The allylic chloride moiety is the cure site for polychloroprene polymers (Fig. 2). The reaction of the labile allylic chlorides with bifunctional nucleophiles, metal oxides, or thioureas covalently joins interpolymer chains into a polymer network. The polymer cross-link density is proportional to the concentration of allylic chlorides on the polymer backbone. Thus mechanical goods with high modulus are made from polymers of high allylic chloride concentration. On the other hand, high levels of allylic chlorides decrease the thermal stability of polychloroprene polymers per mechanism described for thermal degradation of unsaturated diene polymer (56,57)

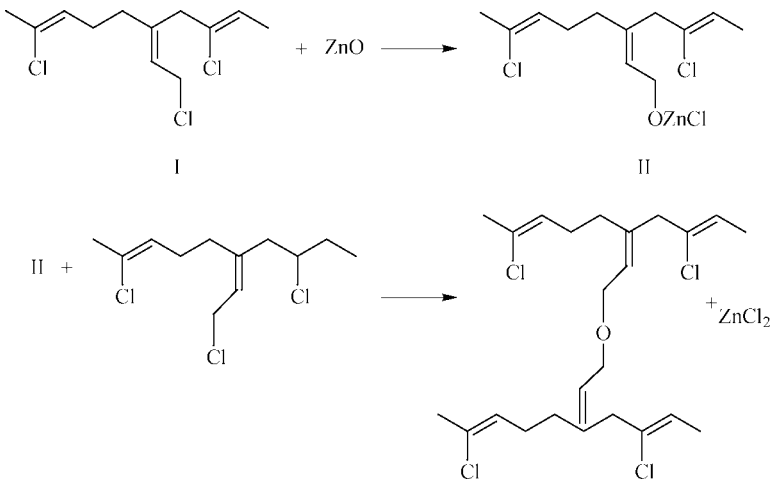

Fig. 2. Function of the allylic chloride in polychloroprene curing.

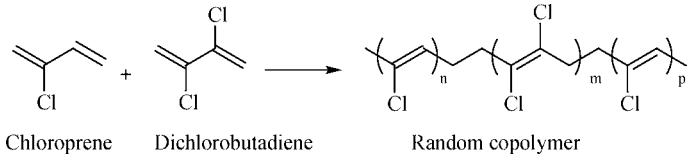
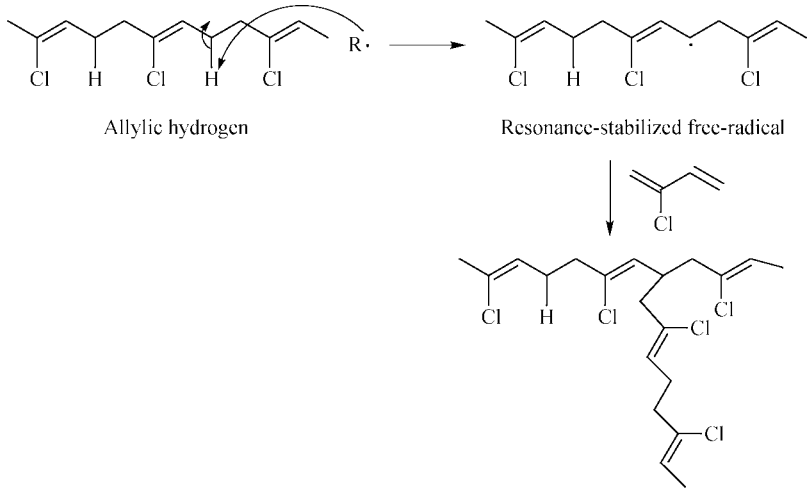
In 1964, Ferguson and co-workers conducted one of the first studies of microstructure by ^{1}H NMR (15). Ferguson and co-workers determined the relative proportion of head-to-head vs head-to-tail structures. The use of 350 MHz ^{1}H NMR in $CDCl_3$ and C_6D_6 enabled quantitative analysis of head-to-head configurations along with the *E*-configuration (58). With the advent of ^{13}C NMR, a number of additional microstructures were observed. There was good agreement between earlier ^{1}H NMR and ^{13}C NMR techniques (51,55,59–61). Other studies of microstructure have been conducted with the aid of infrared and Raman spectroscopy (62,63)

Copolymerization Microstructure. Dichlorobutadiene is the effective comonomer for polychloroprene copolymerization. The comonomer polymerizes in a 1,4-fashion leading to disruption of the trans chloroprene segments in the polymer chain. Crystallization becomes difficult as polymer chains find it difficult to fit into crystalline lattices. Thus polymers containing dichlorobutadiene are very slow crystallizing. In fact, dichlorobutadiene is frequently referred to as ACR, meaning additive for crystallization resistance.



Branching. Branching is a special case of chain-transfer. Instead of free-radical atom extraction from agents such as dodecyl mercaptan (DDM) or xanthogen disulfides, the extraction is from a preformed polymer chain. For polychloroprene, the chain-transfer is to the allylic hydrogen atoms near the double bond. Upon free-radical extraction of the allylic hydrogen a new resonancestabilized free-radical is formed. This new free-radical initiates the growth of a new polymer chain that originates at the locus of the free-radical formation.



The formation of branched polymer originating at a resonance-stabilized free radical has precedence in the well-understood branching mechanism for vinyl acetate polymerization (65,67). Reaction of polymerizing chloroprene and vinyl acetate with ^{14}C-labeled model compounds was used to determine the relative kinetics of chain-transfer and double bond addition reactions with polymer. Chain-transfer to allylic hydrogens or chlorine atoms on the polymer chain leads to long-chain branching. Addition of the growing chain across a polymer double bond can lead directly to gel formation. Either reaction affects polymer rheology and processability. Vinyl acetate radicals, as a model for initiator fragments, were found to be 570–2427 times faster in chain-transfer reactions than chloroprene radicals. In all cases studied, the rate of double bond addition reactions were significantly faster than transfer reactions. Alternately, rate of chain-transfer can be determined by the method of Mayo (68).

The rates of chain-transfer to polymer and radical addition to double bonds of preformed polymers increase as a function of three variables: (*1*) temperature, (*2*) absence of chain-transfer agent, and (*3*) monomer conversion. Mochel (69) showed that in the absence of a chain-transfer agent, up to 90% of the polymer formed at 30% monomer conversion was gelled.

There are several procedures for determining the extent of long-chain branching.

Long-chain branching is accompanied by increased weight-average molecular weight (M_w) as determined by gel permeation chromatography (GPC)–size-exclusion chromatography (SEC) or ultracentrifugation (22,23). The polydispersity (M_w/M_n) increases as branching increases. Branching has been quantitatively determined using ^1H NMR (16,70).

The effect of branching on the zero-shear-rate intrinsic viscosity is often expressed in terms of branching index, g', defined as the ratio of the zero-shear-rate intrinsic viscosities of a branched to a linear polymer of the same composition and molecular weight.

$$g' = \left[\eta_0^{\mathrm{br}} / \eta_0^{\mathrm{linear}}\right]M \leq 1$$

The zero-shear viscosity of a linear polymer is determined from the Mark–Houwick equation (71,72).

$$\mathrm{IV} = KM^{\alpha}$$

where IV is the intrinsic viscosity, K is the Mark–Houwick coefficient, and α is the Mark–Houwick parameter.

The equation with pertinent constants for polychloroprene is used in determining the extent of branching. Thus, several linear polymers were made under extreme control conditions. The molecular weight distribution and intrinsic viscosities were determined for each polymer. A plot of ln (IV) vs molecular weight yielded α and K values:

$$IV = 1.95 \times 10^{-3} \times M^{0.542}$$

The universal calibration method was then used with the GPC–IV method that involves dual detector measurement of both polymer concentrations by refractive index and the solution intrinsic viscosity by capillary viscometry. The measurements provided full molecular weight distribution and branching distribution of the polymer. Polychloroprene polymers showed branching indices varying from 0.5 to near unity. Polymers designed for different end use applications had different branching parameters, which has been useful in predicting processability (73,74).

Chain-transfer agents such as dodecyl mercaptan or ethyl xanthogen disulfide inhibit long-chain branching and prevent any gel formation up to 60–70% monomer conversion (74). A bis-nonconjugated olefin such as ethylene glycol dimethacrylate is capable of network formation (insoluble gel) during free-radical polymerization with chloroprene monomer (75). The branching index of such a copolymer would be near zero.

The extent of long-chain branching of a series of ethyl xanthogen disulfide modified polymers made at 40°C and varying monomer conversion showed that long-chain branching started near 56% conversion (74). As monomer conversion increased, branching and polydispersity increased. Finally near 82% conversion, the polymer gelled.

Commercial Polymer Manufacture

Commercial polychloroprene rubber is manufactured by aqueous free-radical emulsion polymerization followed by isolation of the solid polymer by one of several processes: freeze roll isolation, drum drying (76), extruder isolation (77), precipitation and drying or spray drying (78,79). Isolation of powdered polychloroprene has been reviewed (80). Of the methods cited, freeze roll and drum drying isolation are commercially important (Fig. 3).

The large-scale commercial manufacture of polychloroprene consists of eight or nine unit operations:

(1) Monomer solution makeup Water solution makeup
(2) Emulsification
(3) Polymerization
(4) Stripping of residual monomer
(5) Peptization for chloroprene–sulfur copolymers
(6) Freeze roll isolation Drum drying
(7) Drying of freeze-rolled film
(8) Roping
(9) Cutting and packaging (25kg)

Manufacture of Chloroprene–Sulfur Copolymer. The process for manufacture of a chloroprene–sulfur copolymer taken from the patent literature will illustrate the batch process (82,83).

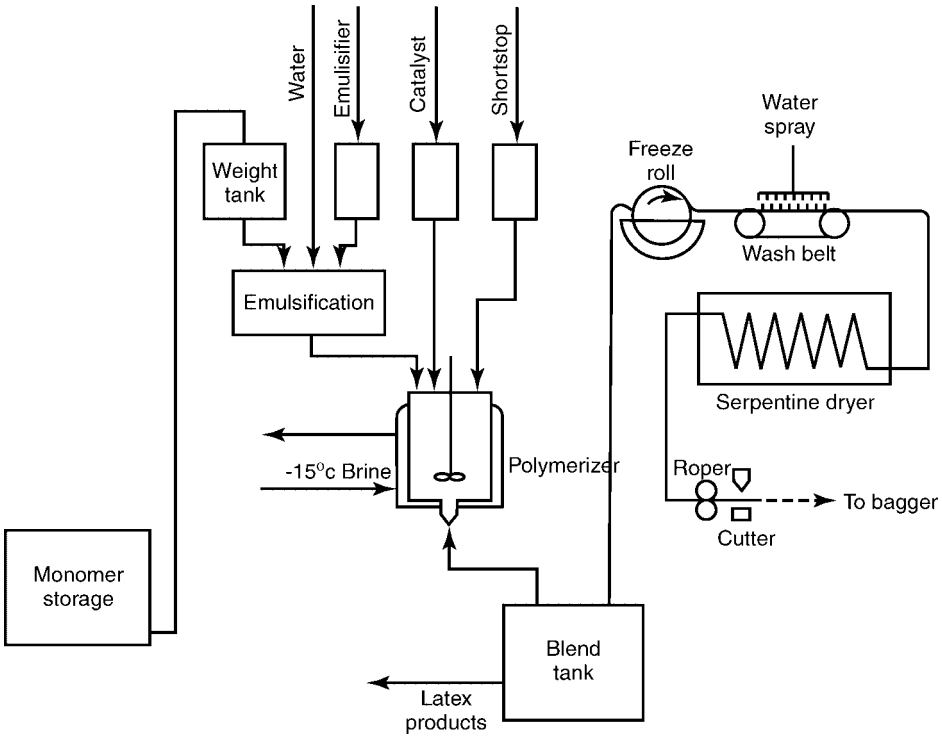


Fig. 3. Commercial manufacturing scheme (81).

The monomer solution makeup involves addition and solubilization of elemental sulfur and rosin (substituted diterpenes) in the chloroprene monomer. The water solution is made in a second vessel. Deionized water, sodium hydroxide, and a dispersant are mixed to form the water solution. The dispersant is a condensation product of naphthalene–sulfonic acid and formaldehyde. The monomer and water solutions are mixed with centrifugal pumps to form an oil-in-water emulsion. The emulsion formed by virtue of formation of the sodium salt of rosin and resin components (abietic and dehydroabietic acids) having hydrophobic and hydrophilic ends. The large carbon-bearing portion of sodium abietate is hydrophobic and thereby solubilizes the monomer. The sodium carboxylate portion of sodium abietate is the hydrophilic end that extends into the aqueous phase and forms the electronic double layer that is critical to emulsion stability (84,85). In the patent example, the emulsion was added to the reactor and the temperature was increased to 40°C polymerization temperature (Table 3).

The reactors in modern commercial processes are brine-jacketed, glass-lined, and fitted with a glass-lined agitator. Glass-lined construction is important to prevent multivalent cations from contaminating the system, and precipitating polymer as coagulum.

Polymerization was initiated by addition of an aqueous potassium persulfate solution to the reactor. The emulsion temperature was maintained near 40°C by control of a combination of three variables: (*1*) reactor jacket temperature, (*2*) agitator speed, and (*3*) catalyst addition rate. The progress of polymerization (86) was

Table 3. Polychloroprene Branching[a]

Parameter	Value					
Conversion, %	11.7	33.6	55.9	62.8	71.9	82.3

[a]Emulsion polymerization at 40°C using xanthate modification (74).

measured by specific gravity, which is continually monitored by computer in modern commercial processes. In the patent example, the initial monomer emulsion had 0.95 specific gravity. During polymerization, the specific gravity increased to a goal value owing to continue formation of polymer having nominal 1.23 specific gravity. The free-radical polymerization was quenched at 91% monomer conversion (1.069 specific gravity) by the addition of a xylene solution of tetraethyl thiuram disulfide.

The emulsion was cooled to 20°C. A dithiocarbamate salt or secondary amine was added and the emulsion aged for 8 h to peptize the polymer. The bulk Mooney viscosity of the polymer was thus reduced to levels suitable for rubber processing.

The emulsion or polymer dispersion containing flammable and toxic chloroprene monomer was next steam stripped with the aid of a turbannular stripper (87). The stripped emulsion contained less than 0.1% residual chloroprene monomer. At this point in the process, the emulsion can be further processed into a dry polymer or sold as a liquid dispersion.

Conversion to the dry polymer involved destabilization of the active surfactant, freeze coagulation, and drying. Thus, the stripped emulsion was acidified to pH 5.5–5.8 with 10% acetic acid solution. The surface-active behavior of the sodium rosinate surfactant was thereby effectively destroyed. The marginal colloidal stability of the emulsion was controlled exclusively by the naphthalene sulfonic acid condensate. Since the sulfonate is a salt of a strong acid it cannot be acidified by acetic acid. Acidified emulsion was contacted with the surface of a rotating chilled (−15°C) stainless steel drum (ie the freeze roll) thereby causing the polymer to plate or freeze out onto the drum. The coagulated film was skived from the roll by a stationary knife and conveyed to a woven stainless steel belt where it was thoroughly washed with water sprays to remove electrolytes and other impurities added or formed during polymerization. After washing, approximately 25% of the excess water and serum is squeezed from the film with the use of a squeeze roll. The film was then conveyed onto cloth-covered aluminum girts where it was carried through an air-circulating serpentine dryer having heating compartments with temperatures that start from 120°C. The final dryer compartment operated near 50°C to cool the dried film. The film was cooled further at the exit of the dryer by contacting a rotating cooling roll. In a modern commercial process, the film is gathered into a rope and then conveyed to cutters, where it is cut into small chips. The product is then packaged into bags weighing 25 kg each.

In the patent examples, there were five key features that permitted freeze-roll isolation. The emulsion was of sufficient colloidal stability to prevent spontaneous coagulation before contacting the rotating freeze roll. The sulfonic acid salt

was critical in that connection. The polymer had sufficiently low glass-transition temperature to prevent cracking from the freeze roll at typical (−15°C) freeze-roll operating conditions. The film maintained sufficient strength to be conveyed along the wash belt and through the dryer. In that connection, freeze-roll isolation of very low Mooney viscosity polymers or fluid polymers is difficult or virtually impossible. The dryer cooling temperature and cooling-roll temperature were controlled to prevent polymer cold flow leading to massing after the polymer has been packaged.

Continuous polymerization is a second process practiced on a large commercial scale (88). An illustrative example taken from the patent literature illustrates the continuous polymerization process. Thus a mixture of chloroprene, 2,3-dichloro-1,3-butadiene, dodecyl mercaptan, and phenothiazine (15 ppm) was fed to the first of a cascade of seven reactors. Water solution containing disproportionated potassium abietate, potassium hydroxide, and formamidine sulfonic acid catalyst were fed with the monomer solution to the first reactor. Polymerization initiated immediately. The emulsion was then cascaded to the second reactor and the process continued. The residence time in each reactor was 25 min at 45°C. The emulsion exited the reaction train at 66% monomer conversion. In a second similar process, the catalyst was fed to each reactor along the reaction train.

The descriptions presented above are intended as an overview of polychloroprene technology as practiced over the commercial life of polychloroprene. Product and processes have changed since 1930 to meet changing consumer needs, to upgrade product quality, to improve the quality of the workplace and environment, to improve efficiency of operation, and to meet the demands of a changing global economy. The commercial chloroprene–sulfur copolymers were commercialized in 1937 (89). Low temperature polymerizations for adhesive applications were discovered in the late 1940s. The mercaptan-modified chloroprene homopolymers were commercialized in 1950. The crystallization-resistant chloroprene–dichlorobutadiene copolymers were introduced in 1951. The fluid polychloroprene polymers were commercialized in the late 1950s. The sol–gel blends or "pre-crosslinked" grades were introduced in the 1960s for improved processability. Modifications to these basic types have continued into the twenty-first century.

Commercial Polychloroprene Polymers

At one time, 10 worldwide producers manufactured 160 dry polychloroprene types and 66 liquid dispersions or latex types. More recently six major producers produce 93 dry types. The polymers offered globally fall into five categories: (*1*) standard general-purpose grades, (*2*) crystallization-resistant grades, (*3*) adhesive grades, (*4*) specialty grades, and (*5*) liquid dispersions or latex grades (Table 4). The chloroprene–sulfur copolymers, mercaptan-modified homopolymers, and mercaptan-modified sol–gel blend polymers constitute the standard general-purpose grades. Crystallization resistant grades are made by two commercial processes. Copolymerization of chloroprene with 2,3-dichloro-1,3-butadiene is the method adopted by most producers. High temperature and high pressure emulsion polymerization is a second process used. Adhesive grades are generally made by low temperature polymerizations. The specialty grades are based on xanthogen disulfide chain-transfer during either homopolymerization or copolymerization

Table 4. Polychloroprene Grades—Advantages and Limitations

Polymer Description	Advantages	Limitations
(*1*) Standard general purpose grades		
Chloroprene–sulfur copolymers	Peptizable Good building tack Good tear strength Good flex resistance Low tan delta	Poor heat resistance High compression set Poor shelf stability
Mercaptan-modified homopolymers	Easy molecular weight control Good heat stability Low compression set Good shelf stability	Not peptizable Requires accelerator Low flex resistance
Sol–Gel blends	Improved rheology Low nerve Fast extrusion Low die swell Smooth extrudate surface Collapse resistance Better calendering	Low tensile strength
(*2*) Crystallization resistant grades		
Copolymers of 2,3-dichloro-1,3-butadiene, styrene	Low crystallization rates	Slightly higher T_g
High temperature and high pressure polymerization	Low crystallization rates	Poorer heat resistance
(*3*) Adhesive grades		
Low temperature	Rapid crystallization	Thermal stability
Polymerization	Rapid solubility in organics Adheres to wide variety of substrates	Cannot be used if gelled
(*4*) Specialty grades		
Xanthogen disulfide modified homopolymers and copolymers	High stress–strain Faster cure rate Low tan delta Low compression set	Poorer heat resistance than mercaptan modified types
(*5*) Latex		
Emulsion polymerization	High solids Good film former Gelled polymer for adhesives Environmentally desirable for solvent-free adhesives	Freezes Poor thermal stability Sensitive colloid system

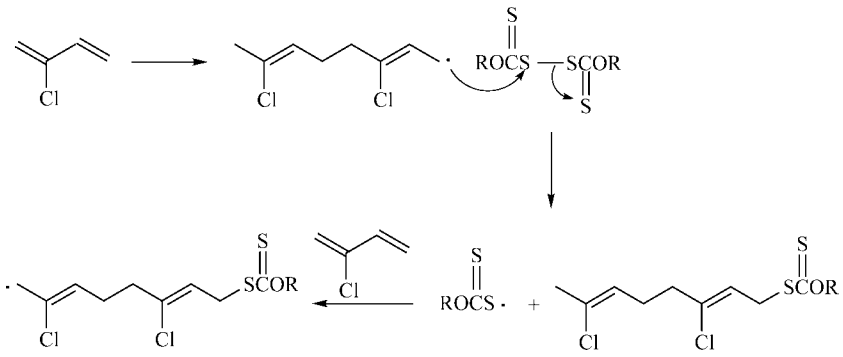
with conventional comonomers or sulfur. Finally, the latex grades are made by the same emulsion polymerization techniques as the dry types but generally with additional surfactants. The latexes are sold as aqueous dispersions. Customers convert the liquid dispersions to dry product according to specific end uses.

Thus, wide ranges of choices are available for a diverse range of properties.

Global Polychloroprene Grades

The six major global producers manufacture all major classes of commercial polychloroprene dry types (90): DuPont Dow Elastomers L.L.C. manufactures Neoprene, Bayer manufactures Baypren, Enichem makes Butachlor, Denki Kagaku makes Denki chloroprene, Tosoh makes Skyprene, and Showa makes Showapren.

Xanthogen disulfide modification has been used in the manufacture of all dry and latex types including chloroprene–sulfur copolymers. The chain-transfer agents have been used in combination with all conventional comonomers. In contrast to dodecylmercaptan modifiers, xanthogen disulfide modification has the advantage that it can be used with chloroprene–sulfur copolymerizations without concerns with reaction with sulfur.



The xanthate-terminated polymers undergo reaction at the end group during vulcanization (91,92). The molecular weight distribution can be wide, leading to better-processing polymers (92,93). In concert with predictions from the Boltzmann's equation, the reactive ends lead to a polymer of greater tensile strength and reduced hysteresis loss and creep.

The sol–gel blend or pre-crosslinked grades of polychloroprene such as the T Type polychloroprenes available from DuPont Dow contain a highly cross-linked network, which that acts as an internal processing aid (94,95). The blend has many of the same characteristics as the sol component, but different compound rheology properties. This composition results in faster extrusion with extrudates having smoother surfaces. Extrudates also retain their shape better with good definition until vulcanized.

Commercial Conversion of Raw Polymers to Final Vulcanizates

Polychloroprene is a multipurpose elastomer that has a good balance or properties that include outstanding physical toughness and wider short-term/long-term

operating temperature range than most general-purpose hydrocarbon elastomers such as EPDM or natural rubber. Polychloroprene has better resistance to hydrocarbon oils, ozone, sun, weather, and heat per ASTM D2000/SAE J2000 categories BC/BE. Finally, it demonstrates flame retardency and self-extinguishing characteristics that purely hydrocarbon-based elastomers lack (96).

As with all elastomers, the properties of the raw polymer can be enhanced by careful choice of rubber compounding formulation (97). Handling precautions, polymer selection guide, compounding guide for specific application, processing guides, and representative formularies are discussed in the *Guide to Grades, Compounding and Processing of Neoprene Rubber* compiled initially by J. C. Bament (98). Future mentions of this document will simply be referenced as the Bament guide published by DuPont Dow (98).

The critical links between the raw polymer and finished vulcanized product used by the global consumer involve the compounding, processing, and curing or vulcanization. There are several major considerations in designing a rubber composition based on polychloroprene dry polymers (Table 5).

Table 5. General Vulcanizate Properties[a,b]

Property	EPDM	CR	NBR
Density	0.86	1.23	1.0
Hardness, shore A	40-95	40-90	45-100
Tensile strength, MPa[c]			
Gum stock	VL	21	VL
Black stock	>21	21	17
Service temperature, °C	−50 to +150	−40 to +120	−20 to +120
Heat resistance	H	FH	M
Cold resistance	M	FH	L–M
T_{10}, °C	−45	−45	−20
Tan delta at 20°C		0.09	0.1–0.18
Set resistance	VH	FH	M–FH
Tear resistance	M	H	M
Aging general	VH	H	M
Ozone/corona resistance	VH	FH–H	M
Aliphatic oil resistance	L	M–H	H
Electrical resistance	H	M	M
Bonding to substrates	M	VH	VH
Useful properties	Excellent aging, medium strength	Low damping; high weather, heat, and flame resistance; moderate oil resistance; good flex & tack	Resists oils chemicals; moderate heat aging
Limiting properties	Self-tack, poor building of composites	Moderate tensile strength	Poor cold resistance

(1) Selection of a CR or polychloroprene type
(2) Choice of a compound formulary for a specific end use
    a. Acid acceptors
    b. Vulcanizing agent
    c. Vulcanizing accelerators and retarders
    d. Antioxidant and antiozonant
    e. Reinforcing and extending fillers
    f. Plasticizers
    g. Processing aids
(3) Modification of the basic formulary to choose critical ingredients necessary to achieve critical end use properties

Compounding and Processing of Polychloroprene. Typically, dry polymers are mixed with compounding ingredients on a rotating two-roll mill or Banbury mixer.

Polychloroprene	100
Magnesia	4
Stearic Acid	0.5
Antioxidants	2
Antiozonants	2
Fillers, Processing Aids, Plasticizers	As required
Accelerators	0.5
Zinc Oxide	5

Typical Dry Type Compound (99)

Owing to the propensity of the unsaturated polymer to degrade and liberate HCl on long-term in-service use, a special grade of magnesium oxide (Maglite D), from Marine Magnesium Co.) is added as an acid acceptor. Because metal oxides can also function as vulcanizing agents, particularly for chloroprene–sulfur copolymers, an optimum level of MgO is used. An antioxidant is required to attenuate the aging process. Antiozonants are added in addition to antioxidants to prevent ozone-induced stress cracking, particularly in dynamic applications. Plasticizers and oils enhance the rheological properties and also improve vulcanizate properties. Fillers are of paramount importance for all polychloroprene compounds. Of all fillers, carbon black is most important. Carbon black reinforces the rubber leading to higher tensile strength, greater resistance to oil swell, weather resistance, and abrasion and tear resistance. Plasticizers aid in the mixing of ingredients. Depending on the plasticizers selected, stress–strain properties may be increased or low temperature stiffness resistance improved without affecting crystallization rates. Finally, zinc oxide and accelerators function both as acid acceptors and curatives that initiate the cross-linking reaction. Retarders such as sodium acetate or salicylic acid are used to balance the cure rate or scorch thereby improving the curing process safety. In this connection, scorch is defined as cure rate measured on compounded rubber (ASTM D3190-95) as Mooney Scorch with small rotor at

121°C (ASTM D1646-96A) or MDR scorch measured with a moving-die rheometer at 160°C (ASTM D5289-95).

Curing Mechanism. Chloroprene–sulfur copolymers can be cured for some applications with zinc oxide alone. All other polychloroprene types will usually require an organic accelerator to cure. Typically thioureas are used in combination with zinc oxide to effect cure. The accepted mechanism for curing involves reaction of thioureas and zinc oxide at the primary allylic chloride moiety that was formed by sn_i' rearrangement during polymerization or curing (100,101) (Fig. 4).

Thioureas such as ethylene thiourea (ETU, NA22) initially react with the primary allylic chloride to yield the thioether. Zinc oxide then reacts at the thiocarbonyl atom. Further reaction at the curing temperature of 160°C eliminates the ethylene urea and leaves the polymer as the zinc sulfide salt. The sulfide salt reacts with the allylic chloride moiety of a second polymer molecule to generate the thioether-cross-linked polymer (102).

Wide ranges of organic accelerators, which are capable of nucleophilic substitution at the allylic chloride atoms, have been used in polychloroprene curing. Polyhydric phenols (103,104), hydroxyphenyl mercapto-substituted triazoles (105), thiolactams (106), thiazolidine and thiones, Vulkacite (Bayer Chemical Co.). CRV (107,108), alkyl thioamides, formaldehyde amine reaction products, amines, guanidines, dithiocarbamates, thiurams, and sulfenamides have all been used as accelerators.

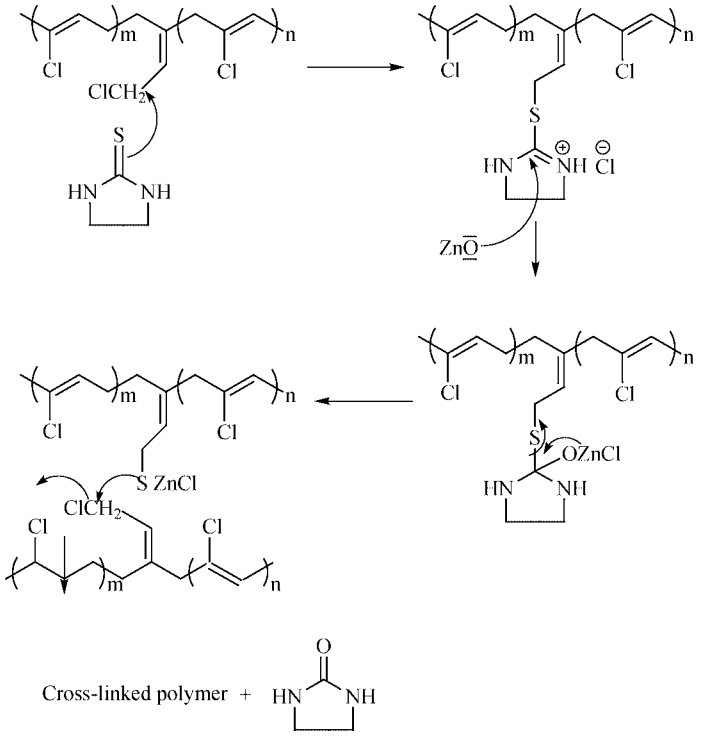

Fig. 4. Curing of chloroprene polymers.

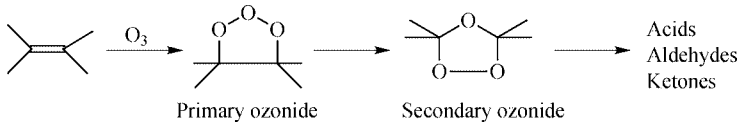
Antioxidants. The sensitivity of polychloroprene to oxidative attack has been discussed (57,109,111). Antioxidants are required for good long-term service. Amines and hindered phenols, and bisphenols are generally the antioxidants of choice. Octylated diphenylamine is frequently used owing to its effectiveness, its nonstraining characteristics, and its noninterfere with the curing reaction (112). Organic monosulfides and phosphates enhance the activity of octylated diphenylamines. *Para*-phenylene-diamines are used but are lightly staining antioxidants. Of the bisphenols, 2,2′-methylene-bis-4-methyl-6-tertiary butyl phenol, 4,4′-thio-bis(2-methyl,6-tertiary butyl phenol) are important. Neozones (ie phenyl-naphthalamines) are staining antioxidants (qv) that have found utility in some applications. When used at levels of 3–5 parts per 100 parts rubber, Neozones are good antioxidants and good antiozonants (99) (see RUBBER CHEMICALS).

Antiozonants. The reaction of atmospheric ozone with olefins is a known organic chemical reaction. Primary and secondary ozonides are formed (113).



Ozonolysis is most pronounced when vulcanizates are tested under stress-cracking conditions in an atmosphere containing ozone. Owing to the presence of the polar chlorine moieties, polychloroprene resists cracking to a much greater extent than natural rubber or polybutadiene. The long-established use of polychloroprene as telephone wire coatings attests to the high ozone resistance of the polymer. Early on, rubber processors considered ozone cracking as a surface phenomenon. Thus, waxes that would bloom to the vulcanizate surface were used for ozone protection (114). The use of waxes was, however, not a panacea for all problems involving ozone cracking. W. F. Tully noted as early as 1939 that *p*-phenylenediamines were effective antiozonants (115). The choice of *p*-phenylenediamine was critical, however because of the bin instability precipitated by reaction of the bifunctional amine with polychloroprene cure sites, leading to increased viscosity (109). The best balance of bin stability and ozone resistance in a dynamic test at 40°C was achieved by use of a diaryl-hindered *p*-phenylenediamine antiozonant (Table 6).

N-(1,3-Dimethyl butyl)-*N*′-phenyl-*p*-phenylene-diamine and phenyl/tolyl-*p*-phenylene diamine showed best balance of properties.

Table 6. Antiozonant Performance

N, *N*′ Group	Viscosity increase as 121°C	Dynamic test: 3 ppm ozone, 40°C (hours to rating of 4)
Hindered diaryls	10	118
Diaryl	24	110
Alkyl-aryl	>200	84
Alicyclic-aryl	103	81
Dialkyl	73	49

Table 7. Plasticizer Properties for Polychloroprene

Desired property	Preferred plasticizers
Low cost	Petroleum oils, naphthenic and aromatic
Light-colored or nonstaining stocks (including black stock)	Ester plasticizers, chlorinated paraffins, or selected petroleum oils
Low temperature service	Ester plasticizers or *cis*-polybutadiene
Heat resistance	Polymeric plasticizers, chlorinated paraffins, polyester plasticizers, and low volatility petroleum oils
Low flammability	Chlorinated paraffins and organic phosphate esters
Fungus resistance	A polyether-[di(butoxy-ethoxy ethyl) formal]
Use with peroxide cure systems	Ester, chlorinated paraffins, or polymeric plasticizers

Of auxiliary agents, linseed oil, unsaturated vegetable oils, rapeseed oil, and hydrocarbon waxes enhance the efficiency of an antiozonant in a dynamic ozone test as they bloom to the surface of the polymer. Ester plasticizers such as dioctyl sebacate impair ozone resistance presumably because of enhanced solubility of polar esters in the polar polychloroprene network polymer. Finally, the mechanism for ozone attack differs appreciably from oxygen attack at allylic atoms. Thus, an antioxidant is generally used in combination with an antiozonant for polychloroprene.

Plasticizers. Plasticizers (qv) are used in polychloroprene to improve compound processability, to modify vulcanizate properties, and to reduce cost (Table 7).

There are five classes of plasticizers normally employed for polychloroprene vulcanization: (*1*) organic esters, (*2*) petroleum oils, (*3*) vegetable oils, (*4*) chlorinated paraffins, and (*5*) polymeric plasticizers (Table 8). Some attributes of the different classes follow:

Mixing. The ability to be mixed in existing equipment used in natural Rubber Compounding (qv) was one factor that contributed to the easy acceptance of polychloroprene after its discovery (Table 9). Mixing of compounds of various sizes can be performed on two-roll mills or in an internal Banbury mixer. A typical 20-min procedure follows:

Several variations of the basic scheme are used in the industry: (*1*) upside-down mixing, (*2*) sandwich mixing, (*3*) straight mixing, (*4*) optimum dispersion mixing, (*5*) masterbatch mixing. In Upside-down mixing all the filler and oil are loaded first into the mixer and then the rubber added on top. The ram is lowered and the mixing starts. This gives cold rubber, which gives more shear on the black at the critical initial stage and you can therefore get shorter mixing times with better dispersion. The downside temperature develops much faster.

The accelerators and zinc oxide are best added on a second mill or in a second operation just before the stock is needed for curing (96,119). Bin stability is thus enhanced.

Calendering and Extrusion. Friction compounds are used to build up composite structures of fabric and rubber. The surface of the calendered fabric must have good green strength or "building" tack. Thus calendered stocks are usually made from slow-crystallizing polychloroprene types. Polychloroprene

Table 8. Classes of Plasticizers for Polychloroprene

Advantages	Disadvantages
Organic esters (eg dioctyl sebacate, butyl oleate): (refs. 83,116,117)	
Best low temperature brittle point	Higher cost
Nonstaining, nondiscoloring	Volatile, leading to poor heat resistance
Useful for nonblack compounds	May craze plastics
Good compatibility	Decreases stress–strain and tear
	Increases crystallization rates (116,117)
Petroleum oils:	
Low cost	Aromatic oil stain and interfere with peroxide cure Paraffinic oils have low compatibility
General purpose	
Aromatic oils have good compatibility	
Naphthenic oils have moderate compatibility	
Chlorinated paraffins (eg chlorowax, chloroflo)	
Better flame resistance than hydrocarbon rubber	Low plasticizer efficiency
	Increased smoke emissions
Good low temperature properties	
Can be used in nonblack stock	
Good heat resistance	
Moderate compatibility	
Vegetable Unsaturated Oils (linseed and rapeseed)	
Good antiozonant properties	Encourages fungus growth
Good heat resistance	
Retards sunlight-induced discoloration	
Polymeric ester plasticizers (hexa-oxypropylene glycol monomethacrylate) (118)	
Good heat resistance and low volatility	Low plasticizer efficiency
Resins (eg coumarone–indene resins)	
Improved building tack	Reduced resilience
Improved heat resistance	Reduced low temperature properties
Improved tear strength	
High vulcanizate hardness	
Improved abrasion resistance	
Improved crystallization resistance	

compounds can be formulated to process well in the four basic calendering operations, which include unsupported sheet, fractioning, plying-up, and skim coating (120). Unsupported sheet calenders use smooth compounds based on sol/gel blend or pre-crosslinked types. These polymers of very low nerve will calender smoothly and rapidly. Plying up is done when smooth sheets are required in a thickness which cannot be calendered in one operation. Plying up gives a better sheet since pin holes and other flaws do not extend through the full thickness of the sheet. Frictioning stocks are very soft and tacky. They permit penetration and adherence

Table 9. Compounding Polychloroprene

Step	Minutes	Cumulative time
Set mill for 6 mm sheet and turn on cooling water		
Mass polychloroprene containing no accelerator	5	5
Add high activity magnesia, retarders, and antioxidants	2	7
Add hard fillers (fine furnace blacks or silicas)	2–5	9–12
Add soft fillers (large furnace and thermal carbon blacks, and mineral fillers and oils)	4–9	13–21
Add wax, petrolatum, stearic acid	2	15–23
Add zinc oxide and accelerators; cut, batch off, dip, and hang to cool	6	21–29

to the interstices of the fabric. Slow-crystallizing polymers are used for this application. Skim coating is similar to plying up with the fractioned fabric as one ply.

Extrusion. Polychloroprene has been employed in a wide variety of extrusion (qv) processes. Intricate cross-sections such as highway compression seals, bulb weather-stripping, and hose represent a few examples. As with calendering, extrusion is very sensitive to nerve. The DuPont Dow neoprene sol/gel blend types are best suited for extrusion applications. Use of low levels of highly structured furnace carbon blacks, stearic acid, petroleum, paraffin wax, triethanolamine benzoic acid, and calcium stearate are particularly effective extrusion aids. The screw of the extruder should have a constant diameter root with increasing pitch. Heat history of the compound should be minimized, with only a brief warm-up before extrusion begins. The barrel and screw should be run cool, 50°C, and the die hot, 95°C (96,119).

Molding. Molding is used widely for fabricating CR into belts, hose, sponge, and a variety of industrial products. All of the standard molding techniques have been used successfully with commercially available equipment. Molding methods include compression molding, transfer molding, injection molding, blow molding, vacuum molding, and tubing mandrel wrap. An optimum cure cycle-time–temperature relationship must be selected based on the curing characteristics of the compound and the suitability of existing equipment. Mold design must take into consideration the easy rapid removal of the cured part without damage (121). The Bament guide contains specific recommendations on cure condition for specific end use applications (81).

Properties of Polychloroprene Polymers

Crystallization. Some elastomers crystallize at temperatures that can significantly impact processing and vulcanizate behavior. Thus it is necessary to account for these behaviors when developing rubber compound formulations and processes. Crystallization is manifested by stiffening and hardening of the raw polymer, uncured compounded polymer, and the vulcanized polymer. Elastomers that crystallize will do so on stretching and thereby exhibit increased tensile strength. Those elastomers (eg polychloroprene and natural rubber) will

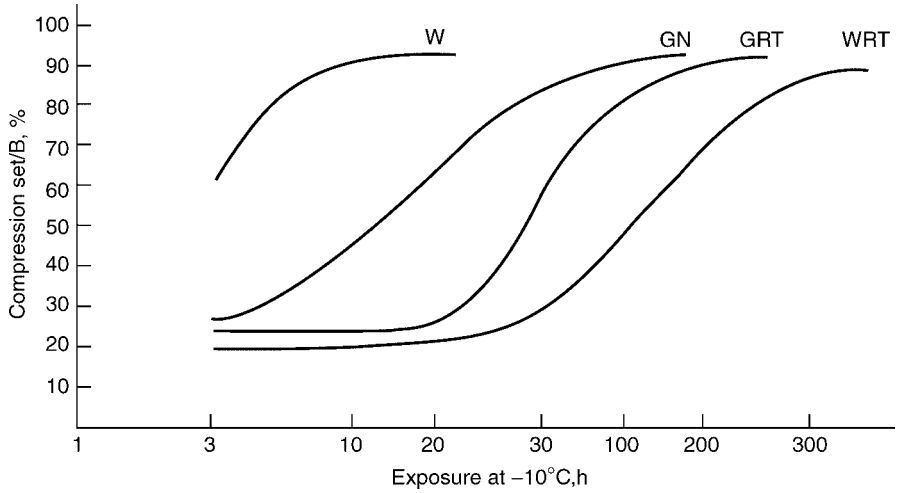


Fig. 5. Profile of low temperature compression set.

require less reinforcing fillers to develop strength than types that do not stress-crystallize (122). Crystallization is also enhanced by compression. Frequently the profile describing the low temperature compression set as a function of time is S shaped, indicating an initial period of nucleation followed by stress-induced rapid crystallization (Fig. 5). The rates of crystallization of some polychloroprene commercial types follow a general trend: homopolymer > chloroprene–sulfur copolymer > chloroprene–sulfur–dichlorobutadiene tripolymer > chloroprene–dichlorobutadiene copolymer having higher levels of dichlorobutadiene (123). Finally, in addition to promoting stress-induced crystallization, polyester plasticizers will also increase crystallization rates. Presumably, the ester plasticizers provide a medium for increased chain mobility that permits polymer chains to migrate to the preferred crystalline cells. Hydrocarbon oil plasticizers and co-blends with hydrocarbon rubbers will retard crystallization rates but may improve low temperature brittleness resistance.

Crystallization is important for some hose manufacturing applications as it imparts some stiffness for braiding. The rapid crystallization of some polychloroprene polymers is fully exploited in adhesive manufacture and use (64).

Crystallization of amorphous polymers is a time-dependent phenomenon. Polychloroprene crystallizes fastest at $-12^{\circ}C$ (123,124). Below this temperature, thermal stiffening commences and restrains molecular motion and alignment. Crystallization rates and degree of crystallization are heavily impacted by several phenomena, of which polymer polymerization temperature and thermal history of the polymer sample before measurements are most important.

Hardness increase, differential scanning calorimetry (DSC), differential thermal analysis (125–127), low temperature compression set, and Gehman torsional stiffness are tests normally employed to measure crystallization properties. The heat of fusion of the crystalline phase of polychloroprene homopolymer is approximately 96 kJ/kg (23 kcal mol^{-1}) and the activation energy for crystallization is 104 kJ/mol (25 kcal mol^{-1}). The extent of crystallization can be calculated from

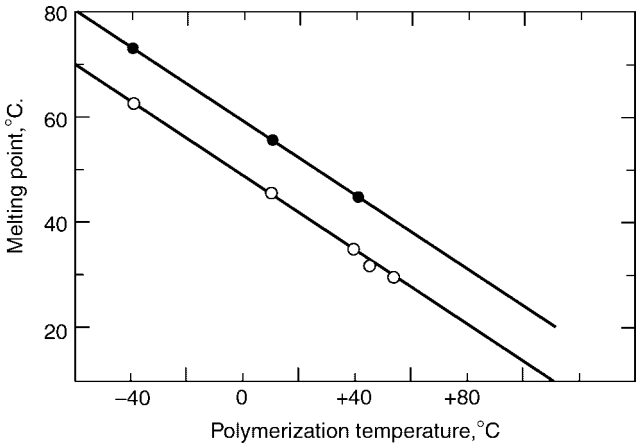

Fig. 6. Effect of polymerization temperature on the crystalline melting point of chloroprene rubbers produced by emulsion polymerization: ●, highest observed value; ○, lowest observed value. From Ref. 124.

the density of amorphous polymer ($\rho = 1.23$) and the crystalline density ($\rho = 1.35$). Thus, a polymer that is polymerized at -40°C melts at 73°C and is 38% crystalline. A polymer polymerized at $+40^{\circ}$C melts at 45°C and is approximately 12% crystalline (Fig. 6).

X-ray diffraction has also been used to measure crystallinity. X-ray diffraction analysis showed that the polychloroprene unit cell is orthorhombic, $a = 0.88$ nm, $b = 1.02$ nm, and $c = 0.48$ nm (128).

Heat Aging and Degradation. The weather and ozone resistance of polychloroprene vulcanizates are enhanced by the presence of chlorine atoms in the molecule. Thus, polychloroprene is more resistant to environmental elements than natural rubber. In comparison to saturated elastomers, polychloroprene is less heat and oxidation resistant. H. C. Bailey studied the degradation of a mercaptan-modified polychloroprene homopolymer and model compound (chlorooctene) under controlled temperature (90–120°C), environmental chamber gas composition, and gas flow rates (124,127,129). Bailey concluded that as the polymer was oxidized hydrogen chloride evolved at a rate that closely matched oxidation or oxygen uptake. Oxidation brought about both scission and cross-linking of the polymer and decreased the proportion of the polymer that was capable of crystallizing. In the early stages of oxidation, cross-linking occurred mainly through the formation of intermolecular peroxides. The activation energies for oxidation and accompanying dehydrochlorination were found to be 17.6 and 25.8 kcal mol^{-1}, respectively, for polychloroprene. Molecular weight determination showed that at low degree of oxidation, scission of polymer molecules predominated over cross-linking. Chain scission resulted from the decomposition of intramolecular peroxides and hydroperoxides, with concomitant evolution of hydrochloride, ketones, and acid chloride moieties. At higher degrees of oxidation, polychloroprene gradually increases in modulus and loses elongation, leading to increased hardness and brittleness.

Oxidation initiates at the allylic hydrogen or chlorine atoms, particularly atoms residing in tertiary positions that are formed during 1,2- or

3,4-polymerization (130–132). After an initial induction period, rapid autoxidation increases with temperature (133). At the low monomer conversion characteristic of mercaptan-modified polymers, the concentration of microstructures arising from 1,2- and 3,4-polymerization is lower than that found in higher conversion types. Thus, polymers made at low polymerization temperatures with mercaptan modification are the most heat-resistant polychloroprene types (93).

Hydrogen chloride evolution with polymer degradation did not occur readily at 120°C in a nitrogen atmosphere (96). At much higher temperatures (eg 275°C), the polychloroprene polymer was carbonized with HCl liberated by a non-free-radical mechanism (134). Polymer polymerized at low temperatures showed better thermal stability (93).

The practical ceiling service temperature in air for conventional polychloroprene polymers used in dynamic applications is approximately 120°C. To reach this high service temperature, antioxidants and antidegradants are added during rubber compounding. Alternately, theory predicts that elimination of tertiary hydrogens and tertiary chlorine atoms would improve heat resistance. Several studies have supported the theory. Thus, post-reaction of polychloroprene with dodecyl mercaptan (135), use of high levels of ethylene thiourea during curing (136), and inclusion of reactive thios such as mercaptobenzimidazole in the cure systems (137) all react away the labile chlorine atoms, thereby improving heat resistance. The latter technique is particularly important in improving the heat resistance of mercaptan-modified polychloroprene.

Commercial Dry Type Applications

The *Guide to Grades, Compounding and Processing of Neoprene Rubber* compiled initially by J. C. Bament lists the major dry type applications and starting formularies for compounds to meet the specific end uses (98).

Formularies for the following applications are included:

Adhesives, automotive, bridge bearing pads, cable jackets, cellular products, coated fabrics, conveyor belts, footwear, hose, power transmission belts, profiles, roll covers, sheeting, and tank lining.

Latex or Liquid Dispersions

Polychloroprene latexes are aqueous dispersions of synthetic polychloroprene polymers with surfactants. The surfactants of choice are markedly different than the protein-based surfactants contained in natural rubber latex that is reportedly at the root of human hypoallergenic reactions associated with the use of natural rubber latex.

Latex products are manufactured in an identical fashion as the dry polymers described earlier. One major exception is that the primary and auxiliary surfactants used in latex manufacture are not destroyed prior to shipment to the end user. Molecular weight control is identical with mercaptan, organic halides, and xanthogen disulfides chain-transfer agents typically used. Copolymerizations are conducted with the same variety of comonomers that include

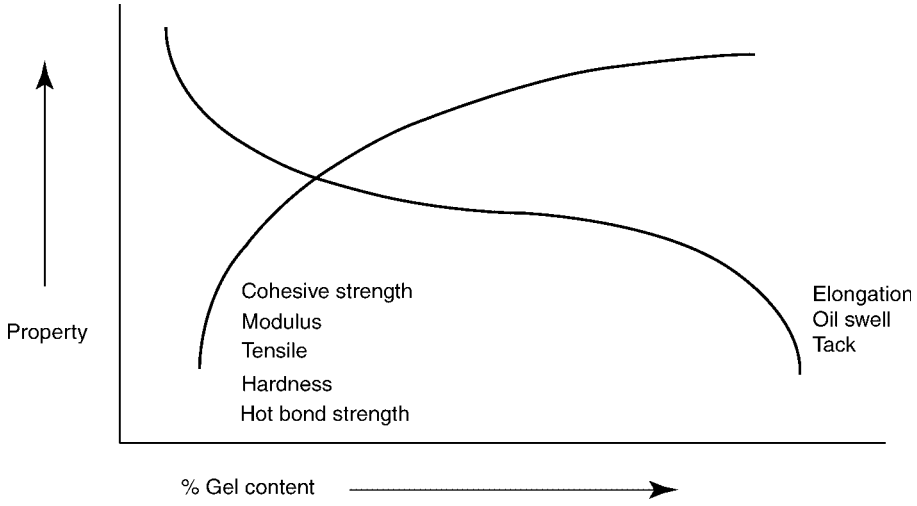

Fig. 7. Properties as a function of gel content.

2,3-dichloro-1,3-butadiene, sulfur, and acrylic acids and esters. Polymerization temperatures are varied from 5° to 50°C at atmospheric pressures to control polymer microstructure and crystallinity. The choice of surfactant package for latex products is much more critical than for dry types, since the latex must remain colloidally stable for time periods measured in weeks or months instead of hours as required in dry-type manufacture.

Since the latexes contain discrete stabilized polymer particles that are dispersed in the aqueous medium, the latex displays good rheological properties. The latex polymer structures can differ appreciably from dry types. Long-chain branching and gelled structures are more tolerable in latex, since the polymer does not need to be isolated by freeze roll. The branched and gelled structures offer advantages to the end users who fabricate adhesives having a high cohesive strength, good stress–strain characteristics, and high bond strength at elevated temperatures (Fig. 7).

Low temperature polymerization yields crystalline polymers having high room-temperature bond strength, high cohesive strength, and good stress–strain characteristics (Fig. 8).

These two phenomena form the basis for propagating the global adhesives product line of which the following is indicative.

Global Latex Product Line. There are three general classes of polychloroprene latexes: anionic, cationic, and nonionic. By far, the anionic latex class constitutes the largest commercial volumes for general use. Cationic latexes are usually made with quaternary ammonium salts and are made in the smallest volume types. The nonionic latexes differ appreciably from ionic lattices in several important aspects, of which chemical and mechanical stability are the most different (Table 10).

The Theoretical Basis of Latex Stabilization. The colloidal stability of each class of latex is primarily dependent on the effectiveness of the surfactant. In the high permittivity of water, most polymer colloid particles carry an electric

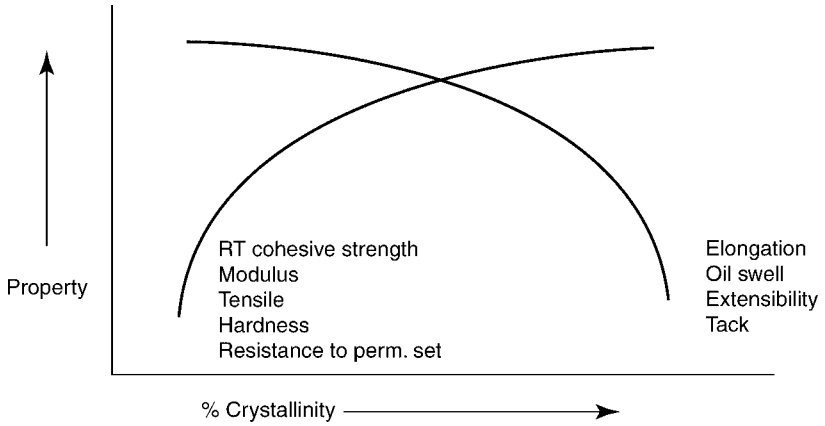

Fig. 8. Properties as a function of crystallinity.

charge. These electric charges arise from the ionization of groups at the polymer surface. In ionic polychloroprene emulsions, the electric charges are formed by the neutralization of substituted carboxylated diterpenes (rosins and resins) with caustic during the emulsification process.

The surface of the polymer particle is smooth and charges are uniformly distributed over the surface. To satisfy the condition of electroneutrality, the sodium carboxylate moiety resides at the interphase with sodium counterions solubilized in the aqueous phase near the carboxylate coions. The spatial distribution of coions and counterions form the electronic "double layer" of $1/\kappa$ thickness. This boundary layer stabilizes the colloid (139). In the 1940s Derjagin, Landau, Verway, and Overbeek suggested that the electrostatic stability (84,85) of latexes could be explained on the basis of three potential energy terms that include repulsive potential

Table 10. Comparison of Anionic and Nonionic Latexes

Comparisons (138)	Anionic	Nonionic
Surfactant type	Sodium or potassium resinates	Poly(vinyl alcohol)
Colloidal stabilization mechanism	Electrostatic	Steric
Stability		
Mechanical	Good	Exceptional
Electrolytic to ionic contaminants	Good	Excellent
Storage	Poor–fair	Excellent
	Good	Gel increases
pH	12 +	7–8
% Solids	38–60	47

Average weight of average particle size, nm	100	300

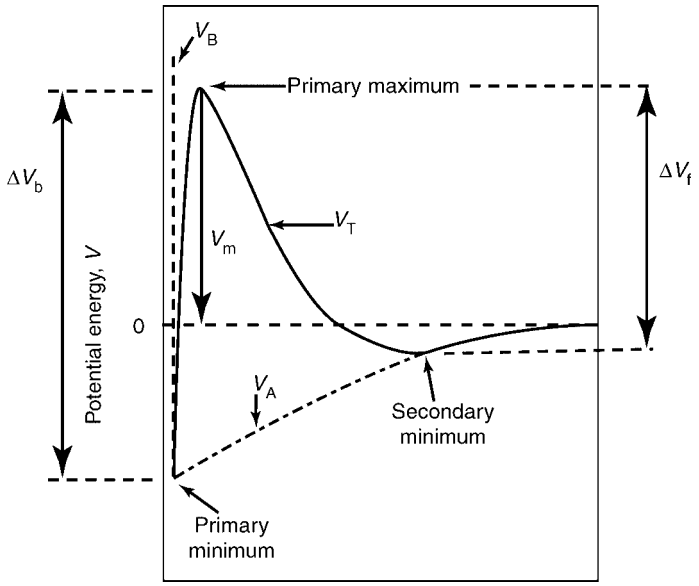

Fig. 9.

energy (V_R), van der Waals attraction (V_A) and the Born potential (V_B). This theory became widely known as the DLVO theory.

$$V_{Total} = V_R + V_A + V_B$$

Latex stability is achieved when the electrostatic repulsion term, V_R, dominates attractive forces at the interparticle distance near $4/\kappa$. At very close interparticle distances, a potential energy barrier is encountered. If particles are forced over the potential energy barrier to the primary minimum, permanent coagulation occurs (Fig. 9).

Thus, stability is heavily dependent on repulsive energies, which are functions of at least three variables: (*1*) boundary layer thickness, (*2*) valence of the counterion and ionic contaminants, and (*3*) concentrations of electrolyte. As electrolyte concentration is increased, the electronic double layer thickness decreases, the particles move toward the primary maximum, and coagulation occurs. Multivalent counterions are important adjuvant for dipped goods manufacture where chemical coagulation is required (Table 11).

In the latex end use applications, DLVO stabilization must be considered in designing a latex compound.

Latex Compounding. Polychloroprene latexes are used in six general applications: adhesives, binders, coatings, dipped goods, elasticizers, and foam. The conversion of the raw latex to a tough finished product depends on compounding and curing. Latex compounding has one complication not present for dry types. The colloid chemical and mechanical stabilities of the aqueous dispersion containing added compounding ingredients must be considered. Masterbatching vs individual dispersion make-up will minimize introduction of electrolytes,

Table 11. Double Layer Thickness with changing Electrolyte Concentration

Electrolyte concentration moles/d^3	$1/\kappa$, nm	$1/\kappa$, nm (high counterion valence)	$1/\kappa$, nm (higher counterion valence)
10^{-5}	96.3	55.6	39.3
10^{-4}	30.4	17.6	12.4
10^{-3}	9.63	5.00	3.93
10^{-2}	3.04	1.76	1.24
10^{-1}	0.96	0.56	0.39

facilitate dispersion of difficult materials, minimize processing mistakes, lower cost, increase production rates, and generally generate less waste. Mechanical stability during compounding is enhanced by control of seven variables:

(1) Use of tanks and pipes having smooth interiors.
(2) Use of low shear and low speed agitators with no dead spots.
(3) Use of gravity flow where possible.
(4) Where gravity flow is not possible, use of positive displacement pumps—no gear or pinch pumps.
(5) Use of air pressure only to transfer but not to store latex.
(6) Use of areas of high humidity to decrease evaporation rates.
(7) Filtration of the compound if viscosity permits.

Depending on the application, a latex compound may contain up to nine compounding ingredients: (*1*) deionized water, (*2*) antifoam, (*3*) colloidal stabilizers, (*4*) polymer stabilizers, (*5*) curatives, (*6*) tackifiers, (*7*) fillers, and (*8*) thickeners. All have specific functions that contribute to the outcome of the finished part (see LATEX TECHNOLOGY).

Polychloroprene Latex

The latex can be chosen from a wide variety of liquid dispersions available on the basis of the crystallization and gel properties desired (Fig 10). For example, Neoprene water-based polychloroprene latexes available from DuPont Dow have the following properties (96,140,141) (Table 12).

Additives.

Antifoam. It is best to prevent foam from forming in the latex than to eliminate foam by use of defoamer. To prevent foam formation,we need to avoid free fall of latex or any dispersion and emulsion, which contains surfactants that will facilitate foam formation. When mixing latex with other ingredients, the agitator impeller should be turned off until the blade is covered with latex. Any fillers, which may have absorbed air on the particles, should be prewetted and foam allowed to subside before adding the fillers to the latex compound.

Colloidal Stabilizers. Colloidal stabilizers are normally added to increase shear stability of anionic latexes, improve chemical stability of nonionic latexes,

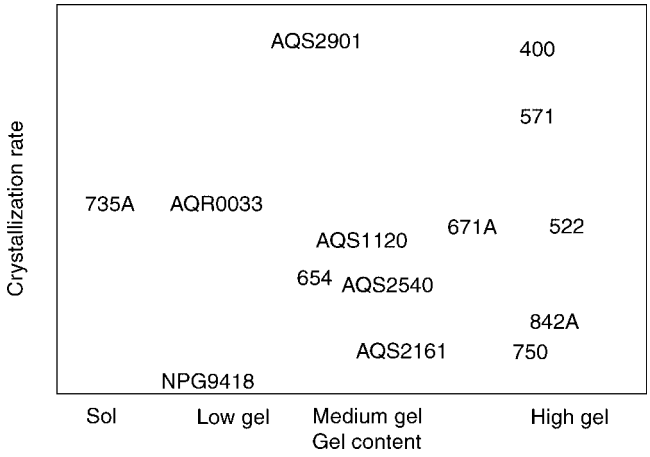

Fig. 10. Crystallization rate vs gel content of water-based polychloroprene latexes.

and to sequester cations. The surfactants are also used to wet-water insoluble additives. Anionic stabilizers such as potassium resinates, potassium caseinate or Darvan WAQ (R. T. Vanderbilt Co.) are used with anionic latexes to improve the mechanical stability in coating and binders. Darvan SMO, sodium sulfated methyloleate, is specifically recommended for use in dipping compounds to improve smoothness and to eliminate striations. Tritons (Dow Chemical Co.), Igepals (Rhodia Chemical Co.), Tergitols (Dow Chemical Co.) are added to nonionic latexes to improve chemical stability. Cationic latexes require cationic or nonionic surfactants (Darvan NS). Cations are normally sequestered with Calgon (Calgon Corporation), sodium silicate, or trisodium phosphate.

Polymer Stabilizers or Antioxidants. No polychloroprene latex compound is complete without additives that give adequate protection against polymer oxidation. The oxidation studies for dry types also apply to polymers contained in latexes. Hindered phenols are used in many applications. When used at 1-phr,

Table 12. Polychloroprene Latex Compound

Neoprene latex	100 Dry weight
Deionized water	Wherever needed
Antifoam	0.05–0.10
Darvan WAQ (R. T. Vanderbilt)	0–1.0
Potassium caseinate	0–1.0
Triton X-100 (Dow Chemical Co.)	0–1.0
Sodium silicate	0.25
Wingstay L (Goodyear Tire and Rubber Co., Chemical Division)	2.0
Zinc oxide	5.0
Sulfur	0–1.0
Thiocarbanilide	0–1.0
Hi/Lo MP tackifiers	As needed
Fillers	As needed
Polyacrylate	As needed

Wingstay L (butyrated-*p*-cresol-bicyclopentadiene) (Goodyear Tire and Rubber Co.) provides adequate protection in most adhesive applications. The bisphenols are nonstaining and generally nondiscoloring.

Curatives. Consistent with dry type technology, metal oxides have three functions in a latex compound. Zinc oxide participates in the curing reaction. Zinc oxide is an effective acid scavenger. In applications where the substrate is not acidic, zinc oxide is not needed. Such substrates include chrysoltile asbestos gaskets or the hydraulic cement in elasticized concrete.

Sulfur is occasionally added to polychloroprene latexes to achieve a higher state of cure. Added sulfur is not effective for chloroprene–sulfur copolymer latexes. Films containing 1-phr sulfur darken considerably upon curing. Retention of elasticity of such films decreases further on continued exposure to heat.

Accelerators. Accelerators catalyze the cross-linking of the polymers by a similar mechanism described for dry types. The latex version has some advantage over dry types in that many of the crosslinks for latex types were formed during polymerization. The use of Thiocarbanilide (*N*,*N*′-thiourea) yields products of higher modulus, lower tensile strength, and best oil swell resistance. Butyl Zimate (zinc dibutyl dithiocarbamate) (R. T. Vanderbilt Co.) is practically equivalent to Thiocarbanilide cures but imparts less color change. Tepidone (sodium dibutyl dithiocarbamate) and tetraethyl thiuram disulfide (TETD) give products of lower modulus, higher tensile strength, higher elongation, and less color.

Ultraviolet Ray Screeners. Carbon black and red iron oxide provide additional resistance to degradation from exposure to sunlight. They are used only sparingly, however, because of discoloration at the adhesive line.

Fillers. Fillers are used in compounds to increase viscosity, increase solids, and to lower cost. Most fillers used in latex do not exhibit the reinforcing effect that is characteristic of their use in dry-type polychloroprene. Water-washed whiting (calcium carbonate) can be added directly to the latex. Most clays are acids and must be neutralized and slurred before adding to the latex. When used at levels ranging from 10- to 20-phr, fine clays such as DIXIE Clay (R. T. Vanderbilt Co.) can add some degree of reinforcement. Hard clays have much smaller particle size than soft clays. Feldspar can be added directly to the latex but will tend to settle quickly. Hydrated alumina is used primarily to improve flame retardancy and improve water resistance. Large-particle-size hydrated alumina can be added directly to the latex.

Thickeners. Thickeners are always the last ingredients to be added. Polyacrylates are the preferred thickeners for polychloroprene latex. They are usually diluted with equal parts of water to generate a pourable fluid, which can be added directly to the compound. Algums have higher viscosity stability than polyacrylates at high pH. Cellulose derivatives are effective thickeners but are much more difficult to handle, usually requiring backmixing with a small amount of latex before adding it to the compound. Bentonite clay is a favorite thickener for very high viscosity adhesives such as mastics. Fumed silica is a good choice for latex formulations having a pH of 7–10.

Biocides. Waterborne systems of pH < 10- are prone to bacterial attack. The phenomenon is normally not a problem with solvent-borne systems. Bacterial infestation normally manifests itself by malodor, discoloration, and gas evolution. Nuosept 95 (Creanova Co.) is an effective biocide.

Latex Applications

A good way to remember the applications for latex is to follow the first six letters of the alphabet: A, adhesives; B, binders; C, coatings; D, dipped goods; E, elasticizers; and F, foam.

Adhesives. An adhesive is a continuous film sandwiched between two substrates. Polychloroprene latexes are used as waterborne contact bond adhesives where a latex-based adhesive compound is placed on both substrates to be bonded. Immediately before the two coated surfaces dry, the two substrates are placed together and bonded. Many of the environmental, personnel exposure and potential fire hazards associated with the use of aromatic-hydrocarbon–solvent adhesives are avoided by the use of latex adhesives. Both anionic and nonionic latexes are used in adhesive applications. The high uncured strength, high cohesive strength, high internal strength, and good contactibility of polychloroprene with a variety of substrates are attributes that make polychloroprene useful in this application. The high uncured strength of the adhesive arises from the crosslinks made in the latex during polymerization.

Binders. A binder is a mixture of discrete polymer particles distributed throughout a matrix. The particulates can be cellulosic, ground leather, or ground rubber. The high internal bond strength of polychloroprene makes the latexes useful for binding cellulosic fibers in sandpaper. Up to 17,000,000 lb/year of polychloroprene latex have been used for shoeboard applications. Regenerated leather made by use of polychloroprene latex to bind ground leather scraps is a prominent example of use as a binder. Wet-web saturation with polychloroprene is used in shoeboard applications requiring a flexible polymer of high binder efficiency, adhesive solvent resistance, and moisture and chemical resistance. The high durability, resistance to weather, and resilience without curing are polychloroprene properties that find utility in fabrication of resilient surfaces such as tennis courts and athletic tracks.

Coatings. Coatings are continuous films adhering to one substrate. The substrate can be fiber glass, fiber glass bats, fabrics, composite laminates, or carpet. Polychloroprene has been used in all of these applications due to its erosion resistance, chemical resistance, abrasion resistance, weather resistance, sound dampening characteristics, thermal insulation properties and the inability of properly formulated polychloroprene to support combustion. Fiber glass and fiber glass bats used in construction ducts are coated with polychloroprene latex to prevent fiber glass particles from contaminating air that passes through the ducts. Polychloroprene-coated fiber glass provides good thermal insulation and sound dampening. Polychloroprene-coated fiber glass is used under automotive hoods to provide a degree of flame retardancy and sound dampening.

Woven fabrics used for printer blankets are coated with polychloroprene to provide resistance to solvent and inks. Polychloroprene composite laminates for industrial suits (eg firefighter's suits) are coated with polychloroprene to provide chemical resistance, weather/abrasion resistance, durability, and a degree of flame retardancy.

Rugs and upholstery can be coated with polychloroprene latex, particularly those used in aircraft. Flame retardancy is a key property highlighted.

There are advantages and disadvantages to using polychloroprene latexes in these applications. The gelled polymer from polymerization provides high uncured strength, particularly in applications where post curing is not practical. The disadvantage lies in the high pound/volume cost. Thus, latexes that permit high filler loading reduced cost without much sacrifice of properties are successful in these applications.

