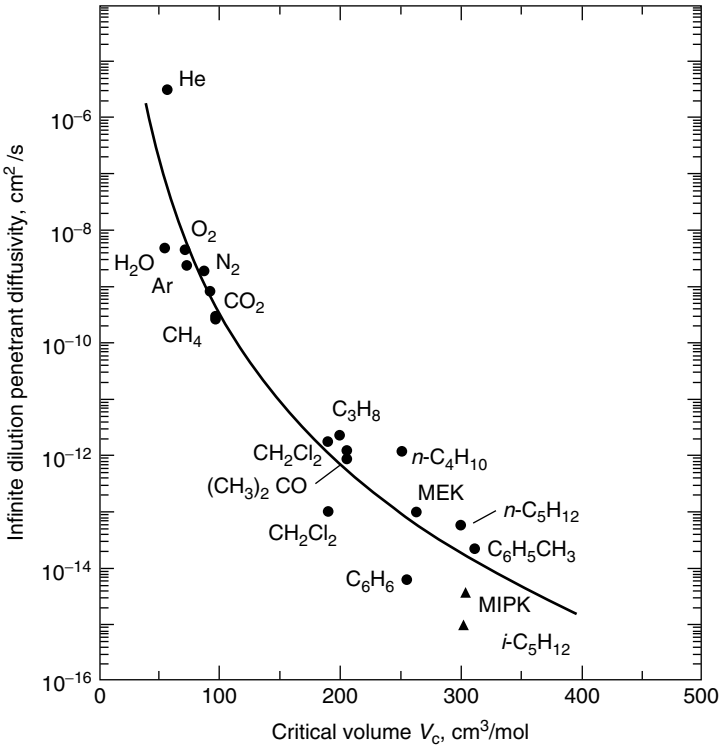

Fig. 18. Effect of penetrant size on infinite dilution, amorphous phase diffusion coefficients in PET at 25°C ((71) and unpublished data). ▲ Branched pentrants. MEK is methyl ethyl ketone and MIPK is methyl isopropyl ketone. The best-fit parameters of equation 31 are $\tau = (5.7 \pm 1.2) \times 10^8$ (cm^2/s) $(cm^3/mol)^{9.1}$ and $\eta = 9.1 \pm 0.9$.

weight fraction of the penetrant in the polymer. Equation 32 is strictly valid for large penetrants satisfying the size criterion $V_s \gg V_f$, where V_s is effective steric volume of the penetrant (83). The penetrant molecular shape dependence is represented by the three-termed expression within the parentheses of equation 32. The equation can be applied to penetrants of a wide variety of molecular shapes (83). This model has been tested using data for diffusion of plasticizers in PVC (83).

"Migration Modeling" of Polymer Additives into Packaged Foods and Beverages. One of the key applications of barrier polymers is food and beverage packaging. Several low molecular weight components, eg, monomers and oligomers, as well as additives such as lubricants, stabilizers, and plasticizers, which are necessary for processing and stability, can be present in polymers used for packaging. Hence, there exists a potential for permeation (or migration) of these additives into the food or beverage with subsequent contamination (84–86). To ensure the safety of packaged food components, the U.S. Food and Drug Administration (FDA) established a 'Threshold of Regulation' approach which sets upper limits on the additive concentrations in the food (84). Since traditional migration testing methods are time consuming, expensive, and the analysis can

be difficult (especially at low penetrant concentrations), the FDA has developed models for predicting the additive concentration in the food simulant and rate of transport of additives (84):

$$q = 2C_0\rho\sqrt{\frac{D_p t}{\pi}} \tag{34}$$

where q is total mass of permeating species per unit surface area, C_0 is initial additive concentration in the polymer, ρ is polymer density, D_p is additive diffusion coefficient, and t is the package shelf life. This equation assumes that (84) (*1*) permeation is diffusion-controlled and follows Fick's law, (*2*) no solubility-limited partitioning occurs between the polymer and the food, and (*3*) other external phase mass transfer resistances (eg, mixing, reaction with food) are negligible. The following empirical equation has been developed for predicting diffusion coefficients (84):

$$D_p = 10^4 \times \exp\left[A_p - a \times \mathrm{MW} - b\left(\frac{1}{T}\right)\right] \tag{35}$$

where D_p is additive diffusion coefficient (cm^2/s), A_p is constant for a particular polymer, MW is additive molecular weight (g/mol), and a, b are correlation constants with values of 0.01 mol/g and 10,450 K respectively. The A_p values are 9 for LDPE, −3 for PET, and 5 for HDPE and PP (84). A semiempirical model for predicting diffusion coefficients has also been developed (87):

$$\ln D_P = \ln A + \alpha\left(\mathrm{MW}\right)^{1/2} - \frac{K\left(\mathrm{MW}\right)^{1/3}}{T} \tag{36}$$

where A, α, and K are constants determined from experimental data. The diffusion coefficients follow Arrhenius-type behavior and are taken to be independent of penetrant concentration (84). These models do not explicitly account for the effect of polymer crystallinity or orientation on additive diffusion coefficients.

The approach of the European Commission (EC), on the other hand, has been to assign 'specific migration limits' to different substances with adverse toxicological properties (86). A Fickian diffusion-based model, called the Piringer migration model, which uses the 'Migratest Lite' program, has been used (85,86), and its mathematical form is given below:

$$M_t = C_0\rho L\left(\frac{\alpha}{1+\alpha}\right)\left[1 - \sum_{n=1}^{\infty} 2\alpha\left(1+\alpha\right)\left(1+\alpha+\alpha^2 q_n^2\right)\exp\left(\frac{-D_p t q_n^2}{L^2}\right)\right], \qquad \alpha = \frac{1}{K}\frac{V_F}{V_p},\ \tan q_n = -\alpha q_n \tag{37}$$

where L is film thickness, K is partition coefficient, and V_F and V_p are the volumes of food and polymer, respectively. The diffusion coefficient can be estimated from equation 35.

The sorption and transport of flavor and aroma compounds from the food simulant into the packaging walls can affect the migration of additives from the

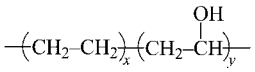
walls into the food simulant. Neither approach (FDA or EC) takes this effect into account. In general, these migration models provide conservative estimates (from a safety viewpoint) of additive concentrations in the food simulant and their diffusion coefficients. However, there are certain cases when they can fail (84) (eg, in cases where the flavor and aroma compounds from the food simulant plasticize the polymer, or if the additive reacts either with the polymer or with the food simulant to produce a species that is not detectable), and attempts are being made to improve them.

Chemical Structures and Properties of Barrier Polymers

Barrier polymers can be broadly classified as high barrier and moderate to low barrier polymers, depending on the degree to which they restrict the passage of gases such as O_2 or CO_2 and water vapor. The boundaries between these classifications, while somewhat arbitrary, are based on the effect of the barrier properties of the polymer on the shelf life of the packaged products. This section discusses various properties of different classes of barrier polymers. The selection of a barrier polymer for a particular packaging application depends not only on its barrier properties but also on other physical properties, and a comparison of physical, mechanical, and optical properties of some commonly used barrier polymers is, therefore, presented in Table 4 (88). Permeabilities of light gases (O_2 and CO_2) and water vapor are presented in Tables 5 and 6 respectively (27), and Table 7 presents permeability, diffusivity, and solubility of flavor and aroma compounds in various high and moderate barrier polymers (63). Permeability data of light gases and water vapor in barrier polymers (93–97) are more widely available than those of flavor and aroma compounds (98–100). Proper caution should be exercised when using or comparing data from different sources since, as discussed in the previous sections, polymer permeability values depend on a wide variety of factors.

High Barrier Polymers. High barrier polymers are generally understood to be those polymers which offer a high resistance to gas transmission. There are no specific limits for the gas transmission rates, but this category comprises polymers with gas permeabilities low enough to significantly prolong the shelf life of packaged products.

Ethylene–Vinyl Alcohol Copolymers. The general structure of ethylene–vinyl alcohol (EVOH) resins is as follows (101):



EVOH resins are random copolymers of ethylene and vinyl alcohol made by the hydrolysis of ethylene vinyl acetate copolymers (101). The leading manufacturers are Kurray (EVALCA) and Nippon Gohsei (57). In commercial grades of EVOH used in packaging, ethylene concentration ranges from 29 to 44 mol% (EVAL Co., U.S.). No additives are required in their processing as the presence of ethylene units renders the otherwise intractable vinyl alcohol melt processable in conventional molding and extrusion equipments. A high concentration of

ethylene is also recommended for thermoforming (102). At low to moderate RH, EVOH copolymers provide an excellent barrier to gases. The hydroxyl units (or OH groups) contribute strongly to increasing chain cohesive energy density and improving barrier properties, and so the greater the fraction of OH groups, the lower the permeability (103). Figure 19 shows the effect of ethylene concentration on oxygen and water vapor permeability of EVOH (27). This figure also presents permeation properties of poly(vinyl alcohol) (PVOH) [ie, fully hydrolyzed poly(vinyl acetate)] and HDPE (which has no OH groups) for comparison with the EVOH series (see VINYL ALCOHOL POLYMERS). As RH increases, the barrier properties of EVOH copolymers decrease (cf Fig. 13). The OH groups are also responsible for the hydrophilic nature of the polymer. Hence, the greater the percentage of vinyl alcohol units, the greater the influence of humidity on gas barrier properties of EVOH copolymers (27). Conversely, high proportions of ethylene units improve resistance to moisture (as shown in Fig. 13) and decrease the water vapor transmission rate, as shown in Figure 19. Moisture sensitivity can also be decreased somewhat by biaxial orientation (57). EVOH also offers very high barrier to flavor and aroma compounds and these barrier properties are not as sensitive to

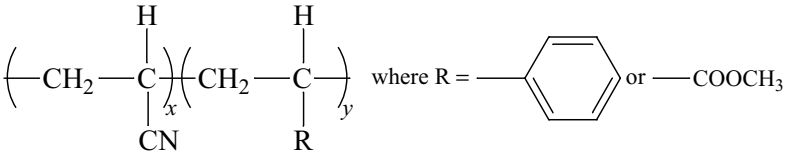
moisture as its oxygen barrier (57). In the majority of commercial applications, EVOH is used in a multilayer structure with moisture barrier and/or structural layers on each side, a typical example being multilayer bottles with polypropylene (PP) for ketchup (57). EVOH has also been used as a flavor barrier on the inside of PE-coated paperboard containers, a typical application being packaging of orange juice, where it minimizes the loss of limonene from the juice into the PE layer (57). EVOH is used as a barrier layer in many other rigid and flexible packaging applications.

Nitrile Polymers. The general structure of nitrile copolymers is shown below (101):



Application of PAN in packaging started in the 1960s. Despite processing difficulties, PAN was used because of its excellent barrier properties. A group of copolymers were developed in the 1970s. Comonomers are methyl acrylate and styrene at concentration up to 20 mol% (103). They are efficient oxygen barriers and have high grease and oil resistance, strength, and stiffness. Lopac (Monsanto Co.), Barex (Sohio), and Cycopac (Borg-Warner Chemicals) are three

[c] At 25°C; values are not expected to show any significant variations with RH (92).

commercial nitrile copolymers that have been used in packaging applications. Their compositions are shown in Table 8. Barex and Cycopac are rubber-modified for improved mechanical properties, and the barrier properties of these copolymers are relatively insensitive to moisture. Concerns about the possible migration of

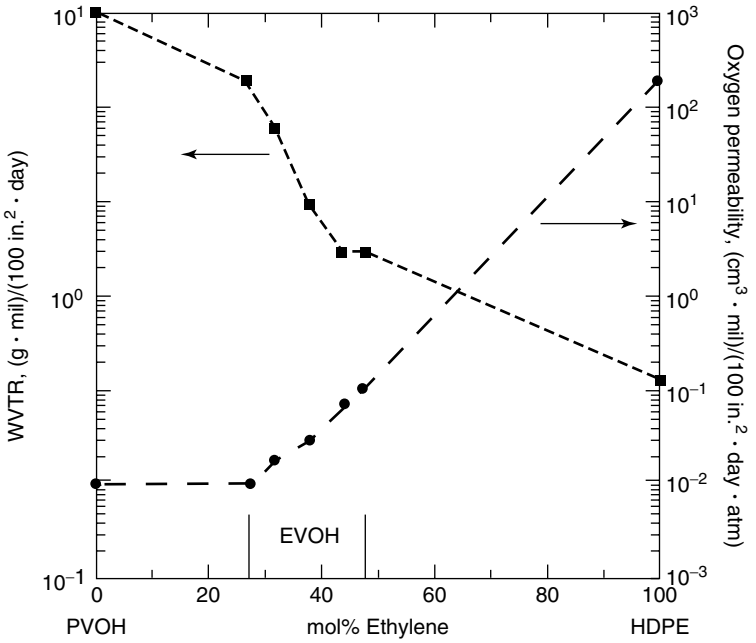

Fig. 19. Effect of ethylene content on oxygen permeability (20–23°C, 65% RH) and WVTR (40°C) of EVOH. The figure also shows data for PVOH and HDPE for comparison (27).

acrylonitrile monomer, a toxic compound (57), have limited the use of nitrile polymers in food contact applications (see ACRYLONITRILE AND ACRYLONITRILE POLYMERS).

Vinylidene Chloride Copolymers. Copolymers of VDC with vinyl chloride and acrylonitrile were among the first high barrier polymers to be widely used. During their commercial appearance in the late 1930s, they had the lowest permeabilities among plastics to gases and water vapor (103). Poly(vinylidene chloride) (PVDC) homopolymer is soluble only in hot dichlorobenzene (among common solvents) and has a melting point only a few degrees below its decomposition temperature (103). These characteristics make it difficult to fabricate by melt-processing

Table 8. Compositions of Commercial, High Barrier Nitrile Copolymers[a]

Polymer	Manufacturer[b]	Chemical composition[c]
Lopac	Monsanto Co.	70% acrylonitrile + 30% styrene
Barex	Sohio	74% acrylonitrile + 26% methyl methacrylate + 10% butadiene graft rubber

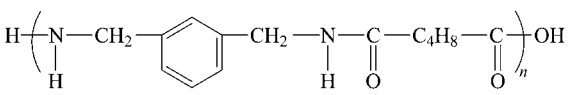
[b]Manufacture are listed from Ref. 63. However, these copolymers are now manufactured by BP Amoco Chemicals.
[c]Data from FDA regulations for corresponding materials.

techniques. Copolymers were synthesized to overcome these drawbacks. Acrylates were found to be among the most useful comonomers, along with vinyl chloride and acrylonitrile (103). By adding comonomers, the melting point can be decreased to a range of 140–175°C (as compared to 198–205°C for PVDC), thus making melt processing feasible (104). These copolymers are semicrystalline and soluble in only a limited range of solvents. The most notable attributes of VDC copolymers are their chemical resistance and extremely low permeabilities to gases and water vapor (cf Tables 5 and 6). The structure of the most widely used vinylidene chloride–vinyl chloride copolymer is shown below:

where x is 85–90 mol% (103). VDC copolymers are commercially available under a variety of trade names such as Saran (The Dow Chemical Co.), Daran (W. R. Grace), Amsco Res (Union Oil), and Serfene (Rohm and Haas) within the United States; Haloflex (Neoresins), Diofan (Solvin), Ixan (Solvin), and Polyidene (Scott-Bader) in Europe (see VINYLIDENE CHLORIDE POLYMERS). Copolymers are available in the following forms (103): (*1*) lattices of approx. 1000–1500 Å which can be applied as coatings to paper and plastic films to improve their barrier properties, (*2*) soluble resins for coating plastic films (especially cellophane) to improve their barrier properties, (*3*) melt-processable resins for extrusion, coextrusion, and molding, and (*4*) clear, transparent films for commercial packaging applications. Small amounts of processing aids and heat stabilizers are added to extrusion and molding resins.

Polyamides. The standard semicrystalline polyamides (PA) (nylon-6, nylon-6,6, etc) used in packaging have medium gas barrier properties, and their barrier properties are affected by humidity (101). However, specialty grades of polyamides with higher gas barrier properties are available. Commercial grades of Selar amorphous polyamides (AmPA) (E. I. du Pont de Nemours & Co., Wilmington, Del.), for example, exhibit good O_2 barrier and reduced dependence of gas barrier properties on RH. In fact, their gas barrier properties improve with increasing RH (cf Fig. 13). At an RH of 80% or more, their O_2 barrier is similar to that of PAN (102). Moreover, at 95–100% RH, the O_2 barrier is equivalent to that of EVOH at similar conditions, and substantially better than that of nylon-6. The amorphous nature of Selar results in a much broader range of processing conditions than those of semicrystalline nylon-6 (105). The mechanical and barrier properties of AmPA can be improved by orientation (see POLYAMIDES, PLASTICS; POLYAMIDES, AROMATIC).

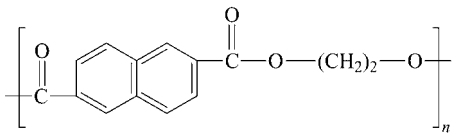
Another high barrier polyamide is MXD-6 resin (Mitsubishi Gas and Chemical Co., and Toyobo, Japan), which was developed in the 1970s. It is made from the reaction of *m*-xylylenediamine and adipic acid (57):



It provides improved clarity, mechanical, thermal, and barrier properties relative to standard nylons. It has better gas barrier properties than nylon-6 and PET at all humidities, and is better than EVOH at 100% RH. The barrier properties of MXD-6 are relatively unaffected by moisture up to an RH of 70% (57). Because of its cost and the lack of a domestic source, MXD-6 has found limited applications in the United States. It has a much wider market in Japan, appearing in commercial applications such as nonpasteurized plastic beer bottles and carbonated soft drink bottles (57).

Polyesters. The most widely used member of the polyester family for food and beverage packaging applications is PET (see POLYESTERS, THERMOPLASTIC). However, PET offers a moderate barrier to gases and water vapor. Poly(ethylene naphthalate) (PEN) offers a much higher barrier to gases and water vapor than PET and can be classified as a high barrier polyester.

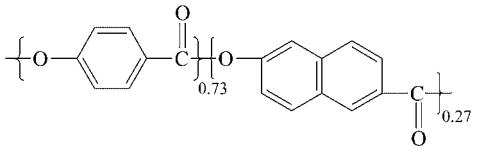
PEN is a homopolymer of dimethyl-2,6-naphthalene dicarboxylate (NDC) and ethylene glycol (106):



The rigid double-ring structure in the polymer backbone results in increased mechanical strength, heat stability, and barrier properties as compared to PET. As with PET, orientation produces a substantial reduction in gas permeability, and the oxygen permeability of oriented PEN is a factor of 5 lower than that of oriented PET (57). Teijin (Japan) and ICI (U.K.) have been the leaders in manufacturing PEN films. Teijin manufactures both resin and films, the latter under the trade name Teonex. Since 1990, DuPont and Teijin have had a worldwide joint venture in polyester films, including PEN. DuPont has also acquired ICI's Melinex PET film and Kaladex PEN film operations. The main disadvantages of PEN are its high cost, and unsettled sources of monomer technology and supply (57). One of the leading manufacturers of NDC, BP Amoco Chemicals (Decatur, Ala.) has developed a technology that uses *o*-xylene rather than naphthalene as the feedstock, which could reduce the manufacturing cost of PEN resin (57). Other newer NDC technologies from Kobe Steel (Japan) and Mobil Chemicals could also lead to reduced cost for PEN. Another way of addressing the price issue is by using blends or copolymers of PEN with PET. Gas and vapor permeability has been found to decrease continually as PEN is added to PET (107,108).

Liquid Crystalline Polymers. Liquid crystalline polymers, main-chain (qv) (LCPs) offer excellent thermal and chemical resistance, and exhibit very high barrier properties that are almost unmatched by existing barrier polymers (16,109,110). They also offer adequate mechanical properties for certain packaging applications (111). LCPs are very efficiently packed, highly oriented, and often semicrystalline materials. Commercially available LCPs such as Vectra (Celanese AG), Zenite (E. I. du Pont de Nemours & Co.), and Xydar (Solvay Advanced

Polymers, Alpharetta, Ga.) are aromatic copolyesters that have a significantly higher degree of chain orientation than typical polyesters such as PET (111).



Structure of Vectra

LCPs of this kind were first introduced to the market in the 1980s. Table 9 shows a comparison of properties of biaxially oriented LCP films with those of PET films (112). Figure 20 compares barrier properties of LCPs with other barrier polymers. LCPs offer the best combination of water vapor and O_2 barrier properties among all known classes of polymers. They also offer excellent barrier to CO_2, N_2, and other gases and vapors (111). However, commercial applications of LCPs have been limited primarily because of their high cost, lack of transparency, and processing characteristics (111). One key to unlocking the potential of LCPs in barrier packaging is to be able to process thin uniform layers in coextruded multilayer structures. Recently, three-layered structures (PET–tie layer–LCP) have been coextruded (Superex Polymer, Inc., Waltham, Mass.) with a total thickness of 25–50 μm and 10–30% LCP layer thickness. This multilayer film is claimed to offer a high performance–cost ratio (111).

Poly(hydroxy amino ethers). Poly(hydroxy amino ethers) (PHAE) are a new family of high barrier epoxy-based thermoplastics. The general chemical structure of amide-containing PHAE, which are formed by the reaction of

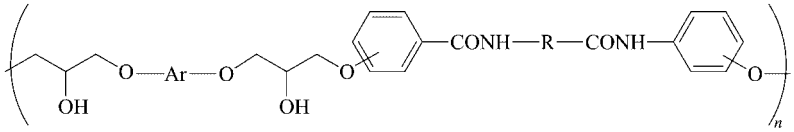
amide-containing bisphenols with aromatic diglycidyl ethers (113), is shown below:



where R can be $-(CH_2)_n-$ ($n = 1, 2, 3\ldots$) or an aromatic group, and Ar designates an aromatic moiety.

These polymers are amorphous, with T_g values ranging from 90 to 133°C. They incorporate both amide and hydroxyl moieties on the chain backbone. In order to prevent cross-linking, the hydroxyl groups are generated during the polymerization of preferred amide-containing monomers (113). The presence of aromatic groups between the amide groups in the polymer backbone can result in high T_g and good barrier properties. It has also been observed that the presence of *m*-phenylene units instead of *p*-phenylene units can reduce O_2 permeabilities (as much as 30–40%) by increasing the chain packing efficiency of the polymer (113). This phenomenon is, in fact, rather general among aromatic polymers. Often, meta-linked aromatic rings in polymer backbones have lower permeability coefficients than their para-linked analogues (114,115). Lower O_2 permeabilities can also be obtained when hydrogen bonding interactions in the polymer backbone are increased either by reducing the number of nonpolar methylene units or by increasing the population density of polar amide groups (113). Unlike other hydroxyl-containing polymers such as EVOH, the barrier properties

of amide-containing PHAE improve with increasing RH (19,113). For example, a decrease in O_2 permeability from 1.4 (cm^3·mil)/(100 $in.^2$·day·atm) at 5% RH to 0.8 (cm^3·mil)/(100 $in.^2$·day·atm) at 75–80% RH has been reported. On the basis of preliminary work involving density and pals studies, it has been postulated that water molecules not only occupy free-volume elements in these materials but also enhance interchain cohesion, thus inhibiting the transport of other nonpolar gases (116).

A series of polymers from the PHAE family has recently been commercialized by Dow Chemical Co. (Midland, Mich.) under the trade name BLOX Adhesive and Barrier Resins (90,117). They offer high gas barrier properties, excellent adhesion to a variety of substrates, high optical clarity, and good mechanical properties. For example, BLOX 4000 series resins exhibit an oxygen transmission rate of 0.1 (cm^3·mil)/(100 $in.^2$·day·atm) at 23°C and 60% RH (90). The BLOX resins have found some commercial applications in barrier packaging, starch-based foam packaging, and powder coatings (117).

Polychlorotrifluoroethylene. Polychlorotrifluoroethylene (PCTFE) is a flexible thermoplastic made from fluorinated–chlorinated resins. It was first discovered in the 1950s and has been commercially produced since the 1960s (118). Its chemical structure is as shown below:

$$-\left(\mathrm{CFCl}-\mathrm{CF_2}\right)_n-$$

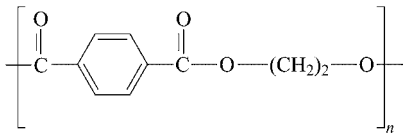
The key characteristics of this polymer are its high optical clarity and excellent moisture barrier properties (118). In commercial Aclar resins (Honeywell, Morristown, N.J.), the polymer is generally modified by copolymerization, resulting in a semicrystalline material with T_g of about 45°C and melting point of about 190°C (104). It shows excellent thermal and chemical stability, and high water vapor and O_2 barrier properties (120) (cf Tables 5 and 6). For example, Aclar films typically have water vapor transmission rates less than 0.04 (g·mil)/(100 in^2·day) (23°C) and oxygen transmission rates less than 14 (cm^3·mil)/(100 in^2·day) (25°C) (119). PCTFE is most widely used for producing blister packs in pharmaceutical applications (118). The moisture barrier properties can be tailored by varying the PCTFE layer thickness in coextruded multilayer structures, thereby adjusting the performance-to-cost ratio. An example of a commercial coextruded structure is Aclar NT AE-1 (Honeywell, Morristown, N.J.), which is 33 μm thick, and contains about 8.4 μm of PCTFE (118). PCTFE can also be laminated with PP, PAN, PET, HDPE, LDPE, and PVC and then formed into blister packs. Other applications of the same technology include electronic component packaging where lower moisture barrier may be acceptable, resulting in more favorable economics (118).

Moderate Barrier Polymers. Polymers in this category include polyesters, polyolefins, poly(vinyl chloride), polystyrene, and certain semicrystalline polyamides. The polymers included in this section are typically more widely available, have more manufacturers, and are less expensive than the specialty barrier resins described in the previous section.

Polyesters. Polyesters represent a class of versatile barrier plastics. PET is by far the most important member in this family from a commercial

viewpoint. It is extensively used in the food and beverage packaging industries and is especially known for its widespread use in bottles for carbonated beverages (120) (see POLYESTERS, THERMOPLASTIC). The other members in this category are poly(trimethylene terephthalate) (qv) (PTT) and Polylactide (PLA).

Poly(ethylene terephthalate). PET is a linear thermoplastic made from ethylene glycol and terephthalic acid, or ethylene glycol and dimethyl terephthalate (101). The structure of PET is shown below:

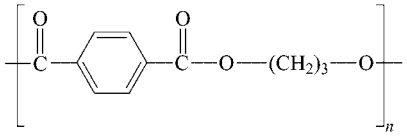


PET is used in many rigid food and beverage containers because of a good balance of physical and mechanical properties, barrier properties, processibility and formability, ecological and toxicological characteristics, and economics (121). As a result, PET bottles have virtually replaced glass packages for carbonated soft drinks in the United States. In the glassy state, it is strong, stiff, ductile, and tough. It can be oriented by stretching during molding and extrusion, which further increases its strength, stiffness, and barrier properties. One of the early drawbacks of PET was its low heat distortion temperature of 60°C (140°F), which prevented it from being used in applications requiring filling at elevated temperatures (121). However, careful heat-treatment increases the heat distortion temperature of crystalline PET containers and recently commercialized processes claim resistance to temperatures of up to 90–92°C (194–196°F) (121). It has moderate barrier properties for light gases, but is a good barrier for flavors and aroma compounds. Its barrier properties can be improved by increasing crystallinity and orientation (121). A 4× biaxial orientation of amorphous PET at temperatures near 100°C produces significant strain-induced crystallization and decreases the permeability of O_2 and CO_2 by a factor of about 2 (71).

Oriented and heat-set PET films have also found use in a broad range of flexible packaging applications because of their high strength, good barrier, high clarity, heat resistance, and good metalizability. There are more than 50 specific application areas for PET films (122). Manufacturers have met the product requirements of each of the diverse end-use markets by tailoring formulations and process conditions. For example, in the food and beverage packaging industries, many types of PET films have been developed, including metallized PET films for packaging of coffee, wine, and meats, poly(vinylidene chloride)-coated PET films for meat and cheese packaging, and coextruded multilayer PET films for heat-sealable packaging (122). Commercial manufacturers of PET films include DuPont Teijin Films (Mylar, Melinex, Tetoron) and Mitsubishi Polyester Film, LLC. (Diafoil, Hostaphan).

Poly(trimethylene terephthalate). PTT is made from the polycondensation reaction of trimethylene glycol (also called 3G) with either terephthalic acid or dimethyl terephthalate (57). Although this polymer was first synthesized in 1941, it was never commercialized because of lack of an economical source of 3G. In the

early 1990s, Shell Chemical Co. announced a catalyst breakthrough to make 3G economically by hydroformylation of ethylene oxide (57).

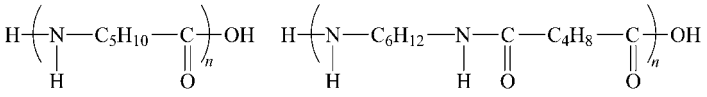


PTT is an engineering resin and has been targeted mainly toward injection-molding applications. However, there have been claims about its barrier properties (57), and it is therefore included in this article for completeness.

Because of the presence of an odd number of methylene units in the chain backbone, PTT has physical properties different from PET (57). Its O_2 permeability is about 6 $(cm^3 \cdot mil)/(100\ in.^2 \cdot day \cdot atm)$ at 0% RH, and moisture absorption rate is typically 0.03% after 24 h and 0.15% after 14 days (57). Typical properties of PTT are as follows: it has a melting point of 228°C, a T_g of 45–65°C, and can be produced with crystallinity values up to 45 wt%.

Polylactide. Polylactide (PLA) is a semicrystalline, linear thermoplastic made from lactic acid, especially as derived from corn (maize). Polylactide (qv) is new to the commercial market (123). Its applications are still being explored. However, its barrier is adequate for some food packaging uses, especially for management of flavor and aroma profiles. It can be heat sealed and thermoformed. It has a glass-transition temperature of 55–65°C. The principal manufacturer of PLA is Cargil Dow, LLC (NatureWorks).

Polyamides. This category of moderate barrier polymers includes nylon-6 and nylon-6,6. Nylon-6 is made by the polymerization of caprolactam, and nylon-6,6 is made by the reaction of hexamethylenediamine and adipic acid (101). Their chemical structures are shown below:



Nylon-6 Nylon-6,6

In general, nylons have good gas and aroma barrier properties, but poor moisture barrier properties (57) (cf Tables 5 and 6). Absorbed water has a plasticizing effect that leads to a reduction in tensile strength and increase in impact strength. Uniaxial and biaxial orientations can improve their flex-crack resistance, mechanical, and barrier properties (101). Biaxially oriented nylons offer better gas barrier properties, softness, and puncture resistance, compared to oriented PET, which offers better rigidity and moisture barrier properties (101). Nylons are less widely used in the packaging industry than polyolefins or PET, with the majority of the applications being blow-molded bottles (coextrusion and blending of nylon-6 with PE), for industrial and household chemical markets (57).

Polyolefins. PE and PP are two of the most widely used polymers in the food and beverage packaging industry. These polymers find use as films, moldings, coatings, adhesives, and closures (124). They are available in a wide variety of

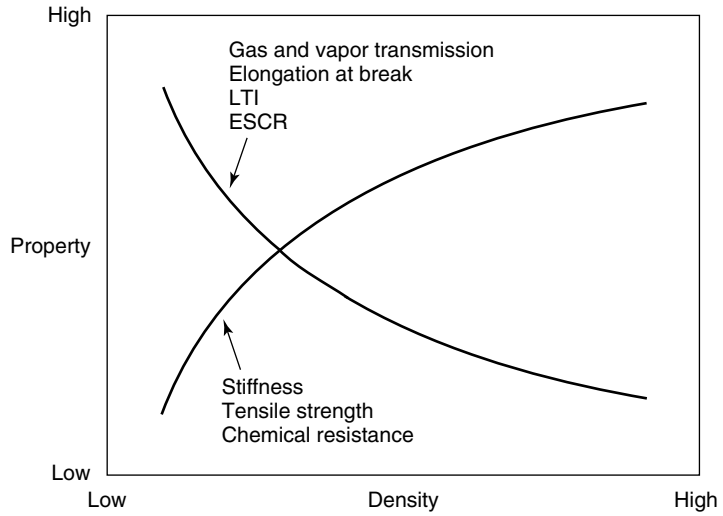


Fig. 21. Typical effect of density on various properties of PE. LTI is low temperature impact strength and ESCR is environmental stress-crack resistance (124).

types and grades. Although they have much higher permeabilities to gases than many other barrier polymers, they are very good moisture barriers (cf Tables 5 and 6).

PE, whose structure is shown below, was one of the first olefinic polymers to be used commercially in the packaging industry:

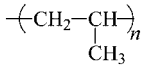
$$-\left(CH_2-CH_2\right)_n-$$

It is classified on the basis of density (see ETHYLENE POLYMERS, HDPE; ETHYLENE POLYMERS, LDPE; ETHYLENE POLYMERS, LLDPE; ETHYLENE POLYMERS, VLDPE). Figure 21 shows the effect of density on various properties of PE (124). A branched structure for low density PE (LDPE) results from exceptionally high temperature and pressure during its manufacture. It is tough, flexible, can be easily melt processed, and has good moisture barrier properties. It is a semicrystalline polymer with crystallinity typically in the range of 40%. Medium density PE (MDPE) is stronger, stiffer, and has better barrier properties than LDPE. High density PE (HDPE) is essentially unbranched and is the strongest and most rigid polymer in this family. It offers barrier properties to moisture and gases that are superior to those of LDPE and MDPE.

If unsaturated comonomers such as butene, hexene, or octene are added to the HDPE polymerization process in the presence of a stereospecific catalyst, it results in the formation of a linear polymer with short branch-like pendant groups (104). Its density is in the same range as LDPE, but the degree of branching is greatly reduced. This polymer is called linear LDPE (LLDPE) and its density depends on the amount of comonomer added. The larger the amount of the comonomer, the lower the density of the copolymer (104). LLDPE combines the

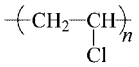
clarity and excellent heat-seal properties of LDPE with the strength and toughness of HDPE. It is often blended with LDPE in order to optimize the benefit obtained from both materials (104).

PP, whose chemical structure is shown below, can be made by the catalytic polymerization of propylene at high temperature and pressure (124):



Isotactic PP (with all methyl groups on same side of the polymer chain) is the commercially desired form for packaging applications (124) (see PROPYLENE POLYMERS (PP)). The concentration of atactic PP (with irregular arrangement of methyl groups) is kept low by suitable catalysts and polymerization conditions (124). PP offers high resistance to water vapor permeation and is widely used in rigid as well as flexible food packaging applications. PP films can be oriented, which improves their barrier properties, mechanical strength, and optical properties. For example, oriented PP has about three times higher resistance to water vapor transmission than unoriented PP (27). These properties can be varied over a wide range by the choice of the manufacturing process.

Poly(vinyl chloride). Poly(vinyl chloride), also known as vinyl or PVC, is made by low pressure free-radical polymerization of vinyl chloride at temperatures in the 38–71°C range (101). Its chemical structure is shown below:



PVC is a versatile polymer that can be formulated to meet the requirements of many applications in packaging and other industries (88) (see VINYL CHLORIDE POLYMERS). Its properties can be tuned over a very wide range by incorporating comonomers, plasticizers, and other additives. When used as a rigid sheet or bottle, little modification is required, but PVC requires the addition of plasticizers to make it useful as a barrier film for flexible packaging (88). The plasticizers increase chain flexibility and reduce the processing temperature of PVC. For example, addition of 40 vol% dioctyl phthalate plasticizer reduces the T_g of PVC from 100°C to about 5°C (125). The increase in chain flexibility of plasticized PVC also results in a reduction in its gas barrier properties primarily as a result of higher diffusion coefficients in plasticized films. Figure 22 presents a comparison of diffusion coefficients of several penetrants in plasticized and unplasticized PVC films (126) (see PLASTICIZERS).

PVC has some drawbacks as a food-packaging material (88): Vinyl chloride monomer is an animal carcinogen and causes liver cancer in humans. Thus the amount of monomer in the finished polymer should be brought down to 1 ppm or less. There is concern about the toxicity of plasticizers and other additives used in PVC. Moreover, there have also been concerns that incineration of chlorine-containing plastics can possibly lead to the formation of dioxin, a chlorinated toxic molecule. Finally, the release of plasticizers over long periods of time can lead to gradual embrittlement of PVC films. However, none of these drawbacks significantly affect the functionality of PVC and it is used to make flexible films,

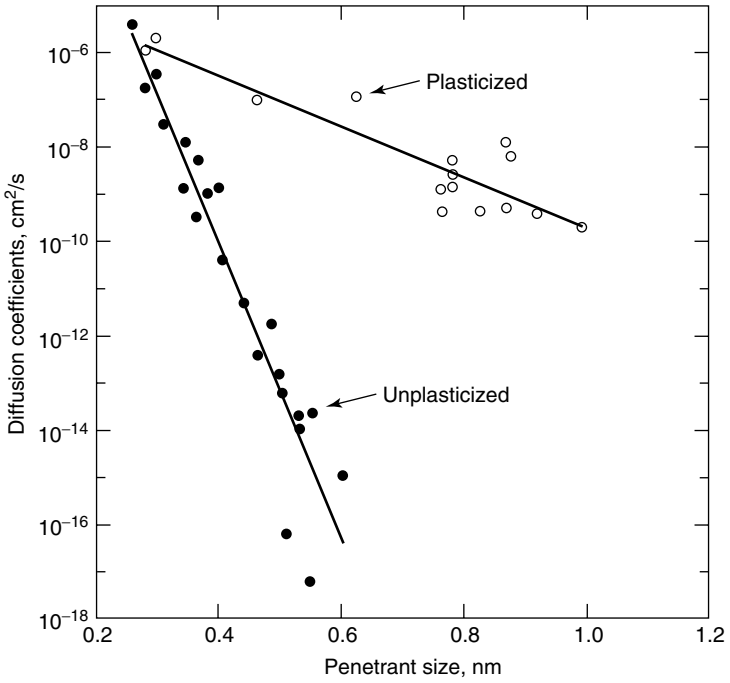


Fig. 22. Diffusion coefficients in unplasticized and plasticized PVC at 30°C as a function of penetrant molecular diameter (126).

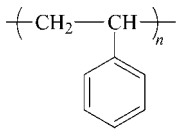
rigid sheets, and bottles for a variety of food (eg, fresh fruits, vegetables, and poultry packaging in the United States) and nonfood packaging applications (104).

Polystyrene. Polystyrene (PS) is made by the peroxide-catalyzed bulk or suspension polymerization of styrene (101) (see STYRENE POLYMERS). The polymerization reaction takes place at low pressure and temperature in the range of 250–400°F, and the polymer chemical structure is given by



Polymer molecular weight, which affects the processing characteristics of the resin, is often in the range of 40,000–220,000; variations in molecular weight can be obtained by changing the catalysts and polymerization conditions. PS is an amorphous, clear, hard, brittle, low-strength material with poor impact resistance (101). It has low to moderate moisture and gas barrier properties (88). Copolymerization with butadiene or other rubbers increases its impact strength and decreases stiffness (88). This copolymer is commonly referred to as high impact polystyrene (HIPS). Comonomers such as α-methyl styrene can improve the heat resistance of PS by increasing the heat distortion temperature to 100°C or

higher (88). PS can be foamed by adding foaming agents such as pentane to the reaction mixture during the suspension polymerization. This so-called expanded polystyrene (EPS) is a very low density, yet highly rigid material that is used for making egg cartons, and trays for meat, poultry, and other products (88). However, EPS has poor gas barrier properties.

Improving Barrier Properties of Polymers

Barrier Structures. As mentioned in the previous sections, the principal application of barrier polymers is in the food and beverage packaging industries. Combining two or more polymers, or other materials, can achieve performance advantages not available in any of the materials taken alone. In many cases, to achieve better barrier performance, it is more efficient and economical to use a thin layer of an expensive high barrier polymer (eg, EVOH) sandwiched between layers of less expensive, moderate barrier, structural polymers (eg, PP, PET) than to increase the monolayer thickness of the moderate barrier polymer. Multilayer structures can be obtained by coextrusion, lamination, and coating. Barrier polymers may also be combined to form miscible and immiscible blends.

Multilayer Structures. Steady-state barrier properties of multilayer films can be described by their permeability, which can be calculated by treating the individual layers as resistances in series (63):

$$\frac{1}{P'} = \frac{L_t}{P_t} = \frac{L_1}{P_1} + \frac{L_2}{P_2} + \cdots + \frac{L_n}{P_n} \tag{38}$$

where P_t, L_t, and P' are permeability, thickness, and permeance of the composite structure, and P_1, P_2, ..., P_n and L_1, L_2, ..., L_n are the permeabilities and thicknesses of the individual layers. The permeability P_t (or permeance P') can be used to evaluate the performance of the composite structure for packaging applications. Figure 23 illustrates the effect of barrier layer thickness on permeability of a hypothetical two-layer sheet, the permeability of the barrier layer being 0.1 (cm^3·mil)/(100 $in.^2$·day·atm) and that of the nonbarrier layer being 100 (cm^3·mil)/(100 $in.^2$·day·atm). For moisture-sensitive polymers (eg, EVOH or nylon), it is important to use the permeability that corresponds to the effective RH that the layer will experience in the composite structure.

Coextrusion (qv) is one of the most cost-effective techniques for producing multilayer barrier polymer films (127). Although coextruded films typically have 3–7 layers, as many as 11 layers can be extruded simultaneously (128). This technique allows for the thinnest possible layers of the individual polymer resins within the structure. Resins that do not bond well can be bonded together with an adhesive 'tie' layer (128). The materials must be compatible in terms of their melt temperatures and viscosities in order to undergo simultaneous coextrusion. Figure 24 presents a comparison of processing temperatures of various commonly used barrier polymers (129). Figure 25 shows a schematic of a typical 9-layer coextruded structure. A coextrusion line will have several different extruders, each extruder responsible for supplying individual polymer resins (127).

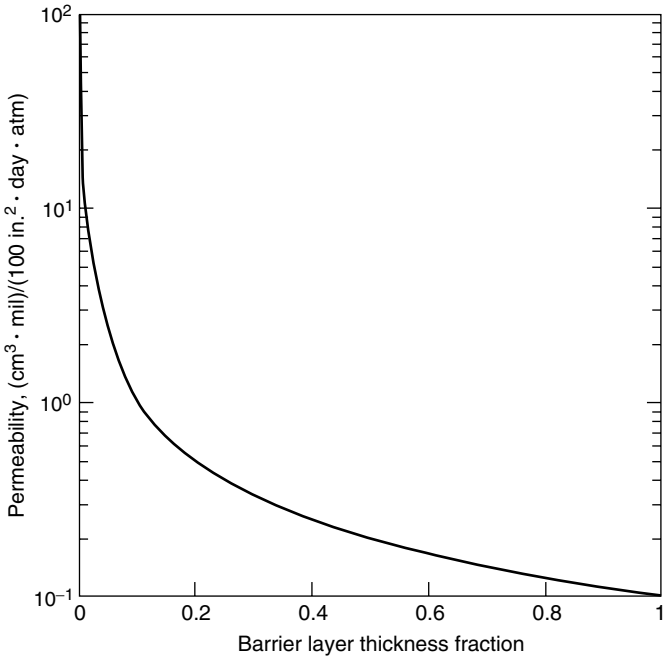


Fig. 23. Effect of thickness of barrier layer on permeability of a hypothetical two-layer barrier composite structure.

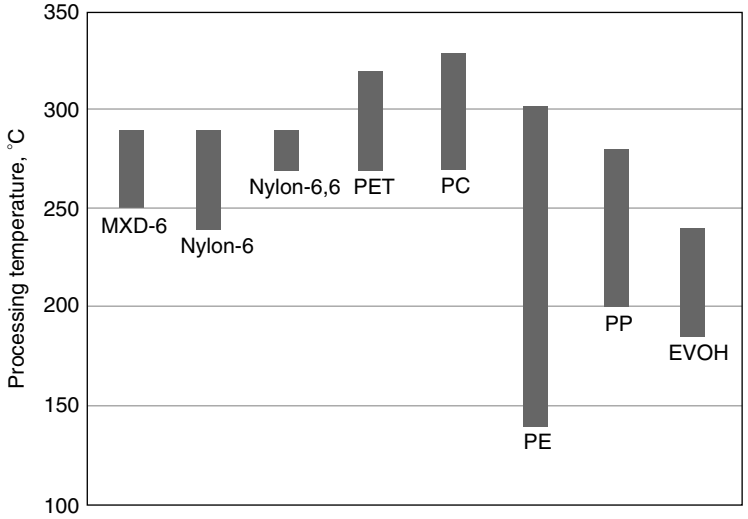

Fig. 24. A comparison of processing temperatures of various commercially used barrier polymers (129).

Coating and lamination are two additional processes for producing multilayer structures and are especially useful in applications where a nonpolymeric material is part of the structure. Coatings can be melt extrusions of a polymer onto a base film or can be made by applying solutions or dispersions of polymers to the

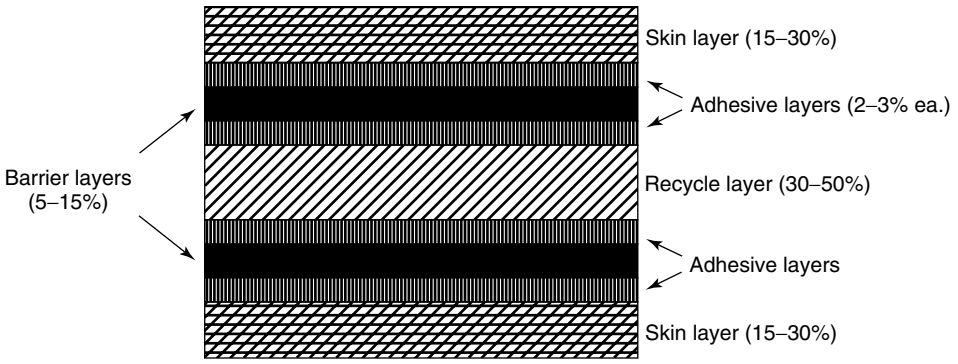

Fig. 25. An example of a typical symmetrical nine-layer coextruded barrier composite structure (128).

base film (128). Barrier polymers that resist water vapor and provide gas barrier are often laminated to paper and paperboard. Cellophane, a flexible transparent gas barrier polymer, can also be made 'moisture-proof' by coating or laminating with other polymer films (27). A commercial application of solvent coating with barrier polymers is VDC resin dissolved in a polar solvent and coated onto cellophane or PET (63). Water-based emulsion coatings of VDC are used for plastic PET beer bottles, primarily in the United Kingdom. They can typically lower O_2 permeability of PET bottles by nearly 60% (57). Several companies produce PVDC emulsions for coating films such as nylon, PE, PP, and PET to improve their O_2 and moisture barrier properties (57). In the mid-1990s, PPG Industries, Inc. introduced Bairocade external epoxy-amine organic coatings for improving barrier properties of PET bottles (130,131). It is claimed that these coatings can reduce O_2 permeability of PET bottles by a factor of 6 or more with the level of barrier improvement depending on the thickness and formulation used, and that coated bottles extend the shelf life of carbonated beverages by a factor of 3, and beer by a factor of 20 relative to uncoated bottles (131).

Another way of improving barrier properties of polymers is by coating them with thin inorganic layers (57,132,133). This can typically improve barrier properties by a factor of 100, whereas the thickness of the barrier coating applied is less than 0.5% of the base film (57). Laminations and coatings of aluminum foil or aluminum oxide on barrier polymers can provide significant improvements in gas barrier properties (57). These metallized films contain an extremely thin layer of aluminum, which not only enhances the barrier properties of the base film, but also provides a shiny metallic appearance. Because the layer is very thin, it does not appreciably affect the strength and flexibility of the base film (134). The barrier properties of metallized films can approach those of pure aluminum foil. However, unlike aluminum foil, metallized films are not subject to flex-cracking and hence, are better at maintaining their barrier properties (134). Barrier polymers that have been successfully metallized include PP, nylons, PET, and unplasticized PVC. As an example, 99% decrease in oxygen permeability and 98.5% decrease in water vapor permeability have been reported for metallized PET films as compared to unmetallized PET films (135). Metallized films are widely used in the

flexible packaging industry, an example being potato chip packages consisting of multilayer structures of oriented PP, PE, and metallized PP (136).

However, one of the main disadvantages of metallized structures is that they may not be transparent—a desirable feature for many packaging applications. In part to address this shortcoming, several alternative high barrier coating technologies, typically producing amorphous carbon or glass-like layers, are being investigated. These newer coatings have achieved limited market penetration to date, with most of the commercial activity in Europe and Japan. It is still unclear what their eventual importance will be, but these technologies are being actively pursued. Among the various glass and ceramic materials used as barrier coatings, silicon dioxide (silica) has been the most widely used (57,133). These barrier composite structures are clear, microwaveable, and recyclable. Electron-beam treatment and plasma-enhanced chemical vapor deposition (PECVD) are two of the most widely used techniques for depositing thin silica layers on barrier polymers (57,137). In the electron-beam treatment, a high energy electron-beam source is used to vaporize silica, which then precipitates onto the polymer film, forming a continuous coating as the film passes through a vacuum chamber. The resulting coatings are uniform and can be as thin as 0.04 μm. PECVD has the advantage of being able to control coating density and thickness, by changing the process variables (137). Figure 26 presents the effect of coating thickness on oxygen permeability of a PECVD silica-coated PET film (137). Barrier properties of silica-coated polymers can be superior to those of high barrier polymers such

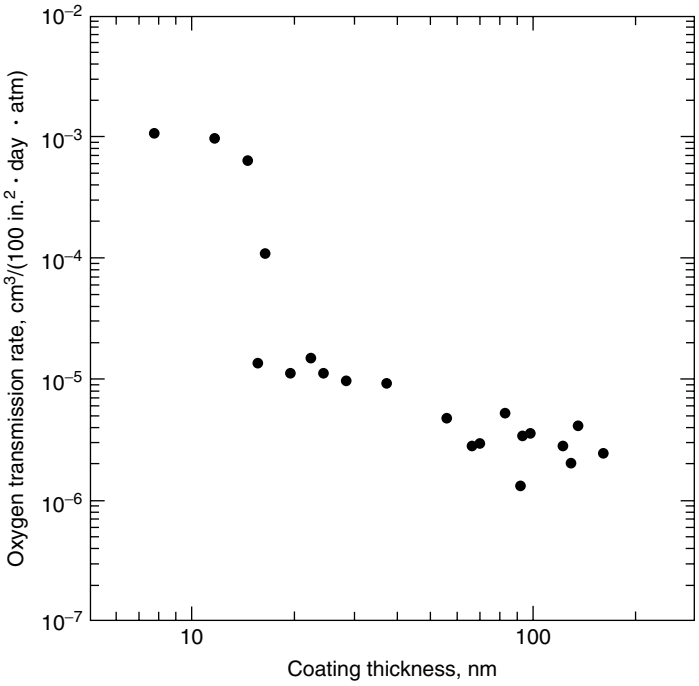

Fig. 26. Effect of plasma-deposited silica coating thickness on steady-state oxygen transmission rates (33°C, 0% RH) of PET films that have an uncoated thickness of 13 μm (137).

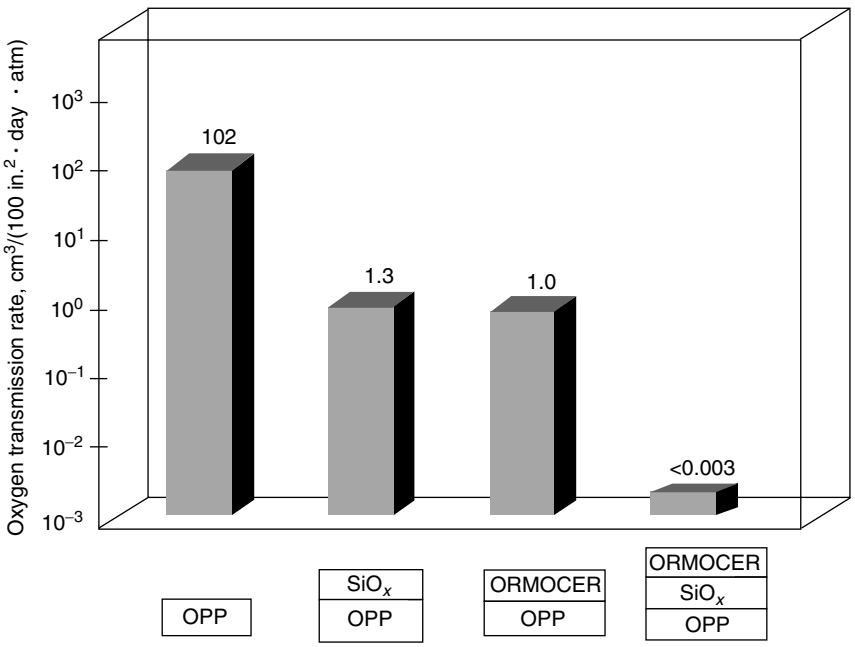

Fig. 27. Influence of ORMOCER coatings on oxygen transmission rates (OTRs) of SiO_x-coated oriented polypropylene (OPP) (OTR measured at 23°C and 70% RH) (138).

as PVDC and EVOH. Moreover, they are not influenced by moisture and temperature (57). However, because of poor adhesion and mechanical properties, for all practical applications silica-coated films have to be laminated.

Recently, inorganic–organic hybrid polymers have been developed, which can be used as laminating agents and in conjunction with silica to enhance barrier properties of polymers (138,139). An example is ORMOCER or organically modified ceramic (Fraunhofer Gesellschaft, Germany). Such materials can be used as coatings as well as high barrier laminating agents in multilayer structures. The use of ORMOCER as a top layer on silica-coated PP can significantly improve its oxygen barrier properties, as shown in Figure 27. The composite structure also offers good water vapor barrier properties. Similar improvements in barrier properties of PET have been reported (138). Figure 28 shows a comparison of O_2 and water vapor barrier properties of different barrier polymer composite structures (140).

Another potential candidate as an effective barrier coating is *diamond-like carbon* (DLC) (132). DLC refers to a group of amorphous, hard, and chemically inert materials consisting of carbon bonded partially as diamond (sp^3) and partially as graphite (sp^2) and containing 0–40% hydrogen atoms. These coatings are transparent, flexible, extremely impermeable, biocompatible, and adhere well to a wide range of polymers.

Among the most recent commercial applications of barrier polymeric containers coated with thin inorganic layers is plastic beer packaging. Glaskin (Tetra

Pak, Geneva, Switzerland) is a proprietary technology that utilizes a vacuum deposition process for coating clear, extremely thin layers of silicon oxide on the inside of blown plastic bottles (141). It offers excellent barrier properties for O_2, CO_2, and flavor compounds, and it is completely recyclable. For beer packaging, a shelf life of 6 months has been claimed using this technology. BESTPET (Barrier Enhanced Silica Coated PET) is another silica-based coating technology developed by the Coca Cola Co. (Atlanta, Ga.) in conjunction with Applied Films (Longmont, Colo.) and Krones (Nevtraubling, Germany). The exterior surface of PET bottles is coated with a thin silica layer and improvements in barrier properties of PET by a factor of at least 2 have been claimed, which results in a shelf life of over 6 months for packaged beer (142). A carbon-based high-barrier bottle coating technology is ACTIS (Amorphous Carbon Treatment on Internal Surface technology) (Sidel, France) (143). In this process, the internal surface of plastic bottles is coated with a 0.15 μm thick layer of highly hydrogenated amorphous carbon obtained from a food-safe gas (eg, acetylene) in its plasma state. This technology has been claimed to improve O_2 barrier properties of PET bottles by a factor of 30, and CO_2 barrier properties by a factor of 7. Another carbon-based DLC coating technology (Kirin Brewery, Japan) claims to improve the barrier properties of PET for O_2, CO_2, and H_2O by factors of 20, 7, and 8 respectively (142).

Miscible and Immiscible Blends. Polymer blending offers an alternative, simple, unique, and economical approach for improving barrier properties for several applications (see POLYMER BLENDS). In general, the goal is to add small

amounts of a high barrier polymer (generally more expensive) to a selected matrix polymer (generally low cost) (40). High cost polymers such as PEN and LCPs can be blended with lower cost polymers such as PET to achieve a balance of barrier properties and cost. A common objective of blending is to attenuate the deficiencies while maintaining as much as possible the desirable properties of each component. Occasionally, synergistic effects result in blend properties better than those of the individual components (40). Reactive blending is also possible, for example, with the mixing of different polyester polymers (transesterification), or polyester and nylon (polyesteramide formation) (40).

In general, polymer blends can be broadly classified as homogenous or miscible blends and multiphase or immiscible blends. The permeability coefficient P of miscible blends as well as copolymers often follows an empirical semilogarithmic additivity rule (40):

$$\ln P = \phi_1 \ln P_1 + \phi_2 \ln P_2 \tag{39}$$

where ϕ_i is volume fraction of the ith component and P_i is the component's permeability coefficient. This simple additivity rule is generally obeyed only if there are no interactions between the components. Deviations from this rule can either be positive or negative depending on the nature and magnitude of interactions (40). For example, a miscible blend of styrene–acrylonitrile copolymers (SAN) containing 9% acrylonitrile (AN) and tetramethyl bisphenol A polycarbonate (TMPC) shows negative deviations from the linear additivity rule, indicating strong polymer–polymer interactions. On the other hand, blends of SAN containing 13.5 and 28% AN, and PMMA show positive deviation from the linear additivity rule (40).

When immiscible polymers are blended, or when inorganic filler is added to a polymer matrix, it results in the formation of a dispersion of one component in a continuous matrix of the other. Figure 29 shows several schematic examples of such systems (144). Immiscible polymer blends are far more common than miscible blends (40). Barrier properties of an immiscible blend depend on the permeabilities of the individual components, their volume fractions, phase continuity, and the aspect ratio of the dispersed (or discontinuous) phase (40). The aspect ratio L/W refers to the shape of the particles in the dispersed phase. Spheres and cubes have an aspect ratio of 1, whereas platelets and rods have higher aspect ratios.

The presence of an impermeable dispersed phase lowers the permeability by increasing tortuosity. The Maxwell model can be used to calculate the permeability of a polymer blend, P, with impermeable spherical particles dispersed in a continuous phase (40):

$$P = \frac{P_{\mathrm{m}}\left(1 - \phi_{\mathrm{d}}\right)}{1 + \phi_{\mathrm{d}}/2} \tag{40}$$

where P_{m} is permeability of the continuous polymer phase and ϕ_{d} is volume fraction of the dispersed phase. Different models for permeation in a heterogeneous medium wherein the dispersed phase is impermeable and represented by

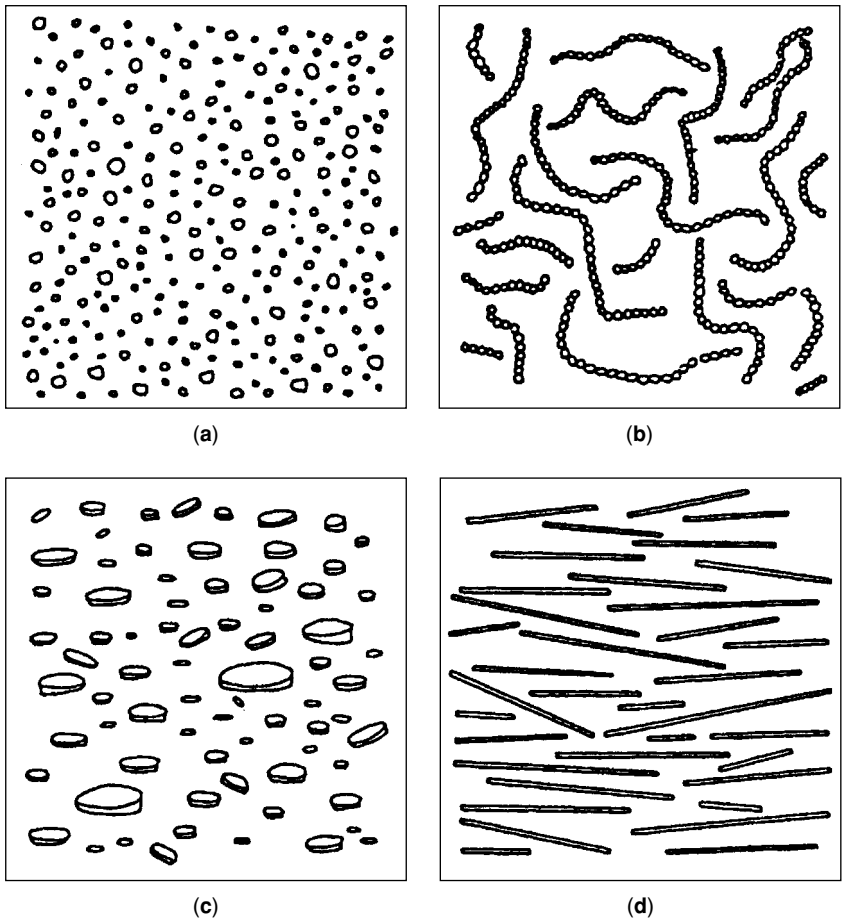

Fig. 29. Examples of heterogeneous, immiscible blends. (**a**) Random spheres in a dispersed phase, (**b**) aggregated spheres in a dispersed phase, (**c**) oriented platelets in a dispersed phase, and (**d**) oriented rods in a dispersed phase (144).

different geometrical shapes have been reviewed (144). Several modifications to the Maxwell model have been made to describe permeation behavior in platelets and ellipsoid-shaped particles dispersed in a more permeable continuous phase (40). For example, oxygen barrier properties of blends of oriented PET and EVOH have been successfully modeled with one such modification (Fricke model) (145). Robeson extended the Maxwell model by applying it to blends in which both the polymers contribute to the continuous phase (40). This model considers the practical implications of attempts to increase the barrier performance of a moderate barrier polymer by adding small amounts of a high barrier polymer to it. According to this model, a multilayer structure provides the highest barrier followed by a blend in which the high barrier polymer is the continuous phase (40).

Figure 30 shows the improvement in O_2 barrier properties of PE–EVOH blends as a function of EVOH volume fraction. Blends of PET with MXD-6 nylon

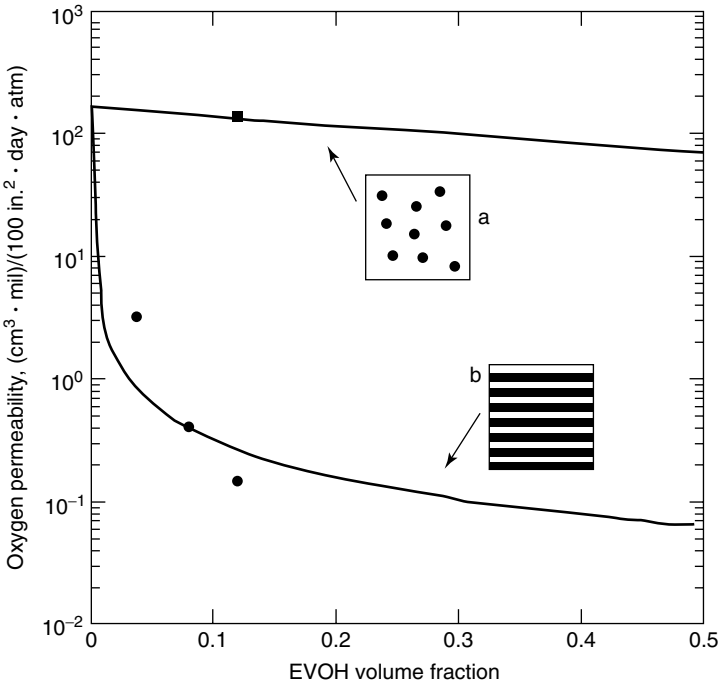

Fig. 30. Effect of EVOH content on oxygen permeability of PE–EVOH blends that exhibit (**a**) discontinuous morphology and (**b**) co-continuous lamellar morphology (40).

(Mitsubishi Gas Chemical Co.) have shown significant reduction in O_2 and CO_2 permeability coefficients relative to those of PET and are being investigated for use in plastic containers (40). PET–EVOH blends have been promoted (Kuraray Co.) for potential applications in the beverage industry (57). The transport properties of PET–LCP blends have also been studied, and Table 10 shows the reductions in permeabilities of O_2, N_2, and CO_2 that have been reported for blown films containing 2, 10, and 30 wt% LCP (146).

Polymer Nanocomposites. Polymer nanocomposites are immiscible blends made by adding nanometer-size particles to barrier polymers. Since nanometer-size grains, fibers, and plates have dramatically increased surface area compared

Table 10. Gas Permeabilities[a] of LCP–PET blends[b]

%LCP[c] in PET	CO_2 permeability	O_2 permeability	N_2 permeability

to conventional-size materials, the chemistry of nanosized materials is different from other conventional materials. Polymers filled with nanometer-size particles have significantly different properties than those filled with conventional inorganic materials (147). Properties of nanocomposites such as high tensile strength can be achieved by using higher conventional filler loading, but other properties such as improved clarity cannot be duplicated by filled resins at any loading (148).

Polymer nanocomposites were developed in the late 1980s, and were first commercialized by Toyota, which used nanocomposite parts in one of its car models for several years (57). Initial developments focussed on the use of nylon resins and very fine smectite clay particles, with surface area of about 750 m^2/g, as fillers (57). Ube Industries developed its first nylon nanocomposite in 1989 for an automotive timing belt cover. They have also developed other nylon nanocomposites called nylon clay hybrids (57). More recently, novel nanocomposite nylon-6 resins developed by Honeywell Engineered Applications and Solutions (Morristown, N.J.) have been claimed to improve O_2 and CO_2 barrier properties by a factor of 3–4 (149). It has also been claimed that these nanocomposites double the heat resistance of nylon-6 and improve other mechanical properties by 30–50% (149). Others such as Nanocor, Inc. (150) are also actively developing nanocomposites for enhanced barrier performance. Commercial products are available for PP and fluoropolymers. Some of the other potential candidate polymers for nanocomposites include polyesters, PS, and ethylene vinyl acetate copolymers (57). Several polymer nanocomposites, including amorphous nylon and EVOH matrixes, intended for high barrier applications are in various stages of development.

Oxygen-Scavenging Systems. Another strategy for improving the barrier properties of polymers is the introduction of reactive groups in the polymer. These groups can reduce the transmission of penetrants such as oxygen and water vapor and the term “active barrier” is often used to describe this approach to distinguish it from “passive barrier” packages that rely on reduced permeability to decrease gas transmission. By using an oxygen scavenger, which absorbs the residual oxygen after packaging, quality changes of oxygen-sensitive foods can be minimized (151–153). Although oxygen-scavenging technology is rapidly evolving and encompasses a wide variety of chemistries, the majority of current commercial oxygen-scavenger packages probably still employ sachets that remove oxygen from the headspace via iron oxidation. Ageless (Mitsubishi Gas Chemical Co., Japan) oxygen absorbers are the most commonly used sachets that are placed inside the food package (57). If the initial oxygen concentration and oxygen permeability of the packaging polymer is known, then an oxygen scavenger can be chosen with a higher capacity than the theoretically needed capacity, and near total absence of oxygen can be maintained during the expected shelf life of the product (151). Other iron-based oxygen-scavenger sachets are ATCO (Standa Ind., France), Freshilizer (Toppan Printing Co., Japan), Vitalon (Toagosei Chem. Ind., Japan), Freshpax (Multisorb Technologies Inc., U.S.), and Sanso-cut (Finetec Co., Japan) (151).

An alternative to sachets is to incorporate the oxygen scavenger into the barrier polymer structure itself (151). An example of this strategy is Oxbar (Crown Cork and Seal, Philadelphia, Pa.), which involves cobalt-catalyzed oxidation of nylon MXD-6 polymer used in multilayer PET bottles for packaging of

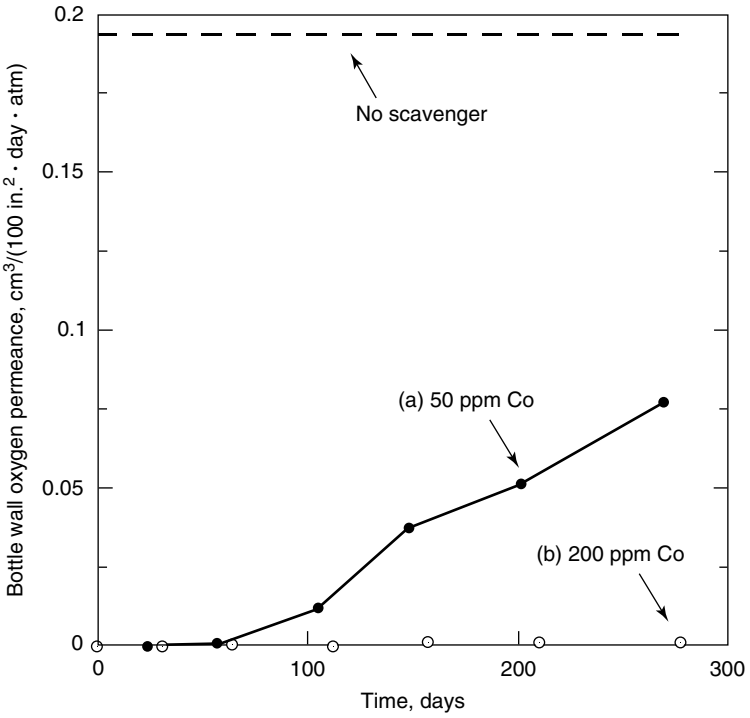

Fig. 31. Reduction in oxygen transmission rates due to oxygen scavenging in blends of PET and nylon MXD-6 (157). The measurements were made at 23°C and 50% RH. (**a**) 4 wt% MXD-6 and 50 ppm cobalt (as metal); (**b**) 4 wt% MXD-6 and 200 ppm cobalt (as metal). For comparison, the dotted line indicates oxygen permeance in the absence of cobalt catalyst (no scavenging).

beverages. Another example of a polymer-based absorber is Amosorb (BP Amoco Chemicals), which can reportedly be incorporated into various rigid and flexible packaging structures (151). This is a rapidly evolving field and several other companies have also introduced or announced oxygen-scavenging resins. Among those active in this area are EVAL Co., U.S., Kuraray Co., Japan and Darex Co., U.S., with DarEval (154); Owens-Illinois/Continental PET Technologies with CPTX-312; Honeywell International, Inc. with scavenging nylon resin (155); Cryovac with OS 1000; and Chevron Phillips Chemical Co. with their OSP scavengers (156). While the speed and capacity of oxygen-scavenging films are considerably lower than iron-based oxygen-scavenger sachets (151), oxygen ingress into the package can be reduced to very low levels with appropriately designed scavenger structures. Figure 31 presents an example of the reduction in oxygen transmission rate due to oxygen scavenging in blends of PET and nylon MXD-6 (157). Scavengers can also be incorporated into the liner of bottle closures where they can significantly reduce the ingress of oxygen into the package through the closure liner (158).

A recent study (159) has shown that incorporation of inorganic fillers as well as reactive groups in barrier polymer films can significantly improve the shelf life of packages. According to that theory, the presence of immobile reactive groups dramatically increases the *time lag* (ie, the time required to achieve steady-state permeability), but do not affect steady-state transport of penetrants across barrier polymer films. For example, in LDPE and PVDC films containing 10% flakes of mica or clay and linolenic acid as the oxygen-scavenging species, the time lag for permeation of O_2 dramatically increased by about 3 orders of magnitude to 40 h and 3 years, respectively (159).

Conclusions

Barrier polymers are widely used in food, beverage, and other packaging industries. Some of the their advantages over traditional packaging materials such as glass, paper, and metals are flexibility, light weight, toughness, versatility, and printability. The selection of a polymer for a particular packaging application depends on its barrier as well as other physical properties. A comparison of these properties and current as well as potential future applications for different types of barrier polymers has been presented. Additionally, important factors governing permeability (eg, penetrant size, polymer chemical structure, temperature, humidity) as well as ways to measure and predict permeability have also been discussed.

Unlike glass and metals, no polymer offers an infinite gas barrier. Despite this limitation, monolayer polymer structures in many instances satisfy the barrier requirements for a package. In other situations, combinations of different polymers, or polymers with inorganic materials, in the form of multilayer structures or blends, can provide cost-effective barrier for the intended shelf life of packaged products. As a result, plastic packaging is ubiquitous. Market pressures, however, drive the need for continual improvements in packaging materials. Hence, there is an ongoing interest in improving the barrier properties of polymers used in packaging, and the search for improved barrier polymers and structures is ongoing. Inorganic materials such as silicon and aluminum oxides and clays can be used to significantly enhance gas barrier and other mechanical properties of polymers. One area of recent activity is polymer nanocomposites, which involves dispersion of nanoscale barrier particles in a polymer matrix. A considerable amount of research is also being focussed on techniques for developing thin layers of inorganic coatings on barrier polymer films and containers. In addition, work in the field of oxygen-scavenging technologies (so-called active packaging systems) has resulted in several developments. While advances in these newer barrier technologies have recently opened up several commercial applications, with plastic beer packaging being perhaps the most publicized, it is much too early to accurately predict their eventual success in the market place. Constructions with established "passive" barrier polymers currently dominate the barrier packaging market, and these materials are expected to be commercially important for many years to come.

BIODEGRADABLE POLYMERS, MEDICAL APPLICATIONS

Introduction

Traditional applications of synthetic polymers are mostly based on their relative inertness to biodegradation compared with natural macromolecules, such as cellulose, and proteins. Biodegradation of the polymers can occur in several ways including photodegradation, oxidation, and hydrolysis. Practically, biodegradation involves enzymatically promoted breakdown caused by living organisms, usually microorganisms, but it is now well accepted that the biodegradation can occur by hydrolysis, oxidation, or photooxidation in a biological environment. These polymers have been used in many aspects of life, eg, in environmentally friendly packaging materials (1,2), agriculture (3,4), drug delivery (5,6), gene delivery (7,8), and tissue engineering (9,10). (See CONTROLLED RELEASE TECHNOLOGY; ENVIRONMENTALLY DEGRADABLE POLYMERS; GENE-DELIVERY POLYMERS; TISSUE ENGINEERING). This article emphasizes the various biodegradable polymers obtained either synthetically or from natural resources and their uses for biomedical applications.

Factors Affecting Biodegradation

Effect of Polymer Structures. Synthetic biodegradable polymers contain hydrolyzable linkages along the polymer chain; for example, amide enamine, ester, phosphate, phosphazene, carbonate, anhydride, urea, and urethane linkages are susceptible to biodegradation by microorganisms and hydrolytic enzymes. In addition, polymers containing substituents such as benzyl, hydroxy, carboxy, methyl, and phenyl groups have been prepared in the hope that an introduction of these

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

substituents might increase biodegradability (11). Among benzylated polymers, mixed results have been obtained for polyamides. Since most enzyme-catalyzed reactions occur in aqueous media, the hydrophilic–hydrophobic character of synthetic polymers greatly affects their biodegradability. A polymer containing both hydrophobic and hydrophilic segments seems to have a higher biodegradability than those polymers containing either hydrophobic or hydrophilic structures only. A series of poly(alkylene tartrate)s was found to be readily assimilated by *Aspergillus niger*. However, the polymers derived from C6 and C8 alkane diols were more degradable than the more hydrophilic polymers derived from C2 and C4 alkane diols or the more hydrophobic polymers derived from the C10 and C12 alkane diols. Among the degradable poly(α-aminoacid-*co*-ε-caproic acid)s, the hydrophilic copolyamide derived from serine was more susceptible than those containing only hydrophobic segments. For a synthetic polymer to be degradable by enzyme catalysis, the polymer chain must be flexible enough to fit into the active site of the enzyme. This aspect most likely accounts for the fact that while the flexible aliphatic polyesters are readily degraded by biological systems, the more rigid aromatic poly(ethylene terephthalate) is generally considered to be inert (12).

Effect of Polymer Morphology. Selective chemical degradation of semicrystalline polymer samples shows certain characteristic changes (13–16). During degradation, the crystallinity of the sample increases rapidly at first and then levels off to a much slower rate as the crystallinity approaches 100%. This effect is attributed to the eventual disappearance of the amorphous portions of the sample. The effect of morphology on the microbial and enzymatic degradation of poly(ε-caprolactone) (PCL), a known biodegradable polymer with a number of potential applications, has been studied (17,18). Scanning electron microscopy has shown that the degradation of a partially crystalline polycaprolactone film by filamentous fungi proceeds in a selective manner, with the amorphous regions being degraded prior to the degradation of the crystalline region. The microorganisms produce extracellular enzymes responsible for the selective degradation. This selectivity can be attributed to the less-ordered packing of amorphous regions, which permits easier access for the enzyme to the polymer chains. The size, shape, and number of crystallites all have a pronounced effect on the chain mobility of the amorphous regions and thus affect the rate of degradation. This effect has been demonstrated by studying the effects of changing orientation via stretching on the degradation (17,18).

Degradation in biological medium, cells, tissues, and body fluids proceeds differently from chemical degradation as enzymes, biological reagents in the cell organelles, and fluids are involved in the degradation process. Enzyme is able to degrade the crystalline regions faster than hydrolysis. The enzyme system shows no intermediate molecular weight material but shows a much smaller weight shift with degradation as compared to chemical degradation. This shift indicates that although degradation is selective, the crystalline portions are degraded shortly after the chain ends are made available to the exoenzyme. The lateral size of the crystallites has a strong effect on the rate of degradation because the edge of the crystal is where degradation of the crystalline material takes place, because of the crystal packing. A smaller lateral crystallite size yields a higher crystallite edge surface in the bulk polymer. Prior to the saturation of the enzyme active

sites, the rate is dependent on available substrate; therefore, a smaller lateral crystallite size results in a higher rate of degradation. The degradation rate of a PCL film is zero order with respect to the total polymer, but is not zero order with respect to the concentrations of the crystallite edge material. The drawing of PCL films causes an increase in the rate of degradation, whereas annealing of the PCL causes a decrease in the rate of degradation (19). This phenomenon is probably due to opposite changes in lateral crystallite sizes. *in vitro* chemical and enzymatic degradations of polymers, especially polyesters, were analyzed with respect to chemical composition and physical properties. It was found quite often that the composition of a copolymer giving the lowest melting point is most susceptible to degradation (19). The lowest packing order, as expected, corresponds with the fastest degradation rate.

Effect of Molecular Weight. Microorganisms produce both exoenzymes, which degrade polymers from terminal groups, and endoenzymes, which degrade polymers randomly along the chain. One might expect a large molecular effect on the rate of degradation in the ease of exoenzymes and a relatively small molecular weight effect in the case of endoenzymes. Low molecular weight hydrocarbons, however, can be degraded by microbes. They are taken in by microbial cells, "activated" by attachment to coenzyme A, and converted to cellular metabolites within the microbial cell. However, these processes do not function well (if at all) in an extracellular environment, and the plastic molecules are too large to enter the cell. This problem does not arise with natural molecules, such as starch and cellulose, because conversions to low molecular weight components by enzyme reactions occur outside the microbial cell. Photodegradation or chemical degradation may decrease molecular weight to the point that microbial attack can proceed. Hydrolytic degradation of polyesters and polyanhydrides is affected by the molecular weight as a result of differences in water accessibility to large molecular weight polymeric materials.

Effect of Radiation and Chemical Treatment. Photodegradation with UV light and the γ-irradiation of polymers generate radicals and/or ions that often lead to cleavage and cross-linking. Oxidation also occurs, complicating the situation, since exposure to light is seldom in the absence of oxygen. Generally this changes the material's susceptibility to biodegradation. Initially, one expects the observed rate of degradation to increase until most of the fragmented polymer is consumed and a slower rate of degradation should follow for the cross-linked portion of the polymer. Similarly, photooxidation of polyalkenes promotes (slightly in most cases) the biodegradation (20). The formation of carbonyl and ester groups is responsible for this change. Processes have been developed to prepare copolymers of alkenes containing carbonyl groups so that they will be more susceptible to photolytic cleavage prior to degradation. As expected, γ-ray irradiation greatly affects the rate of *in vitro* degradation of polyesters (21,22). For polyglycolide and poly(glycolide-*co*-lactide), the pH of the degradation solution decreased as the process proceeded. The change–time curves exhibit sigmoidal shapes and consist of three stages: early, accelerated, and later; the lengths of these three regions were a function of γ-irradiation. Increasing radiation dosage shortens the time of the early stage. The appearance of the drastic pH changes coincides with loss of tensile breaking strength.

Classification

On the basis of the formation, biodegradable polymers can be classified into two groups including synthetic biodegradable polymers and natural biodegradable polymers.

Synthetic Biodegradable Polymers. A representive list of synthetic biodegradable polymers is given in Table 1, which includes chemical backbone structures of these polymers. These polymers can be catagorized into two types on the basis of their backbone structures, namely (*1*) polymers with hydrolyzable backbone and (*2*) polymers with carbon backbone.

Polyester. Polyesters having hydrolyzable ester bond in their backbone are considered the best biomaterial with regard to design and performance. Among polyesters, poly(lactic acid) (PLA) can be made of the lactic acid monomers which contain an asymmetric α-carbon atom with three different isomers as D-, L-, and DL-lactic acid (see POLYLACTIDE). The physiochemical properties of optically active homopolymers poly(D-lactic acid) (PDLA) or poly(L-lactic acid) (PLLA) are the same, whereas the racemic PLA has very different characteristics (25). Racemic PLA and PLLA have glass-transition temperatures (T_g's) of 57 and 56°C respectively, but PLLA is highly crystalline with a melting temperature (T_m) of 170°C; racemic PLA is purely amorphous. The polymer characteristics are affected by the comonomer composition, the polymer architecture, and molecular weight (26). The crystallinity of the polymer, an important factor in polymer biodegradation, varies with the stereoregularity of the polymer. Sterilization using γ-irradiation decreases the polymer molecular weight by 30–40% (26). The irradiated polymers continue to decrease in molecular weight during storage at room temperature. This decline in molecular weight affects the mechanical properties and the release rate from the polymers. PLA and its copolymers with less than 50% glycolic acid content soluble in common solvents such as chlorinated hydrocarbons, tetrahydrofuran, and ethyl acetate. Poly(glycolic acid) (PGA) is insoluble in common solvents but in hexafluoroisopropanol and hexafluoroacetone sesquihydrate (HFASH). In its highly crystalline form, PGA has a very high tensile strength of 69–138 MPa (10,000–20,000 psi) and modulus of elasticity of about 6900 MPa (~1,000,000 psi). The solubility parameters were in the range of 16.2 and 16.8, which are comparable to those of polystyrene and polyisoprene (27).

A comparison study on the physicomechanical properties of several biodegradable polyesters was reported (28). The thermal properties, tensile properties, and the flexural storage modulus as a function of temperature were determined. The following polymers were compared: poly(L-lactic acid), poly(DL-lactic acid), poly(glycolic acid), poly(ε-caprolactone), poly(hydroxybutyrate) and copolymers with hydroxyvaleric acid, and poly(trimethylene carbonate). The thermal and mechanical properties of several of the polymers tested are summarized in Table 2 (28). A comprehensive review on the mechanical properties of several biodegradable materials used in orthopedic devices has been published (29). The tensile and flexural strength and modulus, as well as the biodegradation of various lactide/glycolide polymers, poly(orthoester), and polycaprolactone have been summarized in a tabular or diagram format.

Polycaprolactone. Poly(ε-caprolactones) (PCL) are synthesized by ring-opening polymerization of ε-caprolactones and are soluble in chlorinated and

A plasma glycoprotein belonging structurally to the keratin–myosin group. Synthesized and secreted by hepatic parenchymal cells. Essential to the clotting of blood. The molecular weight is 340,000. Soluble, but forms an insoluble gel on conversion to fibrin. Fibrin monomer is fibrinogen from which one or two peptides have been removed by means of thrombin.	Fibrinogen
Polypeptide substance comprising one third of the total protein in mammalian organisms; main constituent of skin, connective tissue, and the organic substance of bones and teeth. Different types of collagens exist.	Collagen (qv)
A heterogeneous mixture of water-soluble proteins of high average molecular weight. Derived from collagen. Swells up in water to form a gel/insoluble in organic solvents.	Gelatin (qv)

[a] The structures of polymers and description of their properties and applications can be found in either Ref. 23 or Ref. 24.

aromatic hydrocarbons, cyclohexanone, and 2-nitropropane but insoluble in aliphatic hydrocarbons, diethyl ether, and alcohols (30). The homopolymer of PCL melts at 59–64°C with a T_g of −60°C. Copolymerization with lactide increases the T_g with the increase in the lactide content in the polymer (31). The crystallinity of the polymer decreases with the increase in polymer molecular weight; polymer of weight 5000 is 80% crystalline whereas the polymer of weight 60,000 is 45% crystalline (32).

Tokiwa and Suzuki (33) have discussed the hydrolysis and biodegradation of PCL by fungi, and have shown that PCL can be degraded enzymatically. Blends of PCL and polyesters prepared from alkanediols and alkane dicarboxylic acids with natural substances such as tree bark have been molded into shaped containers for horticultural seeding plantouts (34). After 3 months of soil burial, the PCL

containers were found to be embrittled, disintegrated, and biodegraded, which suggests that the extracellular enzymes in the soil may cleave the polymer chain prior to the assimilation of the polymer by microorganisms.

Poly(β-hydroxybutyrate). Poly(β-hydroxybutyrate) (PHB) is made by a controlled bacterial fermentation (see POLY(3-HYDROXYALKANOATES). The producing organism occurs naturally. An optically active copolymer of 3-hydroxybutyrate (3HB) and 3-hydroxyvalerate (3HV) has been produced from propionic acid or pentanoic acid by *Alcaligenes eutrophus*. PHB is characterized as having a high molecular weight (>100,000, $[\eta] > 3$ dL/g) with a narrow polydispersity and a crystallinity of around 50%. The melting point depends on the polymer composition; P(3HB) homopolymer melts at 177°C with a T_g at 9°C, the 91:9 copolymer with 4HB melts at 159°C, and the 1:1 copolymer with 3HV melts at 91°C. The PHB properties in the living cells of *A. eutrophus* were determined using X-ray and variable-temperature ^{13}C NMR relaxation studies (35). PHB is an amorphous elastomer with a T_g around −40°C in its "native" state within the granules. The biodegradation of these polymers in soil and activated sludge show the rate of degradation to be in the following order (36):

$$\text{P(3HB}-co-9\%\text{4HB)} > \text{P(3HB)} = \text{P(3HB}-co-50\%\text{3HV)}$$

Microspheres degraded slowly in phosphate buffer at 85°C and after 5 months, 20–40% of the polymer eroded under these conditions. Copolymers having a higher fraction of 3HV and low molecular weight polymers were more susceptible to hydrolysis (36).

Poly(phosphoesters). Poly(phosphoesters) are synthesized from the reaction of ethyl or phenyl phosphorodichloridates and various dialcohols including bisphenol A and poly(ethylene glycol) of various molecular weights (37). Leong and co-workers (38) have incorporated phosphoester groups into poly(urethanes). Poly(urethanes) have been used as blood-contacting biomaterials because of their having a broad range of physical properties: from hard and brittle to soft and tacky (38). Leong and co-workers has designed inert biomaterial for controlled release application by introducing phosphoester linkage in poly(urethane) (38). Introduction of phosphoester linkage does not change the mechanical properties inherent in the poly(urethanes) and provides excellent biodegradable materials.

Polycarbonates. Polycarbonates are synthesized from the reaction of dihydroxy compounds with phosgene or with bischloroformates of aliphatic dihydroxy compounds by transesterification, and by polymerization of cyclic carbonates (39). These polymers have been synthesized from carbon dioxide and the corresponding epoxides in the presence of organometallic compounds as initiators. Poly(ethylene carbonate) and poly(propylene carbonate) are linear thermoplastic polyesters of carbonic acid with aliphatic dihydroxy compounds (39). Poly(dihydropyrans) were developed for contraceptive delivery. The *in vivo* and *in vitro* release of contraceptive steroids and antimalarial agents from polymer matrices has been studied. Poly(*p*-dioxanone) is clinically used as an alternative to poly(lactide) in absorbable sutures with similar properties to poly(lactide) with the advantage of better irradiation stability during sterilization (40). This polymer has not yet been developed as a carrier for controlled drug delivery. Biodegradable polymers derived from naturally occurring, multifunctional hydroxy acids and amino acid have been investigated by Lenz and Guerin (41).

Poly(amides). The utilization of amide-based polymers, especially natural proteins, in the preparation of biodegradable matrices have been extensively investigated in recent years (42). Microcapsules and microspheres of cross-linked collagen, gelatin, and albumin have been used for dug delivery (43). The synthetic ability to manipulate amino acid sequences has seen its maturity over the last two decades with new techniques and strategies continually being introduced.

Poly(amides) such as poly(glutamic acid) and poly(lysine) and their copolymers with various amino acids have also been studied as drug carriers (41,44,45). Pseudopoly(amino acids), prepared from N-protected trans-4-hydroxy-L-proline, and poly(iminocarbonate) from tyrosine dipeptide as monomeric starting material have been reported (46–48). The properties, biodegradability, drug release, and biocompatibility of this class of polymers have been reviewed (42,46).

Polyphosphazenes. The polymers are most commonly synthesized by a substitution reaction of the reactive poly(dichlorophosphazene) with a wide range of reactive nucleophiles such as amines, alkoxides, and organometallic molecules. The reaction is carried out in general at room temperature in tetrahydrofuran or aromatic hydrocarbon solutions (49). Two different types of polyphosphazenes are of interest as bioinert materials: those with strongly hydrophobic surface characteristics and those with hydrophilic surfaces. Polycarbonates (qv) bearing fluoroalkoxy side groups are some of the most hydrophobic synthetic polymers known (50,51). Such polymers are as hydrophobic as poly(tetrafluoroethylene) (Teflon), but unlike Teflon, polyphosphazenes of this type are flexible or elastomeric, easy to prepare, and they can be used as coatings for other materials.

The uniqueness of the polyphosphazenes stems from its inorganic backbone (N=P) which with certain organic side groups can be hydrolyzed to phosphate and ammonia. Several polymer structures have been used as matrix carriers for drugs (51) or as a hydrolyzable polymeric drug, where the drug is covalently bound to the polymer backbone and released from the polymer by hydrolysis (52). A comprehensive review on the synthesis, characterization, and medical applications of polyphosphazenes was published (53).

Poly(orthoesters). Poly(orthoesters) were first designated as Chronomer and later as Alzamer (54). They were prepared by a transesterification reaction. The molecular weight of poly(orthoesters) were significantly dependent on the type of diol and catalyst used for synthesis. A linear, flexible diol like 1,6-hexanediol gave molecular weights greater than 200 kDa, whereas bisphenol A in the presence of catalyst gave molecular weights around only 10,000 kDa (55). Mechanical properties of the linear poly(orthesters) can be varied over a large range by selecting various compositions of diols. It was shown that the T_g of the polymer prepared from 3,9-diethylidene-2,4,8,10-tetraoxaspiro[5,5]undecane can be varied from 25 to 110°C by simply changing the amount of 1,6-hexanediol in trans-1,4 cyclohexane dimethanol from 100% to 0% (29). A linearly decreasing relationship between the T_g and percentage of 1,6 hexanediol is observed. One could take advantage of the above relationship in selecting the polymer for *in vivo* applications because *in vivo* the T_g of the polymer would drop because of the inhibition of water, resulting in the loss of stiffness and rigidity of the polymer.

Polyanhydrides. The majority of the polyanhydrides (qv) are prepared by melt polycondensation. The sequence of reaction involves first the conversion of a dicarboxylic acid monomer into a prepolymer consisting of a mixed anhydride of the diacid with acetic anhydride. This is achieved by simply refluxing the diacid monomer with acetic anhydride for a specified length of time. The polymer is obtained subsequently by heating the prepolymer in vacuo to eliminate the acetic anhydride (56). Almost all polyanhydrides show some degree of crystallinity as manifested by their crystalline melting points. An in-depth X-ray diffraction analysis was conducted with the homopolymers of sebacic acid (SA), bis(carboxyphenoxy)propane (CPP), bis(carboxyphenoxy)hexane (CPH), and fumaric acid, and the copolymers of SA with CPP, CPH, and fumaric acid (57). The results indicated that the homopolymers were highly crystalline and the crystallinity of the copolymers was determined, in most cases, by the monomer of highest concentration. Copolymers with a composition close to 1:1 were essentially amorphous (57). The melting point of the aliphatic–aromatic copolyanhydrides is proportional to the aromatic content. For this type of copolymers there is characteristically a minimum T_m between 5 and 20 mol% of the lower melting component (57).

The majority of polyanhydrides dissolve in solvents such as dichloromethane and chloroform. However, the aromatic polyanhydrides display much lower solubility than the aliphatic polyanhydrides. In an attempt to improve the solubility and decrease the T_m, copolymers of two different aromatic monomers were prepared. These copolymers displayed a substantial decrease in T_m and an increase in solubility than did the corresponding homopolymers of aromatic diacids (57).

Natural Biodegradable Polymers. Biopolymers formed in nature during the growth cycles of all organisms are referred to as natural polymers. Their

synthesis generally involves enzyme-catalyzed, chain-growth polymerization reactions of activated monomers, which are typically formed within cells by complex metabolic processes.

Polysaccharides. For materials applications, the principal polysaccharides of interest are cellulose and starch because of their easy and cheap resources, but increasing attention is being given to the more complex carbohydrate polymers produced by bacteria and fungi, especially to polysaccharides such as xanthan, curdlan, pullulan, and hyaluronic acid (see CARBOHYDRATE POLYMERS).

Starch. Starch thermoplastic (qv) is a polymer that occurs widely in plants. The principal crops used for its production include potatoes, corn, and rice. In all of these plants, starch is produced in the form of granules, which vary in size and somewhat in composition from plant to plant. In general, the linear polymer, amylose, makes up about 20 wt% of the granule, and the branched polymer, amylopectin, the remainder. Research on starch includes investigation of its water-adsorptive capacity, the chemical modification of the molecule, its behavior under agitation and high temperature, and its resistance to thermomechanical shear. The starch molecule has two important functional groups, the —OH group that is susceptible to substitution reactions and the C—O—C bond that is susceptible to chain breakage. By reaction of its —OH group, modification of various properties can be obtained. One example is the reaction with silane to improve its dispersion in polyethylene (58). Cross-linking or bridging of the —OH groups changes the structure into a network while increasing the viscosity, reducing water retention and increasing its resistance to thermomechanical shear. Acetylated starch does have several advantages as a structural fiber or film-forming polymer as compared to native starch. Starch acetate has an improved solubility compared to starch and is easily cast into films from simple solvents. The degree of acetylation is easily controlled by transesterification, allowing polymers to be produced with a range of hydrophobicities.

Since isocyanates are highly reactive with hydroxyl groups, they can be used to prepare a number of reactive resins that cross-link with starch. The addition of starch to isocyanate resins considerably reduced costs and improved solvent resistance and strength properties (59). Starch can be modified with nonpolar groups, such as fatty esters, before the isocyanate reaction to improve the degree of reactivity (60).

Cellulose. Cellulose (qv) is a very highly crystalline, high molecular weight polymer, which is insoluble in water and organic solvents. It is soluble in aggressive, hydrogen bond-breaking solvents such as *N*-methylmorpholine-*N*-oxide. Because of its insolubility, cellulose is usually converted into derivatives to make it more processable. The important derivatives of cellulose are reaction products of one or more of the three hydroxyl groups, which are present in each glucopyranoside repeating unit, including (*1*) ethers (61,62), eg, methyl cellulose and hydroxylethyl cellulose; (*2*) esters (63), eg, cellulose acetate and cellulose xanthate, which are used as soluble intermediates for processing cellulose into either fibre or film forms, during which the cellulose is regenerated by controlled hydrolysis; and (*3*) acetals (64), especially the cyclic acetal formed between the C2 and C3 hydroxyl groups and butyraldehyde.

Chitin and Chitosan. Chitin is a macromolecule found in the shells of crabs, lobsters, shrimps, and insects (see CHITIN AND CHITOSAN). It consists of

2-acetamide-2-deoxy-*b*-*d*-glucose through the *b*-(1-4)-glycoside linkage. Chitin can be degraded by chitinase. Chitin fibers have been utilized for making artificial skin and absorbable sutures (65). Chitin is insoluble in its native form but chitosan, the partly deacetylated form, is water-soluble. The materials are biocompatible and have antimicrobial activities as well as the ability to chelate heavy metal ions. They also find applications in the cosmetic industry because of their water-retaining and moisturizing properties. Using chitin and chitosan as carriers, a water-soluble prodrug has been synthesized (66). Modified chitosans have been prepared with various chemical and biological properties (67). *N*-Carboxymethylchitosan and *N*-carboxybutylchitosan have been prepared for use in cosmetics and in wound treatment (68). Chitin derivatives can also be used as drug carriers (69), and a report of the use of chitin in absorbable sutures shows that chitins have the lowest elongation among suture materials including chitin (70), PGA, plain catgut, and chromic catgut. The tissue reaction of chitin is similar to that of PGA (71).

Alginic Acid. Alginate is a binary linear heteropolymer containing 1,4-linked α-l-guluronic acid and β-*d*-mannuronic acid. Alginates have been studied extensively for their ability to form gels in the presence of divalent cations (72,73). Alginic acid forms water-soluble salts with monovalent cations, low molecular weight amines, and quaternary ammonium compounds. It becomes water-insoluble in the presence of polyvalent cations such as $Ca^{2+}\cdot$, $Be^{2+}\cdot$, $Cu^{2+}\cdot$, $Al^{3+}\cdot$, and $Fe^{3+}\cdot$. Alginate gels have been used widely in controlled release drug delivery systems (73). Alginates have also been used to encapsulate various herbicides, microorganisms, and cells.

Naturally Occurring Polypeptides. The proteins that have found applications as materials are, for the most part, neither soluble nor fusible without degradation and so they are used in the form in which they are found in nature. This description is especially true for the fibrous proteins wool (qv), silk (qv), and collagen (qv). All proteins are specific polymers with regular arrangements of different types of a-amino acids; so the biosynthesis of proteins is an extremely complex process involving many different types of enzymes. In contrast, the enzymatic degradation of proteins, with general-purpose proteases, is a relatively straightforward, amide hydrolysis reaction.

Gelatin. Gelatin (qv), an animal protein, consists of 19 amino acids joined by peptide linkages and can be hydrolyzed by a variety of proteolytic enzymes to yield its constituent amino acids or peptide components (74). This nonspecificity is a desirable factor in intentional biodegradation. Gelatin is a water-soluble, biodegradable polymer with extensive industrial, pharmaceutical, and biomedical uses, which has been employed for coatings and microencapsulating various drugs (75,76) and for preparing biodegradable hydrogels (77).

A method was developed to prepare a simple, flexible gelatin film-based artificial skin that could adhere to an open wound and protect it against fluid loss and infection. The approach was to mix polyglycerols, either as is or after reaction with epichlorohydrin, with commercially available gelatin and then cast films on Teflon-covered trays (78). The films were tough and adhered to open wounds spontaneously. They could be loaded with bioactive molecules, such as growth factors and antibiotics that would be released over several days. The films could be sterilized with γ-rays or prepared under sterile conditions.

Toxicity and Biocompatibility

In all the potential uses of polymeric materials, a direct contact between the polymer and biological tissues is evident; therefore, for the eventual human application of these biomedical implants and devices, an adequate testing for safety and biocompatibility of the specific polymer matrix is essential. Biocompatibility deals with how the tissue reacts to foreign materials and the ability of a material to perform with an appropriate host response in a specific application.

Poly(lactic-*co*-glycolide). Whenever a synthetic polymer material is to be utilized *in vivo*, the possible tissue–implant interactions must be taken into consideration. In the case of biodegradable matrices, not only the possible toxicity of the polymer has to be evaluated, but also the potential toxicity of its degradation products. Moreover, biocompatibility is considered as the foundation for biocompatibility of degradable polymer systems. Thus, PLLA is defined as a safe biomaterial for *in vivo* use because its degradation product L-lactic acid is a natural metabolite of the body. Even though PLGA is extensively used and represents the gold standard of degradable polymers, increased local acidity due to its degradation can lead to irritation at the site of polymer implant. Agrawal and Athanasiou (79) have introduced a technique in which basic salts are used to control the pH in local environment of PLGA implant. The feasibility of lactide/glycolide polymers for the controlled release of bioactive agents is well proven, and they are the most widely investigated biodegradable polymers for drug delivery. The lactide/glycolide copolymers have been subjected to extensive animal and human trials without any significant harmful side effects (80). However, some limited incompatibility of certain macromolecules with lactide/glycolide polymers was observed. Bezwada and co-workers (81) studied *in vitro* and *in vivo* biocompatibility and efficacy of block copolymer of poly(glycolide) and PCL in the form of Monocryl (Ethicon) sutures.

Poly(caprolactone). The biocompatibility and toxicity of poly(caprolactone) have mostly been tested in conjuction with evaluations of Capronor (Schering), which is an implantable 1-year contraceptive delivery system composed of a levonorgestrel-ethyl oleate slurry within a poly(caprolactone) capsule. In a preliminary 90-day toxicology study of Capronor in female rats and guinea pigs, except a bland response at the implant site and a minimal tissue encapsulating reaction, no toxic effects were observed (82). The Capronor-polycaprolactone contraceptive delivery system was also tested implanted in rats and monkeys (83). Based on animal clinical and physical data such as blood and urine analysis, ophthalmoscopic tests, and histopathology after necropsy, no significant differences between the test and control groups was observed. Phase I and II clinical trials with Capronor were recently carried out in different medical centers (83).

Polyphosphazenes. Biocompatibility and safety testing of polyphosphazenes by subcutaneous implantation in animals have shown minimal tissue response (84). The connection between hydrophobicity and tissue compatibility has been noted for classical organic polymers (85). Thus, these hydrophobic polyphosphazenes have been mentioned as good candidates for use in heart valves, heart pumps, blood vessel prostheses, or as coating materials for

pacemakers or other implantable devices; however, more *in vivo* testing and clinical trials are needed (53).

In their bioerosion reactions polyphosphazenes display a uniqueness that stems from the inorganic backbone, and the appropriate side groups can undergo facile hydrolysis to phosphate and ammonia. The phosphate can be metabolized and the ammonia excreted. Theoretically, if side groups attached to the polymer are released by the same process being excretable or metabolizable, then the polymer can be eroded under hydrolytic conditions without the danger of a toxic response. Polyphosphazenes of this type are potential candidates as erodible biostructural materials for sutures, or as matrices for controlled delivery of drugs (53).

Poly(orthoesters). As mentioned previously, the Chronomer poly(orthoester) material from Alza Corp. or Alzamer has been investigated as bioerodible inserts for the delivery of the narcotic antagonist naltrexone, and for the delivery of the contraceptive steroid norethisterone (86,87). *In vitro* studies have shown that good control over release of tetracycline could be achieved, and very good *in vitro* adhesion to bovine teeth demonstrated (88). However, studies in beagle dogs with naturally occurring periodontitis were not successful because ointment-like polymers with a relatively low viscosity are squeezed out of the pocket within about 1 day, despite good adhesiveness (54).

Naturally Occurring Polymers. The use of natural biodegradable polymers to deliver drugs continues to be an area of active research despite the advent of synthetic biodegradable polymers (43). Natural polymers remain attractive primarily because they are natural products of living organisms, readily available, relatively inexpensive, and capable of a multitude of chemical modifications (89). Most investigations of natural polymers as matrices in drug delivery systems have focused on the use of proteins (polypeptides or polyamides) such as gelatin, collagen, and albumin. Collagen is a major structural protein found in animal tissues where it is normally present in the form of aligned fibers. Because of its unique structural properties, collagen has been used in many biomedical applications as absorbable sutures, sponge wound dressings, composite tissue tendon allografts, injectables for facial reconstructive surgery, and as drug delivery systems especially in the form of microspheres (90).

Besides the collagen biocompatibility and nontoxicity for most tissues (91), several factors including the possible occurrence of antigenic responses, tissue irritation due to residual aldehyde cross-linking agents, and poor patient tolerance of ocular inserts have adversely influenced its use as a drug delivery vehicle (90). For example, 5-fluorouracil and bleomycin cross-linked sponges made from purified bovine skin collagen were implanted in rabbit eyes to test their posssible use in preventing fibroblast proliferation following ophthalmic surgery, resulting in a chronic inflammatory reaction elicited by the sponges even in the absence of drug (92).

Noncollagenous proteins, particularly albumin and to a lesser extent gelatin, continue to be developed as drug delivery vehicles. The exploitable features of albumin include its reported biodegradation into natural products, its lack of toxicity, and noninmunogenicity (93).

Medical Applications

Over the past decade the use of polymeric materials for the administration of pharmaceuticals and as biomedical devices has increased dramatically. Important biomedical application of biodegradable polymers is in the areas of controlled drug delivery systems (92–96) and in the form of implants and devices for fracture repairs (97–100), ligament reconstruction (101), surgical dressings (102), dental repairs, artificial heart valves, contact lenses, cardiac pacemakers, vascular grafts (103), tracheal replacements (104), and organ regeneration (105).

Biomaterials in general are used for the following purposes:

(1) to replace tissues that are diseased or otherwise nonfunctional, as in-joint replacements, artificial heart valves and arteries, tooth reconstruction, and intraocular lenses;
(2) to assist in the repair of tissue, including the obvious sutures, but also bone fracture plates and ligament and tendon repair devices;
(3) to replace all or part of the functions of the major organs, such as in haemodialysis, oxygenation (lungs), left ventricular or whole heart assistance (heart), perfusion (liver), and insulin delivery (pancreas);
(4) to deliver drugs to the body, either to targeted sites (eg, directly to a tumor) or sustained delivery (insulin, pilocarpine, contraceptives).

Biodegradable plastics have been developed as surgical implants in vascular and orthopedic surgery, as implantable matrices for the controlled long-term release of drugs inside the body, as absorbable surgical sutures, and for use in the eye (106,107).

Surgical Sutures. Tissue damage that results in a loss of structural integrity, for example, a deep cut in soft tissue or a fracture of a bone, may not be capable of unassisted self-healing. The insertion of a device to hold the tissue together may facilitate the healing process. The classic examples are the use of sutures to hold both deep and superficial wounds together. Once the healing is complete, the suture becomes redundant and can impose undesirable constraints on the healing tissues. It is preferable to remove the material from the site, either physically or by self-elimination.

Synthetic absorbable sutures were developed in the 1960s, and because of their good biocompatibility in tissues they are now widely used in tracheobronchial surgery, as well as general surgery. They are multifilament-type sutures, which have good handle ability (106). However, for continuous suturing, braided sutures with nonsmooth surfaces are not useful. Monofilament sutures have smooth surfaces and are adequate for continuous suturing. For a monofilament suture, PGA or PLA are too stiff and inflexible. The more flexible polydioxanones and polyglyconates can be used as sutures because of their lower bending moduli (108). Furthermore, copolymers of l-lactide and ε-caprolactone-poly(caprolactone-lactic acid) are bioabsorbable elastic materials and their clinical applications have been studied (109).

Bone Fixation Devices. Although metal fixation in fracture treatment for undisturbed bone healing is a successful procedure, cortical bone and steel have

very different mechanical properties. The elasticity constant of bone is only 1/10 of implanted steel while tensile strength is 10 times lower (110). Thus, the removal of metal implants can result in weakened bone with a danger of refracture. Biodegradable implants can meet the dynamic processes of bone healing, decreasing the mechanical strength of the material. After months, the entire material will disappear and no secondary surgery will be required. PGA, PLA, polydioxanone, and PHB have potential roles in this area. For clinical applications, polydioxanone was recommended for ligament augmentation, for securing a ligament suture, as a kind of internal splinting suture, and as a kind of internal splinting to allow for early motion of the extremities after an operation (108,109).

Biodegradable polymers are useful for many other applications. A marrow spacer can help to save autologous bone material. A plug for closing the bone marrow is employed for endoprosthetic joint replacement. Fibers are used for filling large bone defects without mechanical loads (110).

Vascular Grafts. Many studies have been undertaken to develop acceptable small diameter vascular prostheses. Niu and co-workers (111) designed small diameter vascular prostheses with incorporated matrices that can be absorbed into a growing anastomotic neointima. It was pointed out that a gelatin–heparin complex when adequately cross-linked, could simultaneously function as a temporary antithrombogenic surface and as an excellent substructure for an anastomotic neointima.

Adhesion Prevention. Tissue adhesion after surgery occasionally causes serious complications. Materials that prevent tissue adhesion should be flexible and tough enough to provide a tight cover over the traumatized soft tissues, and should be biodegradable and reabsorbable after the injured tissue is completely regenerated. Matsuda and co-workers (112,113) developed photocurable mucopolysaccharides for a newly designed tissue adhesion prevention material that meets numerous requirements such as nonadherent surface characteristics, biocompatibility, biodegradability in accordance with the wound healing rate, and nontoxicity. Mucopolysaccharides (hyaluronic acid and chondroitin sulphate) partially functionalized with photoreactive groups, such as cinnamate or thyamine, were subjected to UV irradiation to produce water-insoluble gels via intermolecular photodimerization of the photoreactive groups (113). Photocured films with lower degrees of substitution, which had high water swellability and flexibility, prevented tissue adhesion and exhibited enhanced biodegradability. It was suggested that these newly designed mucopolysaccharide gels may aid injured tissue repair in a bioactive manner.

Artificial Skin. For healing burns, skin substitutes or wound dressings made of biodegradable polymeric materials have recently been developed. Until now, most of the commercially developed artificial skins have utilized biodegradable polymers such as collagen (114), chitin, and poly-l-leucine (115,116) which are enzymatically degradable polymers. Recently, Koide and co-workers (117) developed a new type of biomaterial for artificial skin, in the form of a sponge, by combining fibrillar collagen (F-collagen) with gelatin. The sponge was physically and metabolically stabilized by introducing cross-links. Although several types of collagen-based artificial skins have been developed (118–120), some undesirable characteristics of native collagen were noticed (121), such as inducing rod-like shapes in fibroblasts and enhancing the expression of collagenase genes

in fibroblasts. F-collagen with gelatin was found to overcome the above problems. Yasutomi and co-workers (122) developed a biosynthetic wound dressing with a drug delivery capability. This medicated wound dressing is composed of a spongy mixture sheet of chitosan-derivatized collagen, which is laminated with a gentamycin sulphate impregnated polyurethane membrane. From *In vitro* evaluation, it was shown that this wound dressing is capable of suppressing bacterial growth and minimizing cellular damage. Evaluation of this wound dressing was conducted in 80 clinical cases including superficial second-degree burns, deep second-degree burns, donor sites, and pressure sores, and achieved excellent results. The development of hybrid artificial skins is also another important target in biomedical engineering. Here, synthetic polymers and cell cultures are combined to form a synthetic–biological composite. In this case, a biodegradable polymer may be required as the template for growing cells and tissue cultures *in vivo*.

Drug Delivery Systems. Biodegradable and non-degradable polymers have been used for controlled delivery of drugs (see CONTROLLED RELEASE TECHNOLOGY). The limitations of conventional methods of drug delivery, by tablet or injection for example, are well known. As a dose is applied, the plasma levels will be raised, but these will be rapidly decreased as the drug is metabolized and will soon be below therapeutic levels. The next dose takes the plasma level high again and a cyclic pattern may be established, with most of the drug plasma levels possibly being outside the optimal range. In addition, the drug usually permeates throughout the body and it is not targeted to the location where it is specifically required. Among the many possible solutions to these problems is the use of controlled drug delivery systems (123,124), from which the drug is released at a constant, predetermined rate, and possibly targeted to a particular site. One of the most prominent approaches is that in which the drug is contained within a polymer membrane or is otherwise encapsulated in a polymer matrix, and where the drug diffuses out into the tissues following implantation, and erosion or dissolution of the polymer contributes to the release mechanism. It sounds, therefore, feasible to produce systems that allow easy and safe processing and can be injected into a body cavity without the need for surgical retrieval after completion of the release. Furthermore, the differential rates of drug delivery might be of profound interest for cases where elevated drug doses are necessary in the beginning of treatment.

BIOMOLECULES AT INTERFACES

Introduction

Many biomolecules are amphiphilic, that is, possess certain regions that interact favorably, and others that interact less favorably, with an aqueous solvent. As such, these biomolecules tend to reside at the interfacial region separating an aqueous phase from another phase of matter. The process of interfacial attachment is referred to as "adsorption"; "adsorbed molecules" or "adsorbates" are terms describing molecules having undergone adsorption (qv). The principal forces leading to adsorption have been identified; these are the ionic, van der Waals, hydrogen bonding, donor/acceptor, and solvation interactions (1). Attachment by a chemical bond is also possible. Proteins, peptides, amino acids, polysaccharides, lipids, and nucleic acids are examples of biological molecules known to adsorb at solid–liquid, liquid–liquid, and/or liquid–vapor interfaces. To fully understand a biomolecule, one must understand its behavior at relevant interfaces, for it is the rare biomolecule not exhibiting a strong tendency to adsorb!

Many examples of biomolecules at interfaces come from nature. Membrane proteins—a term describing those spanning the cell membrane—actually reside at two interfaces (intracellular matrix–cell membrane and extracellular matrix–cell membrane) and serve to regulate transport into and out of cells. Plasma proteins—those existing in blood—attach to the surface of an unrecognized material and initiate the clotting cascade. Other examples come from technological applications. The above-mentioned clotting process unfortunately occurs onto medical implants as well. Interfacial adsorption is ubiquitous during bioprocessing applications; this can have the deleterious effects of vessel fouling and product structural alteration. Adsorption is one common mechanism by which bioseparations are conducted and biocatalysts are immobilized. Adsorbed protein layers are known to have a strong influence on living cells; this effect is exploited in tissue engineering and cellular bioreactors. Finally, both the fabrication of, and detection using, biosensors involve biomolecules residing at interfaces.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

The purpose of this article is to introduce, expand interest in, and grow awareness of, the field of biomolecules at interfaces. Motivation for study in any field is typically driven by either application or curiosity. Workers investigating biomolecules at interfaces are fortunate in that numerous important technological applications exist together with several intriguing and perplexing (and for the most part unsolved!) intellectual curiosities. In most areas of science and engineering, important advances accompany the close interplay between theoretical prediction and experimental measurement. Biomolecules at interfaces is no exception, and a summary of key theoretical tools and experimental methods comprises the subsequent two sections. Note that no attempt is made toward an exhaustive coverage of biomolecule/interface systems. The reader is also invited to consult other excellent reviews related to this topic (1–3).

Technological Applications

A number of important technological applications motivate the study of biomolecules at interfaces. In this section, discussion focuses on important examples in two areas: biomaterials and biosensors.

Biomaterials. Biomaterials find important application as medical implants and tissue engineering substrates. In each case, clinical or scientific effectiveness strongly depends on the behavior of interfacial biomolecules. Other articles in this encyclopedia discuss various aspects of biomaterials. In this section, important aspects dealing with adsorbed biomolecules are briefly presented.

Medical Implants. The insertion of medical implants serving as teeth, bones, skin, blood vessels, and even organs has become commonplace. A universal problem concerns unwanted biological responses; these may be thrombogenic, inflammatory, immunological, or infectious (4–6). It is now well established that protein adsorption precedes and directs these unfavorable events. For example, it is the plasma protein fibrinogen that is thought to initiate thrombogenesis. A small conformational change in the adsorbed fibrinogen is now known to cause platelet adhesion and subsequent aggregation; these events are followed by fibrin formation (6).

Not surprisingly, focus has been directed toward preventing protein adsorption altogether or promoting adsorption of "passivating" proteins (ie those known not to trigger subsequent biological responses). A preeminent strategy for preventing initial protein adsorption involves the grafting of hydrophilic polymer chains to a material surface. Polyethylene oxide (PEO) is particularly effective in this capacity (7–17). The originally suggested mechanism by which PEO prevents protein adsorption involved hydrodynamic currents due to the motion of the grafted chains (7). Subsequent theoretical work has shown that proteins residing within reach of the polymeric brush reduce the conformational freedom of the grafted chains; the polymer layer thus provides an entropic barrier to adsorption (18–25). Very recent work has also demonstrated the importance of the conformational freedom of the individual PEO monomeric units to the prevention of protein adsorption (17).

An alternative to the complete prevention of protein adsorption is the controlled placement of certain biomolecules that act against thrombogenesis. One

natural choice is heparin, an anticoagulant. A number of studies suggest that surfaces with grafted heparin show a diminished thrombogenic response (26,27), but controversy remains as to whether the mechanism is due to heparin-catalyzed antithrombin deactivation of coagulation proteases (28) or to a suppressed adsorption of cell adhesion proteins (29). In addition, although success has been achieved with heparin-coated surfaces, results are not uniformly favorable (30).

Tissue Engineering Substrates. Tissue Engineering (qv) is a field of biomedical study in which techniques are sought to create functional replacements for diseased human tissues and organs (31–36). Successful tissue engineering offers the potential for considerable prolongation of the length and quality of human life. Additionally, it has been estimated that the availability of engineered tissues could reduce expenses related to tissue loss and end-state organ failure by $400 billion per year (31). The key issue in tissue engineering is the availability of materials onto which cells attach, spread, grow, differentiate, and eventually organize to form a desired tissue. Reasoning that the presence of an artificial material would tend to inhibit cellular activity, early efforts were directed toward developing biologically inert materials. The current view, however, is one of a material possessing chemical/biological sequences and patterns capable of signaling and controlling the cellular response (32,37). Materials promoting a natural response, inducing a supernormal response, and/or inhibiting a naturally occurring (but unwanted) response are needed to engineer replacement human tissues.

Tissues or cells typically interact with a biomaterial indirectly through a layer of adsorbed protein. Certain matrix proteins are known to promote cell attachment and growth. One example is fibronectin, a large, extracellular glycoprotein whose constituent modules contain binding sites for a wide range of biomolecules and biological units (38). Its cell-binding site, consisting of the tripeptide amino acid sequence argenine–glycine–asperigine (RGD), is known to bind to the integrin proteins located within the cell membrane; this triggers events that ultimately induce the adhesion, spreading, and growth of cells. Thus, one strategy toward biomaterials for tissue engineering applications is to attach to the biomaterial surface, either chemically or physically, a layer of matrix protein (39–48).

An important alternative to the surface placement of entire proteins is the direct attachment of the cell-binding peptide sequences, such as the RGD sequence in fibronectin (32,37,49–59). This is an example of a "biomimetic" strategy, ie one that mimics biology. Advantages over direct placement of proteins are the greater degree of control of peptide density, spatial arrangement, and orientation and the diminished risk of the material triggering an immune response (37). Disadvantages include the need for additional chemical surface modification (one must generally attach the peptide units and grafted linear polymer chains such as PEO to ensure that proteins do not adsorb and cover the peptides) and the loss of biological signaling from other peptide sequences on the proteins. A number of successes have been reported and it is safe to say that this is currently the most actively researched approach to develop biomaterials as tissue engineering substrates.

Biosensors. A biosensor is an analytical device for the detection of a target biomolecule (60–63). Although many variations are possible, all biosensors combine a detector, where a biological recognition event takes place, with a transducer, which produces an output signal from the recognition event. A biosensor

must be selective for the target molecule in a mixture of structurally similar species. Robustness, cost, size, and real-time measurement capability are additional factors governing the effectiveness of a given biosensing configuration. A number of clinical and biomedical applications are envisioned, but to date the most successful examples of commercialization are the glucose detectors used in the management of diabetes. Other important applications are found in food production, environmental monitoring, and defense/security.

A biosensor's detector typically consists of chemical receptors attached or "immobilized" to a material surface (typically the transducer surface). These are often themselves biomolecules. Detection involves an interaction between these immobilized molecules and biomolecules from solution that approach the detector surface. In this sense, both the fabrication of, and detection using, biosensors involve biomolecules at interfaces.

Biosensor Fabrication. A crucial step in biosensor fabrication is the immobilization of chemical receptors. Chemical receptors may be of two types: catalytic or affinity. In both cases, the target molecule binds specifically to a chemical receptor. In the former, the binding event triggers a measurable change in the transducer. In the latter, the specific binding event leads to a catalyzed chemical reaction, often involving the target molecule itself. The presence of the catalyzed reaction product(s) then triggers a measurable change in the transducer. An important example is the catalytic glucose sensor, in which an oxidation of glucose takes place by immobilized glucose oxidase to gluconic acid and hydrogen peroxide. Hybrid biosensors, in which both catalytic and affinity receptors are utilized, are also possible.

The principal methods for the immobilization of chemical receptors are (*1*) physical adsorption to a solid surface, (*2*) chemical adsorption (covalent attachment) to the surface, (*3*) affinity binding to physically or chemically bound species, and (*4*) entrapment within a matrix. Since physical adsorption relies on relatively weak forces (van der Waals, ionic, solvation, donor/acceptor), molecules placed in this way may detach over time and/or exhibit nonuniform biological activity because of a distribution of surface orientations/conformations. However, this method is clearly the simplest of the four and therefore often finds use. An example is the popular enzyme-linked immunosorbent assay (ELISA) used in medical diagnostics.

A more robust and controllable means of surface attachment is through a covalent bond. Large biomolecules such as proteins typically possess a number of functional groups capable of chemical binding; these include amino, carboxyl, sulfhydryl, phenolic, thiol, and imidizol groups. The best choice for preserving biological activity and optimizing accessibility of the receptor's active site is often a functional group far from the active site. Suitable complementary reactive groups are available on some surfaces (for example, hydroxyl groups on silica), but in many cases, surface modification is needed. A popular means of surface modification is to employ self-assembled monolayers (SAMs) (64). SAMs are closely packed, (approximately) vertically aligned alkane chains residing at an interface. Through chemically functionalized termini, the tailoring of physical and chemical properties of the surface is possible. Chemical immobilization results from a reaction between a specific functional group at a SAM molecule terminus and a biomolecule. (In some cases, a bifunctional reagent is used to achieve the coupling.) A SAM may be placed onto a surface by the Langmuir–Blodget method

(65), via reaction of silanes with a metal oxide surface (66), or via reaction of alkane thiols, alkane sulfides, or alkane disulfides with a metal surface (67,68). Another popular means of surface modification is through a grafted polysaccharide gel (69). Attachment occurs via straightforward chemistry, beginning with an EDC/NHS modification of the polysaccharide layer (70) followed by coupling of an amine, thiol, or aldehyde group on the protein with an NHS ester. The result is a three-dimensional film of receptor molecules.

Affinity binding offers a level of control over receptor molecule orientation and conformation that can significantly exceed that of either physical or chemical attachment. Typically, monoclonal antibodies (IgGs) specific to a region of the receptor molecule away from the active site are used. Binding constants are very high, typically in the range of 10^9–$10^{12}\ M^{-1}$. The antibody itself may be attached physically, chemically, or via specific linkages between its F_c (constant) region and a preadsorbed Protein A or G molecule (71). Additionally, the antibody may be chemically modified via an attached biotin group; in this case, specific binding occurs between the biotin and a complementary site on a molecule of preadsorbed avidin or streptavidin (72,73).

Finally, biomolecules may be immobilized via entrapment within a polymer gel matrix. A number of polymers may be used, eg cellulose acetate (74), poly(vinyl alcohol) (75), and polypyrrole (76). Although high density biomolecule films are possible, a drawback is gradual leakage. This may be alleviated somewhat by cross-linking the biomolecules via chemical reaction. In the case of proteins or peptides, this may be achieved via glutaraldehyde, a reagent that couples with lysine amino acids.

Biosensor Detection. As mentioned above, detection occurs via a measurable change in the biosensor's transducer. Binding of a target molecule to an immobilized chemical receptor may bring about measurable changes that are electrochemical, electrical, thermal, magnetic, optical, or piezoelectric. The principles behind some of these mechanisms are further described in the section entitled Experimental Methods. Additional information can be obtained from a recent review (62).

Intellectual Challenges

A number of experimental observations concerning biomolecules at interfaces are at first glance quite puzzling. Many of them stem from a tendency of these (typically) large molecules to display an adsorptive behavior dependent on history. One example from the literature concerns the adsorption of human serum albumin onto synthetic hydroxyapatite (77). In a series of experiments, the concentration of bulk protein to which hydroxyapatite particles were exposed was varied and the adsorbed amount measured. As shown in Figure 1, when the adsorbed density versus concentration in solution (ie the adsorption isotherm) is plotted (Fig. 1), one finds a significant dependence on the "concentration trajectory," ie on the concentrations to which the surface was exposed at earlier times. Another example is the stepwise adsorption of cellulose onto silica (78). In this experiment, a sample is alternately exposed to solutions of increasing or decreasing cellulose concentration (between each concentration, a rinse is conducted in cellulose-free solution). As shown in Figure 2, it is found that the adsorption isotherm differs, depending

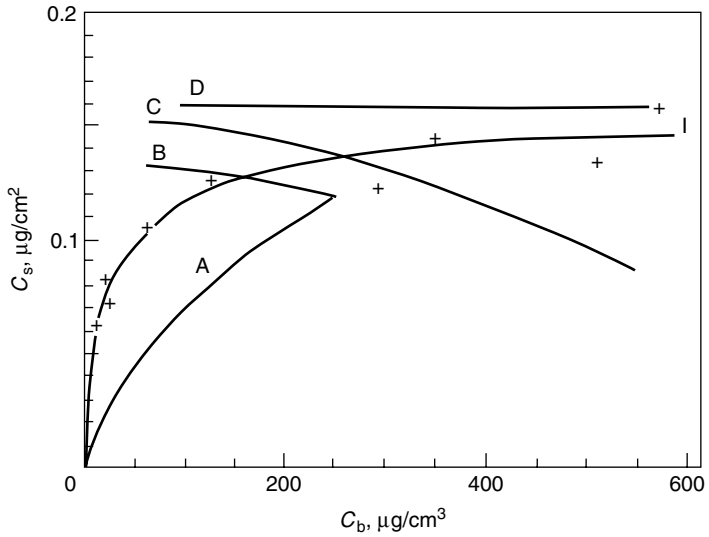

Fig. 1. The concentration of human serum albumin adsorbed to hydroxyapatite particles versus bulk protein concentration along several concentration "trajectories." Curve A: a gradual increase in bulk protein concentration via flow of 0.066 g/L protein solution into chamber of particles. Curve B: a gradual decrease in bulk protein concentration via flow of buffer solution without protein. Curve C: a protein concentration of 0.695 g/L for 30 min followed by a gradual decrease in bulk protein concentration via flow of buffer solution. Curve D: a protein concentration of 0.858 g/L for 8 h followed by a gradual decrease in bulk protein concentration via flow of buffer solution. Curve I: Protein concentrations corresponding to the horizontal axis for 8 h. Taken with permission from Ref. 77.

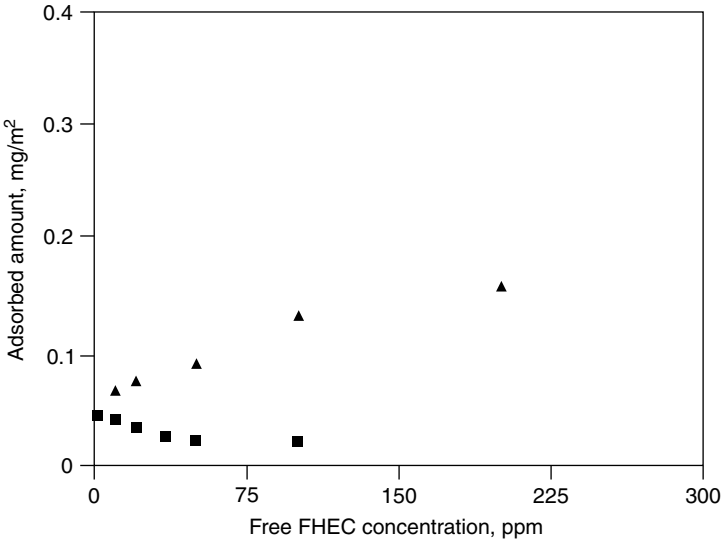

Fig. 2. The density of hydroxyethylcellulose adsorbed to silica versus bulk concentration for a series of alternating 40-min exposures to pure buffer and biopolymer solutions. Curves representing progressively increasing (squares) and decreasing (triangles) concentrations are shown. Taken with permission from Ref. 78.

upon whether the steps are of increasing or decreasing concentration. In fact, the adsorbed density increases with solution concentration only along the decreasing series. A final example is the multistep kinetic measurement of fibronectin onto silica–titania (79). As in the previous example, a surface is alternately exposed to a protein solution and an otherwise identical solution containing no protein. As shown in Figure 3, when the time between the first and second adsorption step is short, the rates of adsorption along both steps are roughly identical. However, when a longer time period separates the two steps, the rate of adsorption during the second step greatly exceeds—for a given amount of adsorbed protein—the rate during the initial step.

These features may be explained by considering two interesting features of biomolecular adsorption (features also exhibited by many synthetic macromolecules): (*1*) the presence of irreversibility and (*2*) the presence of post-adsorption "relaxation" events on a time scale exceeding that of adsorption. Irreversibility is demonstrated in Figure 4, where the kinetics of cytochrome P450 adsorption to a lipid bilayer are shown (80). One sees that replacement of the protein solution by an identical solution without protein results in only a fraction of the adsorbed molecules leaving the surface, the others being essentially irreversibly adsorbed. The insensitivity of isotherm D in Figure 1 to dilution can be explained by irreversible adsorption occurring at the initial (highest) concentration. The history-dependent behavior observed in Figures 2 and 3 can be explained by post-adsorption relaxation mechanisms. The decreasing nature of the ascending concentration branch of Figure 2 may be explained by the presence of post-adsorption conformational changes. These changes lead to a flatter, more elongated adsorbed molecule and are favored when the rate of adsorption is slow, as occurs when the bulk concentration is low. In contrast, when the rate of adsorption is high, relaxation to the flatter structure is sterically blocked by molecules adsorbing at neighboring positions. If the same type of post-adsorption event occurred in the system whose kinetics are displayed in Figure 3, one would find a decreased rate of adsorption during the second step because of the greater surface area covered by the more conformationally altered molecules. Instead, the increased second-step adsorption rate is caused by another type of post-adsorption structural change: clustering or aggregation among the adsorbed molecules. This event opens up space on the surface in much the same way as clustering furniture in the corner of a room opens space for a social gathering.

The history dependence engendered by the slow rate, relative to that of initial attachment, of subsequent relaxation events (eg internal conformational changes, aggregation with other adsorbed molecules) renders challenging the theoretical treatment of biomolecules (as well as many synthetic macromolecules) at interfaces. Nonequilibrium methods must generally be employed, but these are less well developed than their equilibrium counterparts. The quest for a theoretical description is therefore a daunting one; progress along this front is the topic of the next section.

Theoretical Approaches

The ultimate objective in any physical science is often to understand a system or phenomenon quantitatively, that is, within the framework of a mathematical

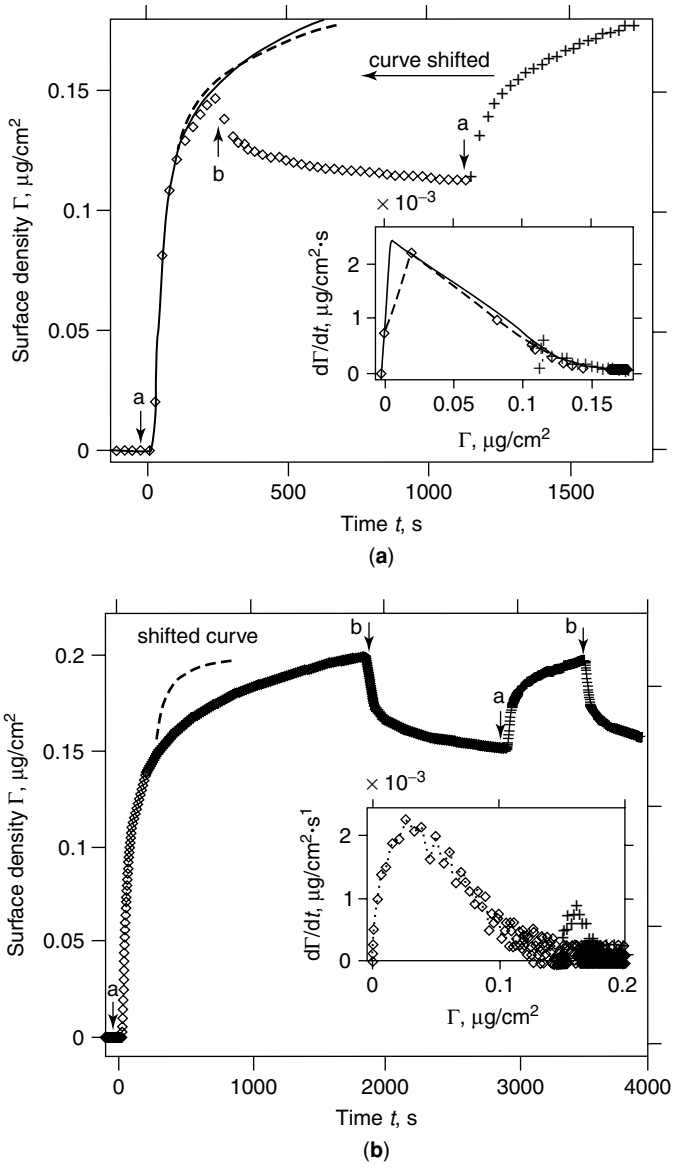

Fig. 3. The density of fibronectin adsorbed to silica–titania versus time for a multistep experiment in which exposure to a flowing solution of 0.05 g/L protein concentration is interrupted by exposure to a flowing solution without protein. (**a**) A short initial adsorption step and rinse. (**b**) A longer initial adsorption step and rinse. Taken with permission from Ref. 79.

model. Attempts to model biomolecules at interfaces—where, as mentioned above, history-dependent behavior is rampant—fall principally along five lines. The first and simplest is the site description in which interfacial behavior is modeled as the filling of discrete adsorption sites at the interface. Borrowing heavily from theories on gas adsorption, many closed-form mathematical models are available. A second is the particle description in which the biomolecule is approximated by

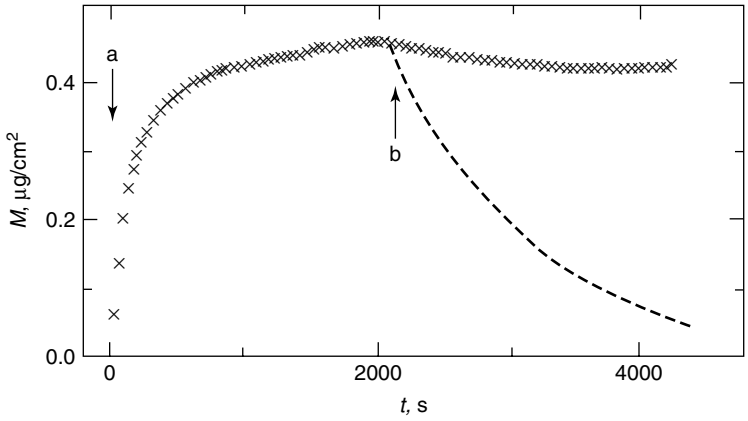

Fig. 4. The density of cytochrome P450 adsorbed to a lipid bilayer versus time. Points A and B denote the onset and termination of exposure to the protein solution and the dashed line represents the expected curve assuming first-order kinetics and fully reversible adsorption. Taken with permission from Ref. 80.

a simple geometric object whose adsorption behavior is governed by a few lumped phenomenological parameters. A third is the colloidal approach combining the simple particle geometry with an explicit, continuum approach to the forces of interaction. A fourth is the polymer description, in which the chain-like structure of most biomolecules (linear sequence of amino acids in proteins and peptides, linear sequence of nucleic acids in DNA and RNA) is used to justify a treatment using theoretical methods developed for synthetic polymers. Finally, a fifth is the atomistic description in which the detailed molecular architecture of the biomolecule is taken into account. A molecular force field is invoked and the energy from the biomolecule–surface interactions is summed. (Solvent molecules are often implicit.) Of course, the level of detail within each of these approaches varies according to the system and the objectives of study. Generally, the particle description is preferred for modeling systems of all but infinitely dilute surface densities.

Site Description. The adsorption of biomolecules at an interfacial region can be modeled as the filling of discrete surface sites. Although such models are more appropriate for gas adsorption, their mathematical simplicity has made them convenient and frequently used tools for modeling biomolecular adsorption as well. The most well known is the Langmuir model, in which fully reversible adsorption occurs onto noninteracting sites. The kinetic expression is

$$\frac{d\Gamma}{dt} = k_a c_s \left(1 - \frac{\Gamma}{\Gamma_{max}}\right) - k_d \Gamma \tag{1}$$

where Γ is the adsorbed density, t is the time, k_a is the intrinsic adsorption rate, c_s is the concentration of adsorbing species in solution at the surface, Γ_{max} is the density of adsorbed species when all surface sites are filled, and k_d is the intrinsic rate of desorption. The solution to equation 1 is

$$\frac{\Gamma(t)}{\Gamma_{max}} = \frac{Kc_s}{1+Kc_s}\left[1 - e^{-(k_a c_s/\Gamma_{max} + k_d)t}\right] \tag{2}$$

where $K = k_a/k_d$.

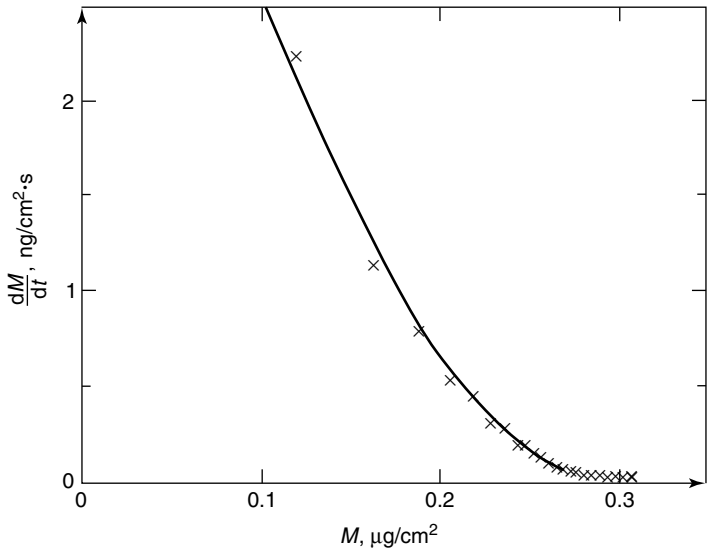

Fig. 5. The rate of adsorption of transferrin onto silica–titania versus adsorbed amount. Taken with permission from Ref. 81.

A consideration of Figure 4 demonstrates the inadequacy of the Langmuir approach to most biomolecular systems. For one, the saturation is approached much more slowly than the exponential behavior predicted by equation 2. Secondly, by setting c_s=0, equation 1 would predict a complete desorption during a rinse. Instead, desorption of only a small fraction of the adsorbed molecules results. Finally, equation 1 predicts a linear relationship between adsorption rate and adsorbed amount. In fact, most systems demonstrate a nonlinear relationship. An example is shown in Figure 5 for transferrin adsorption onto silica–titania (81). Despite these and other drawbacks, the Langmuir model continues to find use in a number of instances.

Extensions to account for experimentally observed features of biomolecular adsorption have appeared. For example, the case of adsorption followed by subsequent "spreading" has been treated in the context of a Langmuir approach (82,83). Other examples are models employing interactions between molecules on neighboring sites (or sets of sites in cases of multiple occupancy). Two-dimensional protein ordering or aggregation has been modeled using hexagons adsorbing to a hexagonal lattice (84) and tetramers adsorbing to a square lattice (85). A model additionally considering surface site heterogeneity has also appeared (86).

Particle Description. If the adsorption rate reflects the amount of available surface for adsorption, then the nonmonotonic decrease in adsorption rate with adsorbed density of Figure 5 may be interpreted as being due to the filling of a continuous surface by geometric objects. This result is not surprising; when one considers that the greater size of most biomolecules compared to the expected distance between surface attachment sites, adsorption essentially occurs onto a continuum. Such an approach to biomolecular adsorption is called a particle description and, through its more realistic treatment of surface exclusion effects, represents an improvement over a site description. At first thought, modeling a

complicated biological molecule as a simple geometric object (eg sphere, ellipsoid) seems a ridiculous oversimplification. After all, millennia of evolution have produced biomolecules of exquisite complexity. However, unlike synthetic molecules, certain biomolecules (eg proteins) possess a unique folded three-dimensional structure (many are crystallizable!) and so long as the interfacial perturbation is not too great, may keep this structure and behave, to a first approximation, as a rigid object. (Of course, a large interfacial perturbation may cause the biomolecule to unfold to a degree where a polymer description becomes more appropriate.) In fact, the particle description is able to predict many interesting features of biomolecular adsorption (an important example of this is shown in Figure 5).

When adsorption is completely irreversible, the particle description reduces to the random sequential adsorption (RSA) model (87–89). An RSA process is one in which hard objects are added randomly and sequentially to a surface at a given rate and in which any object placed in a position so as to overlap with another object is immediately removed. The governing kinetic equation is

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}t} = k_{\mathrm{a}} c_{\mathrm{s}} \Phi \tag{3}$$

where Φ is the fractional surface available for adsorption. For line segments adsorbing to an infinite line, an analytical solution is available (90,91). In higher dimensions, analytical solutions have been elusive. However, exact theoretical treatment is possible in the limits of low and high surface coverage. At low surface coverage, Φ may be expressed as a power series in surface coverage (92):

$$\Phi = 1 + A_1\theta + A_2\theta^2 + \cdots \tag{4}$$

where θ is the fraction of the surface covered by the vertically projected area of the particles. At high surface coverage, the time evolution of the size distribution of isolated regions of empty space may be deduced and related to the overall rate of adsorption. This gives

$$\Phi = Ct^{-\nu} = (\theta_\infty - \theta)^{\frac{\nu}{\nu - 1}} \tag{5}$$

where C is a constant, θ_∞ is the surface coverage approached as $t \to \infty$, and ν is an exponent whose value depends on the particle geometry. For example, in the case of a disk, $\nu = 3/2$ (93,94); while for an elongated, convex 2-D object, $\nu = 4/3$ (95). A reasonable approximate expression for Φ valid at all times is found in the form of a Pade approximant (92):

$$\Phi \approx \frac{(\theta_\infty - \theta)^{\frac{\nu}{\nu - 1}}}{1 + B_1\theta + B_2\theta^2 + \cdots} \tag{6}$$

where the coefficients B_i are evaluated in terms of the known A_is by matching the first few terms in the θ expansion of equation 6 with those in the θ expansion of equation 4.

Most biomolecular adsorption systems exhibit only partial irreversibility (see, eg, Fig. 4). The RSA model may be extended to include desorption and post-adsorption structural changes. In this case, one must write at least two kinetic

equations (one for each structure or "state" of the adsorbed molecule) (96–102):

$$\frac{d\Gamma_\alpha}{dt} = k_a c_s \Phi_\alpha - k_d \Gamma_\alpha - k_s \Gamma_\alpha \Psi_{\alpha\beta} \tag{7}$$

$$\frac{d\Gamma_\beta}{dt} = k_s \Gamma_\alpha \Psi_{\alpha\beta} \tag{8}$$

In equations 7 and 8, Γ_α and Γ_β are the adsorbed densities of molecules in their initial and surface-altered structures, Φ_α is the fractional available area for adsorbed molecules in their initial state, $\Psi_{\alpha\beta}$ is the probability that an adsorbed molecule in its initial state has available area around it sufficient to allow for a conversion to the surface-altered state, and k_s is the intrinsic rate of structural alteration. (Extensions are straightforward to cases of several adsorbed states.) Theoretical approximations to the functions Φ_α and $\Psi_{\alpha\beta}$ have been made in cases of (*1*) purely irreversible adsorption ($k_d = 0$, no surface diffusion) using methods analogous to those used to derive equations 4–6 (97), and (*2*) high surface mobility using the equilibrium-scaled particle method (101,102). Simulations have also been performed (96,98–100). Nonuniform or time-dependent rate constants have also been incorporated in these expressions (99,100,103) and an extension accounting for protein clustering has been developed (104,105). A model combining the site and particle descriptions has been proposed (106). A complete description of the adsorption process may be obtained by coupling equations 7 and 8 to bulk transport equations (107).

Another particle description is the molecular mean field treatment in which the free energy of a system of molecules near to an interfacial region is expressed as a functional of the density distribution (108). This approach was inspired by the single-chain mean-field method developed to study the behavior of grafted polymer layers. The equilibrium adsorbate density distribution is just that which minimizes the free-energy functional subject to certain excluded volume constraints. The system's dynamics may also be determined through a generalized diffusion equation; the diffusive flux is proportional to the chemical potential gradient, and the position-dependent chemical potential is determined as the functional derivative of the (nonequilibrium) free energy with respect to density. Although more computationally intensive than the particle methods discussed above, the major advantages of this method are the straightforward extensions to mixtures, multiple conformational states, realistic intermolecular potentials, and the presence of grafted polymer layers (20–25,109).