Dipped Goods. Dipped goods have continuous films (supported or unsupported) that are usually formed by chemical coagulation of latex compounds. Polychloroprene latexes are used in a variety of dipped goods applications including automotive, tractor shift controls, convoluted parts, windshield wiper blades, supported and unsupported gloves, and meteorological balloons. The major advantages of polychloroprene are ozone resistance in objects having sharp contours, durability, chemical resistance, flexibility, feel, tear strength, oil/chemical/abrasion resistance and resistance to ultraviolet rays. Generally the latexes are sold to a latex compounder who formulates the latex for the end use fabricators. Polychloroprene latexes have many advantages over natural rubber in terms of resistance to household and industrial detergents and chemicals. Gloves made from polychloroprene have 100% chemical resistance, oil resistance, ozone resistance, and heat resistance.

A unique application involves meteorological balloons. Balloons made from polychloroprene are used to convey sensors up to 150,000 feet into the atmosphere for purposes of determining the direction of weather currents. A special combination of stress–strain properties, resistance to ozone, and ultraviolet sunrays are important for optimum functioning of the balloon.

Elasticizers. Elasticizers are composites of small particles of near molecular size that are distributed throughout some medium. Latexes are formulated into elasticized concrete to minimize stress cracking that is precipitated by concrete expansion and contraction. The application is extremely important for decks on ships, decks in high rise garages, hospital floors, kitchens, and gym floors. Latex-modified concrete provide vibration dampening in the workplace that reduce fatigue to personnel (eg operating rooms) who need to stand for extended periods of time while working.

Latex-modified asphalt and bitumen represent other elasticizers. Latex modification not only reduces stress cracking but also provides adhesion for rocks and chip asphalt fillers. The adhesion prevents chips from flying out of the asphalt on highways and breaking windshields. Many states in the United States require latex-modified asphalt in road construction. All classes of latexes can be used in concrete and asphalt modification.

Foam. Foam is a continuous open-celled matrix produced from froth or coagulation onto a preformed cellular matrix. Over the years, polychloroprene latexes have been used in nursing homes, in mattresses, in journal boxes, in seagoing vessels, and in cushioning and seating. Properly formulated froth and parts made from polychloroprene latexes are water resistant and have a high degree of flame retardency. The journal box application for locomotive lubricants depends on the oil resistance of polychloroprene to deliver oil from the reservoir to the axle of the train. Polychloroprene suffers from two major disadvantages in foam applications: costs and weight. Both limit full utility of these foams in aircraft applications.

Two processes have been used to make foams from froth. For thin foams, dry coagulation is an effective procedure. For thicker foams, chemical coagulation, and chemical and heat gelation are used.

Quality Management. For major polychloroprene producers the quality management systems are described by the international ISO9001-2000 protocol.

Health, Safety, and Environment

Since chloroprene and dichlorobutadiene monomer will undergo runaway reaction, the successful producers of polychloroprene polymers have learned how to safely handle the hazardous monomers and monomer intermediates in large-scale quantities. Monomer synthesis and storages represent the largest concentration of monomers during commercial manufacture. Polymerization, albeit in aqueous media, present safety challenges owing to the presence of free radicals.

Prevention of runaway reactions involving these highly reactive monomers involve strict adherence to six fundamental principles for monomer handling: (*1*) keeping it cold, (*2*) keeping it free of air and oxygen by storage in a nitrogen atmosphere, (*3*) keeping it inhibited where possible, (*4*) keeping it moving, (*5*) keeping it free of contaminants such as popcorn polymer and iron, and (*6*) keeping it diluted where possible.

Residual monomer remaining after polymerization pose a lesser degree of hazard owing to low concentration and the engineering measures implemented in the workplace to prevent personnel exposure to the monomer. Neoprene liquid dispersions contain less than 0.1% residual chloroprene monomer.

The amount of excess caustic in Neoprene polychloroprene liquid dispersions is approximately 0.1%. The liquid dispersions are, however, very basic having pH near 12. While not corrosive in animal tests, eye protection and skin protection are essential in areas where personnel exposure is possible because of possible irritation.

Some dry polychloroprene types have been shown to have low oral toxicity rates. Human patch test for several dry types showed no skin reactions (142). The FDA status of Neoprene polychloroprene is described in the literature (143).

COLLOIDS

Introduction

Matter of colloidal size, just above atomic dimensions, exhibits physicochemical properties that differ from those of the constituent atoms or molecules yet are also different from macroscopic material. The atoms and molecules of classical chemistry are extremely small, usually having molar masses <1000 g/mol and measurable by freezing point depression. Macroscopic particles fall into the realm of classical physics and can be understood in terms of physical mechanics. Residing between these extremes is the colloidal size range of particles whose small sizes and high surface area-to-volume ratios make the properties of their surfaces very important and lead to some unique physical properties. Their solutions may have undetectable freezing point depressions, and their dispersions, even if very dilute, may sediment out very slowly, and not be well described by Stokes' law. Whereas the particles of classical chemistry may have one or a few electrical charges, colloidal particles may carry thousands of charges. With such strong electrical forces, complete dissociation is the rule rather than the exception. In addition, the electric fields can strongly influence the actions of neighboring particles. In industrial practice it is very common to encounter problems associated with colloidal sized particles, droplets, or bubbles.

The field began to acquire its own identity when Graham coined the term colloid in 1861 (1–3). Since that time the language of colloid science has evolved considerably (4–6) and makes two principal distinctions: lyophobic (thermodynamically unstable) and lyophilic (thermodynamically stable) colloidal dispersions. Examples of lyophobic and lyophilic colloidal dispersions are suspensions of gold particles and surfactant micelles in solution, respectively. Colloidal particles (or droplets or bubbles) are defined as those having at least one dimension between $\sim$1 nm and 1 μm. In dealing with practical applications, the upper size limit is frequently extended to tens or even hundreds of micrometers. For example, the principles of colloid science can be usefully applied to emulsions whose droplets exceed the 1-μm size limit by several orders of magnitude (ie, in cases for which the surface properties of the dispersed phase dominate). Simple colloidal dispersions are two-phase systems, comprising a dispersed phase of small particles, droplets, or bubbles, and a dispersion medium (or dispersing phase) surrounding them. In modern practice, the terms lyophilic and lyophobic (especially hydrophilic and hydrophobic) are often used to characterize surfaces in addition to colloidal dispersions. This sometimes leads to confusing usage. For example, a clay dispersion in water could be classified as a lyophobic colloid with hydrophilic surfaces.

Various types of colloidal dispersions occur, as illustrated in Table 1. In practice, many colloidal dispersions are more complex and are characterized by the nature of the continuous phase and a primary dispersed phase, according to the designations in Table 1.

One reason for the importance of colloidal systems is that they appear in a wide variety of practical disciplines, products, and processes. The colloidal involvement in a process may be desirable, as in the stabilizing of emulsions in mayonnaise preparation, or undesirable, as in the tendency of very finely divided and highly charged particles to resist settling and filtration in water treatment

Table 1. Types of Colloidal Dispersion

Dispersed phase	Dispersion medium	Name	Examples
Liquid	Gas	Liquid aerosol	Fog, mist
Solid	Gas	Solid aerosol	Smoke, dust
Gas	Liquid	Foam	Soap suds
Liquid	Liquid	Emulsion	Milk, mayonnaise
Solid	Liquid	Sol, suspension	Ink, paint, gel
Gas	Solid	Solid foam	Polystyrene foam, pumice stone
Liquid	Solid	Solid emulsion	Opal, pearl
Solid	Solid	Solid suspension	Alloy, ruby-stained glass

plants. Examples of the variety of practical problems in colloid chemistry include control of filtration operations, breaking of emulsions, regulating foams, preparing catalysts, managing fluid flow, and cleaning surfaces (see Table 2).

The variety of systems represented or suggested by Tables 1 and 2 underscores the fact that the problems associated with colloids are usually interdisciplinary in nature and that a broad scientific base is required to understand them completely. A wealth of literature exists on the topic of colloidal dispersions, including a range of basic reference texts (7–11), dictionaries (4–6,12), and treatises on the myriad of applied aspects, of which only a few are cited here (13–24).

Preparation and Stability of Dispersions

Preparation. Colloidal dispersions can be formed either by nucleation with subsequent growth or by subdivision processes (7,8,11,25,26). The nucleation process requires a phase change, such as condensation of vapor to yield liquid or solid, or precipitation from solution. Some mechanisms of such colloid formation are listed in Table 3.

The subdivision process refers to the comminution of particles, droplets, or bubbles into smaller sizes by applying high shearing forces, using devices such as a propeller-style mixer, colloid mill, or ultrasound generator. A complex technology has developed to conduct and to control comminution and size-fractionation processes. Mathematical models are available to describe changes in particle size distribution during comminution, but these are generally restricted to specific processes. Comprehensive reviews of the developments in preparing colloidal solids by subdivision should be consulted for further details (27,28). A wide range of techniques is now available, including, eg, atomizers and nebulizers of various designs used, to produce colloidal liquid or solid aerosols, and emulsions having relatively narrow size distributions. Monosized powders and monodispersed colloidal sols are frequently used in many products, eg, pigments, coatings, and pharmaceuticals.

Colloidal suspensions of uniform chemical and phase composition, particle size, and shape are now available for many elements (including sulfur, gold, selenium, and silver, carbon, cobalt, and nickel), many inorganic compounds

Table 2. Some Occurrences of Colloids

Field	Liquid aerosol	Solid aerosol	Foam	Emulsion	Suspension	Solid foam	Solid emulsion	Solid suspension
Environment and meteorology	Fog, mist, cloud, smog	Volcanic smoke, dust, smog	Polluted river foams	Water/sewage treatment emulsions, oil spill emulsions	River water, glacial runoff			
Foods			Champagne, soda and beer heads, whipped cream, meringue	Milk, butter, mayonnaise, cheese, cream liqueurs	Jellies	Leavened breads		
Geology, agriculture, and soil science	Crop sprays		Foam fumigant, insecticide and herbicide blankets	Insecticides and herbicides	Quicksand, clay soil suspensions	Pumice stone, zeolites	Opal, pearl	Pearl
Manufacturing and materials science	Paint sprays	Sand blasting	Foam fractionation, pulping black liquor foam	Polishes	Ink, gel, paints, fiber suspensions	Polystyrene foam, polyurethane foam	High impact plastics, alkaline battery fill	Stained glass, ceramics, cement, plastics, catalysts, alloys, composites
Biology and medicine	Nasal sprays	Airborne pollen, inhalant drugs	Vacuoles, insect excretions, contraceptive foam	Soluble vitamin and hormone products, biological membranes, blood	Liniment suspensions, proteins, viruses	Loofah plant		Wood, bone

Table 2. (Continued)

Field	Liquid aerosol	Solid aerosol	Foam	Emulsion	Suspension	Solid foam	Solid emulsion	Solid suspension
Petroleum production and mineral processing			Refinery foams, flotation froths, fire extinguishing foams, explosion suppressant foam	Oilfield emulsions, asphalt emulsion	Drilling fluids, drill cuttings, mineral slurries, process tailings		Oil reservoir	
Home and personal care products	Hair spray		Shampoo suds, shaving cream, contraceptive foams, bubble bath foam	Hair and skin creams and lotions		Sponges, carpet underlay, cellular foam insulation		Bakelite products

Table 3. Industrially Produced Colloidal Materials and Related Processes

Mechanism	Examples[a]
Vapor → liquid → solid ↓→→→↑	Oxides, carbides via high intensity arc; metallic powders via vaccum or catalytic reactions
Vapor + vapor → solid	Chemical vapor deposition, radio-frequency-induced plasma, laser-induced precipitation
Liquid → solid	Ferrites, titanates, aluminates, zirconates, molybdates via precipitation
Solid → solid	Oxides, carbides via thermal decomposition

[a] Refs. 27 and 28.

(including halide salts, sulfates, oxides, hydroxides, and sulfides), and many organic compounds [including, poly(vinyl acetate), polystyrene, poly(vinyl chloride), styrene–butadiene rubber, poly(acrylic acid), polyurea, poly-styrene–poly(acrylate), and poly(methacrylate)–poly(acrylate)]. Stability. A complete characterization of colloid stability requires consideration of the different processes through which dispersed species can encounter each other: sedimentation (creaming), aggregation, and coalescence. Sedimentation results from a density difference between the dispersed and continuous phases and produces two separate layers of dispersion that have different dispersed-phase concentrations. One of the layers will contain an enhanced concentration of dispersed phase, which may promote aggregation. Aggregation is when two or more dispersed species clump together under the influence of Brownian motion, sedimentation, or stirring, possibly touching at some points, and with virtually no change in total surface area. Aggregation is sometimes referred to as flocculation or coagulation (although in specific situations these latter terms can have slightly different meanings). In aggregation, the species retain their identity but lose their kinetic independence since the aggregate moves as a single unit. Aggregation of droplets may lead to coalescence and the formation of larger droplets until the phases become separated. In coalescence thin film drainage occurs, leading to rupture of the separating film, and two or more particles, droplets, or bubbles fuse together to form a single larger unit, reducing the total surface area. In this case the original species lose their identity and become part of a new species. In emulsions, inversion can take place, in which the emulsion suddenly changes form, from oil-in-water (O/W) to water-in-oil (W/O), or vice versa. For example, butter results from the creaming, breaking, and inversion of emulsified fat droplets in milk. Kinetic stability can thus have different meanings. A colloidal dispersion can be kinetically stable with respect to coalescence but unstable with respect to aggregation. Or, a system could be kinetically stable with respect to aggregation but unstable with respect to sedimentation. In summary, lyophobic colloids are

thermodynamically unstable, but may be relatively stable in a kinetic sense, and it is crucial that stability be understood in terms of a clearly defined process.

Dispersed Species Characterization and Sedimentation

The characterization of colloids depends on the purposes for which the information is sought, because a complete description would be an enormous task. Among the properties to be considered are the nature and/or distributions of purity, crystallinity, defects, size, shape, surface area, pores, adsorbed surface films, internal and surface stresses, stability, and state of agglomeration (27,28).

Surface Area, Porosity, and Permeability. Some very interesting and important phenomena involve small particles and their surfaces. For example, SO_2 produced from mining and smelting operations that extract metals such as Cu and Pb from heavy metal sulfide ores can be oxidized to SO_3 in the atmosphere, thus contributing to acid rain problems. The reaction rate depends not only on the concentration of the SO_2 but also on the surface area of any catalyst available, such as airborne dust particles. The efficiency of a catalyst depends on its specific surface area, defined as the ratio of surface area to mass (17). The specific surface area depends on both the size and shape, and is distinctively high for colloidal-sized species. This is important in the catalytic processes used in many industries for which the rates of reactions occurring at the catalyst surface depend not only on the concentrations of the feed stream reactants but also on the surface area of catalyst available. Since practical catalysts frequently are supported catalysts, some of the surface area is more important than the rest. Since the supporting phase is usually porous the size and shapes of the pores may influence the reaction rates as well. The final rate expressions for a catalytic process may contain all of these factors: surface area, porosity, and permeability.

The total surface area can be estimated by measuring the amount of gas needed to form an adsorbed monolayer by physical adsorption (29,30), in which case the number of molecules adsorbed divided by the area per molecule yields the surface area. The classic models for physical adsorption are those of Langmuir (monomolecular adsorption and constant ΔH_{ads}, independent of the extent of surface coverage) and Brunauer, Emmett, and Teller (BET, multilayer adsorption and several ΔH_{ads} components); while many other models are available as well (8,10,17). These models require a knowledge of the area each molecule occupies on the surface. Chemisorption can be studied in the same fashion as described for nitrogen adsorption but using a gas that is chemisorbed, ie, that bonds chemically. This yields a specific chemisorption surface area. In evaluating supported catalyst samples, both kinds of surface area may need to be measured since particle size changes would be reflected in the specific surface area while site deactivation might change only the specific chemisorption area.

The Langmuir and BET equations work well with nonporous solids, but not as well for porous solids because the pores influence the local numbers of adsorption layers formed. By using adsorption gases of different molecular size or by varying the temperature, pores of different size will be accessible to the adsorbing molecule. Coupling this with the appropriate mathematical interpretation allows for the determination of solid porosity using BET analysis. The porosity of a solid

(pore volume divided by bulk volume) is most easily determined by the imbibition method, frequently used in the petroleum industry. A sample of solid is dried and weighed, then saturated with a wetting liquid (often water or heptane) under vacuum. The pore volume accessible is calculated by a material balance. In prepared catalysts, the pore sizes may be quite uniform. However, in most naturally occurring materials there is a wide range of pore sizes. The actual pore size distribution can be obtained from methods such as porosimetry, in which a nonwetting liquid (usually mercury) is pumped into a solid sample (7,8,10,17,29,31). According to the Laplace equation each increment of applied pressure will cause only pores down to a certain size to be filled, and employing a series of pressure increments allows the pore size distribution to be obtained.

The ease with which a fluid can flow through a porous medium, permeability, can be determined through the measurement of pressure drop (Δp) across the porous medium under steady flow. The intrinsic permeability (k) is defined by Darcy's law and is given by $k = (Q/A)(\eta L/\Delta p)$, where Q is the discharge flow rate, A is the cross-sectional area normal to the main flow direction, η is the flowing fluid viscosity, L is the length of the flow path (sample), and Δp is the pressure gradient along the medium (15). Mercury porosimetry can also be used to assess permeability (17,29).

Size and Size Distribution. If the sizes of particles, droplets, bubbles, or their aggregates in a colloidal dispersion are large enough, then optical microscopy can be used to determine the shape, size, and size distribution, but if they are smaller than $\sim$0.5 μm they will not be resolved in a typical optical microscope. Confocal scanning laser microscopes can extend this resolution up to $\sim$0.1 μm. For dispersions of such smaller-size species, the most direct methods include scanning and transmission electron microscopy. Adaptations, such as cryogenic-stage scanning electron microscopy, can be used for emulsions and foams (32,33).

Small, dispersed particles or droplets cause the "cloudy" or "milky" appearance of such diverse colloids as dust clouds, rain clouds, suspended sediment in a river, and milk. This appearance is due to light scattering. When a beam of light enters a colloidal dispersion some light is absorbed, some is scattered, and some is transmitted. The intensity of the scattered light depends largely on the size and shape of the colloidal species, and on the difference in refractive index between the phases. Light scattering analysis is very powerful because it can yield the complete dispersed-phase size distribution. This is important in emulsions that are commonly, but generally incorrectly, characterized in terms of a specified droplet size whereas there is inevitably a size distribution. The theory underlying the determination of size distribution for a colloidal dispersion is quite involved (8,34). Rayleigh theory predicts that larger particles scatter more light than do smaller ones. Since the scattering intensity is proportional to $1/\lambda^4$, blue light ($\lambda = 450$ nm) is scattered much more than red light ($\lambda = 650$ nm). With incident white light a scattering material will, therefore, tend to appear blue when viewed at right angles to the incident light beam, and red when viewed end-on. Thus the sky can appear blue overhead while the sun appears yellowish red when viewed across the horizon as it is rising or setting. When a test tube containing a dilute suspension of particles so small that they would be invisible under the light microscope is held up to the light, it may appear to have a blue colour due to Rayleigh scattering. This

phenomenon provides a way to indirectly observe particles that would otherwise be invisible. In the dark-field microscope, or ultramicroscope, the light scattered by small particles is viewed against a dark background. This method is applied in observing the electrophoretic motions of colloidal particles (35).

Other indirect techniques for determining colloidal species' size or size distribution include sedimentation–centrifugation, conductometric techniques, X-ray diffraction, gas and solute adsorption, ultrafiltration, diffusiometric, and ultrasonic methods (7,8,31,36). Care must be taken in selecting an indirect method since these require assumptions about either the real size distribution, the shape, or the process on which the analysis is based. For example, conductometric "sensing zone" equipment relies on the assumption of sphericity, which is reasonable for emulsion droplets but may not hold for particles in a suspension. Similarly, light-scattering techniques are reliable only if the particle shape and refractive index is known or assumed, and adsorption analyses rely on model adsorption isotherms, the uniformity of particle size and porosity, and the orientation of adsorbed species. In all cases, one must be careful that sample preparation techniques do not change the size distribution (32). Typically, more than one method is needed to characterize size and/or size distribution properly.

Nearly all colloidal systems undergo some aggregation leading to a distribution of aggregate sizes. Ultramicroscopy is the preferred method for measuring the rate and/or extent of aggregation because it is direct. The indirect methods listed above can also be used when tailored to suit the specific colloidal system in hand. More than one technique is required to assess the state of aggregation when a wide range of colloidal dimensions exists. If aggregates larger than approximately 5 μm are present, the aggregate-size distribution can be evaluated using classical techniques such as sieving (27,28,37), as long as such methods do not themselves induce or break aggregates.

Sedimentation. Whereas the use of light scattering to determine a complete size range distribution is quite involved, if the particles or droplets are not too small, a simpler approach can be used that yields an approximate average size. This is done by measuring settling velocities. Consider the small particles in a dust cloud, or suspended sediment in a river. It is principally the small size that keeps these particles from rapidly settling out. If a particle or droplet is placed in a fluid it will fall, or sediment out, if its density is greater than that of the fluid. The driving force is that of gravity. In the Stokes model, the terminal settling velocity is proportional to gravity and the square of particle size and inversely proportional to the fluid viscosity (7,8,31). This assumes that the species is uncharged and spherical, the situation being more complicated for charged and/or asymmetric particles. Further, if the particle concentration is high then the particles do not sediment independently but are influenced by the motions of surrounding particles, producing slower, hindered, settling. Sedimentation under gravity is only practical down to $\sim$1 μm diameter, but the centrifuge or ultracentrifuge can be used to study sedimentation of colloidal systems since the added centrifugal forces can be employed to overcome the mixing tendencies of diffusion and convection. Centrifugal force, like gravitational force, is proportional to the mass but the coefficient is not the acceleration due to gravity (g) but rather the square of the angular velocity (ω) times the distance of the particle from the axis of rotation (x). Since

$\omega^2 x$ is substituted for g in the governing equation, one speaks of multiples of g in a centrifuge. For example, using a conventional laboratory bench-top centrifuge capable of applying thousands of "gs" one can reduce the time needed to sediment out 0.2 μm particles, from an aqueous suspension, to ~20 min compared with the 16 days that would be needed to achieve the same sedimentation from a standing column. In an ultracentrifuge, even greater centrifugal forces (~40,000g) can be employed.

Rheology

For calculations involving pumping and mass transfer, industrial process streams can sometimes be treated as simple, "single phase" fluids that obey Newton's law of viscosity, $\tau = \eta\ \dot{\gamma}$, in which the shear stress, τ, is given as a linear function of the shear rate, $\dot{\gamma}$, with the proportionality constant being the viscosity, η. In fact many industrial process streams occur as colloidal dispersions, introducing the complication that in many cases viscosity is not expressed by a single number at constant temperature and pressure, but also depends on whether the material is flowing, and even its recent history (see RHEOLOGICAL MEASUREMENTS). Because of polydispersity, high dispersed phase content, mutual orienting, and/or structure formation of the dispersed species under flow a non-Newtonian dispersion exhibits a viscosity that is not constant, but is itself a function of the shear rate, [ie, $\tau = \eta\ (\dot{\gamma})\dot{\gamma}$]. The function itself can take many forms (38–43). Many different terms are used to express specific kinds of viscosities, including absolute, apparent, differential, intrinsic, reduced, relative, and inherent viscosity. These are defined elsewhere, as is an entire lexicon of terms used to describe the different rheological classifications of colloidal dispersions (4–6,39,42). Typical rheological classifications are listed in Table 4. Some descriptions appropriate to different yield stresses and some approximate values of shear rate appropriate to various industrial processes are given in Reference 44.

A colloidal system can exhibit several of these characteristics at once. For example, paint must be plastic and thixotropic so that it will flow when brushed on and (only) immediately after brushing (for a smooth finish); a further benefit is that vigorous mixing readily disperses the pigments, which then stay dispersed for some time when standing (high yield stress). Finally, shortly after brushing on, the paint should cease to flow so that it doesn't "run."

A range of methods are available for making rheological measurements (qv) (39–42). A frequently encountered problem involves knowing the particle/droplet/bubble size and concentration in a dispersion and the need to predict the suspension, emulsion, or foam viscosity. Many equations have been advanced for this purpose. In the simplest case, a colloidal system can be considered Einsteinian. Here, the viscosity of the colloidal system depends on that of the continuous phase, η_0, and the volume fraction of colloid, ϕ, according to the Einstein equation, which was derived for a dilute suspension of noninteracting spheres:

$$\eta = \eta_0(1 + 2.5\ \phi)$$

Table 4. Typical Rheological Classifications

Rheological classification	Description	Examples
Pseudoplastic (shear-thinning)	As shear rate increases viscosity decreases.	In paint, a suspension of pigment particles in a liquid, irregular particles can align to match the induced flow, lowering the viscosity.
Dilatant (shear-thickening)	As shear rate increases viscosity increases	In the "drying" of wet beach sand when walked on, a dense packing of particles occurs. Under low shear the particles can move past each other, whereas under high shear the particles wedge together such that the fluid cannot fill the increased void volume.
Pseudoplastic with yield stress (plastic)	Pseudoplastic or Newtonian flow begins only after a threshold shear stress, the yield stress, is exceeded.	In an oil well drilling mud the interparticle network offers resistance to any positional changes. Flow only occurs when these forces are overcome.
Thixotropic	Time-dependent pseudoplastic flow. At constant applied shear rate, viscosity decreases. In a flow curve hysteresis occurs.	In bentonite clay "gels" which "liquefy" on shaking and "solidify" on standing there is a time-dependent aligning to match the induced flow. After the shear rate is reduced it takes some time for the original alignments to be restored.
Rheopectic	Time-dependent dilatant flow. At constant applied shear rate viscosity increases. In a flow curve hysteresis occurs.	A suspension that sets slowly on standing but quickly when gently agitated due to time-dependent particle interference under flow.
Rheomalaxic	Time-dependent behavior in which shear-rate changes cause irreversible changes in viscosity.	An emulsion that when sheared inverts to a higher (or lower) viscosity emulsion, and does not reinvert when the shear is removed.

This relationship forms the basis for the use of volume fraction as the theoretically favored concentration unit in rheology. In practice once ϕ reaches between 0.1 and 0.5 dispersion viscosity increases and can also become non-Newtonian (due to particle/droplet/bubble "crowding," or structural viscosity). The maximum volume fraction possible for an internal phase made up of uniform, incompressible spheres is 0.74, although emulsions and foams with an internal volume fraction of >0.99 can exist as a consequence of droplet/bubble distortion.

Many empirical and theoretical modifications have been made to Einstein's equations. A useful extension to dilute suspensions of anisotropic particles, such as clays, is given by the Simha Equation, which is approximately

$$\eta = \eta_0(1 + a\phi/1.47b)$$

where a is the major particle dimension and b the minor particle dimension. Many of the other viscosity equations are empirical extensions of Einstein's equation for a dilute suspension of spheres, including virial expansions such as

$$\eta = \eta_0\left(1 + \alpha_0\phi + \alpha_1\phi^2 + \alpha_2\phi^3 + \cdots\right)$$

These equations usually apply if the particles or droplets are not too large, and if there are no strong electrostatic interactions. Additional equations are tabulated elsewhere (6,45).

Size distribution also has an important influence on viscosity. For electrostatically or sterically interacting drops, emulsion viscosity will be higher when droplets are smaller. The viscosity will also be higher when the droplet sizes are relatively homogeneous, ie, when the drop size distribution is narrow rather than wide. The rheological properties also depend on any specific interactions among the colloidal species, the dispersing medium, and the solute additives, ie, salts, surfactants, and polymers.

There are many important influences of rheology in industrial practice. From Stokes' law the terminal settling velocity is inversely proportional to the viscosity of a colloidal dispersion, which has a direct impact on sedimentation in, eg, treatment of waste water and on mineral fractionation and/or flotation (46,47). Another major application area is transport behavior, involving the pumping of fluid systems containing colloids, such as in extrusion in the polymer industry, the processing of gelatinous foods and cosmetic items, the fabrication of high performance materials in the ceramic and metallurgical industries, transportation in the petroleum industry, and the preparation and handling of pigment slurries in the paint industry. The prediction and control of suspension, emulsion, and foam rheology, especially the thixotropic and dilatant tendencies, is primarily important for these and other uses.

Interfacial Energetics

In colloidal dispersions, a thin intermediate region or boundary, known as the interface, lies between the dispersed and dispersing phases. Each interface has a certain free energy per unit area that has a great influence on the stability and structure of the colloidal dispersion, and that has a great influence in practical areas such as mineral flotation, detergency, and waterproofing.

Surface and Interfacial Tensions. For a liquid exposed to a gas the attractive van der Waals forces between molecules are felt equally by all molecules except those in the interfacial region. This makes the latter molecules tend to move to the interior and causes the interface to contract spontaneously. This is the reason droplets of liquid and bubbles of gas tend to adopt a spherical shape.

For two immiscible liquids a similar situation applies, except it may not be so immediately obvious how the interface will tend to curve but there will still be an imbalance of intermolecular forces and a configuration that minimizes the interfacial free energy, or interfacial tension. Surface tension can be thought of as either the contracting force around the perimeter of a surface, or as the surface free energy associated with area change. Emulsions and foams represent colloidal systems in which interfacial properties are very important because emulsified droplets and dispersed gas bubbles have large interfacial areas, so that even a modest interfacial energy per unit area can become a considerable total interfacial energy. There are many methods available for the measurement of surface and interfacial tensions (48–51).

Pressure and Curved Surfaces. Interfacial tension causes a pressure difference to exist across a curved surface such that the pressure inside a bubble or drop exceeds that outside. The pressure difference is given, in terms of the principal radii of curvature and surface or interfacial tension, by the Young–Laplace equation (8,10). For spherical droplets of liquid in a gas, $\Delta p = 2\gamma/R$, ie, the pressure difference, Δp, varies inversely with the radius, R. Thus the vapor pressure of a drop should become higher as the drop becomes smaller. This is shown by the Kelvin equation (8,31), which gives the pressure, at equilibrium, above a spherical surface of given radius, r, and surface tension, γ, as $RT \ln(p/p_0) = 2V_L\gamma/r$, where p_0 is the normal vapor pressure and V_L is the molar volume of the liquid. By replacing pressure with activity of dissolved solute and relating activity, in turn, to molar solubility the Kelvin equation can be used to describe a number of supersaturation phenomena, including supercooled vapors and supersaturated solutions.

Contact Angle and Wettability. When a drop of liquid is placed on a solid surface the liquid may form a bead on the surface, or it may spread to form a film. A liquid having a strong affinity for the solid will seek to maximize its contact (interfacial area) and form a film. A liquid with much weaker affinity may form into a bead. This affinity is termed the wettability (10,25,26). To account for the degree of spreading, the contact angle, θ, is defined as the angle, measured through the liquid, that is formed at the junction of the three phases, eg, at the solid–liquid–gas (S-L-G) junction. Whereas interfacial tension is defined for the boundary between two phases, contact angle is defined for a three-phase junction. If the interfacial forces acting along the perimeter of the drop are represented by the interfacial tensions, then an equilibrium force balance is given by Young's equation as $\gamma_{L/G} \cos\theta = \gamma_{S/G} - \gamma_{S/L}$. The solid is completely wetted if $\theta = 0$ and only partially wetted otherwise. Although in theory complete nonwetting would be at $\theta = 180^\circ$, this is not seen in practice and values of $\theta > 90^\circ$ are considered to represent "nonwetting" whereas values $< 90^\circ$ are often considered to represent "wetting." This rather arbitrary assignment is based on correlation with the visual appearance of drops on surfaces.

An example is provided in enhanced oil recovery. In an oil-bearing reservoir the relative oil and water saturations depend on the distribution of pore sizes in the rock, the pressure in a pore, the interfacial tension, and the contact angle according to the Young–Laplace and Young equations. The same relationships determine how water or other fluids can be injected to change pressure, interfacial tension,

and/or contact angle and thereby change the liquid saturations and increase oil recovery (13,52).

Some compounds, like short-chain fatty acids, can be soluble in both water and oil because one part of the molecule has an affinity for oil (the nonpolar hydrocarbon chain) and one part has an affinity for water (the polar group). The energetically most favorable orientation for these molecules is at an interface so that each part of the molecule can reside in the solvent medium for which it has the greatest affinity. These molecules that form oriented monolayers at interfaces show surface activity and are termed surfactants. Some consequences of surfactant adsorption at a surface are that it causes a reduction in surface tension and an alteration in the wettability of the surface. Surfactant molar masses range from a few hundreds up to several thousands of grams per mole.

Surfactants can be used to selectively alter wettability. For example, in mineral flotation surfactant can be added to adsorb on metal ore particles increasing the contact angle, so they attach to gas bubbles. The surfactant is chosen so that it will not adsorb much on silicates, so the latter do not attach to gas bubbles. The surfactant may also stabilize a foam containing the desired particles, thereby facilitating their recovery as a particle-rich froth that can be skimmed. Flotation processes thus involve careful modification of surface tension and wettability.

Another problem in colloids is detergency, which involves the action of surfactants (originally soaps were used) to alter interfacial properties so as to promote dirt or oil removal from solid surfaces. The detergent's role is to alter interfacial tensions in order to reduce the amount of mechanical energy required to dislodge the dirt. If the dirt is solid then it is a simple matter of wettability alteration.

Surfactants play an important role in the formation and stability of emulsions and foams. Surfactant adsorption at fluid interfaces can, eg, lower interfacial tension, increase surface elasticity, increase electric double-layer repulsion (ionic surfactants), lower the effective Hamaker constant, and sometimes increase surface viscosity. For emulsions, the nature of the surfactant can also determine the arrangement of the phases (ie, which phase will form the dispersed vs continuous phase). Several empirical rules and scales have been developed for categorizing emulsifying agents, including the oriented wedge and Bancroft theories, the hydrophile–lipophile balance, HLB, and the phase inversion temperature, PIT (13,26,45). Although there are exceptions to each of these rules, they remain useful for making initial predictions.

Lyophilic Colloids. Another key feature of surfactants is that above a certain solution concentration they form organized aggregates called micelles (19, 26) in which the lipophilic parts of the surfactants associate in the interior of the aggregate, leaving hydrophilic parts to face the aqueous medium. A solution of micelles is a good example of a thermodynamically stable lyophilic colloidal dispersion. The concentration at which micelle formation becomes significant is called the critical micelle concentration (CMC). The CMC is a property of the surfactant and several other factors, since micellization is opposed by thermal and electrostatic forces. A low CMC is favored by increasing the lipophilic part of the molecule, lowering the temperature, and adding electrolyte. Compilations of CMC values are given in References 19 and 53.

The ability of biological amphiphilic molecules to aggregate into spherical and nonspherical clusters, ie, vesicles, may have been important for the development of early living cells (54). Cellular biological membranes in plants and animals share features with these colloidal systems, although the molecular and hierarchical membrane structures, their hydration, and their dynamic properties are complex (54–57). The macroscopic nature of concentrated gels, such as lubricating greases formed by dispersing short-chain surfactants, eg, lithium 12-hydroxystearate, in mineral oil (58), is akin to the behavior of biological amphiphiles, being also dependent on self-assembly mechanisms. The associations between fibrous clusters, the length of threadlike surfactant strands, and the density of their contact points (cross-links) govern the grease's shear resistance (58).

Microemulsions, like micelles, are considered to be lyophilic, stable, colloidal dispersions. In some systems, the addition of a fourth component, a cosurfactant, to an oil–water–surfactant system can cause the interfacial tension to drop to near-zero values, easily on the order of $10^{-3} - 10^{-4}$ mN/m, allowing spontaneous or nearly spontaneous emulsification to very small drop sizes, ~10 nm or smaller. The droplets can be so small that they scatter little light, and the emulsions appear to be transparent and do not break on standing or centrifuging. Unlike coarse emulsions, microemulsions are thought to be thermodynamically stable. The thermodynamic stability is frequently attributed to transient negative interfacial tensions, but this, and the question of whether microemulsions are really lyophilic or lyophobic dispersions are areas of some discussion in the literature. As a practical matter, microemulsions can be formed, have some special qualities, and can have important applications in areas such as enhanced oil recovery, soil and aquifer remediation, foods, pharmaceuticals, cosmetics, herbicides, and pesticides (13,16,45,59–61).

Electrokinetics

Charged Interfaces. Most substances acquire a surface electric charge when brought into contact with a polar medium such as water. The origin of the charge can be ionization, as when carboxyl and/or amino functionalities ionize when proteins are put into water; ion adsorption, as when surfactant ions adsorb onto a solid surface; ion dissolution, as when Ag^+ and I^- dissolve unequally when AgI is placed in water; or ion diffusion, as when a clay particle is placed in water and the counterions diffuse out to form an electric double layer. In the AgI example, the ions Ag^+ and I^- will be potential-determining because either may adsorb at the interface and change the surface potential. Conversely, indifferent ions, such as Na^+ and NO_3^-, will not change the surface potential.

Surface charge influences the distribution of nearby ions in a polar medium: ions of opposite charge (counterions) are attracted to the surface while those of like charge (coions) are repelled. Together with mixing caused by thermal motion a diffuse electric double layer is formed. The electric double layer (EDL) can be viewed as being composed of two layers: an inner layer that may include adsorbed ions, and a diffuse layer, where ions are distributed according to the influence of electrical forces and thermal motion. Gouy and Chapman proposed a simple

quantitative model for the diffuse double layer assuming an infinite, flat, uniformly charged surface, and ions that can be regarded as point charges (also that solvent effects arise only through a uniform dielectric constant, and that the electrolyte is symmetrical [*z*-*z*]). The surface potential is designated as Ψ^0 and the potential at a distance x as Ψ. The Poisson–Boltzmann equation comes from a combination of the Boltzmann distribution of concentrations of ions (in terms of potential), the charge density at each potential (in terms of the concentration of ions), and the Poisson equation (describing the variation in potential with distance). Given the physical boundary conditions, assuming low surface potentials, and using the Debye–Hückel approximation yields,

$$d^2\Psi/dx^2 = [e^2\Psi/(\varepsilon\ \kappa T)]\sum\nolimits_i c_i z_i^2$$

If we now define the cluster of constants as $\kappa^2 = (e^2/\epsilon kT)\ \sum_i\ c_i\ z_i{}^2$ (having units of distance^{-2}) then this can be simplified to

$$d^2\Psi/dx^2 = \kappa^2\Psi \quad \text{or} \quad \Psi = \Psi^0\ \exp(-\kappa x)$$

This is the Debye–Hückel expression for the potential at a distance from a charged surface. The parameter $1/\kappa$ is called the double layer thickness and is given for water at 25°C by $\kappa = 3.288\ \sqrt{I}\ (\text{nm}^{-1})$, where $I = (1/2)\ \sum_i\ c_i\ z_i{}^2$. For 1-1 electrolyte $1/\kappa$ is 1 nm for $I = 10^{-1}\ M$, and 10 nm for $I = 10^{-3}\ M$.

There remain some problems. In order to handle higher (more practical) potentials, the Gouy–Chapman theory can be applied, but with a more complicated result. One such result is

$$\Upsilon = \Upsilon^0\ \exp(-\kappa x)$$

where Υ is a complex ratio involving Ψ given by

$$\Upsilon = \frac{\exp[ze\Psi/2kT] - 1}{\exp[ze\Psi/2kT] + 1}$$

At low surface potentials this equation reduces to the Debye–Hückel expression above. Second, an inner layer exists because ions are not really point charges and an ion can only approach a surface to the extent allowed by its hydration sphere. The Stern model incorporates a layer of specifically adsorbed ions bounded by a plane, the Stern plane. In this case, the potential changes from Ψ^0 at the surface, to $\Psi\ (\delta)$ at the Stern plane, to $\Psi = 0$ in bulk solution.

Electrokinetic Phenomena. Electrokinetic motion occurs when the mobile part of the electric double layer is sheared away from the inner layer (charged surface). There are several types of electrokinetic measurements, electrophoresis, electroosmosis, streaming potential, sedimentation potential, and two electroacoustical methods. The first four methods are described in References 35 and 62. Of these the first finds the most use in industrial practice. The electroacoustical methods involve detection of the sound waves generated when dispersed species are made to move by an imposed alternating electric field, or vice versa (63). In all of the electrokinetic measurements either the liquid is made to move across a

solid surface or vice the versa. Thus the results can only be interpreted in terms of charge density (σ) or potential (zeta potential, ζ) at the plane of shear. The location of the shear plane is generally not exactly known and is usually taken to be approximately equal to the potential at the Stern plane, $\zeta \approx \Psi(\delta)$. Several methods can be used to calculate zeta potentials (11,35,62).

Colloid Stability

A consequence of the small size and large surface area in colloids is that quite stable dispersions of these species can be made. That is, suspended particles may not settle out rapidly and droplets in an emulsion or bubbles in a foam may not coalesce quickly. Charged species, when sedimenting, present a challenge to Stokes' law because the smaller counterions sediment at a slower rate than the larger colloidal particles. This creates an electrical potential that tends to speed up the counterions and slow down the particles. At high enough electrolyte concentrations the electric potentials are quickly dissipated and this effect vanishes.

Although some lyophobic colloidal dispersions can be stable enough to persist for days, months, or even years, they are not thermodynamically stable. Rather, they possess some degree of kinetic stability, and one must consider the degree of change and the timescale in the definition of stability. Having distinguished coalescence and aggregation as processes in which particles, droplets, or bubbles are brought together with and without large changes, respectively, in surface area it is clear that there can be different kinds of kinetic stability. Finally, stability depends upon how the particles interact when this happens, since encounters between particles in a dispersion can occur frequently due to diffusion (as in Brownian motion), sedimentation, or stirring.

Electrostatic and Dispersion Forces. Several repulsive and attractive forces operate between colloidal species and determine their stability (7,8,10,25, 31,54). In the simplest example of colloid stability, particles would be stabilized entirely by the repulsive forces created when two charged surfaces approach each other and their electric double layers overlap. The overlap causes a Coulombic repulsive force acting against each surface, and that will act in opposition to any attempt to decrease the separation distance. One can thus express the Coulombic repulsive force between plates as a potential energy of repulsion. There is another important repulsive force causing a strong repulsion at very small separation distances where the atomic electron clouds overlap, called the Born repulsion.

There also exist dispersion, or London–van der Waals, forces that molecules exert towards each other. These forces are usually attractive in nature and result from the orientation of dipoles, whether dipole–dipole (Keesom dispersion forces), dipole–induced dipole (Debye dispersion forces), or induced dipole–induced dipole (London dispersion forces). Except for quite polar materials the London dispersion forces are the more significant of the three. For molecules, the force varies inversely with the sixth power of the intermolecular distance, whereas for particles, etc, the force varies approximately inversely with interparticle distance.

DLVO Theory. Derjaguin and Landau (64,65) and Verwey and Overbeek (66) developed a quantitative theory for the stability of lyophobic colloids, referred to as DLVO theory. It was known from experiment that classical colloids (AgI, Au)

coagulated quickly at high electrolyte concentrations and slowly at low concentrations, with a very narrow electrolyte concentration range over which the transition from kinetically stable to kinetically unstable occurred. Thus a critical coagulation concentration (CCC) could be defined. Using DLVO theory one can calculate the energy changes that take place when two particles approach each other by estimating the potential energies of attraction (London–van der Waals dispersion, V_A) and repulsion (electrostatic including Born, V_R) versus interparticle distance. These are then added together to yield the total interaction energy, V_T. The theory has been developed for two special cases, the interaction between parallel plates of infinite area and thickness, and the interaction between two spheres. The original calculations of dispersion forces employed a model due to Hamaker although more precise treatments now exist (54).

The parameter V_R decreases exponentially with separation distance, having a range about equal to κ^{-1}, while V_A decreases inversely with separation distance. Figure 1 shows how van der Waals forces can predominate at small and large interparticle distances. Repulsive forces can predominate at extremely

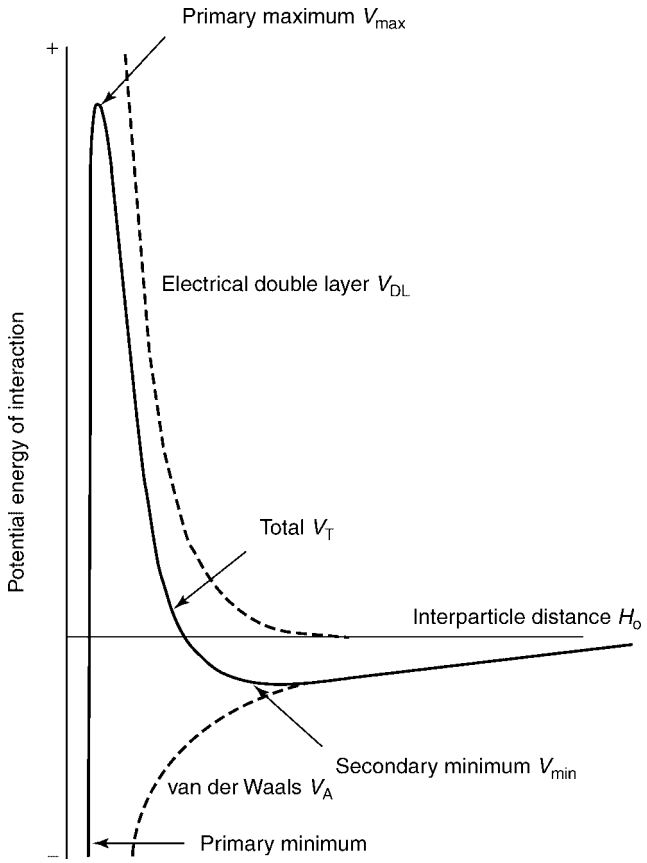

Fig. 1. Potential energies of interaction between two colloidal particles as a function of their distance of separation, for electrical double layers due to surface charge (V_{DL}), London–van der Waals dispersion forces (V_A), and the total interaction (V_T).

small (Born) and intermediate (electric double layer) separation distances. If the colloidal species are charged and have an interfacial potential of ~25–50 mV, the DLVO model predicts for binary particle interactions that a substantial repulsive potential energy barrier will inhibit the close approach of the particles, thereby stabilizing them against aggregation (V_{max} in Fig. 1). The primary maximum usually ensures stability, if its magnitude (V_{max}) exceeds the range 10–15 kT; smaller barriers lead to irreversible aggregation in the primary minimum (7,8,11,31,35,64–66). The secondary minimum (V_{min}) can promote a loose, easily reversible aggregation of particles, if its magnitude is on the order of 10 kT or more (54). In clay colloids, this is part of the explanation for flocculation as distinguished from coagulation. The overall energy barrier to coagulation in the primary minimum is given by $V_{barrier} = V_{max} - V_{min}$, where the primary minimum represents the potential energy at contact. Stability ensues if the magnitude of $V_{barrier}$ exceeds 10–15 kT and is therefore large compared to the thermal energy of the particles. Note that the primary minimum is a finite number because of the contributions that come into play for very small particle separations, ie, the Born repulsion (54).

The classic DLVO models are for flat planes and spheres, but more complex shapes arise in practice. For example, there will be some distortion of originally spherical emulsion droplets as they approach each other and begin to seriously interact, causing a flattening. The model has been extended to systems with particles that differ in size, shape, and chemical composition (64,65), and to those with particles that have an adsorbed layer of ions (7,8,10,11,31,35,64–66), as depicted in Figure 2.

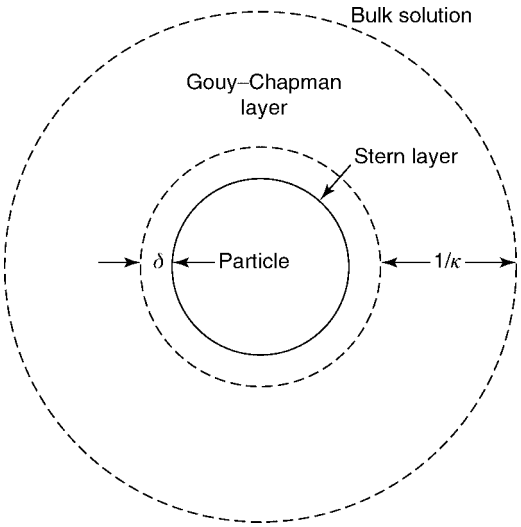

Fig. 2. Schematic diagram of a suspended colloidal particle, showing relative locations of the Stern layer (thickness, δ) that consists of adsorbed ions and the Gouy–Chapman layer ($1/\kappa$), which dissipates the excess charge, not screened by the Stern layer, to zero in the bulk solution (67). In the absence of a Stern layer, the Gouy–Chapman layer dissipates the surface charge.

The role of electrostatic repulsion in the stability of suspensions of particles in nonaqueous media is not entirely clear. In attempting to apply DLVO theory it can be difficult to judge the electrical potential at the surface, the appropriate Hamaker constant, and the ionic strength to be used for the nonaqueous medium. The ionic strength will be low so the electric double layer will be thick, the electric potential will vary slowly with separation distance, and so will the net electric potential as the double layers overlap. As a result the repulsion between particles can be expected to be weak (68).

Returning to aqueous systems, it will be apparent that the DLVO calculations can become quite involved, requiring considerable foreknowledge about the systems of interest. There are empirical "rules of thumb" that can be used to give a first estimate of the degree of colloidal stability a system is likely to have if the Zeta potential is known. For example, in the case of colloids dispersed in aqueous solutions, one such rule stems from observations that the colloidal particles are quite stable when the Zeta potential is $\sim$30 mV (positive or negative) or more, and quite unstable due to aggregation when the Zeta potential is between $+5$ and -5 mV. The transition from stable dispersion to aggregation usually occurs over a fairly small range of electrolyte concentration. This makes it possible to determine aggregation concentrations, often referred to as critical coagulation concentrations (CCC). The Schulze–Hardy rule summarizes the general tendency of the CCC to vary inversely with the sixth power of the counterion charge number (for indifferent electrolyte). The ability to predict CCCs was the first success of DLVO theory.

Steric and Hydrodynamic Effects. Additional influences on dispersion stability beyond those accounted for by the DLVO theory, like steric, surface hydration, and hydrodynamic effects have received considerable attention over the past several decades (54). More generally, the stability of a dispersion can be enhanced (protection) or reduced (sensitization) by the addition of material that adsorbs onto particle surfaces. Protective agents can act in several ways. They can increase double layer repulsion if they have ionisable groups. The adsorbed layers can lower the effective Hamaker constant. An adsorbed film may necessitate desorption before particles can approach close enough for van der Waals forces to cause attraction.

Long-chain surfactants and natural and synthetic high molecular weight polymers can be adsorbed at the surfaces of dispersed species such that a significant amount of adsorbate extends out from the surfaces. In this situation, an entropy decrease can accompany particle approach, providing a short-range stabilization mechanism referred to as steric stabilization. Molecular structure and solvation, adsorption layer thickness and hydrodynamic volume, and temperature determine the effectiveness of steric stabilization (69–73). Finally, the adsorbed material may form such a rigid film that it poses a mechanical barrier to droplet coalescence. Sensitizing agents are the opposite of protective agents. Again there are several possible mechanisms of action. If the additive is oppositely charged to the dispersed particles then decreased double layer repulsion will result. In some kinds of protecting adsorption a bilayer is formed, with the outer layer having lyophilic groups exposed outward; the addition of enough additive to form only the single layer will have lyophobic groups oriented outward, with a sensitizing effect. If the additive is of long chain length, sometimes a bridging between

particles occurs. Colloidal destabilization by electrolytes and bridging flocculation by polymers have been addressed both experimentally and theoretically. Comprehensive reviews on the relevant phenomena that derive from soluble and adsorbed polymers are available (69–73).

Oilfield W/O emulsions may be stabilized by the presence of a protective film around the water droplets. Such a film can be formed from the asphaltene and resin fractions of the crude oil. When drops approach each other during the process of aggregation, the rate of oil film drainage will be determined initially by the bulk oil viscosity, but within a certain distance of approach the interfacial viscosity becomes important. A high interfacial viscosity will significantly retard the final stage of film drainage and promote kinetic emulsion stability. If the films are viscoelastic, then a mechanical barrier to coalescence will be provided, yielding a high degree of emulsion stability (74,75).

Another example can be found in the field of water and wastewater treatment. Water treatment, whether for drinking water or for disposal of industrial wastes, involves the removal of suspended solids usually silt, clay, and organic matter. The electric charge on the solids is often sufficiently negative to yield a stable dispersion that settles slowly and is difficult to filter. The solution to this problem is to reduce the Zeta potential to values that permit rapid coagulation increasing both sedimentation and filterability. A first step toward coagulating the suspension might be to add aluminum sulfate (alum), from which the trivalent aluminum ions will have a powerful effect on the Zeta potential (according to the Schulze–Hardy rule). Figure 3**a** shows an example of this effect. In practice, however, the alum required to reduce the Zeta potential to below about −10 mV or so reduces the solution pH too much (unreacted alum becomes carried to other parts of the plant and forms undesirable precipitates). A second step can be introduced, in which a cationic polyelectrolyte is added to reduce the Zeta potential to about zero without changing the pH. As a final step a high molecular weight anionic polymer may be added (MW 500,000–1,000,000, or more) whose molecules can bridge between agglomerates yielding very large, rapid-settling flocs. Figure 3**b** shows how two New York water samples were treated in this way.

Kinetic Properties

The best experimental technique for monitoring colloid stability is usually dictated by the nature of the specific colloidal material and the dispersing medium. In principle, any distinctive physical property of the colloidal system in question can be used, at least empirically, to monitor changes in the dispersed state. The more complex a system is (chemically or with respect to its particulate heterogeneity), the less likely it is that a single property uniquely and completely describes changes in the colloidal state. Aggregation and/or coalescence of colloidal material can be monitored by a wide variety of techniques including light scattering, neutron scattering, microscopy, rheology, conductivity, filtration, sedimentation, and electrokinetics.

Encounters between colloidal species can occur frequently due to any of Brownian motion, sedimentation, or stirring. If velocity or shear gradients are present and are sufficiently large, the frequency of collisions depends on the volume fraction of solids and the mean velocity gradient. Assuming that sedimentation is slow compared to other collision mechanisms, the overall aggregation rate, $-\mathrm{d}N/\mathrm{d}t$, is

$$-\mathrm{d}N/\mathrm{d}t = k_\mathrm{d}N^2 + k_sN$$

where N is the number concentration of dispersed species, k_d and k_s are the respective rate constants corresponding to diffusion-controlled and shear-induced collision processes, and the minus sign denotes that the number concentration decreases with time t. The constants k_d and k_s depend on particle/droplet/bubble properties such as chemical composition of the bulk and surface phases, dielectric constant, dipole moment, size, size distribution, shape, surface charge, solid-phase distribution within particles, and particle anisotropy. Properties of the liquid-dispersing medium that contribute significantly to the values of these rate constants are the dielectric constant, the dipole moment, and the ability to dissolve electrolytes and polymers, in addition to the properties cited earlier. The k_d term usually dominates in quiescent systems containing submicrometer particles. The full expression for $(-\mathrm{d}N/\mathrm{d}t)$ and its use are treated in more detail elsewhere (7,8,31,77).

Chemical reactions can also affect the k_d and k_s terms and thereby influence or control colloidal stability (78). Pertinent examples are dissolution, precipitation, hydrolysis, precipitation, and chemical complexing. The last reaction may involve either simple species, eg,

$$\mathrm{Al}^{3+} + \mathrm{SO_4}^{2-} \rightleftarrows \mathrm{AlSO_4}^{+}$$

or complicated solutes such as $\mathrm{Al_8(OH)_{20}}^{4+}$, chelated metals (75), synthetic and natural polymers (25,69–73), or a variety of surfactants and dispersants (19,79). Many of the possible bulk solution chemical reactions that influence colloidal stability, along with specific sample reactions and their general interfacial analogues, are listed in Table 5.

Table 5. Representative Solution and Surface Equilibria Influencing Colloidal Stability

Solution	Surface analogue
Hydrolysis	
$CH_3(CO)OCH_3 + H_2O \rightleftarrows CH_3(CO)OH + CH_3OH$	$M_2O + H_2O \rightleftarrows 2\,MOH$
$PO_4^{3-} + H_2O \rightleftarrows HPO_4^{2-} + OH^-$	$MOH + H_2O \rightleftarrows MOH_2^+ + OH^-$
Dissociation	
$Al(OH)_3 \rightleftarrows Al^{3+} + 3\,OH^-$	$MOH_2^+ \rightleftarrows MO^- + 2\,H^+$
$C_6H_5(CO)OH \rightleftarrows C_6H_5(CO)O^- + H^+$	$MOH \rightleftarrows MO^- + H^+$
Dissolution	
$ZnC_2O_4\,(S) \rightleftarrows Zn^{2+} + C_2O_4^{2-}$	
$Al(OH)_3(S) + OH^- \rightleftarrows AlO_2^- + 2\,H_2O$	
Complexation	
$Cu^{2+} + 4\,OH^- \rightleftarrows Cu(OH)_4^{2-}$	$MO^- + Na^+ \rightleftarrows MO^-Na^+$
$n\text{–}C_{12}H_{25}N(CH_3)_2 + HCl \rightleftarrows n\text{–}C_{12}H_{25}NH^+(CH_3)_2Cl^-$	$MOH + HCl \rightleftarrows MOH_2^+\,Cl^-$

Applications

General Uses. Diffusion, Brownian motion, sedimentation, electrophoresis, osmosis, rheology, mechanics, interfacial energetics, and optical and electrical properties are among the general physical properties and phenomena that are primarily important in colloidal systems (7,8,27,28,31). Chemical reactivity and adsorption often play important, if not dominant, roles. Any physical and chemical feature may ultimately govern a specific industrial process and determine final product characteristics and colloids are deemed either desirable or undesirable on the basis of their unique physiochemical properties.

Although colloids may be undesirable components in industrial systems, particularly as waste or by-products and, in nature, in the forms of fog and mist, they are desirable in many technologically important processes such as mineral beneficiation and the preparation of ceramics, polymers, composite materials, paper, foods, textiles, photographic materials, drugs, cosmetics, and detergents. The remainder of this section specifies some applications for colloidal solids, liquids, and gases and illustrates how colloids affect many technologically important systems in a positive manner.

Colloidal Solids. Some uses of solid colloids include reinforcement aids in metals, ceramics, and plastics; as adhesion promoters in paints and thermoplastics; as nucleating agents in cloud seeding; as activated powder catalysts; as thickening agents in gels and slurries; and as abrasives in toothpastes (7,8,27,28,31,37,80–83). When used as reinforcement agents, the colloidal particles may be spherical, angular, fibrillar, or flake-shaped. Alumina and thoria are used to reinforce aluminum and nickel, respectively, by providing obstacles to the movement of dislocations in the metals, and zirconia and silicon carbide to reinforce a variety of ceramics (eg, alumina, silicon nitride, and glass, by inhibiting the propagation and opening of cracks in the matrix). (See COMPOSITE MATERIALS; REINFORCEMENT). Stable but ordered suspensions can be regarded as precursory systems for ordered, prefired, ceramic components; outlets for such systems include various processing techniques such as slip, tape, freeze, pressure,

centrifugal, and ultrasonic casting, as well as isostatic, and hot pressing (84,85). Asbestos, crystalline silicas, and organic solids are added to concrete to improve its strength by providing an interlocking particulate structure within the concrete matrix (81); asbestos, various oxides, and carbon black are added to reinforce polymers by inducing a stiffened or high yield matrix (27,28,78–81).

The magnitude of the strengthening often depends on particle shape. Fibrillar fillers are used as discontinuous fibers in metals and plastics, eg, in epoxy resin (78–80) and as whiskers in ceramics (86). Glass and aluminum oxide are common fillers that are occasionally pretreated with a polymeric or metallic coating; silica and various clays are also used. The mechanism by which ceramics and metals are reinforced often involves precipitation of colloidal material during thermal treatment of the matrix composition, eg, TiO_2 in borosilicate glasses designed for enamels (87). Strengthening mechanisms (27,28) include precipitation and dispersion when the reinforcing phase is metallic and the toughened materials are metals or ceramics. When inorganic, nonmetallic ceramics strengthen metals or polymers (45), the mechanism may be dispersion or reinforcement, eg, by cross-linking. Reinforcement implies a higher volume fraction than in dispersion hardening. Fillers can be added not only to improve mechanical properties such as impact strength, fracture toughness, and tensile strength of structural ceramics, but also to enhance optical properties, as is done for colored glasses containing colloidal gold or crystalline, chromium-based oxides.

Particle suspensions have long been of great practical interest because of their widespread occurrence in everyday life. Some important kinds of familiar suspensions include those occurring in foods (batters, puddings, sauces), pharmaceuticals (cough syrups, laxative suspensions), household products (inks, paints, "liquid" waxes) and the environment (suspended lake and river sediments, sewage). In the petroleum industry alone, suspensions may be encountered throughout each of the stages of petroleum recovery and processing, including migrating fine solid suspensions during secondary and enhanced oil recovery, dispersions of asphaltenes in crude oils, produced (well-head) solids in oil recovery, drilling muds, well stimulation and fracturing suspensions, well cementing slurries, and oilfield surface treatment facility sludges.

Other applications of colloidal solids include the preparation of rigid, elastic, and thixotropic gels (78–80), aerogel-based thermal insulators (79), and surface coatings (25,27,28,79). Commercial uses of silica gel and sol–gel processing (88) often focus on rigid gels having 20–30 vol% SiO_2. The principal interparticulate forces in a rigid gel are chemical and irreversible, and the colloid improves the gel's mechanical strength. Elastic gels are commonly associated with cellophane, rubber, cellulosic fibers, leather, and certain soaps. Many thixotropic gels and surface coatings contain colloidal solids, eg, clays, alumina, ferric oxide, titania, silica, and zinc oxide. Consumer and industrial pastes belong to this category; putty, dough, lubricating grease, toothpaste, and paint are some examples.

Colloidal Liquids. These fluids are commonly used in the form of emulsions by many industries. Permanent and transient antifoams consisting of an organic material, eg, polyglycol, oils, fatty materials, or silicone oil dispersed in water, is one application (10,89,90) that is important to a variety of products and processes: foods, cosmetics, pharmaceuticals, pulp and paper, water treatment,

and minerals beneficiation. Other emulsion products (see Table 2) include foods, insecticides and herbicides, polishes, drugs, biological systems, asphalt paving emulsions, personal care creams and lotions, paints, lacquers, varnishes, and electrically and thermally insulating materials.

Emulsions may be encountered throughout all stages of the process industries. For example, in the petroleum industry both desirable and undesirable emulsions permeate the entire production cycle, including emulsion drilling fluid, injected or *in situ* emulsions used in enhanced oil recovery processes, well-head production emulsions, pipeline transportation emulsions, and refinery process emulsions (13). Such emulsions may contain not just oil and water, but also solid particles and even gas, as occur in the large Canadian oil sands mining and processing operations (13–15).

Some emulsions are made to reduce viscosity so that an oil can be made to flow. Emulsions of asphalt, a semisolid variety of bitumen dispersed in water, are formulated to be both less viscous than the original asphalt and stable so that they can be transported and handled. In application, the emulsion should shear thin and break to form a suitable water-repelling roadway coating material. Another example of emulsions that are formulated for lower viscosity with good stability are those made from heavy oils and intended for economic pipeline transportation over large distances. Here again the emulsions should be stable for transport but will need to be broken at the end of the pipeline.

Some special problems arise at sea: when crude oil is spilled on the ocean a slick is formed that spreads out from the source with a rate that depends on the oil viscosity. With sufficient energy an O/W emulsion may be formed, which helps disperse oil into the water column and away from sensitive shorelines. Otherwise, the oil may pick up water to form a W/O emulsion, or mousse ("chocolate mousse"). These mousse emulsions can have high water contents and have very high viscosities and, with weathering, they can become semisolid and considerably more difficult to handle. The presence of mechanically strong films makes it hard to get demulsifiers into these emulsions, so they are hard to break.

Demulsification, ie, the breaking of emulsions, is an important process, with the oil industry being a common one in which the process is often critical. The stability of emulsions is often a problem. Demulsification involves two steps. First, there must be agglomeration or coagulation of droplets. Then, the agglomerated droplets must coalesce. Chemical and particulate agents that displace the surfactant and permit an unstabilized interface to form are used for this purpose. Only after these two steps can complete phase separation occur. It should be realised that either step can be rate-determining for the demulsification process. This is a large subject in its own right; see References 13,16 and 89–91.

Other common applications of colloidal liquids include liquid aerosols, such as those occurring in the areas of environment (fog, mist, cloud, smog), agriculture (crop sprays), manufacturing (paint sprays), medicine (nasal sprays), and personal care (hair spray).

Colloidal Gases. Fluid foams are commonplace in foods, shaving cream, fire-fighting foam, mineral flotation, and detergents (10,92–95). Thus, in view of the fact that the concentration of bubbles greatly affects the properties of foams, the production, dispersion, and maintenance of colloidal gas bubbles are basic to foams and related materials. Often, natural and synthetic soaps and surfactants

are used to make fluid foams containing colloidal gas bubbles. These agents reduce the interfacial tension and, perhaps, increase the viscosity at the gas–liquid interface, making the foam stable. Also, some soluble proteins that denature upon adsorption or with agitation of the liquid phase can stabilize foams by forming insoluble, rigid layers at the gas–liquid interface (89).

A class of enhanced oil recovery processes involves injecting a gas in the form of a foam. Suitable foams can be formulated for injection with air–nitrogen, natural gas, carbon dioxide, or steam (14,16). In a thermal process, when a steam foam contacts residual crude oil, there is a tendency to condense and create W/O emulsions. On the other hand, in a nonthermal process, the foam may emulsify the oil itself (now as an O/W emulsion), which is then drawn up into the foam structure; the oil droplets eventually penetrate the lamella surfaces, destroying the foam (14).

Microfoams (also termed colloidal gas aphrons) comprise a dispersion of aggregates of very small foam bubbles in aqueous solution. They can be created by dispersing gas into surfactant solution under conditions of very high shear. The concept is that, under the right conditions of turbulent wave breakup, one can create a dispersion of very small gas bubbles, each surrounded by a bimolecular film of stabilizing surfactant molecules. Under ambient conditions the bubble diameters are typically in the range 50–300 μm. There is some evidence that such microfoams tend to be more stable than comparable foams that do not contain the bimolecular film structure (96–98). Some interesting potential applications have been reported: soil remediation (97,99–102) and reservoir oil recovery (94,103,104), but the literature for these applications is sometimes inconsistent; more work needs to be done in this area.

Some agents will act to reduce the foam stability of a system (termed foam breakers or defoamers) while others can prevent foam formation in the first place (foam preventatives, foam inhibitors). There are many such agents, Kerner (92) describes several hundred different formulations for foam inhibitors and foam breakers. In all cases, the cause of the reduced foam stability can be traced to changes in the nature of the interface, but the changes can be of various kinds. The addition to a foaming system of any soluble substance that can become incorporated into the interface may decrease dynamic foam stability if the substance acts in any combination of increased surface tension, decreased surface elasticity, decreased surface viscosity or decreased surface potential. Such effects may be caused by a cosolubilization effect in the interface or by a partial or even complete replacement of the original surfactants in the interface. Some branched, reasonably high molecular mass alcohols can be used for this purpose. Not being very soluble in water they tend to be adsorbed at the gas–liquid interface, displacing foam-promoting surfactant and breaking or inhibiting foam. Alternatively, a foam can be destroyed by adding a chemical that actually reacts with the foam-promoting agent(s). Foams may also be destroyed or inhibited by the addition of certain insoluble substances such as a second liquid or solid phase. Antifoaming and defoaming represent a large subject on their own (see References 105 and 106).

Other common applications of colloidal gases include solid foams, such as those occurring in the areas of food (leavened breads), geology (pumice stone, zeolites), manufacturing (polystyrene foam, polyurethane foam), and personal care

(synthetic sponges). Solid foams such as polyurethane foam contain dispersed gas bubbles that are often produced via viscoelastic polymer melts within which gas, eg, carbon dioxide, bubbles are nucleated (107).

Chemical and Surface Analysis

Any classical wet-chemical analyses or instrumental techniques that are routinely used to analyze the bulk composition of solids and liquids are, in principle, also suitable for colloids. The available instrumental methods range, eg, from spectrographic analysis for chemical composition, which is limited to crude estimates for impurities, to Raman spectroscopic identification of chemical functionalities, which can be very accurate (see VIBRATIONAL SPECTROSCOPY). These techniques can also be used to analyze adsorbed layers if they can be quantitatively desorbed and collected for study. Surface-chemical analyses that cannot be conducted using conventional methods designed for bulk materials are usually accomplished by optical, diffraction, and spectroscopic techniques; these are often applied under conditions of an ultrahigh vacuum. The spectroscopies measure the responses of solid surfaces to beams of electrons, ions, neutral species, and photons (see SURFACE ANALYSIS). Each spectroscopy has unique attributes (10), making it suitable for certain colloids but unsuitable for others. Although too numerous to list here, descriptions and tabulations of surface techniques and their synonyms and acronyms are given in References 6,10,108, and 109. A wide range of information can be obtained including surface and adsorbed layer compositions (including heterogeneity); surface morphology, atom packing, and structure; and surface reactions and their kinetics. Advances in these fields continue at a significant rate (see SURFACE PROPERTIES).

Hazards of Colloidal Systems

The occurrence of some materials in the form of a colloidal dispersion can introduce or enhance safety hazards. Considering that the dispersion of a material down to colloidal size results in a high specific surface area, colloidal chemical reactivity may differ considerably from that of the identical macroscopic material with less surface area. This is particularly important if the colloidal surface is easily and rapidly oxidized. Dust explosions and spontaneous combustion are potential dangers whenever certain materials exist as finely divided dry matter exposed to oxidizing environments (67,110) (see COATING METHODS, POWDER TECHNOLOGY). Dispersions of charged colloidal particles in nonaqueous media occur throughout the petroleum industry. The flow of petroleum fluids in tanks or pipelines, combined with the low conductivity of the petroleum fluids themselves, can allow the buildup of large potential gradients and a separation of charges. Sufficient charging for there to be an electrostatic discharge can cause an explosion (68).

Health problems can be caused by solids and liquids suspended in air or water. Specific potential hazards have been associated with a diverse spectrum of colloidal materials, including chemicals, coal, minerals, metals, pharmaceuticals, plastics, and wood pulp. Limits for human exposure for many particulate,

hazardous materials are published (108,109). The effects of the colloidal solids and liquids that comprise smog are widespread and well known. Liquid droplets may also constitute a hazard; eg, smog can contain sulfuric acid aerosols. Elements such as lead, zinc, and vanadium that are released into the atmosphere as vapors can subsequently condense or be removed as solid particulates by rain (111,112). Similarly, exposure to airborne pollutants found indoors and in confined spaces, many of which are particulates or microbes of colloidal size, can lead to complex physiological responses. This hazard ranges from short-term allergic reactions (eg, pollen and household dust causing asthma and hay fever) to long-term, possibly fatal effects (eg, silicosis, asbestosis, and black lung disease).

There is a need to understand the environmental properties and risks associated with any large-volume chemicals. The mass of surfactants that could ultimately be released into the environment, for example, is significant. A 1995 estimate of the global use of linear alkylbenzenesulfonates, alcohol ethoxylates, alkylphenol ethoxylates, alcohol sulfates, and alcohol ether sulfates totaled 3 million ton (113). Surfactant usage in industry will probably increase as new applications are found. The toxicity and persistence of surfactants is now fairly predictable for a variety of environmental situations (111,114,115), and although surfactants are not generally viewed as a serious threat to the environment (111) they can exhibit considerable toxicity to aquatic organisms. In addition to products, many industries produce waste containing significant amounts of suspended matter for which treatment incurs significant technological challenges and costs (116–118). Trace metals that are commonly found as suspended matter in the chemical form of hydrous oxides and other insoluble matter are tabulated elsewhere (67,110). Large fractions of readily hydrolyzable metals exist as adsorbed species on suspended (colloidal) solids in fresh and marine water systems and can also be anticipated to exist in industrial wastewater. Continued research is needed to understand the health hazards linked to colloidal pollutants.

Emerging Areas in Colloid Science

Advances on the theoretical front continue to be aided by advances in bulk and surface analytical technology (composition) and in physical surface characterization technology (topology, structure, and forces). Applications of atomic force microscopy in particular continue to expand into diverse areas, including magnetic force microscopy (119).

Much is known about colloids, their formation, properties, and applications, but considerably more surely remains unknown. In particular, the full potential to control colloids is not presently realized. There are several types of mixed colloids that are only poorly understood. For example, the properties of colloids in which more than one type of colloidal particle is dispersed may be dominated by the behavior of the minor dispersed-phase component. The nature and properties of colloids within colloids, such as suspended solids in the dispersed phase of an emulsion, or emulsified oil within the aqueous lamellae of a foam, are only beginning to be understood (13–15).

Nanotechnology refers to the production of materials and structures in the 0.1–100 nm range by any of a variety of nanoscale physical and chemical methods.

This is a rapidly growing area of materials science. As the size range indicates, there is an overlap between nanotechnology and colloid science since they share some similarity of scale, both dealing with matter having dimensions of tens and hundreds of nanometers. Although many areas of nanotechnology do not directly deal with colloidal dispersions, such as nanotubes and nanoelectronic devices, other areas do, eg, the use of colloidal ink dispersions in robocasting to build near-nanometer-scale three-dimensional structures. Examples of work at the interface between these fields is provided by current research aimed at controlling the solubility of nanotubes (120), and in the fabrication of nanoengineered films on colloidal particles (121).

Smart colloids are colloidal dispersions for which certain properties, such as size and structure, can be altered by changing an external influence, such as temperature, eg, cross-linked polymer gels of poly(*N*-isoproplyacrylamide). Such polymer systems can swell or shrink in response to temperature changes, and are also termed "thermo-shrinking polymers." (see References 122–124).

COMPOSITE FOAMS

Introduction

Foams or cellular materials are materials that have a regular arrangement of cells and solid struts as shown in the schematic in Figure 1. *Composite polymer foams* are materials defined as a polymer phase with voids and an additional solid or hollow phase distributed throughout the polymer. They can be thought of as conventional single-phase polymer foams with an additional dispersed solid phase. Thus, the term *composite foam* excludes conventional, single-phase foams made by expanding polymers such as polystyrene, polyurethane, or polypropylene (see CELLULAR MATERIALS; MICROCELLULAR PLASTICS). Also excluded are structures with single-phase core materials and covered with a solid skin because the second phase, the skin, is not dispersed throughout the polymer phase. The fact that voids are engineered into the material results in the most attractive feature of foams, namely low density leading to high specific properties.

Composite foams can be categorized as follws: syntactic foam, particle-reinforced foam, and fiber-reinforced foam. The additional solid constituents are incorporated to enhance certain properties important to the function of the composite foam part such as stiffness, strength, electrical or thermal conductivity, etc. Examples of foams containing particles or fibers are shown in Figures 2**a** and 2**b**. Figure 2**a** shows tungsten particles in polystyrene foam (1), while Figure 2**b** shows Kevlar fibers in a poly(vinyl chloride) foam (2). A syntactic foam is a special type of particle-reinforced foam where the reinforcing particle is hollow. In this case, the additional dispersed solid phase also contains void. Figure 3 is a photograph of Lockheed's Deep Quest submarine, which shows extensive use of a composite foam; a syntactic foam material made from micrometer-sized, hollow glass microballoons (MB) in an epoxy matrix (3). The deep submersible vehicle Deep Quest was designed, built, and operated by Lockheed Missiles & Space Co. Its broad program of research was available to both commercial activities and the U.S. Navy. Deep Quest was launched in June 1967, and it operated from Lockheed's laboratory in San Diego. Deep Quest held the record, for a time, of diving to 2700 m. The submersible was designed and equipped for a variety of missions, including salvage, seafloor survey and inspection, and other special assignments. Deep Quest made its last dive on 9 September 1980.

In this article, we review the processing, characterization, properties, and applications of composite foams and highlight the advantages they have over traditional single-phase foams.

General Characteristics of Foams. Foams, in general, and composite foams, in particular, can provide interesting combination of physical and mechanical properties. Among these are the following characteristics:

(1) Very low density: the density is significantly decreased by the presence of cells containing gas
(2) High specific stiffness and compressive strength, ie, stiffness and strength divided by density: these can be further improved via sandwich construction (two dense faces and a foam core)

Processing and Microstructure

The processing of composite foams is done in much the same way as the processing of single-phase foams and can be classified under the broad categories of

(1) Introduction of a gas
   a. Physical blowing agent
   b. Chemical blowing agent
   c. Mixing

It is important to remember that the objective of processing a material into foam material is to intentionally introduce voids in the finished material. The size and distribution of the voids will vary depending on the process chosen, which in turn will control the material properties. Below, we provide highlights of each of the three processing methods with examples, advantages, and disadvantages.

The first method is to introduce gas into the composite material while the material is solidifying or curing. In case of the starting polymer matrix material being a thermoset, one should be able to control the degree of cure, while in the case of a thermoplastic there must be careful control of the temperature during the foaming process.

A *physical blowing agent* is a material that undergoes vaporization during processing. Examples of this are hydrochlorofluorocarbons and pentane. Also included in this category are gases such as nitrogen and carbon dioxide, which dissolve into the polymer material under high pressure. When the pressure is released, the dissolved gas comes out of the solution, blowing the polymer into a foam.

Chemical blowing occurs through (*1*) decomposition of a chemical additive to the polymer or (*2*) when using a thermosetting matrix, one of the reaction products is in the gaseous phase. A well-known example is a "hydrogen-blown" polydimethylsiloxane (PDMS) reinforced with silica as shown in Figure 4, and the simplified chemistry of which is shown in Figure 5.

The actual chemistry involved in making the foams is very complex and involves several molecular weight PDMS reactants in addition to cross-linking agents and tin octoate catalyst. Another example of a chemically blown foam

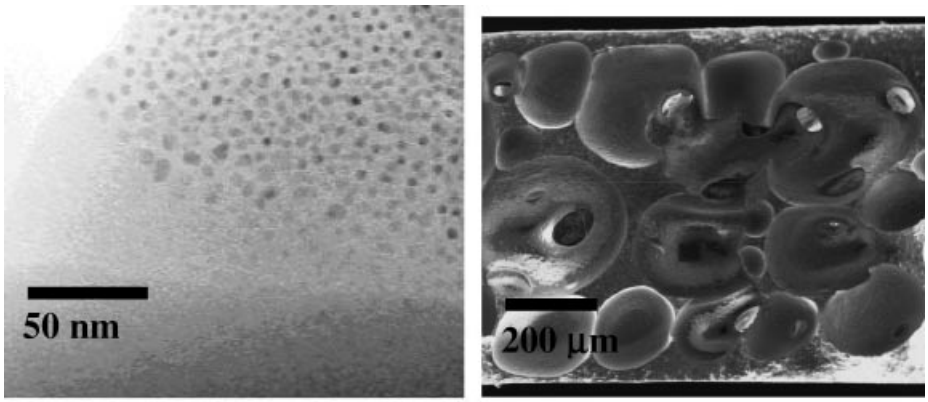

Fig. 4. (**a**) TEM micrograph showing the silica reinforcement in a PDMS matrix; (**b**) SEM micrograph of the structure obtained from a silica-reinforced PDMS hydrogen-blown foam.

occurs in the polyurethane material which can generate CO_2 as a product of the curing reaction. Another interesting chemically blown material occurs in manufacturing hollow phenolic microspheres, a material extensively used as a component in syntactic foams. The patent (4) identifies many examples of chemical blowing agents that decompose and blow individual polymer droplets into hollow structures. Included are carbonates, sulfites, nitrates, and bicarbonates.

When a chemical blowing agent evolves from a cross-linking reaction, careful control is required of the rheological properties of the polymer and kinetics of the reaction generating the blowing agent. If the gas evolves and the resin does not have a high enough viscosity, the foam will be overblown and collapse. The interplay among the reinforcement, viscosity, and gas generation also has direct effect on the cell size in the finished structure.

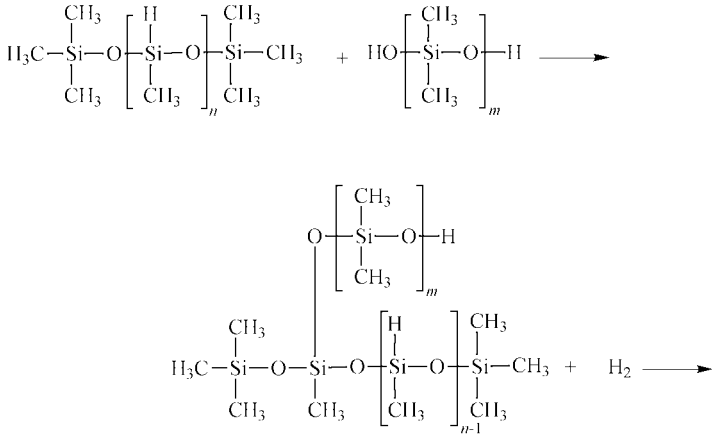

Fig. 5. Chemical reaction illustrating the chemistry involved in a hydrogen-blown PDMS foam.

Mechanical mixing or stirring is another way of introducing voids into a material. It is easy to achieve, but very difficult to control, the type, size, distribution, and volume fraction of voids. The procedure involves vigorously stirring the polymer melt, thus entraining air.

Removal of sacrificial material is an excellent method of ensuring cell size uniformity; however, in order that the method be suitable for manufacturing, a very high volume of sacrificial material must be introduced into the material so that the porosity approaches 100% open-celled. This allows for removal of the sacrificial material in a reasonable time period. A common foam prepared by this method is silica-reinforced PDMS. The PDMS in this case starts out as a gum (high viscosity polymer), and urea prills with dimensions of the desired cell size are introduced by milling. Once a high enough loading of the urea prills is achieved to ensure an open cell structure, the material is molded into the desirable geometry and cured. At this point the composite foam contains the cross-linked PDMS polymer matrix, silica reinforcement, and the sacrificial urea prills. Urea, being soluble in water, is then leached out by placing the part in a water bath. The leaching process can be accelerated if the bath is agitated. A drawback of this method is that the leaching process is efficient only for thin cross sections. Figure 6 shows a silica/PDMS foam from which the urea particles have been leached out.

The last category is the bonding together of spheres, powders, and fibers. This is a broad category that encompasses syntactic foams and frit-type material.

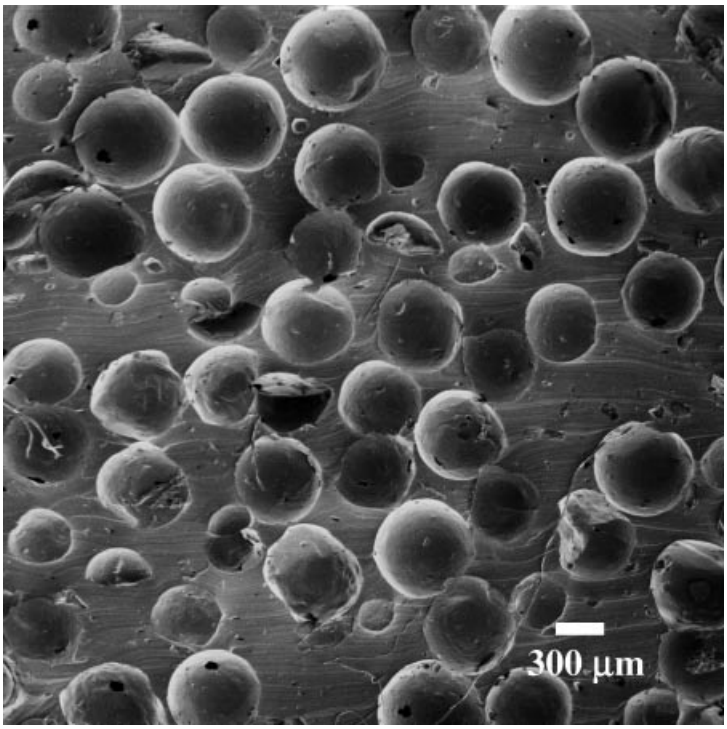

Fig. 6. TEM micrograph showing a silica/PDMS foam from which the urea particles have been leached out.

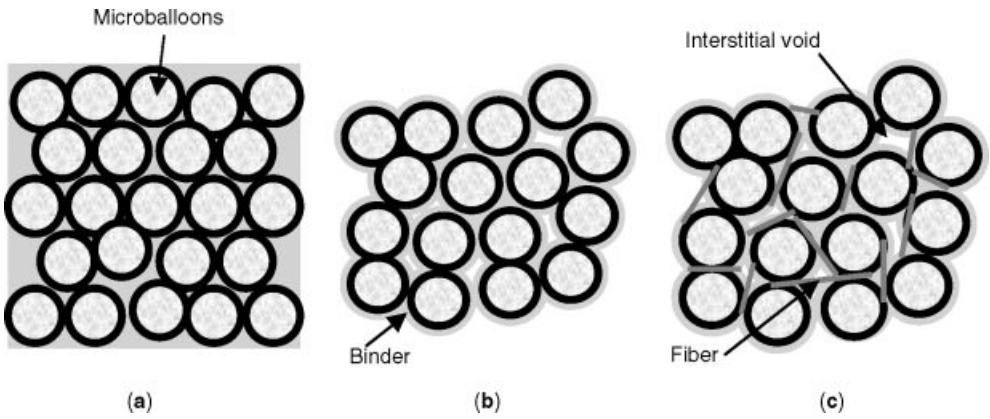

Fig. 7. Schematic structures of different syntactic foams: (**a**) two-phase foam, (**b**) three-phase foam, and (**c**) four-phase foam.

Syntactic foams consisting of hollow spheres distributed in a matrix have become quite important. The word *syntactic* comes from Greek, meaning "to arrange parts together in a unit." Typically, the resin matrix phase in syntactic foam has a large amount of open, interstitial voids. Strictly speaking, the matrix can be a polymer, metal, or ceramic. The polymer matrix can be epoxy, phenolic, ester cyanate, bismalemide (BMI), etc. Hollow spheres range in size from hundreds of nanometers to a few millimeters. When the hollow spheres are in the micrometer-size range, they are commonly referred to as *microballoons*. They may consist of glass, carbon, metal, polymer, or ceramic materials, although most commonly hollow glass microspheres (20–200 μm) are used. The microballoons can be mixed in a polymer either in a liquid or in a solid powder form. By far, the most common syntactic foam is the glass microballoon/epoxy matrix material.

Syntactic foams can be further subdivided into two-, three- or four-phase foams. The microstructure of a two-phase foam has only the polymer binder and hollow microspheres (see Fig. 7**a**). Note that there is enough binder phase to fill the volume between microspheres. In contrast, in a three-phase material there is not enough binder volume to fill the spaces between microspheres (Fig. 7**b**). The voids in the binder constitute the third phases. Of course, fibers can be added to make the fourth constituent in the composite foam (Fig. 7**c**).

A schematic of the processing of a syntactic foam by mixing carbon microballoons in a BMI polymer binder is shown in Figure 8. Short fibers can be added along with the microspheres. The addition of fibers can lead to an increase in mechanical properties, but good dispersion in the binder can be difficult (5–13). Figure 9**a** shows an optical micrograph of syntactic foam consisting of carbon microballoons and a small amount of BMI resin, while Figure 9**b** shows a higher magnification SEM micrograph wherein individual microballoons can be distinguished. The volume fraction of resin in this syntactic foam is about 8%.

Syntactic foams are an attractive design option because they are relatively simple to make. Since the microballoons are hollow, the voids are inherently present and all that is required is to mix the microballoons into the desired polymer matrix. Phenolic microballoons, produced by Asia Pacific Microspheres, and Glass

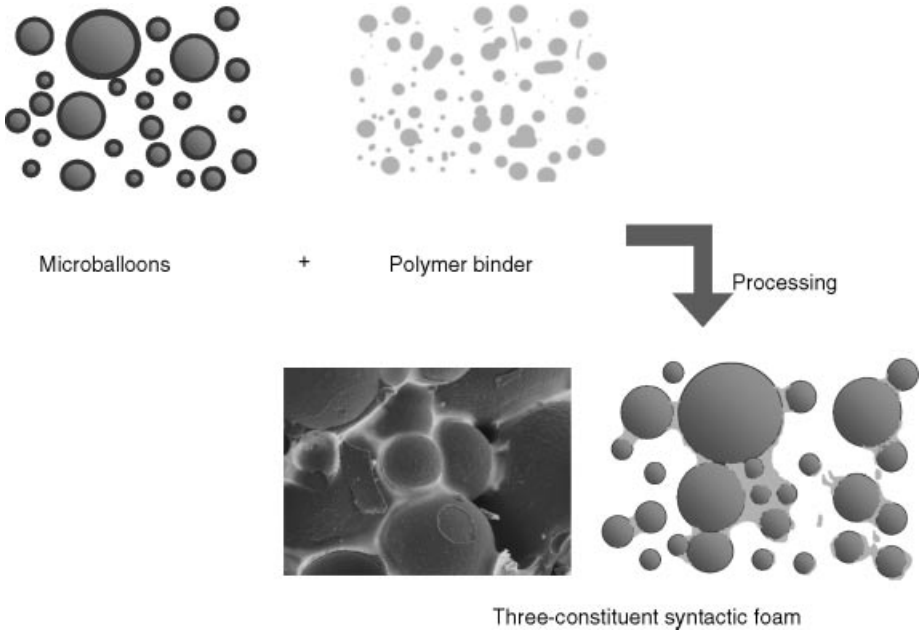

Fig. 8. Schematic of the construction of a three-phase syntactic foam (14).

Microbubbles, produced by 3M, are examples of microballoons that are readily available commercially.

Cell Size. The cell size is an important microstructural parameter. Properties of composite foam depend on the cell size. Typically, one examines the cell structure in two-dimensional micrographs. The average diameter of a circular segment, d, can be obtained by taking the average of nominal cell diameters in a given micrograph. It is important to recognize that the average spherical diameter D is greater than the average circular segment diameter d obtained from a

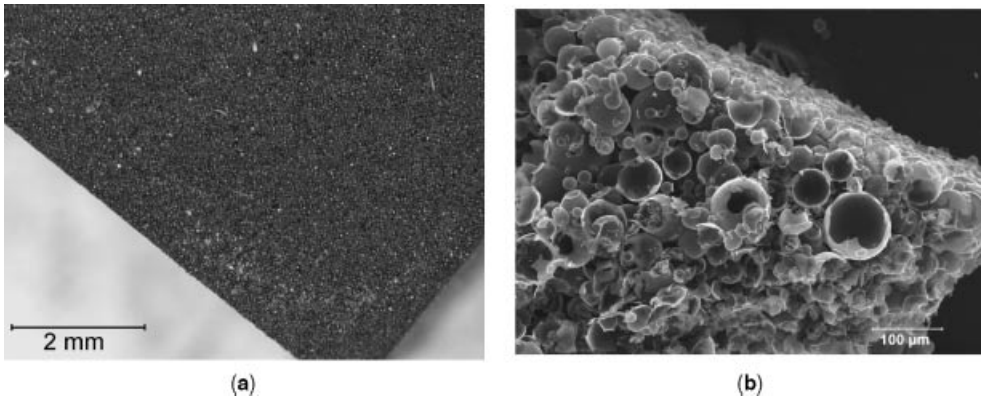

Fig. 9. (**a**) Low magnification optical micrograph showing bulk structure; (**b**) SEM micrograph showing individual carbon microballoons/BMI syntactic foam (14).

two-dimensional micrograph. This is because the cells are randomly truncated along the depth. The ASTM standard D3576 gives the following expression relating d to D:

$$D = \frac{4d}{\pi}$$

It should be pointed out that three-dimensional images can be obtained by computer-tomography technique, which provides cell size and distribution in three dimensions.

Properties

Some foam characteristics are present in both a single-phase foam and a composite foam. For example, both can be classified as either closed-celled or open-celled. If there is material forming the cell wall then it is classified as a closed-cell foam, while an open-celled foam has a discontinuous cell face as shown in Figure 1. They can be rigid or flexible and come in a wide range of densities.

Density. The density of a composite foam material, ρ_f, can be related to the density of the constituents and the void volume fraction by a simple rule of mixtures equation:

$$\rho_f = \frac{m_1 + m_2 + m_3 + \cdots + m_i}{V_f}$$

where m is the mass of constituent 1, 2, 3 ... i, respectively, and V_f is the bulk volume of foam that can usually be measured directly or calculated by the following equation:

$$V_f = V_v + V_1 + V_2 + V_3 + \cdots + V_i$$

where the subscript "v" indicates void and the other symbols are as indicated above.

Because, in a syntactic foam, the reinforcing microballoons can have a wall thickness that varies from batch-to-batch, one can achieve a fixed density foam with various volume fractions of microballoons. The tap density of microballoons that have been made from the same material is an indirect measure of the wall thickness. Assuming that the particles arrange into the same packing factor (settle to the same volume fraction), the wall thickness increases as the tap density increases. Additionally, average dimension of microballoons and ratios of wall thickness to radius can be inferred. Despite the comparative nature of the tap density test, it is an important technique to characterize microballoons and using it can provide an extra degree of freedom in designing syntactic foams. It is the authors' observation that phenolic microballoon manufacturers can control the tap density to ± 0.002 g/cm^3.

Relative Density. One very important parameter in regard to any kind of foam is its *relative density* ρ_r, which is defined as the ratio of the foam density ρ_f

to the theoretical density of the solid material, ρ_s:

$$\rho_r = \frac{\rho_f}{\rho_s}$$

As the relative density ρ_r of the foam increases, its cell walls become thicker. According to Gibson and Ashby (15), above a relative density of about 0.3, there occurs a transition from an open-cell foam to a closed-cell foam. In engineering practice, the parameter relative density, ρ_r, becomes very useful because it is easy to determine:

$$\rho_r = \frac{\rho_f}{\rho_s} = C\frac{t}{D}$$

where ρ_f is the density of the foam, ρ_s is the density of cell wall material, C is a constant, t is the cell wall thickness, and D is the cell diameter. Almost all properties of foam are affected by and are a function of its relative density. Typically, the stiffness and strength increase with increasing relative density.

In the case of a syntactic foam, at a constant volume of fraction of microballoons, a higher relative density implies a higher aspect ratio (wall thickness/diameter) of the microsphere.

Dielectric Constant. The dielectric constant of a syntactic foam generally decreases linearly with decreasing relative density. Some silica microspheres have very low dissipation factors, which makes them suitable for low loss syntactic foams suitable for applications in radomes. Radomes require minimum absorption of electromagnetic energy (16).

Elastic Constants. A number of expressions are available in the literature giving the elastic constants of the foam in terms of the elastic constants and volume fractions of the constituents. Following expressions are due to Nielsen (17):

Shear modulus of the foam,

$$G_F = \left(\frac{1 + AB\phi_2}{1 - B\psi\phi_2}\right)G_1$$

where

$$A = \frac{(7 - 5\nu_1)}{(8 - 10\nu_1)} \quad B = \frac{\left(\frac{G_H}{G_1} - 1\right)}{\left(\frac{G_H}{G_1} + A\right)} \quad \psi \approx 1 + \left(\frac{(1 - \phi_2)}{\phi_M^2}\right)\phi_2$$

In these expressions, G is shear modulus, a and b are respectively the inner and outer radii of the microballoon, ν is Poisson's ratio, ϕ_m is the maximum packing factor that can be achieved, and ϕ_2 is the volume fraction of microballoons. The maximum packing factor, ϕ_m, is about 62.5% (18). The subscript H, S, F, and 1 indicate the hollow sphere, the solid sphere, the foam, and the polymer matrix, respectively. The shear modulus can be converted to Young's modulus by

the following equation valid for isotropic materials:

$$E = 2G(1 - \nu)$$

In general, such equations due to Nielsen or others show a decrease in the modulus or stiffness of the foam with increasing amount of microspheres, assuming a constant wall thickness of the microspheres.

The above analytical model will give a reasonable approximation when designing a syntactic foam material. There are examples of more complicated numerical models available throughout literature if more detailed analysis is desired. We refer the reader to Gibson and Ashby (15) for analytical relationships for elastic properties for both open- and closed-celled foam that are based on the properties of the unfoamed material and relative density of the foam.

Stress–Strain Behavior in Compression. A representative schematic of the compressive stress–strain behavior of an elastic–plastic foam under uniaxial compression is shown in Figure 10. The curve shows a series of regimes. The first regime occurs at small strains and is characterized by elastic bending of struts. The long plateau region at medium strains is plastic yielding of the material. The final regime is densification, where the slope of the stress-strain curve increases rapidly. In this region, cells are collapsing, ie the top of the cell is touching the bottom. In this type of foam (eg polyurethane) full densification can occur and the slope of the stress–strain curve will approach the modulus of the unfoamed material. In practice, mechanical response of such a part in service depends on the amount of compression the part undergoes when installed.

When a brittle composite foam is deformed in compression, the following common features are observed:

(1) Density changes when a cellular material is deformed.
(2) Plastic deformation occurs, which involves successive collapse of cells in localized bands.

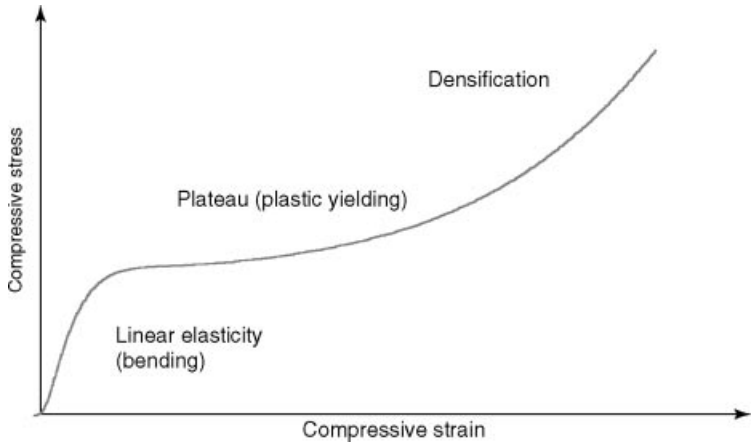

Fig. 10. Generalized compressive response of an elastic–plastic foam.

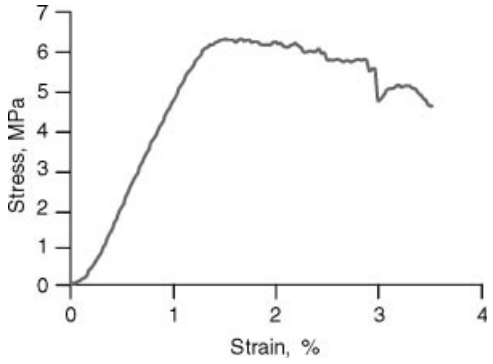

Fig. 11. Compressive behavior of a crushable carbon microballoons/BMI syntactic foam (14).

(3) Stress drops and becomes almost constant when only few noncollapsed cells are left.

An example of crushable syntactic three-phase foam (microballoons undergo crushing) compressive stress versus apparent strain of a carbon microballoon/BMI, is shown in Figure 11. After an initial elastic compression, the microspheres in the foam start fracturing and the stress–strain curve starts to decrease and shows characteristic dips corresponding to isolated crushing of microballoons. Eventually, enough microballoons are broken along a section so that exfoliation or spalling occurs, which is indicated by the large dip in the curve. Continued loading in compression leads to a gradual decrease in the curve and loading of the fractured material that formed the walls of the microballoons.

The behavior of the same syntactic three-phase foam as above under compressive cyclic loading is shown in Figure 12. In the elastic regime, the loading and unloading curves coincide, as expected, and no permanent set or damage results. This figure also shows that when unloaded after attaining the crushing strength

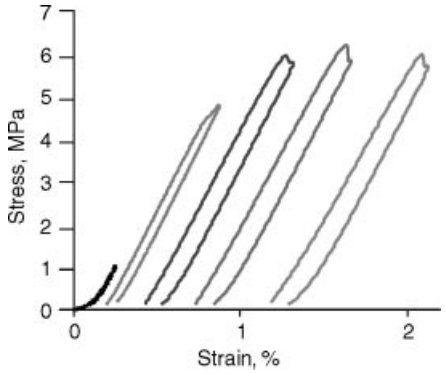

Fig. 12. Mechanical response of a crushable syntactic foam under compressive cyclic loading showing permanent damage on (——) cycle 1,770 MPa; (▬▬) cycle 6,700 Mpa; (▬▬) cycle 11,626 MPa; (▬▬) cycle 13,612 MPa; (▬▬) cycle 17,597 MPa.

of some microballoons, there results a permanent damage. The magnitude of this permanent damage stabilizes with continued cycling.

The strength of two-phase syntactic foam composites will decrease with decreasing content of hollow microspheres. This is due to two factors: a decreased load bearing cross-sectional area and a stress concentration effect of the microporosity. One can combine these effects in the following form (19):

$$\sigma_1 = k \cdot \sigma_m(1 - V_v) \tag{1}$$

where σ_1 is the strength of the foam, σ_m is the strength of the matrix, V_v is the volume fraction of the porosity or voids, and $1/k$ is the stress concentration factor. This expression should give a reasonable approximation when the strength of the microballoon is negligible compared to the matrix surrounding it and applies to two-constituent syntactic foams. The reinforcing effect of these microballoons can be expressed as

$$\sigma_2 = (V_{mb} - V_v)\sigma_{mb} \tag{2}$$

where σ_2 is the strength contribution due to the microballoons, V_{mb} is the volume fraction of the material that forms the microballoons, V_v in the volume fraction of the voids, σ_{mb} is the strength contributed by the material that forms the microballoons. Combining equations 1 and 2, we can write

$$\begin{aligned} \sigma_c &= \sigma_1 + \sigma_2 = k \cdot \sigma_m(1 - V_v) + (V_{mb} - V_v)\sigma_{mb} \\ \sigma_c/\sigma_m &= k(1 - V_v) + (V_{mb} - V_v)\sigma_{mb}/\sigma_m \\ &= k - (k - V_{mb}\sigma_{mb}/\sigma_m)V_v \end{aligned}$$

This expression indicates the expected trend of decreasing strength with increasing void volume fraction in the composite foam. Okuno and Woodhams observed reasonably good agreement with experimental results when an appropriate choice was made of the stress concentration factor k.

In three-phase composite foams, shown in Figure 9**b**, the compressive strength and modulus increase with increasing content of microballoons. In three-phase syntactic foams, where very little polymer binder is present, the strength of the microballoon can contribute to the syntactic foam strength. This is in contrast to a two-phase syntactic foam, where increasing microballoon content results in a decrease in density by the addition of microballoons. Unlike the two-phase foam, in a three-phase syntactic foam an increase in the volume fraction of microballoons will result in a decrease in the interstitial voids and increase in mass because of the increase in total cell walls.

Flammability, Smoke Density, and Toxicity. Along with the conventional mechanical and physical characteristics (stiffness, strength, toughness, density, thermal conductivity, etc), one needs to consider flammability, smoke density, and toxicity of the foam. This set of characteristics is commonly referred to as FST. By far, one of the most important applications of syntactic foams is for building material in deep-sea vehicles (see Fig. 3). Before the introduction of syntactic foams in subsea applications, liquid paraffins lighter than water, such as gasoline, were used to provide the needed buoyancy. Fire hazards, poor

compressive strength, and thermal contraction are the main disadvantages of such materials (20).

Today, using syntactic foams can result in significant improvement in mechanical performance while retaining FST properties comparable to conventional polyurethane foam.

Applications

An important point to recognize is that in most cellular materials, there is always a trade-off between the requirement of a low density and strength required to bear a certain load. This is particularly true for applications involving buoyancy where syntactic foams have been in use since the 1970s. With increasing depth in water, the hydrostatic pressure increases. This requires a syntactic foam with higher strength. The additional strength is obtained by increasing the density of the foam, which means a loss in buoyancy. Below, we give some examples of applications of composite foams.

Buoyancy-Related Subsea Applications. Offshore exploration of oil and gas requires insulated pipelines in order to prevent formation of waxes and hydrates (21). If the temperature of the pipeline drops too low, the heavy fractions in the crude oil can turn waxy. Natural gas can form hydrates. Both of these products can result in the clogging of the pipeline. Syntactic foams are suitable insulating materials for such buoyancy-related applications in deep water because of their higher compressive strength compared to that of conventional foam. Examples of such applications include buoys and floats, and submarine void filler for encapsulating instruments.

Two characteristics that make syntactic foam an efficient buoyancy material are high compressive strength and low density. The low density of the syntactic foam allows buoyant lift to be designed into the insulation system. As an example, Cuming Microwave Corporation makes a series of syntactic foams (low loss dielectric as well as treated lossy materials), which are ultralight and high strength and can be adjusted to specifications. These materials are available in different forms: uncured, pack-in-place, cured sheet, and molded to shape. The pack-in-place variety has the consistency of a snowball, which can be readily packed into complex shapes.

Elastic Compression. Any syntactic foam under hydrostatic pressure will undergo some elastic compressive strain. This will result in a loss of some of its buoyancy. We can write the following relationship from the theory of elasticity:

$$\sigma_{\mathrm{p}} = K \frac{\Delta V}{V}$$

where σ_{p} is the hydrostatic pressure, K is the bulk modulus, and $\Delta V/V$ is the change in volume per unit volume, ie the volumetric strain of the material (in the present case, it is the syntactic foam). For an isotropic material, there exists the following relationship among the bulk modulus K, Young's modulus E, and

Poisson's ratio ν:

$$E = K/[3(1-2\nu)]$$

A typical value of Poisson's ratio for a syntactic foam is 0.15, which would give the Young's modulus to be about $2K$, or K is about $E/2$. Typically, the upper limit on volumetric strain under service conditions is between 1 and 2%, which corresponds to about 65–70% of the critical stress corresponding to the onset of collapse or crushing of foam. This loss of buoyancy will be instantaneous upon the application of hydrostatic pressure.

Water Absorption. Typically, the surface of syntactic foam has microscopic cracks and voids. When immersed in water, they will absorb water because of hydrostatic pressure. Of course, even ambient moisture will get absorbed. The weight gain due to moisture absorption will result in a long-term loss of buoyancy. Typical damage to syntactic foam material is similar to that in fiber-reinforced polymers composites: swelling and debonding accompanied by a degradation in mechanical properties (11,22).

Insulation. Micrometer-sized pores in composite foams, together with their extremely low density, minimize conductive heat transfer. Addition of a small amount of fibers provides some rigidity to the foam. It is easy to visualize that a structure containing billions of cells will block convection and reflect heat energy back to its source. Excellent thermal insulating properties make such composite foams very useful in civil construction as well as in refractory applications.

EMI Shielding. Syntactic foams based on carbon microballoons or silver-coated ceramic microballoons can be used for shielding against electromagnetic interference (EMI) (23). Such syntactic foams can provide the requisite electrical conductivity at very low density, thus avoiding the weight penalty imposed by conventional EMI shielding techniques.

Biomedical Applications. Although applications of composite foams in biomedical area are not commercialized as yet, there is very active research into these materials as porous bioresorbable composite foams for applications as scaffolds in tissue engineering. A thermally induced phase separation technique was used to prepare foams of poly(lactide-*co*-glycolide) (PLGA) that contained up to 50 wt% bioactive glass particles. These composite foams showed well-defined, oriented, and interconnected porosity. An interesting result of this work was that they could control the *in vitro* degradation behavior of PLGA foam composite scaffolds by tailoring the concentration of bioactive glass (24).

Conclusions

(1) Composite foams, a whole new class of materials, are natural extensions of conventional foams.

(2) Additional constituents are incorporated in the formulation of composite foams to improve their overall performance/properties.

(3) Syntactic foams with appropriate control of the size, morphology, and distribution of microballoons can provide a wide range of properties.

(4) Addition of particles or fibers (long or short) provides another microstructural parameter to improve strength and damage tolerance of composite foams.

(5) Composite foams find a wide range of applications: offshore exploration of oil and gas, shielding against electromagnetic interference (EMI), thermal and acoustic insulation, damping, cores in sandwich construction, etc.

COMPOSITE MATERIALS

Introduction

Composite materials are made by combining two or more materials to give a unique combination of properties. Many common materials are indeed "composites," including wood, concrete, and metals alloys. However, fiber-reinforced composite materials differ from these common materials in that the constituent materials of the composite (eg the two or more phases) are macroscopically distinguishable and eventually mechanically separable. In other words, the constituent materials work together but remain essentially in their original bulk form (apart from the thin hybrid interface between the phases).

The main component of a composite is the matrix material. The reinforcement (qv) can be fibers, particulates, or whiskers. The fibers can be continuous, long, or short. In advanced composites, the fibers (ie the reinforcing phase) are present as unidirectional strands or woven fabric and provide strength and stiffness to the composite. The matrix acts as a load transfer medium assuring rigidity and protects the fibers and the whole composite from environmental attack. Short chopped fibers and mat are used in nonstructural polymer matrix composites. In these cases the fibers provide comparatively less strength and stiffness to the composite.

Fiber-reinforced polymer matrix composites are the most common advanced composites. Early glass-fiber-reinforced composites resins were used in the 1930s to build parts of boats and aircraft. Since the 1970s, application of composites has widely increased owing to the development of new fibers such as carbon, boron, and aramids (see HIGH PERFORMANCE FIBERS). Thermosetting polymers such as epoxy, polyester, and urethane resins are, among the others, the most widely used matrices of advanced composites. (see THERMOSETS). In the 1980s the development of new, cost-effective thermoplastic polymers such as PEEK (poly-ether-ether-ketone) and PEI (Poly-ether-imides) allowed the development of a new class of high performance composites (see ENGINEERING THERMOPLASTICS, OVERVIEW; POLYIMIDES).

Thermosetting and thermoplastic matrix composites are in many ways superior materials compared to common metals and ceramic materials. Their reliability is confirmed by their large use in the aerospace industry. Mechanical advantages of polymer composites are expressed in terms of two main parameters (ie specific modulus and strength) reflecting the key role of density on the selection of high performance materials. The specific modulus E_s is defined as the ratio between the Young's modulus E and density ρ of the material. The other parameter, the specific strength (σ_s), is defined as the ratio of the ultimate strength σ_{ult} and the density

$$E_s = \frac{E}{\rho} \tag{1}$$

$$\sigma_s = \frac{\sigma_{ult}}{\rho} \tag{2}$$

The coefficient of thermal expansion (CTE) of composite structures can be made close to zero by selecting suitable materials and lay-up sequence. Dimensional stability is, in fact, one of the key requirements that many metals cannot satisfy (owing to their higher CTE) in aerospace applications. A CTE that can be tailored for a specific application gives rise to an increased amount of design flexibility with respect to common metals. In Table 1 the relevant thermomechanical properties of common and fiber-reinforced composite materials are reported. The last three columns of Table 1 explain why specific stiffness, strength, and CTE are, among the others, the key parameters in the selection of composite materials in aerospace applications where both performance and cost are a concern. High specific performance of composite materials allows weight saving, with consequent increase in payload and fuel savings. Composite materials can be highly fatigue- and corrosion-resistant, with enhanced life and reduced maintenance costs. The following drawbacks represent limits in using polymer-based composites:

(1) The high cost of fabrication of composites for aerospace applications is still a critical issue. Today most of the effort and investment in this area is devoted toward improving processing and manufacturing techniques in order to lower costs. Medium performance composites, on the contrary, can be made using manufacturing techniques such as sheet molding compound (SMC), structural reinforced injection molding (SRIM), and resin transfer molding (RTM), in which both the cost and the production time have been consistently optimized to compete within the automotive industry.

(2) Unlike metals, fiber-reinforced composites are anisotropic, that is, their properties depend on both the fiber orientation and the lay-up sequence in the laminate. In-plane quasi-isotropic materials can, however, be made by opportune selection of a lay-up sequence (eg a $[0/\pm 45/90]_{2s}$ lamination sequence realizes in-plane equivalent properties from an engineering point of view) or when continuous random mats of fibers are utilized as the reinforcing system (this is the case in parts obtained by SRIM or RTM). In both cases, however, the fibers remain perpendicular to the third direction, and it is this drawback that renders the design procedures far more complicated and intensive than those normally utilized for isotropic materials. In other words, while monolithic materials such as aluminum require only two elastic constants to establish the stress–strain relationship in each body point for a given system of forces acting on it, composite materials require many more elastic constants. For example, in unidirectional composites (where all the fibers lay in one direction) under plane stress conditions (no out-of-plane loads) four elastic constants are required. In addition, the mechanical characterization of a composite structure is far more complex than that of a metal structure if one considers that the techniques for the evaluation and measurement of some composite properties, such as fracture toughness and compressive strength, are still debatable.

(3) The reinforcing fibers in composites offer unique properties but create complications in recycling. Thermoplastic composites have the potential of primary and secondary recycling since the reprocessing of waste can result in a product with the same or comparable properties, whereas thermoset

composite scraps usually are tertiary recycled (in order to recover the fibers so they can be reused in molding compounds) or essentially burned off.

(4) Repairing composite parts is a very complex process and not always accessible.

(5) Most of the effectiveness of nondestructive techniques for the inspection of metal parts (such as eddy currents, X-ray) is lost when it comes to detection of flaws and cracks in composite structures, unless appropriate modifications are made to the instrumentation hardware or the inspection procedure. Ultrasound, laser (shearography), and acoustic emission techniques are usually preferred for inspecting the crack initialization (see NONDESTRUCTIVE TESTING).

Many of the above drawbacks forced the composite industry to focus significant effort on the development of manufacturing procedures in which the fabrication process is controlled with the highest level of real-time monitoring tools. It is well established that the quality of a composite structure depends almost completely on the process quality. Controlling the manufacturing process depends, first of all, on a deep knowledge of the overall physical and chemical changes occurring within the part. Mathematical modeling then provides estimates of optimum process parameters for a given manufacturing process to produce a high quality product.

Composite Manufacturing Techniques

Composite parts are made using either thermoset or thermoplastic resins with some form of reinforcements. Techniques for manufacturing polymer matrix composites are covered in Composites, Fabrication (qv). Filament winding and robotic winding are used for making pipes and tanks. Pultrusion is used for low cost high volume productions. Autoclave processing is used when high quality panels and structures sometimes having complex shapes are required. RTM is used extensively to make small and large complex structural parts in a cost-effective manner using low cost tooling. Compression molding processes are widely used in the automotive industry for high volume production capabilities and injection molding (qv) is adopted when the production rate is a critical issue, mainly for consumer and automotive applications.

Filament winding consists of drawing resin-impregnated fibers that are wound over a mandrel. Winding patterns are decided at the design stage depending on the desired properties of the product. The winding process of a high quality pressure vessel is shown in Fig. 1.

Pultrusion is a simple, continuous process in which resin-impregnated fibers are pulled through a die to make a part. During passage through the heated die resin-impregnated yarns consolidate due to the incoming cross-linking reaction. Objects with constant cross-section and smooth finish can be obtained.

Autoclave processing is used with prepregs with lay-up realized by automated means or by hand. The assembly is vacuum-bagged in order to minimize the presence of volatile substances (responsible for void/defect growth during the

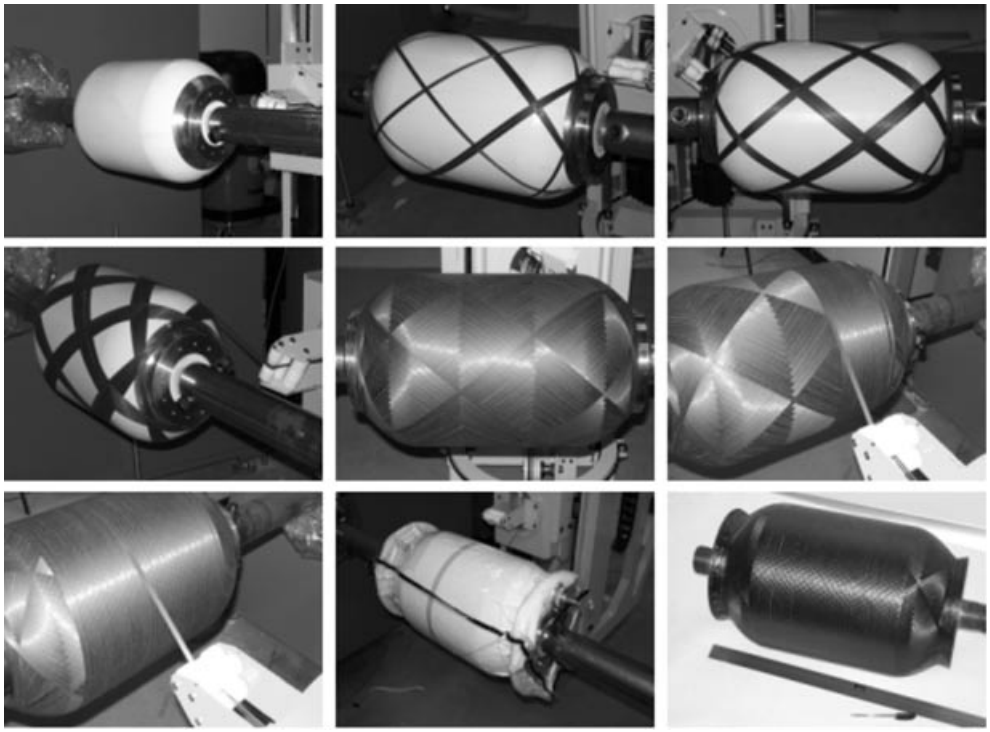

Fig. 1. Filament winding process of high composite pressure vessel. By courtesy of CIRA.

process) and placed inside an autoclave. After the process cycle, consisting, generally, of a sequence of heat and pressure inputs, the part is removed from the tool. It takes several hours generally to complete the process.

In RTM a low viscosity resin is injected under low pressure into a closed mold which contains the fiber preforms or fabrics used as reinforcements. RTM has gained increasing importance, because of its potential for making structural components (due to the use of continuous fibers) in a cost-effective manner.

Compression molding of sheet molding compounds (SMCs) or bulk molding compounds (BMCs) is typically used in the auto industry mainly because of the similarity to stamping technology. In the compression molding operation, the SMC is cut into rectangular shapes and "charged" on the bottom half of a preheated mold. The SMC covers only a part of the mold (between 30 and 90%) while the remaining surface is filled by forcing flow of the "charge" by pressure. When the mold is closed, lying down, and has a constant displacement rate (ie 40 mm/s) the upper half of the mold, the SMC, starts to flow inside the mold, filling the cavity. The molds are generally preheated to about 140–150°C.

Injection Molding (qv) has been generally used for thermoplastic materials for many years. Only during the last decade, because of the increasing demanding has it been considered and successfully applied in the thermoset industry. The mold injection, the subsequent cross-linking of the system, and the final demolding and expulsion of the part takes between 30 and 60 s; therefore this process is

particularly considered when very high volume production is requested. In some cases, using multiple-cavity molds for the consolidation of different element parts at the same time can further increase the production rate.

Many other techniques have been developed over the years. However, each manufacturing process consists of four basic steps, wetting/impregnation, lay-up, consolidation, and solidification, which in case of composites require low energy compared with those for traditional materials. In fact, composites do not have high pressure and temperature requirements for part processing as compared with metal. This is the reason why composite processing techniques such as those described above have the potential of producing complex, high strength, high stiffness, and near-net-shape structures. Therefore the applications of polymer matrix composites range from the aerospace industry to the sporting goods. Composites are the material of choice in space applications owing essentially to two factors: high specific modulus and strength, and dimensional stability. Graphite–epoxy composites are increasingly used in bicycles, sometimes allowing frames to consist of one lightweight piece, or in golf club shafts, using the saved weight in the head. Tennis and racquetball rackets with graphite–epoxy frames are now commonplace. The military aircraft industry has mainly led the use of polymer composites in structural applications while in commercial airlines the use of composites has been conservative because of safety concerns. The graphite–epoxy and aramid honeycomb tail fin of Airbus A310-300 is an example of using composites in the primary structure in commercial airlines. The weight of the tail fin was reduced by 300 kg, together with the number of parts, which decreased from 2000 to 100. Infrastructure applications of polymer composites include bridges—due to low weight, corrosion resistance, longer life cycles, and limited earthquake damage. The application of fiber glass in boats is well known even when hybrids of Kevlar–glass/epoxy are now receiving attention because of the improved weight savings, vibration damping, and impact resistance.

Today's automobile industry uses low amounts of composite parts owing to the unavailability of cost-effective manufacturing techniques. Nowadays about 8% of automobile parts are made of composites.

Process Modeling

During the fabrication process (eg RTM, autoclave, filament winding) a combination of pressure–temperature steps are applied with given histories in order to assure well-consolidated parts with minimum defects. The solidification or curing process involves a number of physical, chemical, and mechanical phenomena in the composite materials. Generally speaking, the formation of a structure due to cross-linking reactions or to the melting and consolidation of thermoplastic polymers is the macroscopic effect of heat and pressure inputs: in real terms continuous changes in degree of cure or crystallinity, gelation (the formation of an infinite polymer network as a consequence of chemical reaction) and vitrification (the passage from a molten/rubbery to a glassy state) occur. As a consequence of the above phenomena, the evolving chemical and thermal shrinkage give rise to the development of stress and strain within the part, whereas the presence

of volatiles in the form of residual plasticizing agents or unreacted resins can eventually induce void growth and resin–fiber debonding.

In all, thermal shrinkage, chemical shrinkage, time–temperature–degree of cure dependent resin properties, viscosity, and structural relaxation shrinkage are the matrix properties to control. Therefore, since the evolution of polymer properties is strongly influenced by processing history, each parameter has to be investigated at each stage of the manufacturing process. Moreover considering that the level of temperature reached during the manufacturing of composite parts does not affect the fiber content, investigations are almost always carried out on the polymer system matrix. Significant progress has been made in quantitatively evaluating process-related parameters such as mold shape, mold material and surface, void content, fiber volume fraction, lay-up sequence. However, considerable work remains to be done to account for constituent resin-related properties. In particular, when new resins are developed a number of experimental tests are necessary to completely characterize the resin (such as toughened epoxies) so as to perform a general analysis of the physical and chemical phenomena and to code it by mathematical tools.

Mathematical modeling of a manufacturing process provides a tool for the process control with minimum costs and high quality production. Typical aerospace manufacturing processes for composites are characterized by a two-step cure cycle. In such a cycle the temperature of the material is increased from room temperature to the first dwell temperature and this temperature is held constant for the first dwell period (~1 h); during this stage the material reaches the minimum value of viscosity to fill the mould and/or compact the whole system. The temperature is then increased again to the second dwell temperature and held constant for the second dwell period (~2–8 h). Post-cure reaction takes place during this second stage. Following this second dwell period the part is cooled down to room temperature at a constant rate or by air to allow the extraction from the mould. It is during the polymerization reaction that the strength and related mechanical properties of the composite are developed, together with incipient flaws (eg voids, resin–fiber debonding) and residual stresses.

The transient heat transfer phenomena induce peculiar property changes at each body point. In this respect, the temperature profiles and the chemorheological functions (viscosity, degree of cure/crystallinity) need to be included within the energy balance equation:

$$\rho C_{\mathrm{P}} \frac{\partial T}{\partial t} = \nabla(K \nabla T) + \rho \dot{Q} \tag{3}$$

where ρ is the density, C_{p} is the specific heat, t is the time, K is the thermal conductivity, and $\dot{Q}$ is the rate of heat generated either by the exothermic polymerization reaction in the case of a thermosetting matrix system or by the crystallization process for thermoplastic matrix.

From the micro-mechanical point of view, the process modeling strategies must consider simultaneous interplay of the following "intrinsic" factors: initial and boundary conditions in terms of pressure and temperature, fiber content and stacking, sequence of layers (ie ply-to-ply orientation), thermal shrinkage, chemical shrinkage, time–temperature–degree of cure dependent resin properties, and

structural relaxation shrinkage. The above factors can play a different role when an even more complex scenario arises for thick composite parts. Therefore a detailed analysis of temperature distribution during the process is crucial for the determination of the complex evolution of the properties at each material point of the composite part. A simple analogy could be made with metals in order to understand this complex scenario. The evolution of the structure for metals inevitably leads to a distribution of grain size as a result of the different temperature profiles experienced during the forming process. In the case of polymeric matrices, the same assumption can be reasonably made considering that each material point will undergo a completely different temperature profile, owing to the relative position occupied in respect to the heat source. For this reason, a thermosetting system matrix necessarily presents a distribution of polymerization reactions at each body point, according to the experienced thermal histories; in the case of thermoplastic systems, because of the strong dependency of the crystallization process upon the temperature profile, a distribution of grain size through the thickness (ie skin–core fine to coarse structure) is obtained. The temperature distribution can be suitably determined using finite element analysis (FEA) software; the temperature at a given point in the structure depends on the boundary and initial conditions, as well as the materials' properties evolution. In fact, as the evolution of the structure is highly dependent on the thermal history, within a thick composite different material properties arise at each material point.

The correct analysis then would be an investigation of the temperature distribution with appropriate boundary conditions for the determination of real temperature profile as a function of the material point. This analysis would be coupled with a structural analysis, which takes into account the whole set of constraint conditions imposed by the mould, as in the case of RTM, or any other tool for a different manufacturing process. Figure 2 illustrates the flow-chart of a generic process modeling procedure.

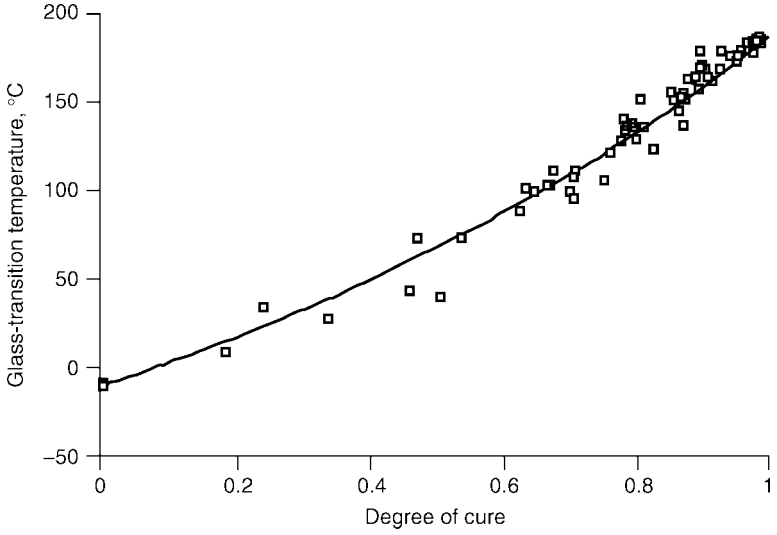

Fig. 2. Experimental data for glass-transition temperature and DiBenedetto model predictions: □, experimental data; ———, fitting model.

Different material parameters need to be quantified to be able to perform the thermostructural analysis. The complex interactions of the different phenomena occurring during the manufacturing process could be schematized as follows.

(1) Both crystallization and polymerization reactions are temperature-activated phenomena, allowing the transformation of the system from a liquid-like to an almost solid-like material. The structure evolution can be suitably monitored by a degree of conversion parameter, which follows an analytical kinetics model.
(2) Thermal (specific heat, thermal conductivity) and viscoelastic properties of the material change during the process owing to both temperature variations (as for traditional materials) and level of conversion.
(3) Variation of the specific volume can be originated by three different phenomena:
   a. thermal expansion (or contraction) due to positive (negative) temperature change,
   b. chemical/physical shrinkage due to the densification (polymerization/crystallization) of the material according to the conversion level, and/or
   c. contraction due to the thermodynamic instability associated with the nonequilibrium kinetics of glass transition (structural relaxation).

The experimental evaluation and the modeling of each contribution still represent a difficult task for many researchers, and at the same time it is the main issue for the correct prediction of

(1) the residual stress formation and warpage effect in thick composite parts
(2) voids and flaw formation, and
(3) resin flow behavior dependent compaction and consolidation feature.

Coupled with the energy equation along with the specific initial and boundary conditions, the mathematical description of the above factors (through the use of suitable submodels for a given manufacturing process) allows the complete analysis of a generic manufacturing process, providing at the same time a fundamental "tool" for the production of high quality parts.

Cure Kinetics and Glass-Transition Model

As stated above, during the cure, at each level of conversion, a thermosetting material could be assimilated to a completely new material with specific thermomechanical properties. Then, the possibility of following with a monitoring variable the level of conversion reached by the system during the manufacturing process represents an important issue.

Thermal analysis provides useful information upon which to construct an adequate kinetics model under both isothermal and dynamic temperature

conditions. The mathematical model selected on the basis of the experimental data generally represents the primary component in studies on the optimization of thermoset molding processes (resin transfer molding, reaction injection molding, prepreg cure, etc). Reliable methods are required to predict the degree of conversion and to control the evolution of the exothermic heat of reaction. Correct kinetics models are also essential to predict the evolution of the structure under more complicated temperature profiles; or to correlate the changes in thermal and mechanical properties of the neat resin through all the manufacturing processes. Thus, the knowledge of the level of conversion of the polymer matrix is fundamental information to monitor the evolution of properties. Curing raw data needed to implement the kinetics models can be obtained, by nearly standardized procedures, through isothermal and dynamic differential scanning calorimetry (DSC) tests.

There are essentially two kinetic models used to describe thermoset-curing reactions.

(1) *Phenomenological Models* (macroscopic level) assume that there is an overall order of reaction and fit this model to the experimental kinetic data. This type of model provides no information about the kinetic mechanism of the reaction and is predominantly used to provide models for industrial applications.
(2) *Mechanistic models* (microscopic level) are derived from a rather complex analysis of the individual reactions occurring during the cure, and require detailed measurements of the concentrations of reactants, intermediates, and products. Mechanistic models are much more complex than empirical models, but are not restricted by changes in the composition of the system.

Despite the efforts that have been made in recent years, in the exploitation of kinetic models for polymerization of thermosetting resin systems (see Table 1), two main problems still arise:

(1) no general model for the cure mechanisms of all systems is available (although many authors in the past have already searched for a generalized model), and
(2) in many cases, for a given resin system, different models are needed to describe isothermal and nonisothermal experimental condition.

The first problem still represents a severe limitation on the industrial application of any monitoring or control system that requires significant prior knowledge of the cure kinetics, which will affect either the time or cost of production. Acquired thermal data are generally fitted with chose kinetics equation to establish the best set of kinetics parameters to predict the conversion evolution for a generic temperature history at every location.

In Table 2, the most used kinetic equations are reported. Advances in the description of cure kinetics were recently used to model the cure of an RTM epoxy

Table 2. Mathematical Models for Cure of Resins

Kinetic model	Expression	Notes
First Order (1)	$\frac{d\alpha}{dt} = A \exp\left(\frac{E_a}{RT}\right)(1-\alpha)$ $k = A \exp\left(\frac{E_a}{RT}\right)$	k = Rate constant E_a = Activation energy A = Rate coefficient
nth order (2–4)	$\frac{d\alpha}{dt} = k(1-\alpha)^n$	n = Reaction order
Polynomial (5)	$\frac{d\alpha}{dt} = k(a_0 + a_1\alpha + a_2\alpha^2)$	a_0, a_1, a_2 = Constant
Autocatal. −1 (6,7)	$\frac{d\alpha}{dt} = (k_1 + k_2\alpha^m)(1-\alpha)^n$	n, m = Reaction orders k_1, k_2 = Rate constants

resin system by Karkans (11). The kinetics equation used can be stated as

$$\frac{d\alpha}{dt} = k_1(1-\alpha)^{n_1} + k_1\alpha^{n_2}(1-\alpha)^{n_1} \tag{4}$$

where k_1 and k_2 are kinetic reaction rate constants, having an Arrhenius temperature dependence.

$$K_{iT}(T) = k_i \exp\left(-\frac{E_i}{RT}\right) \tag{5}$$

and n_1, m, and n_2 are the model parameters and E_i ($i = 1, 2$) the activation energy.

According to the Rabinowitch theory (12) the reaction is driven by two parallel phenomena, the chemical mechanism and the diffusion-controlled mechanism, as

$$\frac{1}{k_i} = \frac{1}{k_c(T_c)} + \frac{1}{k_d(\alpha, T_c)} \tag{6}$$

where T_c is the curing temperature and k_d is the rate of the diffusion-controlled mechanism based on free volume models as proposed by Simon and Gillham (13)

in the following from:

$$k_d(T) = k_{d0} \exp\left(-\frac{b}{f}\right) \tag{7}$$

In the above equation b is an adjustable parameter to achieve a suitable fit, while the parameter f encapsulates the driving force of the diffusion-controlled mechanism by means of the Doolittle (14) equation, to model the free volume as follows:

$$f(\alpha) = (4.8 \times 10^{-4})\,[T_c - T_g(\alpha)] + 2.5 \times 10^{-3} \tag{8}$$

The diffusion-controlled mechanism occurs during vitrification in the latter stage of the reaction. It is obvious that for a chemical reaction to occur, reactive groups are required to be close to each other and also to be orientated so that eventually the cross-link can be formed. In the early stages of the cure, when the material is very much in a liquid state, the rate of cure is predominantly controlled by chemical kinetics; this essentially means that in the "reaction zone" the temperature of the system is capable of activating a reaction between monomers. Since these processes are very fast owing to the short characteristic times of the liquid state compared to the time of experimental observations, the rate coefficient for the reaction is constant at constant temperature, hence the validity of Arrhenius-type analysis. Theoretical models of this stage of the cure have been extensively discussed by Mita and Horrie (15) using a reptation theory model, and by Rozenberg (16), who also tried to determine the topological area of the reaction associated with reactive groups that are isolated within the gelled structure. Experiments have demonstrated that analytical methods are not sensitive enough to detect these unreacted groups and for this reason it is not possible to evaluate their concentration during the final stages of the curing process. It is clear then, that the overall reaction rate cannot be a function of the temperature alone, but that a dependency on a structural parameter has to be included, which at certain isothermal temperatures will lower the reaction rate, limiting the extent of the reaction.

The glass-transition temperature can be regarded as a suitable structural parameter for following the progressive evolution of the cross-linked system in case of diffusion-controlled mechanism; therefore, a suitable model is needed. The evolution of the glass-transition temperature is modeled according to a widely accepted DiBenedetto equation (17), stated as follows:

$$T_g(\alpha) = \frac{(1-\alpha)T_{g0} + \lambda\alpha T_{g\infty}}{(1-\alpha) + \lambda\alpha} \tag{9}$$

where T_{g0} and $T_{g\infty}$ are the glass-transition temperatures for the uncured and fully cured resin, respectively; λ is the adjustable parameter for a given resin system. Figure 3 reports the experimental determinate values of the glass-transition temperature along with the found model predictions.

Most of the time, the complete kinetics model can result in a multiparameter model characterized by nonunique set of best parameters. Therefore, reliable

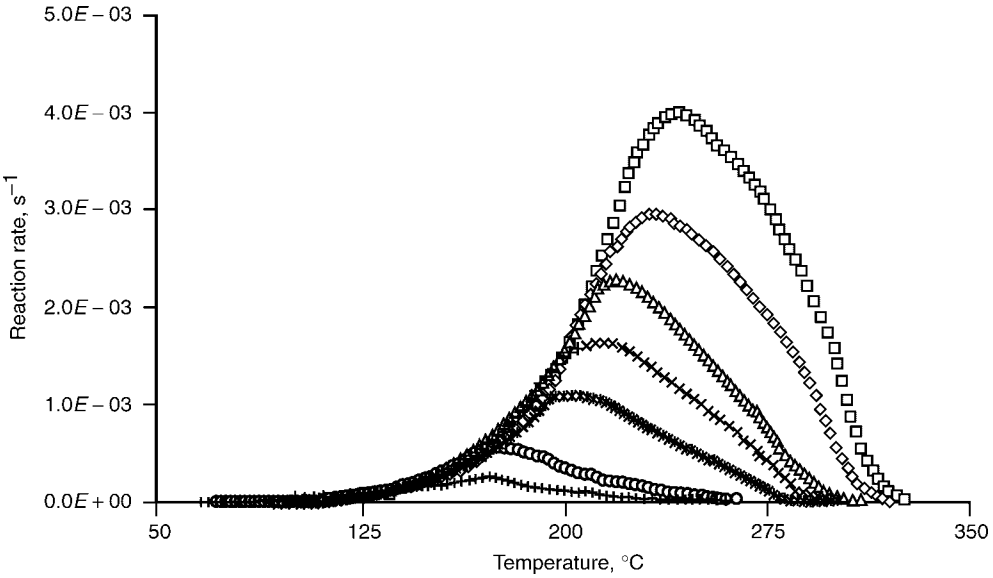

Fig. 3. Experimental reaction rate profiles obtained by DSC scans at different heating rates: □, 20°C/min; ◇, 15°C/min; △, 10°C/min; ×, 7.5°C/min; —×—, 5°C/min; ○, 2°C/min; +, 1°C/min.

fitting techniques based on nonlinear least square fitting algorithms are generally required to determine a suitable set of kinetic parameters. Along with traditional techniques, novel programming algorithm techniques, recently widely used to solve complex problems of optimization in the area of industrial engineering, are being used for kinetics model definition. Appreciable results have been achieved using a hybrid algorithm in the case of a complex empirical model characterized by 14 fitting parameters. This two-stage fitting procedure was implemented considering an "evolutionary type" algorithm (genetic algorithm) to identify the most probable region of the minimum for the least square function followed by a traditional non-linear least square method (ie Lavenber–Marquardt) to determine the precise value of each fitting parameter.