A brief mention is merited for models treating biomolecular (typically protein) adsorption in the presence of tethered polymer chains. Early efforts utilized the Alexander–de Gennes theory to describe the steric repulsion felt by proteins near the polymer layer in its "brush" regime (18). Although results are qualitatively correct, this approach requires the chains to be longer than those used experimentally, so quantitative applicability is limited. A subsequent effort employed a self-consistent field approach, but again only long chains were considered (19). The treatment of systems with chain lengths closer to those of experiment became possible through the single-chain mean-field theory (20–25). This theory allows for the incorporation of detailed molecular structure for both polymer and protein and has been used to accurately predict the long- and short-time adsorptive properties of biomaterials containing grafted polymer chains (24,110).

Colloidal Description. A colloidal approach combines the simple particle geometry with an explicit, continuum approach to the forces of interaction (111–113). At the heart of this approach is a treatment of electrostatics via the Poisson equation,

$$\nabla^2\phi = -\frac{\rho(\vec{r})}{\varepsilon} \tag{9}$$

where ϕ is the electric potential, ρ is the charge density, and ε is the dielectric permittivity. Within a solid adsorbent or a (assumed rigid) protein, the charge density distribution results from the presence of immobile charged species. In solution, the charge density distribution results from dissolved ionic species, which may be assumed to be distributed in a Boltzmann manner,

$$\rho_i(\vec{r}) = \rho_{i,\text{bulk}} z_i \exp\left(-z_i e\phi(\vec{r})/k\text{T}\right) \tag{10}$$

where $\rho_{i,\text{bulk}}$ is the bulk density of ionic species i, z_i is its valence, e is the elementary charge, k is the Boltzmann constant, and T is the absolute temperature. The resulting electric potential—which for all but the simplest geometries must be determined numerically—is used to calculate the total interaction energy

$$U_{\text{elec}} = \sum_i z_i e\phi(\vec{r}_i) \tag{11}$$

where the sum runs over all charges in the system. (The sum becomes an integral in the case of a continuous charge distribution.)

Colloidal approaches also frequently account for van der Waals interactions, ie interactions due to fluctuating dipoles. For atomic species, these interactions vary as distance to the minus sixth power. For protein/surface systems modeled via a colloidal description, this $1/r^6$ dependence is integrated over the volumes of the interacting bodies. The result is the product of a Hamaker constant, which depends upon material properties, and a term dependent on the system's geometry. In addition, forces related to solvation (114) and donor/acceptor (115) affects may also be included.

Although not amenable to predictions of irreversibility or conformational change, colloidal approaches have been successful in predicting qualitative trends in—and, to a certain extent, quantitative values of—equilibrium constants in the case of fully reversible adsorption at low surface coverage (116–120). In many cases, simple protein geometries and charge distributions suffice. In other cases, such as when adsorption is controlled by charged patches (121,122), more realistic models must be used. An accounting of protein–protein interactions to allow for a finite surface coverage has also been made (123–126).

The colloidal approach has also been applied to the adsorption of DNA on to a charged surface (127,128).

Polymer Description. A lattice model heteropolymer (129–131) provides a simple yet instructive description of a protein molecule. In general, the coarse graining is such that each segment represents a portion of the protein (ie many amino acids). In the simplest case, two types of segments are present; these may be thought of as polar and hydrophobic (132–138). In other cases, a distribution

of segmental interactions is employed (139–143). The minimalist nature of this model allows for efficient sampling of conformational space via simulation (for chains of less than 20 segments, exact enumeration of all conformations is possible). Despite its apparent simplicity, for a proper choice of segment–segment nearest-neighbor interaction strength, this model is capable of exhibiting the essential physics of protein folding (eg coil–globule and globule–folded transitions and the presence of a glass transition). Of particular importance have been 27 segment models in which certain sequences fold into a unique $3 \times 3 \times 3$ cubic structure (134,136–143). Recently, uniquely folding sequences have been studied at liquid–solid (99,144–146) and liquid–liquid (147) interfaces. An interesting observation has been the initial continuous transition of the model protein to an unfolded, fully flattened state followed by an activated transition to a partially refolded, less-flattened state (145,146). Proteins modeled as shorter chains, where exact enumeration is possible, have also been studied at the liquid–solid interface (148,149).

Other lattice polymer efforts have been based on the self-consistent field theory of Scheutjens and Fleer (150,151). This approach differs from previously posed statistical theories for chain molecules in that the partition function is expressed in terms of the distribution of chain conformations rather than the distribution of segment densities. The equilibrium distribution of chain (ie model protein) conformations is thus calculable. Quantities predicted using this approach include the force between parallel plates coated with protein (152,153), the adsorption isotherm (154,155), and the segmental density distribution (154–157).

A simple yet instructive model for determining general features of certain biomolecules at interfaces is the random heteropolymer description (158–174). A random heteropolymer is defined as one whose sequence of monomers follows a statistical distribution. A collection of random heteropolymers is therefore an example of a quenched–annealed system, that is, one in which certain degrees of freedom are fixed and follow a known distribution (in this case, the heteropolymer sequence) and others equilibrate with respect to these fixed degrees of freedom (in this case, the spatial distribution of the segments). Special methods developed for treating such systems (175) are therefore applicable and have been useful in determining properties of single (160) and sets of (162,164) adsorbed chains.

Clearly, nucleic acids are also amenable to a polymer description. Theoretical (176) and simulation (177,178) methods have been used to determine the structure, dynamics, and thermodynamics of nucleic acid chains on surfaces.

Atomistic Description. Molecular modeling at the atomistic level has become commonplace. The dual challenges of accurate potential force field description and efficient configurational sampling have been met to a degree where predictive capabilities now exist for many single- and multicomponent systems of simple molecules. The extension of these methods to biomolecules, and more specifically to biomolecules at interfaces, presents a challenge because of the size and complexity of these molecules. However, some attempts to calculate physical properties of atomistically modeled biomolecules at interfaces have appeared (see Molecular modeling (structure, molec. graphics)).

Early efforts were essentially static calculations of the interaction energy between a rigid protein and a surface (112,114,121,179–181). Pairwise atomistic potential energy descriptions were used to calculate the van der Waals and electrostatic contributions. In the case of hydrophobic surfaces, solvation energies

were estimated from partition coefficients of the individual amino acids between aqueous and organic phases (114,180). Some of these studies treated the electrostatic interactions in a colloidal manner (112,121). The calculated energies for various geometries were helpful in understanding chromatographic behavior. Similar calculations of individual amino acids on self-assembled monolayers have also been conducted with the hope of uncovering trends useful for predicting behavior of entire protein molecules (182).

Molecular dynamics (MD) is a method in which Newton's equations of motion are solved for a molecular system obeying a differentiable potential function. A few efforts at modeling proteins at interfaces using MD have appeared (183–187). Obviously, these studies provide dynamic as well as thermodynamic information on biomolecules at interfaces. Systems studied have included lysozyme and myoglobin on polyethylene glycol (183), cytochrome c on hydrophilic and hydrophobic self-assembled monolayers (184), leucine enkephalin near a crystalline polyethylene surface (185), thermal hysteresis proteins on ice (186), and lysozyme on polyvinylimidazole (187).

Experimental Methods

Progress in any field requires information on the state of well-defined systems as a function of conditions. Advancement is thus intimately linked to the availability of experimental probes capable of providing accurate and detailed information. Important metrics of biomolecules at interfaces include the interfacial composition; distributions in molecular orientation, molecular spatial arrangement, and intramolecular conformation; and biological activity. In this section, several experimental techniques probing the physical properties of biomolecules at interfaces are introduced; these are grouped into optical, piezoelectric, and scanning probe methods. Further details can be found in other excellent reviews (62,188,189).

Optical Methods. Optical methods involve directing polarized monochromatic light toward the solid–liquid interface and measuring a response, eg the polarity or intensity of reflected or emitted light. Various schemes have been proposed, as described below, and these allow for the determination of adsorbed-layer thickness, density, and composition as well as information on internal conformation. Principal advantages of optical experimental probes include nondestructiveness and the capability of continuous, real-time measurements.

Reflection-based methods (190–194) involve measuring the reflection of polarized light at the interface between two optical media. In fact, two reflections are measured: one for the electric field component perpendicular to the plane of incidence (transverse electric or *s*-wave) and one for the electric field component parallel to the plane of incidence (transverse magnetic or *p*-wave). At a certain angle of incidence (the Brewster angle), the *p*-wave reflection vanishes and around this angle, the reflectivity, or square of the amplitude of the *p*-wave reflection, and ellipticity, or ratio of *p*- and *s*-wave reflections, become very sensitive to interfacial heterogeneity, as brought about eg by adsorption of biomolecules. By assuming the adsorbed layer to be uniform in refractive index, both its thickness and refractive index may be determined. By further assuming a linear dependence of refractive index on concentration, the adsorbed density is calculable (195).

Optical waveguide methods (188,196–198) are based on the phase shift associated with multiple interfacial reflections: when either the *s*- or *p*-wave undergoes a total phase shift equal to an integral multiple of 2π upon one complete traversal of a planar, dielectric waveguide sandwiched between media of lower refractive index, a standing wave is excited in the waveguiding film. Because of their dependence on reflection, the phase shifts are sensitive to interfacial heterogeneity—and the thickness, refractive index, and density of an adsorbed biomolecular layer can be readily determined.

When light traversing an optically dense medium approaches an interface with a more optically rare medium at an angle exceeding a critical value, $\theta_{crit} = \sin^{-1}(n_{rare}/n_{dens})$, a total internal reflection occurs and an evanescent wave of exponentially decaying intensity penetrates the rarer medium. This phenomenon is at the heart of certain spectroscopic methods used to probe biomolecules at interfaces (199). In total internal reflection fluorescence (TIRF) spectroscopy (200–202), the evanescent wave excites fluorescent probes attached to the biomolecules, and detection of the emission associated with their decay provides information on the density, composition, and conformation of adsorbed molecules. In fourier transform infrared attenuated total reflection (FTIR-ATIR) spectroscopy (203,204), the evanescent wave excites certain molecular vibrational degrees of freedom, and the detected loss in intensity due to these absorbances can provide quantitative data on density, composition, and conformation.

Surface plasmon resonance (SPR) (205–209) is an optical method in which the *p*-wave of incident light excites a propagating, nonradiative charge density oscillation at a metal–dielectric interface. The resonant condition is the matching of the wave vector component of the *p*-wave parallel to the interface to the wave vector of the surface plasmon. The latter is sensitive to the optical properties of a fluid or adlayer near the interface, so by monitoring changes in the angular distribution of the intensity of reflected light, physical properties of adsorbed species may be determined.

Piezoelectric Methods. A *piezoelectric crystal* is one in which a mechanical stress induces an electric current. Conversely, application of an alternating voltage to a piezoelectric crystal induces a vibration. The frequency of oscillation is extremely sensitive to the mass contacting the crystal, and it is the frequency shift due to adsorption that is the basis for piezoelectric methods (210). A quartz crystal microbalance (QCM) (211–214) consists of a thin disk of (piezoelectric) crystalline quartz sandwiched between thin-film metal electrodes. Upon application of an alternating voltage, the crystal undergoes thickness shear mode vibration. The mass adsorbed to the electrode surface—here, unlike in the optical methods described above, the mass includes trapped solvent—is simply proportional to the frequency shift. In addition, the dissipation of energy following voltage removal, as measured by the decay of the oscillation amplitude, is a sensitive measure of the viscoelastic properties of an adsorbed layer. QCM thus provides a valuable complement to optical methods through information concerning conformation (via the amount of trapped solvent in an adsorbed film) and rigidity (via the film viscoelastic response).

Scanning Probe Methods. Scanning probe methods (215–217) involve probing a solid surface with a very sharp tip and measuring its deflection or other physical change in order to create a topographical image or to determine a surface force profile. Two common methods for imaging biomolecules at interfaces

are contact-mode and tapping-mode atomic force microscopy. In the former, the tip is scanned over the surface while remaining essentially in contact with the surface or adsorbed species. In the latter, the probe oscillates as it scans and only in the "valley" of each oscillation does it contact the substrate. An advantage to the tapping-mode method is the elimination of shear forces capable of damaging soft samples (eg biomolecules) that can diminish image resolution. Atomic force microscopy in force–distance mode provides information on the intramolecular, intermolecular, and molecule–surface forces. The experiment involves directing the tip (often coated with biomolecules) toward the surface and measuring the resulting force as a function of tip–surface distance. The capability to extract information from individual molecules is the principal advantage to scanning probe methods; in contrast, optical and piezoelectric methods give information on the collective properties of an adsorbed layer.

Conclusions

Biomolecules at interfaces continues to be a challenging and important subject of basic research and biotechnological development. Despite intense investigation for several decades, a number of significant challenges remain, including the complete prevention of protein adsorption onto blood-contacting biomaterials, the controlled placement of biologically active molecules on sensing and tissue engineering substrates, and the quantitative prediction of events occurring as biomolecules approach and reside at the interfacial region. Recent experimental developments, particularly those in optical, scanning probe, and piezoelectric instrumentation—and advances in statistical–mechanical modeling, interatomic force field development, and computational power—are converging to provide new insights, at an unparalleled rate, in order to meet these and other emerging challenges.

BULK AND SOLUTION POLYMERIZATIONS REACTORS

Introduction

This article discusses polymerization reactors where the continuous phase is a solution of a polymer in its own monomer or in a solvent. When the low molecular weight species is primarily monomer, the reaction is a bulk polymerization; and when it is a solvent, the reaction is a solution polymerization. This distinction has little practical importance. The important consideration is that a high viscosity polymer solution is the continuous phase and is in contact with the reactor walls and the agitator. In contrast, suspended-phase polymerizations (such as emulsion, dispersion, and suspension) and gas-phase polymerizations have a low viscosity continuous phase (see HETEROPHASE POLYMERIZATION).

Table 1 lists representative bulk and solution polymerizations. All these polymerizations give a polymer-rich continuous phase that, at the end of the reaction, will have a viscosity $10^4 - 10^7$ times higher than the feed solution. Laminar flow is the norm. Heat and mass transfer coefficients are much lower than is common in the chemical industry, and specialized equipment is often necessary.

The manner in which viscosity increases with conversion has a strong influence on reactor design. Polymerizations with long chain lives, such as condensation and anionic polymerizations increase chain length and viscosity slowly. When half the monomer has reacted, the number-average chain length will be about 2 and the viscosity of the mixture will be about twice that of the pure monomer. Polymerizations with short chain lives, as is typical of free-radical and transition-metal catalyses, yield high molecular weight polymers from the onset. A mixture containing 50% monomer by weight might contain a polymer with an

Table 1. Representative Bulk and Solution Polymerizations

Polymer	Type of polymerization	Process	Reaction medium	Heat of reaction, kJ/mol[a]	Reaction exotherm, K	By-product to be removed
Polyethylene	Vinyl addition	High pressure	Solution of polyethylene in ethylene	95.0	1610	Heat
High density Polyethylene	Vinyl addition	Solution	Solution of polyethylene in hexane	95.0	1610	Heat
Poly(vinyl chloride)	Vinyl addition	Bulk	Polymer-rich phase in contact with a (suspended) vinyl chloride phase	95.8	730	Heat
Polystyrene	Vinyl addition	Bulk	Solution of polystyrene in styrene and ethyl benzene	69.9	320	Heat
PMMA	Vinyl addition	Bulk	Solution of polymer in methyl methacrylate	56.5	270	Heat
Nylon-6	Ring opening	Bulk	Solution of polymer in caprolactam	15.9	68	None
Polysulfone	Condensation	Solution	Solution of polymers and monomers in monochlorobenzene with a suspended NaCl phase	25.1	24	NaCl
Polycarbonate	Condensation	Interfacial	Polymer solution in methylene chloride in contact with an aqueous NaOH phase	0	0	HCl (as NaCl)
Poly(butylene terephthalate)	Condensation	Bulk	Polymer solution in diglycol terephthalate	0	0	Ethylene glycol

[a]To convert kJ/mol to kcal/mol, divide by 4.184.

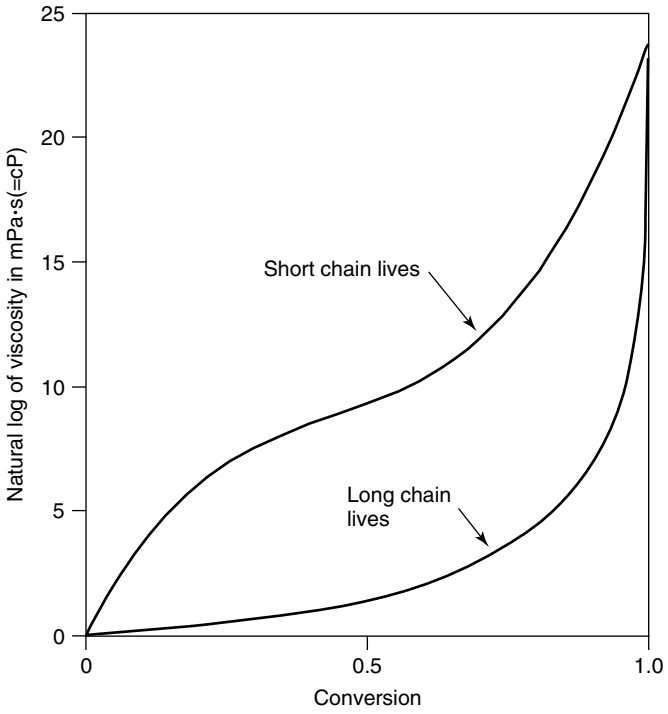

Fig. 1. Representative curves of viscosity as a function of conversion for short and long chain lives. The end point in both cases is a number-average chain length of 1000 and 0.1% residual monomer.

average chain length of 1000 and a viscosity that is 10^4 times that of the monomer. Figure 1 illustrates the difference between short and long chain lives for a polymerization that starts and ends at the same points but proceeds by different mechanisms.

There are three key design issues in bulk and solution polymerizations:

(1) Removing the heat of polymerization. This is applicable mainly to vinyl addition polymerizations.
(2) Achieving adequate stoichiometry and by-product removal to obtain high molecular weight polymers. This is applicable mainly to condensation polymers.
(3) Achieving desired copolymer composition distributions.

Managing the Reaction Exotherm

For vinyl addition and diene polymerizations, heat removal is a primary concern. The reaction exotherm listed in Table 1 is the heat of polymerization divided by the specific heat of the polymer. It is a fictitious quantity for energetic polymerizations since bonds break and the polymer reaches a ceiling temperature well before

Table 2. Methods for Temperature Control

Method for controlling temperature	Example system
React to low conversion	High pressure polyethylene
Dilute with solvent	Solution polyethylene
Dilute with dead polymer	PMMA casting
Adiabatic reactors	Nylon-6 casting
Boiling CSTRs	Polystyrene bulk continuous
Cold feed to a CSTR	PMMA bulk continuous
CSTRs with heat transfer to jackets or internal coils	Specialty polymers in small reactors
Flow inside a single tube	High pressure polyethylene
Shell-and-tube reactors	Solution polyethylene
Stirred-tube reactors	Polystyrene bulk continuous

the full exotherm is realized, but it provides a rough measure of the difficulty of controlling the reaction temperature.

The vinyl addition polymers undergo polymerization by opening a double bond in a substituted ethylene molecule. The energy release is 50–100 kJ/mol. The reaction exotherm varies over a broader range since it depends on the mass of the substituted groups. Thus ethylene and vinyl chloride polymerizations have the same heat of reaction per mole but very different exotherms due to the relative mass of the monomers. The vinyl addition polymerizations are too energetic to allow adiabatic polymerizations, except in very special cases. Heat removal is a dominant consideration in reactor design. In sharp contrast, a condensation polymer such as poly(ethylene terephthalate) is formed by a series of ester exchange reactions where the bonds being made and broken have nearly the same energy. Adiabatic polymerizations are possible for such polymers, and heat may even be added to evaporate the condensation by-product. Conversion is typically limited by by-product removal.

Table 2 lists various methods that have been used to control the temperature in bulk and solution polymerizations. All these processes continued to be practiced industrially but some would no longer be chosen for new construction.

Reaction to low conversion and the use of large amounts of solvent are conceptually similar. The high pressure process for low density polyethylene limits conversion to about 15%. This reduces the exotherm to about 250°C. A similar result is achieved in the solution process for high density polyethylene, where the conversion of monomer is high but the reactor contains about 85% solvent. Both processes rely on supplemental cooling by sensible heat transfer to tube walls. The high pressure uses a single tube and is “once through” with respect to polymer. The solvent process employs a shell-and-tube heat exchanger in a recycle loop.

Figure 2 shows the reaction exotherm for the semi adiabatic batch polymerization of a methyl methacrylate casting system. The methyl methacrylate monomer has been diluted with dead polymer to limit the exotherm and to increase the viscosity of the casting syrup. The polymerizing mass undergoes a glass transition and polymerization stops before the temperature reaches the atmospheric boiling point of methyl methacrylate, thus avoiding bubbles in the cast

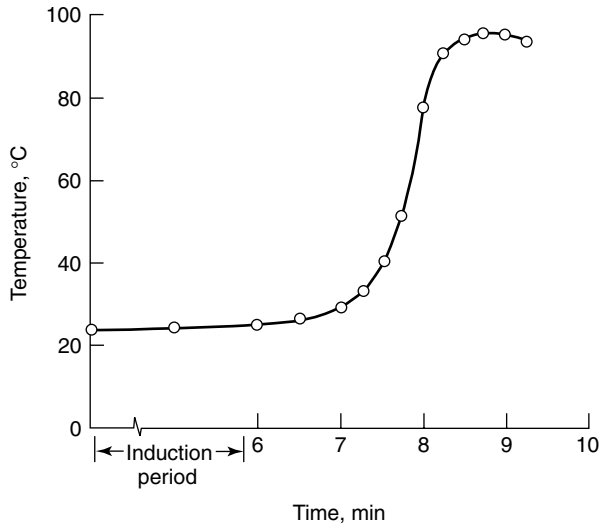

Fig. 2. Reaction exotherm for a methyl methacrylate casting system.

product. A less energetic polymerization such as that for polycaprolactam can be cast in large parts without need for dilution with dead polymer.

Continuous-flow stirred-tank reactors (CSTRs) can be cooled in three ways. The most elegant method is to allow boiling of the monomer or solvent so that the heat of reaction is removed in an overhead condenser. The pressure in the vessel is set to give the desired temperature. The condensate can be returned to the vessel or recycled back to the feed. This process is commonly used for polystyrene. Chilling the feed is another means for managing the exotherm in a CSTR. Refrigeration to -40°C has been used for the bulk, continuous polymerization of PMMA. Laboratory reactors and small-scale industrial reactors can be cooled using jackets or internal coils, but this method scales up poorly.

Removing Chemical By-products

Most condensation polymerizations are reversible and become limited by equilibrium unless the condensation by-product is removed. Spontaneous removal occurs when the by-product is insoluble in the reaction medium. The low solubility of NaCl in organic solvents means reactions like those for polysulfone and phenoxy (ie a high molecular epoxy) proceed irreversibly with the chain length depending only on the reaction time and initial stoichiometry. Phenol–formaldehyde condensations are limited both by the initial stoichiometry and by the formation of by-product water. Dual limitations are difficult to satisfy when a high molecular weight polymer is desired, and it is common to change the chemistry so that the stoichiometric limitation is eliminated. If poly(ethylene terephthalate) were made by the direct condensation of its two monomers, terephthalic acid and ethylene glycol, exact stoichiometry and removal of by-product water would both be needed to achieve high molecular weights. The standard industrial process uses

a preliminary esterification and separation to obtain a self-condensing monomer, diglycol terephthalate. The monomer has inherently perfect stoichiometry, but its polymerization is strictly limited by the presence of by-product ethylene gycol. By-product removal is easy when the viscosity is low. A typical process has one or two stirred tanks in series that remove ethylene glycol in overhead condensers. The effluent from the last stirred tank is fed to a specially designed reactor that approximates piston flow (also known as plug flow). It is typically a twin-screw device machine that exposes the now viscous polymer solution to vacuum while moving it forward.

Copolymerization

Random Copolymerization. Bulk and solution polymerizations are well suited to copolymerization where a second or third monomer is added to achieve desired physical properties. Minor amounts of an alpha-olefin, such as 1-butene or 1-hexene, are copolymerized with ethylene to control crystallinity and density, producing linear low density polyethylene. A second diol is used to control crystallinity in poly(ethylene terephthalate). Examples are the two monomers used in substantially equal quantities, styrene/acrylonitrile polymers and ethylene/propylene rubbers. The need in all these examples is to achieve a uniform distribution of the various monomers within a polymer chain and between chains produced at different points or times in the reactor. Batch and tubular reactors are poorly suited to this task because the monomers react at different rates. When the chain life is short, molecules formed early and late in the polymerization will have different average compositions. When the chain life is long, a substantial composition difference can exist within individual molecules. These problems can be avoided by using a continuous-flow stirred tank or the functionally equivalent loop reactor. A loop reactor that consists of a pump, heat exchanger, and recycle piping provides the same mixing environment as a stirred tank but is more easily scaled up when heat must be transfer through the vessel walls. Boiling CSTRs also scale well for heat transfer purposes. In either geometry, ie a conventional tank with an internal agitator or the loop reactor, entering feed is rapidly mixed and distributed throughout the vessel to provide a chemically uniform environment.

Block Copolymerization. A polymerization with long chain lives can be used to make block copolymers (qv). An important commercial example is styrene/butadiene blocks produced by anionic polymerization (qv). A solution polymerization is done in a batch reactor, starting with one of the two monomers. That monomer is reacted to completion and the second monomer is added while the catalytic sites on the chains remain active. This produces a block copolymer of the AB form. Early addition of the second monomer produces a tapered block. If the second monomer is reacted to completion and replaced by the first monomer, an ABA triblock is obtained. This process is not easily converted to continuous operation because polymerizations inside tubes rarely approach the piston-flow environment that is needed to react one monomer to completion before adding the second monomer. Designs using static mixers (also known as motionless mixers) are a possibility.

Kinetic Models

A process model for any type of polymerization must begin with a kinetic model. Condensation polymerizations have relatively simple kinetics. The forward reaction is typically modeled as a second-order reaction with respect to the end groups, using a single rate constant assumed to be independent of chain length. The reverse reaction is also modeled as second order. Addition polymerizations are more complex, consisting of initiation, propagation, chain transfer, and termination steps. The mathematics are understood but the necessary constants are rarely published. A significant exception is the classic kinetic study by Hui and Hamielec (1) on styrene polymerization that, with minor modifications, has had wide industrial use and serves as a prototype for similar studies.

The gel effect is a special phenomenon encountered in free-radical polymerizations, that can have a major effect on reactor design. As the polymerization proceeds, the viscosity of the reaction mix increases. The diffusivity of all molecular species decreases, but chain entanglements cause the diffusivity of long polymer molecules to decrease to a much greater extent than the monomer. The initiation rate is unaffected when a chemical initiator is used and is largely unaffected even for thermal initiation. Propagation involves a small molecule reacting with a growing chain and continues at a reasonable rate. However, the termination step involves interactions between two large molecules so that the termination rate decreases significantly at high conversion. The concentration of free radicals increases, as do the total polymerization rate and the average chain length. This leads to still larger reductions in the termination rate and to an autoaccelerating reaction that can be almost explosively fast. Poly(methyl methacrylate) provides the classic example of the gel effect. The autoacceleration shown in Figure 1 is due to the combined effects of the exotherm and chain entanglements. A commercial process for polystyrene uses a single stirred tank operated at about 70 wt% polymer. The entire vessel operates in the gel region and thus has a very high volume productivity.

Tubular Reactors

Polymerizations in tubular reactors have been extensively studied. Most results are proprietary, although quite comprehensive models for the polymerization of styrene in a tube are available in the literature. Tubular reactor models combine the equations for diffusion, reaction, and heat transfer. They are coupled with the equations of motion owing to the dependence of viscosity on temperature and composition. The non-Newtonian nature of the polymer solution is of secondary importance. The resulting set of simultaneous equations is readily solved on a computer. Results depend on a large number of parameters that are specific to each polymerization, but the following generalizations are possible:

(1) The low velocities near the tube wall give higher polymer concentrations and higher viscosities. This further lowers velocities near the wall and increases velocities near the centerline. In extreme cases, hydrodynamic instabilities

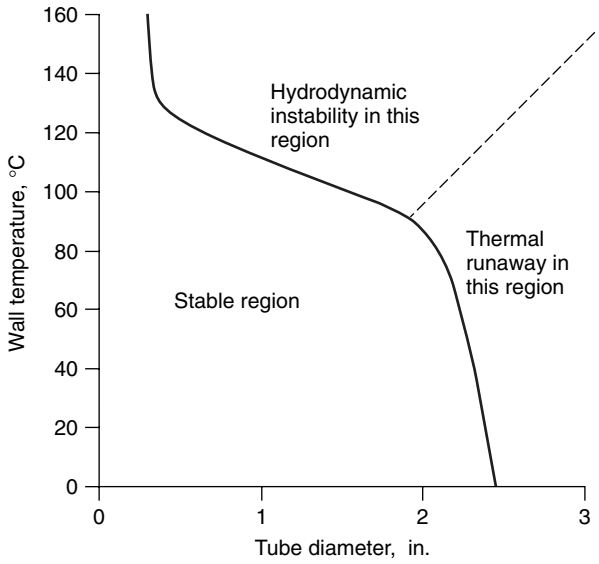

Fig. 3. Stability diagram for the thermally initiated bulk polymerization of styrene with an inlet temperature of 135°C.

lead to oscillations and the jetting of unreacted monomer down the center of the tube.

(2) The heat of polymerization distorts the temperature profile. When there is cooling at the walls, the maximum temperature will occur at an intermediate radial position. For energetic polymerizations, there is a maximum tube diameter beyond which a runaway becomes inevitable.

(3) Tube-to-tube instabilities can arise when multiple tubes are fed in parallel from a single pressure source. If extra polymerization should occur in one tube, the flow through that tube will decrease, leading to still more polymerization. When the feed stream is relatively inviscid, it cannot displace polymer from a tube and the tube plugs.

Figure 3 shows a stability diagram for a bulk styrene polymerization. Performance is governed by four variables: the monomer inlet temperature, the tube diameter, the wall temperature, and the mean residence time in the tube. Figure 3 shows the effects of wall temperature and tube diameter for plausible values of the other variables. Very small tubes are stable for any wall temperature. Intermediate size tubes are subject to hydrodynamic instability and large tubes are subject to thermal runaway. The maximum conversion for a tube larger than 0.95 cm is 20% and is achieved in a 5-cm tube.

The instabilities possible in tubular reactors have had a major influence on the process design. A model of the high pressure process for polyethylene is available in the literature (2) and there are even more sophisticated proprietary models. The highpressure process for polyethylene uses a single tube about 4.5 cm in diameter and several miles long to avoid thermal runaway and tube-to-tube

instabilities. Hydrodynamic problems still exist, and some plants have used a forced oscillation to alleviate them. The discharge valve on the reactor is quickly opened and closed every few minutes, temporarily lowering the discharge pressure from about 240 to 69 MPa (35,000 to 10,000 psi) and causing a sudden surge in flow that redistributes the polymer in the tube.

For most polymerizations starting from monomer, tubular reactors have been avoided because of the various stability problems. They can be used in recycle loops where the per-pass conversion is low, in solution polymerizations with large amounts of solvent, and in post- or finishing reactors intended to drive a polymerization to completion. Shell-and-tube designs with as many as 1000 tubes are used in polystyrene processes where they also serve as devolatilization preheaters. The entering polymer solution has a concentration of about 70%, and its viscosity is high enough to avoid tube-to-tube instabilities.

Kenics-type static mixers have been used as inserts in tubular reactors. Compared to an open tube operated at the same pressure drop, the static mixer gives about 40% more heat transfer. Stand-alone mixer reactors of the Koch or Sultzer SMR type have been used as post-reactors and devolatilization preheaters. The polymer flows through the shell side of the SMR and the heat transfer fluid flows inside tubes that have been strategically placed to promote radial mixing of the polymer. One bulk polystyrene process used the SMR as in a recycle loop as the first reactor, but the capital cost is high compared to alternatives such as a boiling CSTR or a proprietary stirred-tube reactor.

Some tubular reactors have internal agitation. These include conventional single- and twin-screw extruders used for grafting (eg maleation) or other modification reactions that start with a prepolymerized feed. They can provide a surprisingly uniform reaction environment but are extremely expensive in terms of reactor volume. Economics limit residence times to a few minutes and so they are rarely used for polymerizations starting from monomer. Specialized designs are used as polyester finishing reactors, and they are now able to produce the high molecular weights needed for blow-molded bottles, eliminating the previous need for solid-state polymerization.

Conveyor belt and moving web reactors give a piston-flow reaction environment. The polymer layer is usually thin enough so that heat transfer is not a serious issue, but the confinement of vapors to meet environmental requirements can be expensive. Thus waterborne or condensation polymerizations without by-products (eg polyurethanes) are preferred. Ultraviolet and electron beam curing is common. Applications include photographic and xerographic films, breathable fabrics, coated abrasives, and printed films, as well as polymers manufactured on belt flakers.

Stirred-Tank Reactors

Conventional stirred tanks are commonly used for both batch and continuous polymerizations. Normal design practice is to use pitched blade turbines, with impeller to tank diameter ratios of 40–70%, for viscosities up to 10 Pa·s (100 P) and sometimes up to 100 Pa·s. Helical ribbon and sometimes anchor agitators

are used for viscosities of from 10 to 1000 Pa·s, and intermeshing, dual impellers are used for the highest viscosities. Jacket heating or cooling is used for small reactors and for start-ups. Boiling reactors have overhead condensers. Typically, the condensed monomer or solvent is simply returned to the upper surface of the liquid, but is sometimes sprayed over the vapor dome to dissolve any polymer that might polymerize there. A modern polystyrene process consists of a CSTR followed by several stirred-tube reactors in series (3). The stirred-tube reactor is nonboiling and uses internal coils to remove the heat of polymerization. The design scales poorly, and it seems that these reactors have reached their maximum size. Productivity increases are achieved by putting several of them in series. Other nonboiling reactors use an external circulation loop with a shell-and-tube heat exchanger in the loop. In some processes, the stirred tank has been eliminated and the heat exchanger provides most of the reactor volume.

An important design criterion for a stirred-tank reactor, whether batch or continuous, is that the mixing time must be short compared to the reaction half-life. Correlations for mixing time are available in the literature. They range from a few seconds in laboratory glassware to a few minutes in industrial reactors. A secondary criterion for continuous-flow stirred tanks is that the circulation rate must be a large multiple of the net throughput. This criterion ensures that the residence time distribution approximates the exponential distribution of an ideal CSTR. A ratio of 10:1 is normally adequate for this purpose. Some loop reactors have been designed with recycle ratios of 100:1, but this was done to achieve better heat transfer and shorter mixing times.

Solvent Recovery

Removal of solvent including any unreacted monomer is a necessary step in most bulk and solvent polymerizations. One possible method is antisolvent coagulation. The polymer solution is contacted with large quantities of another solvent that is compatible with the original solvent but not with the polymer. When done correctly, the process gives a suspension of nontacky, microporous particles of polymer that are substantially free of solvent. The particles are collected by filtration or centrifugation and are further dried. Antisolvent coagulation is the standard preparative tool of the research chemist but is rarely used industrially because the separation and recycle streams are so large. It is common for the flow rate of stream containing the combined solvents to be more than 50 times that of the polymer stream.

Devolatilization removes volatile components by exposure to heat and vacuum. Single- and twin-screw extruders are commonly used for this purpose, and wiped-film evaporators are used for low volume, specialty polymers. All these devices generate surface area by a combination of mechanical milling and foaming, but generation of surface area by foaming scales up more easily than mechanical generation. Flash devolatilization (qv) relies exclusively on foaming and is the preferred method for high volume polymers.

BUTADIENE POLYMERS

Introduction

1,3-Butadiene was first prepared in 1863, and its conjugated structure was proposed in 1886 (1,2). However, the ability of butadiene to polymerize was not recognized until almost 50 years later when, in 1909, a rubbery polymer was first reported as being prepared from butadiene via thermal polymerization (3). Shortly thereafter, the more controlled polymerization of butadiene initiated by sodium metal was reported in 1911 (4). During this time period, a sharp rise in natural rubber prices prompted the Bayer Corp. to develop methyl rubber from 2,3-dimethylbutadiene. Though interest in synthetic rubber faded after World War I, in 1926 a rise in price of natural rubber prompted the German company I. G. Farbenindustrie to resume research on the sodium-initiated polymerization of butadiene. This work eventually led to the German commercialization of two synthetic rubbers: Buna 32 and Buna 115 (from *bu*tadiene and *na*trium). Concurrently, in the 1920s research on the emulsion polymerization of butadiene was being carried out in Germany and the United States. The first butadiene–styrene copolymer prepared from an emulsion polymerization (Buna S) at I. G. Farbenindustrie proved to be superior to polybutadiene (5). From this work, Buna-N, a copolymer of butadiene and acrylonitrile, was developed for its solvent and oil resistance. Although the products of this work were inferior to natural rubber, their technology, with considerable modification and improvement, formed the basis for synthetic rubber production (GR-S and GR-N) in the United States. Under the government-established Rubber Reserve in World War II, GR-S and SBR became a general-purpose rubber with an annual production of ca 717,700 t in 1945.

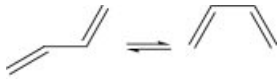
Butadiene Monomer

1,3-Butadiene, $CH_2{=}CH{-}CH{=}CH_2$, is the simplest conjugated diene, and its structure has received much theoretical attention because of its symmetry and simplicity (6). Heats of hydrogenation and combustion reveal that the stabilization contributed by the conjugation of the double bonds is 12.5–14.6 kJ/mol (3–3.5 kcal/mol) (7). Electron diffraction reveals a planar molecule with bond lengths C=C, 0.1337 nm; C–C, 0.1483 nm; and C–H, 0.1082 nm; the bond angles are C=C–C 122.4° and C=C–H 119.8° (8). The values for the C–C bond lengths predicted by valence bond approximations are in close agreement with these observed figures (9). The C–C single bond between the two double bonds is shorter than the usual 0.154 nm of an isolated single C–C bond. Some of the proposed explanations for this shortened bond, which indicates some double bond character, can be expressed in polar resonance or terminal diradical structures with some long bond or interaction between the end carbons. However, because the energies of these structures are high, molecular orbital calculations indicate that there is little resonance in the ground state and that the bond lengths are determined by the state of hybridization of carbon (10). The resistance to rotation about the central bond is attributed to π-conjugation and leads to two conformers, the nonpolar *s-trans* and polar *s-cis* form as seen in the conformational equation (1).



(1)

Although at dry ice temperature the *s-cis* form predominates (11), chemical (12) and spectroscopic (13,14) evidence suggests that *s-cis*-butadiene is present to the extent of only 3% at room temperature. The energy difference between the two forms has been variously determined as 7.1 ± 2.1 kJ/mol (1.7 ± 0.5 kcal/mol) (15) and 9.6 kJ/mol (2.3 kcal/mol) (16).

The ultraviolet spectrum of gaseous butadiene is highly complex, but the origin of each of the transitions in the 230–135 nm region has been identified (17). In hexane solution butadiene absorbs at λ_{max} 217 nm, $\epsilon = 21{,}000$ (18). The bathochromic effect of conjugation is evident upon comparison with those values for ethylene, λ_{max} 170 nm, $\epsilon = 17{,}000$ in the vapor (19).

The infrared spectrum has been recorded in the gaseous (20), liquid (20,21), and solid states. Raman spectra (14,22) are also available. Rotational constants have been calculated from the pure rotational Raman spectrum (23).

The complex proton magnetic resonance spectrum of 1,3-butadiene has been analyzed, and the calculated spectrum for this AA′BB′CC′ system has been determined (24,25). The temperature-sensitive coupling constant for the protons on carbons 2 and 3 suggests an equilibrium between the predominant *s-trans* conformer and a skewed conformer having out-of-plane double bonds (25). The comparatively simple ^{13}C spectrum shows little effect of conjugation on the chemical shifts of the carbons (26).

The microwave spectrum has been examined in an effort to detect the *s-cis* conformer (27). The appearance potentials and relative abundances of the

principal ions from the mass spectrum (28) of butadiene, as well as x-ray data for the crystalline material (29), have been reported.

Physical Properties. At room temperature 1,3-butadiene is a highly reactive, colorless gas with a mildly aromatic odor (30). Physical properties are given in Table 1. Plots of heat of vaporization, vapor pressure, vapor and liquid heat capacity, liquid density, surface tension, and vapor and liquid viscosity are available as functions of temperature (32), as are plots of vapor and liquid thermal conductivity and heat of formation and free energy of formation of the gaseous butadiene (36). The vapor pressure of butadiene in Pascals

can be calculated at any temperature in degrees Celsius by using the Antoine equation:

$$\log P = A - \frac{B}{C + t}$$

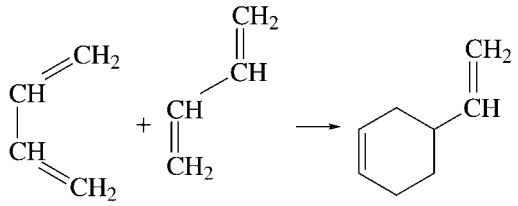
with the constants $A = 9.74022$ (6.85941 for mm Hg), $B = 935.531$, and $C = 239.554$ (31).

Butadiene is soluble in organic solvents such as ethanol, diethyl ether, acetone, benzene, and hexane (Table 2) (38). Solubilities in liquid ammonia, methanol, *n*-octane, toluene, xylene, ethylene glycol, acetone (39), and water (40,41) have been reported.

Reactions. Because of the rich chemistry associated with conjugated diene structures, the reactivity of 1,3-butadiene has been studied extensively. However, the hundreds of polymers and copolymers described in the literature represent by far the most important commercial uses for butadiene.

Butadiene and atmospheric oxygen form an explosive polyperoxide (42,43). At 50°C the liquid-phase reaction is independent of oxygen pressure between 5.33 and 120 kPa (40 and 900 mm Hg). Below an oxygen pressure of 5.33 kPa (40 mm Hg) the oxidation rate decreases with decreasing oxygen pressure; increased temperature and free-radical initiators accelerate the reaction. The polyperoxide is composed of equal amounts of 1,4- and 1,2-butadiene units separated by peroxide, $-O_2-$, units. It is only slightly soluble in butadiene and accumulates as a second phase in neat butadiene.

Butadiene dimerizes by a Diels–Alder reaction thereby forming mainly 4-ethenylcyclohexene (4-vinylcyclohexene) (eq. (2)). In this dimerization reaction, butadiene acts as both diene and dienophile. The dimerized product is always present in butadiene unless freshly distilled. Although this reaction occurs spontaneously, selective catalysts based upon nitrosyliron compounds do exist (44). Vinylcyclohexene is a starting material for plasticizers and antioxidants. It should be noted that this reaction also gives smaller amounts of 1,2-divinylcyclobutane and 1,5-cyclooctadiene (45).



(2)

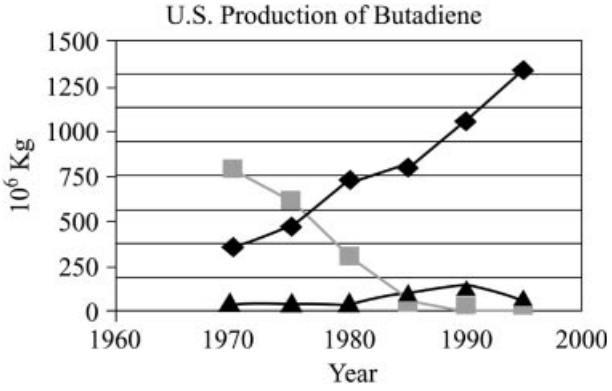


Fig. 1. Butadiene manufacture in the United States. —◆—, Co-produced; —■—, On-purpose; —▲—, Other.

Manufacture.

Ethylene Coproduction. Historically, butadiene was first prepared in pilot plant quantities via an uneconomical electric arc process. However, the primary source of butadiene in the world today is as a by-product of thermal pyrolysis of hydrocarbon feedstocks in ethylene production. In the United States, production of coproduct butadiene exceeded that of "on-purpose" butadiene for the first time in 1977 and by 1990 high cost on-purpose butadiene production was essentially eliminated in the United States (Fig. 1) (46,47). In 1996, the total US production of butadiene was 1.75 million, 93% of which was co-produced (47). Steam cracking of hydrocarbons yields varying amounts of butadiene, depending on the nature of the feedstock, the volume of ethylene produced, and the severity of the cracking operations (48–50). For example, when feedstocks are switched from atmospheric gas oils and napthas to propane and butane, yields of butadiene drop by as much as 60% (51).

An analysis of the typical by-products in the C_4 stream derived from cracking a full-range Middle East naphtha is given in Table 3. The range reflects composition at medium and high severity during steam cracking.

Table 3. Typical Composition of a Crude C_4 Stream[a]

Component	Wt%
C_3 hydrocarbons	0.3
Butanes	6.5–3.4
1-Butene	16.0–13.7
cis-2-Butene	5.3–4.8
trans-2-Butene	6.6–5.8
Isobutene	27.4–22.2
1,3-Butadiene	37.0–47.5
Acetylenes	0.4–1.8
C_5 hydrocarbons	0.5

[a]Ref. 48.

A spike in crude oil prices in late 1999 and 2000 has led many steam-cracking operations to switch from heavy to light feedstocks, resulting in lower yields of butadiene. This factor, combined with historically poor investment economics for added butadiene extraction capacity, should lead to tight butadiene supplies through 2004 when additional extraction capacity is expected to become fully on-line. Further expansion of butadiene extraction capacity in North America will be limited by crude butadiene supplies unless new domestic ethylene capacity is added (52).

In addition, dehydrogenation of *n*-butane or *n*-butene also affords butadiene. For example, the Houdry process for conversion of *n*-butane to butadiene requires temperatures of about 620°C and involves passing *n*-butane over a fixed bed reactor containing a chromium–alumina catalyst. Single-pass conversions reach only 30–40% requiring multiple recycling passes of unreacted intermediate butylenes and *n*-butane. The other primary means of dehydrogenation is conducted by passing a preheated stream of *n*-butene, steam, and air over fixed bed reactors containing a heterogenous autoregenerative catalyst. Bismuth molybdate catalysts have been studied in this process (53), but patents suggest that zinc ferrite catalysts have been used commercially (54–57). Nickel phosphate and Li–Sn–P catalysts have been patented by Phillips (58,59).

Other techniques for the preparation of butadiene have also been used commercially, including the aldol condensation of acetaldehyde and the reaction of acetylene and formaldehyde. However, these processes are no longer employed commercially. Both India and the former USSR have developed ethanol-based production of butadiene (60–64). While these routes have a major advantage in terms of low capital and operational costs, raw material costs are prohibitive in most areas (47). Such plants are only viable in areas where there is little domestic petroleum but abundant ethanol supply.

Purification. For polymerization, butadiene that is at least 99 mol% pure is required. Although alkynes are the most troublesome impurities, separation of the butadiene from other C_4 products is also necessary. Simple fractional distillation is effective for removing the light (C_3) and heavy (C_5) ends from butadiene, but not for removing the various C_4 species because of the closeness of the boiling points to each other and to butadiene. Further complicating purification, butadiene forms azeotropes with *n*-butane and 2-butene. The most widely used recovery systems are extraction with aqueous cuprous ammonium acetate (CAA) and solvent extractions with furfural, acetonitrile, dimethylformamide, dimethylacetamide, or *N*-methylpyrrolidinone (65,66).

Cuprous ammonium acetate extraction. Butadiene is purified by aqueous CAA extraction in a liquid–gas countercurrent process developed by Exxon (67–69). The cuprous salt forms a soluble addition complex with butadiene, which is decomposed by heat; thus the process is adaptable to countercurrent multistage equipment. Typically, the C_4 hydrocarbon mixture with a butadiene content of 30–40% contacts the CAA solution in a countercurrent fashion in a series of mixer–settlers. Cooling to ca −15°C is required to promote complex formation. The more saturated hydrocarbons, butanes, and butenes are first removed by distillation. Butadiene is released from the complex by further heating to 80°C. After ammonia is removed by washing with water, distillation produces butadiene that is 98–99% pure. Acetylenes and allenes are extracted with the butadiene but must

be removed; acetylenes can lead to foaming and plugging by polymer formation (70–76).

Solvent extraction. This purification method is based on the alteration of the relative volatilities of the C_4 hydrocarbons by selective solvents. The volatilities follow the order of the boiling points. 1-Butene (bp = −6.3°C), for example, is more volatile than butadiene (bp = −4.4°C); *n*-butane (bp = −0.5°C) is less volatile. Selective solvents change this order, making the impurities more volatile than butadiene. Hence, separations become easier. Furfural (77), acetonitrile (78), *N*,*N*-dimethylformamide (79), *N*,*N*-dimethylacetamide (80), and *N*-methylpyrolidinone (81) appear to be most widely used (82). β-Methoxyproprionitrile (78), dimethylsulfoxide (83), and *N*-acetylmorpholine (84) have also been studied. The commercial processes generally do not require prehydrogenation. They employ countercurrent extraction of the C_4 stream where the butanes and butenes are removed at the top, and the butadiene-rich solvent at the bottom. The butadiene is stripped from the solvent and further purified by fractional distillation. The butadiene is at least 99% pure and contains a few ppm acetylenes.

Specifications and Standards. Commercial polymerization-grade butadiene is at least 99% pure; higher purity grades up to 99.86% are available from specialty gas suppliers (85). A representative specification and analysis is given in Table 4. A pure grade has been analyzed for hydrocarbon impurities by gas chromatography (see Table 5).

Health and Safety.

Toxicity. Short-term exposure to <1000 ppm butadiene has not been associated with significant adverse acute effects; however, higher levels may cause eye irritation or transient nervous system depressant effects. The International Agency for Research in Cancer assessed human and laboratory cancer data, and judged there to be limited evidence in humans for cancer, sufficient evidence in animals, and an overall qualification as a "2A" chemical (probably carcinogenic to humans) (89). The monograph cites several studies of rubber and monomer

production workers, some of which contain suggestive evidence for leukemogenic activity for butadiene. However, there is uncertainty of butadiene's association with leukemia because of inconsistent findings in data between studies (lymphosarcomas vs leukemias, decreased cancer risk association with longer employment, other chemical factors implicated in etiology). Support for a lack of human carcinogenicity for butadiene despite positive mouse findings (multiple tissues at low exposures) is that the mouse enzymatically transforms the chemical to mutagenic and carcinogenic metabolites (eg, butadiene diepoxide) whereas rats and humans are less prone to do so (90). The US EPA considers butadiene a "probable human carcinogen" (91). The potential for butadiene to cause mutations in rodents is known, while effects associated with reproductive and/or developmental functions are currently under investigation.

Butadiene had previously been considered nontoxic (92). It is mildly narcotic when inhaled at concentrations below 2%. At higher concentrations it has anesthetic effects that can cause respiratory paralysis and death (93). Butadiene is an irritant of the eyes and upper respiratory tract; contact of the liquid with the skin may have frostbite-like effects.

Occupational Guidelines. US OSHA has set an 8-h time-weighted average air standard for occupational settings of 1 ppm, and 5 ppm for a 15 min short-term exposure limit (94). The ACGIH has established a threshold limit value of 2 ppm for butadiene, and considers the chemical a "suspected human carcinogen." An odor threshold for the chemical is reported as 1.0–1.6 ppm in air (95). Potential nonoccupational exposures to the public occur as a result of the presence of butadiene in combustion gases (fossil fuels, tobacco smoke).

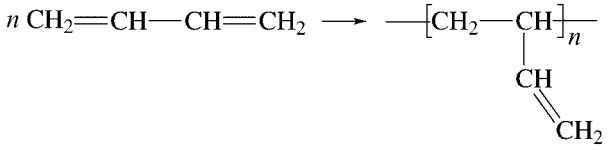
Handling and Storage. Butadiene is dangerous because of its explosiveness when mixed with air (38). Because of the high vapor pressure of the liquid, it must be kept under pressure. Butadiene reacts with air to form explosive peroxides and must be inhibited. Peroxides or rusty iron surfaces may initiate the formation of "popcorn" polymer which can plug pipelines. Butadiene material fires are fought like other hydrocarbon fires, with carbon dioxide or dry chemical extinguishers. Safe handling and storage require careful exclusion of oxygen, thorough grounding of all equipment, and avoidance of excessive temperatures in closed vessels.

Inhibited butadiene of polymerization purity is available in cylinders (3.8–454 L), tank cars, tank trucks, and pipelines (96,97). The cylinders may be shipped by motor or rail freight (98). Containers are subject to regulations of the Department of Transportation and must be labeled "Flammable Gas" (96). Butadiene is usually stored in bulk under refrigeration rather than pressure in order to suppress formation of the dimer 1-vinylcyclohexene (99). Smaller quantities in cylinders under pressure should be kept away from sources of ignition and heat.

Polymer Structure

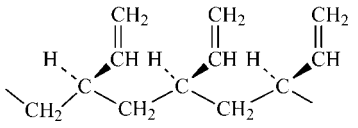
Microstructure refers to the disposition of the double bonds present in the polymer chain and macrostructure refers to long chain features such as extent of branching, molecular weight, and molecular weight distributions.

Polybutadiene Microstructure. Butadiene polymerizes by addition. Having two double bonds, it forms a variety of polymer structures. One of these, known as the vinyl or 1,2-type, results from addition across just one of the double bonds (eq. 3).



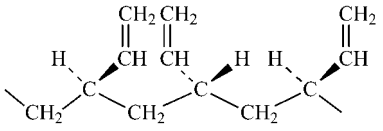
(3)

Actually, three vinyl structures are possible: the isotactic (**1**), in which all the vinyl groups are attached to a backbone carbon with the same spatial arrangement, either the D or L isomer; the syndiotactic (**2**), in which the vinyl groups are attached to backbone carbons with alternating D and L configuration; and the atactic with a random mixture of the D and L isomers.



isotactic polybutadiene

(**1**)

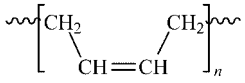


syndiotactic polybutadiene

(**2**)

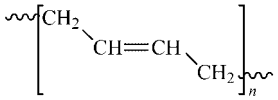
A second type of structure arises by 1,4 addition when both double bonds participate. The resulting double bond in the polymer backbone permits two 1,4

structures, the *cis*-1,4 (or Z) (**3**) and the *trans*-1,4 (or E) (**4**) isomers. In the absence of side chains, there is no tacticity that can arise from 1,4-addition.



cis-1,4 isomer

(**3**)



trans-1,4 isomer

(**4**)

In an actual polymer it is possible to have any or all of the several forms in a single chain. The structures indicated have all been synthesized individually, as well as in various mixtures, to give polymers with a preponderance of either 1,2- or 1,4 units.

The microstructure of polybutadienes has been determined by infrared (100–102) and Raman spectroscopy (103). The 965 cm^{-1} band is due to trans double bonds; the 740 cm^{-1} band to cis double bonds in polymers of high cis content, shifting to 725 cm^{-1} for low cis; and the 911 cm^{-1} band is due to the vinyl double bonds.

Sequence and tacticity information can be obtained from both ^{1}H and ^{13}C nmr spectra; ^{1}H is most useful at high fields where separations of peaks are sufficient to allow determination of cis, trans, and vinyl contents from both the olefinic and aliphatic resonance peaks (104). Spin decoupling of the olefinic peaks gives triad distributions of the cis and trans isomers (105). At low fields, determination of only 1,2- and 1,4 units is possible because of the severe overlapping of the resonances. The ^{13}C nmr spectrum of a polybutadiene contains two groups of resonances arising from aliphatic and olefinic carbons (106,107). Microstructures (108), sequence distribution (107), and tacticity of the vinyl units can be determined (109,110).

The glass-transition temperature (T_g) and the melting point (T_m) of polybutadienes are microstructure-dependent (Table 6).

cis-1,4, *trans*-1,4, and vinyl polybutadiene microstructures are well understood in terms of conditions influencing their formation during polymerization and the effect of the population distribution and tacticity of these microstructures on the thermal properties of the polymer. However, literature cites another microstructure inherent to polybutadiene that is not as well understood. Certain polymerization conditions favor formation of a cyclic structure in the growing polymer chain during anionic polymerization. Unlike polysiloxane polymerizations in which a percentage of macrocyclic polymer is regularly formed (115), or post-conversion reactions which cyclize polyisoprene (116), this cyclic form of polybutadiene appears to form during normal anionic polymerization reactions. This structure was mentioned in the anionic polymerization of poly(2-phenylbutadiene) as the authors noted lower levels of unsaturation than

expected, and found evidence for five-membered rings using ozonolysis/mass spectroscopy techniques (117). Most early work citing the cyclic structure involves methods producing low molecular weight polybutadiene oils and resins (118,119). These references discuss possible polymerization conditions conducive for cyclic structure formation, including monomer-starved conditions and elevated temperatures. Several subsequent publications developed these ideas further and proposed a backbiting mechanism that involves the two penultimate monomeric groups in the chain (120,121). Noting that the polymerization conditions in these references involve polar modification, it would appear that relatively high vinyl levels are inherent to the formation of cyclic polybutadiene. The most in-depth work to date involves nuclear magnetic resonance analysis of commercially available polybutadiene resins and develops evidence for vinyl-substituted cyclopentane units as part of the polymer backbone (122,123). Experimental evidence included in these references cites a range of incorporation of cyclic structure between 0 and 45% by weight. In-depth polymerization studies to elucidate the thermodynamic and kinetic conditions favoring this structure formed by anionic polymerization techniques have not been published, and the contribution to glass-transition temperature and other thermal properties of cyclic polybutadiene elastomers has not been established.

Many references exist for cyclic diene structures formed during certain cationic polymerizations (124–127). The exact mechanism involved in the formation of the ladder-like fused ring structure has yet to be determined.

The sequence distribution of two copolymerizing monomers depends on the catalyst or initiator used, the method of polymerization, and the concentration and reactivities of the monomers. Reactivity ratios for many monomer pairs have been measured for free-radical, anionic, and coordination polymerization of butadiene (128).

Polybutadiene Macrostructure. Macrostructure refers to the molecular weight, molecular weight distribution, and extent of branching in a polymer. Branch sites along a polymer backbone can be either comb-like short-chain random branching (in the case of polybutadiene, most often derived from grafting reactions), random long-chain branching, or highly branched dendritic structures

(129). Often the nature and extent of branching and the breadth of the molecular weight distribution is dependent on the catalyst/initiator system and polymerization conditions.

Free-Radical Polymerization. The highly reactive nature of radical species results in polymerization products with high levels of branching. The relative levels of recombination and disproportionation termination reactions determines the breadth of the molecular weight distribution. Chain-transfer agents also affect the macrostructure of the polymer.

Ziegler–Natta Polymerization. The macrostructure of Ziegler–Natta polybutadiene varies considerably and is most dependent on the metal catalyst's ability to undergo chain-transfer events. Typically, early transition metals are less likely to participate in metal-hydride elimination chain-transfer reactions than the more electron-rich late transition metals (130). This phenomenon allows early metal systems, such as titanium, to catalyze the formation of polymers with narrow molecular weight distributions and low branching. Conversely, nickel systems are dominated by chain-transfer reactions and therefore generate polybutadienes with very large molecular weight distributions. Cobalt, also a late transition metal, catalyzes the formation of branched polybutadiene presumably by reinsertion of a terminated conjugated diene end group. Another factor controlling the macrostructure of Ziegler–Natta polybutadiene is the propensity of the catalyst to chain transfer to the aluminum co-catalyst. This type of chain-transfer reaction is dominant in neodymium systems leading to linear polymers but with broad molecular weight distributions.

Anionic Polymerization. Complementing the diversity in microstructure inherent to anionic chemistry, living anionic polymerization based on alkali metal alkyl initiating systems can also afford a wide range of macrostructural possibilities for polybutadiene products.

Batch polymerization methods can produce narrower molecular weight distributions than continuous processes (131), resulting in materials with lower hysteresic properties. Low vinyl polybutadiene can be produced with either linear or branched macrostructure. Polymerizations of polybutadiene performed at moderate temperatures produce linear chains in comparison to high temperature processes which give rise to random thermal branching. Divinylbenzene is a difunctional monomer that is commonly added to promote long-chain branching. This common cold-flow-reducing agent effectively incorporates into the polymer chain to generate a macromonomer that can further polymerize to give long-chain branching (132). Coupling agents of various functionality can be added at full conversion to produce star polymers with enhanced rheological properties (133,134). These branched materials not only have greatly reduced cold flow, but can also offer improved high shear mixing and extruding properties over more linear counterparts (135,136).

In contrast to the inherent linearity exhibited by unmodified low vinyl polybutadiene polymerized at moderate temperature, medium to high vinyl polybutadiene produced in continuous systems have the tendency to be highly branched. The common use of alkali metal alkoxides with or without additional polar modifiers to increase the vinyl content results in a superbasic system with a high tendency to metallate the polymer chain (137–141). The metallated site can reinitiate in the presence of continuously fed monomer and produce random

long-chain branching (142,143). Proper design of the continuous polymerization process or choosing initiator/alkali metal alkoxide/polar modifier systems with decreased superbasic activity can reduce the overall levels of branching (144,145).

Synthesis of Polybutadiene

Free-Radical Polybutadiene. Free-radical emulsion polymerization of butadiene has yet to gain commercial importance. Unlike emulsion styrene–butadiene copolymers, which exhibit excellent abrasion resistance, crack-growth resistance, and easy processing (146), emulsion polybutadiene does not perform as well in typical rubber applications as its solution counterpart. The main difference between these two types of rubber stems from the lack of T_g control in the free-radical polymerization process. The indiscriminate nature of free-radical chain propagation results in a polybutadiene containing a mixture of 1,4- and 1,2-microstructure (147). Although the cis/trans ratio of the 1,4-enchainment can be controlled with temperature, the total vinyl content remains constant between 15 and 20% (Table 7). In most cases, the resulting polybutadiene will have a T_g near -80°C, which is a full 20° higher than that of high *cis*-polybutadiene produced with Ziegler–Natta catalysts (qv).

Another drawback of emulsion polybutadiene is the rapid formation of gel during the polymerization. In order to avoid significant quantities of gel it is necessary to terminate the polymerization below 60% conversion. In this fashion, as monomer concentration is depleted, the reaction of a growing chain with the backbone of another chain can be avoided. One material that actually takes advantage of the rapid recombination of growing chains in a free-radical polymerization is hydroxytelechelic polybutadiene (HTPB). HTPB is typically prepared in a butanol solvent with the use of hydrogen peroxide as an initiatior (149–156). Termination of growing chains via primary radical recombination results in the formation of dihydroxy functional polybutadienes. Molecular weights are limited, but nevertheless a market exists for oligomers of both carboxytelechelic and hydroxytelechelic polybutadienes. Advances in controlled radical polymerization techniques (157–161) have led to a number of recent studies covering hydroxy radical initiated butadiene polymerizations (162,163).

Ziegler–Natta Polybutadiene. Ziegler–Natta polybutadiene is the generic name given to materials produced from polymerization catalysts based on transition metals (see ZIEGLER–NATTA CATALYSTS). These catalysts follow a

Table 7. Effect of Temperature on the Microstructure of Emulsion Polybutadienes[a]

70	20.8	59.4	19.8

[a]Ref. 148.

coordination polymerization mechanism and typically employ insoluble metal halides or soluble metal carboxylates in conjunction with aluminum alkyl co-catalysts (164,165). The commercial success of Ziegler–Natta type polymerizations is related to the ability of this broad class of catalyst to afford *stereoregular* polybutadienes. All the three types of possible microstructure for polybutadiene—1,4-*cis*, 1,4-*trans*, and 1,2-vinyl—can be achieved in near 100% regularity with the appropriate metal catalyst. The most significant of these materials being high *cis*-polybutadiene. This polymer, with a T_g below -100°C, has very good abrasion resistance, high resilience, and low heat buildup and is used in many tire-related applications. Such properties have made *cis*-polybutadiene the second largest volume synthetic rubber, behind only emulsion SBR (146).

cis-1,4-Polybutadiene. At least four different metal catalysts have been commercialized for the production of *cis*-polybutadiene, namely, titanium, cobalt, nickel, and most recently neodymium. Each of these catalysts generate polymers that vary in microstructure, such as cis content, as well as in macrostructure, which includes molecular weight, molecular weight distribution, and degree of branching. The end user must consider both the microstructure and macrostructure obtained with each catalyst system when optimizing an elastomer for a given application (166).

Titanium Catalysts. The titanium catalyst was the first system to be commercialized in the 1950s by Phillips Petroleum (167). Generally, titanium-catalyzed polybutadiene is characterized by its low branch content and narrow molecular weight distribution leading to good tensile properties and fatigue resistance but poor processibility (168,169). The catalyst is comprised of a titanium halide precursor and an aluminum alkyl co-catalyst. The most studied system consists of treating titanium tetraiodide with three to eight equivalents of triisobutyl aluminum (TIBA) in an aromatic solvent at 30°C. This results in polymerization of butadiene to *cis*-polybutadiene having a cis content greater than 90% (170,171). Polymer molecular weight is inversely dependent on catalyst concentration with high molar mass polymers being obtained at low catalyst levels. To prepare materials that are easily processed, approximately 1–2 millimoles of titanium tetraiodide per hundred grams of monomer (mmphm) is required (172). The catalyst is heterogeneous, and although catalyst activity is sensitive to the Al/Ti ratio, the overall cis content is only slightly affected. The cis content is, however, very sensitive to the type of halogen employed in the polymerization. As Table 8 shows, the cis content drops significantly as iodide is replaced with more electronegative halides. The dependence of microstructure on halide is apparent for all of the cis-specific transition metal catalysts except neodymium. A number of alternative

Table 8. Cis Content %, as a Function of Metal Halide and Transition Metal in Polybutadiene Polymerization[a]

[a]Refs. 173 and 174.

catalysts to the classic binary titanium system exist, including combinations of $TIBA/I_2/TiCl_4$ (175–177) $(C_2H_5)_2$ $AlI/TiCl_4$ (178), $(C_2H_5)_3Al/TiCl_4/TiI_4$ (179,180), and $DIBAlH/AlI_3/TiCl_4$ (181). The $TIBA/I_2/TiCl_4$ systems used in a molar ratio of 8:1.5:1 has been optimized for conversion, molecular weight, and *cis*-1,4-content and has been used in the commercial production of *cis*-polybutadiene (182,183).

Cobalt Catalysts. The preparation of high *cis*-polybutadiene with cobalt catalysts was first disclosed by B. F. Goodrich and is characterized by a high degree of branching and good processibility (184). By analogy to the titanium halide catalysts, early cobalt work focused on $CoCl_2$ as the catalyst precursor. Unlike titanium, the use of trialkyl aluminum species does not lead to an active catalyst. Instead, an alkyl aluminum *halide* must be employed as co-catalyst in these systems (185–191). Moreover, maximum activity appears to be linked to the Lewis acidity of the co-catalyst. For example, the use of aluminum ethyl sesquichloride $[Al_2(C_2H_5)_3Cl_3]$ in place of diethyl aluminum chloride results in a more active catalyst. Increasing the strength of the Lewis acid even further, by using ethyl aluminum dichloride or aluminum trichloride, results in competitive gel formation. The balance of activity and gel content has been achieved through the use of water as a third catalyst component. Maximum activity is achieved when water is added at approximately 10 mol% to the diethyl aluminum chloride (192). Above this concentration, water begins to act as a catalyst poison retarding the rate of polymerization. Presumably the water is reacting with $(C_2H_5)_2AlCl$ to generate the Lewis acidic ethylchloroaluminoxane $[O(AlC_2H_5Cl)_2]$ (193). Degree of branching, as a measure of solution viscosity at equal molecular weight, decreases with increasing water content.

Catalyst systems based on $CoCl_2$ are heterogeneous in nature and require catalyst levels as high as 10 mmphm in order to achieve good conversion. Much lower levels are used when soluble cobalt salts are employed. These salts include pyridine adducts of $CoCl_2$, cobalt octanoates, cobalt acetylacetonates, and cobalt versatates in the plus two or three oxidation state. When soluble salts are utilized, catalyst levels can drop to as low as 0.01 mmphm of cobalt with Al/Co ratios of 100–1000/1. Typical cis contents range from 95 to 98%. Catalyst activity and molecular weight are also dependent on the solvent used for polymerization. Benzene is the solvent of choice resulting in the most active polymerizations (194); however, mixtures of aromatic and aliphatic solvents are used in production plants in an effort to reduce the amount of benzene emissions (195). Molecular weight must also be regulated in these systems through the use of a chain-transfer agent. Suitable transfer agents are those that regulate molecular weight without adversely affecting the rate of chain propagation and polymer microstructure. For the cobalt systems hydrogen, ethylene, propylene, and allenes such as 1,2-butadiene are all effective regulators (196).

Nickel Catalysts. Nickel-catalyzed high *cis*-polybutadiene, first developed by Bridgestone (197–199), is typically less branched than commercial cobalt polybutadiene but exhibits an equally high cis content of 98%. The polymer is also characterized by a large molecular weight distribution of 4–5 giving the material good processibility. The commercial process utilizes a soluble nickel(II)carboxylate, aluminum trialkyl, and a halogen source (200). Of these three components, the process is most dependent on the choice of halogen. As was seen in Table 5, use of nickel-iodide yields mostly *trans*-polybutadiene while Br, Cl,

and F all favor cis polymerization (201–203). Initially boron trifluoride etherate was used as a halogen source but later hydrogen fluoride was also implemented in large-scale production (204). Catalyst activity is similar to the cobalt system, with reasonable rates and molecular weights being achieved with 0.01 mmphm nickel. Typical Al/Ni ratios are 10–50/1 with an F/Al ratio of 2–3/1. Unlike the cobalt system, chain transfer readily competes with propagation in the nickel system resulting in broad molecular weight distributions. Maximum molecular weights are achieved during the first 50% of conversion and then level off for the remainder of the polymerization (205). The final molecular weight is inversely dependent on catalyst levels. Alternatively, to obtain low molecular weights an olefin containing molecular weight modifier such as 1-butene or 1,5-hexadiene may be used when low catalyst levels are employed. Studies with nickel octanoate have shown that microstructure is a function of molecular weight (206). As the molecular weight increases the cis content increases at the expense of both the trans and vinyl; the amount of trans is always about twice the amount of vinyl. At 10,000 M_n the cis content increases to over 90% and at 100,000 M_n or more, cis content is $>$96%. Recent advances have also been made in the control of nickel polybutadiene macrostructure, resulting in the commercial availability of a branched, improved processing material (207).

Because of the unique ability of nickel to readily form stable metal-allyl complexes, many mechanistic studies of this system have been undertaken. From these, it is clear that nickel allyl species are indeed involved in the coordination polymerization of polybutadiene (208–212). Whether generated *in situ* or added directly as catalyst, the type of polymer produced from π allyl NiX complexes is determined by the nature of X, electron-donating or accepting additives, and the transition metal. The chloride complex gives cis polymer, the iodide trans, and the bromide a mixed microstructure (213). Catalytic activity is low and yields are poor with the latter catalysts. Complexes of more electronegative anions, such as trichloroacetate and trifluoroacetate, exhibit high catalytic activity and afford polymers of very high cis contents (214). Electron-donating additives, such as oxygen, ethers, alcohols, and phosphites, tend to inhibit π-allyl polymerization and increase the trans content. On the other hand, electron-accepting additives, such as tin and titanium halides, metal salts, and iodine, increase the activity of π-allyl nickel halides. π-Allyl nickel chloride retains the high cis microstructure in the polymer with most added metal salts. Iodide complexes of these electron acceptors produce high cis polymers, rather than the expected trans polymer.

It is also clear that in many instances the stereoregular outcome of monomer insertion is dependent on the initial mode of monomer coordination and rate of anti-syn allyl isomerization. For example, in a now classic experiment (215–217), the polymerization of butadiene with π-allyl nickel(II)trifluoroacetate in the absence of an external ligand yields high *cis*-polybutadiene. Upon addition of a trialkylphosphite, however, the stereo control is completely reversed and *trans*-polybutadiene is formed. One explanation put forth to explain this behavior is that in the absence of a ligand the incoming monomer can bind to the metal in an η^4-cis configuration (218,219). This bonding mode will result in the formation of a syn-allyl upon migration of the growing polymer chain and subsequently a cis configuration in the polymer. Conversely, if a ligand is present, the incoming monomer will favor η^2-monodentate complexation. Migration of the growing

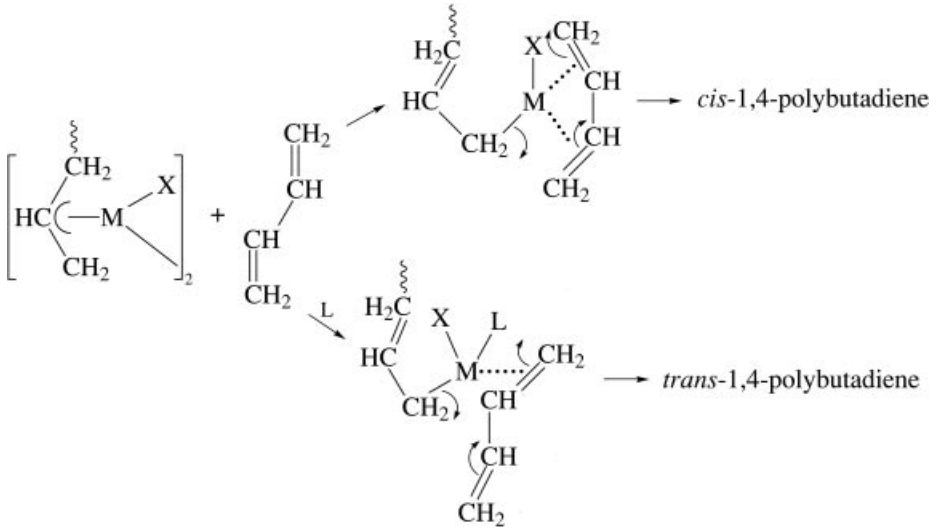

Fig. 2. Coordination and insertion mechanisms leading to *cis*- and *trans*-1,4-polybutadiene.

polymer into this bond will result in the generation of an anti-allyl leading to trans polymer (Fig. 2). The mechanism is, however, dependent on the assumption that no isomerization from η^3-syn-allyl to η^3-anti-allyl occurs or that η^4-trans coordination of butadiene is not favored (220,221). A comparison of the mechanism of isolated nickel-allyl catalyzed diene polymerization with the traditional Ziegler–Natta nickel system has been reviewed (222).

Neodymium Catalysts. The most recent catalyst system developed for the commercial production of high *cis*-polybutadiene is based on the rare earth metal neodymium. Although it was recognized in the 1960s that lanthanide catalysts, in general (223–225), and neodymium, in particular, were viable *cis*-polybutadiene catalysts, it was not until the 1980s that the process was commercialized (226–229). Polymer produced from this class of catalyst is characterized by a linear macrostructure and a very high cis content of greater than 98% giving the rubber excellent abrasion and fatigue performance. The linearity of the material, coupled with high molecular weight, makes this rubber more difficult to process than the other high cis polymers. This problem has been addressed and there are now versions of neodymium polybutadiene available, which contain long chain branches reducing cold flow and improving processability while maintaining a high cis microstructure (230,231).

The chemistry of the neodymium catalyst has very recently been reviewed (233,234), and although the resulting polymer is similar to other high *cis*-polybutadienes the change from a transition metal based system (Ti, Co, Ni) to a lanthanide metal with valance *f*-electrons creates striking differences in the polymerization chemistry. There are two main types of catalyst systems (235). The first is a ternary system based on soluble neodymium carboxylates in conjunction with a trialkylaluminum cocatalyst and a halogen source (236,237). The second system is a binary catalyst comprising of an insoluble neodymium halide

complexed with three equivalents of a Lewis base such as alcohols, amines, or phosphonates and a trialkylaluminum (238–240). In general, the two systems behave similarly; however, the homogeneous ternary system appears to have gained acceptance commercially (241). As with the transition metal based systems, a halogen must be present for high cis-polymerization; however, any halogen will suffice (172). Chloride and bromide derivatives make more active catalysts but the cis content is equally high for fluoride or iodide complexes. Typical catalyst concentrations are between 0.10 and 0.30 mmphm Nd, placing the activity of these systems between titanium on the low side and cobalt or nickel on the high side. Branched trialkylaluminum and dialkylaluminum hydrides used in an Al/Nd ratio of 10–40/1 in conjunction with two to three equivalents to Nd of a halide source such as diethylaluminum chloride or *tert*-butylhalides treated with a branched long-chain neodymium carboxylate give the highest activity (242). Polymer molecular weight is inversely proportional to overall catalyst levels as well as aluminum alkyl concentration. As the aluminum to Nd ratio increases, the molecular weight of the polymer decreases (243). This effect is most pronounced for diisobutylaluminum hydride, and in light of the fact that typical chain-transfer agents such as hydrogen, olefins, and 1,2-butadiene are ineffective in this system (244), aluminum hydrides are often used as molecular weight regulators. Another difference between the Nd catalysts and Ti, Co, or Ni, is that Nd is more efficient in hydrocarbon solvents than in aromatics (245). Presumably, benzene can compete with monomer for open coordination sites on the large *f*-block metal through η^6-coordination. Enhanced reactivity in hydrocarbon solvents makes this class of catalysts very amenable to commercial solution polymerization.

trans-1,4-Polybutadiene. Polybutadiene with a high trans microstructure is a crystalline resin-like material with a melt temperature of 95°C for the alpha form and 145° for the beta form. A number of metal catalysts have been used to prepare high *trans*-polybutadiene including vanadium (246–249), titanium (250–252), cobalt (253), nickel (254,255), neodymium (256,257), and rhodium (258). As is the case for the cis specific catalyst, these trans systems are typically comprised of an insoluble metal halide or soluble metal carboxylate in conjunction with an aluminum alkyl co-catalyst. In general, trans catalysts are less active than cis catalysts.

Vanadium Catalysts. The vanadium system is heterogeneous in nature and combines VCl_3 with triethylaluminum in an Al/V ratio of 2–10/1 to achieve a 99% *trans*-polybutadiene (259,260). Formation of high molecular weight polymer coupled with the highly crystalline nature of the material causes the polymer to precipitate during the polymerization. Encapsulation of active catalyst in the insoluble polymer particles can be a conversion-limiting occurrence. From a process standpoint, dispersion of the heterogeneous catalyst particles becomes a very important issue. Along these lines, mixed metal systems of VCl_3 with $TiCl_3$ in a 1:4 ratio have been found to create a highly dispersed active trans catalyst (261).

Cobalt Catalysts. Cobalt catalysts have the advantage of being readily available as soluble metal salts. Combining cobalt carboxylates with diethyl aluminum chloride in the presence of a Lewis base such as triethylamine at an Al/Co/NR_3 ratio of 10:1:10 results in reasonable conversion of butadiene to polybutadiene with a 95% trans content (253). Control of microstructure is possible through changes

in catalyst concentration and make-up allowing for a range of trans contents from 72 to 95% with the rest of the polymer being made up of mostly 1,2-vinyl.

Nickel Catalysts. The use of a Lewis base to convert an otherwise cis catalyst into a trans catalyst has already been demonstrated for nickel (212–214). Similarly, the cis-specific nickel catalyst can also be converted into a trans catalyst by replacing Ni–F complexes with Ni–I. Polymers obtained from these systems can have up to 97% trans content (262).

Neodymium Catalysts. Neodymium catalysts are known to polymerize butadiene to *trans*-polybutadiene in the absence of a halogen source. For example, when $Nd(versatate)_3$ is treated with magnesium dialkyl in a critical ratio of 1:10, a polymer with 90–95% trans content is obtained (256). Molecular weights are typically below 100,000 and the catalyst must be used at levels above 0.25 mmphm to obtain reasonable conversion. More recently, a trans-specific system has been described in which a neodymium phosphate is treated with four equivalents of butyl lithium, yielding a high trans polymer in good conversion (257). Interestingly, a neodymium halide species treated with tributylphosphate and dibutyl magnesium also yielded high *trans*-polybutadiene (263).

Rhodium Catalysts. An extremely interesting system for the production of high *trans*-1,4-polybutadiene is based on a rhodium catalyst used in an emulsion-type aqueous polymerization (258,264). In a typical recipe, rhodium(III)nitrate or rhodium(III)chloride is shaken in the presence of water, sodium dodecylbenzenesulfonate, and butadiene achieving 99% *trans*-1,4-polybutadiene, albeit in low conversion (265). The polymerization is very dependent on the emulsifier present, with the most active catalysts being generated from long-chain alkyl sulfates or aryl sulfonates (266). In the absence of an aluminum alkyl co-catalyst, the dependence on the sulfonate group may arise from the need for rhodium alkyls to form from the migration of an Rh-sulfonate bond (267). The kinetics of this system has been explored (268,269) and a very thorough review exists (270).

1,2-Polybutadiene. Unlike *cis*- and *trans*-1,4-polybutadiene, high vinyl 1,2-polybutadiene has a chiral center which can exist in one of three different stereochemically related forms. The material can either be atactic, leading to an amorphous elastomer, or it can be isotactic or syndiotactic, both of which are crystalline. The elastomeric amorphous form has found utility in tire tread applications (271) and although certain molybdenum (272) coordination catalysts can produce this material, commercialization has focused on anionic alkali metal initiators modified with Lewis bases. Of the two crystalline forms, isotactic 1,2-polybutadiene with a melting temperature of 126°C is the most elusive isomer. A few chromium systems based on soluble salts and aluminum alkyls have been reported to give 45% of the isotactic polymer in a mixture of the atactic isomer (273,274).

Most Ziegler–Natta catalysts for high vinyl 1,2-polybutadiene yields syndiotactic polymer with a melting temperature that ranges between 90 and 220°C depending on the degree of crystallinity. The microstructure of this material was first recognized by Natta (272) in 1955 and can be prepared with cobalt (275–280), vanadium (281), molybdenum (282,283), chromium (274,284), and titanium (285) salts treated with aluminum alkyl co-catalysts.

A high melting (>200°C) material and a low melting material (90°C), both produced from cobalt catalysts, have been commercialized by Ube

Industries (286) and Japan Synthetic Rubber Co. (JSR) (287) respectively. The high melting polymer is made from a preformed cobalt octoate/triisobutylaluminum/butadiene/carbon disulfide catalyst formed in a ratio of 1:3:20:1 and charged at a level between 0.1 and 0.2 mmphm. High crystalline material having greater than 98% 1,2-microstructure is obtained with a melt temperature of 195–205°C. Use of other modifiers such as diethyl fumarate results in a lower degree of crystallinity and a melt temperature of 150°C (288). The very low melting syndiotactic 1,2-polybutadiene from JSR utilizes a cobalt–phosphine catalyst system. The catalyst is generated by treating bis(triphenylphosphine)cobalt dibromide with triisobutlyaluminum in the presence of water in a ratio of 1:20:10. Typically, the polymer has 90% 1,2-microstructure and a melt temperature of 90°C. Mechanistic studies aimed at uncovering the differences in these systems have been described (289,290).

A very unique system for the polymerization of syndiotactic 1,2-polybutadiene with varying degrees of crystallinity and melts ranging from 120 to 190°C has been disclosed by The Goodyear Tire & Rubber Co (291). In this example, cobalt octoate treated with butadiene, triisobutylaluminum, and carbon disulfide has been shown to polymerize butadiene in an emulsion polymerization. This example represents a rare case of a Ziegler–Natta polymerization process tolerant of water. The lack of reactivity towards water could be due to the formation of an impenetrable capsule of crystalline polymer around the cobalt catalyst. In this fashion, only the lipophilic butadiene is able to diffuse into the region of active catalyst.

Frontiers of Ziegler–Natta Catalysts. There are a number of areas of Ziegler–Natta polybutadiene research that have attracted recent attention. These include the use of new co-catalysts, metallocene, or single-site catalysts, and development of supported Ziegler–Natta catalysts for gas-phase polymerization. Much of this work can be tied to the discovery by Kaminsky and Sinn (292–294) that methylaluminoxane (MAO) acts as an extremely efficient co-catalyst in metallocene-catalyzed ethylene polymerization. Examination of MAO in Ziegler–Natta type conjugated diene polymerization includes work on catalysts such as vanadium (295,296), titanium (297–299), cobalt (300–302), nickel (298,303,304), and neodymium (305–307). In certain cases, the use of MAO in place of traditional trialkylaluminum co-catalysts has resulted in the formation of highly active cis catalysts even in the absence of a halogen source. The use of MAO with homogeneous metallocene catalysts for butadiene polymerization has focused mainly on cyclopentadienyltitanium trichloride systems (298,299,309–311). Although this system has comparable activity to traditional Ziegler–Natta catalysts, the overall cis content is only 80%. Unlike the plastics industry where metallocenes and well-defined single-site catalysts have rapidly gained commercial success, the use of these systems for polybutadiene production has not, as of yet, matured. However, one area that is certain to be dominated by this class of catalyst is the area of gas-phase polymerization. In-roads to such a process for high *cis*-polybutadiene have been made by Bayer through the use of an inorganic supported neodymium allyl/MAO complex (312). Similarly, supported cyclopentadienyltitanium complexes, also activated with MAO, have been used for the gas-phase polymerization of high *trans*-polybutadiene (313). Nickel (314) and cobalt (315) systems have also been disclosed.

Anionic Polybutadiene. Anionic polymerization (qv) is perhaps the most versatile technology for producing polybutadiene in terms of microstructural and macrostructural control. The relative stability of the anionic propagating center allows for excellent control and manipulation of the conformation of enchained monomeric units and the overall structure of the polymer backbone. Coordination catalyst technologies are best employed if highly stereospecific and/or highly tactic microstructures are desired. Although high *trans*-1,4- and high *cis*-1,4-polybutadiene elastomers can be produced by a variety of Ziegler–Natta technologies (316), a wider range of thermal and rheological properties can be realized with anionic polymerization systems resulting in a broader range of applications for this technology.

As mentioned previously, during World War I, alkali metals were investigated early in the search for a suitable elastomeric substitute for natural rubber. German and Russian researchers used sodium metal to polymerize dienes (317,318), but these materials proved ill-suited for tire applications. An alkali metal catalyst was later developed by Firestone researchers (319), which was used to produce *cis*-1,4-polybutadiene on a commercial scale. Alkyl lithium initiators have since been utilized to produce very high molecular weight polybutadienes with approximately 70% *cis*-1,4 structures. Lithium-based initiators produce the lowest vinyl content and highest 1,4-enchainment when compared to the other alkali metals. These properties were desired when efforts to emulate natural rubber dominated synthetic rubber research. Presently, research efforts have shifted focus from low vinyl products to higher vinyl, higher glass-transition temperature materials. This shift follows a trend toward higher performance tires with improved traction and handling characteristics, while not sacrificing wear and fuel economy properties. Anionically prepared polybutadienes with elevated vinyl contents and controlled long-chain branching characteristics can be used in many applications when a balance between traction and fuel economy is desired.

Anionic polymerization of 1,3-butadiene allows for a wide range of heterotactic vinyl enchainment levels. The structures obtained in hydrocarbon solvents with alkali metal initiators are shown in Table 9. Lithium polybutadiene maintains the lowest vinyl, highest 1,4 content possible via anionic polymerization. The microstructure produced via a free-radical emulsion polymerization is provided as a reference.

Polar modifiers are most often employed to control the level of vinyl structures formed during living lithium-based anionic polymerization processes in nonpolar solvents. Relatively small amounts of added polar modifier, based on the

Table 9. Microstructure of Alkali Metal Initiated Polybutadienes[a]

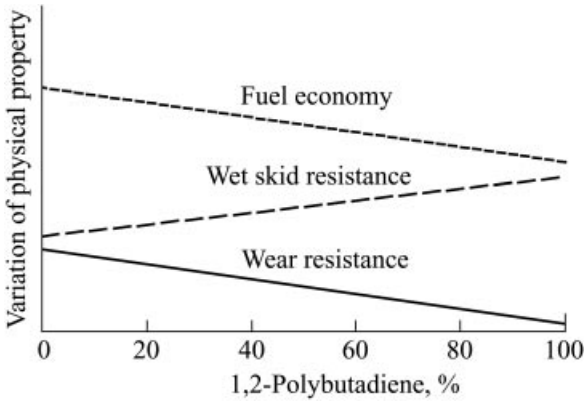

Fig. 3. Glass-transition temperature as a function of vinyl content.

stoichiometry of anionic propagating centers, can have profound vinyl-directing effects (322,323). The vinyl content correlates directly to the glass-transition temperature, as seen in Figure 3 (271) and in other references (324,325). Higher modifier to chain-end ratios produce higher vinyl levels. The vinyl-directing strength of most polar modifiers can also be a function of polymerization temperature (326).

Increased polymerization temperatures decrease the vinyl-directing strength and result in lower glass-transition temperatures for the product. In commercially produced polybutadiene, the vinyl content can be controlled by the choice of polar modifier, its relative concentration to the propagating centers, and the polymerization temperature. Polybutadiene products with elevated vinyl contents can be made at normal polymerization temperatures (50–100°C) with many conventional polar modifiers, including tetrahydrofuran (327), chelating diamines (328), bi-1,3-dioxanes (329), bisdipiperidinoethane (330), and alkyl ethers derived from tetrahydrofurfuryl alchohols (331). Recently, with varying success, attempts have been made to model the vinyl-directing strengths of polar modifiers based on a number of parameters (332,333).

Polymerization propagation rate constants for unmodified lithium systems have a fractional order dependence on chain-end concentration and are relatively slow when compared to modified systems. The dienyl-lithium chain end has a tendency to aggregate in hydrocarbon solutions (334), and give lower polymerization rates. The order of aggregation is reported to be dependent on factors such as chain-end concentration (335,336), monomer concentration, temperature, and solvent (337). The use of polar modification not only increases vinyl contents, but generally interferes with aggregation and drives the equilibrium to monomeric chain-end species with subsequent increases in the polymerization rates.

In addition to the use of specific Lewis bases to influence the vinyl content of products formed via anionic polymerizations, the use of alkali metal alkoxide salts in lithium polymerizations can also affect the ratio of vinyl enchainment (338). Salts of lithium have little to no effect on microstructure at typical molecular weights and commercial polymerization temperatures, while those of sodium, potassium, and rubidium increase the vinyl content significantly. The addition of

polar solvents into these anionic systems also increases the vinyl content of the product.

Commercial lithium-based anionic polybutadienes at typical molecular weights and polymerization temperatures, regardless of polar modification, have *cis*-/*trans*-1,4 ratios of approximately 0.5–0.7. Higher cis contents can be attained for unmodified polybutadiene in solution at very low initiator concentrations (very high molecular weights) or in neat monomer (339). High *trans*-1,4 structure can also be promoted in lithium-based systems. The use of barium salts with lithium can produce elevated *trans*-1,4 content relative to *cis*-1,4 at lower temperatures (340,341). Other systems that produce *trans*-1,4 products include complexes of dibutylmagnesium or alkyl lithium and potassium salts (342,343). The products of these systems, polymerized in hydrocarbon solvents, displayed both a soluble high vinyl fraction and an insoluble high *trans*-1,4 fraction.

Low Vinyl Polybutadiene. Typical glass-transition temperatures range between −95 and −80°C for commercial unmodified to slightly modified lithium polybutadiene (10–30% vinyl). These products are made by a variety of producers via living anionic initiators resulting in amorphous polybutadiene of 10% vinyl, 35% *cis*-1,4, and 55% *trans*-1,4 structure. Several review articles and books describing the anionic polymerization to make low vinyl polybutadiene have been published (323,327,344,345). These materials generally show good wear properties because of the low glass-transition temperatures when compounded in tire formulations. Hysteresis is generally lower than higher vinyl products but remains a function of the long-chain branching content. Low vinyl polybutadienes do have lower green strengths than the high *cis*-1,4 Ziegler–Natta catalyzed products, because of a lack of strain crystallization. However, where amorphous characteristics are desired, optimally compounded carbon black stock prepared with lithium polybutadiene shows very little difference in performance compared to the Ziegler–Natta catalyzed high cis-1,4 material. It is believed that the essential requirement is a high overall 1,4 content regardless of whether it is primarily cis or more equally distributed between cis and trans. High *cis*-1,4-polybutadienes (Ziegler–Natta) do show improved tack and process more easily, primarily because of macrostructural differences including broader molecular weight distributions and higher branching levels.

Medium and High Vinyl Polybutadiene. Many tire performance properties are closely related to the glass-transition temperature of the polymer system used (324,325,346). As the glass-transition temperature is increased, wet and dry traction is increased, but abrasion resistance is compromised (347). Again, hysteretic properties are more a function of macrostructure than glass-transition temperature. Figure 4 depicts the trends in tire performance properties as a function of polybutadiene vinyl content (271).

An interest in the medium to high vinyl polybutadienes has been encouraged by rising styrene monomer prices. Medium vinyl polybutadienes of similar T_g offer an alternative to poly(styrene–butadiene) copolymers in the tire industry and can also be used in other applications, including shoe soles, conveyer belts, and other engineered rubber products (348). Commercial medium vinyl materials typically display glass-transition temperatures in the −75 to −55°C range (35–55% vinyl). The vinyl content is increased relative to low vinyl polybutadiene by polar modification of the living anionic chain end.

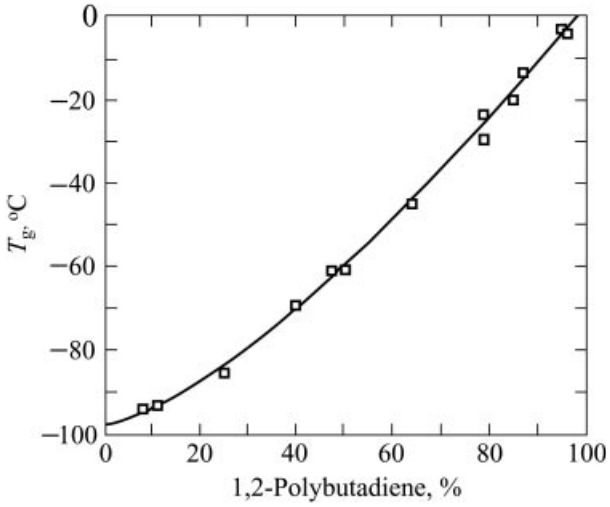

Fig. 4. Tire performance properties as a function of vinyl content.

Amorphous high vinyl polybutadienes (>70% vinyl) have glass-transition temperatures higher than −40°C (349). These materials are typically made with lithium initiators combined with a mixed alkali metal alkoxide and/or polar modifier system. As a result, commercial high vinyl polybutadienes are typically quite branched but display excellent traction properties. These materials are most often used in silica-filled tire applications.

Functionalization. Anionically prepared polybutadiene offers the unique advantage of near quantitative chain-end functionalization. Through a variety of functional initiating and/or terminating agents, a variety of reactive moieties can be attached to the polymer termini (350). For example, there are several methods available that introduce hydroxyl groups at both the α- and ω-chain ends (351,352). In addition, functional initiators can be utilized to provide hydroxyl, amine, and tin functionality (353). Cyclic amine functionalization at either termini can provide hysteresis improvements in carbon black filled compounds (354,355). The polymer macrostructure can also be modified by adding functional linking agents such as tin (or silicon) tetrachloride. Tin-coupled polymers give benefits in processing and have been reported to also decrease compound hysteresis (356–358). Using a combination of functional initiators and terminators, polybutadienes containing two types of end groups can be synthesized (359), enabling greater control of post-conversion polymer chemistries.

Cationic Polymerization. Like anionic polymerization, cationic polymerization is an addition reaction involving a relatively stable ionic propagating species. Cationic polymerization proceeds by an attack on the monomer by an electrophilic species, resulting in heterolytic cleavage of a double bond producing a carbocation. In the case of olefins, the carbocation is of the carbenium form. The most complete reference to date acknowledging the importance of cationic polymerization chemistry is a 1975 book (360).

Early research demonstrated that 1,3-butadiene can be polymerized by strong organic acids (361) or Lewis acids at low temperatures (361–363). Typical

microstructures were primarily *trans*-1,4 linkages with the remainder being mostly vinyl. For the synthesis of low molecular weight oils and resins, aliphatic ethers were used in conjunction with metal halide/hydrogen halide mixtures (364).

Later studies reported polybutadiene produced from combinations of diethyl aluminum chloride and various salt hydrates in benzene at 20°C (125). These same studies highlighted the disagreement between theoretical unsaturation amounts and that which were actually found. An intramolecular backbiting mechanism producing pendent cyclohexene groups was postulated. An overview of many papers proposing that cationically polymerized diene monomers by a mixed initiating system of magnesium bromide/titanium tetrachloride in benzene produced cyclized structures was published in 1969 (365). Structures inferred by infrared spectroscopy included cyclic ladder units alternating with linear *trans*-1,4 segments that generate a heat-stable form of cyclopolybutadiene (126,366). Similar studies using highly acidic alkyl aluminum chloride/titanium tetrachloride mixtures in *n*-heptanes produced insoluble polymer (367). The insolubility was attributed to either cross-linking or a ladder-like structure comprised of joined rings.

These cyclic structures were found to be inherent to most cationically polymerized dienes in nonpolar solvents (368). It has been reported that these cyclic structures could also be produced by typical cationic polymerization in the presence of ubiquitous proton-donating impurities, chain-transfer reactions (to monomer and aromatic solvents), and more conventional elimination reactions (369).

In contrast, high molecular weight soluble cationically polymerized polybutadiene products can be produced with relatively high rates with the ion pair $(C_2H_5)_2Al^+$ $C_2H_5AlCl_3^-$ in conjunction with cobalt. By mixing either $(C_2H_5)_2AlCl$ with C_2H_5AlCl or $(C_2H_5)_3Al$ with $AlCl_3$, this ion pair can produce high *cis*-1,4 microstructures (>90%) (370).

It should be noted that the only cationically polymerized butadiene product commercialized is DuPont's Budium®, which is an oligomeric resin used for tin-can linings. This product is produced using $BF_3{\cdot}(C_2H_5)_2O/H_2O$ in hexane at low temperature (371).

Polymerization Processes

Polybutadiene can be prepared by a number of processes, including bulk, solution, suspension, emulsion, and gas-phase polymerizations. Of the commercially significant polymerization processes, production of polybutadiene by solution technologies are the most predominant. The relative popularity of these processes follow the limitations dictated by the chemistries most practiced when producing polybutadiene commercially, including Ziegler–Natta, anionic, free-radical, and single-site technologies. Several of the more commercially relevant processes are outlined in detail below.

Solution Polymerization Process. Solution polymerization processes are often used when polymerization thermodynamics are largely exothermic, as in the case of polybutadiene. The solvent not only acts as a diluent, but also allows for efficient transfer of the heat of polymerization to a heat sink. Given the proper

choice of solvent, lower solution viscosities can also be maintained. Polybutadiene polymerizations can be carried out in aliphatic, cycloaliphatic, or aromatic solvents. Chain transfer to solvent may be a concern, as are impurities inherent to the solvent feed stream. Solution polymerization systems may be either batch or continuous in operation, with the broadness of the molecular weight distribution dependent on the configuration used. Ziegler–Natta and anionic polymerization technologies are the most common types used in solution polybutadiene production. Commercial high *cis*-polybutadiene can be made via either technology in solution systems, though Ziegler–Natta systems predominate by a wide margin. High *trans*-polybutadiene can also be produced by Ziegler–Natta catalysts. High vinyl elastomeric materials are typically produced via anionic solution polymerization.

Ziegler–Natta solution polymerization processes are very sensitive to impurities. Both the monomer and solvent streams must be well purified. Carbonyl and acetylenic impurities, common in crude monomer streams, must be removed along with the common polymerization inhibitor *tert*-butylcatechol. Molecular weight control is often accomplished by the addition of chain-transfer agents in certain Ziegler–Natta systems.

In anionic solution systems the feed stocks are typically dried over various types of dessicants because the systems are sensitive to water contamination. When using continuous anionic solution polymerization systems, it is necessary to employ low (ppm) concentrations of a chain-transfer agent in order to discourage gelation and fouling; 1,2-butadiene is often used for this purpose in commercial applications. Alkyl-lithium-initiated polybutadiene is less prone to contain gel and does not contain the heavy metal catalyst residues associated with Ziegler–Natta catalyzed products.

The polybutadiene produced by solution processes must be adequately desolvated in order to maintain low residual monomer and solvent in the product. Steam stripping is often employed in commercial processes in order to recover the solvent for recycling, followed by mechanical drying (extruder) and/or hot air drying of the wet polymer crumb.

Emulsion Polymerization. The free-radical polymerization of butadiene in a homogeneous system results in chain lengths that are too short for high quality elastomers. If the free-radical concentration in homogeneous media is high enough to give a useful reaction rate, it is also high enough to favor termination reactions or monomer depletion before high molecular weights are achieved.

In contrast to homogeneous free-radical systems, emulsion free-radical polymerization affords high propagation rates and high molecular weight products of elastomeric quality (372,373). The propagating radical chains are somewhat physically isolated and thus prevented from recombining as rapidly as they would in solution or bulk media. The emulsion process allows convenient temperature control, which is advantageous in the highly exothermic polymerization of butadiene (1.4 kJ/g). Heat removal and temperature control are considerably more difficult at high reaction rates in viscous solution or bulk processes.

A typical emulsion system contains water, monomer(s), initiator, emulsifier (soap), and a molecular weight modifier. Upon vigorous stirring, an emulsion consisting of monomer droplets dispersed in an aqueous phase is formed. The aqueous

phase contains the initiators, dispersed monomer droplets, and micelles formed from the emulsifier. Primary initiation centers, formed in the aqueous phase, diffuse into the micelles where polymerization proceeds (374,375). The polymer particle formed within the micelle then tends to absorb monomer from the surrounding aqueous phase because the monomer in the vicinity of the polymer particle has been consumed by polymerization. Continued uptake of monomer results in growth of the polymer particle at the expense of the monomer droplets. As the polymer particles grow, the emulsifier adsorbs on the increasing surface area and eventually leads to the disappearance of micellar soap as well as the monomer droplet phase. Relatively little polymer is believed to form in the aqueous phase or in the monomer droplet phase.

In a continuous process, butadiene, soap, initiator, and activator (an auxiliary initiating agent) are pumped continuously from storage tanks through a series of agitated reactors at such a rate that the desired degree of conversion is reached at the last reactor. A terminator is added, the latex warmed with steam, and the unreacted butadiene flashed off. After addition of an antioxidant, the latex is coagulated by the addition of brine, followed by dilute sulfuric acid or aluminum sulfate. The coagulated crumb is washed, dried, and baled for shipment.

Gas-Phase Polymerization Processes. Gas-phase polymerization is the newest process in development for the commercial polymerization of conjugated dienes. Although primarily utilized for the polymerization of ethylene and propylene monomers, commercial gas-phase processes are being extended to include the manufacture of polybutadiene. Many polymer manufacturers have reported researching gas-phase processes for diene monomers, and several have established significant patent portfolios including Amoco, Bayer, Exxon, Mitsui, and Union Carbide. To date, Bayer appears to be closest to commercializing a gas-phase process for producing polybutadiene rubber (376,377).

The purported benefits of gas-phase technology include the reduction in overall waste streams, including no waste water, lower solid waste, and reduced overall emissions. Solvent recycling is no longer necessary, and costly polymer product isolation and drying steps are not required. Products are typically isolated from the reactor as powder or crumb. Production costs have the potential to be significantly lower than either solution or emulsion technologies.

The chemistries utilized in gas-phase technologies employ the same Ziegler–Natta (314,315) and single-site (metallocene) catalysts (313) described in the processes included below. In gas-phase systems, however, the catalysts are generally solid-supported, but produce the same range of polybutadiene microstructures inherent to the nonsupported catalyst. Several patents also include anionic polymerization systems as useful in gas-phase processes (378). Kinetic modeling work has also been done to better predict the gas-phase polymerization behavior of 1,3-butadiene (379).

Economic Aspects

The economics of polybutadiene production are characterized by overcapacity on a global basis. Total world capacity increased by 649,000 t from 1995 to 1999; however, actual production increased by only 167,000 t during this same period

Table 10. Global Capacity and Production for Polybutadiene by Region—1999[a]

	Capacity	Production	Net trade	Consumption
United States	675	600	51	544
Western Europe	498	332	−53	385
Japan	344	290	116	191
Other	1463	880	−118	837
Total	*3019*	*2102*	*0*	*1957*

resulting in a drop in global capacity utilization from 82 to 70% (380). Global production figures are tabulated in Table 10. Major polybutadiene producers are listed in Table 11.

The average annual growth rate in consumption between 1990 and 1999 was 2.0% per year on a global basis. However, because of an unusual increase of natural rubber prices in 1994, polybutadiene use in tires in the United States increased by 6.1% per year from 1994 to 1996 (380). This was, however, followed by the return of natural rubber prices to their historic norm and a resulting decrease in polybutadiene use in tires. During the period from 1996 to 1999, tire shipments increased by 4.3% whereas polybutadiene use in tires lagged behind—increasing at only 2.5% per year (380). While the combination of predominately small cars, radial tires, and low car sales drastically reduced butadiene production in the early 1980s, in the 1990s this was followed by a significant market shift to larger vehicles, sport-utility vehicles (SUV), and high performance tires. Of the trends in consumer demand, only high mileage tires demand high levels of polybutadiene in the tread compound. High performance tires require higher T_g materials and SUV tires place traction and durability demands on compounds that cannot be met by polybutadiene.

The portion of polybutadiene going into nontire applications continues to increase. Between 1980 and 1999, the portion of polybutadiene consumed in tire

Table 12. Typical U.S. List Prices, $/kg, for Selected Grades of Polybutadiene[a, b]

	Clear rubber grade	Clear plastics grade	Oil extended 37.5 phr oil[c]	Oil-black masterbatch[d]
Jan. 1982	1.49–1.65	1.53–1.67	1.54	1.10
Oct. 1989	1.49–1.76	1.53–1.80	1.69	1.23
Jan. 1993	1.49–1.76	1.53–1.80	1.67	1.21
Jan. 1996	1.71–1.94	1.75–1.94	1.90	1.39–1.50
Feb. 2000	1.69–1.96	1.72–1.96	1.85–1.94	1.39–1.50

[a]Ref. 380.
[b]Prices are FOB Gulf Coast manufacturing plant, freight collect, for truckload and car quantities.

[d]Contains 77 parts per hundred of resin (phr) of N-302 or N-303 carbon black and 53 phr of highly aromatic oil.

applications decreased by 11–67% of world production. Use of polybutadiene in high impact polystryene modification and ABS resin manufacture account for 15–20% of global demand (380,381). Polybutadiene used in these applications must be essentially gel free and colorless. The remaining markets for polybutadiene are divided among industries including golf balls and footwear and assorted industrial products including, but not limited to, conveyor belts, v-belts, seals, gaskets, and wire insulation. In the mid 1990s the number of rounds of golf played in the United States increased at roughly a 10% annual rate (380). However, this rate of growth has not been sustained in the latter part of the 1990s and into the 2000s with total rounds of golf being flat in recent years. Despite a leveling off in rounds of golf played in the latter part of the 1990s and into 2000, changes in ball construction, including the predominance of solid core over wound core golf balls, has maintained stability in this market segment.

Prices typically vary depending on the market segment and grade of polymer sold. Typical United States prices are given in Table 12.

BUTYL RUBBER

Introduction and Background

Isobutylene has been of interest since the early days of synthetic polymer research when Friedel Crafts catalysts were used to prepare elastic materials. Isobutylene polymers of commercial importance include homopolymers and copolymers containing small amounts of isoprene or *p*-methylstyrene. Currently, chlorinated and brominated derivatives of butyl(poly[isobutylene-*co*-isoprene]) have the highest sales volume.

Isobutylene was first observed to polymerize in 1873 but high molecular weight polymers were not made until work at I. G. Farben in Germany established that molecular weight increases with decreasing polymerization temperature. Polyisobutylene was synthesized at -75°C using BF_3 as a catalyst. However, as the polymer was saturated, it could not be cross-linked into a rubbery network and no commercial uses were found (1).

Poly[isobutylene-*co*-isoprene] or butyl rubber was synthesized in 1937 at the Standard Oil Development Co., forerunner of ExxonMobil Chemical Co. (2). The first sulfur-curable copolymer was prepared in ethyl chloride over an aluminum chloride catalyst with 1,3-butadiene as the comonomer; however, it was soon found that isoprene was a better comonomer and that methyl chloride was a better polymerization diluent. During World War II, the natural rubber supply to the United States was drastically curtailed, boosting the production of synthetic rubber. The commercial production of butyl rubber in 1943 was an enormous scientific and engineering achievement given the very early state of the art and complexity of this technology.

The discovery of butyl rubber was, in fact, the discovery of the limited-functionality elastomers. Unlike natural rubber and polybutadiene, which have

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

reactive sites on every monomer unit, the unsaturation in butyl rubber is widely spaced along a saturated, flexible hydrocarbon chain. The principle of limited functionality has been subsequently used in other elastomers, eg, ethylene–propylene terpolymers and chlorosulfonated polyethylene. Halogenated butyl rubber was first synthesized at Goodrich (3). A brominated butyl rubber was commercialized via a small-scale batch method in 1954 starting from *N*-bromosuccinimide and butyl rubber. The product was withdrawn in 1969. Following the withdrawal of Goodrich bromobutyls from the market, Polymer Co. of Canada developed the commercial process using elemental bromine, which is the currently used commercial process. Chlorinated butyl rubber was developed at ExxonMobil and commercialized in 1961. It is made by the continuous chlorination of a solution of butyl rubber (4). Currently, brominated butyl rubber is also manufactured by a similar continuous-solution process.

The first use for butyl rubber was as inner tubes, whose air-retention characteristics contributed significantly to the safety and convenience of tires. Good weathering, ozone resistance, and oxidative stability have led to applications in mechanical goods and elastomeric sheeting. Automobile tires were manufactured for a brief period from butyl rubber, but poor abrasion resistance curtailed this development.

Halogenated butyl rubber greatly extended the usefulness of butyl rubber by providing much higher vulcanization rates and improving the compatibility with highly unsaturated elastomers, such as natural rubber and styrene–butadiene rubber (SBR). These properties permitted the production of tubeless tires with chlorinated or brominated butyl innerliners. The retention of air pressure (5) and low intercarcass pressure (6) extended tire durability.

Polyisobutylene is produced in a number of molecular weight grades and each has found a variety of uses. The low molecular weight liquid polybutenes have applications as adhesives, sealants, coatings, lubricants, and plasticizers, and for the impregnation of electrical cables (7). Moderate molecular weight polyisobutylene was one of the first viscosity-index modifiers for lubricants (8). High molecular weight polyisobutylene is used to make uncured rubbery compounds and as an impact additive for thermoplastics.

Process Chemistry

Butyl rubber is prepared from 2-methylpropene [115-11-7] (isobutylene) and 2-methyl-1,3-butadiene [78-79-5] (isoprene). Isobutylene with a purity of >99.5 wt% and isoprene with a purity of >98 wt% are used to prepare high molecular weight butyl rubber. Water and oxygenated organic compounds are minimized by feed purification systems because these impurities interfere with the cationic polymerization mechanism. Copolymers of isobutylene can also be prepared from mixed C_4 olefin containing streams that contain *n*-butene. These copolymers are generically known as polybutenes.

Isobutylene Polymerization Mechanism. The carbocationic polymerization of isobutylene and its copolymerization with viable comonomers like isoprene and *p*-methylstyrene is mechanistically complex (9–11). The initiating system is typically composed of two components: an initiator and a Lewis

acid coinitiator. Typical Lewis acid coinitiators include $AlCl_3$, (alkyl)$AlCl_2$, BF_3, $SnCl_4$, $TiCl_4$, etc. More recently uncommon Lewis acid such as methylaluminoxane (MAO) (12,13) and specifically designed weakly coordinating Lewis acids such as $B(C_6F_5)_3$ (14,15) have been used as Lewis acids in initiating systems for isobutylene polymerization. Common initiators include Brønsted acids such as HCl, RCOOH, H_2O, alkyl halides, eg, $(CH_3)_3CCl$, $C_6H_5(CH_3)_2Cl$, esters, ethers, peroxides, and epoxides. More recently, transition-metal complexes, such as metallocenes and other single-site catalyst systems, when activated with weakly coordinating Lewis acids or Lewis acid salts, have been used to initiate isobutylene polymerization (16). In the initiation step, isobutylene reacts with the Lewis acid coinitiator–initiator pair to produce a carbenium ion. Additional monomer units add to the formed carbenium ion in the propagation step. Temperature, solvent polarity, and counterions affect the chemistry of propagation. These reactions are fast and highly exothermic. The propagation rate constant has been determined to be around 10^8 L/(mol · s), essentially diffusion-limited (17,18). Polymerizations at low temperature give extremely high polymerization rates in either hydrocarbon or halogenated hydrocarbon solvents. Isoprene is copolymerized mainly by trans-1,4-addition (>90%), and to a lesser extent by either 1,2-addition (19,20) or as a branched 1,4-addition product (21). The propagation proceeds until chain transfer or termination occurs.

In the chain-transfer step, the carbenium ion chain end reacts with isobutylene, isoprene, or a species with an unshared electron pair, ie, RX, solvents, counterion, and olefins. Reaction with these species terminates the growth of this macromolecule and permits the formation of a new chain. The activation energy of chain transfer is larger than propagation, thus the molecular weight of the polymer is strongly influenced by the polymerization temperature. Lower temperatures lead to higher molecular weight polymer. As comonomers exhibit their own chain-transfer characteristics, the presence of comonomer can also influence the final molecular weight of a copolymer. Higher isoprene contents typically lower the molecular weight of prepared butyl rubber (22,23). Termination results from the irreversible destruction of the propagating carbenium ion and discontinuance of the kinetic chain. Termination reactions include the collapse of the carbenium ion–counterion pair, hydride abstraction from comonomer, formation of dormant or stable allylic carbenium ions, or by reaction of the carbenium ion with nucleophiles, eg alcohols or amines. The reactivity ratios are strongly affected by the polymerization conditions (Table 1). A laboratory procedure for the preparation of butyl rubber is described in Reference 34.

Fundamental rate constants for the initiation, propagation, chain-transfer, and termination steps in the polymerization process are difficult to measure because of the rapid rate of reaction. However, recent work (35) has shown that the propagation rate constant is of the order of 6×10^8 L/(mol · s).

Studies of the living cationic polymerization of isobutylene and copolymerization with isoprene have begun (36,37). The living copolymerization of isobutylene and isoprene has so far produced a random copolymer with narrow molecular weight distribution and a well-defined structure. For example, the BCl_3/cumyl acetate polymerization system in methyl chloride or methylene chloride at -30°C provides for copolymers with 1–8 mol% trans-1,4-isoprene units and M_n between 2000 and 12,000 with a M_w/M_n of under 1.8. The advent of living polymerization

Table 1. Copolymerization Reactivity Ratios of the Isobutylene/Isoprene System[a]

Initiating system	Solvent	T,°C	r_1	r_2	Reference
$AlCl_3$	CH_3Cl	−103	2.5 ± 0.5	0.4 ± 0.1	24
$EtAlCl_2$	CH_3Cl	−100	2.17	0.5	25

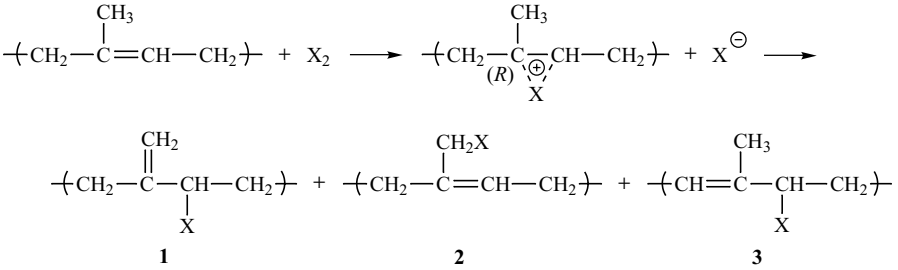
[a]Ref. 24.

of isobutylene has brought about the preparation of a large number of new isobutylene-based materials.

High molecular weight copolymers of isobutylene and isoprene have been prepared at temperatures 40–50°C higher than is commercially practiced using metallocene and single-site initiators (12–16). Newer Lewis acids like methylaluminoxane and weakly coordinating anions or their salts like $B(C_6F_5)_3$ or $R^+[B(C_6F_5)_4]^-$ also prepare high molecular weight copolymers at these higher temperatures (12–16).

Modification of Butyl Rubbers.

Halobutyls. Chloro- and bromobutyls are commercially the most important derivatives. The halogenation reaction is carried out in hydrocarbon solution using elemental chloride and bromine (equimolar with the enchained isoprene). The halogenation is fast and proceeds mainly by an ionic mechanism. The structures that may form include the following:



(1)

Normally structure **1** is dominant (>80%) (38,39). More than one halogen atom per isoprene unit can also be introduced. However, the reaction rates for excess halogens are lower and the reaction is complicated by chain fragmentation (40).

Other Derivatives. Various other derivatives have appeared on the market or reached the market development stage. Conjugated-diene butyl is obtained by the controlled dehydrohalogenation of halogenated butyl rubber (41). The product

can be cross-linked with peroxide or exposure to radiation. Free-radical grafting with vinyl monomers, eg styrene, can be used in a graft cure, leading to a transparent rubber with a T_g of about -59°C. Carboxy-terminated polyisobutylene useful in forming networks with epoxies or aziridine has been prepared from high molecular weight butyl rubber or a poly(isobutylene-*co*-piperylene) [26335-67-1] copolymer (42). The resulting carboxy-terminated polymers are viscous liquids. High molecular weight isobutylene–cyclopentadiene rubbers containing up to 40% cyclopentadiene were produced and developed by ExxonMobil (43) and were recently reexamined by Daelim (43). Highly branched polyisobutylene are prepared by use of an appropriately designed initiator that is also a comonomer in the polymerization (44).

Isobutylene–Isoprene–Divinylbenzene Terpolymers. A partially cross-linked terpolymer of isobutylene, isoprene, and partially reacted divinyl benzene is commercially available from Rubber Division, Bayer Inc., Canada. The residual vinyl functionality may be cross-linked with peroxides, a treatment that would normally degrade conventional butyl rubbers. This material is used primarily in the manufacture of sealant tapes and caulking compounds (45).

Liquid Butyl Rubber. Degradation of high molecular weight butyl rubber by extrusion at high shear rates and temperatures produces a liquid rubber with a viscosity average molecular weight (M_v) between 20,000 and 30,000. The relatively low viscosity aids in formulating high solids compounds for use in sealants, caulks, potting compounds, and coatings. Resulting compounds can be poured, sprayed, and painted.

New Materials.

Star-Branched (SB) Butyl. Butyl rubbers have unique processing characteristics because of their viscoelastic properties and lack of crystallization of compounds on extension. They exhibit both low green strength and low creep resistance as a consequence of high molecular weight between entanglements. To enhance the strength of uncured traditional butyl rubber a relatively high molecular weight is required. Increasing molecular weight also causes an increase in relaxation time along with high viscosity. In such situations it is usually helpful to broaden the molecular weight distribution, but this is difficult to accomplish in conventional butyl rubber polymerization. Physical blending of low and high molecular weight polymer can also provide broader molecular weight distributions, but it results in other processing problems such as high extrudate swelling in flow-through shaping dies.

SB butyl has a bimodal molecular weight distribution with a high molecular weight branched mode and a low molecular weight linear component. The polymer is prepared by a conventional carbocationic copolymerization of isobutylene and isoprene at low temperature, but in the presence of a polymeric branching agent. The high molecular weight branched molecules are formed during the polymerization via a graft-from or a graft-onto mechanism. A graft-from reaction takes place when a macroinitiator/macrotransfer reagent, such as hydrochlorinated poly(styrene-*co*-isoprene) or chlorinated polystyrene, is used. A graft-onto reaction takes place when a multifunctional terminating agent, eg, poly(styrene-*co*-butadiene), is employed as the branching agent. In general, the SB butyl has 10–20% high molecular weight branched molecules, which have a random comblike structure with 20–40 butyl branches. Although this is not a true star topology,

it approaches a star structure since the branching agent is relatively short and the branching density is relatively high, ie, the molecular weight between branching points is low compared to the segment length of the butyl branches. SB butyl rubbers offer a unique balance of viscoelastic properties, resulting in significant processability improvements. Dispersion in mixing and mixing rates are improved. Compound extrusion rates are higher, die swell is lower, shrinkage is reduced, and surface quality is improved. The balance between green strength and stress relaxation at ambient temperature is improved, making shaping operations such as tire building easier. Several grades of ExxonMobil SB butyl polymers including copolymer, chlorinated, and brominated copolymers are now commercially available.

Brominated Poly(isobutylene-co-p-methylstyrene). *para*-Methylstyrene [622-97-9] (PMS) can be readily copolymerized with isobutylene via classical carbocationic copolymerization using a strong Lewis acid, eg, $AlCl_3$ or alkyl aluminum in methyl chloride, at low temperature. The copolymer composition is very similar to the feed monomer ratio because of the similar copolymerization reactivity ratios, ie, $r_1 = 1$ and $r_2 = 1.4$, under commercial polymerization conditions. These new high molecular weight copolymers encompass an enormous range of properties, from polyisobutylene-like elastomers to poly(*p*-methylstyrene)-like tough, hard plastic materials with T_gs above 100°C, depending on monomer ratio. A highly reactive and versatile benzyl bromide functionality, $C_6H_5CH_2Br$ can be introduced by the selective free-radical bromination of the benzyl group in the copolymer. The brominated copolymer can be cross-linked with a variety of cross-linking systems. This new functionalized copolymer preserves polyisobutylene properties, low permeability, and unique dynamic response, while adding the behavior of inertness to ozone, a property similar to ethylene–propylene rubbers. Copolymers with PMS below 10 mol% are most useful for elastomeric applications because the T_gs are near −60°C. Several grades of the brominated copolymer (Exxpro Polymers) are available from ExxonMobil (46,47).

The benzyl bromide in the brominated copolymer can also be easily converted by nucleophilic substitution reactions to a variety of other functional groups and graft copolymers as desired for specific properties and applications (47). Ionomers (48), grafted copolymers (49), radiation-cured rubbers (50), and rubber-toughened nylons (51) are a few examples of the derivatives and functions that modification of brominated poly(isobutylene-*co*-*p*-methylstyrene) can offer.

Thermoplastic Elastomers. With the structural control inherent in living polymerization, new block copolymers (qv) containing polyisobutylene are now possible (36). ABA triblock copolymers (A = polymethyl vinyl ether, B = polyisobutylene) that provide morphologies capable of exhibiting properties of an elastomer at use temperature, while processing like a thermoplastic, have been made from polyisobutylene and several styrenic derivatives (52–58) (see ELASTOMERS, THERMOPLASTIC). As thermoplastic elastomers, these materials offer other advantages owing to the intrinsic properties of polyisobutylene, namely low permeability and low dynamic modulus. More recently, star block copolymers of the A_2B_2 type have been prepared and exhibit unique physical properties (59). Many more architecturally designed polyisobutylenes are possible through living polymerization techniques. Kuraray Inc., Japan, commercially test-marketed polyisobutylene–polystyrene block copolymers. Also, Kaneka Inc., Japan, produce Epion, a functionalized polyisobutylene.

Manufacturing

Most of the butyl polymers made commercially are produced by copolymerizing isobutylene and isoprene in precipitation processes that use methyl chloride as the diluent and a catalyst system comprising a Lewis Acid and an alkyl halide. The Lewis acid used in many of the commercial butyl rubber plants is aluminum chloride, which is low cost, a solid, and soluble in methyl chloride. Aluminum alkyls are now becoming popular because they simplify catalyst preparation and have been shown to increase monomer conversion.

The manufacture of butyl rubber, poly(isobutylene-*co*-*p*-methylstyrene) (Exxpro backbone) and high molecular weight polyisobutylene (Vistanex) requires a complex manufacturing process consisting of feed purification, feed blending, polymerization, slurry stripping, and finishing. A schematic flow diagram (Fig. 1) shows the major units in a butyl plant.

An alternative solution process, developed in Russia, uses a C_5–C_7 hydrocarbon as solvent and an aluminum alkyl halide as the initiator. The polymerization is conducted in scraped surface reactors at -90 to $-50^{\circ}C$. The solution process avoids the use of methyl chloride, which is an advantage when butyl rubber is to be halogenated. However, the energy costs are higher than for the slurry process because of the higher viscosity of the polymer solution. Consequently, it is unlikely that the well-established slurry process will be displaced.

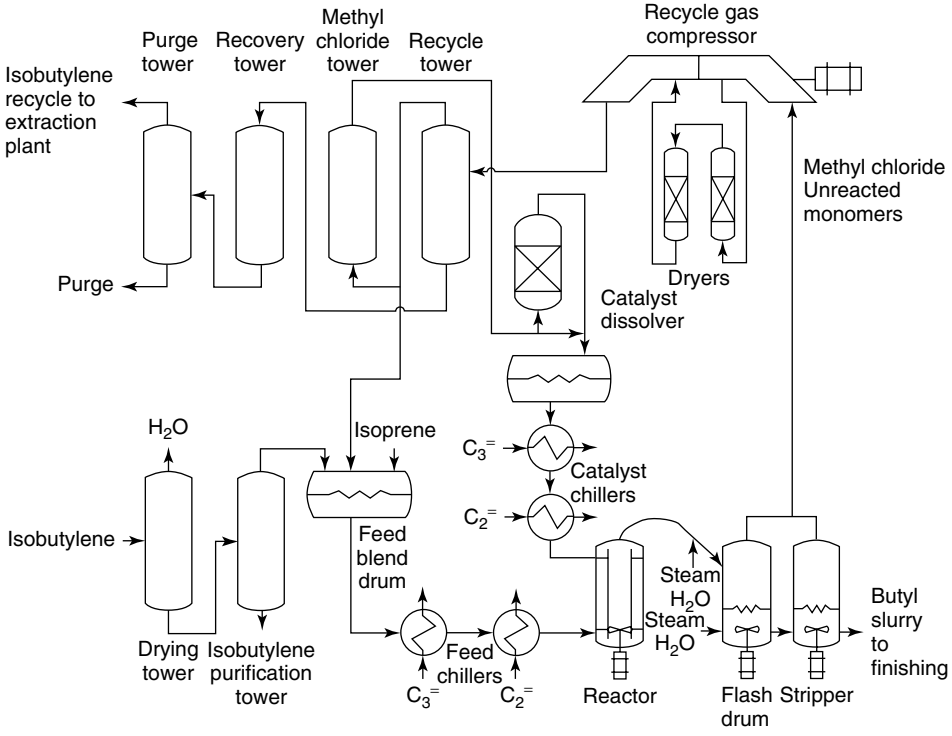


Fig. 1. Butyl plant flow plan.

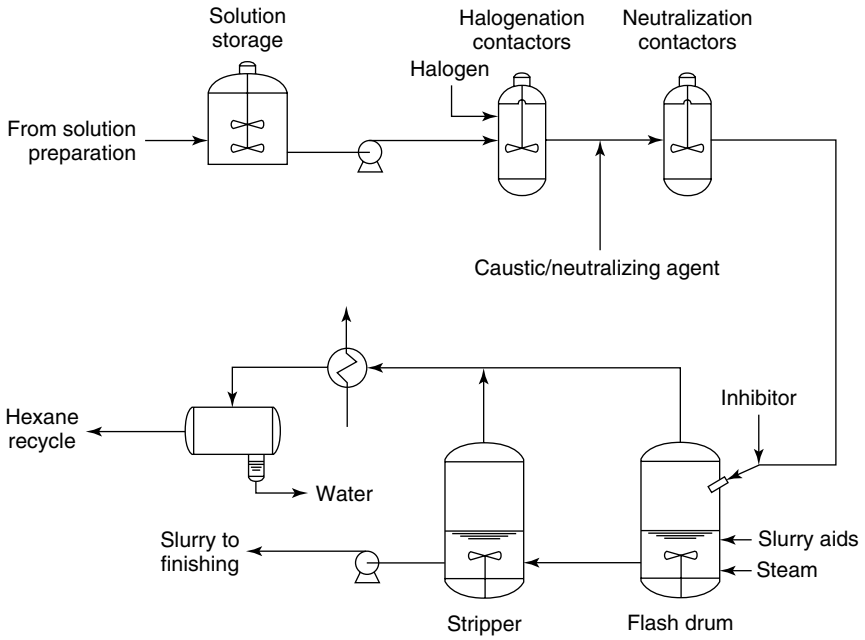

Fig. 2. Block diagram of halogenation.

The manufacture of halobutyl rubbers such as Bromobutyl, Chlorobutyl, and Exxpro [bromopoly(isobutylene-*co*-*p*-methylstyrene)] requires a second chemical reaction: the halogenation of the polymer backbone. This can be achieved in two ways, the finished polymer produced in the butyl plant can be dissolved in a hydrocarbon solvent such as hexane or pentane, or a solvent replacement process can be used to dissolve the polymer from the slurry leaving the reactor. A schematic flow diagram of the halogenation process is shown by Figure 2.

Monomer Purification. To make high molecular weight polymers with good isobutylene conversion and good reactor service factor, the feed must be pure and dry. We must start with high quality isobutylene (>99%), dry it, and remove other olefins, eg butene-1, butene-2, propene, and oxygenated hydrocarbons such as dimethyl ether and methanol. A number of commercial processes are available for production of the required high purity isobutylene. An extraction process based on sulfuric acid has been developed by several companies (60,61) and is used extensively. Significant quantities of isobutylene are also produced by dehydration of *tert*-butyl alcohol (62). The highest purity isobutylene is produced by MTBE (methyl-*t*-butyl ether, [1634-04-4]) decomposition plants. This process starts with the selective reaction of dilute isobutylene in a C_4 stream with methanol over an acid ion-exchange resin, eg, Amberlyst 15, to form MTBE. This ether is produced mainly as a high octane blending component for low lead gasoline. Catalytic decomposition at 170–200°C and 600 kPa (5.9 atm) over a fixed-bed acid catalyst, eg, $SiO_2Al_2O_3$ or Amberlyst 15, produces high purity isobutylene (63–65).

The isobutylene is then dried by azeotropic distillation and purified in a super-fractionating distillation column to reduce the butenes to less than 1000 ppm. Note that if water is not removed it will cause icing in the feed chillers and this will lead to a poor reactor service factor.

The purified isobutylene is then blended with a recycled methyl chloride stream containing a low level of isobutylene (∼5%). Finally, the comonomer, isoprene or *p*-methylstyrene, is added. In this blending process, control of the ratio of comonomer to isobutylene is very important. This is because it has a significant impact on the composition of the polymer produced, the conversion of monomer, and the stability of reactor operation. For these reasons, a combination of both an analyzer and a mass balance control can be used to maintain the composition of the feed blend. The feed blend contains 20–40 wt% of isobutylene and 0.4–1.4 wt% of isoprene or 1–2 wt% of *p*-methylstyrene, depending on the grade of butyl rubber to be produced; the remainder is methyl chloride.

Polymerization. Catalyst solution is produced by passing pure methyl chloride through packed beds of granular aluminum chloride at 45°C. The concentrated solution formed is diluted with additional methyl chloride to which a catalyst activator is added and the solution later stored. The feed blend and catalyst solutions are chilled to −100 to −90°C in a series of heat exchangers before entry to the reactor.

The cold feed and catalyst are introduced continuously to a reactor comprising a central vertical draft tube surrounded by concentric rows of cooling tubes. The reactors have an aspect ratio of 28 (length) to 8 (diameter) and contain an axial flow pump located at the bottom of the draft tube that circulates the slurry through the cooling tubes. The reactor is constructed with 3.5 or 9 wt% nickel steel, or alloys that have adequate impact strength at the low temperature of the polymerization reaction. The production of high molecular weight butyl requires a polymerization temperature below −135°F (−90°C) and the reaction is exothermic, generating 0.82 MJ/kg (350 Btu/lb) of polymer. This requires a two-stage refrigeration system that uses boiling propylene or propane and ethylene as the refrigerants. In some plants ammonia is used in the first stage of the refrigeration process.

The reactors are the epicenter of all butyl plants and are mechanically complex. The operation of the remainder of the plant is dictated by the reactors. Essentially, the reactors are stirred tanks that contain a heat exchanger to keep them cold.

In the reactor, polymer chains are initiated by the catalyst and propagate in solution. Chain propagation occurs in microseconds but the overall reaction rate is controlled by the slower initiation sequence. As individual polymer molecules are formed they precipitate to produce a fine milky slurry of sub–micron-size particles. These particles grow in the reactor by accreting new polymer chains and by agglomeration.

The polymer slurry circulates through the reactor tubes, and boiling liquid ethylene in the reactor jackets keeps the reactor contents cold. The butyl polymerization process is complex because of the combination of low temperature operation, polymer slurry formation, and difficulty in directly measuring polymer quality. To achieve high molecular weight, the reaction temperature must be kept low to reduce the amount of chain transfer. In the slurry process, the viscosity

is relatively low, and good heat transfer can be achieved. To maintain a stable slurry, the temperature must be kept below the glass-transition temperature, T_g, of polyisobutylene (−68°C) and, as the slurry is shear-thinning, there must be a high level of shear. The axial flow pump that provides a high degree of circulation in the reactor achieves this.

One of the common theories to explain fouling in a butyl reactor is that rubber particles in the reactor slurry are not completely glassy because of diluent and monomers in the surface layer. This causes them to be sticky as well as agglomerating, and the particles will stick to the heat-transfer surfaces in the reactor. This causes the heat-transfer resistance to increase and the slurry temperature to warm. Eventually, this warming can cause the slurry to destabilize and the viscosity to increase rapidly. Ultimately, this could lead to plugging, which requires extended solvent washing to clean the reactor. Therefore, production in a reactor is stopped every 2–4 days for solvent washing. This forces a cyclical multireactor operation in which some reactors are producing polymer while others are being washed to remove rubber fouling. Typical runs are from 18 to 60 h, depending on feed purity, slurry solids concentration, and production rate.

The production rate is 2.0–4.5 t/h, depending on feed rate, monomer concentration in the feed, and monomer conversion. The conversion of isobutylene and isoprene typically ranges from 75–95% and 45–85%, respectively, depending on the grade of butyl rubber being produced. The molecular weight of the polymer produced is set by the ratio of chain-making to chain-terminating processes. In commercial plants the molecular weight and composition of the polymer formed are controlled by the concentration of monomers in the reactor liquid phase and the amount of terminating or transfer species present to interrupt chain growth. The slurry composition depends on the monomer content of the feed stream and the extent of monomer conversion. In practice, the flow rate and the composition of catalyst to the reactor is the principal operating variable; reactor residence time is often in the range 30–60 min.

The original reactor design, known as the draft tube reactor, has been used commercially since the initial development of butyl in the 1940s. An improved design in which the draft tube is replaced by additional tubes and the circulation pump is redesigned has recently been proposed (66).

In addition to these changes to the mechanical design of the reactor, improvements to the polymerization chemistry and diluent have been investigated in the last decade. Examples are the use of supercritical carbon dioxide (67) and the use of aluminum alkyls in the catalyst system (68).

Halogenation. Chlorinated and brominated butyl rubber can be produced in the same plant in blocked operation. However, there are some differences in equipment and reaction conditions. A longer reactor residence time is required for bromination because of the slower reaction rate compared to chlorination. Separate facilities are needed to store and meter the individual halogens to the reactor. Additional facilities are required because of the complexity of stabilizing bromobutyl rubber.

The halogenation process begins with the preparation of a hexane solution of butyl rubber with the desired molecular weight and unsaturation. Slurry from a butyl polymerization reactor is dissolved (69–71) by transferring it into a drum containing hot liquid hexane that rapidly dissolves the fine slurry particles.

Hexane vapor is added to flash methyl chloride and unreacted monomers overhead for recovery and recycle. The solution of butyl in hexane passes to a stripping column where the final traces of methyl chloride and monomers are removed. The hot solution is brought to the desired concentration for halogenation, typically 20–25 wt% in an adiabatic flash step.

Alternatively, bales of finished butyl rubber are chopped or ground to small pieces and conveyed to a series of agitated dissolving vessels or to a large vessel divided into multiple stages. Solutions containing 15–20% polymer can be prepared in 1–4 h depending upon temperature, particle size, and agitation. This method has the advantage of being independent from the butyl polymerization process but requires storage and careful inventory control between the two stages of the process. This process also requires two finishing operations: one to produce dry butyl backbone, the second to finish the halobutyl product. Investment costs for the two dissolving processes are similar, but energy costs for the dissolving process can be higher.

Halogenation is the second major chemical reaction in the production of halobutyl polymers. It is usually carried out by adding bromine liquid or chlorine vapor to a solution of rubber in hydrocarbon solvent (hexane or pentane), which is often referred to as cement. The cement must be essentially free of monomers, or low molecular weight toxic species will be formed during the chlorine or bromine reactions. The halogenation of the butyl backbone is an ionic-substitution reaction in which the halogen is added to the cement stream in a well-mixed reactor (eq. 1). This reaction is unusual for polymers where it's more typical for the bromine to add across the double bond.

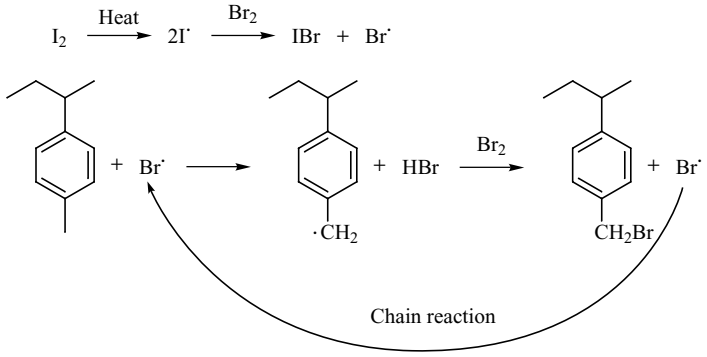
Insufficient mixing will lead to poor distribution of the halogen on the polymer, which can cause the product cure characteristics to be unsatisfactory. Another potential problem is the vigorous reaction of liquid chlorine with hydrocarbon. This leads to complete breakdown of some of the polymer, producing carbon and HX. This causes the polymer to be gray rather than the normal off-white and the product properties to be adversely affected.

For both chloro- and bromobutyl rubber two isomers are formed as shown in equation 1. The ratio of these isomers must be carefully controlled in order to keep consistent product properties.

The by-product from this reaction, HX, is normally reacted with aqueous caustic solution to give a soluble salt. Incomplete neutralization will leave HX in the rubber, and subsequent reactions during the drying process can destabilize the polymer. The key to good neutralization is good mixing of the halogen and cement. Further improvements to the neutralization process can be achieved by the addition of a surfactant (72).

Because of the generation of HCl or HBr, the maximum efficiency for halogen usage in this process is 50%. An improvement in efficiency can be achieved by adding hydrogen peroxide to the process to convert the acid back to halogen (73).

The bromination reaction required to produce Exxpro requires a free-radical reaction because there is no unsaturation in the backbone. The bromine and a free-radical initiator are added to the cement, mixed well, and then passed through a series of stirred tank reactors where the chain reaction shown by equation 2 occurs.



(2)

An alternative process is bulk-phase halogenation (74–76). Dry butyl rubber is fed into a specially designed extruder reactor and contacted in the melt phase with chlorine or bromine vapor. By-product halogen acids are vented directly, avoiding the need for a separate neutralization step. Halogenated rubbers comparable in composition and properties to commercial products can be obtained.

Finishing. The halogenated rubber solution then passes into a vertical drum where the solvent is flashed and stripped by steam and hot water. Calcium stearate is added to the slurry in this drum to prevent polymer agglomeration. A second vessel in series provides additional residence time for the solvent to diffuse from the rubber and be vaporized. The final solvent content and the steam usage for solvent removal depend on the conditions in each vessel. Typically, the lead flash drum is operated at 105–120°C and 200–300 kPa (29–43.5 psi). Conditions in the final stripping stage are 101°C and 105 kPa (15 psi). The hexane can be reduced to 0.5–1.0 wt% with a steam usage of 2.0–2.5 kg/kg rubber.

The resultant polymer/water slurry is kept agitated and then screened to separate the bulk water from the rubber. The polymer is then dried in a series of extrusion dewatering and drying steps to a final moisture content of <0.3 wt%. Antioxidants and stabilizers, eg, BHT and epoxidized soybean oil, protect against dehydrohalogenation and are added in the final extrusion step. Fluid-bed conveyors and/or airvey systems are used to cool the product to an acceptable packaging temperature. The resultant dried product is in the form of small "crumbs," which are subsequently weighed and compressed into 75-lb bales for wrapping in polyethylene film and packaged into wooden or metal crates or cardboard containers.

Structure, Properties, and Product Applications of Isobutylene-Based Polymers

Molecular Structure.

Polyisobutylene. Isobutylene polymerizes in a regular head-to-tail sequence to produce a polymer having no asymmetric carbon atoms. The two pendant methyl groups bonded to alternative chain atoms in polyisobutylene (PIB) produce steric crowding, for which a partial relief is achieved by a distortion of the methylene carbon to 124° as compared to 110° for the tetrahedral carbon (73,74).

Methyl crowding is further alleviated by distorting the dihedral angle, leading to a splitting of the trans-rotational isomer by about 25° (73–75). The splitting of the trans isomer in two equivalent states is a special feature of PIB, not observed in its vinyl analogue, and has significant impacts on its local chain-segment dynamics (76). The additional fast trans-to-trans skeletal relaxation process in PIB results in a faster segmental motion and a lower glass-transition temperature despite the fact that PIB is a sterically strained and crowded macromolecule (76). The glass-transition temperature of PIB is about −70°C (77). It is an amorphous elastomer in the unstrained state. On extension at room temperature, PIB of high molecular weight crystallizes into crystals of an 8/3 helix with an alternating distorted trans-gauche structure (78). One chain end of PIB is typically unsaturated because of chain-transfer and termination mechanisms. Molecular weights could range from several hundred to several millions. There is no long-chain branching unless special synthesis methods are employed. The molecular weight distribution is commonly the most probable with $M_w/M_n = 2.0$.

Polybutenes. Copolymerization of mixed isobutylene and 1-butene containing streams with a Lewis acid catalyst system yields low molecular weight copolymers, from several hundreds to a few thousand, that are clear, colorless, and viscous liquids. The chain ends are unsaturated and are often chemically modified to provide a certain functionality (79,80).

Butyl Rubber. In butyl rubber, isoprene is enchained predominantly (90–95%) by 1,4-addition and head-to-tail arrangement (81–84). The remaining minor isoprene species may be interpreted spectroscopically either as 1,2-enchained (83,84) or as branched species from 1,4-addition (85). Depending on the grade, the unsaturation in butyl rubber is between 0.5 and 3 mol%. The glass-transition temperature of butyl rubber is about −65°C (86). With the low content of isoprene and a near-unity reactivity ratio between isoprene and isobutylene (87), a random distribution of enchained isoprene monomer in butyl rubber is achieved. The molecular weight distribution in butyl rubber is mostly with M_w/M_n of 3–5.

Halogenated Butyl Rubber. Halogenation at the isoprene site in butyl rubber proceeds by a halonium ion mechanism leading to the formation of a predominated exomethylene alkyl halide structure in both chlorinated and brominated rubbers (88,89). Upon heating, the exo allylic halide rearranges to give an equilibrium distribution of exo and endo structures (90–92). Halogenation of the unsaturation has no apparent effects on the butyl backbone and on the butyl glass-transition temperature. However, cross-linked halobutyl rubbers do not crystallize on extension as a result of the backbone irregularities introduced by the halogenated isoprene units.

Star-Branched (SB) Butyl. Introduction of a branching agent of styrene–butadiene–styrene (SBS) block copolymer during cationic polymerization of butyl leads to a SB butyl that, in general, contain 10–15% of star polymers, with remaining linear butyl chains (93,94). SB butyl is a reactor blend of linear polymers and star polymers, where the star molecules were synthesized during polymerization by cationic grafting of propagating linear butyl chains onto the branching agent (95). In the solid state, these star polymers aggregate to form ∼30-nm-diameter spherical domains separated by about 90 nm and covered by about 6 vol% (96,97). It was proposed that these domains consist of predominantly the styrene–butadiene–styrene branching agent (96). A much broader molecular

weight distribution is achieved in SB butyl with M_w/M_n greater than 8. Halogenation of SB butyl results in the same halogenated structure in the linear butyl chains and in the linear butyl chain arms of the star fraction as that in the halogenated butyl. Unreacted butadiene blocks of the SBS branching agent were 100% brominated and 60% chlorinated after halogenation (98).

Brominated Poly(isobutylene-co-p-methylstyrene). Copolymerization of isobutylene with *para*-methylstyrene (PMS) produces a saturated copolymer backbone with randomly distributed pendant *para*-methyl-substituted aromatic rings. During radical bromination after polymerization, some of the substituted *para*-methyls are converted to bromomethyls for vulcanization and functionization (99,100). Brominated poly(isobutylene-*co*-*p*-methylstyrene) polymers are saturated terpolymers containing isobutylene, 1–6 mol% PMS, and 0.5–1.5 mol% BrPMS (brominated *para*-methylstyrene). Their T_gs increase with increasing PMS content and is around -60°C. The molecular weight distribution of brominated poly(isobutylene-*co*-*p*-methylstyrene) is narrow, with M_w/M_n less than 3 (99).

Physical Properties.