Experimental reaction rate profiles as obtained by thermal analysis tests are reported in Figure 4 for different temperature rates. Cure conversion profiles along with kinetics model predictions, respectively, for dynamic and isothermal conditions are given in Figures 5 and 6.

Shrinkage

Thermal Shrinkage. As for traditional materials, temperature variations during the manufacturing process are associated with local thermal expansion or contraction depending on the sign of the change. For thermosetting systems, it is reasonable to assume that the lower degree of cure leads to a higher mobility of the evolving cross-link structure compared with the fully cured state. Moreover, the content of free volume frozen within the structure will necessarily affect the dimensional stability of the system because of the temperature variation during

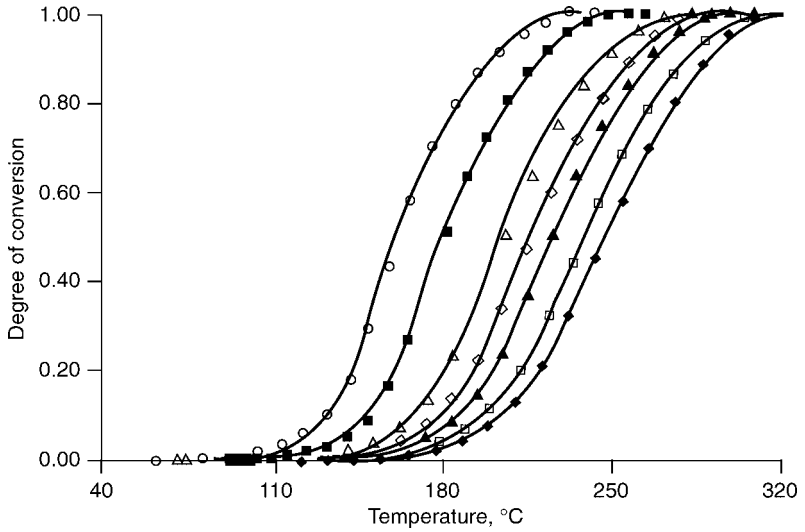

Fig. 4. Experimental matrix conversion profile and model predictions at different dynamic heating rates: ◆, 20°C · min (Exp); □, 15°C · min (Exp); ▲, 10°C · min (Exp); ◇, 7.5°C · min (Exp); △, 5°C · min (Exp); ■, 2°C · min (Exp); ○, 1°C · min (Exp) ———, fitting.

the processing. The effects of volume variation related only to temperature change are known as *thermal shrinkage*.

The evolving structure of the polymeric system can be considered as a "novel" material at each degree of cure as different thermo-mechanical properties are identified. Therefore, coefficients of thermal expansion are necessarily varying with

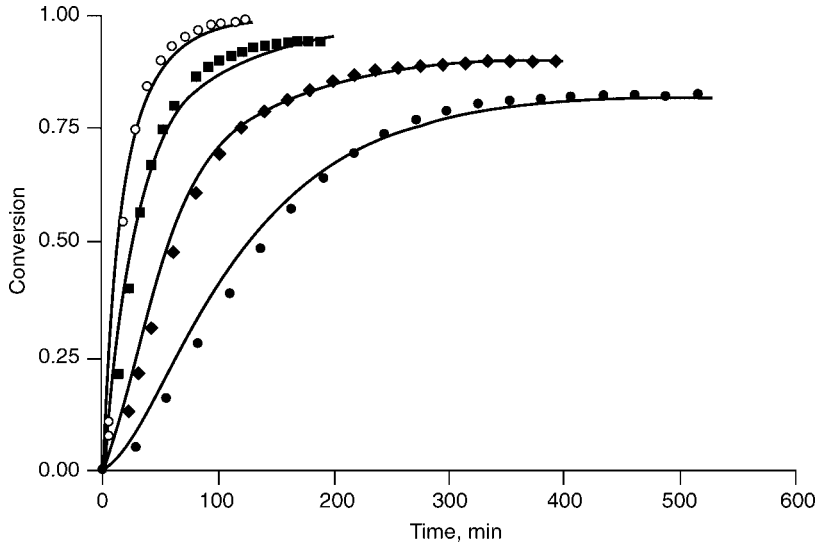

Fig. 5. Experimental matrix conversion profiles at different isothermal temperatures: ———, fitting; ○, 180°C (Exp) ■, 160°C (Exp) ◆, 140°C (Exp); ●, 120°C (Exp).

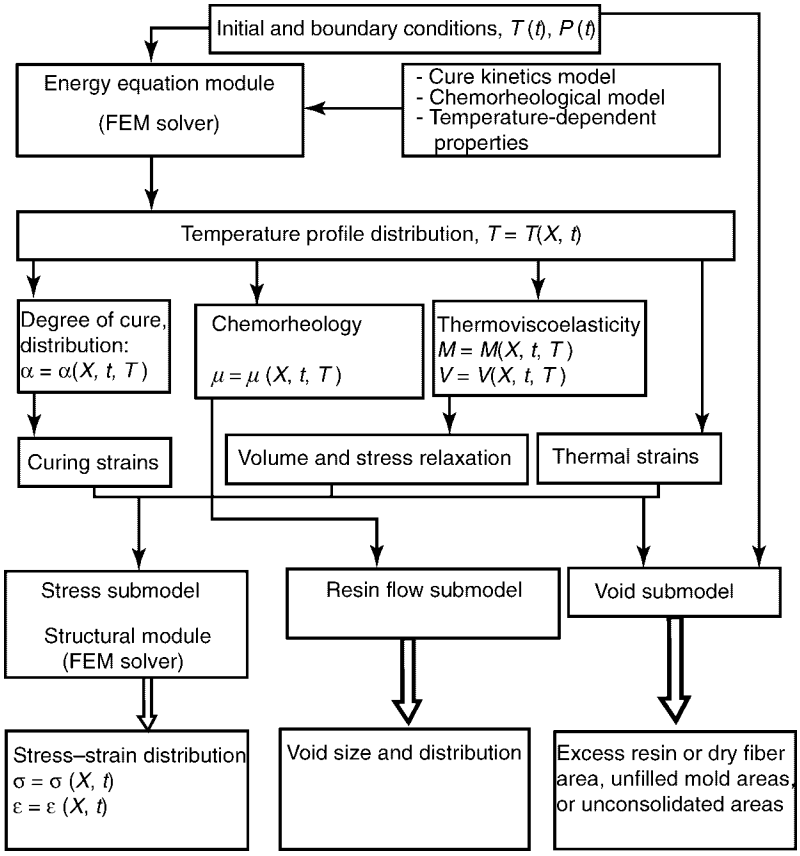

Fig. 6. Schematic flow chart for a generic process modelling sequence.

the degree of cure. A traditional technique which can be used to evaluate the coefficient of thermal expansion at various degrees of conversion is thermomechanical analysis (TMA). Two problems arise when using the TMA procedure:

(1) no test can be performed if the specimen is not solid, and
(2) post-cure reactions will affect the result above the glass-transition temperature.

Since the equipment to measure the temperature-induced dimension variation employs an LVDT displacement sensor, the requirement of a solid sample is mandatory. The effects of post-cure reaction on the measurement, instead, need much more detail and discussion. For a partially cured thermosetting resin, a post-cure reaction is expected when the actual temperature rises above the corresponding glass-transition temperature, T_g. Above this temperature, the volume variation due to post-cure reactions is superimposed upon thermal expansion (18). For this reason, TMA is a technique for measuring the CTE of the partially cured sample that is suitable only within the glassy region ($T < T_g$), while for a fully cured sample useful information can also be obtained for the CTE in the rubbery

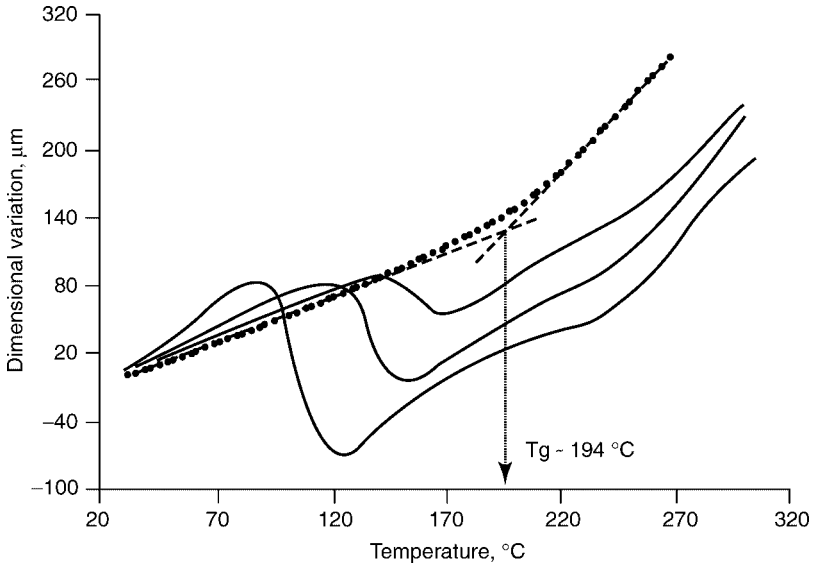

Fig. 7. Thermomechanical curve of data obtained for partially cured samples: ———, sample A; ———, sample B;——, sample C; •, sample E.

region. Figure 7 shows TMA curves for partially cured samples A, B, C, and E. In the case of sample A, when the resin approaches the glass-transition region (110°C) it softens and the measured linear dimensional change drops owing to the static holding force applied by the probe to the specimen during the test. To verify that the characteristic inflections shown by the thermomechanical curves for the partially cured samples are respectively due to the glass transition and the simultaneous effects of temperature and post-cure reaction, it seems appropriate to compare DSC and TMA curves for the same sample (see Fig. 8).

Above the glass transition, the material starts to undergo post-cure reactions, so that the linear thermal expansion is attenuated by the contemporaneous chemical shrinkage effect until the post-cure reaction is completed. At the end of the post-cure reaction, the now fully-cured system expands, only because of temperature changes. Penetration of the probe into the top of the resin specimens cannot be excluded. This further condition will be limiting for any further possible analysis of the curves at $T \geq T_g$.

The glassy coefficients of thermal expansion can then be evaluated as the slopes of the thermal volumetric strain vs. temperature curves below the glass-transition temperature (see Fig. 9), defined at the onset of the first step for each curve. For these curves, in fact, the following relationship can be written:

$$\varepsilon_V(T, \alpha) = \frac{(l - l_o)}{l} = \gamma^{CTE}(\alpha)\Delta T \tag{10}$$

where ε_V is the thermal volumetric strain, l and l_0 are respectively the final and initial sample length; $\gamma^{CTE}(\alpha)$ and ΔT are the coefficient of thermal expansion and the temperature variation. Experimental value determined for the partially cured

samples, $\alpha \in [0.6;1]$, are reported in Figure 10 along with a linear interpolation model.

Chemical Shrinkage. Chemical shrinkage is the result of a progressive matter densification due to the advancement of the reaction. For the resin matrix, volume variations are measured during cure for different isothermal temperatures. The results compared with experimentally determined degree-of-cure profile allow to evaluate the chemical shrinkage coefficient of the matrix system.

Thermal shrinkage is the most obvious source of the residual stresses generated during the manufacturing process of composite laminates or component parts with a polymeric matrix (19). However, other important factors contribute to setting up of residual stresses, or the warpage or poor quality of the manufactured composite part and so need to be investigated. With special reference to composites with a thermosetting matrix, chemical shrinkage comes up as one of the most important factors that need to be taken into account. In fact, organic thermosetting polymers, of the type currently used as a matrix for polymer composites, undergo volumetric changes as a result of the polymerization reaction. Typical values of volumetric shrinkage during cure are 1–5% for epoxy (20) resin and 7–10% for polyester resins (21); however, some thermoplastic polymers may exhibit some degree of crystallization as the matrix cools down from the forming temperature to room temperature, resulting in a volumetric shrinkage of 2 to 36% (22).

Table 3 reports reproducible data for volumetric shrinkage obtained from dilatometric experiments (21,22,24). Modelling of chemical shrinkage, therefore, is of particular relevance for a correct analysis. The absolute volumetric change in a cubic element can be modeled as follows: Considering the dimensions of the cube to be l_1, l_2, l_3 and their relative finite changes as Δl_1, Δl_2, Δl_3, the absolute

Table 3. Shrinkage Measurements on Epon 828 Cured with Different Curing Agents, TETA and DTA[a]

[a]From Ref. 23.

volume change is

$$|\Delta V^{\mathrm{r}}| = V_{\mathrm{final}} - V_{\mathrm{initial}} = [(l_1 + \Delta l_1)(l_2 + \Delta l_2)(l_3 + \Delta l_3)] - (l_1 l_2 l_3) \tag{11}$$

On dividing by the total unit volume of the element, equation 11 can be expressed in terms of the strain components as follows:

$$\frac{\Delta V^{\mathrm{r}}}{V^{\mathrm{r}}} = \varepsilon_1 + \varepsilon_2 + \varepsilon_3 + \varepsilon_1\varepsilon_2 + \varepsilon_2\varepsilon_3 + \varepsilon_1\varepsilon_3 + \varepsilon_1\varepsilon_2\varepsilon_3 \tag{12}$$

where ε_i for $i = 1, 2, 3$ represents the general strain component in the principal direction.

Assuming that the volumetric shrinkage is isotropic, and neglecting all higher order terms, the strain, $\Delta\varepsilon^{\mathrm{r}}$ corresponding to volume resin shrinkage, $|\Delta V^{\mathrm{r}}|$, can be written as

$$\Delta\varepsilon^{\mathrm{r}} = \frac{1}{2}\left(-1 + \sqrt{\left(1 + \frac{3}{4}\Delta V^{\mathrm{r}}\right)}\right) \tag{13}$$

Although dimensional changes are important in such operations as designing tooling for processing plastics or achieving the tolerances required in electronic and computing applications, and in encapsulating and laminating processes, these dimensional changes are not as important in themselves as they are in determining the stresses set up in the cured resin as a result of chemical shrinkage. When these aspects of polymerization shrinkage are considered, it becomes apparent that from the practical point of view the most important phase of the shrinkage to predict (and, hopefully, to control) is that occurring after gelation. If it is possible to locate on the shrinkage/time curve the point of gelation, then data on shrinkage after gelation become directly available. Shrinkage after gelation is minimized when gelation occurs late in the curing reaction, since constrained conditions arise just at the end of the curing process, thereby reducing the length of the crucial stage during which residual stresses can be set up. Lascoe (25) has reported a very comprehensive study on the volume and linear shrinkage of an epoxy resin system.

Interpolated dilatometric curves obtained during isothermal cure at different temperatures, $T = 120, 130, 140, 150$, and 160°C, are reported in Figure 11. Results

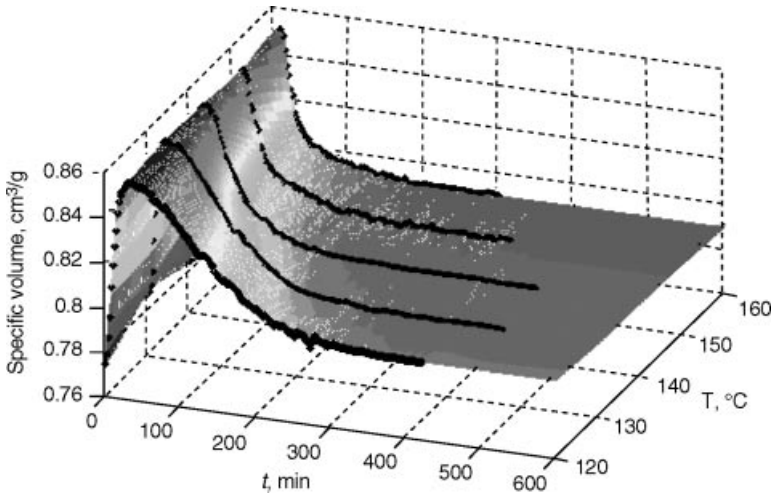

Fig. 11. Linear interpolation of acquired data of specific volume variation during cure at different isothermal temperatures.

have shown that the densification due to polymerization reaction (see Fig. 12) is a linearly dependent phenomena, by a factor of 0.054.

Thermomechanical Properties

The evolution of conversion, α, gives rise to a progressively stiffer material. The passage from a liquid-like to a solid-like material can be suitably described by relaxation modulus as a function of the degree of conversion and temperature.

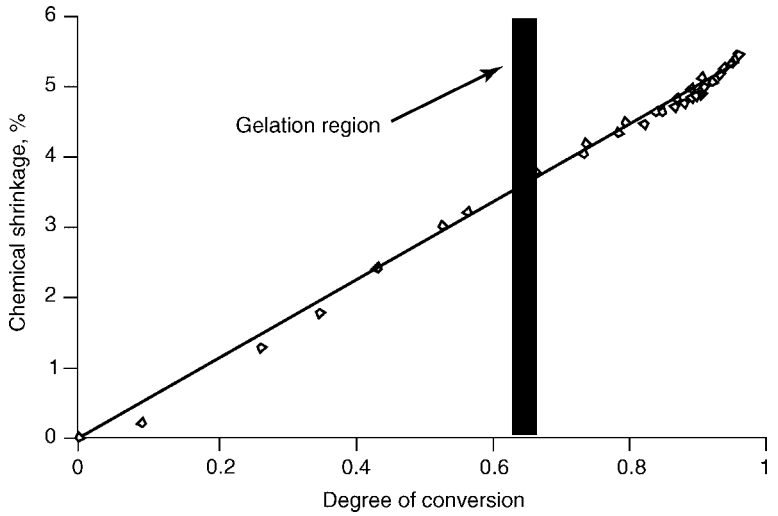

Fig. 12. Linear profile of specific volume change vs. degree of cure.

Mapping the relaxation modulus in each body point then requires the experimental evaluation of such quantity.

The data can be obtained from dynamic mechanical analysis (DMA) tests used to construct the stress relaxation master curves at different levels of conversion, within the frame of time-temperature superposition principle. Curves of stress relaxation modulus can be modeled using the stretched Kohlrausch–William–Watts (KWW) exponential function at each level of conversion, as follows:

$$E(t,\ T,\ \alpha) = E\infty(\alpha)\ \exp\left[-\left(\frac{\xi(t,\ T,\ \alpha)}{\tau_{\mathrm{p}}(\alpha)}\right)^{\beta(\alpha)}\right] \tag{14}$$

where $E\infty$ indicates the fully relaxed modulus and τ_{p} and β are the KWW model parameters. The functionality of the ultimate modulus and the KWW parameters over the degree of conversion is related to the physical assumption to consider as a "new material" the system at each level of conversion. A liner function was found satisfactory to model the nonexponential parameter β vs. conversion; Mijovic and co-workers (26) established the same linear dependency applied to dielectric constant decay function. Assuming that the molecular mobility influences the glass transition through the same mechanism that controls the stress relaxation function, then the behavior of the glass-transition temperature at a fixed degree of cure can be normalized with respect of its value for a given conversion. This normalization will lead to the definition of a potential function, which is identical to that obtained by normalizing in the same way the characteristic relaxation times with respect to the relaxation time at the same fixed conversion. From the mathematical point of view, it can be stated that

$$\frac{T_{\mathrm{g}}(\alpha)}{T_{\mathrm{g}}(\alpha_{\mathrm{ref}})} = g_{T_{\mathrm{g}}}(\alpha) \tag{15}$$

where $T_{\mathrm{g}}(\alpha)$ is the glass-transition temperature as a function of the degree of cure, and $T_{\mathrm{g}}(\alpha_{\mathrm{ref}})$ is the particular value for the fixed conversion. If the same mechanism drives the change in normalized relaxation time, then it follows that

$$\frac{\tau_{\mathrm{p}}(\alpha)}{\tau_{\mathrm{p}}(\alpha_{\mathrm{ref}})} = g_{\tau_{\mathrm{p}}}(\alpha) \tag{16}$$

and therefore,

$$g_{T_{\mathrm{g}}}(\alpha) = g_{\tau_{\mathrm{p}}}(\alpha) \tag{17}$$

where $\tau_{\mathrm{p}}(\alpha)$ is the relaxation time expressed as a function of the degree of cure, and $\tau_{\mathrm{p}}(\alpha_{\mathrm{ref}})$ is the value for the fixed conversion α_{ref}. Figure 13 shows good correlation between the normalized principal stress relaxation time and the normalized value of the glass-transition temperature. Using the transformed KWW model, stress relaxation modulus can be predicted over the whole range of conversion according to the kinetics model at each material point. Figure 14 reports the KWW model prediction for different levels of conversion.

Structural Relaxation

When a material is cooled from above to below T_g, the resulting glass is unstable and its density will gradually increase with time. This process toward thermodynamic equilibrium (called *structural relaxation* or generally *physical aging*)

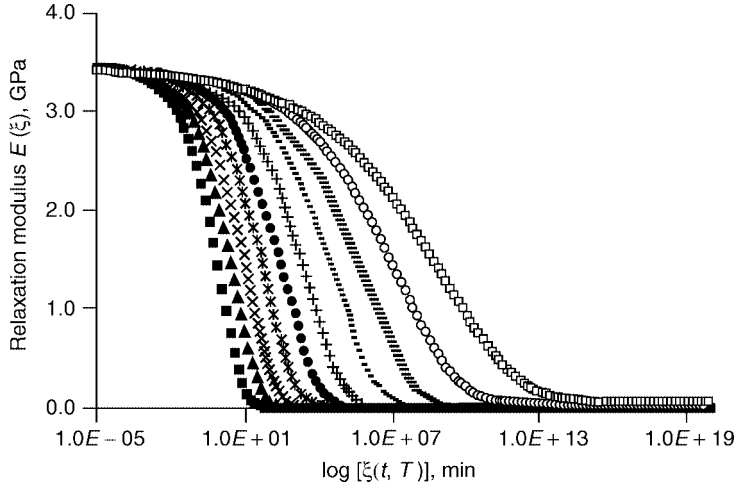

Fig. 14. KWW model prediction for the whole range of conversion: ■, 0.1; ▲, 0.2; ×, 0.3; —×—. 0.4; •, 0.5; +, 0.6; –, 0.7;—, 0.8; ○, 0.9; □, fully cured.

occurs more rapidly at temperatures close to T_g, being an activated phenomenon, and manifests itself through a continuous change of a large number of properties including but not restricted to density, enthalpy, entropy, and consequently all the related viscoelastic functions. The structural relaxation cannot be avoided; it occurs in all glasses even when cooling is performed such that the temperature gradients over the material are small and the resulting thermal stresses are negligible.

The structural relaxation is a direct consequence of the considerably longer time scale of molecular relaxations within and below the glass-transition region compared to the experimental time scale of the applied signal. In other words, even the slowest experimentally attainable cooling rate is much too fast for the polymer chains to relax to equilibrium. The nonequilibrium structure first experiences an abrupt contraction and then undergoes a time-dependent rearrangement toward the equilibrium state. Monitoring the kinetics of any structure-sensitive property changes such as enthalpy or specific volume can follow the gradual rearrangement of the non-equilibrium structure. The multi-parameter phenomenological model for structural relaxation based on the Tool–Narayanaswamy–Mohinyan (TNM) theory was largely utilized in the literature for a number of organic and inorganic glasses.

In principle, the knowledge of TNM model parameters allows the prediction of volume as well as enthalpy relaxation under arbitrary thermal histories. As such, the volume as well as enthalpy fluctuations, which arise when polymers are cooled from the molten rubbery state, can be calculated at each body point provided the local thermal history is known.

Typical experimental volumetric and calorimetric data obtained under different thermal histories are shown in Figures 15 and 16 for given thermal histories (details of the numerical procedure are given in Reference 27). The key parameter of the modeling procedure based on TNM phenomenological approach, is the fictive temperature, T_f. As discussed in the above-cited references, T_f can be conveniently

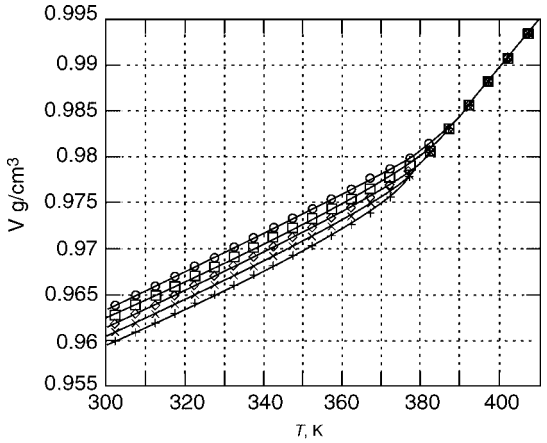

Fig. 15. Experimental specific volume (V) vs. Temperature (T) data during a cooling scan at 1°C/min (open circles) and the corresponding model predictions (full lines) at different cooling rates: ○, 10000°C/min; □, 1000°C/min; ◇ 100°C/min; ×, 10°C/min; +, 1°C/min.

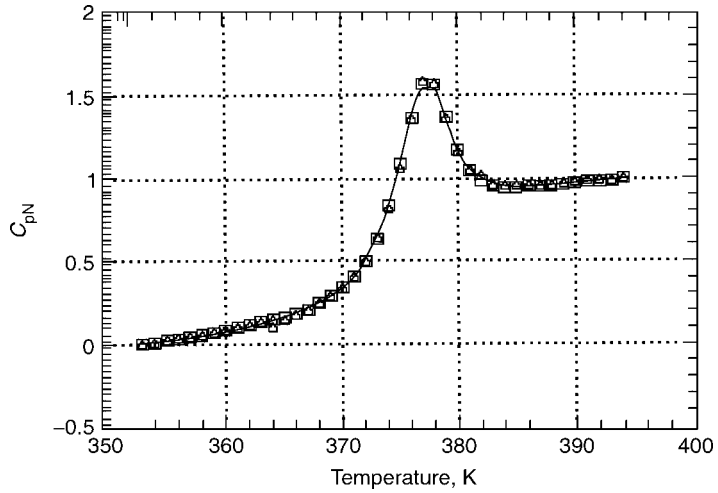

Fig. 16. Normalized specific heat for 1-h-aged sample at $T = 90^{\circ}$C. Heating rate 10°C/min: △, calculated; □, experimental.

regarded as a measure of the actual structural state. Mathematically it is defined as

$$\int_{T}^{T_r} \frac{\partial(P - P_g)}{\partial T}\, dT = \int_{T_f}^{T_r} \frac{\partial(P_e - P_g)}{\partial T}\, dT \tag{18}$$

If P represents the specific volume V, then taking the derivatives of both sides of equation 8 it can be written,

$$\frac{dT_f}{dT} = \frac{\alpha_v - \alpha_{vg}}{\alpha_{vl} - \alpha_{vg}} = \frac{dV^N}{dT} \tag{19}$$

where subscripts l and g stand for liquid and glassy state, respectively and α_v represents the temperature derivative of specific volume. The variation of the normalized functions are described by a relaxation function $\phi(t)$. The most widely used relaxation function is the so-called stretched exponential equation, which is related to the structural sensitive property P according to the following equation

$$\phi(t) = \frac{P - P_e}{P_o - P_e} = \exp\left[-\left(\int_{t_0}^{t} dt'/\tau\right)^{\beta}\right] \tag{20}$$

In equation 16, t' is the time when the change in temperature occurs, β is the exponent, and τ is the characteristic relaxation time. Nonexponentiality (*memory effect*) is reflected in the value of $\beta < 1$. When treating nonisothermal situations (*arbitrary thermal history*) the relaxation function can be represented by the superposition of responses to a series of temperature jumps constituting the actual thermal history. The fictive temperature is defined as the actual

non-equilibrium parameter and takes on the following form:

$$T_f(T) = T_0 + \int_{T_0}^{T} \left\{ 1 - \exp\left[-\left(\int_{t(T)}^{t(T)} \mathrm{d}t/\tau \right) \right] \right\} \mathrm{d}T' \tag{21}$$

with T_0 being the initial temperature. The next input needed by the model is an expression for the structural relaxation time τ, which appears in equation 6. Following Tool's original work, various expressions for the structural relaxation time have been proposed, all in exponential form and containing temperature and fictive temperature as variables.

The Narayanaswamy–Moynihan (NM) expression has the following form:

$$\tau = A \exp\left[x\frac{\Delta h^*}{RT} + (1-x)\frac{\Delta h^*}{RT_\mathrm{f}} \right] \tag{22}$$

where τ is the structural relaxation time, A is a constant (preexponential factor), Δh^* is the characteristic activation energy, and x the partitioning parameter ($0 < x < 1$) that defines the degree of nonlinearity.

The experimental data of Figures 15 and 16 can be utilized to find the optimum set of parameters (A, Δh^*, x, β) that best describes the behavior of the material functions in the glass-transition region. From Figure 17 the coefficient of thermal expansions for a given temperature history (and, therefore, for a given body point during the cooling process) can be obtained.

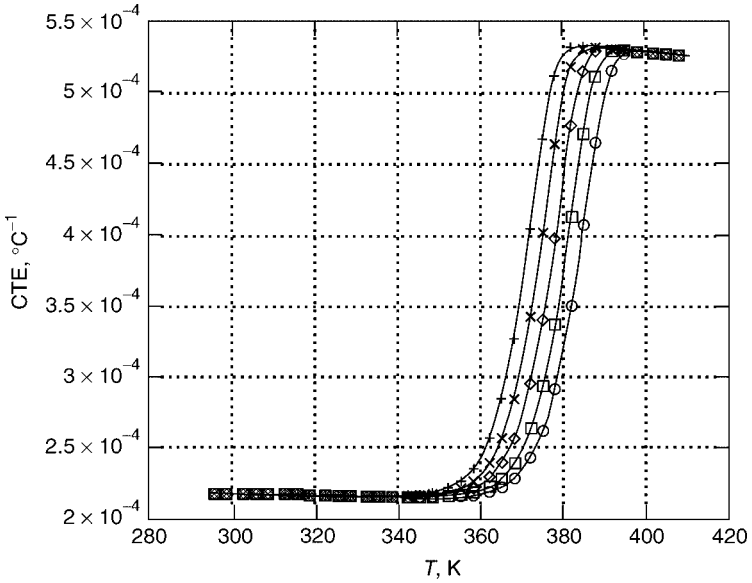

Fig. 17. Model prediction of coefficient of thermal expansion (CTE) as a function of temperature (T) at different cooling rates: ○, α-10000°C/min; □, 1000°C/min; ◇, 100°C/min; ×, 10°C/min; +, 1°C/min.

Submodels

Resin Flow Submodel. Resin flow analysis in a manufacturing process provides estimates of resin flow, and fiber and resin distribution and compaction. In the early stage of the autoclave process, after the prepregs are staked and vacuum bagged, the system is pressurized while the temperature is increased in order to minimize the resin viscosity. In this way the resin flow removes the excess resin from adjacent plies and makes uniform the fiber distribution. In the RTM process the dry fibers inside the mold can be considered as a porous medium through which the resin is injected from a single or multiple inlets: Darcy's law can be used to perform a two-dimensional flow analysis. Darcy's law can be written as

$$\begin{bmatrix} u(x,y) \\ v(x,y) \end{bmatrix} = -\frac{1}{\mu} \begin{bmatrix} k_{xx} & k_{xy} \\ k_{yx} & k_{yy} \end{bmatrix} \begin{bmatrix} \dfrac{\partial P(x,y)}{\partial x} \\ \dfrac{\partial P(x,y)}{\partial y} \end{bmatrix} \tag{23}$$

where k_{ij} is the generic component of the permeability tensor, μ is the viscosity, P is the pressure, and v and u are the components of the velocity in the x- and the y-directions, respectively. If the resin is considered to be an incompressible fluid then the continuity equation can be reduced to the following form:

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \tag{24}$$

and the mass balance in an RTM process assumes the following form, provided the directions x and y coincide with the principal directions of the fiber perform/mat (28).

$$\frac{\partial}{\partial x}\left(\frac{k_{xx}}{\mu}\frac{\partial P}{\partial x}\right) + \frac{\partial}{\partial y}\left(\frac{k_{yy}}{\mu}\frac{\partial P}{\partial y}\right) = 0 \tag{25}$$

In autoclave forming the main resin flow is normal to the tool surface and Darcy's law is again used but in its one-dimensional form:

$$V = -\frac{S}{\mu}\frac{\mathrm{d}P}{\mathrm{d}z} \tag{26}$$

where S is the apparent permeability and z is the direction normal to the tool.

Resin flow parallel to the tool plate takes place along the parallel and perpendicular fiber directions. Between the two mechanisms, the resin flow along the fibers is the most prominent as, in fact, the flow perpendicular to the fibers is small because of the resistance created by the fibers.

The flow along the fiber direction can be modeled as a channel flow (the viscous flow between two parallel plates). Loss and Springer (29) validated thermomechanical models, including the chemorheological behavior of resin and resin flow models.

Void Growth Model. The resin flow during composite processing inevitably leads to the formation and growth of voids. Although all the manufacturing processes of composite materials are based on solid engineering principles, current technologies cannot assure a part-by-part reliability required by the production and assembly of the parts for a complex and larger composite structure. For thick composite parts (30) the occurrence of voids has been widely verified and their detrimental effects proved. The void formation necessarily occurs during the fabrication process and involves the different concurrent phenomenology of heat, mass, and momentum transfer. An even more complex scenario comes out considering that polymerization reaction occurs for the matrix while thermomechanical properties are varying with time, temperature, and degree of conversion. In some cases the system can be considered multiphase.

The correct mechanism of void formation is related to the system being used and to the specific manufacturing process. Even when a part appears to be fully impregnated by the resin and the resin matrix has been previously degassed at the prescribed temperature, in order to eliminate mechanically entrapped air bubbles, void formation still occurs. During a general manufacturing process the voids can be formed either by the mechanical entrapping of air or by a nucleation process. In the first case, it can be related to gas bubbles associated with the mixing operation of the resin bulk, by bridging of particles of additives, by air and wrinkles when the lay-up sequence is built, or by the resin flow during tow impregnation. Particularly important for injection type processes (like RTM, injection molding, or resin film infusion) this latter mechanism leads to the formation of microvoids and consequently dry spots within the low-permeability area of the perform. Schematically, the voids formation associated with the resin flow can be divided in to four stages, as follows:

(1) the flow reaches the tow to be impregnated,
(2) the flow front comes around the tow or bundle and it passes,
(3) still the resin has to penetrate and fill the space inside the tow among the different fibers, and
(4) air voids remain inside the tow and eventually move in the resin between tows owing to the high pressure acting on the tow.

Modeling of void formation is intimately related with cure kinetics and viscosity profiles of the resin system. For modeling purposes it can be conveniently divided into three different phases:

(1) formation and stability of the forming voids,
(2) void growth and/or dissolution by diffusion, and
(3) void transport process.

A nucleation process is generally described assuming the initial formation of the voids to be in accordance with the classical nucleation theory. It can be assumed that nucleation occurs between resin and fiber or resin and added particle (heterogeneous nucleation) or within the resin itself (homogeneous nucleation).

Application of classical nucleation theory (31) leads to favorable results, especially for the case of homogeneous nucleation, for which critical size nuclei can be formed at rate N, given by the following equation:

$$\dot{N} = \left[\frac{P^T}{\sqrt{2\pi MkT}}\right] 4\pi^2 \exp\left(-\frac{\Delta F}{kT}\right) \tag{27}$$

where P stands for the total water plus air pressure, M is the molecular weight of the vapor phase, n the molecular density in the formed nuclei, ΔF the maximum free energy for the nucleation process, and k and T are respectively the Boltzmann constant and the absolute temperature. When the nuclei are formed, several factors determine the stability and the growth of the voids. Changes in temperature and pressure cause an increase in the solubility in the resin leading to the dissolution of the voids. Generally, a void becomes stable when its inner pressure equals or exceeds the surrounding resin hydrostatic pressure plus the surface tension forces. This condition can be stated as follows:

$$P_v - P_{sr} = \frac{\gamma_{r-v}}{R_{v-a}} \tag{28}$$

where P_{v} and P_{sr} are respectively the void and resin pressure, $\lambda_{\mathrm{r-v}}$ is the resin–void surface tension, and $R_{\mathrm{v-a}}$ is the ratio of the volume and surface of the voids. As the temperature and pressure change with time, from a product-quality point of view it is most important to model the time-dependent growth process.

This phenomenon, however, would require the solution of many time-dependent and coupled partial differential equations, which would result in too difficult an approach. To overcome the intrinsic difficulties related to changes physical properties and the excessive computational time of the equation solver, two "equivalent" physical schemes are generally studied assuming that the void growth perpendicular to the ply (critical capillary scheme) or through an isotropic pseudo-homogeneous medium where the growth occurs not preferentially perpendicular to the plies. This latter approach seems to be more realistic considering the physical possibility of pure water vapor growing for diffusion into the surrounding resin or into a void initially consisted of entrapped air and it become equivalent to bubble growth in a liquid medium.

The main assumptions in building a general void growth model are

(1) the voids remain between two plies and move with respect to the fixed coordinates system in the laminate;
(2) the voids are considered spherical and their characteristic dimension is calculated based on an equivalent sphere;
(3) no interactions between two voids are considered;
(4) during the lay-up process and at the beginning of the cure process, void nucleation occurs almost instantaneously;
(5) temperature and moisture concentration are time independent; and
(6) the void growth is limited by the flow rate of arrival of the diffusing species.

Structural Analysis

The complex interactions between material property evolution and the manufacturing stages represent a critical issue for correct part design and for controlling the entire production process. In order to evaluate the integrity of the manufactured part, a structural analysis needs to be performed to simulate the effects of mechanical, nonmechanical, and geometric part constraints due to the manufacturing tools utilized during the specific process.

Modeling of the coupled transfer phenomena (mass, heat, and momentum) need to be solved considering appropriate constitutive equations for the evolving properties in order to optimize the integrity of the final material system and at the same time to control the final shape of produced composite element.

If, as we can recognize, the curing process involves thermal variations from room temperature to cure temperature, then thermal expansion is a necessary part of that process. A common hypothesis has been proposed in past papers (32–36) to simplify the complex phenomenology, that is, no stresses develop prior to completion of the curing process.

Even if it is possible to obtain good results using a simulation model, in which it is assumed that the crucial stage for formation of residual stresses is the period of cooling from cure to ambient temperature, recent work has demonstrated that the residual stress formation mechanism is strongly influenced by the overall curing process (37–43). Moreover, using this approach, the phenomenon of structural relaxation, which occurs near the glass-transition region of the developing structure, is not considered at all. The above phenomena needs much more effort in order to be well quantified and eventually taken into account. In fact, these chemical/physical changes cause more deformation in the transverse directions than in the longitudinal direction since resin-dominant properties are experienced within the ply in that direction.

Mechanical Tests: Review

Mechanical tests for advanced composite materials conform in many respects to the conventional test typology used for traditional isotropic materials. Despite the complication associated with the heterogeneity of composite systems, the interface between fiber and matrix, and the anisotropy at the micro- and macroscopic levels, the same characteristic property definitions generally used for conventional materials can be identified for these novel materials. In some cases additional constants are required and some differences in nomenclature are introduced especially when no isotropic counterpart exists.

Mechanical characterization of composite materials is a complex scenario to deal with, either because of the infinite number of combinations of fiber and matrix that can be used, or because of the enormous variety of spatial arrangements of the fibers and their volume content. The foundation of the testing methods for the measurement of mechanical properties is the classical lamination theory; this theory was developed during the nineteenth century for homogeneous isotropic materials and only later extended to accommodate features enhanced by

fiber-reinforced material, such as inhomogeneity, anisotropy, and anelasticity. Two basic approaches are proposed to determine the mechanical properties of composite materials: *constituent testing and composite sample testing*.

Academically, composite constituents could be tested separately and then composite properties evaluated by simple or more complex mixture rules according to the wanted level of accuracy. Many references can be found in the literature for this approach. Mechanical properties of composites are generally assumed to be dependent on the following variables:

(1) properties of the fiber,
(2) properties of the matrix,
(3) properties of any other additive or phase constituting the composite,
(4) volume fraction of the fiber,
(5) spatial distribution of the fiber (or a third phase), and
(6) nature of interface.

From a strictly theoretical point of view, the so-called constituent testing approach or micromechanics approach is the most valuable. Tests performed on composite constituents supply the required material constants of each phase of the composite material—namely for long-fiber-reinforced composite—for the fiber and the matrix, to use in appropriate mixture rules. These rules obtained by physical and mechanical considerations are the basic relationships between the composite constituents, and they leads to a complete characterization of the final composite.

Fibers can be tested in the form of single fiber, tow, or fabric; all tests can be grouped into three main categories:

(1) Chemical Tests. They are generally used for elemental analysis and surface investigation. Following is a list of the most important chemical tests:
   a. X-ray photoelectron spectroscopy (XPS)
   b. Low-energy electron diffraction (LEED)
   c. Scanning Electron Microscopy (SEM)
   d. Carbon assay (CA)
   e. Fourier transform infrared spectroscopy (FTIS)
   f. Sizing Content (SC)
   g. Thermal desorption mass spectrometry (TDMS)
   h. Auger electron spectroscopy (AES)
(2) Physical tests. They are generally performed to measure different physical properties for fiber and for fabric. Properties of interest required for specific application design are
   a. Density (ASTM D792 using displacement, ASTM D3800 based on Archimedes principle and ASTM D1505 by means of density gradient column)
   b. Weight per length, typically in g/μm
   c. Weight per unit area or aerial weight, reported in g/m^2

d. Filament diameter measured by microscopy image according to the standard ASTM D578
e. Electrical conductivity
f. Thermal expansion
g. Number of twists
h. Tensile strength (ASTM D579)

(3) Mechanical test. It is important to point out that these mechanical tests are chosen based on whether the fiber sample is single fiber, tow, or fabric. For this reason, it is extremely important to define the specific fiber sample typology used during the tests when a mechanical test campaign is started. The main mechanical tests generally performed are

a. Single-filament tensile test [ASTM D3379 (44)]
b. Tensile test for tow [ASTM D4018 (45)]
c. Tensile test for dry fabric [ASTM D579 (46)]

For resin matrix, several tests (chemical, physical, and mechanical) are generally performed by the supplier; their results are used not only for design but also for processing control and optimization. Along with traditional tests, some specific procedures, such as stress relaxation or creep, are considered if viscoelastic effects are investigated. The experimental setup for the stress relaxation test is shown in Figure 18; while stress relaxation raw data, for an epoxy-toughened resin matrix used for aerospace structural composite materials, are reported in Figure 19. Despite the fact that testing of a single constituent could eliminate inherent difficulties related with material handling, this approach is not representative of composite performance; in fact, many factors associated with the manufacturing process and the realistic arrangement of the fiber into the composite system are not taken into account as modeling assumptions are necessary even in the case of more complex schematization.

The second approach, which determines the mechanical properties of the composites by directly testing a composite laminate, is a much more straightforward procedure, widely implemented to determine composite properties required for analysis and design. The whole philosophy of testing a laminate of composite material is essentially based on the classical laminate theory. CLT employs elasticity theory to derive the basic relationships between stress and strain and, therefore, to identify material properties. These relationships are quite simple for traditional homogeneous and isotropic materials, however, for composites they can be either extremely complex or, in some case, these equations are imperfect "tools" for modeling (ie it is not possible to estimate the stress state at the tip of a crack by classical laminate theory). Static and fatigue tests are generally performed on composite laminates as well as on traditional systems; for these novel materials, however, some new test typologies need to be introduced to evaluate specific properties or to describe particular failure modes not shown by traditional materials. Despite inherent imperfections and simplifications, the existing formal framework contains justification for the various constraints and stipulations that have been imposed on test configurations and procedures for long-fiber composites.

Fig. 18. Stress relaxation test in 3-point bending mode for a typical aerospace toughened epoxy composite matrix.

The principal features and precautions arising from the testing of long-fiber composites are in relation to

(1) generation of uniform stress in the critical reference volume,
(2) avoidance of overwhelming "end-effects,"
(3) tension-shear coupling effects,
(4) adequate loading levels to avoid failure or damage at loading points, and
(5) appropriate sample dimensions compared to the scale of structural inhomogeneity.

Even though the inhomogeneity and anisotropy of composite materials give rise to various additional configurations, the above precautions apply similarly to the testing of homogeneous isotropic materials.

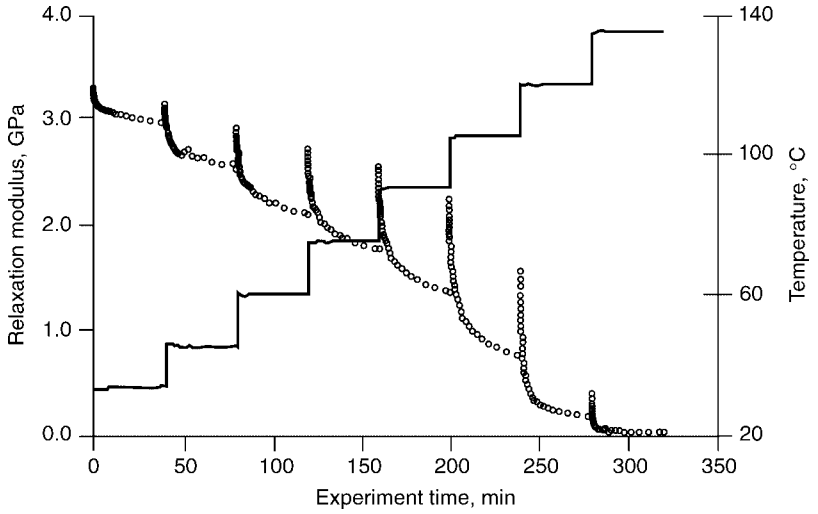

Fig. 19. Typical data obtained from a stress relaxation experiment in 3-point bending mode performed on a toughened epoxy resin system used for aerospace structural composite material: ○, relaxation modulus (resin plate B); ———, temperature (resin plate B).

Specimens for mechanical tests on composites are usually taken in three different forms: pultrusion, filament-would tubes, and flat sheet. For each form, tests can be performed on the entire sample or on coupons of given fixed dimensions. It is extremely important to notice that the first two forms are generally considered for their convenience of fabrication and also because for composite materials, the specific manufacturing process employed strongly influences the final performance of the material in its final application. Therefore, testing on the "realistic" configuration leads to more reliable results in terms of mechanical characterization. Commercially available flat sheets are in the form of randomly oriented fiber, various sequences of UD or woven laminate and sandwich structures. The mechanical properties of these items as well as of the extracted coupons vary with the stacking sequence, the alignment of the specimen's axis in relation to the pattern of the fiber and with the in-plane position of the specimen.

To evaluate the performance of a composite or for a general characterization of a composite system, the following mechanical properties are generally investigated:

(1) Uniaxial tensile modulus
(2) Tensile strength
(3) Uniaxial compression modulus
(4) Compressive strength
(5) Flexural modulus
(6) Flexural strength
(7) In-plane shear modulus
(8) Lateral contraction ratios

Table 4. Mechanical Testing Plan for Mechanical Characterization of Composite for Aeronautical Applications

Tensile strength at room temperature
Uniaxial compression at room temperature
Interlaminar shear at room temperature
Open hole tension at room temperature (see Fig. 19)
Open hole compression at 93°C
Hot/wet compression strength
Edge-plate compression strength after impact, at room temperature

(9) Apparent interlaminar shear strength
(10) Facture toughness

With time, an extensive variety of test methods and procedures have been introduced to develop new applications of composite materials and more in general to sustain the diffusion in various fields of these novel materials. However, the complexity of the properties, the great variety of their applications, and the diversity of their features compared with traditional materials have resulted in the developments, often arbitrary and in some cases more specific, to satisfy particular sectors of the industry.

No single organization or industry is likely to carry out a general investigation program to identify a general routine procedure for mechanical characterization of composite materials, supported by solid theoretical considerations. In order to satisfy the various downstream requirements, which vary from company to company, different test programs have been stipulated. In USA, a large commercial airplane has proposed the test program reported in Table 4 as fundamental for the "initial" evaluation phase of composites, which differs from the test plan identified by U.S. automotive industries, whose test plan is reported in Table 5.

For composite materials, the exposure to critical environment is also an important issue; therefore while selecting an appropriate test method for evaluating composite mechanical properties the extreme conditions experienced during service for a particular application must be taken into account. Environmental exposure can be "accidental" during the specimen preparation and instrumentation, or "planned" to investigate the moisture effect, chemical attack, or cycling

Table 5. Mechanical Test Program Agreed by Important Automotive Manufacturers

Elastic and strength properties at temperature in the range 40–150°C
Effect of loading rate on tensile and compressive properties in the range 0.00167–16.7 s^{-1}
Creep
Creep and stress relaxation
Residual strength after fatigue
Fatigue
Effects of notches and holes
Energy absorption after impact
Manufacturing effects
Joints and fastener characterization

temperature. In both cases, extensive and very expensive tests are performed to assess the performances of the composite material during service at these extreme conditions.

In 1987, a survey (47) of currently available mechanical standardized tests concluded that the existing standardized, semistandardized, or available procedure were deficient in respect to three main aspects:

(1) too many variants were used for a single test and there was no evidence of the effects of the variation of generated data on reliability,
(2) some tests were not fit for their intended purpose, and
(3) some important phenomena were neglected either because they were not properly understood or because they were too time-consuming to assess.

The above-mentioned report has attributed this state of the art to poor interactions between academy and industry and to the failure to establish an adequate common infrastructure among composite experts and manufacturers. In the last few years, many laboratories in the area of composite materials have launched inter-laboratory testing programs to establish common procedures for investigation of mechanical properties by various techniques. Many round-robin test programs (48–54) are still running in the area of interlaminar fracture mechanism on composite laminate fracture toughness of new 3-D-reinforced-fiber materials, dynamic mechanical analysis, through thickness crack propagation test, and fatigue tests. These research programs aim either to harmonize or to build a common framework for parameters acquisition to be used for the analysis and design of high quality composite structure.

Following is a list of the main testing mode adopted to characterize advanced composite materials along with reference standards:

(1) Tension: ASTM D3039, BS 2782-320, CRAG 300-301, CRAG 302, and ISO 572
(2) Compression: ASTM D695M, ASTM 3400, and CRAG 400
(3) Shear: ± 45 tension test, 10° off-axis test, rail shear test, V-notched beam test, plane-twist test, and torsion of thin-walled sample
(4) Flexure: ASTM D790M-93, CRAG report 88012, BS2782-1005, and ISO 14125
(5) Through-thickness testing: BS EN ISO 14 and 130, ASTM D3846, and ASTM D 5379
(6) Interlaminar fracture toughness
(7) Impact: BS 2782, ASTM D3029-FA, ASTM 2930-FB, ISO/DIS 6603/2
(8) Fatigue

Structural tests on real-scale elements are also performed to validate the design criteria and manufacturing settings as a final verification of the desired components. In Figure 20, a typical test is shown for a real-scale composite panel for aeronautical applications. The panel is loaded in shear mode under both static and dynamic conditions.

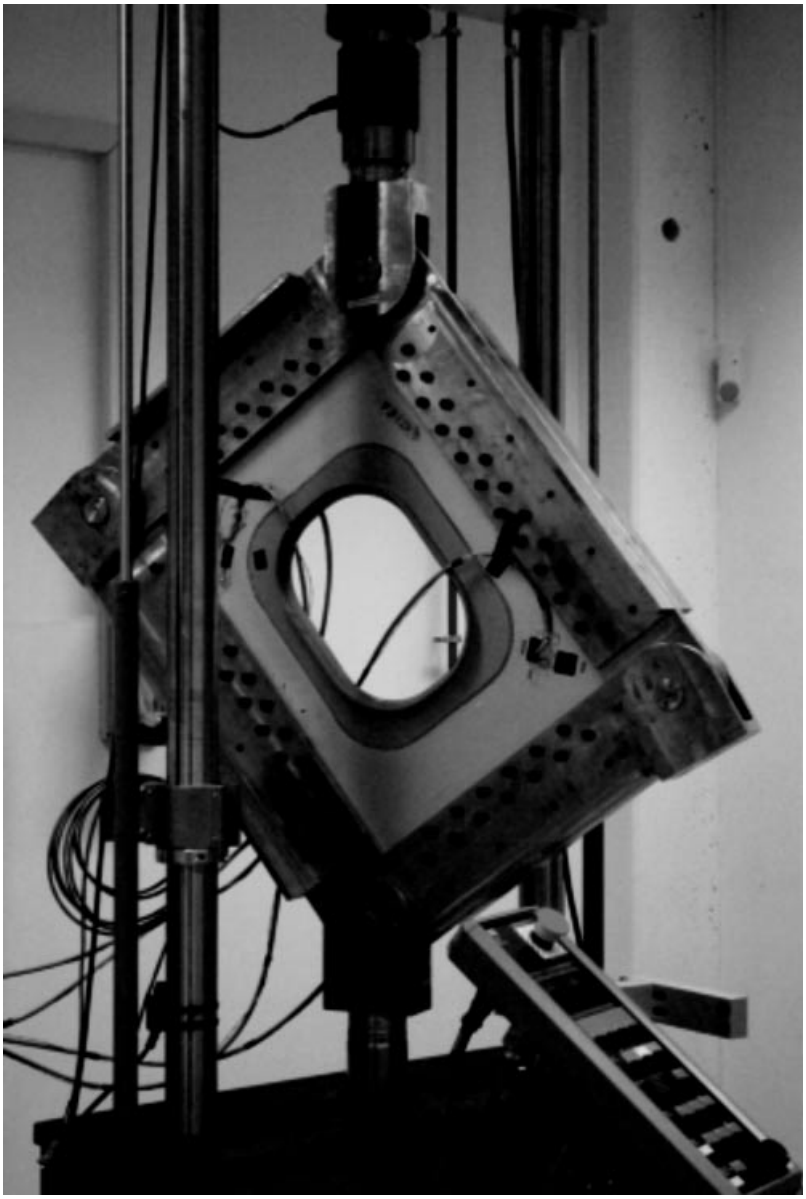

Fig. 20. Structural mechnical test on real scale composite panel for aeronautical application.

COMPUTATIONAL QUANTUM CHEMISTRY FOR FREE-RADICAL POLYMERIZATION

Introduction

Chemistry is traditionally thought of as an experimental science, but recent rapid and continuing advances in computer power, together with the development of

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

efficient algorithms, have made it possible to study the mechanism and kinetics of chemical reactions via computer. In computational quantum chemistry, one can calculate *from first principles* the barriers, enthalpies, and rates of a given chemical reaction, together with the geometries of the reactants, products, and transition structures. It also provides access to useful related quantities such as the ionization energies, electron affinities, radical stabilization energies, and singlet–triplet gaps of the reactants, and the distribution of electrons within the molecule or transition structure. Quantum chemistry can provide a "window" on the reaction mechanism, and assumes only the nonrelativistic Schrödinger equation and values for the fundamental physical constants.

Quantum chemistry is particularly useful for studying complex processes such as free-radical polymerization (see RADICAL POLYMERIZATION). In free-radical polymerization, a variety of competing reactions occur and the observable quantities that are accessible by experiment (such as the overall reaction rate, the overall molecular weight distribution of the polymer, and the overall monomer, polymer, and radical concentrations) are a complicated function of the rates of these individual steps. In order to infer the rates of individual reactions from such measurable quantities, one has to assume both a kinetic mechanism and often some additional empirical parameters. Not surprisingly then, depending upon the assumptions, enormous discrepancies in the so-called "measured" values can sometimes arise. Quantum chemistry is able to address this problem by providing direct access to the rates and thermochemistry of the individual steps in the process, without recourse to such model-based assumptions.

Of course, quantum chemistry is not without limitations. Since the multielectron Schrödinger equation has no analytical solution, numerical approximations must instead be made. In principle, these approximations can be extremely accurate, but in practice the most accurate methods require inordinate amounts of computing power. Furthermore, the amount of computer power required scales exponentially with the size of the system. The challenge for quantum chemists is thus to design small model reactions that are able to capture the main chemical features of the polymerization systems. It is also necessary to perform careful assessment studies, in order to identify suitable procedures that offer a reasonable compromise between accuracy and computational expense. Nonetheless, with recent advances in computational power, and the development of improved algorithms, accurate studies using reasonable chemical models of free-radical polymerization are now feasible.

Quantum chemistry thus provides an invaluable tool for studying the mechanism and kinetics of free-radical polymerization, and should be seen as an important complement to experimental procedures. Already quantum chemical studies have made major contributions to our understanding of free-radical copolymerization kinetics, where they have provided direct evidence for the importance of penultimate unit effects (1,2). They have also helped in our understanding of substituent and chain-length effects on the frequency factors of propagation and transfer reactions (2–5). More recently, quantum chemical calculations have been used to provide an insight into the kinetics of the reversible addition fragmentation chain transfer (RAFT) polymerization process (6,7). For a more detailed introduction to quantum chemistry, the interested reader is referred to several excellent textbooks (8–16).

Basic Principles of Quantum Chemistry

Ab initio molecular orbital theory is based on the laws of quantum mechanics, under which the energy (E) and wave function (Ψ) for some arrangement of atoms can be obtained by solving the Schrödinger equation 1 (17).

$$\hat{H}\Psi = E\Psi \tag{1}$$

This is an eigenvalue problem for which multiple solutions or "states" are possible, each state having its own wave function and associated energy. The lowest energy solution is known as the "ground state," while the other higher energy solutions are referred to as "excited states." The wave function is an eigenfunction that depends upon the spatial coordinates of all the particles and also the spin coordinates. Its physical meaning is best interpreted by noting that its square modulus is a measure of the electron probability distribution. The term ($\hat{H}$) in equation 1 is called the Hamiltonian operator and corresponds to the total kinetic ($\hat{T}$) and potential energy ($\hat{V}$) of the system.

$$\hat{H} = \hat{T} + \hat{V} \tag{2}$$

$$\hat{T} = -\frac{h^2}{8\pi^2}\sum_i \frac{1}{m_i}\left(\frac{\partial^2}{\partial x_i^2} + \frac{\partial^2}{\partial y_i^2} + \frac{\partial^2}{\partial z_i^2}\right) \tag{3}$$

$$\hat{V} = \sum_{i<}\sum_j \left(\frac{e_i e_j}{r_{ij}}\right) \tag{4}$$

In these equations, the kinetic and potential terms are summed over all particles in the system (nuclei and electrons), and each particle is characterized by its Cartesian coordinates, its mass (m) and its electric charge (e). In addition, h is Planck's constant and r_{ij} is the distance separating particles i and j. It can thus be seen that the only empirical information required to solve the Schrödinger equation are the masses and charges of the nucleus and the electrons, and the values of some fundamental physical constants. For this reason, quantum-chemical calculations are referred to as "ab initio" ("without assumptions") procedures.

In applying the Schrödinger equation to problems of chemical interest, two major simplifications can be made. Firstly, the Hamiltonian described by equations 2–4 above is nonrelativistic, and it is valid provided that the velocities of the particles do not approach the speed of light. This is generally reasonable except for the inner shell electrons of heavy atoms, and in these cases corrections for relativistic effects can be made (18). Secondly, the Hamiltonian is further simplified by neglecting the kinetic energy contribution of the nuclei. This is known as the Born–Oppenheimer approximation (19), and amounts to assuming that, since nuclear motion is much slower than electronic motion, the electron distribution depends only upon the positions of the nuclei and not on their motions. Thus, the Schrödinger equation can be rewritten as an electronic Schrödinger equation, as

follows:

$$\hat{H}^{\text{elec}}\Psi^{\text{elec}}(\boldsymbol{r}, \boldsymbol{R}) = E^{\text{eff}}(\boldsymbol{R})\Psi^{\text{elec}}(\boldsymbol{r}, \boldsymbol{R}) \quad (5)$$

In this equation, Ψ^{elec} is the electronic wave function (which depends on the electronic coordinates $\boldsymbol{r}$, as well as the nuclear coordinates $\boldsymbol{R}$) and $\hat{H}^{\text{elec}}$ is the electronic Hamiltonian in which the total kinetic energy is summed over all electrons only. The Born–Oppenheimer approximation is valid provided that the ratio of electron mass to nuclear mass is sufficiently small.

The objective of computational quantum chemistry is to solve this nonrelativistic, electronic Schrödinger equation for $E^{\text{eff}}(\boldsymbol{R})$, that is, the energy corresponding to a given arrangement of nuclei. If the Schrödinger equation is solved for all possible arrangements of nuclei in a system, one obtains the *potential energy surface*. (In fact, one yields the ground-state potential energy surface and any number of excited-state surfaces; however, for the remainder of this chapter we will focus largely on the ground states.) This contains the information required for the quantitative description of chemical structures and processes. For example, by identifying the nuclear coordinates corresponding to local minima in the potential energy surface, one can determine the equilibrium geometries of chemical species. By comparing the energies of alternative local minima, one can determine the relative energies of alternative conformers and isomers, and thus identify the preferred (ie, global minimum energy) structure. Alternative local minima on a potential energy surface may correspond to the reactant(s) and product(s) in a chemical reaction, and by comparing their total energies (including zero-point vibrational energy) one can calculate the reaction enthalpy at 0 K. The transition structure for a chemical reaction can also be identified from the potential energy surface as a first-order saddle point, that is, a stationary point in which the energy is a local maximum in one dimension (corresponding to the reaction coordinate), and a local minimum in all other dimensions. By comparing the total energies at the transition structure and the reactants, one can calculate the energy barrier for the chemical reaction. Having identified the equilibrium geometry of a molecule, one can calculate the second derivative of the energy at that point in the potential energy surface, and this yields the vibrational frequencies of the molecule (ie, the peak positions in its IR and Raman spectra) (see VIBRATIONAL SPECTROSCOPY). The vibrational frequencies can be used to calculate the total zero-point vibrational energy, and also the vibrational contribution to the enthalpy and entropy of a molecule at any temperature. Finally, the potential energy surface provides the information required to calculate the rates of chemical reactions.

Solving the Schrödinger equation also yields the ground-state wave function for the given arrangement of nuclei. Since the square modulus of the wave function is related to the electron probability density, quantum-chemical calculations thus enable us to determine the distribution of electrons within a molecule, and hence the charge distribution. In fact, assigning charges to specific atoms within a molecule raises a number of philosophical problems, as under quantum mechanics electrons do not "belong" to any specific nucleus but are distributed throughout the molecule in *molecular* orbitals. To determine the charge on a specific atom within a molecule, it is necessary to define a scheme for dividing the molecular volume into atomic subspaces. A number of such schemes exist, and the main

ones include the Mulliken population analysis (8), the natural bond orbital analysis (20), and Atoms in Molecules (AIM) theory (21). In very broad terms, the former two schemes assign electrons to a nucleus if they are located in orbitals centered on that nucleus, but differ in the manner in which those "orbitals" are defined. By contrast, AIM theory uses a spatial definition for the atom, and generally provides the most rigorous and the most physically meaningful charges, though it is also the most computationally expensive method. A detailed discussion of wave function analysis methods is provided in Reference (9).

In summary, by solving the Schrödinger equation, one has direct access to electronic-structure information and can calculate from first principles the mechanism, kinetics, and thermodynamics of chemical reactions. In principle, such calculations can be extremely accurate, relying only upon the validity of quantum mechanics, and values for the fundamental physical constants. However, in practice, the multi-electron Schrödinger equation has no analytical solution and numerical approximations must instead be made. These approximations are a potential source of error in the calculations, and it is thus important to understand their underlying assumptions. This article is primarily concerned with ab initio molecular orbital theory, which is one of the principal approaches to solving the electronic Schrödinger equation. In this section, the main principles of ab initio molecular orbital theory are detailed. Other approaches to solving the Schrödinger equation include density functional theory and semiempirical methods, and these are also briefly outlined. Finally, the additional theoretical calculations required in order to use the output of quantum-chemical calculations to obtain the rate coefficients for chemical reactions are described. The method of molecular mechanics (MM)—which is an empirical procedure that is *not* based on solving the Schrödinger equation—is described elsewhere (22–24).

Ab Initio Molecular Orbital Theory

In ab initio molecular orbital theory, the wave function is approximated using one-electron functions or "spin orbitals" (χ). Each spin orbital is a product of a molecular orbital, $\psi(x, y, z)$, which depends on the Cartesian coordinates of the electron, and a spin function, α or β, which corresponds to the spin angular momentum of the electron being aligned along the positive or negative z-axes, respectively. The molecular orbitals (ψ_i) are represented mathematically as a linear combination of a set of N one-electron functions called *basis functions* (ϕ_μ).

$$\psi_i = \sum_{\mu=1}^{N} c_{\mu i}\phi_\mu \tag{6}$$

In this equation, the coefficients $c_{\mu i}$ are called the molecular orbital expansion coefficients, and are optimized during the computational procedure. In chemical terms, one can think of the basis functions as the sets of constituent atomic orbitals, which mix to form the molecular orbitals of the molecule. In order to approach the exact solution to the Schrödinger equation, an infinite set of basis functions would be required, as this would introduce sufficient mathematical

flexibility to allow for a complete description of the molecular orbitals. Of course, in practice a finite set of basis functions must be chosen, and this introduces a potential source of error to the calculations.

Having formed a set of N linearly independent molecular orbitals, these orbitals must then be occupied to form the wave function. In ab initio molecular orbital theory the wave function is formed as the determinant of a matrix, which for an n-electron closed-shell system [ie, n is even (If n were odd, and the system was a doublet species (having one unpaired electron), we could instead form $(n+1)/2$ orbitals, one of which would be singly occupied. The treatment of open-shell systems is discussed in more detail below.)] might be written as follows.

$$\Psi = (n!)^{-1/2} \begin{vmatrix} \psi_1(1)\alpha(1) & \psi_1(1)\beta(1) & \psi_2(1)\alpha(1) & \psi_2(1)\beta(1) & \cdots & \psi_{n/2}(1)\alpha(1) & \psi_{n/2}(1)\beta(1) \\ \psi_1(2)\alpha(2) & \psi_1(2)\beta(2) & \psi_2(2)\alpha(2) & \psi_2(2)\beta(2) & \cdots & \psi_{n/2}(2)\alpha(2) & \psi_{n/2}(2)\beta(2) \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ \psi_1(n)\alpha(n) & \psi_1(n)\beta(n) & \psi_2(n)\alpha(n) & \psi_2(n)\beta(n) & \cdots & \psi_{n/2}(n)\alpha(n) & \psi_{n/2}(n)\beta(n) \end{vmatrix} \tag{7}$$

This is usually abbreviated as follows.

$$\Psi = |\chi_1(1)\chi_2(2)\ldots\chi_n(n)| \tag{8}$$

In this determinant, which is known as the Slater determinant (25), the first row corresponds to all possible assignments of electron 1 to all of the spin orbitals, the second to all possible assignments of electron 2, and so on. The factor of $(n!)^{-1/2}$ ensures that the total probability of finding an electron anywhere in space is 1.

We have already seen that, from our set of N basis functions (where N should approach infinity), we can form N linearly independent molecular orbitals. However, in an n-electron system, we choose only $n/2$ of these orbitals (if n is even) to occupy in our Slater determinant. Clearly the most appropriate orbitals to occupy should be the $n/2$ lowest energy orbitals, and this is the basis of the well-known *Hartree–Fock theory* (26). While Hartree–Fock theory performs adequately in many cases, its use of a single determinant wave function can also frequently lead to considerable error. The problem is that this approach fails to account for Coulombic electron correlation. That is, it is assumed that each electron "sees" the other electrons as an average electric field and thus no instantaneous electron–electron interactions are included. To approach the exact solution to the Schrödinger equation, the wave function must instead be represented as a linear combination of (an infinite number of) Slater determinants. In each of the additional determinants, one or more of the lowest energy orbitals are substituted with the (previously unoccupied) higher energy orbitals. In chemical terms, one might think of this as allowing for contributions to the wave function from the various possible excited configurations. This approach is known as *configuration interaction* (CI), and when all possible excited configurations are included the method is known as *Full CI*.

Under ab initio molecular orbital theory, the exact solution to the Schrödinger equation could be obtained using the Full CI method in conjunction with an infinite basis set. Since this is impractical, computational methods must place restrictions

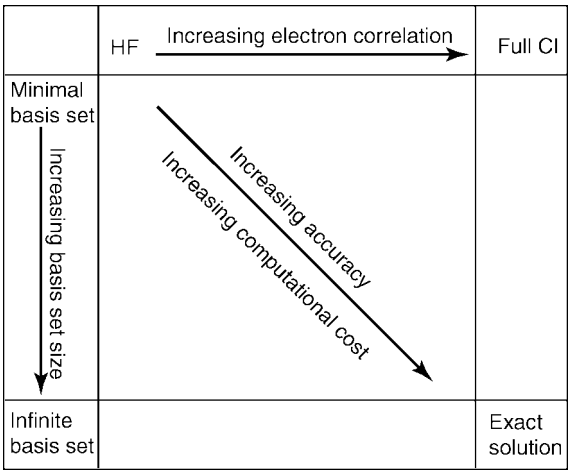

Fig. 1. Pople diagram (8) illustrating the dependence of the accuracy of a computational method on the basis set and the treatment of correlation.

on the number of basis functions included in the calculation, and (in general) simplify the method for treating correlation. The combination of method and basis set chosen for a calculation forms the "level of theory," and by convention is written as "*method*/*basis set*" (using the standard abbreviations for the particular method and basis set chosen). By increasing the size of the basis set and/or improving the method, one can improve the accuracy of the calculation but also its computational cost (see Fig. 1). Furthermore, the performance of a given level of theory can vary considerably depending upon the chemistry of the system, and the type of properties being calculated. The choice of level of theory is therefore very important, and a qualitative understanding of the approximations made at the various levels of theory is thus helpful in choosing appropriate theoretical procedures. For the remainder of the present section, the main qualitative features of commonly used methods and basis sets are described. The accuracy and applicability of these methods for studying the reactions of relevance to free-radical polymerization is discussed in a following section.

Basis Sets.

LCAO Scheme. A basis set is a set of one-electron functions, which are combined to form the molecular orbitals of the chemical species. This is known as the Linear Combination of Atomic Orbitals (LCAO) scheme. To approach the exact solution to the Schrödinger equation, an infinite set of basis functions would be required, as this would introduce sufficient mathematical flexibility to allow for a complete description of the molecular orbitals. In practical calculations, we must use a finite number of basis functions, and it is thus important to choose basis functions that allow for the most likely distribution of electrons within the system. This is achieved using basis functions that are based on the atomic orbitals of the constituent atoms of the molecule. For example, if a chemical system contained an oxygen atom, the chosen basis set would include functions describing each of the 1*s*, 2*s*, and three 2*p* orbitals of an oxygen atom.

The basis functions that are typically used in practice are called Gaussian-type orbitals, and examples of their functional form for s-type and p_y-type orbitals are shown below.

$$g_s(\alpha, r) = \left(\frac{2\alpha}{\pi}\right)^{3/4} e^{-\alpha r^2} \tag{9}$$

$$g_y(\alpha, \boldsymbol{r}) = \left(\frac{128\alpha^5}{\pi^3}\right)^{1/4} y\, e^{-\alpha r^2} \tag{10}$$

The exponent α determines the size of the orbital, and standard values have been determined for the different orbitals on the different atoms. Gaussian-type orbitals such as those shown in equations 9 and 10 are called *primitive Gaussians*. *Contracted Gaussians* are also used, and these consist of linear combinations of primitive Gaussians:

$$\phi_\mu = \sum_p d_{\mu p} g_p \tag{11}$$

The coefficients in this expression ($d_{\mu p}$) are fixed for the basis set of a given atom, and should not be confused with the molecular orbital expansion coefficients ($C_{\mu i}$) of equation 6, which are determined for a given system during the ab initio calculation.

Basis sets thus contain sets of primitive or contracted Gaussians, which correspond to the atomic orbitals of the constituent atoms. *Minimal basis sets* typically contain exactly the number of functions required to accommodate the electrons in the system while maintaining the overall spherical symmetry. For example, a minimal basis set would contain a 1s function for each hydrogen atom, 1s, 2s, and three 2p functions for each carbon atom, and so on. However, in cases where the low lying unoccupied orbitals are frequently involved in bonding (eg, the 2p orbitals of Li or Be), popular minimal basis sets (such as STO-3G) include these additional functions as well.

The problem with minimal basis sets is that the size and shape of the atomic orbitals are fixed, and all that can be varied in the quantum chemical calculation is their contribution to the overall molecular orbitals. However, in reality, the size and shape of the atomic orbitals (and especially the valence orbitals) can depend heavily upon the molecular environment. For example, in polar environments, we might expect a greater degree of asymmetry in the 2p orbitals of oxygen, compared with the same orbitals in nonpolar environments. One way of resolving this problem would be to create individual basis sets for each atom in each conceivable molecular environment, but this would not only be impractical, it would also defeat the purpose of performing ab initio calculations. Instead, a practical solution to this problem is to include additional basis functions of varying sizes and shapes. By varying their individual contribution to the overall molecular orbitals, one effectively introduces flexibility to the size and shape of the constituent atomic orbitals. Some of the main extensions to a minimal basis set are outlined in the following.

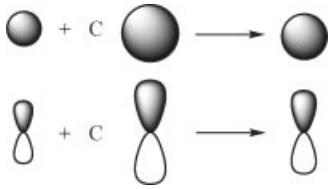

Fig. 2. Demonstration of how the mixing of two basis functions of different size is equivalent to introducing a single basis function with variable size. The basis functions are represented schematically as the boundary surface within which there is a 90% probability of finding the electron. In the first example, two *s*-type basis functions are mixed, while in the second example two *p*-type functions are mixed.

(1) *Double zeta, triple zeta, and quadruple zeta basis sets* include additional sets of each basis function (2, 3, or 4 sets respectively), with each additional set having a different size. By varying the relative contribution of the alternative sizes to the overall molecular orbital, one effectively introduces a single function with a variable size (see Fig. 2).

(2) *Split-valence basis sets* are a simplification to the double, triple, and quadruple zeta basis sets described above. Since the inner shell orbitals are not usually involved in bonding, and their energies are reasonably independent of their molecular environment, it is usually only necessary to include the extra basis functions for the valence orbitals. Basis sets that include different numbers of basis functions for the inner shell and valence electrons are known as split-valence basis sets.

(3) *Polarization functions* are typically included in basis sets to allow for asymmetry in the electron distribution (see Fig. 3). They also allow for the participation of the low lying unfilled atomic orbitals in bonding. Polarization functions typically consist of basis functions corresponding to the low lying unfilled atomic orbitals. For example, the basis set for an oxygen atom might typically include a set of *d*-type orbitals, while those for hydrogen might include a set of *p*-type orbitals. Larger basis sets often include additional polarization functions of higher angular momentum. For example, the 6-311 + G(3df,2pd) basis set includes a set of *f*-type functions and three sets of *d*-type functions for each first row atom, as well as two sets of *p*-type functions and a set of *d*-type functions for each hydrogen atom.

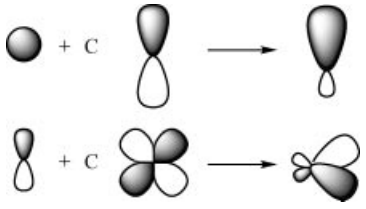

Fig. 3. Demonstration of the effect of polarization functions. In the first example an *s*-type and a *p*-type function are mixed, while in the second case a *p*-type and a *d*-type function are mixed. The mixing of higher angular momentum basis functions allows for an asymmetric distribution of electrons.

(4) *Diffuse functions* are basis functions that have very large amplitudes, far from the atomic nucleus. Sets of diffuse functions are typically added to the basis set when describing species (such as anions) where the electrons are not held very tightly to the nucleus.

(5) *Effective core potentials* (ECPs) are typically used to replace the basis functions of the inner shell electrons for atoms beyond the third row. This reduces the computational cost of the calculations, and is possible because the inner shell electrons on such heavy atoms are relatively unaffected by the molecular environment. Effective core potentials also include corrections for relativistic effects, which are significant for the inner shell electrons of heavy atoms. One of the most commonly used ECPs is called LANL2DZ.

Two commonly used families of extended basis sets are the Pople basis sets (8) and the Dunning basis sets (27). It is worth making a few brief comments on their notation.

(1) *Pople basis sets* have names such as "6-311 + G(3df,2p)." The "6-311" part refers to the fact that it is a split valence set with one copy of each basis function on the inner shell electrons, and three copies on the valence electrons. The "6" refers to the fact that the basis functions on the inner shell electrons consist of a contracted Gaussian-type orbital formed from 6 primitive Gaussians. The "311" part refers to the fact that one set of basis functions on the valence electrons are contracted Gaussians, each formed from 3 primitive Gaussians, while the other two sets of basis functions are primitive Gaussians. The "+" part refers to the fact that one set of *s*-type and *p*-type diffuse functions have been included for each heavy (ie, bigger than hydrogen) atom. The 6-311 ++ G basis set includes an additional set of *s*-type diffuse functions on hydrogen atoms as well. The functions in the bracketed part of the expression (3df,2p) are the polarization functions. The "3df" part refers to the fact that 3 sets of *d*-type functions and one set of *f*-type functions are included for each heavy atom, and "2p" implies that two sets of *p*-type functions are included for each hydrogen atom. Finally, the notations 6-31G* and 6-31G** are also frequently used. The first "*" is an abbreviation for (d) and indicates that a set of *d*-type functions are included for each non-hydrogen atom, while "**" stands for (d,p) and indicates that in addition to the d-type functions for the non-hydrogen atoms, a set of *p*-type functions are included for each hydrogen atom.

(2) *Dunning basis sets* have names such as "cc-pV*n*Z." This notation stands for "correlation-consistent polarized valence *n*-zeta." For a double zeta basis set, *n* is replaced by a "D," for a triple zeta basis set, *n* is replaced by a "T," for a quadruple zeta basis set, *n* is replaced by a "Q," for a quintuple basis set we use a "5," and for a sextuple basis set we use a "6." When diffuse functions are included, an "aug" prefix is included in the name, as in "aug-cc-pVTZ." The cc-pVTZ basis set generally has a performance similar to 6-311G(2df,p). A special feature of the Dunning basis sets is that they have been designed so the series DZ, TZ, QZ, 5Z, 6Z... *systematically* converges on the infinite basis set limit (27). This feature has been exploited in the

infinite basis set extrapolation procedure of Martin and Parthiban (28) (see below).

Plane Waves. While standard ab initio calculations use the LCAO scheme almost exclusively, density functional theory (DFT) calculations (discussed later) sometimes use *plane wave* basis sets. These are solutions of the Schrödinger equation for a free particle and take the general form,

$$g^{PW} = \exp[i\vec{\boldsymbol{k}}\vec{\boldsymbol{r}}] \tag{12}$$

where the vector $\vec{\boldsymbol{k}}$ is related to the momentum $\vec{\boldsymbol{p}}$ of the wave through $\vec{\boldsymbol{p}} = \hbar\vec{\boldsymbol{k}}$. One of the advantages of plane wave basis sets is that they can handle calculations with periodic boundary conditions, and they are thus used widely in solid-state physics. However, a disadvantage is that large basis sets are normally required to achieve acceptable accuracy and, as a result, plane waves are rarely used in calculations of molecular systems. For a detailed discussion of plane wave basis sets, and their application to Car–Parrinello (29) ab initio direct dynamics techniques, the reader is referred to a review by Blöchl and co-workers (30).

Methods.

Hartree–Fock (HF). The foundation of ab initio molecular orbital theory is the Hartree–Fock (HF) method. As we saw above, it is based on a single-determinant wave function (eq. 7) in which the electrons are assigned to the lowest energy orbitals. In fact the Slater determinant of equation 7 applies to *closed-shell systems*, that is, the n electrons occupy the $n/2$ orbitals in pairs of opposite spin. This method is known more specifically as restricted Hartree–Fock (RHF). For *open-shell systems* (that is, those having one or more unpaired electrons), two approaches are possible. In restricted-open-shell Hartree–Fock (ROHF), the determinant is formed from a set of molecular orbitals, which are either doubly or singly occupied, according to the multiplicity of the species. For example, for a radical (doublet) species, the determinant would be formed from $(n + 1)/2$ orbitals, and one of these would be singly occupied. This ensures that there is exactly one unpaired spin in the system, and the species is indeed a pure doublet. In unrestricted Hartree–Fock (UHF), the α and β spin orbitals are defined and optimized separately. Thus there would be $(n + 1)/2$ occupied α spin orbitals, and $(n - 1)/2$ occupied β spin orbitals. The principal differences between the RHF, ROHF, and UHF theory are illustrated in Figure 4.

The UHF method offers some advantages over the ROHF method. In particular, the additional freedom in the wave function (with the provision for noninteger natural orbital occupation numbers) allows it to account in part for nondynamic electron correlation, and leads to lower energies and a better qualitative description of bond dissociation (9). Through its introduction of spin polarization effects, the UHF method can also provide a better (though by no means perfect) qualitative treatment of hyperfine coupling constants (31). However, a disadvantage of UHF is that the independent optimization of the α and β spin orbitals can result in nominally equivalent α and β orbitals having slightly different eigenvalues. In other words, a doublet species could have effectively more than one unpaired electron in the system. This physically unrealistic phenomenon is known as *spin*

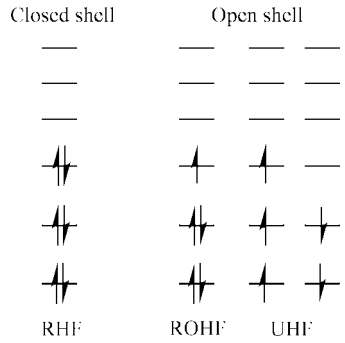

Fig. 4. Electron configuration diagrams highlighting the differences between restricted Hartree–Fock theory (RHF), restricted open-shell Hartree–Fock theory (ROHF), and unrestricted Hartree–Fock theory (UHF).

contamination, and can be a particular problem for the transition structures in the propagation steps of free-radical polymerization. Assessment studies (32,33) for such reactions have revealed that spin-contaminated UHF wave functions make poor starting points for Möller–Plesset (MP) perturbation theory calculations (see below). By contrast, MP calculations based on ROHF wave functions (such as ROMP2) show improved agreement with higher level values. Interestingly, it has been found that for high level methods such as coupled cluster theory (see below), the choice of the starting wave function (ie, UHF vs ROHF) makes little difference to the final calculated energies and geometries for radical reactions (34).

Having constructed a wave function, the remaining unknown parameters in the Schrödinger equation are the molecular orbital expansion coefficients ($c_{\mu i}$), as defined in equation 6. Determining the optimum values of these coefficients is thus the principal task of an ab initio calculation. It is beyond the scope of this chapter to outline the mathematical equations and numerical algorithms used to achieve this, but it is worth describing the general approach in qualitative terms. The basis of this procedure is the *variational principle*. It merely states that for any antisymmetric normalized function of the electronic coordinates (eg, a Slater determinant), the energy of this function is always greater than the expectation value of the exact wave function for the ground state. In other words, the exact wave function serves as a lower bound to the energies calculated from our approximate wave function, and the optimal coefficients $c_{\mu i}$ are merely those that minimize the energy. This principle leads to the Roothaan–Hall equations (35), which are solved iteratively until the $c_{\mu i}$ coefficients converge. At convergence the coefficients are "self-consistent," and hence the HF theory is also known as self-consistent field (SCF) theory.

Configuration Interaction (CI). The description of the wave function using a single determinant (as in HF theory) fails to take electron correlation into account. To obtain the exact solution to the Schrödinger equation we instead need to construct the wave function as a linear combination of determinants, with each additional determinant corresponding to one of the various possible excited configurations obtained when electrons are promoted to the previously unoccupied higher energy orbitals (see Fig. 5). The resulting wave function is written as follows.

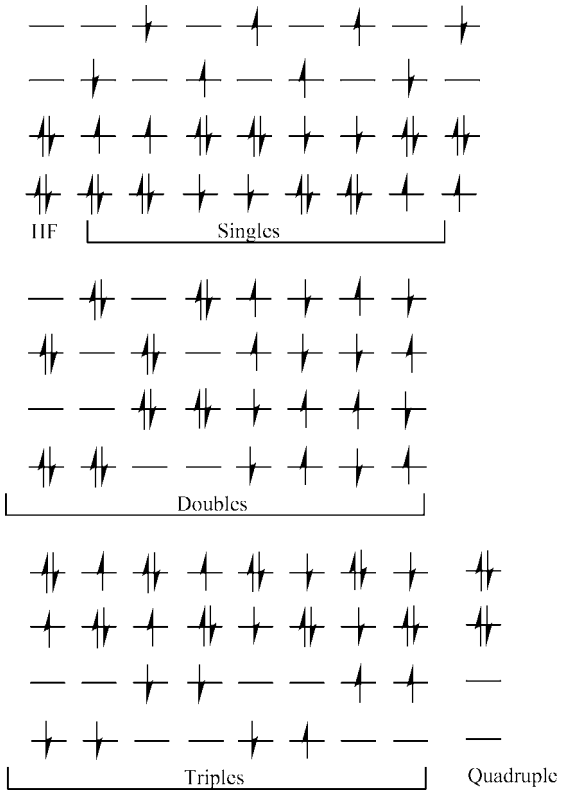

Fig. 5. Electron configuration diagrams showing the configurations corresponding to the HF wave function, and the various possible excited configurations. For this 4-electron system, the combination of single, double, triple, and quadruple excitations constitutes full CI. However, with an infinite basis set, there would be an infinite number of unoccupied orbitals (instead of the two shown here) to promote the electrons into, and thus an infinite number of determinants would be required to obtain the exact solution to the Schrödinger equation.

$$\Psi = a_0\Psi_0 + \sum_{s>0} a_s\Psi_s \tag{13}$$

The Ψ_0 wave function is the HF wave function, while the various Ψ_s determinants correspond to the various excited configurations. The CI method introduces a further set of unknown parameters into the calculation, the coefficients (a_s). These coefficients are optimized as part of the ab initio calculation in order to minimize the energy, in line with the variational principle. CI methods can be based on an RHF wave function (RCI), a UHF wave function (UCI), or an ROHF wave function (URCI).

Full CI is impractical with an infinite basis set (and hence an infinite number of virtual orbitals), or indeed with a finite basis set and a reasonably small number of electrons. For example, even for water with the small 6-31G(d) basis set, the full CI treatment would involve nearly 5×10^8 configurations. For this

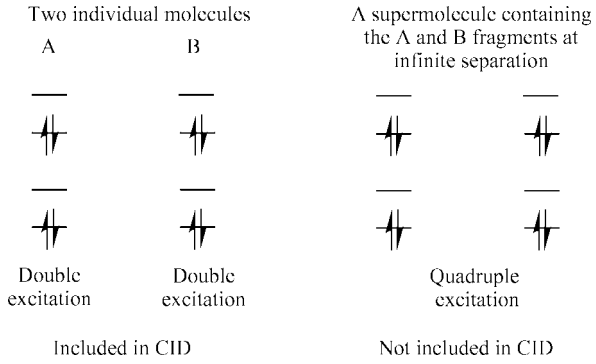

Fig. 6. Electron configuration diagrams illustrating the lack of size consistency in truncated CI. In the first case, A and B are treated separately by CID, and the treatment thus considers the double excitations of electrons in each molecule. In the second case, A and B are calculated as a supermolecule having the A and B fragments at (effectively) infinite separation. Now the simultaneous excitation of two electrons from each of the A-type and B-type orbitals constitutes a quadruple excitation, which is not included in the CID method.

reason, methods based on a truncated CI procedure are generally used in practice. These methods consider a limited number of excited determinants, such as all possible single excitations (CIS) or all possible single and double excitations (CISD). Restricting the CI procedure to single, double, and possibly triple excitations is usually a reasonable approximation, since excitations involving one, two, or three electrons have a considerably higher probability of occurring, and thus contributing to the wave function, compared with excitations of several electrons simultaneously.

However, simple truncated CI methods suffer from a lack of *size consistency*. That is, the error incurred in calculating molecules A and B separately is different from that incurred in calculating a single species, which contains A and B separated by a large (effectively infinite) distance. This can be seen quite clearly in the example shown in Figure 6. The lack of size consistency can be a major problem as it introduces an additional error to calculations of barriers and enthalpies in nonunimolecular reactions. This problem is addressed by including additional terms in the wave function, and the methods based on this approach include *quadratic configuration interaction* (QCI) and *coupled cluster theory* (CC). These methods are typically applied with single and double excitations (QCISD or CCSD), and the triple excitations are often included perturbatively, leading to methods such as QCISD(T) and CCSD(T). When applied with an appropriately large basis set, these methods usually provide excellent approximations to the exact solution to the Schrödinger equation. However, these methods are still very computationally expensive.

Möller–Plesset (MP) Perturbation Theory. By convention, the correlation energy is simply the difference between the Hartree–Fock energy and the exact solution to the Schrödinger equation. Rather than approximate the exact solution to the Schrödinger equation by attempting to build the exact wave function through configuration interaction, an alternative (and considerably less expensive approach) is to estimate the correlation energy as a perturbation on the

Hartree–Fock energy. In other words, the exact wave function and energy are expanded as a perturbation power series in a perturbation parameter λ as follows.

$$\Psi_\lambda = \Psi^{(0)} + \lambda\Psi^{(1)} + \lambda^2\Psi^{(2)} + \lambda^3\Psi^{(3)} + \cdots \quad (14)$$

$$E_\lambda = E^{(0)} + \lambda E^{(1)} + \lambda^2 E^{(2)} + \lambda^3 E^{(3)} + \cdots \quad (15)$$

Expressions relating terms of successively higher orders of perturbation are obtained by substituting equations 14 and 15 into the Schrödinger equation, and then equating terms on either side of the equation. Having obtained these expressions, it simply remains to evaluate the first terms in the series, and this is achieved by taking the $\Phi^{(0)}$ term as the Hartree–Fock wave function. In practice, the MP series must be truncated at some finite order. Truncation at the first order (ie, $E^{(1)}$) corresponds to the Hartree–Fock energy, truncation at the second order is known as MP2 theory, truncation at the third order as MP3 theory, and so on. MP methods based on an RHF, UHF, or ROHF wave function are referred to as RMP, UMP, or ROMP respectively.

When truncated at the second, third, or possibly fourth orders, the MP methods offer a very cost-effective method for estimating the correlation energy. They are also size-consistent methods. However, the validity of truncating the series at some finite order depends on the speed of convergence of the series, and this will vary considerably depending on how closely the Hartree–Fock energy approximates the exact energy. Indeed in some cases, the MP series can actually diverge, and the application of MP methods can in such cases increase rather than decrease the errors in the calculation. As noted above, a relevant example of this problem occurs in the transition structures for radical addition to alkenes for which UMP2 calculations (based on the spin-contaminated UHF wave function) are frequently subject to large errors (32,33). Furthermore, when truncated at some finite order, the MP methods are not variational, and may thus overestimate the correction to the energy. Hence, although MP procedures frequently provide excellent cost-effective performance, they must be applied with caution.

Composite Procedures. The use of CCSD(T) or QCISD(T) methods with a suitably large basis set generally provides excellent approximations to the exact solution of the Schrödinger equation. However, such methods are computationally expensive, and in practical calculations smaller basis sets and/or lower cost methods must be adopted. A major advance in recent years has been the development of high level composite procedures, which approximate high level calculations through a series of lower level calculations. Some of the main strategies that are used are described in the following.

Firstly, it has long been realized that geometry optimizations and frequency calculations are generally less sensitive to the level of theory than are energy calculations. For example, as will be discussed in a following section, detailed assessment studies (36,37) have shown that even HF/6-31G(d) can provide reasonable approximations to the considerably more expensive CCSD(T)/6-311 + G(d,p) level of theory, for the geometries and frequencies of the species in radical addition to multiple bonds (such as C=C, C≡C, and C=S). By contrast, very high levels of

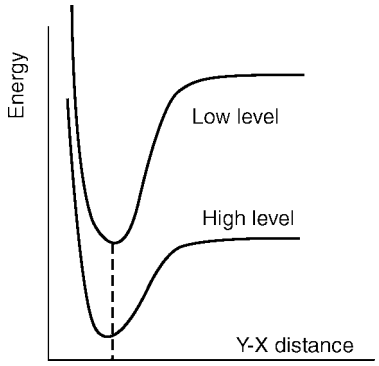

Fig. 7. Illustration of the relative performance of the high and low levels of theory for geometry optimizations and energy calculations. The low level of theory shows a very large error for the absolute energy of structure, a smaller error for the Y—X bond dissociation energy (ie, the well depth), and a very small error for the optimum geometry of the Y—X bond. This reflects the increasing possibility for cancelation of error. In the bond dissociation energy, errors in the absolute energies of the isolated $Y^{\bullet}$ and $X^{\bullet}$ species are canceled to some extent by errors in the Y—X energies. In the geometry optimizations, further cancelation is possible because the position of the minimum energy structure depends on the relative energies of Y—X compounds having very similar Y—X bond lengths.

theory are required to describe the barriers and enthalpies of these reactions. The improved performance of low levels of theory in geometry optimizations and frequency calculations can be understood in terms of the increased opportunity for the cancelation of error, as such quantities depend only upon the *relative* energies of very similar structures (see Fig. 7). In contrast, reaction barriers and enthalpies depend upon the relative energies of the reactants and transition structures or products, and these can have quite different structures, with different types of chemical bonds. It is thus possible to optimize the geometry of a compound at a relatively low level of theory, and then improve the accuracy of its energy using a single higher level calculation (called a "single point"). Since geometry optimizations and frequency calculations are more computationally intensive than single-point energy calculations, this approach leads to an enormous saving in computational cost. By convention, the final composite level of theory is written as "energy method/energy basis set//geometry method/geometry basis set."

Secondly, an extension to the above strategy is known as the *IRCmax* (intrinsic reaction coordinate) *procedure*. It was developed (38) for improving the geometries of transition structures, though techniques based on the same principle have also been used to calculate improved imaginary frequencies and tunneling coefficients (39–41). While low levels of theory are generally suitable for optimizing the geometries of stable species, the geometries of transition structures are sometimes subject to greater error at these low levels of theory. To address this problem, the minimum energy path (MEP) for a reaction is first calculated at a low level of theory, and then improved via single-point energy calculations at a higher level of theory. Now, the transition structure is simply the maximum energy structure along the MEP for the reaction. By identifying the transition structure from the high level MEP (rather than the original low level MEP), one effectively optimizes the reaction coordinate at the high level of theory (see Fig. 8).

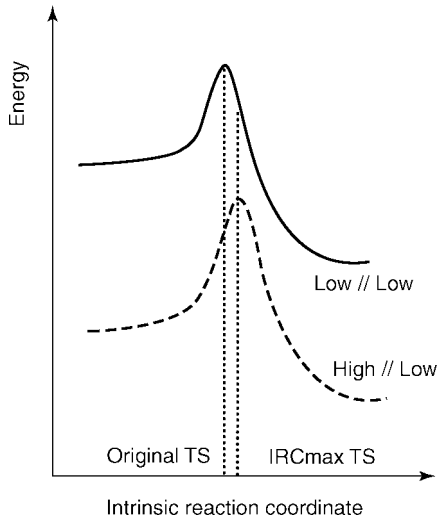

Fig. 8. Illustration of the IRCmax procedure. The minimum energy path (MEP, also known as the intrinsic reaction coordinate or IRC) is optimized at a low level of theory, and then improved using high level single-point energy calculations. The improved transition structure is then identified as the maximum in the high level MEP. This effectively optimizes the reaction coordinate (often the most sensitive part of the geometry optimization) at a high level of theory.

Thirdly, one can improve the single-point energy calculations themselves using additivity and/or extrapolation procedures. In the former case, the energy is first calculated with a high level method (such as CCSD(T)) and a small basis set. The effect of increasing to a large basis set is then evaluated at a lower level of theory (such as MP2). The resulting basis set correction is then added to the high level result, thereby approximating the high level method with a large basis set. The calculation may be summarized as follows.

$$\begin{array}{l} \text{High Method/Small Basis Set} \\ +\text{Low Method/Large Basis Set} \\ -\text{Low Method/Small Basis Set} \\ \hline \approx\text{High Method/Large Basis Set} \end{array} \qquad (16)$$

Procedures for extrapolating the energies obtained at a specific level of theory to the corresponding infinite basis set limit have also been devised. The two main procedures are the extrapolation routine of Martin and Parthiban (18), which takes advantage of the systematic convergence properties of the Dunning DZ, TZ, QZ, 5Z, ... basis sets, and the procedure of Petersson and co-workers (42), which is based on the asymptotic convergence of MP2 pair energies. For the mathematical details of these extrapolation routines, the reader is referred to the original references. The Martin extrapolation procedure is easily implemented on a spreadsheet, while the Petersson extrapolation procedure has been coded into the GAUSSIAN (43) computational chemistry software package.

Building on these strategies, several composite procedures for approximating CCSD(T) or QCISD(T) energies with a large or infinite basis set have been devised. The main families of procedures in current use are the G3 (44), Wn (28), and CBS (42) families of methods. These are described in the following.

(1) In the G3 methods, the CCSD(T) or QCISD(T) calculations are performed with a relatively small basis set, such as 6-31G(d), and these are then corrected to a large triple zeta basis set via additivity corrections, carried out at the MP2 and/or MP3 or MP4 levels of theory (44). There are many variants of the G3 methods, depending upon the level of theory prescribed for the geometry and frequency calculations, the methods used for the basis set correction, and depending on whether CCSD(T) or QCISD(T) is used at the high level of theory. Of particular note are the RAD variants (45) of G3 (such as G3-RAD and G3(MP2)-RAD), which have been designed for the study of radical reactions. G3 methods include an empirical correction term, which has been estimated against a large test set of experimental data, and spin-orbit corrections (for atoms). The G3 methods have been extensively assessed against test sets of experimental data (including heats of formation, ionization energies, and electron affinities) and are generally found to be very accurate, typically showing mean absolute deviations from experiment of approximately 4 $kJ \cdot mol^{-1}$.

(2) In the Wn methods, high level CCSD(T) calculations are extrapolated to the infinite basis set limit using the extrapolation routine of Martin and Parthiban (28). Additional corrections are included for scalar relativistic effects, core-correlation, and spin-orbit coupling in atoms. No additional empirical corrections are included in this method. The Wn methods are very high level procedures, and have been demonstrated to display chemical accuracy. For example, the W1 procedure was found to have a mean absolute deviation from experiment of only 2.5 $kJ \cdot mol^{-1}$ for the heats of formation of 55 stable molecules. For the (more expensive) W2 theory, the corresponding deviation was less than 1 $kJ \cdot mol^{-1}$.

(3) In the CBS procedures, the complete basis extrapolation procedure of Petersson and co-workers is used (42). This calculates the infinite basis set limit at the MP2 level of theory. This is then corrected to the CCSD(T) level of theory using additivity procedures, as in the G3 methods. The CBS procedures also incorporate an empirical correction, and an additional (empirically determined) correction for spin contamination. The accuracy of this latter term for the transition structures of radical addition reactions has recently been questioned (36,37). Nonetheless, the CBS procedures also show similar (excellent) performance to the G3 methods, when assessed against the same experimental data for stable molecules (42).

In summary, using composite procedures, high level calculations can now be performed at a reasonable computational cost. With continuing rapid increases in computer power, details on the computational speeds of the various methods would be rapidly outdated. However, it is worth noting that, at the time of writing, the most cost-effective G3 procedures can be routinely applied to molecules as big

as $CH_3SC^{\bullet}(CH_2Ph)SCH_3$, while the state-of-the-art Wn methods are restricted to smaller molecules, such as $CH_3CH_2CH(CH_3)^{\bullet}$. However, in the near future one can look forward to applying these methods to yet larger systems. In general, the composite procedures described above offer "chemical accuracy" (usually defined as uncertainties of 4–8 $kJ \cdot mol^{-1}$), with the best methods offering accuracy in the kJ range. However, careful assessment studies are nonetheless recommended when applying methods to new chemical systems. A brief discussion of the performance of computational methods for the reactions of relevance to free-radical polymerization is provided in a following section.

Multireference Methods. The post-SCF methods discussed above are all based on a HF or single configuration starting wave function. At the impractical limit of performing full CI (or summing all terms in the MP series) with an infinite basis set, these methods will yield the exact solution to the nonrelativistic Schrödinger equation. However, when truncated to finite order, the use of a single reference wave function can sometimes lead to significant errors. This is particularly the case in the calculation of diradical species (such as the transition structures for the termination reactions in free-radical polymerization), excited states, and unsaturated transition metals. In such situations, the starting wave function itself should be represented as a linear combination of two or more configurations, as follows.

$$\Psi = \sum_j a_j \Psi_j \tag{17}$$

In this equation, the individual wave functions are formed from the lowest energy configuration, and various excited configurations of the Slater determinants, and the a_j coefficients are optimized variationally. While this method, which is known as multireference self-consistent field (MCSCF), may seem analogous to the single-reference CI methods discussed above, there is an important difference between them. In MCSCF, the molecular orbital coefficients (the $c_{\mu i}$ in eq. 6) are optimized for all of the contributing configurations. In contrast, in single-reference methods, the molecular orbital coefficients are optimized for the Hartree–Fock wave function, and are then held fixed at their HF values.

The optimization of both the orbital coefficients and the contribution of the various configurations to the overall wave function can be very computationally demanding. As a result, MCSCF methods typically only consider a small number of configurations, and one of the key problems is choosing which configurations to include. In complete active space self-consistent field (CASSCF), the molecular orbitals are divided into three groups: the inactive space, the active space, and the virtual space (see Fig. 9). The wave function is then formed from all possible configurations that arise from distributing the electrons among the active orbitals (ie, full CI is performed within the active space). It then remains to decide which occupied and virtual orbitals should be included in the active space. Where possible, it is advisable to include all valence orbitals in the active space, together with an equivalent number of virtual orbitals. However, as with any full CI calculation, the computational cost rapidly increases with the number of electrons and orbitals included, and CASSCF calculations are currently limited to active spaces of approximately 16 electrons in 16 molecular orbitals. Thus, for large chemical

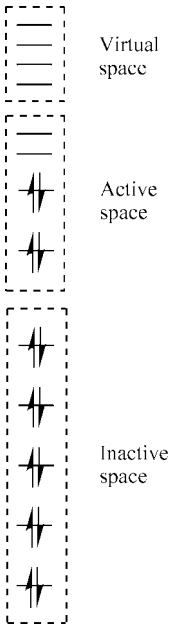

Fig. 9. The partitioning of orbitals between the inactive, active, and virtual spaces in a CASSCF calculation.

systems, full valence active spaces are not as yet possible, and instead a restricted number of orbitals must be chosen.

In non-full valence CASSCF, the active space is typically selected on the basis of "chemical intuition," and might include orbitals that are directly involved in the chemical reaction, or are interacting strongly with the reacting orbitals. For example, in the case of radical–radical reactions, a simplified multireference approach would be a CAS(2,2) method, in which the active space would consist of the two singly occupied molecular orbitals. However, such restricted methods must be used cautiously as they recover correlation in the active space, but not in the inactive space or between the active and inactive spaces. As a result, such procedures can sometimes introduce a bias, which, for example, might lead to an overestimation of the biradical character in systems with nearly degenerate singlet and triplet states (9).

Multireference methods primarily account for nondynamic electron correlation, which arises from long-range interactions involving nearly degenerate states. It is still necessary to correct for dynamic correlation, which arises from short-range electron–electron interactions, and which is primarily addressed in the single-reference post-SCF methods, such as QCISD or MP2. For example, in the case of CI-based methods, it would be necessary to consider excitations from the inactive (as well as active) space orbitals, into all of the virtual orbitals. Multireference versions of post-SCF methods have been derived, including multireference CI (eg, MR(SD)CI, which includes all single and double excitations) and multireference perturbation theory (eg CASPT2, which is a multireference analogue of MP2). The former of these methods is generally more accurate but

also more computationally demanding. For more information on multireference methods, the reader is referred to an excellent review by Schmidt and Gordon (46).

Semiempirical Methods

Semiempirical methods are often used to study large systems for which ab initio calculations are not feasible. A number of different procedures are available, with the main methods being CNDO, INDO, MNDO, MINDO/3, AM1, and PM3. The latter two procedures are generally the best performing of the current available methods, and are thus the most popular in current use. Semiempirical methods are based on ab initio molecular orbital theory, but neglect several of the computationally intensive integrals that are required in Hartree–Fock theory. Depending on the procedure, certain interactions between orbitals are either completely neglected or replaced by parameters that are either derived from experimental data for the isolated atoms or obtained by fitting the calculated properties of molecules to experimental data. This greatly reduces the computational cost of the calculations; however, it can also introduce enormous errors. For more detailed information on the principles and limitations of semiempirical methods, the reader is referred to an article by Stewart (47).

In general, the semiempirical methods perform reasonably well, provided that the species (and properties) being calculated are very similar to those for which the method was parameterized. However, there are many situations in which these methods fail dramatically, and hence such methods should be applied with caution and their accuracy should always be checked against high level calculations for prototypical reactions. In this context it should be noted that such testing has already been performed for the case of radical addition to C=C bonds (32). In this work, semiempirical methods were shown to fail dramatically, and hence (current) semiempirical methods are not generally recommended for studying the kinetics and thermodynamics of the propagation step in free-radical polymerization.

Density Functional Theory

Density functional theory (DFT) is a different quantum chemical approach to obtaining electronic-structure information. The basis of DFT is the Hohenberg–Kohn theorem (48), which demonstrates the existence of a unique functional for determining the ground-state energy and electron density exactly. In the ab initio methods described above, we recall that their objective was to determine the wave function (an eigenfunction) of a system, which thereby enables the energy (the eigenvalue) and electron density (the square modulus of the wave function) to be evaluated. The Hohenberg–Kohn theorem implies that the electronic energy can be calculated from the electron density and there is thus no need to evaluate the wave function. This represents an enormous simplification to the calculation since, in an n-electron system, the wave function is a function of $3n$ variables, whereas the electron density is a function of just 3 variables. Unfortunately, the

Hohenberg–Kohn theorem is merely an existence proof, rather than a constructive proof, and thus the exact functional for connecting the energy and electron density is not known. Hence, although in principle DFT can provide the exact solution to the Schrödinger equation, in practice an approximate functional must be used, and this introduces error to the calculations.

The DFT methods used in practice are based on the equations of Kohn and Sham (49). They partitioned the total electronic energy into the following terms.

$$E = E^{\mathrm{T}} + E^{\mathrm{V}} + E^{\mathrm{J}} + E^{\mathrm{X}} + E^{\mathrm{C}} \tag{18}$$

In this equation, E^{T} is the kinetic energy term (arising from the motions of the electrons), E^{V} is the potential term (arising from the nuclear–electron attraction and the nuclear–nuclear repulsion), E^{J} is the electron–electron repulsion term, E^{X} is the exchange term (arising from the antisymmetry of the wave function), and E^{C} is the dynamical correlation energy of the individual electrons. The sum of the E^{T}, E^{V}, and E^{J} terms corresponds to the classical energy of the charge distribution, while the exchange and correlation terms account for the remaining electronic energy. The task of DFT methods is thus to provide functionals for the exchange and correlation terms. As a matter of notation, DFT methods are typically named as *exchange functional–correlation functional*, using standard abbreviations for the various functionals.

Before discussing the functionals themselves, it is worth making a few comments on *unrestricted Kohn–Sham theory* (50). The effective potential of the Kohn–Sham equations contains no reference to the spin of the electrons, and the energy is simply a functional of the total electron density. (It will only become a functional of the individual spin densities if the potential itself contains spin-dependent parts, such as it would in the presence of an external magnetic field.). Hence, if the exact functional were available, there would normally be no need to consider the α and β spin densities individually, even for open-shell systems. However, in practice we must use approximate functionals, and (for open-shell systems) these are generally more flexible if they explicitly depend on the α and β spin densities. In an analogous manner to UHF, unrestricted Kohn–Sham theory allows the α and β spin densities to optimize independently, and this allows for a better qualitative description of bond-breaking processes but leads to physically unrealistic spin densities and symmetry breaking problems. A more detailed discussion of the advantages and disadvantages of the unrestricted and spin-restricted theories may be found in the excellent textbook by Koch and Holthausen (11), while an example of a practical application of unrestricted Kohn–Sham theory to reactions with biradical transition structures may be found in a paper by Goddard and Orlova (51). On balance, the unrestricted Kohn–Sham theory is normally preferred for open-shell systems; however, as always, careful assessment studies are recommended in order to establish the suitability of any computational method for a specific chemical problem.

Since the exact functional relating the energy to the electron (or spin) density is unknown, it is necessary to design approximate functionals, and the accuracy of a DFT method depends on the suitability of the functionals employed. Many different functionals for exchange and correlation have been proposed, and it is beyond the scope of this article to outline their mathematical forms (these may

be found in textbooks such as Refs. 10 and 11), but it is worth mentioning their main assumptions. Pure DFT methods may be loosely classified into "local" methods and "gradient-corrected" methods. The local DFT methods are based on the local density approximation (LDA, also known as the local spin density approximation, LSDA), in which it is assumed that the electron density may be treated as that of a "uniform electron gas." From this assumption, functionals describing the exchange (called the "Slater" functional, S) (52) and correlation (Vosko–Wilk–Nusair, VWN) (53) can be derived, and the resulting method is known as S-VWN. The treatment of electron density as that of a uniform electron gas is of course an oversimplification of the real situation, and, while it can often provide reasonable molecular structures and frequencies, the LDA model fails to provide accurate predictions of thermochemical properties such as bond energies (for which errors of over 100 $kJ \cdot mol^{-1}$ are typical) (54).

Gradient-corrected DFT methods (also sometimes referred to as nonlocal or semilocal DFT) attempt to deal with the shortcomings of the LDA model through the generalized gradient approximation (GGA). This corrects the uniform gas model through the introduction of the gradient of the electron density. In introducing the gradient, empirical parameters are often incorporated. For example, the Becke-88 exchange functional (55) was parameterized against the known exchange energies of inert gas atoms. This is commonly used in combination with the "LYP" gradient-corrected correlation functional (56), to give the B-LYP method. Another example of a gradient-corrected functional is the Perdew-Wang 91 (PW91) functional, which has both an exchange and a correlation component (57). The GGA methods show improved performance over the LDA model, especially with respect to thermochemical properties. In this regard, the errors generally obtained in standard thermochemical tests of these methods are of the order of 25 $kJ \cdot mol^{-1}$ (54). However, the GGA methods (as well as the LDA methods) perform poorly for weakly bound systems (such as those in which Van der Waal's interactions are important), and they also perform poorly for reaction barriers (54).

The DFT methods described above are pure DFT methods. Another important class of methods is called *hybrid DFT*. In these methods the exchange functional is replaced by a linear combination of the Hartree–Fock exchange term and a DFT exchange functional. In addition, the various exchange and correlation functionals may themselves be constructed as linear combinations of the various available methods. For example, the popular hybrid DFT method, B3-LYP, is defined as follows (58).

$$E_{\mathrm{B3LYP}}^{\mathrm{XC}} = E_{\mathrm{LDA}}^{\mathrm{X}} + c_0\left(E_{\mathrm{HF}}^{\mathrm{X}} - E_{\mathrm{LDA}}^{\mathrm{X}}\right) + c_{\mathrm{X}}\left(E_{\mathrm{B88}}^{\mathrm{X}} - E_{\mathrm{LDA}}^{\mathrm{X}}\right) + E_{\mathrm{VWN}}^{\mathrm{C}} + c_{\mathrm{C}}\left(E_{\mathrm{LYP}}^{\mathrm{C}} - E_{\mathrm{VWN}}^{\mathrm{C}}\right) \tag{19}$$

The coefficients in this expression, $c_0 = 0.20$, $c_{\mathrm{X}} = 0.72$ and $c_{\mathrm{C}} = 0.81$, were obtained by fitting the results of B3-LYP calculations to a test set of experimental atomization energies, electron affinities, and ionization potentials.

Hybrid DFT methods frequently provide excellent descriptions of the geometries, frequencies, and even reaction barriers and enthalpies for many chemical systems. However, owing to their empirical parameters, such methods are increasingly becoming semiempirical in nature and as such can frequently fail when applied to systems other than those for which they were parameterized. A good example of this is the hybrid DFT method MPW1K (59). This was fitted to

a test set of hydrogen abstraction barriers, and performs very well for these reactions. However, the same method has recently been shown to have large errors when applied to the problem of predicting the enthalpies for radical addition to multiple bonds (36,37). Nonetheless, hybrid DFT methods currently present the most cost-effective option for studying larger chemical systems but, as always, the performance of such methods should be carefully assessed for each new chemical problem.

Calculation of Reaction Rates from Quantum-Chemical Data

Quantum and Classical Reaction Dynamics. In the quantum-chemical calculations described above, we solve the *electronic* Schrödinger equation to determine the energy corresponding to a fixed arrangement of nuclei. If such calculations are performed for all possible nuclear coordinates in a chemical system, this yields the *potential energy surface*. However, as we saw above, in constructing this potential energy surface we made the Born–Oppenheimer approximation, and thus ignored the contribution of the motions of the nuclei to the total kinetic energy. This approximation was appropriate for calculating the electronic energy at a specific geometry, but is clearly not very useful for studying the motions of the atoms in chemical reactions. In order to calculate reaction rates, we must construct a new Hamiltonian in which the kinetic energy of the nuclei is taken into account. In this Hamiltonian, the potential energy is simply the total electronic energy, which we obtain from our quantum-chemical calculations. Once we have formed our new Hamiltonian we can then solve the Schrödinger equation again, this time to follow the motion of the nuclei. This procedure is known as *quantum dynamics*, and can in principle yield the exact reaction rates for a chemical system (within the Born–Oppenheimer approximation).

However, there are several practical limitations to quantum dynamics. Firstly, we have already seen that, for all but the simplest chemical systems, obtaining accurate solutions to the electronic Schrödinger equation for a single set of nuclear coordinates is very computationally intensive. Secondly, to construct a potential energy surface, these expensive calculations must be repeated for "every" possible arrangement of nuclei. Efficient algorithms are available for choosing only those geometries necessary for an adequate description of the chemical system (60). However, even using these algorithms, large numbers of quantum-chemical calculations are nonetheless required. For example, approximately 1000 quantum-chemical calculations were required to construct a reliable potential energy surface for the $OH + H_2$ system (61). Furthermore, the number of data points required increases substantially with the number of atoms in the system (due to the increasing dimensionality). Finally, we have the problem of solving the nuclear Schrödinger equation. In practice, this is intractable for all but the simplest systems, as atoms (being heavier) require even more basis functions than are needed to solve the electronic Schrödinger equation. With current available computing power, quantum dynamics calculations are thus restricted to very small systems, such as $OH + H_2$ (61). In this (state-of-the-art) 4-atom calculation, the energies at approximately 10^7 different points on the potential energy surface were required

in order to solve the nuclear Schrödinger equation, and this requirement scales exponentially with the number of atoms in the system.

Classical reaction dynamics provides a strategy for calculating the rate coefficients of larger chemical systems. Having used quantum-chemical techniques to calculate the potential energy surface, the motions of the nuclei are studied by solving the laws of classical or Newtonian dynamics. This is often a reasonable approximation, since the atoms (being heavier) are considerably less subject to quantum effects than the electrons. Nonetheless, standard classical reaction dynamics calculations are still limited by the need to calculate a full potential energy surface (including the first and second derivatives at each point). As a result, standard classical dynamics calculations *involving accurate ab initio potential energy surfaces* are also currently restricted to relatively small chemical systems, such as $H_3C_3N_3$ (62).

An alternative approach to constructing the entire potential energy surface for a chemical system is provided by *direct dynamics*. In both standard classical reaction dynamics and direct dynamics, the basic principle is the same. A starting arrangement of atoms is adjusted (by a small amount) according to the forces acting on them during a small "step" in time, using the laws of classical mechanics. This "time step" is then repeated using the force corresponding to the new geometry, and so on. The process is repeated for many thousands of time steps, until a complete trajectory is mapped out. The process is then repeated for many trajectories until the reaction probability (and other related information) is established to within an acceptable level of statistical error. As we saw above, in standard classical reaction dynamics, the force acting on the molecule as a function of geometry is obtained from the potential energy surface. In direct dynamics, also known as on-the-fly ab-initio dynamics, this force is calculated (using quantum-chemical calculations) at each new position (63). The latter approach is simpler, but less computationally efficient, and is still restricted to relatively small systems (if accurate levels of theory are used to calculate the forces).

It should be noted that the classical reaction dynamics of much larger systems can be studied using approximate potential energy surfaces, constructed using empirical or semiempirical procedures. In particular, the method of molecular mechanics (MM), which is described elsewhere in this *Encyclopedia*, is commonly used to simulate the motion of polymers and proteins. However, the accuracy of MM simulations are limited by the accuracy of the "force field," which is the set of potential functions that are used to govern relative motions of the constituent atoms. Force fields are typically derived on the basis of empirical and semiempirical information, and are typically only accurate for the type of system for which they were parameterized. Recently, much effort has been directed at deriving accurate force fields for reacting systems, and prominent examples include ReaxFF (64) and MMVB (65). However, such force fields are nonetheless approximate, and only suitable for the types of reactions for which they were designed. Accurate force fields for studying the kinetics of free-radical polymerization do not currently exist, and instead high level ab initio calculations are necessary in order to model these reactions accurately.

Transition-State Theory. To study reactions in larger chemical systems using accurate ab initio calculations we need a much simpler approach, and this is provided by *transition-state theory* (66). In its simplest form, it assumes that, in

the space represented by the coordinates and momenta of the reacting particles, it is possible to define a dividing surface such that all reactants crossing this plane go on to form products, and do not recross the dividing surface. The minimum energy structure on this dividing plane is referred to as the transition structure of the reaction. Transition-state theory also assumes there is an internal statistical equilibrium between the degrees of freedom of each type of system (reactant, product, or transition structure), and that the transition state is in statistical equilibrium with the reactants. In addition, it assumes that motion through the transition state can be treated as a classical translation. From these assumptions, the following simple equation relating the rate coefficient at a specific temperature, $k(T)$, to the properties of the reactant(s) and transition state can be derived (66).

$$k(T) = \kappa (c^{\circ})^{1-m} \frac{k_{\mathrm{B}} T}{h} \frac{Q_{\ddagger}^{\ddagger}}{\prod_{\text{reactants}} Q_{\mathrm{i}}} \mathrm{e}^{-E_0/RT} \tag{20}$$

In this equation κ is called the transmission coefficient and is taken to be equal to unity in simple transition-state theory calculations, but is greater than unity when tunneling is important (see below), c° is the inverse of the reference volume assumed in calculating the translational partition function (see below), m is the molecularity of the reaction (ie, $m = 1$ for unimolecular, 2 for bimolecular, and so on), k_{B} is Boltzmann's constant (1.380658×10^{-23} J · molecule^{-1} · K^{-1}), h is Planck's constant ($6.6260755 \times 10^{-34}$ J·s), E_0 (commonly referred to as the reaction barrier) is the energy difference between the transition structure and the reactants (in their respective equilibrium geometries), $Q_{\ddagger}$ is the molecular partition function of the transition state, and Q_{i} is the molecular partition function of reactant i.

Transition-state theory thus reduces the problem of calculating the potential energy surface for "every" possible geometric arrangement of nuclei, to the consideration of a very small number of "special" geometries; namely, the transition structure and the reactant(s). The transition structure is the minimum energy structure on the dividing surface between the reactants and products, and must be located so as to make the "no re-crossing" assumption as valid as possible. In simple transition-state theory, the transition structure is located as the maximum energy structure, along the minimum energy path connecting the reactants and products. This is generally a good approximation for reactions having barriers that are large compared to $k_{\mathrm{B}}T$. However, for reactions with low or zero barriers, a more accurate approach is required. To this end, in *variational transition-state theory*, the transition structure is located as the structure (on the minimum energy path) that yields the lowest reaction rate. In thermodynamic terms, this may be thought of as the maximum in the Gibb's free energy of activation, rather than the maximum internal energy of activation.

In order to calculate reaction rates via transition-state theory, one needs to identify the equilibrium geometries of the reactants, and also the transition structure, and calculate their energies. This information is of course accessible from quantum-chemical calculations. The molecular partition functions for these

species are also required. These serve as a bridge between the quantum mechanical states of a system and its thermodynamic properties, and are given by

$$Q = \sum_i g_i \exp\left(-\frac{\varepsilon_i}{k_B T}\right) \tag{21}$$

The values ε_i are the energy levels of a system, each having a number of degenerate states g_i, and are obtained by solving the Schrödinger equation. In theory, this equation should be solved for all active modes but in practice the calculations can be greatly simplified by separating the partition function into the product of the translational, rotational, vibrational, and electronic terms, as follows.

$$Q = Q_{\text{trans}} \times Q_{\text{rot}} \times Q_{\text{vibr}} \times Q_{\text{elec}} \tag{22}$$

This is generally a reasonable assumption, provided that the reaction occurs on a single electronic surface. Finally, if we assume that reacting species are ideal gas molecules, analytical expressions for the partition functions are as follows:

$$Q_{\text{trans}} = V\left(\frac{2\pi M k_B T}{h^2}\right)^{3/2} = \frac{RT}{P}\left(\frac{2\pi M k_B T}{h^2}\right)^{3/2} \tag{23}$$

$$Q_{\text{vib}} = \prod_i \exp\left(-\frac{1}{2}\frac{h\nu_i}{kT}\right) \times \prod_i \frac{1}{1-\exp\left(-\frac{h\nu_i}{kT}\right)} \tag{24}$$

$$Q_{\text{rot, linear}} = \frac{1}{\sigma_r}\left(\frac{T}{\Theta_r}\right) \quad \text{where} \quad \Theta_r = \frac{h^2}{8\pi^2 I k_B} \tag{25}$$

$$Q_{\text{rot, nonlinear}} = \frac{\pi^{1/2}}{\sigma_r}\left(\frac{T^{3/2}}{(\Theta_{r,x}\Theta_{r,y}\Theta_{r,z})^{1/2}}\right) \quad \text{where} \quad \Theta_{r,i} = \frac{h^2}{8\pi^2 I_i k_B} \tag{26}$$

$$Q_{\text{elec}} = \omega_0 \tag{27}$$

In equations 23–27 R is the universal gas constant ($8.314\ \text{J}\cdot\text{mol}^{-1}\cdot\text{K}^{-1}$); M is the molecular mass of the species; V is the reference volume, and T and P the corresponding reference temperature and pressure: ν_i are the vibrational frequencies of the molecule; I is the principal moment of inertia of a linear molecule, while for the nonlinear case I_x, I_y, and I_z are the principal moments of inertia about axes x, y, and z respectively; σ_r is the symmetry number of the molecule which counts its number of symmetry equivalent forms (67); and ω_0 is the electronic spin multiplicity of the molecule (ie, $\omega_0 = 1$ for singlet species, 2 for doublet species, etc). The information required to evaluate these partition functions is routinely accessible from quantum-chemical calculations: the moments of inertia and symmetry numbers depend on the geometry of the molecule, while the vibrational frequencies are obtained from the second derivative of the energy with respect to the geometry.

A number of additional comments need to be made concerning the use of equations 23–27. Firstly, in the calculation of the translational partition function (eq. 23), a reference volume (or equivalently, a temperature and pressure) is assumed. This is needed for the calculation of thermodynamic quantities such as enthalpy and entropy, but the assumption has no bearing on the calculated rate coefficient, as the reference volume is removed from equation 20 through the parameter $c^\circ (= 1/V)$. Secondly, the vibrational partition function (eq. 24) has been written as the product of two terms. The first of these corresponds to the zero-point vibrational energy of the molecule, while the latter corresponds to its additional vibrational energy at some nonzero temperature T. The zero-point vibrational energy is often included in the calculated reaction barrier E_0. When this is the case, this first term must be removed from equation 24, so as not to count this energy twice. Thirdly, the external rotational partition function is calculated using equation 25 if the molecule is linear, and equation 26 if it is not.

It is also worth noting that there is an entirely equivalent thermodynamic formulation of transition-state theory.

$$k(T) = \kappa \frac{k_B T}{h} (c^\circ)^{1-m} \, e^{\Delta S^\ddagger / R} \, e^{-\Delta H^\ddagger / RT} \tag{28}$$

A derivation of this expression, which is obtained by noting the relationship between the thermodynamic properties of a system (eg enthalpy, H, and entropy, S) and the partition functions, can be found in textbooks on statistical thermodynamics (12–16). The enthalpy of activation ($\Delta H^\ddagger$) for this expression can be written as the sum of the barrier (E_o), the zero-point vibrational energy (ZPVE), and the temperature correction ($\Delta\Delta H^\ddagger$).

$$\Delta H^\ddagger = \Delta E_0 + \mathrm{ZPVE} + \Delta\Delta H^\ddagger \tag{29}$$

The temperature correction ($\Delta\Delta H$) and ZPVE for an *individual* species can be calculated from the vibrational frequencies as follows.

$$\mathrm{ZPVE} = R \frac{1}{2} \sum_i h\nu_i / k_B \tag{30}$$

$$\Delta\Delta H = R \sum_i \frac{h\nu_i / k_B}{\exp(h\nu_i / k_B / T) - 1} + \frac{5}{2} RT + \frac{3}{2} RT \tag{31}$$

In equation 31, the first term is the vibrational contribution to the enthalpy, the second term is the translational contribution, and the third term is the rotational contribution. The entropy of activation ($\Delta S^\ddagger$) is calculated from the vibrational (S_v), translational (S_t), rotational (S_r), and electronic (S_e) contributions to the entropies of the individual species, in turn expressed as follows.

$$S_v = R \sum_i \left(\frac{h\nu_i / k_B T}{\exp(h\nu_i / k_B T) - 1} - \ln(1 - \exp(-h\nu_i / k_B T)) \right) \tag{32}$$

$$S_{\mathrm{t}} = R\left(\ln\left(\left(\frac{2\pi M k_{\mathrm{B}} T}{h^2}\right)^{3/2} \frac{k_{\mathrm{B}} T}{P}\right) + 1 + 3/2\right) \tag{33}$$

$$S_{\mathrm{r,\ linear}} = R\left(\ln\left(\frac{1}{\sigma_r}\left(\frac{T}{\Theta_r}\right)\right) + 1\right) \tag{34}$$

$$S_{\mathrm{r,\ nonlinear}} = R\left(\ln\left(\frac{\pi^{1/2}}{\sigma_r}\left(\frac{T^{3/2}}{(\Theta_{r,x}\Theta_{r,y}\Theta_{r,z})^{1/2}}\right)\right) + 3/2\right) \tag{35}$$

$$S_e = R\ \ln(\omega_0) \tag{36}$$

The parameters required to evaluate these expressions are the same as those used in evaluating the partition functions, as described above.

Finally, by evaluating the derivative of (28) with respect to temperature, it is possible to derive a relationship between the above thermodynamic quantities and the empirical Arrhenius expression for reaction rate coefficients (15):

$$k(T) = Ae^{-Ea/RT} \tag{37}$$

The frequency factor (A) in this expression is related to the entropy of the system, as follows.

$$A = (c^{\circ})^{1-m} e^m \frac{k_{\mathrm{B}} T}{h}\ \exp\left(\frac{\Delta S^{\ddagger}}{R}\right) \tag{38}$$

The Arrhenius activation energy is related to the reaction barrier, as follows.

$$E_{\mathrm{a}} = E_0 + \mathrm{ZPVE} + \Delta\Delta H^{\ddagger} + mRT \tag{39}$$

From these expressions it can be seen that the so-called temperature-independent parameters of the Arrhenius expression are in fact functions of temperature, which is why the Arrhenius expression is only valid over relatively small temperature ranges. It should also be clear that the ZPVE-corrected barrier (E_0 + ZPVE), the enthalpy of activation ($\Delta H^{\ddagger}$), and the Arrhenius activation energy (E_{a}) are only equal to each other at 0 K. At nonzero temperatures, these quantities are nonequivalent and thus should not be used interchangeably.

Extensions to Transition-State Theory. Many variants of transition-state theory have been derived, and a comprehensive review of these recent developments has been provided by Truhlar and co-workers (68). As already noted, one of the main extensions to transition-state theory is variational transition-state theory which, in its simplest form, locates the transition structure as that having the maximum Gibb's free energy (rather than internal energy). Other variations of transition-state theory arise through making different assumptions as to the statistical distribution of the available energy throughout the different molecular modes, and through deriving expressions for the partition functions for cases other than ideal gases. In addition, two simple extensions to the transition-state theory

equations are the inclusion of corrections for quantum-mechanical tunneling, and the improved treatment of the low frequency torsional modes. Since these are of importance in treating certain polymerization-related systems, these are briefly described below.

Tunneling Corrections. One of the assumptions inherent in simple transition-state theory is that motion along the reaction coordinate can be considered as a classical translation. In general, this assumption is reasonably valid since the reacting species, being atoms or molecules, are relatively large and thus their wavelengths are relatively small compared to the barrier width. However, in the case of hydrogen (and to a lesser extent deuterium) transfer reactions, the molecular mass of the atom (or ion) being transferred is relatively small, and thus quantum effects can be very important. Corrections for quantum-mechanical tunneling are incorporated into the κ coefficient of equation 20, and are known as tunneling coefficients.

There is an enormous variety of expressions available for calculating tunneling coefficients. The most accurate tunneling methods, such as *small curvature tunneling* (69), *large curvature tunneling* (70), and *microcanonical optimized multidimensional tunneling* (71), involve solving the multidimensional Schrödinger equation describing motion of the molecules at every position along the reaction coordinate. To calculate such tunneling coefficients, specialized software (such as POLYRATE (72)) is used, and additional quantum-chemical data (such as the geometries, energies, and frequencies along the entire minimum energy path) are required. As a result, simpler (and hence less accurate) expressions are often adopted. These are derived by treating motion along the reaction coordinate as a function of one variable, the intrinsic reaction coordinate, and hence solving a one-dimensional Schrödinger equation. When this is done using the calculated energies along the reaction path, the procedure is known as *zero-curvature tunneling* (73). However, this procedure still entails the numerical solution of the Schrödinger equation, and hence an additional simplification is also often made. Instead of using the calculated energies along this path, some assumed functional form for the potential energy is used instead. This is chosen so that the Schrödinger equation has an analytical solution, and thus a closed expression for the tunneling coefficient can be derived. The derivation of these simple tunneling coefficients is described by Bell (74), and the main expressions used in practice are as follows.

The simplest tunneling coefficients are based on the assumption that the change in energy along the minimum energy path can be described by a truncated parabola. This functional form provides a good description of the energies near the transition structure (where tunneling is most significant), but a very poor description elsewhere. The equation for the tunneling coefficient is given as the following infinite series, which is frequently truncated after the first few terms.

$$\kappa = \frac{\frac{1}{2}u_{\ddagger}}{\sin\left(\frac{1}{2}u_{\ddagger}\right)} - u_{\ddagger}y^{-u_{\ddagger}/2\pi}\left\{\frac{y}{2\pi - u_{\ddagger}} - \frac{y^2}{4\pi - u_{\ddagger}} + \frac{y^3}{6\pi - u_{\ddagger}} - \cdots\right\} \tag{40}$$

where

$$u_{\ddagger} = \frac{h\nu_{\ddagger}}{kT} \quad \text{and} \quad y = \exp\left(-\frac{2\pi V}{u_{\ddagger}kT}\right)$$

Equation 40 is called a *Bell tunneling* correction (74), and in this expression V is the reaction barrier and $\nu_{\ddagger}$ is the imaginary frequency (as obtained from the frequency calculation at the transition structure). By taking the first term of equation 40, expanding it as an infinite series, and then truncating at an early order, the (even simpler) *Wigner* (75) *tunneling* expression is obtained (74).

$$\kappa \approx \frac{\frac{1}{2}u_{\ddagger}}{\sin\left(\frac{1}{2}u_{\ddagger}\right)} \approx 1 + \frac{u_{\ddagger}^2}{24} + \frac{u_{\ddagger}^4}{5760} + \cdots \approx 1 + \frac{u_{\ddagger}^2}{24} \tag{41}$$

A slightly more realistic description of the change in potential energy along the minimum energy path is provided by the following *Eckart* function (76):

$$V(x) = \frac{Ay}{(1+y)^2} + \frac{By}{(1+y)} \quad \text{where} \quad y = e^{x/\Delta} \tag{42}$$

To ensure that the function passes through the reactants, products and transition structures, the parameters A and B are defined as the following functions of the forward (V_{f}) and reverse (V_{r}) reaction barriers (where the reaction is taken in the exothermic direction).

$$A = (\sqrt{V_{\mathrm{f}}} + \sqrt{V_{\mathrm{r}}})^2 \quad \text{and} \quad B = V_{\mathrm{f}} - V_{\mathrm{r}} \tag{43}$$

The remaining parameter Δ is chosen so as to give the most appropriate fit to the minimum energy path. If this fit is biased toward the points near the transition structure (where tunneling is most important), it can be calculated as the following function of the imaginary frequency $\nu_{\ddagger}$ (where c is the speed of light) (39,41):

$$\Delta = \frac{i}{2\pi c \nu_{\ddagger}} \sqrt{\frac{1}{8} \frac{(B^2 - A^2)^2}{A^3}} \tag{44}$$

The Δ value obtained from this expression is in mass-weighted coordinates, which enables the reduced mass to be dropped from the standard (76) Eckart formulae (41), resulting in the following expression for the permeability of the reaction barrier $G(W)$ as a function of the energy W:

$$G(W) = 1 - \frac{\cosh(\alpha - \beta) + \cosh(\delta)}{\cosh(\alpha + \beta) + \cosh(\delta)} \tag{45}$$

where

$$\alpha = \frac{4\Delta\pi^2}{h}\sqrt{2W},\ \beta = \frac{4\Delta\pi^2}{h}\sqrt{2(W-B)},\ \delta = \frac{4\Delta\pi^2}{h}\sqrt{2A - \frac{h^2}{16\pi^2\Delta^2}}$$

The Eckart tunneling correction (κ) is then obtained by numerically integrating $G(W)$ over a Boltzmann distribution of energies, via the formula (74):

$$\kappa = \frac{\exp(V_F/k_BT)}{k_BT}\int_0^\infty G(W)\exp(-W/k_BT)\,dW \tag{46}$$

Although this expression requires numerical integration, it does not require sophisticated software and can be easily implemented on a spreadsheet.

Finally, it is worth making a few comments on the use of the tunneling procedures. Firstly in very general terms, tunneling is important for reactions involving the transfer of a hydrogen or deuterium atom or ion. The importance of tunneling can also be established through examination of the parameter $u_\ddagger$ in equation 40, a value of $u_\ddagger < 1.5$ *usually* indicating negligible tunneling effects (74). Secondly, in principle, the more accurate multidimensional tunneling coefficient expressions should always be used. However, in practice, the more convenient one-dimensional expressions are often adopted. Of these expressions, the Eckart tunneling coefficient is significantly more accurate and should be preferred. For example, the small curvature tunneling method gives a tunneling coefficient (κ) of approximately 10^2 at 300 K, for the hydrogen abstraction reaction between $^{\bullet}NH_2$ and C_2H_6 (77). At the same level of theory, the corresponding κ values for the Wigner, Bell, and Eckart corrections are approximately 5, 10^3, and 10^2 respectively, and hence only the Eckart method yields a tunneling coefficient of the right order of magnitude for this (typical) reaction. The success of the Eckart tunneling method has also been noted by Duncan and co-workers (78), who rationalized it in terms of a favorable cancelation of errors.

Treatment of Low Frequency Torsional Modes. In the vibrational partition function (eq. 24), all modes are treated under the *harmonic oscillator approximation*. That is, it is assumed that the potential field associated with their distortion from the equilibrium geometry is a parabolic well, as in a vibrating spring (see Fig. 10**a**). This is a reasonable assumption for bond stretching motions, but not for hindered internal rotations (see Fig. 10**b**). For high frequency modes ($\nu >$ 200–300 cm^{-1}), the contribution of these motions to the overall partition function is negligible at room temperature (ie $Q_{vib,i} \approx 1$) and thus the error incurred in treating these modes as harmonic oscillators is not significant. However, for the low frequency torsional modes, these errors can be significant and a more rigorous treatment is often necessary, and this is especially the case for the reactions of relevance to free-radical polymerization (3–5,79).