Permeability. Primary uses of polyisobutylene and isobutylene copolymers of butyl, halobutyl, SB butyl, and brominated poly(isobutylene-*co*-*p*-methylstyrene) in elastomeric vulcanized compounds rely on their properties of low air permeability and high damping. In comparison with many other common elastomers, polyisobutylene and its copolymers are notable for their low permeability to small-molecule diffusants as a result of their efficient intermolecular packing (101–103) as evidenced by their relative high density (density of 0.917 g/cm^3). This efficient packing in isobutylene polymers leads to their low fractional free volumes and low diffusion coefficients for penetrants (101). In combination with the low solubilities of small-molecule diffusants in isobutylene polymers, low permeability values for small molecules, such as He, H_2, O_2, N_2, CO_2, and others, are observed in isobutylene polymers as compared with other elastomers (104).

As shown in Figure 3, diffusion coefficients of nitrogen in both various diene rubbers and in butyl rubber increase with increasing differences between the measurement temperature and the corresponding rubber's glass-transition temperature. However, although the rate of increase in diffusion coefficient with $T-T_g$ is about the same between diene rubbers and butyl rubber, the absolute values of diffusion coefficient in butyl rubber are significantly less than that of diene rubbers. Considering isobutylene, copolymers discussed contain only small amounts of comonomers besides isobutylene, their temperature-dependent permeability values follow the same curve in Figure 3 for butyl rubber. With brominated poly(isobutylene-*co*-*p*-methylstyrene) having the highest T_g among isobutylene copolymers, it has the corresponding lowest permeability value at room temperature among isobutylene copolymers (105).

Dynamic Damping. Polyisobutylene and isobutylene copolymers are high damping at 25°C, with loss tangents covering more than eight decades of frequencies even though their T_gs are less than -60°C (106,107). This broad dispersion in PIB's dynamic mechanical loss modulus is unique among flexible-chain polymers and is related to its broad glass–rubber transition (108). The narrowness of the glass–rubber transition, as defined by the steepness index, for PIB is 0.65, which is much smaller than most polymers. In addition, PIB has the most symmetric

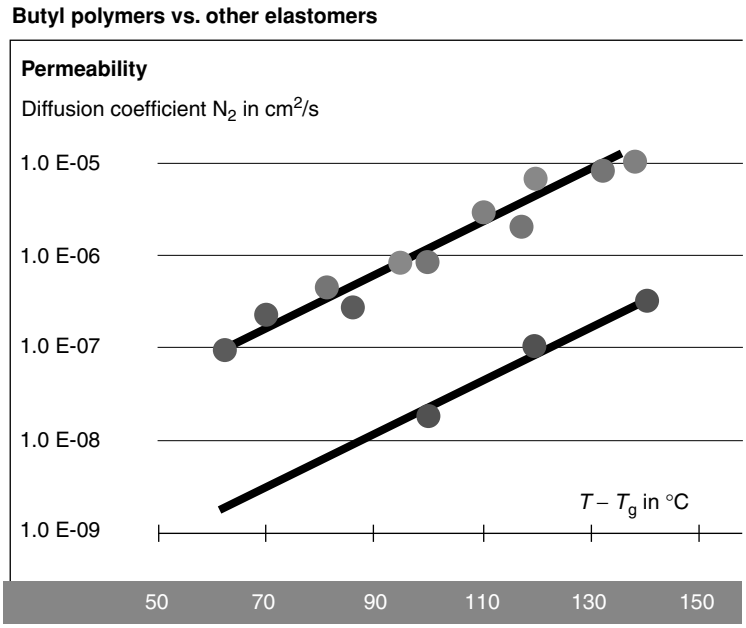


Fig. 3. Diffusion coefficients of nitrogen in diene rubbers and in butyl rubber as a function of $T - T_g$ (Data from Ref. 104). ■ Chloroprene rubber (neoprene); ■ styrene butadiene rubber; ■ natural rubber; ■ nitrile butadiene rubber; ■ butyl rubber.

and compact monomer structure among amorphous polymers, which minimizes the intermolecular interactions and contributes to its unique viscoelastic properties (109,110). As a result, a separation in time scale between the segmental motion and the Rouse modes is broader in glass–rubber transition, leading to the appearance of the sub-Rouse mode (108,109). In Rouse's theory, a polymer chain is represented as a sequence of equivalent Gaussian submolecules. The Rouse mode refers to motions of these submolecules, and sub-Rouse mode involves motions of chain units smaller than these submolecules. Considering the differences in temperature dependencies of these motions, the glass transitions of PIB and its copolymers are thermo-rheological complexes and they do not follow time–temperature superposition (108,111). PIB and its copolymers have high entanglement molecular weights (112) and corresponding low plateau moduli which, in turn, contribute to their high tack or self-adhesion in the uncross-linked state. Entanglement molecular weight of PIB is about 9000 as compared with 1300 for polyethylene, 1700 for ethylene–propylene copolymer, 2000 for 1,4-polybutadiene, 3000 for styrene–butadiene copolymer, and 6100 for hevea rubber.

Chemical Properties. PIB is a saturated hydrocarbon where the unsaturated chain ends could undergo reactions typical of a hindered olefin. These end groups are used, particularly in low molecular weight materials where plenty of chain ends are available, as a route to functionization, such as the introduction of amine groups to PIB for producing dispersants for lubricating oils. As for butyl rubbers, their in-chain unsaturations could be attacked by atmospheric-ozone-leading degradation and, hence, require protection by antioxidants (113).

Chlorobutyls are thermally more stable than bromobutyls. Upon thermal exposure up to 150°C, no noticeable decomposition took place in chlorobutyl except for some allylic chlorine rearrangement, whereas the elimination of HBr occurred in bromobutyl concurrently with isomerization to produce conjugated dienes that subsequently degrade (91,92). Brominated poly(isobutylene-*co*-*p*-methylstyrene), without any unsaturation, is the most thermally stable isobutylene copolymer. In addition, the strong reactivity of the benzylic bromine functionality in brominated poly(isobutylene-*co*-*p*-methylstyrene) with nucleophiles allows functionization and grafting in addition to its uses for vulcanization (99,100). Polyisobutylene and its copolymers, including butyl, halobutyl, and brominated poly(isobutylene-*co*-*p*-methylstyrene), are readily soluble in nonpolar solvents where cyclohexane is an excellent solvent, benzene is a moderate solvent, and dioxane is a nonsolvent (114).

Elastomeric Vulcanizates. As with almost all rubbers, the applications of isobutylene copolymers in rubber goods require compounding and subsequent vulcanization, or cross-linking. During compounding, various fillers, processing aids, plasticizers, tackifiers, curatives, and antidegradants are added.

Fillers. Filler addition is a common practice in rubber industries to stiffen and strengthen amorphous rubbers. In addition to the reinforcement, fine and particulate fillers, most notably carbon black, suppress elasticity of gum rubbers and render better processability, such as less die swell, less shrinkage, less melt fracture, and less nerve (or less elastic spring-back in uncured state) (115). Physical interactions between carbon blacks and rubber are strong but can yield upon stressing. The effects of carbon black on properties of butyl, halobutyl, and brominated poly(isobutylene-*co*-*p*-methylstyrene) rubbers are similar to that of other elastomers. As particle size decreases with a corresponding increase in specific surface area, the strength, modulus, hardness, viscosity, and damping of carbon-black-filled vulcanized rubbers increase (116,117). Tensile strength, in general, is raised to a maximum with carbon black content and then decreases at higher loading. For butyl rubber, this maximum tensile strength is obtained at 50–60 phr (part per hundred of rubber) of carbon black.

Beyond filler addition in rubbers, elastomeric behavior can be tailored by proper blending of filled elastomers. Major reasons for the usage of blends are to reduce compound cost, to improve processability, and to enhance final product performance (118). But, in this case, selective filler partition may alter the blend morphology and produce significant changes in blend properties. Elastic and fracture properties, such as resilience, tear strength, and fatigue resistance, of rubber blends have been found to depend strongly on filler phase distribution (119,120). Carbon aggregates were known to preferentially reside in the polymer with higher unsaturation, lower viscosity, and higher polarity, generally in that order of significance (121). Hence, a preferential filler partition into the diene rubber phase, such as BR and SBR, in diene rubber blends with butyl rubber was found (122,123). However, with the strong interactions between allylic bromine or benzylic bromine in bromobutyl and in brominated poly(isobutylene-*co*-*p*-methylstyrene), respectively, and carbon blacks (124), the opposite in terms of preferential filler partition into the bromobutyl or brominated poly(isobutylene-*co*-*p*-methylstyrene) phases in their blends with high diene rubbers was indicated (125,126).

Mineral fillers are used for light-colored rubber compounds for cost reduction and physical improvement. In butyl and halobutyl, alkaline fillers, such as calcium silicates, and hygroscopic fillers can strongly retard cure, while acid clays can accelerate cure. Silicas provide maximum reinforcement among mineral fillers but they promote compound stiffness and strongly affect cure rates by their absorption of curatives. Clays are less reinforcing and calcined clay is particularly suited for pharmaceutical stopper applications for its purity, low water content, and particle size uniformity. Talc is semireinforcing and improves resistance to fragmentation during needle penetration and withdrawal in pharmaceutical closures. Nonreinforcing fillers, such as calcium carbonate, are added to lower compound cost without affecting cure. Strong reductions in permeability in black or light-colored compounds of isobutylene copolymers could be achieved by adding small percents (less than 5 wt%) of exfoliated high-aspect-ratio atomic-thickness sheets of layered mineral, such as organonanoclays, without significant compromises in flexibility (127–129). The alignment of the nanoclay leads to a nematic-phase morphology and introduces torturosity for the diffusants, resulting in the lowering in permeability (130).

Plasticizers and Processing Aids. Petroleum-based oils are commonly used as plasticizers to lower compound viscosity and to improve processability and low temperature properties but with an increase in compound air permeability. Plasticizers are selected for their compatibility with isobutylene polymers and for their low temperature properties. Butyl rubber has a solubility parameter that is similar in value to that of polybutene, and paraffinic and naphthenic oils for which they are preferred. Although not to be considered as solvating agents, paraffin waxes and low molecular weight polyethylene are added for improved processing. For an improvement in low temperature flexibility, ester-type plasticizers, such as adipates and sebacates, can be used. In addition to functioning as a plasticizer, Struktol 40 MS can enhance filler dispersion and cure adhesion to high diene rubber substrates. Materials such as mineral rubber and asphaltic pitch have also been used for this dual function.

Other Ingredients. Other compound ingredients include tackifiers, flame retarders, odorants, and lubricants. Hydrocarbon tackifier resins improve the tack of unvulcanized compounds without any side reactions but are less effective than the phenolic type. However, phenol-formaldehyde tackifier resins react with halobutyl through their methylol groups, leading to premature cure. Hindered phenolic antioxidants added during manufacture of butyl and halobutyl prevent oxidation during their finishing, storage, and usage. These antioxidants also improve the resistance of vulcanized butyl and halobutyl compounds to ozone cracking. Additional stabilization against dehydrohalogenation at elevated temperature is required for halobutyls (26,131). Calcium stearate is used in chlorobutyl and a combination of calcium stearate and an epoxidized soybean oil is applied in bromobutyl to prevent dehydrohalogenation. No antioxidants or other stabilizers are added in brominated poly(isobutylene-*co*-*p*-methylstyrene).

Vulcanization. Vulcanization or curing in isobutylene polymers introduces chemical cross-links via reactions involving either allylic hydrogen or allylic halogen in butyl or halobutyl, respectively, or benzylic bromine in brominated poly(isobutylene-*co*-*p*-methylstyrene) to form a polymer network. In butyl

and halobutyl, most vulcanizates have about 1×10^{-4} mol of cross-links per cm^3, or about 250 backbone carbon atoms between cross-links.

Butyl. The basic curing agent for butyl rubber is elemental sulfur, with the formation of sulfide cross-links. Because of the low unsaturation in butyl rubbers, sulfur accelerators, such as thiurams or dithiocarbamates, are required to obtain acceptable rates and states. To activate accelerators and to stabilize cross-links already formed, butyl compounds require zinc oxide. Sulfur cross-links rearrange at elevated temperatures as a result of their low bonding energy that could lead to creep and permanent set in strained butyl at high temperatures. The resin cure in butyl rubber is based on the reaction of the methylol groups in the phenol-formaladehyde resin with allylic hydrogen in butyl, usually with a Lewis acid catalyst, to yield carbon–carbon cross-links that are thermally stable. Resin cure is preferred in butyl tire-curing bladders for their required thermal fatigue stability.

Halobutyl. The basic curing agent for halobutyl is zinc oxide, with the formation of carbon–carbon cross-links by alkylation catalyzed by a zinc halide produced after dehydrohalogenation of halobutyl (90,91,132). The ease of halogen elimination is the main difference between chlorobutyl and bromobutyl during curing where the bromobutyl cures faster (133). Esterification occurs at the halogen site in the presence of stearic acid. As a result, stearic acid accelerates cure rate and lowers the cure state. The zinc oxide cure is sensitive to acidic and basic compounding ingredients. In general, acids accelerate cure while bases retard. Water is a strong retarder because it complexes with reactive intermediates. In some applications, such as special pharmaceutical stoppers, the absence of zinc is mandatory. On the baseis of the strong reactivity between amine and allylic halogen (134), diamines can be used as the curative. While regular butyl undergoes molecular weight breakdown in the presence of peroxide, halobutyl can be cross-linked with organic peroxides. The best cure rate and optimal properties are achieved with a suitable co-agent, such as *m*-phenylene bismaleimide, at high temperatures.

Brominated Poly(isobutylene-co-p-methylstyrene). Using mainly zinc oxide and stearic acid, the cross-linking of brominated poly(isobutylene-*co*-*p*-methylstyrene) involves the formation of carbon–carbon bonds through Friedel–Crafts alkylation coordinated by a zinc complex (135,136). Unlike halobutyls, brominated poly(isobutylene-*co*-*p*-methylstyrene) cures extremely slowly with zinc oxide alone. A nucleophilic agent, such as zinc stearate, is needed to promote rapid displacement of benzyl bromide. The zinc stearate can be added directly or can be formed during vulcanization through the reaction of zinc oxide and stearic acid. In cases where faster cure is desired, dinucleophilic substitution using dinucleophiles, such as diamines, is the method of choice.

Uses. The polyisobutylene portion of the isobutylene copolymers, such as butyl, halobutyl, and brominated poly(isobutylene-*co*-*p*-methylstyrene), imparts chemical and physical characteristics that make them highly useful in a wide variety of applications. The low degree of permeability to gases accounts for the largest uses of butyl and halobutyl rubbers, namely as inner tubes and tire innerliners. These same properties are also of importance in air cushions, pneumatic springs, air bellows, accumulator bags, and pharmaceutical closures. The thermal stability of butyl rubber makes it ideal for rubber tire-curing bladders, high

temperature service hoses, and conveyor belts for hot material handling. With the added thermal stability in brominated poly(isobutylene-*co*-*p*-methylstyrene), it has made inroads in applications of bladders and curing envelopes.

Isobutylene-based polymers exhibit high damping and have uniquely broad damping and shock absorption ranges in both temperature and frequency. Molded rubber parts from butyl and halobutyl find wide applications in automobile suspension bumpers, exhaust hangers, and body mounts.

Blends of halobutyl or brominated poly(isobutylene-*co*-*p*-methylstyrene) with high diene rubbers are used in tire sidewalls and tread compounds (137–139). In sidewalls, ozone resistance, crack cut growth, and appearance are critical to their performance. Properly formulated blends with high diene rubbers that exhibit phase cocontinuity yield excellent sidewalls (140). The property balance for tire tread compounds can be enhanced by the incorporation of a more damping halobutyl or brominated poly(isobutylene-*co*-*p*-methylstyrene) rubber phase (141). Improvements in wet-, snow-, and ice-skid resistances and in dry traction without compromises in abrasion resistance and rolling resistance for high performance tires can be accomplished by using bromobutyl or brominated poly(isobutylene-*co*-*p*-methylstyrene) up to 30 phr in tread compounds (142).

Blends of isobutylene polymers with thermoplastic resins are used for toughening of these compounds (143,144). High-density polyethylene and isotactic polypropylene are often modified with 5–30 wt% of PIB. In some cases, a halobutyl phase is cross-linked as it is dispersed in the plastic phase to produce a highly elastic compound that is processable in thermoplastic molding equipment (145,146). The strong reactivity of the benzylic bromine group in brominated poly(isobutylene-*co*-*p*-methylstyrene) with amines during blending of brominated poly(isobutylene-*co*-*p*-methylstyrene) with polyamides results in surface-reactive compatibilization that suppresses coalescence and leads to extremely fine dispersions in these blends (147). Combining the low permeability values of both polyamides and brominated poly(isobutylene-*co*-*p*-methylstyrene), dynamic vulcanized thermoplastic blends of polyamides with brominated poly(isobutylene-*co*-*p*-methylstyrene) have been demonstrated to be suitable for tire innerliner applications (148–151).

Polybutenes enjoy extensive uses as adhesives, caulks, sealants, and glazing compounds. They are also used as plasticizers in rubber formulations with butyl, SBR, and natural rubber. In linear low density polyethylene (LLDPE) blends, they induce cling to stretch-wrap films. Polybutenes when modified at their chain-end unsaturations with polar functionality are widely employed in lubricants as dispersants. Blends of polybutene with polyolefins produce semisolid gels that can be used as potting and electrical-cable filling materials.

It should be noted that proper compounding and formulation are critical to the successful uses of all elastomer materials. It is recommended that the suppliers be contacted for information.

Health and Safety Factors

Polyisobutylene, isobutylene–isoprene copolymers, and isobutylene-*p*-methylstyrene copolymers are considered to have no chronic hazards associated

Table 2. Annual Butyl and Halogenated Butyl Rubber Production Capacity (YE 2002)

Producer	Products	Capacity, 10^3 t
ExxonMobil Chemical Co.		
Baton Rouge, La.	Halobutyl rubbers	143
Baytown, Tex.	Butyl rubber	27
	Halobutyl rubbers and Exxpro	75
Notre Dame de Gravenchon, France	Butyl rubber	54
Fawley, U.K.	Halobutyl rubbers	97
Japan Butyl Co., Ltd.[a]		
Kawasaki, Japan	Butyl rubber	78
Kashima, Japan	Halobutyl rubbers	52
Bayer (152)		
Sarnia, Ontario, Canada	Butyl, halobutyl rubbers	140
Zwijndrecht, Belgium	Butyl, halobutyl rubbers	115
CIS (152)		
Nizhnekamsk, Russia	Butyl rubbers	60
Togliati, Russia	Butyl rubbers	35
Sinopec (152)		
Yanshan, P.R. China	Butyl rubbers	30

[a]Jointly owned with Japan Synthetic Rubber Co., Ltd.

with exposure under normal industrial use. Some grades can be used in chewing-gum base and are regulated by the FDA in 21 CFR 172.615. Vulcanized products prepared from butyl rubber or halogenated butyl rubber may contain small amounts of toxic materials as a result of the particular vulcanization chemistry. Although many vulcanizates are inert, eg, zinc oxide cured chlorobutyl is used extensively in pharmaceutical stoppers, specific recommendations should be sought from suppliers.

Economic Aspects

Table 2 shows the manufacturing capacity for the world's major butyl and halobutyl polymers manufacturers. In addition to ExxonMobil Chemical and Bayer, during the last 10 years, butyl rubber produced at both Nizhnekamsk and Togliati has been sold throughout the world. Also, in the last 5 years, Sinopec has started to produce butyl polymers at its Yanshan plant in the People's Republic of China. All of the world's butyl plants use the more efficient slurry process except for the Togliati plant, which uses the solution process.

Manufacturing capacity has continued to expand in the last decade to keep up with the increasing demand due to expanding car sales and the growth in popularity of sports–utility vehicles, particularly in the United States. Apart from the economic downturns in 1992 and 2001, Figure 4 shows the worldwide sales of halobutyl polymers increasing steadily at approximately 4% per year. The widespread use of halobutyl innerliners in the tires of both passenger cars and light trucks accounts for most of these sales, although there is a small market for pharmaceutical stoppers. For most of the decade, halobutyl manufacturing plants have been running well above 85% capacity.

Fig. 4. Worldwide halobutyl sales. Halobutyl, worldwide; Halobutyl, Americas.

In the 1990s, sales of regular butyl polymers have not seen the same rate of growth as halobutyl. The majority of sales are to inner tube and tire bladder applications and, except for trucks and in some developing countries, these markets have been overtaken by the more popular tubeless tire. The introduction of the Russian and Chinese manufacturers has also dampened demand and not until the early 2000s has there been significant growth. Figure 5 shows the sales of regular butyl polymers during the past decade.

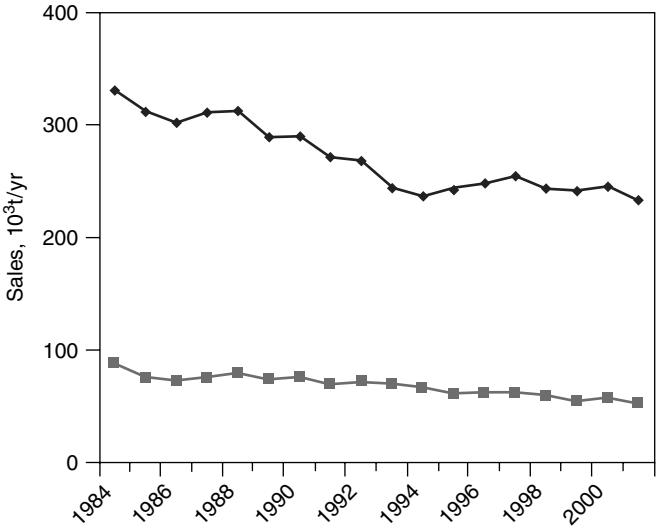

Fig. 5. Worldwide butyl sales. Regular butyl, worldwide; Regular butyl, Americas.

CARBOCATIONIC POLYMERIZATION

Introduction

Cationic polymerization is a chain-growth reaction where the active center is positively charged. In the case of *carbocationic polymerization*, the active center is a carbenium ion. The term *cationic* polymerization also covers polymerizations where the active center contains a heteroatom (eg, oxonium, sulfonium, ammonium, or phosphonium ion); these are not included in this chapter. The focus will be on carbocationic polymerization.

In order to get a perspective about the importance of *carbocationic* polymerization in polymer science and engineering, its positioning in the overall picture needs to be considered. The estimated total volume of polymers produced commercially by *cationic* polymerization is around 3–3.5 million tons per annum (1). This constitutes about 3% of the total synthetic polymer market. Polymers produced commercially by *carbocationic* polymerization make up about 2% of the total polymer market. On the basis of these numbers, *carbocationic* polymerization appears to be insignificant.

The main products are poly- and oligoisobutylenes, poly(butenes), hydrocarbon resins, and poly(vinyl ethers)—these will be discussed in more detail under Industrial Carbocationic Processes. Estimated worldwide production capacities are listed in Table 1.

It can be seen that isobutylene-based products are the most important; they range from viscous oils to high molecular weight elastomers, such as butyl and halobutyl rubbers (see BUTYL RUBBER). The latter exemplify most strikingly the practical importance of *carbocationic polymerization*. Butyl and halobutyl rubbers are used as inner tubes or inner liners in vehicle tires, because of their exceptional impermeability toward gases and moisture (3,4). Had butyl and halobutyl

rubbers not been discovered, we would have to pump up our car and bicycle tires daily as the air would escape through the rubbers used to build the body of these tires. Butyl and halobutyl rubbers have very high damping properties and therefore are used in machinery mounts to reduce vibration; unique examples include dampeners for bridges and foundations for earthquake-resistant buildings. They also have outstanding oxidative, environmental, and chemical stability, rendering them suitable for applications as industrial rubber goods, seals, adhesives, condenser caps, and pharmaceutical stoppers. An interesting application is chewing gums (considered essential by our children as any parent can testify). Emerging applications of polyisobutylene-based rubbers include biomedical implants that could save lives (5). These examples highlight the importance of carbocationic polymerization.

This article discusses the most important aspects of carbocationic polymerization, with references to more detailed information for specialists.

Historical Background

Carbocations are extremely reactive. Because of their high reactivity, identification or direct observation of carbocations is extremely difficult—although they are the intermediates of many organic reactions. The existence of carbocations became generally accepted in the 1920s and 1930s through the work of Whitmore, Ingold, and Meerwein (6). Analytical proof was first given by Olah in 1963 (7,8). Reacting SbF_5 and alkyl halides in "superacid" media, he was able to prepare carbocations stable enough for ^1H NMR characterization. He proposed to use the term *carbenium ion* for classical trivalent sp^2 carbocations (such as CH_3^+) and *carbonium ion* for the pentavalent carbocation (CH_5^+) (7,8). This nonclassical entity has a two-electron, three-center-bound pentacoordinated carbon; ammonium (NH_4^+), oxonium (R_3O^+), or sulfonium (R_3S^+) ions can be considered as similar "nonclassical" structures.

The first example of carbocationic polymerization, the resinification of turpentine oil by sulphuric acid (9), dates back a couple of centuries. Other examples

from the 1800s include the polymerization of pinene with $SnCl_4$ and BF_3 (10), turpentine with BF_3 (11), and styrene and isobutylene with sulphuric acid (11,12).

Hunter and Yohe laid out the first mechanism of carbocationic polymerization in 1933 (13). According to their proposal, the metal halide–monomer interaction leads to the formation of a "zwitterion" (the German word *zwitter* stands for "between"):

$$MtX_n + CH_2{=}C(CH_3)_2 \rightarrow MtX_n^- {-}CH_2{-}(CH_3)_2C^+$$

Polymerization then proceeds by reaction of monomer with the carbenium ion. In this system, the metal halide was considered the "catalyst." For thermodynamic reasons, this mechanism was criticized (14,15) and later abandoned as Polanyi's school put forth the idea of coinitiation on the basis of the study of the isobutylene–$TiCl_4$ system (16). Polanyi suggested that the true initiator in this system would be derived from the reaction between a cationogen such as water, and $TiCl_4$, the coinitiator (eq. 1):

$$TiCl_4 + H_2O + CH_2{=}C(CH_3)_2 \rightarrow CH_2{-}(CH_3)_2C^+TiCl_4OH^- \quad (1)$$

This reaction can be written in a more generalized form (eq. 2):

$$MtX_n + I{-}B + CH_2{=}C(CH_3)_2 \rightarrow I{-}CH_2{-}(CH_3)_2C^+MtX_nB^- \quad (2)$$

where I represents the true initiating species, such as a proton or carbenium ion, and B represents a basic group, eg, a hydroxide or a halide. The metal halide coinitiators are still called "catalysts" in the industry, as the processes used today were originally developed many decades ago. It would be helpful to all if the scientifically accepted terms were more commonly used.

Classical carbocationic polymerization is very rapid and therefore difficult to control, and is riddled with side reactions and incomplete monomer conversion. In contrast, *living* (or *controlled*) carbocationic polymerization opened new avenues for macromolecular engineering, ie, the design and synthesis of well-defined structures with efficient processes (17–20).

Monomers for Carbocationic Polymerizations

The most common monomers in carbocationic polymerization are alkenes, often termed "vinyl" monomers. Carbocationic polymerization of vinyl monomers proceeds by the electrophilic attack of the initiating and/or propagating carbenium ion on the double bond of the monomer. In order to sustain the chain reaction of propagation in competition with termination or transfer reactions, the carbenium ion has to be sufficiently stable and the monomer has to be sufficiently nucleophilic to ensure long enough lifetime of the active center to propagate.

Stability of Carbenium Ions. In terms of thermodynamic stability, carbenium ions can be ranked on the basis of gas-phase hydride affinity, heats of ionization, ionization equilibrium in solution, and S_N1-solvolysis rate (21). The "stability scales" obtained by these different methods correlate reasonably well

Table 2. Ranking of Carbenium Ions by Stability

Carbenium ion	$\Delta_R H^0$, kJ/mol (R—H → $R^+ + H^-$)[a]	log k (R—Cl, EtOH, 25°C)[b]
CH_3^+	1306	—
$CH_3—CH_2^+$	1143	—
$CH_3—CH^+—CH_3$	1034	−10.8
$Ar—CH_2^+$	—	−9.4
$(CH_3)_3C^+$	963	−7.1
$Ar—CH^+—CH_3$	963	−6.8
$(CH_3)_3—CH_2—C(CH_3)_2^+$	—	−5.6
$(CH_3)_2C{=}CH—CH_2^+$	940	−4.6
$Ar—C(CH_3)_2^+$	921	−3.4
$CH_3—O—Ar—CH^+—CH_3$	—	−1.7
$(Ar)_3C^+$	—	0.8
$[CH_3—O—Ar]_2—CH^+$	—	1.8

[b] Solvolysis rate constant of the corresponding alkyl chlorides in ethanol (21). Original data from Ref. 23.

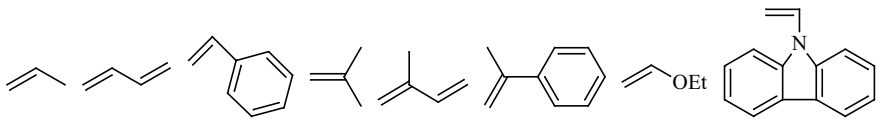
(21). Table 2 lists selected carbenium ions in order of increasing stability, along with their hydride affinity and the solvolysis rate constants of the corresponding alkyl halides.

It can be seen that as the stability of carbenium ions increases as a result of inductive or resonance effects, their reactivity (electrophilicity) decreases.

Nucleophilicity of Monomers. Figure 1 shows cationically polymerizable monomers in order of increasing nucleophilicity. The numbers listed are nucleophilicity parameters (N) developed by Mayr (24,25). N values were derived by measuring the rate of reaction between diarylcarbenium ions and various monomers using UV–vis spectroscopy and are discussed more later in this article.

Optimum combination of carbocation stability and monomer nucleophilicity is necessary for effective polymerization. Indeed, isobutylene positioned in the middle of both the carbocation stability and monomer nucleophilicity scales can be polymerized effectively to yield high molecular weight polymers, while the other monomers listed above mostly yield low molecular weight products by carbocationic polymerization.

Examples of Active Monomers. A vinyl monomer can undergo carbocationic polymerization only if the double bond is the most basic site of the monomer. For example, acrylates and vinyl acetate cannot be polymerized cationically



N: −2.63 −1.15 0.78 1.07 1.12 2.39 3.9 5.02

Fig. 1. Ranking of monomers by nucleophilicity.

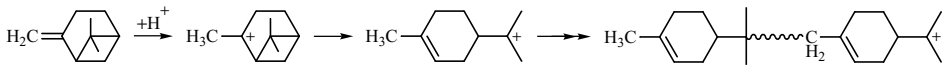


Fig. 2. Release of steric hindrance by isomerization in the carbocationic polymerization of β-pinene.

because the carbonyl oxygen of the ester group is more basic than the vinyl group. If the stability of the chain-carrier carbenium ion forming from a particular monomer is too high or too low, it cannot undergo carbocationic polymerization; *N*-vinyl amines readily react with cationic initiators, but the formation of stable ammonium salts prevents their polymerization. Alkyl vinyl ethers can be polymerized readily, although the oxygen is certainly more basic than the vinyl group. However, in this case protonation of the vinyl group leads to the formation of a carbocation stabilized via charge delocalization. Another example of these n,π-donor monomers is *N*-vinylcarbazole. In these monomers the combination of an unsaturation with an electron-donating heteroatom leads to very easy polymerization (26); the monomers are highly nucleophilic and form very stable carbenium ions (see Table 2 and Fig. 1) As a consequence, their polymerization can be initiated by initiators that would be inefficient with less-reactive monomers. However, the high stability of their carbenium ions restricts their ability to copolymerize with monomers of lower nucleophilicity. Ethylene, propene, or *n*-butenes only give oligomers because of the low stability/high reactivity of the corresponding carbenium ions. Hydride transfer from oligomers prevents the formation of high molecular weight product. For example, the primary cation formed from ethylene will abstract a hydride ion from the secondary carbon of the oligomer.

In addition to carbocation stability and monomer nucleophilicity, steric factors are also important. For example 1,1-diphenylethylene, a very reactive monomer can only be dimerized, because of the formation of a sterically buried carbenium ion (27). Other monomers that cannot be polymerized to high polymers because of steric congestion in the transition state are 2,4,4-trimethyl-1-pentene, 1,2-diphenylethylene (stilbene), 3-methylindene, and 2-methylenenorbornane.

In some monomers, such as β-pinene (Fig. 2) or methylene–norbornene, isomerization of the initially formed carbenium ion helps overcome the steric restriction (27,28):

Monomers containing more than one double bond (conjugated or nonconjugated dienes and trienes) with similar reactivity lead to ill-defined mixtures of cyclized, branched, or cross-linked polymers (27).

Monomers active in carbocationic polymerization have been periodically reviewed over the years (26–30). Isobutylene remains the monomer with optimum combination of nucleophilicity, carbocation stability, and steric factors, yielding high molecular weight elastomers.

Initiating Systems

Carbocationic polymerization can be initiated by a wide variety of chemical and physical methods. Examples are initiation by Brönsted acids, Lewis acids, Lewis

acids in combination with a proton or carbenium ion source, stable carbenium ions, UV or γ-irradiation, photochemical reactions, and the application of a high electric field.

The inverse relationship between stability and reactivity of carbenium ions plays an important role in the initiation step. In order to achieve high initiator efficiency, it is essential to match the stability of the propagating carbenium ion with that of the initiating species. For instance, *primary* and *secondary* alkyl halides were found to have low initiation efficiency in the polymerization of isobutylene coinitiated by $(C_2H_5)_2AlCl$ at $-50^\circ C$, because of the high reactivity and hence short lifetime of the corresponding ions compared with the growing *tertiary* carbocation (31). Better initiation efficiency was achieved using *tert*-butylchloride, because of the positive inductive and hyperconjugative stabilizing effect of the three methyl groups. However, further stabilization of the carbenium ion by aryl groups resulted in decreasing initiation efficiency. Hundred percent initiation efficiency was achieved when 2-chloro-2,4,4-trimethyl pentane was used in conjunction with $TiCl_4$ (32). This can be explained with the effect of *back-strain*. The solvolysis rate of 2-chloro-2,4,4-trimethyl pentane was found to be 21 times higher than that of *tert*-butylchloride, attributed to back-strain, ie, the release of steric strain during rehybridization from sp^3 to sp^2 (33). On the basis of the relative rates of reactions between selected alkyldiphenyl carbenium ions and *tertiary* carbocations with allylsilanes, the 2,4,4,6,6-pentamethyl-2-heptyl cation was a perfect match for a polyisobutylene cation with 33 repeat units (34).

The stability and nucleophilicity of the counteranion (sometimes called "gegenion," based on the German equivalent word) is equally important in the initiation step as well as in the subsequent propagation, chain-transfer, and termination steps. Detailed reviews of various initiating systems are available (15,35–37). The most important initiating systems will be discussed briefly.

Brönsted Acids. The ability of Brönsted acids to initiate carbocationic polymerization is strongly dependent on their acidity (pK_a value), the basicity and nucleophilicity of the counteranion derived from the Brönsted acid, and the stability of the carbenium ion formed from the monomer (37). Highly nucleophilic counteranions will result in the formation of covalent bonds between anion and cation, preventing polymerization. Highly basic counteranions will promote chain transfer by proton elimination. Strong Brönsted acids, such as trifluoromethane sulfonic acid (triflic acid) or perchloric acid, are capable of polymerizing most of the cationically active monomers. The kinetic order of the initiation reaction with respect to the acid is typically higher than one, indicating the involvement of additional acid molecules in the initiation step (38). Weaker Brönsted acids such as hydrogen halides can only polymerize monomers, yielding very stable carbenium ions, such as *N*-vinylcarbazole (39,40). Although the pK_a values of trichloro- or trifluoroacetic acid are higher than those of hydrogen halides, they can readily polymerize monomers such as styrene derivatives or cyclopentadiene (37). The likely reason for this is the participation of a second acid molecule in the ionization step and/or in the stabilization of the counteranion (eq. 3):

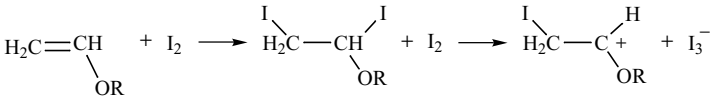
(3)

Lewis Acids. Certain Lewis acids or their mixtures are capable of initiating carbocationic polymerization in the absence of a cation or proton source. This type of initiation is called direct initiation. Hunter and Yohe (13) proposed the formation of zwitterions. The more accepted mechanism is auto-ionization of a Lewis acid dimer, followed by its addition to the monomer (eq. 4):

$$Mt_2X_{2n} \rightleftharpoons MtX^+_{n-1}MtX^-_{n+1} + >C{=}C< \rightarrow [MtX_{n-1}{-}>C{-}C<]^+[MtX_{n+1}]^- \qquad (4)$$

Auto-ionization of dimer Lewis acids was first suggested by Korshak and Lebedev (41). Friedel–Crafts metal halide Lewis acids show various degrees of association in hydrocarbons. Aluminum halides can form dimers and trimers (42), but $TiCl_4$ was shown to be monomeric in CH_2Cl_2 (43). The low temperature polymerization of isobutylene in *n*-heptane initiated by $AlBr_3$ is an example of auto-ionization (44). Other possible mechanisms have been postulated for direct initiation, such as formation of the carbenium ion by the interaction of a halogenated solvent with the Lewis acid, electron transfer from the monomer to the Lewis acid, and allylic hydride transfer; for a summary see Reference 45. Recently, direct initiation of isobutylene polymerization by haloboration of the monomer was demonstrated (46).

Another example of direct initiation is the initiation of vinyl ethers or styrenes by iodine (eq. 5). In this case the initiator is formed *in situ* by the addition of iodine to the double bond (47).



(5)

It has also been suggested that the elimination of HI from the monomer–iodine adduct, followed by hydro-iodization of another monomer, supplies the real initiator (48); this proposal is represented in Fig. 3 for styrene.

Because of these consecutive steps, initiation by iodine is slow. Purposeful addition of HI with I_2 leads to significantly better initiation and, in the case of *t*-butyl vinyl ether, living polymerization (49).

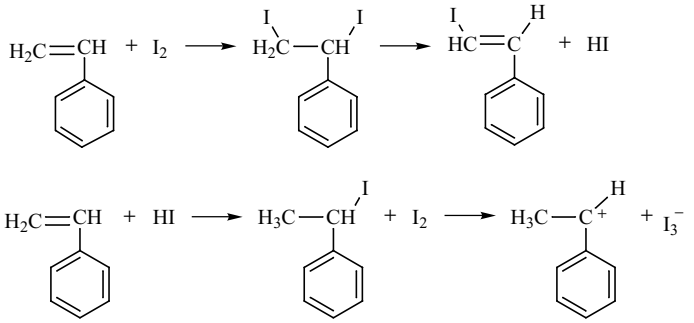


Fig. 3. Initiation of the carbocationic polymerization of styrene by I_2.

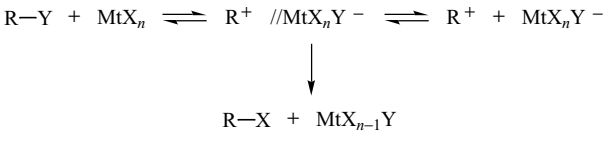
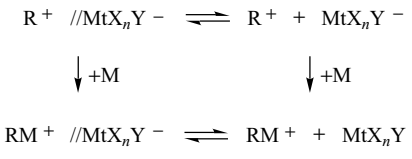
Combination of Lewis acids with proton or cation sources (moisture, Brönsted acids, alkyl or aralkyl halides, esters, ethers, peroxides, or epoxides) results in a significantly more efficient initiating system. The wide variety of cation sources available allows close matching of the stability of the initiating and growing carbenium ions, a prerequisite for high initiator efficiencies and the synthesis of polymers with controlled structure. This type of initiation can be written in a general form as follows:

Ionization



(6)

Initiation



(7)

where $R^+//MtX_{n+1}^-$ and R^+ represent paired and free ions, respectively. The above equilibria are strongly dependent on the nucleophilicity of the Y group, the strength of the Lewis acid, the stability of the carbenium ion, the stability/nucleophilicity of the counteranion, and the type of the polymerization medium used. The strength of a Lewis acid generally increases with increasing atomic number within the same group ($BCl_3 < AlCl_3 < GaCl_3$), with the oxidation state ($SnCl_2 \ll SnCl_4$), and with ligands in the following order: aryl, alkyl, $\ll$ carboxyl, alkoxyl < I < Br < Cl < F (50).

The ion pairs or free ions can either initiate polymerization as shown in the second set of equilibria, or "collapse," with the counteranion forming covalent species as indicated by the downward arrow in the first equilibrium. This latter reaction could lead to counteranion exhange as shown, deactivating the initiating system because of the decreased Lewis acidity of the $MtX_{n-1}Y$ formed (eg, when halide ligands are replaced with alkoxy, hydroxyl, or carboxyl groups) or the formation of inactive R—X species (eg, formation of R—F in case of R—X/BF_3 or SbF_5 systems).

Initiation rate constants (ie, the rate constant of addition of the initiating carbocations to the monomer as shown in the set of equilibria in eq. 7) were determined for a large number of monomers using carbocations derived from the reaction of diaryl and substituted diarylmethyl chlorides with various Lewis acids (21). As indicated by the reaction scheme shown in equation 7, initiation can occur with the participation of solvent-separated ion pairs or free ions. According to Mayr's results, paired and free carbenium ions have identical reactivity and the reaction rates are independent of the nature of the counteranion. Rate constants were found to increase only slightly with increasing solvent polarity

($k_{CH_3NO_2}/k_{CHCl_3} = 4.8$). A careful review of published carbocationic polymerization rate constants (51) also found small differences (one order of magnitude) between $k^{+/-}$ and k^+. The magnitude of and differences between $k^{+/-}$ and k^+ as well as the very high rate constants of carbocationic isobutylene and styrene polymerizations coinitiated by Lewis acids, reported by Mayr (24) and Faust (52), are debated (53).

Initiation by Organometallic Complexes. Considering the industrial importance of isobutylene and the difficulties associated with the processes necessary to produce high molecular weight polyisobutylene-based polymers (eg, low temperature, methyl chloride diluent), it is not surprising that considerable efforts have been made to find catalyst systems capable of polymerizing isobutylene by coordination mechanism. This goal so far has not been achieved. It has repeatedly been shown that isobutylene can easily be polymerized using Ziegler–Natta-type catalysts or cationic metallocene complexes, but the polymerization mechanism remained carbocationic in nature. For a review of these efforts see Reference 54. Nevertheless, these research efforts had some important outcomes. They underscored the importance of counteranions in chain termination and/or transfer processes (55–61) and led to the synthesis of isobutylene/ethylene copolymers by insertion polymerization (62,63).

It has been shown that initiating systems with non- or weakly coordinating counteranions produce higher molecular weight polyisobutylene than do "conventional" initiating systems at the same temperature. The classical example is γ-ray-induced polymerization of isobutylene (see next section), but certain solid-phase initiating systems yielded similarly high molecular weight polyisobutylenes (64). This was attributed to the reduction/elimination of counteranion-assisted chain termination and/or transfer processes. Organometallic or metallocene-based initiating systems with non- or weakly coordinating counteranions such as $B(C_6F_5)_4^-$, $R{-}B(C_6F_5)_3^-$, and $HO{-}B(C_6F_5)_3^-$ (55–61) also led to molecular weights similar to that obtainable by γ-ray or solid-phase–induced isobutylene polymerization (64). It was suggested that these systems polymerize via "counteranion-unencumbered" carbocations.

Essentially alternating isobutylene/ethylene copolymers were prepared using (dimethylsilyl)(tetramethylcyclopentadienyl)(cyclododecylamido)dimethyltitanium activated with tetrakis(pentafluorophenyl)borate, triphenylmethyltetrakis(pentafluorophenyl)borate, or MAO (62,63). Since the reactivities of cations derived from ethylene and isobutylene are vastly different (ethylene yields only oligomers by carbocationic mechanism), this copolymerization most likely proceeds by insertion mechanism. This is further supported by the absence of PIB homopolymer, and the absence of IB–IB diads as demonstrated by ^1H NMR analysis of copolymers with as high as 45 mol% IB content. This indirectly confirms that IB will not homopolymerize to high polymers by insertion mechanism.

Initiation by Electromagnetic Radiation. In this type of initiation electromagnetic radiation such as light, γ-radiation, high energy electrons, or high intensity electric fields induces carbocationic polymerization. Activation by γ-radiation and high energy electrons used to be the most investigated of these methods (65), but recently photoinitiation has generated a lot of interest.

In initiation by γ-radiation, the first step is the formation of radical cations, which then react with the monomer forming the initiating carbocation together

with free radicals:

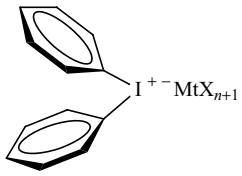
$$M \xrightarrow{\gamma\text{-radiation}} M^{+\cdot} + e^{-}$$

$$M^{+\cdot} + M \longrightarrow M^{+} + M^{\cdot} \qquad (8)$$

The cation is more reactive than the free radical, thereby dominating the initiation reaction. Radical cations can also be formed by high energy electrons, vacuum UV radiation, high intensity electric fields, or anodic oxidation of the monomer. Nuclear chemical initiation involves the use of tritium; this method produced very high molecular weight polyisobutylenes and polystyrenes (65).

Photoinitiation. Photoinitiation has been very popular in recent years. This also proceeds through the formation of radical cations. One example is the polymerization of isobutylene initiated by illuminating a quiescent heptane solution of the monomer containing VCl_4 or $TiCl_4$ (66). Interestingly, charge-transfer interaction between electron-rich donor monomers (*N*-vinylcarbazole, vinyl anthracene, or vinyl ethers) and strong electron acceptors (tetracyanoethylene, *o*- or *p*-chloranil, maleic anhydride) can lead to carbocationic polymerization even in the absence of light (67).

Crivello discovered a fundamentally different type of photoinitiation (68). He showed that onium salts, such as diaryl iodonium (**1**), initiate cationic polymerization of a wide



(**1**)

variety of monomers: olefins, *N*-vinylcarbazole, alkyl vinyl ethers, epoxides, or lactams. The photoexcitation of the salt leads to heterolytic and homolytic cleavage of the carbon–iodine bond. Further reaction of the aryl cations and aryl iodide cation radicals with solvents, monomers, or impurities leads to the formation of the ultimate initiating species, $HMtX_n$. Triarylsulfonium salts are also effective in this type of initiation. These initiators are currently used in applications such as printing inks, stereolithography, holographic recording, and microelectronic photoresists. An alternative initiating system is based on allylic onium salts (eg allylthiophenium, allylpyridinium salts), which in conjunction with radical initiators can lead to thermal or photoinitiated carbocationic polymerization (69).

Polymerization Media

Solvents. The polymerization medium is a very important element in carbocationic polymerization. Although generally the term "polarity" is used to characterize solvents/diluents in carbocationic polymerization, it is ill-defined and

oversimplifies the role of the polymerization medium. In the literature, solvents are almost exclusively characterized by their dielectric constant. The use of dielectric constant to describe solvent effects is based on Born and Bjerrum's simple theoretical approach to ion–solvent interaction, and on the equation derived later by Laidler and Eyring for the dependence of ion–molecule interactions on the reaction medium (70–72). The application of this "hard spheres in continuum" model is limited to large ions, which remain practically unsolvated. As this model completely ignores the structural aspects of solvent interaction and the charge redistribution within and between solute and solvent, it fails to describe most of the experimental findings (73).

The more advanced, dynamic coordination or functional approach considers the solute–solvent or ion–solvent interactions as a result of electron pair donor–acceptor interactions, and inductive and mesomeric effects. According to this theory, the equilibrium between nonionized species and solvent-separated ion pairs is a function of the dynamic electron pair acceptor and donor properties of the solvent, not simply their "static" polarity (73,74). Ionization may be affected by a nucleophilic attack of a donor (D) or by an electrophilic attack of an acceptor (A) directed to the substrate R—Y. The strong donor–acceptor interactions first lead to charge redistribution between and within the molecules (pile-up and spill-over effects), and ultimately to the heterolytic scission of the covalent R—Y bond (eq. 8):

$$D_m \curvearrowright R{-}Y \curvearrowright A_z \rightleftharpoons [RD_m]^+ \quad [YA_z]^- \tag{8}$$

where the arrows (↷)indicate the coordinative interactions between molecules, and subscripts m and z refer to the number of donor and acceptor molecules participating in this reaction. In carbocationic polymerization this simple ionization scheme is further influenced by coordinative interaction between R—Y (initiator) and the Lewis acid MtX_n:

$$D_m \curvearrowright R{-}Y \curvearrowright MtX_n \curvearrowright A_z \rightleftharpoons [RD_m]^+ \quad [Y\,MtX_n\,A_z]^- \tag{9}$$

The ion pairs shown in equation 9 may subsequently undergo electrolytic dissociation leading to the formation of "free" ions. The separation of the ions is primarily dependent on the dielectric constant of the solvent. According to this dynamic view of solvent–solute interactions, in addition to the static dielectric constant, a measure of electron acceptor and electron donor ability is required to interpret the role of solvents in ionic polymerizations. The empirical acceptor and donor numbers (AN and DN), developed by Gutmann, provide a good measure of electron pair accepting and donating ability of solvents. These parameters were used to describe solvent effects in carbocationic polymerization (75). From this approach it is clear that solvents with high electron acceptor and low electron donor properties are required for carbocationic polymerization. Indeed, solvents most frequently used for carbocationic polymerization have low DN and high AN (see Table 3). At the same time, the electron-pair–accepting ability of the solvent should not exceed that of the monomer.

Ionization and dissociation equilibria during initiation and propagation can be shifted by the adjustment of the electron-pair–accepting ability of the solvent

Table 3. Dielectric, Electron Acceptor, and Donor Properties of Solvents[a] Used for Carbocationic Polymerization

Solvent	ε (20°C)	AN	DN
n-Hexane	1.89	0	0
Cyclohexane	2.02	0	0

or solvent mixture used. Solvents with high dielectric constant should be selected for shifting the equilibria in the direction of greater ionization and/or dissociation. This will be discussed in more detail in the Controlled Carbocationic Polymerization section.

The use of liquid and supercritical CO_2 as an alternative, environmentally friendly or "benign" solvent should be mentioned here. De Simone reported the first examples of carbocationic polymerization in liquid and supercritical CO_2. Vinyl ethers and oxetane containing fluorinated side chains yielded low molecular weight products (77). Kennedy reported the carbocationic polymerization of isobutylene in supercritical and liquid CO_2 (78), also yielding low molecular weight polymer. Butyl rubber was reportedly produced in liquid CO_2/hexane mixture (79). However, it seems that the initial excitement surrounding liquid and supercritical CO_2 as alternative solvents for polymerization has disappeared.

Temperature. In terms of temperature, the first consideration in carbocationic polymerization—as in any enthalpy-driven chain reaction—is the ceiling temperature T_c. T_c is the limiting temperature above which the rate of depropagation exceeds the rate of propagation at a given monomer concentration:

$$M_n^+ + M \underset{k_{dp}}{\overset{k_p}{\rightleftharpoons}} M_{n+1}^+ \tag{10}$$

The reaction temperature therefore must be below the T_c of the monomer at that concentration. This typically is not a problem since the synthesis of high molecular weight polymers by carbocationic polymerization often requires low temperatures (−80 to −100°C). The rationale is that chain-breaking reactions that have higher activation energy than propagation may be "frozen out" at low temperatures. Interestingly, Mayr argues that in the carbocationic polymerization of certain monomers (isobutylene, styrene), k_p is in the diffusion-limiting range; thus propagation itself proceeds virtually without activation energy (24). The dielectric constant of solvents increases with decreasing temperature, yielding more charge separation and higher reactivity at lower temperatures. This could result in negative apparent activation energies of propagation observed in some carbocationic polymerizations (80–85).

Kinetics and Mechanisms of Carbocationic Polymerizations

The elementary reactions in carbocationic polymerization are initiation, propagation, termination, and chain transfer. The formation of a high molecular weight polymeric product requires that the rate of propagation R_p be much higher than the rates of chain-breaking reactions

$$\mathrm{DP}_n = R_p \Big/ \left(\sum R_i + \sum R_{tr} \right) \tag{11}$$

where DP_n stands for the number-average degree of polymerization, and R_i and R_p stand for the rates of initiation and propagation. In addition, the rate of initiation R_i must be equal to or higher than the rate of termination during the entire process, or initiation must be completed in the early stages of the process and the rate of irreversible termination must be zero or very small. If low molecular weight oligomeric products are required, the chain-breaking processes should be fast relative to propagation (26).

The kinetics and mechanism of carbocationic polymerization are difficult to study, owing to the high reactivity of the carbocations. Monomer consumption can be monitored by dilatometry, gravimetric sampling, or on-line techniques such as UV–vis (86) or FTIR monitoring (87,88). Very fast reactions can be followed by stop-flow techniques (89). Adiabatic calorimetry has been used extensively, although admittedly this technique is not kinetically rigorous. In the case of very fast reactions (eg, the carbocationic polymerization of isobutylene and styrene under certain conditions), it may be physically impossible to remove the polymerization heat fast enough to maintain isothermal conditions in a laboratory batch reactor, thus kinetic investigations in these systems must be viewed with caution. This chapter will discuss general aspects of the kinetics and mechanisms of carbocationic polymerizations.

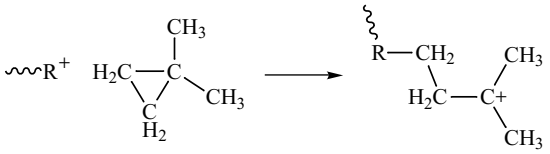
Initiation. Mechanistic and kinetic aspects of the initiation step in carbocationic polymerizations have been discussed under Initiating Systems. It should be emphasized here that the overall rate of initiation is usually influenced by a series of consecutive and competitive reactions such as those shown in equations 6 and 7. The rate of initiation, ie, the rate of addition of the initiating carbocations to the monomer must be clearly differentiated from the overall rate. Measuring the initiator consumption under polymerization conditions is often very difficult, especially when very low initiator concentration is used to obtain high molecular weight polymers. In addition, the rate constant of initiation can only be deduced from initiator consumption data when the exact mechanism of the initiation and the active-center concentration is known independently. More often than not, these are debated. The so-called diffusion clock method employs competitive experiments: between the reaction of the monomer with *in situ* generated carbocations, and the reaction of these carbocations with a reference nucleophile reacting with a known rate constant (90). Using this method, $k_i = 6 \times 10^8$ $\mathrm{dm^3/mol/s}$ was obtained in isobutylene oligomerization initiated with 2-chloro-2,4,4-trimethyl pentane/$TiCl_4$ (91). This value is in excellent agreement with that

calculated from the linear free energy relationship introduced by Mayr (92),

$$\log k = s(N + E) \tag{12}$$

where N is the nucleophilicity parameter and $\boldsymbol{s}$ is the slope of the log k vs E (electrophilicity) plot. $E(An_2CH^+)$ was set 0 and $\boldsymbol{s}$(2-methyl-1-pentene) was set 1.0 and N corresponds to the intercept of the correlation line with the abscissa (log $k = 0$). Detailed discussion of this novel method is not possible here, but this approach could serve as a foundation to design effective initiators, especially for controlled carbocationic polymerization.

Propagation. Cationic polymerizations with carbenium ion chain carriers are almost exclusively limited to vinyl monomers; notable exceptions include the polymerization of strained rings such as 1,1-dimethylcyclopropane (93), shown in equation 13.



(13)

Carbocationic polymerization of vinyl monomers proceeds by repeated electrophilic addition of the monomer to the growing carbenium ion, following Markovnikov's rule, which leads to the formation of regular head-to-tail polymers (Fig. 4).

In general, carbocationic polymerizations are highly exothermic ($-\Delta H$ = 80−120 kJ/mol), owing to the formation of a C—C single bond from a π-bond. Similar to most other chain-growth polymerizations, carbocationic polymerizations are enthalpy driven; the entropy loss of about −120 J/mol/K related to the loss of freedom in mobility of the polymer chain must be counterbalanced by the enthalpy change $\Delta G = \Delta H - T\Delta S \leq 0$.

The open transition state—sp^2-hybridized carbocations—has low stereoselectivity, thus mostly atactic polymers are formed (94). At the same time, reportedly the very first synthetic stereoregular polymer was an isotactic poly(isobutyl vinyl ether) prepared by carbocationic polymerization initiated with $BF_3/O(C_2H_5)_2$ at −78°C (95). Other examples of stereoregular crystalline polymers synthesized by homogeneous and heterogeneous carbocationic polymerization are polymers of vinyl ether derivatives, and 2,5-dimethyl styrene or α-methylstyrene (95–100). Stereoregular vinyl ether polymers have also been synthesized using

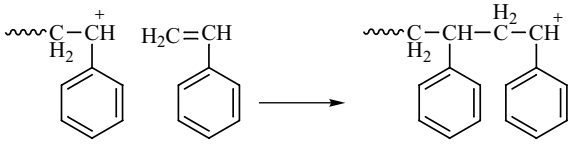


Fig. 4. Head-to-tail addition in carbocationic polymerization.

Table 4. Propagation Rate Constant of Various Monomers in Bulk Polymerization

Monomer	Temperature, °C	k_p dm^3/mol/s	Reference
Isobutylene	0	1.5×10^8	110
Isoprene	0	2×10^3	111
Cyclopentadiene	−78	5.8×10^8	112

Isobutyl vinyl ether	0	4×10^4	118

solid-supported catalysts, metal oxides, and modified Ziegler–Natta catalysts (101–107). Several mechanisms have been suggested to account for the formation of stereoregular polymers in carbocationic polymerization. One suggested mechanism involves an sp^3-hybridized transition state due to coordination with the counteranion (108). Others suggested ring structures forming at the end of the growing chain (98,109). Controlling the microstructure of polymers synthesized by carbocationic polymerization may be one of the most challenging areas of future research (94).

In general, carbocationic homopolymerization is characterized by low activation enthalpy, low concentration of active species (10^{-8}–10^{-5} mol/dm^3), high propagation rate constants (10^3–10^8 dm^3/mol/sec), and short lifetime of the carbenium ion (94). Table 4 lists propagation rate constants determined in bulk carbocationic polymerization of various monomers initiated by γ-radiation, electron pulse, or field ionization techniques.

High propagation rates and low concentration of active species renders kinetic measurements/calculations difficult and leaves plenty of room for debate concerning the mechanism and kinetics of carbocationic polymerizations. Kinetic evaluation is further hampered by the coexistence of covalent species with ion pairs and "free" ions as originally suggested by Winstein (119) for reactions involving cationic intermediates:

$$\underset{\text{covalent}}{\text{R—X}} \rightleftharpoons \underset{\text{ion pairs}}{\text{R}^+\text{X}^-} \rightleftharpoons \underset{\text{contact or tight}}{\text{R}^+\text{//X}^-} \rightleftharpoons \underset{\text{solvent-separated or loose ion pairs}}{\text{R}^+ + \text{X}^+} \quad \underset{\text{free ions}}{}$$

Ions termed "free" may be involved in electrostatic interactions with the counteranion, or in similar interactions limiting their "freedom," but in relative terms these effects are long-range interactions. Similar to anionic polymerization, both free carbocations and ion pairs are capable of polymerization. However, the difference between their reactivity is significantly smaller than in the case of anionic polymerization. As mentioned before, it was recently suggested that in fact there is no difference between $k_p{}^+$ and $k_p{}^{+/-}$ (21) – this is currently debated and needs

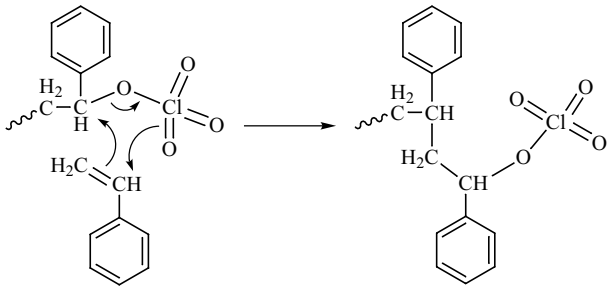

Fig. 5. "Pseudocationic" mechanism proposed for the polymerization of styrene initiated by perchloric acid.

close examination. In anionic polymerization, the k_p of the free ions can be three orders of magnitude higher than that of the tight ion pairs (120). In contrast, the $k_p^+/k_p^{+/-}$ ratio in perchloric acid–initiated polymerization of styrene was measured to be 20 at −80°C, and only 8 at −60°C (121). This difference between the $k_p^+/k_p^{+/-}$ ratios in cationic and anionic polymerization is related to the bulkiness of the counteranion in cationic polymerization. The interionic distance of contact or tight ion pairs in carbocationic polymerization is closer to that of the solvent-separated ion pairs of anionic polymerization (122). Determination of k_p^+ and $k_p^{+/-}$ in cationic systems is very difficult because of the extremely low concentration of the active species. By spectroscopic techniques (NMR, UV) only the most stable carbenium ions can be detected under polymerization conditions.

The existence of a dynamic equilibrium between dormant (covalent) and active (ionic) species in controlled carbocationic polymerizations had been debated for years. It has been argued that under certain conditions, polarized covalent species can directly react with monomer; examples are the "pseudocationic" mechanism proposed for the polymerization of styrene initiated by perchloric acid (123,124) (Fig. 5) or the "two-component group transfer polymerization" proposed for the polymerization of isobutylene initiated by the dicumylacetate/BCl_3 system (125) (Fig. 6). Recent results and theoretical considerations support the now generally accepted view that the true active species are ions, and the dormant species serve as a reservoir from which the propagating ion pairs are formed (126–131). The existence of a dynamic equilibrium between dormant and active species and the ability to suppress the formation of free ions made possible the synthesis of polymers with controlled molecular architecture via carbocationic polymerization.

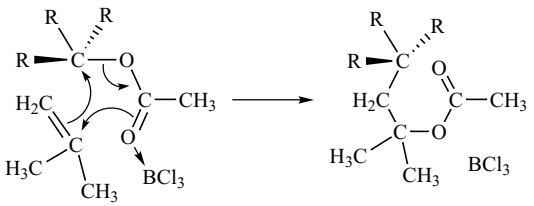

Fig. 6. "Two-component group transfer polymerization" proposed for the polymerization of isobutylene initiated by the dicumylacetate/BCl_3 system.

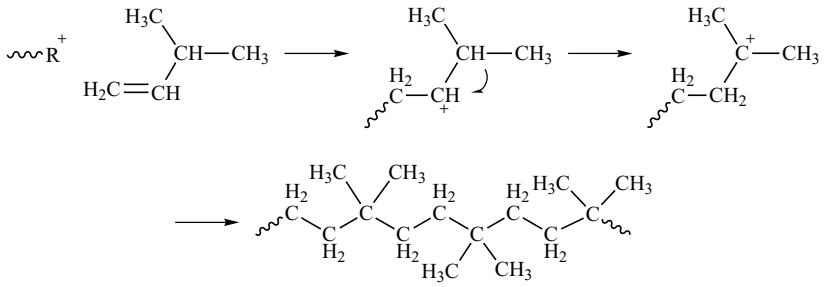

Fig. 7. Hydride shift in the polymerization of 3-methyl-1-butene, yielding crystalline stereoregular polymer.

This equilibrium can be compared to the equilibrium between active propagating chains and ion-pair agglomerates in anionic polymerization—such aggregates have not been found in carbocationic polymerizations.

Carbenium ions are inherently reactive species and can readily undergo side reactions. These side reactions can be part of the propagation step or lead to the termination of the polymeric and/or kinetic chain. For example, the propagating chain end may rearrange to an energetically more favored structure prior to the next propagation step, as in the isomerization polymerization of β-pinene (see Fig. 2). The isomerization step may involve hydride or methide shifts. An interesting example of 1,2-hydride shift is the carbocationic polymerization of 3-methyl-1-butene. Below -100°C, crystalline polymer containing 1,3 repeat units, shown in Figure 7, was obtained (132). Above this temperature, amorphous polymer containing both regular 1,2 and 1,3 repeat units formed (132). Isomerization may also lead to chain-breaking; this will be discussed in the next section.

Conjugated dienes can be readily polymerized by carbocationic techniques. In fact, cyclopentadiene is considered to be one of the more reactive carbocationic monomers (126). However, the carbocationic polymerization of conjugated dienes leads to polymers with rather unattractive physical properties owing to side reactions such as cross-linking and cyclization. Products obtained range from low molecular weight oils through tacky resins to cross-linked and brittle materials, depending on the monomer and the polymerization conditions. Loss of unsaturation has been frequently observed and it was mainly attributed to cyclization (133). For example, trans-1,4 enchainment of butadiene or isoprene can readily undergo carbocationic cyclization (134,135), as shown in Figure 8. Not surprisingly, no reports were found on the controlled carbocationic polymerization of dienes. One exception is the synthesis of polyisobutylene–polyisoprene multiblock copolymers and their use for the preparation of UV-cured transparent flexible coatings by living carbocationic polymerization using sequential monomer addition (136). Nevertheless, carbocationic copolymerizations involving dienes are very important—the industrial butyl process is a copolymerization of isobutylene with a small amount of isoprene (3,4).

Chain-Breaking Reactions. When discussing chain-breaking reactions, kinetic chain and polymer chain should be distinguished. Chain transfer involves polymer chain termination, but the kinetic chain remains unbroken. True termination breaks both the polymer and kinetic chains. The so-called reversible

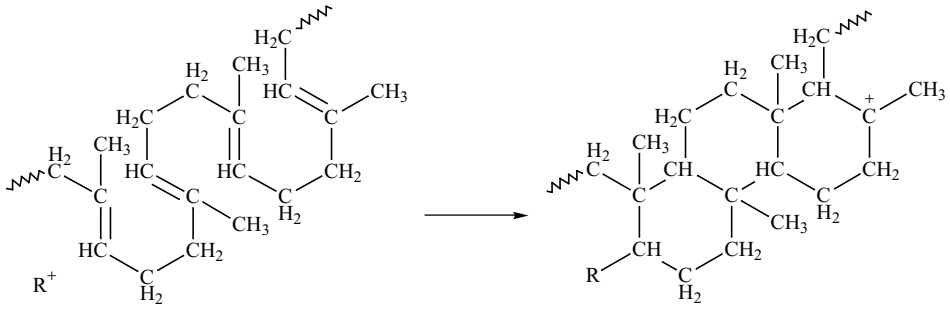

Fig. 8. Cyclization in the carbocationic polymerization of isoprene.

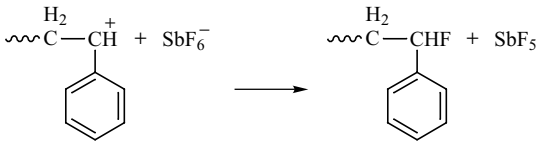
termination slows down the formation of the polymer without permanently terminating the kinetic chain (137). This is the key to controlled carbocationic polymerizations, which will be discussed separately in the next section. Interestingly, strong nucleophiles or electron-pair–donor compounds, which are considered to be strong terminating agents, were found to mediate controlled carbocationic polymerizations (138,139). The mechanism of the role of these additives remains unclear (140).

Termination. Termination will break the kinetic chain, yielding inactive species. Termination reactions have been classified as follows (141):

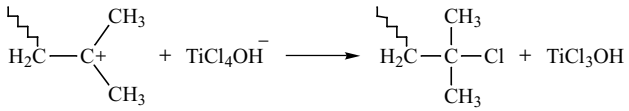
(1) Spontaneous charge neutralization
(2) Degradative transfer
(3) Reaction with nucleophiles

Spontaneous charge neutralization involves transfer of a negatively charged group from the counteranion to the carbenium ion and might lead to the formation of inactive covalent chain ends (142). An example is shown in equation 14



(14)

Other examples are alkylation of the chain end in alkylaluminum halide coinitiated isobutylene polymerization (143). This type of counteranion exchange can also result in the formation of a Lewis acid that is too weak to ionize the chain end, as depicted in equation 15.



(15)

The rate of termination decreases with increasing acid strength of the counteranion (144). Counteranion stabilization by solvation will slow down termination by charge neutralization (145). Reversible termination by charge neutralization can lead to controlled carbocationic polymerization (see under Controlled Carbocationic Polymerization).

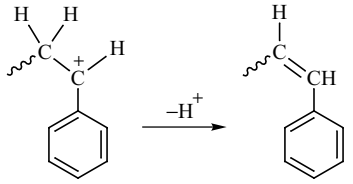
Degradative chain transfer involves the formation of carbocations too stable to propagate and will be discussed under Chain Transfer.

Nucleophilic compounds may react directly with the carbenium ion to yield an unreactive compound, or with the Lewis acid reducing its acid character. If the weakened Lewis acid is not able to activate the chain end, termination occurs. Strong bases may also abstract and trap β-hydrogens, leading to termination instead of chain transfer (146). It should be mentioned here that controlled isobutylene and styrene polymerizations yielding narrow MWD are mediated by strong nucleophiles in small concentrations. The mechanism of this effect remains controversial (147). Alcohols are regarded as strong terminating agents; but in concentrations not exceeding the concentration of the Lewis acid, they can act as initiators (148) and accelerate carbocationic polymerization (149). In addition, added alcohols and other nucleophiles can lead to a molecular weight increase. For example, the highest molecular weight of polyisobutylene achievable in the presence of ethanol was obtained at 1:1 ethanol/$AlCl_3$ concentration ratio (149). Termination may also be caused by complexation of the catalyst or coinitiator with the monomer, or occlusion of the active growing species in the precipitated polymer (150).

It was proposed that the apparent negative overall activation energies observed in carbocationic polymerizations (80–82) are the consequence of relatively high activation energies of kinetic termination reactions, compared to the activation energies of initiation and propagation (144). Kennedy and Trivedi (151) found that in the carbocationic polymerization of isobutylene the activation enthalpy difference of molecular weight is lowest under conditions when the molecular weight is controlled by termination, and highest where the molecular weight is controlled by chain transfer to monomer. Termination control occurs at low temperature, indicating that for this monomer the activation energy for transfer is higher than the activation energy for termination. In the controlled carbocationic polymerization of isobutylene initiated by $TiCl_4$-based systems, negative apparent activation energies were found, while in the case of BCl_3 slight positive values were obtained (152). This seems to contradict the reasoning that the negative apparent activation is due to exothermic ionization, ie, in systems coinitiated with strong Lewis acids the activation enthalpy of ionization is higher than that of propagation (153). BCl_3 is a stronger Lewis acid than $TiCl_4$ (154); but forms a less stable counteranion, leading to rapid termination (155).

Chain Transfer. Chain transfer is the most important chain-breaking reaction in carbocationic polymerization. It can be considered as a subcase of termination, when this latter is accompanied by reinitiation. In chain-transfer reactions the active center is "transferred" to a new site: to unreacted monomer or initiator, the preformed polymer, or the solvent. This can happen by β-proton elimination from the growing chain, or Friedel–Crafts alkylation of aromatic rings. β-Hydrogen atoms of the propagating carbenium ions are quite acidic owing to the delocalization of the positive charge. In isobutylene, vinyl ether, and styrene

polymerization β-hydrogens may carry as much as 7–12% of the positive charge (156). Loss of proton leads to the formation of an end group with an unsaturation, shown in equation 16 for styrene polymerization.



(16)

Spontaneous proton elimination is unlikely, but β-protons can be abstracted by basic compounds (solvent, counteranion, additives) in the system, including the monomer in competition with propagation (94). Mayr and co-workers (91) found that in the case of 1,2-dialkyl-substituted ethylenes, electrophilic attack on the double bond and hydride abstraction have comparable activation energies, so these systems are riddled with chain transfer, while in the case of 1,1-dialkyl and higher alkylated ethylenes the attack of carbocations at the C=C double bond is preferred.

Electrophilic aromatic substitution (Friedel–Crafts alkylation) catalyzed by acids can occur inter- or intramolecularly. Intramolecular alkylation leads to indanyl ring formation in styrene polymerization, as shown in Figure 9a. Intermolecular reactions involving two or more polymer chains lead to branching—see Figure 9b. Isomerization by hydride or alkyl transfer (157,158) leading to more stable carbenium ions can also be considered as a form of chain transfer. The protons or new active sites forming in chain-transfer reactions can initiate new chains. While the overall concentration of active sites does not change with chain transfer, polymerization kinetics may be affected, depending on the relative reactivity and concentration of the new active sites. For instance, when the new active site is very unreactive, reinitiation will be slow or may not happen. These

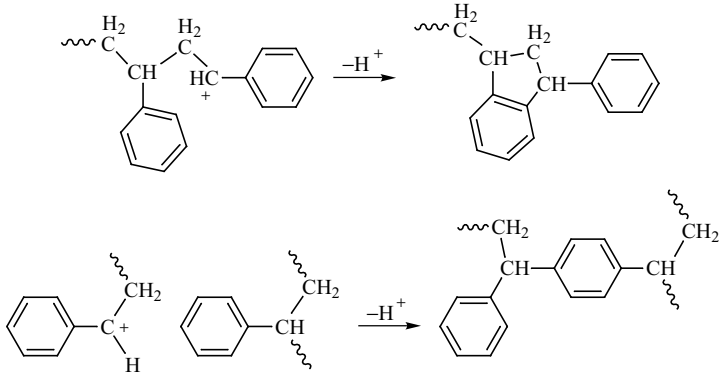


Fig. 9. (**a**) Chain transfer by intramolecular alkylation in styrene polymerization. (**b**) Chain transfer by intermolecular alkylation leading to branching in styrene polymerization.

processes are termed *degradative chain transfer* or *degradative termination*. In all cases, polymer chains are terminated, which leads to the decrease of the average molecular weight or degree of polymerization, and broadening of the molecular weight distribution. In the case of isobutylene polymerization initiated by $AlCl_3$-based systems, competition between transfer to monomer and solvent manifested itself in the so-called inversion temperature (159). At this temperature, the degree of polymerization was found to be independent of monomer concentration. In contrast, below or above this temperature, monomer concentration had an effect on the degree of polymerization; at low temperatures DP_n decreased with increasing [M], while above the inversion temperature an opposite trend was observed. It was rationalized that below the inversion temperature, the rate of transfer to monomer exceeds the rate of transfer to solvent, so increasing monomer concentration leads to a lower degree of polymerization.

Kennedy and Squires investigated termination and transfer processes in isobutylene polymerization initiated by $AlCl_3$ at $-78^\circ C$ in *n*-pentane (160) and devised a scale of termination or "poison" and transfer coefficients. Most compounds acted as both "poisons" and chain-transfer agents. In industry, chain-transfer agents are often deliberately used to control polymerization processes (161).

Kinetic evaluation of various transfer and termination processes uses an adopted form of the Mayo equation derived from the general formula

$$1/\mathrm{DP}_n = \left(\sum R_\mathrm{t} + \sum R_\mathrm{tr}\right) \Big/ R_\mathrm{p} \tag{17}$$

where DP_n stands for the number-average degree of polymerization, and R_t, R_{tr}, and R_p stand for the rates of termination, transfer, and propagation, respectively. Equation 17 defines the instantaneous DP_n, and has frequently been used to evaluate transfer and termination coefficients (in case of transfer to monomer and spontaneous termination, $C_{tr} = k_{tr}/k_p$; $C_t = k_t/k_p$) at low conversion. At high conversion, the integrated form of the equation has to be used, and depending on the complexity of the reaction, analysis may become quite complicated (162).

Copolymerization

In carbocationic homopolymerization, propagation rate constants are relatively high for all monomers, in spite of major differences in nucleophilicity (24,25). The reason for this lies in the fact that the stability of the carbenium ion formed from the corresponding monomer increases with the nucleophilicity of the monomer. This can be illustrated by comparing isobutylene, a weakly nucleophilic monomer producing a very reactive carbocation, and *N*-vinylcarbazole, a very nucleophilic monomer producing a very stable carbocation. Very high propagation rate constants were reported for both monomers (6×10^8 dm^3/mol/s for isobutylene and 1×10^7 dm^3/mol/s for *N*-vinylcarbazole at $20^\circ C$), based on model studies (25,91). However, in case of copolymerization, differences between the stability of carbenium ions and the nucleophilicity of the monomers hinder the formation of random copolymers. For example, the rate constant of addition of isobutylene monomer (1)

to a growing polymer chain with a carbocation derived from *N*-vinylcarbazole (2) would be $k_{21} = 2 \times 10^3$ dm^3/mol/s, calculated using the reference scale and method (see eq. 12) developed by Mayr (92,163). This cross-propagation constant is four to five orders of magnitude lower than the corresponding homopolymerization rate constants, rendering the copolymerization of the two monomers impossible. This is why there is no example of copolymer formation between monomers having significantly different nucleophilicity such as the isobutylene/*N*-vinylcarbazole or isobutylene/alkyl vinyl ether pairs.

The simplest copolymerization model is the terminal model, according to which the reactivity of the growing chain is determined by the last (terminal) monomer unit. In this case two reactivity ratios (r_1 and r_2) are sufficient to describe the instantaneous composition of a binary copolymer:

$$\frac{d[M_1]}{d[M_2]} = \frac{[M_1]}{[M_2]} \frac{r_1[M_1] + [M_2]}{r_2[M_2] + [M_1]} \tag{18}$$

where $r_1 = k_{11}/k_{12}$, $r_2 = k_{22}/k_{21}$ and k_{11} and k_{22} are the propagation rate constants of the homopolymerization and k_{12} and k_{21} of the cross-propagation steps. Reference 164 provides a good summary of the methods available for the determination of reactivity ratios as well as an excellent collection and assessment of 643 cationic copolymerization systems. On the basis of this extensive data set, it appears that the terminal model describes most of the carbocationic copolymerization systems investigated. There are few exceptions where the effect of the penultimate unit has to be considered; one example is the copolymerization of indene with 3-methylindene (165).

Table 5 lists some selected copolymerization reactivity ratios. It is clear from the data that the monomer yielding the more stable carbocation dominates the copolymerization. Considering the importance of carbocation stability, it is not surprising that in some instances reasonable correlation was obtained between $\log(1/r_1)$ and Hammett's σ or Brown's σ^+ values of the substituents of the second monomer. Examples are the copolymerization of α-methylstyrene with substituted styrenes (169) or styrene with substituted 1- and 2-phenylbutadienes (172). It is thus expected that ideal copolymerization ($r_1 = r_2 = 1$) in carbocationic systems is unlikely—the only reported ideal system is the copolymerization of

Table 5. Effect of Carbenium Ion Stability on Copolymerization Reactivity Ratios

isobutylene with β-pinene at −130/−120°C in ethyl chloride initiated with "H_2O"/EtAlCl combination (173). Large differences in reactivity ratios render the synthesis of polymers with uniform composition at the microscopic level difficult in carbocationic systems. This was circumvented by the so-called forced ideal copolymerization method. The comonomer mixture was fed into the reaction mixture at rates not exceeding the overall copolymerization rate. Under these conditions, α-methylstyrene/styrene or isobutylene/styrene copolymers with composition identical to the composition of the comonomer mixture were obtained (174,175).

Reaction conditions such as temperature and nature of the solvent and coinitiator can have a profound effect on the reactivity ratios (164). There are several examples in carbocationic copolymerization indicating that for $r > 1$, the reactivity ratio decreases with decreasing temperatures. Table 6 lists some selected data.

This trend is opposite to that observed in radical polymerization, in which reactivity ratios approach unity with increasing temperature; this was attributed to similar entropies of activation (177). Apparently, entropy effects cannot be neglected in carbocationic copolymerization (178).

It has been observed that in carbocationic copolymerization the molecular weight of the resulting copolymer is always lower than that of the individual homopolymers prepared under identical conditions (179). This was explained by the high k_{tr}/k_p ratio of the favored cross-propagation step (reaction of the most reactive chain end with the monomer giving the most stable carbenium ion), compared to the respective homopolymerization k_{tr}/k_p ratios (173).

Copolymerizations involving dienes such as the copolymerization of isobutylene with isoprene are important from the industrial point of view (3,4). Isoprene acts as a strong chain-transfer and terminating agent in the carbocationic polymerization of isobutylene (161), and at high concentration it leads to a crosslinked, insoluble product (180). Because of the limited composition range available for analysis, determination of the reactivity ratios in this system is rather difficult. Reactivity ratios published for the isobutylene/isoprene system are listed in Table 7.

Interestingly, controlled copolymerization was achieved in the isobutylene/2,4-dimethyl pentadiene-1,3 system, explained by the internal strain exerted by the methyl groups of the 2,4-dimethyl pentadiene-1,3 incorporated into the copolymer, and the presence of electron-pair donors forming *in situ* from the initiators (190).

Table 7. Copolymerization Reactivity Ratios of the Isobutylene (1)/Isoprene (2) System

Copolymerization studies provide a very useful tool to assess the effect of polymerization medium, coinitiator, counteranion, and additives on polymerization kinetics. However, the interpretation of results is difficult because of the interrelationships between these parameters. For examples and details see Reference 164.

Controlled Carbocationic Polymerization

Traditionally, carbocationic polymerizations have been considered uncontrollable, owing to the high reactivity of the chain carriers. Similar to radical polymerization (qv), they were treated as random processes, governed by the statistical probability of side reactions such as chain transfer and termination, relative to propagation. Real control in polymerization processes was first achieved in anionic systems (see ANIONIC POLYMERIZATION). The term "living polymerization" was introduced by Szwarc (191), although controlled polymerizations without chain-breaking processes had been observed experimentally much earlier (18,192). Similar to the history of living anionic polymerization, living conditions in carbocationic systems had been achieved experimentally as early as 1974 (193,194), before systematic research had begun to be carried out into living carbocationic conditions. The breakthrough was the successful production of high molecular weight and nearly uniform polymers with controlled carbocationic polymerization, by Kennedy's group (19). Carbocationic polymerizations reportedly exhibiting living characteristics have been called "pseudocationic," "quasiliving," then "truly living." All of these provide control over the molecular weight of the polymer, defined as the ratio of converted monomer to initiator:

$$M_n(\text{g/mol}) = \Delta M(\text{g})/I(\text{mol}) \tag{19}$$

where ΔM is the amount of monomer converted into polymer, and I is the molar amount of initiator. According to Szwarc's classical definition, in living polymerizations M_n increases linearly with conversion, and in the case of instantaneous initiation, the polymers produced in a batch reactor will have a polydispersity

described by the Poisson distribution:

$$M_w/M_n = DP_w/DP_n = 1 + 1/DP_n \tag{20}$$

where M_n and DP_n, and M_w and DP_w are the number- and weight-average MW and DP, respectively. Under controlled conditions, nearly uniform polymers can be produced at sufficiently high MWs. Since the active centers do not enter into side reactions, their concentration remains constant and the monomer consumption rate will obey a linear first-order dependency. The early experimental examples of living carbocationic polymerizations were riddled with broad molecular weight distribution, and thus were not acknowledged to be controlled polymerizations. In fact, the achievement of carbocationic living polymerization was considered to be impossible, because of the inherently high reactivity of carbocations, which tend to enter into irreversible termination and chain-transfer reactions via β-proton expulsion (142). It was then recognized that the key to controlled carbocationic polymerization was the promotion of an equilibrium between dormant and active propagating chain ends and thereby providing sufficient time for synthetic manipulations. Importance of reversible termination in order to obtain control over the polymerization was first outlined by the original "quasiliving" concept (137) (eq. 21)

$$\begin{array}{ccc} P_n & \rightleftharpoons & P_n^* \\ \text{inactive} & & \text{active} \end{array}$$

$$P_n^* + M \Longrightarrow P_{n+1^*} \tag{21}$$

Remarkably, the same key concept applies in living radical polymerizations. It has been suggested that the term "temporary deactivation" is more appropriate than "reversible termination," to emphasize control (20).

In controlled carbocationic polymerizations the initiating systems are usually Lewis acids in conjunction with a carbocation source such as an alkyl, allyl, or aralkyl halide, ester, ether, or epoxide (18). The Lewis acid coinitiators reactivate or reinitiate the inactive polymer chain to produce the active growing carbocations. The existence of the dynamic equilibrium between dormant covalent and active ionic species in carbocationic polymerizations is now generally accepted. Ligand exchange and dynamic NMR studies supported the evidence of the involvement of ionic species even in polymerizations that were thought to proceed by a "pseudocationic" or "insertion" mechanism (18). The temporary deactivation also allows for MWD control. This concept was introduced by Puskas, and co-workers (195) and is valid for all polymerization systems with temporary deactivation. According to this treatment, MWD is governed by the run length l, which is defined as the average number of monomer units incorporated into the polymer chain during a productive ionization period:

$$DP_w/DP_n = 1 + l/DP_n \tag{22}$$

This general equation reduces to the Poisson distribution when $l = 1$. The magnitude of l will define the narrowness of the MWD. At sufficiently high MW, $l = 25$ still yields $DP_w/DP_n < 1.1$. The MWD criteria for living polymerizations

can then be defined as follows:

$$DP_w - DP_n = l = \text{constant} \tag{23}$$

Since the Poisson distribution is a subcase of the general definition of MWD for $l = 1$, Poisson or very narrow MWD does not seem to be necessary in the definition of living polymerization. Living (controlled) carbocationic polymerization can be viewed as a process where the most probable distribution of monomer incorporation during an active ionization period is superimposed on a Poisson distribution of the repeating events of ionization periods. Depending on the lifetime of the active cationic species, the run length l can be $l \gg 1$, resulting in broader MWD. For instance, at $l = 50$, and at $DP_n = 50$, the MWD will be $M_w/M_n = 2$. With increasing conversion, the MWD will get progressively narrower.

The temporary deactivation process seems to protect the active species from side reactions long enough for synthetic manipulation. It is understood that chain-breaking processes might be identified in polymerizations, which are considered living today (20). The real power of controlled polymerizations in general, and controlled carbocationic polymerizations in particular, is their ability to control the polymerization process in order to design and build new polymeric structures. Since certain monomers can only be polymerized via a carbocationic mechanism, the significance of controlled carbocationic polymerization is evident. Polyisobutylene is a very important example—it has a fully saturated backbone with excellent stability and is thus a prime candidate for building model structures (Fig. 10) for systematic structure–property studies. Structure–property relationship studies are considered to be of critical importance. Hopefully, controlled carbocationic polymerization will make an important contribution in this area (196).

From an industrial point of view, controlled carbocationic polymerization has serious drawbacks. Except for block copolymer production, narrow MWD is a disadvantage, since broad distribution or polydispersity improves the physical properties and/or processability of commodity polymers (3). In controlled carbocationic polymerization, one initiator molecule produces only one polymer chain. Since the coinitiator, usually a Lewis acid such as $TiCl_4$ and BCl_3, is used in at least a tenfold excess over the initiator, the *catalyst efficiency*, a term used in industry to express the activity of the initiating system in terms of grams of polymer per grams of Lewis acid, is very poor in comparison with commercial processes (a few hundred vs several thousands). However, the ability of controlled carbocationic polymerization to produce new polymeric structures in a controlled manner may override these and other concerns. Anionic living polymerizations have long been commercialized, producing branched polybutadienes for high impact polystyrene production, styrene–isoprene–butadiene terpolymers and various functionalized

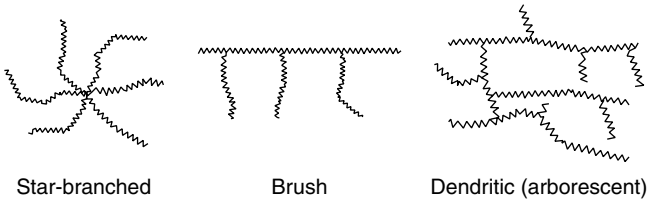

Fig. 10. Model polymer structures for structure–property relationship studies.

rubbers for tire production, and styrenic block copolymers (thermoplastic elastomers or recyclable rubbers). Under laboratory conditions, anionic polymerization is considered a difficult experimental technique (197). The relative newcomer, controlled carbocationic polymerization, is similarly viewed as a difficult-to-master method in the laboratory. In addition, it often is perceived to be inferior to living anionic polymerization. Ironically, large-scale commercial ionic polymerizations require less stringent conditions than laboratory procedures, because of the much smaller surface area-to-volume ratios. Commercial examples of controlled carbocationic polymerizations include poly(vinyl ethers) used in liquid-crystal technology (198), polystyrene–polyisobutylene–polystyrene block copolymers and functionalized polyisobutylenes, which have been test-marketed recently by Kuraray and Kaneka Co. of Japan (19). Several reviews provide detailed description of controlled carbocationic polymerization (18–20,199–201). It should be mentioned here that controlled polymerization of *p*-hydroxy styrene was also achieved in aquoeus media (202). This may prove to be a revolutionary breakthrough in controlled carbocationic polymerization.

Industrial Carbocationic Processes

There are relatively few surveys available on industrial carbocationic polymerization (1,2,203,204). In this section, the most important commercial polymers produced by carbocationic polymerization will be discussed.

Polyisobutylene. The polymerization of isobutylene by strong acids at room temperature was first reported in 1873 (12). The reaction yielded a "sticky liquid" (mainly dimers and trimers). In 1929, Otto at I.G. Farbenindustrie discovered that high molecular weight polymer could be prepared by cooling the reaction mixture with dry ice (205). Presently low, medium, and high molecular weight polyisobutylenes are produced commercially, with significantly more volume for the former two (see BUTYL RUBBER). The unique properties of polyisobutylene are low permeability, good thermal and oxidative stability, ozone resistance, chemical resistance, high hysteresis (mechanical dampening), and tack. The BASF process to produce high molecular weight polyisobutylene was developed on the basis of Otto's pioneering work. In the original process a mixture of ethylene and isobutylene was sprayed on a moving belt along with a solution of BF_3 in ethylene (206); the reaction heat was removed by the evaporation of ethylene. The original ESSO process was developed by Standard Oil of New Jersey (now known as ExxonMobil) and used methyl chloride and $AlCl_3$ to produce high molecular weight polyisobutylenes (1). These processes most likely have been modified, although the fundamentals may be the same. The molecular weight of polyisobutylenes produced by these processes ranges from few hundred thousand to few hundred million. High molecular weight PIB is used as binder in sealing tapes. It is also used to modify asphalt to improve weathering and low temperature properties as well as toughness and abrasion resistance of the mix. Polyethylene and polypropylene modified with polyisobutylene display improved barrier, flex, and stress-cracking properties. Polyisobutylene compounded into natural rubber (NR) or styrene–butadiene rubber (SBR) improves aging, cut growth, flex, and stress-cracking properties. Low (few hundred) and medium (few thousand) molecular weight polyisobutylenes are produced at higher temperatures to reduce molecular weight. BASF uses a batch

process, polymerizing isobutylene in isobutane with the CH_3OH/BF_3 initiating system. Medium molecular weight is achieved by using higher purity isobutylene and lower temperatures (−25 to −40°C, compared to −10°C for low molecular weight polymer). Infineum (a joint venture between ExxonMobil and Shell) uses a continuous process in hexane, initiating the reaction with a suspension of $AlCl_3$ in hexane and regulating molecular weight with the process temperature (1,2). Low and medium molecular weight polyisobutylenes are used as viscosity modifiers, fuel and lubricating oil additives, tack improvers in adhesive formulations, and primary binders in caulking and sealing compounds. Blending them into waxes used for paper coating reduces the penetration of the wax into the paper, and improves moisture resistance. In lubrication the main advantage of polyisobutylene is that it decomposes without residues. In the mid 1990s Shell started to commercialize an amine-functionalized low molecular weight PIB as fuel/oil additive. Emulsification of sludge particles by functionalized PIB is an important aspect of this application.

Isobutylene-Based Elastomers. Butyl elastomer is a random copolymer of isobutylene and a small amount (0.7–2.2 mol%) of isoprene. The dominant form of the incorporated isoprene is 1,4-trans. This copolymer was the first example of low unsaturation elastomers. The starting point of the development of butyl rubber was a collaborative research effort carried out by Otto (I.G. Farbenindustrie) and Thomas (Standard Oil Development Co.) in 1933–1935. Thomas suggested the use of the $AlCl_3$/ethyl chloride polymerization system, instead of BF_3/ethylene. The goal was the production of elastomers that could be cured to yield cross-linked polyisobutylene-based rubbers. First butadiene was copolymerized with isobutylene to provide the necessary double bonds for curing sites. Later butadiene was replaced by isoprene because of its higher reactivity as a comonomer, and ethyl chloride was replaced by methyl chloride as diluent because of its higher stability (207,208). Currently the $AlCl_3$-coinitiated copolymerization of isobutylene with isoprene in methyl chloride is the basic technology for the production of butyl elastomers. The first butyl plants using this technology, located in Baytown and Baton Rouge, Louisiana, and Sarnia, Canada, were constructed as part of the Synthetic Rubber Procurement program during World War II. It is interesting to note that this was the second most important program next to the Manhattan Project. Although numerous incremental process improvements were reported since World War II, production of butyl rubber is still based on the original technology (3,4). Butyl rubber is produced in a continuous slurry process at low temperatures (−90 to −100°C) using methyl chloride as diluent and a solution of $AlCl_3$ dissolved in methyl chloride as the initiating system. Small amounts of water or HCl as cationogen sources are used to promote initiation. The reactor resembles a heat exchanger, with the slurry circulating inside the pipes that are cooled by boiling ethylene in the jacket. The product is separated from the diluent and unreacted monomers by coagulating it in hot water. More detailed information can be found in References 3,4, and 203. A solution process called the "Russian process" was developed in the former Soviet Union (209). Polymerization is carried out in isopentane at around −90°C, initiated with water/alkylaluminum chloride(s).

The most important physical properties of butyl rubber are essentially the same as those of poly-isobutylene; low permeability, good chemical and thermal stability due to the low unsaturation content, and high damping. Butyl elastomers

are cross-linked (cured) with sulphur to yield cross-linked rubbers. The most important application of butyl rubbers is tire inner tubes. Other applications include tank liners, vibration dampeners, protective clothing, tire curing bladders, railway pads, wire and cable coating, belting, hoses, and chewing gum base.

Halogenation of the isoprene enchainments in butyl elastomers yields halobutyl elastomers. Reaction of the isoprene units with elementary bromine or chlorine leads to the formation of allylic halide units along the chain—a substitution as opposed to addition across the double bonds. This leads to much faster curing, which permitted the development of tubeless tires, as adhesion of halobutyl to the rest of the tire could be achieved. Halobutyls are primarily used by the tire industry to form the inner liner of the "tubeless" tire. Other applications are similar to that of butyl. Chlorobutyl is also used in pharmaceutical stoppers.

Over the years additional polyisobutylene-based elastomers were developed and commercialized. Butyl partially cross-linked with divinyl benzene with a high gel content has high resistance to cold flow (creep), improved green strength (green strength refers to the ability of a yet uncured tire to keep its shape, which relates to the 300% modulus of the raw elastomer) and elasticity, and good recovery after deformation. These properties are especially important to prevent the sag and cold flow of caulking compounds, sealants, and adhesives (210). Unlike regular butyl, it can be cured by peroxides via the unreacted pendent vinyl groups of the divinylbenzene units. Star-branched butyls are produced by the addition of polystyrene–polybutadiene block copolymer to the reactor (211). A fraction of the growing chains grafts onto the block copolymer; the star-branched portion of the final product is about 10–15 wt%, with the rest of the chains being linear. This combination leads to improved green strength, coupled with enhanced processability.

It should be noted here that commercial high molecular weight isobutylene-based elastomers are characterized by the so-called Mooney viscosity, not by molecular weight or molecular-weight distribution. This standardized low shear viscosity measurement is used to grade all synthetic and natural elastomers and rubbers (212). Interestingly, this highly prevalent method in industry is rarely ever mentioned in textbooks or encyclopedias.

Polybutenes. Polybutenes are ill-defined copolymers of isobutylene with butenes (203). They are low molecular weight (M_n = 300–2000 g/mol), clear oily or viscous liquids, with 85–95% isobutylene content. They are produced by the carbocationic polymerization of C_4 refinery stream, using $AlCl_3$ or in some cases BF_3 as coinitiator, and impurities or purposefully added HCl or H_2O as initiators. The C_4 stream is a product of crude oil distillation, containing a mixture of C_4 hydrocarbons such as isobutylene, *cis*- and *trans*-2-butenes, 1-butene, and butane. Molecular weight is controlled by temperature (-10 to $+30^\circ$C) and initiator concentration. Intensive chain-transfer reactions result in exo and endo terminal double bonds. The exo double bond is more reactive and is preferred for further functionalization with, for example, maleic anhydride or phosphorous pentasulfide. The most important use of polybutenes is in the production of lubricating oil additives. Functionalized polybutanes improve wear resistance because of their ability to emulsify small metal particles.

Hydrocarbon Resins. Hydrocarbon resins are ill-defined, low molecular weight products of the carbocationic polymerization of aliphatic or aromatic mono and diolefins, ranging from viscous liquids to high melting point thermoplastics.

These resins are generally grouped into three main categories depending on the source of the raw material (1,203,204). The indene–coumarone resins are coal tar based. Aliphatic, aromatic, and dicyclopentadiene resins are made from distillate fractions of cracked petroleum. Polyterpene resins are produced using monomers isolated from turpentine oil (α- or β-pinene) or etheral oils of lemon, orange, mandarin, or caraway (*d,l*-limonene or dipentene and *d*-limonene).

Commercial production of the coal tar based indene–coumarone (benzofuran) resins started in the early 1900s, using sulphuric acid as initiator in the temperature range of -10 to $+50^{\circ}$C. The subsequent use of $AlCl_3$ and BF_3-based initiating systems resulted in a lighter-colored product. Polymerization is carried out in bulk or naphtha. The primary use of indene–coumarone resins is in adhesives, coatings, inks, and additives for the rubber industry. Starting from the mid-1900s, petroleum-based aromatic resins gradually replaced indene–coumarone resins. Petroleum-based resins consist of aliphatic, aromatic, and dicyclopentadiene-based polymers. Aliphatic resins are produced from C_5 feed stream, a mixture of isoprene, cyclopentadiene, and piperylene (1,2-pentadiene) along with various monoolefins. Cyclodienes lead to gel formation and they are removed before polymerization. Aromatic resins are produced from C_8–C_{10} petroleum distillate fraction (styrene, α–methylstyrene, vinyl toluenes, indene, methylindene, dicyclopentadiene, cyclopentadiene/methyl–cyclopentadiene dimer, and methyl–cyclopentadiene dimer). Petroleum-based resins are produced by carbocationic or thermally induced free-radical polymerization. In the case of dicyclopentadiene resins, free-radical polymerization is the dominant mode of synthesis. The most frequently used Lewis acid carbocationic initiators are $AlCl_3$ and BF_3. $AlCl_3$ leads to higher molecular weight products, but the loss of unsaturation via cyclization is more pronounced. Frequently the Lewis acid is complexed with ethers, phenols, or aldehydes to reduce reactivity, increase solubility, and alter product properties (molecular weight, molecular weight distribution, and chain structure).

Petroleum resins have excellent tack properties, so they are used to improve tack in hot-melt and pressure-sensitive adhesive formulations, floor coverings, sealants, caulks, mastics, and rubber compounds. They are also used in printing inks as binder and protective coatings, and in paints and varnishes to improve gloss and water resistance.

Water-white resins are a recent commercial development. They are made by the homo- or copolymerization of pure vinyl aromatic monomers such as styrene or alpha-methylstyrene. Polymerization is carried out in aromatic solvents using BF_3 or complexes of BF_3 at 15–40°C. A controlled amount of water is added in order to improve initiation efficiency. The molecular weight of the product is low as a result of the extensive chain transfer processes at this temperature. Water-white resins are used where color stability is important.

The production and application of polyterpene resins are very similar to those of petroleum-based resins (1,203,204).

Poly(vinyl ethers). Homopolymers of vinyl ethers are produced via carbocationic polymerization. Polymerization is carried out either in bulk or solution using BF_3 or its complexes, $AlCl_3$, or $SnCl_4$. Commercially important poly(vinyl ethers) are made of methyl, ethyl, isobutyl, and octadecyl vinyl ethers [$T_g = -34$, -42, -19, and 50°C (1)]. Depending on their glass-transition temperature and molecular weight, commercial poly(vinyl ethers) are viscous oils, tacky resins, or

elastomeric solids. Poly(vinyl ethers) are added to pressure-sensitive adhesives in order to increase tack. They are also used as viscosity improvers in lubricants or as plasticizers in elastomers and coatings.

CELLULAR MATERIALS

Introduction

Cellular polymers, otherwise known as foamed polymers or polymeric foams, or expanded plastics, have been important to human life since primitive people began to use wood, a cellular form of the polymer cellulose. Cellulose (qv) is the most abundant of all naturally occurring organic compounds, comprising approximately one-third of all vegetable matter in the world (1). Its name is derived from the Latin word *cellula*, meaning very small cell or room, and most of the polymer does indeed exist in cellular form, as in wood, straws, seed husks, etc. The high strength-to-weight ratio of wood, good insulating properties of cork and balsa, and cushioning properties of cork and straw have contributed both to the incentive to develop and to the background knowledge necessary for development of the broad range of cellular synthetic polymers in use.

The first cellular synthetic plastic was an unwanted cellular phenol–formaldehyde resin produced by early workers in this field. The elimination of cell formation in these resins, as given by Baekeland in his 1909 heat and pressure patent (2), is generally considered the birth of the plastics industry. The first commercial cellular polymer was sponge rubber, introduced between 1910 and 1920 (3). Most plastic polymers can be foamed. However, a relative few have commercial significance, such as polystyrene, polyolefins, poly(vinyl chloride), polyimides, and polyurethanes.

Cellular polymers have been commercially accepted in a wide variety of applications since the 1940s (4–13). The total usage of foamed plastics in the United States has risen from 1.4×10^6 t in 1982 to 2.2×10^6 t in 1992 and has been projected to rise to about 3.1×10^6 t in 2002 (14).

Classification

A cellular plastic has been defined as a plastic of which the apparent density is decreased substantially by the presence of numerous cells dispersed throughout its mass (15). In this article the terms *cellular plastic*, *foamed plastic*, *expanded plastic*, and *plastic foam* are used interchangeably to denote all two-phase gas–solid systems in which the solid is continuous and composed of a synthetic or natural polymer.

The gas phase in a cellular polymer is distributed in voids, pores, or pockets called cells. If these cells are interconnected in such a manner that gas can pass from one to another, the material is termed *open-celled*. If the cells are discrete and the gas phase of each is independent of that of the other cells, the material is termed *closed-celled*.

The nomenclature of cellular polymers is not standardized; classifications have been made according to the properties of the base polymer (16), the methods of manufacture, the cellular structure, or some combination of these. The most comprehensive classification of cellular plastics, proposed in 1958 (17), has not been adopted and is not consistent with some of the common names for the more important commercial products.

One ASTM test procedure has suggested (18) that foamed plastics be classified as either rigid or flexible, a flexible foam being one that does not rupture when a $20 \times 2.5 \times 2.5$-cm piece is wrapped around a 2.5-cm mandrel at a uniform rate of 1 lap per 5 s at 15–25°C. Rigid foams are those that do rupture under this test. This classification is used in this article.

In the case of cellular rubber, the ASTM uses several classifications based on the method of manufacture (19,20). These terms are used here. Cellular rubber is a general term covering all cellular materials that have an elastomer as the polymer phase. Sponge rubber and expanded rubber are cellular rubbers produced by expanding bulk rubber stocks and are open-celled and closed-celled, respectively. Latex foam rubber, also a cellular rubber, is produced by frothing a rubber latex or liquid rubber, gelling the frothed latex, and then vulcanizing it in the expanded state.

The term structural foam has been defined as flexible or rigid foams produced at greater than about 320 kg/m^3 density having holes in a foamed core rather than a typical lower density structure of pentagonal dodecahedron type (21). Integral foams are also structural foams having a foamed core that gradually decreases in void content to solid skins (22).

Theory of the Expansion Process

Foamed plastics can be prepared by a variety of methods. The most important process, by far, consists of expanding a fluid polymer phase to a low density cellular state and then preserving this state. This is the foaming or expanding process. Other methods of producing the cellular state include leaching out solid or liquid materials that have been dispersed in a polymer, sintering small particles, and dispersing small cellular particles in a polymer. The latter processes are relatively straightforward processing techniques but are of minor importance.

The expansion process consists of three steps: creating small discontinuities or cells in a fluid or plastic phase; causing these cells to grow to a desired volume; and stabilizing this cellular structure by physical or chemical means.

Initiation and Growth of Cells. The initiation or nucleation of cells is the formation of cells of such size that they are capable of growth under the given conditions of foam expansion. The growth of a hole or cell in a fluid medium at equilibrium is controlled by the pressure difference (ΔP) between the inside and the outside of the cell, the interfacial surface tension (γ), and the radius r of the cell:

$$\Delta P = 2\frac{\gamma}{r} \tag{1}$$

The pressure outside the cell is the pressure imposed on the fluid surface by its surroundings. The pressure inside the cell is the pressure generated by the blowing agent dispersed or dissolved in the fluid. If blowing pressures are low, the radii of initiating cells must be large. The hole that acts as an initiating site can be filled with either a gas or a solid that breaks the fluid surface and thus enables the blowing agent to surround it (23–26).

During the time of cell growth in a foam, a number of properties of the system change greatly. Cell growth can, therefore, be treated only qualitatively. The following considerations are of primary importance: (*1*) the fluid viscosity is changing considerably, influencing both the cell growth rate and the flow of polymer to intersections from cell walls, leading to collapse; (*2*) the pressure of the blowing agent decreases, falling off less rapidly than an inverse volume relationship because new blowing agent diffuses into the cells as the pressure falls off according to equation 1; (*3*) the rate of growth of the cell depends on the viscoelastic nature of the polymer phase, the blowing agent pressure, the external pressure on the foam, and the permeation rate of blowing agent through the polymer phase; and (*4*) the pressure in a cell of small radius r_2 is greater than that in a cell of larger radius r_1. There is thus a tendency to equalize these pressures either by breaking the wall separating the cells or by diffusion of the blowing agent from the small to the larger cells. The pressure difference ΔP between cells of radii r_1 and r_2 is shown in equation 2.

$$\Delta P = 2\gamma\left(\frac{1}{r_2} - \frac{1}{r_1}\right) \tag{2}$$

Stabilization of the Cellular State. The increase in surface area corresponding to the formation of many cells in the plastic phase is accompanied by an increase in the free energy of the system; hence the foamed state is inherently unstable. Methods of stabilizing this foamed state can be classified as chemical, eg, the polymerization of a fluid resin into a three-dimensional thermoset polymer, or physical, eg, the cooling of an expanded thermoplastic polymer to a temperature below its second-order transition temperature or its crystalline melting point to prevent polymer flow.

Chemical Stabilization. The chemistry of the system determines both the rate at which the polymer phase is formed and the rate at which it changes from a

viscous fluid to a dimensionally stable cross-linked polymer phase. It also governs the rate at which the blowing agent is activated, whether it is due to temperature rise or to insolubilization in the liquid phase.

The type and amount of blowing agent governs the amount of gas generated, the rate of generation, the pressure that can be developed to expand the polymer phase, and the amount of gas lost from the system relative to the amount retained in the cells.

Additives to the foaming system (cell growth-control agents) can greatly influence nucleation of foam cells, either through their effect on the surface tension of the system, or by acting as nucleating sites from which cells can grow. They can influence the mechanical stability of the final solid foam structure considerably by changing the physical properties of the plastic phase and by creating discontinuities in the plastic phase that allow the blowing agent to diffuse from the cells to the surroundings. Environmental factors such as temperature and pressure also influence the behavior of thermoset foaming systems.

Physical Stabilization. In physically stabilized foaming systems the factors are essentially the same as for chemically stabilized systems, but for somewhat different reasons. Chemical composition of the polymer phase determines the temperature at which foam must be produced, the type of blowing agent required, and the cooling rate of the foam necessary for dimensional stabilization. Blowing agent composition and concentration controls the rate at which gas is released, the amount of gas released, the pressure generated by the gas, escape or retention of gas from the foam cells for a given polymer, and heat absorption or release owing to blowing agent activation.

Additives have the same effect on thermoplastic foaming processes as on thermoset foaming processes. Environmental conditions are important in this case because of the necessity of removing heat from the foamed structure in order to stabilize it. The dimensions and size of the foamed structure are important for the same reason.

Manufacturing Processes

Cellular plastics and polymers have been prepared by a wide variety of processes involving many methods of cell initiation, growth, and stabilization. The most convenient method of classifying these methods appears to be based on the cell growth and stabilization processes. According to equation 1, the growth of the cell depends on the pressure difference between the inside of the cell and the surrounding medium. Such pressure differences may be generated by lowering the external pressure (decompression) or by increasing the internal pressure in the cells (pressure generation). Other methods of generating the cellular structure are by dispersing gas (or solid) in the fluid state and stabilizing this cellular state, or by sintering polymer particles in a structure that contains a gas phase.

Foamable compositions in which the pressure within the cells is increased relative to that of the surroundings have generally been called expandable formulations. Both chemical and physical processes are used to stabilize plastic foams from expandable formulations. There is no single name for the group of cellular plastics produced by the decompression processes. The various operations used to

make cellular plastics by this principle are extrusion, injection molding, and compression molding. Either physical or chemical methods may be used to stabilize products of the decompression process.

A summary of the methods for commercially producing cellular polymers is presented in Table 1. This table includes only those methods thought to be commercially significant and is not inclusive of all methods known to produce cellular products from polymers.

Expandable Formulations.

Physical Stabilization Process. Cellular polystyrene [9003-53-6], the outstanding example, poly(vinyl chloride) [9002-86-2], copolymers of styrene and acrylonitrile (SAN copolymers [9003-54-7]), and polyethylene [9002-88-4] can be manufactured by this process.

Polystyrene. There are two types of expandable polystyrene processes: expandable polystyrene for molded articles and expandable polystyrene for loose-fill packing materials.

Expandable polystyrene for molded articles is available in a range of particle sizes from 0.2 to 3.0 mm, and in shapes varying from round beads to ground chunks of polymer. These particles are prepared either by heating polymer particles in the presence of a blowing agent and allowing the blowing agent to penetrate the particle (27) or by polymerizing the styrene monomer in the presence of blowing agent (28) so that the blowing agent is entrapped in the polymerized bead. Typical blowing agents used are the various isomeric pentanes and hexanes, and mixtures of these materials (29).

The fabrication of these expandable particles into a finished cellular-plastic article is generally carried out in two steps (30–33). First the particles are

expanded by means of steam, hot water, or hot air into low density replicas of the original material, called prefoamed or preexpanded beads. After proper aging, enough of these prefoamed beads are placed in a mold to just fill it; the filled mold is then exposed to steam. This second expansion of the beads causes them to flow into the spaces between beads and fuse together, forming an integral molded piece. Stabilization of the cellular structure is accomplished by cooling the molded article while it is still in the mold. The density of the cellular article can be adjusted by varying the density of the prefoamed particles.

Expandable polystyrene for loose-fill packaging materials is available in various sizes and shapes varying from round disks to S-shaped strands. These particles can be prepared either by deforming the polystyrene under heat and impregnating the resin with a blowing agent in an aqueous suspension (34) or by the extrusion method with various die orifice shapes (35). The expansion of these particles into a product is usually carried out in two or three expansions by means of steam with at least one day of aging in air after each expansion (36). Stabilization is accomplished by cooling the polymer phase below its glass-transition temperature during the expansion process.

Poly(vinyl chloride). Cellular poly(vinyl chloride) can be produced from several expandable formulations as well as by decompression techniques. Rigid or flexible products can be made depending on the amount and type of plasticizer used (37).

Polyethylene. Because polyethylene has a sharp melting point and its viscosity decreases rapidly over a narrow temperature range above the melting point, it is difficult to produce a low density polyethylene foam with nitrogen or chemical blowing agents because the foam collapses before it can be stabilized. This problem can be eliminated by cross-linking the resin before it is foamed, which slows the viscosity decrease above the melting point and allows the foam to be cooled without collapse of cell structure.

Cross-linking of polyethylene can be accomplished either chemically or by high energy radiation. Radiation cross-linking is usually accomplished by X-rays (38) or electrons (39,40). Chemical cross-linking of polyethylene is accomplished with dicumyl peroxide (41), di-*tert*-butyl peroxide (42), or other peroxides. Radiation cross-linking (43) is preferred for thin foams, and chemical cross-linking for the thicker foams.

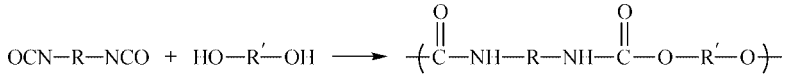
Expandable polyethylene foam sheet can be made by a four-step process: (*1*) mixing of polyethylene, chemical blowing agent, and cross-linking agent (in the case of chemical cross-linking) at low or medium temperature [examples of decomposable blowing agents used for expandable polyethylene are azodicarbonamide, 4,4′-oxybis(benzenesulfonyl hydrazide), and dinitrosopentamethylene-tetramine] (29); (*2*) shaping at low or medium temperature; (*3*) chemical cross-linking at medium temperature or radiation cross-linking; and (*4*) heating and expanding at high temperature. Expansion of the cross-linked, expandable polyethylene sheet can be accomplished either by floating the sheet on the surface of a molten salt bath at 200–250°C and heating from above with IR heaters or by circulating hot air, or by expanding in the mold with high pressure steam.

Liquid Chemical Stabilization Processes. This method is more versatile and thus has been used successfully for more materials than the physical

stabilization process. Chemical stabilization is more adaptable for condensation polymers than for vinyl polymers because of the fast yet controllable curing reactions and the absence of atmospheric inhibition.

Polyurethane Foams. The most important commercial example of the chemical stabilization process is the production of polyurethane foams, which began in the mid-1950s. Depending on the choice of starting materials and processing techniques, it is possible to generate a wide variety of foams for such diverse uses as wood replacement in decorative cabinetwork or all-foam mattresses; to insulate portable coolers or for ultrasoft furniture cushions; as a sprayed-on insulating foam for pipes; or molded seat cushions for cars. Excellent summaries of the chemistry and technology of these polymers have been published (7,44,45) (see POLYURETHANES).

The urethane-forming ingredients in a polyurethane foam formulation are the isocyanate (**1**) and the polyol (**2**) as shown in equation 3.



(3)

Another useful reaction is the reaction of water with isocyanate to generate CO_2 and urea groups that modify the polymeric structure. This vigorous reaction is also a prime source of exothermic heat to drive equation 3 to completion.

$$OCN{-}R{-}NCO + 2\ HOH \rightarrow NH_2{-}R{-}NH_2 + 2\ CO_2 \quad (4)$$

Further reaction of the active hydrogens on nitrogen in the urethane groups (**3**) can occur with additional isocyanate (**1**) at higher temperatures to cause formation of allophanate structures. The active hydrogens in urea groups can also react with additional isocyanate to form disubstituted ureas, which can still further react with isocyanate to form biurets (7).

The urethane-forming reaction (eq. 3) is known as the gelling reaction since it is the primary means of polymerizing the starting materials into long-chain polymer networks. The CO_2-forming reaction is known as the blowing reaction because of its contribution of CO_2 as an *in situ* blowing agent. The amount of blowing reaction is controlled by the water level of the formulation. The gelling and blowing reaction rates are determined by the catalyst choices. Typically, tertiary amines are used to foster the blowing reaction and organometallics are used to promote gellation although both contribute to both reactions. Urethane reactions often use a combination of catalysts to achieve the desired reactivity balance. Additional blowing may be obtained through the use of an auxiliary blowing agent such as methylene chloride, CFC-11, or HCFC-141b. On the basis of the Montreal protocol on climate change, the previous blowing agents are being phased out and the current blowing agents in use or under consideration include hydrocarbons such as isopentane, HFC-245fa, HFC-365mfc, and CO_2 (46).

Silicone surfactants are used to assist in controlling cell size and uniformity through reduced surface tension and, in some cases, to assist in the solubilization

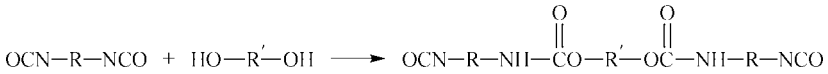
of the various reactants (47,48). Recently, non-silicone lower cost surfactants for rigid polyurethane foams have been developed by Dow with the tradename Vorasurf and are based on copolymers of butylene oxide and ethylene oxide (49).

The foam process may be described as follows: the materials are metered in appropriate quantities into a mixing chamber and thoroughly mixed. Tiny air (or gas) bubbles are generated in the liquid to effect nucleation. After a short induction period the blowing agents begin to diffuse into and enlarge the tiny nucleation bubbles, causing a creamy appearance. The period from mixing to this point is known as the cream time, which is normally about 6–15 s for flexible foams. As more blowing agents are generated the foaming mixture continues to expand and becomes more viscous as the polymerization occurs in the liquid phase. The total number of bubbles remains constant during the foam rise. The reduction of surface tension by the surfactant stabilizes the tender foaming mixture to prevent coalescing of the bubbles.

About 100–200 s after mixing, the blowing reaction ceases but the gelling reaction continues, strengthening the struts of the foam, cells. The thin cell walls of a flexible foam then burst (blow-off) and the gases are released throughout the foam which has polymerized sufficiently to prevent collapse. The period from mixing to full rise (with blow-off in flexible foams) is known as rise time. The polymerization continues until the foam has gelled, usually 20–120 s after rise time. Loss of surface tackiness is known as tack free time. Rigid foams display a gel time prior to full rise. Additional cure time is necessary to achieve full polymer physical properties. This is a time–temperature characteristic that may vary from hours to days in duration.

The physical properties of the final foam can be varied broadly by controlling the degree of cross-linking in the final polymer as well as the structure of R and R′ in (**1**) and (**2**). The average molecular weight between cross-links is generally 400–700 for rigid polyurethane foams, 700–2500 for semirigid foams, and 2500–20000 for flexible foams (7). The structure of the diisocyanate is limited to some six or eight commercially available compounds (7). For this reason the variation between cross-links is controlled primarily by the polyol (**2**); it is common to use the equivalent weight (the ratio of molecular weight to hydroxyl units) as a criterion for the expected foam rigidity. The equivalent weights of polyhydroxy resins used for rigid foams are less than 300, for semirigids between 70 and 2000, and for flexibles between 500–3000.

Two general types of processes have been developed for producing polyurethanes on a commercial scale: the one-shot process and the prepolymer process. In the one-shot process, which is most widely used today, all primary streams (some of which may be premixed) are delivered to the foam mixing head at once for mixing and dispensing. In the prepolymer process the polyhydroxy component first reacts with isocyanate as shown in equation 5 to form an isocyanate-terminated molecule, which can ultimately react with water to liberate CO_2 for foaming and obtain chain linkage via the urea groups. Use of excess isocyanate results in the formulation of an isocyanate/polyol adduct, which contains a quantity of free isocyanate as well as a structured prepolymer. This adduct may be used as the source of isocyanate in a conventional system using additional polyol, catalysts, blowing agents, etc.



(5)

The foam-forming ingredients are carefully metered to obtain the proper ratio of reactants, thoroughly mixed by either mechanical or impingement means, then applied as a liquid, a spray, or a froth with subsequent expansion and curing.

Polyisocyanurates. The isocyanurate ring formed by the trimerization of isocyanates is known to possess high thermal and flammability resistance as well as low smoke generation during burning (50–53). Cross-linking via the high functionality of the isocyanurates produces a foam with inherent friability. Modification of the isocyanurate system with a longer chain structure such as that of polyether polyols or terephthalate-based polyester polyols increases the abrasion resistance of the resultant foam. Aluminum foil-faced sheets of modified isocyanurate-based foams are now widely used as an insulation material. The manufacturing process for isocyanurate foams is similar to that for rigid polyurethane foams (see ISOCYANATE-DERIVED POLYMERS).

Polyphenols. Another increasingly important example of the chemical stabilization process is the production of phenolic foams (54–57) by cross-linking polyphenols (resoles and novolacs) (see PHENOLIC RESINS). The principal features of phenolic foams are low flammability, solvent resistance, and excellent dimensional stability over a wide temperature range (54), so that they are good thermal-insulating materials.

Most phenolic foams are produced from resoles and acid catalyst; suitable water-soluble acid catalysts are mineral acids (such as hydrochloric acid or sulfuric acid) and aromatic sulfonic acids (58). Phenolic foams can be produced from novolacs but with more difficulty than from resoles (54). Novolacs are thermoplastic and require a source of methylene group to permit cure. This is usually supplied by hexamethylenetetramine (59).

A typical phenolic foam system consists of liquid phenolic resin, blowing agent, catalyst, surface-active agent, and modifiers. Various formulations and composite systems (60–62) can be used to improve one or more properties of the foam in specific applications, such as insulation properties (58,63–66), flammability (67–69), and open cell (70–73) quality.

Several manufacturing processes can be used to produce phenolic foams (54, 74): continuous production of free-rising foam for slabs and slab stock similar to that for polyurethane foam (65,75); foam-in-place batch process (56,76); sandwich paneling (58,77,78); and spraying (65,79).

Other Materials. Foams from epoxy resins (54,55,80,81), silicone resins (26,55,82,83), and polyimides (84,85) can also be formed by a chemical stabilization process. In certain applications such as aircraft, ships, and railway, specific properties such as high temperature performance and low smoke generation are demanded. As such foam attributed like high temperature resistance while maintaining strength in all directions, inherent fire resistance and chemical resistance are required. For many advanced structural composites, ROHACELL (trademark of Rohm, GmbH, Darmstadt, Germany) closed-cell rigid structural foam produced from polymethacrylimide (PMI) by cured foam molding process serves as core

material (85). Its chemistry allows the material to have self-extinguishing characteristics and service conditions at room temperature as well as in high temperature and high pressure.

Decompression Expansion Processes.

Physical Stabilization Process. Cellular polystyrene, cellulose acetate, polyolefins, and poly(vinyl chloride) can be manufactured by this process.

Polystyrene. The extrusion process for producing cellular polystyrene and copolymers of styrene is probably the oldest method utilizing physical stabilization in a decompression expansion process (86). A solution of blowing agent in molten polymer is formed in an extruder under pressure. This solution is forced out through an orifice onto a moving belt at ambient temperature and pressure. The blowing agent then vaporizes and causes the polymer to expand. The polymer simultaneously expands and cools under such conditions that it develops enough strength to maintain dimensional stability at the time corresponding to optimum expansion. The stabilization is due to cooling of the polymer phase to a temperature below its glass-transition temperature by the vaporization of the blowing agent, gas expansion, and heat loss to the environment. Polystyrene foams produced by the decompression process are commercially offered in the density range of 23–53 kg/m^3 (1.4–3.3 lb/ft^3) as well as at higher densities (87).

The extrusion of expandable polystyrene beads or pellets containing pentane blowing agent was originally used to produce low density foam sheet (88,89). The current method is to extrude polystyrene foam in a single-screw tandem line or twin-screw extruder and produce foam sheet by addition of pentane or fluorocarbon blowing agents into the extruder (90,91). For sheet thicknesses of less than 500 μm (20 mil), the blown-bubble method is normally used. This method involves blowing a tube from a round or annular die, collapsing the bubble, and then slitting the edges to obtain two flat sheets. For greater sheet thicknesses the sheet is pulled over a sizing mandrel and slit to obtain a flat sheet. Cooling of the expanded material by the external air is necessary to stabilize the foam sheet with a good skin quality.

Cellular polystyrene can also be produced by an injection-molding process. Polystyrene granules containing dissolved liquid or gaseous blowing agents are used as feed in a conventional injection-molding process (92). With close control of time and temperature in the mold and use of vented molds, high density cellular polystyrene moldings can be obtained.

Cellulose Acetate. The extrusion process has also been used to produce cellular cellulose acetate (93) in the density range of 96–112 kg/m^3 (6–7 lb/ft^3). A hot mixture of polymer, blowing agent, and nucleating agent is forced through an orifice into the atmosphere. It expands, cools, and is carried away on a moving belt.

Polyolefins. Cellular polyethylene, polypropylene, and their copolymers are prepared by both extrusion and molding processes. High density polyolefin foams in the density range of 320–800 kg/m^3 are prepared by mixing a decomposable blowing agent with the polymer and feeding the mixture under pressure through an extruder at a temperature such that the blowing agent is partially decomposed before it emerges from an orifice into a lower pressure zone. Simultaneous expansion and cooling take place, resulting in a stable cellular structure owing to rapid crystallization of the polymer, which increases the modulus of the polymer enough to prevent collapse of cell structure (23,33,94). This process is widely used

in wire coating and structural foam products. These products can also be produced by direct injection of inert gases into the extruder (95,96).

Low density polyethylene foam products (thin sheets, planks, rounds, tubes) in the range of 32–160 kg/m^3 (2–10 lb/ft^3) have been prepared by an extrusion technique using various gaseous fluorocarbon blowing agents (97,98). The techniques are similar to those described earlier for producing extruded polystyrene foam planks and foam sheets.

Thermoplastic Structural Foams. Structural foams having an integral skin, cellular core, and a high strength-to-weight ratio are formed by means of injection molding, extrusion, or casting, depending on product requirements (99,100,100). The two most widely used injection molding processes are the Union Carbide low pressure process (102) and the USM high pressure process (103).

In the low pressure process, a short shot of a resin containing a blowing agent is forced into the mold, where the expandable material is allowed to expand to fill the mold under pressures of 690–4140 kPa (100–600 psi). This process produces structural foam products with a characteristic surface swirl pattern produced by the collapse of cells on the surface of molded articles.

In the high pressure process, a resin melt containing a chemical blowing agent is injected into an expandable mold under high pressure. Foaming begins as the mold cavity expands. This process produces structural foam products with very smooth surfaces since the skin is formed before expansion takes place.

Extruded structural foams are produced with conventional extruders and a specially designed die. The die has an inner, fixed torpedo located at the center of its opening, which provides a hollow extrudate. The outer layer of the extrudate cools and solidifies to form solid skin; the remaining extrudate expands toward the interior of the profile. One of the most widely used commercial extrusion processes is the Celuka process developed by Ugine–Kuhlmann (104).

Large structural foam products are produced by casting expandable plastic pellets containing a chemical blowing agent in aluminum molds on a chain conveyor. After closing and clamping the mold, it is conveyed through a heating zone, where the pellets soften, expand, and fuse together to form the cellular products. The mold is then passed through a cooling zone. This process produces structural foam products with uniform, closed-celled structures but no solid skin.

Poly(vinyl chloride). Cellular poly(vinyl chloride) is prepared by many methods (105), some of which utilize decompression processes. Unlike the typical process used for thermoplastic resins where the melt is heated to a temperature considerably above its second-order transition temperature so the resin can flow, poly(vinyl chloride) requires the assistance of a plasticizer to fuse into a plastisol resin. This process is used because the poly(vinly chloride) resin is susceptible to thermal degradation.

The fusion of a dispersion of poly(vinyl chloride) resin in a plasticizer provides a unique type of physical stabilization process. The viscosity of a resin–plasticizer dispersion shows a sharp increase at the fusion temperature. In such a system expansion can take place at a temperature corresponding to the low viscosity; the temperature can then be raised to increase viscosity and stabilize the expanded state.

Extrusion processes have been used to produce high and low density flexible cellular poly(vinyl chloride). A decomposable blowing agent is usually blended

with the compound prior to extrusion. The compounded resin is then fed to an extruder where it is melted under pressure and forced out of an orifice into the atmosphere. After extrusion into the desired shape, the cellular material is cooled to stabilize it and is removed by a belt.

Another type of extrusion process involves the pressurization of a fluid plastisol at low temperatures with an inert gas. This mixture is subsequently extruded onto a belt or into molds, where it expands (106,107). The expanded dispersion is then heated to fuse it into a dimensionally stable form.

Injection molding of high density cellular poly(vinyl chloride) can be accomplished in a manner similar to extrusion except that the extrudate is fed for cooling into a mold rather than being maintained at the uniform extrusion cross-section.

Microcellular Foams. Two notable methods to produce microcellular foams include gas supersaturation in combination with an extrusion process developed by MIT/Trexel (108) and the continuous extrusion process by Dow (109). These processes promote a high level of nucleation, which can result in cell sizes as small as 5 μm.

Polymer Chemical Stabilization Processes. Cellular rubber and ebonite are produced by chemical stabilization processes. Most elastomers can be made into either open-celled or closed-celled materials. Natural rubber, SBR, nitrile rubber, polychloroprene, chlorosulfonated polyethylene, ethylene–propylene terpolymers, butyl rubbers, and polyacrylates have been successfully used (110–112).

Cellular Rubber. This material is an expanded elastomer produced by expansion of a rubber stock, whereas latex foam rubber is produced from a latex. The following general procedure applies to production of cellular rubbers from a variety of types of rubber (110). A decomposable blowing agent, along with vulcanizing systems and other additives, is compounded with the uncured elastomer at a temperature below the decomposition temperature of the blowing agent. When the uncured elastomer is heated in a forming mold, it undergoes a viscosity change, as shown in Figure 1. The blowing agent and vulcanizing systems are chosen to yield open-celled or closed-celled cellular rubber. Although inert gases such as nitrogen have been pressurized into rubber and the rubber then expanded upon release of pressure, the current cellular rubbers are made almost entirely with decomposable blowing agents as exemplified by sodium bicarbonate [144-55-8], 2,2′-azobisisobutyronitrile [78-67-1], azodicarbonamide [123-77-5],

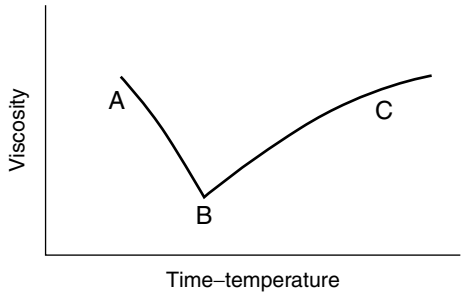


Fig. 1. Viscosity of cellular rubber stock during a production cycle (110).

4,4′-oxybis(benzenesulfonyl hydrazide) [80-51-3], and dinitrosopentamethylenetetramine [101-25-7]. The compound named is the most important commercial compound in its particular class.

To produce open-celled cellular rubber the blowing agent is decomposed just prior to point A in Figure 1 so that the gas is released at the point of minimum viscosity. As the polymer expands, the cell walls become thin and rupture; however, the connecting struts have developed enough strength to support the foam. This process is ordinarily carried out in one step inside a mold under pressure.

The timing for blowing agent decomposition is more critical in making closed-celled cellular rubber; it must occur soon enough after point A to cause expansion of the elastomer but far enough past point A to allow the cell walls to become strong enough not to rupture under the blowing stress. The expansion of closed-celled rubber is often carried out in two main steps: a partial cure is carried out in a mold that is a reduced-scale replica of the final mold; removed from this mold, it expands partly toward its final form. It is then placed in an oven to complete the expansion and cure.

A continuous extrusion process, as well as molding techniques, can be used as the thermoforming method. A more rapid rate of cure is then necessary to ensure the cure of the rubber before the cellular structure collapses. The stock is ordinarily extruded at a temperature high enough to produce some curing and expansion and then oven-heated to complete the expansion and cure.

A unique process for chemical stabilization of a cellular elastomer upon extrusion has been shown for ethylene–propylene rubber: the expanded rubber obtained by extrusion is exposed to high energy radiation to cross-link or vulcanize the rubber and give dimensional stability (113). EPDM is also made continuously through extrusion and a combination of hot air and microwaves or radio frequency waves, which both activate the blow and accelerate the cure.

Cellular Polyurethane. Polyurethane structural foam produced by reaction injection molding (RIM) is a rapidly growing product that provides industry with the design flexibility required for a wide range of applications. This process is more efficient than conventional methods in producing large-area, thin-wall, and load-bearing structural foam parts. In the RIM process, polyol and isocyanate liquid components are metered into a temperature-controlled mold that is filled 20–60%, depending on the density of structural foam parts (114). When the reaction mixture then expands to fill the mold cavity, it forms a component part with an integral, solid skin and a microcellular core. The quality of the structural part depends on precise metering, mixing, and injection of the reaction chemicals into the mold.

Cellular Ebonite. Cellular ebonite is the oldest rigid cellular plastic. It was produced in the early 1920s by a process similar to the processes described for making cellular rubber. The formulation of rubber and vulcanizing agent is changed to produce an ebonite rather than rubber matrix (115).

Dispersion Processes. In several techniques for producing cellular polymers, the gas cells are produced by dispersion of a gas or liquid in the polymer phase followed, when necessary, by stabilization of the dispersion and subsequent treatment of the stabilized dispersion. In frothing techniques, a quantity of gas is mechanically dispersed in the fluid polymer phase and stabilized. In another method, solid particles are dispersed in a fluid polymer phase, the dispersion

stabilized, and then the solid phase dissolved or leached, leaving the cellular polymer. Still another method relies on dispersing an already cellular solid phase in a fluid polymer and stabilizing this dispersion. This results directly in cellular polymers called syntactic foams.

Frothing. The frothing process for producing cellular polymers is the same process used for making meringue topping for pies. A gas is dispersed in a fluid that has surface properties suitable for producing a foam of transient stability. The foam is then permanently stabilized by chemical reaction. The fluid may be a homogeneous material, a solution, or a heterogeneous material.

Latex Foam Rubber. Latex foam rubber was the first cellular polymer to be produced by frothing. (*1*) A gas is dispersed in a suitable latex; (*2*) the rubber latex particles are caused to coalesce and form a continuous rubber phase in the water phase; (*3*) the aqueous soap film, breaks owing to deactivation of the surfactant in the water, breaking the latex film, and causing retraction into the connecting struts of the bubbles; (*4*) the expanded matrix is cured and dried to stabilize it.

The earliest frothing process developed was the Dunlop process, which made use of chemical gelling agents, eg, sodium fluorosilicate, to coagulate the rubber particles and deactivate the soaps. The Talalay process, developed later, employs freeze-coagulation of the rubber followed by deactivation of the soaps with carbon dioxide. The basic processes and a multitude of improvements are discussed extensively in Reference (3). A discussion more oriented to current use of these processes is given in Reference (116).

Latex rubber foams are generally prepared in slab or molded forms in the density range 64–128 kg/m^3 (4–8 lb/ft^3). Synthetic SBR latexes have replaced natural rubber latexes as the largest-volume raw material for latex foam rubber. Other elastomers used in significant quantities are polychloroprene, nitrile rubbers, and synthetic *cis*-polyisoprene (116).

One method (117) of producing cellular polymers from a variety of latexes uses primarily latexes of carboxylated styrene–butadiene copolymers, although other elastomers such as acrylic elastomers, nitrile rubber, and vinyl polymers can be employed.

Urea–Formaldehyde Resins. Cellular urea–formaldehyde resins can be prepared in the following manner: an aqueous solution containing surfactant and catalyst is made into a low density, fine-celled foam by dispersing air into it mechanically. A second aqueous solution consisting of partially cured urea–formaldehyde resin is then mixed into the foam by mechanical agitation. The catalyst in the initial foam causes the dispersed resin to cure in the cellular state. The resultant hardened foam is dried at elevated temperatures. Densities as low as 8 kg/m^3 can be obtained by this method (118).

Polyurethanes. Polyurethane foam systems have also been frothed using both low boiling dissolved materials and whipped-in air or other gas. Rigid polyurethane foam systems using a previously mixed polyol, surfactant, and catalyst system pressurized in a container with blowing agent are used for froth discharge into pour-in-place cavity filling (119). Flexible polyurethane foam is mechanically frothed by whipping dry gas such as air into the combined polyol and isocyanate. The thick, creamy froth is then doctored onto a carpet or textile back to form a variety of coatings ranging from a very thin unitary to a 1.8-cm-thick resilient foam (120).

Syntactic Cellular Polymers. Syntactic cellular polymer is produced by dispersing rigid, foamed, microscopic particles in a fluid polymer and then stabilizing the system. The particles are generally spheres or microballoons of phenolic resin, urea–formaldehyde resin, copolymers of vinylidene chloride and acrylonitrile (121), glass, or silica, ranging 30–120 μm diameter. Commercial microballoons have densities of approximately 144 kg/m^3 (9 lb/ft^3). The fluid polymers used are the usual coating resins, eg, epoxy resin, polyesters, and urea–formaldehyde resin.

The resin, catalyst, and microballoons are mixed to form a mortar, which is then cast into the desirable shape and cured. Very specialized electrical and mechanical properties may be obtained by this method but at higher cost. This method of producing cellular polymers is quite applicable to small-quantity, specialized applications because it requires very little special equipment.

In a variation on the usual methods for producing syntactic foams (122,123), expandable polystyrene or styrene–acrylonitrile copolymer particles (in either the unexpanded or prefoamed state) are mixed with a resin (or a resin containing a blowing agent) which has a large exotherm during curing. The mixture is then placed in a mold and the exotherm from the resin cure causes the expandable particles to foam and squeeze the resin or foamed matrix to the surface of the molding. A typical example is Voraspan, expandable polystyrene in a flexible polyurethane foam matrix (124). These foams are finding acceptance in cushioning applications for bedding and furniture.

Other Processes. Some plastics cannot be obtained in a low viscosity melt or solution that can be processed into a cellular state. For these cases two methods have been used to achieve the needed dispersion of gas in solid: sintering of solid plastic particles and leaching of soluble inclusions from the solid plastic phase.

Sintering has been used to produce a porous polytetrafluoroethylene (10). Cellulose sponges are the most familiar cellular polymers produced by the leaching process (125). Sodium sulfate crystals are dispersed in the viscose syrup and subsequently leached out. Polyethylene (126) or poly(vinyl chloride) can also be produced in cellular form by the leaching process. The artificial leather-like materials used for shoe uppers are rendered porous by extraction of salts (127) or by designing the polymers in such a way that they precipitate as a gel, with many holes (128).

Phase Separation. Microporous polymer systems consisting of essentially spherical, interconnected voids, with a narrow range of pore and cell-size distribution have been produced from a variety of thermoplastic resins by the phase-separation technique (129). If a polyolefin or polystyrene is insoluble in a solvent at low temperature but soluble at high temperatures, the solvent can be used to prepare a microporous polymer. When the solutions, containing 10–70% polymer, are cooled to ambient temperatures, the polymer separates as a second phase. The remaining nonsolvent can then be extracted from the solid material with common organic solvents. These microporous polymers may be useful in microfiltrations or as controlled-release carriers for a variety of chemicals.

A recent aproach to microporous foams involves the polymerization of high internal-phase water in oil emulsions (130). These flexible, hydrophilic open-celled foams are suitable for absorption of aqueous fluids and are being

considered as a replacement for the absorbent cores in absorbent articles such as diapers.

Properties of Cellular Polymers

The mechanical properties of rigid foams vary considerably from those of flexible foams. The tests used to characterize these two classes of foams are, therefore, quite different, and the properties of interest from an application standpoint are also quite different. In this discussion the ASTM definition of rigid and flexible foams given earlier is used.

Several countries have developed their own standard test methods for cellular plastics, and the International Organization for Standards (ISO) Technical Committee on Plastics TC-61 has been developing international standards. Information concerning the test methods for any particular country or the ISO procedures can be obtained in the United States from the American National Standards Institute. The most complete set of test procedures for cellular plastics, and the most used of any in the world, is that developed by the ASTM; these procedures are published in new editions each year (131). There have been several reviews of ASTM methods and others pertinent to cellular plastics (26,54,132–134).

The properties of commercial rigid foamed plastics are presented in Table 2. The properties of commercial flexible foamed plastics are presented in Table 3. The definition of a flexible foamed plastic is that recommended by the ASTM Committee D 11. The data shown demonstrate the broad ranges of properties of commercial products rather than an accurate set of properties on a specific few materials. Specific producers of foamed plastics should be consulted for properties on a particular product (139–141,149–152).

The properties that are achieved in commercial structural foams (density $>$ 0.3 g/cm^3) are shown in Table 4. Because these values depend on several structural and process variables, they can be used only as general guidelines of mechanical properties from these products. A good engineering guide has been published (100).

Structural Variables. The properties of a foamed plastic can be related to several variables of composition and geometry often referred to as structural variables.

Polymer Composition. The properties of foamed plastics are influenced both by the foam structure and, to a greater extent, by the properties of the parent polymer. The polymer phase description must include the additives present in that phase as well. The condition or state of the polymer phase (orientation, crystallinity, previous thermal history), as well as its chemical composition, determines the properties of that phase. The polymer state and cell geometry are intimately related because they are determined by common forces exerted during the expansion and stabilization of the foam.

Density. Density is the most important variable in determining mechanical properties of a foamed plastic of given composition. Its effect has been recognized since foamed plastics were first made and has been extensively studied.

Cell Structure. A complete knowledge of the cell structure of a cellular polymer requires a definition of its cell sizes, cell shapes, and the location of each cell in the foam.

Cell size has been characterized by measurements of the cell diameter in one or more of the three mutually perpendicular directions (153) and as a measurement of average cell volume (154,155). Mechanical, optical, and thermal properties of a foam are all dependent upon the cell size.

Cell geometry is governed predominantly by the final foam density and the external forces exerted on the cellular structure prior to its stabilization in the expanded state. In a foam prepared without such external forces, the cells tend to be spherical or ellipsoidal at gas volumes less than 70–80% of the total volume, and they tend toward the shape of packed regular dodecahedra at greater gas volumes. These shapes have been shown to be consistent with surface chemistry arguments (154,156,157). Photographs of actual foam cells (Fig. 2) show a broad range of variations in shape.

In the presence of external forces, plastic foams in which the cells are elongated or flattened in a particular direction may be formed. This cell orientation can have a marked influence on many properties. The results of a number of studies have been reviewed (54,55).

The *fraction of open cells* expresses the extent to which the gas phase of one cell is in communication with other cells. When a large portion of cells are interconnected by gas phase, the foam has a large fraction of open cells, or is an open-celled foam. Conversely, a large proportion of noninterconnecting cells results in a large fraction of closed cells, or a closed-celled foam.

The nature of the opening between cells determines how readily different gases and liquids can pass from one cell to another. Because of variation in flow of different liquids or gases through the cell-wall openings, a single measurement of the fraction of open cells does not fully characterize this structural variable, especially in a dynamic situation.

Gas Composition. In closed-celled foams, the gas is partitioned between the polymer phase and the void space. The gas dissolved in the polymer phase affects the mechanical properties. The gas in the void phase or cells can contain some of the blowing agent (called captive blowing agent), gas components of air that have diffused in, or other gases generated during the foaming process. Such properties as thermal and electrical conductivity can be profoundly influenced by the cell gas composition. In open-celled foams the presence of air exerts only a minor influence on the static properties but does affect the dynamic properties such as cushioning.

Rigid Cellular Polymers. A separate class of high density, rigid cellular polymers has grown continually since the 1970s to become significant commercially. These are the structural foams with a density >300 kg/m^3. They are treated here as a separate category of rigid foams.

Compressive strength and modulus are widely used as general criteria to characterize the mechanical properties of rigid plastic foams. Rigid cellular polymers generally do not exhibit a definite yield point when compressed but instead show an increased deviation from Hooke's law as the compressive load is increased (158,159). For precision the compressive strength is usually reported at some definite deflection (commonly 5 or 10%). The compressive modulus is reported as extrapolated to 0% deflection unless otherwise stated. Structural variables that affect the compressive strength and modulus of a rigid plastic foam are, in order of decreasing importance, plastic-phase composition, density, cell structure, and

plastic state. The effect of gas composition is minor, with a slight effect of gas pressure in some cases.

Compressive Behavior. Density and polymer composition have a large effect on compressive strength and modulus. In general, compressive strength and

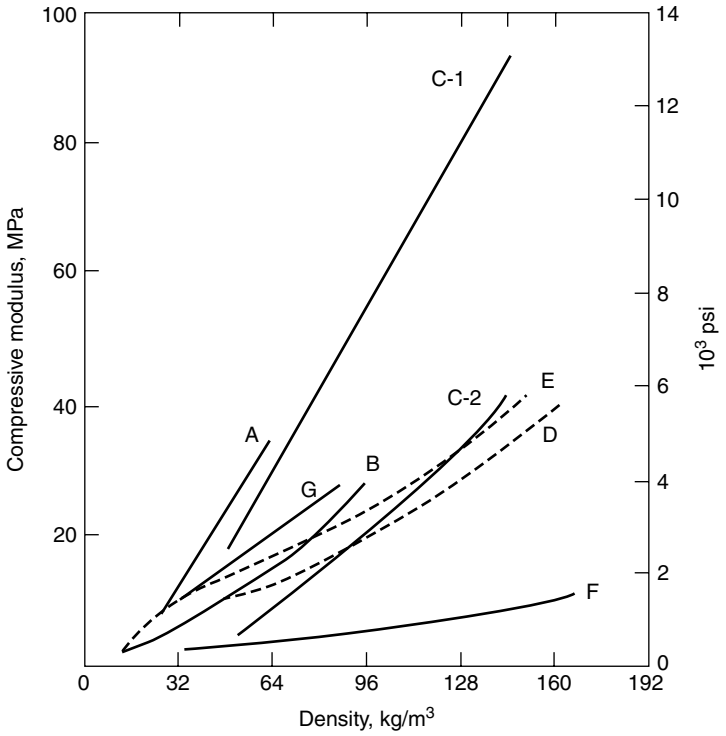

Fig. 3. Effect of density on compressive modulus of rigid cellular polymers. To convert kg/m^3 to lb/ft^3, multiply by 0.0624.

modulus of closed-cell low density foams may be expressed as

$$\text{Strength or modulus} = A\rho^a$$

Where A, a are constants, and ρ represents the foam density. This relationship is illustrated in Figure 3. The dependence of compressive properties on cell size has been discussed (16). The cell shape or geometry has also been shown important in determining the compressive properties (16,54,55,163,164). In fact, the foam cell structure is controlled in some cases to optimize certain physical properties of rigid cellular polymers.

Strengths and moduli of most polymers increase as the temperature decreases (165). This behavior of the polymer phase carries into the properties of polymer foams, and similar dependence of the compressive modulus of polyurethane foams on temperature has been shown (161).

Tensile strength and modulus of rigid foams have been shown to vary with density in much the same manner as the compressive strength and modulus. General reviews of the tensile properties of rigid foams are available (16,54,55, 134,166).

Those structural variables most important to the tensile properties are polymer composition, density, and cell shape. Variation with use temperature has also been characterized (167). Flexural strength and modulus of rigid foams both increase with increasing density in the same manner as the compressive and tensile properties. More specific data on particular foams are available from manufacturers' literature and in References 16,54,55,134 166. Shear strength and modulus of rigid foams depend on the polymer composition and state, density, and cell shape. The shear properties increase with increasing density and with decreasing temperature (167).

Creep. The creep characteristic of plastic foams must be considered when they are used in structural applications. *Creep* is the change in dimensions of a material when it is maintained under a constant stress. Data on the deformation of polystyrene foam under various static loads have been compiled (168). There are two types of creep in this material: short-term and long-term. Short-term creep exists in foams at all stress levels; however, a threshold stress level exists below which there is no detectable long-term creep. The minimum load required to cause long-term creep in molded polystyrene foam varies with density, ranging from 50 kPa (7.3 psi) at foam density 16 kg/m^3 (1 lb/ft^3) to 455 kPa (66 psi) at foam density 160 kg/m^3 (10 lb/ft^3).

The successful application of time–temperature superposition (169) for polystyrene foam is particularly significant in that it allows prediction of long-term behavior from short-term measurements. This is of interest in building and construction applications where load bearing and dimensional change are important.

Structural Foams. Structural foams are usually produced as fabricated articles in injection molding or extrusion processes. The optimum product and process match differs for each fabricated article, so there are no standard commercial products for one to characterize. Rather there are a number of foams with varying properties. The properties of typical structural foams of different compositions are reported in Table 4.

The most important structural variables are again polymer composition, density, and cell size and shape. Structural foams have relatively high densities (typically $>$300 kg/m^3), and cell structures similar to those in Figure 2d that are primarily composed of holes in contrast to a pentagonal dodecahedron type of cell structure in low density plastic foams. Since structural foams are generally not uniform in cell structure, they exhibit considerable variation in properties with particle geometry (100).

The mechanical properties of structural foams and their variation with polymer composition and density has been reviewed (100). The variation of structural foam mechanical properties with density as a function of polymer properties is extracted from stress–strain curves. However, because of possible anisotropy of the foam, the data must be considered as apparent data. These relations can provide valuable guidance toward arriving at an optimum structural foam, however.

Flexible Cellular Polymers. The application of flexible foams has been predominantly in comfort cushioning, packaging, and wearing apparel (142,170, 171), resulting in emphasis on a different set of mechanical properties than for rigid foams. The compressive nature of flexible foams (both static and dynamic) is their most significant mechanical property for most uses (Table 3). Other

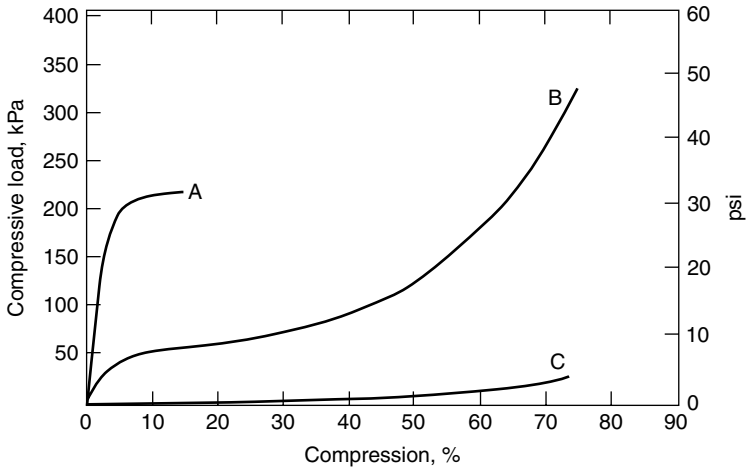

Fig. 4. Load vs compression for plastic foams (159). A, polystyrene, 32 kg/m^3; B, polyethylene, 32 kg/m^3; C, latex rubber foam, 32 kg/m^3. To convert kg/m^3 to lb/ft^3, multiply by 0.0624.

important properties are tensile strength and elongation, tear strength, and compression set. These properties can be related to the same set of structural variables as those for rigid foams.

Compressive Behavior. The most informative data in characterizing the compressive behavior of a flexible foam are derived from the entire load–deflection curve of 0–75% deflection and its return to 0% deflection at the speed experienced in the anticipated application. Various methods have been reported (3,142,172–175) for relating the properties of flexible foams to desired behavior in comfort cushioning. Other methods to characterize package cushioning have been reported. The most important variables affecting compressive behavior are polymer composition, density, and cell structure and size.

Polymer composition is the most important structural variable (Fig. 4). Although the polystyrene and polyethylene foams are approximately the same density and the open-celled latex foam significantly more dense, all three show markedly different compressive strengths. The compressive behavior of latex rubber foams of various densities (3,176) is illustrated in Figure 5. Similar relationships undoubtedly hold for vinyl and flexible polyurethane foams as well. In the case of polyurethane foams there are many variables in addition to density that heavily influence compressive behavior (26,44,55). For example the effects of reaction water content, polyol molecular weight, polymer polyol content, and isocyanate index on polymer tensile stiffness have been described (177). A further strong variation of flexible polyurethane foam compressive behavior can occur as a result of changes in the closed-cell content as measured by means of an airflow manometer described in ASTM method D3574.

Various geometric coring patterns in polyurethanes (174,178) and in latex foam rubber (179) exert significant influences on their compressive behavior. A good discussion of the effect of cell size and shape on the properties of flexible foams is contained in References (60) and (163). The effect of open-cell content in polyethylene foam is demonstrated (173).

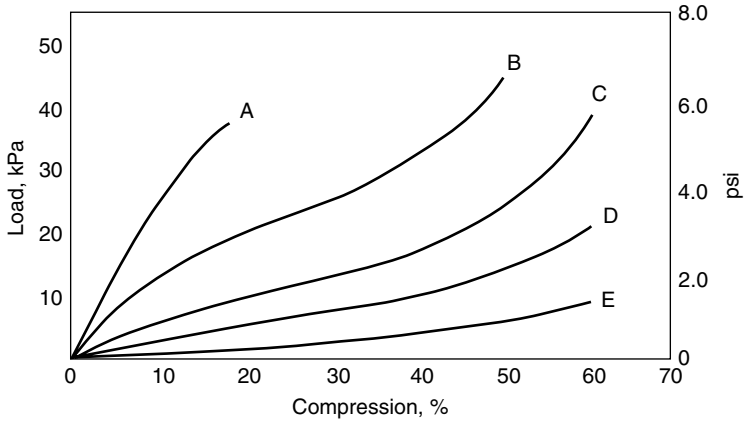

Fig. 5. Effect of load on compression for latex foams of different densities (3,173). A, 304 kg/m^3; B, 208 kg/m^3; C, 179 kg/m^3; D, 139 kg/m^3; E, 99 kg/m^3. To convert kg/m^3 to lb/ft^3, multiply by 0.0624.

Tensile Strength and Elongation. The tensile strength of latex rubber foam has been shown to depend on the density of the foam (159,180) and on the tensile strength of the parent rubber (180,181). At low densities the tensile modulus approximates a linear relation with density but increases with a higher power of density at higher densities. Similar relations hold for polyurethane and other flexible foams (166,182,183).

The tensile elongation of solid latex rubber has been shown to correlate well with the elongation of foam from the latex (181). The elongation of flexible polyurethane has been related to cell structure (183,184).

Tear Strength. A relation for the tearing stress of flexible foams that predicts linear increase in the tearing energy with density and increased tearing energy with cell size has been developed (180). Both relationships are verified to a limited extent by experimental data.

Flex Fatigue. Considerable information on the measurement and cause of flex fatigue in flexible foams has been published (185–187). Changing compressive strength and volume upon repeated flexing over long periods of time is a significant deterrent to the use of polyurethane foam in many cushioning applications. For polyurethane foams these changes have been correlated mainly with changes in chemical structure.

Compression Set. The compression set is an important property in cushioning applications. It has been studied for polyurethane foams (188,189), and has been discussed in reviews (26,55,166). Compression set has been described as flex fatigue and creep as well.

Other Properties. The thermal, electrical, acoustical, and chemical properties of all cellular polymers are of such a similar nature that the discussions of these properties cannot be separated into rigid and flexible groups.

Thermal Properties.

Thermal Conductivity. More information is available relating thermal conductivity to structural variables of cellular polymers than for any other property.

Several papers have discussed the relation of the thermal conductivity of heterogeneous materials in general (190,191) and of plastic foams in particular (135,153,161,192–194), with the characteristic structural variables of the systems.

The following separation of the total heat transfer into its component parts, even if not completely rigorous, proves valuable to understanding the total thermal conductivity k of foams:

$$k = k_s + k_g + k_r + k_c \tag{6}$$

where k_s, k_g, k_r, and k_c are the components of thermal conductivity attributable to solid conduction, gaseous conduction, radiation, and convection, respectively.

As a good first approximation (190), the heat conduction of low density foams through the solid and gas phases can be expressed as the thermal conductivity of each phase times its volume fraction. Most rigid polymers have thermal conductivities of 0.07–0.28 W/(m·K) and the corresponding conduction through the solid phase of a 32 kg/m^3 (2 lb/ft^3) foam (3 vol%) ranges 0.003–0.009 W/(m·K). In most cellular polymers this value is determined primarily by the density of the foam and the polymer-phase composition. Smaller variations can result from changes in cell structure.

Although conductivity through gases is much lower than that through solids, the amount of heat transferred through the gas phase in a foam is generally the largest contribution to the total heat transfer because the gas phase is the principal part of the total value (ca 97 vol% in a 32 kg/m^3 foam). Table 5 lists values of the thermal conductivity for several gases that occur in the cells of cellular polymers. The thermal conductivities of the halocarbon gases are considerably less than those of oxygen and nitrogen. It has, therefore, proved advantageous to prepare cellular polymers using such gases that measurably lower the k of the polymer foam. Upon exposure to air the gas of low thermal conductivity in the cells can get mixed with air, and the k of the mixture of gases can be estimated by a mixing rule such as the Riblett (eq. 7).

$$k_m = \sum_i k_i M_i^{1/3} P_i / \sum_i M_i^{1/3} P_i \tag{7}$$

where k_m is the k of the gaseous mixture; k_i, M_i, and P_i are the component thermal conductivity, molecular weight, and partial pressure, respectively. Changes in total k calculated using equations (6) and (7) with change in gas composition agree well with experimental measurements (154,194,195,198,199).

There is ordinarily no measurable convection in cells of diameter less than about 4 mm (153). Theoretical arguments have been in general agreement with this work (161,194,195). Since most available cellular polymers have cell diameters less than 4 mm, convection heat transfer can be ignored with good justification. Studies of radiation heat transfer through cellular polymers have been done (153,161,194,195,200,201).

The variation in total thermal conductivity with density has the same general nature for all cellular polymers (153,192). The increase in k at low densities is owing to an increased radiant heat transfer; the rise at high densities to an increasing contribution of k_s.

The thermal conductivity of most materials decreases with temperature. When the foam structure and gas composition are not influenced by temperature, the k of the cellular material decreases with decreasing temperature. When the composition of the gas phase may change (ie, condensation of a vapor), then the relationship of k to temperature is much more complex (153,194,195,202).

The thermal conductivity of a cellular polymer can change upon aging under ambient conditions if the gas composition is influenced by such aging. Such a case is evidenced when oxygen or nitrogen diffuses into polyurethane foams that initially have only a fluorocarbon blowing agent in the cells (26,133,153,193–195, 202–207).

Thermal conductivity of foamed plastics has been shown to vary with thickness (201). This has been attributed to the boundary effects of the radiant contribution to heat transfer. Other modifications to the thermal conductivity of foamed plastics are directed at reducing the radiation heat transfer. Radiation heat transfer varies inversely with extinction coefficient, and two techniques are current available for moderating transmission. When the average cell size is reduced, while maintaining a constant density, the total length and surface area of struts available to absorb radiation are increased. Also by using infrared (IR) blockers radiation heat transfer can be reduced by 15 to 20%. These materials, such as carbon black particles, graphite and aluminum flakes, when included in the polymer cell walls can improve the foam thermal conductivity (208,209). As opaque materials, they make the foam less transparent to IR wavelengths where appreciable

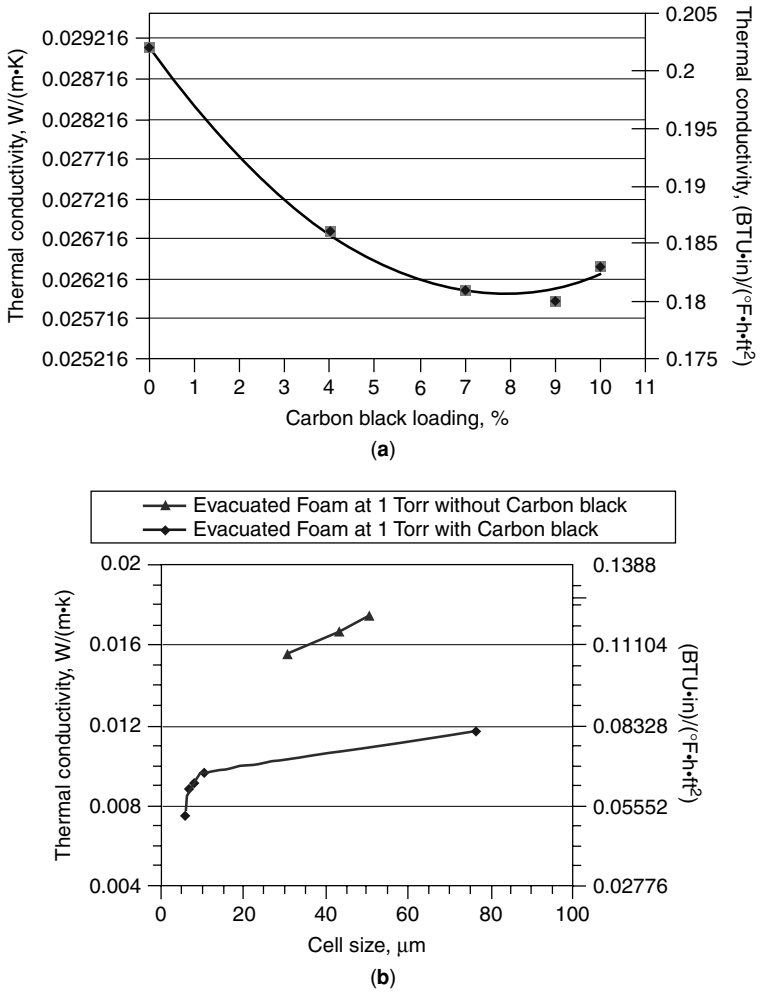

Fig. 6. (**a**) Effect of carbon black loading on thermal conductivity (209); (**b**) Effect of cell size and carbon black IR attenuator on the thermal conductivity of polystyrene foam panel core material (208).

thermal radiation is emitted at room temperature. Too large an amount of the solid filler can cause the effective conductivity to increase because solid conductivity begins to dominate (209). Figure 6a shows the effect of carbon back loading on the thermal insulation performance of polystyrene foam. Additionally, using IR-attenuating fillers in conjunction with vacuum insulation can decrease the effective thermal conductivity of foam materials (208). Figure 6b show the comparative performance of filled and unfilled foam as a function of cell size.

Specific Heat. The specific heat of a cellular polymer is simply the sum of the specific heats of each of its components. The contribution of the gas is small and can be neglected in many cases.

Coefficient of Linear Thermal Expansion. The coefficients of linear thermal expansion of polymers are higher than those for most rigid materials at ambient

temperatures because of the supercooled-liquid nature of the polymeric state, and this applies to the cellular state as well. Variation of this property with density and temperature has been reported for polystyrene foams (210) and for foams in general (16). When cellular polymers are used as components of large structures, the coefficient of thermal expansion must be considered carefully because of its magnitude compared with those of most nonpolymeric structural materials (211).

Maximum Service Temperature. Because the cellular materials, like their parent polymers (212), undergo a gradual decrease in modulus as the temperature rises rather than a sharp change in properties, it is difficult to precisely define the maximum service temperature of cellular polymers. The upper temperature limit of use for most cellular polymers is governed predominantly by the plastic phase. Fabrication of the polymer into a cellular state normally builds some stress into the polymer phase; this may tend to relax at a temperature below the heat-distortion temperature of the unfoamed polymer. Of course, additives in the polymer phase or a plasticizing effect of the blowing agent on the polymer affect the behavior of the cellular material in the same way as the unfoamed polymer. Typical maximum service temperatures are given in Tables 2, 3, and 4.

Flammability. The results of small-scale laboratory tests of plastic foams have been recognized as not predictive of their true behavior in other fire situations (213). Work aimed at developing tests to evaluate the performance of plastic foams in actual fire situations continues. All plastic foams are combustible, some burning more readily than others when exposed to fire. Some additives (134,138), when added in small quantities to the polymer, markedly improve the behavior of the foam in the presence of small fire sources. Plastic foams must be used properly, following the manufacturers recommendations and any applicable regulations.

Moisture Resistance. Plastic foams are advantageous compared with other thermal insulations in several applications where they are exposed to moisture pickup, particularly when subjected to a combination of thermal and moisture gradients. In some cases the foams are exposed to freeze–thaw cycles as well. The behavior of plastic foams has been studied under laboratory conditions simulating these use conditions as well as under the actual use conditions.

In a study (214) of the moisture gain of foamed plastic roof insulations under controlled thermal gradients, the apparent permeability values were greater than those predicted by regular wet-cup permeability measurements. The moisture gains found in polyurethane are greater than those of bead polystyrene and much greater than those of extruded polystyrene.

Moisture pickup and freeze–thaw resistance of various insulations and the effect of moisture on the thermal performance of these insulations has been reported (215). In protected membrane roofing applications the order of preference for minimizing moisture pickup is extruded polystyrene $\gg$ polyurethane $>$ molded polystyrene (215).

Water pickup values for insulation in use for 5 years were, extruded polystyrene, 0.2 vol%; polyurethane without skins, 5 vol%; and molded polystyrene; 8–30 vol%. These correspond to increases in k of 5–265%. For below-grade applications extruded polystyrene was better than molded polystyrene or polyurethane without skins in terms of moisture-absorption resistance and retention of thermal resistance. Increased water content has been related with increased thermal conductivity of the insulations (216–220).

Electrical Properties. Cellular polymers have two important electrical applications (16). One takes advantage of the combination of inherent toughness and moisture resistance of polymers along with the decreased dielectric constant and dissipation factor of the foamed state to use cellular polymers as electrical-wire insulation (94). The other combines the low dissipation factor and the rigidity of plastic foams in the construction of radar domes. Polyurethane foams have been used as high voltage electrical insulation (221).

Environmental Aging. All cellular polymers are subject to a deterioration of properties under the combined effects of light or heat and oxygen. The response of cellular materials to the action of light and oxygen is governed almost entirely by the composition and state of the polymer phase (16). Expansion of a polymer into a cellular state increases the surface area; reactions of the foam with vapors and liquids are correspondingly faster than those of solid polymer.

Foams prepared from phenol–formaldehyde and urea–formaldehyde resins are the only commercial foams that are significantly affected by water (16). Polyurethane foams exhibit a deterioration of properties when subjected to a combination of light, moisture, and heat aging; polyester-based foam shows much less hydrolytic stability than polyether-based foam (44,203,204).

A great deal of work has been done to develop additives that successfully eliminate environmental degradation (222). The best source of information on specific additives for specific foams is the individual manufacturer of the foam. The resistance to rot, mildew, and fungus of cellular polymers can be related to the amount of moisture that can be taken up by the foam (160). Therefore, open-celled foams are much more likely to support growth than are closed-celled foams. Very high humidity and high temperature are necessary for the growth of microbes on any plastic foam.

Miscellaneous Properties. Cellular polymers are useful for acoustic insulation. Sound transmission is altered only slightly because it depends predominantly on the density of the barrier (in this case, the polymer phase). Therefore by themselves cellular polymers are very poor materials for reducing sound transmission. They are, however, quite effective in absorbing sound waves of certain frequencies (160). Open-cell foams with the cells open to the surface are particularly effective. Recently, low modulus closed-cell polyolefin foams having a large cell size of >5 mm have been developed by the Dow Chemical Co with the trademark QUASH. These foams have shown unique sound absorbtion properties by utilizing the vibration of large, flexible low modulus cell windows (223). The combination of other advantageous physical properties with fair acoustical properties has led to the use of several different types of plastic foams in sound-absorbing constructions (224,225). The sound absorption of a number of cellular polymers has been reported (15,160,224,226). Cellular urea–formaldehyde and phenolic resin foams have been used to some extent in interior sound-absorbing panels and, in Europe, expanded polystyrene has been used in the design of sound-absorbing floors (227). In general, cost, flammability, and cleaning difficulties have prevented significant penetration of the acoustical tile market. The low percent of reflection of sound waves from plastic foam surfaces has led to their use in anechoic chambers (225).

The permeability of cellular polymers to gases and vapors depends on the fraction of open cells as well as the polymer-phase composition and state. The

[b]Projected.

presence of open cells in a foam allows gases and vapors to permeate the cell structure by diffusion and convection flow, yielding very large permeation rates. In closed-celled foams the permeation of gases or vapors is governed by composition of the polymer phase, gas composition, density, and cellular structure of the foam (198,203,204,224,228,229).

The penetration of visible light through foamed polystyrene has been shown to follow approximately the Beer–Lambert law of light absorption (16). This behavior presumably is characteristic of other cellular polymers as well.

Comfort Cushioning. Comfort cushioning is the largest single application of cellular polymers; flexible foams are the principal contributors to this field. Historically, cushioning in particular and flexible foams in general have been the greatest volume of cellular polymers. However, the rapid growth rate of structural, packaging, and insulation applications has brought their volume over that of flexible foams during the past few years. Table 6 shows U.S. consumption of foamed plastics by resin and market (14).

The properties of greatest significance in the cushioning applications of cellular polymers are compression–deflection behavior, resilience, compression set, tensile strength and elongation, and mechanical and environmental aging; of these, compression–deflection behavior is the most important. The broad range of compressive behavior of various types of flexible foam is one of the strong points of cellular polymers, since the needs of almost any cushioning application can be met by changing either the chemical nature or the physical structure of the foam. Flexible urethanes, vinyls, latex foam rubber, and olefins are used to make

foamed plastic cushioning for automobile padding and seats, furniture, flooring, mattresses, and pillows. These materials compete with felt, fibers, innerspring, and other filling materials.

Latex foam rubber was initially accepted as a desirable comfort-cushioning material because of its softness to the touch and its resilience (equal to that of a steel spring alone but with better damping qualities than the spring).

Cellular rubber has been used extensively as shoe soles, where its combination of cushioning ability and wear resistance, coupled with desirable economics, has led to very wide acceptance. In this case the cushioning properties are of minor importance compared with the abrasion resistance and cost. Other significant cushioning applications for cellular rubbers and latex foam rubbers are as carpet underlay and as cushion padding in athletic equipment.

Thermal Insulation. Thermal insulation is the second largest application of cellular polymers and the largest application for the rigid materials. The properties of greatest importance in determining the applicability of rigid foams as thermal insulants are thermal conductivity, ease of application, cost, moisture absorption and transmission permeance, and mechanical properties (see INSULATION, THERMAL). Plastic foams containing a captive blowing agent have considerably lower thermal conductivities than other insulating materials, whereas other rigid cellular plastics are roughly comparable with the latter. Vacuum insulation panels containing rigid open-celled microcellular polystyrene foam enclosed in a nonpermeable membrane on which a vacuum has been applied have shown very low thermal conductivities (230). Super-insulating materials are made by encapsulation of a filler material inside a barrier film, aluminum foil or metallized film. These materials exhibit 5 to 7 times the R-value of typical nonvacuum insulating materials, depending on vacuum level and barrier and filler type. Uses for these vacuum insulation panels (VIP) include refrigeration and controlled-temperature shipping containers. Several key issues that have to be addressed with vacuum panel technology include the vacuum level required to achieve super insulation and functionality of the panels during use. First, the evacuated envelope must be impermeable enough to maintain the desired vacuum over the lifetime of the insulation. The envelope cannot be made of heavy metal foil, which is a good gas barrier, but can cause substantial thermal short-circuiting around the circumference of the package and severely increase the effective conductivity. Second, the ease of manufacturing panels in various shapes that lend itself to functional use. A technology based on a polystyrene foam core material seems to have resolved these issues in their commercial offering of an Instill (trademark of the Dow Chemical Company) product that combines performance with durability (230). Figure 7 shows the comparative performance of an Instill over less durable vacuum panel technologies.

Domestic Refrigeration. The very low thermal conductivity of polyurethanes plus the ease of application and structural properties of foamed-in-place materials gives refrigeration engineers considerable freedom of styling. This has resulted in an increasingly broad use of rigid polyurethane foams in home freezers and refrigerators that has displaced conventional rock wool and glass wool.

Commercial Refrigeration. Again, low thermal conductivity is important, as are styling and cost. Application methods and mechanical properties are of

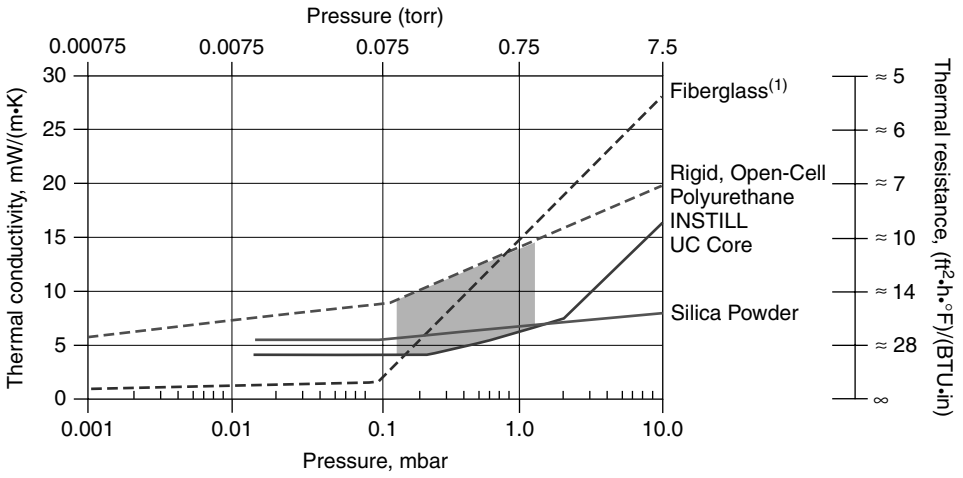

Fig. 7. Comparative performance of vacuum panel core materials (230).

secondary importance because of design latitude in this area. For example, large institutional chests, commercial refrigerators, freezers, and cold-storage areas, including cryogenic equipment and large tanks for industrial gases, are insulated with polystyrene or polyurethane foams. Polystyrene foam is still popular where cost and moisture resistance are important; polyurethane is used where spray application is required. Polystyrene foam is also widely used in load-bearing sandwich panels in low temperature space applications.

Refrigeration in Transportation. Styling is unimportant. The volume of insulation and a low thermal conductivity are of primary concern. Volume is not large, so application methods are not of prime importance. Low moisture sensitivity and permanence are necessary. The mechanical properties of the insulant are quite important owing to the continued abuse the vehicle undergoes. Cost is of less concern here than in other applications. Polystyrene foam is widely used in this application.

Residential Construction. Owing to rising energy costs, the cost and low thermal conductivity are of prime importance in wall and ceiling insulation of residential buildings. The combination of insulation efficiency, desirable structural properties, ease of application, ability to reduce air infiltration, and moisture resistance has led to the use of extruded polymeric and polyisocyanurate foam in residential construction as sheathing, as perimeter and floor insulation under concrete, and as a combined plaster base and insulation for walls.

Commercial Construction. The same attributes desirable on residential construction applications hold for commercial construction as well, but insulation quality, permanence, moisture insensitivity, and resistance to freeze–thaw cycling in the presence of water are of greater significance. For this reason cellular plastics have greater application here. Both polystyrene and polyurethane foams are highly desirable roof insulations in commercial as well as in residential construction.

Cellular polymers are also used for pipe and vessel insulation. Spray and pour-in-place techniques of application are particularly suitable, and polyurethane and epoxy foams are widely used. Ease of application, fire properties, and low thermal conductivity have been responsible for the acceptance of cellular rubber and cellular poly(vinyl chloride) as insulation for smaller pipes.

The insulating value and mechanical properties of rigid plastic foams have led to the development of several novel methods of building construction. Polyurethane foam panels may be used as unit structural components (231) and expanded polystyrene is employed as a concrete base in thin-shell construction (232).

Packaging. Because of the extremely broad demands on the mechanical properties of packaging materials, the entire range of cellular polymers from rigid to flexible is used in this application. The most important considerations are mechanical properties, cost, ease of application or fabrication, moisture susceptibility, thermal conductivity, and aesthetic appeal.

The proper mechanical properties, particularly compressive properties, are the primary requirements for a cushioning foam (233,234). The reader is referred to the following sources for more specific information: package design (235); general vibration and shock isolation (236); protective package design (237); selection of cushioning material (233,238); and characterization of cellular polymers for cushioning applications (234,236,237,239).

Creep of a cushion packaging material when subjected to static stresses for long periods of storage or shipment is also an important consideration. Polystyrene foam shows considerable creep (168) at high static loadings but that creep is insignificant under loadings in the static stress region of optimum package design (16). The ability of polystyrene foam to withstand repeated impacts has also been studied (162,240).

The low density of most cellular plastics is important because of shipping costs for the cushioning in a package. Foams with densities ranging from 4 to 32 kg/m^3 are used in this application. The inherent moisture resistance of cellular plastics is of added benefit where packages may be subjected to high humidity or water. Many military applications require low moisture susceptibility. Foamed polystyrene is used as packaging inserts and as containers such as food trays, egg cartons, and drinking cups, which require moisture resistance, rigidity, and shock resistance. Foamed polyurethane is also used as specialty packaging materials for expensive and delicate equipment.

The clean, durable, non–dust-forming character of polyethylene foam has led to its acceptance in packaging missile parts (241). Polyethylene foam sheet has also displaced polystyrene foam sheet for packaging glass bottles and containers because of its greater resiliency and tear resistance.

Antistatic protection is an important consideration within the electronic industry, and various antistatic agents are used commercially to alleviate this problem in cushion packaging materials.

Structural Components. In most applications structural foam parts are used as direct replacements for wood, metals, or solid plastics and find wide acceptance in appliances, automobiles, furniture, materials-handling equipment, and in construction. Use in the building and construction industry account for more than one-half of the total volume of structural foam applications. High impact

polystyrene is the most widely used structural foam, followed by polypropylene, high density polyethylene, and poly(vinyl chloride). The construction industry offers the greatest growth potential for cellular plastics.

The sandwich-type structure of polyurethanes with a smooth integral skin produced by the reaction injection molding process provides a high degree of stiffness as well as excellent thermal and acoustical properties necessary for its use in housing and load-bearing structural components for the automotive, business machine, electrical, furniture, and materials-handling industry.

Buoyancy. The low density, closed-celled nature of many cellular polymers coupled with their moisture resistance and low cost resulted in their immediate acceptance for buoyancy in boats and floating structures such as docks and buoys. Since each cell in the foam is a separate flotation member, these materials cannot be destroyed by a single puncture.

The combination of structural strength and flotation has stimulated the design of pleasure boats using a foamed-in-place polyurethane between thin skins of high tensile strength (242). Other cellular polymers that have been used in considerable quantities for buoyancy applications are those produced from polyethylene, polystyrene, poly(vinyl chloride), and certain types of rubber. The susceptibility of polystyrene foams to attack by certain petroleum products that are likely to come in contact with boats led to the development of foams from copolymers of styrene and acrylonitrile that are resistant to these materials (243,244).

Electrical Insulation. The substitution of a gas for part of a solid polymer usually results in large changes in the electrical properties of the resulting material. The dielectric constant, dissipation factor, and dielectric strength are all generally lowered in amounts roughly proportional to the amount of gas in the foam.

For low frequency electrical insulation applications, the dielectric constant of the insulation is ideally as low as possible (see INSULATION, ELECTRICAL). The lower the density of the cellular polymer, the lower the dielectric constant and the better the electrical insulation. Dielectric strength is also reduced at lower density; the insulation is, therefore, susceptible to breakdown from voltage surges from such sources as lightning and short circuits. Because physical properties are also diminished proportionally to density, optimum density is determined by a compromise in properties. For many applications this compromise has been at an expansion of two or three volumes, mainly because the minimum physical properties required for fabrication and use are obtained at that point. Polyolefin foams have been most used as low frequency electrical insulation; poly(vinyl chloride) and polystyrene foams are used also. Producing a completely homogenous, closed-celled foam at lower densities in high speed wire-coating apparatus is difficult.

In high frequency applications, the dissipation factor is of greater importance. Coaxial cables using cellular polyolefins have been quite successfully used for frequencies in the megahertz range and above. Cellular plastics have also been used as structural materials in constructing very large radar-receiving domes (245). The very low dissipation factor of these materials makes them quite transparent to radar waves.

Space Filling and Seals. Cellular polymers have become common for gasketing, sealing, and space filling. Cellular rubber, poly(vinyl chloride), silicone (100), and polyethylene are used extensively for gasketing and sealing of

closures in the automotive and construction trade (110). Most cellular materials must be predominantly closed-celled in order to provide the necessary barrier properties. The combination of chemical inertness, excellent conformation to irregular surfaces, and ability to be compressed to more than 50% with relatively small pressures and still function satisfactorily contribute to the acceptance of cellular polymers in these applications.

In the construction industry, cellular polymers are used as spacers and sealant strips in windows, doors, and closures of other types, as well as for backup strips for other sealants.

Miscellaneous Applications. Cellular plastics have been used for display and novelty pieces since their early development. Polystyrene foam combines ease of fabrication with light weight, attractive appearance, and low cost to make it a favorite in these uses. Phenolic foam has its principal use in floral displays. Its ability to hold large amounts of water for extended periods is used to preserve cut flowers. Cellular poly(vinyl chloride) is used in toys and athletic goods, where its toughness and ease of fabrication into intricate shapes have been valuable.

Commercial Products and Processes

Flexible Polyurethane. These foams are produced from long-chain, lightly branched polyols reacting with a diisocyanate, usually toluene diisocyanate [1321-38-] (TDI), to form an open-celled structure with free air flow during flexure. During manufacture these foams are closely controlled for proper density, ranging from 13 to 80 kg/m^3 (0.8–5 lb/ft^3), to achieve the desired physical properties and cost.

In flexible polyurethane foams, the primary blowing agent is carbon dioxide, which is formed by the reaction of water and toluene diisocyanate. Softer foams with lower densities require an auxiliary blowing agent such as HCFC-141b, or potentially HFC-245fa and HFC-365mfc, hydrocarbons, and CO_2. Since the load-bearing characteristics of the foam are of great importance to the ultimate consumer this property is also closely controlled during manufacture.

Raw Materials. Polyether polyols are used in about 90% of polyurethane foams. The elastomeric polymer is provided additional toughness in the overall polymer matrix by the presence of hard segment urea-based polymers derived from the water/isocyanate reaction (see ISOCYANATES, ORGANIC; URETHANE POLYMERS). Intermolecular hydrogen bonding plays a further role in overall foam hardness. The polyols are typically trifunctional, but di- and tetrafunctional polyols are also used. The polyol chain initiator determines the functionality of the final product; glycerol or trimethylolpropane are the most common triol initiators. Propylene oxide (PO) is then polymerized onto the initiator to form a long-chain triol with an equivalent weight of 1000–1500. PO chains are characterized by pendent methyl groups and terminal secondary hydroxyl groups that provide the lower level of reactivity used for slab foam manufacture. Ethylene oxide (EO) can be used in conjunction with PO to modify the polyether chain by reducing the pendent methyl groups. This is called a hetero polyol, with the possibility of adding a mixed PO/EO feed to form a random hetero or a batch EO feed to form a block hetero polyol. Additionally, EO can be used at the end of the polyol polymerization to produce

primary hydroxyl groups at chain termination. This is known as EO capping and results in polyols with considerably higher reactivities toward isocyanates which is the polyol type required for molded foam production.

Another type of polyol often used in the manufacture of flexible polyurethane foams contains a dispersed solid phase of organic chemical particles (246–248). The continuous phase is one of the polyols described above for either slab or molded foam as required. The dispersed phase reacts in the polyol using an addition reaction with styrene and acrylonitrile monomers in one type or a coupling reaction with an amine such as hydrazine and isocyanate in another. The solids content ranges from about 21% with either system to nearly 40% in the styrene–acrylonitrile system. The dispersed solids confer increased load bearing, and in the case of flexible molded foams also act as a cell opener.

The isocyanates used in the manufacture of flexible foam are TDI and polymeric 4,4′-methylenediphenyl diisocyanate [101-68-8] (MDI). Slab foam manufacturing is based almost entirely on TDI, which is most often supplied as a blend of 80% 2,4-isomer and 20% 2,6-isomer by weight. There have been efforts to develop slab foaming technology using polymeric MDI in place of TDI (249–251). Polymeric MDI is often used in manufacturing molded foams usually blended with TDI, often at a 4: 1 ratio of TDI to MDI by weight. The acidity and isomer distribution are key factors controlling the reactivity of these isocyanates. Foams are generally produced with a slight excess of isocyanate groups. The stoichiometric balance of a foam formulation is known as the foam index, with 100 index as the balance point and 110 index indicating 110% isocyanate equivalents compared to active hydrogen equivalents.

Catalysis of the flexible polyurethane foaming operation is accomplished through the use of tertiary amine compounds, often using two different amines to balance the blowing and gelling reactions. Organometallic compounds, usually stannous salts, are also used to facilitate gelling and promote final cure.

Hydrolyzable or nonhydrolyzable siloxane compounds provide nucleating assistance for fine, uniform cells and surface tension depression for stabilization of the expanding cell walls prior to gelation of the polymer. The slab foam cells are mostly open after ultimate foam rise and blow off. Too much surfactant or too much tin-gelation catalyst cause the foam to have a larger number of closed cells. This tight foam lets very little air pass through a cut block of foam. Tight foams are prone to shrink as the hot gas inside the closed cell cools, thus producing less pressure and volume. Molded foams often need to be crushed after demolding to mechanically open closed cells and prevent shrinkage. Surfactants must be carefully chosen for use in flexible slab, high resilience (HR) slab, and HR or hot-molded systems, since most are not interchangeable.

Fillers (qv) are occasionally used in flexible slab foams; the two most commonly used are calcium carbonate (whiting) and barium sulfate (barytes). Their use level may range up to 150 parts per 100 parts of polyol. Various other ingredients may also be used to modify a flexible foam formulation. Cross-linkers, chain extenders, ignition modifiers, auxiliary blowing agents, etc, are all used to some extent, depending on the final product characteristics desired.

Process and Equipment. The critical requirements for urethane foam dispensing equipment are accurate metering of the ingredients to the mixing chamber, adequate short-cycle mixing, and proper dispensing ability. The polyol,

isocyanate, and water must all be delivered at an accurate rate to maintain the desired stoichiometry that is essential for predicting final foam performance and properties. The other ingredients must also be precisely controlled to obtain optimum processing and performance. Thorough ingredient mixing is made more critical because the components are reactive and thus may not remain in the mixing chamber for more than a few seconds. There is also a wide range of component viscosities; low viscosity isocyanates are dispersed in fairly high viscosity polyols. Additionally the mixing head must deliver the foam ingredients in a smooth flowing manner to minimize air entrainment or splashing.

There are two basic metering/mixing systems (based on pressure) in wide use. Low pressure (less than 2000 kPa) systems use positive displacement pumps to deliver material via a heat exchanger and recycle valve to a mixing chamber with a mechanically driven impeller. High pressure (2000–20000 kPa) systems use precision high pressure pumps to deliver material via flow-adjusting valves and/or orifices to a cylindrical impingement mixing chamber. Following each use the impingement mixing chamber is cleared by advancing a piston that eliminates the need for solvent flushing as is required for low pressure machines.

The mixing head dispenses the foam in several ways depending on the particular foam production process. Flexible foam molding requires the head to be positioned over the open mold, moved in relation to the mold for the best pour pattern and to dispense material on a required quantity shot basis. After the ingredients are placed in the mold cavity the lid is closed and the mold heated. The materials foam and expand to fill the mold, then gel and cure. The mold is then opened, the foam part removed, and a fresh layer of mold release sprayed onto the mold. The foam object is crushed to enhance cell opening and then may be post-cured. The two basic processes for molding are the earlier developed hot process where the molds are subjected to a high temperature (204–371°C) and the cold process where the mold ranges from room temperature to about 120°C. The chemistry used for the cold process is called high resilience (or HR) foam system.

Flexible slab operations often use a traversing arrangement to dispense the foam ingredients back and forth on a layer of polyethylene film carried on a conveyor belt. Side papers are brought up to the edge of the film and the assembly enters a tunnel fitted with an exhaust system. The liquid foam ingredients begin to react and the foam rises to full height within 3–4.5 m after entering the tunnel. As the slab bun exits the tunnel the side papers are pulled off; the bun is then cut into appropriate lengths and delivered to a cure area. Generally a minimum of 24 h is required to cure the bun prior to cutting into blocks for shipping. This simplest form of slab foam manufacture leaves the top of the bun with a rounded cross section much like the top of a loaf of bread. This rounding introduces a waste factor during subsequent cutting of the bun into rectangular blocks for final use as furniture cushions, mattresses, etc. Starting in the late 1970s a number of patented processes were introduced to provide a square block with less wasted foam. These include side paper lifting, top smoothing, and bottom dropping, in which case the foam ingredients are fed to an overflow trough and the expanding foam is allowed to grow down instead of up.

Alternative processes are block-pouring into a large, open-topped box lined with plastic film from which the cured bun is subsequently removed, or a recently introduced vertical foaming operation. In the latter case the foam ingredients

are fed to the bottom of an enclosed trough. As the foam expands vertically it is pulled up by side conveyors. At the top of the square conveyor the foam is cut into length (usually about 2 m) and laid on its side for further curing. Since one of the large foam markets, carpet underlayment, uses long thin sections of foam, it is also desirable to generate cylinders of foam that can then be peeled using a long sharp blade. Round buns of foam are generated by proprietary techniques using conventional conveyors and also with the vertical foaming apparatus modified accordingly. Scrap foam is utilized by shredding into small pieces, adding a prepolymer glue, tumbling to mix, compressing into a mold, then curing with steam. This so-called rebond foam is prepared in a variety of density grades, then cut, sliced, or peeled to proper form for a number of applications, including carpet underlayment.

Economics. Flexible polyurethane foam is generally sold by the board foot, 1in. $\times$ 1 ft $\times$ 1 ft (0.083 ft^3 = 0.0024 m^3), in the United States. Typical densities are 18.5–32.0 kg/m^3 (1.15–2.0 lb/ft^3) for conventional foams and 40.0 kg/m^3 (2.5 lb/ft^3) for HR foam. Foam prices are usually double the cost of the chemicals for standard grades.

Applications. Carpet underlayment as just described is a substantial market. Most furniture cushioning is made from blocks of slab-produced polyurethane foam in the density range of 16–29 kg/m^3 (1.0–1.8 lb/ft^3). For passenger car seating about 90% is made by the molded foam process. A minor portion of the market, 9000–14,000 t (20–30 million pounds), uses 40 kg/m^3 (2.5 lb/ft^3) high resilient (HR) foam for higher priced furniture cushions. The furniture market for polyurethane foams grew strongly until saturation occurred around 1979. Market use now tends to reflect the current economic trends.

Consumption of polyurethane foam in bedding reached a maximum in 1978 and has since declined. The innerspring mattress has remained the standard in the United States whereas all-foam mattresses have gained a dominant market share in Europe.

Textile uses are a relatively stable area and consist of the lamination of polyester foams to textile products, usually by flame lamination or electronic heat sealing techniques. Flexible or semirigid foams are used in engineered packaging in the form of special slab material. Flexible foams are also used to make filters (reticulated foam), sponges, scrubbers, fabric softener carriers, squeegees, paint applicators, and directly applied foam carpet backing.

Rigid Polyurethane. These foams are characterized by closed-celled structure and very high compressive strength. They are produced by reacting a highly branched, short-chain polyol with an aromatic isocyanate of two or more functionality, which is often polymeric. Pour-in-place and free-rise rigid polyurethane foams usually have a density in the region of 32.0 kg/m^3 (2.0 lb/ft^3), although molded rigid foams have densities ranging up to 640 kg/m^3 (40 lb/ft^3) in structural foams. Insulation effectiveness is one of the outstanding characteristics of rigid polyurethane foams that display thermal conductivities as low as 0.017 W/(m $\cdot$ K).

Raw Materials. The highly branched, short-chain polyols used for rigid foams can be initiated from amines such as diethylenetriamine to provide five functional sites or saccharides such as sorbitol or sucrose that have 6 or 8 functional

sites, respectively. Subsequent polymerization of PO and/or EO at low levels further controls viscosity and reactivity of the resultant polyol. The level of oxide addition also contributes to the rigidity of the final foam product by controlling the molecular weight per branch point as well as influencing shrinkage resistance and moisture sensitivity. Amine-initiated polyols tend to be autocatalytic because of the tertiary amine groups residual in the molecule.

The isocyanates used with rigid foam systems are either polymeric MDI or specialty TDIs. Both contain various levels of polymerized isocyanate groups that contribute to molecular weight per cross-link and also may affect reactivity because of steric hindrance of some isocyanate positions.

Surfactants for use with rigid foams are also silicone-based but are quite different from those used for flexible foams. In this case it is more important for the surfactant to also act as a compatibilizer in assisting the intermixing of the isocyanate and polyol during the reaction period. Of course nucleation and cell stabilization during the early phase of foaming are also important functions of the surfactant. Water may also be used in rigid formulations but to a much lesser degree than in flexible foams.

Rigid polyurethane foams are normally foamed with blowing agents having low thermal conductivities and low permeability, such as CFC-11 or HCFC-141b where it is still acceptable, and potentially HFC-245fa, HFC-365mfc, hydrocarbons, and CO_2 because of regulatory pressures. Because of the closed-celled structure of these foams and the low permeability of the blowing agent, the gas is retained in the foam for a long period, providing the superior insulating properties of these products. However, as blowing agents such as hydrocarbons and CO2, which have higher thermal conductivity and permeability, are used, the long-term insulation property will be diminished.

Catalysis is usually accomplished through the use of tertiary amines such as triethylenediamine. Other catalysts such as 2,4,6-*tris*-(*N*,*N*-dimethylaminomethyl)phenol are used in the presence of high levels of crude MDI to promote trimerization of the isocyanate and thus form isocyanurate ring structures. These groups are more thermally stable than the urethane structure and hence are desirable for improved flammability resistance (248). Some urethane content is desirable for improved physical properties such as abrasion resistance.

Miscellaneous chemicals are used to modify the final properties of rigid polyurethane foams. For example, halogenated materials are used for flammability reduction, diols may be added for toughness or flexibility, and terephthalate-based polyester polyols may be used for decreased flammability and smoke generation. Measurements of flammability and smoke characteristics are made with laboratory tests and do not necessarily reflect the effects of foams in actual fire situations.

Process and Equipment. Rigid polyurethane foam processes use the same high or low pressure pumping, metering, and mixing equipment as earlier described for flexible foams. Subsequent handling of the mixture is determined by the end product desired.

Lamination. Rigid foam boardstock with a variety of facer materials is commonly used for insulation in building construction. The boardstock is produced on

a continuous basis by applying the polyurethane (or polyisocyanurate) forming mixture onto one facer sheet, allowing the mixture to begin foaming, applying the second facer on top, and passing the assembly into a fixed gap conveyor to provide heat for cure and to control thickness. This is followed by edge trimming and cutting to board length. In this manner boardstock is produced with facer materials such as kraft paper, aluminum foil, and tarpaper and a foam core thickness ranging up to 10 cm (4 in.).

Pour-in-Place. The polyurethane forming mixture can be poured into a cavity that will then be filled by the flowing, foaming reaction mixture. This method is used for such things as insulating refrigerator cabinets and filling hull cavities in boats and barges.

Molding. The reaction mixture can be discharged into a mold to flow out and fill the cavity. High density (about 320 kg/m^3 or 20 lb/ft^3) moldings can be used for decorative furniture items such as drawer fronts or clock frames. The formulation can be adjusted to produce integral foams.

Bun Stock. By pouring the reaction mixture on a continuous belt a long bun can be produced like the flexible slab foam previously described. After curing, the bun can be cut into slabs or blocks as required by the end use.

Box Foams. A measured quantity of the reaction mixture can be placed in an open-topped crate or box and allowed to foam in a free rise mode. The block is removed after gelling and is cut into end use pieces after curing.

Spray. In spray-on applications the reactive ingredients are impingement mixed at the spray head. Thickness of the foam is controlled by the amount applied per unit area, and additional coats are used if greater than 2.5-cm (1.0-in.) thickness is required. This method is commonly used for coating industrial roofs or insulating tanks and pipes.

Applications. Rigid polyurethane foam laminates for residential sheating (1.2–2.5-cm-thick with aluminum skins) and roofing board (2.5–10.0 cm thick with roofing paper skins) are the leading products, with about 45 t of liquid spray systems also in use. Metal doors insulated by a pour-in-place process constitute another substantial use.

Household refrigerator and freezer designs have been influenced by the increased cost of energy and the need to develop competitive units with comparable energy efficiency ratings. These factors have increased the use of rigid polyurethane foam as pour-in-place insulation in place of the fiber glass insulation now used in only about 30% of the market. Since CFC and now mostly HCFC blown foams have much better insulating effectiveness, the cabinet wall thickness can be reduced from the former fiber-glass-centered design. The pour-in-place cabinet insulating process is carried out in large-scale integrated operations. Commercial refrigeration applications are found in cold storage room insulation, reach-in coolers, and retail display cases. These markets are also using more insulation to offset the higher cost of energy.

The principal use of rigid foam in the transportation market is for insulation of refrigerated truck trailers and bodies as well as refrigerated rail cars. The liquid urethane ingredients are usually poured into large panels held in a fixture. These are then used as integral components: walls, roofs, or floors of the trailer or rail car. Additional uses are insulated truck bodies, recreational vehicles, and cargo containers.

Tanks, pipes, and ducts have been increasingly insulated because of the high cost of energy. For example, oil storage tanks must be kept warm to maintain a moderate viscosity for pumping. The energy required to maintain this temperature can be sharply reduced by insulating the tank with rigid polyurethane foam. This type of insulation is often spray-applied but may also be cut from boardstock.

Packaging constitutes another significant use and is often a foam-in-place operation to protect industrial equipment such as pumps or motors. Furniture articles molded from rigid foam are used in the form of decorative drawer fronts, clock cases, and simulated wooden beams. Flotation for barge repair and sport boats as well as insulation for portable coolers are a few other uses.

Economics. Rigid foam systems are typically in the range of 32 kg/m^3 (2 lb/ft^3) and, are typically about 30–40% higher in price than the pour-in-place foam systems because of differences in raw material costs and process. Unit prices for pour-in-place polyurethane packaging systems fall between the competitive expandable polystyrene bead foam and low density polyethylene foams.

Polystyrene. There are five basic types of polystyrene foams produced in a wide range of densities and employed in a wide variety of applications: (*1*) extruded polystyrene board; (*2*) extruded polystyrene sheet; (*3*) expanded bead molding; (*4*) injection-molded structural foam; and (*5*) expanded polystyrene loose-fill packaging.

Expanded polystyrene (EPS) beadboard insulation is produced with expandable polystyrene beads. These beads are produced by impregnating with 5–8% pentane and sometimes with flame retardants such as hexabromocyclododecane or pentabromomonochlorohexane. The beads are preexpanded by fabricators with steam or vacuum and then allowed to age. The preexpanded beads are fed to the steam-heated block molds where further expansion and fusion of beads take place. The molded blocks are then sliced into various sizes needed for specific applications after curing. Block densities range from 13 to 48 kg/m^3 (0.8–3 lb/ft^3), with 24 kg/m^3 (1.5 lb/ft^3) most common for cushion packaging and 16 kg/m^3 (1.0 lb/ft^3) for insulation applications.

Expanded polystyrene bead molding products account for the largest portion of the drinking cup market and are used in fabricating a variety of other products including packaging materials, insulation board, and ice chests. The insulation value, the moisture resistance, and physical properties are inferior to extruded boardstock, but the material cost is much less.

Expanded polystyrene loose-fill packaging materials are produced normally by extrusion process followed by multiple steam expansions to give low density foam shapes that resemble "S," "8," and hollow shells. They are produced with either pentane or HCF-141b or pentane/HCFC-141b-mixed blowing agents, but with the eventual phase out of HCFC-141b, pentane, or CO_2. Expandable polystyrene loose-fill packaging material is also produced by suspension polymerization process with blowing agent incorporated into the polymer during the polymerization. Recently, starch-based loose-fill packaging products have been introduced using water as the primary blowing agent. These products are used as dunnage or space-filling materials for cushion packaging. Under severe load conditions, vibrational settling may occur, resulting in a nonuniform cushioning protection throughout the package. They have good shock absorbency, excellent resiliency, and are odorless.

The light weight of these products reduces user's shipping costs and conserves energy in transportation. These products are reusable, a key property from economic, ecological, and energy conservation standpoints. Most products are available in bulk densities of 4.0–4.8 kg/m^3 (0.25–0.30 lb/ft^3).

Extruded polystyrene board was first introduced in the early 1940s by Dow Chemical Co. with the tradename Styrofoam (86,252,253). The Styrofoam process consists of the extrusion of a mixture of polystyrene and volatile liquid blowing agent expanded through a die to form boards in various sizes. The continuous boards are then passed through the finishing equipment for further sizing.

In 1979, UC Industries, a joint venture between U.S. Gypsum and Condec Corp., began manufacture of a similar extruded polystyrene foam. Its process is believed to consist of a single-screw tandem extrusion line (114.3-mm main extruder and 152.4-mm extruder as a cooler) and produce foam boardstock in a vacuum chamber connected to a barometric leg that acts as a vacuum seal (254,255). The continuous foam board coming out of a pool of water is then passed through the finishing equipment for sizing.

In 1982, Minnesota Diversified Products, Inc. started to produce a similar extruded polystyrene foam insulation. This process (256) was developed by LMP (Lavorazione Materie Plastiche) SpA, Turin, Italy, and consists of a corotating twin-screw extruder (132-mm diameter, 21:1 L/D) with a single-screw extension as a cooling section, a combination motionless mixer/homogenizer and heat exchanger, a flat die, and finishing equipment for sizing and curing.

In 1992, Dow introduced CO_2 only blown-extruded polystyrene foam with the trademark Avance in response to environmental regulations of ozone, depleting gases (ODP). Later, BASF introduced a CO_2 and ethanol blown-extruded polystyrene foam with the trademark Styrodur C. Other potential non-ODP blowing agents being used are HFC-134a, HFC-152a, HFC-245, and HFC-365 and inorganic blowing agents such as nitrogen and water.

Extruded polystyrene foam sheet is primarily produced in a single-screw tandem extrusion line consisting of a 114.3-mm (4.5-in.) primary extruder, screen changer, 152.4-mm (6.0-in.) secondary extruder as a cooler, and an annular die. Typical throughput rate for this size ranges from 340 to 450 kg (h. The sheet is normally extruded in thicknesses of about 0.4–6.5 mm, and at densities from about 50 to 160 kg/m^3. Polystyrene pellets and a nucleating agent such as talc or a combination of citric acid and sodium bicarbonate are fed to a primary extruder and melted. A blowing agent such as *n*-pentane, isopentane, HCFC-22, or HFC-152a, and inorganics such as CO_2 and water is then injected into the primary extruder and mixed with the molten polymer. The mixture is passed through a secondary extruder to cool the mixture to appropriate foaming temperature. The cooled polymer gel is then passed through an annular die at which point foaming takes place. The foam bubble is pulled over a sizing mandrel and slit to obtain a flat sheet, which is then wound into a roll for storage and curing. The cured sheet is thermoformed into a finished product by either sheet manufacturers or fabricators. The raw material cost for the foam sheet is higher than that for the foam insulation boardstock because of its higher density. On the other hand, the capital cost for the foam sheet line is lower than that for the foam board because of its simpler finishing equipment. Primary application of foam sheet is as a packaging

material in items such as disposable dishes and food containers, trays for meat, poultry and produce products, and egg cartons.

Injection-molded structural foam is used widely for high density items such as picture frames, furniture, appliances, housewares, utensils, toys, pipes, and fittings. Most of these products are produced by injection molding or profile extrusion methods from impact-modified polystyrene. Almost all high density foam products are produced with a chemical blowing agent that releases either nitrogen or carbon dioxide, typically sodium bicarbonate or azodicarbonamides. Medium density products can be produced with either a physical or chemical blowing agent, or a combination of both.

Applications. In residential sheathing insulation, fiber board and oriented strand-board are the most widely used products because of their structural strength and cost. The use of extruded and molded polystyrene foam and of foil-faced isocyanurate foam is increasing, depending on the cost, the amount of insulation required, and compatibility of insulation with other construction systems. In cavity-wall insulation, mineral wool, polyurethane, urea–formaldehyde, and fiber glass are widely used, although fiber glass batt is the most economical insulation for stud-wall construction. In mobile and modular homes, cellular plastics are used widely because of their light weight and more efficient insulation value. The foam density ranges between 23 kg/m^3 (1.4 lb/ft^3) and 40 kg/m^3 (2.5 lb/ft^3) depending on the process and blowing agent used to produce a typical 25-mm (1-in.) sheathing product.

Poly(vinyl chloride). Cellular poly(vinyl chloride) (PVC) foam is available in both flexible and rigid foams. Flexible PVC foams are primarily produced by spread coating and calendering of fluid plastisols by means of a chemical blowing agent or mechanical frothing with air. Flexible PVC foams are also made by the extrusion process. Rigid PVC foams are produced by the extrusion or injection molding processes. Blowing is achieved by a chemical blowing agent or gas injection into the extruder.

Raw Materials. PVC is inherently a hard and brittle material and very sensitive to heat; thus it must be modified with a variety of plasticizers, stabilizers, and other processing aids to form heat-stable flexible or semiflexible products or with lesser amounts of these processing aids for the manufacture of rigid products (see VINYL POLYMERS; VINYL CHLORIDE POLYMERS). Plasticizer levels used to produce the desired softness and flexibility in a finished product vary between 25 parts per hundred (pph) parts of PVC for flooring products to about 80–100 pph for apparel products (248). Numerous Plasticizers (qv) are commercially available for PVC, although dioctyl phthalate (DOP) is by far the most widely used in industrial applications because of its excellent properties and low cost. For example, phosphates provide improved flame resistance, adipate esters enhance low temperature flexibility, polymeric plasticizers such as glycol adipates and azelates improve the migration resistance, and phthalate esters provide compatibility and flexibility (257).

In addition to modifying PVC with plasticizers, it is also necessary to incorporate heat heat stabilizers (qv) into the formulation in order to scavenge the HCl evolved at the processing temperatures, thereby reducing thermal degradation of the polymer. Typical heat stabilizers used for PVC are metallic compounds of barium, cadmium, zinc, lead, and tin; lead and zinc are the most common (257).

Plasticizers containing epoxy linkages such as epoxidized soy bean oil or synergistic compounds such as dibasic lead phthalate and dibasic lead phosphite are also used to enhance heat stability. Non–lead-containing heat stabilizers are currently being developed. Other ingredients such as color pigments and fillers are added to the formulation for the desired coloration and cost reduction, respectively.

There are two principal PVC resins for producing vinyl foams: suspension resin and dispersion resin. The suspension resin is prepared by suspension polymerization with a relatively large particle size in the 30–250-μm range and the dispersion resin is prepared by emulsion polymerization with a fine particle size in the 0.2–2-μm range (257). The latter is used in the manufacture of vinyl plastisols, which can be fused without the application of pressure. In addition, plastisol-blending resins, which are fine-particle-size suspension resins, can be used as a partial replacement for the dispersion resin in a plastisol system to reduce the resin costs.

A very widely used decomposable chemical blowing agent is azodicarbonamide. Its decomposition temperature and rate of evolution of gaseous components are greatly influenced by the stabilizers containing zinc. Lead and cadmium are considered moderate activators for *p*,*p*′-oxybis(benzenesulfonyl hydrazide) (OBSH). OBSH can also be used as a blowing agent for PVC foams.

Process and Equipment.

Flexible Poly(vinyl chloride) Foam. Spread coating is usually carried out by applying a thin coating of plastisol skin coat on a release paper, which is then partially fused in a forced air convection oven in the range of 150°C to facilitate rolling and unrolling of the product. This product passes through the second coating head where a plastisol-containing suitable chemical blowing agent is applied to the plastisol-skin side of the laminate. The fabric is then adhered to the foam plastisol and passed through the final oven at 200–235°C for fusion and foaming. The paper is separated from the vinyl foam and both the paper and the product are taken away by separate winding rolls (257). The optimum oven temperatures depend on the residence time and the type of blowing agent used.

A *calender processing* is also used to produce substantial quantities of vinyl–fabric laminates. Raw materials are first blended in a Banbury mixer operated at either elevated or room temperatures to dissolve the plasticizer into the PVC resin. The blended materials are fluxed into a homogeneous mass of vinyl compound. The material is then discharged to a Banbury mill to cool the batch down. The material can now be fed to an extruder and passed through the various nips between the calender rolls to obtain a sheet of well-controlled gauge. Vinyl foam–fabric, laminates may be produced by combining a vinyl film to be used as the skin layer and a vinyl sheet containing blowing agent with fabric, and activating the blowing agent by passing through a forced air convection oven.

The *chemical expansion method* is most widely used for the manufacture of flexible PVC foam. The three general methods used to produce flexible vinyl foam (258) are (*1*) the pressure molding technique, which consists of the decomposition of the blowing agent and fusion of the plastisol in a mold under pressure at elevated temperatures, cooling the mold, removing the molded part, and post-expansion at some moderate temperature; (*2*) the one-stage atmospheric foaming method in which the blowing agent is decomposed in the hot viscosity range that lies between the gelation and complete fusion of the plastisol; and (*3*) the two-stage atmospheric

foaming method in which the blowing agent is decomposed below the gelation of the plastisol, followed by heating at high temperature to fuse the foamed resin (259).

The *mechanical process* is used to produce low density, open-celled foam by expanding the plastisol before gelation and fusion. The three general methods (258) include the Dennis process (260), elastomer process (261), and the Vanderbilt process (262,263). The Dennis process utilizes a countercurrent adsorption technique by gravity feeding of the liquid plastisol through a packed absorption column under a low pressure (<690 kPa) of carbon dioxide in order to provide the largest surface area for absorption. The chilled plastisol mixture is pumped under pressure through a nozzle or tube and foams as it comes to atmospheric pressure. The wet foam is then gelled (170–182°C) in a conventional oven for thin sections or in a high frequency oven for thick sections.

The elastomer process is very similar to the Dennis process involving a number of steps in which a gas, formerly carbon dioxide and now fluorocarbon, is mixed with a plastisol under pressure. When released to atmospheric pressure, the gas expands the vinyl compounds into a low density, open-cell foam that is then fused with heat.

The Vanderbilt process involves the mechanical frothing of air into a plastisol containing proprietary surfactants by means of an Oakes foamer or a Hobart-type batch whip. The resulting stable froth is spread or molded in its final form, then gelled and fused under controlled heat. The fused product is open-celled with fine cell size and density as low as 160 kg/m^3 (10 lb/ft^3).

Rigid Poly(vinyl chloride) Foam. The techniques that have been used to produce rigid vinyl foams are similar to those for the manufacture of flexible PVC foams. The two processes that have reached commercial importance for the manufacture of rigid vinyl foams (258) are the Dynamit–Nobel extrusion process and the Kleber–Colombes Polyplastique process for producing cross-linked grafted PVC foams from isocyanate-modified PVC in a two-stage molding process.

The Dynamit–Nobel extrusion process (264) utilizes a volatile plasticizer such as acetone that is injected into the decompression section of a two-stage screw and is uniformly dispersed in the vinyl resin containing a stabilizer. The resulting PVC foam has low density and closed cells.

The Kleber–Colombes rigid PVC foam (265,266) is produced by compression molding vinyl plastisol to react and gel the compound, followed by steam expansion. The process involves mixing, molding, and expansion. The formulation consists of PVC, isocyanate, vinyl monomers such as styrene, anhydrides such as maleic anhydride, polymerization initiators, FC-11, and nucleators. The ingredients are mixed in a Werner–Pfleiderer or a Baker Perkins type of mixer, and the resulting plastisol is molded under pressure. The initial temperature of the molds is 100–110°C, which increases to 180–200°C because of exothermic polymerization of the vinyl monomers and anhydride. The mold is cooled and the partially expanded PVC is removed and then further expanded by steam. After the water treatment, the foam is thermoset with a closed-celled structure and a relatively low thermal conductivity.

Applications. Flexible cellular poly(vinyl chloride) was developed as a comfort-cushioning material with compression–deflection behavior similar to latex rubber foam, and with the added feature of flame retardancy (37). It has a

larger compression set than either latex rubber or polyurethane foams. The fact that the plasticizer in flexible vinyl foams can migrate to the surface restricts flexible vinyl foams in some applications. Furniture and motor vehicle upholstery is the largest market for flexible vinyl foams. Because of better aesthetics (leather-like plastics), comfort, and favorable pricing, they are expected to show good growth in upholstery, carpet backing, resilient floor coverings, outerwear, footwear, luggage, and handbags. The only application for flexible vinyl foams in protective packaging applications is for stretch pallet wraps. These wraps are produced by extrusion.

Rigid vinyl foams in construction markets have grown substantially as a result of improved techniques to manufacture articles with controlled densities and smooth outer surfaces. Wood molding substitute for door frames and other wood products is an area that has grown. Rigid vinyl foams are also used in the manufacture of pipes and wires as resin extenders and in sidings and windows as the replacement of wood or wood substitutes.

Economics. The price of rubber-modified flexible PVC foam ranges between about \$2.00 and \$3.00 per board foot (\$800–1200/m^3) and that of unmodified, plasticized PVC foam is about \$0.70 and \$2.50 per board foot (\$300–\$1000/m^3) depending on the volume, thickness, and density of the product.

Polyolefins.

Polyethylene. There are three basic types of polyethylene foams of importance: (*1*) extruded foams from low density polyethylene (LPDE); (*2*) foam products from high density polyethylene (HDPE); and (*3*) cross-linked polyethylene foams. Other polyolefin foams have an insignificant volume as compared to polyethylene foams and most of their uses are as resin extenders.

Extruded low density foam produced from LDPE is a tough, flexible, and resilient closed-celled foam used in a wide variety of applications such as cushion packaging and safety components. The resiliency of this product gives excellent energy absorption so important in cushion packaging, athletic pads, flotation devices, and occupant safety applications. Unlike other resilient products, uniform energy absorption can be achieved with low density polyethylene foam over an extremely wide temperature range from −54 to 71°C. The closed-celled nature of this product leads to negligible water pickup. This is important in military packaging where outdoor tropical storage or shipments in high humidity ship holds is common or where freeze–thaw arctic storage conditions are encountered. These products are produced primarily with, isobutane and a selective permeability modifer, glycerol monostearate. The permeability modifier plays a unique role in achieving the dimensional stability of the flexible low density polyethylene foam over the wide range of temperatures because of its ability to closely match the permeability through LDPE of isobutane with that of air (267).

HDPE foam is primarily used as a high density rigid product. Shipping pallets are a rapidly growing market, at a projected growth rate of about 26% per year for the mid-1990s. Most of these products are produced by thermoforming sheet and injection molding.

Cross-linked polyethylene foams are produced by either radiation or chemical cross-linking of an extruded expandable sheet containing a chemical blowing agent. The cross-linked expandable sheet is subsequently passed over a molten

salt bath or passed through hot-air ovens. This process is somewhat complicated, expensive, and limited to the thin products in the continuous process but thicker foams can be produced in a more complicated batch process. A batch molding process utilizing expandable beads is also used to produce thicker foams. These products can be produced in a wide range of densities and thicknesses, with fine cell size, having more flexibility, higher resiliency, and better thermoforming capability than the extruded foam products from LDPE. These products also have finer texture and a softer, more resilient feel than extruded low density polyethylene foams and are used in comfort, cushioning and cushion-packaging applications.

Kanegafuchi Chemical of Japan has introduced a chemical cross-linking process for producing PE foams by the bead technique similar to EPS. These beads have been used to produce molded articles as cushioning materials, sound insulating panels, etc. Asahi-Dow and BASF have also been reported to have developed similar products.

Polypropylene. Recently the successful production of polypropylene foam plank of large crosssections has been accomplished by the Dow Chemical Co. by using a die that creates a foam product consisting of a plurality of coalesced strands or profiles (268). Among other uses, this unique structural olefinic foam STANDFOAM EA (trademark of The Dow Chemical Co.) has been successfully applied in automotive energy absorption applications (269).

Health and Safety

Flammability. Plastic foams are organic in nature and, therefore, are combustible. They vary in their response to small sources of ignition because of composition and/or additives (268). All plastic foams should be handled, transported, and used according to manufacturers' recommendations as well as applicable local and national codes and regulations.

Among the blowing agents, hydrocarbons and some of the HCFCs and HFCs are flammable and pose a fire hazard in handling at the manufacturing plants.

Atmospheric Emissions. Certain organic compounds are found to be smog-generating substances because of their high photochemical reactivity at ambient conditions. Examples include hydrocarbon, ethanol, and ethyl chloride. Since fully or partially halogenated hydrocarbons, HCFCs and HFCs, are considered to have low reactivity in the lower atmosphere (troposphere), substitution of photochemically reactive compounds for the current blowing agents may reduce ozone depletion in the stratosphere, but may have unacceptable global warming potentials (GWP). Therefore, the blowing agent interaction with the total environment needs to be considered in developing environmentally acceptable alternative blowing agents (46).

Toxicity. The products of combustion have been studied for a number of plastic foams (270). As with other organics the primary products of combustion are most often carbon monoxide and carbon dioxide, with smaller amounts of many other species, depending on product composition and test conditions.

The presence of additives or unreacted monomers in certain plastic foams can limit their use where food or human contact is anticipated. Heavy metals

can also be found in various additives. The manufacturers' recommendations or existing regulations again should be followed for such applications.

CELLULOSE ETHERS

General Considerations

Alkylation of cellulose yields a class of polymers generally termed cellulose ethers. Most of the commercially important ethers are water-soluble and are key adjuvants in many water-based formulations. The most important property these polymers provide to formulations is rheology control, ie, thickening and modulation of flow behavior. Other useful properties include water-binding (absorbency, retention), colloid and suspension stabilization, film formation, lubrication, and gelation. As a result of these properties, cellulose ethers have permeated a broad range of industries including foods, coatings, oil recovery, cosmetics, personal care products, pharmaceuticals, adhesives, printing, ceramics, textiles, building materials, paper, and agriculture.

Total U.S. and worldwide consumption of purified and crude grades of cellulose ethers in 2000 was estimated at 82,500 and 371,000 t, respectively (1). The value of the world market for cellulose ethers was nearly $2.0 billion in 2000, with a projected average annual global growth rate of 2.3% between 2000 and 2005. The consumption in 2000 was approximately 83,000 t in the United States, 180,000 t in Western Europe, 26,000 t in Japan, and 82,000 t in the rest of the world. Prices for the principal products range from about $1.43/kg for crude grades of sodium carboxymethylcellulose to over $19.21/kg for purified grades of ethylcellulose.

Although many cellulose ether compositions have been synthesized since the early 1900s, only a few have gained commercial importance. Cellulose ethers first appeared in the literature in 1905 (2). By 1912, cellulose ethers compositions were patented (3–5). By the mid-1930s, methyl-, ethyl-, and benzylcelluloses were commercially available (6,7). These compositions were soluble in organic solvents.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

Water-soluble cellulose ether compositions grew rapidly through the 1950s and 1960s, and today far exceed commercial value over organic-solvent-soluble compositions. The highest volume cellulose ethers, the industry workhorses, are sodium carboxymethylcellulose, hydroxyethylcellulose, and hydroxypropylmethylcellulose. Cellulose ethers as a class compete with a host of other materials including natural gums, starches, proteins, synthetic polymers, and even inorganic clays. They provide effective performance at reasonable cost and are derived from a renewable, natural resource.

Cellulose ethers are manufactured by reaction of purified cellulose with alkylating reagents under heterogeneous conditions, usually in the presence of a base, typically sodium hydroxide, and an inert diluent. Cottonseed linter fiber and wood fiber are the principal sources for cellulose. Purified cellulose cotton linters, commonly termed chemical cottons, are generally of higher purity and higher maximum molecular weight than purified cellulose from dissolving grades of wood pulp. The base, in combination with water, activates the cellulose matrix by disrupting hydrogen-bonded crystalline domains, thereby increasing accessibility to the alkylating reagent. This activated matrix is commonly termed alkali cellulose (8–12). Other reagents may be used in combination with sodium hydroxide, such as ammonia, surfactants, phase transfer agents, or enzymes, to promote formation of a more uniformly activated cellulose matrix (13–21). The base also promotes the etherification reaction. The several purposes of the inert diluent are to suspend/disperse the cellulose, provide heat transfer, moderate reaction kinetics, and facilitate recovery of the product. The diluent may also help to distribute reagents among fibers to promote a uniform reaction (22). Crude grades of cellulose ethers, most notably sodium carboxymethylcellulose, may be made in the absence of any diluent. Reactions are typically conducted at elevated temperature, ∼50–140°C, and under nitrogen to inhibit oxidative molecular weight degradation of the polymer (23,24), if so desired. After reaction, crude grades are simply dried, ground, and packed out; purified grades require removal of by-products in a separate operation prior to drying. Various additives, such as colloidal silicas, may be added in small amounts to some products prior to drying or before packout to improve dry handling properties. Instead of dry powders, cellulose ethers are also supplied in liquid forms, either as fluidized suspensions or water solutions (25–27). In addition to these unit operations, schematically outlined in Figure 1, a molecular

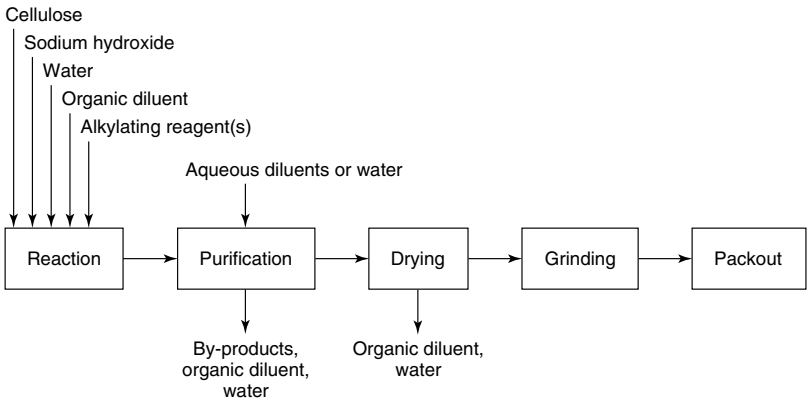

Fig. 1. Unit operations for the manufacture of purified cellulose ethers.

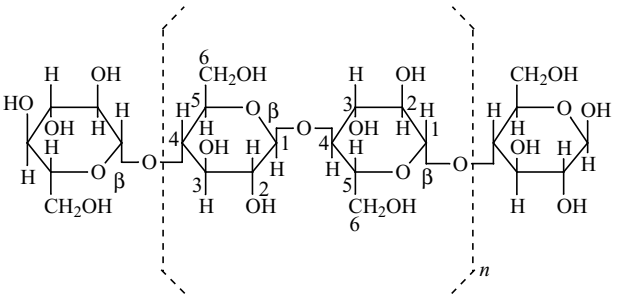
weight reduction operation may be included in the process at any of several points, most notably either in the reaction vessel (before, during, or after the alkylation reaction), after purification before drying, or treatment of dry material (28–30). Hydrogen peroxide is commonly used, though deliberate degradation may also be induced through controlled alkaline-catalyzed autoxidation with oxygen (air) in the reactor. Acids can also be used to cleave the cellulose chain (31,32).

An important characterization parameter for cellulose ethers, in addition to the chemical nature of the substituent, is the extent of substitution. As the Haworth representation of the cellulose polymer shows, it is a linear, unbranched polysaccharide composed of glucopyranose (anhydroglucose) monosaccharide units linked through their 1,4 positions by the β anomeric configuration.



The structurally similar starch amylose polymer is linked through the α anomeric configuration. The three hydroxyl functions per anhydroglucose unit are noteworthy; these hydroxyls are the active sites for ether formation.

The extent of substitution is described as the *degree of substitution* (DS), defined as the average number of hydroxyl groups substituted per anhydroglucose unit. Excluding the terminal residues, each anhydroglucose moiety has three available hydroxyl groups for a maximum DS value of 3. In certain cases the alkylating reagent, such as an alkylene oxide, generates a new hydroxyl group upon reacting which can then further react to give oligomeric chains. The product is then characterized by its *molar substitution* (MS), the moles of reagent combined per mole of anhydroglucose unit. The ratio of MS to DS is a measure of the average chain length of the oligomeric side chains. Organo-soluble ethylcellulose has a DS of 2.3–2.8. Most water-soluble derivatives have DS values of 0.4–2.0. Hydroxyalkyl ethers have MS values typically between 1.5 and 4.0.

MS and DS values are average values, placing no significance on the formal distribution of the substituents within or among polymer chains. Substituent distribution, however, is an important molecular parameter affecting solution rheology and ultimately end use properties. A classic example is offered by sodium carboxymethylcellulose (33). Depending on reaction conditions, sodium carboxymethylcellulose (CMC) of DS ~0.80 can be made to exhibit a varying degree of solution thixotropy, the effect being dependent not so much on DS but rather on the distribution of substituents.

Thixotropic solutions are characterized by a decrease in viscosity on shearing, followed by a time-dependent increase after the shear stress is removed. A plot of shear rate versus shear stress reveals a hysteresis loop. Association among

polymer chains via electrostatic, hydrogen-bonding, or hydrophobic effects can lead to thixotropy. Carboxymethyl substituent uniformity along the polymer chain affects thixotropic behavior of CMC because regions of contiguous unsubstituted anhydroglucose units, ie, blocks, among polymer chains tend to associate through hydrogen bonding (34). The extent of blockiness is controlled by reaction conditions (34,35). Solution thixotropy is important in applications requiring suspension or stabilization of particulates.

As substituent uniformity is increased, either by choosing appropriate reaction conditions or by reaction to high degrees of substitution, thixotropic behavior decreases. CMCs of DS $\geqslant$ 1.0 generally exhibit pseudoplastic rather than thixotropic rheology. Pseudoplastic solutions also decrease in viscosity under shear but recover instantaneously after the shear stress is removed. A plot of shear rate versus shear stress does not show a hysteresis loop.

Other examples illustrating the effect of substituent distribution on properties include (*1*) enzymatic stability of hydroxyethylcellulose (HEC) (36,37), (*2*) salt compatibility of carboxymethylcellulose (38,39), and (*3*) thermal gelation properties of methylcellulose (40). The enzymatic stability of HEC is an example where the actual position of the substituents within the anhydroglucose units is considered important. Increasing substitution at the C-2 position promotes better resistance toward enzymatic cleavage of the polymer chain. Positional distribution is also a factor in the other two examples.

^{13}C NMR is one method used for the compositional and structural characterization of cellulose ethers (41–47). Other structural characterization methods are based on various chromatographic techniques (48–51). The results show that the reactivity of the three hydroxyl groups can vary significantly depending on the alkylating reagent, the type of reaction, and reaction conditions. For most cellulose ethers, substitution occurs primarily at the C-2 and C-6 hydroxyl groups (51–53).

Aside from the chemical nature of the substituent and its DS (MS) and distribution, solution viscosity, ie, polymer molecular weight, is another important characterization parameter. Generally, manufacturers supply cellulose ethers in different viscosity grades, made by choosing a cellulose furnish of appropriate molecular weight, blending celluloses of different molecular weights or by reducing the molecular weight during processing (9–11). Most manufacturers specify solution viscosity data and not polymer molecular weight in their technical literature; however, molecular weight can be estimated from the classical Mark–Houwink equation:

$$[\eta] = KM^a$$

where $[\eta]$ is intrinsic viscosity, K and a are empirically derived constants, and M is the viscosity-average molecular weight, which approximates the weight-average molecular weight, or the degree of polymerization (DP). Values of K and a for various cellulose ethers are available (54,55,123). Mark–Houwink equations for CMC and HEC in 0.02 M KH_2PO_4, pH 5.5, are given below.

$$\text{CMC: } [\eta] = 1.95 \times 10^{-2}[\text{DP}_\text{W}]^{0.83} \text{ (Ref. 54)}$$

$$\text{HEC: } [\eta] = 6.70 \times 10^{-3}[\text{DP}_\text{W}]^{0.92} \text{ (Ref. 55)}$$

Molecular weight from solution viscosity measurements represents an average value of polymer chain lengths. The distribution of chain lengths making up a polymer fraction is commonly termed molecular weight distribution (MWD), a parameter that can influence performance properties, particularly mechanical properties of films. Size exclusion chromatography (SEC), also termed gel-permeation chromatography (GPC), has been the classical method for determining MWD. However, the lack of suitable columns hindered development of aqueous SEC methods for water-soluble polymers until the 1980s. Now, because of the development of high performance packings and columns, the MWD of water-soluble cellulose ethers is a measurable parameter (56–59).

Many cellulose ethers contain mixed substituents (cellulose mixed ethers) in order to enhance or modify the properties of the monosubstituted derivative. For example, incorporation of low levels of hydroxypropyl or hydroxyethyl groups into methylcellulose increases its thermal gelation and flocculation temperatures in aqueous media. Carboxymethylation of hydroxyethylcellulose produces a product having excellent tolerance to mono- and divalent metal ions in solution but which readily cross-links with tri- or tetravalent ions to give highly viscoelastic gels. The solubility of ethylcellulose in organic aliphatic solvents is improved by incorporating hydroxyethyl moieties. The newest commercial cellulose ether composition that has gained considerable importance in the marketplace is a mixed ether, HEC modified with hydrophobic long-chain hydrocarbyl groups (60–62). The hydrophobic groups promote polymer chain association in solution, drastically altering rheology and surface activity properties.

Health and Safety Factors. No adverse toxicological or environmental factors are reported for cellulose ethers in general (33,60–73). Some are even approved as direct food additives, including purified carboxymethylcellulose, methylcellulose, hydroxypropylmethylcellulose, and hydroxypropylcellulose.

The only known hazard associated with cellulose ethers is that they may form flammable dusts when finely divided and suspended in air, a hazard associated with most organic substances. An explosion may result if suspended dust contacts an ignition source. Cloud and layer ignition temperatures generally vary between 290 and 410°C (74). Critical airborne concentrations vary depending on particle size. This hazard can be minimized largely through good housekeeping and proper design and operation of handling equipment.

Another minor hazard is that water-soluble cellulose ether powders form a slippery surface when wet; therefore, spills should be cleaned promptly to avoid slipping accidents.

Commercial Cellulose Ethers

Sodium Carboxymethylcellulose.

Properties. Sodium carboxymethylcellulose [9004-32-4] (CMC), also known as cellulose gum, is an anionic, water-soluble cellulose ether available in a wide range of substitution. The most widely used types are in the 0.7–1.2 DS range. Water solubility is achieved as the DS approaches 0.6; as the DS increases, solubility increases. The rate at which CMC dissolves depends primarily on its particle size. Finely ground material dissolves faster than coarser grades. The coarse material,

however, does not agglomerate as readily when added to water and is therefore easier to disperse. The rate of dissolution also increases with increasing substitution and decreasing molecular weight, ie, viscosity. High molecular weight grades of CMC have viscosities as high as 12,000 mPa·s (=cP) at 1% solids (as recorded on a Brookfield LVT Viscometer at 30 rpm). Lower molecular weight CMCs have viscosities in water as low as 50 mPa·s (=cP) at 4% solids.

CMC is soluble in hot and cold water. Solutions may be pseudoplastic or thixotropic depending on molecular weight, DS, and manufacturing process. High molecular weight, low DS CMCs tend to be more thixotropic. Solutions are viscosity stable at ambient temperature over a wide range of pH. In general, maximum solution viscosity and best stability are obtained at pH 7–9. Above pH 10, a slight viscosity decrease is observed. As pH is lowered below 4, viscosity may first increase and then decrease as intermolecular associations among free acid groups start affecting solubility. CMC is not soluble in organic solvents, but dissolves in mixtures of water and water-miscible solvents such as ethanol or acetone. Low viscosity CMCs are more tolerant of higher levels of organic solvents.

Monovalent cations are compatible with CMC and have little effect on solution properties when added in moderate amounts. An exception is silver ion, which precipitates CMC. Divalent cations show borderline behavior and trivalent cations form insoluble salts or gels. The effects vary with the specific cation and counterion, pH, DS, and manner in which the CMC and salt are brought into contact. High DS (0.9–1.2) CMCs are more tolerant of monovalent salts than lower DS types, and CMC in solution tolerates higher quantities of added salt than dry CMC added to a brine solution.

CMC is compatible with most water-soluble nonionic gums over a wide range of concentrations. When a solution of CMC is blended with a solution of a nonionic polymer such as hydroxyethylcellulose or hydroxypropylcellulose, a synergistic effect on viscosity is usually observed. Such blends produce solution viscosities considerably higher than would ordinarily be expected. This effect is reduced if other electrolytes are present in the system.

Some typical properties of commercial CMCs are given in Table 1.

Manufacture. Common to all manufacturing processes for CMC is the reaction of sodium chloroacetate [3926-62-3] with alkali cellulose complex represented here as R_{cell} OH:NaOH:

$$R_{cell}\ OH + NaOH + H_2O \rightarrow R_{cell}\ OH : NaOH$$

$$R_{cell} : OH + ClCH_2COO^-Na^+ \longrightarrow \underset{\text{Sodium corboxymethyle cellulose}}{R_{cell}\ OCH_2COO^-Na^+} + NaCl + H_2O$$

A by-product is sodium glycolate: [2836-32-0] (sodium hydroxyacetate):

$$ClCH_2COO^-Na^+ + NaOH \rightarrow HOCH_2COO^-Na^+ + NaCl$$

Generally, monochloroacetic acid [79-11-8] (MCA) is added to the reaction slurry containing sufficient excess sodium hydroxide to neutralize the MCA and effect its reaction. The use of esters of MCA has also been reported (75,76). Common

reaction diluents are isopropyl alcohol, *t*-butyl alcohol, or ethyl alcohol (77,78). Dimethoxyethane has also been reported to be effective (79). The product is isolated and washed with aqueous alcohol or acetone to remove by-product salts. Unpurified crude grades are generally prepared in the absence of diluents (80–82).

Economic Aspects. Sodium carboxymethylcellulose remains the most important of the water-soluble compositions; worldwide consumption for 200 is estimated at 179,000 t (Table 2). The projected annual growth rate from 2000 to 2005 is nominal at 1.6% globally. A declining growth rate of 3% is expected in Japan over this period, but this rate is counteracted by a projected 3% growth rate expected in the rest of the world over this same time period, excluding the United States and Western Europe.

CMC consumption declined in detergent applications, but this decline was counteracted by its increased consumption in oil and gas well drilling and its continued growth in the paper segment.

Table 2. World Supply and Demand for CMC,[a] 10^3 t

Region	Capacity[b]	Production	Consumption	Imports	Exports
United States	25.9	16.7	32.3	20.3	4.7
Western Europe	195	148	91.5	2.1	58.6
Japan	44.1	22	14.4	0.3	7.9
Canada, Latin America,[c] Asia and Others	48	NA	14.4	NA	NA
Total	*313*	*186.7*	*179.4*		

[a]In 2000 (1).
[b]Crude and purified grades expressed as 100% CMC.
[c]Mexico and Latin America account for 60% of this capacity.

In the United States, the Aqualon Division of Hercules Inc., is the largest producer, followed by Penn Carbose, Inc., and MAK Chemical Crop. Western Europe has about eight companies manufacturing CMC; the six largest are Noviant if Finland, Sweden, and the Netherlands, Akzo Nobel in Italy and the Netherlands, Aqualon Division of Hercules Inc. in France, Lamberti in Italy, and Micro Technik, Clhariant, and Wolff in Germany. Competitive pressure has precipitated mergers, acquisitions, and rationalization of CMC production facilities, leading to closure of older facilities producing technical grades and favoring modernization and capacity expansion for higher value, purified CMC products.

Noviant, previously Metsa Serla, acquired by J. M. Huber in 2001, is now the world's leading, producer, developer, and distributor of CMC, with about 33% of the world's CMC market.

Among the six CMC producers in Japan, Dai-ichi Kogyo Seiyaku Co., Ltd., Daicel Chemical Industries Ltd., and Nippon Paper Industries Co., Ltd. are the three largest. As seen in Western Europe, production of purified and semipurified grades has been increasing since 1980, reaching 87% of total production in 2000, while technical grade CMC is in a declining trend. The decline in technical grade CMC in Japan is tied to the stagnant construction industry.

In Mexico and South America, the main CMC producers are Quimica Amtex S.A., Latinoquimica S.A., and Celuflok Celuloses e Amidos Ltda, where food/purified, technical, and semipurified grades of CMC are produced.

There are at least nine CMC plants in China. Shanghai Cellulose is among the largest of these producers. The largest CMC producer in Korea is Korean Ginseng Products Co., Ltd. (KOJE). Indonesia and Thailand are among the ASEAN (Association of Southeast Asia Nations) countries producing CMC, with Risjad Brasali Chemindo PT producing purified CMC in Indonesia and Thai Cellulose Products Co., Ltd. producing CMC in Thailand.

Specifications and Standards; Test Methods. *Certain types of purified sodium* carboxymethylcellulose meet standards set by the *U.S. Code of Federal Regulations* (CFR) Title 21, Section 182.1745, substances that are generally recognized as safe (GRAS). The FDA defines the direct food additive as the sodium salt of CMC, not less than 99.5% on a dry weight basis, with a maximum substitution of 0.95 carboxymethyl groups per anhydroglucose unit, and with a minimum viscosity of 25 mPa·s (=cP) in a 2% (by weight) aqueous solution at 25°C. Food-grade cellulose gum meets these requirements. Cellulose gum may also be certified Kosher.

CMC is discloced on European food and cosmetic labels is "sodium carboxymethylcellulose." This nomenclature has caused consumer concerns through association of the name with synthetic additives. There is a proposal to allow CMC to be identified as "cellulose gum" or an equivalent name, with the expectation of increasing CMC consumption in European food and personal care product segments.

Sodium carboxymethylcellulose is listed in the current *U.S. Pharmacopoeia*. Its therapeutic applications include use of sodium carboxymethylcellulose as the primary ingredient in bulk-forming laxatives. Excipient uses include use as a suspension aid, a rheology modifier, and as a tablet binder.

Sodium carboxymethylcellulose 12 (DS 1.15–1.45 minimum) is listed in the *National Formulary* (*NF XX*) for use as a pharmaceutical aid, with similar excipient uses listed.

Table 3. Applications for CMC[a]

Industry	Application	Function
Foods	Frozen desserts	Inhibit ice crystal growth
	Dessert toppings	Thickener
	Beverages, syrups	Thickener, mouthfeel
	Baked goods	Water-binder, batter viscosifier
	Pet food	Water-binder, thickener, extrusion aid
Pharmaceuticals	Tablets	Binder, granulation aid
	Bulk laxatives	Water-binder
	Ointments, lotions	Stabilizer, thickener, film-former
Cosmetics	Toothpaste	Thickener, suspension aid
	Denture adhesives	Adhesion promoter
	Gelled products	Gellant, film-former
Paper products	Internal additive	Binder, improve dry-strength
	Coatings, sizes	Water-binder, thickener
Adhesives	Wallpaper paste	Adhesion promoter, water-binder
	Corrugating	Thickener, water-binder, suspension aid
	Tobacco	Binder, film-former
Lithography	Fountain, gumming	Hydrophilic protective film
Ceramics	Glazes, slips	Binder (promotes green strength)
	Welding rods	Binder, thickener, lubricant
Detergents	Laundry	Soil anti-re-deposition aid
Textiles	Warp sizing	Film-former, adhesion promoter
	Printing paste, dye	Thickener, water-binder

[a]Ref. 33.

Cellulose gum is the accepted term used bt the Cosmetic, Toiletry, and Fragrance Asociation, Inc., for sodium carboxymethylcellulose, and it is listed as such in the Association's *CTFA International Cosmetic Ingredient Dictionary*.

Procedures for the analysis of CMC are available in manufacturers' bulletins (33).

Uses. CMC is an extremely versatile polymer, and it has a variety of applications. A sampling of significant applications is given in Table 3. A more extensive listing can be found in Reference 33.

Hydroxyethylcellulose.

Properties. Hydroxyethylcellulose [9004-62-0] (HEC) is a nonionic polymer. Low hydroxyethyl substitutions (MS = 0.05–0.5) yield products that are soluble only in aqueous alkali. Higher substitutions (MS $\geqslant$ 1.5) produce water-soluble HEC. The bulk of commercial HEC falls into the latter category. Water-soluble HEC is widely used because of its broad compatibility with cations and the lack of a solution gel or precipitation point in water up to the boiling point. The MS of commercial HEC varies from about 1.8 to 3.5. The products are soluble in hot and cold water but insoluble in hydrocarbon solvents. HEC swells or becomes partly to mostly soluble in select polar solvents, usually those that are miscible with water.

Commercially, HEC is available in a wide range of viscosity grades, ranging from greater than 500 mPa·s (=cP) at 1% solids to less than 100 mPa·s (=cP) at 5% total solids. Because HEC is nonionic, it can be dissolved in many salt solutions that do not dissolve other water-soluble polymers. It is soluble in most 10% salt solutions and in many 50% (or saturated) salt solutions such as sodium

chloride and aluminum nitrate. As a rule, the lower substitution grades are more salt-tolerant.

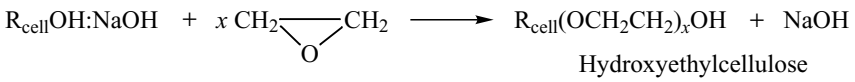
HEC is soluble in both hot and cold water; however, as with most water-soluble thickeners, the particles have a tendency to agglomerate, or lump, when first wetted with water. This is especially evident when the HEC is added to water with poor agitation. Manufacturers have eliminated the problem of lumping and slow dissolving by surface treating the particles, most commonly with glyoxal [107-22-2] (83–86). When added to water, the particles completely disperse. After an initial induction period, commonly termed the delayed hydration time, the dispersed particles begin to dissolve, producing smooth, lump-free solutions. The delayed hydration time can be increased or decreased by lowering or raising, respectively, the pH. Most manufacturers supply dispersible grades.

Solutions of HEC are pseudoplastic. Newtonian rheology is approached by very dilute solutions as well as by lower molecular weight products. Viscosities change little between pH 2 and 12, but are affected by acid hydrolysis or alkaline oxidation under pH and temperature extremes. Viscosities of HEC solutions change reversibly with temperature, increasing when cooled and decreasing when warmed.

HEC is generally compatible with other cellulosic water-soluble polymers to give clear, homogeneous solutions. When mixed with an anionic polymer such as CMC, however, interactions between the two polymers may result in synergistic behavior, ie, viscosities higher than predicted and calculated. HEC has excellent compatibility with natural gums.

Some typical properties of HEC are given in Table 4.

Manufacture. Purified HEC is manufactured in diluent-mediated processes similar to those used to produce CMC, except ethylene oxide [75-21-8] is used in place of MCA (87,88):



A competing reaction that consumes ethylene oxide is hydrolysis to ethylene glycol and oligomeric glycol by-products.

$$HO(CH_2CH_2O)_x^- Na^+ + H_2O \rightarrow HO(CH_2CH_2O)_xH + NaOH$$

Because of the low boiling point of ethylene oxide, reactions are generally conducted in stirred autoclaves at elevated pressures. Staged addition of caustic and ethylene oxide leads to a more uniformly substituted HEC product that is more resistant to molecular weight degradation by enzymes (89–91).

Several other modifications of HEC have been more recently reported in the literature that may find commerical utility in the future. These include modification with allyl (92), sulfoalkyl (93,94), and silyl (95) functional groups.

	Creams, lotions	Thickener, stabilizer
Ceramics	Welding rods	Water-binder, extrusion aid
	Glazes	Water-binder (promotes green strength)

[a]Ref. 63.

Specifications and Standards; Test Methods. Although HEC is not the subject of a direct-food-additive regulation, it is included in the list of materials that are in compliance with requirements of the U.S. FDA for use in adhesives and in resinous and polymeric coatings employed on the food-contact surfaces of metal, paper, or paperboard articles, and other substrates intended for use in food packaging as specified in the U.S. CFR, Title 21, subject to the limitations and requirements of each application. HEC made dispersible by cross-linking with glyoxal is cleared only as an adhesive and as a component of paper and paperboard in contact with food. It has not been cleared as a direct food additive.

Specific grades of HEC are approved for oral and topical pharmaceutical applications as an inert ingredient. These grades of HEC meet or exceed all the requirements of the current editions of the *European Pharmacopoeia* and/or the *National Formulary* (*NF XX*).

Procedures for determing ash, moisture, solution preperation, and viscosity measurements can be found in manufactures product bulletins (63,64) and in ASTM D2364-01 (96), and in the European pharmacopoeia and/or the National Formulary (NFXX).

Uses. HEC is used as a thickener and rheology control agent, protective colloid, binder, stabilizer, suspension aid, sustained-release polymer, and a film-former in aqueous film coating. A guide to the principal uses is given in Table 6.

Mixed Ether Derivatives of HEC. Several chemical modifications of HEC are commercially available. The secondary substituent is generally of low DS (or MS), and its function is to impart a desirable property lacking in HEC.

Carboxymethylhydroxyethylcellulose (CMHEC). This is an anionic modification of HEC manufactured by Aqualon Co. Sodium carboxymethylhydroxyethylcellulose [9088-04-4] is manufactured by reaction of alkali cellulose either simultaneously or sequentially with ethylene oxide and sodium chloroacetate. Various grades, with carboxymethyl DS, CM(DS), of 0.3–0.5 and hydroxyethyl MS, HE(MS), of 0.7–2.0, are available. CMHEC has properties of both HEC and CMC. It is more compatible with salts than CMC because of the presence of nonionic hydroxyethyl groups. In saturated NaCl, only CMC with a CM(DS) $\geq$ 1.0 is completely soluble. CMHEC, on the other hand, is soluble with a CM(DS) as low as 0.3.

Table 7. Typical Properties of Mixed Ether Derivatives of HEC[a]

Property	CMHEC	Cationic HEC	EHEC	HMHEC

[e]MIT double folds.

CMHEC is also very tolerant of Ca^{2+} and consequently readily dissolves in seawater. Unlike HEC, CMHEC in solution may be cross-linked with trivalent cations such as Fe^{3+} and Al^{3+} to give greatly increased viscosity or three-dimensional viscoelastic gels (97).

CMHEC products are used predominantly in oil recovery applications. The high water binding capability, salt compatibility, and adsorption to clay and mineral surfaces give CMHEC ethers excellent control over high salinity fluids (98,99). Water loss in cement slurries is also reduced (100). CMHEC is also used in hydraulic fracturing fluids. Gels formed by cross-linking with multivalent cations can suspend and transport proppants into a well bore and then fracture (97,101). Some typical properties of CMHEC having a CM(DS) ∼0.3 and HE(MS) ∼0.7 are listed in Table 7.

Cationic Hydroxyethylcelluloses. These materials are primarily manufactured by Union Carbide, a subsidiary of Dow Chemical Company, and by National Starch & Chemical, a member of the ICI Group, marketed under the trade names UCARE Polymers and Celquats, respectively (70,71). The cationic substituent on the UCARE Polymer series and the Celquat SC series is 2-hydroxypropyltrimethylammonium chloride. Polyquaternium-10 is the International Nomenclature Cosmetic Ingredient (INCI) name assigned to these materials by the International Nomenclature Committee of the Cosmetic Toiletry & Fragrance Association (CTFA). National Starch & Chemical also manufactures another product under the trade-names Celquat H-100 and Celquat L-200. These materials are the reaction product of HEC with *N*,*N*-diallyl-*N*,*N*-dimethylammonium chloride. Polyquaternium-4 is the INCI name assigned to these materials.

All of these cationic polymers are substantive to the skin and hair, providing conditioning to both substrates through a combination of several mechanisms, including formation of films on these substrates that reduce moisture loss, through

repair of hair protein, and by providing antistat properties to hair. The structure of the cationic functionality, its DS (or MS), and the molecular weight of the HEC backbone affect product performance across the pH range of interest (pH 5–7). These same structural and physical characteristics affect the compatibility of these polymers with surfactants used in various shampoo, conditioner, skin cleansing, and moisturizing formulations (103). Some typical properties of Celquat resins are given in Table 7.

Hydrophobic Hydroxyethylcelluloses. These materials are produced by stepwise or simultaneous reaction of ethylene oxide and a hydrophobic alkylating reagent. Commercial products include ethylhydroxyethylcellulose [9004-58-9] (EHEC), manufactured by Akzo Nobel Berol Kemi AB under the Bermocoll trade name (72), and HEC modified with a long-chain alkyl group, generically termed HMHEC (where HM = hydrophobically modified), manufactured by the Aqualon Division of Hercules Inc. and sold under the trade name Natrosol Plus (62). These products are water-soluble.

Water-soluble EHEC is a moderate ethyl DS (∼1.0) modification of high hydroxyethyl MS (≥ 2.0) HEC. Ethyl groups lower the surface and interfacial tensions, thereby increasing surface activity. This group also modifies adsorption properties of the polymer to particulates found in many formulations such as clays, pigments, and latices. Aqueous solutions have pseudoplastic rheology. High viscosity grades are more pseudoplastic than low viscosity materials, which approach Newtonian flow behavior. Viscosities decrease reversibly with increasing temperature. Above 65°C, EHEC precipitates from solution. Salts lower the temperature at which precipitation occurs. Solution viscosities are insensitive to pH between about 3 and 11. Aqueous solutions are miscible with lower alcohols, glycols, and ketones up to equal proportions. Water-soluble EHECs are used to thicken and stabilize a variety of materials, including waterborne paints, plasters, detergents, cosmetics, and pharmaceuticals (72).

HMHEC is a modification with low levels of much longer hydrocarbon chains (hydrophobes) that not only increase surface activity but also impart associative behavior to HEC; this produces dramatic effects on solution viscosity and rheology (60,104,107). For example, an HEC with a 2% solution viscosity of 10 mPa·s (=cP) modified with ∼2.5 wt% of a C_{14}-chain hydrocarbyl moiety has a viscosity of 800 mPa·s (=cP). The effect has been attributed to micellar aggregation of the hydrophobic groups in solution (37–39). The solubility and rheological properties of HMHEC depend primarily on the molecular weight, the DS and chain length of the hydrophobe, the polymer concentration, and the composition of the aqueous media. It has been found that HMHEC is an efficient rheology control agent in latex paints (62,107). HMHEC also behaves as a polymeric coemulsifier. It can stabilize oil-in-water emulsions without the use of high HLB surfactants, enabling milder personal care and cosmetic formulations. Typical properties of an HMHEC are given in Table 7.

Hydrophobically modified ethylhydroxyethylcellulose (HMEHEC) (108), also having a long hydrocarbon chain, is also commercially available. Its properties are similar to HMHEC.

HEC modified with shorter C_2–C_6 alkyl groups produce nonassociative products that find use in building materials, such as plasters, joint compounds, and cements (109).

Methylcellulose and Its Mixed Ethers.

Properties. Methylcellulose [9004-67-5] (MC) and its alkylene oxide derivatives hydroxypropylmethylcellulose [9004-65-3] (HPMC), hydroxyethylmethylcellulose [9032-42-2] (HEMC), and hydroxybutylmethylcellulose [9041-56-9] (HBMC) are nonionic, surface-active, water-soluble polymers. Each type of derivative is available in a range of methyl and hydroxyalkyl substitutions. The extent and uniformity of the methyl substitution and the specific type of hydroxyalkyl substituent affect the solubility, surface activity, thermal gelation, and other properties of the polymers in solution.

These four MCs are available in a range of substitutions.

	Methyl DS	Hydroxyalkyl MS
MC	1.4–2.0	
HPMC	1.1–2.0	0.1–1.0
HEMC	1.3–2.2	0.06–0.5
HBMC	$\geq$1.9	$\geq$0.04

MC with a methyl DS less than about 0.6 is alkali-soluble. From about 1.6–2.4, it is water-soluble (most commercial grades); above 2.4, it is soluble in a wide variety of organic solvents. MC solutions in water start to gel at $\sim 55^{\circ}$C, independent of molecular weight. The gelation is a function of the DS, rate of heating, and type and amounts of additives such as salts. As the temperature increases, the viscosity initially decreases (typical behavior). When the gelling temperature is reached, the viscosity sharply rises until the flocculation temperature is reached. Above this temperature, the viscosity collapses. This process is reversible with temperature (110).

The mixed derivatives HEMC, HPMC, and HBMC tend to precipitate rather than gel as the temperature is increased. The higher the hydroxyalkyl substitution, the greater the tendency for precipitation. HEMCs and HPMCs tend to have higher gelation and flocculation temperatures (110). The mixed derivatives are generally more tolerant of added salts than MC itself. HPMC and HBMC are tolerant of and are soluble in some organic solvents, especially lower alcohols and glycols.

Solutions of MCs are pseudoplastic below the gel point and approach Newtonian flow behavior at low shear rates. Above the gel point, solutions are very thixotropic because of the formation of three-dimensional gel structure. Solutions are stable between pH 3 and 11; pH extremes will cause irreversible degradation. The high substitution levels of most MCs result in relatively good resistance to enzymatic degradation (36).

MC and its mixed ethers are surface-active cellulose ethers having surface tension values as low as 44 mN/m (=dyn/cm) and interfacial tension values as low as 17 mN/m (=dyn/cm) against paraffin oil.

Typical properties of MC, HPMC, HEMC, and HBMC are given in Table 8.

Manufacture. MC is manufactured by the reaction of alkali cellulose with methyl chloride (111).

$$R_{cell}OH : NaOH + CH_3Cl \rightarrow R_{cell}OCH_3 + NaCl$$

Table 8. Typical Properties of MC Ethers[a]

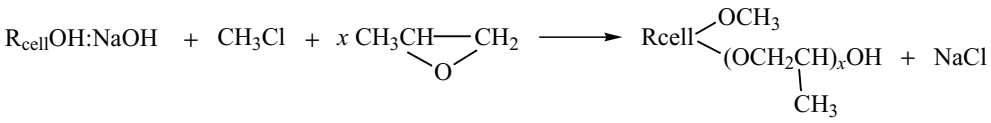
[a]Refs. 65 and 66.
[b]2% solution, Brookfield, 20 rpm.
[c]Against paraffin oil.
[d]To convert MPa to psi, multiply by 145.

The reaction is accompanied by side reactions that lead to methanol and dimethyl ether by-products.

$$CH_3Cl + NaOH \rightarrow CH_3OH + NaCl$$

$$CH_3OH + CH_3Cl + NaOH \rightarrow CH_3OCH_3 + NaCl + H_2O$$

Hydroxyalkyl modification is made by simultaneous or staged addition of an alkylene oxide, as exemplified in the following (112–115):



Similarly, ethylene oxide and 1,2-butylene oxide are used to make methylhydroxyethylcellulose and methylhydroxybutylcellulose, respectively.

Unlike HEC and CMC, which are purified by washing with aqueous organic solvents, MC and its hydroxyalkyl modifications are purified in hot water, where they are insoluble. Ultrafiltration techniques may be used to recover low molecular weight product from the wash water (116–118). As with other cellulose ethers, drying and grinding complete the process.

Table 9. Worldwide Supply and Demand for MC,[a] 10^3 t

Region	Capacity	Consumption	Production	Imports	Exports
United States	28.6	23.3	NA	NA	NA
Western Europe	94.4	58.8	75.2	7	23.4
Japan	12.7	8.9	12	2	5.1
Others	11.5	22.6	NA	NA	NA
Total	*147.2*	*113.6*			

[a]In 2002 (1).

Economic Aspects. A breakdown of salient figures in 2000 for the methylcelluloses is given in Table 9. The Dow Chemical Co. is the only U.S. manufacturer. They produce and market MC, HPMC, and HBMC. European producers include the Aqualon Division of Hercules Inc. in Belgium, Clariant GmbH in Germany, Dow Deutschland Inc. in Germany, Wolff Cellulosics GmbH & Co. in Germany, and Cognis Deutschland GmbH in Germany. Wolff Cellulosics GmbH plans a capacity expansion of 11,000 t in 2003 (1). Shin-Etsu Chemical Co. Ltd. and Matsumoto Yushi-Seiyaku Co., Ltd. are the two Japanese manufacturers.

Specifications and Standards; Test Methods. Premium grades of MC meet the requirements of the *U.S. Pharmacopeia – National Formulary* (U.S.P XXV-NF XX), the *European Pharmacopeia*, and the *Food Chemicals Codex IV*. MC is generally recognized as safe (GRAS), meeting the requirements of Food Additives Regulation CFR Title 21, Section 182.1480, as a multipurpose food substance in nonstandardized foods. The U.S. Department of Agriculture also allows its use in meat products, according to CFR Title 9, Section 318.7, and CFR Title 9, Section 381.147. Premium grades of some HPMCs are also approved for direct food use, meeting requirements of U.S.P. XXV, *Food Chemicals Codex IV*, and Food Additives Regulation CFR Title 21, Section 172.874, which allows their use in nonstandardized foods. Both MC and HPMC are also listed in the *Food Chemicals Codex* with their common names, "modified vegetable gum" and "carbohydrate gum," respectively. These products have also been certified Kosher.

MC and HPMC have also been authorized for use in the European food industry in a Council Directive by the European Union, and are coded E461 and E464, respectively.

MC and HPMC qualify as inert ingredients under CFR Title 40, Section 180.1001, that may be used in formulations applied to growing crops or raw agricultural products and commodities after harvest, and animals.

Analytical test methods and procedures are described in manufacturer's technical bulletins (65,66).

Uses. There are numerous applications for MC and its derivatives. Some important ones are summarized in Table 10.

Ethylcellulose and Hydroxyethylethylcellulose.

Properties. Ethyl cellulose [9004-57-3] (EC) is a nonionic, organo-soluble, thermoplastic cellulose ether, having an ethyl DS in the range of ~2.2–2.7. Actually, EC is water-soluble at DS ~ 1.2, but only those products that are thermoplastic and soluble in organic solvents are of commercial importance, because of

Table 10. Applications for MC and Its Derivatives[a]

Industry	Application	Function
Construction	Cements, mortars	Thickener, water-binder, workability

[a]Refs. 65 and 66.

their ability to form tough, stable films. Above a DS of about 2.5, EC is soluble in many nonpolar solvents.

Film mechanical properties, such as tensile strength, elongation, and flexibility, depend more on the molecular weight (DP) than on substitution. Elongation and tensile strength increase to a maximum with increasing molecular weight; flexibility increases linearly.

EC is subject to oxidative degradation in the presence of sunlight or ultraviolet light, especially at elevated temperatures above the softening point. It must, therefore, be stabilized with antioxidants (67). EC is stable to concentrated alkali and brines but is sensitive to acids.

Table 11 gives typical properties for EC.

Manufacture. EC undergoes reaction with alkali cellulose in high pressure nickel-clad autoclaves. A large excess of sodium hydroxide and ethyl chloride and high reaction temperatures (up to 140°C) are needed to drive the reaction to the desired high DS values ($\geqslant$2.0). In the absence of a diluent, reaction efficiencies in

Table 11. Typical Properties of EC[a]

Property	EC
Powder	
Appearance	White
Volatiles, %	2.000
Bulk density, g/cm^3	0.3–0.35
Softening point, °C	152–162
Film	
Specific gravity	1.140
Refractive index	1.470
Tensile strength, MPa[b]	46–72
Elongation, %	7–30
Flexibility[c]	160–2000
Dielectric constant, 60 Hz	2.5–4.0

ethyl chloride range between 20 and 30%, the majority of the rest being consumed to ethanol and diethyl ether by-products.

$$R_{cell}OH : NaOH + CH_3CH_2Cl \rightarrow R_{cell}OCH_2CH_3 + NaCl + CH_3CH_2OH + (CH_3CH_2)_2O$$

Higher ethyl chloride efficiency is claimed for a process utilizing a hydrocarbon diluent coupled with stepwise addition of sodium hydroxide (119). Product work-up includes distillation to remove residual unreacted ethyl chloride, added diluent, methanol, and diethyl ether; neutralization of excess sodium hydroxide; washing in water to remove salts; drying; and grinding.

Economic Aspects. The Dow Chemical Co. and the Aqualon Division of Hercules Inc. are the only listed principal producers of EC products worldwide. Consumption has remained constant over the past several years, and it is not expected to grow in the future. Production is estimated at 5000 t/year, roughly equally divided between The Dow Chemical Co. and the Aqualon Division of Hercules Inc. As with other cellulose ethers, the price for EC varies by grade.

Specifications and Standards; Test Methods. EC is cleared for many applications in food and food contact under the Federal Food, Drug, and Cosmetic Act, as amended. Examples include binder in dry vitamin preparations for animal feed, coatings and inks for paper and paperboard products used in food packaging, and closures with sealing gaskets for food containers (44). Methods of analyses are given in ASTM D914-72 (19), *National Formulary XX*, and *Food Chemicals Codex IV*.

Uses. A summary of the applications for EC is given in Table 12.

Hydroxypropylcellulose.

Properties. Hydroxypropylcellulose [9004-64-2] (HPC) is a thermoplastic, nonionic cellulose ether that is soluble in water and in many organic solvents. HPC combines organic solvent solubility, thermoplasticity, and surface activity with the aqueous thickening and stabilizing properties characteristic of other water-soluble cellulosic polymers described herein. Like the MCs, HPC exhibits a low critical solution temperature in water.

The substitution of HPC is defined by the MS. Molar substitutions higher than approximately 3.5 are needed for solubility in water and organic solvents.

HPC is available in a number of viscosity grades, ranging from about 3000 mPa·s (=cP) at 1% total solids in water to 150 mPa·s (=cP) at 10% total solids. HPC solutions are pseudoplastic and exceptionally smooth, exhibiting little or no structure or thixotropy. The viscosity of water solutions is not affected by changes in pH over the range of 2–11. Viscosities decrease as temperature is

Table 12. Applications for EC and HEEC[a]

Industry	Application	Function
Coatings	Lacquers, varnishes	Protective film-former, additive to increase film toughness and durability, shorten drying time
Printing	Inks	Film-former
Adhesives	Hot melts	Additive to increase toughness

[a]Ref. 67.

increased. HPC precipitates from water at temperatures between 40 and 45°C. Dissolved salts and other compounds can profoundly influence the precipitation temperature (73,120).

HPC is compatible with many natural and synthetic water-soluble polymers and gums (73). Generally, blends of HPC with another nonionic polymer such as HEC yield water solutions having viscosities in agreement with the calculated value. Blends of HPC and anionic CMC, however, produce solution viscosities greater than calculated ones. This synergistic effect may be reduced in the presence of dissolved salts or if the pH is below 3 or above 10.

Like the MCs, water solutions of HPC display greatly reduced surface tension. A 0.1% solution of HPC at 25°C has a surface tension of about 44 mN/m (=dyn/cm) (and that of water is 74.1 mN/m) and interfacial tension of about 12.5 mN/m (=dyn/cm) against mineral oil. The molecular weight of the HPC has only a slight effect on the surface tension.

Examples of polar organic solvents that dissolve HPC are methanol, ethanol, propylene glycol, and chloroform. There is no tendency for HPC to precipitate as the temperature is raised. In fact, elevated temperatures improve the solvent power of organic liquids.

A low substituted hydroxypropylether of cellulose, "L-HPC" (MS = 0.2–0.4), is produced by Shin-Etsu Chemical Co., Ltd. L-HPC is insoluble, but swell in water. It is used as a binder and a distintegrant for solid medicaments.

Some typical properties of commercial high MS HPC are given in Table 13.

Manufacture. HPC is manufactured by reaction of propylene oxide [75-56-9] with alkali cellulose.

Table 13. Typical Properties of HPC[a]

Property	Value
Powder	
Appearance	Off-white
Volatiles, %	5 max
Ash content (as Na_2SO_4), %	0.2–0.5
Softening point, °C	100–150

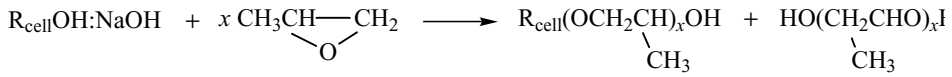
[c] To convert MPa to psi, multiply by 145.
[d] MIT double folds.

Table 14. Applications for HPC[a]

Industry	Application	Function
Polymerization	PVC suspension polymerization	Protective colloid
Pharmaceutical	Tablets	Binder, film-former
Coatings	Paint remover	Thickener
Foods	Whipped toppings	Stabilizer
	Processed foods	Extrusion aid
Ceramics	Slip casts	Binder (promotes green strength)

[a]Ref. 73.



The reaction may be conducted in stirred autoclaves in the presence of hydrocarbon diluents (121,122). Like the MCs, advantage is taken of the low critical solution temperature of HPC and it is purified through multiple washings with hot water. Consequently, very low levels of residual salts and by-products are present in the final products.

Economic Aspects. The Aqualon Co. of Hercules Inc. is the only U.S. manufacturer. It is also produced in Japan by Nippon Soda Co., Ltd. Nippon Soda increased its production capacity to 1000 t at the end of 1998, to meet increasing demand from the pharmaceutical industry. Worldwide production of consumption of HPC in 2000 was estimated at 3000 t.

Specifications and Standards; Test Methods. Food-grade HPC products are manufactured for use in food and conform to the specifications for HPC set forth in CFR Title 21, Sections 121.1160 and 172.870. Food grades of HPC also conform to the specifications for HPC as listed in the current edition of the *Food Chemicals Codex* and by the Food and Agricultural Organization of the the United Nation's World Health Organization (FAO/WHO).

Pharmaceutical and cosmetic grades of HPC, as, for example, Klucel Pharm NF manufactured by the Aqualon Division of Hercules Inc. conform to the requirements of all major pharmacopeias, ie, *National Formulary* (*NF XX*), *European Pharmacopeia* (*EP*), *and Japanese Pharmacopeia (JP)*.

Toxicity testing indicates that HPC is physiologically inert (50).

Procedures for determining the ash content and moisture level, solution preparation, and viscosity measurement techniques are given in the manufacturer's literature (50).

Uses. A summary of significant uses for HPC is given in Table 14.

CELLULOSE FIBERS, REGENERATED

Introduction

Cellulose (qv) is the natural polymer that makes up the living cells of all vegetation. It is the material at the center of the carbon cycle, and the most abundant and renewable biopolymer on the planet. Regenerated cellulose fiber producers have converted it from the fine short fibers that come from trees into the fine long fibers used in textiles and nonwovens for over a century. Regenerated cellulosics nevertheless remain unique among the mass-produced fibers because they are the only ones to use the natural polymer *directly*. Polyesters, nylons, polyolefins, and acrylics all come *indirectly* from vegetation: from the polymerization of monomers obtained from fossil fuels, which in turn are formed by the incomplete biodegradation of vegetation that grew millions of years ago.

The development of manufactured fibers is one of the great industrial successes of the twentieth century, but after 50 years of explosive growth of the original regenerated cellulosic fibers, synthetic polymer fibers now dominate the market. Natural cellulose in the form of cotton, for centuries the most important of all fibers, now takes second place to polyester. All cellulosic fibers appear relegated to little more than niches in a global textile market driven by the ready availability of cheap fossil fuels and the demand for commodity textiles. Is this relative decline of cellulose and regenerated cellulose just another example of the last stage of the growth/maturity/decline life cycle of most products or is there a possibility that, on a longer timescale, sustainable biopolymers like cellulose will prove to be a serious rival for the synthetics?

Fibers manufactured from cellulose are either *derivative* or *regenerated*. A *derivative fiber* is one formed when a chemical derivative of a natural polymer, eg, cellulose, is prepared, dissolved, and extruded as a continuous filament, and

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

the chemical nature of the derivative is retained after the fiber formation process (see CELLULOSE ESTERS). A *regenerated fiber* is one formed when a natural polymer or its chemical derivative is dissolved and extruded and the chemical nature of the natural polymer is either retained or regenerated after the fiber formation process. The difficulties of making solutions of natural cellulose from which fibers can be spun has led to most fabricated cellulosic fibers being regenerated from more readily soluble derivatives of cellulose.

Originally, the word rayon was applied to any cellulose-based manufactured fiber, and therefore included the cellulose acetate fibers. However, the definition of rayon was clarified in 1951 and now includes textiles fibers and filaments composed of regenerated cellulose, excluding acetate. In Europe the fibers are now generally known as *viscose*, the term *viscose rayon* being used whenever confusion between the fiber and the cellulose xanthate solution (also called viscose—see below) is possible. (In this article the terms *regenerated cellulosics*, *rayon*, and *viscose rayon* tend to be used interchangeably.)

All synthetic fibers are produced as continuous filaments, either as yarns or tows. Yarns are fine enough to be woven or knitted directly, but cannot be intimately blended with other fibers on the principal conversion systems used for cotton and wool. For these conversion systems, staple fibers, made by cutting the much larger tows into short lengths, are needed. Tows can also be stretch-broken into slivers or tops, which can then be drawn out and twisted into spun yarns.

Denier and tex are both weight/length measures of fiber fineness: denier is the weight in grams of 9000 m of filament, yarn, or tow; tex is the weight in grams of 1000 m. For filaments, as opposed to tows or yarns, the decitex tends to be used as the measure of fineness, 1 denier being equivalent to 1.11 decitex. Filament strengths are measured in gram force/denier (gf/den) or in centiNewtons/tex (cN/tex): 1 gf/den is equivalent to 8.82 cN/tex. Occasionally, the strength of filaments is seen expressed as N/mm^2 to allow comparison with engineering materials. One N/mm^2 is equivalent to the strength in gf/den $\times$ 9 $\times$ 9.807 $\times$ the fiber specific gravity. For cellulose, the specific gravity = 1.51, so N/mm^2 = gf/den $\times$ 133.277.

History

The first successful attempt to make textile fibers from plant cellulose can be traced to George Audemars (1). In 1855 he dissolved the nitrated form of cellulose in ether and alcohol and discovered that fibers were formed as the dope was drawn into the air. These soft, strong nitrocellulose fibers could be woven into fabrics but had a serious drawback: they were explosive, nitrated cellulose being the basis of guncotton (see CELLULOSE ESTERS, INORGANIC).

Sir Joseph Swan, as a result of his quest for carbon fiber for lamp filaments (2), learned how to denitrate nitrocellulose using ammonium sulfide. In 1885 he exhibited the first textiles made from this new artificial silk, but with carbon fiber being his main theme he failed to follow up on the textile possibilities. Meanwhile Count Hilaire de Chardonnet (3) was researching the nitrocellulose route and had perfected his first fibers and textiles in time for the Paris Exhibition in 1889. There he got the necessary financial backing for the first Chardonnet silk factory

in Besancon in 1890. His process involved treating mulberry leaves with nitric and sulfuric acids to form cellulose nitrate, which could be dissolved in ether and alcohol. This collodion solution could be extruded through holes in a spinneret into warm air, where solvent evaporation led to the formation of solid cellulose nitrate filaments.

Although this first route was simple in concept, it proved slow in operation, difficult to scale up safely, and relatively uneconomical compared with the other routes. Denitration of the fibers, necessary to allow safe use wherever the fabrics may risk ignition, spoiled their strength and appearance. Nevertheless, Chardonnet earned and truly deserved his reputation as the Father of Rayon. His process was operated commercially until 1949, when the last factory—bought from the Tubize Co. in the United States in 1934 by a Brazilian company—burned down.

The second cellulosic fiber process to be commercialized was invented by L. H. Despeissis (4) in 1890 and involved the direct dissolution of cotton fiber in ammoniacal copper oxide liquor. This solvent had been developed by M. E. Schweizer in 1857 (5). The cuprammonium solution of cellulose was spun into water, with dilute sulfuric acid being used to neutralize the ammonia and precipitate the cellulose fibers. H. Pauly and co-workers (6) improved on the Despeissis patent, and a German company, Vereinigte Glanstoff Fabriken, was formed that exploited the technology. In 1901, Dr. Thiele at J. P. Bemberg developed an improved stretch-spinning system, the descendants of which survive today.

Its early commercial success owed much to the flammability disadvantages of the Chardonnet process, but competition from the viscose process led to its decline for all but the finest filament products. The process is still used, most notably by Asahi in Japan, where sales of artificial silk and medical disposable fabrics provide a worthwhile income. However, its relatively high cost, associated with the cotton fiber starting point, prevented it from reaching the large scale of manufacture achieved by the viscose rayon process.

In 1891, Cross, Bevan, and Beadle, working at Kew in the United Kingdom, discovered that cotton or wood cellulose could be dissolved as cellulose xanthate following treatment with alkali and carbon disulfide (7). The treacle-like yellow solution could be coagulated in an ammonium sulfate bath and then converted back to pure white cellulose using dilute sulfuric acid. They patented their process in 1892 without considering its fiber-making potential. In 1893 they formed the Viscose Syndicate, to grant licenses for nonfiber end uses, and the British Viscoid Co. Ltd., to exploit the process as a route to molded materials. These companies were later merged to form the Viscose Development Co. in 1902.

In another laboratory at Kew, C. H. Stearn and C. F. Topham, who had worked for Sir Joseph Swan on lamp filaments, developed the continuous filament spinning process (8) and the machinery needed to wash and collect (9,10) the yarns. A fiber-making method was outlined in 1898, and the Viscose Spinning Syndicate was formed to develop the concept into a commercial proposition.

In 1904, the Kew laboratories were visited by representatives of Samuel Courtauld & Co. Ltd., who were silk weavers looking for new raw materials and new opportunities to grow. The success and profitability of Samuel Courtauld had been built on the nineteenth-century fashion for black silk mourning crepe, and the company was planning its stock market flotation. The visitors to Kew knew that Chardonnet's process was creating a lucrative market for artificial silk in

France. They believed that Cross and Bevan's viscose route could make a similar fiber much more economically. Nevertheless, it took two attempts, the second to a changed Board of Directors after the flotation, before Courtaulds was persuaded to acquire the viscose process rights. On July 14, 1904, the Viscose Spinning Syndicate agreed to sell the viscose process rights and patents to Courtaulds for the sum of £25,000. A new factory was built and the first commercial production was started in Coventry, United Kingdom, in November 1905.

The acquisition of the rights to the viscose process became one of the most profitable investments of all time. Interest in the new fiber was intense, and growth of production capacity was exponential. By 1907, the Courtauld company was selling all the artificial silk it could produce and proceeded to expand into the U.S. market. In 1910 they formed the American Viscose Co. and in 1911 started the first U.S. viscose factory at Marcus Hook. By 1939, Courtaulds had six factories in the United States, seven in the United Kingdom, one in France, one in Canada, and joint ventures in Germany and Italy.

From 1920 to 1931, after the expiration of the viscose patents, world output increased from 14,000 to 225,000 t per year, as more than 100 companies entered the cellulose fiber field. In Europe, Vereinigte Glanstoff Fabriken (VGF, Germany), Enka (Holland), I. G. Farben (Germany), Snia Viscosa (Italy), Comptoir des Textiles Artificiels (CTA, France), Rhodiaceta (France), Tubize (Belgium), and Chatillon (Italy) were among the new starters. In the United States the new entrants included Du Pont (with help from CTA), Tubize, Chatillon, American Enka, The Industrial Fiber Corp. (later The Industrial Rayon Corp.), American Glanzstoff (later North American Rayon), and American Bemberg.

By 1941, as the first synthetic polymers were being converted into fibers (nylon and later polyester), regenerated cellulosic fiber production had risen to 1,250,000 ton. It continued to expand into the 1970s recording its highest ever annual output at 3,856,000 ton in 1973. Since then a steady decline has occurred as more and more end uses switch to the cheaper synthetic fibers based on oil valued at little more than the costs of extraction.

Applications

The original yarns were marketed as silk substitutes for use in apparel, hosiery, lace, home furnishings, ribbons, braids, and in a whole range of fabrics using blends with cotton or wool yarns. As the end uses expanded beyond silk replacement, the harsh metallic luster of the yarn proved disadvantageous, and dull "matt" fibers had to be developed. Oil dulling was invented (11) in 1926, and an improved method using titanium dioxide was developed (12) in 1929.

Commencing in the late 1930s, new developments to make very strong yarns allowed the viscose rayon to replace cotton as the fiber of choice for longer-life pneumatic tires. The pace of this line of development increased during World War II, and by the 1960s a significant part of the production of viscose yarn was for tires and industrial applications.

From 1910 onward waste filament yarn had been chopped into short lengths suitable for use on the machinery designed to process cotton and wool staples into spun yarns. In the 1930s new plants were built specifically to supply the

staple fiber markets. During World War II the production of staple matched that of filament, and by 1950, staple viscose was the most important product. The new spun-yarn outlets spawned a series of viscose developments aimed at matching the characteristics of wool and cotton more closely. Viscose rayon was, after all, silk-like. Compared with wool it lacked bulk, resilience, and abrasion resistance. Compared with cotton, it was weaker, tended to shrink and crease more easily, and had a rather lean, limp hand.

For wool outlets, coarser crimped staple fibers were developed. By the late 1960s these were widely used in the new tufted carpets, which for a period became the single largest application for the cellulosic fiber. For cotton outlets, two distinct lines of development were undertaken, the first being to boost the strength and modulus of rayon so that it could match that of cotton, and the second to alter the shape of the fiber to give bulkier, more cotton-like textures. High wet modulus (HWM) rayons of two types were developed. Staple versions of the tougher tire-yarn fibers (modal HWM fibers) were introduced for use in industrial textiles, and for blending with the rapidly growing synthetics. This class was later subdivided into the low, intermediate, and high strength variants (LWM, IWM, and HWM) as producers tuned the process to market niches. Polynosic HWM fibers with even better wet stability and higher wet modulus were introduced to blend with the better grades of cotton.

In the 1960s and 1970s, viscose producers in Europe, the United States, and Japan made various attempts to make rayon behave more like cotton in both woven fabrics and specialty papers. Avtex (U.S.) and Kurashiki Rayon (Japan) commercialized inflated–collapsed paper-making fibers. Courtaulds (U.K.) developed a range of hollow fibers, of which two were commercialized. The first, having an uncollapsed tubular shape, found worthwhile new business in thermal underwear. The other, having an unevenly collapsed tube shape and a very high absorbency, enjoyed large sales in sanitary protection products. These hollow fibers were replaced in the late 1980s by I- and Y- shaped solid fibers that performed as well as the hollow versions in the main applications.

The Viscose Process

The main raw material required for the production of viscose is cellulose (qv), a natural polymer of D-glucose (Fig. 1). The repeating monomer unit is a pair of anhydroglucose units (AGU). Cellulose and starch (qv) are identical but for the way in which the ring oxygen atoms alternate from side to side of the polymer

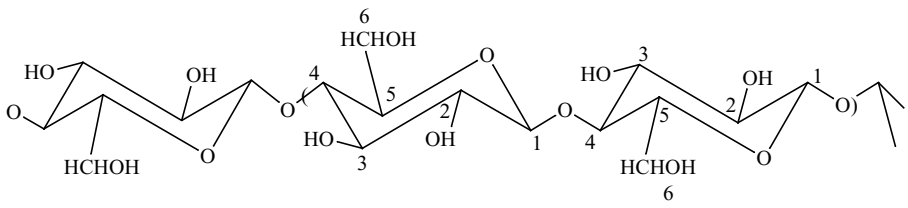

Fig. 1. Anhydroglucose units with 1–4 beta linkages as in cellulose.

chain (beta linkages) in cellulose, but remain on the same side (alpha linkages) in starch.

Cellulose is the most abundant polymer, an estimated 10^{11} t being produced annually by natural processes. Supplies for the rayon industry can be obtained from many sources; but in practice, the wood-pulping processes used to supply the needs of the paper and board industries have been adapted to make the necessary specially pure grade. Of the 3×10^8 t of wood used by the paper and board industry (13) in 1989, about 6×10^6 t were purified to provide the 2.5×10^6 t of dissolving pulp required by the viscose processes.

The trees used to make dissolving pulp are fast-growing hard or soft woods farmed specifically for their high quality pulping. For example, *Eucalyptus grandis* is farmed in relatively poor agricultural areas but grows from seedling to maturity in 7–10 years. It yields about 0.62 kg/m^2 (2500 kg/acre) per year of cellulose for fiber-making, compared with the best cotton fiber yields of 0.074 kg/m^2 (300 kg/acre) per year obtained from prime agricultural land. After sulfite or prehydrolyzed Kraft pulping, the cellulose wood fibers, liberated from the lignin (qv), pass through a sequence of purification stages, eg, chlorination; hot caustic extraction; hypochlorite, peroxide or chlorine dioxide bleaching; and cold caustic extraction.

The final properties of the rayon fiber and the efficiency of its manufacturing process depend crucially on the purity of the pulp used. High tenacity fibers need high purity pulps, and this means pulping to get up to 96% of the most desirable form of cellulose (known as alpha cellulose), and removing most of the unwanted hemicellulose and lignin. Cellulose molecular weight must be tightly controlled, and levels of foreign matter such as resin, knots, shives, and silica must be very low. Of the two main pulping processes, the sulfite route produces higher yields of lower alpha, more reactive pulp, suitable for regular staple fiber. Prehydrolyzed kraft pulps are preferred for high strength industrial yarn or modal fiber production. The highest purity pulps, up to 99% alpha cellulose, are obtained from cotton fiber. These are no longer used in viscose production but are now the main raw material for cuprammonium rayon.

The flow diagram for the viscose process is given in Figure 2. The sequence of reactions necessary to convert cellulose into its xanthate and dissolve it in soda used to be performed batchwise. Fully continuous processes, or mixtures of batch and continuous process stages, are more appropriate for high volume regular viscose staple production.

Steeping. Sheet, roll, or suitably milled flock pulp is metered into a pulper along with vigorously stirred 18% sodium hydroxide solution at 50°C. The resulting slurry, containing about 5% finely dispersed pulp, passes to a buffer tank from which it is metered to a slurry press that sieves out the swollen fiber and returns the pressings soda for concentration correction and reuse. The cellulose reacts with the soda as a complex alcohol to form the sodium salt or alk-cell.

$$\text{Cell—OH} + \text{NaOH} \rightarrow \text{Cell—ONa} + \text{H}_2\text{O} \quad (1)$$

The blanket of alk-cell leaving the slurry press is shredded, and if necessary cooled, before being conveyed to mercerizing (the ripening or aging process).

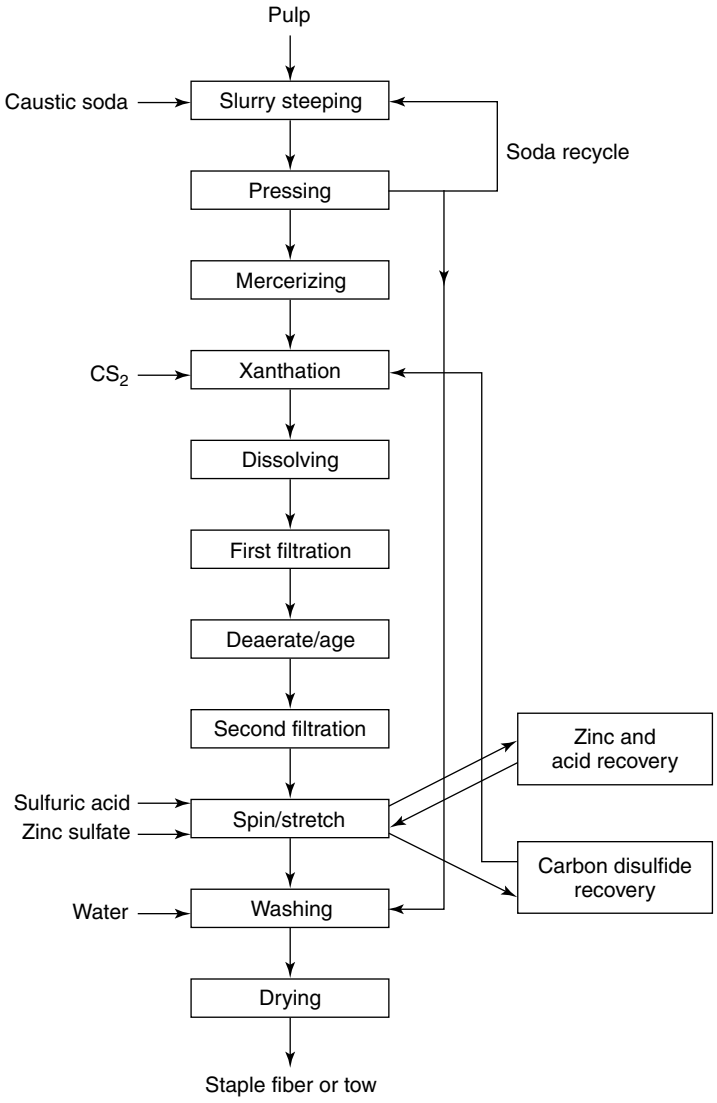

Fig. 2. The viscose process.

Hemicelluloses left over from the cellulose pulping process tend to accumulate in the steep soda, and levels of up to 3.0% are tolerable, depending on the type of fiber being produced. Equilibrium hemicellulose levels may prove to be too high for the production of stronger fibers, and in this case steps must be taken to purify the soda, eg, by dialysis, prior to reuse. In any case a proportion of the soda from the presses is filtered for later use in dissolving and washing; the steep liquor itself is corrected to the required concentration by the addition of fresh hemicellulose-free strong soda.

Mercerizing. Alk-cell mercerizing (or aging) is ideally carried out on a conveyor belt running through a temperature-and humidity-controlled tunnel. Towers, silos, cylinders, or even extended treatment in shredders are used as alternatives to belts. During mercerizing, oxidative depolymerization of the cellulose occurs, and this reduces the molecular weight to a level where the final viscose viscosity and cellulose concentration are within acceptable ranges. The optimum conditions for a given pulp depend on the details of the equipment and the cost–quality balance required by the business. The aging temperature is generally around 50°C, and the humidity is adjusted to prevent any drying of the alk-cell. Catalysts such as manganese (a few parts per million in steep liquor) or cobalt have been added to the steep soda to accelerate the aging process (14) or to allow lower temperatures to be used. Catalyzed aging on a conveyor takes 3–4 h, and at the end of the belt, the alk-cell is blown or conveyed to a fluid-bed cooler.

Whatever system is used, tight control of the aging process is essential for good quality viscose solutions, because the viscosity of the viscose depends on it. Varying viscosity can play havoc with all subsequent operations up to and including spinning. Productivity gains achieved by high-temperature or catalyzed aging tend to be accompanied by increased viscosity variability and reduced reactivity in xanthation.

Xanthation. The viscose process is based on the ready solubility of the xanthate derivative of cellulose in dilute sodium hydroxide. The reaction between alkali cellulose and carbon disulfide must therefore be as uniform as possible to avoid problems with incompletely dissolved pulp fibers that will later have to be filtered out of the viscous solution.

In theory, for regular rayon manufacture only one of the hydroxyl groups on each pair of anhydroglucose units needs to be replaced by a xanthate group, ie, the target degree of substitution (DS) is 0.5, which to achieve without waste would need 23% CS_2 on cellulose.

The desired reaction is

$$\mathrm{CellO^-\ Na^+ + CS_2 \rightarrow CellOCS_2Na} \qquad (2)$$

but side reactions between the CS_2 and the NaOH also occur, one of which is

$$\mathrm{2\ CS_2 + 6NaOH \rightarrow Na_2CO_3 + Na_2CS_3 + Na_2S + 3\ H_2O} \qquad (3)$$

It is the sodium trithiocarbonate from this side reaction that gives the viscose dope its characteristic orange color.

In addition to the cellulose xanthate [9032-37-5] forming reaction, equation 2 being reversible, cellulose can reform by

$$\mathrm{CellOCS_2Na + 2\ NaOH \rightarrow Na_2CO_2S + NaSH + CellOH} \qquad (4)$$

Clearly, free sodium hydroxide in alkali cellulose leaving the slurry presses causes problems in xanthation, and the presses have to be operated to minimize reactions 3 and 4.

Carbon disulfide [75-15-0] is a clear colorless liquid that boils at 46°C, and should ideally be free of hydrogen sulfide and carbonyl sulfide. The reaction with alkali cellulose is carried out either in a few large cylindrical vessels known as wet churns, or in many smaller hexagonal vessels known as dry churns. In the fully continuous viscose process, a Continuous Belt Xanthator, first developed by Du Pont, is used (15).

In a large wet churn operation, a weighed batch of alk-cell (5–10 t) is charged into the churn, which is then evacuated. Carbon disulfide (0.5–1 t) is admitted over a 20-min period and vaporizes in the partial vacuum. Churns are rotated slowly to encourage the solid–vapor interaction or they are stirred with a large slow-moving paddle. The reaction with alk-cell is slightly exothermic, and churns are generally cooled to maintain the temperature between 25 and 30°C. Under these conditions the xanthation reaction is completed in about 100 min and its progress can be monitored by observing the partial vacuum redeveloping as the gas is adsorbed by the solid.

About 25% of the CS_2 is wasted in side reactions (eg, reaction 3), and this means that to achieve the ideal 0.5 DS, the CS_2 charge is about 30% by weight of the cellulose. Higher charges (up to 50%) are needed for the strongest high wet modulus rayon production. Lower charges are possible if steps are taken to increase the reactivity of the alk-cell, or to suppress the undesirable side reactions, or to ensure that viscose filtration is good enough to cope with more undissolved material.

The incomplete accessibility of the cellulose molecules in alk-cell prevents complete xanthation, ie, the formation of the trixanthate, no matter how much CS_2 is used. The trixanthate would imply a DS of 3, sometimes known as a gamma value of 300 CS_2 groups per 100 AGUs. In practice, gamma values over 100 are hard to achieve in the churn, but levels up to 200 can be reached by a combination of churn addition and liquid CS_2 injection into the viscose where the cellulose accessibility is at its greatest. For regular staple production, gamma values tend to be around 50 at the churn and 30–35 at spinning.

At the end of xanthation, any remaining traces of CS_2 are flushed from the wet churn prior to, or in some cases by, admitting a charge of the dissolving or mixer soda in order to commence dissolution. For a dry churn operation, the vessel is opened to allow the golden xanthate crumbs to be discharged into a separate mixer.

Dissolution. Cellulose and its derivatives dissolve more easily in cold alkali than in hot, and the initial contact between cellulose xanthate and the mixer soda should occur at the lowest temperature possible. Two percent NaOH at no more than 10°C is admitted to the wet churn and the paddle speeded up to wet out all the crumb prior to discharge. Some of the required mixing soda charge can be retained to wash out the churn before restarting the cycle. Discharge occurs, through cutters that eliminate any large lumps of agglomerated xanthate, into the batch tank where dissolution is completed. Here it is stirred for about 2 h to allow the xanthate to dissolve. The mixing conditions are crucial. High shear mixing certainly speeds up the process but can cause local heating, which can regenerate cellulose from the xanthate.

The final composition of the solution is controlled by the ratio of xanthate to mixer soda, the concentrations of cellulose and NaOH in the xanthate, and

the concentration of NaOH in the mixer soda. For regular staple processes the cellulose/soda ratio is within the range 8.5:6.0 to 10.0:5.0, the latter tending to give lower quality viscose solutions. High quality textile yarns require a 7.5:6.5 ratio, whereas the strongest high wet modulus processes use a 6.0:6.0 ratio. Here lower cellulose concentrations are necessary to allow the use of higher molecular weights (less mercerizing), which allow higher strength development.

It is possible to add modifiers or delustrants at the dissolving stage. However, modern viscose dope plants feed several spinning machines, which are often expected to make different grades of fiber. It is therefore now more common to add the materials needed to make special fibers by injection close to the spinning machines.

Viscose Aging, Filtration, and Deaeration. After the dissolution step, the viscose cannot be spun into fibers because it contains many small air bubbles and particles. Furthermore, the degree of xanthation is too high, with too many of the xanthate groups in positions dictated by their accessibility and not in the ideal positions for uniform dissolution.