The simplest method for treating the hindered internal rotations is to regard them as one-dimensional rigid rotors. An appropriate rotation angle θ is identified, and then the potential $V(\theta)$ is calculated as a function of this angle (eg from 0 to 360° in steps of 10°) via quantum chemistry. In general, it is recommended that these potentials be obtained as relaxed scans; that is, in calculating the energy at a specific angle, all geometric parameters other than the rotational angle are optimized (79). If the rotational potential can be described as a simple cosine function, the enthalpy and entropy associated with the mode can be obtained directly from the tables of Pitzer and co-workers (80). In order to use these tables,

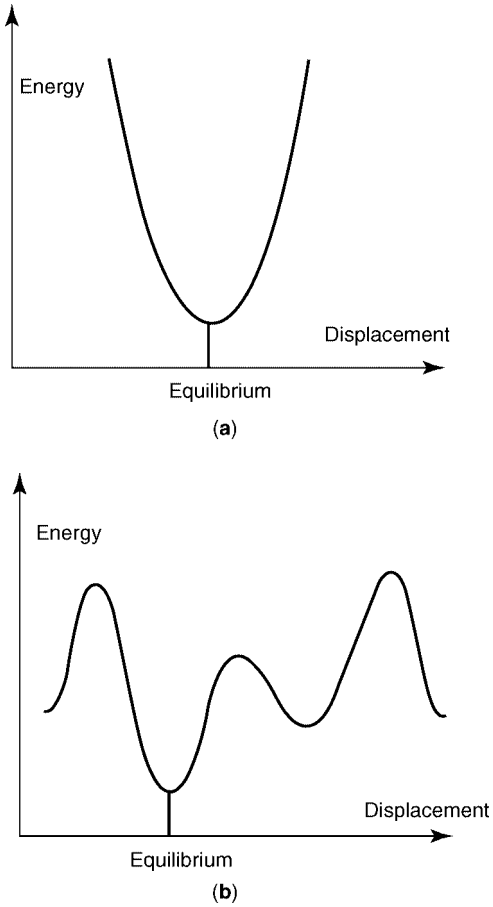

Fig. 10. Typical potentials associated with (**a**) a harmonic oscillator and (**b**) a hindered internal rotation.

one calculates two dimensionless quantities:

$$x = \frac{V}{k_B T} \quad \text{and} \quad y = \frac{\sigma_{int} h}{\sqrt{8\pi^3 I_m k_B T}} \tag{47}$$

In these equations, V is the barrier to rotation, σ_{int} is the symmetry number associated with the rotation (which counts the number of equivalent minima in the potential energy curve), and I_m is the reduced moment of inertia associated with the rotation. This latter parameter is given by the following formula:

$$I_m = A_m \left(1 - \sum_{i=x,y,z} A_m \lambda_{mi}^2 / I_i\right) \tag{48}$$

In this equation, A_m is the moment of inertia of the torsional coordinate itself, I_i is the principal moment of inertia of the whole molecule about axis i, and

λ_{mi} is the direction cosine between the axis of the top and the principal axis of the whole molecule. More information on the calculation of reduced moments of inertia can be found in Reference (81). When the rotational potential cannot be fitted with a simple cosine function (as in Fig. 10**b**), the partition function (and hence the enthalpy and entropy) is obtained instead by (numerically) solving the one-dimensional Schrödinger equation.

$$-\frac{h^2}{8\pi I_m}\frac{\partial^2\Psi}{\partial\theta^2} + V(\theta)\Psi = \varepsilon\Psi \tag{49}$$

This yields the energy levels of the system (ε_i), which are then used to evaluate the partition function via the following equation.

$$Q_{\text{int rot}} = \frac{1}{\sigma_{\text{int}}}\sum_i \exp\left(-\frac{\varepsilon_i}{k_B T}\right) \tag{50}$$

Having obtained the partition function (or equivalently, the enthalpy and entropy) associated with a low frequency torsional mode, this is used in place of the corresponding harmonic oscillator contribution for that mode.

The above treatment of hindered rotors assumes that a given mode can be approximated as a one-dimensional rigid rotor, and studies for small systems have shown that this is generally a reasonable assumption in those cases (82). However, for larger molecules, the various motions become increasingly coupled, and a (considerably more complex) multidimensional treatment may be needed in those cases. When coupling is significant, the use of a one-dimensional hindered rotor model may actually introduce more error than the (fully decoupled) harmonic oscillator treatment. Hence, in these cases, the one-dimensional hindered rotor model should be used cautiously.

Software

There are a large number of software packages available for performing computational chemistry calculations. Some of the programs available include ACES II (83), GAMESS (84), GAUSSIAN (43), MOLPRO (85), and QCHEM (86). Other programs, such as POLYRATE, (72), have been designed to use the output of quantum-chemistry programs to calculate reaction rates and tunneling coefficients. Whereas computational chemistry software has traditionally been operated on large supercomputers, versions for desktop personal computers are increasingly becoming available. In addition, programs for visualizing the output of computational chemistry calculations such as Spartan (87), Molden (88), CS Chem3D (89), Molecule (90), Jmol (91), Gauss View (43), and MacMolPlt (92) are also available. These programs allow one to visualize the geometry and electronic structure of the resulting molecule, and animate its vibrational frequencies. Many of these programs also have built-in computation engines. Computational chemistry is thus increasingly becoming accessible to the nonspecialist user, which brings with it its own problems (see also MOLECULAR MODELING).

Accuracy and Applicability of Theoretical Procedures

By solving the Schrödinger equation exactly, quantum chemistry can, in principle, provide accurate electronic-structure data. However, in practice, approximate numerical methods must be adopted, and these can introduce error to the calculations. As we have already seen, an enormous number of approximate methods are available, and these range from the accurate but computationally expensive to the cheap but potentially nasty. Furthermore, the performance of a particular method varies considerably depending upon the chemical system and the property being calculated. It is therefore very important that computational chemistry studies are accompanied by rigorous assessments of theoretical procedures. In such "calibration" studies, prototypical systems are calculated at a range of levels of theory, and the results are compared both internally (against the highest level procedures) and externally (against reliable experimental data) in order to identify those methods which offer the best compromise between accuracy and expense.

In the present section, the main conclusions from recent assessment studies for the reactions of importance to free-radical polymerization are outlined. In presenting such studies, it must be acknowledged that, with continuing rapid increases in computer power, some of these results will soon be outdated. In particular, as computer power increases, the need to rely upon lower levels of theory for large polymer-related systems will diminish. Instead, the higher levels of theory outlined below will be able to be used routinely. Nonetheless, with increasing computer power, the temptation to apply existing levels of theory to yet larger systems will no doubt ensure that the main conclusions of these studies retain some relevance into the near future.

Radical Addition to C=C Bonds. Radical addition to C=C bonds are of importance for free-radical polymerization as this reaction forms the propagation step, and thus influences the reaction rate and molecular weight distribution in both conventional and controlled free-radical polymerization, and the copolymer composition and sequence distribution in free-radical copolymerization. Numerous studies have examined the applicability of high level theoretical methods for studying radical addition to C=C bonds in small radical systems (32,33,37,93,94). The most recent study (37) included W1 barriers and enthalpies, and geometries and frequencies at the CCSD(T)/6-311G(d,p) level of theory, and is the highest level study to date. The main conclusions from this study, and (where still relevant) the previous lower level studies, are outlined below.

Geometry optimizations are generally not very sensitive to the level of theory, with even the low cost HF/6-31G(d) and B3-LYP/6-31G(d) methods providing reasonable approximations to the higher level calculations (37). In the latter case, there is a small error arising from the tendency of B3-LYP to overestimate the forming bond length in the transition structures, and this can be reduced using an IRCmax technique (94). Alternatively, the error in the B3-LYP transition structures is also reduced when the larger 6-311 + G(3df,2p) basis set is used (37). In addition, the UMP2 method should generally be avoided for these reactions, as they are subject to spin-contamination problems (32,33,37). *Frequency calculations* are also relatively insensitive to the level of theory, especially when the frequencies are scaled by their appropriate scale factors. (Scale-factors for the most commonly used levels of theory may be found in Reference (95). In particular,

the B3-LYP/6-31G(d) level of theory provides excellent performance for frequency factors, temperature corrections, and zero-point vibrational energy calculations, and would be a suitable low cost method for studying larger systems (37).

Barriers and enthalpies are very sensitive to the level of theory. Where possible, high level composite procedures should be used for the prediction of absolute reaction barriers and enthalpies, and of these methods the "RAD" variants of G3 provide the best approximations to the higher level Wn methods (when the latter cannot be afforded) (37). It should also be noted that the (empirically based) spin-correction term in the CBS-type methods appears to be introducing a considerable error to the predicted reaction barriers for these reactions and, until this is revised, these methods should perhaps be avoided for these reactions (37).

When composite methods cannot be afforded, the use of RMP2/6-311 + G(3df,2p) single points provides reasonable absolute values and excellent relative values for the barriers and enthalpies of these reactions (37). In contrast, the hybrid DFT methods such as B3-LYP and MPW1K show considerable error in the reaction enthalpies, even when applied with large basis sets. However, they do provide reasonable addition barriers, owing to the cancelation of errors in the early transition structures for these reactions (37). Interestingly, for the closely related radical addition to C≡C bonds, the situation is reversed and the B3-LYP methods perform well and the RMP2 methods perform poorly (37), and this highlights the importance of performing assessment studies before tackling new chemical problems. Finally, it should be stressed that semiempirical methods do not provide an adequate description of the barriers and enthalpies in these reactions (32).

For *rate coefficients*, the importance of treating the low frequency torsional modes in radical addition reactions as hindered internal rotations has been investigated in a number of assessment studies (37,79,93). For small systems such as methyl addition to ethylene and propylene, the errors are relatively minor (less than a factor of 2) (37). However, for reactions of substituted radicals (such as *n*-alkyl radicals (93) and the ethyl benzyl radical (79)), the errors are somewhat larger (as much as a factor of 6), as there are additional low frequency torsional modes to consider. Nonetheless, the errors are still relatively small, and the harmonic oscillator approximation might be expected to provide reasonable "order-of-magnitude" estimates of rate coefficients.

Radical Addition to C═S Bonds. Radical addition to C═S bonds, and the reverse β-scission reaction, forms the key addition and fragmentation steps of the RAFT polymerization process (96). Ab initio calculations have a role to play in elucidating the effects of substituents on this process, and in providing an understanding of the causes of rate retardation (6,7). A detailed assessment of theoretical procedures has been recently carried out for this class of reactions (36), and the main conclusions are similar to those for addition to C═C bonds (37), as outlined above. In general, low levels of theory, such as B3-LYP/6-31G(d), are suitable for geometry optimizations and frequency calculations, provided an IRCmax procedure is used to correct the transition structures. However, high level composite methods are required to obtain reliable absolute barriers and enthalpies, though reasonable relative quantities can be obtained at the RMP2/6-311 + G(3df,2p) level. As in the case of addition to C═C bonds, the spin correction term in the CBS-type methods appears to require adjustment, and the RAD variants of G3 should be preferred when the higher level Wn calculations are impractical.

Hydrogen Abstraction. Hydrogen abstraction reactions are important chain-transfer processes in free-radical polymerization. In particular, hydrogen abstraction by the propagating polymer radical from transfer agents (such as thiols), monomer, dead polymer, or itself (ie intramolecular abstraction) can affect the molecular weight distribution, the chemical structure of the chain ends, and the degree of branching in the polymer. The accuracy of computational procedures for studying hydrogen abstraction reactions has received considerable attention, and the results of some of the most recent and extensive studies (59,94,97–99) are summarized below.

Geometry optimizations are relatively insensitive to the level of theory; however, there are some important exceptions. In particular, the HF and MP2 methods should be avoided for spin-contaminated systems (99). Moreover, the B3-LYP method does not describe the transition structures very well for a number of hydrogen abstraction reactions (59,97). However, improved performance is obtained using newer hybrid DFT methods such as MPW1K (59) and KMLYP (97), and these methods are suitable as low cost methods, when high level procedures cannot be afforded.

Barriers and enthalpies are more sensitive to the level of the theory, and, where possible, high level composite procedures should be used. In particular, the "RAD" variants of G3 provide an excellent approximation to the higher level Wn methods, and would provide an excellent benchmark level of theory when the latter could not be afforded (99). As in the case of the addition reactions, the spin contamination correction term in the CBS-type methods appears to be introducing a systematic error to the predicted reaction barriers and enthalpies and, until this is revised, this method should perhaps be avoided for spin-contaminated reactions (99). When composite methods cannot be afforded, methods such as RMP2, MPW1K, or KMLYP have been shown to provide good agreement with the high level values (59,97,99), with a procedure such as MPW1K/6-311 + G(3df,2p) providing the best overall performance. By contrast, the popular B3-LYP method performs particularly poorly for reaction barriers and enthalpies (59,94,97–99), and should thus be generally avoided for abstraction reactions. Interestingly, it has been noted that the errors in B3-LYP increase with the increasing polarity of the reactants (98), which suggests that assessment studies based entirely on relatively nonpolar reactions (such as $CH_3^{\bullet} + CH_4$) may lead to the wrong conclusions.

As noted in the previous section, *tunneling* is significant in hydrogen abstraction reactions, and hence accurate quantum-chemical studies of these systems require the calculation of tunneling coefficients. The accuracy of tunneling coefficients is profoundly affected by both the tunneling method and the level of theory at which it is applied. A systematic comparison of the various tunneling methods for the hydrogen abstraction reactions of relevance to free-radical polymerization does not appear to have been performed. However, in the example provided in the previous section, it was seen that the Eckart method was capable of providing the tunneling coefficients of the right order of magnitude (when compared with the more accurate multidimensional methods), while the Wigner and Bell methods respectively underestimated and overestimated the tunneling coefficients by an order of magnitude. Hence, when multidimensional tunneling methods are not convenient, the Eckart tunneling method should be preferred as the best low cost method. An assessment of the effects of level of theory on the tunneling

coefficients, as calculated using this Eckart method, has recently been published (41). It was found that errors in the imaginary frequency at the HF level (with a range of basis sets) leads to errors in the calculated tunneling coefficients of several orders of magnitude (compared to high level CCSD(T)/6-311G(d,p) calculations). The B3-LYP and MP2 methods performed significantly better, showing errors of a factor of 2–3. However, even better performance could be obtained by correcting the HF values to the CCSD(T)/6-311G(d,p) level via an IRCmax procedure.

Applicability of Chemical Models

Assuming high levels of theory are used, quantum-chemical calculations might be expected to yield very accurate values of the rate coefficients for the specific chemical system being studied. With current available computing power, this would in all likelihood consist of a small model reaction in the gas phase. If, for example, this information is then to be used to deduce something about solution-phase polymerization kinetics, the effects of the solvent and (in most cases) the effects of chain length need to be considered. Unfortunately, the treatment of these effects at a high level of theory is not generally feasible with current available computing power, and hence the neglect of these effects (or their treatment at a crude level of theory) remains a potential source of error in quantum-chemical calculations. In this section, these additional sources of error are briefly discussed.

Solvent Effects. The presence of solvent molecules may affect the polymerization process in a variety of ways (100). For example, if polar interactions are significant in the transition structure of the reaction, the presence of a high dielectric constant solvent may stabilize the transition structure and lower the reaction barrier. Solvents may also affect the reactivity of the reacting radicals, and even the mechanism of the addition or transfer reaction, through some specific interaction such as hydrogen bonding or complex formation. In addition, the preferential sorption of the monomer or solvent around the reacting polymer radical may lead to the effective concentrations available for reaction being different to those in the bulk solution, resulting in a difference between the observed and predicted rate coefficients. Solvent effects such as these result in the experimentally measured rate coefficients for a free-radical polymerization varying according to the solvent type.

Over and above these system-specific solvent effects, there is a more general "entropically based" difference between the rate coefficients for gas-phase and solution-phase systems. Whereas in the gas-phase an isolated molecule might be expected to have translational, rotational, and vibrational degrees of freedom, in the solvent phase the translational and rotational degrees of freedom are effectively "lost" in collisions with the solvent molecules. In their place, it is necessary to consider additional vibrational degrees of freedom involving a solute-solvent "supermolecule" (101). Since the vibrational, translational, and rotational modes make different quantitative contributions to the enthalpy and entropy of activation, significant differences might be expected between the gas and solution phases. For bimolecular reactions this effect can be considerable, because the main contribution to the entropy of activation is the six rotational and translational

degrees of freedom in the reactants, which are converted to internal vibrations in the transition structure. In contrast, for unimolecular reactions, the entropically based gas-phase/solution-phase difference is generally much smaller, as the rotational and translational modes are similar for the transition structure and reactant molecule, and thus their contribution largely cancels from the reaction rate.

The treatment of solvent effects varies according to their origin. The influence of the dielectric constant on polar reactions can be dealt with routinely using various continuum models (102), implemented using standard computational software, such as GAUSSIAN (43). However, it should be stressed that these models do not account for the entropically based gas-phase/solvent-phase difference, nor do they deal with direct solvent interactions in the transition structure. When direct interactions involving the solvent are important, it is necessary to include solvent molecules in the quantum-chemical calculation. In theory, one should include many hundreds of solvent molecules but in practice one includes a small number of molecules, and combines this with a continuum model (102). However, even with this simplification, the additional solvent molecules increase the computational cost of the calculations, and it is not currently feasible to apply these methods (at any reasonable level of theory) for polymer-related systems. Even when additional solvent molecules are included in the ab initio calculations, various extensions to transition-state theory are required in order to model the rates of solution-phase reactions (68,101). Unfortunately, the existing models are complicated to use and require additional parameters which are not readily accessible for polymerization-related systems. The development of simplified yet accurate models for dealing with solvent effects is an on-going field of research.

While strategies for calculating solution-phase rate coefficients exist, with the current available computing power these methods are not generally feasible for polymer-related systems. Instead, the following practical guidelines for dealing with solvent effects are suggested. Firstly, when the solvent participates directly in the reaction, the inclusion of the interacting solvent molecule in the gas-phase calculation is essential for gaining a mechanistic understanding of the reaction. Secondly, when polar interactions are expected to be important, the use of a continuum model is recommended, especially if the results are to be used to interpret the polymerization process in polar solvents. Thirdly, for bimolecular reactions, if the a priori prediction of *absolute* rate coefficients is required, a consideration of the entropically based gas-phase/solution-phase difference is necessary. This "entropic" solvent effect might be estimated by comparing corresponding experimental solution- and gas-phase rate coefficients for that class of reaction. For example, solution-phase experimental values for radical addition reactions generally exceed the corresponding gas-phase values by approximately one order of magnitude (103). One might also benchmark the gas-phase calculations by calculating the rate coefficient for a similar reaction, and comparing the calculated result with reliable experimental data. Fourthly, provided that specific interactions are not important, one might expect that solvent effects should largely cancel from *relative* rate coefficients, and hence the gas-phase values should generally be suitable for studying substituent effects and solving mechanistic problems. Finally, when specific interactions are important, simple gas-phase calculations are still useful, as they can provide complementary information about the underlying influences on the mechanism in the absence of the solvent.

Chain-Length Effects. The other simplification that is necessary in order to use high level ab initio calculations on polymer-related systems is to approximate the propagating polymer radical (which may be hundreds or thousands of units long) as a short-chain alkyl radical. Provided that the reaction is chemically controlled, this is not an unreasonable assumption. In chemical terms, the effects of substituents decrease dramatically as they are located at positions that are increasingly remote from the reaction center. For example, the terminal and penultimate units of a propagating polymer radical are known to affect its reactivity and selectivity in the propagation reaction (104); however, substituent effects beyond the penultimate position are rarely invoked in copolymerization models. In order to include the most important substituent effects, it is generally recommended that propagating radicals be represented as γ-substituted propyl radicals (as a minimum chain length). For some systems this is not currently possible without resorting to a low (and thus inaccurate) level of theory. In those cases, the possible influence of penultimate unit effects must be taken into account when interpreting the results of the calculations.

The entropic influence of the chain length on the reaction rates extends slightly beyond the penultimate unit. For example, Deady and co-workers (105) showed experimentally that there was a chain-length effect on the propagation rate coefficient of styrene, which converged at the tetramer stage (ie an octyl radical). Heuts and co-workers (3) have explored this chain-length dependence theoretically, and suggested that it arises predominantly in the translational and rotational partition functions. More specifically, they suggest that there is a small effect of mass that can be modeled by including an unrealistically heavy isotope of hydrogen at the remote chain end. For example, in the propagation of ethylene, a model such as $X{-}(CH_2)_n{-}CH_2^{\bullet}$ could be used, and in this model X is set as a hydrogen atom that happens to have a molecular mass of 9999 amu! They also noted that there is an effect of chain length on the rotational entropy (and especially the hindered internal rotations), which required the more subtle modeling strategy of using slightly longer alkyl chains (ie $n > 1$). Nonetheless, using their "heavy hydrogen" approach, their calculated frequency factors converged to within a factor of 2 of the long chain limit at even the propyl radical stage (ie $n = 2$). More recently it was shown that the consideration of the propagating radical as a substituted hexyl radical (without a heavy hydrogen at the remote chain end) was also sufficient to reproduce experimental values for the frequency factors of propagation reactions (106). For short-chain branching reactions, it has been shown that inclusion of just one methyl group beyond the reaction center is sufficient for modeling the long-chain reactions, provided that the additional methyl group is substituted with a heavy (ie 9999 amu) hydrogen atom (5). Thus, in general, it appears that small model alkyl radicals are capable of providing a reasonable description of polymeric radicals in chemically controlled reactions.

Finally, it is worth noting that the chain-length effects on the propagation steps amount to approximately an order of magnitude difference between the first propagation step and the long chain limit, with the small radical additions having faster rate coefficients. This chain-length error is of the same magnitude and acts in the opposite direction to the gas-phase/solvent-phase difference in bimolecular reactions, and hence substantial cancelation of error might be expected in these cases. Indeed an (unpublished) high level G3(MP2)-RAD calculation of the

propagation rate coefficient for methyl acrylate at 298 K produced the value of $2.0 \times 10^4\ L \cdot mol^{-1} \cdot s^{-1}$, which is in remarkable agreement with the corresponding experimental value (also $2.0 \times 10^4\ L \cdot mol^{-1} \cdot s^{-1}$ at ambient pressure) (107), despite the fact that both the medium and chain-length effects were ignored in the calculation. Hence, careful efforts to correct for chain-length effects but not solvent effects (or vice versa) may actually introduce greater errors to calculated rate coefficients.

Applications of Quantum Chemistry in Free-Radical Polymerization

Quantum chemistry provides a powerful tool for studying kinetic and mechanistic problems in free-radical polymerization. Provided a high level of theory is used, ab initio calculations can provide direct access to accurate values of the barriers, enthalpies, and rates of the individual reactions in the process, and also provide useful related information (such as transition structures and radical stabilization energies) to help in understanding the reaction mechanism. In the following, some of the applications of quantum chemistry are outlined. This is not intended to be a review of the main contributions to this field, nor is it intended to provide a theoretical account of reactivity in free-radical polymerization (108). Instead, some of the types of problems that quantum chemistry can tackle are described, with a view to highlighting the potential of quantum-chemical calculations as a tool for studying free-radical polymerization (see RADICAL POLYMERIZATION).

A Priori Prediction of Absolute Rate Coefficients. The a priori prediction of accurate *absolute* rate coefficients is perhaps the most demanding task in computational chemistry. For example, high level ab initio calculations (at the G3(MP2)-RAD level as a minimum) are required for the calculation of accurate reaction barriers (and enthalpies) in radical addition reactions and, with current available computing power, these can be performed routinely on systems of up to 12–14 non-hydrogen atoms. This allows for the most common polymerization substituents to be included, and often allows for penultimate unit effects to be taken into account. However, it does not allow for the accurate treatment of solvent or chain-length effects. Of course, with continuing rapid increases in computer power, these problems should soon be overcome. In addition, as was noted above, for a bimolecular reaction, the chain-length effects and solvent effects act in opposite directions and may in fact largely cancel, leading to surprisingly accurate results. Certainly, with current available computing power, the prediction of rate coefficients to within 1–2 orders of magnitude (or better) is possible for most chemically controlled polymerization-related reactions, and further increases in accuracy should be attainable in the near future.

The prediction of absolute rate coefficients via quantum chemistry is particularly useful when direct experimental measurements are not possible. A good example of this is in the RAFT polymerization process (96), in which the experimentally observable quantities (such as the overall polymerization rate, the overall molecular weight distribution, and the concentrations of the various species) are a complicated function of the rates of the various individual reactions. In order to measure the rates of these individual steps, it is necessary to relate their rate coefficients to the observable quantities via some kinetic-model-based assumptions. Depending upon the assumptions, enormous discrepancies arise in the estimated

rate coefficients. For example, alternative experimental measurements for the fragmentation rate in cumyl dithiobenzoate mediated polymerization of styrene at 60°C differ by six orders of magnitude (109,110), and this difference arises, at least in part, in the model-based assumptions of the alternative experimental techniques (For a discussion of problems measuring fragmentation rate coefficients, the reader is referred to Reference 111). Recent ab initio calculations of the fragmentation rate coefficient for a model of this system were able to provide direct evidence in support of one measurement (and hence one set of assumptions) over the other, and in doing so provide an insight into the causes of rate retardation in the RAFT process (6).

As accurate calculations become routine, there will be many other applications for the a priori prediction of absolute rate coefficients. The calculation of propagation rate coefficients (which can be measured experimentally via pulsed laser polymerization or PLP (112)) is currently used to benchmark theoretical procedures, but accurate calculations may also be helpful as a stand-alone technique for toxic and hazardous monomers, and in other cases where PLP is difficult (due to problems such as the monomer absorbing at the wavelength of the laser or reactions such as chain transfer broadening the molecular weight distribution). It has also been noted that ab initio calculations may provide the best means of studying long- and short-chain branching in free-radical polymerization (5). Quantum chemistry will also be helpful in extracting the rate coefficients of the individual reactions in other complicated reaction schemes, such as free-radical copolymerization, and the various types of controlled radical polymerization systems.

Prediction of Relative Rate Coefficients: Discriminating Models and Mechanisms. High level ab initio calculations can already predict *relative* rate coefficients with remarkable accuracy. This is because accurate relative values of quantities such as barriers and enthalpies can generally be obtained at lower levels of theory than corresponding absolute values, because of substantial cancellation of error. In addition, one might generally expect that chain-length effects and solvent effects should be reasonably consistent for a series of similar reactions, and thus cancel from the comparative values. The prediction of relative rate coefficients is important for modeling and hence optimizing various aspects of the polymerization process, and some of these applications are outlined below. The prediction of relative rate coefficients is also important for understanding the effects of substituents on the various individual reactions, and these applications are discussed in the following section.

Copolymerization. In free-radical copolymerization (qv), the relative rates of addition of the various types of radical to the alternative monomers are called reactivity ratios, and are the key parameters governing the composition and sequence distribution of the resulting copolymer. Experimentally, these parameters are "measured" for a given system by treating them as adjustable parameters in a least-squares fit of some assumed kinetic model to experimental values of the composition, sequence distribution, and/or propagation rate coefficients. However, there are two important problems with this approach (104). Firstly, it is not always (if ever) clear which copolymerization model (eg the terminal model, the implicit or explicit penultimate model, etc) is appropriate for a given system. If a physically incorrect model is chosen, then the estimated parameters will lack their assumed physical meaning, and will thus be unsuitable for mechanistic studies,

or for predicting other copolymerization properties. Secondly, even if the correct model is chosen, there are often more adjustable parameters than are numerically needed to fit the data, and this can result in large and highly correlated uncertainties in the estimated parameters. The problems in the experimental estimation of reactivity ratios are discussed in more detail in the article on copolymerization (qv).

Quantum chemistry is able to address these problems, as it allows the reactivity ratios to be calculated directly from the rate coefficients for the various types of reaction, without making kinetic-model-based assumptions. Furthermore, quantum chemistry can assist in determining which kinetic model is most appropriate for a given system. For example, by measuring the effects of substituents at the penultimate position of the propagating radical, quantum chemistry can be used to determine whether a terminal or penultimate model is appropriate for a given system. In this respect, quantum chemistry has already made an important contribution to this field by providing evidence for penultimate unit effects in the barriers (1,106) and frequency (2,106) factors of a variety of different systems. Such calculations can thus simplify the model discrimination process by ruling out either the terminal- or penultimate-based models for a given system, and by providing estimates for the main model parameters (ie the reactivity ratios). In addition, quantum chemistry can provide a simple and cost-effective method for screening the reactivity ratios for a wide variety of monomer pairs (including hazardous and yet-to-be synthesized monomers). This may allow the identification of monomer pairs with suitable reactivity ratios for a given application.

Chain Transfer. The relative rate of abstraction to propagation for a specific propagating radical is known as the chain-transfer constant, and is a key parameter governing the molecular weight of the resulting polymer. High level ab initio calculations allow chain-transfer constants to be predicted for a given propagating radical and transfer agent, and thus provide an effective means of screening large numbers of transfer agents. This in turn may assist in the selection of suitable transfer agents for a given polymerization system, and can also aid in our understanding of reactivity in the chain-transfer processes. Already ab initio calculations have been used to study intramolecular chain-transfer processes in free-radical polymerization (5,106), in order to provide estimates of the short-chain branching ratios. Another study investigated the kinetics and thermodynamics of the hydrogen abstraction *by* and *from* the monomer in ethylene polymerization (113), and demonstrated that abstraction from the monomer was the kinetically (but not thermodynamically) preferred process. There is also an enormous body of literature concerning ab initio calculations of hydrogen abstraction reactions in general, and in applications of relevance to other fields such as biochemistry (114,119).

Controlled Radical Polymerization. In recent years, the field of free-radical polymerization has been revolutionalized by the development of techniques for controlling the molecular weight and architecture of the resulting polymer, including nitroxide-mediated polymerization (NMP) (120), atom-transfer polymerization (ATRP) (121), and reversible addition fragmentation chain transfer (RAFT) polymerization (96) (see LIVING RADICAL POLYMERIZATION). In order to control polymerization, these processes aim to minimize the influence of bimolecular

termination processes via a delicate balance of the relative rates of two or more competing reactions. Quantum chemistry can assist in optimizing these processes by providing reliable values for the rate coefficients of the competing reactions, across a wide range of systems. More generally, quantum chemistry can help to provide a detailed understanding of the kinetics and mechanisms of the individual reactions, which can in turn allow for the design of improved control agents.

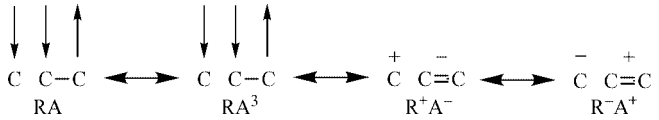
Quantum chemistry has already been used to study the RAFT process (6,7). As noted above, high level ab initio molecular orbital calculations have been used to obtain direct measurements of the rates of addition and fragmentation in model dithiobenozate-mediated systems, which in turn provided evidence that slow fragmentation is responsible for rate retardation in these systems (6). More recently, ab initio calculations have revealed a new and unexpected side reaction (β-scission of the alkoxy group) in certain xanthate-mediated systems, which may provide an explanation for the experimentally observed inhibition in those systems (7). The ab initio calculations also indicated that fragmentation was considerably faster in the xanthate-mediated systems (compared with other dithioester systems), because of the stabilizing influence of the alkoxy group on the thiocarbonyl product (7). In addition to these ab initio calculations, semiempirical methods have been used to survey the transfer enthalpies for a series of RAFT agents in styrene, methyl methacrylate, and butyl acrylate polymerization (122). Despite the low level of theory used, and the limited accuracy of the quantitative predictions at this level, the calculations were nonetheless shown to have some qualitative value in determining which transfer agents would show the best molecular weight control in RAFT polymerization.

Understanding Reactivity via the Curve-Crossing Model. We have already seen that quantum chemistry can be used to calculate the absolute (and hence relative) rate coefficients for the individual reactions in free-radical polymerization, and is well suited to compiling systematic surveys of the rate coefficients for homologous series of reactions. When such calculations are combined with qualitative theoretical models, quantum chemistry can help to provide an understanding of trends in reactivity. It is beyond the scope of this chapter to provide an account of the main qualitative models and concepts in general theoretical chemistry. However, it is worth introducing one such model—the *curve-crossing model* (123)—as this model has been used extensively to provide a qualitative rationalization of the effects of substituents in some of the key radical reactions that occur in free-radical polymerization, including radical addition to alkenes (103) (ie the propagation step), and hydrogen abstraction (115,116,124) (ie, chain-transfer processes). The main qualitative features of the model and its application to free-radical polymerization are described below; for a more detailed description, the reader is referred to the original references 123, and also the excellent book by Pross (125).

The curve-crossing model (also referred to as the valence-bond state correlation model, the configuration mixing model, or the state correlation diagram) was developed by Pross and Shaik (123) as a unifying theoretical framework for explaining barrier formation in chemical reactions. It is largely based on valence bond (VB) theory (126,127), but also incorporates insights from qualitative molecular orbital theory (128). To understand the curve-crossing model, it is helpful to think of a chemical reaction as being composed of a rearrangement of electrons,

accompanied by a rearrangement of nuclei (ie a geometric rearrangement). We can then imagine holding the arrangement of electrons constant in its initial configuration (which we call the reactant VB configuration), and examining how the energy changes as a function of the geometry. Likewise, we could hold the electronic configuration constant in its final form (the product VB configuration), and again examine the variation in energy as a function of the geometry. If these two curves (energy vs geometry) are plotted, we form a "state correlation diagram." The overall energy profile for the reaction, which is also plotted, is formed by the resonance interaction between the reactant and product configurations (and any other low lying configurations). State correlation diagrams allow for a qualitative explanation for how the overall energy profile of the reaction arises, and can then be used to provide a graphical illustration of how variations in the relative energies of the alternative VB configurations affect the barrier height. This in turn allows us to rationalize the effects of substituents on reaction barriers, and to predict when simple qualitative rules (such as the Evans–Polanyi rule (129)) should break down.

This procedure is best illustrated by way of an example, such as the case of radical addition to alkenes. For this type of reaction, the principal VB configurations that may contribute to the ground-state wave function are the four lowest doublet configurations of the three-electron–three-center system formed by the initially unpaired electron at the radical carbon (R) and the electron pair of the attacked π bond in the alkene (A) (103).



The first configuration (RA) corresponds to the arrangement of electrons in the reactants, the second (RA^3) to that in the products, and the others (R^+A^- and R^-A^+) to possible charge-transfer configurations. The state correlation diagram showing (qualitatively) how the energies of these configurations vary as a function of the reaction coordinate is provided in Figure 11 (103). Let us now examine how this plot could be made for a specific system.

The anchor points on these diagrams are generally accessible from quantum-chemical calculations. For example, the energy difference between the RA configuration at the reactant geometry, and the RA^3 configuration at the product geometry, is simply the energy change of the reaction. The energy difference between the RA and RA^3 configurations at the reactant geometry is simply the vertical singlet-triplet gap of the alkene. At the product geometry, the RA $-$ RA^3 energy difference is also an excitation energy, but this time between the ground state of the doublet product and an excited doublet state (In fact, studies of radical addition to alkenes have ignored the influence of this excitation gap, without detriment to the predictive value of the results (103). This is probably due to the fact that the transition structure is very early in these reactions. However, in studies of hydrogen abstraction reactions, the RA and RA^3 gaps at both the reactant and product geometries can be important. These are calculated as the singlet-triplet gap of the closed-shell substrate in each case.) The charge-transfer configurations can be anchored at the reactant geometry, where they are given as the energy for

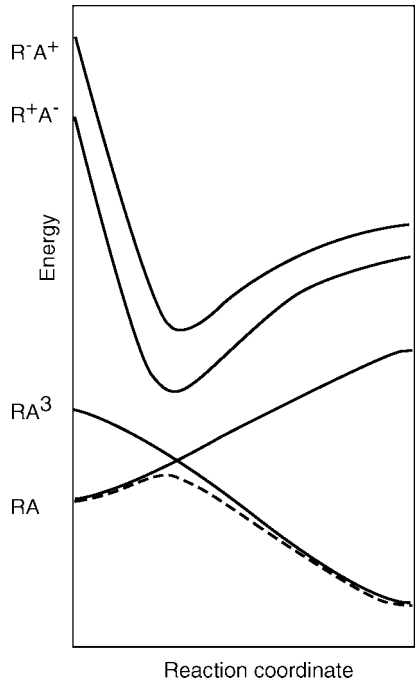


Fig. 11. State correlation diagram for radical addition to alkenes showing the variation in energy of the reactant (RA), the product (RA^3), and the charge-transfer configurations (R^+A^- and R^-A^+) as a function of the reaction coordinate. The dashed line represents the overall energy profile of the reaction.

complete charge transfer between the isolated reactants. For example, the energy difference between the R^+A^- and the RA configuration at the reactant geometry would be given as the energy change of the reaction $R + A \rightarrow R^+ + A^-$. It can be seen that the energy change of this reaction is simply the difference between the ionization energy ($R \rightarrow R^+ + e-$) of the donor species and electron affinity ($A^- \rightarrow A + e-$) of the acceptor.

Although the anchor points in the diagram are obtained quantitatively, we generally interpolate the intervening points on the VB configuration curves qualitatively, on the basis of spin pairing schemes and VB arguments (123). At this point it should be stressed that the overall energy profile for the reaction is of course quantitatively accessible from our quantum-chemical calculations. The objective of the curve-crossing model analysis is not to generate the overall reaction profile but to understand how it arises—and a qualitative approach to generating the VB configuration curves is generally adequate for this purpose. If we consider first the product configuration, its energy is lowered during the course of the reaction because of bond formation between the radical and attacked carbon. At the same time, the relative energy of the reactant configuration increases because the π bond on the attacked alkene is stretched, and this is not compensated for by bond formation with the attacking radical. The energies of the charge-transfer

configurations are initially very high in energy, but are stabilized by Coloumb attraction as the reactants approach one another.

The overall energy profile for the reaction can be formed from the resonance interaction of these contributing configurations. In the early stages of the reaction, the reactant configuration is significantly lower in energy than the others and dominates the ground-state wave function. However, in the vicinity of the transition structure, the reactant and product configurations have similar energies, and thus significant mixing is possible. This stabilizes the wave function, with the strength of the stabilizing interaction increasing with the decreasing energy difference between the alternate configurations. It is this mixing of the reactant and product configurations which leads to the avoided crossing, and accounts for barrier formation. Beyond the transition structure, the product configuration is lower in energy and dominates the wave function. The charge-transfer configurations generally lie significantly above the ground-state wave function for most of the reaction. However, in the vicinity of the transition structure, they can sometimes be sufficiently low in energy to interact. In those cases, the transition structure is further stabilized, and (if one of the charge transfer configurations is lower than the other) the mixing is reflected in a degree of partial charge transfer between the reactants. Since the charge distribution within the transition structure is accessible from quantum-chemical calculations, this provides a testable prediction for the model.

Using this state-correlation diagram, in conjunction with simple VB arguments, the curve-crossing model can be used to predict the influence of various energy parameters on the reaction barrier. For radical addition to alkenes (103), the barrier depends mainly on the reaction exothermicity (which measures the energy difference between the reactant and product configurations at their optimal geometries), the singlet-triplet gap in the alkene (which measures the energy difference between the reactant and product configurations at the reactant geometry), and the relative energies of the possible charge-transfer configurations. The effects of individual variations in these quantities are illustrated graphically in Figure 12. It can be seen that the barrier height is lowered by an increase in the reaction exothermicity, a decrease in the singlet-triplet gap, or a decrease in the relative energy of one or both of the charge-transfer configurations (provided that these are sufficiently low in energy to contribute to the ground-state wave function).

A strategy for understanding the effects substituents in the barriers of radical reactions, such as addition, is to calculate these key quantities [ie, the reaction exothermicity, the singlet-triplet excitation gap of the closed-shell substrate(s), and the energy for charge transfer between the reactants], and look for relationships between these quantities and the barrier heights. In this way, one could establish, for example, the extent of polar interactions in a particular class of reactions. As noted at the beginning of this section, a number of such studies have already been performed for the key reactions in free-radical polymerization. The curve-crossing analysis of radical addition reactions, which is reviewed in detail elsewhere (94,99), indicate that, in the absence of polar interactions, the barrier height depends on the reaction exothermicity, in accordance with the Evans–Polanyi rule (129). However, for combinations of electron-withdrawing and electron-donating reactants, polar interactions are significant,

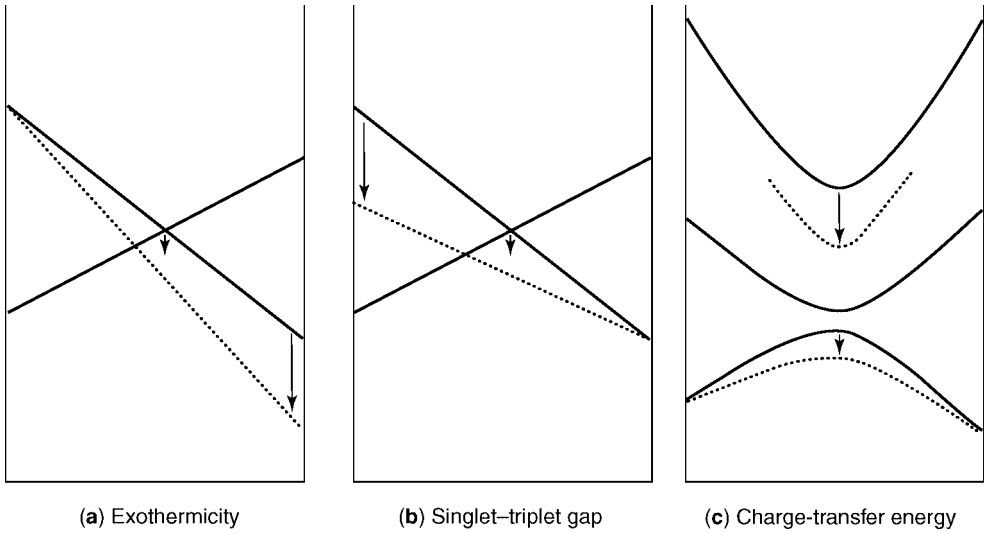

Fig. 12. State correlation diagrams showing separately the qualitative effects of (**a**) increasing the reaction exothermicity, (**b**) decreasing the singlet–triplet gap, and (**c**) decreasing the energy of the charge-transfer configuration. For the sake of clarity the adiabatic minimum energy path showing the avoided crossing, as in Figure 9, is omitted from (**a**) and (**b**).

and cause substantial deviation from Evans–Polanyi behavior. More recently, the curve-crossing model has been used to explain the relative reactivity of the C=C, C=O, and C=S bonds (which is of relevance to RAFT polymerization) (130), and to examine why alkynes are less reactive to addition than alkenes (131). In these cases the differing singlet-triplet gaps of the alternative substrates are also important in governing their relative reactivities. Curve-crossing studies have also been applied to various types of hydrogen abstraction reactions (115,116,124), and, depending upon the substituents, the singlet-triplet gaps (in this case of *both* the reactant and product substrates), exothermicities, and polar interactions have all been found to be important in governing reactivity in these reactions.

The Future

There are many more potential applications for quantum chemistry in free-radical polymerization. As computer power increases, one will be able to calculate rate coefficients for yet larger systems, and at much greater accuracy. In this way, quantum chemistry has a role to play in modeling the kinetics and mechanism of polymerization processes, and predicting the properties of the resulting polymer (such as the molecular weight distribution, the copolymer composition, and the degree of branching). Quantum chemistry may also help in designing improved agents or processes for controlling polymerization, and in identifying their mechanisms. Of course, quantum chemistry may also be used effectively to study other types of polymerization processes, such as ring-opening processes. Provided care

is taken to ensure the accuracy of the methods used, quantum-chemical methods provide a powerful tool for studying free-radical polymerization, and should be seen as a valuable complement to experimental approaches.

CONTROLLED RELEASE FORMULATION, AGRICULTURAL

Introduction

Most controlled release formulations (CRF) are based upon macromolecules (usually polymers) as the inert components (sometimes combined with clays, salts, etc). This is because large molecules tend not to move in the environment (being often water-insoluble and nonvolatile) and they can entrap small and large molecules such as pesticides. Thus, formulation with polymers provides the construct needed to entrap the pesticide and to build into the resulting depot device the mechanism for reliable release rates. Such polymers are best degradable so as to remove them from the environment following their use. In selecting polymers for formulation cost is of great importance in agriculture, when compared to medical drug delivery systems where benefits are considered more commercially valuable (see CONTROLLED RELEASE TECHNOLOGY).

CRF aim to make available pesticides at rates appropriate for efficient control of pests under field conditions. These formulations are combinations of the pesticidal active agent with inert materials that protect, and release, the active agent according to the pest control needs. A depot or reservoir of active agent, within the releasing device or particle, is released at a defined rate, or variable rate, into the environment over a specified period. The releasing systems are usually solid and can vary in size from microparticles to large devices several centimeters across. However, the aspect which differentiates CRF from conventional formulations such as emulsifiable concentrates, wettable powders, soluble liquids, and water-dispersible granules is time, and the kinetics of release are central to CRF. In contrast, in the case of conventional formulations, complete availability of the active agent is usually considered to be immediate or rapid following deployment.

CRF can be used with a wide range of pesticides, including inorganic substances, conventional low molecular weight organic substances, high molecular weight substances such as peptides or proteins, microbials (such as mycopesticides), and semiochemicals (which, eg pheromones, modify pest behavior). Applications may be in agriculture, veterinary, and public health sectors and may be aimed at controlling a variety of pest organisms such as insects, mites, rodents, nematodes, weeds, and microorganisms as well as at improving crop production with plant growth regulators. Within the term of "controlled release" there exists a variety of release types such as extended, slow, fast, delayed, programmed, sustained, and pulsed.

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

As for all pesticide formulations, CRF need to be applied, or placed, in the field appropriately for targeting the pests. In crop protection, this usually means application to the crop, or crop area, by means that achieve good distribution. Such distribution depends on how the pesticide moves to the target organism following application and often needs small particle size to provide this. Thus, the standard application methods of spraying and granules are important in agricultural pesticide delivery, which in turn limits the device size of the controlled release systems deployed. Greatest advances in CRF in agriculture have thus been found with sprayable, and to a lesser extent, granular methods. More specialized methods, eg, based on pheromones or baits, have been commercially possible using larger devices (1).

Controlled release technology aims to manipulate the bioavailability of the pesticide in the local environment following application (2). This approach has many benefits compared to conventional formulations which include increased safety to the environment, workers, and consumers. Lower concentrations of released pesticide in the environment lead to reduced losses, such as leaching, evaporation, degradation, and binding. Reduced losses may mean better pest control, less nontarget impacts, reduced crop phytotoxicity, and safer formulations. Numerous benefits have been given on behalf of CRF, including

(1) protection of active ingredients from environmental degradation,
(2) manipulation of bioavailability and persistence,
(3) reduction of toxicity and operator hazards,
(4) reduction of phytotoxicity to seeds and crops,
(5) improved selectivity between target and nontarget organisms and usage in IPM (integrated pest management),
(6) reduction in repellency (also reduction in odors),
(7) allowing coformulation, especially of incompatible pesticides (eg, of chemical and microbial pesticides),
(8) permitting elimination of solvents,
(9) improving formulation of actives with phase changes near ambient temperatures,
(10) improving handling qualities of formulations and ease of cleaning sprayers, possible reduced application rates.

However, these advantages have been known for some decades (in fact an early publication on a site-specific release formulation of an insecticide dates back to 1948 (3)) but their exploitation has been slow to develop in commercial practice. The first microcapsule formulation came on the market in 1974 (4); since then, uptake represents only a small portion of total pesticide formulations. This is in contrast to the drug sector where controlled release and delivery has been rapidly expanding.

This slow uptake in the pesticide market may be related to the increased costs of the new technology on a product basis (but not on an “effect” basis) and there is a need for a change in attitude to pest control. However, there are also

technical problems involved in active agent delivery in the open environment which may restrict extensive uptake. Renewed interest in good pesticide delivery could be prompted by the inexorable increase in limitations on pesticide numbers and their use as the Environmental Protection Agency (EPA), and other organizations, phases out more pesticides. New active ingredients coming to the market are currently fewer and registration is slow and expensive. In this situation the commercial benefits of new safer CRF may be starting to outweigh the perceived disadvantages and the usual route of new molecule introduction.

Principles of CRF for Use in the Environment

Pesticide Delivery. As with all treatments, based on biologically active molecules, targeting is fundamental to its success. If the substances do not reach the pest, then logically no control will be achieved. Delivery to the target pest is considered both in time and place; sometimes the pesticide moves toward the target (eg, with foliar herbicides (5)) and sometimes the target moves toward the pesticide (residual insecticides (6)). Thus, the efficiency of this delivery process can be defined as the ratio of the amount of pesticide reaching the pest divided by the amount applied, per unit cropping area. For many pest organisms the amount of pesticide needed for control can be ascertained, thus giving some idea of the efficiency of the delivery process. This delivery process is the sum of the placement methods, ie, spraying, granules, bait, etc, and the subsequent movement of the pesticide combined with the movement and growth of the pest itself. Sometimes, the pesticide is activated following application, in which it is chemically transformed into a more pesticidal substance. Transfer of the pesticide occurs through contact and also in mobile phases such as air and water.

Losses and Half Life. During delivery the pesticide is lost by a multitude of processes. The most rapid loss mechanisms cause the greatest amount of loss in which the pesticide is removed from the cropping location. These include spray drift, evaporation, leaching, run-off, sorption, dispersal, and dilution below active concentrations. Slower loss mechanisms include degradation of the pesticide caused by light (photodegradation), by biological processes (especially by microorganisms in soil), and by chemical processes (such as hydrolysis and oxidation) (7). Degradation produces breakdown products (metabolites) that may be more or less toxic than the parent molecule and may be more or less prone to moving away from the application site. The environmental hazard of the metabolites may be greater than the pesticide but usually degradation represents a reduction of the pesticidal activity and overall toxicity. Alternatively, the pesticide, and its metabolites, may be bound into plants or into the organic matter (or clay) of soil.

The tendency for any pesticide to be degraded is characteristic of its molecular properties and can be expressed in the DT_{50} (time for 50% disappearance) or $t_{1/2}$ (half-life), typical values for agricultural soils. This value is based on a pseudo-first-order kinetic for loss. Pesticides with long half-lives, which persist for long periods, are more effective in pest control, and are thus more efficient in contacting the pest, than those with short half-lives. However, such pesticides are less desirable environmentally, as long persistence can allow the substance to migrate, or otherwise cause detrimental impacts, such as by entering the food chain if having a high partition coefficient. In contrast, other bioactives may have short

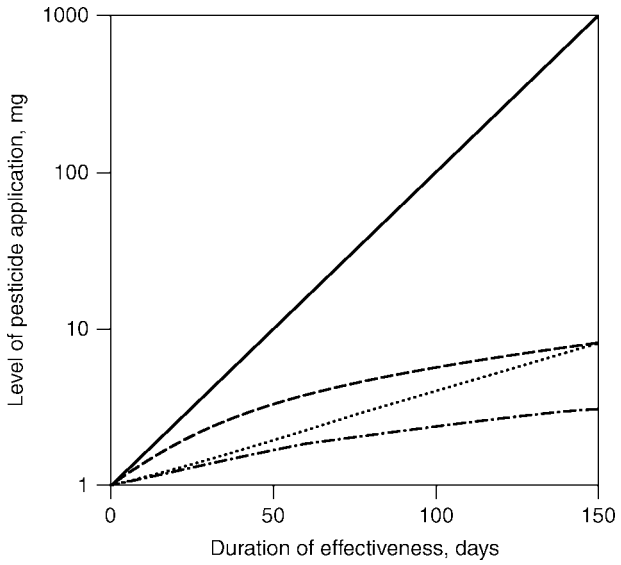

Fig. 1. Relationships between the level of application and the duration of action of two pesticides, P-1 and P-2, with differing half-lives, for conventional (A) and controlled release (B) formulations. _____ P-1 (A); _ _ _ _ P-1 (B); ..... P-2 (A); _.-._.-. P-2 (B).

half-lives, thus requiring large application rates to provide an adequate period of effective control. This is demonstrated in Figure 1 where the durations of control provided by two pesticides, P-1 with a half-life of 15 days and P-2 with a half-life of 50 days, are shown. Both require a minimum active level of 1 mg to provide control, and the two plots "A" compare the periods of control, on a logarithmic basis. It can be seen that the faster degrading pesticide P-1 requires an initial application of 1000 mg whereas the slower degrading P-2 only needs 8 mg to be effective up to 150 days. In this case, the high initial concentration in the environment forms a reservoir or depot albeit exposed to degradation and losses, which is available above the level required for control (ie, 1 mg) for the duration of the control period. Thus, the proportion of pesticide which is lost (ie, wasted) increases as the half-life decreases.

Controlled Delivery. As pesticide loss is concentration-dependent, reducing environmental concentrations will reduce losses. If the concentration at the target pest could be kept at the minimum (or just above) for effective pest control by continuous supplementing for that portion lost or dissipated, then the overall losses could be minimized (8). Keeping this minimum for the duration of control needed would represent the ideal approach with highest possible level of efficiency of delivery.

To maintain the concentration at the target, pesticide needs to be supplied at the same rate at which it is dissipated. Thus, the supply can be set equal to the loss, as in the following equation:

$$(\text{Rate of supply})\ \frac{dS}{dt} = \frac{dM}{dt}(\text{Rate of loss}) \qquad (1)$$

Approximating the loss processes occurring in the environment, the rate of loss at any time is directly proportional to the amount of the pesticide

$$\text{The rate loss } \frac{\mathrm{d}M_t}{\mathrm{d}t} = -kM_t \tag{2}$$

where M_t is the amount of the pesticide at time t and k is the loss coefficient. After integration this gives the relationship:

$$\ln \frac{M_t}{M_0} = -kt \tag{3}$$

and M_0 is the amount of pesticide applied.

The time taken for the initial pesticide application M_0 to dissipate and fall to the minimum level required at the pest for control t_m is

$$t_\mathrm{m} = \frac{1}{k} \ln \frac{M_0}{M_\mathrm{m}} \tag{4}$$

which is used to plot the logarithmic lines in Figure 1 (lines "A").

If the pesticide is delivered from a formulation at a continuous rate to replace that which is lost in the environment

$$\frac{\mathrm{d}S}{\mathrm{d}t} = kM_t \tag{5}$$

$$\mathrm{d}S = kM_t\mathrm{d}_t \tag{6}$$

The incremental change is thus given by

$$\frac{M_0 - M_\mathrm{m}}{M_m} = kt_\mathrm{m} \tag{7}$$

Using this relationship the amount released from the formulation to replace that lost and to prevent the environmental amount from falling below 1 mg can be calculated (8). This provides the curves "B" in Figure 1 for each of the two pesticides. It can be seen that the amount needed to give 150 days control has now fallen to 7.9 mg for P-1 (from 1000 mg) and to 3.1 mg for P-2 (from 8 mg). The areas between the two sets of curves represent logarithmically the pesticide that is lost and that only serves the purpose of a degradable reservoir. The amounts saved at shorter periods are less than for 150 days. Comparing the two sets of curves the potential for saving is substantially greater for the pesticide with the short half-life. In fact, using an ideal controlled delivery system for this pesticide produces an efficiency over the 150 days equivalent of using the second pesticide with the longer half-life.

CRF, combined with other aspects of pesticide application, thus offer the feasibility of improving pesticide delivery, reducing losses, and benefittng the environment. The above model is based on many assumptions, including a constant and uniform environment. The agricultural situation is characterized by continual fluctuation and thus the theoretical objective can only be partially realized.

However, it does demonstrate that compounds of short persistence (such as insect pheromones) may be used effectively in place of long-persistent compounds when appropriately formulated. Loss kinetics for any individual pesticide vary depending on the environmental location considered; for example, loss by evaporation or photodegradation at the surface of plants may be much more rapid than published data giving half-life values for soils (7).

Types of Formulation: Physical, Chemical, Biological

Physical Systems, Matrix, and Reservoir. The role of delivery of pesticides is becoming more recognized as it has been a much neglected part of pest management; in fact, the position of delivery places second only to the discovery of new biologically active molecules. Indeed, with the widespread advent of proteinaceous pesticides the ability to deliver these to the crop plant using genetically modified varieties has reached the level of 100% efficiency, but not with 100% bioavailability or delivery to the pest organism. However, this ability does not apply to all pest problems and situations and it is desirable to maintain a multiplicity of pest management methods (including conventional pesticides), and CRF as described here have an important role in good delivery. In terms of integrated pest management (IPM) controlled delivery has a major contribution to the combination of pesticides with biocontrol methods when compared to conventional formulations.

For environmental application of pesticide delivery, CRF have been traditionally divided into chemical and physical types (9). More recently, a third approach the biological approach, has appeared, partly in response to delivery requirements for genetically engineered pesticides. The types of CRF described to date can be categorized as follows:

Chemical	Physical	Biological
Backbone linking Side-chain bonding Matrix degradation Carrier molecules such as cyclodextrins	Reservoir with membrane (micro- and macroencapsulation, coated solids, laminates, and large devices) Reservoir without membrane (hollow fibers, porous solids and foams, gels, osmotic pumps) Monolith or matrix (films, paint, sheets, slabs, pellets, strips, granules, microparticles, powders, and microspheres)	Living, or dead, cells (microorganisms) as delivery mechanisms

All formulation types have been prepared and tested but not all have reached commercial practice. The more important types are described in the following but this description is not comprehensive and the opportunities are only limited by innovation and development of new approaches (10). The basic configurations of CRF are given in Figure 2.

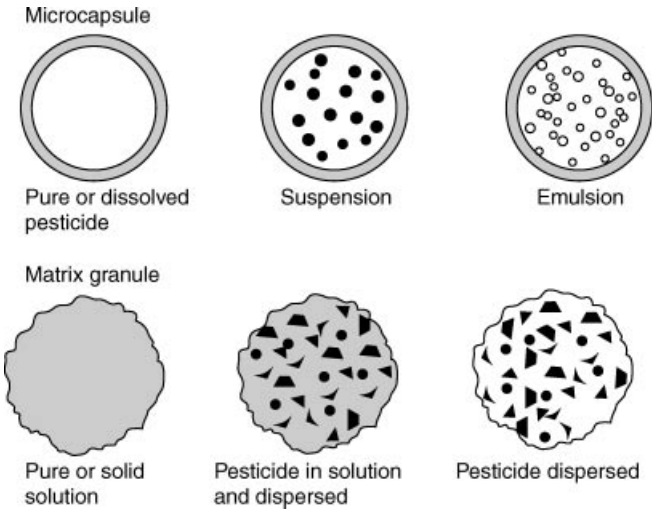

Fig. 2. Various configurations of capsule and matrix formulations.

Kinetics and Characteristics. There is a great deal of variation in the release kinetics of pesticides from the various formulation types described above. However, on the basis of mathematical treatment, the main types of release kinetics are represented in Figure 3. In order to discern the kinetics the rate-controlling step needs to be identified (11). This should be done under controlled conditions ie, in the laboratory, but it does not necessarily follow that this will be true in

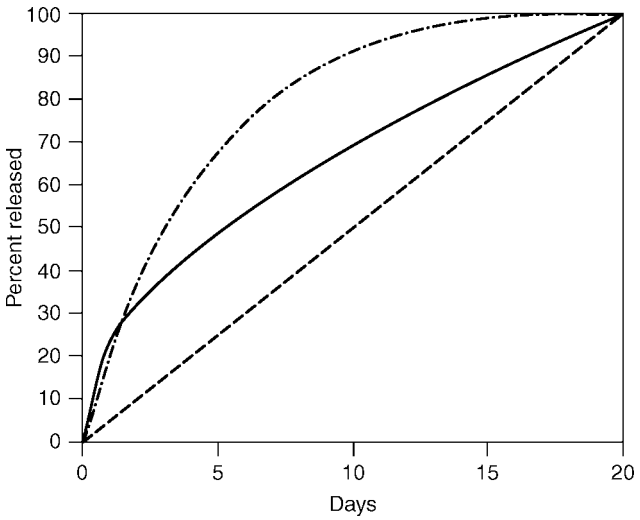

Fig. 3. Cumulative release provided by various release kinetics. A, Constant release, independent of time (zero order), such as that possible from a membrane reservoir device free of lag time or initial burst effects. B, Matrix or monolithic sphere with square root time release. C, First-order release. ---- A-zero order; -.-.-. C-first order; ——— B-square root.

the environment where the formulation is to be used. To study the basic kinetics, ie, those independent of the environment, the formulation has to be placed under "sink" conditions. These prevent the released pesticide from accumulating in the immediate vicinity of the surface of the formulation and the slowing of the release rate. The type of test environment will depend on the interfacial transport mechanism, especially movement into aqueous media or into the vapor phase or uptake by a biological system (12). Ideally, release kinetics ought to be determined under field conditions but this often presents insurmountable problems (especially those resulting from the variability of the open environment) and instead the biological response to the released pesticide is observed over time to validate the performance of any formulation.

Mechanisms of Release. In Figure 3, Line A represents release from a reservoir system with a large core relative to the wall mass. This could be a microcapsule releasing by steady-state diffusion through a uniform nonerodible wall. Transport through the polymer membrane (or matrix) occurs by a dissolution–diffusion process, where the active ingredient first dissolves in the polymer and then diffuses across the polymer to the external surface where the concentration is lower. The diffusion is in accordance with Fick's first law:

$$J = -D\mathrm{d}c_\mathrm{m}/\mathrm{d}x \tag{8}$$

where J is the flux of pesticide, D is the diffusivity, and dc_m/dx is the concentration gradient of the active ingredient. The rate remains constant as long as the internal and external concentrations of the pesticide and the concentration gradient are constant. A lag phase may occur while the system reaches this steady state (7).

Release by Erosion. The rate is independent of the concentration of pesticide remaining in the device. This zero order is also typical of certain surface erodible devices but their geometry is important and only laminar shapes produce a true constant rate as the device is eroded from one or both faces (2). Cylindrical, spherical, and irregular granular shapes provide a decreasing rate (as these particles lose surface area as erosion proceeds) and the overall release rate can be sustained only if hollow (concave) surfaces are available. These erodible systems have not been substantially exploited in pesticide delivery, mainly because of cost. Erosion can occur by dissolution of surface polymer or by degradation of the matrix, the best examples of which are the many polyesters such as d,l-polylactic acid or polyhydroxybutyrate (see POLY(3-HYDROXYALKANOATES); POLYLACTIDES). In this case, erosion may be through bulk hydrolysis of the polymer (13).

Release from Reservoir Systems. Most controlled release systems, including microcapsules, are positively rate-dependent on temperature, which makes effective delivery during cool night periods when interspersed with hot days (such as that required for pheromone release for control of nocturnally mating insect pests) problematic. For microcapsules, if the activity of the pesticide within the reservoir decreases then the release rate will also decrease; this effect will vary according to the capsule dimensions. This leads to a consideration of the polydispersity, or the range of sizes in a given number of microparticles (14). Although the release rate from individual particles may be constant, the duration of this release will varying according to the size of each particle. Thus, small particles become depleted before large particles and the overall release from a population

of particles will decrease with time. This has been shown in laboratory and field tests where overall first-order rates from microcapsules (Penncap-M; 20–40 μm) have been observed (15).

Release from Polymeric Matrices. In nonsurface erodible matrix systems diffusion of the active ingredient occurs from the interior of the particle to the surface. This gives rise to a declining rate of release according to the square root of time ($t^{-1/2}$) as shown by curve B in Figure 3. In practice, the approximate Higuchi model (16) applies and is true up to 60–70% of release, typically from a sphere or microsphere. The pesticide may be dissolved or dispersed in the polymer; for dissolved pesticide the second phase of release is by first-order kinetics. For dispersed pesticide the $t^{-1/2}$ kinetics last for almost all the release. These kinetics are a special case of the generalized description (17) of proportional release (at time t) from matrix or monolithic devices, as follows:

$$\frac{M_t}{M_\infty} = kt^n \tag{9}$$

where k is a constant incorporating characteristics of the polymer and the pesticide, and n is the diffusional exponent and indicative of the transport mechanism. In these cases $n = 0.5$ and indicates Fickian diffusion as the rate-controlling step in release.

Swellable Matrices. In matrix systems where water uptake or swelling can occur, such as may be possible in moist soil or water, the rate-controlling step may be solid-state diffusion or relaxation of the polymer by incoming water or a combination (18). Thus, the time exponent of the equation characterizing the release rate (19) may vary from 0.5 (square root of time) for Fickian diffusion to 1.0 (zero order) for swelling according to the nature of the matrix and the pesticide. Generally, the higher the water solubility of the pesticide the faster will be its rate of release. Less polar molecules with high partition coefficients tend to transport slower. In the case of irregular particles, such as granules, and where polydispersity exists, the overall time exponent will typically be less than the corresponding value for microspheres. For diffusion-controlled systems a typical low value is $n = 0.43$ (19).

First-Order Release. Finally, in situations where a chemical reaction liberates the active species, or where boundary conditions are rate-limiting, the rate of release depends on the concentration in the solid phase (20), and first-order kinetics are seen as in Figure 3 as curve C. Where more than one mechanism (including also diffusion) operates, complex release patterns occur.

Design and Preparation of CRF

Chemical Methods. Chemical methods involve the formation of a chemical bond with the pesticide and another molecule; this bond is then broken in the field to allow the release of the pesticide. The bond energy relates to the ease of breaking and thus the rate of release of the pesticide (21). Where the structure of the pesticide permits, it can be homopolymerized through a condensation reaction and the pesticide forms the backbone of a resulting high molecular weight polymer, which is in effect a polymeric propesticide. In the environment this polymer

depolymerizes to release the original pesticide, usually from each end of the chain (unzipping). Often breakdown of such homopolymers is slow and there is need for copolymerization with another appropriately functional monomer. Pesticides capable of homo- or copolymerization are few and include those containing functional groups such as amino, hydroxyl, and carboxyl groups.

A second approach to chemical-based formulations is where the pesticide is attached to a side chain of a high molecular weight polymer or macromolecule. This polymer may be either preformed, and the pesticide is then bound to appropriate side-chain functional groups, or the pesticide is first attached to a polymerizable monomer which is subsequently polymerized to yield the pesticide-bound polymer (22). Again, the release rate will depend on the energy of the bond holding the pesticide to the polymer which then undergoes scission to release the pesticide moiety (21).

The third approach to chemical-based release of pesticides is where the active is trapped in a network of a cross-linked polymer. Chemical breakdown of this polymer then allows the release of the pesticide. This mechanism incorporates physical processes of diffusion within the release mechanism.

The first two of the chemical release mechanisms usually involve covalent bonding of the pesticide and the formation of a molecular species different to the original structure. As a result of the registration requirements of new pesticide molecules, this approach implies considerable additional costs which outweigh the putative formulation benefits. Thus, true chemical approaches are often proscribed in favor of physical methods.

Physical Methods. Physical methods are divided into two general approaches. The pesticide is entrapped within a physical structure either at a molecular or micro-domain level or the pesticide in the form of a reservoir is enclosed within a polymeric envelope (2). In the first approach, the pesticide is mixed with the polymer (or other material with high energy density) to form a monolithic structure or matrix. Release is normally through diffusion through the matrix or dissolution and erosion of the matrix. In the second approach, structures are based upon a reservoir of the pesticide enclosed by the polymer, from nano-scale up to centimeter-sized devices. The shapes of these devices are varied and include spherical, such as microcapsules, and laminar or layered structures with the reservoir bounded by permeable membranes. These membranes provide a permeable barrier which controls the release rate. Other mechanisms of release include capsule rupture and erosion of the membrane.

As these "physical" methods provide the most important technologies for CRF of pesticides, they will be presented in more detail in the following sections.

Reservoir-Based Formulations with Membrane

In this method a reservoir or depot of the pesticide is bounded by a polymeric membrane, which protects (and separates) it from the environment and also provides a mechanism for its release. Thus, the specifications for the chemical nature and structure of this membrane are critical in the performance of such formulations. This makes for exacting requirements in the manufacturing processes if the desired release rates are to be consistently obtained in the field.

The method most suitable for use for pesticides is microencapsulation, where particle sizes are of the order of 10–100 μm and can be delivered by standard agricultural spraying. Microencapsulation has been defined (23) as the placing of a layer on the surface of a single *liquid* droplet. Conversely, coating refers to the covering of a single *solid* particle, whereas a matrix particle contains the *solid* or liquid active agent dispersed throughout a binding material. Even though these matrix particles are usually granular (they can be similar in size to microcapsules and are also intended for spraying as suspensions), they should be considered as matrices, and are described below.

Microencapsulation. Microencapsulation (qv) has now been commercially practiced for more than 30 years, following the first application of the technology to carbonless copying paper. Pesticide formulations based on microcapsules appeared in 1974 with the product Penncap-M containing the insecticide methyl parathion (4). Since then many microcapsule suspension formulations have been introduced and form the major group of CRF.

Production of microcapsules is based on three main methods (24,25). The oldest, that of phase separation or coacervation, uses emulsification to produce core droplets containing the pesticide dispersed in an immiscible phase in which the wall material is dissolved but then precipitates around the core droplets. Interfacial encapsulation is done by emulsifying or dispersing the pesticide solution in a continuous phase and a polymerization reaction takes place at the interface. Finally, in the physical methods the wall material is spread around the pesticide containing core to make the microcapsule.

Microcapsule Preparation by Interfacial Polymerization. The polymer forming the wall of the microcapsule can be made by addition or condensation polymerization or by *in situ* condensation polymerization. Addition polymerization using unsaturated monomers and free-radical-generating catalysts may start with the monomer in the pesticide-containing dispersed oil phase and the water-soluble catalyst in the aqueous phase. Other combinations of monomer and catalyst distributed between the two phases are possible but less practical. Pesticide impurities can interfere with the polymerization producing unsatisfactory capsules (26).

The condensation route to wall polymers is the best method for pesticide encapsulation. In this process the two reactive monomers, one dissolved in each of the two phases (of the emulsified oil/pesticide in water), polymerize at the interface and generate the wall material. Typically, the oil-phase monomers are polyfunctional isocyanates (A) or acid chlorides (B) and the water-phase reactants are polyalcohols or amines. Compounds sufficiently reactive are chosen such that when they meet at the interface the condensation polymer forms the capsule wall (Fig. 4). Alternatively, the two reactants (a diol and a diisocyanate) and a low boiling solvent make up the oil phase of the emulsion along with the pesticide. When heated the solvent evaporates bringing the monomers together at the droplet surface to form the capsule wall (27).

The resulting polyamide wall tends to be weak and soft, but the polyurea and polyester produce tough and strong materials (28). Other combinations of reactants give tough and strong polyurethane walls (polyamine and bis-haloformate or polyol and polyisocyanate) or epoxy walls (amine and epoxide) (see POLYURETHANES; EPOXY RESINS).

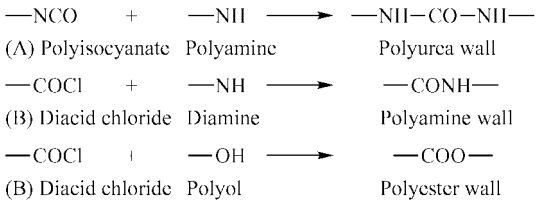

Fig. 4. Various routes to capsule wall formation through condensation polymerization.

For *in situ* condensation polymerization only the oil-phase isocyanate reactant is used (29). When the emulsion is heated, the isocyanate reacts with water at the interface to form an amine which then reacts in turn with the remaining isocyanate. The resulting polyurea wall material formed is thin and strong, providing good release properties for environmental applications. The permeability (the product of the diffusion coefficient and the solubility coefficient) of the wall can be varied by incorporating cross-linking monomers into the oil phase. A typical monomeric system is toluenediisocyanate and polymethylene-polyphenylisocyanate, a multifunctional monomer which causes cross-linking of the wall polymer (see Fig. 5). Both isocyanate monomers react with water at their own rates (see ISOCYANATE-DERIVED POLYMERS).

Forming the wall is only part of the successful microcapsule formulation. Recombination during microcapsule formation or subsequent storage to give large irregular shapes is a problem. Protective colloids offset this and reduce loss of the active ingredient into the continuous phase. Commercial colloids used include poly(methyl vinyl ether/maleic anhydride) cross-linked with poly(vinyl alcohol), styrene/maleic anhydride coplymers, vinylpyrrolidinone/vinyl acetate copolymers, vinylpyrrolidinone/styrene copolymer, and lignin sulfonate. A typical capsule suspension formulation made in this way may have up to 60% of the active ingredient, solvent (up to 20%), polymer (5–10%), protective colloids (1–20%), emulsifiers (1–5%), UV-protectant (0–5%), buffer (5%), viscosity/structure modifiers (2–10%), and water to make up the bulk (26).

Microcapsule Preparation by Phase Separation Methods. The earlier methods used for pesticide microencapsulation were based on phase separation.

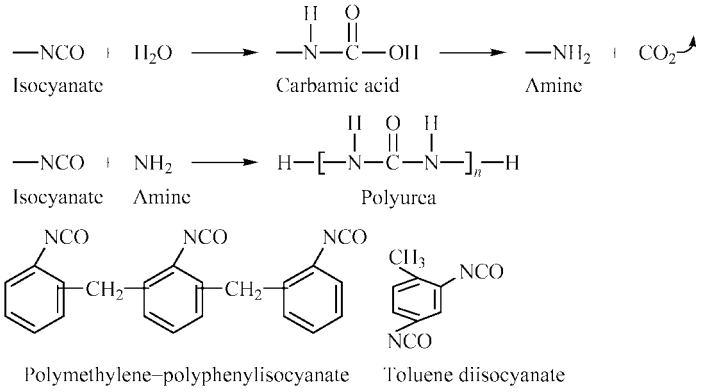

Fig. 5. Monomers and polymer forming reaction for *in situ* microcapsule wall formation.

There are two main approaches to coacervation, based on phase separation. Simple coacervation is when an aqueous solution of a hydrophilic polymer separates into two phases (solid and liquid) on addition of salt, alcohol, or other water-miscible solvents (29). An example would be the phase separation from an aqueous solution of poly(vinyl alcohol) by a nonsolvent such as propyl alcohol or by a salt solution, such as sodium sulfate. Complex coacervation occurs when polymers in solution with opposite electric charge come together and separate from the water. The most common example of complex coacervation is based on gelatin and gum arabic, two natural hydrophilic colloids. The process involves gelatin solution mixed with the core material in oil which is emulsified and the gum arabic added. The emulsion is heated and the phase separation is induced by dilution, reducing pH or cooling. If the pH is reduced below 4.5, the gelatin is then below its isoelectric point (pH 4.5) and its charge becomes positive; it then reacts with the gum arabic which has a residual negative charge and coats the oil droplets. Alternatively phase separation can be caused by dilution. The emulsion would then be cooled and treated with formaldehyde to cross-link and strengthen the capsule wall.

Phase separation can also be produced from solutions of polymers in organic solvents. By addition of a nonsolvent for the polymer to the solution containing the core material the polymer will precipitate around the emulsified core to form microcapsules (30). This can allow for the encapsulation of aqueous solutions or suspensions of pesticides. For example, such an aqueous solution can be emulsified in oil containing the dissolved polymer. Addition of the nonsolvent to the oil phase separates out the polymer, which can then form the wall around the water droplets.

Microcapsule Preparation by Physical Methods. These microcapsules are prepared by passing the two phases, core and wall material, through a small opening such that the wall material coats the core (31). This can be achieved using biliquid extrusion nozzles or with centrifugation in which the two liquids pass through many orifices. These allow the wall material to be cooled or dried after leaving the nozzle, thus forming a rigid wall structure. These processes generally give high wall-to-core ratios and cannot be used to prepare very small microcapsules ($<100\,\mu$m).

Coating of Solid Particles. Covering a solid particle with a polymeric wall is usually referred to as coating although the product may be termed a microcapsule. Various methods may be used with degrees of uniformity of the wall structure (32). Pan coating is well established in which the core particles (>1–2 mm) are tumbled in a rotating drum while the coating solution is sprayed slowly; warm air circulates to remove the solvent. For smaller particles a fluidized bed is needed. The core particles (down to 100–150 μm) are fluidized in a rising air current and the coating solution slowly sprayed into the bed. Spray drying in which the core material and the coating solution is atomized and the droplets dried rapidly in hot air gives poorer quality of encapsulation. There are numerous other methods for encapsulation, many specialized for specific applications.

Laminate Formulations. The laminate system comprises a reservoir layer of pesticide-containing polymer sealed between two other plastic layers (33). The two outer layers of this multilaminate structure protect and release the active ingredient by diffusion driven by the concentration gradient. Often one of the layers is impermeable and functions as a support for adhesion to suitable surfaces. At the surface the pesticide is continually removed by evaporation, degradation,

leaching, or by mechanical contact by humans, insects, moisture, wind, dust, or other agents.

The form and structure of the laminate varies according to the active agent and the intended application. The laminate may be used as a sheet for covering surfaces or may be cut into strips, ribbons, wafers, flakes, confetti, or even into granules or sprayable powders. Laminate strips (2.5×10 cm) consisting of a reservoir of an insecticide in PVC on a base of impermeable Mylar sheet and covered with a 0.127-mm layer of PVC have been developed for indoor cockroach control (Hercon Insectape). The insecticides include chlorpyrifos, diazinon, and propoxur. The tape is intended to be affixed to surfaces frequented by cockroaches and provide control for up to 3–5 months, especially valuable in areas where spraying is not desirable.

The laminate tape may also be used in its strip form as part of a collar for control of ticks and fleas on pet animals. Durations of control of these pests have been demonstrated to be up to 8 months for tick control.

An important application is for release of insect pheromones and attractants for insect control. A combination of the insecticide propoxur with the cockroach attractant periplanone-B provides 1 month of control in a laminate bait strip. Delivery of volatile compounds to the atmosphere surrounding crops is a crucial part of the mating disruption technique for many insect pests (34). The number and disposition of devices releasing the volatile pheromones depends on the pest, crop, and other environmental factors. Laminates can thus be dispersed in the crop as individual large devices (adhesive strips) or as small flakes or confetti applied by aircraft (applied with adhesive to ensure retention toward the top of the crop canopy) according to the control requirements. Among a number of crop pests an important use has been for pink bollworm in cotton. The use of a plastic film for controlling release of pheromones can take the form of the laminate, or film enclosing a reservoir of the active agent on a porous substrate, or even in the form of polyethylene bags, vials, tubes, and caps.

Applications of Microcapsule Formulations

Even though the first microcapsule formulation (using phase separation technology) was introduced into commerce in 1960 for the purpose of releasing ink in carbonless copying, it was not until 1974 that the first pesticide microcapsule appeared (15). This was Penncap-M (Pennwalt), methyl parathion encapsulated within a polyamide/polyurea wall material, prepared from the reaction of sebacoyl chloride and polymethylene polyphenylisocyanate with ethylenediamine and diethylenetetramine, suspended in water (240 g/L). This product showed reduced toxicity and extended insect control. This was followed by a similar formulation based on diazinon for indoor control of cockroaches. Superior and extended pest control was achieved, compared to conventional formulations. Mammalian toxicity was reduced as can be seen for these microcapsule formulations in Table 1. These pioneering formulations were followed by similar types using other insecticides such as ethyl parathion, permethrin, cypermethrin, and chlorpyriphos.

Microcapsule formulations have been made, based on pesticides, for control on crops and soils, on timber and other surfaces for structural and indoor

Table 1. Acute Mammalian Toxicities for Encapsulated and EC Formulations of Methyl Parathion and Diazinon[a]

Formulation	Rat oral LD_{50} mg/kg	Rabbit dermal LD_{50} mg/kg
Diazinon	350	600
Knox Out 2FM	>21,000	>10,000
Methyl parathion	25	400
Penncap-M	600	>5,450

[a]Ref. 35.

pests, and on seeds and livestock. A few examples of microcapsule formulations available worldwide are given in Table 2. Electron micrographs of a pesticide microcapsule formulation are shown in Figure 6. Each particular formulation is designed for its specific application and method of use. Variables that can be exploited for this purpose include capsule size and size range, wall thickness, wall permeability and strength (provided by degree of cross-linking), nature of wall material, adjuvants, and other formulation constituents. Release is usually through diffusion of the active agent through the capsule wall but other mechanisms can be used, such as rupture triggered by mechanical, erosion or degradation, thermal processes, or by osmotic swelling. An example of how encapsulation variables can influence release has been provided by Tsuji for a fenvalerate formulation (36). This polyurethane microcapsule was prepared by interfacial polymerization of polyisocyanate and ethylene glycol and was to have various wall thicknesses and mass median diameters.

Efficacy against the important brassica pest, diamond-back moth (*Plutella xylostella*), was assessed and it was found that the LC_{50} value decreased for the larger capsules (diameter D) when wall thickness (T) was constant and for the thinner wall when the diameter was kept constant. For any batch of microcapsules the ratio of diameter (expressed as the mass median diameter in μm) to the wall thickness (in μm) can be determined. The value D/T can be interpreted as relating to the strength of the capsules. As the ratio D/T increased, the 48-h LD_{50} value decreased. This means that the rupture of the capsules, by insects or other factors, is the important factor in biological efficacy. The availability of the insecticide depends on the strength of the capsule, and thus the persistence

Table 2. Selection of Some of the Microcapsule Formulations

Trade name	Active ingredient	Wall material	Company

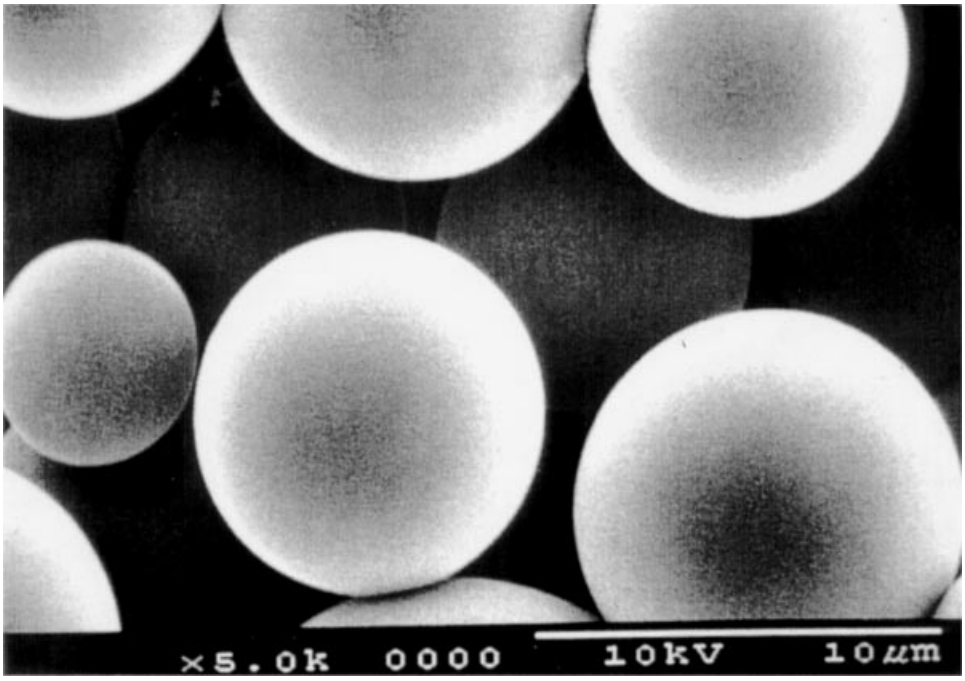

Fig. 6. Electron micrograph of a pesticide microcapsule fomulation.

of action of such microcapsule formulations will depend on having an optimum diameter-to-wall ratio with the wall thickness, neither too thin nor too thick. Other similar microcapsule formulations for use in agriculture have been made based on insecticides fenitrothion and fenpropathrin, which also showed better safety to sensitive crops and also to nontarget organisms such as fish. In extending this technology, formulations based on permethrin were developed for use in transplanted rice, and on fenitrothion and fenobcarb for aerial application in rice for bug and planthopper control.

The mechanism of release for these capsules, ie, by rupture or breakage, is suitable for controlling insect pests on surfaces. Formulations were developed for the control of cockroaches (based on fenitrothion or cyphenothrin), for termites (based on fenitrothion either applied to surfaces or incorporated into the glue of plywood), and for mosquitoes and flies on aggressive surfaces such as cement (based on fenitrothion and lambda-cyhalothrin). In the case of cockroach control the pickup of microcapsules and the efficient delivery (often by grooming and ingestion of dust plus capsules) can give control of individuals resistant to diazinon or fenitrothion.

Formation of microcapsules by *in situ* interfacial polymerization (where the monomers are entirely in the oil phase of the capsule core) yields microcapsules with a high core-to-wall ratio and a bilayer wall with an outer layer (about 0.05 μm) and an inner reinforcing spongy layer (0.5 μm). This method has been used to encapsulate a range of insecticides, pheromones, and herbicides, many of which have been available commercially (37). The capsule size may be varied from submicrometer to 100 μm diameter and the permeability selected for rapid or slow release of

the pesticide. Release is by diffusion through the wall rather than rupture. For an effective formulation the capsule suspension formed after polymerization needs protective stabilizers, dispersants, flow, etc. to provide a high active ingredient content with good shelf life and acceptable handling at dilution.

Applications for MC formulations include seed treatment (especially where an insecticide may be phytotoxic at dosages required), soil treatment of insecticides and herbicides, and treatment of surfaces for cockroach and mosquito control.

Reservoir-Based Formulations without Membrane

Reservoir systems that lack a bounding membrane to protect and regulate the release are usually designed for liquid actives that are volatile. The liquid is held in place through capillary forces and is released in the vapor phase. The rate of evaporation is regulated by diffusion of the vapor through the static air phase above the liquid surface. The simplest example is the hollow fiber, which is a fine polymeric capillary closed at one end and filled (or partially filled) with the liquid active (38). This diffuses through the air column to the opening from where it disperses. This method has been mostly developed to deliver many of the volatile sex pheromones for insect pest control to maintain a minimum concentration in the air surrounding the crop to be protected.

Operating by a similar process are the porous and foam polymers. The active is held in the pores of the structure and released by diffusion through the pores to the surface where it moves away from the particle. The diffusion is driven by evaporation or by dissolution in environmental water which penetrates the porous particle. Highly absorbent polymers such as Culigel (Stockhausen Inc.) have been developed for delivery in water bodies for mosquito control (39).

Matrix Formulations. These formulations, also known as monolithic, consist of a uniform continuous phase with the pesticide dissolved or dispersed throughout. Their preparation is generally easier, requiring less process control but can exhibit a rich variety of release types according to the material and structure of the matrix. An almost endless selection of materials is available for the matrix. Elastomers (rubbers) as well as thermoplastics and thermosets can be used and many applications for pesticides have been developed using the technologies of the rubber and plastics industries (9). Generally, a range of additives such as plasticizers, light protectants, pigments, antioxidants, processing aids, etc are usually included (40). The products can be produced in a number of forms or shapes, especially sheets, ropes, extruded cylinders, slabs, and granules. As release is inversely related to device size, the production of simple powders involves difficulty in uniformity as well as minimal reduction in release kinetics compared to conventional formulations. Many of these large formulation types are, or have been, popular for aquatic applications, such as for insect and mollusc vectors of human disease causing organisms, with few applications in agriculture. Examples have been larvicidal sheets containing temephos, malathion, or chlorpyrifos using polyamide, PVC, polyethylene, and polyurethane. Current survivors of this approach are thermoplastic formulations of chlorpyrifos (Dursban 10CR), of dichlorvos (No Pest PVC strips), and of tributyltin fluoride (Ecopro 1330) for controlling freshwater snails (*Biomphalaria glabrata*), the vector of *Schistosoma*

mansoni, and the causal agent of bilharzia (35). Monolithic systems such as these require appropriate plasticizers to promote migration of the pesticide to the surface, even so a substantial proportion will still remain entrapped when the rate of release declines below effective levels. This is less of a problem with elastomers where diffusion is faster (because of lower intermolecular forces) at similar temperatures.

Pesticide-Containing Films. In the agricultural field the use of plastic mulch and plastic films for plant growing has become widespread, as it advances and enhances cropping when temperatures are low. It also encourages pests, particularly weeds and disease-causing agents. The use of pesticides in these conditions can cause problems (eg, crop phytotoxicity), not least a result of the need for reapplication after the film has been laid. Incorporation of the pesticide into the film obviates both of these problems. Release of the pesticide can occur predominantly on the underside of the film and this pesticide is transported away (to the soil/crop) by condensation (41). Pesticides can be incorporated into agricultural films prior to their being formed by blown extrusion or into other forms such as sheets, tapes, cords, and ropes and chopped pieces such as confetti. Herbicides incorporated into EVA films are said to reduce by two to four times the amounts needed in covering early season vegetables such as cabbage, sweet corn, and celery. Using coating processes films may be applied to seeds (42), which provides a very effective means of controlled delivery of pesticides to the seed region and to the emerging seedling.

Matrix Particles. Small particles based on a matrix can range in size from powders (microparticles) to granules (fine to macrogranules) to pellets (43). Microspheres can be considered as the matrix equivalent to microcapsules. Most controlled release granules are matrix-based, although some have a solid core or reservoir of pesticide (with a coating).

Microparticles. Size matters; release rates depend on surface area, ie, a function of the square of the radius of a spherical particle, and thus larger particles release for longer and are able to manipulate the external availability of the pesticide. Small microparticles are therefore limited in their scope for controlling release but can be used in traditional spraying of dispersions onto soils and crops as well as for seed dressing. Suspension concentrate formulations of matrix microparticles have been developed based on various rosins, phenolic resins, waxes, and bitumens. These have focused on lipophilic pesticides such as trifluralin and chlorpyrifos and reductions in volatility have been demonstrated (43).

Granules. While microparticles refer to sizes up to 100 μm, granules are typically 0.5–2.0 mm (fine granules 0.3–1.0 mm, microgranules 0.1–0.6 mm, macrogranules 2–6 mm). Granular CRF can be achieved by coating as well as from matrices. Although controlled release granules have not been as popular as microcapsules, there have been significant developments for applications to soil especially where extended control is required.

Cane grubs are a widespread pest problem in sugarcane growing and attack the roots of the plant over long periods. Conventional control has used persistent organochlorine insecticides applied at or soon after planting to optimize placement and residual protection. The introduction of long release granule formulations of short-lived insecticides such as chlorpyrifos (suSCon Blue) allowed the phase out of the organochlorines whilst giving good protection to the sugarcane (44). The

Table 3. Acute Oral Toxicities (as LD_{50} Values) of Controlled Release (suSCon) Granules Compared to Technical-Grade Pesticides[a]

Product	Acute oral rat LD_{50}, mg/kg
suSCon Blue (140 g/kg chlorpyrifos)	>1000
Technical chlorpyrifos	135–165
Marshal suSCon (100 g/kg carbosulfan)	>1000
Technical carbosulfan	185–250
suSCon Fu Ming (100 g/kg phorate)	319
Technical carbosulfan	1.6–3.7
G22001 (140 g/kg parathion)	578 (male)
Technical parathion	3.6 (female), 13 (male)

[a] Ref. 44.

formulation is a 2-mm diameter extruded cylindrical granule of polyethylene containing 140 g of active ingredient per kilogram with an additive that sustains release by pore formation, through leaching by soil moisture. Single applications at planting can provide up to 3 years protection through the first harvesting and to several follow-on ratoon crops. This approach to pest control has since been further extended to other problems, especially of concealed insects where systemic insecticides can be used effectively. Shoot borers in sugarcane and forestry, termites and weevils in forestry and ornamentals, and borers and nematodes in a number of crops are examples of potential targets.

In addition to improved delivery and replacing persistent organochlorine pesticides with nonpersistent compounds, controlled release granules also provide reduced toxicity of the product. For example, the acute oral toxicities of these granules are much reduced (giving higher LD_{50} values) compared to unformulated or conventional sprayable formulations, as shown in Table 3.

Other granule formulations are based on biodegradable polymers (qv) which also offer the possibility of using wastes and by-products from biological industries such as farming and forestry. New uses for cornstarch developed by the USDA included processes for the formulation of pesticides based on cross-linking of starch (45). The method involves the use of a corotating twin-screw extruder for mixing and gelatinizing starch with water (90–95°C), introducing the pesticide and providing the extrudate, which is then cut and dried to give the pelleted product. Hydrogen bonding occurs between the starch molecules (a process called *retrogradation*) to give a water-insoluble matrix entrapping the pesticide. Release occurs following soil placement by swelling. Evaluation of this granule formulation, especially of herbicides, has shown good efficacy at the same time, reducing environmental losses and detrimental effects on surface and groundwater quality (46). In field experiments significant reductions in herbicide volatility, surface run-off losses, and leaching have been observed compared to commercial formulations. These effects are particularly noticeable very shortly after application, when commercial formulations make the herbicide rapidly available at high concentrations.

Another natural polymer type abundantly available is the polyphenolic lignin. This aromatic macromolecule which occurs in terrestrial plants is obtained

as a water-insoluble waste or by-product from the pulping of wood. Its natural protective attributes that it contributes to the success of plants can be exploited to protect, and deliver, pesticides (47). It can be melt-processed with compatible pesticides (similar polarity) by blending or screw extrusion to provide granules or powders. Release of pesticides from the granules declines with time, depending on diffusion kinetics according to a swelling-diffusion model (48). Formulations based on a wide range of soil-applied pesticides have been evaluated and field trialed extensively. For example, carbofuran-containing lignin-based granules in tropical flooded rice gave good control of virus disease (through controlling the insect vector of the virus) but using one third of the amount of pesticide compared to conventional formulations (49). This approach afforded safe handling to applicators and reduced risks (to bare feet) during the transplanting of the rice seedlings. A wide range of pesticides have been controlled release formulated by this method.

Other matrix methods for the preparation of granules can use gelating polymers such as alginic acid and other polyelectrolytes (qv). This approach effectively entraps pesticides through cross-linking with polyvalent ions such as Ca^{2+}; combined with adsorbents useful release profiles can be obtained (50). This method of preparation, using mild conditions in aqueous media at ambient temperatures, is used for formulating microbial pesticides to protect and extend the active lives and release of propagules of such living pesticidal agents (51). A wide range of bacteria, fungi, viruses, protozoa, and nematodes have been formulated by this method, and related methods, to provide effective sustained formulations.

Biological Methods

Finally, the use of living cells (such as yeasts) as encapsulating materials has been under investigation for many years. The problems associated with the encapsulation of pesticides within preformed cells have been overcome by using proteinaceous pesticides such as the toxin from *Bacillus thuringiensis* (Bt). The genes for the production of the toxin have been introduced into the soil bacterium *Pseudomonas fluorescens*; the toxin is expressed and is seen as a crystalline inclusion. Following production by fermentation the cells are killed and fixed to provide the capsule formulation which is registered for use on brassicas (52).

COPOLYMERIZATION

Introduction

This article is primarily concerned with chain copolymerization. Chain copolymerization is important as it allows a wide array of functional molecules to be designed and incorporated into polymeric materials. In addition, fundamental studies on copolymerization allow the mapping out of monomer structure–reactivity relationships that underpin our knowledge of polymerization reaction mechanisms.

In recent years it has become evident that the reaction mechanism involved in free-radical copolymerization propagation is appreciably more complicated than originally postulated in the terminal model developed back in the 1940s. There is still some reluctance to acknowledge this fact as it is often more convenient to simplify the mechanism. In some instances this may be appropriate; however, in many cases where specific information about radical reactivity is garnered from the data reduction, significant problems may arise if the interpretation is oversimplified. In an attempt to clarify the position, we would like to draw an analogy with the development of understanding in the study of a human cell. As experimental techniques (particularly the electron microscope) have become more sophisticated for studying cells, our recognition of the complexity of cellular processes has been enhanced and new theories and ideas have been advanced to accompany the increased appreciation of cellular processes, leading to an understanding of the importance and role of apoptosis in designing new cancer treatments. In a similar way as experimental methods have improved to study free-radical copolymerization (most notably, size-exclusion chromatography, pulsed-laser polymerization, soft ionization mass spectrometry and ab initio calculations) our understanding of the complexity of radical copolymerization has improved and it would be a mistake if all these new experimental data were ignored, leaving theory restricted to the basic terminal model developed in the 1940s on the basis of fairly rudimentary experimental data. The complexity of radical processes should be recognized while allowing for the fact that by using carefully designed synthetic methods where some kinetic pathways are suppressed (ie, controlled/living radical polymerization) we can largely overcome many of the side reactions to generate bespoke polymer structures. In 1985–1987 the implicit copolymerization model was developed by Professor Fukuda, when his team discovered that the terminal model failed in the prediction of average propagation rate coefficients. In subsequent years it has become clear, mainly through advanced quantum calculations, that the cause of failure of the terminal model can be ascribed to a combination of radical stabilization, entropic interactions, and partial charge transfer in the transition state (so-called polarity effects), which are all significantly influenced by penultimate units. This leads to a conclusion that the physical chemistry underpinning copolymerization can be best described by an explicit modelling approach. This complexity causes some problems in the data reduction of copolymerization experiments. However, for the simple prediction of composition the terminal model, although fairly crude, provides an adequate method in many instances. The problems only arise when it is used to study absolute rate coefficients (cross-propagation rate coefficients) or when it is used to predict other quantities such as average propagation rates or sequence distribution. Therefore it is imperative that the limitations of the terminal

model are recognized particularly when adding layers of experimental complexity (controlled/living radical copolymerization). Very similar arguments can be made for the area of termination in free-radical copolymerization with the recent development of SP-laser experiments, enabling the study of the reaction with greater precision and accuracy than was previously possible. A continuous development of knowledge via copolymerization research should result from a simultaneous progression in both experimental techniques and modified theory.

This article progresses to discuss the newly emerging field of controlled/living radical copolymerization, and the novel materials that can be made using these highly versatile synthetic methods. Finally we cover in brief ionic chain copolymerization and cross-linking copolymerization.

Propagation Kinetics and Copolymerization Models

Copolymerization propagation kinetics have perhaps the most significant impact on copolymer properties. The rates of the individual propagation reactions in a free-radical copolymerization not only affect the overall rate of polymerization and the molecular weight distribution of the resulting polymer, but also directly govern the copolymer composition and microstructure (ie, whether the monomers form block, alternating, or random copolymers), and the chain-end composition of the living radicals (which in turn affects the chain-end composition of the dead polymer). Furthermore, it is the geometry of the transition structure in the propagation reaction that governs the stereochemistry of the resulting polymer. The ability to understand the fundamental influences on the propagation reaction (both from a kinetic and mechanistic point of view) thus enables these important properties to be modeled, and hence controlled, simply by manipulating the reaction conditions (such as solvent type, monomer feed composition, and temperature).

There are an enormous number of different copolymerization models available in the literature. The simplest kinetic model, the terminal model, was derived in the 1940s and, while it continues to receive widespread use, 60 years of experimental and theoretical studies have revealed serious deficiencies in this model for a wide range of systems. In response to these problems, numerous alternative copolymerization models have been derived. These models differ primarily in their assumptions as to what factors affect the rate of the propagation step. For example, in the terminal model it is assumed that the composition of the terminal unit of the propagating radical (ie, the α- and β-substituents) and the monomer affect the propagation rate, while in the penultimate model it is assumed that the penultimate unit of the propagating radical (ie, the γ- and possibly δ-substituents) is also important. Other models incorporate possible side reactions that might affect the overall propagation rate, such as depropagation or various types of solvent effect.

In what follows we briefly outline the assumptions and equations corresponding to the most important copolymerization models. To keep this as a compact and accessible summary, we do not present derivations for the equations. Neither do we present the lengthy equations needed to predict the various triad and pentad fractions under specific models. For more detailed information of this nature, the reader is referred to the original references. In addition, a general account of the main steps in deriving a copolymerization model is found in Reference 1.

For the sake of simplicity, we present equations for each of the types of models in their low-conversion, "instantaneous" forms, but conclude with a brief discussion of the extension of the models to their conversion-dependent "integrated" form. Having outlined all of the models, we then discuss the main experimental evidence for or against them, and make some general suggestions concerning their applicability to specific types of system. We then conclude with a short discussion of reactivity in free-radical copolymerization. More fundamental aspects of this topic are addressed in a separate article (see COMPUTATIONAL QUANTUM CHEMISTRY FOR FREE-RADICAL POLYMERIZATION).

Terminal Model

In the terminal model it is assumed that the terminal unit of a propagating polymer radical is the only factor influencing its reactivity, and that side reactions are not significant. As a result, there are only four types of propagation reaction in the free-radical copolymerization of any two given monomers (M_1 and M_2):

$$RM_i\cdot + M_j \xrightarrow{k_{ij}} RM_iM_j\cdot \quad i,j = 1 \text{ or } 2$$

From this assumption, Jenkel (2), Mayo and Lewis (3), and Alfrey and Goldfinger (4) all independently derived an expression for the copolymer composition (F_1/F_2) as a function of the monomer feed fractions (f_1 and f_2) and the reactivity ratios (r_1 and r_2) of the monomers:

$$\frac{F_1}{F_2} = \frac{f_1}{f_2}\cdot\frac{r_1 f_1 + f_2}{r_2 f_2 + f_1} \quad \text{where} \quad r_i = \frac{k_{ii}}{k_{ij}}\ i \neq j \quad \text{and} \quad i,j = 1 \text{ or } 2 \tag{1}$$

Alfrey and Goldfinger (4) also derived expressions for the sequence distribution and the number-average degree of polymerization expected for a copolymerization obeying the terminal model. They later extended the terminal model to describe polymerizations involving three or more monomers (5,6). Fukuda and co-workers (7) derived the following expression for the copolymerization propagation rate constant $\langle k_p \rangle$ under the terminal model:

$$\langle k_p \rangle = \frac{r_1 f_1^2 + 2 f_1 f_2 + r_2 f_2^2}{[r_1 f_1 / k_{11}] + [r_2 f_2 / k_{22}]} \tag{2}$$

This equation follows from the kinetic analysis of copolymerization by Melville and co-workers (8) and Walling (9), who arrived at an expression for the overall rate of copolymerization assuming a terminal model for both propagation and termination.

Explicit and Implicit Penultimate Models

In the *explicit penultimate model*, it is assumed that both the terminal and penultimate units of a polymer radical may affect the rate of the propagation reaction. As in the terminal model, side reactions are considered to be insignificant. The explicit penultimate model was first suggested in 1946 by Merz and co-workers (10), who derived equations for predicting the composition and sequence distribution under this model. A full description of the model—including an expression for $\langle k_p \rangle$—has since been provided by Fukuda and co-workers (11), and it is their notation that is used below. In addition, penultimate model equations for the case of terpolymerization have been published by Coote and Davis (12).

In the presence of a penultimate unit effect, there are eight different types of propagation reactions:

$$RM_iM_j\cdot + M_k \xrightarrow{k_{ijk}} RM_iM_jM_k\cdot \quad i,j,k = 1 \text{ or } 2$$

From their eight different propagation rate constants, four different monomer reactivity ratios (r_i and r_i') and two radical reactivity ratios (s_i) can be defined as follows.

$$r_i = \frac{k_{iii}}{k_{iij}} \quad r_i' = \frac{k_{jii}}{k_{jij}} \quad s_i = \frac{k_{jii}}{k_{iii}} \quad \text{where} \quad i \neq j \quad \text{and} \quad i,j = 1 \text{ or } 2$$

These are used to calculate the adjusted parameters $\bar{r}_i$ and $\bar{k}_{ii}$:

$$\bar{r}_i = r_i'\left(\frac{f_i r_i + f_j}{f_i r_i' + f_j}\right) \quad \text{where} \quad i,j = 1 \text{ or } 2 \quad \text{and} \quad i \neq j \tag{3}$$

$$\bar{k}_{ii} = k_{iii}\left(\frac{r_i f_i + f_j}{r_i f_i + f_j/s_i}\right) \quad \text{where} \quad i,j = 1 \text{ or } 2 \quad \text{and} \quad i \neq j \tag{4}$$

These are used in place of r_i and k_{ii}, in the terminal model expressions for composition and $\langle k_p \rangle$ (ie, eqs. 1 and 2 above).

The *implicit penultimate model* was first suggested by Fukuda and coworkers (7) in 1985, in order to describe their observation that the terminal model could be fitted to the composition data for the copolymerization of styrene with methyl methacrylate, though it could not simultaneously describe the propagation rate coefficients. In this model, the following restriction is placed on the explicit penultimate model.

$$r_i\left(=\frac{k_{iii}}{k_{iij}}\right) = r_i''\left(=\frac{k_{jii}}{k_{jij}}\right) = \frac{k_{ii}}{k_{ij}} \quad \text{where} \quad i \neq j \quad \text{and} \quad i,j = 1 \text{ or } 2 \tag{5}$$

The penultimate unit effect is thus assumed to be absent from the monomer reactivity ratios, which are equivalent to their terminal model forms, and only to

exist in the radical reactivity ratios (ie, through values of $s_i \neq 1$). This amounts to assuming that the magnitude of the penultimate unit effect on reactivity is independent of the type of monomer with which it is reacting (since the equality $k_{jii}/k_{iii} = k_{iij}/k_{iij}$ follows directly from the assumption that $r_i = r_i'$). In other words, it assumed that there is a penultimate unit effect on reactivity but not selectivity. On the basis of this assumption (ie, eq. 5), equation 3 collapses into

$$\bar{r}_i = r_i''\left(=\frac{k_{jii}}{k_{iij}}\right) = r_i\left(=\frac{k_{iii}}{k_{iij}}\right) = \frac{k_{ii}}{k_{ij}} \quad \text{where} \quad i \neq j \quad \text{and} \quad i,j = 1 \text{ or } 2 \qquad (6)$$

Thus the adjusted monomer reactivity ratios of the penultimate model are replaced simply by their corresponding terminal model values. However, since the penultimate unit effect can remain in the radical reactivity ratios (ie, through values of $s_i \neq 1$), equation 4 does not collapse to its equivalent terminal model form (ie, $\bar{k}_{ii} \neq k_{iii}$). Since the composition and triad/pentad fraction equations contain only $\bar{r}_i$ terms, they collapse to the corresponding terminal model equations. However, since it contains both $\bar{r}_i$ and $\bar{k}_{ii}$ terms, the propagation rate equation, though simpler than that of the explicit penultimate model, continues to differ from that of the terminal model. There is thus an implicit penultimate unit effect—that is, a penultimate unit effect on the propagation rate but not the composition or sequence distribution.

Solvent Effects

Solvent Polarity Effects. When polar interactions are important in the transition structure of the propagation reaction, the polarity of the solvent may affect the propagation rate. This may be explained as follows. Polar interactions are said to occur when the transition structure is stabilized by charge transfer between the reacting species (13). The amount of charge transfer, and hence the amount of stabilization, is inversely proportional to the energy difference between the charge transfer configuration and the product and reactant configurations that combine to make up the ground-state wave function of the transition structure. Now it is known that polar solvents can stabilize charged species, as seen in the favorable effect of polar solvents on both the thermodynamics and kinetics of reactions in which charge is generated (13). Thus, when charge transfer in the transition structure is important, the relative stability of the charge-transfer configuration, and thus of the transition structure, will be affected by the polarity of the solvent. Hence, when polar interactions are important in a propagation reaction, a polar solvent can stabilize the transition structure and hence lower the reaction barrier.

When such effects are important, the polarity of the solvent affects radical selectivity as well as radical reactivity. This is because the extent to which charge-transfer stabilization can occur, and hence the extent to which polar solvents can further enhance these effects, depends on both reacting species. For instance, in a free-radical copolymerization, it is likely that polar interactions would be more important in the cross-propagations (when the monomer and radical bear different substituents and thus have different electronic properties) than in the

homopropagations (when the monomer and radical bear the same substituents). Hence the effect of solvent polarity on the stability of the transition structure (and thus the propagation rate) would generally be expected to be greater in the cross- than in the homopropagation reactions. Thus, there would be a net effect of solvent polarity on the reactivity ratios of the copolymerization (regardless of whether or not these polar interactions are influenced by the penultimate unit, or merely by the terminal unit).

There are two cases to consider when predicting the effect of solvent polarity on copolymerization propagation kinetics:

(1) the solvent polarity is constant as a function of the monomer feed composition for the given copolymerization system, as would be the case if the solvent polarity is dominated by an added diluent, or if the comonomers have similar dielectric constants, such as in the bulk copolymerization of styrene with methyl methacrylate

(2) the solvent polarity varies with the comonomer feed mixture for the given system, as would be the case in a bulk copolymerization of monomers with significantly different dielectric constants, such as styrene and acrylonitrile

In case (*1*), the effect on copolymerization kinetics is simple. The various reactivity ratios would vary from solvent to solvent, but, for a given copolymerization system, they would be constant as a function of the monomer feed ratios. The copolymerization kinetics would simply follow the appropriate base model for that system (according to which side reactions were assumed to be important, and which units were assumed to affect radical reactivity).

In case (*2*), the effect of the solvent on the copolymerization kinetics is more complicated since the various reactivity ratios would not be constant as a function of the monomer feed. To model such behavior, it would first be necessary to select an appropriate base model for the copolymerization (based on the usual assumptions). It would then be necessary to replace the various reactivity ratios (included in the base model as constants) by functions of the composition of the comonomer feed mixture. These functions would need to relate the reactivity ratios to the solvent polarity, and then relate the solvent polarity to the comonomer feed composition, and would thus vary depending upon the particular chemical properties of the monomers. It is therefore difficult to suggest a general kinetic model to describe these systems, but it is clear that such effects would result in deviations from the behavior predicted by their appropriate base model.

Radical Complexes. Solvents can also interfere with the propagation step via the formation of radical–solvent complexes. When complexation occurs, the complexed radicals are generally more stable than their corresponding uncomplexed radicals as it is this stabilization that drives the complexation reaction. Thus, in general, one might expect complexed radicals to propagate more slowly than their corresponding uncomplexed radicals, if indeed they propagate at all. However, in the special case that one of the comonomers is the complexing agent, the propagation rate of the complexed radical may instead be enhanced if propagation through the complex offers an alternative less-energetic reaction pathway. In any case, the complexed radicals would be expected to propagate at a rate

different from their corresponding free radicals; thus, the formation of radical–solvent complexes would affect the copolymerization propagation kinetics.

A terminal radical–complex model for copolymerization was formulated by Kamachi (14). He proposed that a complex is formed between the propagating radical and the solvent (which may be the monomer) and that this complexed radical propagates at a different rate compared with the corresponding uncomplexed radical. Under these conditions (and assuming that the terminal unit is the only unit affecting radical reactivity), there are eight different propagation reactions to characterize in a binary copolymerization. These are as follows:

$$\mathrm{RM}_i\cdot + \mathrm{M}_j \xrightarrow{k_{ij}} \mathrm{RM}_i\mathrm{M}_j\cdot \text{ or } \mathrm{RM}_i\mathrm{M}_j\cdot\ \mathrm{S} \quad \text{where} \quad i, j \quad 1 \text{ or } 2$$

$$\mathrm{RM}_i\cdot\mathrm{S} + \mathrm{M}_j \xrightarrow{k_{cij}} \mathrm{RM}_i\mathrm{M}_j\cdot \text{ or } \mathrm{RM}_i\mathrm{M}_j\cdot\ \mathrm{S} \quad \text{where} \quad i, j = 1 \text{ or } 2$$

There are also two equilibrium reactions for the formation of the complex (assuming that there is only one complexing agent which can complex with either radical):

$$\mathrm{RM}_i\cdot + \mathrm{S} \xleftrightarrow{K_i} \mathrm{RM}_i\cdot\ \mathrm{S} \quad \text{where} \quad i, j \quad 1 \text{ or } 2$$

On the basis of these reactions, Kamachi (14) derived expressions for the copolymer composition under this model. Fukuda and co-workers (15) later provided expressions for the composition, triad/pentad fractions, and propagation rate by deriving expressions for $\bar{r}_i$ and $\bar{k}_{ii}$, which could be used in place of r_i and k_{ii} in the terminal model equations (ie, eqs. 1 and 2 above). These are as follows:

$$\bar{k}_{ii} = k_{ii}\frac{1+\bar{s}_{ci}K_i[\mathrm{S}]}{1+K_i[\mathrm{S}]} \tag{7}$$

$$\bar{r}_i = r_i\frac{1+\bar{s}_{ci}K_i[\mathrm{S}]}{1+(r_i/\bar{r}_{ci})\bar{s}_{ci}K_i[\mathrm{S}]} \tag{8}$$

$$\text{where} \quad r_i = \frac{k_{ii}}{k_{ij}}, \quad \bar{r}_{ci} = \frac{k_{cii}}{k_{cij}}, \quad \bar{s}_{ci} = \frac{k_{cii}}{k_{ii}}, \quad i, j = 1 \text{ or } 2 \quad \text{and} \quad i \neq j$$

Variants of this model may be derived by assuming an alternative basis model (such as the implicit or explicit penultimate model) or by making further assumptions as to the nature of the complexation reaction. For instance, in the special case that the complexed radicals do not propagate (ie, $\bar{s}_{ci} = 0$ for all i), the reactivity ratios are not affected (ie, $\bar{r}_i = r_i$ for all i), and the complex formation serves only to remove radicals (and monomer, if monomer is the complexing agent) from the reaction, resulting in a solvent effect that is analogous to a bootstrap effect (see below).

Monomer Complexes. A solvent may also interfere in the propagation step via complexation with the monomer. As was the case with radical–solvent complexes, complexed monomer might be expected to propagate at a rate different from that of free monomer, since complexation might stabilize the monomer, alter its steric properties, and/or provide an alternative pathway for propagation. In

examining the effect of such complexation on copolymerization kinetics, there are a number of different mechanisms to consider. In the case that the complex is formed between the comonomers, there are three alternatives:

(1) The monomer–monomer complex propagates as a single unit, competing with the propagation of free monomer.
(2) The monomer–monomer complex propagates as a single unit, competing with the propagation of free monomer, but the complex dissociates during the propagation step and only one of the monomers is incorporated into the growing polymer radical.
(3) The monomer–monomer complex does not propagate, and complexation serves only to alter the free monomer concentrations.

In the case that the complex is formed between one of the monomers and an added solvent, there are two further mechanisms to consider:

(4) The complexed monomer propagates, but at a different rate to that of the free monomer.
(5) The complexed monomer does not propagate. Models based on mechanisms (*1*) and (*2*) are known respectively as the monomer–monomer complex participation (MCP) and dissociation (MCD) models. Mechanisms (*3*) and (*5*) would result in a solvent effect analogous to a bootstrap effect (see below), while mechanism (*4*) would result in a model similar to the MCD model, though it would be based on a slightly different equilibrium expression. The MCP and MCD models are outlined in the following paragraphs.

The *Monomer–Monomer Complex Participation (MCP) Model* was first suggested by Bartlett and Nozaki (16), later developed by Seiner and Litt (17), and refined by Cais and co-workers (18). In this model, it is assumed that the two monomers can form a 1:1 donor–acceptor complex and add to the propagating chain as a single unit in either direction. Assuming that the terminal unit is the only unit affecting radical reactivity, eight addition reactions and an equilibrium constant are required to describe the system.

$$RM_i\cdot + M_j^0 \xrightarrow{k_{ij}} RM_iM_j\cdot \quad \text{where} \quad i, j \quad 1 \text{ or } 2$$

$$RM_i\cdot + M_iM_j \xrightarrow{k_{iij}} RM_iM_iM_j\cdot \quad \text{where} \quad i, j = 1 \text{ or } 2 \quad \text{and} \quad i \neq j$$

$$RM_i\cdot + M_jM_i \xrightarrow{k_{iij}} RM_iM_jM_i\cdot \quad \text{where} \quad i, j \quad 1 \text{ or } 2 \quad \text{and} \quad i \neq j$$

$$M_1^0 + M_2^0 \xleftrightarrow{K} M_1M_2$$

The composition and propagation rate can be expressed in terms of the following parameters (15).

$$\frac{F_1}{F_2} = \frac{f_1^\circ}{f_2^\circ} \frac{(A_2B_1)r_1f_1^\circ + (A_1C_2)f_2^\circ}{(A_1B_2)r_2f_2^\circ + (A_2C_1)f_1^\circ} \tag{9}$$

$$\langle k_p \rangle = \frac{(A_2B_1)r_1(f_1^\circ)^2 + (A_1B_2)r_2(f_2^\circ)^2 + (A_1C_2 + A_2C_1)f_1^\circ f_2^\circ}{(A_2r_1f_1^\circ/k_{11}) + (A_1r_2f_2^\circ/k_{22})} \tag{10}$$

where

$$\begin{array}{cccc} A_1 = 1 + r_1 s_{1c} Q f_1^\circ & \text{and} & A_2 = 1 + r_2 s_{2c} Q f_2^\circ \\ B_1 = 1 + s_{1c}(1 + r_{1c}^{-1}) Q f_2^\circ & \text{and} & B_2 = 1 + s_{2c}(1 + r_{2c}^{-1}) Q f_1^\circ \\ C_1 = 1 + r_1 s_{1c}(1 + r_{1c}^{-1}) Q f_1^\circ & \text{and} & C_2 = 1 + r_2 s_{2c}(1 + r_{2c}^{-1}) Q f_2^\circ \end{array}$$

$$2Qf_i^\circ = \left\{[Q(f_j - f_i) + 1]^2 + 4Qf_i\right\}^{1/2} - [Q(f_i - f_j) + 1] \quad \text{and} \quad Q = K[\mathrm{M}]$$

f_i = feed composition of M_i and $f_i^0 = [M_i^0]/[M]$

where [M] is the total monomer feed and $[M_i^\circ]$ the uncomplexed M_i

$$r_i = \frac{k_{ii}}{k_{ij}}, \quad r_{ic} = \frac{k_{iij}}{k_{ijj}}, \quad s_{ic} = \frac{k_{iij}}{k_{ii}} \quad \text{where} \quad i, j = 1 \text{ or } 2 \quad \text{and} \quad i \neq j$$

As with all of the models, variations are possible by making a different assumption as to which units can affect radical reactivity. For instance, Brown and Fujimori (19) have derived expressions for composition and sequence distribution for the "Comppen" model, a complex-participation model that is based on the penultimate model.

In the *Monomer–Complex Dissociation (MCD) Model* it is assumed that the monomer–monomer complex described in the MCP model dissociates upon addition to the chain, with only one unit adding (20). A model based on this mechanism was first formulated by Karad and Schneider (21), and later generalized by Hill and co-workers (22). Assuming that only the terminal unit of the radical affects the propagation step, eight rate constants and two equilibrium constants are required to describe the system.

$$\mathrm{RM}_i\cdot + \mathrm{M}_j \xrightarrow{k_{ij}} \mathrm{RM}_i\mathrm{M}_j\cdot \quad \text{where} \quad i, j = 1 \text{ or } 2$$

$$\mathrm{RM}_i\cdot + \mathrm{M}_j\mathrm{C} \xrightarrow{k_{ijc}} \mathrm{RM}_i\mathrm{M}_j\cdot \quad \text{where} \quad i, j = 1 \text{ or } 2$$

$$\mathrm{M}_i + \mathrm{C} \underset{}{\overset{K_i}{\rightleftharpoons}} \mathrm{M}_i\mathrm{C} \quad \text{where} \quad i = 1 \text{ or } 2$$

As with the penultimate and radical–complex models, it is possible to express the model in terms of equations for $\bar{r}_i$ and $\bar{k}_{ii}$, which could be used in place of r_i and k_{ii} in the terminal model equations 1 and 2. These are as follows (15):

$$\bar{k}_{ii} = k_{ii}\,\frac{1 + s_{ic}K_i[\mathrm{C}]}{1 + K_i[\mathrm{C}]} \tag{11}$$

$$\bar{r}_i = r_i\,\frac{1 + s_{ic}K_i[\mathrm{C}]}{1 + (r_i/r_{ic})s_{ic}K_i[\mathrm{C}]} \tag{12}$$

$$\text{where} \quad r_i = \frac{k_{ii}}{k_{ij}}, \quad r_{ic} = \frac{k_{iic}}{k_{ijc}}, \quad s_{ic} = \frac{k_{iic}}{k_{ii}}, \quad i,j = 1 \text{ or } 2 \quad \text{and} \quad i \neq j$$

This form of the model is for monomer–solvent complexes generally. Under the MCD model, the complexing agent C is the other monomer (M_j). As with all of the solvent effects models, variations are possible by making a different assumption as to which units can affect radical reactivity.

Monomer Partitioning: The Bootstrap Effect. In the bootstrap model, solvent effects on the propagation rate are attributed to solvent partitioning and the resulting difference between bulk and local monomer concentrations. In this way, a solvent could affect the measured propagation rate coefficient without changing the reactivity of the propagation step. Bootstrap effects may arise from a number of different causes. As noted above, when radical–solvent or monomer–solvent complexes form and the complexes do not propagate, the effect of complexation is to alter the effective radical or monomer concentrations, thereby causing a bootstrap effect. Alternatively, a bootstrap effect may arise from some bulk preferential sorption of one of the comonomers around the growing (and dead) polymer chains. This might be expected to occur if one of the monomers is a poor solvent for its resulting polymer. A bootstrap effect may also arise from a more localized form of preferential sorption in which one of the comonomers preferentially solvates the active chain end rather than the entire polymer chain. In all cases, the result is the same: the effective free-monomer and/or radical concentrations differ from those calculated from the monomer feed ratios, leading to a discrepancy between the predicted and actual propagation rates.

Copolymerization models based upon a bootstrap effect were first proposed by Harwood (23) and Semchikov (24). Harwood suggested that the terminal model could be extended by the incorporation of an additional equilibrium constant relating the effective and "bulk" monomer feed ratios. Different versions of this so-called bootstrap model may be derived depending upon the baseline model assumed (such as the terminal model or the implicit or explicit penultimate models) and the form of equilibrium expression used to represent the bootstrap effect. In the simplest case, it is assumed that the magnitude of the bootstrap effect is independent of the comonomer feed ratios. Hence in a bulk copolymerization, the monomer partitioning may be represented by the following equilibrium expression:

$$\frac{f_1}{f_2} = K\left(\frac{f_{1\,\text{bulk}}}{f_{2\,\text{bulk}}}\right) \tag{13}$$

The equilibrium constant K may be considered as a measure of the bootstrap effect. Using equation 13 to eliminate the effective monomer fractions (f_1 and f_2) from the terminal model (ie, eqs. 1 and 2 above), replacing them with the measurable "bulk" fractions (f_1 bulk and f_2 bulk), the following equations for composition (25) and $\langle k_p \rangle$ may be derived (26).

$$\frac{F_1}{F_2} = \left(\frac{K f_{1\,\text{bulk}}}{f_{2\,\text{bulk}}}\right)\left(\frac{r_1 K f_{1\,\text{bulk}} + f_{2\,\text{bulk}}}{r_2 f_{2\,\text{bulk}} + K f_{1\,\text{bulk}}}\right) \tag{14}$$

$$\langle k_p \rangle = \left(\frac{1}{f_{2\,\text{bulk}} + K f_{1\,\text{bulk}}} \right) \left(\frac{r_1 K^2 f_{1\,\text{bulk}}^2 + 2K f_{1\,\text{bulk}} f_{2\,\text{bulk}} + r_2 f_{2\,\text{bulk}}^2}{r_1 K f_{1\,\text{bulk}} / k_{11} + r_2 f_{2\,\text{bulk}} / k_{22}} \right) \quad (15)$$

It should be noted that the above equations are applicable to a bulk copolymerization. When modeling solution copolymerizations under the same conditions, the same equations may be used for predicting copolymer composition since it is only the relationship between bulk and local monomer feed ratios that determines the effect on the composition and microstructure of the resulting polymer. However, some additional information about the net partitioning of monomer and solvent between the bulk and local phases is required before the propagation rate can be modeled. Modeling of the propagation rate in a solution copolymerization could be achieved by rewriting the above equilibrium expression in terms of molar concentrations (rather than comonomer feed ratios), and including the solvent concentration in this expression.

The bootstrap model may also be extended by assuming an alternative model (such as the explicit penultimate model) as the baseline model, and also by allowing the bootstrap effect to vary as a function of monomer feed ratios. Closed expressions for composition and sequence distribution under some of these extended bootstrap models may be found in papers by Klumperman and co-workers (25,27).

Depropagation

All of the models discussed thus far have assumed that the propagation steps are irreversible. However, while this is usually a reasonable assumption, at high temperatures (and, for some bulky or exceptionally stable monomers, even at low temperatures) the depropagation reaction is significant. Consideration of the depropagation reactions leads to kinetic models that are quite different from the terminal model and thus some deviations from the terminal model may be caused by the reversibility of one or more of the propagation steps. A large number of depropagation models are possible, depending upon both the basis model assumed and the assumptions that are made as to the nature of the depropagation reaction (such as which units can depropagate, and which units of the polymer radical can affect the depropagation rate). Early depropagation models were derived by Barb (28) (who incorporated depropagation into a simplified terminal MCP model), and Walling (29) (who incorporated depropagation into a simplified penultimate model). Lowry (30) and later Wittmer (31,32) derived composition equations for a number of different sets of assumptions concerning the depropagation reaction, assuming the terminal model for propagation. Howell and co-workers (33) generalized these equations, and provided corresponding expressions for the sequence distribution. Expressions for the propagation rate coefficient for some of these cases have recently been published by Martinet and Guillot (34) and by Kukulj and co-workers (35). Given the large number of possible depropagation models, the various equations will not be reproduced here but can be found in the original papers.

Conversion-Dependent Models

The equations for copolymer composition presented thus far are "instantaneous" or low-conversion equations, relating the copolymer composition to the exact monomer feed present in the reactor. However, during the course of copolymerization, monomers with differing reactivities tend to be incorporated into copolymers at different rates. As a result, in a batch reaction, this leads to a drift in the comonomer feed composition, which in turn leads to a drift in the copolymer composition. To model this behavior it is necessary to integrate the copolymer composition equation. This is achieved by noting that the copolymer composition, given as F_1/F_2 in the instantaneous equations, is in its more general form actually the derivative $d[M_1]/d[M_2]$ which can be integrated. Let us consider, as an example, the following integrated equation for the terminal model, published by Mayo and Lewis (3):

$$\log\left(\frac{[M_2]}{[M_2^0]}\right) = \frac{r_2}{1-r_2}\log\left(\frac{[M_1][M_2^0]}{[M_2][M_1^0]}\right) - \frac{(1-r_1r_2)}{(1-r_1)(1-r_2)}\log\left(\frac{1-r_2+(r_1-1)\frac{[M_1]}{[M_2]}}{1-r_2+(r_1-1)\frac{[M_1^0]}{[M_2^0]}}\right) \tag{16}$$

In this equation, $[M_1]$ and $[M_2]$ refer to the instantaneous monomer concentrations and $[M_1{}^0]$ and $[M_2{}^0]$ to the initial concentrations. An alternative form (expressed in terms of total molar conversion of monomer) was later published by Meyer and Lowry (36):

$$\frac{[M]}{[M^0]} = \left(\frac{f_1}{f_1^0}\right)^{\alpha}\left(\frac{f_2}{f_2^0}\right)^{\beta}\left(\frac{f_1^0-\delta}{f_1-\delta}\right)^{\gamma} \tag{17}$$

$$\text{where} \quad \alpha = \frac{r_2}{1-r_2}, \quad \beta = \frac{r_1}{1-r_1}, \quad \gamma = \frac{1-r_1r_2}{(1-r_1)(1-r_2)}, \quad \delta = \frac{1-r_2}{2-r_1-r_2}$$

Using either form of the equation, one can calculate the instantaneous comonomer feed composition as a function of the conversion, knowing the initial feed composition. This can then be used to calculate the copolymer composition, sequence distribution, and propagation rate using the corresponding instantaneous equations.

Model Discrimination: Which Model to Use for a Given System?

The choice of copolymerization model for any given system is often one of great debate in the polymer literature. This, to a large extent, is caused by the fact that all of the alternative models contain a number of characteristic constants (such as monomer and radical reactivity ratios). Since these are difficult to measure directly, they are usually (if not always) estimated by treating them as adjustable parameters and fitting the copolymerization model to the available data. As a result, many different models can often be made to fit the same experimental data. If the sole purpose of the model is merely to provide a shorthand version of the existing experimental data, provided the model provides a good fit to that data, any of the fitted models are appropriate to use. If however the estimated parameters are then to be used to make other model predictions or to deduce something about

the reaction mechanism, it is necessary to select the copolymerization model with the correct assumptions.

In what follows we examine which assumptions are likely to be valid for different types of copolymerization systems. In doing this, we make a distinction between what we refer to as a "basis model," a model containing the set of assumptions likely to be applicable to most of the copolymerization systems, and models for "exceptional systems," in which additional system-specific influences are likely to be operating in conjunction with those accounted for by the basis model. We have recently reviewed and assessed the experimental evidence for the different copolymerization models both for basis systems (37) and exceptional systems (38) and will not attempt to reproduce these reviews here. Instead we merely outline the main conclusions of this work and make some general comments concerning the applicability of the alternative models.

Basis Model. For many years, people believed that the terminal model was the basis of copolymerization propagation kinetics because it could be fitted to the composition data for most systems tested. However, in 1985 Fukuda and coworkers (7) demonstrated that the terminal model failed to predict the propagation rate coefficients for the copolymerization of styrene with methyl methacrylate—a system for which the composition data had been widely fitted by the terminal model (see Fig. 1). These results were later confirmed by several independent groups, both for the styrene–methyl methacrylate system (under a wide range of different conditions), and also several other copolymerizations—indeed for almost all systems so far tested (37). It now appears likely that the failure of the terminal model to describe simultaneously the composition and propagation rate coefficients of ordinary free-radical copolymerization systems is general, with the terminal model being applicable only to those exceptional systems in which the comonomers have very similar reactivities.

Although there is strong evidence against the terminal model, there has been much reluctance to abandon this model since this would undermine the 50

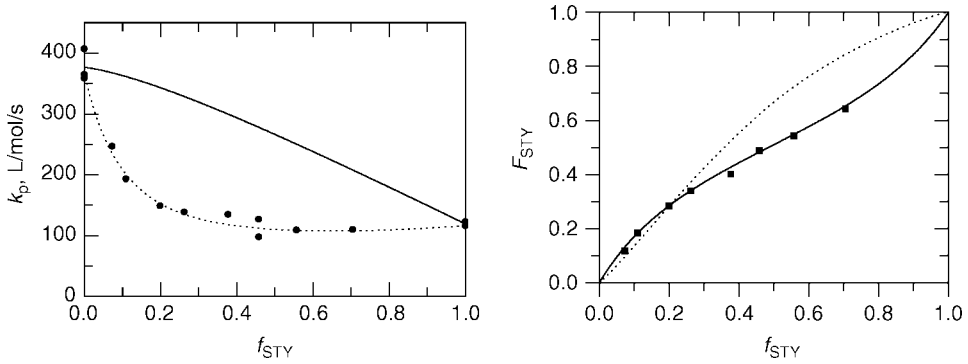

Fig. 1. Shown here is Fukuda's 40°C $\langle k_p \rangle$ data (**a**) and composition data (**b**) (7). The solid line on each graph is the terminal model predictions using the reactivity ratios that provide the best fit to the composition data ($r_{STY} = 0.523$ and $r_{MMA} = 0.460$) while the dotted line in each graph is the terminal model predictions using the reactivity ratios that provide the best fit to the $\langle k_p \rangle$ data ($r_{STY} = 2.5724$ and $r_{MMA} = 0.7973$). Clearly the terminal model can fit the composition or the $\langle k_p \rangle$ data but not both simultaneously.

years of terminal model reactivity ratios that have been and continue to be published (see, eg, the large listing of terminal model reactivity ratios in the *Polymer Handbook* (39), and the various empirical schemes, such as the Patterns (40) and *Q*–*e* schemes (41), that have been developed for predicting these parameters). The implicit penultimate model was proposed as a solution to this problem. As seen above, by assuming that the penultimate unit affected only the reactivity but not the selectivity of the propagating radical, it is possible to obtain a copolymerization model that retains the terminal model composition equation but includes a non-terminal model $\langle k_p \rangle$ equation. This thus enabled the failure of the terminal model $\langle k_p \rangle$ equation to be accounted for without abandoning the terminal model composition equation and the accompanying large database of reactivity ratios.

However, recent experimental and theoretical work has shown that the *assumptions* of the implicit penultimate model are unlikely to be applicable to the majority of copolymerization systems. We have recently published a review of this evidence (37,42), which draws on direct experimental and theoretical measures of reactivity ratios, model testing in a range of copolymerization systems, and other tests of the mechanism of the propagation step via, for example, the examination of solvent effects on reactivity ratios. These studies provide strong evidence for penultimate unit effects but, in all cases where penultimate unit effects have been measured directly, effects on radical selectivity have been shown to be significant. In other words all available evidence contradicts the assumption of the implicit penultimate model that the penultimate unit affects reactivity but not selectivity.

Furthermore, recent theoretical studies have provided a rationalization for this result that suggests it is likely to be a general feature of free-radical polymerization. As noted earlier, for a penultimate unit effect in the reaction barrier to be *implicit*, it is necessary for this penultimate unit effect to occur in the absence of polar, steric, or other forms of direct interaction that, by their very nature, are dependent on and will thus vary with the chemical structure of the reacting monomer. Fukuda proposed (11) that an implicit effect could occur if the penultimate unit affected *only* the radical stability. A radical stabilization penultimate unit effect would affect the reaction enthalpy, and the reaction barrier (via the Evans–Polanyi rule). Provided there are no other types of penultimate unit effect operating (eg, steric or polar effects), such a penultimate unit effect would be implicit. However, high-level ab initio molecular orbital calculations of a representative range of model propagation reactions have shown that, although penultimate unit effects in radical stability are significant, these effects largely cancel from the reaction barrier—owing to the early transition structure in these exothermic reactions (43). As a result, for such a penultimate unit effect in the barrier to be significant, the corresponding effect on radical stability has to be enormous and thus requires substituents with very strong electron-withdrawing or -donating properties. The theoretical calculations demonstrated that large penultimate unit effects of this nature simultaneously affected the charge-transfer configurations of transition structure, leading to explicit polar penultimate unit effects. Given that the majority of copolymerization systems have highly exothermic propagation steps and thus early-transition structures, it would seem that, in general, implicit radical stabilization penultimate unit effects are unlikely to occur in the absence of explicit polar effects.

In addition, steric penultimate unit effects should also lead to explicit (rather than implicit) penultimate unit effects, as they would obviously be sensitive to the steric properties of the monomer with which they were reacting. Recently, experimental evidence for significant entropic penultimate unit effects has been published (44), confirming predictions made in an earlier theoretical study (45). These studies further confirm that, if there are penultimate unit effects in free-radical copolymerization, then they are most likely to be explicit effects.

To summarize, we know firstly from simple model-testing studies spanning the last 20 years that for almost all systems tested, the terminal model can be fitted to $\langle k_p \rangle$ or composition data for a copolymerization system, but not both simultaneously. Secondly, more recent experimental and theoretical studies have demonstrated that the assumption of the implicit penultimate model—that the penultimate unit affects radical reactivity but not selectivity—cannot be justified. Therefore, on the basis of existing evidence, the explicit penultimate model should replace the terminal model as the basis of free-radical copolymerization propagation kinetics, and hence *the failure of the terminal model* $\langle k_p \rangle$ *equation must be taken as a failure of the terminal model and hence of the terminal model composition equation*. This means that the terminal model composition equation is not *physically valid* for the majority of systems to which it has been applied.

Exceptional Systems. It is likely that side reactions are also important in a large number of copolymerization systems. As seen above, their presence further complicates the copolymerization kinetics by adding extra parameters to the copolymerization models, thereby making model discrimination even more difficult. Indeed (with the possible exception of those few systems that have been shown to obey the terminal model in all respects) it is very difficult to find any copolymerization system for which there is consensus about the type of copolymerization model that should be applied. There is, however, strong independent evidence for the various types of side reactions in specific copolymerization systems, and hence for these systems such side reactions need to be incorporated into copolymerization models and taken into account when studying the propagation reaction. Indeed, for some systems, the presence of side reactions such as complexation may provide a means of controlling the composition and microstructure of the copolymer and, in some cases, even its stereochemistry. In what follows, we make a few general comments about the types of systems in which the various side reactions are likely to be occurring.