Dexanthation, and the redistribution of xanthate groups into the most favorable positions on the cellulose molecules, occurs automatically as the viscose ages. For regular staple fibers the process takes about 18 h, but for the stronger fibers, shorter times and more difficult spinning conditions have to be tolerated. During this aging process, reaction 2 goes into reverse and the xanthate groups attached to the 2- and 3- positions on the AGU (Fig. 1) hydrolyze 15–20 times as fast as those on C-6. Transxanthation occurs (16); the unoccupied C-6 hydroxyl competing with reaction 2 for the CS_2 that is leaving C-2 and C-3. The reactions favoring more spinnable viscose are in turn favored by aging for longer times at the lowest possible temperature. Cold viscoses are unfortunately much more viscous, and therefore harder to filter and deaerate.

Filtration of viscose is not a straightforward chemical engineering process. The solution of cellulose xanthate contains some easy-to-deal-with undissolved pulp fibers, and also some gel-like material that is retarded rather than removed by the filters. The viscose is unstable and tends to form more gel as it ages. Its flow characteristics make the material close to the walls of any vessel or pipe move more slowly, get older, and gel more than the mainstream viscose. So while filtration can hold back gels arising from incomplete mixing, new gels can form in the pipework after the filters.

The removal of particles that would block the spinneret holes occurs in several stages. The traditional plate-and-frame first-filters dressed with disposable multilayers chosen from woven cotton, cotton wadding, or wood pulp have now been replaced by durable nylon needlefelts that can be cleaned by automatic backwashing (17). Second filtration, usually after deaeration, is also changing to fully automatic systems with sintered steel elements that do not need manual cleaning. Third-stage filtration, close to the spinning machines, is used to provide a final polishing of viscose quality, but is only justifiable for the premium quality fibers. All processes nevertheless use small filters in each spinneret to catch any particulate matter that may have eluded, or been formed after, the main filter systems.

Continuous deaeration occurs when the viscose is warmed and pumped into thin films over cones in a large vacuum tank. The combination of the thinness

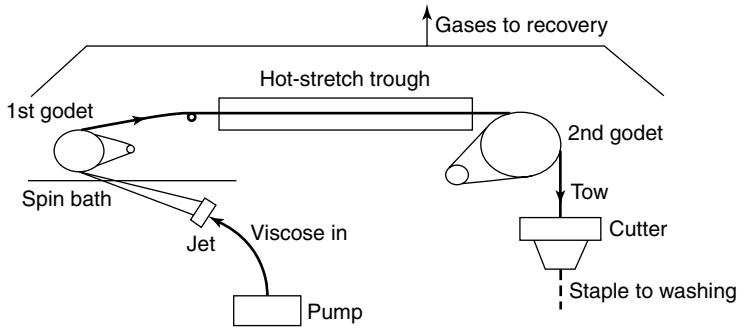

Fig. 3. One "end" of a staple fiber–spinning machine.

of the liquid film and the disruption caused by the boiling of volatile components allows the air to get out quickly. Loss of water and CS_2 lower the gamma value and raise the cellulose concentration of the viscose slightly. Older systems use batch deaeration, where the air bubbles have to rise through several feet of viscose before they are liberated.

The correct viscose age or ripeness for spinning varies according to the type of fiber being made. Ripeness can be assessed by establishing the salt concentration necessary to just coagulate the viscose dope. The preferred test uses sodium chloride (salt figure) although the alternative method (Hottenroth number) is based on ammonium chloride.

Spinning. Properly filtered and deaerated viscose of the right salt figure can be coagulated into filament by pumping it through a suitable orifice (jet or spinneret) into a coagulating bath. The forming filaments are pulled through the bath by the first godets, which in some systems also serve as an anchor against which stretch can be applied by the second godets or traction units. The assembly of pumps, spin baths, jets, godets, stretch baths, traction units, and ventilation systems is known as the spinning machine. It can take many forms depending on the type of fiber being made and the priority given to achieving a geometrically similar path for the tows from each jet. Figure 3 illustrates one end of a staple fiber–spinning machine that would have hundreds of ends making up the final tow entering the cutter.

Jets for continuous filament textile yarn are typically 1-cm-diameter gold–platinum alloy structures with 20–500 holes of 50–200-μm diameter. Tire yarn jets are also 1 cm in diameter but typically use 1000–2000 holes to give the required balance of filament and yarn denier. Staple fiber jets can have as many as 70,000 holes and can be made from a single dome of alloy or from clusters of the smaller textile or tire yarn jets. The precious metal alloy is one of the few materials that can resist the harsh chemical environment of a rayon machine and yet be ductile enough to be perforated with precision. Glass jets have been used for filament production, and tantalum metal is a low cost but less durable alternative to gold–platinum.

The basic chemistry of fiber formation is however independent of the hardware. Spin-bath liquors are mixtures of sulfuric acid (5–15%), zinc sulfate (0.05–7%), and sodium sulfate (10–28%) controlled at temperatures ranging from

30 to 60°C. They are circulated past the jets at carefully controlled rates and fully recycled. The liquid filament emerging from the jet coagulates at the interface between acid bath and alkaline viscose to form a cuticle, and later a skin, through which the rest of the coagulation and regeneration is controlled. This regeneration mechanism causes the skin–core nonuniformity, which is characteristic of regular rayon fiber cross sections.

$$2\ \text{Cell}{-}OCS_2Na + H_2SO_4 \rightarrow 2\ \text{Cell}{-}OCS_2H + Na_2SO_4 \quad (5)$$

As coagulation proceeds into the center of the forming fiber, the outside regenerates to cellulose at a rate dependent on the temperature and composition of the bath.

$$\text{Cell}{-}OCS_2H \rightarrow \text{Cell}{-}OH + CS_2 \quad (6)$$

In processes making regular staple fiber, reactions 5 and 6 occur practically simultaneously, but in high wet modulus processes, reaction 5 predominates in the spin bath, with reaction 6 occurring while stretching the filament in a hot water or steam bath. The carbon disulfide liberated in spinning and stretching can be recovered from the extracted air and from the spin-bath liquor.

Zinc salts are added to the spin bath to slow down the regeneration reaction by forming a less easily decomposed zinc cellulose xanthate intermediate. This allows greater stretch levels to be applied and results in fibers with thicker skins. There is still uncertainty as to whether the zinc cellulose xanthate gel acts by hindering acid ingress or water loss. High levels of zinc in the spin bath allow the production of tough fibers for tire reinforcement and industrial use.

Washing and Drying. In staple fiber production the filaments from all the jets on the spinning machine are combined into a few large tows and cut to length prior to washing. In filament yarn production, the yarns are kept separate and collected either as acid cakes for off-line cake washing, or wound onto bobbins after on-line washing and drying.

Again, irrespective of the hardware the chemistry is consistent. The partially regenerated fiber from the spinning machine is contaminated with sulfuric acid, zinc sulfate, sodium sulfate, carbon disulfide, and the numerous incompletely decomposed by-products of the xanthation reactions. The washing and drying systems must yield a pure cellulose fiber, suitably lubricated for the end use, and dried to a moisture level of around 10%.

The sequence of treatments is illustrated in Figure 4. Water consumption in washing is minimized by using a countercurrent liquor flow, clean water entering the system at the point where the fiber leaves, and dirty liquor leaving for chemical recovery at the point where the fiber enters.

In the staple fiber system, the tows from spinning are cut to length and sluiced onto a 30–40-m-long wire-mesh conveyor that carries the blanket of fiber through cascades of the various wash liquors. Sluicing is a critical operation because the cut lengths need to be opened just enough to allow good washing and not so much that the individual fibers entangle. Sluicing must also lay a uniformly permeable blanket of fibers several centimeters thick and a meter or so

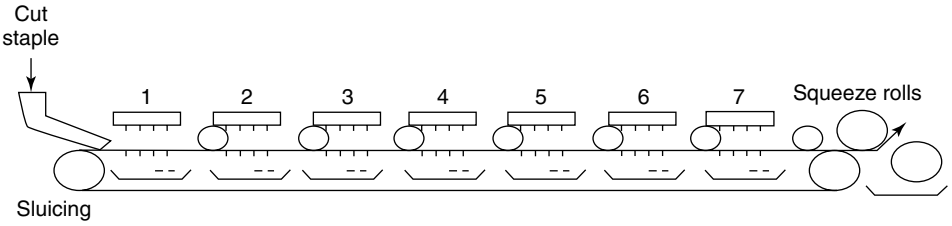

Fig. 4. Staple fiber washing sequence: 1, a *hot acid wash* (2% H_2SO_4 at 90°C) decomposes and washes out most of the insoluble zinc salts. This wash completes the regeneration of xanthate and removes as much sulfur as possible in the form of recoverable CS_2 and H_2S; 2, an alkaline sodium sulfide *desulfurization bath* solubilizes sulfurous by-products and converts them into easily removed sulfides; 3, a *sulfide wash* to remove the sulfides created in bath 2; 4, a *bleach bath* (optional) uses very dilute hypochlorite or peroxide to improve fiber whiteness; 5, a dilute acid or *sour bath* removes any remaining traces of metal ions and guarantees that any residual bleaching chemicals are destroyed; 6, a controlled-pH freshwater *final wash* removes the last traces of acid and salt prior to drying; and 7, a *finish bath* gives the fiber a soft handle for easy drying and subsequent processing.

wide because uneven laying results in uneven washing. Washing tows before cutting breaks out of the restrictions imposed by sluicing but results in the need to reoptimize processing conditions.

Cakes of textile yarn, collected in Topham boxes immediately after spinning, are processed on cake-wash machines. The cakes are wrapped in a porous paper and mounted in groups on stainless steel tubes through which the wash liquors can be forced. These tubes are mounted on a cake-wash box, which is a trolley on an overhead conveyor carrying the cakes to the different pumping stations on the machine. Each cake-wash box holds 100–200 cakes, and the permeability of each cake is critical to uniform washing. With permeability being determined largely by the degree of swelling of the fiber leaving spinning, very good control of all regeneration parameters is required to make yarn with consistent properties.

Yarn-drying procedures are far more critical than staple-drying procedures. All cellulosic fibers expand when wetted and contract on drying, the changes of size being greatest the first time the freshly made fiber is dried. If the contraction is hindered in any way, the yarn will possess a latent strain that will recover at a later stage, giving inferior weaving and dyeing. Furthermore, freshly formed regenerated cellulose undergoes a permanent change in molecular structure as it is heated, and this reduces its absorbency and hence its dye uptake.

Cakes are dried in low temperature, high humidity conditions for a long time in order to minimize strain and absorbency variability. The continuing usage of the cake system almost a century after its invention owes much to the desirable strain-free yarn arising from its washing and drying operations.

Industrial yarn uses a continuous washing and drying process based on self-advancing reels. Whereas the processing of cake yarn can take many days to complete, the continuous process is over in minutes. The process is less labor-intensive and more productive than the cake system, but the engineering and maintenance requirements are easily underestimated. It is most used for industrial yarns—still the reinforcement of choice for radial tire carcasses. For

these applications the strain built in by fast drying is no disadvantage because the yarns are expected to be at their best when bone dry. Dyeing is not required and an off-white color is tolerable. The main objective of the washing system is to remove acid and sulfur compounds that would affect the strength of the yarn during prolonged operation at high temperature.

Modified Viscose Processes. The need for ever stronger yarns resulted in the first important theme of modified rayon development and culminated—technically if not commercially—in the 0.88 N/tex (10 gf/den) high wet modulus industrial yarn process.

Tire Yarns. A method to increase the strength of viscose yarn from the 0.2 N/tex (2.2 gf/den) standard to levels needed in tires was first patented by Courtaulds in 1935 (18). By raising the zinc concentration in the spin bath to 4%, the thread could be stretched more by immersing it in a hot dilute acid bath during extension. Filament strengths increased to about 0.3 N/tex (3.3 gf/den), and the cross section became rounder, with a thicker skin than regular viscose. Pairs of these yarns were capable of being twisted into tire cords that outperformed traditional cotton cords.

The next significant strength improvement followed the 1950 Du Pont (19) discovery of monoamine and quaternary ammonium modifiers, which, when added to the viscose, prolonged the life of the zinc cellulose xanthate gel, and enabled even higher stretch levels to be used. Modifiers have proliferated since they were first patented and the list now includes many poly(alkylene oxide) derivatives (20), polyhydroxypolyamines (21–23), and dithiocarbamates (24).

Fully modified yarns had smooth, all-skin cross sections, a structure made up of numerous small crystallites of cellulose, and filament strengths around 0.4 N/tex (4.5 gf/den). They were generally known as the Super tire yarns. Improved Super yarns [0.44–0.53 N/tex (5–6 gf/den)] were made by mixing modifiers, and one of the best combinations was found to be dimethylamine with poly(oxyethylene glycol) of about 1500 mol wt (25). Ethoxylated fatty acid amines have now largely replaced dimethylamine because they are easier to handle and cost less.

The strongest fibers were made using formaldehyde additions to the spin bath while using a mixed modifier system (26–29) or using highly xanthated viscoses (50% + CS_2). Formaldehyde forms an *S*-methylol derivative with xanthate, which decomposes slowly, permitting high levels of stretch. It also reacts with the cellulose backbone to form cross-links that render the fiber high in modulus and low in extension. Unfortunately, problems associated with formaldehyde side reactions made the processes more expensive than first thought, and the inevitable brittleness that results whenever regenerated cellulose is highly oriented restricted the fibers to nontextile markets. The commercial operations were closed down in the late 1960s.

The formaldehyde approach is still used by Futamura Chemical (Japan). They make spun-laid viscose nonwovens where the hydroxymethylcellulose xanthate derivative formed from formaldehyde in the spin bath allows the fibers to bond after laying. This process was originally developed by Mitsubishi Rayon (30), who later found that the derivative was thermoplastic, and the web could be calender-bonded (120°C) prior to regeneration (31).

High Tenacity Staple Fibers. When stronger staple fibers became marketable, the tire yarn processes were adapted to suit the high productivity staple

fiber processes. Improved staple fibers use a variant of the mixed modifier approach to reach 0.26 N/tex (3 gf/den). The full 0.4 N/tex (4.5 gf/den) potential of the chemistry is unnecessary for the target end uses and difficult to achieve on the regular staple production systems.

The full potential of the mixed modifier tire yarn approach is, however, achieved in the modal or HWM (high wet modulus) staple processes using special viscose-making and -spinning systems. Courtaulds produced such fibers under the Vincel brand both in the United Kingdom and in Canada. Avtex made Avril (Fiber 40) until their closure in 1989. Lenzing still makes Modal staple in Austria. These fibers are most popular in ladies' apparel for their soft handle and easy dyeing to give rich coloration. They are made in finenesses down to 1 dtex (0.9 den) for fine yarns and hydroentangled nonwoven production (32).

Polynosic Rayons. The foregoing viscose process variants depend on the presence of zinc in the spin bath and modifiers in the viscose for their efficacy. Another strand of development began in 1952 when Tachikawa (33) patented a method for making strong, high modulus fibers that needed neither zinc nor modifier. The process was in fact related to the Lilienfeld (34) route to high strength, high modulus yarns that had failed in the 1930s because of the need for a spin bath containing 50–85% sulfuric acid. Both processes depend (33,34) on the fact that minimally aged alk-cell can, after xanthation with an excess of carbon disulfide, be dissolved at a low cellulose concentration to give very viscous viscoses containing high molecular weight cellulose. These viscoses have sufficient structure to be spun into cold, very dilute spin baths containing no zinc and low levels of sodium sulfate. The resulting gel filaments can be stretched up to 300% to give strong, round-section, highly ordered fibers, which can then be regenerated.

Toyobo's Tufcel is an excellent example of a modern polynosic fiber process, probably the most difficult viscose process to run efficiently, (35). On-line process control allows only four persons per shift to make 10,000 t/year of a variety of special fibers, including Flame Retardant, Deep Dyeing (two types), Activated Carbon Fiber, and Super Fine 0.55 dtex (0.5 denier). Alk-cell and mixing soda quality are maintained by pressings soda centrifugation, filtration, and dialysis to remove 90% of the hemicellulose. Ion-exchange membranes are used to give 50 times the life and twice the efficiency of the old dialyzer bags used in tire-yarn production. Dissolution of the 500 DP xanthate is augmented by crumb grinders on the churn outlets and by in-line homomixers, which together reduce the dissolution time from three hours to one. Spinnerets for the finer yarns have 40-μm holes, and these are protected by automatic backflush filters, removing gels down to 15-μm diameter.

The polynosic rayons enjoyed a revival of fortunes in the 1990s when the new lyocell fiber produced by Courtaulds (Tencel®)—a solvent spun fiber with polynosic properties—became popular in ladies' apparel and denim. By 2001 however the Toyobo Tufcel plant in Japan had been closed and at the time of writing, it is likely to be transferred to China where lower labor costs would allow it to compete more effectively with lyocell (see below).

Bulky Rayons. Unlike the thermoplastic synthetic fibers, viscose rayon cannot be bulked by mechanical crimping processes. Crimpers impart crimp to a regenerated cellulose fiber, but it is not a permanent crimp and will not survive wetting out.

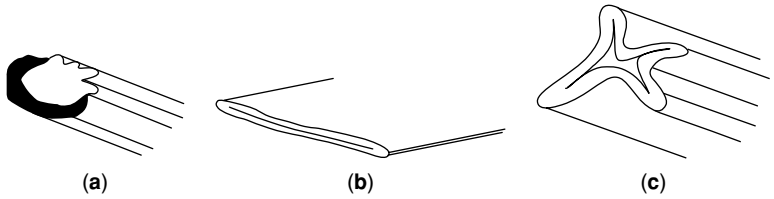

Fig. 5. Bulky rayons: (**a**) crimped rayon; (**b**) inflated–collapsed rayon; (**c**) super inflated rayon.

Permanent chemical crimp can be obtained by creating an asymmetric arrangement of the skin and the core parts of the fiber cross section. Skin cellulose is more highly ordered than core cellulose and shrinks more on drying. If, during filament formation in the spin bath, the skin can be forced to burst open to expose fresh viscose to the acid, a fiber with differing shrinkage potential from side to side is made, and crimp should be obtained (Fig. 5**a**).

Whether or not it is obtained depends on the washing mechanism allowing the shrinkage, and hence the crimp, to develop prior to the completion of regeneration. Crimp development occurs fully only in staple fiber processes, where the sluicing operation allows the cut tufts of acid tow to expand freely in ample volumes of hot liquor.

Even when crimp is fully developed it is easy to pull out (low energy) and difficult to translate into noticeably bulkier woven and knitted fabrics. It does however improve the absorbency and the cohesion of the staple (important in spun-yarn and nonwoven making) and gives a subtly different texture to woven fabrics. Coarse crimped rayon was the leading synthetic carpet fiber in Europe in the 1960s, but has since been replaced by the highly durable bulked continuous filament nylon yarns. Crimp is most important in rayon used for hygienic absorbent products.

Process conditions that favor chemical crimp formation are similar to those used for improved tenacity staple (zinc/modifier route). However, spin-bath temperature should be as high as possible (ca 60°C) and the spin-bath acidity as low as possible (ca 7%). Attempts have been made to overcome some of the leanness of high strength rayons by increasing the crimp levels. ITT Rayonier developed the Prima crimped HWM fiber (36) and made the process available to their customers. Avtex developed Avril III. Neither remain in production.

Cross-sectional modifications of a more extreme nature than skin-bursting, which nevertheless do not form crimp, have grown in importance since the early 1980s. These yield a permanent bulk increase, which can be translated into bulky fabrics without the need for special care. The first commercial staple fiber of this type was Courtaulds hollow Viloft, developed in the 1970s using a carbonate inflation technique (37).

Inflation had long been known as an intermittent problem of textile yarn manufacture. It was caused by the skin forming too quickly to allow the escape of gases liberated by the regeneration reactions, or as a result of air in the viscose at the jet. In the 1920s attempts were made to produce hollow naturally dull yarns by inclusion of gas (38) and by the addition of gas-generating agents to the

viscose (39). It was also possible to cause inflation by capturing the regenerated gases when spinning a low soda viscose (40). In 1942–1943 Du Pont used air injection to produce Bubblfil yarns as a kapok replacement for lifejackets, as thermal insulation for sleeping bags, and for aviators' uniforms.

All these early inflation processes (41) were difficult to control, and after World War II they were neglected until the 1960s. Companies in Japan, the United States, and Europe then started to develop inflated–collapsed rayons (Fig. 5**b**) for speciality papers (42) and wet-laid nonwovens.

Although none of these survived commercially for more than a few years, their development led to an increased understanding of the inflation process and the identification of conditions that could yield a continuously hollow staple fiber in large-scale production (43).

The basis of this process was the injection of sodium carbonate solution into the viscose, although direct injection of carbon dioxide gas that reacts with the viscose soda to form sodium carbonate could also be used (44). The carbonate route yielded a family of inflated fibers culminating in the absorbent multilimbed super inflated (SI) fiber (Fig. 5**c**).

In its original form (45), the fiber was intended for use in toweling where the bulk, firm handle, and high rate of wetting made it one of the few fibers that would blend with cotton without spoiling the wet texture. An even higher absorbency version was developed (46) for use in nonwovens and tampons (47), where it comfortably outperformed cotton by reexpanding like a sponge on wetting.

By the mid-1980s a different approach to the production of fine fibers with novel cross sections became possible. Noncircular spinneret holes, eg, rectangular slots, allowed the large-scale production of flat fibers down to 2.2 dtex (2 den) (Fig. 6a). These I-shaped fibers were capable of replacing the inflated hollow fibers in textile applications, providing similar levels of bulk, warmth, and handle while having a much more regular shape. They were followed by the development of solid Y- and X-shaped multilimbed fibers (48) (Fig. 6b), which performed like SI fiber but had much lower levels of water imbibition than the inflated version. Their shape and relative stiffness enabled them to absorb more fluid between, as opposed to inside, the fibers. They were therefore as absorbent in use as the inflated versions (49,50) but did not require the extra process chemicals, and were easier to wash and dry in production and use. They are the most important bulky rayons now in production.

Alloy Rayons. It is possible to produce a wide variety of effects by adding materials to the viscose dope. The resulting fibers become mixtures or alloys of

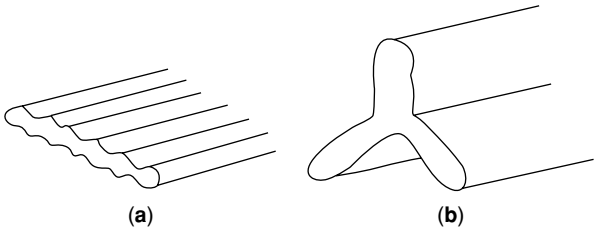

Fig. 6. (**a**) I-section rayon; (**b**) Y-section rayon.

cellulose and the other material. The two most important types of alloy arise when superabsorbent or flame-retardant fibers are made.

American Enka (51,52) and Avtex (53) both produced superabsorbent alloy rayons by adding sodium polyacrylate, or copolymers of acrylic and methacrylic acids, or sodium carboxymethylcellulose to the viscose. The resulting alloys contained about 20% of the water-soluble polymer, giving water imbibitions up to double those of the unalloyed rayons. (See SUPERABSORBENT POLYMERS). They performed particularly well in tampons, where the presence of the slippery polymer at the fiber surface encouraged wet-expansion of the compressed plug. Their use in this, the only real market that developed, declined after the Toxic Shock Syndrome outbreak (54,55) in the early 1980s. Other polymers that have formed the basis of absorbent alloys are starch (56), sodium alginate (57), poly(ethylene oxide) (58), poly(vinyl pyrrolidinone) (59), and sodium poly(acrylamido-2-methyl-2-propane sulfonic acid) (60).

Alloys of cellulose with up to 50% of synthetic polymers (polyethylene, poly(vinyl chloride), polystyrene, polytetrafluoroethylene) have also been made, but have never found commercial applications. In fact, any material that can survive the chemistry of the viscose process and can be obtained in particle sizes of less than 5 μm can be alloyed with viscose.

Flame retardancy can be obtained by adding flame-retardant chemicals to make up about 20% of the fiber weight (61). The first commercial products used tris(2,3-dibromo-1-propyl) phosphate, but the P—O bonds made these susceptible to hydrolysis by strong alkali, and the bromine increased the rate of photodegradation. The chemical was found to cause cancer in laboratory tests and in the late 1970s fell from favor (62). Propoxyphosphazine (Ethyl Corp.) retardants were later used in Avtex's PFR fiber, and a bis(5,5-dimethyl-2-thiono-1,3,2-dioxaphosphorinanyl) oxide powder (Sandoz) was the basis of later European FR fiber developments. Alloys with inorganic salts such as silicates or aluminates are possible, the salts being converted to fibrous polyacids when the cellulose is burnt off (63). This latter approach is the basis of the Visil flame-retardant fiber introduced by Kemira Oy Saeteri (64).

Cuprammonium Rayon

Asahi Chemical Industries (ACI, Japan) are now the leading producers of cuprammonium rayon. In 1990 they made 28,000 t/yr of filament and spunbond nonwoven from cotton cellulose (65). Their continuing success with a process that has suffered intense competition from the cheaper viscose and synthetic fibers owes much to their developments of high speed spinning technology and of efficient copper recovery systems. Bemberg SpA in Italy, the only other producer of cuprammonium textile fibers, was making about 2000 t of filament yarn in 1990.

The process operated by ACI is outlined in Figure 7. Bales of cotton linter are opened, cooked in dilute caustic soda, and bleached with sodium hypochlorite. The resulting highly purified cellulose is mixed with pre-precipitated basic copper sulfate in the dissolver, and 24–28% ammonium hydroxide cooled to below 20°C is added. The mixture is agitated until dissolution is complete. If necessary, air is introduced to allow oxidative depolymerization and hence a lowering of the dope viscosity.

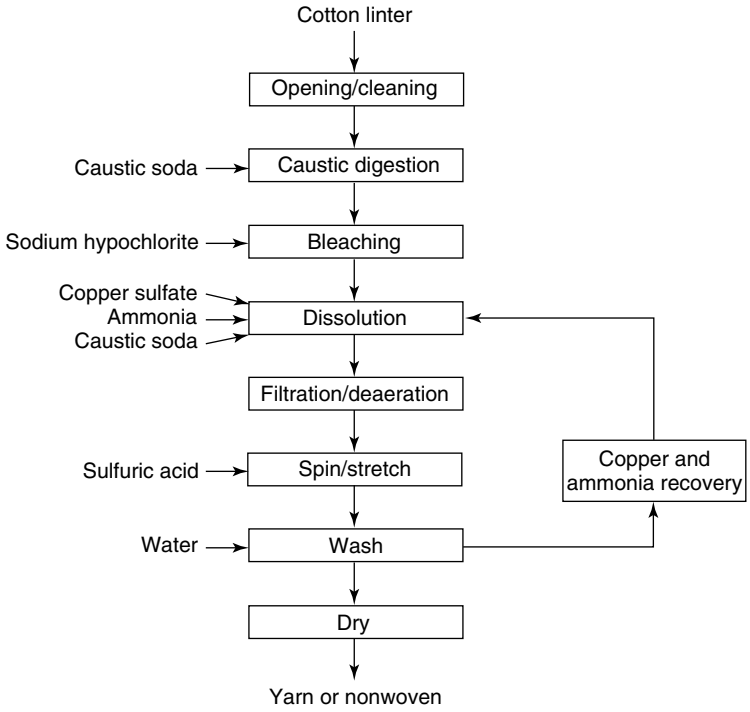

Fig. 7. The cuprammonium process.

The dark blue solution containing 5–10% of cellulose with a DP of 1000–2000 is filtered through a series of plate-and-frame filter presses using fine-mesh metal screens to remove any particles that might block the spinneret holes. It is then deaerated under vacuum and stored ready for spinning. Unlike viscose dope, the cuprammonium cellulose [9050-09-3] solution is relatively stable.

In the old classical spinning technique developed by Bemberg, the deaerated and filtered dope is extruded into a funnel-shaped glass tube through which slightly alkaline water is forced. The water carries the regenerating cellulose gel while stretching it by about 10,000% as it accelerates to the exit. The yarn then passes through a bath containing about 5% sulfuric acid, which completes the regeneration of cellulose and converts the ammonia and copper residues into their sulfates.

In the original batch process, the blue-colored yarn was collected on hanks for separate washing, lubrication, and drying treatments. The continuous process was first patented in the United States in 1934 (66) and 1935 (67), and operated by American Bemberg. This process (68) combined the batch process washing treatments in a series of tanks through which a warp of yarns (from hundreds of spinnerets) were pulled prior to drying and beaming.

The high speed continuous filament process (69) was first used for manufacturing in 1974, and this enabled the yarn production rates to be raised from 150 to 380 m/min. This system uses a pair of net conveyor belts to protect and transport an overfed warp of yarns through washing and drying. After spinning, excess bath

is stripped from the yarns by a shaking mechanism that damages the yarn less than the old comb stripper guides. In 1987, Asahi commercialized their "mark 2" high speed spinning system, which operated at 1000 m/min, and are now working on systems that will exceed 2000 m/min.

Also in 1974, ACI started the direct spinning of Bemliese nonwoven fabrics using the same conveyor belt washing technique (70). This process uses wide spinnerets and spinning cells to produce a curtain of filaments, which fall in the spinning liquor onto the conveyor. The conveyor is oscillated from side to side in order to lay the continuous fibers down in sinusoidal waves. After washing, the webs, which have strength resulting from the self-bonding nature of the fibers as spun, can be further strengthened and finished by hydroentanglement.

Almost total copper recovery needs to be achieved to meet the economic and environmental criteria for a modern cellulosic fiber process. In the basic process (71), spent spin-bath liquor was passed through ion-exchange resins and the effluent from these resins was reused in the funnels. The copper washed out of the yarn was precipitated with sodium carbonate, forming the basic copper sulfate sludge, which was reused in cellulose dissolving. Only 95% copper recovery was possible using this system. Recovery efficiencies of up to 98% were claimed for the Russian Kustanai Plant in a document (72), which also records a 99.9% recovery achieved by Japan Organo Co., Ltd. Asahi claims to have perfected copper recovery to a point where it is no longer an issue.

A high percentage of the ammonia can be recovered from the spin-bath effluent and by washing prior to the final acid bath. During acidification, remaining ammonia is converted to the sulfate and recovered when the acid wash liquor is treated with carbonate to recover the copper. Ammonia residuals in the large volumes of washwater can only be removed by distillation. Overall about 75–80% of the ammonia required to dissolve the cellulose can be recovered.

Asahi's innovations have done much to transform the cuprammonium process from an uneconomic competitor for viscose and synthetics into the fastest wet-spinning system in the world. They now claim it to be competitive both economically and environmentally with the viscose filament process.

Direct Dissolution Processes

Regenerated fibers produced via the direct dissolution of cellulose in organic solvents are generically known as lyocell fibers.

The production routes already described cope with the difficulties of making a good solution by going through an easy-to-dissolve cellulose derivative, eg, xanthate or a cellulose complex, such as cuprammonium. The ideal process, one that could dissolve the cellulose directly from ground wood, is still some way off, but since the early 1980s significant progress has been made.

There have been reviews of the early work on direct dissolution (73,74). The efforts to dissolve cellulose directly as a *base* using phosphoric, sulfuric, and nitric protonic acids, or zinc chloride, thiocyanates, iodides, and bromides as Lewis acids are recorded (73,74). With regard to cellulose acting as an *acid*, sodium zincate, hydrazine, and sodium hydroxide are listed as inorganic solvents, and quaternary ammonium hydroxides, amines, dimethylamine–DMSO mixtures, and

amine oxides as organic bases. Cellulose solutions of 16% have been achieved in lithium chloride–dimethylacetamide systems (75), and 14% solutions in dinitrogen tetroxide–dimethylformamide systems (76). Solutions of up to 14% cellulose were achieved in an extensive study of the ammonia–ammonium thiocyanate solvent system (77). The dimethylsulfoxide–paraformaldehyde system (78) is capable of dissolving a wide range of DPs without causing degradation. However, despite early promise, the problems of developing fiber production routes using these systems have, with the exception of the amine oxide route, proved insurmountable.

The cellulose-dissolving potential of the amine oxide family was first realized (79) in 1939, but it was not until 1969 that Eastman Kodak described the use of cyclic mono(*N*-methylamine-*N*-oxide) compounds, eg, *N*-methylmorpholine-*n*-oxide [7529-22-8] (NMMO), as a solvent size for strengthening paper (80) by partially dissolving the cellulose fibers.

Other patents (81,82) covered the preparation of cellulose solutions using NMMO and speculated about their use as dialysis membranes, food casings (sausage skins), fibers, films, paper coatings, and nonwoven binders. NMMO emerged as the best of the amine oxides, and its commercial potential was demonstrated by American Enka (83,84). Others (85) have studied the cellulose–NMMO system in depth; one paper indicates that further strength increases can be obtained by adding ammonium chloride or calcium chloride to the dope (86).

Both American Enka (87) and Courtaulds set up pilot-plant work in the early 1980s with the objectives of developing fiber spinning and solvent-recovery operations. The Austrian viscose producer Lenzing studied various systems (88) and commenced pilot operations on an NMMO system at the end of the 1980s. At the time of writing, only Courtaulds and Lenzing have proceeded to a commercial scale.

American Enka decided not to commercialize the process and stopped the research in 1981, probably because at that time engineering issues associated with the difficulty of avoiding exothermic reactions looked too hard to resolve economically. However when Courtaulds had demonstrated practical solutions to the many problems discovered during American Enka's early work, they (Enka that is) reentered the field with the continuous filament version of the lyocell process under their brand name "Newcell." The Akzo deal with Courtaulds involved their gaining access to Courtaulds technology in exchange for granting Courtaulds rights to use some of the key steps in the early patents mentioned above. However, Akzo–Nobel had earlier granted a lyocell license to Lenzing, the Austrian viscose fiber maker, allowing Lenzing to enter the field with a very similar process to Courtaulds. The ensuing patent litigation between Lenzing and Courtaulds was to prove costly to both companies.

Lenzing obtained a patent in the U.S.A. for a process, some aspects of which had been operated by Courtaulds for many years, and indeed were used in production at Courtaulds Tencel plant in Alabama. Courtaulds naturally objected, and applied for summary dismissal of both the U.S. and the subsequent European patent. In Europe, the Munich court would not allow the Lenzing patent to be dismissed summarily and the case went to trial. Courtaulds won, and Lenzing's European patent was disallowed, with no right of appeal. In the U.S.A., the Lenzing patent was summarily dismissed, but Lenzing appealed successfully. At this point the two companies reached a settlement out of court. The lyocell patent

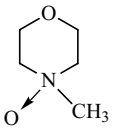
estates of both companies were pooled, to be available royalty-free to both companies. The settlement only covered patented technology; there was to be no sharing of "knowhow" gained in the operation of the process, which at the time had only been commercialized by Courtaulds.

Akzo–Nobel acquired Courtaulds in 1998, and formed Acordis Fibers, bringing together in one company all the key lyocell technologies.

The Courtaulds Lyocell Process. The increasing costs of reducing the environmental impact of the viscose process coupled with the increasing likelihood that the newer cellulose solvents would be capable of yielding a commercially viable fiber process led Courtaulds Research to embark on a systematic search for a new cellulosic fiber process in the late 1970s.

The project, code-named Genesis, did not involve basic research into new solvents for cellulose so much as screening the known solvents against criteria felt to be important for the cellulosic fiber process of the future. The solvent chosen had to be recyclable at a very high level of efficiency, and hence as near to totally containable in the process as possible. It had to be safe to work with and safe in the environment in the event of any losses. It had to be able to dissolve cellulose completely without reacting with it or degrading it, and the resulting process had to be less energy-intensive than the viscose route, which was already proven to be less energy-intensive than the synthetics in an independent study (89). It was especially important to choose a system that, like the melt-spun synthetics, would not require costly gaseous- or liquid-effluent treatment systems. Finally, the process would be capable of making good textile fibers to maintain, or even extend, the cellulosics' share of the global market against fierce competition from melt-spun synthetics based on cheap but nonrenewable oil reserves.

By 1980, *N*-methyl morpholine-*n*-oxide (NMMO) was shown to be the best solvent, provided well-known difficulties associated with its thermal stability could be avoided by appropriate chemical engineering.



***N*-methyl morpholine-*n*-oxide (NMMO)**

(**1**)

Filaments obtained from the first single-hole extrusion experiments had promising properties, so Courtaulds committed the resources in 1982 to build a small pilot plant to test the feasibility of overcoming the solvent handling and recovery problems that had prevented earlier commercial exploitation. This system, capable of making up to 100 kg of fiber per week, met its objectives and allowed the first serious end use development to begin. Scale-up to 1000 kg/week pilot line was possible in 1984, and in 1988 a 25,000 kg/week semicommercial line was commissioned in Grimsby, United Kingdom, to allow a thorough test of the engineering and end-use development aspects. Commericalization of the fiber as Tencel followed in 1990 and rapid sales buildup, especially in Japan, led to a 16,000-t plant being built and started up in Mobile, Alabama, in 1992. A second 20,000-t factory followed in Mobile in 1995 and a third 40,000-t plant was commissioned in Grimsby in 1998.

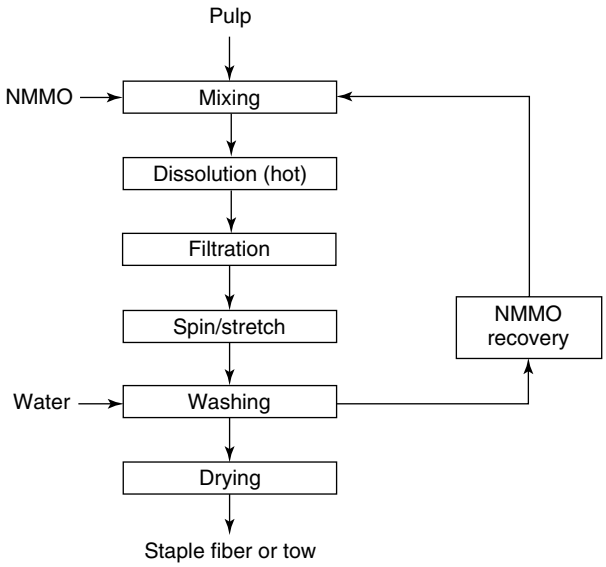


Fig. 8. Direct dissolution: Acordis Tencel process.

The Acordis system is illustrated in block, diagram form in Figure 8. Dissolving-grade woodpulp is mixed into a paste with NMMO and passes through a high temperature dissolving unit to yield a clear viscous solution. This is filtered and spun into dilute NMMO, whereupon the cellulose fibers precipitate. These are washed and dried, and finally baled as staple or tow products as required by the market. The spin-bath and wash liquors are passed to solvent recovery systems that concentrate the NMMO to the level required for reuse in dissolution.

Figure 9 is an outline flow sheet illustrating the layout of the key process steps provided courtesy of Acordis. Unlike both the viscose process and the later Lenzing Lyocell process, the fiber is washed, dried, and crimped in tow form prior to cutting. Unlike the viscose spinning process, the cellulose solution is extruded into warm air prior to immersion in the aqueous NMMO spinning solution. (This is known as dry-jet wet-spinning to distiguish it from the totally dry acetate spinning process and the totally wet viscose spinning.)

Lyocell Applications

Dry-jet wet-spinning of lyocell fiber has been described (90) as being similar to the extrusion of lyotropic rigid-rods, giving rise to a highly microfibrillar structure that is consistent across the entire cross section of the fiber—ie differing from the skin–core structure observed in viscose rayon. Wide-angle X-ray diffraction data shows lyocell to have a crystallinity of 60% (cf 40% for viscose), the celluose crystals having a a lateral dimension of about 4 nm. However, microfocus small-angle X-ray scattering (91) has recently shown a definite skin–core structure, with the thin skin having better-oriented voids than the core. This observation is more in

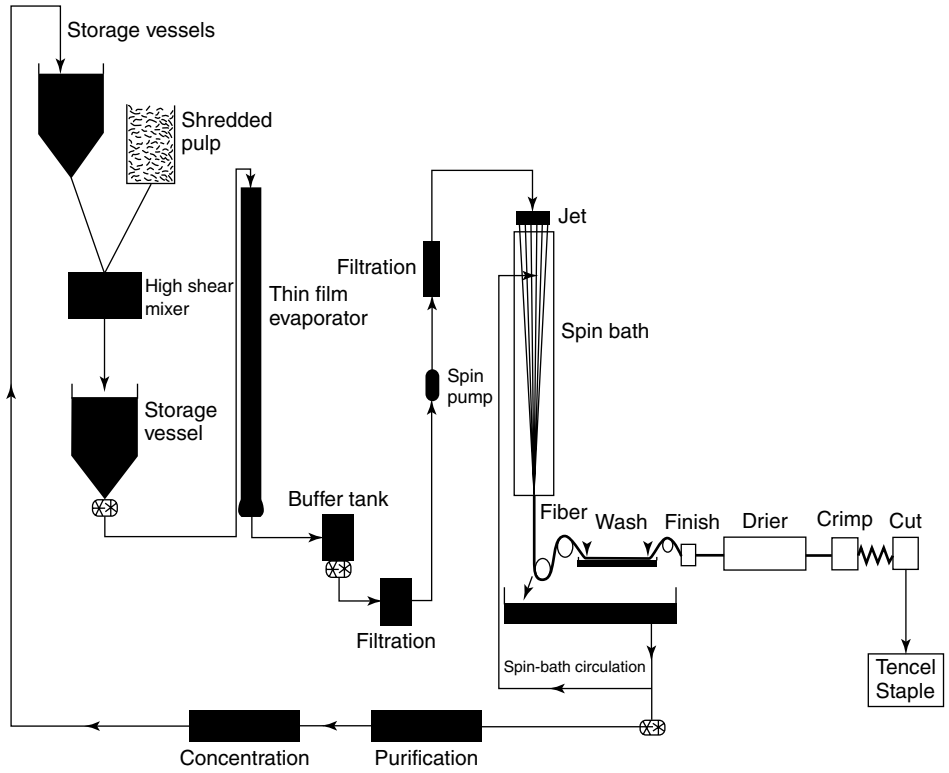

Fig. 9. Direct dissolution: Acordis Tencel Flow Diagram.

keeping with the macro observations of fibrillation in paper-making—the surface appearing to fibrillate easily—whereas breaking up the core region of the fiber proves very difficult.

The new fiber thus had physical properties (Table 1) sufficiently different from regular rayon to allow an initial market development strategy that did not erode the position of the traditional viscose fiber. The unique strength, texture, and coloration potential of the fiber enabled it to command premium prices in up-market mens' and ladies' outerwear, largely due to the fibrillation tendency being harnessed by creative finishing processes to produce "soft-touch" or "peach-skin" textures. However while premium pricing allowed the process to expand rapidly, it was only achievable while the special characteristics of lyocell were in fashion, and before the soft-touch characterisics had been developed using other cellulosics such as polynosic rayon and cotton. Furthermore the uncontrolled fibrillation that occurred when textiles made from early lyocell fibers were conventionally dyed, finished, or washed led to unacceptable fabric appearance and texture. The fibrils splitting away from the fiber surface became apparent as a frosty-looking surface that prevented the true dyed color from emerging. In extreme cases, and especially on knitted fabrics where the fibers were less tightly bound to the structure, the fibrils caused these looser fibers to entangle and form pills. Thus early lyocell had restricted potential in mass-market textiles, being confined to woven

Table 1. Properties of Selected Commercial Rayon Fibers

Property	Cuprammonium	Regular rayon	Improved rayon	Modal	Polynosic	Y-Shaped rayon[a]	Solvent spun rayon[b]

products dyed and finished by gentle processes to lighter shades for dry-clean-only garments.

This unacceptable situation was addressed by developing production processes to allow the manufacture of lyocell fiber with minimal fibrillation tendency—even if this meant increasing process cost. This was achieved in part by altering the spinning conditions, and in part by the use of cross-linking agents in washing, to bond the fibrillar fiber structure more strongly. It was also addressed by investigating nonwoven applications for lyocell, thereby avoiding wet processing except in areas (eg paper-making and hydroentanglement) where fibrillation could be an advantage.

Several studies of its performance in nonwovens had shown it capable of yielding fabric strengths 2–3 times higher than hitherto possible with regenerated cellulosics (92,93). It appeared particularly suitable for the latest hydroentanglement systems, where its basic strength and an ability to develop a microfiber surface under the action of high pressure water jets enabled it to make very strong nonwoven fabrics having textile-like properties. The effect of high pressure water jets on lyocell fiber was first described publicly in 1989 (94). In addition to the higher fabric strengths, extensive fibrillation had occurred, making the fabrics stiffer (bonding between the fibrils). The fiber took on a chalky white appearance as bonding proceeded (light scattering from the fibrils), and absorbent capacity and wicking rates were higher than that for the higher water-imbibition viscose rayon controls: this too being an effect of the microfiber content. However the most significant alteration in properties caused by fibrillation was in the dry and wet texture of the fabrics.

Dried conventionally after hydroentanglement, hydrogen bonding between the fibrils of the highly fibrillated fibers stiffened up the fabrics, giving them an unattractive papery handle. Once rewetted, however, the material took on a suede or chamois-leather-like texture, which proved interesting to makers of durable wipes for car and window cleaning and for artificial leather, especially for shoe construction, where the inherent absorbency of the fiber could improve the comfort of leather substitutes made from, for example, splittable synthetic/lyocell blends.

Current lyocell, like the almost identical polynosic viscose rayons developed half a century ago (33), has so far proved to have similarly limited and variable potential in the fashion textile markets for which it, and the process for making it, was designed. Whether a cheaper, high-fibrillation version would improve lyocell's prospects in nonwovens is still open to debate.

Other Sovent Routes

Work on other routes to cellulosic fibers continues, some driven by a desire to identify an environmentally benign route to cellulosic fibers that can utilize the large capital investment in the viscose process equipment and hence cost less than a completely new fiber process such as lyocell.

The Finnish viscose producer Kemira Oy Saeteri collaborated with Neste Oy on the development of a carbamate derivative route. This system is based on work (95) that showed that the reaction between cellulose and urea gives a derivative easily dissolved in dilute sodium hydroxide:

$$\text{Cell—OH} + \text{NH}_2\text{—CO—NH}_2 \rightarrow \text{Cell—O—CO—NH}_2 + \text{NH}_3 \qquad (7)$$

Neste patented an industrial route to a cellulose carbamate pulp (96) that was stable enough to be shipped into rayon plants for dissolution as if it were xanthate. The carbamate solution could be spun into sulfuric acid or sodium carbonate solutions, to give that when completely regenerated had similar properties to viscose rayon's. When incompletely regenerated they were sufficiently self-bonding for use in paper-making. The process was said to be cheaper than the viscose route and to have a lower environmental impact (97). It has not been commercialized, so no confirmation of its potential is yet available.

It has been claimed that solutions containing 10–15% cellulose in 55–80% aqueous zinc chloride can be spun into alcohol or acetone baths to give fibers with strengths of 0.13–0.18 N/tex (1.5–2 gf/den). However, if these fibers were strain-dried (ie, stretched) and rewetted while under strain, strengths of 0.46 N/tex (5.2 gf/den) were achieved (98).

Asahi has been applying the steam explosion (99) treatment to dissolving pulp to make it dissolve directly in sodium hydroxide (100), and they claim (101,102) a solution of 5% of steam-exploded cellulose in 9.1% NaOH at 4°C being spun into 20% H_2SO_4 at 5°C. The apparently poor fiber properties [best results being 0.16 N/tex (1.8 gf/den) tenacity dry, with 7.3% extension] probably arise

because the fibers were syringe-extruded at 8.3 tex/filament (75 den/fil). Asahi feels that this could be the ultimate process for large-scale production of regenerated cellulose fibers.

Patents (103,104) published in February 1996 describe anisotropic cellulose solutions at concentrations up to 40% in a "solvent containing from 72 to 79 wt% of phosphorous pentoxide." Claiming a highly economical route for the production of tire yarns, the process described therein appears to be simple and elegant.

A twin-screw extruder is fed with dry fluff-pulp and the phosphoric acid solvent. The first cooled zone mixes the cellulose into the solvent and reduces the particle size, the second hotter zone starts the dissolution, and the third zone provides further blending and dissolution time, its temperature being controlled to achieve the desired reduction in cellulose DP. A final low pressure zone allows deaeration and dewatering (or the injection of additives) as necessary, and filters remove particles before spinning.

While "all available types of cellulose" can be used, dissolving pulps are preferred for best spinning and fiber properties. The solvent preparation involves mixing orthophosphoric acid with polyphosphoric acid, in a 80:20 ratio at around 50°C and then cooling and storing for several hours to arrive at the desired concentration of anhydride.

After less than 15 min in the extruder, the cellulose solution, typically containing 20% cellulose, is spun, like lyocell, through a similar-sized air gap, but into cold acetone, followed by water washing, sodium carbonate or soda neutralization, and a final water washing. Tire yarn with a breaking tenacity of 76 cN/tex, an elongation at break of 6.5%, capable of sustaining a load of 20 N/tex without extending by more than 2%, was obtained at 120 m/min spinning speed.

Michelin Research had earlier developed a process using a mixture of phosphoric and formic acids, also for tire yarns. The Akzo–Nobel process, based on phosphoric acid alone, was felt to give easier solvent recovery. A process using phosphoric acid alone (105) emerged from Michelin Research in March 1996.

Further work at Akzo–Nobel (106) showed that if extra water is injected with the solvent, or added to the anisotropic solutions described above, isotropic solutions of cellulose could be obtained at concentrations of 7–20%. A 7.6% cellulose solution could be spun to give fibers with tenacities of 18–38 cN/tex (extension at break declining from 17.4 to 8.4%) as draw ratios were increased from 60 to 150%.

One of the key requirements for making high quality high modulus fibers using the phosphoric acid approach is to keep the level of phosphorus bound to cellulose at a minimum. Allowing it to rise from the $<0.5\%$ level preferred in the above process to more than 3% by increasing the phosphorus pentoxide level in the solvent, or by increasing the storage temperature of the solvent prior to introduction of the cellulose, resulted in weaker, hard-to-handle gel fibers with very high absorbency. Akzo–Nobel therefore postulated the production of superabsorbent fibers using a variation of the phosphoric acid route (107). While the resulting patent covers conventional fiber production, perhaps in recognition of the difficulties of cleaning up such fibers, it also covers the production of fibrids by extrusion into a high shear mixer to obtain a fibrous slurry. Water absorbencies of up to 100 g/g are claimed if the fibers containing more than 6% bound phosphorus are cross-linked with ethylene glycol diglycidyl ether in a 70:30 ethanol/water mixture.

Centrifugal spinning of phosphoric acid solutions of cellulose was also explored (108), and found capable of producing mixtures of filaments with linear densities ranging from 1 to 23, and tenacities of 4 to 90 cN/tex and extensions at breakup from 1 to 15%.

In an attempt to remove the problems associated with the acetone coagulation bath, fibers were air-gap spun into aqueous salt solutions, eg up to 25% of diammonium hydrogen phosphate or potassium phosphate or 5% zinc sulphate (109). This patent also makes it clear that the corrosive nature of the solution is an issue in spinneret design.

None of the above patents address the crucial solvent recovery issues. While recovery of acetone is possible, re-creating concentrated phosphoric acid from either dilute solutions or phosphates appears as difficult as the recovery of sulphuric acid from sulphates in the viscose process. The viscose approach is of course to extract and sell the neutralization product and use fresh concentrated sulphuric acid to make up the recovery shortfall—an option that is apparently unattractive in phosphate systems.

Fiber Properties

The bulk properties of regenerated cellulose are the properties of Cellulose II, which is created from Cellulose I by alkaline expansion of the crystal structure (110,111) (see CELLULOSE). The key textile fiber properties for the most important current varieties of regenerated cellulose are shown in Table 1. Fiber densities vary between 1.53 and 1.50.

A discussion of the fiber properties is complicated by the versatility of cellulose and its conversion routes. Many of the properties can be varied over wide ranges, depending on the objectives of the producer. For instance, dry fiber strengths from less than 1 but up to 10 g/den have been made commercially, and at a given dry strength it has proved possible to vary the elongation and wet properties independently. The water imbibition of pure cellulose fibers has been varied from 45 to 450%, and the cross-sectional shape altered from circular all-skin, to multilobal collapsed tubes that reopen on wetting. Alloying adds further scope for adding properties unachievable with pure cellulose. Chemically, cellulose fibers are well endowed with reactive hydroxyl groups that render them amenable to modification by grafting, which, more so than alloying, allows the properties to be moved in the direction of synthetic polymers if the need arises. The same reactivity makes the fibers more degradable than synthetics, both chemically and biologically, although it must be said that biological degradability is easily halted by inclusion of suitable biocides.

Thermal Properties. Fibers are not thermoplastic and are stable at temperatures below 150°C, with the possible exception of slight yellowing. They begin to lose strength gradually above 170°C, and decompose more rapidly above 300°C. They ignite at 420°C and have a heat of combustion of 14,732 J/g (3.5 kcal/g).

Moisture Regain. The fibers are all highly hydrophilic, with moisture regains at 65% rh, ranging from 11 for the polynosics to 13 for regular rayon. Wetting of cellulose is exothermic, with the regenerated forms giving out 170 J/g (41 cal/g) between 40 and 70% rh, compared with 84 J/g (20 cal/g) for cotton. The

fiber structure swells as fluid is imbibed, and fiber strength and stiffness falls. The contact angle for unfinished fiber is greater than 150°.

Chemical Properties. The fibers degrade hydrolytically when contacted with hot dilute or cold concentrated mineral acids. Alkalies cause swelling (maximum with 9% NaOH at 25°C) and ultimately disintegration. They are unaffected by most common organic solvents and dry-cleaning agents. They are degraded by strong bleaches such as hypochlorite or peroxide.

Optical Properties. The fibers are birefringent. The refractive index parallel to the fiber length ranges from 1.529 for regular rayon to 1.570 for the polynosics. Refractive indexes perpendicular to the fiber length range from 1.512 (regular) to 1.531 (polynosic). Basic fibers are naturally lustrous, but can be made dull by adding opacifiers or by changing the cross-sectional shape.

Electrical. The electrical properties of the fiber vary with moisture content. The specific resistance of the fibers is around $3 \times 10^6 \Omega$/cm at 75% rh and 30°C compared with $1 \times 10^{18} \Omega$/cm for pure dry cellulose. The dielectric constant (100 kHz) is 5.3 at 65% rh and 3.5 at 0% rh. The zeta potential in water is −25 mV.

Environmental Issues: Viscose Process

As noted in the introduction, rayon is unique among manufactured fibers because it is the only one to use a natural polymer (cellulose) directly. Polyesters, nylons, polyolefins, and acrylics all come indirectly from vegetation; they come from the polymerization of monomers obtained from reserves of fossil fuels, which in turn were formed by the incomplete biodegradation of vegetation that grew millions of years ago. The extraction of these nonrenewable reserves and the resulting return to the atmosphere of the carbon dioxide from which they were made is one of the most important environmental issues of current times. Cellulosic fibers therefore have much to recommend them provided that the processes used to make them have minimal environmental impact.

Fossil Reserves. Renewable resources will become increasingly important as the planet's stocks of fossilized reserves are depleted and as governments realize that biomass can provide a truly sustainable, cost-effective source of energy and materials. The viscose route currently needs fossil reserves for energy generation but for little else.

Liquid Effluents. Recycling of acid, soda, and zinc have long been necessary economically, and the acid–soda reaction product, sodium sulfate, is extracted and sold into other sectors of the chemical industry. Acid recovery usually involves the degassing, filtering, and evaporative concentration of the spent acid leaving the spinning machines. Excess sodium sulfate is removed by crystallization and then dehydrated before sale. Traces of zinc that escape recovery are removable from the main liquid effluent stream to the extent that practically all the zinc can now be retained in the process.

Gaseous Effluents. Twenty percent of the carbon disulfide used in xanthation is converted into hydrogen sulfide (or equivalents) by the regeneration reactions. Ninety to 95% of this hydrogen sulfide is recoverable by scrubbers that yield sodium hydrogen sulfide for the tanning or pulp industries, or for conversion back to sulfur. Up to 60% of the carbon disulfide is recyclable by condensation from rich streams, but costly carbon-bed absorption from lean streams is necessary to

recover the remaining 20 + %. The technology to deal with this is becoming available, but there remains the danger that cost increases resulting from the necessary investments will make the fibers unattractively expensive compared with synthetics based on cheap nonrenewable fossil fuels.

Energy Use. Energy consumption in the xanthate process compares favorably with the synthetics. The methodology of assessing the energy usage of products and processes is currently the subject of much debate, and a standardized approach has yet to emerge. Not surprisingly, most of the published work on fibers was carried out during the last energy crises in the 1973–1981 period.

The early attempts to assess the total energy required to make baled staple fiber from naturally occurring raw materials—wood in the case of cellulosics and oil in the case of synthetics—used differing approaches and were insufficiently rigorous to allow hard conclusions to be drawn. In general, the fiber production sequence is broken into monomer making, polymer making, and fiber production, and although a variety of fibers are covered, only viscose rayon and polyester are mentioned in all of them (112–116). Tons of fuel oil equivalent per ton of fiber (TFOE/T) is the most popular unit, with rayon requiring from 1.7 to 2.4 TFOE/T and polyester requiring 2.6 to 4.2 TFOE/T.

The studies all concluded that rayon required less energy to make than polyester but there was little agreement on the magnitude of the difference. The wet-spun cellulosic fibers required more energy than melt-spun polyester for the fiber-making step, but they had no monomer energy requirement. The polymerization requirement was therefore minimal. In the case of the 1.7 TFOE/T figure for rayon, full credit was being given for the fact that the pulp mills energy needs were renewable and not dependent on fossil fuels. Pulp could be fed directly into the viscose process without incurring any transport or drying cost, and the pulp mill could be driven entirely by energy obtained from burning the parts of the tree that were not needed in the final product. This free and renewable energy was not counted.

Fiber Disposal. Cellulosic fibers, like the vegetation from which they arise, can become food for microorganisms and higher life forms; ie, they biodegrade. If necessary they burn with a rather greater yield of energy than natural vegetation. In complete biodegradation or incineration, the final breakdown products are carbon dioxide and water; these disposal methods simply recycle the cellulose to the atmospheric components from which it was made.

It is also possible to liberate and use some of the free solar energy that powered the manufacture of sugars and cellulose during photosynthesis. This can be achieved by burning or by anaerobic digestion. Slow anaerobic biodegradation occurs in all landfill sites dealing with municipal solid waste. This process generates methane from cellulose, which can be burnt to drive gas turbines. If future landfills are lined and operated with moisture addition and leachate recycling, then energy generation and the return of landfill sites to normal use can be accelerated (117).

Environmental Issues: Lyocell Process

The solvent route to rayon reinforces the inherent environmental benefits of regenerated cellulosic fibers by using a modern fiber production process which, being physical rather than chemical, reduces environmental impacts to a minimum.

N-methylmorpholine *n*-oxide (NMMO), the solvent used, is manufactured by methylation and oxidation of morpholine, which comes from a reaction between diethylene glycol and ammonia.

Apart from woodpulp (as used to make viscose rayon) it is the only significant raw material used. It does not react with the cellulose and >99% of the solvent in the dope is recovered in spinning and washing, reconcentrated and reused. It is considered to be practically nontoxic by oral or dermal route and would not be considered harmful by EEC labeling criteria. Similarly it is considered to be minimally irritating to skin and eyes by EEC criteria.

Energy Use. From an energy viewpoint, the solvent route to cellulosic fibers is identical to the viscose route up to the point where the cellulose enters the solvent. The energy content of the noncellulosic raw materials is significantly lower in the case of the solvent route, but the solvent route requires similar energy levels in dope handling, spinning, washing, and recycling. The lower water imbibition of the solvent fiber (65 vs 95%) yields savings in fiber drying and in any subsequent end-product washing and drying operations. Overall, the solvent route is capable of showing a useful economy in this important resource when compared with viscose production on the same scale.

Fossil Reserves. The ethylene glycol for NMMO manufacture currently comes via ethylene from oil refineries. However, as indicated above, the solvent recycling rate is so high that solvent usage is kept down to a few kilos per tonne of fiber, and hence fossil reserve dependence is minimal.

Gaseous Emmissions. The solvent process produces very little atmospheric emission. There are traces of volatile organic compounds associated with the solvent and the soft finish, which will leave the plant in the normal course of ventilation.

Liquid Effluents. The solvent route uses much less water than viscose, and the process effluent needs significantly less treatment.

Production and Consumption

Approximately 3 million metric tons of regenerated cellulose fibers production capacity existed in 2000 (Table 2). The leading producers of filament yarns were the Chinese state-owned factories (118,000-t capacity), Acordis in Europe (69,000 t), and the Russian plants (with 44,000 t). The leading producers of staple fiber and tow were the Chinese with 480,000 t, the Birla Group (India) with 408,000 t, Lenzing (Austria, U.S.A., and Indonesia) with 315,000 t and Acordis with 170,000-t capacity split between the United Kingdom and North America, Formosa Chemicals and Fibers Co. with 162,000 t (in Taiwan). Acordis was formed in 1998 from the fiber businesses of Courtaulds and Akzo–Nobel following the takeover of Courtaulds by Akzo, who later sold Acordis to a consortium of CVC Partners and Acordis management. (Note: since these statistics were compiled, 100,000 ton of Acordis's viscose staple fiber capacity has closed.)

Actual staple fiber consumption figures for 2001 were estimated (118) to be 1.6 million tonnes because of a sharp decline in Eastern Europe masking slight growth elsewhere (Table 3). Asian countires now account for 75% of the consumption of viscose staple in textiles, with Western Europe leading the consumption in nonwovens.

Table 2. 2000 World Capacity for Regenerated Cellulose Fibers

Fiber type	Production, 10^3 t
Industrial filament yarns	105
Textile filament yarns	390
Regular staple fiber and tow	2300
High wet modulus staple	100
Lyocell staple	100
Total	2995

Table 3. The Top 10 Consuming Countries in 2000

Country	Consumption, Ton
China	400,000
Western Europe	280,000
India	225,000
Indonesia	175,000
U.S.A	85,000
Taiwan	80,000
Turkey	60,000
Japan	55,000
Thailand	30,000
Korea	25,000

Commercial Aspects

Since the early 1980s, the viscose-based staple fibers have, like the cuprammonium and viscose filament yarns in the 1970s, ceased to be commodities. They have been repositioned from the low cost textile fibers that were used in a myriad of applications regardless of suitability, to premium priced fashion fibers delivering comfort, texture, and attractive colors in ways hard to achieve with other synthetics. They are still widely used in blends with polyester and cotton to add value, where in the 1980s they would have been added to reduce costs.

Such repositioning inevitably means reduced production volume, and this is illustrated using CIRFS data (www.cirfs.org) in Figure 10. Most capacity reductions have been in North America and especially eastern Europe. This has been offset in part by capacity increases in the Far East. Rayon is no longer a significant component of carpets, and has lost the disposable-diaper coverstock business to cheaper and more easily processed polypropylene. It has, however, gained share in health and hygiene products and is now a principal component of tampons worldwide.

Figure 11 llustrates the major share changes over the last century, this time combining the natural (mainly cotton) and regenerated cellulosics as "biopolymers".

Roughly half of the 50 million tonnes of fiber consumed annually is now made from polymers synthesized from fossil fuels.

The aesthetic, absorbency, and comfort advantages still enjoyed by the biopolymer fibers has unquestionably slowed synthetic penetration of the apparel

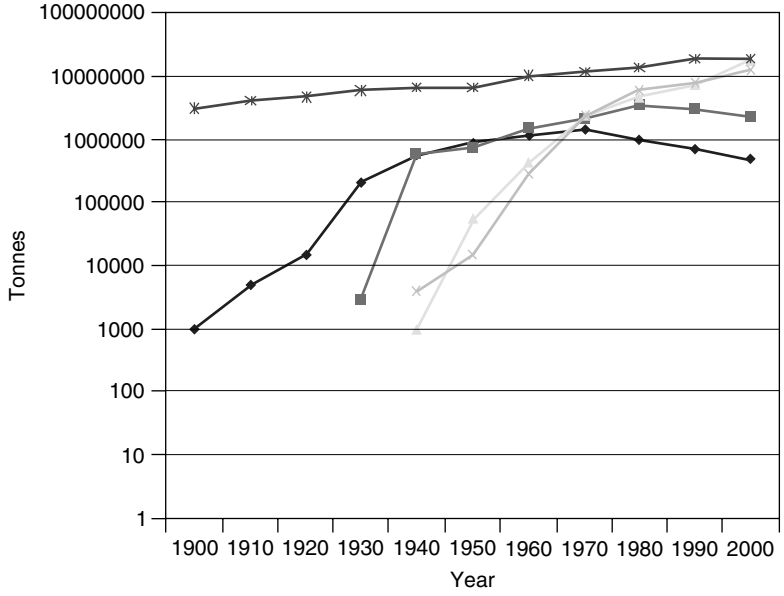

Fig. 10. World fiber production in 20th centry cf Cotton Usage—Log Scale. —◆— Cellulosic filament; —■— cellulosic staple; —✳— synthetic filament; —▲— synthetic staple, —✳— cotton.

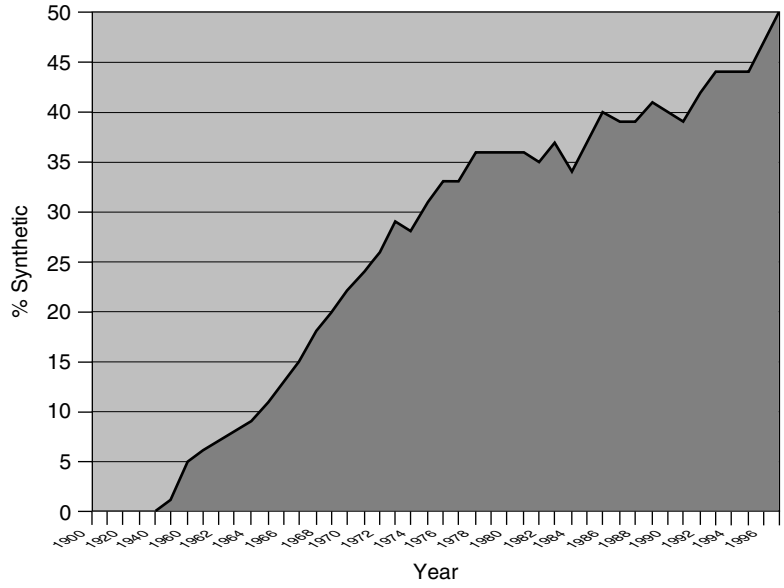

Fig. 11. Synthetics vs biopolymers in the 20th century

sector. Synthetics are used mainly for their low-cost, easy-care and durability characteristics. In the absence of fibers combining all these properties, polyester/cellulosic blends have been a most popular combination. Ratios varying between 35% cellulosic and 35% synthetic depending on the market positioning of the fabric and the relative prices of the fibers are typical.

Within the cellulosic part of the blend, rayon has to compete with cotton and can do this only

(1) when rayon prices (esp. modal or polynosic) are below cotton prices,
(2) when a fashion in a particular sector values the softness, leaness, and drape of rayon above the crisper, fuller, stiffer handle of cotton, and
(3) when the enhanced absorbency, uniformity, and processability of rayon (in this case compared with overbleached cotton at a higher price) is technically desirable, for instance in disposable nonwovens.

The lyocell process offers an environmentally acceptable way of converting natural cellulose into a premium quality rayon fiber with tensile properties approaching those of polyester. Furthermore the technology offers the potential for converting pulp to fiber on a scale and at a cost to give polyester and cotton some serious competition. The high levels of investment in the first lyocell plants necessitated launching the fiber at a premium price and therefore into the quality fashion-apparel market. This proved highly successful and led to rapid expansion up to the current capacity of around 100,000 ton. However this represents about one half of one percent of the current cellulosic fibers market, and lyocell fiber is still only available from two sources, Acordis and Lenzing.

At the time of writing, demand for lyocell has yet to increase to absorb the latest expansions, and some repositioning of the fiber in the market appears necessary.

Possible Futures

Johnson (119) argued that continued population growth and increased per capita fiber use will result in a demand for a further 70 million tonnes of fibers by 2050. With the potential for further cotton yield or hectarage increases now limited, and with the synthetics still looking unlikely to provide the comfort element of future textiles, Johnson postulates a "Cellulosics Gap" of up to 20 million tonnes.

He points out that for 60 years, cotton production has grown almost entirely because of increased fiber yield per hectare. Land area under cotton cultivation has been constant for that period, and pressure for the same top quality agricultural land will increase because of the need to feed increased population. Better irrigation, higher pesticide use, higher chemical fertilizer use, and genetic improvements achieved the cotton yield increase. In fact cotton cultivation in Russia became so intensive that despite its benign environmental image it has been the origin of environmental degradation on a massive scale (120). In the 1980s, a tonne of Central Asian cotton required approximately 800 kg of fertilizers, 100 kg of pesticides, and an aggregate of 1.5-m depth of water per square meter of growing area. In recent years cotton yield per acre has levelled off.

It is taken for granted that the implied need for an additional 50 million tonnes of synthetics could be readily provided. The predicted 20 million tonnes shortfall in absorbent or "comfort" fibers is likely to be filled by a combination of a variety of technologies:

(1) Development of more comfortable blends containing progressively less cellulosic fiber.

(2) Some increased yield of cotton per hectare from genetic engineering advances yet to be achieved.
(3) Some increased use of prime agricultural land for cotton growing.
(4) Development of low cost viscose and lyocell fibers.
(5) Development of soft flax fibers encouraged by agricultural subsidies and improved fiber-separation methods.
(6) Development of truly hydrophilic synthetics.
(7) The direct use of wood fiber in textiles.

In order for rayon to benefit from the opportunity offered by this increasing demand for fibers, the price differential between cellulosics and polyester must be reduced. The technology to achieve this does exist, but the justification for the necessary long-term investment becomes increasingly difficult as research into ever more comfortable synthetics pays off. Existing rayon plants will be unable to compete with polyester plants unless the relative costs of woodpulp and oil change dramatically in woodpulp's favour. The sustainability of cellulose and the transience of fossil reserves means that this change is likely, but not in the timeframe beloved of today's investors. In the meantime 350,000 ton/annum lyocell plants linked to a major source of low cost pulp and using a modified process to make fiber with properties similar to current viscose rayon would appear to be one of the few options for further growth of the regenerated cellulosic class of fibers.

COATING METHODS, POWDER TECHNOLOGY

Introduction

Powder coating is a process for applying coatings on a substrate using heat fusible powders. Materials used in the process are referred to as coating powders, finely divided particles of organic polymer, either thermoplastic or thermosetting, which usually contain pigments, fillers, and other additives. After application to the substrate, the individual powder particles are melted in an oven and coalesce to form a continuous film having decorative and protective properties associated with conventional organic coatings.

The origin of powder coating technology dates back to the late 1940s when powdered thermoplastic resins were applied as coatings to metal and other substrates by flame spraying. In this process, a powdered plastic was fed through a flame spraying apparatus where the plastic particles are melted and propelled by the hot gases to the substrate. A patent issued in Great Britain to Schori Metallising Process, Ltd., in 1950 described a process for forming a coating in which powdered thermoplastics were applied to a heated substrate by dipping or rolling the heated article in the plastic powder (1). This process was difficult to practice, however, and never achieved commercial success.

A major breakthrough in powder coating occurred in the mid-1950s, when Erwin Gemmer conceived the fluidized-bed coating process, in which a heated object is dipped into a fluidized bed of powder. Gemmer was involved in developing flame spraying processes and materials in the laboratories of Knapsack-Griesheim (Hoechst), a manufacturer of specialty gases, and was searching for a more efficient method than flame spraying for coating objects with powder. The first patent applications were filed in Germany in May 1953, and the basic patent was issued

in September 1955 (2). The first United States patent was issued in 1958 (3), and the Polymer Corp., Reading, Pa, acquired rights to the Knapsack-Griesheim patents. The Polymer Corp. mounted an aggressive effort to develop, license, and sell fluidized-bed coating technology in North America. However, acceptance of this coating process was rather slow. In 1960, the annual sales of coating powders in the United States were below 450 t, in part because of a lack of expertise in the methodology. In addition, the available powder coating materials were expensive, efficient production techniques had not been worked out, and volume of production was low.

Today, powder coating is widely accepted, with thousands of installations in the factories of original equipment manufacturers (OEMS) and custom coating job shops. It is the preferred method for coating many familiar items such as lawn and garden equipment, patio and other metal furniture, electrical cabinets, lighting, shelving and store fixtures, and many automotive components.

In the fluidized-bed coating process, the coating powder is placed in a container having a porous plate as its base. Air is passed through the plate causing the powder to expand in volume and fluidize. In this state, the powder possesses some of the characteristics of a fluid. The part to be coated, which is usually metallic, is heated in an oven to a temperature above the melting point of the powder and dipped into the fluidized bed where the particles melt on the surface of the hot metal to form a continuous film or coating. Using this process, it is possible to apply coatings ranging in thickness from about 250 to 2500 μm (10–100 mils). It is difficult to obtain coatings thinner than about 250 μm, and therefore, fluidized-bed applied coatings are generally referred to as thick-film coatings, differentiating them from most conventional paint-like thin-film coatings applied from solution or as a powder at thicknesses of 20–100 μm (0.8–4 mils).

In the electrostatic spray process, the coating powder is dispersed in an air stream and passed through a corona discharge field where the particles acquire an electrostatic charge. The charged particles are attracted to and deposited on the grounded object to be coated. The object, usually metallic and at room temperature, is then placed in an oven where the powder melts and forms a coating. Using this process it is possible to apply thin-film coatings comparable in thickness to conventional paint coatings, ie, 20–75 μm. A hybrid process based on a combination of high voltage electrostatic charging and fluidized-bed application techniques (electrostatic fluidized bed) has evolved, as well as triboelectric spray application methods. Powder coating methods are considered to be fusion-coating processes; that is, at some time in the coating process the powder particles must be fused or melted. Although this is usually carried out in a convection oven, infrared, resistance, and induction heating methods also have been used. Therefore, with minor exceptions, powder coatings are factory applied in fixed installations, essentially excluding their use in maintenance applications. Additionally the substrate must be able to withstand the temperatures required for melting and curing the polymeric powder, limiting powder coating methods to metal, ceramic, and glass (qv) substrates for the most part, although recently some plastics and wood products have been powder coated successfully.

Compared to other coating methods, powder technology offers a number of significant advantages. These coatings are essentially 100% nonvolatile, ie, no solvents or other pollutants are given off during application or curing. They are ready

to use, ie, no thinning or dilution is required. Additionally, they are easily applied by unskilled operators and automatic systems because they do not run, drip, or sag, as do liquid (paint) coatings. The rejection rate is low and the finish tougher and more abrasion resistant than that of most conventional paints. Thicker films provide electrical insulation, corrosion protection, and other functional properties. Powder coatings cover sharp edges for better corrosion protection. The coating material is well utilized: overspray can be collected and reapplied. No solvent storage, solvents dry off oven, or mixing room are required. Air from spray booths is filtered and returned to the room rather than exhausted to the outside. Moreover, less air from the baking oven is exhausted to the outside thus saving energy. Finally, there is no significant disposal problem because there is no sludge from the spray booth wash system. Any powder that cannot be reclaimed and must be discarded is not considered a hazardous waste under most environmental regulations. Although the terms coating powder and powder coating are sometimes used interchangeably, herein the term coating powder refers to the coating composition and powder coating to the process and the applied film.

Coating powders are frequently separated into decorative and functional grades. Decorative grades are generally finer in particle size and color and appearance are important. They are applied to a cold substrate using electrostatic techniques at a relatively low film thickness, eg, 20–75 μm. Functional grades are usually applied in thick films, eg, 250–2500 μm, using fluidized-bed, flocking, or electrostatic spray coating techniques to preheated parts. Corrosion resistance and electrical, mechanical, and other functional properties are more important in functional coatings.

Coating powders are based on both thermoplastic and thermosetting resins. For use as a powder coating, a resin should possess low melt viscosity, which affords a smooth continuous film; good adhesion to the substrate; good physical properties when properly cured, eg, high toughness and impact resistance; light color, which permits pigmentation in white and pastel shades; good heat and chemical resistance; and good weathering characteristics, ie, resistance to degradation by uv light, hydrolysis, and environmental pollutants. The coating powder should remain stable on storage at 25°C for at least 6 months and should possess a sufficiently high glass-transition temperature T_g so as to resist sintering on storage.

The volume of thermosetting powders sold exceeds that of thermoplastics by a wide margin. Thermoplastic resins are almost synonymous with fluidized-bed applied thick-film functional coatings and find use in coating wire, fencing, and corrosion resistant applications whereas thermosetting powders are used almost exclusively in electrostatic spray processes and applied as thin-film decorative and corrosion resistant coatings.

Thermoplastic resins have a melt viscosity range that is several orders of magnitude higher than that of thermosetting resins at normal baking temperatures (see Table 1). It is, therefore, difficult to pigment thermoplastic resins sufficiently to obtain complete hiding in thin films, yet have sufficient flow to give a smooth coating since incorporation of pigments reduces melt flow even further. In addition, thermoplastic resins are much more difficult to grind to a fine particle size than thermosetting resins, and so grinding must usually be carried out under cryogenic conditions. Because powders designed for electrostatic spraying generally have a maximum particle size of about 75 μm (200 mesh), the thermoplastic

Table 1. Physical and Coating Properties of Thermoplastic Powders[a,b]

Property	Vinyls	Polyamides	Polyethylene	Polypropylene	PVDF[c]

powders are predominant in the fluidized-bed coating process where heavier coatings are applied and a larger particle size can be tolerated. Fluidized-bed powders typically contain only about 10–15% of particles below 44 μm (325 mesh), whereas the high end of the particle-size distribution ranges up to about 200 μm (70 mesh). Most thermoplastic coating powders require a primer to obtain good adhesion and priming is a separate operation that requires time, labor, and equipment and typically involves solvents. In automotive applications, some parts are primed by electrocoating. Primers are not usually required for thermosetting powder coatings.

Thermoplastic Coating Powders

Thermoplastic resins used in coating powders must melt and flow at the application temperatures without significant degradation (see Table 1). Attempts to improve the melt flow characteristics of a polymer by lowering the molecular weight and plasticizing or blending with a compatible resin of lower molecular weight can result in poor physical properties or a soft film in the applied coating. Attempts to improve the melt flow by increasing the application temperature

are limited by the heat stability of the polymer. If the application temperature is too high, the coating shows a significant color change or evidence of heat degradation. Most thermoplastic powder coatings are applied between 200 and 300°C, well above the generally considered upper temperature limits for adequate heat stability. However, the application time is short, usually ≤5 min. The principal polymer types are based on plasticized poly(vinyl chloride) [9002-86-27] (PVC), Polyamides, plastics (qv), and other specialty thermoplastics. Thermoplastic coating powders have one advantage over thermosetting coating powders: they do not require a cure and the only heating necessary is that required to complete melting or fusion of the powder particles. Thermoplastic resins have uses in coating wire, fencing, and other applications where the process involves continuous coating at high line speeds. Typical properties of thermoplastic coating powders are given in Table 1.

PVC Coatings. All PVC powder coatings are plasticized formulations (see VINYL CHLORIDE POLYMERS). Without plasticizers (qv), PVC resin is too high in melt viscosity and does not flow sufficiently under the influence of heat to form a continuous film. Suspension and bulk polymerized PVC homopolymer resins are used almost exclusively because vinyl chloride–vinyl acetate and other copolymer resins have insufficient heat stability. A typical melt-mixed PVC coating powder formulation is given in Reference 4. Dispersion grade PVC resin is added in a postblending operation to improve fluidizing characteristics (5). Additional information on the formulation and application of PVC coating powders can be found in Reference 6. While most PVC coating powders are made by the dry-blend process, melt-mixed formulations are used where superior performance, such as in outdoor weathering applications and electrical insulation, is required (see Fig. 1). Almost all PVC powder coatings are applied by the fluidized-bed coating process. Although some electrostatic spray-grade formulations are available, they are very erratic in their application characteristics. The resistivity of plasticized PVC powders is low compared to other powder coating materials and the applied powder quickly loses its electrostatic charge. Dishwasher baskets are coated with fluidized-bed PVC powder. Other applications are various types of wire mesh and chain-link fencing. PVC coatings have a very good cost/performance balance that is difficult to match with any of the other thermoplastic materials. Properly formulated PVC powders have good outdoor weathering resistance and are used in many applications where good corrosion resistance is required. These coatings are also resistant to attack by most dilute chemicals except solvents. In addition, PVC coatings possess excellent edge coverage.

Powder coatings as a class are superior to liquid coatings in their ability to coat sharp edges and isolate the substrate from contact with corrosive environments. PVC coatings are softer and more flexible than any of the other powder coating materials. Primers used for PVC plastisols have been found generally suitable for powder coatings as well (7).

Polyamides. Coating powders based on polyamide resins have been used in fusion-coating processes from the earliest days. Nylon-11 [25587-80-9] has been used almost exclusively; however, coating powders based on nylon-12 [24937-16-4] also have been sold. The properties of these two resins are quite similar. Nylon-6 [25038-54-4] and nylon-6,6 [32131-17-2] are not used because the melt viscosities are too high.

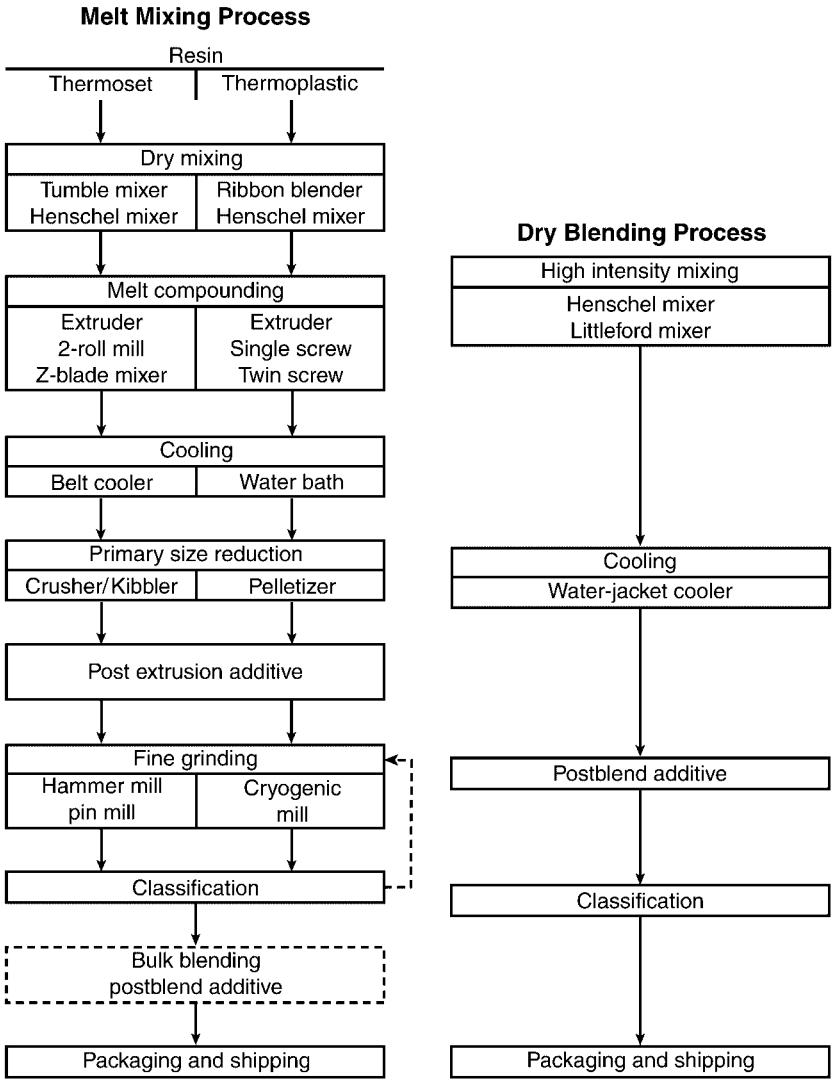

Fig. 1. Flow diagram for coating powder manufacture (adopted from *Encyclopedia of Chemical Technology*, 4th ed.).

Polyamide powders are prepared by both the melt-mixed and dry-blend process. In the latter, the resin is ground to a fine powder and the pigments are mixed in with a high intensity mixer (see Fig. 1). Melt-mixed powders have a higher gloss, eg, 70–90 on the 60° gloss meter, whereas dry-blended powders have a gloss in the range of 40–70. Because the pigment is not dispersed in the resin in the dry-blend process, it must be used at very low concentrations, usually less than 5%. Even in melt-mixed formulations, the concentration of pigment and fillers (qv) seldom exceeds about 20% of the composition (see POLYAMIDES, PLASTIC).

Nylon coating powders are available for both electrostatic spray and fluidized-bed application. Nylon coatings are very tough, resistant to scratching

and marring, have a pleasing appearance, and are suitable for food contact applications when properly formulated. These coatings are used for chair bases, hospital furniture, office equipment, knobs, handles, and other hardware. Because of expense, nylon is generally applied only to premium items. Nylon coatings have good solvent and chemical resistance and are used for dishwasher baskets, food trays, hot water heaters, plating and chemical-etching racks, and large diameter water pipes in power-generating stations. For maximum performance, a primer is used. Nylon coating powders are discussed in more detail in Reference 8.

Other Thermoplastic Coating Powders. Coating powders based on polyethylene [9002-88-4] and polypropylene [9003-07-1] have been available for many years but have achieved limited commercial success. A primary problem in using polyolefin-based powders is poor adhesion to metal. However, ethylene copolymers functionalized with acrylic acid, sold under the tradename Envelon (9), and certain grades of ionomer resins (10) have been formulated into coating powders and are enjoying some measure of commercial success. Self-adhering clear coatings based on a combination of ionomer resins and high melt index ethylene/acrylic acid copolymers are described in a recent patent (11).

Thermoplastic polyester coating powders achieved some commercial success during the mid-1980s; however, these were eventually replaced by nylon coating powders in functional coatings and thermosetting polyester coating powders in decorative applications because of lack of any unique characteristics or price advantages (see POLYESTERS, THERMOPLASTIC).

Coating powders based on poly(vinylidine fluoride) [25101-45-5] (PVDF) are available and are used in architectural applications where long-term exterior performance is required. Most are modified with thermoplastic acrylic polymers (12) or other fluoropolymer resins containing comonomers to improve melt flow and application characteristics (13). A method for preparing pigmented PVDF powders which does not require melt compounding and cryogenic grinding is described in Reference 14.

Several other thermoplastic powders are available based on specialty polymers such as ethylene–chlorotrifluoroethylene [25101-45-5], poly(phenylene sulfide) [25212-74-2], and tetrafluoroethylene–ethylene [68258-85-5] copolymers. Such powders are used in functional applications where resistance to corrosion and elevated temperatures are required. They are usually applied by fluidized-bed coating techniques but can also be applied by electrostatic techniques to a heated substrate (15). Extremely high application temperatures in the range of 250–350°C are required for these polymers because of high melting point and high melt viscosity.

Thermosetting Coating Powders

Thermosetting coating powders, with minor exceptions, are based on resins that cure by addition reactions. Thermosetting resins are more versatile than thermoplastic resins in the formulation of coating powders in that many types are available varying in melt viscosity, functional groups, and degree of functionality; numerous cross-linking agents are available, thus the properties of the applied film can be readily modified; the resin/curing agent system possess a low melt

[j] Inorganic; dilute.

viscosity allowing application of thinner, smoother films and necessary level of pigments and fillers required to achieve opacity in the thin films can be incorporated without unduly affecting flow; gloss, textures, and special effects can be produced by modifying the curing mechanism or through the use of additives; and manufacturing costs are lower because compounding is carried out at lower temperatures and the resins are friable and can be ground to a fine powder without using cryogenic techniques. The properties of thermosetting coating powders are given in Table 2.

Ideally, the appearance of a powder coating should equal that of a water borne or solution coating at the normal thickness range, eg, 20–60 μm (ca 1 to >2 mils). While significant advances have been made in the formulation and application of powder coatings over the last 10 years, it is more difficult to apply powders uniformly in thin films that match the smoothness and appearance of conventional liquid finishes. However, the gap is closing rapidly. Automotive powder clear coats have been applied by BMW to several models on a production basis since 1998. As of May 2000, over 1000 car bodies per day are being powder coated on completely automated lines (but at a film thickness still higher than desired) (16).

In order to retain their particulate form and free-flow characteristics, coating powders must resist sintering or clumping during transportation, storage, and handling. To maintain these properties, the glass-transition temperature T_g, of the formulated powder must be, at a minimum, about 40°C and preferably above 50°C. In the case of epoxy resins, because of their highly aromatic backbone, the

Table 3. Melt Viscosity, T_g, and Equivalent Weight of Various Thermosetting Resins

Resin type	Equivalent weight	T_g, °C	Melt viscosity, mPa·s (=cP) at indicated temperatures

Glycidyl methacrylate	510–560	39–56	390–470	[a]

[a] Too low to measure.

necessary T_g is attained at a relatively low molecular mass. In contrast, polyester resins require linear comonomers to achieve the desired degree of flexibility leading to a lower T_g. Thus, to attain the desired T_g, higher molecular mass resins must be used resulting in higher melt viscosities (17). At an equivalent range of T_g, polyester resins have a melt viscosity about 10 times higher than for epoxy resins (see Table 3).

The main parameters affecting film formation and flow of thermosetting coating powders are surface tension and melt viscosity (18). While a high surface tension promotes the coalescence and flow of molten powder particles, a low surface tension is necessary to wet the substrate. The so-called flow control additives are used in almost all coating powders to eliminate surface defects such as craters and pinholes. A more accurate term would be "surface tension modifiers," since this is their primary effect. They are believed to function by creating a uniform surface tension at the air/surface interface of the molten coating as a result of the particle compatibility (19). The most widely used flow control additives are acrylic oligomers (20). Most are primarily based on *n*-butyl acrylate [9003-49-0] and copolymers of ethyl acrylate and 2-ethylhexyl acrylate [26376-86-3] (see ACRYLIC ESTER POLYMERS).

While there is little difference between the surface tension lowering effects of various acrylic flow additives (21), monomer composition and molecular mass can have a significant effect on the flow and orange peel of the final coating (22). The relationship between flow and melt viscosity of the binder resin(s) is more obvious. Significant efforts on the part of resin manufacturers have been made to optimize the melt viscosity of the polymers while still maintaining the required T_g. Monomer composition (23), molecular mass, and functionality (24) are among the most important variables. The degree of reactivity between the resin and the curative has a significant effect on flow and smoothness. For ideal flow and leveling of the coating, the time between melting of the powder and the start of cross-linking should be maximized. Most resins are intended for use with a

particular curing agent, and so the functionality of the resin is designed accordingly. Rapid heating of the applied powder layer, ie, high curing temperatures, results in the lowest level of melt viscosity, but also in a faster increase in viscosity once the crosslinking starts (25). Chemorheological measurements have proven useful in determining the most desirable resin/curing agent reactivity and functionality in specific thermosetting systems (26). Optimum curing conditions can be predicted based on the reaction kinetics of the coating powder (27). In addition to the chemical and rheological factors already mentioned, smoothness of the cured coating is also related to the structure of the electrostatically deposited powder layer. The initially applied powder layer is much more porous than would be expected from random close packing of particles and shows appreciable powder segregation and patterning. A comprehensive study of powder application, coalescence, and flow indicates that the orange peel, with its millimeter length scale and micron-scale amplitude, arises partly from incomplete leveling of the largest scales of unevenness originally present in the deposited powder layer (28). Previous studies have also noted the relationship between clusters or large agglomerates of particles and orange peel (29). Finer particle size powders eliminate some of the large agglomerates and result in smoother films (30), but finer particles are more cohesive, less free flowing, and more difficult to manipulate (31).

The higher degree of orange peel exhibited by powder coatings in comparison to conventional liquid coatings is a fundamental shortcoming. Determining the ultimate cause of this deficiency and correcting it will lead to even greater acceptance and use of powders in finishing processes.

Formulation. In many respects, the formulation of coating powders is similar to that for conventional paints. The resinous binder plays a major role in the basic properties of the final coating such as exterior durability, chemical resistance, flexibility and impact resistance and, to some extent, appearance. While in conventional paints, solid ingredients such as pigments and fillers are dispersed in the liquid vehicle using a mill, in coating powders, the solid ingredients are dispersed in the molten binder in an extruder. Paint dispersions must be stabilized to prevent pigment agglomeration and settling. Flooding, floating, and pigment agglomeration are not a problem in a solid binder so rheological and dispersing additives are not necessary and seldom used in coating powders. A significant formulating advantage for conventional paints is that there are few constraints on the T_g of the binder resins; they can even be liquids. In addition to the binder resin(s), curing agents, which can range from crystalline solids to polymers, flow agents, additives, pigments, and fillers are utilized in coating powders. An important formulating variable is the ratio of pigments and fillers to the binder, the pigment:binder, or P:B ratio. Typical pigment:binder ratios used in formulating various types of coating powders are listed in Table 4. In general, the P:B ratios used in coating powders are much lower than for conventional paints since there are no other liquid ingredients present to wet out the pigments. Thus the pigment volume concentration in coating powders is correspondingly lower and seldom exceeds about 25%. Higher levels of pigments or fillers significantly reduce the flow out of coating powders resulting in a rough grainy coating.

In addition to the acrylate flow control additives, silicones, primarily the polyether modified types, and fluoropolymer flow agents are also used. Care must be exercised when using powders with differing flow additives or significantly

Table 4. Pigment: Binder Ratios for Various End-Use Applications

Pigment:binder ratio	% Pigment and fillers	Approx. PVC[a]	Application
0.01–0.10	1–9	0.3–2.9	Transparent, flamboyant, clear metallic, special effects

[a]Pigment volume concentration (PVC) calculated using pigments and fillers having a specific gravity of 4.0.

different binder resins since cross contamination can occur resulting in loss of gloss, surface imperfections, and loss of smoothness. These incompatibilities arise from differences in the surface tension of the various powders (32). Low melting thermoplastic additives such as benzoin [119-53-9] are used in coating powders to promote bubble release and air entrapment (33). Many of the additives used in coating powders, such as uv absorbers, light and heat stabilizers, mar and slip agents, have their basis in conventional coatings. However, others, such as electrostatic or tribocharging additives and postblend additives, mixed with the finished powder to improve dry, free-flow characteristics (34) are unique to coating powders.

Many of the pigments used in conventional paints are also used in coating powders. These include inorganic pigments such as titanium dioxide, nickel/titanium rutile, iron oxides, and complex inorganic pigments. Lead and cadmium based pigments have not been used for many years in the United States and Europe and are being phased out in the rest of the world. Typical organic pigments used include phthalocyanine blues and greens, various azo types, quinacridones, carbazoles, diketo-pyrrolo pyrroles among others. In general, inorganic pigments are used to provide opacity while organic pigments are used for their chroma or saturation. Because of their high surface area and high binder demand, organic pigments cannot be used at very high levels, ie, >5–6%, before a noticeable reduction in flow and increase in orange peel of the coating starts to occur. Therefore, as a rule of thumb, the level of inorganic pigments should be maximized and the level of organic pigments minimized consistent with the requirements for opacity and chroma. As noted, even inorganic pigments, with their higher opacity and lower binder demand, are not used at as high levels in coating powders as in paints. To obtain complete opacity with a white coating powder containing 30% TiO_2 (P:B ratio = 0.46) a film thickness of 89 μm is required. The addition of only 0.001% carbon black reduces the thickness required for complete hiding to 63 μm and to 37 μm with the addition of 0.005% (35).

Fillers such as calcium carbonate, blanc fixe and barium sulfate [07727-43-7], and wollastonite [13983-17-0] are used in coating powders to modify gloss,

hardness, permeability, and other coated film characteristics, and to reduce costs (36). Clays and talcs are seldom used, except in textured coatings, because of their high binder demand and adverse affect on flow and smoothness. Silicas are usually avoided because of their abrasiveness during extrusion and grinding, with the exception of colloidal silica used as a postextrusion additive.

Matting or flattening agents are employed to control gloss, which is dependent on microscopic surface smoothness (37). Thus, nonmelting or incompatible thermoplastic resins of proper particle size such as Teflon and polypropylene are used to disrupt surface smoothness and reduce gloss (38). Similarly, incompatible waxes concentrate at the surface of the coating, also reducing gloss but resulting in a waxy feel, which is prone to showing blemishes, eg, fingerprints. Coarse grades of fillers such as barytes, calcium carbonate, or wollastonite are also used for gloss control, usually with other techniques. Curing agents having widely different reactivities cause a two-stage polymerization to occur, resulting in incompatible domains and impaired microscopic surface smoothness (39). In a similar fashion, low gloss is achieved by mixing two powders varying significantly in reactivity (40). Gloss can be controlled over a wide range using combinations of glycidyl methacrylate functional resins with acid functional polyester resins (41). In summary, there are many methods of gloss control available to the coating powder formulator covering the full range of gloss in both interior and exterior durable systems.

Special Finishes. Clear coatings are formulated using curing agents and flow additives, which have a high degree of compatibility with the resin. Conventional uv and hindered amine light stabilizers can be added to improve exterior durability. Metallic finishes can also be prepared but the metal flake must be added after the powder has already been ground to prevent break up of the metallic flakes and preserve the metallic appearance (42).

Hammertones, veins, and other special effects are prepared by the judicious addition of surface tension lowering ingredients, eg, silicones or flow control/resin master batches, usually in conjunction with a dry-blended metallic or mica-flake pigment. Textured coatings are produced by controlling the flow and particle size of the powder particles as well as with nonmelting polymers of controlled particle size. Wrinkle finishes are obtained using selected curing agents and catalysts (43).

Epoxy Coating Powders. Thermosetting coating powders based on epoxy resins [25068-38-6], $C_{15}H_{16}O_2 \cdot (C_3H_5ClO)_x$ have been used longer than any other resin system. This is because solid epoxy resins (qv) were commercially available when thermosetting coating powders were being developed and had the necessary combination of low molecular mass, T_g, and melt viscosity (see Table 3). Further, a variety of latent curing agents were also known, which allowed the development of stable, one component powders. Early efforts to develop powders based on dry-blend processing methods, such as by ball milling, were generally not commercially acceptable because the resultant coatings were low in gloss and lacked smoothness and good appearance, especially with greater than minimal levels of pigments and fillers. These problems were overcome when powders were processed by melt mixing, eg, extrusion (see Fig. 1 and related text). The earliest powders were based on dicyandiamide [461-58-4], a latent curing agent. However, these powders were too slow curing, requiring 15–30 min at 200°C to achieve full properties. A wide variety of catalysts for the dicyandiamide epoxy reaction were

evaluated, but the clear choice after several years of trial and error were imidazoles, especially 2-methyl imidazole [693-90-1]. Dicyandiamide has a high melting point and limited solubility in epoxy resins. Dicyandiamide derivatives having aromatic substitution were developed, which are more compatible with epoxy resins, easier to disperse, and more reactive while still retaining their latency. Typical of these substituted dicyandiamide derivatives are o-tolyl biguanide [93-69-6] and 2,6-xylenyl biguanide (44). Highly reactive, compatible, and low melting curatives are also prepared by reacting an epoxy resin with excess imidazole. Another class of curatives, developed somewhat later, are the linear phenolics. These have the same structure as epoxy resins but are terminated with bisphenol A [80-05-07] rather than epoxide groups and contain significant levels of free bisphenol A. Since they have a functionality of only 2, the functionality of the epoxy resin in the binder must be increased, usually by blending with an epoxidized phenol novolak resin, to give an average functionality of about 2.5–3.0. The epoxy/phenolic hydroxyl reaction is relatively slow for many applications, and so an imidazole catalyst is often included in the formulation (45). Most of these curatives are still used today in both decorative and functional epoxy coating powders and provide compositions which cure in the typical range of 10–15 min at 180–200°C or in the low temperature range of 15–20 min at 140–180°C.

Many other types of curing agents have been evaluated in formulating epoxy-based coating powders but have found use in only specialized applications. Conventional phenol or cresol novolak resin curatives impart a high degree of cross-link density but result in rather brittle coatings with undesirable color. Aromatic amines give very reactive, fast curing systems but are marginal in storage stability and their health and safety characteristics are questionable. Of course, primary aliphatic amines cannot be used because they react even at room temperature and cannot be compounded at elevated extrusion temperatures. Dihydrazides have also been evaluated but their cost/performance base can seldom justify their use. Many anhydride curing agents have been considered but only a few have found their way into commercial formulations. For a time, trimellitic anhydride [552-30-7] cured powders catalyzed with metal-organic salts were used in the formulation of very reactive, fast cure powders, such as those used for coating concrete reinforcing bars (rebars) and pipe coatings (46). However, health and safety concerns led to the decline in use of this chemistry. Benzophenone tetracarboxylic dianhydride yields highly cross-linked coatings with very good heat and chemical resistance and is used in specialized functional applications (47).

Decorative epoxy powders are used in a wide variety of applications, eg, for lighting fixtures, garden equipment, motor control cabinets, and many automotive under the hood items including coil springs, shock absorbers, mechanical parts, and even engine blocks. Low melt viscosity resins of the type “3” are most widely used in decorative applications (see Table 3). Type “4” resins and higher with a higher molecular mass and melt viscosity are more often used in functional applications such as for electrical insulation and corrosion resistance where thicker coatings are needed and a higher degree of edge coverage is necessary. Epoxy powders are used almost exclusively in rebar and pipe coatings (48). In outdoor applications, epoxy coatings chalk readily and lose gloss; however, they protect the substrate for many years. Figure 2 compares the gloss retention of epoxy coatings with other thermoset types on exterior exposure.

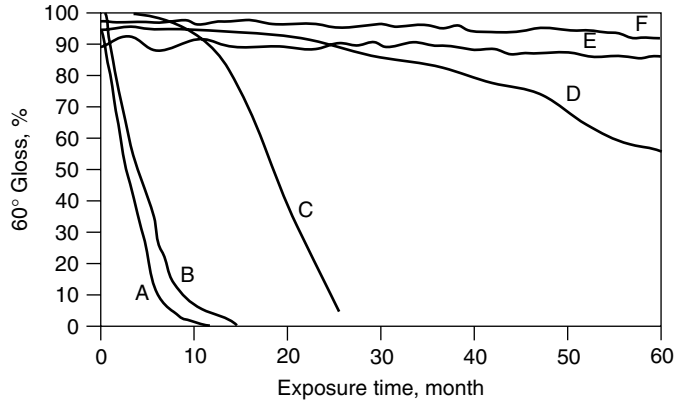

Fig. 2. Gloss retention in outdoor exposure in Florida for various powder coatings: A, epoxy; B, epoxy–polyester hybrid; C, polyester TGIC, HAA, and urethane (dark brown); D, super durable polyester TGIC, HAA, and urethane (dark brown); E, super durable polyester, clear, no light stabilizers; F, GMA acrylic, clear, light stabilized (after Ref. 49 and 50).

Epoxy–Polyester Hybrids. A major class of interior grade coating powders is based on a combination of epoxy and acid functional polyester resins. As noted, epoxy resins cured with anhydrides have desirable properties but never gained a high degree of commercial acceptance. Most anhydrides are respiratory irritants and are difficult to work with. Also, they are hygroscopic and the reactivity of coating powders cured with anhydrides varies on storage depending on the ambient humidity and the degree of conversion of the anhydride to acid. On the positive side, anhydride cured powders possess heat resistance and good color stability in contrast to the tendency for most amine cured powders to discolor on exposure to heat or exterior exposure. Therefore, programs were initiated in the research facilities of polyester resin manufacturers to develop resins which retained the desirable characteristics of anhydrides while eliminating their undesirable characteristics. This work resulted in the development of acid functional, relatively linear, saturated polyester resins specifically designed for curing bisphenol A based epoxy resins. The original resins developed had an acid number of 70–80 (equivalent weight range 700–800), and so they were used at 50:50 ratio with type "3" epoxy resins (see Table 3). The functionality is about 2.5–3, to provide good curing characteristics and cross-link density when used with the essentially bifunctional epoxy resins. Because polyester resins are less expensive than epoxy resins, higher equivalent weight polyester resins were subsequently developed which are used at a stoichiometric ratio of 60:40 and even 70:30 ratios to epoxy resin. Properties of these polyester–epoxy hybrids are similar to those of a straight epoxy, but differ in several respects. The overbake resistance (resistance to color change after extending curing) and resistance to discoloration on exposure to sunlight is superior. Because the cross-link density for hybrid coating powders is generally less than for straight epoxies, cured hybrid coatings are inferior in solvent resistance and hardness. They are also somewhat inferior in salt spray and corrosion resistance. Polyester resins, having a higher melt viscosity than epoxy resins (see Table 3), result in the hybrids having more

Table 5. 1998 Thermoset Powder Coatings Production by Resin Type[a]

Resin type	North America	Europe
Epoxy	15.0%	8.5%

Total	*100.0%*	*100.0%*

[a]Ref. 54.

orange peel than epoxy-based coatings, especially at the higher polyester–epoxy ratios.

The reaction rate between carboxyl end groups of the polyester and the epoxide groups of the epoxy resin is generally quite slow, requiring a catalyst to obtain a practical baking time. Catalysts are frequently mixed with the polyester resin by the resin manufacturer. The ideal catalyst should exhibit good reactivity at the desired baking temperature, eg, 150–180°C, while providing good flow and shelf stability (51). Tertiary amines, amic acids, and quaternary phosphonium compounds are effective catalysts for the epoxy-carboxyl reaction (52,53).

Epoxy–polyester hybrid coatings are marginally better than straight epoxy-based coatings in gloss retention on exterior exposure (Fig. 2) but generally are not recommended for exterior applications. For the most part, applications for the hybrid powders are the same as those for decorative epoxy coating powders. The latter are being replaced by the hybrid coating powders and are increasing in market share in the United States. In Europe, hybrid coating powders are the most widely used powder type (see Table 5).

Polyester–Triglycidylisocyanurate Cured. A principal class of exterior durable powder coatings is based on acid functional, saturated polyester resins cured using triglycidylisocyanurate [02451-62-9] (TGIC) (see Fig. 2). This system was first developed in Europe in the early 1970s. The acid functional polyester resins used in TGIC-cured coating powders are similar to those used in epoxy–polyester hybrids. However, the resins for curing with TGIC have a higher equivalent weight, typically in the range of 1600–1900, and a lower degree of functionality. Thus most resins are used at a 93:7 ratio of resin to TGIC. Acid functional resins are normally prepared by a two-step process: the reaction of excess polyol and dibasic acids followed by esterification of the hydroxyl terminated resin using dibasic acids or anhydrides (55). This technique yields a resin where the functional groups are at the end of the molecule rather than occurring randomly along the polymer chain. The excellent exterior durability of polyester resins cured with TGIC is primarily a result of the nonaromatic structure of TGIC in contrast to that of the bisphenol A based epoxy resins used in polyester–epoxy hybrid coating powders. Monomer composition of the resin also plays a significant role. It is recognized that the exterior durability of polyester powder coatings is affected by factors other than resistance to uv radiation. Accumulation of moisture on the surface of the coatings, especially at elevated temperatures (darker colors), and exposure to oxygen leads to hydrolysis, oxidation, and degradation of the

resin. Environmental factors such as acid rain or alkaline bird droppings as well as cyclic heating and cooling also contribute to molecular breakdown and loss of properties. For these reasons, accelerated weather testing now frequently includes cyclic exposure to elevated temperatures and moisture as well as uv light (56).

The recent development of so-called super durable polyesters has validated the cyclic accelerated weathering approach. Super durable polyester resins are based almost exclusively on isophthalic acid while most standard resins contain terphthalic acid as well. Super durable polyesters are highly resistant to hydrolysis and degradation by uv light (57,58), which helps to account for their superior exterior durability. Compared with a standard TGIC-cured polyester powder coating in a dark color, which loses about 50% of its original gloss after about 2 years of Florida exposure, a super durable polyester cured with TGIC will last at least four times as long until the same loss of gloss occurs. Figure 2 is a plot of % gloss retained vs original level, measured on a 60° gloss meter, comparing super durable polyesters with several other types of powder coatings. Super durable polyesters are generally inferior in flexibility and impact resistance but recent advances have shown significant improvements in this regard (59).

TGIC-cured coating powders have gained a significant market share in the exterior durable market in both Europe and North America. Many buildings coated with TGIC powders in various European locations from the early 1970s and later are still in good condition, exhibiting minimal corrosion and good retention of gloss and color. In the past 10 years, some concerns have developed over health and safety issues related to TGIC, especially with regard to mutagenic characteristics. In the United States, it is generally believed the hazards are adequately addressed by the OSHA Hazard Communication Standard and the low exposure level of 0.05 mg/m^3 established (60). However, in Europe, the European Union ruled that the symbol **T** (Toxic, symbolized by a skull and crossbones) accompanied by the relevant Risk Phase R46, relating to substances considered to cause heritable genetic damage, is to be used in labeling any product containing TGIC. This requirement went into effect in June of 1998 and had the result of powder manufacturers replacing TGIC in their products. Since that time the market share of TGIC-cured polyester coating powders has decreased significantly in Europe, being largely replaced by hydroxyalkylamide-cured powders (61). Other glycidyl compounds such as a mixture of diglycidyl terphthalate [7195-44-0] and triglycidyl trimellitate [7237-83-4] (62) as well as tris(β-methyl glycidyl) isocyanurate [26147-73-3] (63) are being evaluated as TGIC replacements as well.

Polyester–Hydroxyalkylamide Cured. Hydroxyalkylamide curatives were developed in the late 1970s and early 1980s (64). Evaluation as a curative in coating powders was described in early 1991 (65). The primary commercial product is bis(*N*,*N*-dihydroxyethyl) adipamide [6334-25-4] sold under the trade name Primid XL 552 by EMS Chemie. It reacts with acid functional polyester resins by esterification and the elimination of water. The toxicological profile of this curative is benign, and it does not fall under the provisions of any current health and safety or environmental regulations. It has been shown that the ester linkage formed with Primid XL 552 and polyester resins has essentially the same characteristics as the TGIC–polyester bond (66). Practical experience has confirmed that polyester coating powders cured with Primid are essentially equivalent in weatherability and other properties to TGIC-cured powders (67).

Because the functionality of the hydroxyalkylamide curative is about 4, the functionality of the polyester resins used with them has to be designed accordingly (68).

Urethane Polyesters. In the United States the search for exterior durable coating powders led to technology based on hydroxyl functional polyester resins. The earliest curing agents evaluated were based on melamine–formaldehyde resins, such as hexa(methoxymethyl) melamine [68002-20-0], which are widely utilized as curing agents in conventional paint systems (see AMINO RESINS). Coating powders based on this chemistry suffer limitations: the melamine resin depresses the T_g of the coating powder to the point where the powder sinters during storage, especially at elevated temperatures, and the methanol generated during the curing process becomes trapped in the film, especially at thicknesses above about 50 μm, resulting in a frosty or visually nonuniform surface. An amino resin, specifically developed for use in coating powders, tetramethoxymethyl glycouril [17464-88-9], overcomes many of these disadvantages, but still requires the use of higher T_g resins and special acid catalysts (69). Coating powders based on this chemistry have not achieved a high level of commercial acceptance for general-purpose use; however, with selected catalysts, attractive wrinkle finishes are produced (70,71), which find use in special applications. Curing agents based on polyisocyanates blocked with caprolactam [00105-60-2] give an excellent combination of properties in the final film (see Table 2). Because the unblocking reaction does not start to occur until about 160°C, the powder has a chance to flow out and give a smooth uniform film prior to any substantial cross-linking. Not all of the caprolactam evolves during the curing process and some remains in the film acting as a plasticizer. Thus, urethane polyesters yield a smoother, more orange-peel-free film than the TGIC polyesters and are more preferred in the United States and Japan than in Europe (see Table 5).

The hydroxyl functional polyester resins used in this technology are similar in monomer composition to the acid functional polyesters and are based primarily on terephthalic acid [100-21-0], $C_8H_6O_4$, isophthalic acid [121-91-5], $C_8H_6O_4$, neopentylglycol [126-30-7], $C_5H_{12}O_2$, and branched using trimellitic anhydride or trimethylol propane [77-99-6]. A variety of other polylols and dibasic acids are used to modify specific resin properties such as T_g, melt viscosity, curing characteristics, and others. (72,73). Resins ranging in OH number from 30–300, equivalent weight of about 190–1870, are used in the formulation of urethane coating powders. Since the blocked isocyanate curatives are three to four times the cost of the polyester resin, the lower OH number resins are preferred for general purpose formulations, with a 50 OH number resin providing a good balance between raw material cost, physical properties, and appearance. While the higher OH number resins require higher levels of curative, the final coatings have outstanding hardness and chemical resistance. Blends of high and low OH number resins and the stoichiometric level of curative form the basis of low gloss coatings. Hydroxyl functional super durable resins, similar in monomer composition to the acid functional resins cured with TGIC, are also available. When cured with IPDI-based isocyanates, they possess exterior durability equal to that of the super durable/TGIC-based coatings (see Fig. 2). The most commonly used curing agents are trimerized isophorone diisocyanate [4098-71-9] (IPDI) ($C_{12}H_{18}N_2O_2$) blocked with caprolactam and the trimethylol propane adduct of IPDI blocked with caprolactam. Blocking agents, which unblock at lower temperatures, provide the basis for urethane powders

which cure at lower temperatures (74). New curatives have been developed which do not rely on blocking agents to mask the reactivity of the isocyanate group. Most are based on the uretdione structure, a four-membered ring formed by the reaction of isocyanate groups with each other (75). While uretdione-based curatives have been available for many years, they have high melt viscosities and require higher temperatures for curing than the blocked isocyanates. Newer versions have overcome these problems to some extent (76).

Urethane polyesters have not received widespread commercial acceptance in Europe primarily because of the caprolactam (or other blocking agents) emitted during curing. Despite the development and commercial availability of the uretdione-based curatives, which do not give off volatiles during cure, the European market for exterior grade polyester powders is still based primarily on acid functional resins (see Table 5).

Unsaturated Polyester Powders. A special class of coating powders is based on unsaturated polyester resins. They are utilized in matched metal die molding operations such as those based on sheet molding compounds and bulk molding compounds where the mold is coated with the powder prior to placing the resin charge in the mold (see POLYESTERS, UNSATURATED). The powder melts and flows on the mold surface, and when the mold is closed, the powder reacts with the molding compound forming a coating on the molded part. This process is known as in-mold coating. Unsaturated polyester resin powder coatings can provide a colored and finished exterior molded surface or a finish ready for painting. Normally, a primer/sealer must be applied to molded articles prior to painting. In addition to the unsaturated polyester resin, multifunctional resins prepared from unsaturated monomers such as triallyl cyanurate [101-37-1] or diallyl phthalate [131-17-9], suitable peroxide initiators (qv) or mixtures thereof, and mold Release Agents (qv) are used to formulate the coating powder (77).

Acrylic Powders. Coating powders based on acrylic resins have been available in Europe, the United States, and Japan since the early 1970s but have not achieved significant commercial success until recently. However, since 1997 BMW has been applying an acrylic clear-coat powder to several models and currently (2000) is powder coating over 1000 cars/day (16). Acrylic-based powders are also used in exterior trim (pigmented) and wheels (clear). The majority of clear coatings are based on a glycidyl functional methacrylic resin (GMA) cured with dodecanedioic acid [693-23-2] or a polyacid/anhydride polymer (78). Acrylic powders based on GMA resins have poor compatibility with epoxy- and polyester-based powders. If cross contamination occurs, surface defects in the form of pinholes, craters, and excessive orange peel are common.

The GMA clear coatings have outstanding exterior durability, hence their acceptance in the automotive sector (see Fig. 2). Pigmented GMA acrylic powders have not found widespread use in market areas other than automotive, eg, architectural applications. Hydroxyl functional acrylic resins cured with blocked isocyanates or uretdione-based curatives have also found use in automotive applications and their exterior durability is only somewhat less than that of the GMA acrylic powders (50). Carboxyl functional acrylic resins are also commercially available. They can be cured with TGIC for exterior applications or with bisphenol A epoxy resins. The latter combinations are sometimes called acrylic–epoxy hybrid coating powders and are noted for their excellent hardness, stain, and chemical resistance. They find use primarily in appliance coatings (79).

Recent Developments. As noted, powder coating technology has advanced to the point where powders are now routinely applied in critical automotive applications. Another market area where intense work is in progress is the development of powders having low temperature curing capabilities such that they can be used to coat wood, plastics, and other temperature sensitive substrates. A coating powder must have a high enough T_g and molecular mass so that it does not sinter on the one hand while on the other hand a low melting point and melt viscosity is desirable for low temperature application and smoothness. It is a difficult task to balance these diverse requirements. This is especially true in the case of thermally cured powders compared with uv-curable powders. In the latter case, the flow and leveling of the coating are separate from the curing reaction while with heat curable powders, cross-linking occurs even as melting and flow are in progress.

One technique for dealing with this low temperature cure/reactivity dilemma is to use a two component powder system. The resin and other binder components comprise one component and the curative and other nonreactive binder ingredients, the other (80). In the case of uv curable powders, an unsaturated polyester resin is one of the major binder components but more reactive binder components such as oligomers with high allyl functionality (81) or vinylether/ester groups (82) must also be present. Crystalline resins with reactive methacrylyl groups have also been disclosed (83). A review of photoinitiators, additives, and other components of uv-curable powders are given in References 84 and 85.

Manufacture

The vast majority of thermosetting coating powders are prepared by melt mixing. Some thermoplastic powders are also produced by this method but most are manufactured by the dry-blend process as shown in Figure 1. Production methods based on spray drying from solution (86) and precipitation from solution (87) have been evaluated but never achieved commercial success because of difficulties in solvent and/or water removal from the powders. Many types of coating powders are still manufactured in small batches, eg, 50–1500 kg, due to differences in color or chemistry, where chemical processes are not economical.

Melt Mixing. Dry ingredients, resins, curatives, additives, pigments, etc, are weighed into a batch mixer such as high-speed impeller mixers, container mixers, horizontal plow mixers, or tumble mixers where they are thoroughly blended. High-speed impeller mixers such as the Henschel give the best distributive mixing and the cycle time is relatively short, eg, 1–2 min. However, these mixers have relatively small capacity, eg, 100–300 kg, and many individual batches must be prepared for longer production runs. Horizontal plow mixers require a slightly longer mix cycle but have a larger capacity, 500–1000 kg. They also provide good distributive mixing but require longer cleaning times. Tumble mixers have a high capacity and are adequate for general purpose powders, but mixing cycles are long, 30–60 min, and distribution of ingredients is sometimes marginal. With container mixing systems, only one mixer is required and generally satisfactory distributive mixing is obtained. However many mixing containers, which become the hopper for feeding the extruder, are required as well as a mixer for each size of mixing

container. The premix is then melt-compound in a high shear extruder where the ingredients are compacted, the resin(s) melt, and individual components are thoroughly dispersed in the molten resin. These compounding machines generate sufficient heat through mechanical shear so that after start-up, little external heat needs to be supplied. Both single screw machines, with a reciprocating screw which intermeshes with fixed baffles in the barrel, such as the Buss Ko-Kneader, and twin screw extruders, primarily corotating, intermeshing types as supplied by Krupp Werner Pfleider, Baker Perkins, and others are used (see EXTRUSION). Residence time in the extruder is short, usually less than 1 min and melt temperatures low, typically 90–120°C, slightly above the melting points of the resinous components. Because of these processing conditions, very little reaction between the thermosetting components occurs. In a study carried out based on epoxy resin compositions, it was determined that 6–11% of the epoxy groups initially present reacted during extrusion (88). Significant improvements have been made in both single and twin screw extruders and for a given size machine throughput rates have increased by a factor of 3–4 over the last 10 years or so. Product quality is more consistent as a result of improved process control (89). The molten compound is cooled rapidly by passing it through water-cooled nip rolls and subsequently onto a watercooled continuous stainless steel belt or drum. The cooled compound is broken into small chips, about 10–12 mm, suitable for fine grinding. Thermosetting resins are quite friable and are usually ground to final particle size in an air classifying mill. In this grinder, a blower generates an air stream through the mill in which the product is entrained and which also serves to remove the heat of grinding. A variable speed separator controls airflow in the grinding chamber so that only the particles with the desired particle size escape. The fine powder is separated from the air stream with a cyclone separator or bag house. Powders with a finer average particle size produce smoother coatings than powders with a larger particle size. While the addition of a colloidal silica or alumina to the powder, either to the chips prior to grinding or to the ground powder, significantly improves the dry flow, handling, and transport characteristics (90), the presence of high levels of superfine particles adversely affects these same characteristics. Recent advances in grinding equipment include in-line air classifiers and baffles in the cyclone separators, which allow the production of powders with a narrower particle size distribution (91). This means that powders with a finer average particle size can be produced without a significant increase in superfine particles, ie, those below about 8–10 μm.

Dry Blending. Most plasticized PVC powders are prepared by a dry-blend process in which the plasticizers, stabilizers, pigments, and additives are absorbed on the porous PVC particles at elevated temperatures while they are being agitated in a high speed mixer (6). Other thermoplastic powders are pigmented in this fashion. Attempts to prepare thermosetting powders by a dry-blend process have proven to be unsatisfactory because of the poor wetting and dispersion of pigments and the poor appearance of the subsequent coatings.

Recent Developments. A completely new process for the manufacture of coating powders has been recently developed by the Ferro Corp. It involves solvating resinous components in supercritical gas, typically carbon dioxide (CO_2), and dispersing the pigments and other solid ingredients with an impeller or dispersion blade. After dispersion is completed, the material is hydraulically atomized

into a second vessel at a lower pressure. The CO_2 vaporizes and a combination of particles or easily grindable solid is obtained (92). A similar process for preparing coating powders is described in Reference 93. The main advantage of these processes over conventional extrusion and grinding technology is that processing temperatures are lower, eg, 40–70°C, and it is possible to form powders directly. At present, there are no powders commercially available prepared by these methods.

Another recent development is the successful application of powders from aqueous dispersions. This process is being used to apply both primer surfacers and powder clear coats to the Mercedes A Class automobiles (94). An advantage of this process is that a very fine particle size powder can be used, 100% less than 10 μm (95), and it can be applied using conventional wet spray equipment. The concept of applying powders by aqueous dispersion is not new (96) but this is the first time it has been commercially successful. Now that there are large volume applications for powder coating in the automotive sector as primer surfacers and clear coats, it is anticipated that novel methods for preparing either powders or powder dispersions utilizing efficient chemical processing methods will be developed.

Application Methods

Fluidized-Bed Coating. Fluidized-bed coating, the first significant commercial process for applying powdered polymeric materials to a substrate to form a uniform coating, is the method of choice for many applications where a heavy functional coating is required. The process is relatively simple. The main variables are the temperature of the part as it enters the fluidized bed, the mass of the part being coated, dip time, and postheat temperature. Other variables, such as motion of the part in the bed and the density and temperature of the powder in the bed, also affect the quality of the coating. The process is especially useful in coating objects having a high surface to mass ratio such as fabricated wire goods and expanded metal. Sharp edges and intersections are well covered because of the heavy film thickness, eg, 250–500 μm (10–20 mils), applied. The size of parts that can be coated is limited because the fluidized-bed container must be large enough to readily accommodate them.

Electrostatic Fluidized-Bed Coating. In an electrostatic fluidized bed, the fluidizing container and the porous plate must be constructed of a nonconductive material, usually plastic. Ionized air is used to fluidize and charge the powder. The parts to be coated are passed over the bed and charged powder is attracted to the grounded substrate. The rate of powder deposition varies significantly depending on the distance of the part from the fluidizing powder. Therefore, this process is usually utilized only when the object to be coated is essentially planar or symmetrical and can be rotated above the charged powder. Electrostatic fluidized-bed coating is an ideal method for continuously coating webs, wires, fencing, and other articles that are normally fabricated in continuous lengths and are essentially two-dimensional. In a variation of this process, two electrostatic fluid beds are arranged back to back and the continuous web of material is passed between them, coating both sides simultaneously. Millions of lineal meters of window screen have been coated using this technique (97).

Electrostatic Spray Coating. Electrostatic spray coating is the most widely utilized method for the application of powder coatings. In a typical high voltage system, powder is maintained in a fluidized-bed reservoir, injected into an air stream, and carried to the gun where it is charged by passing through a corona discharge field. The charged powder is transported to the grounded part to be coated through a combination of electrostatic and aerodynamic forces. Ideally, the powder should be projected toward the substrate by aerodynamic forces so as to bring the powder particles close to the substrate where electrostatic forces then predominate and cause the particles to be deposited. The powder is held by electrostatic forces to the surface of the substrate, which is subsequently heated in an oven where the particles fuse and form a continuous film. The processes involved are powder charging, powder transport, adhesion mechanisms, back ionization, and self-limitation. As charged powder particles and free ions generated by the high voltage corona discharge approach the powder layer already deposited, the point is reached where the charge on the layer increases until electrostatic discharge occurs. At this point, any oncoming powder is rejected and loosely adhering powder on the surface falls off. It has been demonstrated that some imperfections in the final coating are a result of defects in the powder layer (98).

The characteristic of the electrostatic spray process to form self-limiting films enables operators to apply satisfactory coatings after only brief training and instruction. It is almost impossible to create runs, drips, or sags characteristic of spray-applied liquid finishes. Furthermore, the practical design of automatic spray installations is possible. Multiple electrostatic guns mounted on reciprocators are positioned in opposition to each other in an enclosed spray booth and parts to be coated are moved between the two banks of guns where a uniform coating of powder is applied. Oversprayed powder is captured in the reclaim system and reused. Powder coating booths have been designed with interchangeable filter units to facilitate change from one powder type of color to another. A state-of-the-art automatic powder spray system using a combination of cyclone separators to reclaim the majority of overspray powder and cartridge filters to capture the remaining powder is shown in Figure 3. The cyclone units are designed for quick cleaning and are much easier to clean than a bank of cartridge filters; quick color changes are facilitated. For very short runs, the cyclone separators can be removed and oversprayed powder is not recovered.

One disadvantage of the electrostatic powder spray process using corona discharge guns is that a high voltage field is set up between the gun and the parts to be coated. Parts having deep angles or recesses are sometimes difficult to coat because of the Faraday Cage effect. One method of overcoming the Faraday Cage effect is by the use of triboelectric guns in which powder charging occurs by the frictional contact of the powder particles and the interior surface of the gun. Electrons are separated from the powder particles, which become positively charged and attracted to the substrate. Because there is no electrostatic field between the gun and the article being coated, a Faraday Cage is not developed and particles are able to more readily penetrate into recessed areas of the substrate. There are a number of commercial powder coating systems using triboelectric charging technology, but this number is quite small compared to those based on the more conventional corona guns. The powder application rate of triboelectric guns is lower than that for corona guns; additionally, powders based on a wide

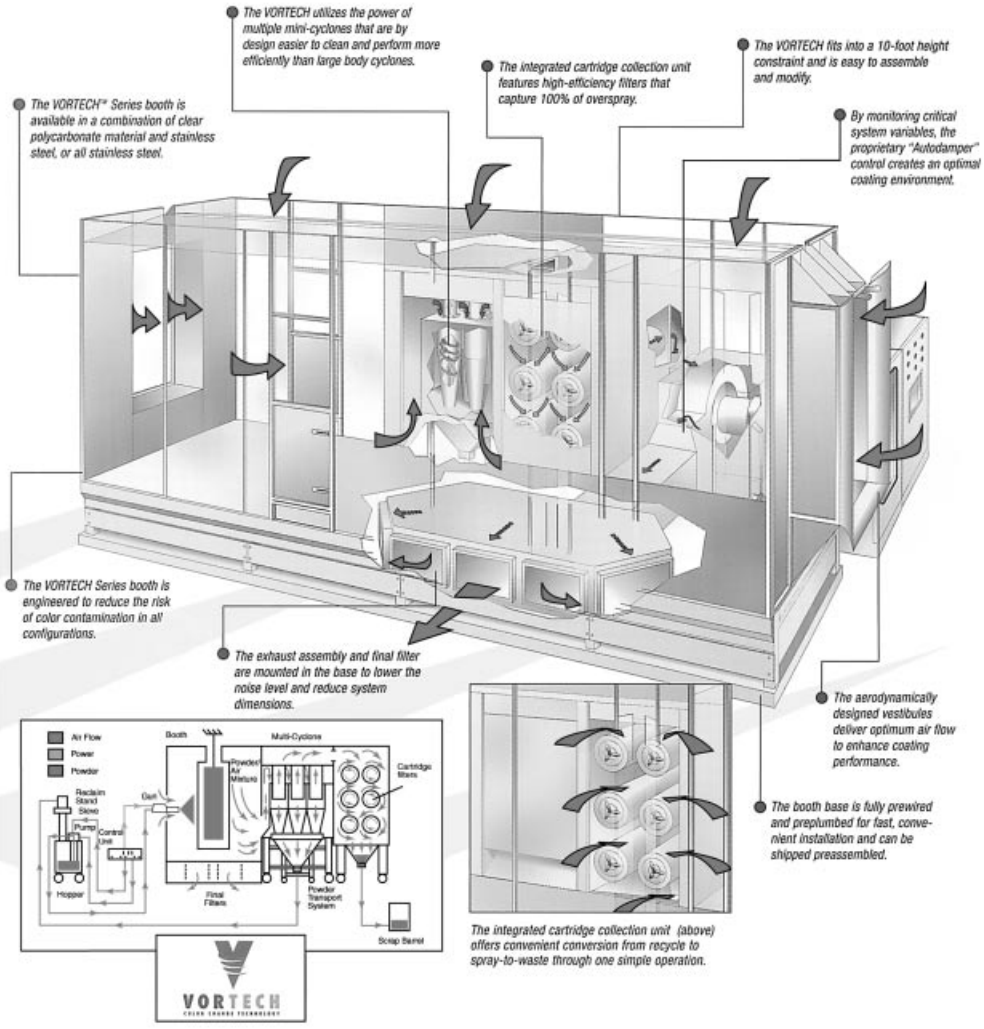

Fig. 3. Schematic diagram of an electrostatic powder spray system. Courtesy of ITW Gema.

variety of resins and formula types charge and apply readily with corona guns, whereas only certain resin systems charge well in triboelectric guns. However, additives have been developed which improve the tribocharging characteristics of powders (99).

While the basic principles of the electrostatic powder spray process have not changed, many advances in the equipment and process design have been made to improve process efficiency and quality of finish (100). Significant improvements have been made in reducing the time to change types of powders or make color changes. Much effort has gone into improving the first pass transfer efficiency, that is, the ratio of powder deposited on parts to that sprayed (101). High transfer efficiencies mean less overspray to reclaim. Less powder to reclaim means the recovery system can be reduced in size and requires less air volume and energy to

operate. Some of the means to improve transfer efficiency include programmable logic controls to adjust the motion of the guns and spray patterns for the specific parts being coated and to recognize the parts passing through the booth, shutting off powder flow when a vacancy in the line occurs or the line stops (102), sensors that detect the amount of powder in the air and modulate the air flow accordingly (103), and nonconductive spray booths and filter belts to facilitate powder reclaim (104). In the ideal case of 100% transfer efficiency, a powder reclaim system would be unnecessary and no cleanup required between color changes.

Improvements have also been made in materials. Stricter control of particle size distribution improves powder handling and transport characteristics, spray patterns, and transfer efficiency (105,106). Reduction of the superfine fraction, ie, particles below about 8–10 μm, also results in less fines in the overspray powder and less load on the reclaim system (107). More spherical powders charge more efficiently and show improved spraying characteristics (108).

Recent Developments. A major recent development is the commercial application of powders to auto bodies as primer surfacers and clear coatings. Also, specialized coating lines have been developed for the application of powders to metal blanks and coil. In the case of blank coating, sheet stock is cut and punched and coated on a flat line, using either standard or tribocharging guns. Powders are applied at a lower thickness (ca 25–40 μm) and must cure rapidly, eg, 1–2 min, to accommodate the relatively high line speeds (109). Coated blanks are shipped to the manufacturer flat, and assembled there into the final shape, eg, a refrigerator box. This eliminates an in-house coating line.

The continuous powder coating of steel coils is being carried out at a number of locations in Europe and the United Stated (110). Lines are now operating on coils 60 in. (1.52 m) wide at line speeds 250–300 ft/min (76–91 m/min) (111) and developments are in progress in which line speeds up to 1000 ft/min (305 m/min) are expected (112). Many special finishes, such as textures, hammertones, and wrinkles, are possible with powder while smooth finishes are only possible with liquid coatings. Because of the high line speeds and volume of powder applied, a novel powder charging and application system was developed (113).

Specialized application equipment has also been designed to coat the interior of can bodies (114). Powders having a finer particle size are required as well (115). A significant new powder application method has been developed utilizing photocopying and laser printing technology. Designated Electro-Magnetic Brush (EMB) Technology, it is possible to apply very thin powder coatings continuously on flat stock, either metallic or nonmetallic. Using a clear uv curable powder on a 17-in. wide EMB machine, rolls of wallpaper were coated at a thickness of 5–7 μm (0.2–0.3 mils) at a line speed of 60 m/min (197 ft/min) (116).

Hot Flocking. Several nonfluidized-bed coating methods are based on contacting a preheated substrate with powder to form a coating. Although these techniques are not widely used, for certain parts they are the preferred method of application. For example, the coating of motor stators using a thermosetting powder provides primary insulation between the core and windings. The part is preheated to about 200°C and the powder is directed from a fluidized bed using an air venturi pump, similar to those used to supply powder from the reservoir to electrostatic guns, through flexible tubes and directed at the preheated part which is rotating on a mandrel. Multiple tubes, usually in pairs in opposition to each other, are

normally used. In a similar fashion, the inside diameter of pipe can be coated by entraining powder in an airstream and blowing it through a preheated section of pipe (117). Very uniform coatings in the range of 200–300 μm can be applied by this process to provide corrosion protection for drill pipe, and water injection and gathering pipe in diameters up to ~50 cm.

Metal Cleaning and Preparation. As in any finishing operation, the surface of the object to be coated must be clean, dry, and free from rust, mill scale, grease, oil, drawing compounds, rust inhibitors, or any soil that might prevent good wetting of the surface by the coating powder. Steel should be sandblasted or centrifugally blast-cleaned to give a near white finish. Phosphate coatings are normally a pretreatment for most fabricated steel parts while nonchrome and organometallic conversion coatings are used on aluminum (118).

Economic Aspects

The worldwide market for coating powders increased at an annualized growth rate (AGR) of almost 10% during the 1990s in North America compared with a 12–13% AGR during the 1980s. Even though the rate of growth has decreased somewhat, it is estimated that powder coating represents only about 4–5% of the industrial paint market in North America. Globally, the penetration of powder coatings in the industrial paints sector is 6% with Europe leading at about 9%. By 2010, global penetration of powder coatings is expected to reach the 10% level (110).

While the primary driving force for growth during the 1980s was environmental regulations, growth during the 1990s has been driven additionally by superior performance and application economies. Powder coating is seen as an environmentally friendly technology because no solvents are present, volatile organic compounds, are absent, for the most part, venting, filtering, and solvent recovery systems are not necessary, process air is recycled, and there is little waste since most overspray powder can be collected and reused. Further, any waste generated is not classified as a hazardous waste under current regulations. Further, permits required for new coating facilities or additions to existing lines are much easier to obtain when the installation utilizes powder coating processes. Future growth will largely depend on advances in both coating materials and application technology in comparison with advances in other environmentally friendly coating methods.

The worldwide production of coating powders in 1999 is estimated at 727,100 t having a value of $803,861,000, a 6.9% increase over the quantity sold in 1998 (119) (see Table 6). This compares with a production of 236,000 t in 1989, a growth rate of over 12% per year. Europe is still the largest market, accounting for almost half, followed by North America and the Far East, each with 20%+ market share.

An indication of the growth of the powder coating in North America is reflected in the membership statistics of the Powder Coating Institute, a trade organization representing the industry. From 1987 to 2000, the number of members who manufacture coating powders increased from 5 to 28; suppliers of powder application equipment from 3 to 8; custom powder coaters from 1 to 200; and raw material suppliers from 5 to 114 (119).

Table 6. 1999 World Thermoset Powder Coatings Production[a]

	Production	
Region	Metric tons	Percent
Europe–West and East	329,100	45.3
Far East	161,585	22.2
North America	175,600	24.2
South America	29,950	4.1
Rest of World	30,865	4.2
Total	*727,100*	*100.0*

[a]Ref. 119.

Thermoset decorative coatings are by far the largest segment of coating powder production accounting for over 90% of pounds produced. Other market segments are thermoplastic powders, essentially all of which are used in fluidized-bed coating and functional thermoset powders, which find use in the pipe coating, rebar, and electrical insulation markets.

The distribution of coating powder production by resin type for several geographical areas is given in Table 5. The epoxy–polyester hybrid powder coatings account for the largest resin type in both Europe and North America. Increasing market share is mostly at the expense of the 100% epoxy-based powders, as a result of more favorable economics. In Europe, weatherable carboxyl polyesters cured with TGIC are being replaced with carboxyl functional polyesters cured with hydroxylalkylamides, other glycidyl curatives and, to some extent, urethane polyesters. While the hydroxyl functional polyester resins cured with blocked isocyanates or uretdione curatives, that is, urethane polyesters, have a significant market share in the North American market, they are still a relatively small part of the European market.

The vast majority of acrylic powders in both Europe and North America find use in the automotive industry, as clear coats for wheels and bodies and as pigmented coatings in exterior trim, "blackout" coatings, and primer surfacers.

The automotive market is the largest and fastest growing segment of the powder coating market in North America, accounting for over 16% market share, followed by appliance coatings at 15%, architectural at 3%, lawn and garden at 7%, and the balance in general metal finishing.

Test Methods

Methods for evaluating the performance of powder coatings are the same as those used for conventional coatings. Test methods for coating powders include particle size distribution, powder free flow, sintering, fluidization characteristics, and others. They have been reviewed in detail and reported in the literature (120,121). In addition, the American Society for Testing and Materials has issued a comprehensive standard that covers the most important test methods for the evaluation and characterization of powder coatings (122).

Environmental and Energy Considerations

A significant factor contributing to the growth of powder coating processes has been the proliferation of federal, state, and local environmental regulations. Starting with the Clean Air Act of 1970, which defined Hazardous Air Pollutants (HAPs), Volatile Organic Compounds (VOCs), and set standards for nationwide air quality, many additional regulations have since been enacted. In nonattainment areas, localities where pollution levels persistently exceed National Ambient Air Quality Standards, the Best Available Control Technology or Maximum Available Control Technology may be necessary to reduce the level of pollutants to that required. Powder coating installations are generally accepted as meeting these levels of control technology. States are charged with the job of achieving compliance. Permits are required by states where new finishing operations are being added to existing facilities. The presence or absence of VOCs and HAPs in coating materials has become a significant factor in the economic analysis in planning new finishing operations.

Being 100% solid materials, coating powders are essentially free of VOCs and HAPs, with the exception of trace quantities of monomers or, in some cases, solvents used in the manufacture of the raw materials (123). Caprolactam and other compounds used as blocking agents in blocked isocyanate curatives are emitted during curing. Typical levels in formulated urethane coating powders are in the range of 4–6%. While caprolactam is considered a VOC, it is not classified as an HAP. Powder coating remains the process of choice where VOCs must be reduced to the lowest possible levels, as in many OEM and automotive coating operations. Permits for additions to existing paint lines or installation of new systems are much easier to justify and obtain than when most liquid coatings are specified. In addition to the environmental advantages, the low volatile emissions of powder coatings during the baking operation has economic and energy saving advantages. Fewer air changes per hour in the baking oven are required for powder coatings than for solvent-based coatings, which saves fuel. Further, in the coating operation almost all powder is recovered and reused, resulting in higher material utilization and waste minimization. The air used in the coating booths during application is filtered and returned to the workplace atmosphere, reducing heating and cooling demands. Additionally because of the need for more sophisticated devices to control emission of VOCs in liquid systems, the capital investment to install a new powder coating line is becoming increasingly more economically favorable. The savings in material and energy costs of powder coating systems has been documented in a number of studies. An economic analysis worksheet for comparing the cost of operating a powder coating line compared with alternate systems can be found in Technical Brief #21 in Reference 121.

The only components in a coating powder which might cause the waste to be classified as hazardous are certain heavy-metal pigments sometimes used as colorants. Lead- (qv) and cadmium-based pigments (qv) are seldom used, however, and other potentially hazardous elements such as barium, nickel, and chromium are usually in the form of highly insoluble materials that seldom cause the spent powder to be characterized as a hazardous waste (124).

Health and Safety Factors

Any finely divided organic material can form ignitable mixtures when dispersed in air at certain concentrations. The most significant hazard in the manufacture and application of coating powders is the potential of a dust explosion. The severity of a dust explosion is related to the material involved, its particle size, and concentration in air at time of ignition. The *lower explosive limit* (LEL) is the lowest concentration of a material dispersed in air that explodes in a confined space when ignited. The LEL for a number of epoxy and polyester powders was measured and found to be in the range of 0.039–0.085 oz/ft^3 (39–85 g/m^3) (125). In powder coating installations, the design of the spray booth and duct work, if any, should be such that the powder concentration in air is always kept below the LEL employing a wide margin of safety. General safety considerations are detailed in Reference 126. The use of flame detection systems in all automatic powder coating installations is required. These devices must respond within 0.5 s or less to arrest all powder flow in the system. If powder ignition should occur, flame detection sensors shut down the power to the system, halting powder spraying and air flow circulation. Another element of safety for a powder coating system is the design of the booth recovery equipment. Some recovery designs utilized today, such as illustrated in Figure 3, are configured so no external venting is required. However, when traditional cyclones or dust collectors, isolated by ducting, are utilized in the coating system, a pressure relief system is necessary. If these units are not located outside the building or properly vented, explosion suppression may also be required. Furthermore, cyclones and dust collectors located inside the building should be near an outside wall and ductwork from the pressure relief vents should be directed through short runs, not exceeding 3 m when possible. Required explosion vent areas and other design considerations can be found in the literature (127). The spray guns, spray booth, duct work, dust collection and powder reclaim system, as well as the work piece, must be properly grounded (128,129).

The health hazards and risk associated with the use of powder coatings must also be considered. Practical methods to reduce employee exposure to powder such as the use of long sleeved shirts and gloves to prevent skin contact should be observed. Furthermore, exposure can be minimized by good maintenance procedures to monitor and confirm that the spray booth and dust collection systems are operating as designed. Ovens should be properly vented and operated under negative pressure so that any volatiles released during curing, eg, caprolactam, do not enter the workplace atmosphere.

In general, the raw materials used in the manufacture of powder coatings are relatively low in degree of hazard. None of the epoxy, polyester, or acrylic resins normally used in the manufacture of thermoset powder coatings are defined as hazardous materials by the OSHA Hazard Communication Standard. Most pigments and fillers used in powder coatings generally have no hazards other than those associated with particulates. Some epoxy curing agents are skin irritants; however, most of these characteristics are greatly diminished when these materials are compounded into the powder coating. In addition to being diluted, the materials are dispersed in a resinous matrix having a low degree of water solubility which appears to make them less biologically accessible. For example,

anhydrides and anhydride adducts generally elicit a strong respiratory or eye irritant response. However, when powder coatings containing anhydride-based curing agents were tested in animal exposures, the coatings were found to be nonirritating to the skin, eye, and respiratory tract (130,131). Similarly, TGIC is a skin irritant, but formulated powders containing TGIC were found not to be (132). Regulations in Europe require cautionary labeling of powders containing TGIC (see under Polyester–Triglycidylisocyanurate Cured).

Although coating powders do not appear to pose significant hazards to personnel working with them, worker exposure should nevertheless be minimized. Coating powders should be treated as Particulates Not Otherwise Classified having a Threshold Limit Value–Time Weighted Average (TLV–TWA) of 10 mg/m^3 for total particulates (133). The TLV should be maintained primarily through environmental controls. Hoods and proper ventilation should be provided during handling and application of powders. When environmental control of dust cannot be maintained below the TLV, protective equipment such as dust and fumes masks or externally supplied air respirators should be used (134).

COLLAGEN

Introduction

Collagen is the most abundant animal protein, It is the principal protein component of all connective tissues, including skin, bone, tendon, and cartilage. All collagens play a structural and/or functional role in the extracellular matrix. As a polymer, each collagen chain has a precise, genetically determined molecular size, which may be further modified after biosynthesis by a range of secondary modification processes. Collagens are widely distributed throughout the animal kingdom, being found even in primitive species. At present, 21 distinct collagen types have been identified in humans. These vary in tissue distribution, and in the length of the triple helix and the presence of non-triple-helical interruptions. All are characterized by the triple-helical structure, which leads to a repeating Gly-X-Y amino acid sequence. This repeating motif is also found in certain other proteins from animals and bacteria, but these are not considered as collagen types as they do not have roles in the extracellular matrix.

Collagen can be commercially produced from a range of sources, with mammalian skins derived as a by-product of the food processing industry being the principal source. Various processes and modification reactions have been used to give a wide range of products. Recently, recombinant methods for collagen production have been described that may prove to be of value in the future for special applications.

Historically, collagen has been an important polymer, as it is the basis of leather and gelatin production, processes that span back several millennia. Collagen is the naturally occurring, triple-helical protein, whereas gelatin is its heat-denatured product that has distinct properties. Gelation of gelatin involves re-forming of the triple helix, but not in the same ordered phase or arrangement

as in native collagen. Current knowledge of the complexity of the protein structure, composition, and biosynthesis has emerged principally over the last 75 years, where economically significant applications of the protein initially drove research. Most recently, studies on applications in various medical fields have proved to be of importance. An understanding of how mutations in collagen can lead to disease has also been critical in providing an understanding of this protein.

Role in the Extracellular Matrix. Collagen plays a critical and complex role in the extracellular matrix (ECM) of all connective tissues. The ECM comprises many components, including insoluble fibers, fibrils, and many different soluble proteins and glycoproteins. Other noncollagen components include various proteoglycans, hyaluronan, elastin, fibronectin, laminin, and numerous other specialized components. The main roles of the ECM are to provide tissues with their specific mechanical and physiochemical properties, and to provide a molecular scaffold with specific recognition and signaling motifs for cell attachment and migration. Although these roles are readily identified, the mechanism by which they are achieved are less obvious and the cellular regulation of biosynthesis and the control of the precise tissue organization remain poorly understood. Although individual collagen molecules may contain information that aids in self-assembly of aggregate structures, cellular interactions with the ECM strongly suggest that cells are playing the dominant role in orchestrating the complex *in vivo* assembly of tissues. Collagen, while clearly fulfilling a structural role, has now been shown to possess numerous binding sites that interact with many other molecules and cell receptors (1).

Structure

The characteristic feature of all collagens is the triple-helical structure, in which three individual polypeptide chains are wound in a coiled-coil, rope-like manner (Fig. 1). Each individual chain forms a left-handed, polyproline II like coil and these are then twisted in a right-handed manner to form the supercoiled triple-helical structure (2). The initial proposal for the triple helix motif by Ramachandran and Kartha (3) was refined by Rich and Crick (4) to eliminate certain stereochemical restrictions. This led to the proposal of two further models (RC I and RC II) that differed in their hydrogen bonding arrangements, both based on models of poly(glycine) with an additional rope twist. Subsequently, quantitative X-ray fiber diffraction data gave a detailed value for the unit twist of the molecular helix of 107.1°, which is close to that expected, 108°, for a helix with 10 units in 3 turns (5). However, there is no specific reason why a helix with a simple relationship should be formed. Later, a fiber diffraction structure of triple-helical $(Gly\text{-}Pro\text{-}Pro)_{10}$ suggested that the helical pitch may be 7/2 (6). Most recently, high resolution structures for the collagen triple helix, based on X-ray diffraction of crystals of other collagen peptides, have suggested that the 7/2 helix may be restricted to regions of very high imino acid content, whereas over the other parts of the molecule where various amino acids occupy the X- and Y-positions a 10/3 helix is present (7,8) (Fig. 2). Variations in symmetry could be important in maintaining spatial relationships between adjacent collagen molecules and in defining

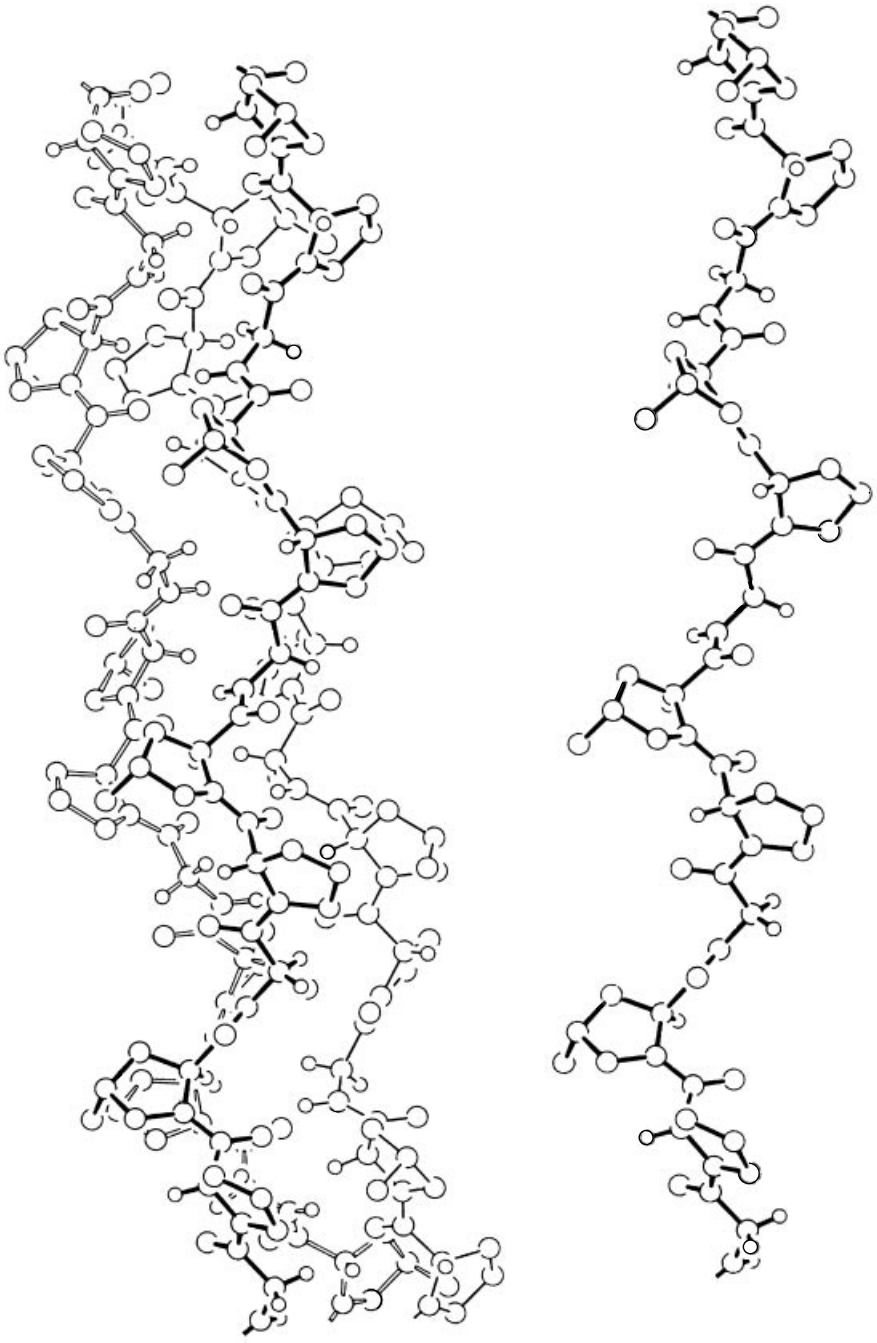

Fig. 1. The chain conformation of the collagen molecule, showing a single chain and a triple helix. Obtained through a linked atom, least-squares refinement of X-ray data obtained from dried kangaroo tail tendon. Hydrogen atoms not attached to the main chain have been omitted. From Ref. 5 with permission.

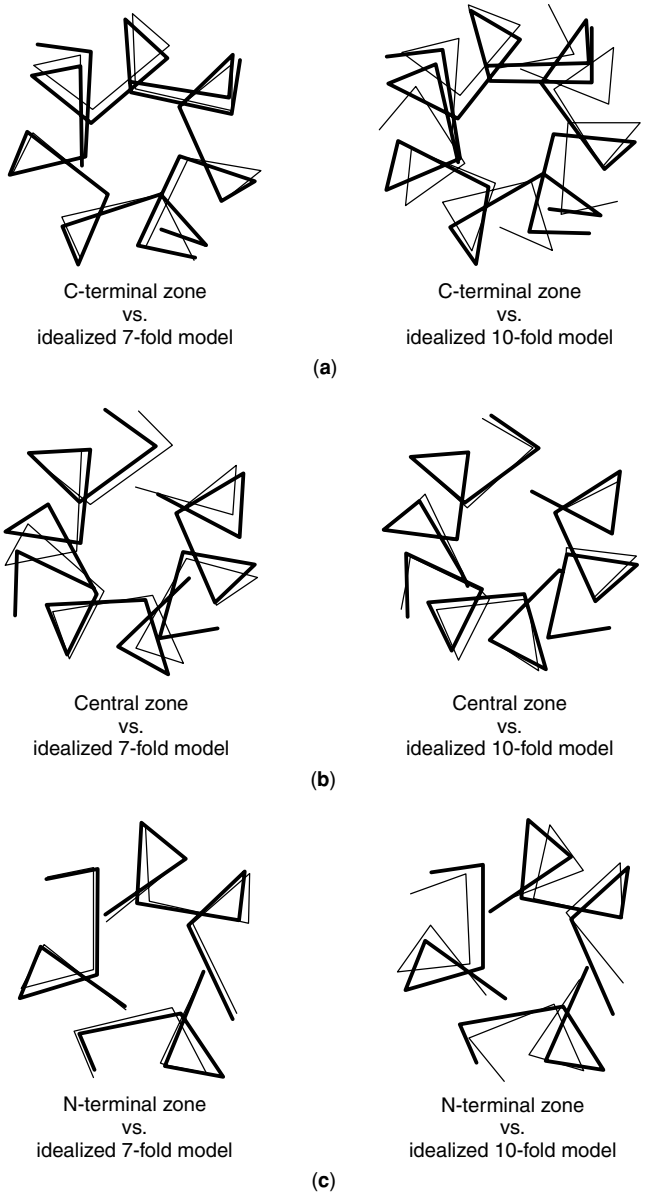

Fig. 2. Alpha carbon traces for the collagen-like peptide T3-785 (thick lines) superimposed on idealized models of 7/2 and 10/3 symmetry (thin lines), showing the variation in helical symmetry in different regions along this peptide. The central zone lacks imino acids while the terminal zones have a high imino acid content as they are Gly-Pro-Hyp repeats. From Ref. 8 with permission.

functional domains along the helix. These crystal structure data also confirmed the hydrogen bonding predicted by the RC II model. Thus, the NH of the Gly is hydrogen bonded to the C=O of the residue in the X-position along the chain through an interceding water molecule (7,9).

The triple-helical structure leads to constraints on the amino acid sequence, as every third residue is located in the close-packed center of this triple helix (5,7). Steric constraints mean that only glycine (Gly), which lacks a β-carbon atom, is small enough to fit, leading to a characteristic repeating Gly-X-Y amino acid sequence in the polypeptide chain (2). The X- and Y-positions are well exposed to solvent, with the X-position being more accessible than the Y-position (10). Either position can be occupied by any amino acid, although Gly and the aromatic amino acids tyrosine and tryptophan are rarely found. Some amino acids show a distinct preference for one position. For example, arginine is most frequently found in the Y-position, where it may provide a stabilizing influence; Phe and Leu are found preferentially in the X-position (11). Modeling studies have suggested potential electrostatic, hydrogen bonding, and steric reasons to account for these observed preferences. Overall, the imino acids proline (Pro) in the X-position and hydroxyproline (Hyp) in the Y-position are the most frequently observed, as they are critical for stabilizing the polyproline II like helix; these residues account for about 20% of the composition (11). The Hyp residues are derived from Pro by secondary modification during biosynthesis, and represent another characteristic of collagen or collagen-like sequences. The Hyp residues are more effective than Pro residues in contributing to the stability of the triple helix, although the mechanism for this observed effect is still not clear. On the one hand, it has been suggested that they contribute to stability through a hydrogen bond network that involves tightly bound water molecules. While the water molecules may or may not be important in stabilization, X-ray evidence indicates that they are an intrinsic part of the triple-helical structure (7–9). Alternatively, it has been suggested that the Hyp residues stabilize the triple helix through inductive and stereoelectronic effects (12). However, it has also been suggested that the stereochemical preferences of Pro and it analogues, such as Hyp, may be sufficient to account for the stabilization provided by Hyp (13).

The triple-helical structure has also been identified in a range of other proteins, such as macrophage scavenger receptor, mannose-binding protein, and C1q, most of which play a role in host defence mechanisms. In these cases, the triple-helical domain often exhibits ligand binding, which is key to the function of the protein (14).

Genetic Diversity and Occurrence

It was only around 1970 that it was realized that there was more than one collagen type. Thus, it was initially found that chick sternal cartilage contained a distinct collagen, termed type II (15). Shortly after, a third collagen, type III, was extracted from skin and aorta (16) and has subsequently been shown to be present in a large number of extensible tissues. Now, at least 21 distinct collagen types have been described (Table 1); however, with the completion of the human genome it is likely that this list will shortly be complete.

Each distinct collagen type has a specific chain composition, with its component chains only being found together in that particular collagen type. In some cases, the collagens are homotrimers with three identical chains, for example in type II or III collagens, whereas in other cases the collagen molecule is a heterotrimer. This can be with either two chain types, as for type I collagen, where

Table 1. Genetically Distinct Collagen Types

Type	Chain(s)	Chromosome	Molecular forms	Distribution and features
I	α1(I) α2(I)	17q21.3-q22 7q21.3-q22	[αl(I)]$_2\alpha$2(I)	Very widespread and most abundant collagen, being the main constituent of major fiber bundles, particularly in dermis, bone, ligament, and tendon
			[α1(I)]$_3$	Appears to be a minor form, found in dermis and dentin
II	αl(II)	12q13-q14	[αl(II)]$_3$	The main collagen of cartilage, where it forms the main, thin fibrils. Also found in intervertebral disk
III	αl(III)	2q24.3-q31	[αl(III)]$_3$	Often with type I, in extensible tissues such as blood vessels, dermis, and intestine. More abundant in foetal tissues
IV	αl(IV)	13q34		Located in basement membranes, with different chain combinations being associated with specific tissues
			[αl(IV)]$_2\alpha$2(IV)	Lens capsule, kidney glomerulus, aorta, bladder, etc
	α2(IV)	13q34	α3(IV)α4(IV)α5(IV)	Lung alveoli, kidney glomerulus
	α3(IV)	2q35-q37	[α5(IV)]$_2\alpha$6(IV)	Epidermis, SMC of aorta and bladder, prostate, developing intestine, colorectal mucosa
	α4(IV)	2q35-q37	[α3(IV)]$_2\alpha$4(IV)	Kidney glomerulus
	α5(IV)	Xq22	[αl(IV)]$_2\alpha$6(IV)	Seminiferous tubule
	α6(IV)	Xq22	[α3(IV)]$_2\alpha$6(IV)	Seminiferous tubule
V	αl(V)	9q34.2-q34.3	[αl(V)]$_3$	Widespread in low quantity; appears associated with type I collagen fibrils, where it may form a core filament
	α2(V)	2q24.3-q31	[αl(V)]$_2\alpha$2(V)	
	α3(V)	19p13.2	αl(V)α2(V)α3(V)	
VI	αl(VI)	21q22.3	αl(VI)α2(VI)α3(VI)	Widespread beaded filaments. Alternative spliced forms
	α2(VI)	21q22.3		
	α3(VI)	2q37		
VII	αl(VII)	3p21	[αl(VII)]$_3$	Forms anchoring filament structure that links the epithelial basement membrane to underlying fibrillar tissue
VIII	αl(VIII)	3q12-q13.1	(?)	Associated with endothelial cell layers, such as Descemet's membrane. In some tissues it forms a hexagonal lattice
	α2(VIII)	1p32.3-p34.3		

IX	αl(IX)	6q12-q14	αl(IX)α2(IX)α3(IX)	Found in cartilage and vitreous body, where it is associated with type II collagen. Can contain a GAG chain
	α2(IX)	1p32		
	α3(IX)	20q13.3		
X	αl(X)	6q21-q22	$[\alpha l(X)]_3$	A short-chain collagen, found in hypertrophic mineralizing cartilage, with a similar structure to type VIII collagen
XI	α1(XI)	1p21	α(XI)α2(Xl)α3(XI)	Forms fibrils that are associated with type II collagen in cartilage and intervertebral disc
	α2(XI)	6p21.2		
	α3(XI)	12q13-q14		
XII	αl(XII)	6q12-q13	$[\alpha l(XII)]_3$	A collagen with an interrupted triple helix associated with type I collagen fibrils
XIII	αl(XIII)	10q22	(?)	Appears to be widespread in low quantity, showing different forms because of a complex pattern of alternative splicing
XIV	αl(XIV)	8q23	$[\alpha l(XIV)]_3$	A fibril-associated collagen with an interrupted triple helix found in skin
XV	αl(XV)	9q21-q22	(?)	Is expressed in fibroblasts and smooth muscle cells; has a triple helix that is interrupted in several places
XVI	αl(XVI)	1p34-p35	(?)	Is expressed in fibroblasts and keratinocytes; has a triple helix that is interrupted in several places
XVII	αl(XVII)	10q24.3	(?)	Bullous pemphigoid antigen. At dermal–epidermal junction
XVIII	α1(XVIII)	21q22.3	(?)	Is expressed in highly vascularized tissues; has a triple helix that is interrupted in several places
XIX	α1(XIX)	6q12-q14	(?)	
XX	α1(XX)		(?)	
XXI	α1(XXI)	6p11.2–12.3	(?)	Expressed in tissues such as heart, stomach, kidney skeletal muscle, and placenta

(?)Indicates that the chain composition has note yet been determined.

[a]Data were calculated from the amino acid sequences reported in SWISSPROT [http://www.expasy.ch/sprot/]. It has been assumed that Pro residues in the Y-position in the Gly-X-Y repeating sequence were all substantially present as 4-Hyp. Hyl and 3-Hyp are also present in small amounts in certain collagens, as determined by chemical analysis, but are not reported in this table.

the two chains are also always in the same ratio, or three different chains, as in collagen VI. Furthermore, for some collagens, for example type IV collagen, a range of different chains is found and the specific combination found is tissue-specific (17) (Table 1).

All chains are characterized by the repeating Gly-X-Y sequence motif, with the high Gly and imino acid (Pro, Hyp) content that arises from the structural constraints (2). Examination of the amino acid compositions of the chains (Table 2) shows that, although Gly content is high, it generally does not exceed the one-third ratio required by the structure, indicating that it is rarely found in the X- or Y- positions (11). In addition, there is a relatively high proportion of charged residues, consistent with the absence of a hydrophobic core as found in globular proteins. There is an excess of Lys and Arg residues compared to Asp and Glu residues, leading to a basic pI value of about 9. Typically, residues such as Trp and Cys are rarely found. A striking characteristic of collagens is the nature and extent of secondary modifications that are present. As noted above, the Hyp residues play an important role in collagen stabilization. In mammalian species, essentially every Pro in the Y-position is converted to 4-Hyp, whereas in organisms that are more primitive this is not the case. The extent of hydroxylation

provides adequate stability to meet the environmental temperature of the species (18), although the melting temperature of the collagen may be slightly lower than this (body) temperature and may vary, for example in fish, when adaptation to a higher temperature takes place. There is also a very low amount of 3-Hyp. This is found in certain chains but only in the X-position, where it is followed by a 4-Hyp in the Y-position. The other significant modification is that of Lys residues, which can be converted to hydroxylysine (Hyl) by the enzyme lysyl hydroxylase. Hyl, like Hyp, is a characteristic marker for collagens.

The lengths of individual collagen chains vary with collagen type (19,20) (Fig. 3, Table 2). Thus, the predominant collagens, type I, II, and III, termed the interstitial collagens (along with type V and XI), all have a triple-helical domain of just over 1000 residues, with short non-triple-helical domain telopeptides, that remain after the loss of propeptide domains. While type IV and VII collagens are both longer (Table 2), most collagens have shorter triple-helical segments. In some collagens, the Gly-X-Y repeat is not continuous and non-triple-helical inserts of various lengths may be present. These interruptions can be as short as a single residue, giving sequences such as -GXYGXGXY-, whereas in other cases much larger interruptions are present. The number of interruptions is also very variable between collagen types. In addition, most mature collagens retain globular domains at either or both the N- and C-terminal regions (19,20) (Fig. 3).

Each collagen type has a characteristic tissue distribution. Thus, while type I collagen is by far the most abundant, other minor collagens may be the dominant component in a specific tissue location. For example, type II collagen is the major collagen in articular cartilage, while type IV collagen plays a critical role in all basal lamina. Most collagens, such as type III collagen, are not found exclusively in a single tissue but are rather found in combination with other collagens. In particular, one group, the fibril-associated collagens with interrupted triple helices (FACIT) collagens are found associated with the interstitial collagens (27). When a particular collagen type, with its constant chain composition, is found in different tissues, it may still vary in the extent of the secondary modification that is present.

Biosynthesis and Catabolism

The majority of data on the biosynthesis and catabolism of collagens has been derived from studies on the most abundant, interstitial collagens, particularly type I collagen, but it is generally believed that most processes will be common to all collagen types (30). Overall, it is a complex process, being similar to the pattern of assembly of other multisubunit proteins, but is characterized by the involvement of a large number of specific intracellular and extracellular post-translational modification reactions (Fig. 4).

Transcription and Translation. There are at least 40 distinct genes coding for different types of collagen chains, and these are located on 15 different chromosomes, with very few of the genes in close proximity (Table 1). Transcription and mRNA processing follow the typical processes, involving 3′- and 5′-capping and 5′-methylation. This is followed by the excision of the noncoding intronic sequences. Collagen genes are composed of many intron/exon domains, requiring extensive splicing; for example, the α1(I) chain has more than 50 exons. Alternative splicing

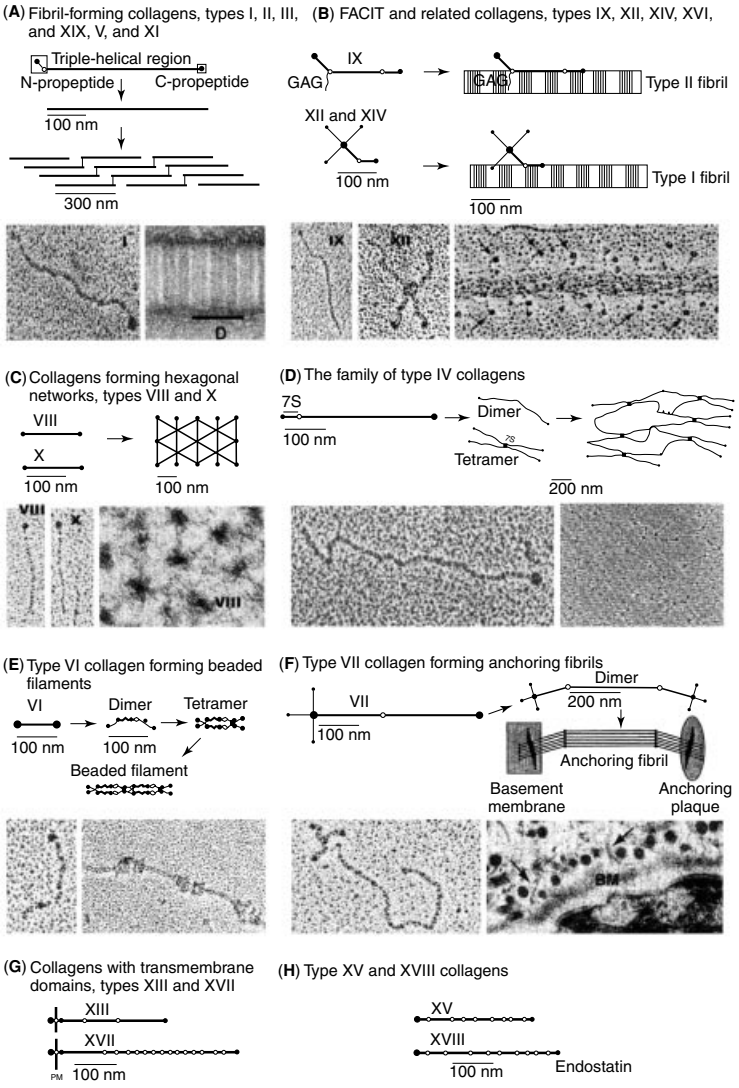

Fig. 3. Schematic illustrations of the variations in the shapes, forms, and packing of various collagen types, representing the eight classes of collagen. Closed circles indicate N- and C-terminal noncollagenous domains while open circles indicate noncollagenous domains that interrupt the triple-helical domains. GAG is glycosamino glycan and PM is plasma membrane. The assembly of groups G and H is not known. Modified from Ref. 20 with permission. Images of collagen molecules by rotary shadowing (unless stated) are included as follows: procollagen I from Ref. 21; TEM of a collagen fibril (negative staining) showing the D-period repeat, courtesy of Jacinta F. White; Type XI collagen from Ref. 22; Type XII collagen from Ref. 23; Type IX collagen decorating a type II collagen fibril, from Ref. 24; Type VIII collagen, from Ref. 25; Type X collagen, from Ref. 26; TEM of the hexagonal packing of type VIII collagen, from Ref. 27; Monomeric type IV collagen, from Ref. 22; Type IV collagen forming an interlocking network, from 28; monmeric type VI collagen, from Ref. 22; beaded filament of type VI collagen, from Ref. 27; monomeric type VII collagen, from 29; TEM showing anchoring filaments (arrows) of type VII collagen at the dermal epidermal junction, from Ref. 24; all with permission. Few published images are available for other collagen types (groups G and H).

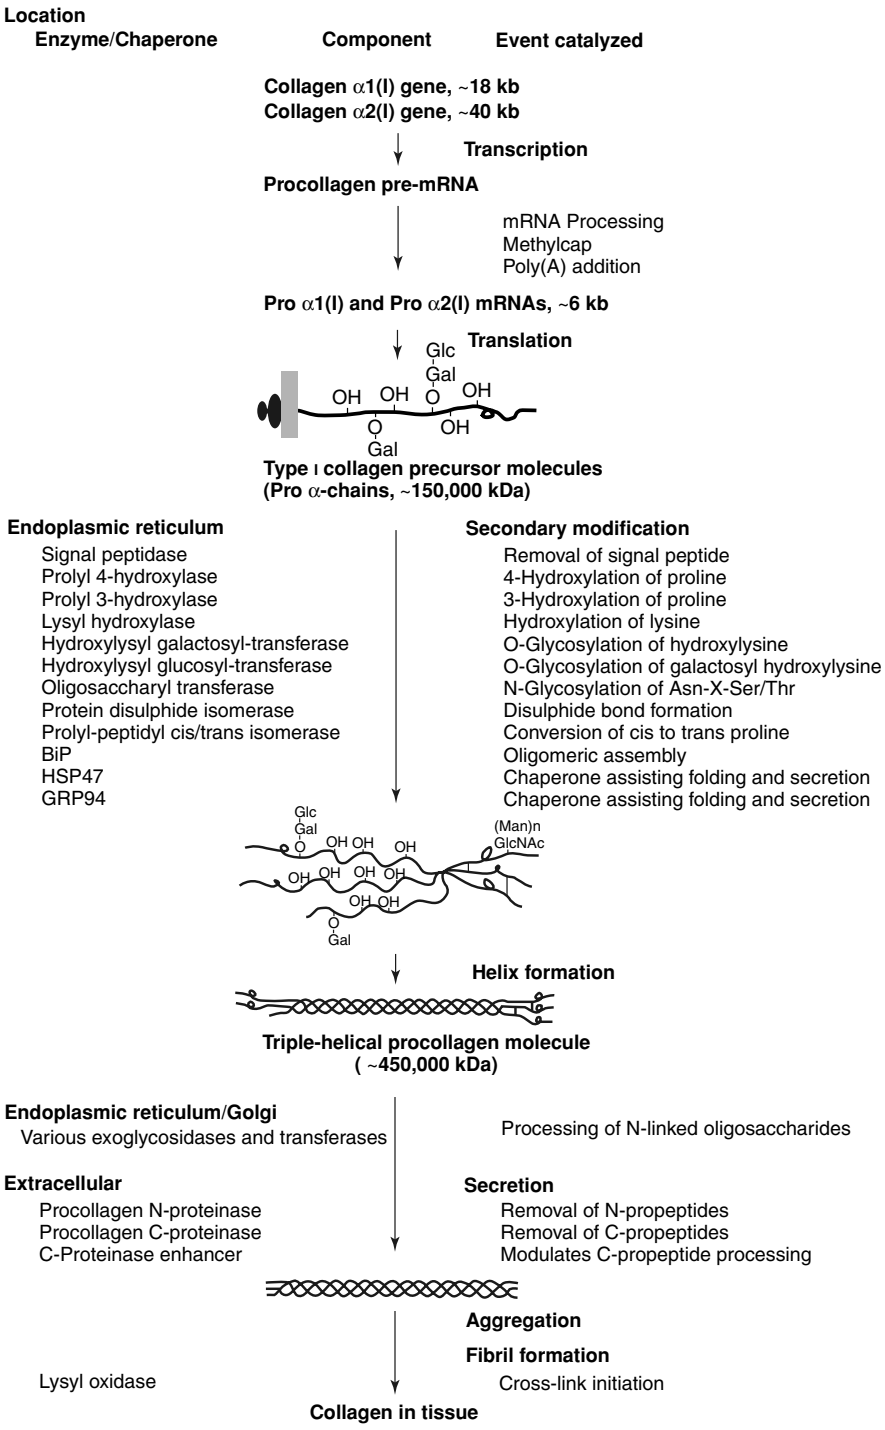

Fig. 4. The pathway for collagen biosynthesis, illustrating the major intermediates in interstitial collagen production, the main steps, and the key enzymes involved in the process. Modified from Ref. 31 with permission.

is found for some collagen types by which numerous variants can be produced. The subsequent translation products are directed into the endoplasmic reticulum (ER). This is directed by a hydrophobic N-terminal signal sequence that interacts with a signal recognition particle that binds to an ER-docking protein; release of the particle is followed by further translation. Signal peptide cleavage is achieved by a membrane peptidase (19) (Fig. 4). The product is a procollagen chain, which includes pro-domains as well as the helical domain.

Post-Translational Modifications. A wide range of intracellular modifications take place within the ER (19). The specific hydroxylation of certain Pro and Lys residues is characteristic of collagens. Lysyl hydroxylase, prolyl-4-hydroxylase, and prolyl-3-hydroxylase are similar in that they all require Fe^{2+}, 2-oxoglutarate, O_2, and ascorbate for activity (32), but differ in structure. Lysyl hydroxylase and prolyl-4-hydroxylase act on X-Lys-Gly and X-Pro-Gly sequences, while prolyl-3-hydroxylase acts on certain Pro-4-Hyp-Gly sequences. The presence of 4-Hyp is essential for the stability of the resulting collagen (33). The prolyl-4-hydroxylase is an $\alpha_2\beta_2$ tetramer, where the β-chains as a dimer also contain the independent protein disulphide isomerase activity that is important during protein, including collagen, synthesis. An alternate form of lysyl hydroxylase acts on the telopeptides. Certain Hyl residues in the helical domain are subject to further modification by glycosylation by two specific glycosidases. The first adds galactose to certain Hyl residues, the second may then add glucose to galactosyl-Hyl (34) (Fig. 4). All these enzyme modifications can only occur on the individual collagen chains before their folding into a triple helix. Asparagine N-linked glycosylation, as mannose oligosaccharide, is also present, found in the C-propeptide domain of interstitial collagens (19).

Procollagen Assembly. In cells that may be producing more than one collagen type, appropriate chain recognition and assembly are key steps in the formation of correct functional collagens. A variety of processes, including recognition at the C-terminal domains, may be involved (19). For almost all collagens, the initial interaction prior to triple helix formation is between C-propeptide domains. Folded propeptide domains are stabilized by intrachain disulphide bonds prior to trimeric association, which is followed by further interchain disulphide bond formation, all catalyzed by protein disulphide isomerase. The folding of the helical domain follows. The effectiveness and stability of this process requires Hyp formation prior to nucleation as the key step; the presence of the propeptide is not essential for nucleation. Efficient triple helix formation then requires acceleration of the rate-limiting isomerization of Pro residues to the trans form required for folding by the enzyme prolyl isomerase. The helix folding rate confirms that this isomerization process is rate-limiting (35). The overall process of folding is complex and involves the interaction of various molecular chaperones, such as HSP47 (19).

Secretion and Extracellular Processing. The secretion pathway for procollagen in part mirrors that for other extracellular proteins. Folded procollagen molecules are transported from the ER through the Golgi complex and are packaged into secretory vacuoles that release collagen from the cell surface by endocytosis. During this step, or after secretion, the interstitial procollagens are further processed by removal of the propeptide domains by specific N- and C-procollagen proteases. For other collagens, including type V collagen, pro-domains

are generally retained. For the major interstitial collagens the C-propeptide seems to be always removed, but the N-propeptide may remain, possibly to control fibril growth. Thus, quantitation of C-propeptide has been used as a measure of collagen synthesis, for example in disease states where collagen production may be altered.

Fibrillogenesis. The processes by which functional fibrils in tissues are formed from procollagen are not well understood. There is now evidence from electron microscopy that suggests that the nucleation steps that initiate fibril formation may occur within cell surface crypts (36), and that nonstaggered aggregates may be involved in this process (37), although it is possible that nucleation may occur in the matrix further from the cell.

Various *in vitro* studies on fibril formation, many utilizing pepsin- or acid-soluble collagen extracted from tissue, have identified different phases in fibril growth, including nucleation during a lag phase followed by a growth phase. These data indicated the importance of the telopeptides in fibrillogenesis (38). Subsequently, it has been suggested that the C-telopeptide binds to a specific region of a collagen fibril during the addition of new collagen molecules (39). However, probably the most significant information has been obtained from *in vitro* studies in which fibrils are formed from either pN-, pC-, or intact procollagen by addition of the specific N- and C-proteases (40). This approach leads to the formation of fibril-like moieties, but with a distinct needle-like morphology, that have the characteristic collagen D-periodic banding pattern (Fig. 3). Those formed by cleavage of pC-collagen by C-propeptidase were exclusively bipolar (41), showing a single polarity reversal in the banding pattern, and having collagen molecules oriented with amino-termini at both ends of the fibrils. The tips were not symmetric, with initial growth occurring preferentially at the sharp (α-) end compared to the blunt (β-) end.

Newly formed fibrils with characteristic D-periodicity (Fig. 5) have been isolated from various embryonic and wound repair tissues (42–44). These fibrils also

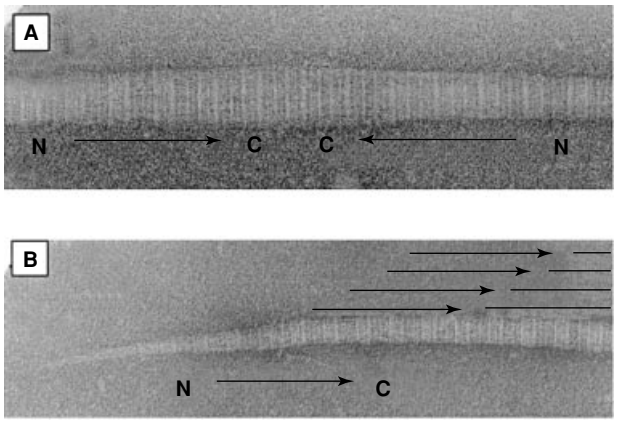

Fig. 5. TEM (negative staining) of a 9-μm fibril from 14-day wound healing tissue showing (**A**) a polarity reversal, and (**B**) a tapered end, with a schematic to illustrate the staggered overlap of individual molecules. Modified from Ref. 44 with permission.

frequently show a single polarity reversal (Fig. 5), particularly if gentle extraction methods are used (44,45), and those showing a reversal have amino-termini at both ends of these fibrils. In some cases, the regions of polarity reversal appeared to be locations where two fibril tips had come together axially. These *in vivo* derived fibrils also have distinct tapers at each end (Fig. 5), although the asymmetry observed *in vitro* is not always seen with *in vivo* samples (44). The mechanism of how these initial fibrils would grow into larger fibrils is not clear. Data suggests, perhaps, that formation of longer fibrils may occur by the fusion of small (1–10 μm) segments (42). If many small fibrils were able to axially associate, larger fibrils with multiple polarity reversals along the length would form; these, however, have not been observed. Indeed, the data on newly formed, immature fibrils contrast with those from mature tissues where polarity reversals are not observed. Lateral association of long or short fibrils provides another mechanism that may lead to thicker fibrils. Evidence suggests that this does not take place immediately, but does so later as the tissue matures (46).

In tendon, collagen type I is almost exclusively found. However, in other tissues, such as the wound repair tissue and those that are extensible, type III collagen can be a significant component along with type I collagen (47). It was of interest that immunoelectron microscopy showed that all fibrils, even at this early stage in fibril formation, were heterotypic, containing both type I and type III collagens (44). It has been suggested that other collagen types, notably type V collagen, may also be present in newly forming fibrils where they may act as a core filament. Immunoelectron microscopy has also shown the presence of type III pN-collagen in embryonic tissues, suggesting that that the N-propeptide may have a role in regulating fibril growth (48). A range of other molecules, including the small proteoglycans decorin and lumican, have also been proposed as being important in the control of fibril growth, as has hyaluronan, which is also present in large amounts in developing connective tissues (42,49). Fibrils extracted from different tissues suggest that the detailed mechanism may also be dependent on the site and function of the particular tissue. The development of knockout mice, where specific molecules that may have a role in fibril development have been deleted, should enable the role of these other molecules to be better defined.

Cross-Linking. Cross-linking is a key element in the formation of functional tissues as it provides the strength to tissues. In normal tissues, little soluble collagen can be extracted, even from young or embryonic tissues, as cross-linking occurs rapidly and provides an extensive network between all collagen molecules. The process is very specific, and is best understood for interstitial collagens (50); the extent, if any, of cross-links involving other collagen types is generally not defined.

Cross-linking is initiated by the formation of allysine and/or hydroxyallysine from specific Lys residues in the telopeptides of the interstitial collagens (Fig. 6). This step requires the action of the specific enzyme, lysyl oxidase. These aldehydes may then form initial bifunctional cross-links, termed reducible cross-links as they can be reduced by sodium borohydride. These are either aldol condensation products or aldimine or ketoamine links. The aldimine and ketoamine involve specific Lys or Hyl residues either from the telopeptides or from the helical domain of the collagen. The sites of these specific residues have been determined (Fig. 6) (50).

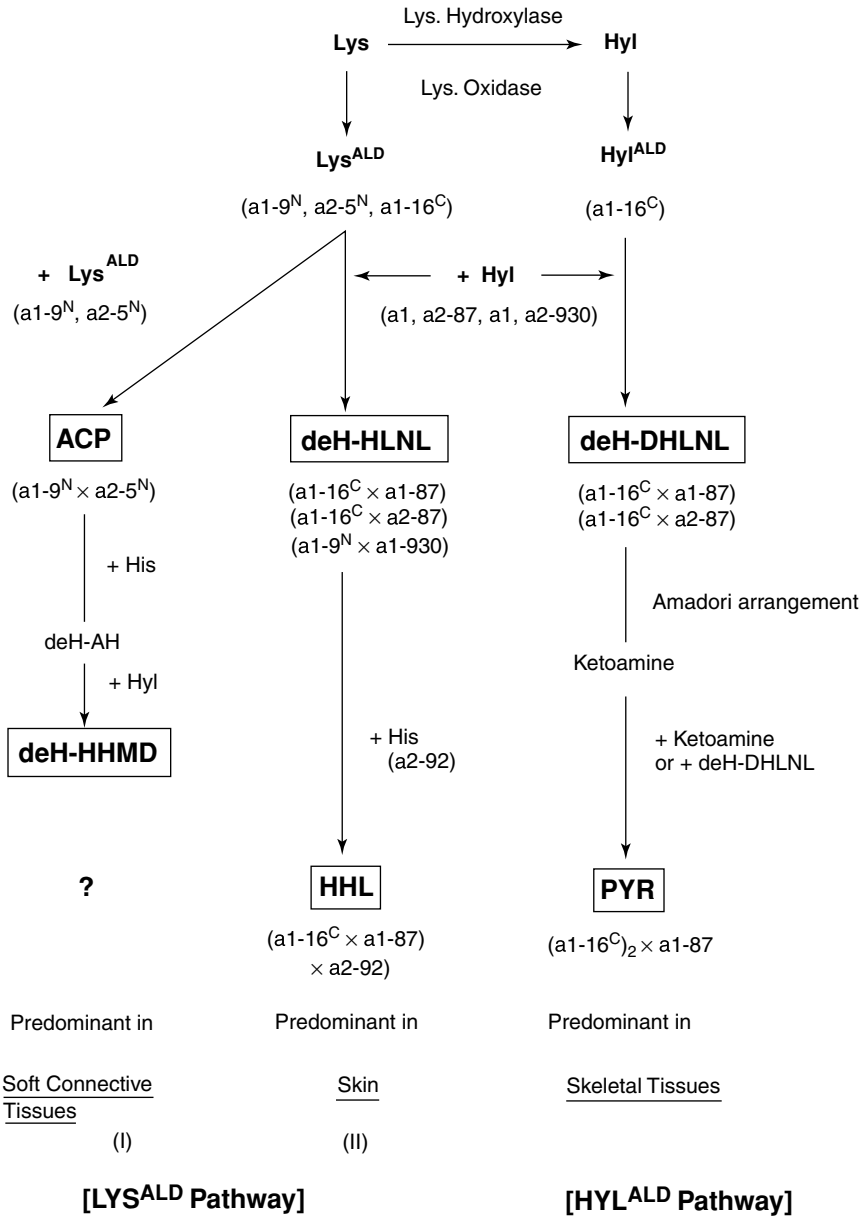

Fig. 6. The major cross-linking pathways for type I collagen. The numbers in parentheses indicate the residues involved in the cross-links, with subscripts N or C indicating telopeptide locations. Abbreviations: Lys, lysine; Hyl, hydroxylysine; LysALD, 5-amino-5-carboxypentanal (allysine); HylALD, 2-hydroxy-5-amino-5-carboxypentanal (hydroxyallysine); ACP, aldol condensation product; deH-HLNL, dehydro-hydroxylysinonorleucine; deH-DHLNL, dehydro-dihydroxylysinonorleucine; deH-HHMD, dehydro-histidinohydroxymerodesmosine; HHL, histidinohydroxylysinonorleucine; PYR pyridinoline. From Ref. 50 with permission.

As tissue ages, these initial cross-links decline in quantity as they are converted into other, more complex mature cross-links. These multifunctional cross-links are key to providing strength and stability to tissues. Despite their importance, however, the determined structures are limited (Fig. 6) and other structures may also be present. For some cross-links, such as histidinohydroxylysinonorleucine and pyridinoline, the structures are well defined and the paths to their formation well understood (Fig. 6). For others, the information is not as complete. The types and extent of cross-links vary between tissues in a specific manner (50). Finally, in addition to these specific cross-links, as tissue ages it may accumulate a range of additional cross-links that form because of nonenzymatic glycosylation of collagen (51).

Fibril and Tissue Structure. The fibrils formed by interstitial collagens have a characteristic banded pattern in electron microscopy with a repeat, the D-period, of about 65–67 nm, equivalent to about 234 amino acids (52) (Fig. 5). The individual collagen molecules are arranged in a staggered overlap structure. As each individual molecule is about 280 nm long, or 4.4 D-periods, there is a gap between the end of one molecule and the beginning of the next (Fig. 5). It is the differential stain uptake between the gap and overlap regions that gives the banding pattern in the electron microscope (52). X-ray fiber diffraction shows that the D-period repeat in tendon is 67 nm, whereas for skin and other extensible tissues it is about 65 nm, suggesting that differences in molecular packing may be present (53). Closer examination of stained fibrils shows that there is a fine structure present. This arises from the distribution of charged amino acids. Other ordered aggregates can be formed from collagen solutions—fibrous-long-spacing (FLS) and segment-long-spacing (SLS) forms—that are not found *in vivo* (52). Other collagen types show a wide range of structures. For example, the FACIT collagens associate with the interstitial collagen on the surface of the fibrils (Fig. 3). Other collagens, types IV, VI, VIII, and X, form a variety of distinct network structures, while type VII collagen forms interlocking anchoring fibrils (Fig. 3) (20). The detailed structure of these aggregate structures has generally been inferred from electron microscopy evidence. For type I collagen, however, a detailed picture of the lateral packing has now emerged from X-ray fiber diffraction data on the type I collagen tissue, rat tail tendon. These data have shown that the individual collagen molecules are packed in a quasihexagonal lattice, and that the telopeptides form a corrugated arrangement of cross-linked molecules that strengthen and stabilize the native fibril (54).

Collagen found in mature tissues is arranged into structures that form macroscopically visible fiber bundles (Fig. 7). These fiber bundles would require a mechanism whereby individual fibrils can associate and broaden to attain a functional mature tissue form (55). There is little data on the length of mature fibrils. Long fibrils (up to 1 mm) have been isolated unbroken only from echinoderms (56). Studies on mature rat tail tendon, where over 1000 fibrils were followed over 1.4 μm by serial sectioning, showed no ends, leading to an estimate for fibril length of up to 10 mm in 6-month-old tendon (57). Serial sectioning to measure the length of fibrils in 14-day chicken embryo tendon showed only one complete fibril, but the proportion of ends seen suggested that the fibrils were shorter than those found in mature tendons (58).

The amounts of different collagen types in a particular tissue may vary with location and age. For example, in skin, the amount of type III collagen is greatest

in embryonic or young tissues and is also in greater amounts in the papillary dermis compared to the reticular dermis (59). The availability of monoclonal antibodies specific to different collagen types has enabled the distribution to be readily examined (Fig. 8) (60–63).

Regulation of Collagen Biosynthesis. In order for the normal morphogenesis and differentiation processes to occur, precise temporal, spatial, and quantitative regulation of collagen biosynthesis is undoubtedly critical. The nature and extent of collagen production is sensitive to modulation by various entities, including growth factors and cytokines. Thus gene transcription is modulated by multiple, cis-acting promoters, enhancers, and silencers, which have been identified in the 5′-flanking region and within the first intron. Regulation of translation may involve sequences proximal to the translation initiation site. Various studies have suggested that the propeptide domains released during secretion and fibril formation may play a role in modulating collagen production, particularly through translational control (19).

Collagen Degradation. The rate of turnover of collagen in tissues is generally very slow, with lifetimes being estimated in years for type I collagen in bone, for type II collagen in cartilage, and for type III collagen in skin. The exception is type I collagen in periodontal ligament, which has an estimated half-life of the order of a week. However, a regulated breakdown of collagen is required for this slow turnover, as well as for wound healing, development, and tissue remodeling. The collagen in the extracellular matrix is a very stable structure, with the triple-helical domains being particularly resistant to proteolysis by typical proteases such as trypsin, chymotrypsin, and pepsin. A set of specific proteases is present in tissues—the matrix metalloproteinases (MMPs)—that are involved in the degradation of most, if not all, proteins in the ECM including collagen and collagen fragments. This set of MMPs includes at least 20 members, each with a different specificity profile, including some with collagenase and gelatinase activities (64). All these MMPs are tightly regulated, through the need for proenzyme activation to achieve activity and the presence of specific tissue inhibitors of metalloproteinases (TIMPs). The enzymes MMP-1, 8, and 13, traditionally called mammalian collagenases, break down triple-helical collagen fibrils through cleavage at a single site in a collagen molecule to give two fragments of about $\frac{3}{4}$ and $\frac{1}{4}$ of the molecular length. The cleavage site occurs in the $\alpha 1$ chain of type I collagen in the sequence -Gly(775)-Ile(776), and at an analogous sequence location in other interstitial collagen chains (65). It has been suggested that the triple helix at this location may be less tightly folded because of an imino acid deficient domain C-terminal in this site (66). After this initial cleavage a range of other enzymes, including those with activities for unfolded collagen chains and telopeptide regions are able to complete the degradation process.

Pathology. Many opportunities for molecular defects leading to disease arise for collagen because of its complex biosynthetic and catabolic pathways and the complex nature of the structural genes (19,67). The most frequently studied "collagen disease" is *Osteogenesis imperfecta* (OI). This disease occurs in a range of severities from mild to perinatal lethal and is caused by changes to type I collagen. More than 100 mutations have been characterized that involve a single base substitution leading to mutation of an obligatory glycine residue within the repeating $(\text{Gly-X-Y})_n$ motif of the collagen triple helix. In addition, a range of deletions and splicing defects has been observed that lead to similar disease outcomes. The observed consequences of replacing a Gly by a larger amino acid residue can include delayed folding, excess post-translational modification, increased intracellular breakdown, reduced secretion of collagen, abnormal fibril assembly, and a possible decrease in helical stability. Collagen mutations are generally dominant because mutant collagen chain can be incorporated into the triple helix resulting in aberrant fibril formation and function. Clinical severity for OI appears to depend on the nature of the residue replacing Gly, its location in the triple helix, and the local sequence environment around the mutation (68). Similar mutations have been observed in many other collagen types, leading to a range of diseases that reflect the tissue distribution of each particular collagen type (Table 3) (67,69).

In addition to pathological consequences arising directly from mutations to the triple-helical domain, diseases have been shown to be due to variations in the secondary modification of collagen, including defects in lysyl hydroxylase, lysyl oxidase, and N-proteinase. There is also a range of common diseases that involve

Table 3. The Involvement of Different Collagen Chains in Genetic Diseases[a]

Collagen type	Chain(s) involved	Disease
Type I	αl(I) α2(I)	Osteogenesis imperfecta
		Ehlers–Danlos syndrome types I, II, VIIA, VIIB
		Osteoporosis
Type II	αl(II)	Osteoarthrosis
		Chondrodysplasias, including
		Achondrogenesis II
		Hypochondrogenesis
		Spondyloepiphyseal dysplasia
		Spondyloepimetaphyseal dysplasia
		Kneist syndrome
		Wagner syndrome
		Stickler syndrome
Type III	αl(III)	Arterial (familial) aneurysm
		Ehlers–Danlos syndrome type IV
Type IV	α3(IV) α4(IV) α5(IV)	Alport syndrome
	α5(IV) α6(IV)	Alport syndrome(DOL, GL)
Type V	αl(V) α2(V)	Ehlers–Danlos syndrome types I and II
Type VI	αl(VI)α2(VI)α3(VI)	Bethlem myopathy
		Ullrich congenital muscular dystrophy
Type VII	αl(VII)	Dystrophic epidermolysis bullosa
Type VIII	α2(VIII)	Corneal endothelial dystrophy
Type IX	αl(IX) α2(IX) α3(IX)	Multiple epiphyseal dysplasia
		Intervertebral disc disease
		Osteoarthrosis
Type X	αl(X)	Chondrodysplasia
		Schmid metaphyseal chondrodysplasia
Type XI	α(XI)α2(Xl)α3(XI)	Nonsyndromic hearing loss
		Osteoarthrosis
		Chondrodysplasias, including
		Stickler syndrome
		Marshall syndrome
		Otospondylomegaepiphyseal dysplasia
		Weissenbacher–Zweymüller syndrome
Type XV	αl(XV)	Skeletal myopathy (possible)
Type XVII	αl(XVII)	Generalized atrophic benign epidermolysis bullosa
Type XVIII	αl(XVIII)	Knobloch syndrome

[a]Based on Ref. 20.

the metabolism or catabolism of collagen rather than mutations to the collagen genes themselves. Thus, a deficiency in ascorbic acid (vitamin C) reduces the levels of Hyp and Hyl, decreasing collagen stability and leading to scurvy. In other cases, such as the accumulation of excess type III collagen in liver fibrosis, or the decreased collagen content seen in osteoporosis, it results from changes in the balance between collagen production and degradation. Collagen degradation has also been shown to be essential for tumor growth and metastasis. Also, while collagen is normally not immunogenic, antibodies to collagen are common in patients with various diseases, such as anti–type II collagen antibodies associated with rheumatoid arthritis (70).

Isolation and Purification

The extent of purification depends on the final use of the collagen. In most cases, the other components of the ECM, such as proteoglycans and serum proteins, are removed, while if hide or skin is the collagen source the hair will also need removal. Each type of collagenous material has its own characteristic processing steps, with collagens to be used in biomedical applications having the most rigorous processing.

Collagenous Tissues. Intact collagenous tissue is used for products as diverse as leather and bioprosthetic heart valves. Thus in leather production, treatment in an alkaline solution, for example in lime, leads to tissue swelling and assists in removal of proteoglycan components, while addition of sulphide leads to removal of the hair. Prolonged alkali treatment, however, can modify the structure of the collagen, principally through loss of the amide groups from asparagine and glutamine amino acid side chains (71). On the other hand, in the preparation of bioprosthetic heart valves the extent of processing beyond trimming, attaching in a sewing ring and stabilization, usually with glutaraldehyde, is minimal as retention of collagen ultrastructure and proteoglycans may have beneficial effects on the long-term performance of the device (72,73).

Fibrillar Collagen. Fibrillar, particulate collagen is prepared either as a wet paste or a dry powder for various commercial applications. A paste is used, for example, for extrusion in casing production or for fabrication into sponges or similar devices for biomedical applications. A dry powder is used, for example, as a haemostatic agent or is reconstituted into wound dressings. The methods for production of these materials are generally of proprietary nature, but involve comminution of the tissue with possible washing or enzyme treatments to enhance purity (31).

Soluble Collagen. Very little soluble collagen can be extracted from mature tissues because of the extensive cross-linking network that is present; young or embryonic tissues provide the best yields, but these are still low. Previously, the extent of cross-linking was reduced, giving better extraction yields if the animals are made lathyritic, for example by feeding β-aminopropionitrile. For some tissues, such as rat tail tendon, aldimine cross-links are present and these can be broken by dilute acid treatment to give a soluble collagen (50) that retains its telopeptides. While this approach is useful for small-scale laboratory work, a different approach is needed for larger scale or commercial applications. The normal large-scale method is to remove the cross-links by cleaving the telopeptides with a proteolytic enzyme, utilizing the resistance of the tightly wound triple helix to proteolysis (74). The preferred enzyme is the acid protease pepsin, to which the triple helix is particularly stable, where the acidic conditions used for digestion also assist in solubilizing the collagen. Purification, for example to remove enzyme and serum digestion products, can be achieved by precipitation, for example with NaCl (75). Fractionation of different collagen types can be achieved using their differential solubility at different pH values (Table 4) (74,75). As well as NaCl, ethanol, $(NH_4)_2SO_4$, or poly(ethylene glycol) are effective precipitation agents. Although proteolysis gives a soluble product, it is normally not monomeric but rather contains a range of small oligomers as well. The oligomers are less soluble at neutral pH, this in turn providing a way of reducing their presence.

Table 4. Purification of Various Collagens by NaCl Precipitation[a]

[NaCl][b]	Neutral,[c] pH 7.5	Acid,[d] pH 2.5
0.7		I, II, III
1.2		IV, V
1.7	III	
2.4	I	
>4.0	II, V

[b]Concentration (M) of NaCl required for precipitation of a given collagen type.
[c]For example, 50 mM acetic acid.
[d]For example, 1.0 M NaCl, 50 mM Tris.

Recombinant Collagen. The most recent development is the availability of recombinant collagens (76–78). This allows the production of natural human collagens that are highly pure and disease free. A recombinant process can be used to produce all types of collagens. This includes those that are of very low abundance in natural tissue and so not readily obtained in commercially practical quantities by traditional tissue extraction methods. These minor collagens may have, however, unique biological properties that are valuable for particular clinical applications. Recombinant approaches also give opportunities for the production of nonnatural molecules that may have applications as scaffolds in tissue engineering for enhancing adhesion, differentiation, and growth of specific cell types (79). These recombinant molecules could include collagens where specific sites such as the collagenase cleavage site have been deleted or modified, or novel molecules based on multiple copies of a specific functional triple-helical motif, or chimeric molecules that combine a collagen fragment together with another component, such as a growth factor (79).

Low yields of collagen have been obtained from mammalian and insect cell constructs (77). Presently, the best yields have been obtained from constructs in various yeasts such as Pichia and Saccharomyces, although constructs in plants also show promise (80). The initial advantage of the yeast system is that the key enzyme prolyl hydroxylase can be introduced in the construct, leading to stable hydroxylated collagens. This approach can now also be applied in plants (81). Although plants contain an endogenous prolyl hydroxylase, it is not active in the initial constructs. Recombinant collagens can also be produced in the milk of transgenic animals where endogenous P4H is active (82). Whichever system is used for production of recombinant collagen, the same approaches that have been successfully used for purification of soluble collagens will equally apply to the new material.

Analytical and Test Methods

Quantitation. Various standard protein analytical methods can be used for quantitation of collagen. These include determination of the total nitrogen content by Kjeldahl analysis, followed by estimation of the collagen concentration

using a conversion factor based on the known structure of collagens. This factor is dependent on the collagen type and the species of origin. However, if the sample is not pure then this method can give erroneous values because of noncollagenous nitrogen content. For fully soluble preparations with concentrations above about 2–3 mg/mL, a Biuret assay is a simple and rapid method for determining collagen concentration, although noncollagenous impurities can again give incorrect values. Amino acid analysis, however, is not as susceptible to contamination by other proteins, since this can be used to determine Hyp, which is characteristic of collagens. The amount of Tyr present can show the extent to which the telopeptides have been removed from interstitial collagens, as this amino acid is generally found only in these regions (65). However, type III collagen does contain a low level of Tyr within the helical domain. Hyp can also be determined by a specific colorimetric assay (83). Various spectroscopic techniques are also applicable for quantitation of collagen solutions. These include ORD, or CD, where determination of ellipticity allows one to determine the concentration.

Purity. A range of methods is available to assess the purity of soluble collagen preparations, but techniques to study insoluble material are limited. Determination of the refractive index of collagen dispersions using the Becke test allows an estimate of the extent of other protein impurities to be made (84). Full digestion of soluble or insoluble collagen samples with highly pure bacterial collagenase, which digests only the collagen present, allows the identification of impurities, for example by electrophoresis (see below). IR spectroscopy, which can be used to show collagen identity, also has potential for assessing the extent of denaturation in a collagen preparation as any gelatin present changes the relative intensity of the bands at 1660 and 1633 cm^{-1} (85).

Electrophoresis. Electrophoresis provides a rapid and cost-effective method for characterizing the composition and assessing the purity of soluble collagens, with various methods being available. In SDS-PAGE (86) the molecular weight distribution of individual chain components after denaturation is shown. The single-chain components, the α-chains, are the fastest moving components from intact collagens. Any significant bands moving faster than the α-chains indicate impurities or degradation products. Cross-linked chain components, for example the dimer β- and trimer γ-chains, move more slowly on the gel. Separation of $\alpha 1$(I) and $\alpha 1$(III) chains may be achieved by reduction with 2-mercaptoethanol during interrupted electrophoresis (87). SDS-PAGE is also useful for characterization of collagens by analysis of the fragments that are formed by CNBr cleavage, where the different location of Met residues in the chains leads to characteristic patterns (74). Electrophoresis can also be performed under nondenaturing conditions at acid pH, where highly porous gels allow the larger collagen molecules to migrate (88). This system does not, however, separate, the individual interstitial collagens. The stains that are used to detect collagen in each of the electrophoretic methods are not collagen-specific but stain all proteins, allowing any protein contaminants to be detected. The use of isoelectric focusing to determine collagen pI is difficult because of the poor solubility of collagen at low ionic strength at certain pH conditions. However, observation of the direction of electrophoretic mobility in native gels at different pH values can provide an indication of its net charge at a given pH. Methods for examination of collagens by capillary electrophoresis have also been described (89).

Chromatography. Gel permeation chromatography can be used to examine the heterogeneity of soluble collagen preparations (see CHROMATOGRAPHY, SEC). Large-scale, low pressure columns allow fractionation of larger quantities of material but do not have particularly good resolution. Analytical, high pressure columns, packed for example with silica-based resins, provide much better resolution, especially when used in tandem, and allow resolution of monomer through pentamer forms of collagen (90). Ion-exchange chromatography has traditionally been used for examining the chain composition of an individual collagen (74). The collagen is denatured into individual chains, either using urea or elevated temperature, and separated using, for example, a cation-exchange cellulose (eg CM-52) at pH 4.8 with elution by (and an increasing linear gradient of) NaCl. This procedure separates individual α-chains, for example from type I collagen, and also resolves various β-components. Individual chains separated by this method are then available for further detail characterization, for example by examining CNBr fragments.

Thermal Stability. Various methods have been described for determining the thermal stability of collagens, where the change in a parameter is followed with increasing temperature. These include spectral methods, such as UV spectroscopy, ORD, CD, and susceptibility to enzyme digestion, and calorimetric methods, such as differential scanning calorimetry (DSC); degraded samples will show a decrease in thermal stability. Variation in melting temperature is seen for collagens from different species, the values approximating to the upper environmental temperature experienced by an organism (18). For a given species, the different collagen types may vary in stability, with, type III collagen, for example, being more stable than type I collagen.

Immunological Methods. The availability of antibodies, particularly monoclonal antibodies that are specific for particular collagen types, or collagen chains, or even for a particular collagen type from a given species, provides a wide range of probes for collagen identification and quantitation (60–62,91). Identification can be achieved by electroblotting from gels or by slot/dot blotting of samples. If monoclonal antibodies are used, then a native gel system may be required since these antibodies are often conformation-dependent and do not work with blots from denaturing SDS-gels (88). Identification and quantitation can be achieved by a variety of ELISA-based methods. Immunohistology provides a method, by using monoclonal antibodies, of distinguishing the distributions of different collagen types in different tissues (63).

Economic Aspects and Uses

Collagen is of major economic importance. For example, it is the key component in leather production, where around 5.5 million tons of raw bovine hides on a wet salted basis are converted into various forms of leather annually. In addition, a further 600,000 t of dry sheep and goat skins are processed to leather. Leather production in turn supports a range of further manufacturing activities, including upholstery, footwear, and fashion activities. Collagen is also the raw material for gelatin production, which is worth more than US$ 1.5 billion per year, and which is a key component for many further products in, for example, the food, confectionary,

Table 5. Examples of the Use of Collagen Materials and Devices in Medical Applications

Medical area	Application
Cardiovascular surgery	Vessel replacement, heart valves
Dentistry	Periodontal attachment, alveolar ridge augmentation
Dermatology	Tissue augmentation
Dressings	Burn dressings, graft site repair, ulcer treatment
General surgery	Hernia repair, adhesion barriers, haemostats, adhesives
Neurosurgery	Nerve conduits, nerve repair, dura mater replacement
Oesophageal surgery	Augmentation
Ophthalmology	Corneal graft, vitreous replacement, retinal reattachment
Orthopaedics	Bone repair, cartilage reconstruction, ligament repair
Otology	Tympanic membrane replacement
Urology	Ureter replacement, renal repair, urinary incontinence

photographic, pharmaceutical and medical industries (see GELATIN). Collagen is also significant in biomedical applications (see below). For example, the market for bioprosthetic heart valves is worth more than US$ 100 million, while the collagen aesthetics market exceeds $50 million per year. Beyond these examples, collagen is used in a diverse range of products, including manufactured casing for the food industry, sporting and surgical gut, and cosmetics, each of which provides significant additional world markets.

Biomedical Uses. Collagen is now an important material in biomedical device applications (Table 5) and has been used successfully in a wide variety of clinical applications (31). These include areas where collagen products have been used regularly as materials of choice for specific indications for over 30 years. Two principal approaches for collagen processing are used. In one, the devices are tissue-based, where the defined shape of the tissue is retained as part of the function of the device. An important example is the bioprosthetic heart valve. In these devices, chemical fixation, typically with glutaraldehyde (92), is used to give strength and durability to the device. This processing also masks the immunogenicity of the tissue, although some sites for cell–matrix interactions may be lost. The principal drawback to this approach is the tendency for these materials to show nonspecific calcification that can impair the long-term function of the device. Various approaches have been examined to minimize or eliminate this calcification, but without full success.

The other approach is to use purified collagen. When pepsin-solubilized collagen is used, it can be purified to remove potential immunogenic contaminants (74). If required, soluble collagen can be reformed into fibrils, for example by warming a neutral-pH solution. Alternatively, comminuted collagen can be used where impurities can be removed by washing or mild proteolysis. Purified collagen can be reconstituted into the desired shape or form for the product. If necessary, the product can then be stabilized, either by a chemical fixation method such as mild glutaraldehyde treatment, or by a physical method such as dehydrothermal cross-linking. Examples include the formation of dry, stabilized collagen sheets for wound dressings, or preparation of collagen paste for soft tissue augmentation. Reconstituted products are characterized by a high biochemical purity associated

with low immunogenicity, controlled turnover (often over short time periods), controlled porosity, and retention of cell-matrix interactions that are important in biological functions in tissues. In the future, the availability of soluble recombinant collagen will lead to a further increase in medical use of collagen (77).

Although glutaraldehyde has become the predominant reagent used for stabilizing collagen products (92–94), it is seen to have certain limitations. These include its potential cytotoxicity (95), and, most importantly, its propensity to lead to unwanted calcification, particularly in bioprosthetic heart valves (96). This has led to a range of variations in the methods used, including incorporation of a range of auxiliary treatments (92–94). A range of alternative stabilizing reagents has been examined. These include other bis-aldehydes, bis-epoxides, bis-isocyanates, and bis-imidates in conjunction with simple aliphatic scaffolds, or alternative scaffolds including polyethylene oxide constructs (97). In these cases, the reagent leaves the scaffold joining the collagen molecules. Other approaches have been examined that do not introduce material into the product. In chemical approaches, such as the use of carbodiimides or acyl azides, peptide bonds are formed between the side chains of lysine and adjacent aspartic or glutamic acid residues (92). In physical methods, such as dye-mediated photooxidation (98), the mechanism is less clear. The alternative glutaraldehyde strategies and other physical and chemical methods give opportunities to produce products with a wide range of physical and biological properties (92–94).

Immunology. A fundamental issue that applies to all collagen biomedical products is the potential for an adverse immunological response to the foreign animal material. The use of recombinant human collagen has the potential to eliminate adverse responses due to the collagen, but introduces the possibility of a response to any residual material from the host organism. Collagen biomedical products are made predominantly from type I collagen, usually from bovine hides, although other collagens, such as type III collagen, may also be present in small amounts (31). The immunological responses that have been observed depend on the host species, and the form of the collagen. Thus, if the collagen still has intact telopeptides an immunodominant response is more likely, and may reflect the structural mobility of this region and the presence of tyrosine residues (69).

A large number of humans have now received soluble bovine atelocollagen implants. About 1.5% of potential patients react positively to a skin test and so are precluded from treatment (99). In these instances there is a high degree of correlation between a positive skin test and the presence of circulating anti-bovine-collagen antibodies (100). A further 1.5% of patients show a reaction after treatment. Studies on sera from these patients indicates there is no clear, single immunodominant region on the collagen molecule (101). Indeed, given the importance of the triple-helical domains in collagens, it is surprising that there are only limited reports on the nature of the epitopes being recognized. For polyclonal human sera, multiple bands have been detected after electrophoresis, although there appear to be distinct immunodominant "hotspots," particularly in α1(I)-CB6 and α2(I)-CB4 fragments (101). In mice, using a library of monoclonal antibodies to collagen type III, a clearer picture has emerged (61), showing a spread of conformational determinants along the full length of the helix.

In mice, the immunogenic determinants in collagens interact with a complex system of different types of T cells, B cells, and antigen-presenting cells, and

the nature of this response is classically T-cell-dependent (102). Identification of immune response gene(s) located in the IA or IB subregion of the major histocompatibility (H-2) locus also support a T-cell-dependent immune response to collagen in mice. The nature of the immune response gene control in humans for collagen priming and immune response is less clear.

In addition to a humoral or antibody response, collagens can also induce a cell-mediated immune response. Both native and denatured collagen can induce cellular responses in guinea pigs presensitized with only native collagen type I (103). Conversely, sensitization with denatured collagen also led to positive skin tests after challenge with native collagen (104). Clearly, the antigenic determinants involved in the cellular-type responses are different to those described for the humoral response to collagens. When collagen is used as a medical implant for soft tissue augmentation, it is this cellular type of "adverse" response that is detected in patients, and which is sometimes associated with antibody responses and extrapolated to autoimmune-type responses (69).

Health and Safety Issues

The successful use of numerous collagen products over millennia, such as leather, gelatin, and catgut sutures indicates that it is a safe material. More recently, the successful use of collagen in a wide variety of medical applications has again confirmed its general safety as a material (31). In these applications, the principal areas of risk are adverse immunological responses, either from collagen or more likely from contaminating proteins, and the possible transmission of infective organisms. Of concern is the risk of prion transmission from bovine products (bovine spongiform encephalopathy), although there is no evidence that this has occurred. On the other hand, the transmission of Creutzfeld–Jacob disease from allogenic transplants has been observed, for example via corneal transplants and from dura mater grafts.

Although collagen is regarded as a generally safe material, possible hazards can arise from the processing steps, both to workers and to the environment. For example, a range of aggressive preservatives has on occasion been used with hides and skins, and the lime and sulphide traditionally used in hide processing represent risks. In addition, agents used for stabilization, such as chromium in the tanning industry or glutaraldehyde in the biomedical industry, are potentially toxic.

COMBINATORIAL METHODS FOR POLYMER SCIENCE

Introduction

Fundamental research of the synthesis and characterization of polymeric materials is driven by their use in applications including structural materials, packaging, microelectronics, coatings, biomedical materials, and nanotechnology. Current trends demand finer control of chemistry, morphology, and surface topography at the micrometer and nanometer scales. To achieve these goals, there are increasing needs for the synthesis and processing of multicomponent mixtures, composites, and thin films. However, these systems are inherently complex due to the interactions of phase transitions, microstructure, interfaces, and transport behavior that occur during synthesis and processing. The synthesis of polymers by emulsion polymerization, for example, involves colloid chemistry, micellization, transport between phases, and complex rate relationships. In the case of coatings and thin films, the mechanical and optical properties, microstructure, and phase and wetting behavior are sensitive and poorly understood functions of thickness. In addition to the complex phenomena involved in polymer synthesis and processing, there is a large variable space involving parameters whose effects often counteract one another. These include reactant composition and structure, synthetic sequence, solvent, temperature, annealing history, pressure, and thickness (eg, in films). Conventional microscopy, spectroscopy, and analytical tools for polymer synthesis and characterization were designed for one-sample-one-measurement utilization, and are suited for detailed characterization over a limited set of variable combinations. This conventional approach is preferred when the most relevant variable combinations are known a priori or can be reliably predicted from theory. However, the complex phenomena and large variable spaces present in

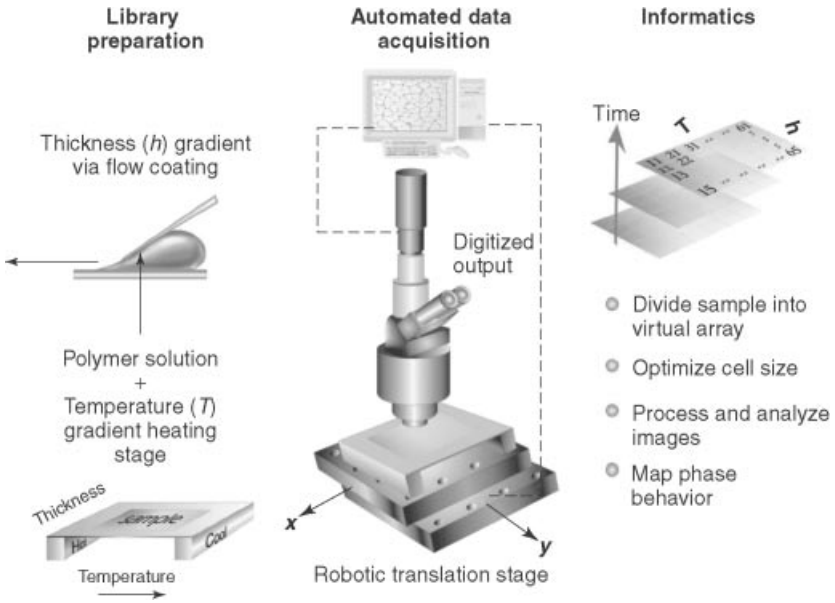

Fig. 1. Schematic of the combinatorial experimental method, as applied to the preparation of thickness and temperature gradient film libraries, high throughput screening with optical microscopy, and informatic analysis of image data as a function of temperature, thickness, and time. Adapted with permission from Ref. 22.

multicomponent, multiphase, bioactive or thin-film polymers often exceed the capabilities of current theory and conventional measurements. Therefore, a strong need exists for experimental techniques capable of highly efficient synthesis and characterization of complex polymeric systems over large numbers of variable combinations.

Combinatorial methods (CM) use experimental design, library creation, high throughput screening, and informatics to efficiently and rapidly develop new materials and measure properties over large numbers of variable combinations (Fig. 1). This is accomplished by preparing samples not one at a time, but rather as sample "libraries" containing hundreds to thousands of variable combinations each. High throughput measurements of relevant chemical and physical properties, combined with informatic data analysis, allow efficient development of structure–processing–property relationships. The benefits include efficient characterization of novel regimes of thermodynamic and kinetic behavior (knowledge discovery) and accelerated development of functional materials (materials synthesis and discovery). Although historically applied to pharmaceutical research, there is an increasing interest in applying CM to materials science, as indicated by recent reports of combinatorial methodologies for a wide range of inorganic (1–8) and organic/polymeric materials (7,9–24).

Early combinatorial *materials* research used sputtering methods to prepare composition gradient libraries for measuring the phase behavior of ternary metal alloys (20) and other inorganic materials (25). However, limitations in computing capacity and instrument automation overshadowed the benefits of combinatorial

materials' characterization until only recently. The primary limitation to *characterizing* polymers, as bulk material or films, with CM has been a shortage of techniques for preparing libraries with systematically varied composition (ϕ), morphology, physical form, thickness (h), and temperature (T). This article is a review of recent advances in applying CM to polymer synthesis and characterization. Applications of CM to the synthesis of a wide range of polymeric materials, including sensors, dendrimers, and biodegradable polymer are presented. Several novel methods developed for the preparation of T, ϕ, h, and surface energy continuous polymer film libraries are discussed. There is particular focus on the novel library preparation and high throughput screening steps, since these have been the principal limiting factors in CM development for polymers. The use of continuous gradient libraries in the measurement of fundamental properties is described for polymer blend phase behavior, block copolymer segregation, and dewetting transitions.

Combinatorial Polymer Synthesis

Despite the recent increase in combinatorial inorganic materials research (2–7,14,15), there are still relatively few studies reporting CM for the synthesis of polymeric materials. One example is the work of Brocchini and co-workers (10,11), where a 112-member combinatorial library of biodegradable polyarylates was prepared by copolymerizing all possible combinations of 14 tyrosine-based diphenols and 8 diacids. The pendant chain and backbone structures were systematically varied by the addition of methylene groups, substitution of oxygen for the methylene, and addition of branched or aromatic structures. The library products displayed diverse properties, as indicated by measurements of the glass-transition temperature T_g, air–water-contact angle (θ_w), and fibroblast proliferation during cell culture. Fibroblast proliferation was found to decrease with increased hydrophobicity except for the main-chain oxygen containing polymers that served as uniformly good growth substrates regardless of the hydrophobicity.

The results of the above study were utilized (13) to test informatic methods for designing *diverse* and *focused* combinatorial libraries. Molecular topology and genetic-algorithm-optimized quantitative structure–property relationships were used to design libraries. These techniques allowed selection of a representative subset of library members for rapid study of the entire library (a diverse subset) or concentration on a specific property of interest (a focused subset). Each monomer pair of the 112-member library was represented by a 2-D topological descriptor, used by the algorithm to select a structurally diverse and representative subset of the library. This subset was utilized to create models for the T_g and θ_w, which were tested by comparing to the T_g and θ_w of the entire library. Focused libraries of polymer structures predicted to meet certain T_g and θ_w specifications were also designed. Good agreement was reported between the calculated and experimental T_g and θ_w values, even for polymers not included in the subset library. Additionally, the focused libraries were shown to be effective in identifying polymer structures within specific T_g and θ_w ranges.

Gravert and co-workers (9) used parallel synthesis to design polymeric supports for liquid-phase organic synthesis. In this work, three polymerization

initiators containing α-nitrile diazene cores were utilized for block copolymer synthesis, while a functionalized methacrylate initiator was used to produce graft copolymers. Five vinyl monomers were used in combination with the initiators to produce approximately 50 block and graft copolymers. Copolymer products were characterized by size exclusion chromatography, nuclear magnetic resonance, and solubility in a range of solvents. Based upon this characterization, a 4-*tert*-butylstyrene-*b*-3,4-dimethoxystyrene block copolymer was selected and used successfully as a support in subsequent liquid-phase syntheses.

Takeuchi and co-workers (18) coupled combinatorial techniques with molecular imprinted polymers to develop sensors for triazine herbicides. The library consisted of a 7×7 array containing different fractions of monomers methacrylic acid (MAA) and 2-(trifluoromethyl)acrylic acid (TFMAA) with constant concentrations of the imprint molecules ametryn or atrazine. After UV-initiated polymerization, the products from the sensor library were characterized by HPLC measurement of herbicide concentration. The receptor efficiency was observed to vary with monomer type: the atrazine receptor efficiency increased with MAA composition and the ametryn receptor was enhanced by increased fractions of TFMAA. Although only monomer concentration was varied in the libraries, the authors conclude that the CM synthetic approach would be useful in analyzing other variables such as solvent, cross-linking agent, and polymerization conditions to produce optimum molecularly imprinted polymer sensors.

Dickinson and co-workers (12) reported CM synthesis of a sensor library consisting of solvatochromic dyes dissolved in polymer. Permeation of the polymer by volatile solvents induced changes in the dye's solvation environment, which were detectable by the fluorescence signal. A combination of methyl methacrylate and dimethyl(acryloxypropyl) methylsiloxane monomers was used to create two sensor libraries. A discrete library was prepared by photo-polymerizing constant concentration solutions of the dye and monomers to produce cones of polymer at different locations on the end of a fiber-optic bundle. A second, continuous library was created by adding methyl methacrylate to the copolymer monomer as UV light was scanned across the fiber-optic bundle, producing a copolymer concentration gradient across the bundle end. Both the discrete and the continuous libraries were characterized by monitoring the fluorescence response (via the fiber-optic cables) as a function of exposure to saturated organic vapors. The deposition of the library directly onto the measurement probe (fiber optic) makes this work a good example of a combined CM polymer synthesis and characterization. For the particular dye and monomer used, the fluorescence response was found to be a nonlinear function of the concentration.

Newkome and co-workers (26) report, a combinatorial strategy for synthesizing dendrimers with modified structure and surface chemistry. Mixtures of three branched isocyanate-based monomers, mixed over a wide range of compositions, were used to synthesize a combinatorial library of dendritic molecules. Based upon ^{13}C NMR spectra, the dendrimer products displayed varying degrees of peripheral heterogeneity, adjustable by controlling the ratios of the three isocyanate monomer groups. The methodology provides for the rapid modification of dendritic properties based upon the chemistry and distribution of peripheral surface groups; for example, some of the dendrimers were amphiphilic, displaying solubility in CH_3OH, H_2O, and $CHCl_3$. The degree of amphiphilicity can be

adjusted to favor solubilization in one of the solvents by varying the proportion of amino vs benzyl ether surface moieties, based upon the ratio of monomer building blocks.

Combinatorial Polymer Characterization

The previous section focused on CM studies in which the production or synthesis of new polymeric materials was the primary goal. In those examples the synthesis steps were combinatorial, but subsequent characterization steps were noncombinatorial. One exception is the fluorescent sensor libraries prepared on fiber-optic bundles, discussed above (12). In this section we describe library preparation and high throughput screening methods for the combinatorial *characterization* of both thick ($\approx$1 to $\approx$50 μm) and thin ($<$1 μm) polymer films and coatings. Here, the primary goal is not to produce new materials, but rather to use CM to measure relevant phase behavior, wetting, and microstructural properties over a large range of parameter combinations. The variables of primary importance in characterizing the physical and chemical properties of polymers in the bulk and film state include the composition in multicomponent mixtures and composites, thickness, temperature (eg, annealing, curing, melt processing), and substrate energy (γ_{so}).

While preparing polymer films and coatings libraries with variations in ϕ, h, T, and γ_{so}, we found that the deposition of films with continuous gradients in each of these properties is a convenient and practical alternative to the deposition of libraries containing discrete regimes. Of course the introduction of chemical, thickness, and thermal gradients drives nonequilibrium transport processes that will eliminate the gradients over time. The timescale and lengthscale over which gradient library measurements are valid are determined in part by the magnitude of these transport fluxes. In most cases high molecular mass ($M_w > 10{,}000$ g/mol) polymers have relatively low transport coefficients, eg, diffusivity and viscosity. (According to ISO 31–8, the term "molecular weight" has been replaced by "relative molecular mass," symbol "Mr". The conventional notation, rather than the ISO notation, has been employed for this publication.) Thus the mass transport and flow lengthscale and timescale are often orders of magnitude lower than those of the measurements, allowing properties to be measured near equilibrium.

Preparation of Polymer Coating and Thin-Film Libraries.

Thickness Gradient Libraries. A velocity-gradient knife coater (21–24), depicted in Figure 1, was developed to prepare coatings and thin films containing continuous thickness gradients. A 50-μL drop of polymer solution (mass fraction 2–5%) was placed under a knife-edge with a stainless steel blade width of 2.5 cm, positioned at a height of 300 μm and at a 5° angle with respect to the substrate. A computer-controlled motion stage (Parker Daedal) moves the substrate under the knife-edge at a constant acceleration, usually 0.5–1 mm/s^2. This causes the substrate coating velocity to gradually increase from 0 to a maximum value of 5–10 mm/s. The increase in fluid volume passing under the knife-edge with increasing substrate velocity results in films with controllable thickness gradients. Figure 2 shows h-gradients for polystyrene (PS) and blends of polystyrene/poly(vinylmethylether) (PS/PVME) films on Si substrates as a function of solution composition. Thin-film-thickness-dependent phenomena can

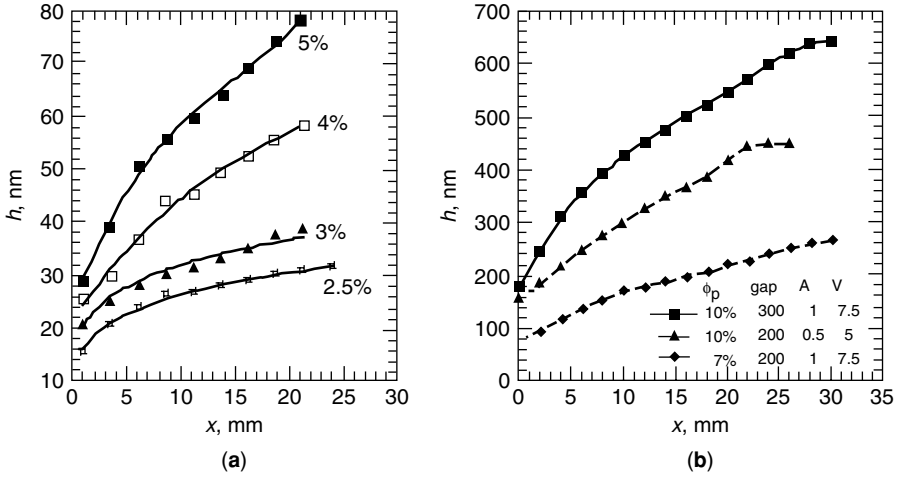

Fig. 2. (**a**) Thickness, h (nm) vs distance x (mm) for various h-gradient film libraries composed of (M_w = 1800 g/mol) on Si as a function of mass fraction PS in the toluene coating solution. (**b**) h (nm) vs x (mm) for h-gradient libraries of mass fraction 20% PS (M_w = 96,400 g/mol)/80% PVME (M_w = 119,000 g/mol) blends on Si as a function of mass fraction polymer composition in the toluene coating solution, blade substrate gap (μm), acceleration A (mm/s^2), and velocity (mm/s). Standard uncertainty in thickness is $\pm$3 nm. Figure 2a adapted with permission from Ref. 22.

be investigated from nanometers to micrometers employing several h-gradient films with overlapping gradient ranges. One can verify that the relatively weak thickness and temperature gradients do not induce appreciable flow in the polymer film over the experimental time scale (21,22). A unidirectional Navier–Stokes model for flow over a flat plate estimates lateral flow at a characteristic velocity of 1μm/h at $T = 135^\circ$C, in response to gravitational action on the thickness gradient (27). This small flow is orders of magnitude slower than the flow induced by the physical phenomena that these libraries are designed to investigate, such as dewetting (22) and phase separation (21). To check for flow, we examined thickness-gradient libraries before and after annealing at $T > T_g$, for a PS film (M_w = 1800) on Si/SiO$_x$ (22). The difference of thickness gradients across the 2 cm $\times$ 3 cm library area before and after annealing was within a standard uncertainty of $\pm$1.5 nm (22).

Composition Gradient Libraries. Three steps are involved in preparing composition gradient films: gradient mixing (Fig. 3a), gradient deposition (Fig. 3b), and film spreading (Fig. 3c). Gradient mixing utilizes two syringe pumps (Harvard PHD2000) that introduce and withdraw polymer solutions (of mass fraction $x_A = x_B$ = 0.05–0.10) to and from a small mixing vial at rates I and W, respectively. (Certain equipment and instruments or materials are identified in the article in order to adequately specify the experimental details. Such identification does not imply recommendation by the National Institute of Standards and Technology, nor does it imply the materials are necessarily the best available for the purpose.) Pump W was used to load the vial with an initial mass M_0 of solution B of $M_0 \approx 1$ g. The infusion and withdrawal syringe pumps were started simultaneously under

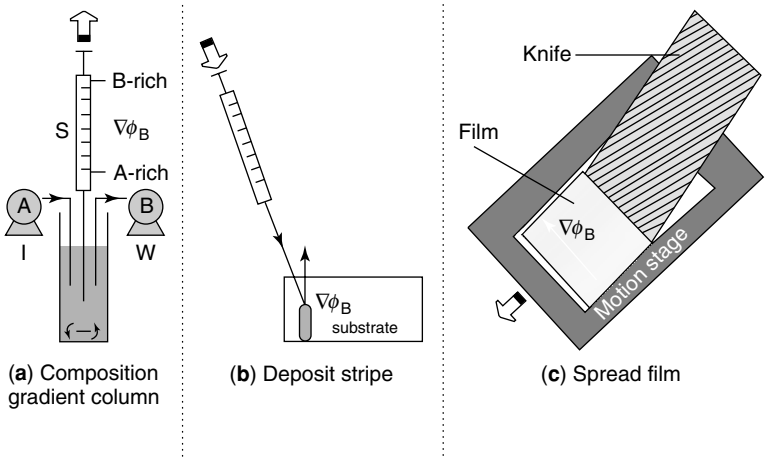

Fig. 3. Schematic of the composition gradient deposition process involving (**a**) gradient mixing, (**b**) deposition of stripe, and (**c**) film spreading. Adapted with permission from Ref. 21.

vigorous stirring of the vial solution, and a third syringe, S, was used to manually extract $\approx$50 μL of solution from the vial into the syringe needle at the rate of $S = 30$–50 μL/min. At the end of the sampling process, the sample syringe contained a solution of polymers A and B with a gradient in composition ∇x_A along the length of the syringe needle. The relative rates of I and W were used to control the steepness of the composition gradient, eg, dx_A/dt. The sample time, t_s, determines the endpoint composition of the gradient. The gradient produced by a particular combination of I, W, S, M_0, and t_s values was modeled by a mass balance of the transient mixing process, given elsewhere (21). This balance predicts that the composition gradient will be linear only if $I = (W + S)/2$, a prediction supported by FTIR measurements of composition. An 18-gauge needle long enough to contain the sample volume ensured that the gradient solution did not enter the syringe itself. This prevented turbulent mixing that might occur upon expansion of the solution from the needle into the larger diameter syringe.

Under the influence of the gradient in the syringe needle, ∇x_A, molecular diffusion will homogenize the composition. However, the timescale for molecular diffusion is many orders of magnitude larger than the sampling time. For example, consider gradient solutions of PS ($M_w = 96.4$ kg/mol, $M_w/M_n = 1.01$, Tosoh Inc.) and PVME ($M_w = 119$ kg/mol, $M_w/M_n = 2.5$) in toluene, a system used to characterize the ϕ-gradient deposition procedure (21,28). For a typical ϕ-gradient with $\Delta\phi \approx 0.025$ mm^{-1}, ϕ_{PS} and ϕ_{PVME} change negligibly by 0.004 and 0.001% in the 5-min period required for film deposition (21). [The diffusive flow rate of PS and PVME were calculated as $J = L\pi r^2 D_i \rho (d\phi_i/dx)_{max}$, where ρ is the solution density, $r = 2.3$ mm is the syringe diameter, and $L = 4.2$ mm is the length of the fluid column in the syringe. We estimate $\Delta\phi_i$ as $(Jt)/(x_p L\pi r^2\ \rho)$, where $x_p = 0.08$ is the total polymer mass fraction in solution.] Fluid flow in the sample syringe remains in the laminar regime, preventing turbulence and convective mixing, discussed elsewhere (21).

The next library preparation step (Fig. 3b) is to deposit the gradient solution from the sample syringe as a thin stripe, usually 1–2-mm wide, on the substrate. This gradient stripe was spread as a film (Fig. 3c) orthogonal to the composition gradient, using the knife-edge coater described above. After a few seconds most of the solvent evaporated, leaving behind a thin film with a gradient of polymer composition. The remaining solvent was removed under vacuum during annealing, described in the next section (T-gradient annealing). Because polymer melt diffusion coefficients D are typically of order 10^{-12} cm^2/s, diffusion in the cast film can be neglected if the lengthscale resolved in measurements is significantly larger than the diffusion length $\sqrt{Dt}$.

Composition gradient films of blends of PS/PVME and poly(D,L-lactide) (PDLA, Alkermes, Medisorb 100DL, M_w = 127,000 g/mol, M_w/M_n = 1.56)/ poly(ε-caprolactone) (PCL, Aldrich, M_w = 114,000 g/mol, M_w/M_n = 1.43) were used to test the ϕ-gradient procedure. FTIR spectra were measured with a Nicolet Magna 550 and were averaged 128 times at 4 cm^{-1} resolution. The beam diameter, 500 μm (approximate), was significantly larger than the diffusion length of 3 μm (approximate) for the experimental timescale. Films 0.3–1 μm thick were coated on a sapphire substrate and a translation stage was used to obtain spectra at various positions on the continuous ϕ-gradient.

Figure 4a shows typical FTIR spectra for a ϕ-gradient film of PS/PVME. As position is scanned along the film, a monotonic increase in PVME absorbances,

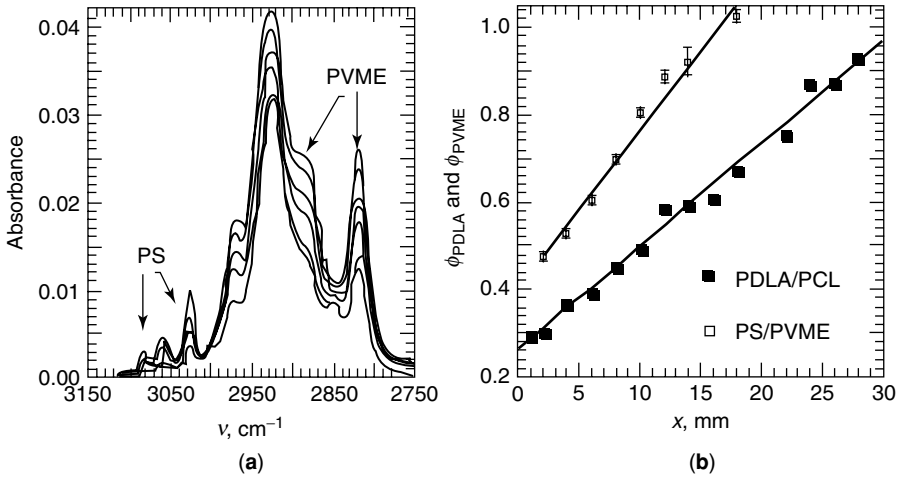

Fig. 4. (**a**) FTIR spectra at X = 2,4,8,10,14,18 mm positions along a ϕ-gradient PS/PVME library, as described in the text. PS absorptions decrease while PVME absorptions increase, monotonically, as one samples spectra across the film (increasing X (mm)). (**b**) Mass fractions ϕ_{PVME} and ϕ_{PCL} vs position x (mm) for typical PCL/PDLA and PS/PVME ϕ-gradient libraries. Composition of PS/PVME blends is calculated by calibration of the ν = 2820 cm^{-1} PVME absorption. Composition in PDLA/PCL blends is calculated by the methodology described in the text. Coating parameters were PS/PVME (I = 0.51 mL/min, W = 1.0 mL/min, S = 20 μL/min, M_0 = 1.57 mL, sample time = 94 s) and PDLA/PCL (I = 0.76 mL/min, W = 1.5 mL/min, S = 26 μL/min, M_0 = 1.5 mL, sample time = 95 s) Unless otherwise indicated by error bars, standard uncertainty is represented by the symbol size. Figure 4b adapted with permission from Ref. 21.

and a corresponding decrease in PS absorbances is observed. For the PS/PVME blend, compositions were measured based upon a direct calibration of the $\nu = 2820\ \text{cm}^{-1}$ peak by using known mixtures, yielding $\varepsilon(2820\ \text{cm}^{-1}) = (226 \pm 3)$[$\varepsilon = A/hc$, where A is the absorbance for this peak, h is the film thickness measured in micrometers, and c is the molar density of PVME in moles per liter.] For PDLA/PCL system, $\varepsilon(\nu)$ values for pure PDLA and PCL were determined over the C—H stretch regime of 2700–3100 cm^{-1}, based upon $\varepsilon_i(\nu) = A_i(\nu)/(ch)$, where A_i is the absorbance for each peak. Unknown PDLA/PCL mass fractions were determined to be within a standard uncertainty of 4% by assuming the observed spectra were linear combinations of pure PDLA and PCL spectra, eg, $A_{\text{mix}} = h(\alpha\varepsilon_{\text{PDLA}}c_{\text{PDLA}} + (1-\alpha)\varepsilon_{\text{PCL}}c_{\text{PCL}})$ and α is related to the mass fraction PDLA. Figure 4b shows typical composition gradients for PDLA/PCL blends coated from $CHCl_3$ and PS/PVME blends coated from toluene. Essentially linear gradients were obtained and the endpoints and slope agree with those predicted from mass balance (21). It is possible to create gradient films with wider composition ranges than those shown in Figure 5, by sampling the mixing vial for longer times (Fig. 4a).

Temperature Gradient Libraries. To explore a large T range, h- or ϕ-gradient films are annealed on a T-gradient heating stage, with the T-gradient *orthogonal* to the h- or ϕ-gradient. This custom aluminum T-gradient stage, shown in Figure 1, uses a heat source and a heat sink to produce a linear gradient ranging between adjustable end-point temperatures. End-point temperatures typically range from $(160 \pm 0.5)^\circ$C to $(70.0 \pm 0.2)^\circ$C over 40 mm, but are adjustable within the limits of the heater, cooler, and maximum heat flow through the aluminum

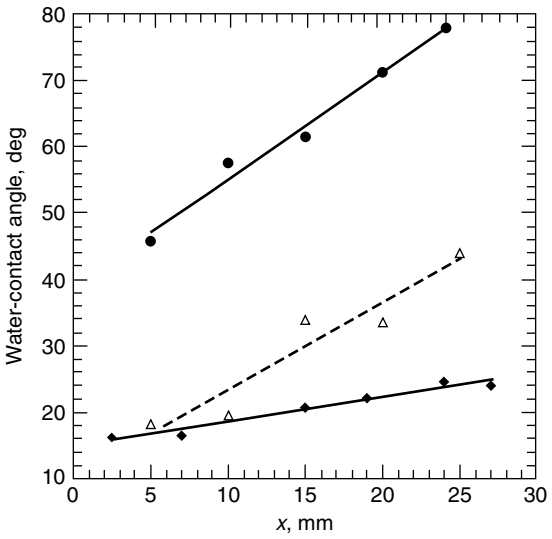

Fig. 5. Deionized water-contact angle vs position (mm) for gradient-etched SiH/Si substrates as a function of both immersion rate and Piranha solution H_2SO_4 composition. Immersion rate and mass fraction H_2SO_4 are as follows: circles, 2.0 mm/s and 30%; triangles, 0.1 mm/s and 30%; diamonds, 2.0 mm/s and 40%. Standard uncertainty in contact angle is $\pm 2^\circ$.

plate. To minimize oxidation and convective heat transfer from the substrate, the stage is sealed with an o-ring, glass plate, and vacuum pump. Each 2-D T–h or T–ϕ parallel library contains about 1800 or 3900 state points, respectively, where a "state point" is defined by the T, h, and ϕ variation over the area of a 200× optical microscope image: $\Delta T = 0.5^{\circ}$C, $\Delta h = 3$ nm, and $\Delta\phi = 0.02$. These libraries allow T, h, and ϕ-dependent phenomena, eg, dewetting, order–disorder, and phase transitions, to be observed *in situ* or postannealing with relevant microscopic and spectroscopic tools.

Surface Energy Gradients. In many polymer coating and thin-film systems, there is considerable interest in studying the film stability, dewetting, and phase behavior on substrates with surface energies varying between hydrophilic and hydrophobic extremes. Therefore, a gradient-etching procedure has been developed in order to produce substrate libraries with surface energy, γ_{s0}, continuously varied from hydrophilic to hydrophobic values (29). The gradient-etching procedure involves immersion of a passivated Si—H/Si substrate (Polishing Corporation of America) into a 80°C Piranha solution (30) at a *constant immersion rate*. The Piranha bath etches the Si—H surface and grows an oxide layer, SiO_x/SiOH, at a rate dependent on T and the volume fraction H_2SO_4 (30). A gradient in the conversion to hydrophilic SiO_x/SiOH results because one end of the wafer is exposed longer to the Piranha solution. After immersion, the wafer is withdrawn rapidly (≈10 mm/s), rinsed with deionized water, and blown dry with N_2. Typical deionized water contact angles are shown in Figure 5. By preparing several gradient substrates covering overlapping ranges of hydrophilicity, it is possible to screen a large range in surface energy, from hydrophilic ($\theta_w \approx 0^{\circ}$) to hydrophobic ($\theta_w \approx 90^{\circ}$) values of the water-contact angle.

In another procedure for varying substrate energy, developed by other authors, mixed self-assembled monolayers (SAMs) of alkanethiolates are deposited with a composition gradient (31). In this procedure, ω-substituted alkanethiolates with different terminal groups, eg, —CH_3 vs —COOH, cross-diffuse from opposite ends of a polysaccharide matrix deposited on top of a gold substrate. Diffusion provides for the formation of a SAM with a concentration gradient between the two thiolate species from one end of the substrate to another, resulting in controllable substrate energy gradients. The polysaccharide matrix is removed after a period of time, halting the diffusion process. These gradient SAM substrates were subsequently used to investigate the effect of surface energy on phase separation of immiscible polymer blends (32).

Uncertainty and Statistical Considerations of Library Measurements. A *potential drawback* of the method is that the polymer libraries are not composed of distinct sample areas, but rather have continuous gradients in ϕ, annealing T, and thicknes h. These gradients induce variance in observed properties, which is not an issue with uniform samples. Many properties measured with combinatorial libraries are obtained from microscope images (optical, fluorescent, AFM, FTIR) or spectroscopy (UV, FTIR). Thus it is important to understand how uncertainties associated with the gradients and the lateral resolution affect properties measured on the libraries. Figure 6 demonstrates how a combinatorial library is divided into a grid of "virtual" measurement sites (eg, microscope images) of lengthscale L. The T and ϕ for each measurement site is taken as the average $\langle T \rangle$ and $\langle \phi \rangle$ over the length L. Because gradients are present on the library, each

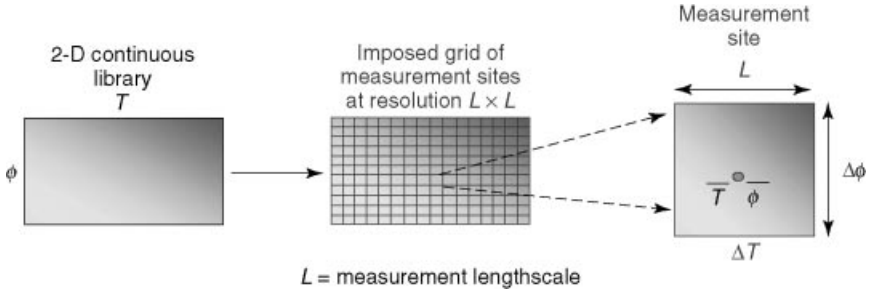

Fig. 6. Distribution of discrete measurement sites of resolution $L \times L$ over a continuous gradient library. Measurement sites have average T and ϕ with gradient variance ΔT and $\Delta\phi$.

measurement site has systematic variances, $\Delta\phi$ and ΔT, that increase as the measurement lengthscale L increases. Hence, lower measurement resolution (lower L) results in lower $\Delta\phi$ and ΔT. A typical 500 μm $\times$ 500 μm image would have reasonable variances of $\Delta\phi = 0.01$ and $\Delta T = 0.3^{\circ}$C. When measuring features within a site, the number of features sampled decreases as L decreases, causing an increase measurement uncertainty.

How to select the optimum measurement scale L, reflecting a balance between counting statistics, $\Delta\phi$ and ΔT?

The effects of these contributions on the variance about the mean of any property $\langle p\rangle$ within a measurement site is accounted for using a standard uncertainty propagation,

$$\Delta\langle p\rangle = (\partial\langle p\rangle/\partial N)\Delta N + (\partial\langle p\rangle/\partial T)\Delta T + (\partial\langle p\rangle/\partial\phi)\Delta\phi \tag{1}$$

Here $\langle p\rangle$ is a function of T, ϕ, and the number of observations made in the measurement site, $N \sim L^2$. It is assumed that the number of features (microstructures, cells, etc) can be counted exactly, so that $\Delta N = 0$. The partial derivatives can be estimated from finite difference approximations of the measured data, eg, $\partial\langle p\rangle/\partial T = [\sum p(T_{i+1},\phi_i) - \sum p(T_i,\phi_i)]/[N(T_{i+1} - T_i)]$. The values of $\Delta\phi$ and ΔT are $\Delta\phi = m_\phi L$ and $\Delta T = m_T L$, where m_T and m_ϕ are the slopes of the linear gradients, known from the library preparation procedure. Making these substitutions shows that the error propagation for property p scales as

$$\Delta\langle p\rangle \sim (m_T + m_\phi)/L \tag{2}$$

Constants have been removed from the above equation in order to reveal only the dependence on gradients and the measurement scale L. Equation 1 demonstrates that the uncertainty of any property measured on the libraries at a given ϕ and T will decrease if the measurement scale L is increased (because more features are counted) and if the magnitude of the gradients are decreased (reducing ϕ and T uncertainty). Thus the following guidelines should be followed during experimental design and data analysis: (*1*) L should be made as large as possible while still being able to resolve features of interest and (*2*) the gradient slopes should then be adjusted to attain an acceptable uncertainty (<1%) in

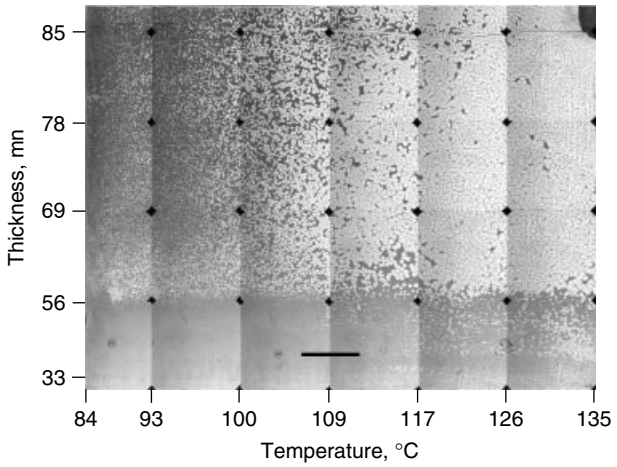

Fig. 7. Composite of optical images of a T–h combinatorial library of PS (M_w = 1800 g/mol) on silicon, $t = 2$ h, 25× magnification. Scale bar = 2.0 ± 0.1 mm. The thickness scale is a power law function (given in text), reflecting the nonlinear thickness gradient deposition procedure. Adapted with permission from Ref. 22.

the measured property. The analysis above considers only uncertainty contributions from the library gradients. Additional sources of uncertainty, arise from the measurements themselves, but these are also present for uniform conventional samples.

Fundamental Property Measurement with Combinatorial Polymer Coating and Film Libraries.

Thin-Film Dewetting. Figure 7 shows a composite of optical microscope images of a T-h library of PS (Goodyear, M_w = 1900 g/mol, M_w/M_n = 1.19) on a SiO_x/SiOH substrate (22). The thickness ranges from 33–90 nm according to $h = 33.1x^{0.30}$ ($1 < x < 28$) mm and 85°C < T < 135°C. The images, taken 2 h after initiation of dewetting, show wetted and dewetted regimes that are visible as dark and bright regions, respectively, to the unaided eye. Repeated examination of combinatorial T-h libraries at thicknesses ranging from 16–90 nm indicates three distinct thickness regimes with different hole nucleation mechanisms. For $h > 55 \pm 4$ nm, discrete circular holes in the film nucleate via heterogeneities (eg, dust) and grow at a rate dependent on T (quantification of the rate is given in Fig. 8).

Below $h \leq 55 \pm 4$ nm, there is a sharp and temperature independent transition to a regime where irregular, asymmetrical holes nucleate and grow more slowly than at $h > 55$ nm. In the regime 33 nm < h < 55 nm, the heterogeneous and capillary instability nucleation mechanisms compete. The asymmetrical holes present in this regime are surrounded by bicontinuous undulations in the film surface, with a characteristic spacing of 7 μm, as indicated by optical microscopy (22). AFM indicates a roughened surface with correlated surface undulations. A similar structure consisting of asymmetrical holes that breakup into a bicontinuous pattern at late stage, termed an "intermediate morphology," has been observed recently for 12-nm-thick films of poly(styrene-*ran*-acrylonitrile) (33). Below

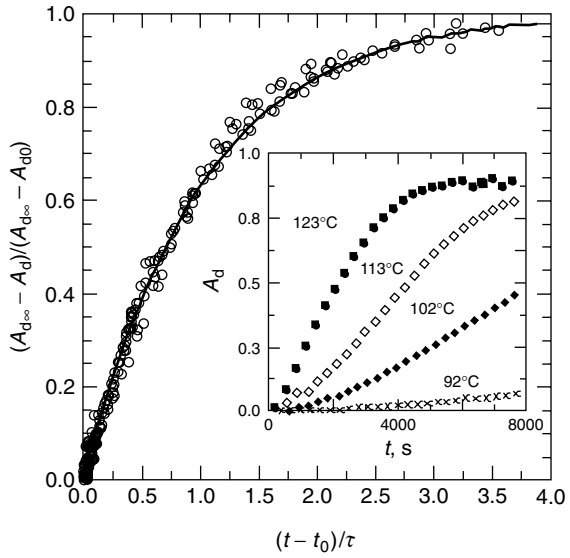

Fig. 8. T–h–t superposition of dewet area fraction data onto a universal curve, 92°C < T < 135°C, 59 nm < h < 86 nm. Inset: raw dewet area fraction vs time, $h = 79$ nm. Adapted with permission from Ref. 22.

$h \approx 33$ nm, another transition in structure and nucleation is apparent. Here, holes are nucleated by capillary instability and grow more quickly than in the region 33 nm < h < 55 nm.

Systematic studies of the temperature dependence of dewetting rates have not been reported to our knowledge. However, through its effect on viscosity, T is expected to have a strong influence on hole drainage rates. By using automated optical microscopy (Fig. 1), a 5 × 5 grid of images covering the T and h range of the library was collected every 5 min for 2 h. Automated image analysis (22) of hole area as a function of T, h, and t assays a broad range of dewetting rates in a single experiment, shown in Figure 8. The inset to Figure 8 shows the raw dewetted area fraction A_d vs t at various temperatures from the T-h library for h = 79 nm. The entire set of A_d vs t profiles for $h > 55$ nm can be fitted with $A_d = A_{d\infty} + (A_{d0} - A_{d\infty}) \exp[-(t - t_0)/\tau]$, where A_{d0} and $A_{d\infty}$ are the dewet fractions at $t = t_0$ and $t = \infty$, τ is the dewetting time constant, and t_0 is a time delay for nucleation. As shown in Figure 8, in reduced units of $(A_{d\infty} - A_d)/(A_{d\infty} - A_{d0})$ vs $(t - t_0)/\tau$, the hole drainage profiles collapse onto the universal exponential curve given above. Figure 8 contains T and h data over a large range 92°C < T < 135°C and 59 nm < h < 86 nm, and τ ranges from 2100 s (high temperatures) to 113,000 s (low temperatures). This T–h superposition for dewetting rates, previously unreported, reflects variations in the film viscosity with T and h, and could be missed altogether by relying solely upon limited numbers of samples.

Phase Behavior. Figure 9 presents a photograph of a typical temperature–composition library of the PS/PVME blend (discussed under Composition Gradient Libraries) after 90 min of annealing. As Figure 9 indicates, the lower critical solution temperature (LCST) cloud point curve can

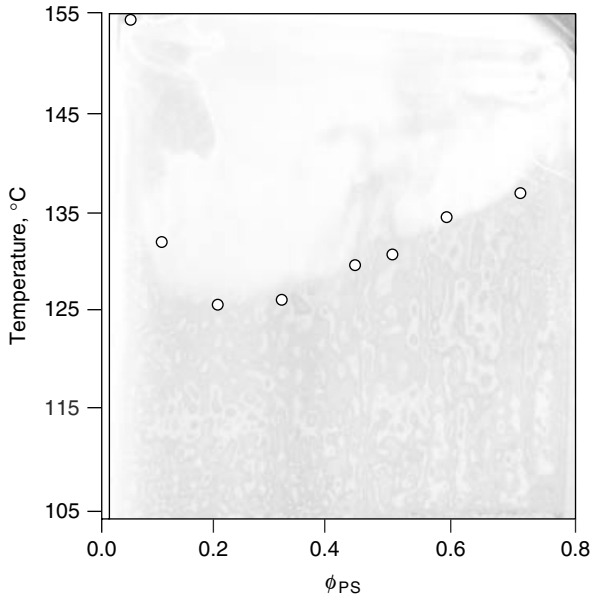

Fig. 9. Digital optical photographs of a PS/PVME T–ϕ library after 90 min of annealing, showing the LCST cloud point curve visible to the unaided eye. The library wafer dimension is 31 mm × 35 mm and the film thickness varies approximately 400–600 nm from low to high ϕ_{PS} values. White circles are light-scattering cloud points measured on separate uniform samples.

be seen with the unaided eye as a diffuse boundary separating one-phase and two-phase regions. Cloud points measured on bulk samples with conventional light scattering are shown as discrete data points and agree well with the cloud point curve observed on the library (21,34). The diffuse nature of the cloud point curve reflects the natural dependence of the microstructure evolution rate on temperature and composition. Near the LCST boundary the microstructure size gradually approaches optical resolution limits (1 μm), giving the curve its diffuse appearance. Based upon a bulk diffusion coefficient of $D \approx 10^{-17}$ m^2/s, the diffusion length ($\sqrt{Dt}$) for a $2h$ anneal is 270 nm. In Figure 9 each pixel covers about 30 μm, which is over 100 times the diffusion length, and ϕ-gradient-induced diffusion has a negligible effect on the observed LCST cloud point curve. The combinatorial technique employing T-ϕ polymer blend libraries allows for rapid and efficient characterization of polymer blend phase behavior (cloud points) in orders of magnitude less time than with conventional light scattering techniques.

Block Copolymer Segregation and Surface Morphology. The morphology of symmetric diblock copolymer thin films has been studied extensively with traditional techniques (35–48). These studies found surface induced formation of lamellae with thickness equal to the equilibrium lamellar thickness L_0 parallel to the substrate. The lamellae form smooth films when the total film thickness h is equal to an integral multiple m of L_0, $h \approx mL_0$ for one block segregating to both the substrate and air interfaces and $h \approx (m + \frac{1}{2})L_0$ for one block preferring

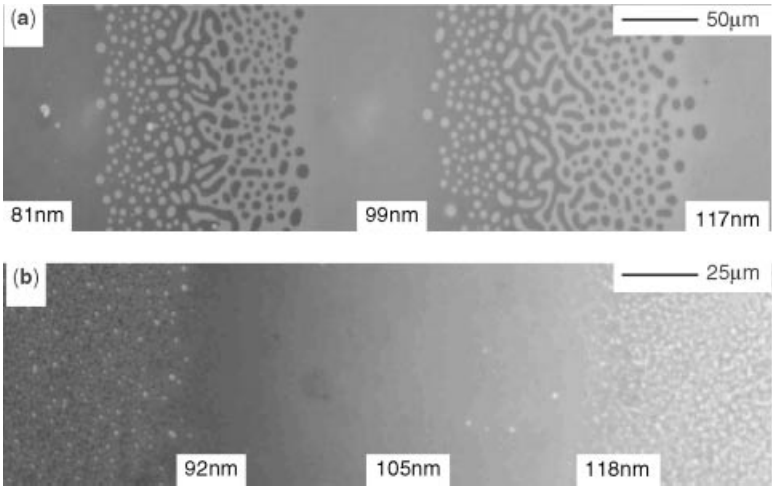

Fig. 10. (**a**) Optical micrograph of a $M_w = 26{,}000$ g/mol PS-*b*-PMMA gradient film showing the addition of two lamellae to the surface. Labels indicate $h = 4.5\ L_0$, $5.5L_0$, and $6.5L_0$ for this M_r copolymer. (**b**) Optical micrograph of a $M_w = 104{,}000$ g/mol PS-*b*-PMMA gradient film showing the change in h across the smooth region. The color change from purple to blue-green indicates a Δh of ≈25 nm across the smooth area. Standard uncertainty in thickness is ±3 nm.

the substrate and the other preferring the air interface. When h deviates from these values, holes or islands of height L_0 are found to form on the film surface so as to reduce the system energy. Although there has been significant previous investigation of these systems, almost no research on the factors controlling the lateral dimensions of these surface features has been reported. In addition, no investigation of the transition regions between the hole and island formations has been performed due to the difficulty in accurately controlling film thickness with traditional spin-coating techniques. These types of questions are ideal for CM where it is possible to produce continuous h-gradient films of symmetric diblock copolymers with various molecular masses (23,24).

Gradients in h of symmetric polystyrene-*b*-poly(methyl methacrylate) (PS-*b*-PMMA) with three different molecular masses were produced using the knife-edge flow coating technique described above. After characterization of h with UV-visible interferometry, the films were annealed at 170°C for up to 30 h to allow lamellar organization. The resulting morphologies were characterized with OM (optical microscopy) and AFM. Figure 10 presents a true color optical micrograph of a $M_w = 26{,}000$ g/mol gradient film showing morphological changes associated with the addition of two lamellae to the surface of the film. Labels denote approximate h values corresponding to $h \approx (m + \frac{1}{2})L_0$ for $m = 4$, 5, and 6. The morphology evolves from a smooth film to circular islands to a bicontinuous hole/island region to circular holes back to a smooth film from left to right in the micrograph and repeats twice. This morphology was observed to consistently repeat for h ranging from $2.0L_0$ to $6.5L_0$ for all molecular masses examined. Notably, the smooth regions of the film form a significant fraction of the morphology, corresponding to a thickness range Δh deviating significantly from an integral multiple of L_0.

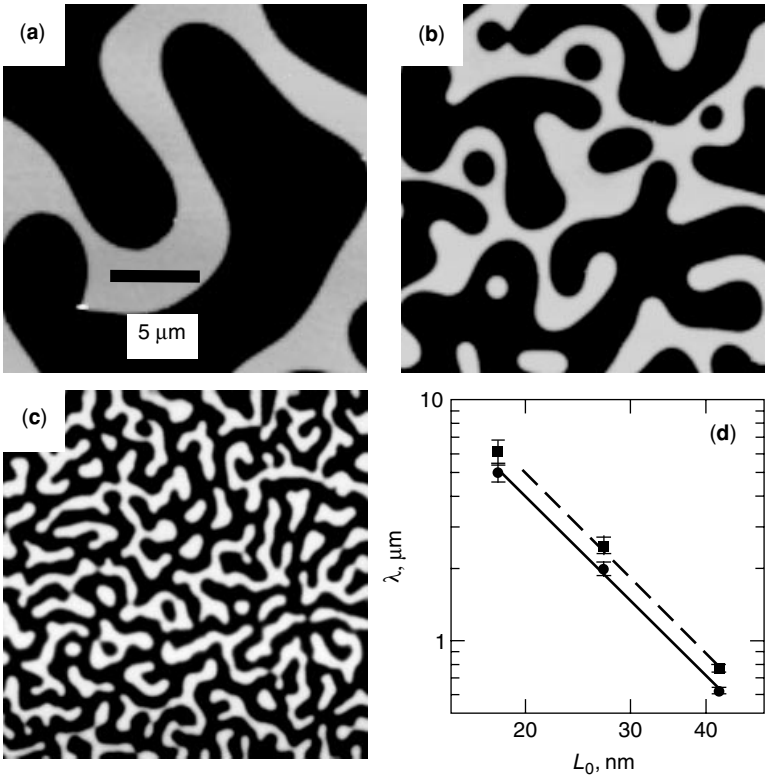

Fig. 11. AFM micrographs of PS-*b*-PMMA gradients annealed 30 h with M_w of (**a**) 26,000 g/mol, (**b**) 51,000 g/mol, and (**c**) 104,000 g/mol showing the decrease in surface feature size with increasing M_w. (Brighter regions correspond to higher topography and scale bar applies to all micrographs.) (**d**) Plot of λ vs. L_0 for samples annealed for 6 h (circle, solid line) and 30 h (square, dashed line) showing the power law dependence of λ on L_0 and M_w.

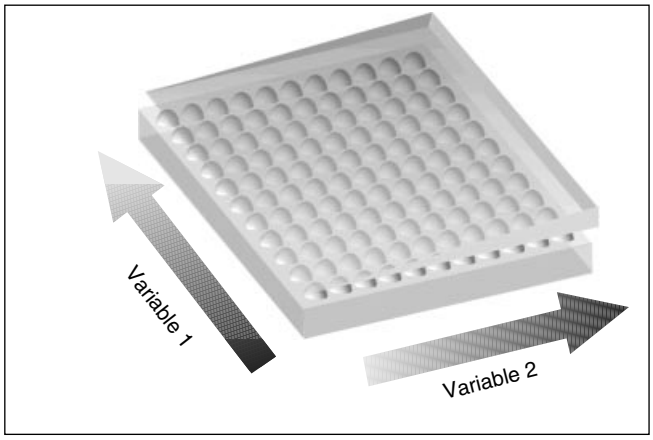
This Δh is confirmed in the optical micrograph presented in Figure 10b where the smooth region of a $M_w = 104{,}000$ g/mol PS-*b*-PMMA gradient film is displayed. The orange features on the left are holes and the yellow-green features on the right are islands and the smooth region changes color from purple to blue-green indicating an h increase. The value of Δh is $\approx 0.28 L_0$ and invariant within standard uncertainty for all M_w and h investigated. This effect is interpreted to arise from a brush-like stretching and compression of block copolymer chains in the outer lamella as the chain density varies with h. Therefore islands and holes form only when the free energy penalty of chain deformation becomes so large that the defect structures are more energetically favorable.

The lateral size of the surface patterns, which can be remarkably large when compared to L_0 or h, was also investigated using the h-gradient block copolymer film libraries. Figure 11 shows AFM micrographs of the surface of PS-*b*-PMMA gradient films with M_w of 26,000 g/mol (Fig. 11a), 51,000 g/mol (Fig. 11b), and 104,000 g/mol (Fig. 11c), annealed for 30 h at 170°C. These micrographs demonstrate that the lateral scale of the surface features decreases with increasing

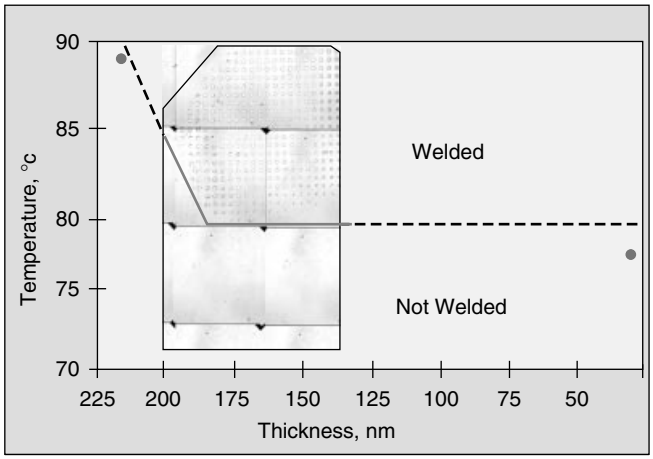
M_w. This fact is quantified by obtaining 2-D Fourier transforms of the micrographs (Fig. 11d) and extracting a characteristic peak wavevector (q^*) for each M_w. Figure 11d contains a plot of $\lambda \equiv (1/q^*)$ vs L_0 for samples annealed for both 6 h and 30 h and the lines correspond to power law fits yielding the relation $\lambda\ (\mu m) \sim {L_0}^{-2.5}$ or correspondingly $\lambda\ (\mu m) \sim {M_w}^{-1.5}$. This decrease of λ with increasing M_w suggests that as M_w of the outer block copolymer layer increases, its viscoelastic nature increases the free energy cost of forming large-scale surface patterns. The large-scale pattern formation in block copolymer films is therefore tentatively ascribed to the increased surface energy required to deform the surface of the block copolymer layers with increasing M_w.

Organic Light-emitting Diodes. We also mention here two characterization studies of the optimization of organic light emitting diodes (OLEDs). Schmitz and co-workers (14–16) used a masked deposition technique to produce thickness gradients in both the organic hole transport layers and the inorganic electron transport and emitting layer. OLEDs with single-gradient and orthogonal 2-D gradient structures were produced in order to evaluate the effects of the various layer thicknesses on the device efficiency. An optimal thickness for both the hole and electron transporting layers was reported. Likewise, Gross and co-workers (17) reported the use of CM to investigate the performance of doped (oxidized) ϕ-conjugated polymers in OLEDs. In these devices the polymers serve as hole transport layers but an energy barrier for hole injection exists between the polymeric material and the inorganic anode. By varying the oxidation level of the polymer this energy barrier can be reduced to lower the device working voltage. The effect of oxidation was studied by electrochemically treating the polymer to create a continuous gradient in the oxidation level of the polymer. A gradient in thickness was created orthogonal to the gradient in oxidation to explore variations of both properties simultaneously. For this reason, this study represents a cross between both combinatorial synthesis (oxidation steps) and process characterization (thickness gradient deposition). The gradient libraries were characterized by monitoring the efficiency and onset voltage of OLEDs fabricated on the gradients.

Combinatorial Adhesion Measurements. More recently, Crosby and co-workers (49) developed a combinatorial technique that can be used to investigate adhesive interactions between a polymer and another polymer, ceramic, or metal. The primary goal in the development of this technique was to design a high throughput, parallel processing adhesion test that allowed the adhesive strength dependence on multivariable environments to be determined. This combinatorial methodology for measuring polymer adhesion is largely built upon the theory of Johnson, Kendall, and Roberts (JKR) (50), which facilitates the measurement of the adhesive forces between two contacting surfaces. In the classical use of this theory, a hemispherical lens of one material is brought into contact with a complementary substrate, and subsequently separated. Rather than using a single hemispherical lens, Crosby and co-workers (49) used an array of microlenses (Fig. 12a). During this process, the contact area and displacement of each microlens is recorded through the use of an image-acquisition system integrated with an optical microscope. With these parameters, the JKR theory can then be used to quantify the adhesion energy between the two contacting materials (51). Along each axis of the array, a gradient in different environmental parameters



(**a**)



(**b**)

Fig. 12. (**a**) Schematic of microlens array used in combinatorial JKR adhesion test with two parameters varying along orthogonal axis. Weld spots are visible features in image. The two isolated data points were collected from independent adhesion tests. Edges of microlens array are indicated by solid black lines.

or material properties can be placed. Examples of such gradient properties are surface energy, temperature, thickness, crosslink density, blend composition, and strain. If two orthogonal gradients are placed on the array, then each microlens contact point will yield a measurement of adhesion for a unique combination of parameters. The reported microlens libraries are capable of measuring 1600 different points of adhesion within a single test.

This methodology is demonstrated by investigating the effect of thickness and temperature on the self-adhesion of PS. In this test, a microlens array was made from poly(dimethylsiloxane) (PDMS). Onto this PDMS array was floated a

thin layer of PS containing a thickness gradient. The complementary substrate for this test was a PS-coated silicon wafer with an applied temperature gradient. During contact, the PS molecules diffused across the interface to entangle and strengthen the interface, thus causing the PS coating of the PDMS microlenses to delaminate within the contact regions. This "welding" of the contact areas occurs above a critical temperature and below a critical thickness over the time scale of the test (Fig. 12b). Such measurements are useful for the microelectronics industry where adhesion of thin-polymer layers determine the integrity of electronic packaging, but the general technique will have impact on the numerous industries where adhesion plays a dominant role.

CONDUCTIVE POLYMER COMPOSITES

Introduction to Electrically Conductive Adhesives

Electrically conductive adhesives (ECAs) are composites of polymeric matrices and electrically conductive fillers. Polymeric matrices have excellent dielectric properties and thus are electrical insulators. The conductive fillers provide the electrical properties and the polymeric matrix provides mechanical properties. Therefore, electrical and mechanical properties are provided by different components, which is different from metallic solders that provide both electrical and mechanical properties. ECAs have been with us for some time. Metal-filled thermoset polymers were first patented as ECAs in the 1950s (1–3). Recently, ECA materials have been identified as one of the major alternatives for lead-containing solders for microelectronics packaging applications. There are two types of conductive adhesives: anisotropically conductive adhesives (ACAs) and isotropically conductive adhesives (ICAs). Utilization of both types of conductive adhesives as lead-free alternatives for flip chip, surface mount technology (SMT), chip scale package (CSP), and ball grid array (BGA) applications are reviewed here.

Anisotropically Conductive Adhesives

Anisotropically conductive adhesives (ACAs) represent the first major division of polymer bonding agents. The anisotropic class of adhesives provides unidirectional electrical conductivity in the vertical or z-axis. This directional conductivity is achieved by using a relatively low volume loading of conductive filler (5–20 vol%) (4–6). The low volume loading is insufficient for interparticle contact

and prevents conductivity in the x–y plane of the adhesive. The z-axis adhesive, in film or paste form, is interposed between the surfaces to be connected. Application of heat and pressure to this stack-up causes conductive particles to be trapped between opposing conductor surfaces on the two components. Once electrical continuity is achieved, the dielectric polymer matrix is hardened by chemical reaction (thermosets) or by cooling (thermoplastics). The hardened dielectric polymer matrix holds the two components together and helps maintain the pressure contact between component surfaces and conductive particles. A series of sketches in Figure 1 illustrates the attachment steps in achieving ACA joints.

Broadly ACAs fall into two categories: those that are anisotropically conductive before processing and those whose anisotropy arises as a result of processing. Their characteristics can be summarized as follows:

(1) Preprocessing anisotropy results from materials characterized by an ordered system of conductor elements interspersed in an adhesive matrix film. They are always in the form of tape or sheet and are evidently complicated to manufacture, requiring an adhesive film to be laser-drilled or etched then filled with conducting materials. They provide predictable contacts and are typically applied to a substrate as preforms.

(2) Postprocessing anisotropy results from materials that are a homogeneous mix of conductive fillers and adhesive matrix and that have no internal structure or order prior to processing. All adhesive pastes and some tapes fall into this category.

Adhesive Matrix. The adhesive matrix is used to form a mechanical bond at an interconnection. Both thermosetting and thermoplastic materials are used. Thermoplastic adhesives are rigid materials at temperatures below the glass-transition temperature (T_g) of a polymer. Above the T_g, polymers exhibit flow characteristics. Thus, the T_g must be sufficiently high to avoid polymer flow during the application conditions, but the T_g must be low enough to prevent thermal damage associated with chip carrier and devices during assembly. The principal advantage of thermoplastic adhesives is the relative ease with which interconnections can be disassembled for repair operations (7,8). However, thermoplastic ACAs suffer from many disadvantages. One of the most serious issues is that adhesion is not sufficient to hold the conductive particles in position, causing the contact resistance to increase after thermal shocks (7,8). Moreover, a phenomenon called spring back increases the contact resistance while the adhesive layer recovers from the stress caused by pressing of an ACA onto the components during bonding. This phenomenon, a creep characteristic exhibited by thermoplastic elastomers, occurs much after an ACA film has been heated to create the electrical joints. The contact resistance sometimes increases to more than three times the initial resistance during spring back (ie unloading) (7).

Thermosetting adhesives, such as epoxies and silicones, form a three-dimensional cross-linked structure when cured under specific conditions. Cure techniques include heat, UV light, and added catalysts. As a result of the cure reaction which is irreversible, the initial uncross-linked material is transformed into a rigid solid. The themosetting ACAs are stable at high temperatures and, more importantly, provides a low contact resistance. This results from a compressive force that maintains the conductive particles in intimate contact after the cure. That is, the shrinking caused by the cure reaction achieves a low contact resistance with long time stability. The ability to maintain strength at high temperature and robust adhesive bonds are the principal advantages of these materials. However, because the cure reaction is not reversible, rework or repair of interconnections is not an option (7,8). The choice of adhesive matrix and its formulation is critical to the long-term life properties of a composite. In practice, many options exist for the adhesive matrix. Acrylics can be used in low temperature applications (under 100°C), while epoxies are more robust and can be used at higher temperatures (up to 200°C). Polyimide is used in the harshest environments where the temperature approaches 300°C (6).

Conductive Fillers. Conductive fillers are used to provide the adhesive with electrical conductivity. The simplest fillers are metal particles such as gold, silver, nickel, indium, copper, chromium, and lead-free solders (SbBi) (6,7,9–11). The particles are usually spherical and range 3–15 μm in size for ACA applications (12). Needles or whiskers are also quoted in some patents (6).

Some ACA systems employ nonconductive particles with a thin metal coat. The core material is either plastic or glass with a metal coating consisting of gold, silver, nickel, aluminum, or chromiun. The basic particle shape of these systems is

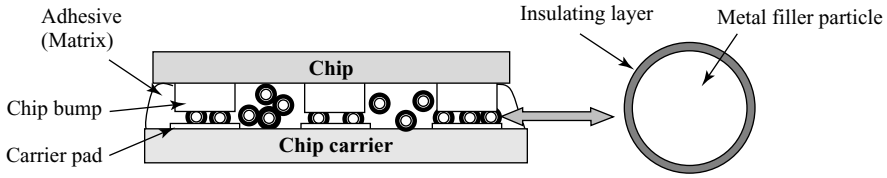

Fig. 2. Schematic depicting the cross section of an interconnection using an MCF-filled ACA.

also spherical. Plastic-cored particles deform when compressed between opposing contact surfaces, and thus provide a large contact area. Polystyrene (PS) is often selected as the core material because the coefficient of thermal expansion (CTE) of metal-coated PS beads is very close thermoset adhesives. The combination of epoxy resin and metal-plated PS beads results in a large improvement in thermal stability (7). In addition, glass can also be selected as the core material. Glass-cored particles coated with metal lead to a controlled bond-line thickness because the glass core is not deformable. Since the conductive particle size is known, the conductivity of the joint can be predicted.

To achieve fine pitch connections, a metal sphere or metal-coated plastic sphere coated with an insulating resin fillers were developed. The insulating resin layer is broken only under pressure to expose the underlying conductive surfaces, referred to as a microcapsule filler- (MCF). A higher filler loading can be achieved with MCFs for fine pitch applications, which avoid creating electrical short circuit conditions between printed circuit features (7,12). A typical cross section of an ACA interconnection with MCF material is illustrated in Figure 2.

Flip Chip Applications Using ACAs

In traditional flip chip packages, solder bumps provide electrical connections between a chip and chip carrier. To achieve high reliability, organic underfill materials are usually required to fill the gap between the chip and chip carrier. The cured underfills create a monolithic structure that evenly distributes the stress over all the material in the gap, not just on the solder connections. In the past several years, much research has been conducted to develop flip chip packages, using ACAs in place of solder bumps. The primary advantages of ACA over lead-bearing solder for flip chips include ACAs' fine pitch capability, lead-free, low processing temperature, absence of flux residue, and generally lower cost. Also, ACA flip chip technology does not require an additional underfilling process because the ACA resin acts as an underfill.

ACA flip chip technology has been employed in many applications where flip chips are bonded to rigid chip carriers (13). This includes bare chip assembly of ASICs in transistor radios, personal digital assistants (PDAs), sensor chip in digital cameras, and memory chip in lap-top computers. In all the applications, the common feature is that ACA flip chip technology is used to assemble bare chips where the pitch is extremely fine, normally less than 120 μm. For these fine applications, it is apparently the use of ACA flip chip instead of soldering which is more cost effective.

ACA flip chip bonding exhibits better reliability on flexible chip carriers because the ability of flex provides compliance to relieve stresses. For example, the internal stress generated during resin curing can be absorbed by the deformation of the chip carrier. ACA joint stress analysis conducted by Wu and co-workers indicated that the residual stress is larger on rigid substrates than on flexible substrates after bonding (14).

ACA Flip Chip for Bumped Dies.

Comparison of ACAs with Hard and Soft Fillers. Kishimoto and co-workers reported (15) ACA pastes using two different fillers: Au-coated rubber particles (soft) and nickel particles (hard). The ACAs were used to bond a flip chip with Au plated bumps to a board with copper metallization. With the application of pressure, the soft particles were brought into contact with surface pads and were deformed, which lowered this contact resistance. The hard particles, however, deformed the bumps and pads, and thus were also in intimate contact with the surfaces to help reduce this contact resistance. Their study showed that their choice of both hard and soft fillers in ACA materials had similar voltage–current behavior, and both exhibited stable contact resistance values after 1000 cycles of thermal cycling and 1200 h of 85°C/85% RH aging conditions (15).

Coated Plastic Filler. Casio developed an advanced ACA film called the Microconnector (Fig. 3) (16–18). This adhesive contains conductive particles made by coating plastic spheres with a thin layer of metal, followed by an additional 10-nm-thick layer of insulating polymeric material. The insulating layer consists of a large number of insulating micropowder particles which electrically insulate the outer surface of the spheres. The thin insulation layer is formed by causing insulating micropowder particles to adhere to the surface of the metal layer via electrostatic attraction. The base adhesive resin is thermoplastic or thermosetting,

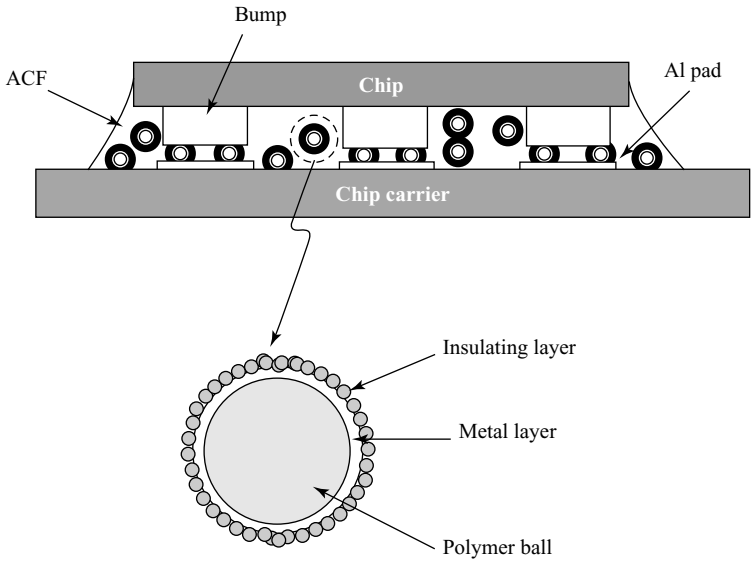

Fig. 3. Schematic depicting Casio's ACF technology – Microconnector.

producing compressive force when cured. When heat and pressure are applied during bonding, the insulating layer, which is in contact with the bump surface of an IC, is broken. However, the insulating layer remains intact on conductive particles not crushed by the bonding pads, thereby producing only *Z*-axis electrical interconnections and preventing lateral short circuit conditions. With an additional insulating layer, a fine pitch and low contact resistance can be achieved without the risk of lateral short circuiting by increasing the filler percentage (ie amount of particles per unit volume base adhesive resin or film). Casio is manufacturing pocket TVs with a liquid crystal using this material (18).

Solder Filler Systems. Unlike most commercial ACAs, where the electrical conductivity is based on the degree of mechanical contact achieved by pressing conductive particles to contact pads on board and chip bumps, solder-filled ACAs establish microscopic metallurgical interconnections. The advantage of these joints is that the metallurgical bonds that are established prevent electrical discontinuities from occurring should the adhesive polymeric matrix undergo relaxation during the operational lifetime. Therefore, solder-filled ACAs combine the benefits of both soldering and adhesive joining resulting in more reliable ACA joints. Furthermore, better electrical performance is achieved as a result of lower contact resistance established through metallurgical bonds (19).

Joints made with SnBi- and Bi-filled ACAs experience brittle intermetallic compound formation and have problems with typical conductor and coating materials such as copper, nickel, gold, and palladium (20). But Bi and BiSn are compatible with tin, lead, zinc, and aluminum. However, Zn and Al are easily oxidized, and so in practice only Sn and Pb are suitable surface finish materials for SnBi- and Bi-filled ACA applications (Fig. 4). Vuorela demonstrated that high quality interconnections were formed by metallurgical bonding SnPb-bumped chips on SnPb-coated substrates at relatively low temperature and pressure utilizing a

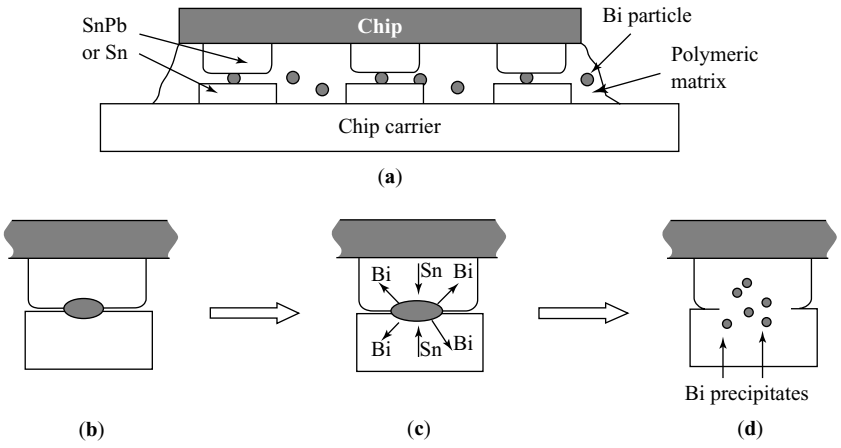

Fig. 4. Schematic illustration of the formation of electrical interconnects between a bumped chip and a mating carrier using a Bi-filled ACA. (**a**) The chip is aligned and placed on a chip carrier. (**b**) The Bi particle is deformed between a chip bump and a carrier pad when a bonding pressure is applied. (**c**) The Bi particle dissolves into the liquid lentils upon exposure of heat. (**d**) Bi diffuses into the Sn–Pb matrix and forms fine solid precipitates.

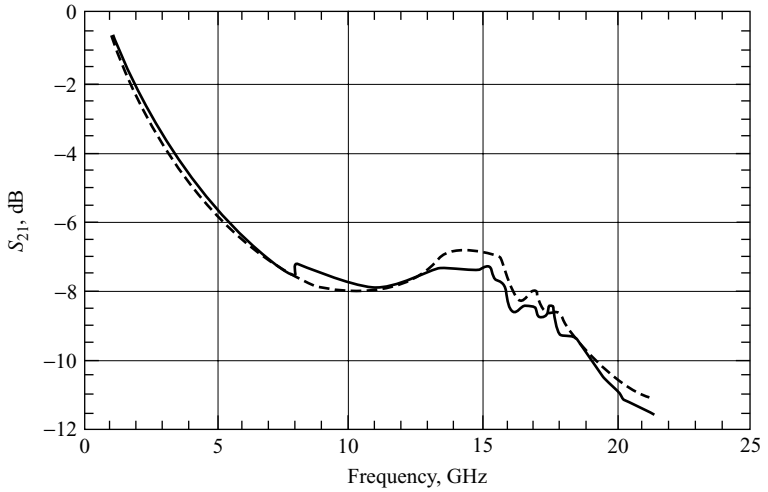

Fig. 5. ACA-bonded flip chips exhibit the same transmission coefficient, S_{21}, as solder-bonded flip chips from 1 to 21 GHz. —— Transmission: ACA; - - - - Transmission: solder.

Bi-particle-filled ACA. The ACA joints exhibited a stable resistance after 2000-h 85°C/85% RH aging or after 1000-h temperature cycle testing (−40 to 125°C). Even though this work was still preliminary, it demonstrated an interesting idea and concept. For lead-free applications, different materials such as pure Sn can be used for chip bumps and surface finish on the substrate (21).

ACA Bumped Flip Chips for High Frequency Applications. The high frequency behavior of ACA interconnections has attracted much attention in the past several years. Sihlbom and co-workers demonstrated that ACA-bonded flip chips can provide performance equivalent to solder flip chips in the frequency range of 45 MHz to 2 GHz on FR4 chip carriers and 1 to 21 GHz on a high frequency Telfon-based chip carrier (Fig. 5). The different particle sizes and materials in the conductive adhesives gave little difference in high frequency behavior of ACA joints (22,23).

Yim and co-workers developed a microwave frequency model for ACF-based flip chip joints based on microwave network analysis and *S*-parameter measurements. By using this model, high frequency behavior of ACF flip chip interconnections with two filler particles, Ni and Au-coated polymer particles, was simulated. It was predicted that Au-coated polymer-particle-filled ACF flip chip interconnections exhibited comparable transfer and loss characteristics to solder bumped flip chips up to about 13 GHz and thus they can be used for up to 13 GHz, but Ni-filled ACF joints can only be used for up to 8 GHz because the Ni particle has a higher inductance compared to the Au-coated particle. Polymeric resins with a low dielectric constant and conductive particles with low inductance are desirable for high resonance frequency applications (24).

ACA for Unbumped Flip Chips. Although ACAs are typically utilized with flip chip bumped dice, they are also used for unbumped flip chips in some cases. For unbumped flip chips, a pressure-engaged contact must be established by bringing the particles to the aluminum chip pads rather than a bump. The

pressure must be sufficient to break the oxide on the aluminum pads. A sufficient quantity of particles must be trapped in the contact pad area and remain in place during bonding and curing to achieve a reliable interconnection. In addition to maximizing the number of particles in the contact area the number of particles located between adjacent pads must be minimized so as to prevent electrical shorts. An additional factor that must be in the case of unbumped flip chips is adhesive flow during bonding and curing. It is essential to control the temperature heating to be sufficiently slow when the polymeric resin is curing so that the conductive filler particles can migrate from the chip carrier side to the chip side pad (25).

Ni/Au Coated Silver Bumps. A flip chip technology developed by Toshiba Corp. utilized an anisotropic conductive film (ACF) to attach bare unbumped chips (with Al pads) onto a printed circuit board (PCB) with bumps formed from a silver paste screen printed on the PCB (26). After curing, Ag bumps were formed (70-μm diameter, 20-μm height), which were subsequently overplated with Ni/Au. It was determined that ACF with a low CTE (28 ppm/$^\circ$C), low water absorption rate (1.3%), and that utilized a Au-plated plastic ball worked best. It was also found that Ni/Au plated Ag-paste formed bumps exhibited a smaller initial connection resistance (22 and 48 $\mu\Omega$ for Ag bumps with and without Ni/Au overplating, respectively) and a smaller connection resistance increase compared to Ag-paste formed bumps which were not overplated with Ni/Au after 1000-h accelerated thermal cycling (ATC) testing (ie the final connection resistances after aging are 294 and 717 $\mu\Omega$ for Ag bumps with and without Ni/Au overplating, respectively).

Conductive Columns. Nitto Denko Corp. developed an ACF for fine pitch flip chip applications (27). The features of this ACF were (*1*) connectability between bumpless chips and fine pitch PCB; (*2*) high electrical conductivity; (*3*) repairability (easy to peal off chips from a printed circuit board at elevated temperatures); (*4*) high reliability; and (*5*) potential storage at room temperature. There are other notable features too: (*1*) ACF is usable at pitches down to 25 μm, (*2*) the conductive elements are micrometallic columns as opposed to random-shaped particles, and (*3*) this adhesive matrix consists of a thermoplastic polymer resin, conductive columns coated with an insulator, and a high T_g polymer, which completely separates the columns from the adhesive (Fig. 6).

It is easy to change the diameter of the conductive columns in order to make the film compatible with a variety of pitches. Sn/Pb or other solder materials are plated on both the top and bottom of the conductive columns (usually copper). The plated solder on the both ends of the conductive columns melts and forms metallurgical connections between the conductive columns and metal pads on a chip and the mating chip carrier, which ensure a good connection. Figure 6a illustrates the cross section of the film structure. A rough surface, a result of plating, has the advantage of providing a good connection with the terminal pads it is in contact with. A typical terminal pad structure of a chip without bumps is shown in Figure 6b. To achieve a good connection, the height of the conductive columns must be larger than the thickness of the passivation layer (t_p). Since t_b (the distance from a Cu pad surface of the chip carrier to the passivation layer surface of the chip) is usually smaller than t_a (the distance from solder mask surface of the chip carrier to the passivation layer surface of the chip), the conductive columns will assume an inclined position during bonding if the thickness of the conductive columns

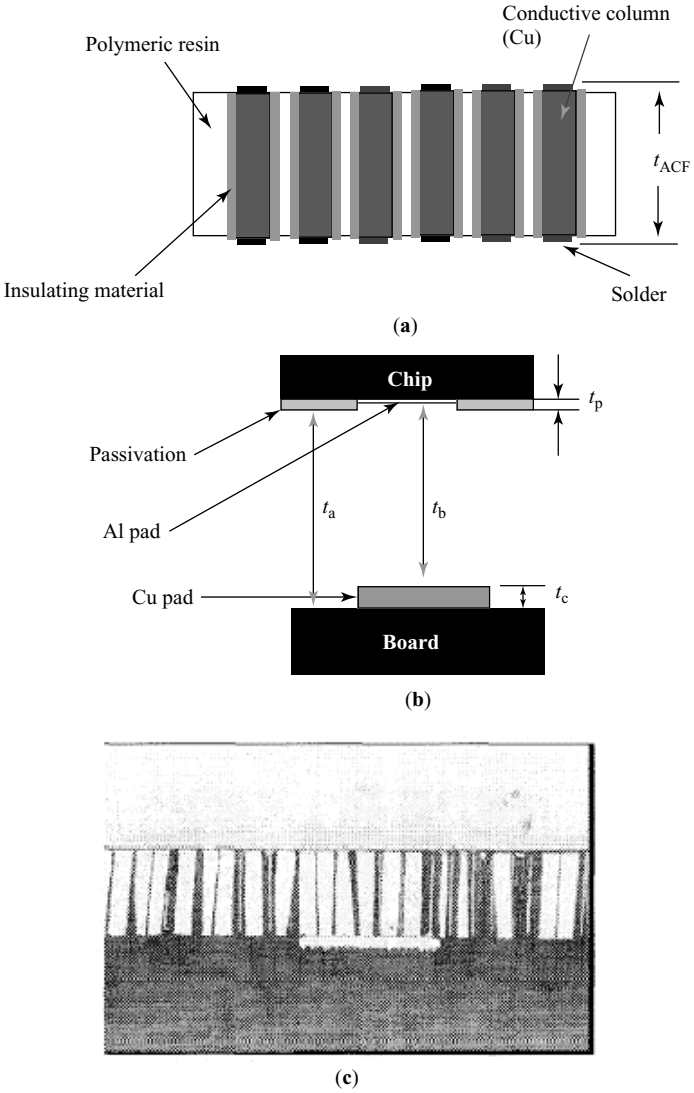

Fig. 6. Illustration of a scheme for fine pitch, flip chip interconnection. (**a**) An ACF filled with micrometallic columns. (**b**) A typical cross-sectional structure of a chip without bumps and the mating chip carrier. (**c**) A cross section of an interconnect formed between an unbumped chip and the mating chip carrier.

is larger than the ACF thickness (t_{ACF}). It is important to adjust the thickness of board or chip carrier pads and ACF thickness to achieve good connection and adhesion. Reliability results indicated that the ACF possessing an adhesive matrix with a high T_g (282°C) exhibited high reliability and the contact resistance remained unchanged after 1000 cycles of ATC testing (−25 to 125°C). Figure 6c is a photography of a cross section of a joint formed between an unbumped die and a chip carrier using this ACF flip chip interconnection method.

ACAs for CSP and BGA Applications

Area Bonding Conductive Adhesives. Aiming at the CSP application market, Merix Corp. and Auburn University collaborated to develop an ACA called *area bonding conductive (ABC) adhesives*. ABC adhesive is a two-region thermoset adhesive with ECA pads surrounded by a continuous oxide-filled dielectric adhesive to form a total area bond. Both regions are solvent-free, B-staged, nontacky epoxies supplied on a Mylar carrier release film. In contrast to conventional ACAs, conductive areas of ABC adhesive are only at bond pad locations. The assembly process for using ABC adhesives is shown in Figure 7. The ABC adhesives potentially can provide a reliable, low cost, low temperature, low pressure process for flip chip and CSP applications (28).

Au-Stud vs Electroless Ni/Au Bumps. As the demand for miniaturization has increased dramatically, concentrated efforts have been made to find cheaper alternatives to established technologies of area array solder bumps.

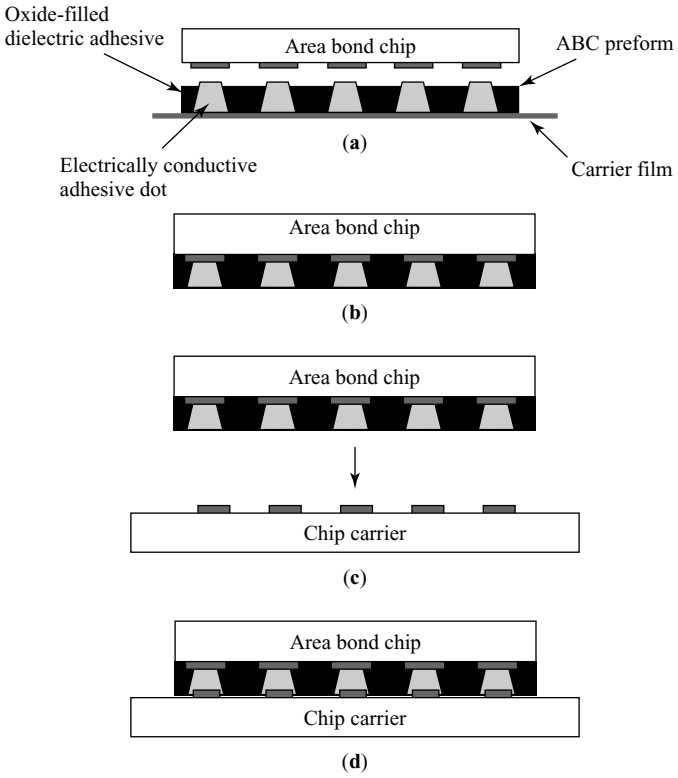

Fig. 7. Schematic depicting a flip chip assembly processing utilizing ABC adhesive. (**a**) A chip is aligned to the ABC preform which is on a carrier film. (**b**) The ABC preform is tacked to the die at 100°C and under a pressure of 150 g for 30 s, and then the carrier film is removed after the chip is cooled down. (**c**) The chip with ABC preform is aligned to a mating chip carrier (FR4 board). (**d**) The chip/ABC preform is attached to the chip carrier at 100°C and under a pressure of 150 g for 30 s, and then the package is cooled down.

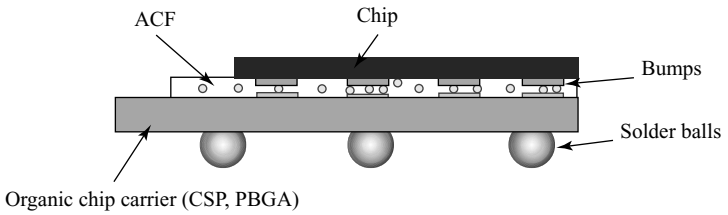

Fig. 8. Schematic depicting the side view construction of a ChipPAC CSP package that utilizes an ACF.

ChipPAC, Inc., demonstrated an alternate process/package concept covering both CSP and PBGA package formats whose construction is illustrated in Figure 8. The concept package consisted essentially of three parts: ACF, metallic bumps on the die bond pads, and an organic chip carrier (29).

Although this packaging solution was not entirely unique, reducing it to a high volume assembly and packaging process, where low cost and high reliability were key, was innovative. This configuration provides an appealing package solution, based on several factors. First, the connection can be implemented at a much finer pitch ($\sim$100 μm) compared to conventional solder bumps, and so there is a potential for a die-size reduction in flip chip IC designs that are normally implemented as multirow perimeter arrays using conventional solder bumps. Second, the ACF interconnect approach allows the use of inexpensive bumping technologies, thereby greatly reducing the wafer bumping cost portion of the overall package cost.

The combination of cured adhesive interconnection, bumps, and organic substrate provides a reliable, cost-effective flip chip CSP. It was determined that Au-stud bumps were preferable to Ni/Au bumps because of the former's compliant nature. Since the planarity control of organic chip carriers is difficult, given the nature of the material, it was simpler to change the interconnection method, ie, using Au-stud bumps. However, electroless Ni/Au bumps are still an option, if the material properties of the ACF and/or chip carrier are altered to provide compliancy.

Double-Layered ACF. Motorola developed a low cost and low profile flip chip on flex (FCOF) CSP package using ACFs (30). The package has the flexibility to utilize the existing wire-bonding pad configuration without adding prohibitive redistribution and wafer solder bumping costs, and eliminated the need for underchip encapsulation. Two types of ACF film were studied: double layer films with the second layer loaded with Ni/Au plated polystyrene–divinylbenzene (PS–DVB) spheres, and solid Ni particles. The film structure, consisting of a nonfilled and a conducting particles-filled adhesive layers, is illustrated in Figure 9. The double-layer design reduces the particle density in x–y spacing of interconnection pads, which serve to enhance the x–y plane insulation characteristics. At the same time, the double-layer film provides more adhesive volume that helps to entrap more particles on the bonding interconnection pads. Both calculated and observed values show that the number of conducting particles trapped is much higher than those in single-layer ACF. This indicate that even though particle density in a

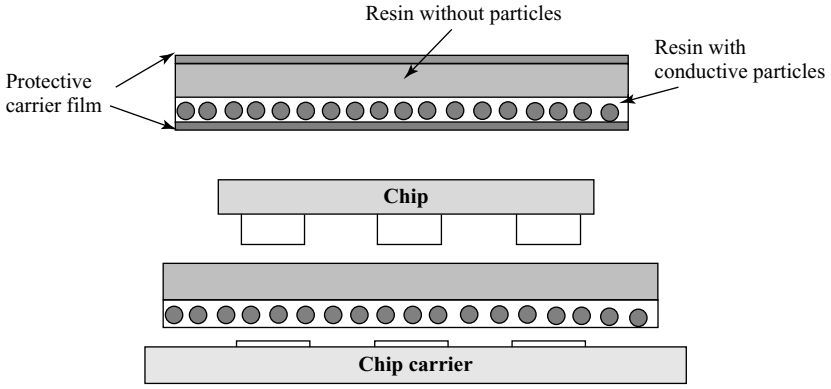

Fig. 9. Schematic of a double layer ACF.

double-layer ACF is low, conducting particles to effect electrical contact with both interconnection pads are trapped more effectively between interconnection pads in the double-layer ACF. The die has Ni/Au plated bonding pads and the chip carrier is flexible polyimide which can provide adequate compensation for the planarity differences. Its compliant nature under compressive bonding operation allows the copper traces at the bonding area to deform and compensate for nonplanarity or irregularity that exists. The ACF adhesive system provided the system with stable contact resistance after 500 cycles of liquid–liquid temperature shock (LLTS) aging (-55 to 125°C).

Ceramic Chip Carriers vs Organic Chip Carriers. A ceramic chip carrier and an organic chip carrier, whose configuration is equivalent to that of microball grid array (μBGA) style CSP and broadly representative of BGA and flip chip devices, were evaluated using ACAs with conducting particles of various sizes (31). The ceramic chip carrier has AgPd thick-film bonding pads and the organic chip carrier is a conventional PCB (1 oz Cu clad FR5 laminate) with submicron Au-coated Cu pads. It was determined that uniform conductivity and high yield were more readily achieved with organic chip carrier rather than ceramic chip carriers. This is because bonding pads on the FR5 chip carrier have better coplanarity compared to the thick-film ceramic chip carrier. ACAs with finer particles exhibited worse overall performance on both chip carriers, while ACAs with larger and polymer-cored particles exhibited better performance because the deformable polymer-cored particles compensated the gap variations between the chip bumps and the chip carriers.

SMT Applications

ACAs have been investigated as replacement for SnPb solder in surface mount (SM) attachment for fine pitch applications. The key attractive advantage is the cost effectiveness of using ACA to bond fine pitch SM components. A limitation of ACAs is the need to cure under a contact pressure. The concept of using an ACA as a solder replacement on rigid chip carriers utilizing conventional SMT

has been demonstrated by Liu and co-workers (32). Fine pitch SM components were bonded to FR4 boards with ACAs using a fine pitch bonder and then components with larger pitches were bonded with ICAs using standard SM equipment. The study demonstrated that standard surface-mounting tools could be used to assemble conductive adhesives. The connection resistance of solder-plated, plastic components (0.65 mm pitch) with ACAs bonded did not change after an accelerated temperature cycling (ATC) test conducted at −40 to 85°C. However, similar parts failed under conditions of −55 to 125°C for 1000 cycles (33). The mechanical stability problem may have been the result of an improper joint geometry, ie not optimized for ACA bonding.

Failure Mechanism

Since the adhesive matrix is a nonconductive material, interconnection joints rely to some extent on pressure to assure contact for conventional ACAs. Adhesive interconnections therefore exhibit different failure mechanisms compared to soldered connections, where the formation of intermetallic compounds and coarsening of grains are associated with the main mechanisms. Basically there are two main failure mechanisms that can affect the contacts. The first is the formation of an insulating film on either the contact areas or conductive particle surfaces. The second is the loss of mechanical contact between the conductive elements due to either a loss of adherence or relaxation of the compressive force.

Oxidation of Nonnoble Metals. Electrochemical corrosion of nonnoble metal bumps, pads, and conductive particles results in the formation of insulating metal oxides and significant increase in contact resistance. Electrochemical corrosion only occurs in the presence of moisture and metals that possess different electrochemical potentials. Humidity generally accelerates oxide formation and so too the increase in contact resistance. Reliability test results for FCOF using gold bumps and ACFs filled with Ni particles indicated that the connection resistance increased with time under elevated temperature and humidity storage conditions (34). In this case, the gold bump acts as cathode and the Ni particle as an anode. A nickel oxide, which is electrically insulating, eventually forms on the surface of the Ni particles.

Loss of Compressive Force. The compressive forces acting to maintain contact among the conductive components are partly achieved because of curing shrinkage achieved when curing the polymeric matrix of ACAs. Both the cohesive strength of the adhesive matrix and the interfacial adhesion strength between the adhesive matrix and the chip and chip carrier must be sufficient to maintain the compressive force. However, the thermal expansion of adhesives, their swelling due to moisture adsorption, and mechanical stresses due to applied loads tend to diminish this compressive force created as a result of curing. Moreover, water not only diffuses into the adhesive layer but also penetrates to the interface between adhesive and chip/chip carrier, causing a reduction in adhesion strength. As a result, the contact resistance increases and can even result in a complete loss of electrical contact (35).

Isotropic Conductive Adhesives

Percolation Theory of Conduction. Isotropic conductive adhesives (ICAs), also called as polymer solder, are composites of polymer resin and conductive fillers. The conductive fillers provide the composite with electrical conductivity through contact between the conductive particles. With increasing filler concentrations, the electrical properties of ICAs transform from an insulator to a conductor. Percolation theory has been used to explain the electrical properties of ICA composites. At low filler concentrations, the resistivities of ICAs decrease gradually with increasing filler concentration. However, the resistivity drops dramatically above a critical filler concentration, V_c, called the percolation threshold. It is believed that at this concentration, all the conductive particles contact each other and form a three-dimensional network. The resistivity decreases only slightly with further increases in the filler concentrations (36–38). A schematic explanation of resistivity change of ICAs based on percolation theory is shown in Figure 10. In order to achieve conductivity, the volume fraction of a conductive filler in an ICA must be equal to or slightly higher than the critical volume fraction. Similar to solders, ICAs provide the dual functions of electrical connection and mechanical bond in an interconnection joint. In an ICA joint (Fig. 11), the polymer resin provides mechanical stability and the conductive filler provides electrical conductivity. Filler loading levels which are too high cause mechanical integrity of adhesive joints to deteriorate. Therefore, the challenge in formulating an ICA is to maximize conductive filler content to achieve a high electrical conductivity without adversely affecting the mechanical properties. In a typical ICA formulation, the volume fraction of the conductive filler is about 25–30% (4,5).

Adhesive Matrix. Polymer matrices of ICAs are similar to ACAs. An ideal matrix for ICAs should exhibit a long shelf life (good room temperature latency), fast cure, relatively high glass-transition temperature (T_g), low moisture pickup, and good adhesion (39).

Both thermoplastic and thermoset resins can be used for ICA formulations. The main thermoplastic resin used for ICA formulations is polyimide resin. An attractive advantage of thermoplastic ICAs is that they are reworkable, eg, can

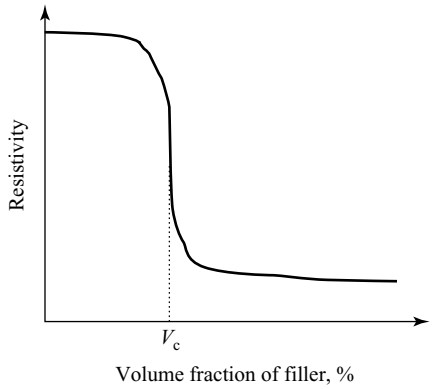

Fig. 10. Effect of filler volume fraction on the resistivity of ICA systems.

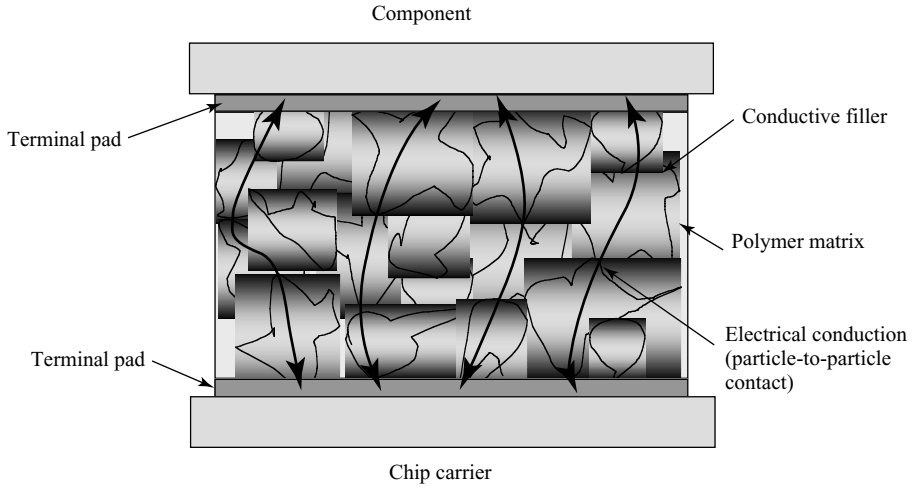

Fig. 11. Schematic that illustrates how electrical conduction paths are established by uninterrupted particle-to-particle contact between the component and chip carrier terminal pads in an ICA joint.

easily be repaired. A major drawback of thermoplastic ICAs, however, is the degradation of adhesion at high temperature. Another drawback of polyimide-based ICAs is that they generally contain solvents. During heating, voids are formed when the solvent evaporates. Most of commercial ICAs are based on thermosetting resins. Epoxy resins are most commonly used in thermoset ICA formulations because they possess superior balanced properties. Silicones, cyanate esters, and cyanoacrylates are also employed in ICA formulations (40–44).

Conductive Fillers. Because polymer matrices are dielectric materials, conductive fillers in ICA formulations provide the material with electrical conductivity. In order to achieve high conductivity, the filler concentration must be at least equal to or greater than the critical concentration predicted by percolation theory.

Pure Silver vs Ag-Coated Fillers. Silver (Ag) is by far the most popular conductive filler, although gold (Au), nickel (Ni), copper (Cu), and carbon (C) are also used in ICA formulations. Nickel and copper-based conductive adhesives generally do not have good conductivity stability because they are easily oxidized. Even with antioxidants, copper-based conductive adhesives show an increase in volume resistivity on aging, especially under high temperature and humidity conditions. Silver-plated copper has been utilized commercially in conductive inks, and should also be appreciable as a filler in adhesives. While composites filled with pure silver particles often show improved electrical conductivity when exposed to elevated temperature and humidity or thermal cycling, this is not always the case with silver-plated metals, such as copper flake. Presumably, the application of heat and mechanical energy allows the particles to make more intimate contact in the case of pure silver, but silver-plated copper may have coating discontinuities that allow oxidation/corrosion of the underlying copper and thus reduce electrical paths (4).

Particle Shape and Size. The most common morphology of conductive fillers used for ICAs is flake because flakes tend to have a large surface area, and more contact spots and thus more electrical paths than spherical fillers. The particle size of ICA fillers generally ranges from 1 to 20 μm. Larger particles tend to provide the material with a higher electrical conductivity and lower viscosity (45). A new class of silver particles, porous nano-sized silver particles, has been introduced in ICA formulations (46,47). ICAs made with this type of particles exhibited improved mechanical properties, but the electrical conductivity is less than ICAs filled with silver flakes. In addition, short carbon fibers have been used as conductive fillers in conductive adhesive formulations (36,48). However, carbon-based conductive adhesives show much lower electrical conductivity than silver-filled ones.

Silver-Copper Fillers. In 1992, a powder with a specific structure was introduced as a filler for conductive adhesives (49). A powder particle consists of two metallic components, copper and silver. Silver is highly concentrated on the particle surface and concentration gradually decreases from the surface to the inner of the particle, but always contains a small amount of silver. Conductive adhesive paste filled with this powder exhibits excellent oxidation resistance, ie can be exposed to oxygen content about 100 ppm in a nitrogen atmosphere. It also exhibits higher solderability than commercially available copper pastes, sufficient adhesion strength even after heating and/or cooling test, and least migration, almost same degree to pure copper paste (49).

Low-Melt Fillers. In order to improve electrical and mechanical properties, low-melting-point alloy fillers have been used in ICA formulations. A conductive filler powder is coated with a low-melting-point metal. The conductive powder is selected from the group consisting of Au, Cu, Ag, Al, Pd, and Pt. The low-melting-point metal is selected from the group of fusible metals, such as Bi, In, Sn, Sb, and Zn. The filler particles are coated with the low-melting-point metal which can be fused to achieve metallurgical bonding between adjacent particles, and between the particles and the bond pads that are joined using the adhesive material (50,51).

Flip Chip Applications Using ICAs

A key factor in achieving a low cost, flip chip technology is the use of ICAs. In comparison to the classical flip chip technologies, the use of ICAs for the bumping and joining provide numerous advantages:

(1) The simplification of the processing and the reduction of indexing steps by the omission of activation and purification process
(2) The smaller temperature load on elements and wiring carriers
(3) The availability of a large spectrum of possible material pairs and combinations
(4) The broad range of applicable adhesive systems and thus the selection of different processing parameters and joining characteristics
(5) Few requisites for under bump metallization (UBM) since alloy phase formation does not have to be considered

Unbumped Flip Chip Joints.

Polymer Flip Chip. Several flip chip bumping and joining techniques have been reported in the literature. Flip chips using ICAs are often called polymer flip chips (PFCs). The PFC process is a stencil printing technology in which an ICA is printed through a metal stencil to form polymer bumps on bond pads of IC devices subsequent to the UBM deposition on aluminum termination pads. The sequential processes to achieve PFC interconnects are UBM deposition, stencil printing an ICA, bump formation (ICA solidification), flip chip attach to achieve electrical connections, and underfill for enhanced mechanical and environmental integrity (52,53).

Protective Chip Pad Layer. As with virtually all flip chip processes, the Al bond pads must be protected to eliminate the formation of nonconductive aluminum oxide. This ensures a low and stable resistance at bond–bond pad interface. The PFC process utilizes an electroless plating technique, using Ni/Au or Pd, to cover the Al bond pads prior to polymer bumping. The typical metal thickness is 0.5–1.0 μm for Pd and 3.0–5.0 μm for Ni/Au.

The PFC process combines high precision stencil printing techniques with highly conductive ICAs. These polymers can be thermosetting or thermoplastic. First the polymer bumps are formed by deposition of an ICA through the metal mask directly onto the metallized bond pads on a wafer. Printed conductive adhesive bumps can offer an attractive alternative to the other bumping technologies in terms of cost and manufacturability. The printing process typically involves a screen or stencil with openings through which bumps are deposited. A screen consists of an interwoven wire mesh with an emulsion that covers the wire mesh. The emulsion is photolithographically patterned to match the bump sites. Stencils are made of metal foil. Holes for bump deposition are made by etching, electroforming (plating), or laser drilling.

During the printing process, the paste is typically dispensed some distance away from the stencil apertures. A schematic of the printing process is shown in Figure 12. Typically, the stencil is separated from a substrate by the snap-off distance. The squeegee is lowered, resulting in contact of the stencil to the substrate or wafer surface. As the squeegee moves across the stencil surface, a stable flow pattern develops in the form of a paste roll. The consequent hydrodynamic pressure developed by the squeegee pushes the paste into the patterned stencil openings. The stencil lifts away from the substrate surface with the paste remaining on the substrate.

Curing. The polymer bumps are then either fully cured or partially cured to the so-called B-stage for thermosetting polymer bumps. For thermoplastic polymer bumps, after stencil printing the solvent is removed to form solid bumps. Bump heights are typically 50–75 μm and process can accommodate pitches down to 5 mil. Bump densities of up to 80,000 bumps/wafer have been formed with excellent coplanarity.

Once the bumped wafers are diced, chips are picked from the wafers, flipped over, and then placed on and bonded to chip carriers. Different process procedures are utilized to bond thermosetting polymer bumps to similar thermoplastic bumps, as noted in Figure 13. Final processing involves a heat cure for thermosetting bumps, while thermoplastic bump connections only require in a few seconds under heat and pressure to melt the thermoplastic.

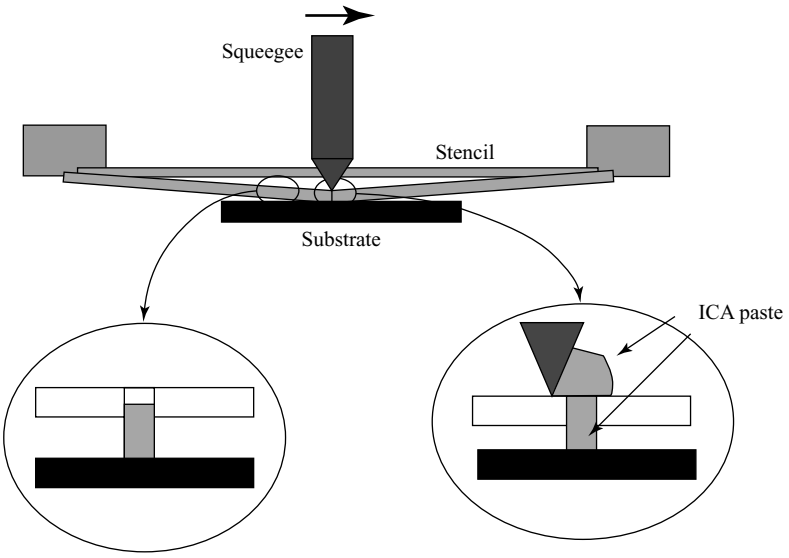

Fig. 12. Schematic depicting the ICA paste stencil printing process.

Underfill. An underfill is then injected into the gap between the chip and chip carrier and then cured to complete the flip chip process. The function of the underfill or encapsulation as it is sometimes referred to is to provide mechanical integrity and environmental protection to a flip chip assembly. Studies have demonstrated that both thermoset and thermoplastic ICAs can offer low initial joint resistances of less than 5 mΩ and stable joint resistances (Au-to-Au flip chip bonding) during all the accelerated reliability testing listed in Table 1. The reliability results have indicated that there is no substantial difference in the performance of thermoset and thermoplastic bumps and both types of polymers apparently offer reliable flip chip electrical interconnections (53).

Micromachined Bumping. A PFC bumping process is known as micromachined bumping (54,55). The bumping procedure is illustrated in Figure 14. Initially Cr/Au contact metal pads for conductive polymer bumps are deposited on Si wafers, followed by patterning a thick photoresist to create bump holes. A high aspect ratio and straight side-wall patterns are very important in shaping the conductive polymer bumps. After the lithography, thermoplastic conductive polymer material, usually thermoplastic paste filled with Ag flake, is applied by either dispensing or screen printing the paste into the bump-hole patterns. The wafer

is heated in a convection oven to remove the solvent. Because of the difference in curing conditions between the thick photoresist and conductive polymer, the photoresist can be carefully stripped to expose the dried polymer bumps. Finally, the wafer is diced into individual chips.

Chips with thermoplastic bumps are placed on chip carriers and preheated to approximately 20°C above the melting point of the polymer, causing the bumps to melt onto the matching chip carrier pads. Mechanical and electrical bonds are

established as the chip carrier cools below the polymer melting temperature. To enhance the mechanical bonding strength, a small amount of pressure can be applied by placing a weight on the chip.

This flip chip bonding technique has high potential to replace conventional solder flip chip techniques for sensor and actuator systems, optical microelectromechanical systems, optoelectronic multichip modules, and electronic system applications (55).

Metal-Bumped Flip Chip Joints. ICAs can also be used to form electrical interconnections with chips that have metal bumps. ICA materials utilize much high filler loading than ACAs to provide electrical conduction isotropically (ie in all directions) throughout the material. In order for these materials to be used for flip chip applications, they must be selectively applied to only those areas that are to be electrically interconnected. Also, the materials are not to spread during placement or curing to avoid creating electrical shorts between circuit features. Screen or stencil printing is most commonly used to precisely deposit the ICA pastes. However, to satisfy the scale and accuracy required for flip chip

bonding very accurate pattern alignment is required. To overcome this difficult requirement, Matsushita developed the transfer method (56).

Raised studs or pillars are required on either the die or the chip carrier. Matsushita uses a conventional ball bonder to form Au-stud bumps. Bumping is significantly faster than creating a complete wire bonds. A ball bumping process eliminates the need for traditional sputtering and plating processes used for standard bump formation. To prevent the bond area from becoming too large, the bumps are formed in a conical shape. The stud-bump bonding process is illustrated in Figures 15–18. The bumps are pressed level by a flat surface which adjusts both height and planarity. The ICA is selectively transferred on the bump tips by contacting the face of the die to a flat thin film of the ICA which is produced by screen printing and whose transfer thickness is controlled by changing the printed film thickness. Then the die is picked, aligned, and placed on a chip carrier. The whole assembly is exposed to heat to cure the ICA and form connections between the

die and chip carrier. Finally, an underfill (an insulating adhesive) is dispensed between the die and the chip carrier and cured. This method offers the options of oven curing an assembly since bonding pressure is not required. A specially formulated ICA is used to avoid silver migration, containing 20% palladium in a silver–palladium alloy. This is done to avoid silver migration. A schematic of the process flow of forming joints with stud-bumped flip chips using ICAs is shown in Figure 15.

Another process for bonding a flip chip with metal bumps consists of screen printing an ICA on a chip carrier, aligning and placing the chip, curing the ICA to form bonds, and underfilling. By using this approach, SINTEF Electronics conducted a comparison study between an ICA-bonded and solder-bonded flip chips on FR4 chip carrier with Ni/Au metallization. The number of thermal cycles (-55 to 125°C) to failure for both solder and ICA flip chip circuits was compared. The study showed that stable contacts could be maintained for at least 1000–2000

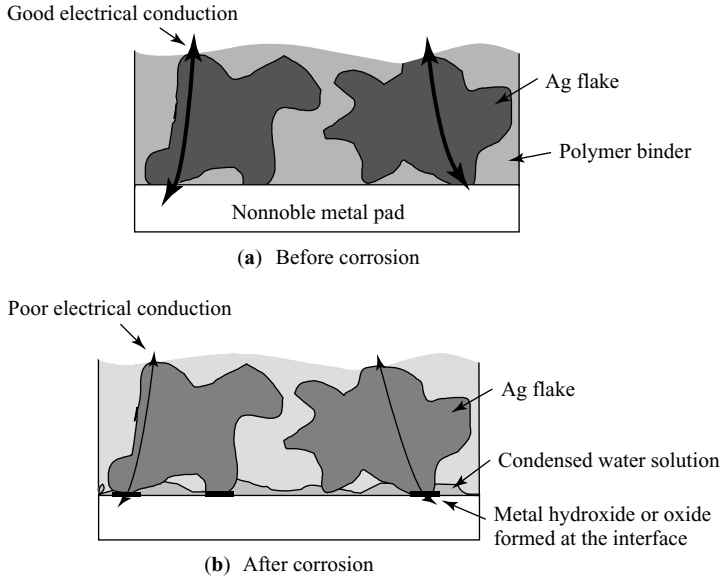

Fig. 17. Schematic depicting the effect of galvanic corrosion of a nonnoble metal pad on electrical conduction of a silver-filled ICA. (**a**) Good electrical conduction before corrosion. (**b**) Poor electrical conduction due to the formation of a metal hydroxide or oxide formation as a result of galvanic corrosion.

cycles for ICA flip chip joints. This is comparable to the lifetime for solder flip chip joints. However, the variation among ICA samples was very high and optimization of assembly processes is needed in order to achieve more reproduciable joint resistance (57).

Other Applications of ICAs

Surface Mount Applications. Tin–lead solders (Sn–Pb) are the standard materials used to interconnect electronic components on PCBs. The most common reflow soldering process is SMT which uses tin–lead solder pastes (58–61). The pressure to reduce the industrial use of lead is growing, particularly in Europe, since it poses as a hazard to human health (62).

Thus, the use of tin–lead solder paste in SMT processes must be reduced or eliminated to both satisfy legislative actions and market-driven pressures as well. Lead-free and environmentally sound interconnect bonding processes are urgently needed. Among the possibilities are ECAs and lead-free solders (63–65). Compared to soldering technology, ECA technology can offer numerous advantages such as fewer processing steps which reduces processing cost, lower processing temperature which makes the use of heat-sensitive and low cost chip carriers possible, and fine pitch capability (64).

However, conductive adhesive technology is still in its infancy, and concerns and limitations do exist. The main limitations of commercial ICAs include lower conductivity than that of solder materials, an unstable contact resistance with nonnoble metal finished components, and poor impact performance. The electrical conductivity ($\sim 10^4\ \Omega^{-1}\cdot cm^{-1}$) of an ICA is lower than Sn–Pb solders ($\sim 10^5\ \Omega^{-1}\cdot cm^{-1}$). Although generally adequate for most electronics applications, the electrical conductivity of ICAs must be improved. Contact resistance between an ICA and nonnoble metal (such as Sn/Pb, Sn, and Ni) finished components is noted to dramatically increase with time especially under elevated temperature and humidity aging conditions (66–69). In addition, PCB assemblies are often subject to significant mechanical shock during assembly, handling, and throughout their product life. Packages cannot survive without adequate impact resistance. However, most microelectronic commercial ICAs exhibit poor impact performance. Components assembled using ICAs tend to separate from the substrate when the package experiences a sudden shock (68,70). For conductive adhesive technology to provide an acceptable solution as a solder replacement, new conductive adhesives with the desired overall properties must be developed (68). There has been a considerable effort to improve the properties of ICAs and to make them more reliable materials. These improvements are described in the following sections.

CSP Applications. Matsushita Electric Industrial Co., Ltd., developed solderless joining technologies using nickel-filled ICAs to mount a ceramic chip scale package (CSP-C) onto a FR4 board (71). Nickel was selected instead of Ag because, unlike Ag, nickel does not migrate. A significant CTE mismatch existed between the CSP-C ceramic chip carrier (CTS = 7 ppm) and the FR4 organic chip carrier (CTE = 16 ppm). This CTE mismatch resulted in large stress to be generated within the solder joints during ATC testing which resulted in early failure due to solder fatigue. ICAs usually exhibit better thermomechanical properties than solders. Also, metal-migration between joints is a great concern because the joints in a CSP area array package are arranged with a close pitch (ie in close proximity).

The packaging procedure was as follows: (*1*) the ICA was screen-printed on the area array lands of the FR4 motherboard; (*2*) the CSP-C was mounted; (*3*) and the ICA was cured to form bonds. The Ni-filled conductive adhesive demonstrated

a much higher resistance to metal migration compared to Ag-filled IACs, and equivalent to solder joints. However, the thermal fatigue life of the Ni-filled ICA joints was five times greater than comparable solder joints.

Performance of ICAs

High Frequency Performance of ICA Joints. Only very limited work has been conducted to investigate the high frequency behaviors of ICA joints. Felba and co-workers (72) investigated a formulation of ICA that performed well as a solder replacement in microwave applications. The study involved in various different adhesive base materials and several types of main (silver flakes, nickel, and graphite) and additional (soot and silver semiflake powder) filler materials. In order to assess the usefulness of a given adhesive formulation, an additional gap in the gold strip of a standard microstrip bandpass filter was made and bridged by an adhesive bonded silver jumper. Both the quality factor (Q) and loss factor (L) of the filter with the bonded jumper were measured at a frequency of 3.5 GHz in a preliminary experiment and at 3.5 and 14 GHz in a final experiment. It was determined that silver flake powders are the best filler materials for ICA for microwave applications because ICAs filled with the silver flake powders exhibit the highest Q-factor and lowest L-factor. Also, addition of soot should be avoided since it decreases the quality factor (72).

A study was made at Georgia Tech, of a flip chip test vehicle mounted on a FR4 chip carrier with a gold-plated copper transmission lines (73). The performance of eutectic Sn–Pb and ICAs were evaluated and compared using this test device. Both ICAs and eutectic Sn–Pb solder were determined to exhibit almost the same behavior at a frequency range of 45 MHz to 2 GHz and the measured transmission losses for both materials were minimal. It was also found that the S_{11} characteristics of both Sn–Pb and ICAs after exposure to 85°C/85% RH aging for 150 h did not vary from the previous signals prior to aging, but S_{12} value of the Sn–Pb joints deviated more than that of ICA joints after the aging.

Fatigue Life of ICA Joints. There have been several studies investigating the fatigue life of ICA joints. Aiming to understand the performance of ICA interconnects under fracture and fatigue loading, Constable and co-workers (74) investigated performance of ICA interconnects under fracture and fatigue loading by monitoring resistance changes (microohm sensitivity) of ICA joints during pull and fatigue testing (cyclic loading up to 1000 cycles). Observation of the fracture surface suggested that the ICA joint life depended upon the adhesive failure of the bond to the metal surface. It was observed that fracture strains for the ICAs were in the range of 20–38%, and resistance remained approximately constant in the elastic region, but the resistance started to increase rapidly as soon as the pull-force departed from linear elastic behavior. For fatigue tests, linear displacement was ramped up the preprogrammed maximum displacement and ramp back to the starting position. It was observed that the shear strain for ICA joints surviving 1000 cyclic loading was typically 10%, which is about an order of magnitude greater than solders. This suggests that using conductive adhesives may be advantageous for some flip chip. It is believed that since silver filler particles of

ICAs cannot accommodate this large strain, the silver filler particles must move relative to one another as the epoxy matrix is strained. The most common pattern of resistance change was only increased to a point corresponding to about a 70% loss in interface contact resistance before sudden failure. This was an indication that the interface crack slightly propagated into the adhesive (74).

In an effort to gain a fundamental understanding of the fatigue degradation of ICAs, Gomatam and co-workers (75) studied the behavior of ICA joints under temperature and humidity conditions. The fatigue life decreased at elevated temperature and high humidity conditions. It was also observed that the fatigue life of the ICA joints decreased considerably as the temperature cycle frequency was decreased. This effect was attributed to the fact that as the frequency was decreased, the propagating crack was exposed to higher loads for longer periods of time, effectively resulting in high creep loading (75).

Improvement of Electrical Conductivity of ICAs

Electrical conductivity of ICAs is inferior to solders (76). Even though the conductivity of ICAs is adequate for most applications, a higher electrical conductivity of ICAs is still needed. To develop a novel ICA for modern electronic interconnect applications, a thorough understanding of the materials is required.

Eliminate Lubrication Layer. An ICA is generally composed of a polymer binder and Ag-flake filler material. A thin layer of organic lubricant is present on the surface of the Ag flakes. This lubricant layer plays an important role in the performance of ICAs, including the dispersion of Ag flakes in adhesives, and the rheology of the adhesive formulations (45,76–78). The organic layer consist of a Ag salt formed between the Ag surface and the lubricant, which typically is a fatty acid such as stearic acid (78,79). This lubricant layer affects the conductivity of an ICA because it is electrically insulating (78,79). To improve conductivity, the organic lubricant layer must be partially or fully removed through the use of chemical substances that can dissolve the organic lubricant layer (78–80). However, the viscosity of an ICA paste may increase if the lubricant layer is removed. An ideal chemical substance (or lubricant remover) should be latent (does not remove the lubricant layer) at room temperature, but be active (capable of removing the lubricant layer) at a temperature slightly below the cure temperature of the polymer binder. The lubricant remover can be a solid short-chain acid, a high-boiling-point ether such as diethylene glycol monobutyl ether or diethylene glycol monoethyl ether acetate, and a polyethylene glycol with a low molecular weight (78–80). These chemical substances can improve electrical conductivity of ICAs by removing the lubricant layer on the Ag-flake surfaces and providing an intimate flake–flake contact (78,79).

Increase Shrinkage. In general, ICA pastes exhibit low electrical conductivity before cure, but the conductivity increases dramatically after they are cured. ICAs achieve electrical conductivity during the cure process, mainly through a more intimate contact between Ag flakes caused by the shrinkage of polymer binder (81). Accordingly, ICAs with a high cure shrinkage generally exhibit the best conductivity. Therefore, increasing the cure shrinkage of a polymer binder is another method for improving electrical conductivity. For ICAs based on epoxy

resins, a small amount of a multifunctional epoxy resin can be added into an ICA formulation to increase cross-linking density, shrinkage, and thus increase conductivity (81).

Apply Electric Field. The electrical conductivity of ICAs can be improved significantly by applying an electrical field before or while curing them. However, the exact reasons for this improvement are not yet clear (82).

Transient Liquid Phase Fillers. Another approach for improving electrical conductivity is to incorporate transient liquid-phase sintering metallic fillers in ICA formulations. The filler used is a mixture of a high-melting-point metal powder (such as Cu) and a low-melting-point alloy powder (such as Sn–Pb). The low-melting-alloy filler melts when its melting point temperature is achieved. The liquid phase dissolves the high-melting-point particles. The liquid exists only for a short period of time and then forms an alloy and solidifies. The electrical conduction is established through a plurality of metallurgical connections formed *in situ* from these two powders in a polymer binder. The polymer binder fluxes both the metal powders and the metals to be joined and facilitates the transient liquid bonding of the powders to form a stable metallurgical network for electrical conduction, and also forms an interpenetrating polymer network providing adhesion (Fig. 16). High electrical conductivity can be achieved using this method (83–85). The ICA joints formed include metallurgical alloying to the junctions as well as within the adhesive itself. This provides a stable electrical connection during elevated temperature and humidity aging. In addition, the ICA joints showed good impact strength due to the metallurgical interconnection between the conductive adhesive and the components. One critical limitation of this technology is that the numbers of combinations of low melt and high melt fillers are limited. Only certain combinations of two metallic fillers which are mutually soluble exist to form this type of metallurgical interconnections.

Improvement of Contact Resistance Stability

Contact resistance between an ICA (generally a Ag-flake-filled epoxy) and nonnoble metal finished components increases dramatically during an elevated temperature and humidity aging, especially at 85°C/85% RH. The National Center of Manufacturing and Science (NCMS) defined the stability criterion for solder replacement conductive adhesives as a contact resistance shift of less than 20% after aging at 85°C/85% RH conditions for 500 h (67).

Causes for Resistance Increase. Two main mechanisms, simple oxidation and corrosion of the nonnoble metal surfaces, have been proposed in the literature as the possible causes for the increase in contact resistance of ICA joints during elevated temperature and humidity aging. Simple oxidation of the nonnoble metal surfaces is claimed to be the main reason for the observed increased resistance. Corrosion is claimed to be the possible mechanism for resistance increase only by several investigators (65,66,68,86,87). One study strongly indicates that galvanic corrosion rather than simple oxidation of the nonnoble metal at the interface between an ICA and nonnoble metal is the main reason for the shift in contact resistance of ICAs (Fig. 17) (88,89). The nonnoble acts as the anode, and is reduced to a metal ion ($M - n\,e^- = M^{n+}$) because of the loss of electrons. The

noble metal acts as a cathode, and its reaction generally is $2\ H_2O + O_2 + 4\ e^- = 4\ OH^-$. Then M^{n+} combines with OH^- to form a metal hydroxide or metal oxide. As a result of this electrochemical (corrosion) process, a layer of metal hydroxide or metal oxide is formed at the interface which is electrically insulating, causing the contact resistance to increase dramatically (88,89).

Prevention. Galvanic corrosion requires the presence of moisture. An electrolyte solution must be formed at the interface before galvanic corrosion can occur. Therefore, one way to prevent galvanic corrosion at the interface between an ICA and the nonnoble metal surface is to lower the moisture pickup of the ICA. ICAs that have a low moisture absorption generally exhibit more stable contact resistance on nonnoble surfaces compared with those with high moisture absorption (90,91). Without the electrolyte, galvanic corrosion rate is very low. The electrolyte in this case is mainly from the impurity of the polymer binder (generally epoxy resins). Therefore, ICAs formulated with high purity resins should perform better.

Use of Corrosion Inhibitors. Another method of preventing galvanic corrosion is to introduce organic corrosion inhibitors into ICA formulations (89–92). In general, organic corrosion inhibitors act as a barrier layer between the metal and environment, forming a film over the metal surfaces (93–96). Some chelating compounds are especially effective in preventing metal corrosion (95). Most organic corrosion inhibitors react with the epoxy resin at a specific temperature. Therefore, if an ICA is epoxy-based, the corrosion inhibitors must not react with the epoxy resin during curing, which would cause them to be consumed and lose their effect. Organic corrosion inhibitors are thoroughly discussed in the literature (94,96). Figure 18 shows the effect of a chelating corrosion inhibitor on the contact resistance between an ICA and a Sn–Pb surface. It can be seen that this corrosion inhibitor is very effective in stabilizing the contact resistance.

Use of Oxygen Scavengers. Since oxygen accelerates galvanic corrosion, oxygen scavengers can be added into ICA formulations to slow down the corrosion rate (93). When oxygen molecules diffuse through the polymer binder, they react with the oxygen scavenger and are consumed. However, when the oxygen scavenger is completely depleted, then oxygen can again diffuse into the interface and accelerate the corrosion process. Therefore, oxygen scavengers can only delay the galvanic corrosion process. Similar to corrosion inhibitors, the oxygen scavengers used must not react with the epoxy resin at its cure temperature. The common oxygen scavengers utilized are listed below (93,97–100):

(1) hydrazine
(2) carbohydrazide
(3) hydroquinone
(4) oximes
(5) gallic acid
(6) propyl gallate
(7) hydroxylamines and related compounds
(8) dihydroxyacetone
(9) 1,2-dihydro-1,2,4,5-tetrazines
(10) erythorbic acid

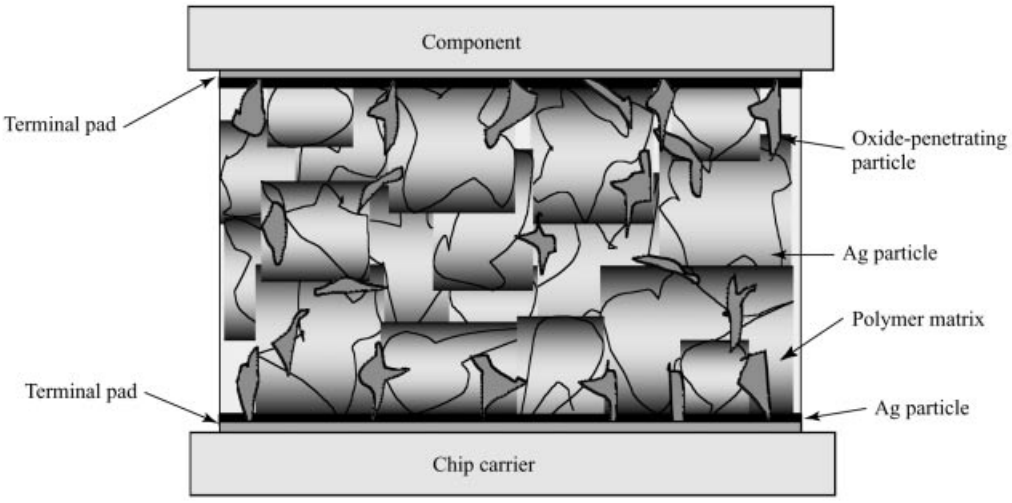

Fig. 19. Schematic depicting an ICA joint containing oxide-penetrating particles and silver filler particles.

Sharp-Edge Filler Particles. Another approach of improving contact resistance stability during aging is to incorporate some electrically conductive particles, which have sharp edges and referred as oxide-penetrating fillers, into the ICA formulations. Force must be provided to drive the oxide-penetrating particles through the oxide layer of adjoining particles and metal pads, and keep them in position. This can be accomplished by employing polymer binders that show high shrinkage when cured (Fig. 19) (101). This concept is used in Poly-Solder which has good contact resistance stability with standard surface-mounted devices (SMDs) on both solder-coated and bare circuit boards (101).

Improvement of Impact Performance

The ability to resist a performance degradation when subjected to mechanical shock is a critical property that solder replacement ICAs must possess. There are ongoing efforts to develop ICAs that exhibit acceptable impact strength, ie capable of passing the standard drop test used to evaluate the impact strength of components attached to a PCB. Among the methods are:

(1) Decrease in the filler loading to improve the impact strength (102), and reduction in the electrical conductivity of the conductive adhesives. A development was reported where conductive adhesives were formulated using low modulus resins that absorb the impact energy developed during a drop (103), but the electrical properties was not noted.
(2) Conformal coating of the SMDs to improve mechanical strength. A study demonstrated that a conformal coating improved the impact strength of conductive adhesives joints (104).

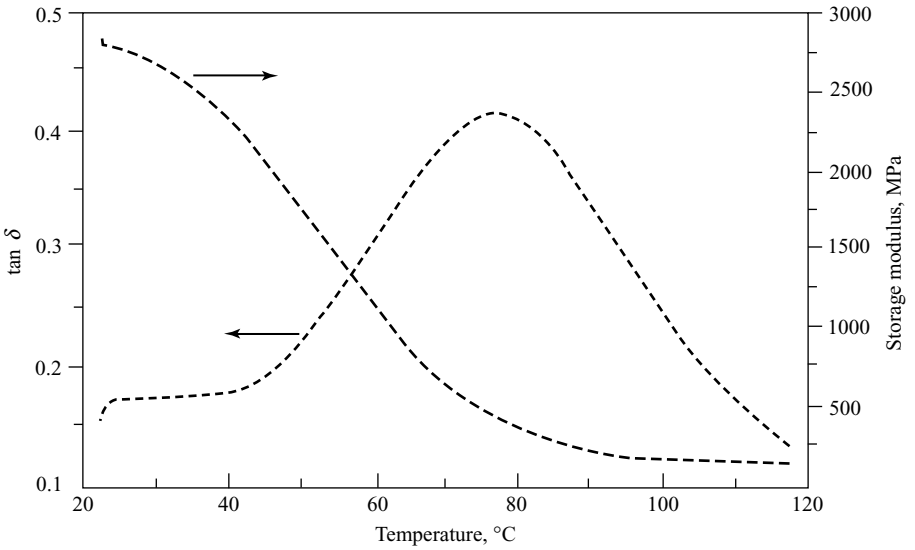

Fig. 20. Changes of tan δ and the storage modulus with temperature of an ETPU-based conductive adhesive as measured by a dynamic mechanical analyzer. To convert MPa to Psi, multiply by 145.

Epoxide-Terminated Polyurethane Systems. A class of conductive adhesives based on an epoxide-terminated polyurethane (ETPU) has been developed (105,106). This class of conductive adhesives exhibits properties typical of polyurethane materials, such as high toughness and good adhesion. The modulus and glass-transition temperature of an ICA can be adjusted by incorporating epoxy resins such as bisphenol-F epoxy resins. Conductive adhesives based on ETPU exhibit a broad loss factor (tan δ) peak with temperature changes and a high tan δ value at room temperature. The tan δ value of a material is a good indication of the damping property and impact performance of a material. In general, the higher the tan δ value, the better the damping property (impact strength) of the material. As an example, changes in tan δ and storage modulus with temperature of an ETPU-based ICA are shown in Figure 20. ICAs based on ETPU resins also exhibit a much higher loss factor over a wide frequency range compared to ICAs based on bisphenol-F epoxy resins (Fig. 21). This indicates that ICAs based on ETPU resins should exhibit good damping property and improved impact performance in a variety of electronic packages. This class of conductive adhesives has demonstrated superior impact performance and a substantial improvement in contact resistance stability with nonnoble metal surfaces, such as Sn–Pb, Sn, and Cu (105,106).

Future Challenges

Anisotropically Conductive Adhesives. Significant research has been conducted on ACAs as a potential solder replacement for some electronics packaging applications. However, many aspects of this technology must be better

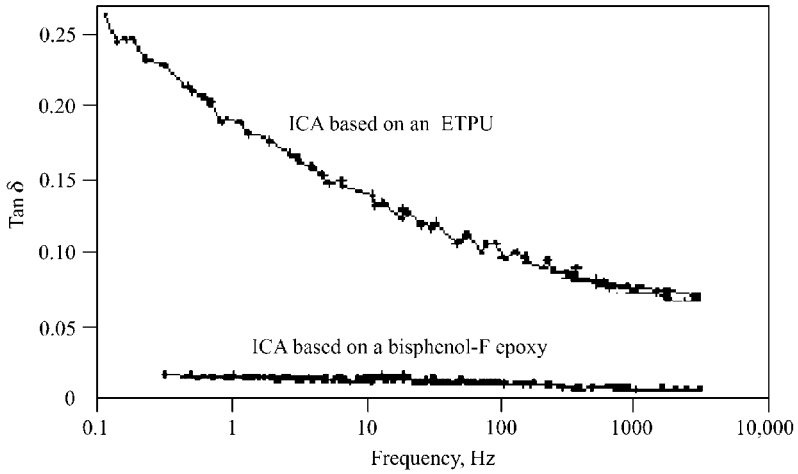

Fig. 21. The effect of frequency on the loss factor for two ICA materials.

understood before it can be widely used to replace lead-bearing solders. Some critical issues that must be addressed in the future are discussed below:

Materials Development. Develop new ACA materials that have good adhesion, high T_g, fast curing, storage stability at ambient, and stable contact resistance after various conditions frequently encountered in the field such as thermal aging and cycling, thermal shock, high temperature/high humidity/bias, etc. Also, ACAs with low CTE are required. Commercially available ACAs typically exhibit very high CTEs because of the low filler loading levels utilized. Some preliminary studies have shown that ACAs with a low CTE created by introducing nonconductive silica fillers have a lower shear strain and better contact resistance stability during thermal cycling test (107).

High Frequency Compatibility. The number of high frequency applications and utilizations are increasing rapidly; thus it is important to characterize the cross talk between particles, coupling with semiconductor devices, and other fundamental behavior of ACAs under high frequency conditions. It is also necessary to maximize the current carrying capability of ACAs at high frequency range, and after exposure to various environment tests.

Reliability. It is necessary to understand the effect of the chip carrier material on ACA join reliability. This is a key issue before ACA technology is widely utilized in manufacturing (ie in high volume and low cost applications). It is also necessary to establish failure rate prediction models for ACA joints for a wide variety of field conditions. It is essential to gain full understanding on effects of high current and high power on ACA joints, degradation, and stress relaxation of polymeric matrices; and the effects of temperature, humidity, and other environments on matrix materials and the effects of fillers.

Isotropically Conductive Adhesives. There have also been a significant number of studies to improve ICA technology. However, several critical issues associated with this technology must also be addressed before it can be used as a replacement for soldering technology:

Electrical Characteristics. The electrical conductivity of ICAs must be vastly improved since their electrical conductivity is typically 1 or 2 orders of magnitudes lower than that of solders. Silver-filled ICAs achieve their electrical conductivity through a physical contact among the Ag flaks. Because of the high particle–particle contact resistance, ICAs exhibit a high bulk resistivity. Although some preliminary work has been done to improve electrical conductivity by introducing low-melting-point alloys which form metallurgical interconnetions with the Ag flakes, additional work is necessary to achieve the desired electrical conductivity. Also, the behavior of ICA joints under high current or high power conditions, and high temperature/humidity/bias is not clear.

High Frequency Performance. The high frequency behavior of ICAs over a wide frequency range must be investigated and compared to that of solders.

Reliability. Silver-filled ICAs have a potential for silver migration, which cause electrical shorts especially in fine pitch applications. A palladium-treated silver filler exhibited a much improved antimigration characteristics compared to standard silver-filled ICAs. However, the preparation of the Pd-coated silver particles is expensive. Some low cost approaches must be developed. More comprehensive understanding of the fatigue resistance of ICA joints is required. Activities in this area have been limited and nonconclusive.

Manufacturability and Yields. Since most commercial ICAs are epoxy based, they are thermosetting materials and thus not reworkable. ICAs with reworkability must be developed by using thermoplastic or thermally degradable resins. Because of their high surface tension, SnPb solders have a self-alignment capability during solder reflow operations. However, conventional ICAs cannot self-align. Therefore, components that are bonded using ICAs require a high placement accuracy. Some preliminary research has been conducted to improve the self-alignment capability of ICAs (108,109), but much more work needs to be done.

Conductive Polymer Composites with Large Positive Temperature Coefficient

Conductive polymer composites (110,111) that contain conductive fillers such as metal powder, carbon black, and other highly conductive particles in a nonconductive polymer matrix have been widely used in electrostatic dissipation (ESD) and electromagnetic interference shielding (EMIS). A special group among electrically conductive polymer composites are conductive polymer composites that have large positive temperature coefficients (PTCs), which in some cases are called positive temperature coefficient resistance. The resistivity of this kind of composite increases several orders of magnitude in a narrow temperature range, as shown in Figure 22. The transition temperature (T_t) is defined by intersection between the tangent to the point of inflection of the resistivity versus temperature curve and the horizontal from the resistivity at 25°C (ρ_{25}). This kind of smart material can change from a conductive material to an insulating material or vice versa upon heating or cooling, respectively. The smartness of this kind of material not only lies in this large PTC amplitude (defined as the ratio of maximum resistivity at the peak or the resistivity right after the sharp increase to the resistivity at

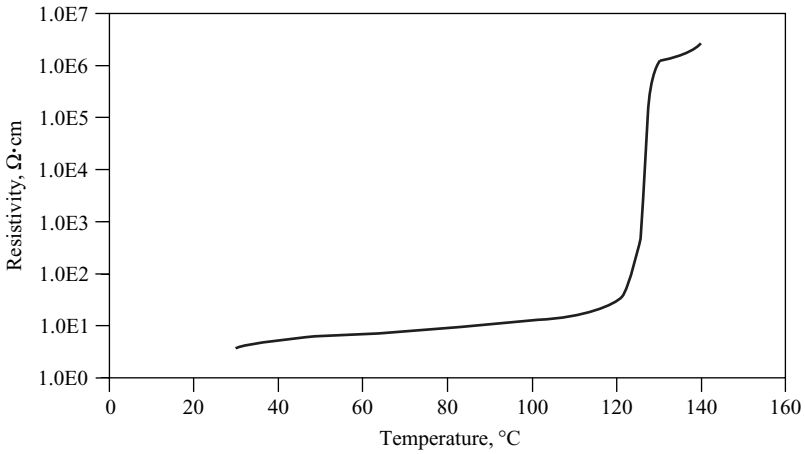

Fig. 22. Resistivity versus temperature behavior of a conductive polymer composite that has a large PTC.

25°C), but also in its reversibility, its ability to adjust the transition temperature, low temperature resistivity, and high temperature resistivity. PTC behavior in a polymer composite was first discovered by Frydman in 1945 (112), but not much attention was paid to it originally. Because Kohler obtained a much higher PTC amplitude from high density polyethylene filled with carbon black in 1961 (113), this kind of temperature-sensitive materials has aroused wide research interest and also led to many very useful applications. In this review, the general theories of PTC conductive polymer are introduced. Carbon-black-filled conductive polymer composites and their PTC behavior are discussed in more detail, in regard to the effects of fillers, the polymer matrix, processing conditions, and additives. At the end, applications of this kind of smart temperature-sensitive material are presented.

Basic Theory of Conductive Polymer Composites and PTC Behavior. The conductivity of polymer composites that contain conductive particles dispersed in a polymer matrix may result from direct contact between conductive particles and electron tunneling. The conductivity of a highly filled conductive adhesive is due to the former mechanism. Matsushige used atomic force microscopy to study the conduction mechanism in a PTC composite on a nanoscale (114). It was proposed that electron tunneling or hopping through the conductive carbon particles in the polymer matrix might be the governing mechanism for organic PTC materials.

There are two very simple mechanisms for small PTC behavior of conductive polymer composites: reduction of the contact area of neighboring conductive particles and an increase in the junction distance in electric tunneling when heated. Although the large PTC phenomenon is well known, its mechanism has not been fully understood. Different theories have been proposed (113,115,116) to explain the large PTC behavior.

Kohler (113) suggested that the PTC is due to the difference in thermal expansion of the materials. His theory was supported by some other researchers

in percolation theory (110). The conductivity of conductive polymer composites increases as the volume fraction of the conductive filler increases. For a polymer filled with conductive particles, a critical volume fraction of filler may exist, which is called the percolation volume fraction. The resistance of the conductive polymer composite whose filler volume fraction is higher than the percolation volume fraction is several orders of magnitude less than that of the composite whose filler volume faction is less than the percolation volume fraction. In the region of low filler concentration, the filler particles are distributed homogeneously in the insulating polymer matrix. There is no contact between adjacent filler particles. The resistance decreases slowly as the volume fraction of filler particles increases. As the filler concentration further increases, filler particles begin to contact other particles and agglomerate. At a certain filler concentration, the growing agglomerates form one-, two-, or three-dimensional network of the conducting phase within the insulating polymer matrix. At this range, the resistivity of the mixture shows a deep decrease to the low value of the conductive network. After the formation of the continuous conductive network, the resistivity of the mixture increases slowly because of the slightly improved quality of the conductive network as the filler content increases.

Many models have been proposed (117) to explain the electrical conductivity of mixtures composed of conductive and insulating materials. Percolation concentration is the most interesting of all of these models. Several parameters, such as filler distribution, filler shape, filler/matrix interactions, and processing technique, can influence the percolation concentration. Among these models, the statistical percolation model (118) uses finite regular arrays of points and bonds (between the points) to estimate percolation concentration. The thermodynamic model (119) emphasizes the importance of interfacial interactions at the boundary between individual filler particles and the polymeric host in the network formation. The most promising ones are the structure-oriented models, which explain conductivity on the basis of factors determined from the microlevel structure of the as-produced mixtures (120).

Because the thermal expansion coefficient of a polymer matrix is generally higher than that of the conductive particles, the volume fraction of a conductive filler in conductive polymer composite decreases as temperature increases; thus, the resistivity increases. If a conductive polymer composite is made of semicrystalline polymer as an insulator and a filler of conducting particles, whose concentration is just above the percolation volume fraction, the relatively large change in specific volume of the polymer at its melting temperature may bring the volume fraction of the conductive filler down below the critical volume fraction when the composite is heated beyond the melting temperature of the polymer crystal. Thus, the resistivity increases greatly. Kohler's theory cannot explain the very small rise in resistance exhibited by such filled polymer systems when they are strained to an amount equivalent to that found at the crystalline melting point. And the PTC amplitude should be a direct function of volume change according to Kohler's theory; however, it is not the case in reality.

Ohe proposed a more complex theory (115). He stated that PTC phenomenon could be explained by the increase of the intergrain gap among the carbon black particles caused by thermal expansion. He visualized that the distribution of the intergrain gaps in conductive composite is rather uniform at low temperature,

and the gap is small enough for extensive tunneling to occur, but the distribution at high temperature becomes random due to thermal expansion. Although the average gap distance does not change greatly, the presence of a significant amount of gap distance too large to allow electron tunneling will result in a great increase in resistance.

Meyer's theory was based on the assumption that a thin (300 Å) crystalline film of polymer is much more conductive than an amorphous film of polymer. It was shown that carbon black particles remain in the amorphous region between crystallites in a conductive composite. The high conductivity at low temperature is due to tunneling through the thin crystallite, and the PTC phenomenon is caused by a preliminary change in state of these crystallites just before the crystalline melting point that leads to a sharp reduction in the ease of tunneling and thus much higher resistivity.

Large thermal expansion during crystal melting surely contributes to a large amplitude of PTC behavior. But it contributes only to a limited level. Ohe's vision of the change from uniform distribution of carbon particle to random distribution is groundless and cannot be justified. Actually, as is shown later, cross-linking can eliminate the redistribution of carbon black after melting and stabilizes PTC behavior. PTC behavior takes place at the same time as melting, rather than before crystalline melting, as stated by Meyer. It probably is true that tunneling is easier in a crystalline region than in an amorphous region. The difference is probably due to polymer chain mobility. The work function of the conductive particle at the interface between the conductive particle and polymer matrix may increase after crystal melting due to the high mobility of the polymer chain. The same theory can explain PTC behavior in conductive polymer composites as well as the conductivity phenomenon in an ECA after curing (80). Before conductive adhesive is cured, the resin matrix has high mobility and prohibits tunneling between conductive particles. After curing, the mobility of the polymer chain is greatly reduced and thus allows tunneling between conductive particles.

Effect of Conductive Fillers on PTC Conductive Polymer. Different conductive fillers have been used as in PTC conductive polymers. Metallic powders that are stable at high temperature, such as tin, gold, and silver, were suggested as conductive fillers in PTC materials (121). In addition, ceramic powder such as tungsten carbide was also used as a filler in PTC conductive polymer composites (122). It was found that V_2O_3 has several phase transitions (110). At 160 K, it is transformed from an antiferromagnetic insulator (AFI) to a paraelectric metallic conductor (PMC), accompanied by a resistivity change from 10^5 to 10^{-2} Ω·cm. At 400 K, it changes from a PMC to a PI (paraelectric insulator) whose resistivity is $10^3 - 10^4$ Ω·cm. Most interestingly, low density polyethylene filled with V_2O_3 shows a square well in the resistivity versus temperature profile by combining a sharp NTC (negative temperature coefficient) around −110°C, and a sharp PTC around 100°C (110,123–125). A PTC transition temperature of conductive polymer composites filled with V_2O_3 was also reported in other polymer system (121,122). The T_t of a V_2O_3-filled system changes in the following manner: 100°C (low density polyethylene) < 150°C (polypropylene) < 260°C (polytetrafluoroethylene). However, the fillers mentioned before are expensive. Work has been done to develop alternative less expensive PTC conductive polymer composites. Most

of the conductive polymers for ESD and EMIS applications are thermoplastics filled with carbon black or carbon graphite because of their very low cost. Carbon black is also one of the major fillers used in so-called PTC conductive polymers (126–128).

There are several important parameters of carbon black (129): particle size (surface area), aggregate structure (carbon black particles aggregate to form a grapelike structure), porosity, crystallinity, and surface functionality. Small particle size and high structure lead to more difficult dispersion. The initial grapelike structure of carbon black formed during the manufacturing of carbon black is highly stable and can be destroyed only by very intensive processing such as grinding in a ball mill. For a given loading of carbon black, a smaller particle size would add more particles to the composite than that using carbon black of larger particle size. Thus, carbon blacks of smaller particle size would produce a composite that has a smaller separation between carbon particles (as well as the probability of more carbon particles in contact), resulting in greater conductivity. Small particle size gives a low critical volume for a carbon-black-filled polymer system (110). However, for fiberlike conductive fillers, large filler particles favor the formation of conducting paths at a low percolation concentration. High structure carbon blacks tend to produce a larger number of aggregates in contact, as well as smaller separation distances that result in greater conductivity. For a given carbon black loading, the more porous carbon black generally provides a larger number of aggregates to the composite. This results in a smaller interaggregate distance and higher conductivity. The increase in the degree of carbon black structuring is found more efficient than the increase of the specific surface of carbon black in conductive polymers. Carbon blacks that have higher oxygen content carbon particles have higher resistance. Removal of the surface oxides increases the conductivity of the original carbon black much more than heat treatment to produce graphitization. Higher graphite content in carbon black leads to higher electrical conductivity.

Although carbon black of small particles size and high aggregated structure (such as BP2000 with a average particle diameter of 12 nm manufactured by Cabot Corp.) can give polymer composites that have low resistivity, this kind of composite does not show large PTC amplitude because the aggregated structure cannot be broken down by the thermal expansion of the polymer (Fig. 23). On the contrary, a polymer composite filled with carbon black that has a large particle size and low aggregate structure (such as N660 with an average particle diameter of 70 nm manufactured by Columbia Chemicals) shows high room temperature resistivity, but high PTC amplitude (130). To obtain a PTC conductive polymer composite that has both lower room temperature resistance and high PTC transition amplitude, porous carbon black is much better than nonporous carbon black. Ueno and coworkers reported that etching a carbon black at an elevated temperature to remove the less crystalline portion and therefore to increase the surface area can improve the PTC characteristics of a conductive polymer filled with carbon black, and this material was suitable for use as a resettable fuse (126).

The PTC amplitude depends on the loading of carbon black. It was shown that for different carbon blacks, a different loading exists at which the composite has a maximum PTC amplitude (131). The carbon black concentration that gives the

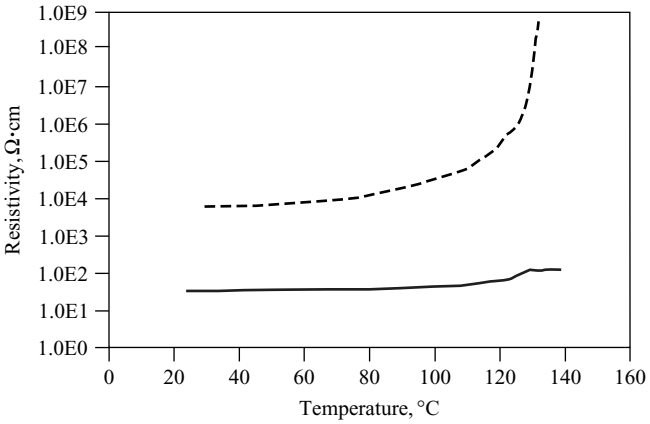

Fig. 23. Resistivity versus temperature of conductive polymer composite with different carbon blacks (the weight percentage of carbon black is 30). —— Filled with BP2000 carbon black; - - - - filled with N660 carbon black.

optimum PTC intensity can be predicted approximately from room temperature data (132).

Effect of Polymer Matrix on PTC Behavior. Polymers used as the matrix in electrically conductive polymer composites can vary from elastomers to thermoplastics and thermosets that have crystallinity varying between 0 and 80%. As mentioned in the previous section, the large PTC anomaly is due to the large thermal expansion of the polymer matrix, especially during melting of a polymer crystal. The PTC transition temperature is determined by the melting point of the polymer matrix. Because polymers that have low and high melting points are available for use in conductive polymer composites, the transition temperature can be controlled by selecting and compounding the matrix polymer for different applications that require different transition temperatures (133). A PTC conductive composite based on high density polyethylene whose melting peak temperature is 129–131°C and whose specific volume increases by approximately 10% due to melting across a narrow temperature range showed a maximum resistivity at 129–131°C (130). The transition temperature can be slightly adjusted by using a copolymer or polymer blend that has more than one homopolymer. A compound of 40 parts weight of carbon black, 60 parts of melted olefin copolymer (ethylene–ethyl acrylate copolymer), and an organic peroxide, had a T_t of 82°C (114). Another reported recipe (134) is a composite of carbon black dispersed in high density polyethylene and poly(ethylene vinyl acetate), whose T_t is 120°C. Ultrahigh molecular weight polyethylene reportedly enhanced the PTC behavior (127). Thermosetting material such as thermosetting polyester resin that was cross-linked by a free-radical reaction, was also reportedly used as a polymer matrix for a PTC conductive polymer composite (135).

The PTC amplitude depends on crystallinity. Meyer (136) showed that crystalline *trans*-polybutadiene filled with carbon black has low room temperature resistivity and a significant anomaly, whereas the amorphous *cis*-polybutadiene filled with the same amount of carbon black has much higher resistivity and no

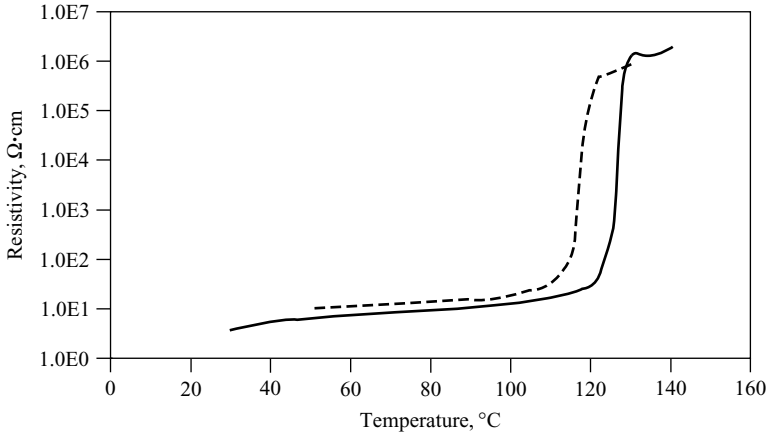

Fig. 24. Resistivity versus temperature for a PTC conductive polymer composite during heating and cooling cycles. —— Heating; - - - - cooling.

anomaly. Within a polymeric family, a polymer that is more crystalline has higher PTC amplitude. But different classes of polymers that have the same crystallinity do not exhibit identical PTC behavior and no relationship was correlated. PTC amplitude depends on polymer type. PTC amplitude increases in the following order with respect to the polymer matrix: nylon-6,6 < polypropylene < polyethylene oxide < low density polyethylene < high density polyethylene.

As mentioned before, the mechanism for the PTC anomaly in semicrystalline polymer composites is accompanied by a relatively large change in specific volume of the polymer at its melting temperature. The resistivity versus temperature curve can be well matched by the specific volume–temperature curve. Crystallization during cooling of a polymer is the reverse of melting of polymer crystal during heating. The PTC transition of this kind of smart material is reversible. During cooling, the same material shows a sharp decrease in resistivity, as shown by Figure 24. The thermal expansion of a polymer depends on its heating and cooling cycle. Because the melting temperature of a polymer crystal is always higher than the recrystallization temperature, the PTC transition of a conductive polymer composite is always higher in the heating cycle than that during the cooling cycle (110). The difference is about 18°C for polyethylene, 34°C for polyoxymethylene, and 50°C for polypropylene. Actually, all factors that affect the melting and recrystallization behavior, such as pressure and heating and cooling rates, influence the PTC behavior of a conductive polymer composite. Meyer showed that the PTC transition temperature increases and PTC amplitude decreases as the pressure increases (136).

In some conductive polymer composites, the NTC effect follows, for example, the resistivity decreases as the temperature increases further after PTC transition. The NTC effect is probably due to the reorientation, reaggregation, or reassembling of carbon black. Initially dispersed particles may become mobile in the temperature range of polymer melting to repair the broken percolation network. The measurement of resistance versus the temperature behavior of the conductive

composite was repeated for the same sample(134,137). Tang (134) observed that the PTC intensity and the base resistance decrease with thermal cycles. The reason is obviously reorganization of carbon at the high temperature.

Radiation was used to cross-link a carbon-black-filled conductive polymer composite. The NTC effect can be alleviated or reduced by cross-linking, and the PTC amplitude is stabilized (the resistance at lower temperature is stabilized) after cross-linking (110,134). The organization of carbon black is hampered in a cross-linked polymer network.

Effect of Processing Conditions and Additives. The effect of mixing time on the resistivity–temperature behavior was also investigated (134). Both the PTC effect and the reproducibility were improved greatly when the sample was mixed for a long time. It was suggested that the improvement is due to increasing absorption of the polymer on the carbon black surface and this absorption forms a polymer layer outside the carbon black particle. The room temperature resistivity increases with mixing time at constant carbon black concentration. It can also be explained that structures are broken down during mixing; thus, the resistivity increases. If the power consumption during mixing is too high, the composition would have too high resistivity at a temperature below T_g and have unsatisfactory electrical stability on aging at elevated temperature. If the power consumption is too low, it can also result in a composition that has a low PTC amplitude.

Tang (134) studied the effect of the interaction between carbon black and the polymer on electrical behavior. The absorption of polymer on the carbon black surface may be physical or chemical. The latter is caused by free-radical reaction between the polymer and carbon black, and it can occur during radiation or the preparation of the composite. In carbon-black-filled high density polyethylene, the cross-linked network of the polymer restricts the freedom of movement of carbon black. The free-radical reaction enhances the binding force between the polymer and carbon black.

Polymeric materials may be broken down under high voltage. The voltage stability of a cross-linked PTC conductive polymer is improved by incorporating a polymerizable monomer such as triallyisocyanurate before it is cross-linked (138). Antimony oxide, which does not degrade the PTC characteristics, can be used as a flame-retardant agent (121). A semiconductive inorganic substance such as silicon carbide or boron carbide was used to improve the high voltage stability (139). Alumina trihydrate can be added to a PTC conductive polymer composite to prevent dielectric breakdown, arcing, and carbon tracking under high voltage (138).

Application of PTC Conductive Polymer Composite. There are many applications for PTC conductive polymer composites, including thermistors (122), circuit protection devices (140), and self-regulating heaters (141). Because the material both heats and controls the temperature, it can be used to manufacture a self-regulating heating device. As the temperature increases, the resistance increases, and thus the power decreases. This kind of self-regulating heater can be used to prevent freezing of water and pipes used in chemical processing. It has also been used to manufacture a heater for heating a hot-melt adhesive to seal a cable splice case (142) as well as a hair curler (143). Self-regulating heaters can be

manufactured into different forms. The blanket form of PTC conductive polymer composite can allow precise temperature control across larger areas. This kind of device has been used in the repair of thermally complex aircraft structures (141,144).

Another application of PTC conductive polymers is in over-temperature and over-current protection. A device manufactured from a PTC conductive polymer composite has low resistance and much less resistance than the rest of the circuit; thus it has no influence on normal performance. But at high temperature, these devices become highly resistant or insulating; thus they dominate the circuit, reduce the current, and protect the circuit. For large abnormal current, the device can rapidly self-heat to a high resistance state, and thus reduces the current. The smartness lies in the over-temperature and over-current protection and also lies in its resettability. After the current drops and the temperature of the device decreases, the device returns to a low resistance state and allows current to pass. A resettable fuse made from a PTC conductive polymer has been on the market. This kind of resettable fuse has been used in battery chargers to terminate the charging function based on the battery temperature and protect the battery from overheating. It is also used in telecommunication equipment, computers, and power supplies.

Summary. A temperature-sensitive PTC conductive polymer composite is a true smart material. Its property can be tailored by the selecting filler, polymer matrix, and processing conditions. Its transition temperature is determined by the melting point of the polymer matrix. Its room-temperature resistivity, high temperature resistivity, and PTC transition amplitude can be adjusted by the filler and its combination with the polymer matrix. PTC transition behavior can be stabilized by cross-linking of the polymer matrix. This kind of smart material can be used in many temperature-sensitive applications such as thermistors, self-regulating heaters, and circuit protection devices.

CONFORMATION AND CONFIGURATION

Introduction

Scientists have devised many models for treating the enormous number of conformations accessible to a flexible chain molecule. Most of these models pay little attention to the real covalent structure of the chain. Therefore they are ill suited to the development of a thorough understanding of why one polymer behaves differently from another. The rotational isomeric state model is unique in that it describes the conformation-dependent properties of the chain in terms of the real covalent structure, and does so in a computationally efficient manner. The data fed into the model include structural information (lengths of bonds, angles between successive bonds, values of the preferred torsion angles) and energetic information (contributions of short-range intrachain interactions to the preferences for specific values of the torsion angles, and specific pairs of torsion angles at neighboring bonds, ie, the interdependence of the torsions). This information is processed in a manner that rapidly gives the average of chain properties, such as the mean square unperturbed end-to-end distance $\langle r^2 \rangle_0$, with the average being performed over all of the accessible conformations.

The rotational isomeric state model is not among the newer models used in polymer science. Its earliest application to polymers was reported half a century ago (1), using mathematical techniques invented 10 years earlier (2). Applications of the model to polymers received a strong boost from Flory's group in the 1960s, leading to the publication of his classic book on the subject at the end of that decade (3). Another book, published 25 years later, updates the techniques and applications (4). The literature now contains rotational isomeric state models for literally hundreds of polymers. A few hundred of the models that appeared in

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

the literature up to the early 1990s have been tabulated in a standard format in lengthy reviews (5,6).

The classic use of the rotational isomeric state model is for the rationalization of the mean square unperturbed dimensions of a long-chain molecule, as measured either in dilute solution in the absence of excluded volume (ie, in a Θ solvent) or in the bulk amorphous state (7). A much simpler model for such a chain uses random flight statistics to write a temperature-independent $\langle r^2 \rangle_0$ as the product of a term N that is directly proportional to the degree of polymerization and another term $\langle L^2 \rangle$ that specifies the mean square step length of a segment.

$$\langle r^2 \rangle_0 = N \langle L^2 \rangle \tag{1}$$

The counterpart of equation (1) in the rotational isomeric state model also has a dependence on the degree of polymerization, through the use of a serial product over all n bonds in the chain.

$$\langle r^2 \rangle_0 = Z^{-1} \mathrm{F}_1 \mathrm{F}_2 \cdots \mathrm{F}_2 \tag{2}$$

Here Z is the conformational partition function, which contains information about the temperature T and the energies of all of the accessible conformations of the chain. The $\mathbf{F}_i$ are matrices that combine geometric information, namely the length of bond i, l_i, the angle between bonds i and $i+1$, θ_i, and the perferred torsion angles at bond i, ϕ_i, with the energetic information contained in Z. The rotational isomeric state model is more realistic than the freely jointed chain model because it includes temperature, different energies for the various preferred conformations, and the geometry of these conformations.

The present description of the rotational isomeric state model has several parts. First, we will describe the formulation and uses of Z, which initially restricts the focus to the thermodynamic (energetic) part of the rotational isomeric state model. Then we will describe how the structural information (l_i, θ_i, ϕ_i) is incorporated in the model. Finally, we will combine the thermodynamic and the structural information, which will take us back to equation (2). Along the way we will mention a few other properties, in addition to $\langle r^2 \rangle_0$, that can be successfully rationalized with the rotational isomeric state model. Finally, several illustrative applications will be presented.

Although developed primarily for the analysis of the conformation-dependent physical properties of flexible chain molecules in the Θ state (essentially a single-chain problem, due to the neglect of excluded volume), the rotational isomeric state model has important applications in other types of problems. It has been used for generation of detailed models for glassy atactic polypropylene at bulk density (8). The rotational isomeric state model is also instrumental in the simulation of the mixing of structurally similar polymers, as illustrated also by polypropylene, where melts of isotactic and atactic polypropylene are miscible, but melts of isotactic and syndiotactic polypropylene are immiscible (9,10). Space limitations will preclude extensive description of these more advanced applications of the rotational isomeric state model.

The Conformational Partition Function *Z*

Although not in any way restricted in application to polyethylene, it is nevertheless useful to adopt this polymer for purposes of illustration because the conformational properties of its small oligomers are likely to be known to the reader. The discussion conveniently begins with the central C—C bond in *n*-butane, CH_3CH_2—CH_2CH_3. The conformational energy, which is a continuous function of the torsion angle at this bond, has been written using the cosine of the torsion angle (11).

$$U(\phi) = 11.8 + 7.66\cos\phi + 4.64\cos 2\phi + 8.8\cos 3\phi \tag{3}$$

Here $U(\phi)$ is in $kJ \cdot mol^{-1}$ and $\phi = 0$ in the *cis* conformation. This function, which is depicted in Figure 1, has the three maxima and three minima summarized in Table 1. When the populations are distributed according to $\exp(-U(\phi)/RT)$, and T has values that are likely to be of interest, there will be a significant population of ϕ near all three minima, but the populations in the vicinity of the maxima will be very small, as shown in Figure 2. This observation suggests a simplification in which the continuous range for ϕ is approximated by a set of three discrete values corresponding to the three regions of ϕ that have significant population. These three regions are named *trans* and *gauche*$^{\pm}$ in *n*-butane. They are often abbreviated as t and $g^{\pm}$. The normalized populations of these three regions are given in the last column of Table 1. The statistical weight of g^+ (or g^-) relative to t is denoted by σ. The value of σ is temperature-dependent. It is less than 1/3 at finite T because the regions near $\phi = \pm 70^\circ$ are of higher energy than the region near $\phi = 180^\circ$. The term in parentheses in the last column of Table 1 $(1 + 2\sigma)$ is the conformational partition function (or sum of statistical weights for

Table 1. Maxima and Minima in the Torsion Potential Energy Function for the Internal C—C Bond in *n*-Butane

ϕ, deg	Maximum or minimum	U, kJ·mol^{-1}	U/kT at 300 K	Population
180	Minimum	0	0	$1(1+2\sigma)^{-1}$
$\sim(\pm 121)$	Local maximum	$\sim$14	$\sim$6	$\sim$0
$\sim(\pm 70)$	Local minimum	$\sim$3	$\sim$1	$\sigma(1+2\sigma)^{-1}$
0	Maximum	$\sim$33	$\sim$13	$\sim$0

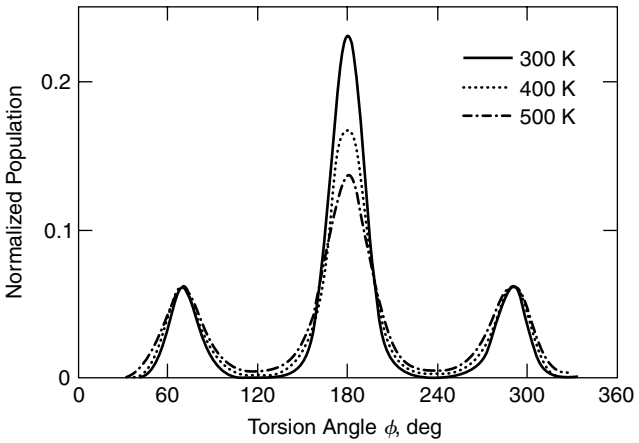

Fig. 2. Normalized populations of the torsion angle at the central C—C bond in *n*-butane at 300, 400, and 500 K. From Ref. 4. Copyright © 1994 John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

all conformations) for *n*-butane in the rotational isomeric state approximation. The probability of any state is its statistical weight u_i divided by the sum of all statistical weights, ie, the conformational partition function $p_i = Z^{-1}\ u_i$, $Z = \sum u_i$.

Extension of this concept to a longer alkane suggests three conformations for each internal C—C bond, or 3^{n-2} conformations for a chain of n bonds. If the bonds were independent of one another, the conformational partition function would be $(1+2\sigma)^{n-2}$. However, interdependence of neighboring torsions destabilizes some of the conformations, with important implications for their statistical weights. The most important interdependence in the *n*-alkanes is the interaction known as the *pentane effect* because *n*-pentane is the smallest alkane in which it is seen. If the two internal C—C bonds of *n*-pentane adopt *g* states, only the two conformations with *g* states of the same sign have conformational energies near $2E_\sigma$, which is the prediction based on the assumption of independent bonds. If the *g* states are of opposite sign, however, the conformational energy is higher than this prediction by nearly 7.5 kJ·mol^{-1} because of the repulsive interaction of the terminal methyl groups in these two conformations. The conformational energy of these two conformations is $2E_\sigma + E_\omega$, with E_ω about 7.5 kJ·mol^{-1}. The conformational

partition function for *n*-pentane is not $(1 + 2\sigma)^2$, as would have been the case if the two internal bonds were independent, but is instead given by $1 + 4\sigma + 2\sigma^2 (1 + \omega)$.

The influence of the interdependence of neighboring bonds is easily incorporated in the formulation of the conformational partition function for long chains. The method employs a statistical weight matrix **U** for each bond. For bond i somewhere within a long chain, $\mathbf{U}_i$ has the following composition:

(1) The number of columns is given by the number of rotational isomeric states at bond i, ν_i;
(2) The number of rows is given by the number of rotational isomeric states at bond $i - 1$, ν_{i-1};
(3) Every element in column η contains the statistical weight required by the first-order (dependent on one torsion) interaction when bond i is in the state indexed by that column;
(4) Every element in row ξ of column η also contains the statistical weight required by the second-order (dependent on two torsions) interaction when bond i is in the state indexed by that column and bond $i - 1$ is in the state indexed by that row.

For polyethylene, the first two points specify dimensions of 3×3 for $\mathbf{U}_i$. Assuming the order of indexing of rows and columns is t, g^+, g^-, the third point specifies the presence of σ in all elements in the second and third columns. The fourth point specifies the appearance of ω in the 2,3 and 3,2 elements. Therefore the statistical weight matrix for polyethylene is the 3×3 matrix in equation (4) (12).

$$\mathrm{U}_i = \begin{bmatrix} 1 & \sigma & \sigma \\ 1 & \sigma & \sigma\omega \\ 1 & \sigma\omega & \sigma \end{bmatrix}_i \tag{4}$$

More generally, $\mathbf{U}_i$ is formulated as the product of a diagonal matrix $\mathbf{D}_i$ with dimensions given by point (*1*), and with the statistical weights for the first-order interactions on the main diagonal, in the order required by the indexing of the columns of $\mathbf{U}_i$ (13). The second-order interactions occur in a matrix $\mathbf{V}_i$ (which has dimensions given by points (*1*) and (*2*)). For polyethylene, the $\mathbf{U}_i$ in equation (4) can be generated as the product of the $\mathbf{V}_i$ and $\mathbf{D}_i$ defined in equation (5).

$$U_i = \mathrm{V}_i\mathrm{D}_i = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & \omega \\ 1 & \omega & 1 \end{bmatrix}_i \begin{bmatrix} 1 & 0 & 0 \\ 0 & \sigma & 0 \\ 0 & 0 & \sigma \end{bmatrix}_i \tag{5}$$

Z for *n*-butane is given by the sum of the elements in the top row of $\mathbf{U}_2$, and Z for *n*-pentane is the sum of the elements in the top row of $\mathbf{U}_2\mathbf{U}_3$. In general, the contribution of bonds 2 through $n-1$ to Z is given by the sum of the elements

in the top row of the serial product $\mathbf{U}_2\mathbf{U}_3 \cdots \mathbf{U}_{n-1}$. This sum can be extracted by appending an initial $\mathbf{U}_1$ defined as [1 0 $\cdots$ 0] and a terminal $\mathbf{U}_n$ that is a column in which all elements are 1.

$$Z = \mathrm{U}_1\mathrm{U}_2 \cdots \mathrm{U}_n \tag{6}$$

Application of this equation yields $Z = 1 + 2\sigma$ for n-butane and $Z = 1 + 4\sigma + 2\sigma^2(1 + \omega)$ for n-pentane, as expected. It correctly incorporates the first-order interaction and the pentane effect for longer chains. Interactions of higher order (depending on three or more successive bonds) are not included. This reliance on short-range (first- and second-order) interactions means that the expression cannot be expected to apply when longer range interactions play an important role, as they do under circumstances where excluded volume is important. The treatment based on short-range interactions is appropriate for the Θ state, where excluded volume is not important.

The serial product in equation (6) implies that the $\mathbf{U}_i$ need not all be identical. The only restriction on their relationship is that all pairs must be conformable for matrix multiplication. Conformability is ensured by the requirements expressed in the first two points before equation (4). Equation (6) can be used with chains in which different types of bonds are present, as in polyoxyethylene (14). It can also be used for chains in which not all bonds have the same number of rotational isomeric states, as in the polycarbonate of bisphenol A (15).

The standard operations of statistical mechanics permit extraction of useful information from Z. The temperature dependence of Z gives the amount by which the average conformational energy and conformational entropy exceed their zero values.

$$\langle E \rangle - E_0 = kT^2(\partial \ln Z/\partial T) \tag{7}$$

$$S = (\langle E \rangle - E_0)/T + k \ln Z \tag{8}$$

The probability that bond i will be in state η, denoted by $p_{\eta;i}$, is calculated with a matrix $\mathbf{U}_{\eta;i}'$ that is obtained from $\mathbf{U}_i$ by zeroing out all of the elements except those in the column indexed by state η at this bond (16).

$$p_{\eta;i} = Z^{-1}\left(\prod_{\mathrm{j}=1}^{i-1}\mathrm{U}_j\right)\mathrm{U}'_{\eta;i}\left(\prod_{k=i+1}^{n}\mathrm{U}_k\right) \tag{9}$$

Equation (9) evaluates the ratio of the sum of the statistical weights for all conformations in which bond i is in state η to the sum of the statistical weights of all conformations, ie, Z. If bond i is in the middle of a long polyethylene chain, the combination of equations (4), (6), and (9), with $\sigma = 0.543$ and $\omega = 0.087$ (as appropriate for a temperature of about 423 K), yields three $p_{\eta;i}$ that have 1 as their sum.

$$p_{t;i} = 0.596 \tag{10}$$

$$p_{g^+;i} = p_{g^-;i} = 0.202 \tag{11}$$

The t state is preferred in the melt at this temperature. The symmetry of the torsion potential energy function in equation (3) for the C—C bond in polyethylene, $U(\phi) = \mathrm{U}(-\phi)$, produces $p_{g^+;i} = p_{g^-;i}$. Knowledge of all of the $p_{\eta;i}$ is often useful in the interpretation of conformation-dependent spectral properties that have a local origin, such as the chemical shift and coupling constants in nmr spectroscopy (17).

The probability that bonds i and $i-1$ are in states η and ξ, respectively, is computed with a $\mathbf{U}_{\xi\eta;i}{}''$ that is obtained from $\mathbf{U}_i$ by zeroing out all of the elements except the single element at row ξ, column η.

$$p_{\xi\eta;i} = Z^{-1}\left(\prod_{\mathrm{j}=1}^{i-1}\mathrm{U}_j\right)\mathrm{U}''_{\xi\eta;i}\left(\prod_{k=i+1}^{n}\mathrm{U}_k\right) \tag{12}$$

The numerical values of $p_{\xi\eta;i}$ are conveniently presented in the form of a matrix that has the same dimensions as $\mathbf{U}_{\xi\eta;i}{}''$. For the same case described in equations (10) and (11), this matrix has elements with the numerical values presented in equation (13).

$$p_{\xi\eta;i} = \begin{bmatrix} 0.321 & 0.138 & 0.138 \\ 0.138 & 0.0591 & 0.00516 \\ 0.138 & 0.00516 & 0.0591 \end{bmatrix}_i \tag{13}$$

Summation of the elements in the individual columns reproduces the results in equations (10) and (11). The result $p_{tg^+;i} = p_{tg^-;i} = p_{g^+t;i} = p_{g^-t;i}$ arises from the symmetry of the torsion potential energy function and the absence of a distinguishable direction along the polyethylene chain. The interdependence of the bonds makes the probability for two successive g states dependent on the relationship of their signs, $p_{g^+g^+;i} = p_{g^-g^-;i} > p_{g^+g^-;i} = p_{g^-g^+;i}$.

Another useful probability can be derived from the previous equations. Given that there is state ξ at bond $i-1$, $q_{\xi\eta;i}$ is the probability for finding state η at bond i.

$$q_{\xi\eta;i} = p_{\xi;i}/p_{\xi\eta;i-1} \tag{14}$$

The numerical results in equation (13) specify nine values that can be presented in matrix form.

$$p_{\xi\eta;i} = \begin{bmatrix} 0.538 & 0.231 & 0.231 \\ 0.682 & 0.292 & 0.026 \\ 0.682 & 0.026 & 0.292 \end{bmatrix}_i \tag{15}$$

The sum of the three elements in each row is 1 in equation (15), whereas the sum of all nine of the elements is 1 in equation (13). The probability for conformation κ in a long chain (where κ is a subscript that uniquely defines that

conformation) is given by the product of the appropriate $p_{\eta;i}$ for bond 2 and the appropriate $q_{\xi\eta;i}$ for all subsequent bond pairs.

$$p_k = p_{\alpha;2} q_{\alpha\beta;3} q_{\beta\gamma;4} \cdots q_{\psi\omega;n-1} \tag{16}$$

Equation (16) can be employed to generate representative samples of chains for purposes such as the evaluation of the distribution function for the end-to-end distance (18).

Geometry of Individual Chain Conformations

Equation (6) writes Z as a serial product of n statistical weight matrices, one matrix for each bond in the chain. The information in Z specifies the probability for each and every conformation of the chain, via equation (16). In preparation for the computation of properties such as $\langle r^2 \rangle_0$ (where the average is over all conformations), it is desirable to formulate r^2 (for a single conformation) as a serial matrix product, just as Z was expressed as a serial matrix product in equation (6).

The end-to-end vector $\boldsymbol{r}$ for a chain is often written as a sum of bond vectors.

$$r = l_1 + l_2 + \cdots + l_n \tag{17}$$

The form adopted in equation (17) assumes that $\boldsymbol{r}$ and all of the $\boldsymbol{l}_i$ are expressed in the same coordinate system. Specification of the elements in any one of the $\boldsymbol{l}_i$ requires knowledge of the length of the bond and its orientation in the coordinate system common to all $\boldsymbol{l}_i$. The rotational isomeric state model uses a different approach. Each $\boldsymbol{l}_i$ is expressed in a local Cartesian coordinate system with axis x_i along bond i, axis y_i in the plane of bonds $i-1$ and i, with a positive projection on bond $i-1$, and z_i completing a right-handed Cartesian coordinate system. The x and y axes for the local coordinate systems of the first two bonds are depicted in Figure 3. In its own coordinate system, each $\boldsymbol{l}_i$ is easily written in terms of the length of this bond.

$$l_i = \begin{bmatrix} l_i \\ 0 \\ 0 \end{bmatrix} \tag{18}$$

The $\boldsymbol{l}_i$ can all be expressed in the coordinate system of the first bond by premultiplication by a serial product of transformation matrices, $\mathbf{T}_1 \cdots \mathbf{T}_{i-1}$, where the form of each $\mathbf{T}$ depends on the conventions adopted for expressing the bond angle and torsion angle. A common form is presented in equation (19).

$$T_i = \begin{bmatrix} -\cos\theta & \sin\theta & 0 \\ -\sin\theta\cos\phi & -\cos\theta\cos\phi & -\sin\phi \\ -\sin\theta\sin\phi & -\cos\theta\sin\phi & \cos\phi \end{bmatrix}_i \tag{19}$$

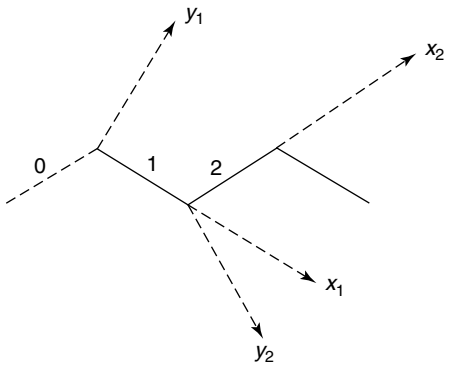

Fig. 3. The local coordinate systems defined by two consecutive bonds. From Ref. 19. Copyright © 1976 John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

The torsion angle at bond i, defined as 0 for a cis placement, is denoted by ϕ_i, and the angle between bonds i and $i+1$ is θ_i. $\mathbf{T}_1$ is the special case where the undefined ϕ_1 is taken to be 180°.

With this notation, equation (17) can be written as a sum of n terms that involve $\boldsymbol{l}_i$ and $\mathbf{T}_i$.

$$r = l_1 + \mathrm{T}_1 l_2 + \mathrm{T}_1\mathrm{T}_2 l_3 + \cdots + \mathrm{T}_1\mathrm{T}_2\cdots\mathrm{T}_{n-1} l_n \tag{20}$$

This sum can be generated as a serial product of n matrices, one for each bond in the chain (20).

$$r = [\,\mathrm{T}\quad \mathrm{l}\,]_1 \begin{bmatrix} \mathrm{T} & \mathrm{l} \\ 0 & 1 \end{bmatrix}_2 \cdots \begin{bmatrix} \mathrm{T} & \mathrm{l} \\ 0 & 1 \end{bmatrix}_{n-1} \begin{bmatrix} l \\ 1 \end{bmatrix}_n \tag{21}$$

A more compact notation writes each of the matrices on the right-hand side of equation (21) as $\mathbf{A}_i$.

$$r = \mathrm{A}_1\mathrm{A}_2\cdots\mathrm{A}_\mathrm{n} \tag{22}$$

If the bond vector is replaced by the dipole moment vector for bond i, $\boldsymbol{m}_i$, an equivalent serial product of matrices produces the dipole moment for this chain.

$$\mu = [\,\mathrm{T}\quad \mathrm{m}\,]_1 \begin{bmatrix} \mathrm{T} & \mathrm{m} \\ 0 & 1 \end{bmatrix}_2 \cdots \begin{bmatrix} \mathrm{T} & \mathrm{m} \\ 0 & 1 \end{bmatrix}_{n-1} \begin{bmatrix} m \\ 1 \end{bmatrix}_n \tag{23}$$

The squared end-to-end distance is generated as a matrix product using the same information that was required for $\boldsymbol{r}$ in equation (21), but processing that information differently (20).

$$r^2 = \mathrm{G}_1\mathrm{G}_2\cdots\mathrm{G}_\mathrm{n} \tag{24}$$

The internal $\mathbf{G}_i$ are 5×5 matrices which can be written in block form with dimensions 3×3.

$$\mathrm{G}_i = \begin{bmatrix} 1 & 2l^{\mathrm{T}}\mathrm{T} & \mathrm{l}^2 \\ 0 & \mathrm{T} & \mathrm{l} \\ 0 & 0 & 1 \end{bmatrix}_i, \quad 1<i<n \tag{25}$$

$\mathbf{G}_1$ is given by the top row of $\mathbf{G}_i$, and $\mathbf{G}_n$ is given by the last column.

The squared dipole moment μ^2 is obtained by the same formalism upon substitution of $\boldsymbol{m}$ for $\boldsymbol{l}$ and m^2 for l^2.

If all of the atoms in the chain are of the same mass, the squared radius of gyration is generated as a matrix product that uses the same information required for $\boldsymbol{r}$ and r^2, but processing that information differently.

$$s^2 = (n+1)^{-2}\mathrm{H}_1\mathrm{H}_2 \cdots \mathrm{H}_{n-1}\mathrm{H}_n = (n+1)^{-2}\prod_{i=1}^{n}\mathrm{H}_i \tag{26}$$

The internal $\mathbf{H}_i$ are 7×7 matrices when written out element by element, but they can also be written in a more compact blocked form.

$$\mathrm{H}_i = \begin{bmatrix} 1 & \mathrm{G}_{\lfloor} & \mathrm{l}^2 \\ 0 & \mathrm{G} & \mathrm{G}_{\rfloor} \\ 0 & 0 & 1 \end{bmatrix}_i \tag{27}$$

Here $\mathbf{G}_{\lfloor}$ denotes the top row of $\mathbf{G}$, $\mathbf{G}_{\rfloor}$ denotes the last column of $\mathbf{G}$, $\mathbf{H}_1$ is formulated as the top row of $\mathbf{H}_i$, and $\mathbf{H}_n$ is formulated as the last column of $\mathbf{H}_n$.

Other conformation-dependent properties can be formulated in a similar manner (4,20).

Averages over All Conformations

The basis for computing the averages over all conformations is illustrated for the case of the mean square unperturbed end-to-end distance $\langle r^2 \rangle_0$ (20). Let $r_\kappa{}^2$ denote the squared end-to-end distance of conformation κ. The probability of this conformation is given by equation (16). The desired result is the weighted sum over all conformations.

$$\langle r^2 \rangle_0 = \sum p_\kappa r_\kappa^2 \tag{28}$$

The probability is the ratio of the statistical weight for conformation κ, denoted by w_κ, to the sum of the statistical weights for all conformations, Z.

$$\langle r^2 \rangle_0 = Z^{-1}\sum w_\kappa r_\kappa^2 \tag{29}$$

The w_κ is the product of statistical weights $w_{\kappa;i}$, that appear in the appropriate elements of the $\mathbf{U}_i$, and ${r_\kappa}^2$ is the serial product of $\mathbf{G}$ matrices, according to equation (25), where the appropriate ϕ_i is used in each $\mathbf{G}_i$. The $w_{\kappa;i}$ can be grouped with the appropriate $\mathbf{G}_{\kappa;i}$.

$$\langle r^2\rangle_0 = Z^{-1}\sum_\kappa \prod_{i=1}^{n} w_{\kappa;i}\mathrm{G}_{\kappa;i} \tag{30}$$

The numerator is merely the expression for Z, with each statistical weight expanded by multiplication onto the appropriate $\mathbf{G}$ matrix. Therefore the desired result is obtained by equation (2) with supermatrices that contain the geometric information in $\mathbf{G}$ and the energetic information in $\mathbf{U}$.

$$\mathrm{F}_i = \begin{bmatrix} u_{11}\mathrm{G}_{\phi_1} & \mathrm{u}_{12}\mathrm{G}_{\phi_2} & \cdots & \mathrm{u}_{1v_i}\mathrm{G}_{\phi_{v_i}} \\ \mathrm{u}_{21}\mathrm{G}_{\phi_1} & \mathrm{u}_{22}\mathrm{G}_{\phi_2} & \cdots & \mathrm{u}_{2v_i}\mathrm{G}_{\phi_{v_i}} \\ \vdots & \vdots & \ddots & \vdots \\ u_{v_{i-1}1}\mathrm{G}_{\phi_1} & \mathrm{u}_{v_{i-1}2}\mathrm{G}_{\phi_2} & \cdots & \mathrm{u}_{v_{i-1}v_i}\mathrm{G}_{\phi_{v_i}} \end{bmatrix}_i, \quad 1<i<n \tag{31}$$

The first bond is treated with $\mathbf{F}_1 = [\mathbf{G}_[\ \mathbf{0}]_1$ and a column of $i-1$ copies of $\mathbf{G}_{[n}$ is used for the last bond.

The mean square unperturbed end-to-end distance is usually reported as the dimensionless characteristic ratio, defined as the ratio of the true $\langle r^2\rangle_0$ to the value that would have been predicted for the same chain, using the freely jointed chain model (eq. (1)).

$$C_n = \langle r^2\rangle_0 / n\langle l^2\rangle \tag{32}$$

The values of C_n approach a limit as n increases if the chain is flexible. The limiting value is denoted by C_∞.

A perfectly analogous approach permits computation of $\langle \boldsymbol{r}\rangle_0$ and $\langle s^2\rangle_0$, substituting the expressions in equation (22) or equation (26) for the one in equation (24).

The FORTRAN source code for a simple yet versatile computer program for calculation of $\langle r^2\rangle_0$ by equation (2) is available in Appendix C of Reference 4. This source code, along with sample input and output files, can be downloaded from www.polymer.uakron.edu/~wlm. The program executes quickly on any modern computer that has a FORTRAN compiler.

Uses of the Expressions

This section provides several illustrative examples of questions that can be addressed with the rotational isomeric state model.

Often useful information is accessible from Z itself. For example, one can inquire into the average number of bonds in a sequence of t placements in a polyethylene melt at 450 K. The solution is obtained as the ratio of the probability of a t state to the probability for the initiation of a sequence of t states. This ratio is $p_{t;i}(p_{g^+t;i} + p_{g^-t;i})^{-1}$, where bond i is in the interior of a long chain, far enough from either end so that it is not subject to end effects. In practice, the chain might have $n = 20$ and $i = 10$. Z is computed from equation (6), using the $\mathbf{U}$ given by equation (4). The probabilities are obtained from equations (9) and (12). The ratio has a value of about 2.4, for reasonable assignment of the numerical values of E_σ and E_ω.

With the incorporation of the matrix expressions for the properties of individual chains, more information becomes accessible. For example, how sensitive are the components of $\langle \boldsymbol{r} \rangle_0$ to the interdependence of the bonds in a polyethylene melt at 140°C? Using the $\mathbf{U}$ in equation (4) with $\omega = 1$ (independent bonds) and again with $\omega = 0$ (strongly interdependent bonds), along with equation (6) for Z and a simple modification (substitution of $\mathbf{A}$ for $\mathbf{G}$) of equation (2) for $\langle \boldsymbol{r} \rangle_0$, yields, in the limit for long chains,

$$\langle r \rangle_0 = \begin{bmatrix} 0.61\text{nm} \\ 0.52\text{nm} \\ 0 \end{bmatrix} \quad \text{for interdependent bonds and}$$

$$\langle r \rangle_0 = \begin{bmatrix} 0.34\text{nm} \\ 0.29\text{nm} \\ 0 \end{bmatrix} \quad \text{for independent bonds.}$$

How quickly does C_n reach its asymptotic limit at large n? The upper curve in Figure 4 depicts the C_n calculated from the $\mathbf{U}$ in equation (4) with $\sigma = 0.43$

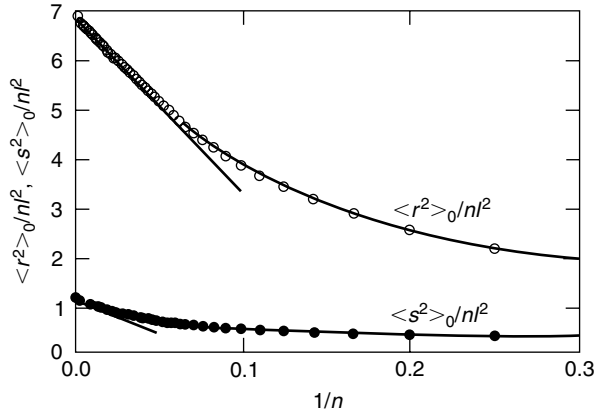

Fig. 4. The dependence of $\langle r^2 \rangle_0$ and $\langle s^2 \rangle_0$ on $1/n$ for unperturbed polyethylene chains. From Ref. 4. Copyright © 1994 John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

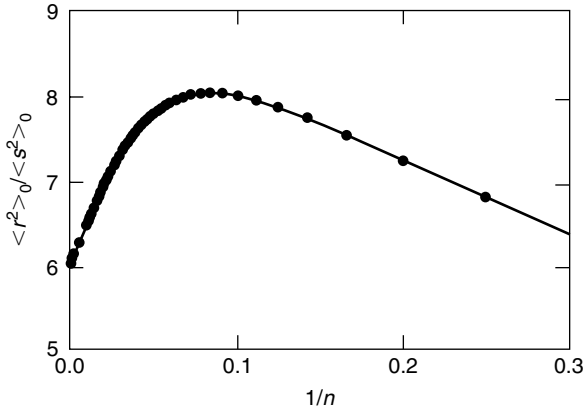

Fig. 5. The dependence of $\langle r^2\rangle_0/\langle s^2\rangle_0$ on $1/n$ for unperturbed polyethylene chains, using the data from Figure 4. From Ref. 4. Copyright © 1994 John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

and $\omega = 0.034$, using Z from equation (6) and $\langle r^2\rangle_0$ from equation (2). The final approach of C_n to C_∞ is linear in $1/n$.

$$C_n = C_\alpha - a/n \tag{33}$$

Here a is a positive constant. C_n is within about 5% of C_∞ in Figure 4 when n reaches 100. The form of equation (33) is common to flexible chains, but the value of a depends on the nature of the chain, with a tendency for a to become larger as the stiffness of the chain increases.

Is the rotational isomeric state model consistent with $\langle r^2\rangle_0/\langle s^2\rangle_0 = 6$ for long flexible chains? The lower curve in Figure 4 depicts the values of $\langle s^2\rangle_0$, calculated in the same manner as the $\langle r^2\rangle_0$ in the upper curve, but with substitution of $\mathbf{H}_i$ for $\mathbf{G}_i$ and division by $(n+1)^2$, as required by equation (26). The ratio $\langle r^2\rangle_0/\langle s^2\rangle_0$ is depicted in Figure 5. It reaches 6 in the limit $n \to \infty$, but the ratio is larger than 6 at small n, because $\langle r^2\rangle_0/nl^2$ reaches its limit faster than does $\langle s^2\rangle_0/nl^2$.

The rotational isomeric state model can be used to rationalize the temperature-dependence of conformation-dependent properties, through the dependence of the statistical weights on temperature. How strong is the temperature dependence of the dimensions of the chains in a polyethylene melt, assuming that we remain above the temperature at which crystallization occurs? Calculations of $\langle r^2\rangle_0$ from equations (2), (4), and (6), assuming that the only temperature dependence is from the Boltzmann factors $\sigma = \exp(-E_\sigma/kT)$ and $\omega = \exp(-E_\omega/kT)$, yields $\partial \ln \langle r^2\rangle_0/\partial T = -0.001\ \mathrm{deg}^{-1}$.

A common use of the rotational isomeric state model is to learn how specific structural properties (at the local level) affect conformational properties at the level of a long chain. Polyisobutylene provides a good example. The bond angles in the backbone of polyisobutylene alternate between 110° (for CH_2—C—CH_2) and 124° (for C—CH_2—C). How strongly, and in what direction, does this alternation in bond angles affect the mean square dimensions of the chains in a polyisobutylene

melt? Using Z from equation (6) and $\langle r^2 \rangle_0$ from equation (2), along with the **U** and ϕ from the rotational isomeric state model for polyisobutylene described in Reference 21, replacement of the two different θ by their average ($\theta = 117^\circ$ for all bond angles) increases $\langle r^2 \rangle_0$ by 21%.

The rotational isomeric state model can also tell us how stereochemical composition affects the conformations of a chain. When selecting from isotactic and syndiotactic poly(2-vinyl pyridine), and isotactic and syndiotactic poly(*N*-vinyl carbazole), which of the four chains has the smallest and the largest unperturbed dimensions? Using the rotational isomeric state models proposed for these two polymers (22,23), the values of C_∞ at 300 K are 4.9 and 7.7, respectively, for isotactic and syndiotactic poly(2-vinyl pyridine), whereas isotactic and syndiotactic poly(*N*-vinyl carbazole) have much larger values of approximately 15 and 39, respectively. The most compact unperturbed chain is isotactic poly(2-vinyl pyridine), and the most extended chain is syndiotactic poly(*N*-vinyl carbazole).

CONTROLLED RELEASE TECHNOLOGY

Introduction

For many decades, pharmaceuticals have primarily consisted of simple, fast-acting chemical compounds that are dispensed orally for the treatment of an acute disease or a chronic illness and have been mostly facilitated by drugs in various pharmaceutical dosage forms, including tablets, capsules, pills, suppositories, creams, ointments, liquids, aerosols, and injections. Even today these conventional dosage forms are the primary mode of drug administration for prescription and over-the-counter drug products. Conventional drug formulations typically provide a prompt release of drug in a bolus form. For drugs which get cleared rapidly from the body, achieving and maintaining the drug concentration within the therapeutically effective range requires a multiple dosing regimen, often more than once a day. Such an inconvenient dosing regimen leads to lack of patient compliance as well as a significant fluctuation in drug levels in the plasma (Fig. 1). The premise of administration methods that allow the patients to safely treat themselves is as significant as any other health care development, particularly in developing countries where doctors, clean syringes, sterile needles, and sophisticated treatments are few and far between (1).

Recently, several technical advancements have resulted in the development of new technologies capable of controlling the administration of a drug at a targeted site in the body in an optimal concentration-versus-time profile (2–4). The term "drug delivery" covers a very broad range of techniques used to get therapeutic agents into human body. These techniques are capable of controlling the rate of drug delivery, sustaining the duration of therapeutic activity, and/or targeting the delivery of drug to a tissue as described in various articles (5–7).

The main objective of this article is to present an overview of controlled release technology, the polymers used for controlled release therapies, as well as the

strategies used for drug encapsulation and release. Furthermore, an emphasis has been laid upon the important applications of this technology in the pharmaceutical and biomedical fields.

Need of Controlled Drug Release Systems

The ways in which drugs or new biological products are administered have gained increasing attention in the past few decades. Controlled release systems provide numerous benefits over the conventional dosage forms. Conventional dosage forms, which are still predominant for the pharmaceutical products, are not able to control either the rate of drug delivery or the target area of drug administration and provide an immediate or rapid drug release. This necessitates frequent administration in order to maintain a therapeutic level. As a result, drug concentrations in the blood and tissues fluctuate widely (Fig. 1). The concentration of drug is initially high, that can cause toxic and/or side effects, then quickly fall down below the minimum therapeutic level with time elapse (1,6). The duration of therapeutic efficacy is dependent upon the frequency of administration, the half-life of the drug, and release rate from the dosage form. In contrast, controlled release

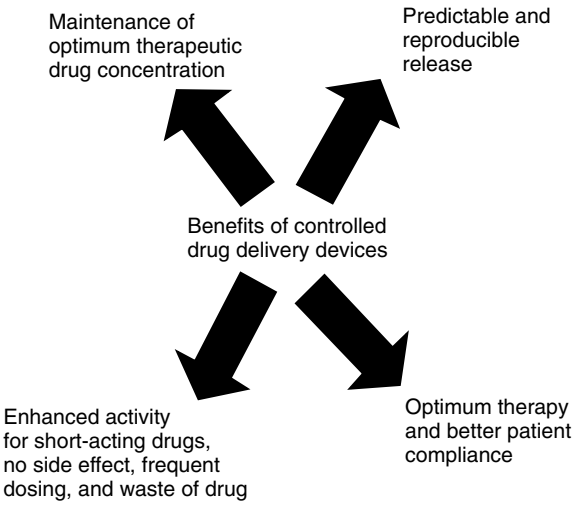

Fig. 2. Benefits of controlled release formulations.

dosage forms are not only able to maintain therapeutic levels of drug with narrow fluctuations but they also make it possible to reduce the frequency of drug administration (8). Drug concentration profile in serum depends on the preparation technology, which may generate different release kinetics resulting in different pharmacological and pharmacokinetic responses in the blood or tissues (9).

Controlled drug release formulations offer several advantages over conventional dosage forms (Fig. 2). Some of the salient features of controlled release formulations are described below.

(1) The drug is released in a controlled fashion that is most suitable for the application. The control could be in terms of onset of release (delayed vs. immediate), duration of release, and release profile itself.
(2) The frequency of doses could be reduced thereby enhancing patient compliance.
(3) The drug could be released in a targeted region. This could be achieved either by tailoring the formulation to release the drug in that particular environment or by timed release of the drug. By targeting drug release, drug efficacy could be maximized.
(4) By targeting the drug to the desired site, systemic exposure of the drug could be reduced, thereby decreasing systemic side effects (especially for toxic drugs).
(5) The drug could be protected from the physiological environment for a longer duration of time. Thus the effective residence time of the drug could be extended.

However, controlled release products do not always provide positive effects for every type of formulation design. Negative effects outweigh benefits in the following circumstances (10,11)

(1) Dose dumping
(2) Less accurate dose adjustment
(3) Increased potential for first-pass metabolism
(4) Dependence on residence time in gastrointestinal (GI) tract
(5) Delayed onset

The limitations of controlled drug release formulations (CDRFs) technology making some drugs unsuitable for formulations are as follows (12,13):

(1) There is a risk of drug accumulation in the body if the administered drug has a long half-life, causing the drug to be eliminated at a slower rate than it is absorbed.
(2) Some drugs have a narrow therapeutic index, and thus, need to administer repeatedly to maintain the serum drug level within a narrow range. Such drugs may not be feasible for CDRF.
(3) If the GI tract limits the absorption rate of the drug, the effectiveness of the CDRF is limited (for oral controlled release).
(4) If a drug undergoes extensive first-pass clearance, its controlled release formulation may suffer from lower bioavailability.
(5) The cost of CDRF may be substantially higher than the conventional form.

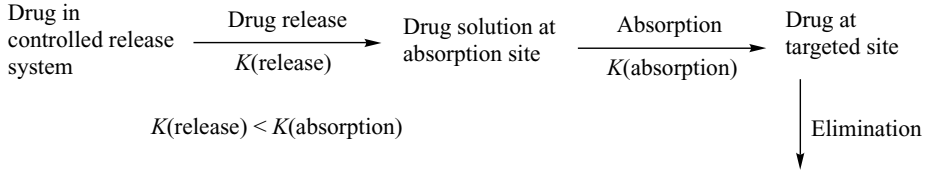
Especially from the point of view of the last factor, improvement of safety and efficacy of the new products alone has not been enough to justify introducing new CDRF products. Evaluation of economic benefits, costs, and quality of life impact need to be assessed.

Design of Controlled Release Systems

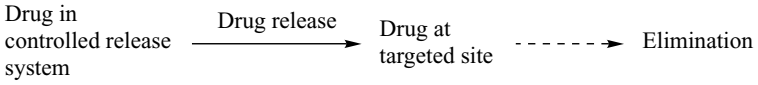
A controlled release system comprises a drug and the material in which the drug is loaded. This system must be biocompatible and friendly with the body. Because of this reason, selection of the drug and the polymer along with desired properties is a prime factor in designing a controlled release system to deliver the drug at the desired site of action in the body (14). Drug properties are discussed in this rection. Polymers used in controlled release and polymer fabrication with drug encapsulation are discussed in subsequent sections.

Drugs-Controlled Release. Before designing a controlled drug release system, one has to select the route of drug delivery with several considerations which include physical and chemical properties of the drug, doses of the drug, route of administrations, type of drug delivery system desired, desired therapeutic effect, physiologic release of the drug from delivery system, bioavailability of the drug at the absorption site, and pharmacodynamics of the drugs (10,15). These properties of the drug can be discussed in two ways, viz. behavior of the drug in its delivery system and behavior of the drug and its delivery system in the body. In the former part, drug properties can influence release characteristics from its delivery systems, for example, in any controlled release system, drug availability is controlled by the drug release kinetics rather than absorption, and the associated

rate constant for drug release are smaller than the absorption rate constant. To control drug release, one can employ a variety of approaches, such as, dissolution (16,17), diffusion (18,19), swelling (20,21), osmotic pressure (22,23), complexation (24), ion-exchange (25,26), and magnetic field (27,28).



In the second part, behavior of the drug and its delivery system is extremely complex, involving the fate of drug during transit to the target area as well as its fate in the biophase. The effectiveness of the drug at its target area depends on the pharmacokinetics of the drug and its carrier in the body (29). These constraints of the drug in a controlled release system have been discussed in the subsequent subheadings.



Physicochemical Properties of Drugs. Physicochemical properties of the drug affect the drug release performance of a controlled drug release system in the body (30). These properties, which include aqueous solubility, drug stability, molecular size, partition coefficient, and protein binding, may prohibit/restrict placement of drug in controlled release, restrict the route of drug administration, and significantly restrict the drug release performance for one reason or the other. Physicochemical properties can be determined from *in vitro* experiment, while biological properties are those that result from typical pharmacokinetic studies on the absorption, distribution, metabolism, and excretion characteristics of the drug and those resulting from pharmacological studies (29). Compounds with very low aqueous solubility usually suffer oral bioavailability problems because of limited GI transit time of the undisclosed particles and limited solubility at absorption site. Unfortunately, for many drugs, the site of maximum absorption is the area in which the drug is least soluble. Thus, choice of oral controlled/sustained release formulations is limited by aqueous solubility of the drug. This property may be useful for matrix-type devises where these limitations can be utilized to achieve sustained/controlled drug release; however, dissolution-limited bioavailability may occur. Partition coefficient (31) and molecular size of the drug influence not only the permeation of a drug across biological membrane but also the diffusion across or through a rate-controlling membrane or matrix (32). Drugs with extremely high partition coefficient (ie, drugs having high oil solubility) readily penetrate the membranes but are unable to proceed further, while the drug with excessive aqueous solubility, for example, low oil–water partition coefficient, cannot penetrate the membranes. Hence, a balance in the partition coefficient is needed to give an optimum flux for permeation through the biological and rate-controlling membranes.

Drug stability in biological media provides the bioavailability; for example, drugs that are unstable in the stomach can be placed in a slowly soluble form or have their release delayed until they reach the small intestine. Drug and plasma protein interaction influences the duration of drug action. It is well known that blood proteins are mostly recirculated and not eliminated; thus, drug protein binding can serve as a depot for drug producing a prolong release profile if a high degree of drug binding occurs.

Biological Properties of Drugs. At the time of designing a system, a comprehensive picture of drug deposition must be very clear and this should be based on a complete examination of pharmacological action of the drug in the *in vivo* experiments, which include adsorption, distribution, metabolism, and excretion (ADME) (Fig. 3). The pharmacological action of a drug can be correlated better with the concentration–time course of the drug (or its active metabolite) in the blood or some other biophase than with the absolute dose administered, and it involves pharmacokinetics and pharmacodynamics of a drug in the body. Pharmacokinetics facilitates predictions of time course of drug concentrations and drug action in the body (29,33), while pharmcodynamics offer a quantitative assessment of the time course of drug effect on the body after administration by any route (29,34). From a pharmacokinetics standpoint, there are two fundamental approaches to design the formulations that allow for the attainment of the desired therapeutic concentration of the drug and are maintained throughout a dosing interval (11). The first approach involves selection of the drugs that have long enough elimination half-lives to be administered infrequently. This approach can be successful if an analog from a class of biologically active drug has a long elimination half-life or can be adopted in the early stage of a new developing drug candidate to avoid a time-consuming and cost-extensive research and development program in animal/human. In the second approach, drug formulations are modified in such a way that

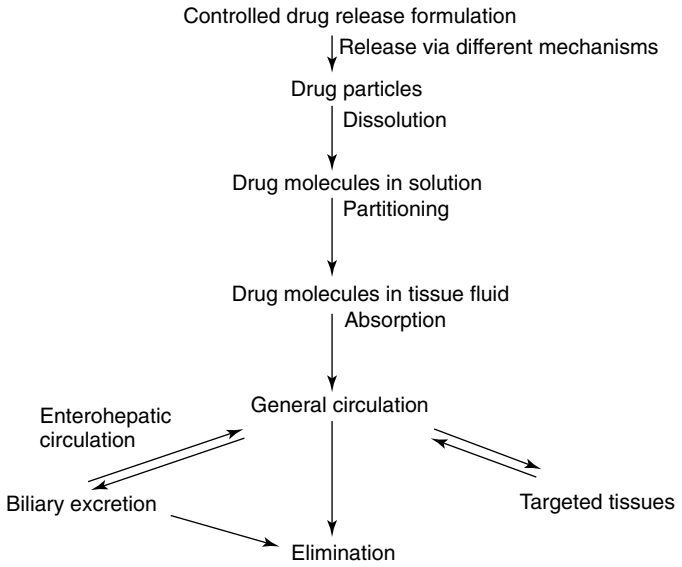


Fig. 3. Fate of drug in controllled release formulation.

the fluctuation in drug concentrations during a dosing interval is reduced. Thus, with a prior knowledge of a drug's elimination and distribution pharmacokinetics and the use of correct approach to the estimation of mean resident time (MRT) (the time a drug molecule takes to traverse through the body and that can be used to compare dosage forms), it is possible to design formulation having particular release characteristics with predictive impacts on the MRT of a drug in the body.

Pharmacodynamics of a drug has a significant impact on the design and development of sustained release products, which can also be approached by two fundamental routes. First, if pharmacokinetics of a drug is known then this can be linked to available pharmacodynamic data, resulting in a unified concept relating the kinetics of the drug (or an active metabolite) to the time course of drug effect (10,35). In the second case where pharmacokinetics of the drug cannot be defined accurately [ie, AUCs (area under the curve) cannot be accurately measured because of assay sensivity limitation] or where drug effect is apparently unrelated to concentrations, alternative approaches can be utilized. In this case, one can study the relationship of drug effect and steady-state drug concentration at various drug-dosing levels in the same individual. By using sustained release dosage forms resulting in varying release rate constants, one can derive valuable information regarding a drug product.

Each drug is characterized by its own pharmacokinetic–pharmacodynamic (PK-PD) profile (as a part of the drug-approval process) on the basis of the physicochemical properties, conformation, and other structural attributes that govern the transport within the body and across various barriers. The number and type of biological hurdles a drug has to overcome governs the design of delivery systems as well as the route of administration. Compared to the general "sigmoid" PK-PD profile for conventional molecules, the PK-PD relationship of biopharmaceuticals is complicated by short biological half-life, instability, multiple biological actions and operation of compensatory regulatory events in the body. Once the PK-PD relations have been established, plasma levels can be substituted for therapeutic effects that can aid in setting PK bioequivalence standards. In near future, one of the major objectives of CDRF technology should be to match medication delivery in time with biological rhythm (36,37). One such CDRF is Covera-HS (Pharmacia Corp; verapamil HCl) tablets, which attempts to match the body circadian rhythm for treatment of blood pressure rate (36). Covera-HS is taken at bedtime and the drug release is retarded during the sleep period (4–5 h) to achieve optimal blood levels between early morning and noon.

Factors That May Make a Drug Unsuitable for CDRF. Some drugs are not fit for controlled release because of the nature of drug action, physical limitations (large dose, duration of drug release), and alternative administration, ie, oral daily doses vs. monthly implant, etc. Drugs that are given at acute situations are usually not useful for controlled extended release, for example, tissue plasminogen activator (TPA) that is given during a heart attack to dissolve blood clotting and allow blood flow. Any delay in medication may result in death. In another example, when someone is suffering from a headache and needs immediate relief, these controlled release systems are not useful. Drugs that have a beneficial effect in the body at specific times during the day should be given only at that time, and not be delivered in large doses of controlled release formulations, which may otherwise result in unnecessary dose dumping.

Thus, the following drug properties and therapeutic requirement should be taken into account in designing a controlled release system:

(1) Drug elimination half-life
(2) Doses to be administered
(3) Therapeutic index
(4) Low solubility
(5) Route of administration
(6) Poor absorption
(7) Extensive first-pass clearance
(8) Difference in time course of circulating drug level with its pharmacological effects
(9) PD vs. PK of the drugs

Polymers in Controlled Drug Release Formulations

Polymers have been widely used to encapsulate drugs in the form of reservoir or matrix to release the drug at the proximity of the desired site (Table 1). Thus, there must be clarity about the biocompatibility, toxicity, and elimination of these polymers (38,39). Novel concepts for polymer-based controlled release systems that have emerged over the years include new polymers, new methods for drug linkages, and new processes for drug encapsulation (40). The active ingredient could be either physically entrapped into the polymer matrix by an emulsification-, atomization-, or agitation-based process or could be linked to the polymer backbone via physical or chemical bonds. The drug release is typically observed to be diffusion-controlled, polymer erosion controlled, or a combination of the two. Hence, drug release properties strongly depend on the physical and chemical properties of the polymer. Even a minor variation in the polymer structure, such as an endgroup modification, may be sufficient to modify its degradation characteristics and subsequently the drug release properties. Furthermore, different polymer properties are desired for different drugs and different applications. This has led to an intensive effort in developing novel polymeric systems for controlled release applications. Development of such novel formulations is further fueled by the growing demand for patient-friendly medicines in the pharmaceutical and biotechnology industries.

Various natural, semisynthetic, and synthetic polymers are in use as the structural backbone for both controlled release and conventional drug delivery systems (Table 1). Polymers selected in the preparation of the dosage form must comply with the following requirements:

(1) **Safety.**

Harmful/toxic impurities must be removed from polymers before their usage in CDRFs. The residual monomers, initiators, and other chemicals used in the polymer synthesis/modification must be removed after

Table 1. Polymers in Controlled Release Technology

Polymer	Controlled release mechanism	Special notes

the polymerization/modification. The chemicals employed in the polymer fabrication processes (ie, additives, stabilizers, plasticizers, and catalyst residues) are carefully selected to meet regulatory requirements.

(2) **Physical and mechanical properties.**

The polymers must possess the necessary mechanical properties required for the dosage form design, such as elasticity, compactability, resistance to tensile, swelling and shear stresses, and resistance to tear and fatigue.

(3) **Biocompatibility.**

The polymer should not cause significant local irritation to the surrounding tissues. If biodegradable, then the polymer degradation by-products must be nontoxic, nonimmunogenic, and noncarcinogenic.

There are many ways to synthesize new polymers and modify existing polymers. Different monomers (for addition polymerization or condensation polymerization) may be used or existing polymers may be modified. However, only a handful of polymers are used in pharmaceutical drug delivery systems because of their commercial availability, established biocompatibility, and government registration. Table 1 is listed with the polymers used or evaluated for controlled release. Most polymers used in pharmaceutical dosage forms were not originally designed for this purpose. However, the production of new, life-saving, genetically engineered drugs (peptides and proteins), which have characteristically short half-lives, presents an opportunity for significant research in the area of polymer development in order to prolong their therapeutic effects in human body.

Polymer Fabrication and Drug Encapsulation

Encapsulation of the therapeutic agent into a polymer matrix can be brought about by a variety of methods. These methods depend on the desired fabrication of the polymer matrix. Some of the common techniques used for drug encapsulation for different polymer forms are described in this section.

Polymer Films and Rods. Polymer films can be cast by various techniques including dip coating, spin coating, hot-melt casting, and solvent casting. Typical applications for polymer films are in the medical device industry as coatings for controlled release from devices and implants such as stents. These applications require the polymer to be elastomeric to allow flexible films at micron-size thickness. The films can be casted with the drug encapsulated by homogenization/solubilization in the polymer melt/solution. The polymer film could also be extruded using a single or double screw extruder. Screw extrusion is also used to fabricate another form of polymer, ie, drug encapsulated rods/cylinders. Such extruded rods could be implanted subcutaneously to provide sustained drug delivery.

Polymer Microspheres. For applications in drug delivery, it is desired that the polymer formulation should be present as an injectable form. From this perspective, the polymer–drug combination could be fabricated as microspheres that can be suspended in an injection vehicle prior to injection. Subcutaneous or intramuscular injections are used for microspheres whereas smaller particles (in the nano range) could be injected intravenously. Microspheres can be fabricated using a variety of techniques, some of which are described below.

(1) **Spray drying.**

In spray drying the polymer and drug are dissolved in a common solvent and spray-atomized to create microspheres. This technique is useful to create particles in the size range of up to 50 μm, wherein the polymer has a sufficiently high glass-transition temperature to allow formation of discrete microparticles during atomization. The size and morphology of microparticles created using the spray drying technique depends on the nature of the polymer as well as the spray dryer operating parameters including chamber volume, flow rate, and nozzle design (41).

(2) **Solvent evaporation.**

In this technique the drug is emulsified/dispersed in the polymer solution. This emulsion/dispersion is further emulsified in a surfactant bath to allow for the formation of solid microparticles consisting of the drug encapsulated within the polymer matrix. Variations of this technique include single emulsion and double emulsion microencapsulation. Since microparticles are created during the slow evaporation of the solvent, this technique is also termed as solvent evaporation technique. Solvent evaporation/emulsification techniques are useful when the desired particle size is higher and/or when the drug is not soluble in the organic solvent (Fig. 4).

(3) **Freeze spray atomization.**

In this process a suspension of drug in an organic polymer solution is atomized into a liquid nitrogen bath. Absolute ethanol is added to extract the organic solvent. This process is particularly feasible for proteins since the protein is in a solid, less reactive form, making it less susceptible to

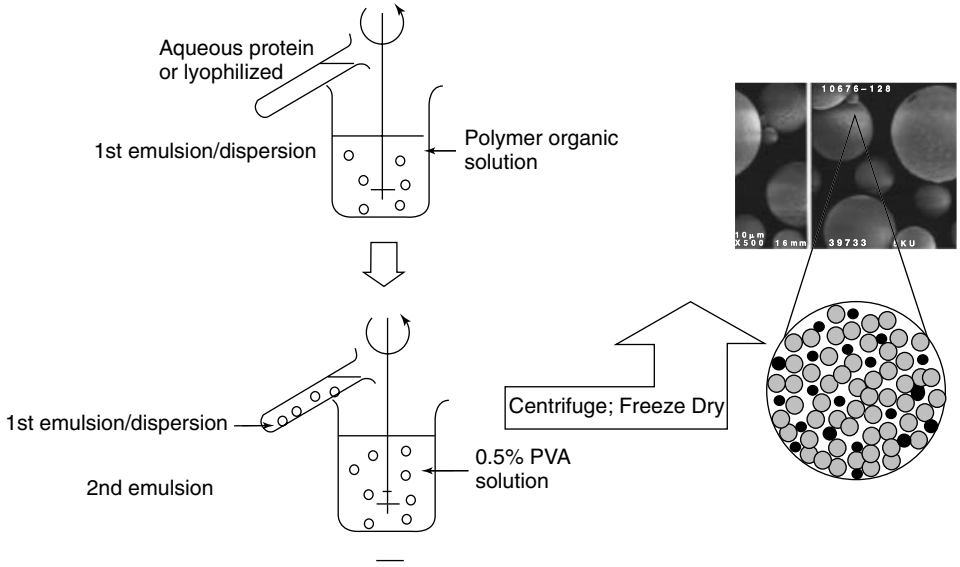

Fig. 4. Schematic representation of the emulsion-based microencapsulation processes; the single emulsion process utilizes lyophilized drug in the first step whereas the double emulsion process utilizes an aqueous solution of the drug in the first step.

damage during processing. Furthermore, the low temperature maintained throughout the process prevents thermal denaturation of the protein (42). This process has been utilized in the production of the first commercially available polymer-based sustained release protein formulation, Nutropin Depot, marketed by Genentech.

Polymer *In Situ* Gels. Drug encapsulation for injectable gels could be carried out by simple mixing of the drug into the polymer gel. To obtain sustained release, it is desirable that the polymer gel should acquire some viscosity upon injection into the body. Such *in situ* gelation characteristics could be achieved by various mechanisms such as those described below:

(1) **Temperature-induced gelation.**

Thermoreversible gelation could be obtained for ABA-type block copolymers wherein A denotes a hydrophilic segment while B denotes a hydrophobic segment. Because of the alternating block structure, such polymers undergo micellization driven by increasing temperature. The formation of micelles is thermodynamically favorable in ABA block structures, especially when the hydrophobic–hydrophilic balance is appropriately achieved. An example of such thermoreversible polymers includes PEG–PLGA–PEG (43) and Pluronics, which are ABA-type block copolymers of PEG and PPG. In each of the examples, the polymers could be engineered to be solutions at room temperature and converted into semisolid gels at body temperature.

(2) **pH-induced gelation.**

If the polymer is soluble at a certain pH and is insoluble at pH 7.4, then it would undergo pH-induced gelation on injection into the body. Examples of such polymers include synthetic polymers such as polyacrylic acid and natural polymers such as chitosan.

(3) **Solvent-induced gelation.**

Solvent-induced gelation could be obtained for a water-insoluble polymer, dissolved in a biocompatible solvent to create an injectable solution. When the solution is injected the solvent diffuses out and water from the physiological environment diffuses in. This diffusion process leads to a phase transition for the polymer as it goes from the solvent phase to a nonsolvent phase and forms a semisolid gel (44). Several factors such as polymer crystallinity, hydrophilicity, and water uptake govern the sol–gel transition and subsequently the drug release characteristics.

Classification of CDRFs

Drug delivery systems have been classified on the basis of route administration, for example, parenteral, eternal, respiratory, transdermal, and miscellaneous Flow (Fig. 5). Controlled release systems are based on the release mechanisms that may be erosion, diffusion, or chemically controlled, and thus these are classified under the heading of various categories of drug delivery. For example, under eternal drug delivery systems, release of a drug can be controlled by various mechanisms like diffusion, osmosis, or chemically controlled mechanism. In the broad way, these devices are of two types, as reservoir devices and matrix devices. The former involve the encapsulation of a drug within the polymeric shell, while the latter describe a system in which a drug is well dispersed throughout within the polymer matrix. However, on the basis of drug release mechanism, these devices can be classified into three types, as shown in Figure 6. Some examples of controlled release systems are described briefly here.

Diffusion-Controlled. Two types of diffusion-controlled systems have been used including reservoir systems (drug coated by a polymer membrane) and matrix systems (drug dispersed in a polymer matrix). In the reservoir systems, the drug is encapsulated by a polymeric membrane through which the drug is released by diffusion. This polymeric membrane is known as solution diffusion membrane (implying the mechanism of drug transport) and can be microporous or nonporous. In nonporous membrane, drug release is governed by the diffusion through polymer and thus, release can be controlled by selecting a polymer showing desirable drug solubility and diffusivity in the polymer matrix (see MEMBRANE TECHNOLOGY). In microporous membranes, pores with the size range 1.0 nm to several hundred millimeters are filled with drug permeable liquid or gel medium. Thus, diffusion of the drug through the medium in the pore will dominate the drug release process. These systems are very useful in the delivery of high molecular

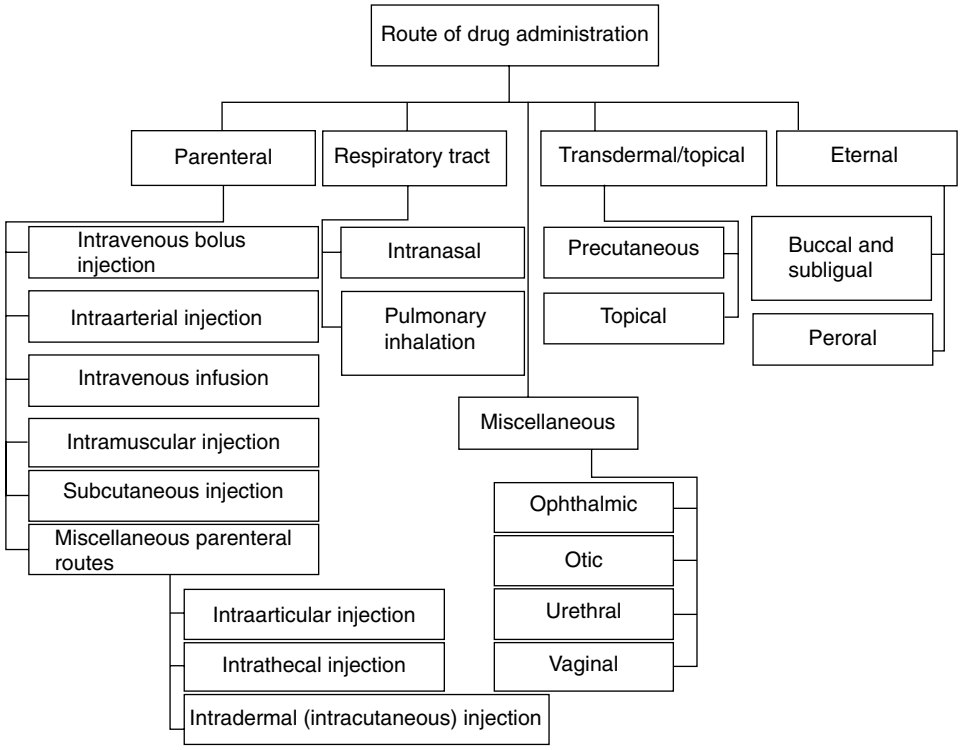

Fig. 5. Various routes of drug administration.

weight drugs such as protein and peptide drugs. Matharu and co-workers (19) reported the theoretical considerations, designing, and engineering of a "barrier coated-reservoir" type of a delivery system for theophylline using poly(vinyl alcohol) (PVA) as the coating material. After getting the desired theoretical *in vitro* release profile, *in vivo* studies were carried out on a dog model.

In monolithic systems, the drug is dissolved or dispersed homogeneously throughout the water-insoluble polymer matrix which may be microporous or nonporous (45). Monolithic systems are not suitable for zero-order release; however, it can be achieved by adjusting the physical shape of the device (46).

Dissolution-Controlled. Dissolution-controlled systems can also be classified as reservoir and matrix devices. Polymers used for these devices are generally water-soluble but water-insoluble polymers can also be used as long as they absorb water and disintegrate the drug. In reservoir devices, drug particles are coated with water-soluble polymeric membranes. The solubility kinetics of the membrane depends on the thickness of the membrane and type of the polymer used. Thus, drug release can be achieved and controlled by preparing devices with alternating layers of drug and polymeric coats or by preparing a mixture of particles which have different coating characteristics. Matrix dissolution devices are generally prepared by compressing powder mix of drug and a water-soluble or water-swellable polymer. They can also be made by casting and drying of a polymer solution containing a suitable amount of dissolved or dispersed drug. A variety of other excipient may optionally be included to aid formulation properties. The

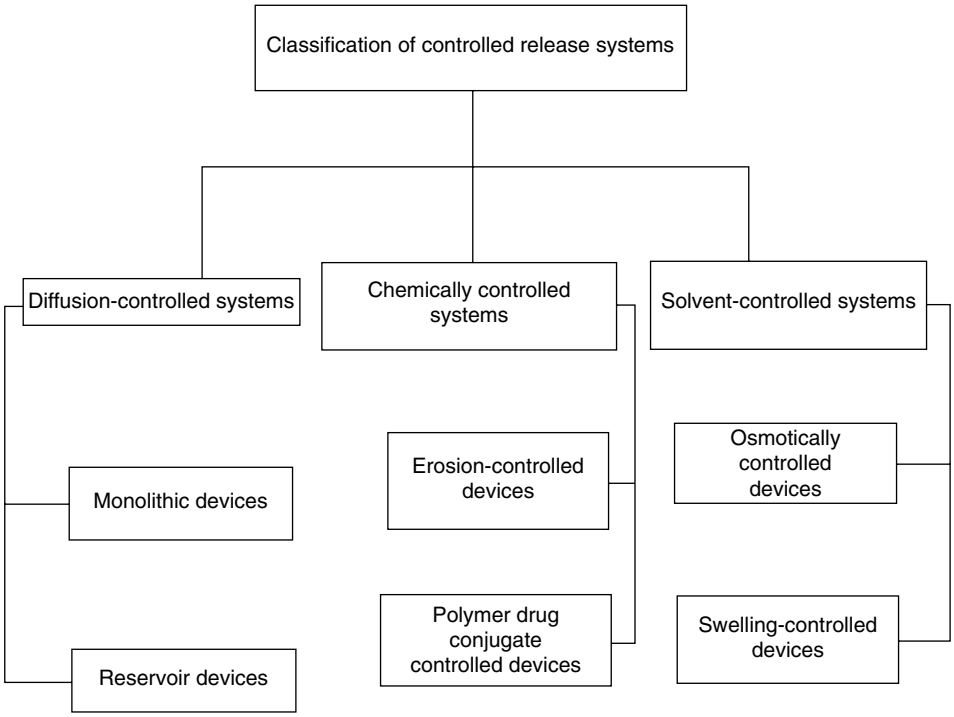

Fig. 6. Classification of controlled release systems.

influence of excipients and formulation factors on the dissolution behavior of the methyl hydroxyethyl cellulose (MHEC) tablets has been investigated (47). The use of drugs with higher solubility leads to a slight acceleration of the release because of the contribution of diffusion to the release process (caused by channels formed as a result of drug solubilization). Furthermore, alterations of the composition of the dissolution medium affect drug release.

Degradation/Erosion-Based Systems. While early research on polymer-based controlled release systems involved both degradable and nondegradable polymers, degradable polymers are preferred for parenteral drug delivery applications. Degradation of the polymer eliminates the need for a surgery to recover the spent polymer after the entire drug is released. It also reduces issues related to the long-term safety of the polymer. For biodegradable polymers, release of the drug is often intricately tied up with the polymer degradation profile. As can be seen in Figure 7, polymer degradation could be either enzymatic (facilitated by specific enzymes in the body), hydrolytic, or a combination of the two. The drug could be either physically entrapped in the polymer matrix wherein it would be released by diffusion and/or erosion of the polymer mass. Alternatively, the drug could also be chemically attached to the polymer backbone. In such a situation, the drug is released by the enzymatic/hydrolytic cleavage of the chemical bond between the polymer and the drug. A further classification of polymer degradation is established based on the polymer mass erosion patterns. If the polymer is hydrophobic then it restricts the diffusion of water into its matrix and hence polymer erosion may be restricted

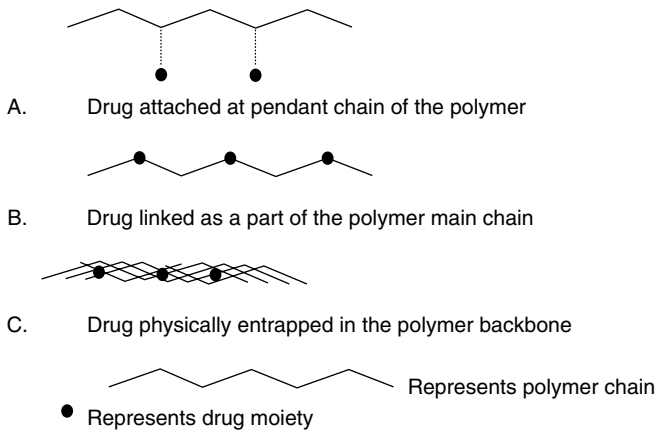

Fig. 7. Schematic representation of different embodiments of polymer-based controlled release formulations.

to the surface (as is the case for certain polyanhydrides). A more conventional case for majority of polymers including PLA and PLGA is when erosion occurs throughout the bulk of the polymer matrix (termed as *bulk erosion*). Bulk erosion is associated with a drop in pH within the interior of the matrix. While such a pH drop is detrimental to pH labile drugs, it could be utilized to stabilize certain type of basic drugs such as campothein (48).

Various diffusion models have been proposed for different scenarios and embodiments (49). Ritger and Peppas (50) proposed an empirical equation that has been successful in modeling the drug release for several formulation scenarios. This equation correlated the fraction of drug released to the time as

$$M_t/M_o = kt_n$$

M_t and M_o denote the drug release at time t and total amount of drug in the formulation respectively. The empirical coefficients k and n are related to the kinetics and diffusion mechanism respectively. When $n = 0.5$, this equation obeys Fick's law of diffusion. On the other hand, $n = 1$ denotes case II diffusion to play a prominent role. The key feature of this model is its simplicity as well as its ability to offer insights on the diffusion mechanisms based on the value of k.

Mathematical models have also been proposed to incorporate polymer degradation kinetics as an integral part of the theoretical framework explaining drug release characteristics (51). Similarly, kinetic models have been used to explain degradation profiles of the polymer. As listed in Table 2, several polymer properties play an important role in their degradation behavior.

Osmotic Delivery Systems. Osmosis-controlled devices comprises a core reservoir of drugs, with or without osmotically active salt, coated with a semipermeable membrane. The presence of salt or drug molecules creates an osmotic pressure gradient across the membrane and the diffusion of water into the device gradually forces the drug molecules out through an orifice made in the device. For a durable device, the mechanical strength of semipermeable membrane should be strong enough to resist the stress building inside the device. The drug release rate

Table 2. Important Properties of the Polymer that Influence Its Degradation Characteristics

Property	Effect on degradation kinetics
Chemical linkages	The type of hydrolytic linkage determines rate of degradation. For example, anhydride bonds are known to degrade faster than ester bonds.
Molecular weight (MW)	Higher the MW, slower is the degradation rate
Morphology	Porous forms (higher surface area) may be more susceptible to hydrolysis because of enhanced access for water penetration
Crystallinity	Higher crystallinity leads to slower degradation
Water uptake	Water uptake leads to faster degradation because of a better access for water to attack the polymer chains.
Polymerization conditions	Use of catalysts, reaction temperature, etc may affect the degradation properties of the polymer
Chain defects	Chain defects are often associated with faster degradation. Lesser the uniformity in structure, higher is the rate of hydrolysis.

from the osmotic devices, which is directly dependent on the rate of external water diffusion, can be controlled by the type, thickness, and area of the semipermeable membrane. Alza developed osmotic devices such as elementary osmotic pump system for oral administration and Alzet osmotic pump for implant. A recent review by Singh and co-workers discusses osmosis as a phenomenon for controlled drug delivery, along with the device concepts such as Rose Nelson pump, Higuchi osmotic pump, and Higuchi Theeuwes osmotic pump (52).

Ion-Exchange Systems. Polyelectrolytes have been used as cross-linker to form water-insoluble ion-exchange resins. The drug is bound to the ionic groups by salt formation during absorption and released after being replaced by appropriately charged ions in the surrounding media. For cationic drug delivery, poly(styrene sulfonic acid) and poly(acrylic acid) can be used as anionic ion-exchange resin where sulfonic and carboxylic groups make the complexes with cationic drugs and hydrogen ions and/or other cation such as sodium or potassium ions activate the release of cationic drugs by replacing them from the drug–resin complex. On the other hand, cationic ion-exchange resins like poly(dimethylamino ethyl methacrylate) have been used for the delivery of anionic drug, in which basic group namely amino or quaternary amino group makes a complex with anionic drugs. The interaction of a series of *O*-*n*-acyl propranolol prodrugs (I, R = C1–9 alkyl or CH_3C) with strong cation exchange resins has been reported and various variables that control loading and release profiles have been investigated (25). The effect of *O*-*n*-acyl chain-length on the loading and release profiles was detected by molecular size, for example, the loading was inhibited for the groups with increased size, and release rates were reduced. Again, this enables some control of release profiles but the approach was found to be most suitable for drugs that were active at low doses, which allow full use of these variations without the necessity for large amounts of resin in the delivery system. Sometimes, the

ion-exchange resins are additionally coated with a polymer film, such as acrylic acid and methacrylate copolymer or ethylcellulose, to regulate the swelling of the resin and to further control the drug release. The Pennkinetic system is an example of the devices based on these mechanism to deliver dextromethorphan from the ethylcellulose-coated poly(styrene sulfonate).

Polymeric Prodrugs. Many water-soluble polymers possess functional groups to which drug molecules can be covalently attached and thus, these polymers that have no therapeutic effect serve as drug carriers. The drug molecules are gradually released from the polymer by hydrolytic or enzymatic cleavage. If the cleavage occurs by chemical hydrolysis, the drug release depends on the nature of the covalent bonds and pH of the environment; however, it is very slow in the body. If the drug molecule is released by enzymatic hydrolysis, the release is mainly dependent on the concentration of enzymes. Thus, the exact release profile depends on the *in vivo* condition and not on the delivery system itself. To be a useful carrier, a polymer should possess certain features:

(1) The polymer should remain water-soluble even after drug loading
(2) Molecular weight of the polymer should be large enough to permit glomerular filtration but small enough to reach all cell types.
(3) Drug-carrier linkages should be stable in body fluid and yet degradable after capturing in target cells.

This can be achieved by making the linkage degradable by lisosomal enzymes, in which the polymer is nontoxic, nonimmunogenic, biocompatible, and degradable by lysosomal enzymes to be eliminated from the body after releasing drugs. Starch derivatives, dextran (53), poly(aminoacids), PVP, and poly(hydroxypropyl methacrylamide) have been used as polymeric drug carriers.

Magnetically Stimulated Systems. The two principle parameters controlling the release rates in these systems are magnetic field characteristics and mechanical properties of the polymer matrix. It was found that when the frequency of the applied field was increased from 5 to 11 Hz, the release rate of the bovine serum albumin (BSA) from ethylene vinyl acetate (EVAc) copolymer matrices rose in linear fashion (54). The mechanical properties of the polymeric matrix also affect the extent of magnetic enhancement (54). For example, the modulus of elasticity of the EVAc copolymer can be easily altered by changing the vinyl acetate content of the copolymer. The release rate enhancement induced by the magnetic field increases as the modulus of elasticity of EVAc decreases. A similar phenomenon was observed for cross-linked alginate matrices: higher release rate enhancement for less rigid matrices (55). Edlemean and co-workers. (56) also showed that enhanced release rates observed in response to an electromagnetic field (50 G, 60 Hz) applied for 4 min were independent of duration of the interval between repeated pulses.

Photostimulated Systems. Photoresponsive gels reversibly change their physical or chemical properties upon photoradiation. A photoresponsive polymer consists of a photoreceptor, usually a photochromic chromophore, and a functional part. The optical signal is captured by the photochromic molecules and then the isomerization of the chromophores in the photoreceptor converts it to a chemical

signal. Suzuki and Tanak (57) reported a phase transition in polymer gels induced by visible light, where the transition mechanism is due to the direct heating of the network polymer by light.

Ultrasonically Stimulated Systems. Kost and co-workers (58) proposed that cavitation and acoustic streaming are responsible for the augmented degradation and release of biodegradable polymers. Miyazaki and co-workers (59) speculated that the ultrasound caused increased temperature in their delivery system, which may facilitate diffusion.

Electrically Stimulated Systems. In the late 1980s, Grimshaw (60) reported four different mechanisms for the transport of proteins and neutral solutes across hydrogel membranes:

(1) Electrically and chemically induced swelling of a membrane to alter the effective pore size and permeability
(2) Electrophoric augmentation of solute flux within a membrane
(3) Electroosmotic augmentation of solute flux within a membrane
(4) Electrostatic partitioning of charged solutes into charged membranes

Kwon and co-workers (61) studied drug release from electric current sensitive polymers. Edrophonium chloride, a positively charged solute, was released in an on-off pattern from a matrix device by an electric field. The mechanism was explained as an ion exchange between positive solute and hydroxonium ion, followed by fast release of the charged solute from the hydrogel. The fast release was attributed to the electrostatic force, the squeezing effect, and the electroosmosis of the gel. However, the release of neutral solute was controlled by diffusion affected by swelling and deswelling of the gel.

Representative Applications

Controlled Release of Peptides and Proteins. Sustained release applications are especially useful for proteins/peptides because of their short half-lives (62). This concept was first utilized commercially in Lupron Depot, which was introduced as a sustained release formulation of a lutenizing hormone-releasing hormone (LHRH), leuprolide acetate, with poly(lactic acid) as the polymer (63). Following the success of Lupron Depot, other sustained release formulations of LHRH analogues have also been commercialized, including Zoladex wherein the LHRH peptide is encapsulated in PLA-extruded rods, and Trelstar depot wherein the peptide is encapsulated in PLGA polymer matrices.

Recently, a once-in-four-weeks formulation of a cyclic peptide Octreotide, encapsulated in biodegradable PLGA–glucose polymer matrix, has also been commercialized under the trade name Sandostatin LAR (Novartis Pharmacenticals Corp.) (64). In 2000, a human growth hormone sustained release formulation (Nutropin Depot) became the first polymer-based sustained release formulation of a therapeutic protein to receive marketing approval from the Food and Drug Administration. This commercialized formulation encapsulates a zinc-complexed form of recombinant human growth hormone in a PLGA matrix (41). Other therapeutic proteins that are being tested for encapsulation in polymer matrices

include bone morphogenic protein (65), erythropoietin (66), and nerve growth factor (67).

Controlled Release of Antirestenotic Agents from Stent Coatings. Stents are tiny wire scaffold-like devices, which have become the most successful and widely used innovation in interventional cardiology of the last decade. These devices are inserted inside blocked sections of coronary arteries and expanded into place using a balloon catheter in a procedure called an angioplasty. In as many as 40% of patients receiving angioplasty, a new blockage develops at the site because of scar tissue growth and inflammation, a condition referred to as restenosis. More than 500,000 Americans are treated for restenosis annually. Stents coated with a biocompatible polymer, encapsulating an antirestenotic agent, have proven to be a successful therapy to reduce or eliminate restenosis. Several drugs including cytostatic agents (Rapamune), antiproferative agent (Paclitaxel), and antiinflamatory agents have been encapsulated in micron-thick films that coat the metallic stent (68). The polymers used for this application are required to be elastic, biocompatible, and hemocompatible. Lewis and co-workers (69) demonstrated the use of phosphorylcholine-based polymers for this application. Other polymers tested for this application include polylactide and polyurethane (70).

Polymeric Systems for the Treatment of Cancer. By providing sustained release at the desired site, high doses of toxic drugs can be delivered to the site without introducing the drug into systemic circulation. This results in a major advantage for the administration of chemotherapeutic drugs, wherein the drugs can be encapsulated into polymer matrices and administered directly into the tumor area. Gliadel (Guilford Pharmaceuticals) implant is a product based on the above concept, encapsulating a chemotherapeutic agent, carmustine, into a biodegradable polymer, fabricated as a dime-sized wafer (see BIODEGRADABLE POLYMERS, MEDICAL APPLICATIONS). Several wafers are implanted by the surgeon into the brain cavity during a tumor resection surgery. By direct release of the drug in the tumor region in the brain, the problem of overcoming the blood-brain barrier is resolved. Also, high doses of the chemotherapeutic agent are delivered at the tumor site, thus making the therapy significantly more effective than systemic administration. Other chemotherapeutic agents that are also being developed as sustained release formulations include paclitaxel and cisplatin (71).

The biggest success of polymer controlled release systems in cancer therapy however has been in the area of prostate cancer treatment. This therapy is unique since it uses a hormone-suppressant rather than a chemotherapeutic agent to minimize cancer cell growth in the prostate. Several products include Lupron Depot (TAP Pharmaceuticals), Zoladex (Astra-Zeneca), and Trelstar Depot (Debio RP, Pharmacia). Lupron Depot involves PLA microspheres, Zoladex formulation is an extruded rod, whereas Trelstar depot consists of PLGA microspheres, all of which incorporate LHRH analogues.

Sustained Release of Drugs for CNS-Related Disorders. Another area of application for polymer-based controlled release technologies is for the sustained delivery of drugs for the central nervous system (CNS) related disorders. CNS-related drugs include a wide range of therapeutics including pain management agents, drugs to prevent substance abuse, as well as drugs for conditions such as schizophrenia, Parkinson's and Alzheimer's disease. Drugs such as lidocaine and bupivicaine have been studied for sustained local anesthesia at the site of surgery (72). For this application, the anesthetic agent is encapsulated

in a biodegradable polymer and injected in the proximity of the site of pain. The drug is released facilitating high concentrations at the local site, without reaching the threshold levels of systemic toxicity. In other cases such as schizophrenia, Parkinson's and Alzheimer's diseases, sustained release of the medication may reduce the chance of missed doses and aid in an effective dose regimen.

Gene Therapy. For more than two decades, researchers have been working to alleviate disease through gene therapy. In this type of treatment a gene is delivered to cells, allowing them to produce their own therapeutic proteins. Traditionally, DNA delivery systems have been classified as viral vector-mediated systems and nonviral vector-mediated systems (73). Currently, because of their highly evolved and specialized components, viral systems are by far the most effective means of DNA delivery, achieving high efficiencies (>90%) for both delivery and expression (74). The most promising nonviral gene delivery system thus far, other than the "gene gun," is the DNA vaccine application, which comprises of ionic complexes formed between DNA and polycationic liposomes (75,76) (see GENE-DELIVERY POLYMERS).

Nonviral vectors can be divided into two broad categories—physical and chemical—according to Huang. Physical methods involve taking plasmids and forcing them into cells through such means as electroporation or particle bombardment. Chemical methods use lipids, polymers, or proteins that will complex with DNA, condensing it into particles and directing it to the cells. Nonviral systems

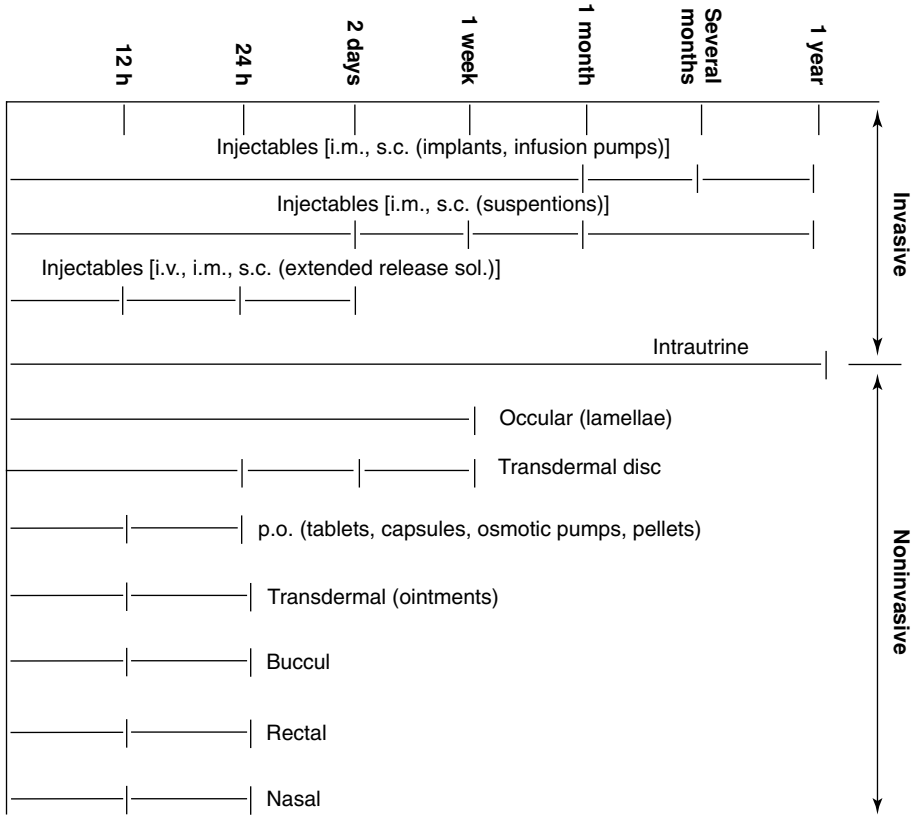

Fig. 8. Route of administration and length of action in the body.

for gene delivery have several potential advantages over viral vectors. Viruses can cause an immune response that can make repeat administrations ineffective. Nonviral vectors can also carry more DNA than viruses, allowing the delivery for larger genes. In addition, nonviral vectors are easier and less expensive to manufacture. The plasmids that are used in nonviral systems can be produced in bacteria such as *Escherichia coli*. The same production facilities can be used to manufacture a variety of plasmids incorporating different genes. Many recent reviews describe various aspects of nonviral vectors for gene therapy including different polymers and success and failure stories (77–79).

Controlled Release Systems in Market

Controlled release has gained a good impact among the various drug delivery technologies because of patient compliances, safety of drug, and minimum side effects. Various controlled release systems according to their drug availabilities, route of administration, and length of action in the body are presented in Figure 8. It had been estimated that the world pharmaceuticals sales was nearly $400 billion during the year 2000 and about 12.5% or $50 billion for drugs involving special drug delivery technology. Sales of drug delivery products are expected to more than double to $104 billion in 2005. Among them, more than 20% share goes to controlled drug release technologies. Examples of controlled release technologies available in the market place are given in Table 3.

Table 3. Some Examples of Controlled Release Products in Market

Technology	Technology name (drug)	Application	Company
Liposome-based formulations	Evacet (Doxorubicin)	Breast cancer and other cancers	Elan with acquisition of Liposome, Inc.
One-yearly drug implant	Viadur (Leuprolide)	Prostate cancer	ALZA/J&J
Biodegradable implants	Gliadel (BCNU[a])	Treatment of brain cancer	Guilford Pharmaceuticals, Inc.
Biodegradable microsphere for sustained-release for peptides/proteins	ProLease	Delivery of peptides and small molecules	Alkermes, Inc.
Time release oral drug release	Pulsincap	Drug release at predetermined time or location in the GI-tract	RP Scherer Corp.
Oral controlled release system to control the release of a specific drug	Geomatrix	Predetermined therapeutic objective for a drug	SkyePharma

COTTON

Introduction

The use of cotton predates recorded history. Although the actual origin of cotton is still unknown, archaeological findings indicate its use in cloth in 3000 BC. Early explorers in Peru found cotton cloth on exhumed mummies that dated to 200 BC. The first cotton mill was built in Beverly, Massachusetts, in about 1790, and in 1794 Eli Whitney was granted a patent for the invention of the cotton gin, the "engine" that separates the cotton from the seed.

Cotton culture has evolved from gathering of the lint and seed from wild plants by indigenous people to the domestication and cultivation of selected species. Cotton is both a fiber (lint) and food (cottonseed) crop. For each 45.36 kg (100 lb) of fiber produced, the plant also produces ~68.04 kg (150 lb) of cottonseed. Cotton, which only has value once the fiber and seed are separated at the gin, is perishable and must be harvested in a timely manner or the fiber and seed can deteriorate in quality and value.

Cotton fiber is the most important natural vegetable textile fiber used in spinning to produce apparel, home furnishings, and industrial products (1). In 2001, worldwide ~37% of the textile fiber consumed was cotton (2). In its marketed form, raw cotton consists of masses of fibers packaged in bales of ~85–230 kg (187–507 lb). A single kilogram (2.2 lb) of cotton may contain 200 million or more individual fibers.

Cottonseed [world's no. 3 oilseed; 26,665 tons (3)] can be fed as whole seed (16% oil, ~45% protein) to dairy cattle or crushed at a cottonseed oil mill to obtain oil [160 kg/ton (320 lb/tons)], hulls [260 kg/ton (540 lb/t)], meal [455 kg/ton (910 lb/tons)], linters [fuzz fibers $\leq$0.33 mm long; 83.5 kg/ton (167 lb/tons)], and manufacturing loss [31.5 kg/ton (63 lb/tons)] (4). The oil is used for human

consumption; the hulls and meal are sources of vegetable protein feed for animals; and the linters are used as a chemical cellulose source and in batting for upholstered furniture and mattresses as well as for high quality paper.

The origin, development, biology/breeding, production, morphology, chemistry, physics, and utilization of cotton have been discussed in many publications (1,4–9).

Cotton fibers are seed hairs from plants of the *Malvaceae* family, the tribe *Gossypieae*, and the genus *Gossypium*. It is a warm-weather shrub or tree that grows naturally as a perennial but for commercial purposes is grown as an annual. Botanically, cotton is a fruit. The principal domesticated species of cotton of commercial importance are *hirsutum, barbadense, arboreum*, and *herbaceum*. Many different varieties of these species have been developed through breeding to produce cotton plants with improved agronomic properties and cotton fibers with improved length, strength, and uniformity. In addition to conventional breeding methods, genetic engineering is being used to produce transgenic cottons with insect resistance (eg, Bollgard; "Bt cottons" incorporting genes from *Bacillus thuringiensis* for boll worm/bud worm resistance) and herbicide tolerance [eg, bromoxynil (Buctril; "BXN cotton") and glyphosate (Roundup; "Roundup Ready cottons") tolerant cottons, which enable reduced use of herbicides] (10). In 2002, transgenic cotton varieties are ∼25–30% of the cotton grown in the world and are being grown in the United States, China, Australia, South Africa, Argentina, Mexico, India, and Indonesia. Research is underway to produce transgenic cottons with other improved agronomic traits as well as improved fiber quality properties.

Gossypium hirsutum, developed in the United States from cottons that originated in Central America and Mexico, includes all of the many varieties of American Upland cotton. Upland cottons now provide >90% of the world's production of raw cotton fiber and vary in length from ∼22 to 36 mm (7/8 to $1\frac{1}{2}$ in.) with micronaire scale [numerical values are roughly the equivalent of linear density (expressed in micrograms weight per inch of length); represents fiber surface area, used as an indicator of fiber fineness (http://www.uster.com/en/prod/main_2_0_4.htm)] ranging from 3.8 to 5.0. *G. hirsutum* is a shrubby plant that reaches a maximum height of 1.8 m (5.9 ft). and is used in apparel, home furnishings, and industrial products.

Gossypium barbadense, originally of early South American origin, has the longest staple length and is commonly referred to as "extra long staple" (ELS) cotton. It includes Sea Island, Egyptian Giza strains, American Pima, and Tanguis cottons. Sea Island is the longest and silkiest of the commercial cottons. *G. barbadense* accounts for ∼8% of current world production. ELS cotton fiber is long and fine with a staple length usually greater than 35 mm ($1\frac{3}{8}$ in.) and a micronaire <4.0. The plant grows from black usually linter-less seeds and reaches a height of 1.8–4.5 m (5.9–14.8 ft). Egypt is the major producer of ELS cotton today. Pima, an ELS, is a complex cross of Egyptian and American Upland strains and is grown in the western United States as well as South America. *G. barbadense* is used in high quality apparel, speciality yarns for lace and knitted goods, and sewing thread.

Gossypium arboreum and *Gossypium herbaceum*, known collectively as "Desi" cottons, are the other commercial species. They are the Asiatic or Old World short staple cottons. Both are of minor commercial importance but are grown in

India and Pakistan. *G. herbaceum* is also grown in China. These cottons are the shortest and coarsest cottons cultivated, ranging from 9.5 to 19 mm ($\frac{3}{8}$ to $\frac{3}{4}$ in.) and micronaire >6.0. *G. arboreum*, the tree wool of India, grows as tall as 4.5–6.0 m (14.8–19.7 ft) and includes both Indian and Asiatic varieties. Its seeds are covered with greenish gray fuzz fibers below the white lint fibers. *G. herbaceum*, the original cotton of India, averages 1.2–1.8 m (3.9–5.9 ft) in height. The fiber is grayish white and grows from a seed encased in gray fuzz fibers.

Commercial cottons are almost all white but recently there has been a renewed interest in naturally colored cottons. They have existed for >5000 years (11,12). The availability of synthetic dyes and the need for high quality, higher yielding cottons caused these cottons that are short, weak, and low yielding to almost disappear. Naturally colored cottons available today are usually shorter, weaker, and finer than regular upland cottons, but can be spun into ring and rotor yarns for some applications alone or when blended with normal white fiber (13). The color can intensify with washing and colors can vary somewhat from batch to batch (13). Colored cottons are being grown presently in the United States, Peru, China, and Australia. The amount available is very small. Shades of brown and green are the main colors available. Other colors (mauve, red) are available in Peru and some other colors are being researched. The color for brown and red-brown cotton appears to be in material bodies in the lumen. The different colors of brown and red-brown are due most likely to tannins derived from (+)-catechin (14) and some may be protein–tannin polymers. The color in green cottons is due to a lipid biopolymer (suberin) deposited between the cellulose microfibrils in the secondary wall. The brown cotton fibers (and white lint cultivars) do not contain suberin like the green cotton fibers. Green cotton fibers are chacterized by a high wax content of 14–17% of their dry weight, whereas white and brown fibers contain only 0.4–0.7% wax (14,15).

At present, cotton is grown in environments that range from arid to tropical, with long to very short growing seasons. Cotton typically requires a growing season of at least 160 days when minimum temperatures are >15°C (60°F) (7). Fairly moist and loamy soil produces the highest yields. Under normal climatic conditions, cotton seeds germinate and seedlings emerge in 7–10 days after planting. Flower buds (known as squares) appear 35–45 days later, followed by open white (Upland cotton) or creamy to dark-yellow (Pima cotton) flowers 21–25 days later. One day after the flower opens the cotton boll begins to grow rapidly, if the flower has been fertilized. Mature bolls open 40–80 days after flowering, depending on variety and environmental conditions. Within the boll are three to five divisions called locks or locules, each of which normally has seven to nine seeds that are covered with both lint and linters (Fig. 1). The linters form a short, shrubby undergrowth beneath the lint hairs on the seed. At least 13,000–21,000 fibers are attached to each seed and there are close to 500,000 fibers in each boll.

Each cotton fiber is a single cell that originates in the epidermis of the seed coat at about the time the flower opens. The fibers first emerge on the broad, or chalazal, end of the seed and progress by degrees to the sharp, or micropylar, end. As the boll matures, the fiber grows until it attains its maximum length, which averages ~2500 times its diameter (Fig. 2). During the first 3 weeks, the cell is composed of a thin wall (primary wall) that is covered with a waxy, pectinaceous material, which encloses the protoplasm or plant juices. The primary wall also

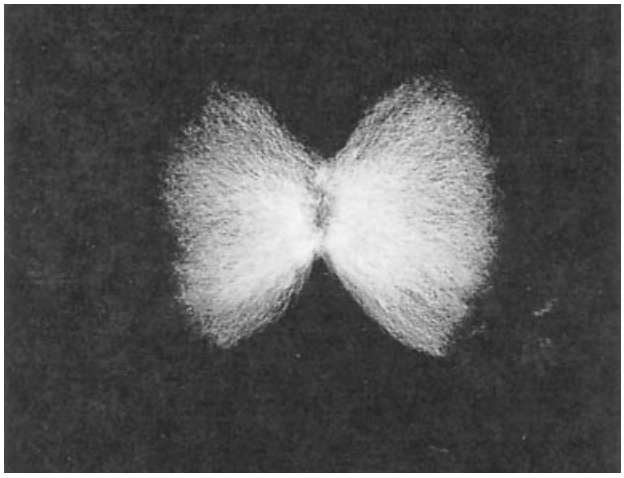

Fig. 1. Cotton butterfly with lint and linters (fuzz fibers).

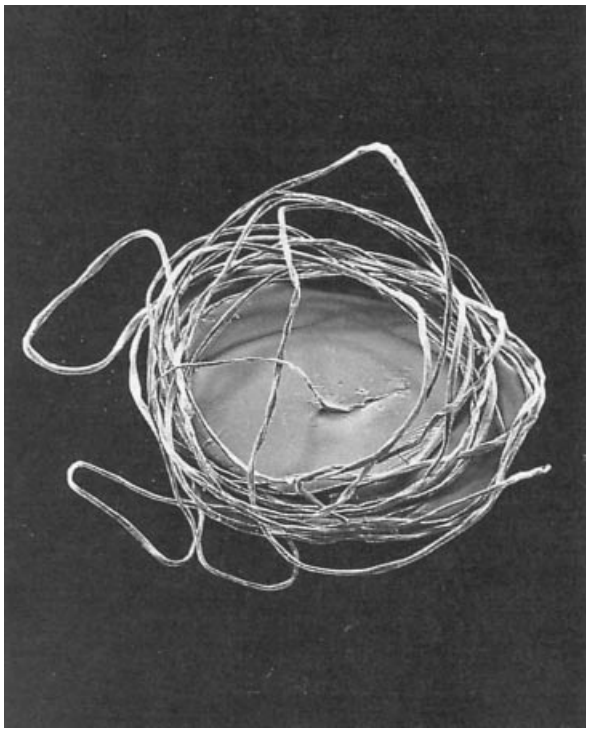

Fig. 2. Single cotton fibers, showing ratio of length to diameter.

contains protein, cellulose, and hemicellulose. In ~17–25 days after flowering (postanthesis), when the boll is half-mature, each fiber virtually attains its full length. Then layers of cellulose (qv) are deposited on the inside of the thin casing, or primary wall. The pattern of deposition is such that one layer of cellulose is formed each day in a centripetal manner until the mature fiber has developed a

thick secondary wall of cellulose from the primary wall to the lumen, or central canal. The fiber now consists of three main parts: primary wall, secondary wall, and lumen. At the end of the growing period when the boll opens, the fibers dry out. The mature cotton fiber is a dead, hollow dried cell wall tubular structure, which is collapsed, shriveled, and twisted, giving the cotton fiber convolutions. The convolutions differentiate cotton fibers from all other forms of seed hairs and are partially responsible for many of the unique characteristics of cotton.

The seed hairs of cultivated cottons are divided into two groups (fuzz fibers or linters and lint) that differ in length, width, pigmentation, and strength of adherence to the seed. The growth of linters is much the same as that of lint, but elongation is initiated about 4 days after flowering. They are usually ~0.33 cm (1.3 in.) long compared with the 2.5 cm (1 in.) average length of lint fibers and are twice as thick, or ~32 μm (Fig. 3). Their color is usually greenish-brown to gray. After lint fibers have been ginned off the seed, the linters remain. Removal of linters is usually done at the cottonseed oil mill and requires a machine similar to that used at the saw cotton gin to remove the fiber from the seed.

Cotton Fiber Biosynthesis

During the cell elongation stage of fiber development, a primary cell wall envelopes the growing fiber. The principal components of fiber primary cell walls are pectins, hemicelluloses, cellulose, and proteins. Relatively few studies on the chemical identity and structure of fiber primary cell wall components have been conducted (16–18). In higher plants, pectins and hemicelluloses are produced in Golgi bodies and are deposited in the wall by fusion of Golgi-derived vesicles with the cell membrane. Cell wall proteins are synthesized in association with the endoplasmic reticulum and may be glycosylated in the Golgi. In contrast, the enzyme complex responsible for cellulose biosynthesis is associated with the cell membrane in structures known as rosettes.

Cellulose biosynthesis has been extremely difficult to characterize biochemically. At maturity, cotton fibers are nearly pure cellulose and should be a rich source of the enzyme cellulose synthase. Unfortunately, it has been difficult to separate a β-1,4-glucan (cellulose) producing activity from a large background of β-1,3-glucan (callose) synthesis. Progress in separating the two enzyme activities from cotton fiber has been reported recently (19); however, detailed structural information comparing the two enzymes is still lacking. With the advent of molecular genetic approaches to study genes expressed during cotton fiber development, a breakthrough has been achieved. By determining the sequence of many messenger RNA (m RNA) molecules produced by immature cotton fibers, two gene transcripts with regions similar to those found in bacterial cellulose synthases were discovered (20). These subunits of the cellulose synthase complex were named CesA1 and CesA2 and are produced concomitantly with the initiation of secondary cell wall biosynthesis in fiber (20). A third CesA gene from cotton has also been described and is expressed both during the cell elongation and secondary wall thickening stages (21). The CesA subunit alone will not produce cellulose, but genetic experiments in the model plant *Arabidopsis* link the CesA gene to cellulose biosynthesis (22). In addition, a membrane-associated cellulase gene has also been implicated in cellulose biosynthesis by induced mutations in *Arabidopsis* (23,24). It seems paradoxical that cellulase, an enzyme capable of degrading cellulose, is involved in cellulose biosynthesis. Initiation of cellulose biosynthesis in cotton fiber has been found to require sitosterol-β-glucoside as a primer (25). It has been suggested that the cellulase activity is required for cleaving the primer from the growing glucan chain. Another enzyme, sucrose synthase, colocalizes with sites of cellulose biosynthesis in cotton fiber membranes, and may function to partition substrate to the cellulose biosynthetic complex (26).

Production

About 80 countries in the world grow cotton. Planting time for cotton varies by locality, varying from February to June in the northern hemisphere; harvest time is in the late summer or early/late fall. In the western hemisphere, cotton is cultivated between about 37°N and 32°S latitude and in the eastern hemisphere, between ~47°N and 30°S.

Cultivation of cotton differs markedly from one country to another, depending upon the degree of mechanization (7). When cotton is grown and processed in a responsible manner, it does not have adverse effects on the environment, the workplace, or the consumer (1,27). In the United States cotton-breeding research as well as management and harvesting practices have increased the yields and so about 30% as much land is needed today to produce the same amount of cotton as in 1930. Through conventional cotton-breeding research, many fine-quality cotton varieties have been developed (28).

Field Preparation. Field preparation practices reflect the varied environments and production systems encountered in the various cotton-growing regions. In the United States, some form of conventional or clean tillage dominates in regions not subject to erosion. This includes incorporation of plant residues in the fall to minimize overwintering insects and food sources for disease organisms; deep tillage in either fall or spring to improve root penetration, water availability, and crop performance; ridges or beds may be formed following tillage to facilitate surface drainage, irrigation, and aeration and speed soil warming; and shallow tillage completes field preparation to enhance soil tilth and seedling growth.

Conservation tillage systems are gaining in popularity in areas subject to soil erosion. Conservation tillage, which includes minimum till, no till, and other forms of maintaining residue on the soil surface, has enabled farmers to increase their production options in response to their specific challenges. These systems became feasible with the advent of specialized equipment and new herbicide chemistry that reduce or eliminate the need for extensive tillage.

Planting. Less than 5% of the cottonseed produced is used for planting seed. Advances in equipment design and engineering have vastly improved the precision of the planting operation. Seed depth and spacing can be adjusted in response to soil, weather, geographical, and seasonal requirements. When coupled with high quality seed and state-of-the art weather forecasts, seeding rates can closely approximate final stand density.

Irrigation. Approximately 70% of the U.S. cotton is rain-grown, but western states (Arizona, California, and New Mexico) grow only irrigated cotton. The use of supplemental irrigation is increasing in some rain-grown areas of Texas, New Mexico, and the mid-south states, so that presently ~70–80% of U.S. cotton uses some form of supplemental irrigation. Whether applied down the furrow via ditches, overhead with moving pipes or below the surface in drip systems, irrigation requires close producer attention. Water demand by the crop is monitored with soil or plant-based instrumentation including calculated evapotranspiration, soil tensiometers, gypsum blocks and neutron probes, leaf pressure chambers, and infrared (IR) thermometers that measure canopy temperature. The specific technique selected reflects the production region, soil characteristics, irrigation capabilities, and management style of the individual producer. Whatever technique is employed, irrigation decisions are made to maximize production efficiency and eliminate waste.

Fertilization. Cotton normally is grown under intense production systems; many fields are planted in cotton year after year. However, in the United States in 2002 ~55–100% of cotton farmers, depending on the state, also grow other crops and have the potential for crop rotation (personal communication from D. K. Lanclos, National Cotton Council, based on a 2002 planting intentions survey).

On average, U.S. cotton is fertilized with 31 kg (68.3 lb) of nitrogen, 10 kg (22 lb) of P_2O_5, and 6.8 kg (15 lb) of K_2O (29). The type and concentration of fertilizer required for high yield depends on many factors such as soil type, previous fertilization rate, cropping system, and irrigation. Therefore, an efficient fertilization program must be based on results of soil and tissue tests and the yield desired from the crop.

Supplying nutrients according to crop demands has replaced traditional methods, as soil and tissue testing have become widespread. Nitrogen can now be metered out on an "as-needed" basis through the use of rapid and reliable soil and tissue testing methods. Unnecessary and undesirable applications are, therefore, avoided, reducing the risk of off-site discharge of nitrates. Potassium fertilization has undergone a similar evolution as application strategies are modified in light of sod characteristics and yield expectations. Soil and tissue testing, coupled with soil or foliar-applied potassium, enables growers to respond rather than anticipate crop needs. Other macronutrients, such as phosphorus, or micronutrients, such as boron, can be applied in a manner consistent with producer philosophy without compromising environmental quality.

Throughout the cotton-growing regions of the United States, the method of applying fertilizer must be tailored to the crop needs and the characteristics of the cropping system. In some production systems, fertilizer is applied during the seedbed preparation, whereas in other systems it may be applied at planting or after emergence. Combinations of preplant and post-emergence applications are common, especially for nitrogen. Foliar application is relatively new. Dilute nitrogen and phosphorus solutions are sprayed on the foliage of the plant at various times during the season, which is an attempt to match fertilizer application to the weekly needs of the plant more closely.

Crop Protection. Cotton can be affected by insects (30), weeds, diseases (31), nematodes, and mycotoxins. About 90% of the U.S. cotton uses Integrated Pest Management (IPM) practices. This approach optimizes the total pest management system by utilizing all available tools, including rotation, crop residue destruction, maximum crop competitiveness, earliness, pest scouting, action thresholds, releases of beneficial insects, sterile insect releases, and selective crop protection chemistry.

New plant protection options including new chemical, biological, and transgenic technologies coupled with good IPM schemes are helping to reduce use of broad spectrum pesticides favored in the past. Weed management (32) is a particularly exciting area as genetically engineered transgenic cotton varieties and less persistent herbicides become available. Diseases (31) and nematode pests (33) are managed by selecting tolerant or resistant cultivars and adopting specific agronomic practices that minimize their impact on cotton performance. Aflatoxin, a mycotoxin by-product (secondary metabolite) of the naturally occurring fungi, *Aspergillus flavus and parasiticus*, can be a serious food safety hazard, if it occurs on cottonseed. A potential biocontrol (competitive exclusion) method (34) for managing aflatoxin in cotton is being evaluated and developed in Arizona. Also ammoniation of the cottonseed is an effective way to eliminate the aflatoxin in seeds used for feeding (35).

Insect management (30) continues to evolve as more selective chemistry reaches commercialization, as insect-resistant trangenic cottons are introduced,

sterile insect technology evolves, and cultural practices are refined. Historically, the most destructive pests of the cotton plant in the United States are the boll weevil (36) and the bollworm/budworm complex. Insects are serious threats to the cotton industry in countries around the world. The boll weevil migrated into the United States from Mexico in around 1892 and spread over the entire cotton belt within 30 years (36). An organized effort to eradicate the boll weevil began in the United States in 1978. Using pheromone technology for trapping and detection, insect diapause control to disrupt reproduction and hibernation, and chemical control technology, the weevil is being systematically eliminated from the United States. Before the boll weevil eradication program started, the domestic cotton crop lost to the weevil was ~$200 million a year, and ~$75 million a year was spent for pesticides to control this destructive pest (37). Because of the boll weevil eradication program, this pest is on the way to being eliminated in the United States. About 33% of cotton-growing states have completed elimination of the boll weevil and ~65% are nearing completion (38).

A serious cotton insect pest in Arizona, California, New Mexico, far western Texas, and northwestern Mexico is the pink bollworm, which overwinters as diapausing (hibernating) larvae in the soil. After feeding on the late-blooming bolls, the larvae drop to the ground and hibernate for the winter, emerging as adults in the spring to lay eggs on the early cotton blooms. The eggs hatch and the new larvae bore into the fresh cotton bolls, go through molting stages, bore their way out, and drop to the ground. Throughout the growing season, the cycle repeats itself, rendering useless vast numbers of cotton plants in a single field.

For >25 years, the San Joaquin Valley of California has been protected from pink bollworm through use of a monitoring and sterile insect release program. Moths are mass-reared, irradiated to render them sexually sterile, and released onto fields where traps indicate a potential reproducing population. Chemical treatments also are effective along with other practices that include early stalk shredding, early and deep tillage, and winter irrigation that drowns diapausing larvae (39). Insect-resistant transgenic cottons are particularly effective in controlling the pink bollworm. Presently, pink bollworm eradication efforts (40) are underway in parts of the United States and northwestern Mexico.

Other insects injurious to the cotton plant include aphids, leafhoppers, lygus bugs, mites, whiteflies, fleahoppers, thrips, cutworms, and leaf miners (30). As boll weevils are being eliminated and transgenic insect protectant plants are reducing damage from bollworms, pests, which traditionally were considered secondary, are now gaining in prominance.

Harvesting

Except for the cotton gin, the introduction of the mechanical harvester has probably had a greater effect on cotton production than any other single event. Commercial mechanical harvesters were introduced into the United States after World War II and by 1955, ~23% of the U.S. cotton was mechanically harvested. Presently, >99% of the U.S. cotton crop is mechanically harvested, but ~75% of the cotton produced in the world is still hand-harvested one boll at a time (41).

When the cotton boll reaches full maturity, it begins to lose moisture and opens. As the boll opens, the drying fiber fluffs or expands outward. After the seed

cotton (linters and lint) has dropped to a moisture content of ∼12% it is ready for harvest. If the cotton is to be mechanically harvested, the plant is usually treated with a harvest-aid chemical (ie, a defoliant or desiccant) (41). A defoliant induces abscission (shedding) of foliage. The removal of leaves helps to minimize the trash harvested with the mechanical harvester and promotes faster drying of early morning dew on the lint. Defoliants should not be applied until ∼60% of the bolls are open and harvest should be delayed for 7–14 days after application. Desiccants (qv) are chemicals that induce rapid loss of water from the plant tissue and subsequent death of the tissue. The dead foliage remains attached to the plant. Harvest can begin in 3–5 days after application.

Once the plant is ready, the cotton is mechanically harvested with either a spindle picker or cotton stripper. The spindle picker selectively harvests seed cotton from open bolls. The unopened bolls are left on the plant and can be picked at a later date. The spindle picker uses a rotating tapered barbed spindle to remove the cotton from the bur (seed case). The seed cotton is wrapped around the spindle, pulled from the bur, removed from the spindle with a rubber doffer, and then transferred to a basket. Two types of cotton strippers are currently in use in the United States. The finger-type stripper uses multiple fingers made from metal angles with the vee turned up and operating at a 15°–20° approach angle with the ground. The roll-type stripper uses two 7-in. diameter (17.8-cm diameter) stripper rolls angled 30° with the ground and rotating in opposite directions. Each roll consists of three brushes and three paddles mounted in alternating sequence.

Strippers are efficient and can harvest up to 99% of the cotton from the plant. They are nonselective and remove not only the seed cotton but also the cracked and unopened bolls, the burs, and other foreign matter. The extra foreign matter requires additional cleaning at the gin.

After harvesting, the seed cotton is transported to the gin where the fiber is separated from the seed. Because the gin capacity is usually not sufficient to keep up with the harvesters, the harvested cotton is often stored in a compacted module and ginned at a later date. The type of storage or seed cotton processing may place additional constraints on the harvest process. If the seed cotton is to be placed in module storage, the cotton should not be harvested until the moisture content is 12% or less and the harvested seed cotton should be free of green plant material, such as leaves and grass.

Ginning

Gin equipment is designed to remove foreign matter, moisture, and cottonseed from raw seed cotton (42). Two types of gins are in common use—the saw gin and the roller gin. Saw gins are normally used for Upland cottons, whereas roller gins are used for the ELS (Pima) cottons. In a saw gin, the cotton enters the saw gin stand through a huller front and the saws grasp the seed cotton and draw it through widely spaced ribs. The ginning action is caused by a set of saws rotating between a second set of narrowly spaced ginning ribs. The saw teeth pass between the ribs pulling the fiber through at the ginning point. The space is too narrow for the seed to pass and so the fiber is pulled from the seed. A roller gin consists of a ginning roll (covered with a compound cotton and rubber material), a stationary

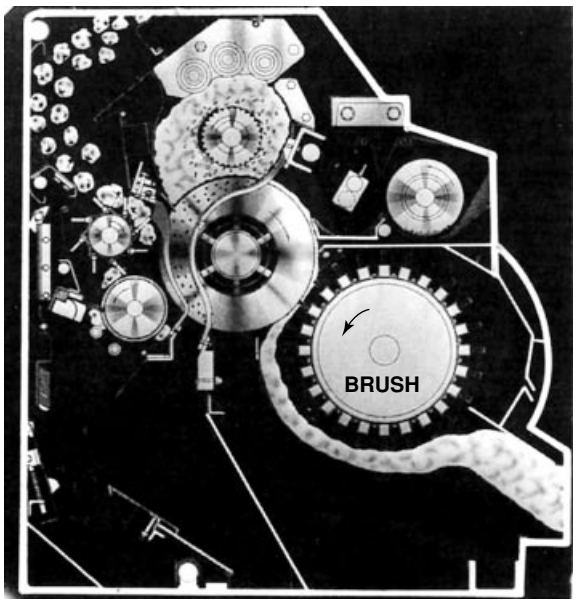

Fig. 4. A modern gin stand that separates fiber from cottonseed.

knife held against the roll, and a rotary knife. The rotating roll pulls the fiber under the stationary knife. The seeds cannot pass under the stationary knife and is separated from the fiber. The rotary knife then pushes the ginned seed away from the ginning point allowing room for more seed cotton to be ginned.

Typical types of gin equipment are cylinder cleaners, stick machines, and lint cleaners for cleaning; hot air driers for removing moisture; gin stands for separating the fiber from the cottonseed; and the bale press for packaging the lint (42). The gin stand (Fig. 4) is actually the only item of equipment required to gin cotton, the other equipment is for trash removal and drying. About 636 kg of seed cotton is required to produce a bale (~227 kg; 500 lb) of lint cotton from spindle-harvested cotton. The remainder consists of about 354-kg seed and 55-kg trash and moisture. Typical gins contain one to four individual gin stands, each rated at 6–15 bales/h. However, a few gins contain as many as eight gin stands and produce up to 100 bales/h. The greatest number [30,498] of gins existed in the United States in 1902. The majority were on plantations, and they processed 10.6 million bales (2.3×10^9 kg) of cotton (43). Since then the number of gins has declined, and the average number of bales processed per gin has increased. In 2000, a total of ~1018 active gins handled a crop of 16,742,000 bales ($\sim 3.65 \times 10^9$ kg) for an average of 16,446 bales (3.58×10^6 kg) per gin plant (44). The number of bales produced in the United States varies substantially from year to year, which places a severe financial burden on the ginning industry.

Mechanical harvesting systems were made possible by the invention of saw-type lint-cleaning systems in the early 1950s. Lint cleaners enabled gins to remove from the cotton the additional trash that resulted from mechanical harvesting. The mechanical systems reduced the harvesting period from 4–5 months to ~6–8 weeks of intensive operation. Severe congestion problems at the gin were eased

with the storage of seed cotton in 8- to 15-bale, freestanding modules. Modules avoided the massive need for wheeled trailers during the compressed harvest season. Storage of seed cotton in modules increased rapidly from the 1970s onward, accounting for >90% of the crop in 2000. At present, the average U.S. cotton ginning capacity is ~30 bales/h. A few gins process in excess of 100 bales/h (45).

Most of the U.S. gins are now operated as cooperatives or as corporations serving many cotton producers. Automatic devices do the work faster, more efficiently, and more economically than hand labor. High volume bulk seed cotton handling systems and hydraulic suction systems to remove cotton from modules, high volume trailers to get cotton into the gin, larger trailers and modules, increased processing rates for gin equipment, automatic controls, automated bale packaging and handling devices, and improved management have all increased efficiency.

After ginning, baled cotton is sampled so that grade and quality parameters can be determined (classification). The fiber quality/physical attributes affect the textile manufacturing efficiency and the quality of the finished product. Cotton bales are normally stored in warehouses in the form of highly compressed bales. The International Organization for Standardization (ISO) specifies that bale dimensions should be of length 140 cm (55 in.), width 53.3 cm (21 in.), height 70–90 cm (27.6–35.4 in.), and density of 360–450 kg/m ^{3} (22.4–28 lb/ft ^{3}) (46). Bales of cotton produced in the United States meet these dimensional standards. Bales of cotton packaged in accordance with these dimensions (ISO 8115) are not considered a flammable solid by the International Maritime Organization and the U.S. Department of Transportation for transportation purposes for vessel and other types of shipment (47,48) and are considered to present no measurable pest risk to the importing country.

Baled cotton fiber is merchandized and shipped by the merchant to the textile mill for manufacturing into products for the consumer. The seed is shipped directly for feeding to dairy cattle or to a cottonseed oil mill for crushing (49–51).

Classification/Measurement of Fiber Quality

Classification is a standardized set of procedures for measuring the quality/physical attributes of raw cotton fiber that affect the quality of finished products and/or manufacturing efficiency (52).

Classing U.S. Upland Cotton. In the United States, the quality of cotton is described (classed) in terms of color, leaf, extraneous matter, fiber length, length uniformity, strength, and micronaire according to the Official Cotton Standards (also called "universal standards") (52). Research to rapidly measure other important fiber characteristics, such as maturity, stickiness, and short fiber content, continues. The transition to all-instrument classification will be completed as soon as the technology can be developed and instruments are sufficiently refined. Practically all cotton grown in the United States is classed by the Cotton Program, AMS, U. S. Department of Agriculture (USDA), on a fee basis at the request of producers. Measurements for fiber length, length uniformity, fiber strength, micronaire (fineness), color grade, and trash are performed by precise high volume instruments (commonly referred to as "HVI" classification, see below). There are

25 official color grades (15 physical standards and 10 descriptive) for American Upland cotton, plus 5 categories of below-grade. Micronaire reading is determined by an airflow measurement. (Micronaire is often associated with maturity since usually the more mature the fiber, the larger the diameter. Such association is a gross estimation and often unreliable measure of maturity.) Classification for leaf grade, preparation, and extraneous matter are still based on subjective (classer) determinations performed by visual observation.

Classing U.S. Long Staple (Pima). Pima (ELS cotton) and Upland cotton-grade standards differ (52). The most significant difference is that the American Upland color grade is determined by instrument measurement and the American Pima color grade by trained cotton classers. Pima is naturally of a deeper yellow color than Upland cotton. The leaf content of Pima standards are peculiar to this cotton and do not match Upland standards. Because it is roller-ginned, Pima cotton's appearance is not as smooth (ie, more stringy and lumpy) as that obtained with the saw gin process. There are six official cotton grades for American Pima color and six for leaf, ranging from grade 1 (highest) to 6 (lowest). All are represented by physical standards and a descriptive standard for cotton, which is below grade.

Classing in Other Countries. The measurement of fiber quality/classing in countries other than the United States can be based on variety and growing area; appearance and visual observation; visual class and length; or classed as seed cotton, ginned by class of seed cotton, and reclassed after ginning. At present, more countries are moving to some type of automated testing system like the HVI. Differences between the U.S. classing system and those of other countries are described in the literature (1).

High Volume Instrument (HVI) Systems. Instruments to measure fiber properties have been used for a number of years, but until recently high costs and the length of time required for the tests have limited their use. However, in the mid-1960s, a cooperative effort between the USDA and instrument manufacturers began what was aimed at developing instruments that are fast enough for classification of the millions of bales of cotton produced each year. This led to the development of HVI systems. Modern HVI systems make use of the latest advances in electronic instrumentation and space-age technology to rapidly and inexpensively measure the more important fiber properties, including length, length uniformity, strength, fineness, color (including color grade), and trash.

At present, the Switzerland-based Zellweger Uster Corp. is the major HVI system manufacturer on the market. Zellweger Uster continues to advance the utilization of its cotton fiber testing technology through measurement systems specifically adapted for utilization in classing offices, gins, and mills. In recent years, other HVI system manufacturers have come into the market providing competing technologies and choices for HVI users. Schaffner Technologies of Knoxville, Tenn., Lintronics, Ltd. of Arad, Israel, and Premier Polytronics, Ltd. of Coimbatore, India are offering HVI systems at various stages of development targeted for use in gins, mills, and classification. At the end of 2001, there were some 1450 HVI systems in 70 countries.

Currently, HVI systems are providing reliable information on six characteristics of quality from a cotton sample in ~30 s that are highly related to the spinning quality and market value of the cotton. Starting with the 1991 crop year,

cotton has been required to be tested by HVI to be eligible for price supports in the United States. Information on every bale of cotton greatly improves the marketing of cotton and encourages the production of cotton with fiber properties desired by users.

Advanced Fiber Information System. The Advanced Fiber Information System (AFIS) (53–55) is a recent development that incorporates several fundamental measures into one system. AFIS measures several fiber properties that are key to predicting the ease of spinning and quality of finished product, including fiber neps (small tangles of fiber), dust, trash, fiber length, short fiber, and maturity. The measurements are unique in that individual fibers and particles (neps and dust) are automatically counted and sized. The principle of operation is that a fiber individualizer aeromechanically opens and separates the sample into single fibers that are injected into an airstream. Dust and trash particles are diverted to a filter while the airstream transports the fibers and neps past an electrooptical sensor that is calibrated to measure the specific size characteristics of the fibers and neps. The AFIS determines the average size and size distribution of neps. Measurements of dust and trash include their particle size distributions, the number of dust and trash particles per gram, and the average size of trash particles.

AFIS length measurements include percentage of short fiber content (<12.7 mm; 0.50 in.) by number and by weight; average length by number and by weight; coefficient of variation of fiber length by number and by weight; upper quartile length (75% of fibers shorter than) by weight; and the 5% length by number (95% of the fibers shorter than). Fiber maturity measurements include fiber fineness (linear density measured in millitex), the immature fiber content (% of immature fibers by number), and the average maturity ratio.

Physical Properties

Fiber length is universally accepted as the most important fiber property, because it greatly affects processing efficiency and yarn quality. The recognized reference machine method for fiber length information is the Suter–Webb Comb Sorter (56). Fibers are sorted and separated by a series of combs into length increments of 1.6 mm (0.063 in.). Each group is then weighed to determine the weight–length distribution parameters, which include the mean length of the longest half (upper-half mean) of the fibers by weight, the mean length, the percentage of the fibers <12.7 mm (0.5 in.), and the coefficient of length variation. Variations of length are unique to specific varieties of cotton and range from <2.5 cm (1 in.) for short-staple Upland varieties to 2.6–2.8 cm (1.02–1.10 in.) for medium-staple Uplands, to >2.85 cm (1.12 in.) for long-staple varieties (Pima, Egyptian, and Sea Island) (52,57).

Next to length, *fiber strength* is the most important physical property that relates to fiber and yarn quality. The recognized reference method for fiber strength is based on measurements made on bundles of parallel fibers (58). One suitable instrument, the Pressley tester, consists of a set of jaws and an inclined lever system in which an ever-increasing load is applied to the specimen until the bundle breaks. The position of the load when the bundle breaks is read from the scale and

used, together with the bundle weight, to calculate bundle strength. An alternate approach to bundle measurements is the Stelometer tester, which uses a somewhat different loading concept but still requires clamped and weighed bundles very much like the Pressley. In this case, the clamp jaws are separated by 3.2 mm (gauge length), a convention that has proven the method to be highly related to yarn strength and processing parameters. Fiber strength is expressed as breaking stress or force to break per linear density of the bundle. These units are newtons [or gram force (gf)] per linear density (tex), where 1.0 tex = 1 g/1000 m. Variations in fiber strength are also unique to specific varieties of cotton and range from 0.176 to 0.216 N/tex (18 to 22 gf/tex) for short-staple Upland varieties to 0.235–0.275 N/tex (24–28 gf/tex) for some medium-staple Uplands to 0.314–0.373 N/tex (32–38 gf/tex) for long-staple varieties (Pima, Egyptian, and Sea Island) (59).

Another important characteristic property of cotton is its *fineness*, or *linear density*, or weight per unit length. The normal units for cotton fineness are millitex (the units of tex are expressed in g/km). Fineness is directly related to the amount of cellulose in the fiber, which is a function of the fiber wall area, excluding the hollow center (lumen), and the fiber length. Variations in fiber fineness range from ∼100 mtex for fine Sea Island cotton to ∼180 mtex for a typical United States Upland variety to in excess of 300 mtex for a coarse Asian cotton (60). The term *fiber maturity* relates to the degree of development or thickening of the fiber wall relative to its outer perimeter. Recent developments in techniques for preparing excellent thin cross sections of cotton coupled with advances in computerized microscopic image analysis allow for rapid and accurate measurements of fiber wall area and perimeter (61,62). An acceptable range of maturity for mill usage is from 75 to 80%. The most commonly used measure/indicator of fiber fineness is the Micronaire reading, an airflow measurement performed on a 3.25-g test specimen, which is compressed to a specific volume in a porous chamber. Air is forced through the specimen and the resistance to the airflow is proportional to the linear density. The Micronaire reading is affected by a combination of both fiber fineness and maturity to the extent that for the same genetic variety with a constant perimeter, the Micronaire will correspond to maturity. Depending on acceptable maturity, a good range of Micronaire is between ∼3.5 and 4.8 (63).

In addition to fiber length, strength, and fineness, two other properties that have significant bearing on fiber and yarn properties are *color* and *trash* measurements, which are measured by instrumentation such as the Nickerson–Hunter Colorimeter (64) and the Shirley Non-Lint Analyzer (65).

Textile Processing

Yarn Manufacturing. Cotton is received by the textile mill in the form of highly compressed bales (∼450 kg/m^3), weighing ∼227 kg (480 lb). Although the seed and a large portion of the plant trash are removed at the gin, baled cotton still contains various forms of trash, including stem, leaf, and seed coat fragments that must be removed in the manufacturing process.

The first step in textile mill processing is opening and blending (66). Cotton properties vary considerably from bale to bale; therefore, to ensure consistency in processing efficiency and product quality, it is important that many bales be blended to produce a homogeneous mix. To do this, bales of cotton are arranged in

a "lay-down" so that sophisticated blending equipment can continuously remove some cotton from >100 bales of cotton at a time, thereby ensuring consistency of fiber properties along the length of the yarn.

After blending, the cotton is fed through a series of opening and cleaning machines containing various types of revolving beaters and sawtooth cylinders that reduce the cotton into smaller masses of less compacted tufts. Most of the dirt and heavier trash is removed through screens or grids as the cotton is tumbled, beaten, shaken, or otherwise manipulated.

The next step is carding, where the cotton is passed between two surfaces set in close proximity to each other and covered with fine brush-like wires. The surfaces move in opposite directions or in the same direction at different speeds, resulting in a combing action that separates the fibers into a fine web. Getting the cotton to this opened condition causes most of the remaining finer trash to be removed. The fine web of fibers delivered from the card is condensed into a rope-like strand called card sliver and coiled into large cans.

Fibers in card sliver are held together by the natural cohesiveness of the cotton. The fibers must now be further aligned and straightened. In a process called drawing, several strands of card sliver (usually eight) are combined to produce a single sliver of improved uniformity and fiber orientation. The drawing frame contains four or five sets of drafting rolls rotating at progressively higher speeds, that attenuate or draft the material down to approximately the original size of the card sliver. The cotton sliver is generally processed through two or three drawings to obtain maximum uniformity and parallelization of individual fibers.

Cotton is combed to produce finer, higher quality yarns and fabrics. In 1990, ~12% of the cotton processed in the United States was combed. Combing mechanically removes as much as 10–15% of the cotton as short fiber. These fibers are used in the production of lower grades of fabric. Yarns not spun from combed cotton are referred to as carded yarns. Because many of the short fibers have been removed, combed yarns are stronger and more uniform than carded yarns. However, the combing process is expensive and adds considerably to yarn costs.

The next process, roving, is an intermediate step in the preparation of the cotton exclusively for ring spinning. On the roving frame, the sliver is attenuated several times by a series of drafting rollers and a small amount of twist is added to hold the smaller mass of stock together. The product, also called roving, is then wound on a special bobbin to accommodate the creel on a ring-spinning frame.

The final process in the yarn manufacturing operation is spinning. Ring spinning is the mainstay of the textile industry and accounts for >50% of all cotton yarn produced in the United States. In ring spinning, the roving is first attenuated to the desired size through a series of drafting rollers. The strand of drafted fibers passes through a metal guide, or traveler, which revolves rapidly around a circular track, or ring, which in turn surrounds a rotating spindle and bobbin. Sufficient twist to obtain the required tensile strength is inserted by the rotation of the spindle and bobbin at speeds of up to ~20,000 rpm. Yarn is wound on the bobbin (spinning tube) by an up and down traversing of the ring. Average production rates for ring-spun yarns range from 18 to 27/m (20 to 30 yard/min).

The newer spinning methods produce yarn directly from drawing sliver, such yarns rarely, if ever, achieving the overall quality of ring, spun yarns. Rotor, or open-end spinning is a method of yarn formation that can produce coarser yarns at

three to five times the rate of ring spinning. Sliver is fed to a pinned or sawtooth-covered opening roller that rotates at a relatively high speed and individualizes the fibers. The opened fibers are then drawn via suction through a conical-shaped duct and then aligned and deposited on the inside of a rapidly revolving rotor (up to 150,000 rpm) from which they are twisted into yarn. Twist is inserted by rotation of the rotor, and the yarn is removed through a tube and wound onto a package. Rotor-spun yarns are more uniform but weaker than ring-spun yarns.

Air-jet spinning is one of the newest yarn formation techniques and can spin yarns at speeds of up to 183 m/min (200 yard/min). A conventional roller drafting system is used to reduce drawing sliver to the proper size. The drafted ribbon of fibers is then opened, twisted, and entangled by jets of compressed air as they pass through nozzle assemblies. Air-jet spun yarns tend to be weaker and harsher than those produced by ring or rotor spinning. Another new method of yarn production in limited use is friction spinning. In this process, the yarn is formed by frictional contact of the fibers with a pair of rotating perforated drums. The rotation of the drums causes the fibers to be rolled into a thread, which is then drawn off axially from the drums as a finished yarn. Production rates for this equipment can exceed 229 m/min (250 yard/min).

Fabric Manufacturing (Weaving and Knitting). Yarns manufactured in the spinning process are used to make woven or knitted fabrics. Weaving and knitting are the two pimary textile processes for manufacturing fabrics. In the modern textile industry, these processes take place on electrically powered automated machines, and the resulting fabrics go into a wide range of end uses, including apparel, home furnishings, and industrial products (67). Most woven and knitted cotton fabrics are produced from single yarns. However, for the manufacture of industrial fabrics such as canvas, it is necessary to combine, or ply twist, several strands of single yarns together to obtain increased strength and resilience. Sewing thread and cordage are also produced from multiple plies of single yarns twisted together.

The weaving process consists of interlacing straight yarns at right angles to one another. Warp yarns are supplied from a large reel, called a warp beam, mounted at the back of the weaving machine. Each warp yarn-end is threaded through a heddles harness, which is used to lift or depress the warp yarns to allow the weaving to be done.

The machine knitting process consists of interlocking loops of yarn on powered automated machines that are equipped with rows of small, hooked needles which draw formed yarn loops through previously formed loops. The hooked needles have a unique latch feature that closes the hook to easily allow the loop drawing, then opening to allow the yarn loop to slide off the needle. There are circular-knitting, flat-knitting, and warp-knitting machines.

Nonwoven Manufacturing. Cotton staple is readily processed to form carded, air laid, or carded/crossed-lapped webs that can be bonded by various techniques to form useful nonwoven materials, eg, needlepunched, spunlaced (hydroentangled), and stitch-bonded nonwovens, and resin-bonded and thermal-bonded carded fabrics (68). Many times a combination of these processes is used to produce hybrid structures and other products. Cotton's share of the nonwovens market in 2002 is 7.8% globally and 2.8% in North America (69). In 2000–2001, ~32–36 million kg (70–80 million lb) of cotton was used in North America to

produce the following nonwovens [in millions of kg (millions of lb)]: swabs [6.4–7.3 (14–16)], bandages [1.8–2.3 (4–5)], cosmetic pads [(13–15)], tampons/feminine pads [6.8–7.7 (15–17)], spunlaced wipes [1.4 (3)], surgical sponges [0.9–1.4 (2–3)], shoulder pads/glove padding [0.9–1.4 (2–3)], jewellery box pads [0.9–1.8 (2–4)], quilt bedding [0.9–1.4 (2–3)], and diapers (see NONWOVENS, STAPLE FIBER).

Chemical Composition and Morphology

The cotton fiber is a single biological cell, 15–24 μm in width and 12–60 mm (4.7–23.6 in.) in length. It has a central canal, or lumen, down its length except at the tip (70). It is tapered for a short length at the tip, and along its entire length the dried fiber is twisted frequently and the direction of twist reverses occasionally (71). These twists (referred to as convolutions) are important in spinning because they contribute to the natural interlocking of fibers in a yarn.

Raw cotton fiber after ginning and mechanical cleaning is essentially 95% cellulose [9004-34-6] (70,71) (Table 1). The noncellulose materials, consisting mostly of waxes, pectinaceous substances, and nitrogenous matter (mainly protein), are located to a large extent in the primary wall, with small amounts in the lumen (72). Analysis of the fiber for metal content (73–75) is given in Table 2. Potassium, magnesium, calcium, sodium, iron, and phosphorus are the most abundant elements; silicon, chlorine, sulfur, and boron are sometimes detected in trace amounts (73); lead and cadmiun are not detected (73); and arsenic levels in untreated cotton is usually <1 ppm (74). Knowledge of the content of metals is important to processors, because metals can contribute to problems in yarn manufacturing, bleaching, and dyeing (1).

Of the noncellulose constituents, nitrogen-containing compounds (mostly protein) normally occur in the largest amounts, almost entirely in the lumen, and are most likely protoplasmic residue left behind after the gradual drying up of the living cell. Most of the pectin in the cotton fiber is in the primary wall. Removal of the pectic substances is accomplished by scouring, which does not change the properties of the cotton greatly.

Table 1. Composition of Typical Cotton Fibers

	Composition, percent of dry weight	
Constituent	Typical	Range
Cellulose	94.0	88.0–96.0
Protein (% N $\times$ 6.25)[a]	1.3	1.1–1.9
Pectic substances	1.2	0.7–1.2
Ash	1.2	0.7–1.6
Wax	0.6	0.4–1.0
Total sugars	0.3	
Pigment	Trace	
Others	1.4	

[a]Standard method of estimating percent protein from nitrogen content (% N).

Table 2. Metal Content of Cotton[a]

Metal	Content, ppm
Potassium	2000–6500
Magnesium	400–1200
Calcium	400–1200
Sodium	100–300
Iron	30–90
Manganese	1–10
Copper	1–10
Zinc	1–10
Lead	n.d.[b]
Cadmium	n.d.
Arsenic	Trace (<1)[c]
Phosphorus	180–1000[d]

The wax of most cottons is located principally on the fiber surface in the primary wall of the fiber and is a complex mixture of higher molecular weight lipids (1); there are some differences among varieties. The green lint cotton, as discussed earlier, contains ~14–17% wax of high melting point. Because the wax becomes established in fibers, largely if not wholly, during the first phase of development, the wax content as a percentage of the whole fiber mass decreases as the fiber maturity or degree of wall thickening increases; the finer cottons tend to have a larger percentage of wax. Wax serves as a lubricant and is essential for proper spinning of the fiber into yarn. After spinning and weaving or knitting, the wax is removed by scouring and bleaching in preparation for dyeing and finishing.

The mature cotton fiber has a primary and secondary wall, and a lumen. It also has a cuticle and a winding layer between the primary walls (Fig. 5). The cellulose of the primary wall exists as a randomly woven network of microfibrils in and on which are deposited noncellulose materials that form the primary wall. Just beneath the primary wall is the winding layer, which is also the first layer of the secondary wall. The winding layer appears to be made up of a single layer of fibrillar bundles composed of highly oriented cellulose microfibrils and oriented at an angle to the fiber axis. The main body of the fiber consists of cellulose fibrils packed tightly in a solid cylinder, which, under certain conditions of chemical swelling, can be induced to separate into more or less concentric layers. These layers seem to have a finer and more regular structure than does the winding layer, because the 20–50 secondary wall layers have cellulose microfibrils compactly aligned along the axis of the fiber (see CELLULOSE).

The gross morphology of cotton, which refers to the relatively large structural elements above, is visible in the electron microscope. The microfibrillate structure includes pores, channels, and cavities that play an important role in the chemical modification of cotton. The fibrils follow a spiral pattern and at times reverse; it is believed that regions of low strength along the length of the fiber occur close

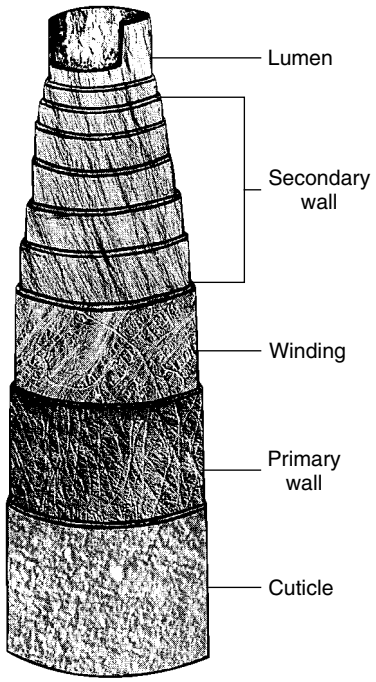

Fig. 5. Schematic diagram of cotton fiber.

to the reversal zones. Microfibrils of the secondary wall are 10–40 nm wide, and these in turn are composed of elementary fibrils (crystallites) 3–6 nm wide.

Chemical modification of the cotton fiber must be achieved within the physical framework of this rather complicated architecture. Uniformity of reaction and distribution of reaction products are inevitably influenced by rates of diffusion, swelling, and shrinking of the whole fiber, and by distension or contraction of the fiber's individual structural elements during finishing processes.

Structure and Reactivity

Chemical Structure. The raw cotton fiber produced in the bolls of the cotton plant is composed almost entirely of the polysaccharide cellulose (see CELLULOSE). Evidence from degradation of cellulose by hydrolysis, oxidation, and other chemical reactions shows that it is a $1 \rightarrow 4$ linked linear polymer of β-D-glucopyranose (Fig. 6). If degradation is extensive, cellobiose (the dimer) or glucose is produced.

The molecular cellulose chains have varying lengths. Measurements of the chain length require that cotton be in solution. Solvents for this purpose include cuprammonium hydroxide solution, phosphoric acid [7664-38-2], nitric acid [7697-37-2], quaternary ammonium bases, cadmium ethylenediamine hydroxide [14874-24-9], cupriethylenediamine hydroxide [111274-71-6] (76), *N*,*N*-dimethylacetamide [127-19-5]–lithium chloride [7447-41-8] (DMAC—LiCl), and

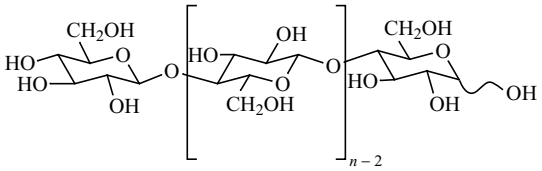

Fig. 6. Chemical structure of cellulose.

1,3-dimethyl-2-imidazolidinone [80-73-9] (DMI) and lithium chloride (77). DMAC–LiCl (27,28), when used in conjunction with gel permeation chromatography (GPC) (78,79), provides both the weight (M_w) and number average (M_n) molecular weight of cellulose in a nondegrading solvent without derivatization. Many researchers have reported weight-average molecular weights for cotton cellulose ranging from 800,000 to 900,000 (~6000 glucose residues) but results vary widely. Those reported for DMAC–LiCl (27,28) are very high (~1,500,000), which may be due to incomplete dissolution of the cotton fibers in this solvent. Cotton cellulose generally has a higher molecular weight than wood cellulose.

Molecular and Supramolecular Physical Structure. The chains of cellulose molecules associate with each other by forming intermolecular hydrogen bonds and hydrophobic bonds. They coalesce to form microfibrils also called crystallites. In cotton, the microfibrils can organize into macrofibrils 60–300 nm wide. The macrofibrils are organized into fibers. Cotton fibers have a complex, reversing, helical arrangement of macrofibrils. There are several different forms or polymorphs [cellulose I to IV and X with recent subclasses Iα and Iβ (80,81)], depending on the source and treatment. There are both different unit cells and different packing arrangements in the unit cell. Native cotton is cellulose I. It has been proposed that cotton and other commercial cellulose, such as wood and ramie, are mostly cellulose Iβ (82). The crystal structure of cellulose Iβ is fairly well understood (83). Despite this, research continues on the crystal structures of it (84) and cellulose II (85) (see CELLULOSE).

Typical one-step commercial mercerization of cotton yarn with caustic or liquid ammonia causes only partial conversion to cellulose II or cellulose III. Cotton cellulose is partially converted to cellulose II by repeated mercerization, the swelling of cellulose in strong alkali (eg, 23% NaOH), followed by rinsing and drying. Cellulose III results from treatment of cellulose with liquid ammonia (ammonia mercerization) or amines. Cellulose III can be made from either cellulose I or II. When treated with water, cellulose III can revert to its parent structure. Cellulose IV can be prepared by treating cellulose I, II, or III in glycerol at temperatures ~260°C. Conversion of the crystal form in cotton fibers to cellulose IV can be effected by heat treatment of ethylamine-treated cotton cellulose in either saturated steam or formamide with minimal fiber degradation (86). Like cellulose III, cellulose IV preparations can revert to their parent structures.

Conversion to cellulose II and cellulose III via caustic mercerization and liquid ammonia treatment are commercial textile processes that are discussed later. Figure 7 shows the characteristic diffractograms (Cu Kα radiation) of native cellulose, cellulose mercerized with sodium hydroxide, and cellulose treated with liquid ammonia.

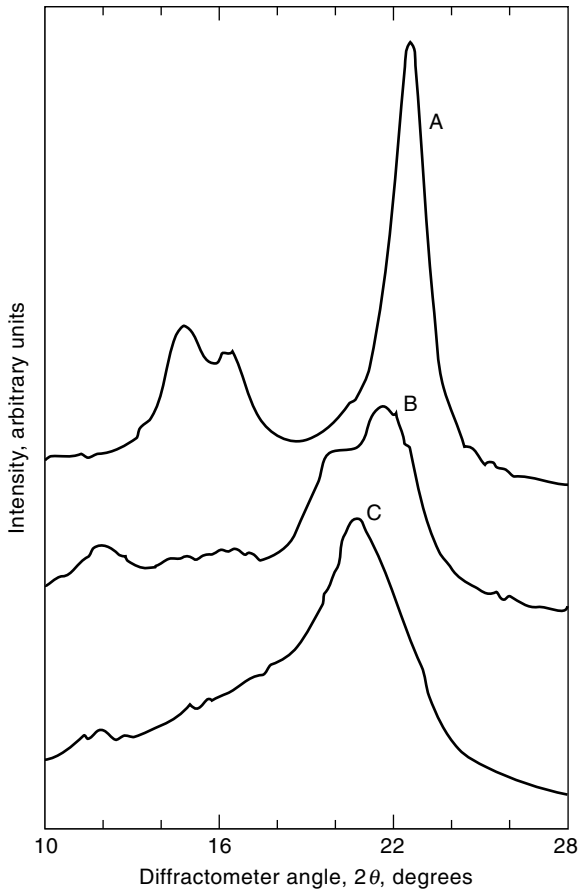

Fig. 7. X-ray diffractograms. A, native; B, NaOH mercerized; C, NH_3-treated.

Pore Structure and Affinity for Water. The cotton fiber is a porous, hydrophilic material that accounts for the comfort of cotton clothing. Moisture is retained tenaciously in cotton. The moisture absorbed from the atmosphere and held under ambient conditions is expressed either as moisture content (amount of moisture as the percentage over the oven-dried weight) or more commonly as moisture regain (amount of moisture as a percentage of the oven-dry sample). Under ordinary atmospheric conditions, moisture regain is 7–11%. Upon immersion in liquid water the cotton fiber swells and its internal pores fill with water. Pure cotton holds a substantial percentage of its dry weight in water under conditions of centrifugation. Values for the liquid water held depend on the test used. The values are ~30% for water of imbibition (87) and 50% for the water retention (88). Centrifugation conditions are less severe in the latter case.

Pores accessible to water molecules are not necessarily accessible to chemical agents. Many uses of cotton, eg, easy care fabric, depend on chemical modification to impart the desired properties. Knowledge of accessibility to dyes and other chemical agents of various sizes under water-swollen conditions is required for better control of the various chemical treatments applied to cotton textiles. The

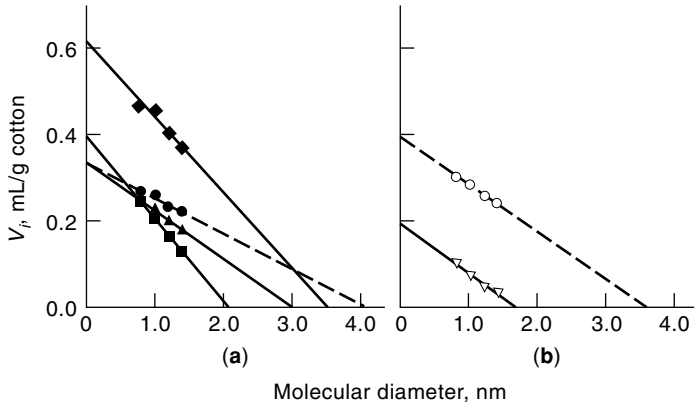

Fig. 8. Internal volume (V_i) that is accessible to sugars as functions of the cotton molecular diameters (89). (**a**) Batting: ▲ greige; ● , scoured–bleached; ♦ , caustic mercerized; ■ , liquid ammonia treated. (**b**) Fabric: ○ , scoured–bleached; ▼, cross-linked.

principle of molecular exclusion by GPC (89) has been used to assess the pore size distribution in cottons after various chemical treatments. Trends for accessibility to sugars of increasing size are depicted in Figure 8. These probes cover the range of molecular sizes of reagents generally used to modify cotton chemically.

Scouring and bleaching slightly increase the accessible internal volume, liquid ammonia treatment of the scoured–bleached cotton decreases it slightly, caustic mercerization substantially enhances accessibility, and cross-linking to impart durable press properties reduces the accessible internal pore volume substantially.

Availability of Hydroxyl Groups. The chemical structure given in Figure 6 shows the 2-OH, 3-OH, and 6-OH groups that are potential sites for the same chemical reactions that occur with common alcohols. However, the regular occurrences of intermolecular and intramolecular hydrogen bonds in the crystalline regions of cotton cellulose render the involved hydroxyl groups unavailable to chemical agents under mild reaction conditions. Chemical agents that have access to the interior pores of the cotton fiber thus find potential reactive sites unavailable for reaction. Direct information on the availabilities of 2-OH, 3-OH, and 6-OH on accessible surfaces has been obtained from chemical measurements based on the reaction of the cellulose with diethylaminoethyl chloride [2210-36-8] under mild conditions (90,91). The order of decreasing availability of hydroxyl groups in cotton is 2-OH $>$ 6-OH $\gg$ 3-OH. Specific values for the relative availability of the 3-OH and 6-OH to the 2-OH depend on the growth (92) and processing (42) history of the fiber. Data on growth and weathering are given in Table 3. Values for relative availability of hydroxyls are maintained throughout the ginning procedure but gradually increase (to $\sim$0.40 and $\sim$0.80 for 3-OH/2-OH and 6-OH/2-OH, respectively) as the fibers are subjected to the stress of processing in the greige mill (93).

Reactions for Practical Objectives

Chemical modification has assisted in building cotton's position in the market place despite the advent of synthetic fibers.

Table 3. Relative Availabilities of Hydroxyl Groups of Cotton Cellulose Throughout Growth and Weathering[a]

Days postanthesis[b]	Period	3-OH/2-OH	6-OH/2-OH

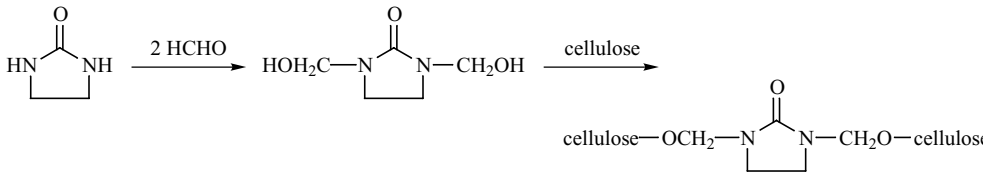
Mercerization. One of the earliest known modifications of cotton that had commercial potential was mercerization. Traditionally, the process employed a cold concentrated sodium hydroxide (caustic soda) treatment of yarn or woven fabric followed by washing and a mild acetic acid neutralization. Maintaining the fabric under tension during the entire procedure was integral to achieving the desired properties. The resultant mercerized cotton has improved luster, dyeability, and strength. A variation of this procedure substitutes hot sodium hydroxide that is allowed to cool while the cotton remains immersed in the caustic solution. More thorough initial penetration increases the efficiency of the mercerizing process. If the cotton is allowed to shrink freely during contact with mercerizing caustic, slack mercerization takes place; this technique produces a product with greatly increased stretch (stretch cotton) that has found application in both medical and apparel fields. Effects similar to those from sodium hydroxide mercerization have been produced by exposure of the cotton to volatile primary amines or to ammonia. A procedure that uses liquid ammonia has found commercial adaptation (94). Improvements in luster and strength are similar to those achieved with sodium hydroxide mercerization, but dyeability is not enhanced. A distinct structural difference exists chemically between cotton mercerized in sodium hydroxide and that treated in liquid ammonia, particularly after nonaqueous quenching (95). With both treatments, there is increased accessibility, but differences in dye receptivity presumably result from differences in swelling loci between sodium hydroxide and liquid ammonia treatments.

Etherification. The accessible, available hydroxyl groups on the 2, 3, and 6 positions of the anhydroglucose residue are quite reactive (96) and provide sites for much of the current modification of cotton cellulose to impart special or value-added properties. The two most common classes into which modifications fall, include etherification and esterification of the cotton cellulose hydroxyls as well as addition reactions with certain unsaturated compounds to produce cellulose ethers (see CELLULOSE ETHERS). One large class of cellulose-reactive dyestuffs in commercial use attaches to the cellulose through an alkali-catalyzed etherification by nucleophilic attack of the chlorotriazine moiety of the dyestuff:

$$\text{Cellulose—O}^- + \text{Cl—Dyestuff} \rightarrow \text{Cellulose—O—Dyestuff} + \text{Cl}^-$$

Cross-linking. By far, the most important commercial modifications of cotton cellulose are those that occur through etherification. For example, commercial modification of cotton to impart durable-press, smooth drying, or shrinkage resistance properties involves cross-linking adjacent cellulose chains through amidomethyl ether linkages. This cross-linking is commonly achieved by immersing the fabric in a solution of the agent and an appropriate catalyst, removing the excess liquid by passing the fabric through squeeze rolls (pad), drying in an oven to remove the remaining water, and heating to a high temperature to effect covalent bond formation to cellulose. This sequence is called a pad-bake process. Methylene, or oligomeric, cross-links from a pad-bake formaldehyde treatment result in severe fabric strength loss. There is, however, a process for cross-linking cotton-containing garments with formaldehyde in the vapor phase that has found commercial acceptance in the uniform-rental garment market. Most reagents for cross-linking cotton cellulose are difunctional or polyfunctional amidomethylol compounds or amido compounds that have pendent hydroxyls on carbons alpha to the amido nitrogen (see AMINO RESINS). The methylol compound is generated by reaction of the amido compound with formaldehyde [50-00-0]. For example, ethyleneurea [120-9-34] reacts as follows (97).



Commercially available cross-linking agents include dimethylolurea [140-95-4], dimethylolethyleneurea [136-84-5], dimethyloldihydroxyethyleneurea [1854-26-8], dimethylolpropyleneurea [3270-74-4], dimethylolalkyl carbamate, tetramethylolacetylenediurea [5395-50-6], methylolated melamine, dimethylolalkyltriazone, dimethoxymethyluron [7327-69-7], dihydroxydimethylethyleneurea [3923-79-3] (dimethylurea–glyoxal adduct), and ethyleneurea–glyoxal [107-22-2] adducts. The cross-linking proceeds via either Lewis or Brønsted acid catalysis (98) by a carbocation mechanism. Gross effects of the cross-linking are increased resiliency (manifested in wrinkle resistance, smooth drying properties, dimensional stability, and greater shape-holding properties) as well as reduced extensibility, strength, and moisture regain. These effects are observed with one cross-link per 20–25 anhydroglucose residues (99). Liquid ammonia treatment of cotton fabric, followed by cross-linking, attenuates the strength loss as well as an accompanying loss in abrasion resistance. This combination contributed to a reappearance of all-cotton fabrics in the woven shirting/sheeting market in the 1970s (100).

Resiliency. Base-catalyzed reactions of cotton cellulose with either monoepoxides or diepoxides to form cellulose ethers also result in fabrics with increased resiliency. Monoepoxides, believed to result only in cellulose hydroxyalkyl ethers or linear graft polymers (101), produce marked improvement in resiliency under wet conditions, but little improvement under ambient conditions. Difunctional

epoxides, which are capable of cross-linking cellulose, can be used to impart increased resiliency to cotton textiles under both wet and ambient conditions (102). Besides imparting resiliency through epoxide etherification, oil and water repellency can be imparted by reactions of monomeric perfluoro epoxides with cotton. Epoxide-reacted cotton also accept dyes not traditionally used for cotton. Etherification of cotton with ethyleneimine [2734-98-8] provides a means for imparting special properties to cotton; the end product depends on the attached group. The cross-linking reaction between bis(hydroxyethyl) sulfone and cellulose is another base-catalyzed etherification that produces fabrics possessing increased resiliency under both wet and ambient conditions. The earliest application of sulfone cross-links to cotton textiles was the reaction of divinyl sulfone under alkaline conditions (103). However, the hazard of working with the vinyl compound led to modifications of the sulfone agent. Vinyl groups were replaced with more stable precursors such as the β-thiosulfatoethyl, β-sulfatoethyl (104), or β-hydroxyethyl groups (105). Etherification of cotton by divinyl sulfone [77-77-0] and its precursors also forms the basis for a large class of fiber-reactive dyes with the general formula of dye-$SO_2CH{=}CH_2$ (106).

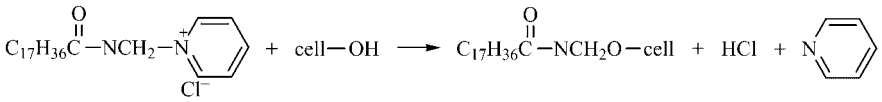
Other Cellulose Ethers. Other cotton cellulose ethers include carboxymethyl, carboxyethyl, hydroxyethyl, carbamoylethyl, cyanoethyl, sulfoethyl, and aminoethyl (aminized cotton) products. Most, with the exception of cyanoethylated and aminized cotton, are of interest in applications requiring solubility or swellability in water or alkali (107). In addition, ethers with pendent acid or basic groups have ion-exchange properties (108). Aminized cotton is of interest because it introduces basic groups onto the cotton that provide sites for attachment of acid dyes. Simultaneous aminization of cotton and dyeing with an acid dyestuff marked the first successful attempt at dye attachment to cellulose through an ether linkage (109).

Flame Resistance. The chemical treatment of cotton with fire retardants to make it flame resistant is discussed elsewhere. Numerous end uses for cotton require it to be flame-resistant. The major factors that influence ignition of cotton materials are airflow, relative humidity of the fabric, the amount of oxygen available, physical factors (geometry, density, thickness, etc), chemical factors (eg, inorganic impurities), heat source, and rate of heating. Thermal analysis studies in air and in 8.4% oxygen indicate that cotton ignites at ~360–425°C (110,111).

Although certain cellulose esters, such as the ammonium salt of phosphorylated cotton and cellulose phosphate [9015-14-9], are flame-resistant, the attachment of most currently used durable polymeric flame retardants for cotton is through ether linkage to the cellulose at a relatively low degree of substitution (DS). Nondurable flame retardants based on liquid-or vapor-phase applications of boric acid [10043-35-3] or methyl borate [121-43-7] are used in treatment of cotton batting for upholstery, bedding, and automotive cushions (112–114). Cotton carpet materials will pass the U.S. Consumer Product Safety Commission (CPSC) federal flammability test for carpets (16 CFR 1630) when cross-linked with polycarboxylic acids such as 1,2,3,4-butanetetracarboxylic acid or citric acid with sodium phosphate, sodium hypophosphite, sodium bicarbonate, or sodium carbonate catalysis (115).

Water Repellency. The development of water-repellent cellulose ethers has been reviewed (116). A typical example of a commercial etherification for

waterproofing cotton is with stearamidomethylpyridinium chloride:



N-substituted, long-chain alkyl monomethylol cyclic ureas have also been used to waterproof cotton through etherification. Other water-repellent finishes for cotton are produced by cross-linked silicone films (117). In addition to the polymerization of the phosphorus-containing polymers on cotton to impart flame retardancy and of silicone to impart water repellency, polyfluorinated polymers have been successfully applied to cotton to impart oil repellency. Chemical attachment to the cotton is not necessary for durability; oil repellency occurs because of the low surface energy of the fluorinated surface (118).

Cyanoethylation. One of the earliest examples of etherification of cellulose by an unsaturated compound through vinyl addition is the cyanoethylation of cotton (119). This base-catalyzed reaction with acrylonitrile [107-13-1], a Michael addition, proceeds as follows:

$$CH_2{=}CHCN + Cell{-}OH \rightarrow Cell{-}OCH_2CH_2CN$$

For most textile uses, a DS <1 is desirable. Cyanoethylation can impart a wide variety of properties to the cotton fabric, such as rot resistance, heat and acid resistance, and receptivity to acid and acetate dyes. Acrylonitrile and acrylonitrile polymers (qv) has also been radiation-polymerized onto cotton with a ^{60}Co source. Microscopical examination of ultrathin sections of the product shows that the location of the polymer is within the fiber (120). Examination of the ir spectrum of cotton-containing polymerized acrylonitrile indicates that grafting occurs at the hydroxyl site of the cellulose (121). Another monomer grafted onto cellulose by irradiation is styrene polymers (qv). Chemical properties, mechanisms, and textile properties of these grafted polymers of cellulose have been summarized (122). Graft polymerization onto cotton has also been induced by both chemical (123) and photochemical (72) initiation.

Irradiation. The effects of high energy radiation (eg, gamma radiation) on cotton properties have also been investigated (124–127). Depolymerization of cellulose occurs with increasing energy absorption; carbonyl formation, carboxyl formation, and chain cleavage occur in the ratio of 20:1:1. With these chemical changes, there is a corresponding increase in solubility in water and alkali and a decrease in fiber strength. The gamma-irradiated cotton has base ion-exchange properties. Irradiation of cotton with near ultraviolet (UV) light (325–400 nm) causes formation of cellulose free radicals and mild oxidative degradation of the cotton (128). Carbonyl and carboxyl contents of the cotton cellulose increase, and DP and tensile strength decrease, with increasing time of irradiation (129). The induction of cellulose free radicals by near uv irradiation forms the basis for photofinishing with vinyl monomers to produce graft polymers on the cotton:

$$\text{Cell—H} \xrightarrow{h\nu} \text{Cell} + \text{H}\cdot$$
$$\text{Cell} + n\text{M} \longrightarrow \text{Cell—(M)}_{n-1}\text{M}\cdot$$

Another useful reaction of cotton cellulose occurs in an ionized atmosphere, which is essentially a surface reaction. Glow discharge treatment of cotton yarn in air increases water absorbency and strength (130), and surface-dependent properties of cotton fabric are drastically changed by exposure to low temperature–low pressure plasma generated by radio-frequency radiation (131). Because only a few extremely high energy electrons (10–15 eV) are generated, ambient temperature is maintained in the chamber. Light microscopy indicates a smoother surface after treatment, but scanning electron microscopy shows no change from native cotton. Spectral changes show some oxidation of the treated cotton, a decreased carbon/oxygen ratio. Free radicals similar to those produced from ^{60}Co radiation are formed. In addition, highly charged species are also formed, allowing such usually inert monomers as benzene to be polymerized onto the cotton with great capacity for bond cleavage. Plasma treatment produces an increased rate of wetting and drying and produces a highly absorbent cotton. The cohesiveness and fiber friction of cotton sliver was increased temporarily through air-trace chlorine corona treatments at 95°C and atmospheric pressure (132,133). With a 15-kV electrode voltage at a frequency of 2070 Hz, no chemical effects on the cotton could be noted. Dyeability, hand, and wettability were unaffected. The increase in cohesiveness allows the production of yarns with increased strength, abrasion resistance, and greater spinnability (134). Thus yarns of significantly lower twist can be produced with strength equal to, or higher than, untreated cotton yarns of higher twist.

Insolubilization. Insolubilization of compounds within textiles parallels the history of humanity; the direct dyeing techniques for cotton were highly advanced in the Bronze Age. With the exception of fiber-reactive dyes discussed earlier, other cotton dyes, ie, vat and sulfur, are insolubilized within the fiber after an oxidization step. Insoluble metal oxides have been used to flameproof cotton, and zirconium compounds have been insolubilized on cotton to render the fabric microbial resistant (135) or mildew resistant (136) via a mineral dyeing process (see TEXTILE FINISHING).

Insolubilization and five other methods for imparting antimicrobial properties to cotton have been described (137). These methods can all be classified under one or more of the chemical reactions of cotton cited earlier; they include fiber reactions to form metastable bonds, grafting through thermosetting agents, formation of coordination compounds, ion-exchange methods, polymer formation with possible grafting, and a regeneration process. Also a commercialized process for antibacterial cotton fabrics uses insoluble peroxide complexes of zirconyl acetate (138).

When exposed to heat, cotton fabrics increase in temperature to an extent that is proportional to their specific heats. Altering the chemical composition of the fabrics such that large amounts of heat are absorbed and released in repeatable cycles of controllable temperature ranges produces fabrics that are described as temperature adaptable. The process insolubilizes polyethylene glycols by cross-linking with methylolamides on the cotton fabric (139). As with flame-retardant cotton, attachment to the cellulose is through an ether linkage at a relatively low DS.

Esterification. There are both inorganic and organic esters of cellulose (140) (see CELLULOSE ESTERS). Of the three most common inorganic esters, cellulose nitrate [9004-70-0], phosphate, and sulfate, only cellulose sulfate [9088-06-6] is soluble in water. Cellulose sulfate attains water solubility at a DS of 3, indicating esterification of all three hydroxyl groups, whereas the sodium salt of cellulose sulfate is soluble in hot and cold water with a DS of only 0.33. Sodium cellulose sulfate is used in applications requiring suspension, thickening, stabilizing, and film-forming properties. The class of phosphonic acid and phosphoric acid dyestuffs attach to cotton through esterification by the phosphonic acid or phosphoric acid group of the dyestuff. Until recently, organic esters of cotton cellulose, with two notable exceptions, were only of academic interest, although partial esterification of cotton by fatty acids has been reported to increase resiliency (141).

Acetylation of cotton to an acetyl content slightly >21% produces a material with greatly increased resistance to fungal and microbiological degradation, in addition to tolerance of high temperatures not exhibited by native cotton; fibrous appearance and physical properties are unchanged by the acetylation. X-ray diffractograms indicate that, at this extent of substitution, only accessible (noncrystalline) regions of the cotton are involved in the acetylation (142).

In the 1960s, esterification of cotton cellulose with polycarboxylic acids to produce smooth-drying fabrics was investigated (143,144). Catalysis was by partial neutralization of the carboxyl groups. Although improvements in resiliency were obtained, the levels were not commercially acceptable. In the late 1980s, better catalyst systems were discovered for the ester cross-linking of cellulose; inorganic salts of phosphorus-containing acids were found to give ester cross-links that are durable to multiple home launderings. Because of the improved catalysis, certain tricarboxylic and tetracarboxylic acids have shown promise for commercialization (145). These acids include 1,2,3,4-butanetetracarboxylic acid [1703-58-8], tricarballylic acid [99-14-9], and citric acid [77-92-9] (146), maleic acid and itaconic acid as copolymers (147,148), and monopolymers/terpolymers of maleic acid (149). An anhydride formation mechanism has been proposed for the esterification cross-linking of cellulose. An advantage of the polycarboxylic acids in finishing for attaining durable press is that these agents do not contain formaldehyde and thus do not release formaldehyde during processing or end use. Finishes from polycarboxylic acids are superior to those from other nonformaldehyde agents mentioned earlier, such as epoxides, sulfones, acetals, and cyclic urea derivatives, because they are innocuous and are durable to home laundering.

Enzymatic Modification

The industrial use of enzymes in the textile industry (150,151) has increased substantially in recent years. Lipases, proteases, and cellulases are being used. Lipases and proteases are used to assist in cleaning textiles. Treatments involving cellulases, which hydrolyze the cellulose polymer, are relatively new and are of particular importance. Cellulases obtained from both bacterial and fungal sources are being used to give fabrics a soft hand, to give cellulosic fabric surfaces a smooth and clear appearance by removing fabric fuzz fibers ("biopolishing"), and to provide a stone-washed appearance to denim ("biostoning") (152–154). Cellulases are

also being added to detergents to maintain the color appearance of cotton cellulose fabrics by removing fabric fuzz fibers and pills that form on wear and laundering. The effectiveness of cellulase for removal of material from the fabric is dependent on the type of mechanical action during processing. This includes the abrasive action of fabric-to-fabric contact or the cascading effect of aqueous solution on the cellulosic substrate (155). One of the main reasons for using enzymes instead of other chemicals as finishing agents for cotton cellulose is that they are environmentally safer. The small catalytic quantities of enzymes that are used for finishing treatments are biodegradeable like proteins in general.

New Products

Smart Cotton-Based Wound Dressings. Cotton gauze is still a standard care item in the management of chronic wounds. However, since the time of ancient Greece, wound care and dressing strategies have primarily relied on empiricism. Smart wound dressings made from cotton gauze have more recently been designed and prepared with a rational approach based on knowledge of how destructive proteases play a role in the pathology of nonhealing wounds. Cotton gauze may be tailored to enhance the biochemistry of wound healing more effectively by designing formulations and conjugates of cotton cellulose that inhibit or neutralize destructive proteases, such as elastase, which prevent wound healing. Three approaches have been taken to develop protease fiber-inhibitors useful for chronic wounds: formulation of inhibitors on the dressing (156), synthesis of elastase recognition sequences on cotton cellulose (157), and the derivatization of cellulose with functional groups having an affinity for elastase (158). Understanding how these new cotton dressings work in accelerating healing of the chronic wound may signal a new product area of smart wound dressings that are useful in medical treatment modalities of pressure ulcers, leg ulcers, and diabetic foot sores.

Composites from Cotton. Cellulose fibers are abundant, readily available, versatile, and highly resistant to heat flow. They should be studied/evaluated as valuable starting materials for the design and development of thin low cost nonwoven composite insulation that can adhere to the walls of homes, office buildings, industrial complexes, warehouses, and tents. These applications currently cannot use fiberglass insulation within their exterior wall spaces. Cotton and other cellulosic fibers have thermal resistance similar to fiberglass. However, they do not cause immune and skin sensitivities, nor pulmonary problems that are associated with fiberglass use. Initial research on evaluating the commercial potential of cotton fibers as insulating materials involved composite nonwoven insulation materials that were made from cotton, kenaf, jute, polyester, polypropylene, sucrose-based epoxy formulations, and aluminum foil (159). The needlepunched fiber batts were rendered flame-resistant by use of inorganic reagents and urea.

Economic Aspects

Marketing/Merchandizing Raw Cotton. There are several routes by which cotton fiber in the United States changes ownership from the grower to its final destination at the spinning mill. The grower may sell cotton directly to

a spinning mill under a grower contract or the grower may sell cotton to a gin, broker, commission firm, or shipper. Some growers, after ginning their cotton, may sell through a cooperative organization or may place the cotton in a depository as collateral under the Commodity Credit Corp. Loan Program, to be either withdrawn on repayment of the loan plus interest and storage or forfeited for sale by the government. These intermediate buyers then sell the cotton to foreign or domestic mills.

World Production, Consumption, and Prices. World production, consumption, and prices are shown in Tables 4 and 5. World cotton production in 2001 was about ~90 million bales (~19.6 million metric tons; 21.6 million tons). Presently the chief cotton-growing countries of the world are China (23%), the United States (20%), India (12%), Pakistan (9%), and Uzbekistan (5%), which produced about ~70% of the world's cotton in 2000 (160). The price is widely variable because it is affected by many factors in the United States and internationally (161).

Table 4. World Cotton Production[a] [million 217.7-kg] (480-lb) bales]

Year	World	China	United States	India	Pakistan	Uzbekistan
1985[b]	80.3	19.0	13.4	9.0	5.6	7.9

Table 6. Number of Items from a Cotton Bale (217.7 kg; 480 lb)

Women's wear	Number	Men's wear	Number	Others	Number
Dresses	274	Dress shirts (woven)	765	Diapers	3085
Jeans	249	Sport shirts (woven)	906	Sheets	249
Socks (mid-calf)	4321	Work shirts	543	Pillow cases	1256
Blouses (woven)	773	Boxer shorts	2104	Bath towels (terry)	690
Sweaters	379	Jockey shorts	2419		
Nightgowns	780	T-shirts	1217		
Slacks (woven)	415	Trousers (dress/sport)	484		
Shorts	733	Trousers (work)	374		
		Jeans	215		
		socks (mid-calf)	3557		

Uses. Cotton is used in many apparel and home furnishing items. Table 6 gives the approximate number of items that can be produced from one bale of cotton.

Health and Safety Factors

Respiratory Disease. Byssinosis is an occupational lung disease that can affect a small number of textile workers after repeated inhalation of the dust generated during the processing of cotton and some other vegetable fibers (eg, flax and soft hemp) (162–166). Byssinosis may cause progressive and disabling airway narrowing. Cotton dust, an airborne particulate matter released into the working environment as cotton is handled or processed in textile processing, is a complex mixture of botanical trash, soil, and microbiological material (ie, bacteria and fungi) (167). The etiological agent and pathogenesis of byssinosis are not known (166–168). However, control studies in experimental cardrooms suggest that endotoxin from Gram-negative bacteria is associated to some degree with worker reaction to dust (170). Appropriate engineering controls in cotton textile processing areas or washing cotton essentially can eliminate incidence of workers' reaction to cotton dust (164,165). The U.S. Occupational Safety and Health Administration (OSHA) issued revised standards for occupational exposure to cotton dust in 1985 (171) and revised the standard again in 2001 (172) to add batch-washed cotton as an acceptable way to wash cotton to eliminate worker reaction to the dust.

Skin Irritation/Dermatitis. Handling or processing of cotton does not cause skin irritation, since nothing naturally on the surface of cotton fiber is known to cause dermatitis. However, it is possible for some atypical cottons that have been treated with something not approved for use on cotton or off-grade highly microbiologically contaminated cottons to cause skin irritation.

Formaldehyde. Formaldehyde is a component of resins used to impart durable-press and other properties to cotton fabrics. It can be released in small quantities from treated cotton fabrics. Formaldehyde is classified as a "probable human carcinogen," because it has been shown to be an animal carcinogen and there is limited evidence to indicate that it is a carcinogen in humans (173). Sensory irritation of the mucous membranes of the eyes and the respiratory tract, and cellular changes in the nasal cavity are the principal noncancer effects of exposure

to low airborne concentrations of formaldehyde (173). Exposure to formaldehyde from cotton textiles is controlled by the chemical technology for low emitting formaldehyde resin technology and nonformaldehyde finishes discussed earlier and by increased ventilation in the workplace. OSHA has issued standards for control of occupational exposure to formaldehyde (174). The U.S. Consumer Product Safety Commission (CPSC) does not regulate formaldehyde in textiles because its studies did not indicate that there is an acute or chronic health problem due to formaldehyde exposures from textiles: "current evidence. . . does not indicate that formaldehyde exposure from resin treated textiles is likely to present a carcinogenic risk" (175–177).

CYCLOPENTADIENE AND DICYCLOPENTADIENE

Introduction

Cyclopentadiene [542-92-7] (CPD), C_5H_6, (**1**), and its more stable dimer, dicyclopentadiene [77-73-6] (DCPD), $C_{10}H_{12}$, (**2**), are the major constituents of hydrocarbon resins, cyclic olefin polymers, and a host of specialty chemicals. They can be transformed into many chemical intermediates used in the production of pharmaceuticals, pesticides, perfumes, flame retardants, and antioxidants. Because of their wide industrial uses, their chemistry has been extensively investigated and documented. Numerous reviews (1–12) have been published on the subject. The production processes and industrial uses of CPD and DCPD are summarized in Reference 13. In addition to the classical organic reactions, CPD forms organic metallic complexes, ferrocene, with transition metals (14). Some of these complexes have been established as excellent olefin polymerization catalysts. Several reviews have been published on this rapid growing field (15–19) (see SINGLE-SITE CATALYSTS).

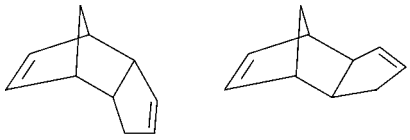
Physical Properties

The physical properties of CPD and DCPD are given in Table 1. DCPD, 3a,4,7,7a-tetrahydro-4,7-methano-1*H*-indene, can exist in two stereoisomers, the endo and exo forms. Because commercially available DCPD is mostly the endo isomer, the properties in Table 1 are pertinent to those of the endo isomer. Spectroscopical information on CPD and DCPD can be found in (20) (mass spectrum), and (21) (nmr spectrum). References 2 (ir, uv, and Raman spectra).



(endo DCPD) (exo DCPD)

DCPD decomposes rapidly at its normal boiling point to two molecules of cyclopentadiene. Purification of DCPD by distillation must be conducted under vacuum conditions. Figure 1 depicts the lowering of the boiling point as a function of pressure. The dimer is the form in which CPD is sold commercially.

Chemical Reactions

Cyclopentadiene is very reactive. In addition to the vast number of reactions one expects from conjugated double bond structures which include Diels–Alder addition, hydrogenation, halogen addition, etc, the highly acidic methylene group

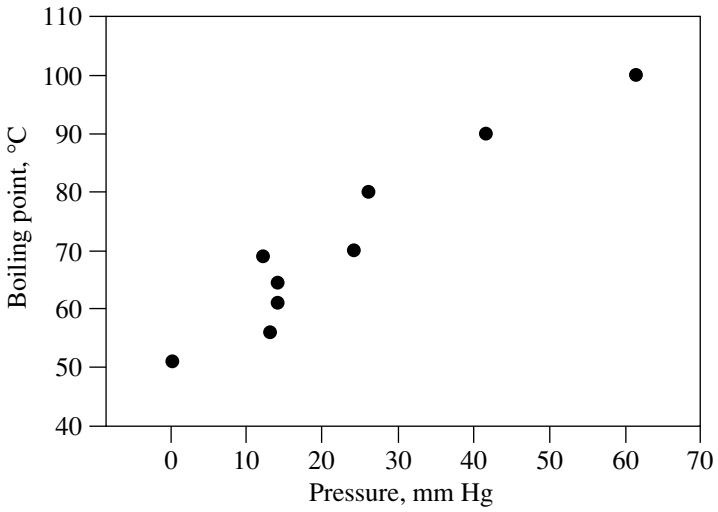


Fig. 1. Boiling point of dicyclopentadiene as a function of pressure. To convert kPa to mm Hg, multiply by 7.5.

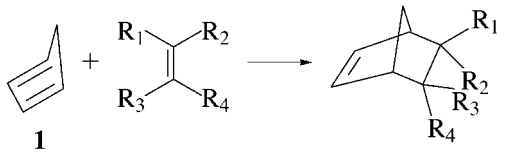
promotes a number of condensation reactions. On the other hand, DCPD behaves like nonconjugated dienes, with the exception that the double bond in the bicycloheptene ring is more reactive than that in the five-membered ring because of the bond angle strain in the bicycloheptene ring.

Diels–Alder Addition. In Diels–Alder addition, the conjugated double bonds of CPD react with the π bond of a dienophile, a compound containing ethylenic or acetylenic unsaturation. The ethylenic or acetylenic group is added across the 1,4 position of the CPD, resulting in a bicyclo[2.2.1]heptene derivative, a cyclohexene derivative with a bridged methylene group. Because of Diels–Alder reactions, many multicyclic compounds can be synthesized with CPD as the building blocks. Examples of these reactions, which are highly exothermic 71–75 kcal/mol, are shown in Table 2.



1

Both CPD and DCPD can be used in the reactions. However for the latter, the reaction needs to be carried out at temperatures above 175°C in order for the DCPD to dissociate rapidly to the CPD monomer. The rate of the reaction is strongly affected by other substituents of the dienophile. For instance, the reaction between CPD and maleic anhydride occurs spontaneously, whereas that between CPD and ethylene requires elevated temperatures and very high pressure. A long floppy chain on the dienophile is also a strong inhibitor of the reaction (22).

Diels–Alder addition is stereochemically specific (22). There is a strong tendency of most substituents of the dienophile to orient in the endo configuration in the bicycloheptene derivative formed from CPD.

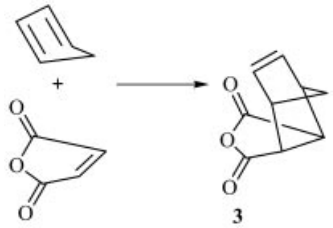
Endo Exo

With maleic anhydride as the dienophile, the reaction leads exclusively to the endo form (23) of the nadic anhydride, *endo-cis*-bicyclo[2.2.1]hept-5-ene-2,3-dicarboxylic anhydride [129-64-6] (**3**).

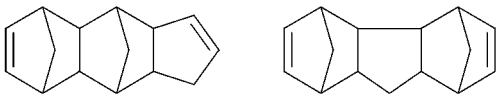


3

Polymerization. Cyclopentadiene dimerizes spontaneously and exothermally at ambient temperature to endo DCPD via the Diels–Alder addition mechanism, in which one of the CPD molecule acts as the dienophile. At temperatures above 100°C, CPD polymerizes thermally to trimers, tetramers, and higher oligomers. Since either one of the nonconjugated double bonds in an oligomer can participate in the Diels–Alder addition to the CPD to form a higher oligomer, the higher oligomers can have several structural isomers. For instance, two trimers, 3a,4,4a,5,8,8a,9,9a-octahydro-4,9:5,8-dimethanobenz-1*H*-[*f*]indene [7158-25-0] (**4**) and 1,4,4a,4b,5,8,8a,9a-octahydro-1,4:5,8-dimethano-1-*H*-fluorene [35184-08-8] (**5**), are formed in the ratio 87:13 by the addition of CPD to DCPD (24).

Table 3. Yield (wt%) of Cyclopentadiene Oligomers at Various Temperatures and Contact Times

Oligomer	14 h at 150–160°C	22 h at 170–180°C	90 h at 200°C
Tricyclopentadiene	40	50	25
Tetracyclopentadiene	10	30	45
Pentacyclopentadiene	2	5	10
Unreacted DCPD	50	10	5

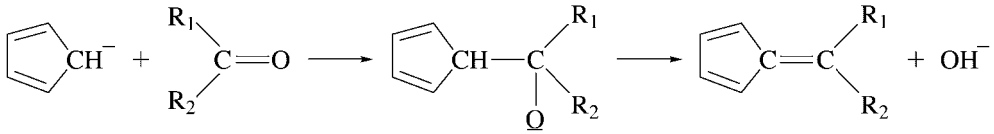


4 **5**

In contrast to DCPD, higher thermal oligomers are crystalline compounds with little odor. The yields of the oligomers at various temperatures and contact times are shown in Table 3.

In addition to thermal polymerization, CPD can be polymerized rapidly at low temperatures with the aid of Lewis acid catalysts (25). The catalysts most often used in the industry are $AlCl_3$ and BF_3, although $AlBr_3$, $TiCl_4$, $SnCl_4$, as well as alkyl aluminum chlorides are all known to be effective catalysts.

Condensation via the Methylene Group. Because of the resonance stabilization of the π electron system, the cyclopentadienyl anion forms readily from CPD after the dissociation of the acidic methylene proton. Under alkaline conditions, CPD undergoes condensation reaction with carbonyl compounds, such as ketones and aldehydes, yielding a family of highly colored fulvene derivatives (26).



The color of the fulvenes increases with the size of R_1 and R_2 (2). The dimethylfulvene is bright yellow whereas fulvenes with aromatic substitutents are blood-red. The aldehyde condensation products are also strongly colored. Because they resinify easily, it is difficult to separate them in the pure form.

Fulvenes can be hydrogenated to the corresponding alkylated cyclopentanes in the presence of nickel or palladium catalysts. Therefore, the condensation reaction provides a convenient route for the synthesis of alkylated cyclopentanes from CPD.

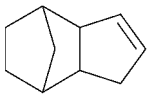
Cyclopentadiene reacts with alkaline oxides and hydroxides forming the alkaline cyclopentadienyl salts. Alkaline hydroxides supported on high surface materials such as kiesclguhr and alumina are good absorbents for trace amounts of CPD contaminant in other hydrocarbons (27).

Hydrogenation. Cyclopentadiene can be hydrogenated stepwise through cyclopentene to cyclopentane in the presence of hydrogen and noble metal catalysts such as palladium (2). The heats of reaction at 82°C are as follows (28):

$$C_5H_6 + H_2 \rightarrow C_5H_8 \qquad 92.9 \text{ kJ/mol}(22.2 \text{ kcal/mol})$$

$$C_5H_6 + 2H_2 \rightarrow C_5H_{10} \qquad 212.8 \text{ kJ/mol}(50.9 \text{ kcal/mol})$$

Similarly, DCPD is hydrogenated first to the dihydro derivative and then to the tetrahydro DCPD (29). The heat of hydrogenation of the double bond of the bicycloheptene ring is 139 kJ/mol (32.2 kcal/mol) whereas that of the five-membered ring is 110 kJ/mol (26.2 kcal/mol) (30). Therefore, the former double bond is more reactive and is the first to be hydrogenated, yielding 3a,4,5,6,7,7a-hexahydro-4,7-methanoindene (**6**), one of the two possible structural isomers of the dihydro DCPD.



6

Oligomers of CPD can also be hydrogenated. The endo isomers of the hydrogenated products are wax-like solids. Physical properties of the hydrogenated oligomers can be found in References 30–32. Hydrocarbon resins produced by polymerization of CPD are hydrogenated to improve their color, light stability, and adhesive properties. Colorless resins obtained this way are used for demanding applications such as adhesives for transparent pressure sensitive tape.

Hydrogenation of CPD and DCPD with noble metal catalysts tends to produce a mixture of dihydro and tetrahydro derivatives. If only the dihydro derivatives are to be produced, selective hydrogenation catalysts must be used. Hydrogenation catalysts designed for the conversions of conjugated diolefins like 1,3-butadiene or isoprene to the olefins have been used for this service. These catalysts are mostly palladium metal modified with one or more promoters (33).

Oxidation. Cyclopentadiene reacts spontaneously with oxygen to form a brown, gummy substance that contains a substantial amount of peroxides. Dicyclopentadiene reacts with air slowly, yielding a gummy deposit. The gum formation in DCPD can be inhibited by the addition of 100–200 ppm by weight of antioxidants such as *t*-butylcatechol and α-naphthol. Vapor-phase catalytic oxidation of CPD over vanadium oxide at 400–525°C yields maleic anhydride, carbon dioxide, and formaldehyde. Dihydroxylcyclopentenes and tetrahydroxylcyclopentane can be prepared by treating CPD with hydrogen peroxide (34–37).

Halogenation. Halogens and hydrogen halides react readily with the conjugated double bonds of CPD, producing a series of halogenated compounds ranging from the monohalocyclopentene to tetrahalocyclopentane. 3-Chlorocyclopentene is not stable. It decomposes on standing, with resinification and the release of hydrogen chloride.

The halogenated derivatives of CPD serve as the starting points for the synthesis of a large number of organic compounds, including amines, alcohols, and thiocyanates. Of all the chloro compounds derived from CPD, only

hexachlorocyclopentadiene [77-47-4] has been used in commercial quantities. It is prepared by a liquid phase chlorination of CPD below 50°C (38). Tetrachlorocyclopentane is produced first, by chlorine addition, and is then converted to octachlorocyclopentane by catalytic chlorination over arsenious oxide or phosphorus pentachloride at 175–250°C. Octachlorocyclopentane is then dehydrochlorinated thermally to the hexachlorocyclopentadiene.

Hexachlorocyclopentadiene is the basis for a number of pesticides such as Chlorodane, Aldrin, Dieldrin, and Kepone. The production of some of these materials has been banned in many regions because of their carcinogenic properties and toxicity to wildlife. Hexachlorocyclopentadiene is also the raw material for chlorendic acid, which is used as a flame retardant (product information from Velsicol Chemical Corp.) for unsaturated polyester resins.

Alkylation. Cyclopentadiene can be multiply alkylated in high yields using alkyl halides, oxo alcohols, and Guerbet alcohols (39,40). The multiply alkylated cyclopentanes obtained by hydrogenation of the diene derivatives have been demonstrated to be useful as synthetic lubricants.

Source and Production

Steam crackers for the production of ethylene are the primary source of CPD and DCPD, although a small amount is still recovered from coal tar distillation. The amount of CPD produced depends on the feedstock to the cracker. The yield from a naphtha cracker is 6–8 times of that from a gas cracker, which uses ethane and propane feed mixture.

The cracked gas leaving the furnace section of a steam cracker contains many chemical components. They are separated by a series of fractionation columns. The bottom stream from the debutanizer column, known as the pyrolysis gasoline in the industry, contains the C5 and heavier fractions of the cracked gas. Typically, CPD plus DCPD constitute 15–25 wt% of the pyrolysis gasoline. Because CPD dimerizes readily, it is usually recovered in the form of the DCPD.

There are two ways by which DCPD can be obtained from the pyrolysis gasoline, depending on whether the pyrolysis gasoline is processed immediately after leaving the debutanizer. When the pyrolysis gasoline is processed immediately, the amount of DCPD present is small. The process scheme generally follows that depicted in Figure 2. The C5 fraction of the pyrolysis gasoline is first separated as the overhead of a depentanizer. The C5 stream is heat-soaked in a dimerizer at about 100°C. The CPD in the C5 stream is converted to DCPD. The separation of the low boiling C5 components from the DCPD is achieved by a second fractionation in which the DCPD is recovered as the bottom product. The DCPD is mainly in the endo form and has a purity of 82–90%.

If the pyrolysis gasoline is placed in storage before it is processed or if the process is supplemented with purchased pyrolysis gasoline, a significant amount of the CPD in the pyrolysis gasoline is already in the form of DCPD, since CPD dimerizes to DCPD at a rate of 9 mol%/h at 35°C. The recovery of the DCPD follows a different process scheme as shown in Figure 3. The pyrolysis gasoline is first heat-soaked in a dimerizer to convert remaining CPD to DCPD. The effluent from the dimerizer is fractionated in one or more columns where the C5–C9 components

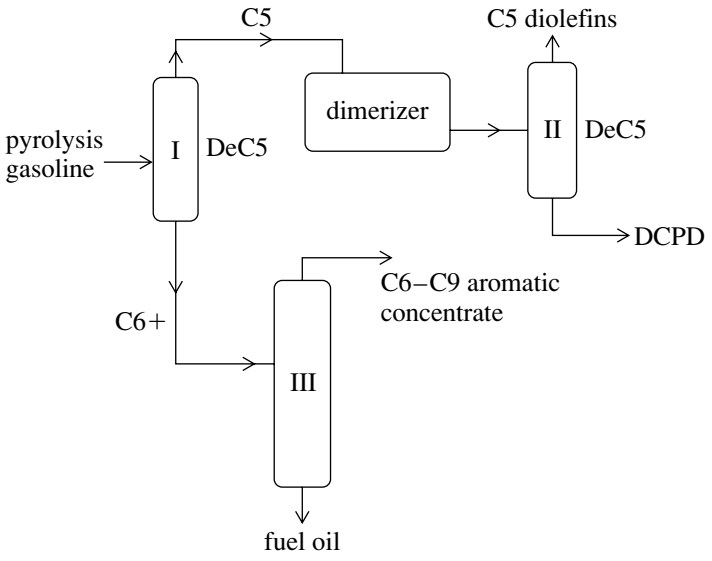


Fig. 2. Process scheme for extracting dicyclopentadiene from pyrolysis gasoline when the gasoline is processed immediately after its production in an ethylene plant.

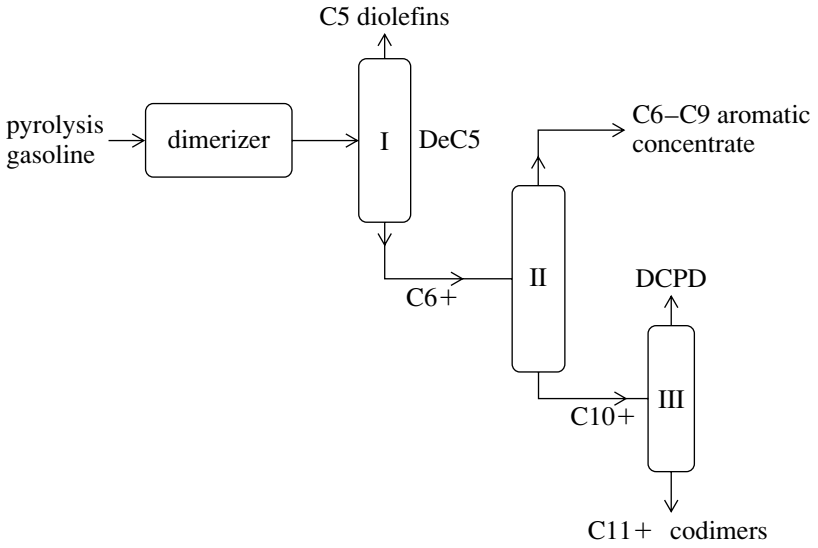

Fig. 3. Process scheme for extracting dicyclopentadiene from pyrolysis gasoline when the gasoline was in storage for an extended period of time after its production in an ethylene plant.

are separated from the C10 and heavier fractions. (Usually, this fractionation is carried out in two steps: First a CPD-lean C5 stream is produced as the overhead of a depentanizer. The bottom stream of the depentanizer is further processed in a second column which separates the C6–C9 components as the overhead while the C10 and heavier fractions become the bottom stream.) The C10 and heavier

stream, which contains 50–70% DCPD, is distilled to yield a DCPD overhead product. The purity of the DCPD is 82–95%.

The process in Figure 2 requires less demanding fractionation, but it has the disadvantage of leaving in the DCPD all the oligomers produced during the heat-soak step. The process scheme in Figure 3 also has the advantage of flexibility in adjusting the DCPD product to a desirable purity by simply varying the fractionation conditions in the last column.

High purity DCPD in the range of 98–99% is produced by thermal cracking of the lower purity DCPD. Pure CPD is separated from the crude DCPD by distillation and is redimerized in controlled conditions to avoid oligomer formation. Unreacted CPD is stripped from the high purity DCPD by mild fractionation (41).

The annual capacity of DCPD production for all grades in the United States is estimated to be in excess of 350 million pounds in 1999. The major U.S. producers are B. F. Goodrich Co., Equistar Chemicals (a joint venture of Lyondell Petrochemical, Milennium Chemicals, and Occidental Petroleum Co.), Exxon Chemical Co., Phillips Petroleum Co., Shell Oil Co., Texmark Chemicals, and Velsicol Chemical Corp. The major consumptions of DCPD in the United States are in the production of hydrocarbon and unsaturated polyester resins (80%), ethylene–propylene terpolymers (10%), reaction injection molding (5%), and miscellaneous uses (5%). The last includes flame retardants, pesticides, antioxidants, and metallocene catalyst production. The demand for DCPD will grow in a rate of 4% per year in the next several years.

Western Europe and Japan have, respectively, annual DCPD production capacities of 176 and 195 million pounds, and predicted annual growth rates of 5 and 6% (42). The major producers in Europe are Exxon, EniChem, Dow, and Shell. Nippon Zeon and JSR are the major producers in Japan.

Storage and Handling

Because CPD monomer dimerizes spontaneously at room temperature and a large quantity of heat (75 kJ/mol or 18 kcal/mol) is released in the process, material containing a substantial amount of CPD should not be stored in any sealed container without the provision of removing the heat. The rate constant of the dimerization is $1.2 \times 10^6 \exp(-16.7/RT)$ L/(mol·s) (2). Thus, the rate of reaction accelerates rapidly with increasing temperature.

Temp,°C	Dimerization rate, mol%/h
−20	0.05
0	0.5
10	1
15	1.5
20	2.5
25	3.5
30	6
35	9
40	15

Without adequate heat dissipation, runaway dimerization occurs. The resulting high temperature leads to the building up of pressure, which will eventually burst the container. Commercial quantity of CPD is usually produced, stored, and shipped in the form of the stable dimer, DCPD. Because of the high freezing point of DCPD, the material is transported in tank cars, rail cars, or barges equipped with heating elements. The heating of the DCPD must be regulated. Otherwise, excess temperature will lead to the formation of the undesirable oligomers. Exposing DCPD to even a trace amount of oxygen or rust at temperatures in excess of 100°C promotes the formation of peroxides and other oxygenates. The oxygenates degrade the quality of the DCPD because they impact undesirable color to the product. DCPD is usually stabilized with 100–200 ppm of antioxidants such as *tert*-butyl catechol to prevent gum deposit during storage.

For commercial applications, which require the CPD monomer, the CPD is obtained from DCPD by thermal cracking. The process involves distilling the DCPD at its normal boiling point (170°C) under an inert atmosphere. At 170°C, DCPD cracks at a rate of 36%/h. By maintaining the overhead temperature of the column at 41–42°C, the boiling point of CPD, an overhead condensate of pure CPD monomer can be obtained. The thermal cracking and distillation can also be accomplished by heating the DCPD in the presence of a heavy oil at about 250°C. The heavy oil functions as a solvent to minimize fouling due to resinification at high temperature. Another method of producing CPD is by cracking the DCPD in the vapor phase at 350–400°C. At these temperatures, the decomposition of the DCPD is instantaneous. The vapor-phase process has the disadvantage that C10 codimers presented in the DCPD also crack at the high temperatures, producing C5 diolefins such as isoprenes and piperylenes. The C5 diolefins make the purification of the CPD much more difficult. To minimize the cracking of C10 codimers, one needs to maintain the temperature below 250°C (43–45).

Because CPD reacts spontaneously with oxygen to form gummy peroxide-containing products, it must be protected from air if not being used immediately. To minimize dimerization, CPD should be stored at a temperature below −20°C.

Health and Safety Concerns

DCPD is a toxic substance. By oral administration in rats, the LD_{50} is 353 mg/kg of body weight, and by skin absorption in rabbits, the LD_{50} is 6.72 mL/kg. An atmospheric concentration of 2000 ppm causes death in rats exposed for a period of 4 h. Studies with rats indicate that DCPD has no deleterious effects on the blood and blood-forming organs. Toxicological effects are similar to terpenes rather than to benzene. The TLV and PEL for DCPD are both 5 ppm as established by ACGIH and OSHA. Chronic exposure causes damages to the liver, kidneys, and lungs.

Uses of Cyclopentadiene and Dicyclopentadiene

There are two general categories of industrial end uses of CPD and DCPD: (*1*) commodity resins and polymers, which include hydrocarbon resins, unsaturated

polyester resins, and ethylene–propylene–diene monomer (EPDM) rubbers and (*2*) specialty polymers and fine chemicals, which include cyclic olefin copolymers, flame retardants, agrochemicals, specialty norbornenes, flavor and fragrance intermediates. Over 90% of the U.S. consumption of CPD and DCPD is in the first category.

Hydrocarbon Resins. About 50% of the DCPD produced is used in hydrocarbon resins. Crude DCPD with 60–75% purity is typically used in this application. Other components in the feedstock may consist of codimers of CPD with isoprene, piperylene, and methylcyclopentadiene, and a small amount of the dimers of methylcyclopentadiene. Both DCPD and the codimers are incorporated into the hydrocarbon resins (46,47). Other C5 diolefins can also be added to the process.

The hydrocarbon resins can be produced by a simple thermal polymerization process (48–50) or by Lewis acid catalyzed reaction (51). The thermal process is carried out at a high temperature in the range of 200–280°C and a reactor pressure above 300 psig. At temperatures below 200°C, the Diels–Alder polymers are formed. They are not desirable in most resins because they are insoluble in aromatic solvents. If reaction temperature exceeds 280°C, decomposition of the resins would occur.

In the acid-catalyzed process, crude DCPD is mixed with a Lewis acid such as BF_3 in the presence of an alcohol or ether (52). An aromatic co-solvent may also be used. Temperature control is critical for producing the resin. After reaction, the Lewis acid is removed by a caustic solution and the resin is further washed with water to remove any caustic and catalyst residues. Unreacted DCPD and the co-solvent are removed by steam stripping.

The DCPD concentration and reaction temperatures have strong influence on the properties of the final resins such as the softening point, color, unsaturation, and reactivity. The resin may be hydro-treated to improve the color and thermal stability. The resins are sold in the solid form as flakes or pellets. The main applications of the resins are in adhesives, tackifiers in tires and floor tiles, surface coating and varnishes, and ink. Water-white resins produced by the hydrogenation process are used in road-marking paint, hot melt adhesives with thermoplastic rubber which can be found in diapers and feminine hygiene products.

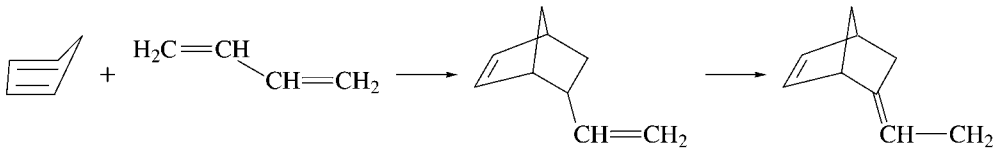
Unsaturated Polyester Resins. Unsaturated polyester resins based on DCPD are produced by reacting glycols, maleic anhydride, and DCPD (12). There are at least four different methods (12,53) in making the DCPD-based polyesters. They are usually two-step batch processes. In one commonly used method, the glycol and maleic anhydride are first allowed to react at a temperature below 150°C, typically around 130°C. Then DCPD is added to the mixture and the reactor temperature is gradually raised to 200°C. After an acid number between 30 and 40 is obtained, the polyester is allowed to cool and is diluted with a mixture of styrene and inhibitors.

Dicyclopentadiene-based polyester resins have several advantages over the conventional polyester resins based on phthalic anhydride. Besides the lower cost of the DCPD, low cost glycols like ethylene glycol can be used instead of the more expensive propylene glycol. Since the DCPD-based resins require less styrene than the phthalic anhydride based resin, there is less styrene emission in the production and processing of the DCPD-based resins.

The resins are used primarily in the fiber-reinforced form as laminates, castings, and coatings (54,55). Glass fiber is one of the common fillers for the reinforcement. Because of the low viscosity of the resin, the DCPD-based sheet molding compounds can incorporate a greater amount of the low cost fillers. The low print-through of the fillers makes the DCPD-based resins ideal for applications in which aesthetic effects are important. These include marine applications (recreation boats, jet ski), automotive parts, safety helmets, bathroom counter tops, shower stalls, and tubs. In the nonreinforced form, the resins have been used as insulation coating for electrical coils (56,57).

Elastomers. Ethylene–propylene–diene monomer (EPDM) rubbers is a terpolymer of ethylene, propylene, and a nonconjugated diene. The diene provides the double bonds in the polymer for the cross-linking, thus increasing the flexibility of the polymer. Dicyclopentadiene and ethylidene norbornene (ENB), a CPD derivative, are among the most important dienes. Typically, high purity DCPD in the >94% range is used. High purity DCPD is also preferred in the synthesis of ENB, which is a two-step process. EPDM rubber has a wide variety of applications, particularly in the automotive industry. It is used in side walls of tires, door and window weatherstripping, cable insulation, radiator and heater hose, and belting (see ETHYLENE–PROPYLENE ELASTOMERS).

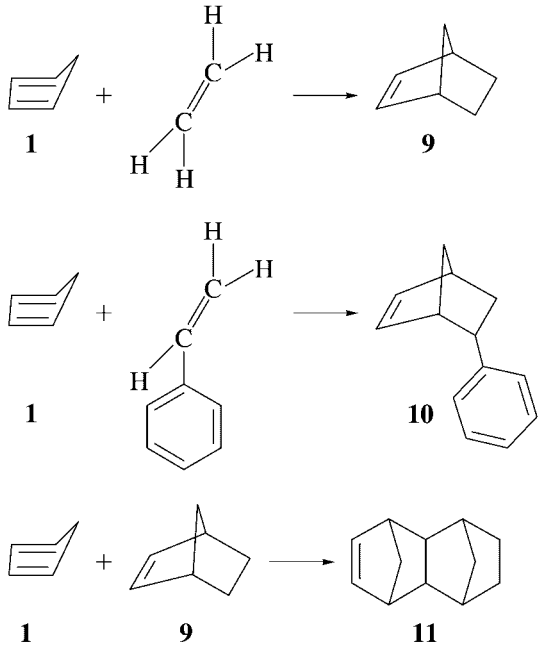
In the ENB production, DCPD is thermally cracked to CPD, which subsequently reacts, via the Diels–Alder mechanism, with butadiene to form 5-vinylbicyclo[2.2.1]-hept-2-ene [3048-64-4] (VNB) (**7**) (58,59). The vinyl double bond is then isomerized in the presence of a selective super-base catalyst such as NaK amide to yield 5-ethylidenebicyclo[2.2.1]-hept-2-ene [16219-75-3] (ENB) (**8**) (60–62).



1 **7** **8**

Cyclic Olefin Copolymers. Cyclic olefin copolymers (COC) are produced by copolymerization of ethylene with a cyclic olefin monomer such as norbornene, dihydro DCPD, phenylnorbornene, and tetracyclododecene. Ziegler–Natta and metallocene catalysts are used in the polymerization processes. COC resins have excellent transparency, near zero birefringence, low density, low water uptake, and good chemical resistance. The target markets for the polymers are in high density electronic storage media such as optical disks, high quality lenses, medical labware, high performance films, and pharmaceutical blister packaging (63).

Cyclic olefin monomers are derivatives of CPD or DCPD. Norbornene derivatives are produced by the Diels–Alder condensation of an olefin and CPD. For instance, 2-norbornene (**9**) is obtained by reacting excess ethylene with DCPD at a high temperature (>200°C) and pressure (>2900 psia), the condition in which the DCPD is cracked to CPD (64). Reactions of CPD or DCPD at high temperatures with styrene and norbornene yield, respectively, the phenylnorbornene (**10**) and tetracyclododecene (**11**) (see ETHYLENE–NORBORNENE COPOLYMERS).



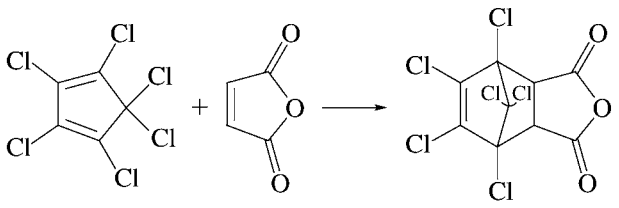
Polydicyclopentadiene. Ultrapure (>98%) DCPD can be polymerized catalytically to form polydicyclopentadiene [25038-78-2], a low viscosity gel which is dark in color and flows like water. Very intricate moldings with good impact resistance can be obtained after curing the polyDCPD. In reaction injection molding, polyDCPD is formed by injecting into a mold two equal amounts of DCPD, one part containing a metal catalyst and the other part containing aluminum alkyl activators (65,66). Upon mixing, the catalyst is activated and initiates the metathesis polymerization. The whole process lasts for 30 s to a few minutes. Reviews of the chemistry and properties of polyDCPD have been published (67,68). Companies like Hercules, B. F. Goodrich, Orkem, Shell, Nippon Zeon, and Teijin hold many patents on the polyDCPD synthesis, catalysts, modifiers, and applications. The major industrial uses of polyDCPD are in moldings for golf carts, automobile bumpers, housing for the hull and body of recreation water vehicles, and body panels for automobiles.

Cyclopentene. High purity cyclopentene is produced from CPD by selective hydrogenation. The process involves the cracking of DCPD to high purity CPD, followed by the selective saturation of one of the two double bonds of CPD in a fixed bed reactor containing a palladium-based catalyst. Cyclopentene is used as an intermediate in the production of many specialty chemicals.

Pesticides. Hexachlorocyclopentadiene, produced by reacting CPD with chlorine, is the starting material for a host of insecticides, including aldrin, chlordane, dieldrin, and heptachlor. Because of environmental regulation, most of the DCPD-based insecticides are no longer produced and used in the United States.

Flame Retardants. Chlorendic anhydride [115-27-5] (**12**), produced by the Diels–Alder condensation of hexachlorocyclopentadiene and maleic anhydride, is

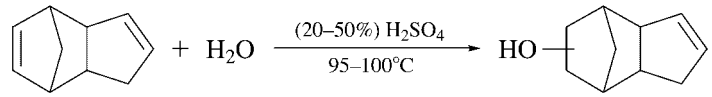
used as a flame retardant for unsaturated polyester resins. The anhydride is incorporated in the resins by the esterification reaction with glycols.



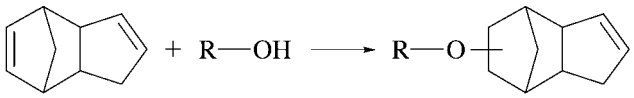
12

Flame retarded polyester formulation may contain 10–50% of the anhydride, with 30% being typical. They are used primarily in construction including shower systems, lavatories, panels in exterior sidings of office buildings, roof lights, glazing, and door panels. The chlorendic anhydride based resins tend to demand high prices because of their translucency and increased corrosion resistance.

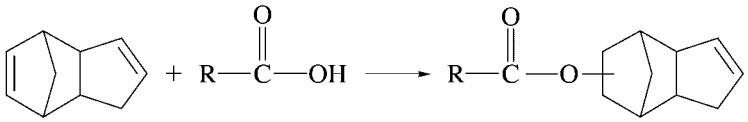
Specialty Uses and Applications. Numerous reactions of DCPD and higher oligomers have been described in the patent literature. These involve the addition of the reacting chemical at the double bond of the bicycloheptene ring of the DCPD molecule to give such products as secondary alcohols (**13**), ethers, esters, and halides. When the reaction is acid-catalyzed at elevated temperatures, the resulting products have the exo configuration even though endo DCPD is used as the starting material. For example, in the presence of sulfuric acid, water adds to DCPD to form the exo secondary alcohol. Dicyclopentadiene alcohol can be used as a component of unsaturated polyester resins, perfumes, and plasticizers. Some DCPD esters are also used as perfume components (69). Dicyclopentadiene alcohol, a number of esters, ethers, and glycol adducts have been claimed as coal and ore flotation aids.



2 **13**



2



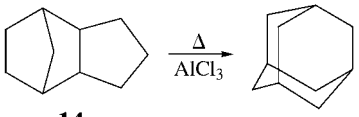
2

Cyclopentadiene oligomers have been formed by vapor deposition of CPD on kaolin to afford a sorbent for removal of oil from water (70). They are also employed as coatings for controlling release rates of fertilizers (71). Thermal addition

of sulfur to a mixture of DCPD and CPD oligomers has led to a number of beneficial applications such as wastewater oil adsorbent powdery foam (72), plasticized backing for carpets and artificial turfs (73), and in modified sulfur cements for encapsulating low level radioactive wastes (74).

Cyclopentadiene itself has been used as a feedstock for carbon fiber manufacture (75). It is also a component of supported metallocene–alumoxane polymerization catalysts in the synthesis of polyethylene and polypropylene polymers (76), as a nickel or iron complex in the production of methanol and ethanol from synthesis gas (77), and as Group VIII metal complexes for the production of acetaldehyde from methanol and synthesis gas (78).

Adamantane, tricyclo[3.3.1.1]decane [281-23-2] (**14**), can be produced by heating tetrahydrodicyclopentadiene [6004-38-2] (**15**) in the presence of aluminum trichloride (79). It is the base for drugs that control German measles and influenza (79,80).



14 **15**

Other specialty applications of DCPD and CPD derivatives include dicyclopentadiene dioxide, dicyclopentadiene diepoxide, and dicyclopentadiene dicarboxylic acid in surface coatings, and the tetrahydrogenated DCPD and CPD as high energy fuels for racing cars, missiles, and jet (81,82).

DEGRADATION

Introduction

Most common polymers are organic materials, with chains mainly of carbon, hydrogen, oxygen, and nitrogen. Their chemical bonds are the same as those in small molecules, as are the intermolecular forces. Polymers derive their useful properties from their long, entangled chains, not from any special properties of the atoms and bonds making up those chains.

The energies of the chemical bonds and the intermolecular forces in polymers are typical of organic molecules. They are in the range that allows both chemical reactions and molecular motions at the temperatures at which polymers are used. Thus polymer properties are typically more sensitive to both temperature and time than are those of other materials, such as metals and ceramics. One consequence of the weak intermolecular forces that hold together thermoplastic polymers is that both chemical changes and molecular rearrangements can take place in time scales which are shorter than the expected lifetime and polymers may lose their desirable properties by both chemical and physical changes.

A molded thermoplastic polymer typically has been heated to 20–100°C above its melting point or glass transition, forced at very high pressure through a small hole into a mold and cooled in a minute or less. Many of the chains, especially those close to the outer surface, cool into the extended state that was induced during flow. As it cools in the mold, the outer sections of the part harden first. Later cooling of the core causes shrinkage stresses which compress the surface and put the core into tension. The thermal expansion coefficient of a polymer is also sensitive to orientation, with more expansion and contraction occurring across the chain axis than parallel to it. Hence large shrinkage stresses can be set up around regions where the polymer was extended during flow. In semicrystalline polymers (qv) the shrinkage on cooling through the melting point can be more