Depropagation is known to become significant with increasing polymerization temperature, and most polymerizations are known to have a ceiling temperature beyond which polymerization will not proceed. This arises because of the exothermic and exentropic nature of the propagation step for most polymerization reactions (ie, since $\Delta G = \Delta H - T\Delta S$ and both ΔH and ΔS are negative, there will exist a temperature T_c such that for all $T > T_c$, $\Delta G > 0$). For most polymerization systems, these ceiling temperatures are well above ordinary operating conditions; however, for polymerizations involving exceptionally stable or bulky monomers such as CO, SO_2, and α-methylstyrene, depropagation is significant at much lower temperatures and thus needs to be incorporated into copolymerization models. The importance of depropagation in a particular system can be determined directly from measurements of the entropy and enthalpy of the propagation reaction, or indirectly by measuring the ceiling temperature of each of

the comonomers. The use of monomers such as α-methylstyrene to assist in the control of molecular weight by exploiting their slow propagation kinetics is often used in industry as a facile method of reaction control (46,47).

Monomer–monomer complexes are known to form in solutions containing an electron donor monomer with an electron acceptor monomer. Many such complexes have been detected spectroscopically (48) and one of the most well-known examples is that between maleic anhydride and styrene. There has been much dispute over the role these complexes play in the reaction mechanism, concerning, for example, whether they can propagate via an MCP or MCD mechanism, or whether they are unreactive and merely result in a bootstrap effect. For some complexes, the heat of formation is less than the heat of propagation and hence it seems unlikely that the MCP model could be appropriate for these systems, as the complex should be disrupted during the propagation step. In other systems, however, this is not the case and there is reasonable circumstantial evidence that these complexes could be propagating as a single unit. For instance, it has been observed that in the copolymerization of *N*-phenylmaleimide with chloroethyl vinyl ether, the stereochemistry at succinimide units is predominately cis (as it would be in the complex) and random elsewhere, and further that the proportion of cis linkages was correlated with the variables with which the concentration of the complex was also correlated (49). It seems likely that, depending on factors such as the strength of the complex, the role of monomer–monomer complexes in free-radical copolymerization will vary and model discrimination should be on a case-by-case basis. However, where there is (spectroscopic) evidence for their existence, they must always be taken into account when deriving copolymerization models.

Radical–solvent complexes are more difficult to detect spectroscopically; however, they do provide a plausible explanation for many of the solvent effects observed in free-radical homopolymerization—particularly those involving unstable radical intermediates (such as vinyl acetate) where complexation can lead to stabilization. For instance, Kamachi (50) observed that the homopropagation rate of vinyl acetate in a variety of aromatic solvents was correlated with the calculated delocalization stabilization energy for complexes between the radical and solvent. If such solvent effects are detected in the homopolymerization of one or both of the comonomers, then they are likely to be present in the copolymerization systems as well. Indeed, radical–complex models have been invoked to explain solvent effects in the copolymerization of vinyl acetate with acrylic acid (51). Radical–solvent complexes are probably not restricted merely to systems with highly unstable propagating radicals. In fact, radical–solvent complexes have even been proposed to explain the effects of some solvents (such as benzyl alcohol, *N*,*N*-dimethyl formamide, and acetonitrile) on the homo- and/or copolymerizations of styrene and methyl methacrylate (52–54). Certainly, radical–solvent complexes should be considered in systems where there is a demonstrable solvent effect in the copolymerizations and/or in the respective homopolymerizations.

Polarity effects can also result in solvent effects in free-radical copolymerization. Recent theoretical studies (43,55–57) of small-radical addition reactions suggest that in a wide range of cross-propagation reactions, the transition structure is stabilized by the contribution of charge-transfer configurations. When this is the case, the extent of stabilization (and hence the propagation rate) will be

influenced by the dielectric constant of the reaction medium. Solvent effects on reactivity ratios have been known for a long time and at least some of these [for instance those for styrene-methyl methacrylate copolymerization (58–60) and styrene–acrylonitrile copolymerization (61,62) in a variety of solvents] have been shown to correlate with the dielectric constant of the reaction medium. Furthermore, it is possible that solvent effects in other systems may in part be attributable to polarity effects, although additional effects (such as radical–solvent complexes or monomer partitioning) obscure a direct correlation. As noted above, polarity effects need only be explicitly considered in a copolymerization model if the polarity of the reaction medium varies significantly as a function of the monomer feed fraction (as it would in a bulk copolymerization of two monomers with widely differing dielectric constants). However, it is worth noting that polarity effects are likely to be operating at least to some extent in copolymerizations of monomers with even moderately different electronegativities and, where such effects do occur, the reactivity ratios (and hence composition and sequence distribution) can be manipulated by varying the solvent polarity.

Bootstrap effects arise from a number of different causes. For instance, a bootstrap effect can be expected if there is preferential sorption of one of the monomers around the growing polymer chain—as might be expected if one of the monomers is a poor or nonsolvent for the resulting polymer. This can sometimes be established by examining the appropriate polymer–solvent interaction parameters. Nonideal mixing of the comonomers can also be independently established via measurements of solution thermodynamics. Indirect evidence for bootstrap effects arising from preferential solvation of the polymer chain can be obtained by examining the copolymer composition as a function of molecular weight, since it would be expected that this type of bootstrap effect would lead to chain length effects on copolymer composition, even for nonoligomeric systems that would normally be expected to satisfy the long-chain assumption. On the basis of this method and measurements of solution thermodynamics, Semchikov (24,63) has shown that such bootstrap effects do indeed operate in a number of bulk copolymerization systems including AN–STY, STY–MA, VAC–STY and VAc–NVP, but not in the system STY–MMA (at 298–343K). Bootstrap effects can also be expected if unreactive monomer–monomer, monomer–solvent, radical–solvent, or radical–monomer complexes form. As noted above, there is evidence for many of these complexes in certain types of system, though there is frequently dispute as to the role these complexes play in the reaction mechanism. Bootstrap effects should certainly be considered when attempting to model systems for which there is demonstrable evidence for the existence of such complexes.

Which Model to Use and When: Practical Recommendations

It is clear from the above discussion that any physically realistic model for free-radical copolymerization kinetics should be based on the penultimate model and, depending on the system, should also incorporate various types of solvent effects and/or depropagation. The resulting model would not only be very complex, but would also contain numerous characteristic constants (ie, reactivity ratios, equilibrium constants). This poses a major problem as such parameters are difficult to

measure directly, and are therefore usually treated as adjustable parameters, and estimated as part of the model-fitting process. As we have argued elsewhere (1), even in oversimplified models there are usually more adjustable parameters than are mathematically required to fit data. This results in large and highly correlated uncertainties in the parameter estimates, with multiple parameter sets providing excellent fits to the experimental data. Hence, the use of physically realistic models may not be practical for most copolymerization systems, unless they are accompanied by independent measurements of the model-parameters.

As a solution to this problem, we recommend that, provided they can be fitted to the data, simplified models such as the implicit penultimate model (and hence the terminal model composition equation) continue to be used for descriptive purposes. However, it is important to recognize that the resulting parameter estimates will at best convey qualitative information about radical reactivity and should not be used to make quantitative predictions of quantities other than those to which they were fitted. When physically meaningful information is required, more direct approaches should be adopted. For example, substituent effects on radical reactivity and selectivity in small-radical models can be studied directly via a host of experimental approaches, and also via high-level ab initio molecular orbital calculations. Various spectroscopic techniques can be used to study radical and monomer complexes, and indeed ab initio molecular orbital calculations could also be used to tackle this problem. Information on possible monomer partitioning can be accessed from polymer–solvent interaction parameters, and other measurements of solution thermodynamics. Likewise, thermodynamic measurements (and ab initio calculations) can assist in the study of depropagation. These direct approaches not only help to identify the physically realistic model for a given system, but can also provide independent measurements of the corresponding reactivity ratios and equilibrium constants (thereby reducing the number of adjustable parameters in the model).

Measurement of Reactivity Ratios

Reactivity ratios are typically measured by fitting the terminal model composition equation to experimental composition data. Depending on the chemical structure of the comonomers, a variety of methods can be used to measure copolymer composition, including ^{1}H NMR, uv–visible spectroscopy, elemental microanalysis, and Fourier transform infrared (FTIR) spectroscopy. For information on these procedures, the reader is referred to Reference 64. In order to fit the model to the data, it is necessary to measure the copolymer composition for multiple initial values of the comonomer feed ratios. As always, choosing an appropriate experimental design is important for minimizing the statistical uncertainties in the parameter estimates. It is worth noting that the common practice of choosing comonomer feed ratios at regular intervals between $f_1 = 0$ and 1 is not the optimum design for measuring terminal model reactivity ratios. Instead, Tidwell and Mortimer (65) recommended multiple determinations at the following two feed ratios:

$$f_1 = \frac{2}{2 + r_1} \quad \text{and} \quad f_1 = \frac{r_2}{2 + r_2} \tag{18}$$

Of course, the implementation of such a design presupposes knowledge of the reactivity ratios we are trying to measure. However, one can normally obtain a useful design using approximate reactivity ratios, as obtained from preliminary experiments or literature values for related systems.

Having obtained the composition data it is then necessary to fit it with the terminal model, using the two reactivity ratios as adjustable parameters. For many years, the standard method for fitting the data was first to linearize the composition equation, as described by Fineman and Ross (66), thereby allowing linear regression or indeed a simple graphical procedure. However, it is now generally accepted that this method transforms error structure in such a way that linear regression is no longer valid (67), and instead nonlinear regression using the original composition equation should be adopted. Nowadays linearization of the equation is in fact unnecessary, as modern mathematical software packages routinely perform nonlinear regression. In particular, a free program called *Contour* (68,69) has been provided specifically for the estimation of reactivity ratios. In implementing the nonlinear regression procedure, it is important to weight the residuals according to the expected error structure in the data (70).

Finally, it should be noted that the above discussion refers to low-conversion copolymerizations, for which composition drift is not significant. For conversion-dependent data, the appropriate integrated composition equation should instead be fitted to the data using an error-in-variables procedure (71) to deal with the statistical uncertainties in the multiple independent variables.

Reactivity in Free-Radical Copolymerization

It is clear from the above discussion that reactivity in free-radical copolymerization depends on a rich array of factors. There is strong evidence that the reactivity of the propagating radical is governed by the nature of both its terminal and penultimate units. Depending on the system, these substituent effects in turn arise from both steric and electronic factors, with the latter itself being a complex result of sigma- and/or pi-effects on the stability of the propagating radical and the monomer, as well as the possible stabilization of the transition structure through partial charge transfer. A consequence of this latter effect is that the reactivity of the propagation reaction can be dependent on the dielectric constant of the reaction medium. The solvent (which may be the monomer) can also affect the propagation reaction by forming a complex with the propagating radical or comonomer, thereby altering its reactivity. In some cases this may result in an altogether different propagation mechanism. In addition, monomer partitioning can at times affect the apparent reactivity of the propagation step, as can depropagation. This complex nature of propagation in free-radical copolymerization offers huge potential for controlling the copolymer composition and microstructure (by, eg, manipulating the feed composition, temperature or solvent type), and even perhaps the stereochemistry (through the manipulation of radical or monomer complexes). An understanding of substituent effects on the reactivity of the propagation step is important for exploiting this potential for control.

The earliest attempts to describe substituent effects on reactivity were empirical schemes, based on the terminal model. The most widely used of these are

the Q–e (41) and Patterns (40) schemes, and as an example we will briefly outline the former. In the Q–e scheme, the rate coefficient for attack of radical i on monomer j is given by the following equation:

$$k_{ij} = P_i Q_j \mathrm{e}^{-e_i e_j} \tag{19}$$

Hence the terminal model reactivity ratios are given by

$$r_i = \frac{Q_i}{Q_j}\ \mathrm{e}^{-e_i(e_i - e_j)} \tag{20}$$

In order to apply this equation, each monomer i is assigned empirically derived Q_i and e_i values, as obtained by fitting equation 20 to sets of experimental reactivity ratios. In this way, provided the Q and e values of the individual monomers are known, reactivity ratios can be predicted for previously unmeasured combinations of monomers. An extensive listing of Q and e values has been provided by Greenley (72).

There are a number of shortcomings in the scheme. As noted above, the terminal model does not provide a physically realistic description of copolymerization kinetics and, as such, predictions (in this case of other reactivity ratios) based on terminal model reactivity ratios may be subject to considerable error. Even in the context of the terminal model, the assignment of independent Q and e values for a "monomer," regardless of whether it is acting as the monomer or radical and regardless of what it is reacting with, is a major oversimplification. In addition, the experimental database of terminal model reactivity ratios used to obtain the Q and e values was largely compiled nearly 50 years ago, using somewhat limited analytical methods. As a result of these problems, the predictions of the Q–e scheme are at best qualitative, and are generally most successful for combinations of monomers that are not subject to strong polar or steric effects.

More modern descriptions of reactivity in copolymerization have arisen from the quantum chemical study of the addition of small radicals to alkenes. Such small-radical models are applicable to propagation because the propagation reaction is chemically controlled, and not generally influenced by substituents beyond the penultimate unit. On the basis of a large collection of both theoretical and experimental studies of substituent effects in radical addition reactions, Fischer and Radom (57) have recently presented a theoretical account of reactivity framed in terms of the curve-crossing model (13). Under this model, the barrier for an addition reaction is dependent on the exothermicity of the reaction, the singlet–triplet gap of the double-bonded substrate and the possibility for low-lying charge-transfer configurations in the transition structure, in turn estimated by a consideration of the ionization energies and electron affinities of the reactants. These quantities are easily accessible from both experiment and high-level ab initio molecular orbital calculations, and the model thus offers a powerful approach for predicting and understanding reactivity in free-radical copolymerization. For more details of the curve-crossing model, and more fundamental aspects of reactivity in radical addition reactions, the reader is referred to References 13 and 57 (also see COMPUTATIONAL QUANTUM CHEMISTRY FOR FREE-RADICAL POLYMERIZATION).

Termination in Free-Radical Copolymerizations

Detailed knowledge of free-radical copolymerization termination rate coefficients is of technical as well as fundamental importance. The radical–radical termination reaction in free-radical polymerization is the most complex reaction in the polymerization process (73,74). Its termination rate coefficient, k_t, is influenced by a multitude of different factors, which are not easily separated. Only within the last 15 years have new methods become available that allow for an accurate measurement of this rate coefficient. The scatter of the termination rate coefficients given in the *Polymer Handbook* (75) reported for the same monomer at the same reaction temperature is a direct manifestation of the influence of these various parameters on k_t. While the advanced techniques available to study termination processes in homopolymerizations and the current theoretical models describing the termination process are discussed in the chapter "Free Radical Polymerization," the present section focuses on the use of kinetic data from free-radical binary and ternary copolymerizations to clarify the termination process as well as on giving practical guidelines for the estimation of termination rate coefficients in copolymerization.

Theoretical Background. Modeling of the (average) termination rate coefficient, $k_{t,copo}$, at low monomer conversions as a function of the initial monomer feed in the reaction mixture has been thoroughly reviewed by Fukuda and co-workers (76). The present chapter considers the most important models presented in Reference 76.

Model A, which has been proposed by Fukuda and co-workers, assumes diffusion-controlled termination to be related to the composition of the generated copolymer according to equation 21

$$k_{t,copo}^{-1} = k_{t\ 11}^{-1} F_1 + k_{t\ 22}^{-1} F_2 \tag{21}$$

where F_i is the mole fraction of comomoner i segments within the copolymer.

Similar in its underlying idea is one of the earliest models for the description of the termination rate coefficient introduced by Atherton and North (77):

$$k_{t,copo} = k_{t\ 11} F_1 + k_{t\ 22} F_2 \tag{22}$$

In *Model B*, two types of free radicals, one carrying a monomeric unit 1, the other with a monomeric unit 2 at the chain end, are considered to sufficiently account for copolymerization k_t according to

$$k_{t,copo} = k_{t\ 11} P_1^{\ 2} + 2k_{t\ 12} P_1 P_2 + k_{t\ 22} P_2^{\ 2} \tag{23}$$

where the k_{tii}'s are the homotermination rate coefficients and the P_i's are the relative populations of the two types of the terminal free radicals ($P_1 = 1 - P_2$). Φ, which is referred to as Walling factor (9), describes the size of the cross-termination rate coefficient ($k_{t12} = k_{t21}$) relative to the geometric mean of the homopolymerization rate coefficients:

$$\Phi = \frac{k_{t\ 12}}{(k_{t\ 11} k_{t\ 22})^{0.5}} \tag{24}$$

It should be noted that a so-called geometric mean rule, which is formally identical to equation 24 has been frequently used in free-radical gas kinetics to estimate cross-recombination rate coefficients k_{AB} from the associated homo-recombination rate coefficients k_{AA} and k_{AB} (78). Two other models given in Fukuda's review (76), C and D, in addition to the terminal unit also consider the penultimate unit at the free-radical chain end as has first been tried by Russo and Munari (79,80). These models are associated with a greater number of individual termination rate coefficients. Given in equation 27 is the expression for $k_{t,copo}$ of a binary copolymerization, for which 10 termination rate coefficients, $k_{tij,kl}$, need to be considered. $k_{tij,kl}$ refers to the reaction of (two) radicals terminating in the monomer units ij and kl, respectively. The P_{ij}'s and P_{kl}'s indicate relative populations of the four types of "penultimate" free radicals (with chains ending in units 11, 12, 21, and 22, respectively). These populations are available from the propagation rate coefficients and reactivity ratios as given below in equations 25 and 26 (15):

$$P_1 = 1 - P_2 = \frac{\bar{r_1} f_1 / \bar{k_{11}}}{(\bar{r_1} f_1 / \bar{k_{11}}) + (\bar{r_2} f_2 / \bar{k_{22}})} \tag{25}$$

and

$$P_{11} = P_1 - P_{21} = \frac{r_{11} f_1 P_1}{r_{11} f_1 + f_2 / s_1} \tag{26}$$

The population P_{22} is calculated analogously to P_{11}.

$$k_{t,copo} = \sum_{l=1}^{2} \sum_{k=1}^{2} \sum_{i=1}^{2} \sum_{j=1}^{2} P_{ij} P_{kl} k_{t\ ij,kl} \tag{27}$$

To reduce the relatively large number of termination rate coefficients, *Model C* replaces rate coefficients for reactions between "unlike" free radicals, $k_{tij,kl}$ (with ij being different from kl), by the corresponding coefficients for termination of the "like" radicals, $k_{tij,ij}$ and $k_{tkl,kl}$, via the arithmetic mean approximation in equation 28 (76):

$$k_{t\ ij,kl} = 0.5(k_{t\ ij,ij} + k_{t\ kl,kl}) \tag{28}$$

Using equation 28 to eliminate all "unlike" termination rate coefficients turns equation 27 into equation 29, which contains only the four "like" (penultimate) termination coefficients:

$$k_{t,copo} = k_{t\ 11,11} P_{11} + k_{t\ 21,21} P_{21} + k_{t\ 22,22} P_{22} + k_{t\ 12,12} P_{12} \tag{29}$$

Model D differs from Model C in that a geometric mean approximation (eq. 30) is applied to reduce the number of penultimate termination rate coefficients from 10 to 4:

$$k_{t\ ij,kl} = (k_{t\ ij,ij} k_{t\ kl,kl})^{0.5} \tag{30}$$

Equation 30 is the expression used by Fukuda and co-workers (76). Russo and Munari in their pioneering study had an additional factor of 2 on the r.h.s. of equation 30, with this formulation being identical to what is used in gas kinetics to estimate cross-termination (78).

Substituting equation 30 into equation 27 yields the expression (eq. 31) for $k_{t,copo}$ according to Model D:

$$k_{t,copo}^{0.5} = k_{t\ 11,11}^{0.5} P_{11} + k_{t\ 21,21}^{0.5} P_{21} + k_{t\ 22,22}^{0.5} P_{22} + k_{t\ 12,12}^{0.5} P_{12} \tag{31}$$

Fukuda and co-workers (76) presented Model D in a slightly different way (eq. 32), with the two penultimate rate coefficients, $k_{t12,12}$ and $k_{t21,21}$, being replaced by two parameters δ_1 and δ_2:

$$k_{t,copo}^{0.5} = k_{t11,11}^{0.5}(P_{11} + \delta_1 P_{21}) + k_{t21,21}^{0.5}(P_{22} + \delta_2 P_{12}) \tag{32}$$

δ_1^2 is defined as

$$\delta_i^2 \equiv \frac{k_{t\,ji,ji}}{k_{t\,ii,ii}} \tag{33}$$

Models A through D have been extensively tested toward their ability to describe the termination rate coefficients in various copolymerization systems.

Binary Copolymerization. A large body of work has been carried out to test the applicability of the Models A to D to copolymerizations of acrylate, methacrylates, and styrenic monomers (76,77,79–82). It has proven advantageous to study the copolymerization termination rate coefficient in related monomer families (eg within the acrylate or methacrylates families). For example, Buback and Kowollik investigated dodecyl acrylate (DA) and methyl acrylate (MA) copolymerizations via the single-pulse pulsed-laser polymerization (SP-PLP) technique. MA and DA have homotermination rate coefficients that differ by orders of magnitude [ie, log (k_t)(L/mol/s) (1000 bar, 40°C, conv. < 0.1, DA) = 6.38 and log (k_t)(L/mol/s) (1000 bar, 40°C, conv. < 0.1, MA) = 8.13]. The ability of the above-mentioned models to describe the experimentally obtained copolymerization termination rate coefficients can be tested by plotting log $k_{t,copo}$ versus the comonomer mixture composition, f^0. Such a plot—together with the corresponding model descriptions—is given in Figure 2.

Models A and B, which both consider only two types of terminating free radicals, seriously fail to represent the experimental $k_{t,copo}$ data. The line referring to Model B has been calculated under the assumption that equation 24 holds with $\Phi = 1$. Even major changes in Φ do not result in a significantly improved quality of representing the experimental data by Model B. Also Model C, which assumes diffusion control with four kinds of penultimate free-radical species, fails to provide an adequate fit of the measured $k_{t,copo}$ data. Model D, on the other hand, allows for an excellent representation of the experimental data. It should be noted that the straight line through the DA–MA data in Figure 2 is not obtained just from a linear least-squares procedure, but is derived from a fit to Model D. The almost linear change of log $k_{t,copo}$ with monomer feed composition f should be particularly

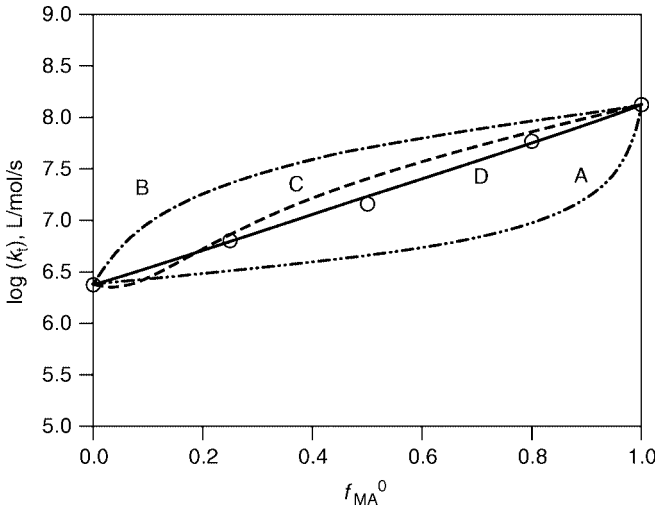

Fig. 2. Copolymerization termination rate coefficients at low conversions in MA/DA copolymerizations at 40°C and 1000 bar plotted against the mole fraction of MA. The lines A through D correspond to the copolymerization k_t models given in the text.

noted. This result bears important mechanistic information. Moreover, this linear correlation may be useful for predicting or estimating copolymerization k_t even in situations where more than two monomers from the same family are polymerized (see below).

The close-to-linear correlation that is seen in acrylate–acrylate copolymerization systems is also found in intrafamily methacrylates copolymerizations. Studies on such systems have been carried out in the past by Ito and O'Driscoll (83) by rotating sector experiments at 30°C and ambient pressure. The data given in their pioneering study differ in the format in which they are presented: In the case of the methyl methacrylates (MMA)–butyl methacrylates (BMA) system k_p and k_t values for the copolymerizations are given, whereas in the case of the MMA–dodecyl methacrylates (DMA) system the termination rate coefficients are given relative to the homotermination rate coefficient of MMA (ie, $k_{t,copo}/k_{t,homo}$). The k_t values given for the homopolymerization of MMA and BMA are not in agreement with the nowadays accepted values. (84) However, the difference of both values is close to the difference which can be deduced from the more recent numbers. The same observation holds true for the propagation rate coefficients presented by these authors. This observation indicates that their measurements are reliable in a relative way, but their absolute numbers are shifted. The data presented by Ito and O'Driscoll are also best represented by Model D (see Fig. 3), which was found to fit the experimental data excellently, with the "like" termination rate coefficient being in between the homopolymerization rate coefficients and very similar in value.

The data for intrafamily copolymerization of acrylate- and methacrylates-type monomers suggest that $k_{t,copo}$ might be generally accessible from homotermination data by employing equation 34, which has been termed the *general*

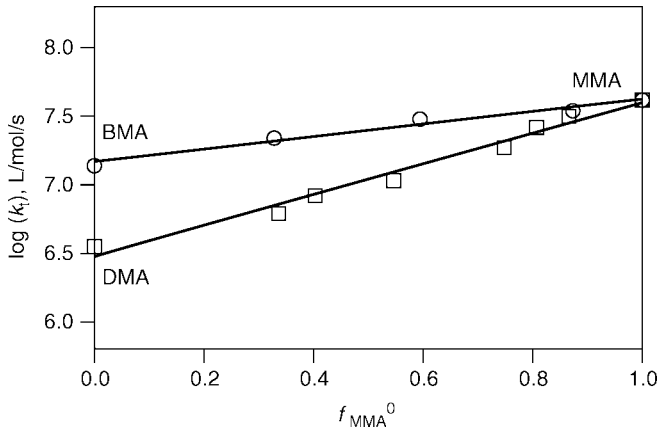

Fig. 3. Termination rate coefficients from Ito and O'Driscoll (83) for dodecyl methacrylate (DMA)–methyl methacrylate (MMA) (at 40°C and 1000 bar, rescaled) and butyl methacrylate (BMA)–methyl methacrylate (MMA) (at 30°C and ambient pressure) copolymerizations. The data in Ref. 83 for the MMA–DMA system are given as relative rate coefficients $k_{t,copo}/k_{t,homo}$. The $k_{t,copo}$ values were calculated using $k_{t,homo}$ from Ref. 84. The lines are best fit representations of Model D.

geometric mean rule (GGM) (79–81):

$$\log k_{t,copo} = f_1^0 \log k_{t,11} + f_2^0 \log k_{t,22} \tag{34}$$

This, however, must not be generally true for two main reasons: (*1*) The linear log $k_{t,copo}$ versus f correlation seen for the above systems will certainly be restricted to situations where the same mechanism controls termination behavior. Under conditions where $k_{t,homo}$ varies with monomer conversion (which indicates a change in the mode of termination rate control), the linear log $k_{t,copo}$ versus f correlation is no longer valid. At total monomer conversion between 20 and 35%, the log $k_{t,copo}$ values for $f_{MA}{}^0 = 1.00$ and 0.80 are almost the same (81), and linear plots as depicted in Figures 2 and 3 can no longer be drawn at this stage of the reaction. (*2*) The theoretical concepts on which equation 34 is based (85) focus on the idea of a purely diffusional controlled reaction. Cullinan and co-workers derived that the composition dependence of the binary mutual diffusion coefficient D_{ij} tends to be linear between the infinitely dilute extremes (85). These authors demonstrated (and found agreement with the existing experimental data) that a modification of absolute rate theory based on thermodynamic aspects yields an expression which predicts the concentration dependence of the binary mutual diffusion coefficient in terms of equation 35:

$$D_{ij} = D_j^{f_j^0} D_i^{f_i^0} \tag{35}$$

which can be easily rearranged into equation 36

$$\log D_{ij} = f_j^0 \log D_j + f_i^0 \log D_i \tag{36}$$

The formal similarity with equation 34 is quite obvious. Understanding termination rate coefficients at low conversions in purely translational diffusion terms may lead to equation 34. However, this concept is not in agreement with the ideas pioneered by Russo and Munari (79,80). These authors assume chemical (most likely steric) effects to be important in the termination reaction. They suggested the penultimate unit effect model (eq. 27). If the termination process was governed by the same translational diffusion mechanism in the initial plateau region for all monomers considered in this work, no curved dependencies of log k_t versus f should be obtained, since equation 34 (and eq. 36) always predicts straight lines. If, however, the termination reaction is to some extent controlled by chemical effects (Model D), curved dependencies may occur, depending on the individual radical populations P_{ij} (which directly go into the modeling procedure). Thus, copolymer systems with a pronounced curvature in the log $k_{t,copo}$ versus f plots provide the best argument against any oversimplification of $k_{t,copo}$ behavior. Indeed, Fukuda and co-workers reported such dependencies for different copolymerizations, eg styrene and ethyl acrylate at 40°C and ambient pressure (76). More recently, Buback and Feldermann (82) reported curved dependencies in the interfamily copolymerizations of MMA–DA and DMA–MA.

Ternary Copolymerization. As technical polymerization processes with more than two monomers are frequently met, it is an interesting question whether a correlation corresponding to equation 34 will hold for terpolymerizations. The resulting expression for terpolymerization k_t would read

$$\log k_t = f_1 \log k_{t,1} + f_2 \log k_{t,2} + f_3 \log k_{t,3} \tag{37}$$

where the monomer mole fractions f_i add up to $f_1 + f_2 + f_3 = 1$ and where $k_{t,3}$ is the homotermination rate coefficient of monomer 3. Buback and Kowollik test equation (eq. 37) for the intrafamily terpolymerizations of MA–BA–DA and MMA–BMA–DMA (86). Remarkably, these two terpolymerization systems adhered strictly to equation 37. It is worthwhile to plot binary low conversion copolymerization data for the systems MA–BA, BA–DA, and MA–DA, together with low conversion data on the MA–BA–DA terpolymerization system. Inspection of Figure 4 shows that all ternary copolymerization k_t values are located on a surface area that is indicated by the triangle (full lines) within the figure. The termination rate surface is restricted to a certain set of initial mole fractions, as they have to add up to 1; eg it is not possible to conduct a terpolymerization at the mole fractions of 0.8 for MA and 0.5 for DA. This (quite obvious) restriction is the reason for the triangular form of the termination rate surface.

The success of equation 37 in describing intrafamily terpolymerization termination rate coefficients provides considerable temptation to propose an expression (eq. 38) that may be useful (or even must be used because of missing alternatives) for modeling k_t of monomer mixtures that contain i monomeric species:

$$\langle k_t \rangle = \prod_{1}^{i} k_{t,i}^{f_i} \tag{38}$$

with the sum over f_i adding up to 1.

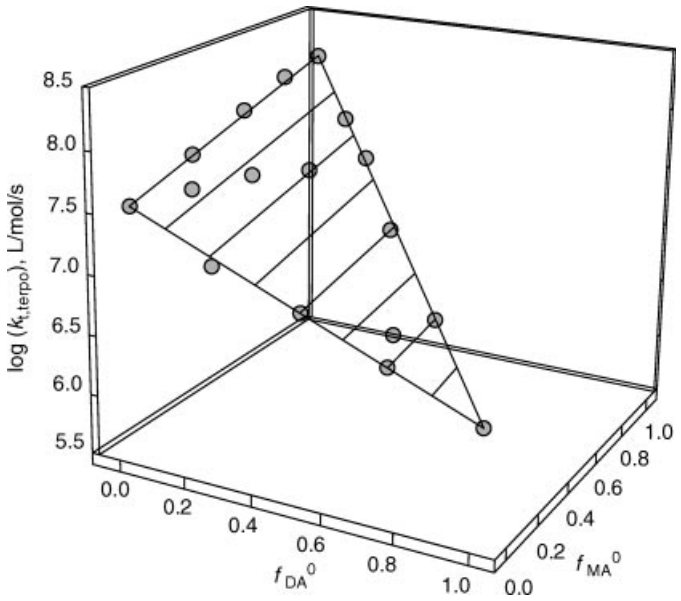

Fig. 4. Low conversion termination rate coefficients, $k_{t,terpo}$, for a MA–BA–DA terpolymerization at 40°C and 1000 bar plotted vs the mole fraction of DA and MA in the initial composition of the reaction mixture (86). The triangle indicates the surface on which the termination rate coefficients are located.

Equation 38 represents the generalized formulation of equations 34 and 37 in nonlogarithmic terms. $\langle k_t \rangle$ refers to the termination rate coefficient of a multimonomer copolymerization in the initial plateau region (at low and moderate conversions, with this range depending on the particular type and concentration of the monomers). $k_{t,i}$ is the homotermination rate coefficient of monomer i in this inital plateau region and f_i is the mole fraction of monomer i in the reaction mixture.

Controlled/Living Radical Copolymerization

Controlled/living radical polymerization (CRP) has been successfully applied to many different radically polymerizable monomers. A recent book has summarized this very rapidly developing field, at least till 2001 (87). Because of limited space available, only the most important issues will be discussed here.

Currently three systems seem to be the most efficient processes for conducting a CRP: nitroxide mediated polymerization (NMP) (eq. 1 in Fig. 5), atom transfer radical polymerization (ATRP) (eq. 2 in Fig. 5) and degenerative transfer systems (eq. 3 in Fig. 5) such as reversible addition–fragmentation transfer (RAFT) or iodine degenerative transfer (IDT) processes (88–90). The key feature of all CRPs is the dynamic equilibration between active radicals and various types of dormant species.

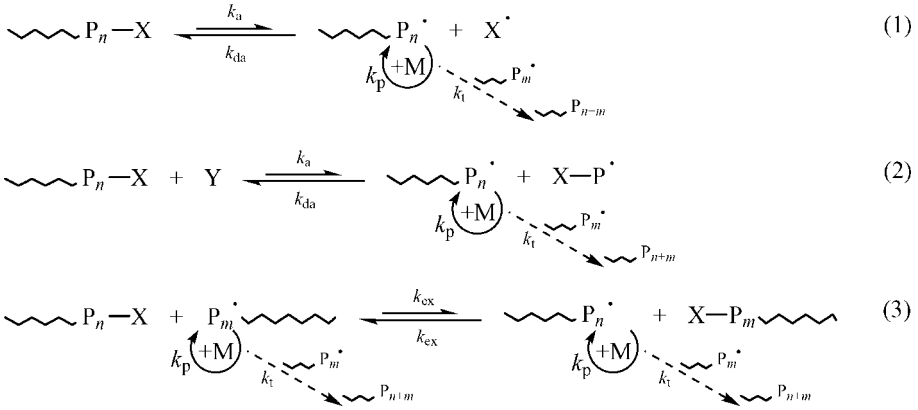

Fig. 5. Three most common mechanisms of exchange between active and dormant species in CRP.

The activation process (k_a) for the dormant species (P_n—X) to form propagating radicals ($P_n^{\bullet}$) may be spontaneous, ie, thermal (alkoxyamines in NMP) (91) or catalytic (activation of alkyl (pseudo)halides by redox active transition-metal complexes (92–94), Y, in ATRP). It may be also bimolecular [dithioesters in RAFT (95) and alkyl iodides in IDT (96)]. The degenerative transfer process may proceed through the addition–fragmentation chemistry or through hypervalent radical intermediates of very short or sometimes longer lifetime. In the latter case some retardation may occur. In all of these systems only radicals propagate (k_p). The conditions for the reaction are selected so that the reversible activation or reversible transfer reaction provides a small steady concentration of growing radicals, at concentrations similar to or smaller than in conventional radical polymerization (RP). Although termination (k_t) does occur in all CRPs, the proportion of dead chains is relatively small (typically between 1 and 10%) in comparison with all living chains. The latter constitutes tiny amounts of growing species (ppm) and a dominating proportion of dormant chains which are potentially active. In NMP and ATRP, the formation of active radicals is accompanied by the generation of a persistent radical species, such as a nitroxide or a higher oxidation state transition-metal complex, which can deactivate growing radicals reversibly. Both processes follow persistent radical effect kinetics (97,98).

In all of these systems, propagation involves radical species, and therefore chemoselectivities (reactivity ratios and transfer coefficients), regioselectivities (head-to-head units), and stereoselectivities (tacticity) determined for CRPs are similar to those in conventional RP.

Developments in CRP were also applied to copolymerizations (99–102). Since CRP is a living system, for the first time segmented copolymers (block and graft copolymers) were prepared in high yield via radical mechanisms. Simultaneous copolymerization results in preparation of statistical copolymers, with comonomers displaying reactivity ratios similar to those in RP. However, since nearly all chains start growing at the same time and continue till the end of the reaction, drift in comonomer feed is reflected in composition variation along the backbone of all chains and results in the preparation of tapered or gradient copolymers. This is in contrast to RP, in which copolymers formed at the early stage of

the copolymerization are rich in one comonomer and at the later stages are rich in another comonomer.

In this section, some peculiarities of copolymerization conducted in CRP systems will initially be discussed and then examples of various types of copolymers will be provided. They will include statistical, gradient, and alternating copolymers, as well as block and graft copolymers. Some special systems will be also presented and they will include preparation of stereoblock copolymers, and various hybrid materials formed by either mechanistic transformation or by growing well-defined polymers from flat, colloidal, or irregular surfaces.

Reactivity Ratios. In CRP, monomer is consumed only in the reaction with growing radicals. Therefore, in the first approximation, composition of copolymers in CRP and RP should be the same and in many cases the simplest four-reaction copolymerization scheme should be applied, with all restrictions discussed earlier in this article (103). The relative rates of comonomer consumption and consequently apparent reactivity ratios in CRP should be the same as in RP. However, some small discrepancies are expected, and indeed have been observed, in the values of reactivity ratios from ATRP and conventional radical polymerizations (104–107). There are a number of reasons for these discrepancies, sometimes as obvious as conducting the copolymerization at different reaction temperatures and in the presence of solvents. Additionally, differences in the rate of chain growth can also alter the observed reactivity ratios. In a controlled polymerization, polymer is slowly formed throughout the reaction and there is a continuous increase in the molecular weight of the polymer, whereas in a conventional system high molecular weight polymer is formed at the beginning of the reaction and the composition of the polymer can be established at low conversion. This difference in the rate of chain growth may also amplify the bootstrap effect (23). The presence of a transition-metal catalyst in ATRP may further complicate the picture by introducing the possibility of complexation of some monomers with the Lewis acidic transition-metal catalysts (108–110). The final, and perhaps most important, cause of discrepancies in reactivity ratios observed in ATRP, are the differences in methodologies of measuring reactivity ratios in controlled and conventional radical polymerizations (106). In a conventional process the monomer reactivity ratios are measured at low conversion with different monomer feeds. However, in the ATRP, measurements at low conversions could be affected by the structure of the initiator, which may preferentially react with one comonomer. For this reason it is necessary to measure the cumulative composition of the copolymers at a conversion higher than in a conventional process. However, as the cumulative composition of a copolymer will always be equal to the monomer feed at 100% monomer conversion, the closer the reaction gets to 100% conversion, the less precise the information that can be obtained on reactivity ratios.

In CRP, the classic copolymerization scheme (Fig. 6) should be supplemented by the reversible activation steps for both initiation and propagation steps:

The values of the individual equilibrium constants should have an effect on the total radical concentration, ie, the overall polymerization rate. However, the reversible activation processes should not affect the relative rates of comonomer consumption, once the steady state between radicals is established. Nevertheless, during the initial stage of the reaction, cross-propagation reactions may not be fully equilibrated and therefore concentration of both growing species in CRP may

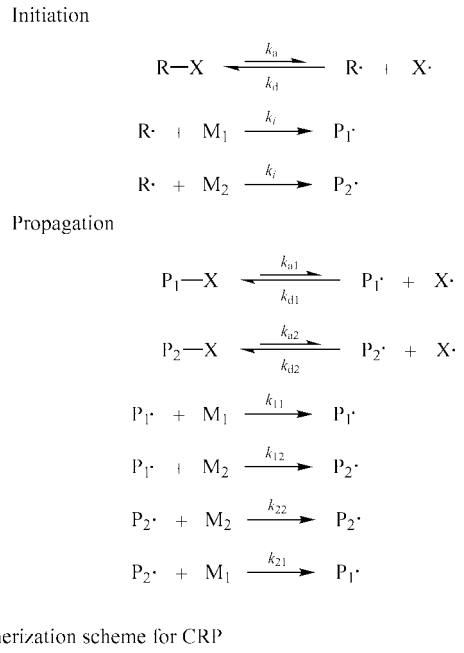

Fig. 6. Simplified copolymerization scheme for CRP.

be different than in conventional RP. Thus, some discrepancies between CRP and RP can be observed (107,111). In addition, diffusion phenomena may play some role, especially in copolymerization of macromonomers (112–115). Nevertheless, in a large majority of CRP systems examined the reported reactivity ratios are very similar to those in conventional RP.

The penultimate effect on the kinetics of the activation/deactivation processes may be quite significant. For example, model studies of activation of various dimers in ATRP copolymerization of methyl acrylate (MA) and methyl methacrylate (MMA) showed the following relative values of k_{act} for dimeric species: H–MA–MA–Br, H–MMA–MA–Br, H–MA–MMA–Br, and H–MMA–MMA–Br to be 1, 4.6, 19, and 96, respectively. The back-strain effect resulting from the presence of a MMA penultimate unit, and formation of a thermodynamically more stable radical from a MMA–Br terminal unit, increased the values of k_{act} by ∼5 and ∼20 times, respectively, in comparison to MA penultimate/terminal units. The combined effects resulted in a ∼100-fold increase of k_{act} for H–MMA–MMA–Br relative to H–MA–MA–Br (116).

Statistical and Gradient Copolymer. As shown in Figure 7, composition along the chain varies in different ways for block, gradient, and random copolymers. The composition does not vary in a block copolymer until after the crossover point between blocks where there is an instantaneous composition change, a random copolymer shows no continuous change in composition, and gradient copolymers are copolymers in which the instantaneous composition varies continuously along the chain contour (117–119).

In order to achieve this continuous change in instantaneous composition, all chains must be initiated simultaneously, and must survive until the end of the

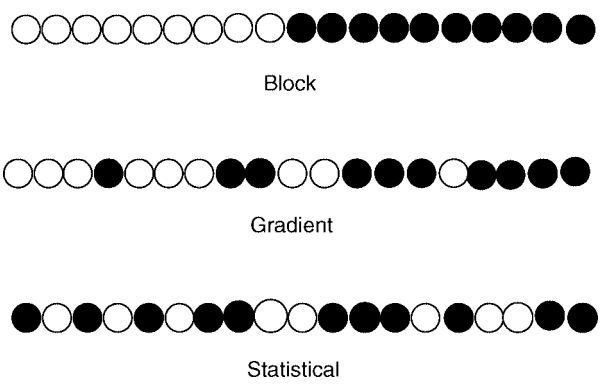

Fig. 7. Schematic representation of block, gradient, and statistical copolymers.

polymerization. Therefore, a living (ionic) or controlled/living radical polymerization technique must be employed, as the significant presence of chain-breaking reactions would lead to heterogeneity in composition as well as in molecular weight.

Because of facile cross-propagation, statistical (or nearly random) copolymerization is very easily achieved in free-radical systems, in contrast to ionic reactions. The reactivity of many comonomers are relatively similar. For example, in RP, methacrylates have similar reactivity to styrene and are ∼3 times more reactive than acrylates. However, in anionic polymerization acrylates are 100 times more reactive than methacrylates and the latter much more reactive than styrene. In cationic polymerization the opposite reactivity order is observed. The copolymerization of monomers with similar reactivity should result in statistical copolymers with no compositional variation during the polymerization. This has been observed for copolymerization of the same type of monomers such as various styrenes, various methacrylates, and various acrylates. This is the case for both CRP and conventional RP. However, in batch copolymerizations of different classes of comonomers there is a continuous change of residual monomer composition in the reaction because one comonomer reacts faster than the other one.

The slow rate of initiation relative to propagation in conventional RP composed of two or more classes of monomers leads to chains which have differing compositions depending on when they were grown. This difference in reactivity results in compositional variation *among the chains* and, in the extreme cases, may result in a mixture of two homopolymers. In CRP, all the chains are initiated early in the reaction and, under proper conditions, retain activity over the entire course of the reaction. Therefore, changes in the instantaneous composition arising from variations in the relative concentrations of monomers are reflected *along all chains*. In the extreme case of very different reactivity ratios, this may lead to formation of block copolymers. At the end of the reaction, the cumulative compositions of the conventional and controlled reactions should be the same but in the conventional case, a variety of compositions will be observed between the chains while in CRP all chains will have a similar structure, a gradient of composition along the chain (118,119). Such gradient (or tapered) copolymers have properties different to either block or random copolymers, making them candidates for

applications such as blend compatibilizers, vibration-dampening materials, and pressure-sensitive adhesives (117,119,120).

The shape of the gradient depends on the reactivity ratios, on the composition of the monomer feed and on whether a mono- or multi-functional initiator was employed. Forced gradient copolymers can also be prepared by CRP processes. In the latter system, one monomer is fed into a reactor already containing another monomer in a semibatch mode. In such a case gradient copolymers can also be obtained from comonomers with the same reactivity ratios.

Because of the relative infancy of CRP, only a limited number of gradient copolymers have been reported (102,119). Spontaneous gradient copolymers were formed in ATRP copolymerization of styrene with *n*-butyl acrylate (nBA) (121,122), and with MMA and nBA (123). Both systems had reactivity ratios similar to those in conventional RP. Preparation of a forced gradient copolymerization was studied for styrene and MMA (99). The molecular weight of the copolymer was controlled, polydispersity was low, $M_w/M_n < 1.25$, and the instantaneous composition of styrene relative to MMA in the backbone decreased as MMA was added. In another study examining the forced gradient copolymerization of methyl acrylate (MA) and styrene, changes in the feed rate of MA (0.085 vs. 0.050 mL/min) resulted in differences in the instantaneous composition of MA in the copolymer. At a higher feed rate, there was more MA incorporated into the chains at a given fractional chain length (conversion) (119). The DSC and dynamic mechanical analysis indicated that gradient copolymers have significantly different properties than block copolymers. The DSC traces showed that the forced gradient copolymer behavior depends on the thermal history. The lower modulus (G′) of the forced gradient copolymer compared to the statistical gradient copolymer demonstrates that materials with different properties were produced. The synthesis of forced gradient copolymers of styrene and acrylonitrile as well as spontaneous gradients of styrene and *n*-butyl acrylate were also reported (119,121,122).

Alternating Copolymers. Alternating copolymers can be formed when reactivity ratios for both comonomers are very low, approaching zero (109). Another option is to use large excess of one comonomer with $r \sim 0$. Both of these systems have been used in CRP. The first successful attempts were based on copolymerization of methyl acrylate and acrylonitrile with a large excess of isobutene using ATRP. Well-defined but low molecular weight alternating copolymers were prepared. Subsequently, well defined alternating structures of styrene with either maleic anhydride or maleimides were prepared by NMP, RAFT, and ATRP (124–126).

A more challenging synthetic task was to force monomers such as styrene and MMA to form alternating copolymers. This was successfully accomplished by complexing MMA, BMA, or MA with Lewis acids such as aluminumalkylchlorides (108). Complexation significantly increased the rate of cross-propagation. By using RAFT as the CRP process, it was possible to prepare not only alternating copolymers but also block copolymers containing segments of both alternating and homopolymer structures (126–128).

Block Copolymers. CRP, as any controlled/living polymerization, can be used for the preparation of well-defined segmented copolymers, ie, block and graft copolymers (qv) with various architectures (101). Block copolymers (qv) can be formed by simple chain extension through the addition of the second monomer

at the end of the polymerization of the first one. They have been synthesized from the isolated macroinitiators and have been also made by the transformation of the chain ends of macroinitiators prepared by another technique, eg ionic, coordination, ring-opening polymerization, step growth, etc. (129–135). By using multifunctional initiators, star-block copolymers have been made (136) (see also BLOCK COPOLYMERS, TERNARY TRIBLOCKS).

Many block copolymers have been prepared by ATRP, NMP, and RAFT (99). Since NMP can not yet be successfully used for the synthesis of polymethacrylates only block copolymers with styrenes, acrylates, and acrylamide segments have been made. RAFT and ATRP can incorporate a broader range of monomers into block copolymers. Efficient blocking requires cross-propagation to be fast relative to the rate of polymerization of the second block. Since the rate of propagation in NMP and ATRP depends on the product of the equilibrium constant and true radical propagation constants, certain rules apply for successful block copolymerization. The same is true for RAFT, which requires fast fragmentation of the first segment to achieve efficient crosspropagation (137,138). In general, more stabilized radicals, such as methacrylates, propagate via RP slower than those forming less stabilized radicals (acrylates). However, equilibrium constants and rates of fragmentation are much higher for stabilized radicals and therefore they dominate the overall rate control. This means that blocking from polymethacrylates to polyacrylates is efficient for both ATRP and RAFT, but the opposite is not true. Similar observations were reported for NMP and ATRP during preparation of block copolymers that required blocking from polyacrylonitrile to poly(butyl acrylate) (139) .

ATRP offers one synthetic setup to overcome this deficiency, via the halogen exchange technique, which allows an approach to combat the crossover problem. This technique utilizes a mixed-halogen system, ie, a bromo-containing initiator and a Cu(I)Cl catalyst, to afford better control over initiation from the macroinitiator and subsequent polymerization of the second methacrylates block, which is particularly useful for preparing acrylate–methacrylate block copolymers (140,141). Halogen exchange provides a method for adjusting the equilibrium when moving from a less reactive macroinitiator (A), with an apparently smaller equilibrium constant, to successfully initiate polymerization of a monomer that has a larger equilibrium constant (B in Fig. 8). Since ATRP equilibrium constants under comparable conditions for methacrylates are ∼1000 times higher than for acrylates (142–144), cross-propagation from polyacrylates to polymethacrylates is inefficient in spite of ∼100 times higher propagation rate constants for the latter (145). However, since alkyl bromides are ∼100 times more active than structurally similar alkyl chlorides (146), the cross-propagation becomes successful.

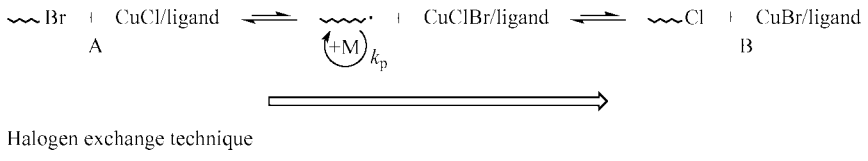

Fig. 8. Halogen exchange technique.

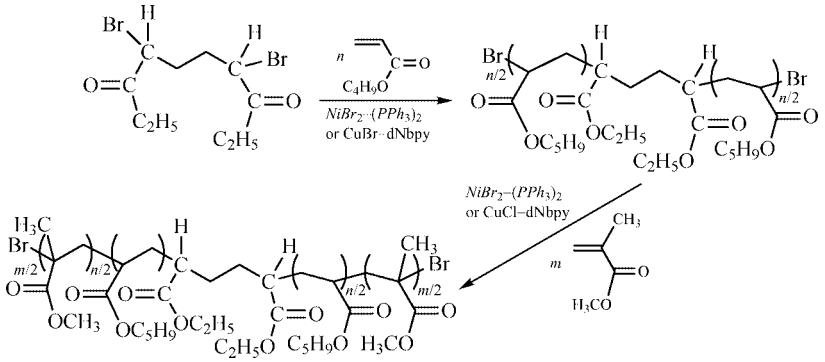

Fig. 9. Preparation of triblock copolymers with poly(butyl acrylate) central and poly(methyl methacrylate) outer segments by ATRP.

When difunctional pnBA was used to prepare ABA block copolymers with MMA using a Ni system, without halogen exchange, it was reported that the mechanical properties of the resulting copolymers were poor compared to those of the copolymers prepared by ionic methods, presumably because of the broad polydispersity of the outer pMMA blocks (see Fig. 9) (147). Complete incorporation of the macroinitiator did not occur until >30% monomer conversion. The block copolymers did, however, microphase separate into ordered structures (148).

In comparison, block copolymers prepared using a copper catalyst employing the halogen exchange technique had predictable molecular weights and narrower molecular weight distributions (141). There was no evidence of slow initiation and the outer pMMA blocks were more uniform. When Moineau and co-workers used this system, the mechanical properties were greatly improved relative to the copolymers prepared with the Ni catalyst (149). It has been also reported that the proper choice of solvent also improves block copolymerization (150).

Another approach to form similar materials is to add MMA to the growing pBA chains before complete consumption of the BA to form gradient A segments. The properties of these triblocks were different than those observed for "clean" ABA blocks, with lowered glass-transition temperatures (T_g) for the mostly hard outer blocks as well as increased tensile strength and elongation, as shown in Figure 10 (120).

The stress–strain curves recorded for the two triblock copolymer samples during cold drawing of films with a constant rate of 1 mm/min are shown in Figure 11. The gradient copolymer has much higher tensile elongation (1000% vs. 300%) but much lower tensile strength (4.5 MPa vs. 7.3 MPa) than the copolymer with pure homopolymeric blocks.

The ABA-isolated sample was a clean triblock, with a pnBA central block of $M_n = 65{,}200$, two blocks of MMA with an $M_n = 13{,}150$, and an overall $M_w/M_n = 1.34$. The ABA-sequential copolymer contained a clean central block of nBA of $M_n = 67{,}500$, and two gradient end block copolymers containing 13 mol% nBA and 87 mol% MMA, with an $M_n = 10{,}600$, and an overall $M_w/M_n = 1.24$ (120). The insert shows the small-angle X-ray scattering intensities for these samples, which correspond to cylindrical morphology of pMMA hard segments. Since both types

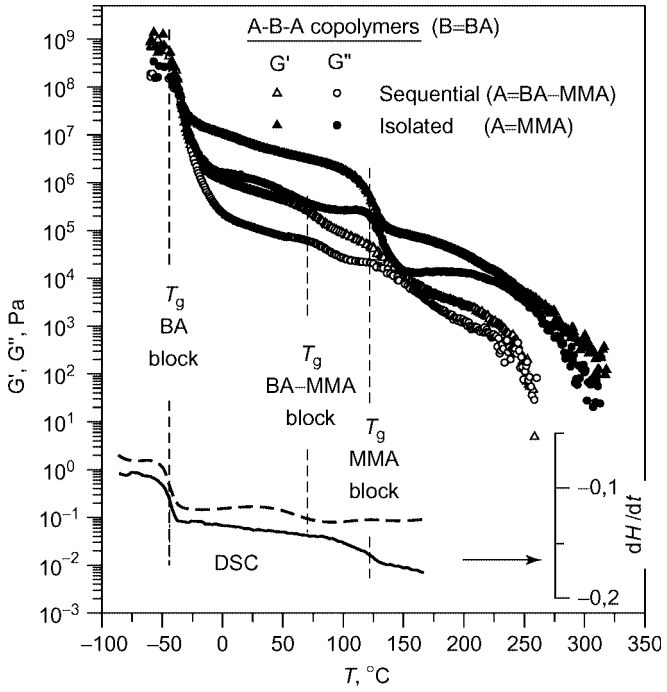

Fig. 10. Temperature dependencies of the real (G′) and imaginary (G″) component of the shear modulus measured at the deformation frequency of 10 rad/s. for the pure and tapered triblock copolymers pMMA-*b*-pBA-*b*-pMMA and p(MMA-*grad*-BA)-*b*-pBA-*b*- p(MMA-*grad*-BA) of approximately the same overall composition, MW and polydispersity. For comparison DSC traces are shown, which help to localize the glass-transition temperatures (T_g) of the microphases.

of block copolymers had similar compositions and only varied in the sequence distribution of the monomers, this type of structural control provides yet another route to tailor make polymers with specific properties by CRP methods.

Graft Copolymers. Graft copolymers can be prepared by three different techniques: grafting from the backbone, grafting through by using macromonomers, and grafting onto the backbone.

CRP has been applied to the synthesis of each segment in the either entire graft system or exclusively to the preparation of specific segments such as backbone, macromonomer, macroinitiator, or the grafting process. For example, NH_2-terminated dendrons were grafted onto backbones made by CRP containing *N*-oxysuccinimide 4-vinylbenzoate (151). Alternatively macromonomers were made by either ATRP or other process (coordination, or conventional RP) and they were subsequently used for grafting through (152,153). In another approach, macromonomers were made by group transfer polymerization, or other controlled polymerization processes, but ATRP was used for the grafting through copolymerization (112,114). Perhaps the simplest is the grafting-from process, which can involve CRP for the synthesis of the backbone, for the grafting-from reaction, or both (Fig. 12).

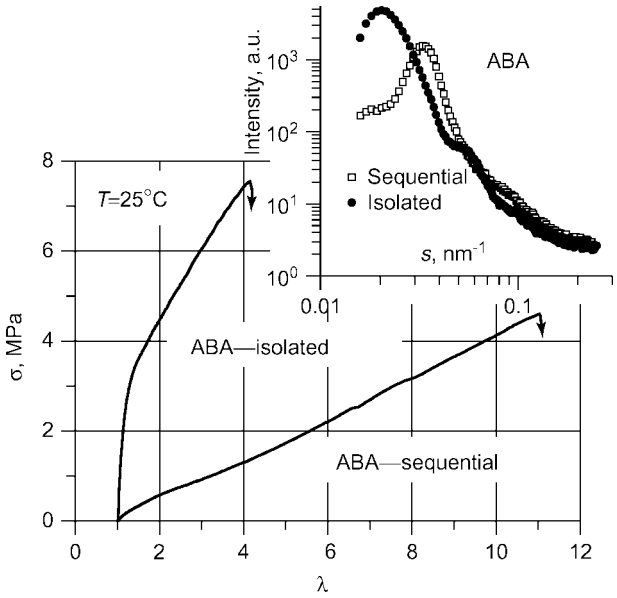

Fig. 11. The stress–strain curves recorded for the two triblock copolymer samples during cold drawing of films with a constant rate of 1 mm/min. ABA-isolated sample was a pure triblock but ABA-sequential contained a pure central block of *n*-butyl acrylate of M_n = 67,500, and two end gradient blocks containing 13 mol% *n*-butyl acrylate and 87 mol% methyl methacrylate, with an $M_n = 10600$, and an overall polydispersity of $M_w/M_n = 1.24$. The insert shows the small angle X-ray scattering intensities for these samples.

Grafting-From Technique. Graft copolymers were among the first materials prepared by CRP. After establishing that a unimolecular TEMPO-based initiator successfully controlled the polymerization of styrene (154), the grafting-from approach was used to demonstrate that graft copolymers were possible using CRP techniques (155). The multifunctional macroinitiator was prepared by free-radical copolymerization of styrene with a vinyl benzyl TEMPO derivative using AIBN at 60°C. The macroinitiator was heated to 130 °C in the presence of more styrene, which led to the preparation of a graft copolymer. The molecular weight of the polymer increased from $M_n = 12{,}000$ ($M_w/M_n = 1.86$) to $M_n = 86{,}000$ ($M_w/M_n = 2.01$). After cleavage of the grafted side chains, analysis of the graft units gave $M_n = 23{,}000$ with $M_w/M_n = 1.26$, in good agreement with the expected value of 21,000 (155).

Expanding on this idea, an alkene-functionalized TEMPO derivative was copolymerized with propylene or 4-methylpentene using a cationic metallocene compound to prepare an α-olefin-based macroinitiator for graft copolymerization [$M_n = 28{,}000$ ($M_w/M_n = 1.80$) or $M_n = 6080$ ($M_w/M_n = 1.65$)] (Fig. 13) (156). Heating the propylene-based copolymer to 123 °C in the presence of 200 equiv St increased its molecular weight to $M_n = 210{,}000$, with $M_w/M_n = 2.0$. The final molecular weights of the graft copolymers were dependent on the concentration of St added to the reaction.

The grafting-from technique can also provide a route to graft copolymers via ATRP. A poly[(vinyl chloride)-*co*-(vinyl chloroacetate)] copolymer, containing

Graft copolymerization of styrene with olefins

Fig. 13. Graft copolymerization of styrene with olefins.

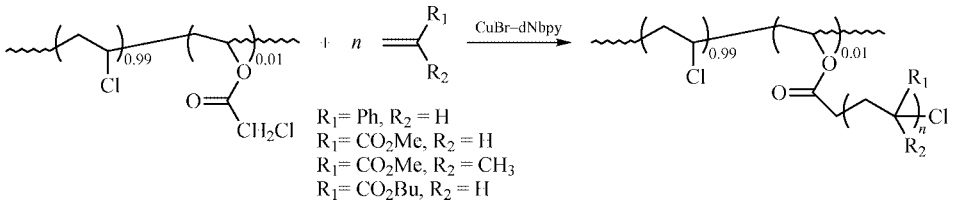

Fig. 14. Grafting from poly(vinyl chloride) by ATRP.

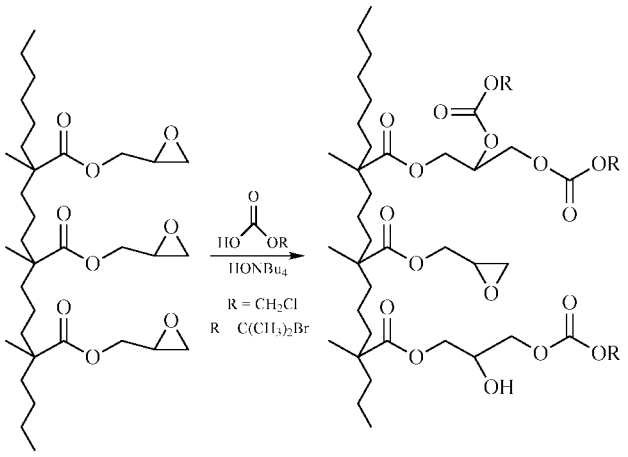
about 1% of the chloroacetate groups, was used to initiate the ATRP of St, MA, nBA, and MMA, resulting in graft copolymers with well-defined graft units (Fig. 14) (157).

^{1}H NMR analysis showed that the molecular weight of the macroinitiator increased substantially after the ATRP graft copolymerization (M_n = 47,400 to M_n = 112,700–363,000). The mole percent of the grafted monomer ranged from 50 to 80% in the copolymer, but GPC analysis was not useful for determining the molecular weight of the copolymers (157). A detailed analysis of the ATRP of nBA using ^{1}H NMR and FT-IR spectroscopy showed that with increasing reaction time, the mole percent of nBA in the copolymer increased and the T_g decreased. This work demonstrated that commercially available macroinitiators can be used to prepare graft copolymers via ATRP. In a similar way grafting was performed from the defects in pVC (158).

Brominated polyethylene or ethylene styrene copolymers were also used as initiators in the presence of a CuBr–PMDETA catalyst for the subsequent ATRP grafting from copolymerization of acrylic monomers. In similar studies, syndiotactic pSt-*g*-pMMA, syndiotactic pSt-*g*-pMA, and syndiotactic pSt-*g*-atactic pSt were synthesized by ATRP using brominated syndiotactic pSt as the initiator and a CuBr–PMDETA catalyst. Both the graft density and the MW of the graft segments were controlled by changing the bromine content of syndiotactic pSt and the amount of monomer used in the grafting-from reaction. The ATRP mechanism for grafting was supported by NMR analysis of the end groups. The thermal properties of the graft copolymers depended on both the graft density and the graft length (159).

Another commercially available polymer, poly(isobutylene-*co*-*p*-methylstyrene-*co*-*p*-bromomethylstyrene), was used as a macroinitiator for the ATRP of St to produce a graft copolymer (160). After 23 h at 100°C, with 1 equivalent of catalyst relative to the number of moles of initiator, monomer conversion was 81%; however, increasing the concentration of catalyst fivefold resulted in the same efficiency after only 11 h. No evidence of unreacted macroinitiator was found in the GPC analysis, indicating that nearly all of the chains contained some grafted sites. Results from mechanical analysis showed that when the wt% of St was high (28%), the graft copolymer exhibited no special properties; however, with only 6 wt% pSt, the polymer was elastomeric and could be reversibly stretched to 500% of its initial dimension (160).

It was demonstrated that the grafting of St and MMA using a similar backbone is better controlled by applying the halogen exchange method (161,162). Mechanical and viscoelastic properties depend strongly on the morphologies of



ATRP grafting from poly(ethylene-*co*-glycidyl methacrylate)

Fig. 15. ATRP grafting from poly(ethylene-*co*-glycidyl methacrylate).

the samples, which are defined by the proportion of the hard and soft segments as well as by the uniformity of the hard pMMA grafts (161).

A commercially available poly(ethylene-*co*-glycidyl methacrylate) [p(E-*co*-GMA)] polymer was transformed into an ATRP macroinitiator (163) by reacting the p(E-*co*-GMA) with either 2-bromoisobutyric acid or chloroacetic acid to prepare a backbone with multiple initiator sites. The resulting polymer was used as a macroinitator for ATRP of St and MMA (Fig. 15). The consumption of both monomers increased with time, as did the weight percent of the side chains in the copolymer. GPC analysis of the cleaved pSt side chains showed a linear increase of molecular weight with monomer conversion, and $M_w/M_n < 1.4$ (163).

ATRP has been also used in the grafting-through process using hyperbranched polyethylene macromonomers with methacrylate functionality prepared by the living Pd-mediated process (164).

Inorganic macroinitiators can also be used for graft copolymerizations. Pendant vinyl functional pDMS was subjected to hydrosilation with 2-(4-chloromethylphenyl)ethyldimethylsilane to prepare a multifunctional ATRP macroinitiator (133,165). The ATRP of St was carried out using a pDMS macroinitiator with an $M_n = 6600$ and an $M_w/M_n = 1.76$ to yield a graft copolymer with an $M_n = 14{,}800$ and an $M_w/M_n = 2.10$. The increased polydispersity was attributed to the variation in the number of initiating sites on the pDMS backbone. ^{1}H NMR analysis showed that less than 5% of the total number of benzyl chloride moieties were left unreacted and that the weight ratio of pSt/pDMS was 1.18 (133).

The field of densely grafted copolymers has received considerable attention in recent years. The materials (also called bottle-brush copolymers) contain a grafted chain at each repeat unit of the polymer backbone. As a result, the macromolecules adopt a more elongated conformation. Examples of brush copolymers have been provided within the context of defining the level of control available through ATRP (152,166,167). Synthesis of the macroinitiator involved the ATRP of 2-trimethylsilyloxyethyl methacrylate followed by esterification of the protected

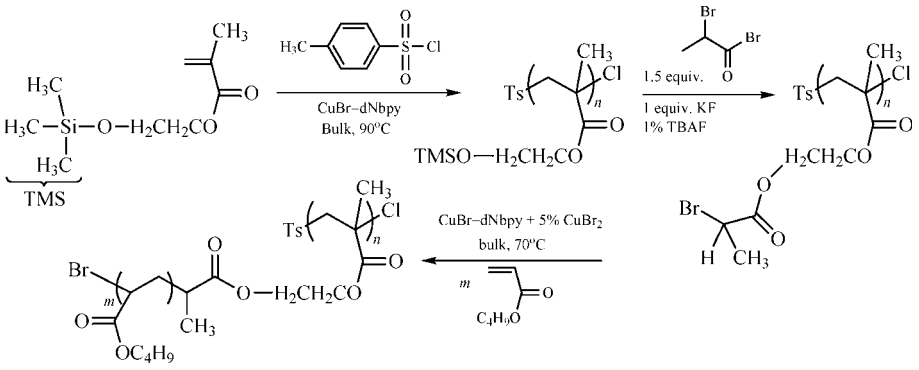


Fig. 16. Synthesis of densely grafted brushes by ATRP.

alcohol with 2-bromopropionyl bromide provided a macroinitiator of well-defined structure ($M_n = 55{,}500$, $M_w/M_n = 1.3$) leading to a brush synthesized entirely by a controlled process (Fig. 16). The macroinitiator was used for either the ATRP of St or nBA, leading to the desired densely grafted structures. The grafting reactions were found to be very sensitive to reaction conditions; the presence of additional deactivator, high concentrations of monomer, and reduced temperatures were all necessary to produce the desired materials without occurrence of any coupling reactions.

Since the aspect ratio and size of the macromolecules were so large, individual chains were capable of being observed by atomic force microscopy (AFM) (153). The brushes with pSt side chains form elongated structures on a mica surface with an average length of 100 nm, a width of 10 nm, and a height of 3 nm. pnBA absorbs well onto the mica surface and forms spectacular single-molecule brushes in which the backbone and side chains can be visualized using tapping mode AFM.

Similarly, core-shell cylindrical brushes were prepared by conducting a block copolymerization. A well-defined backbone with a degree of polymerization of ~500 was initially prepared by ATRP, which was followed by a transesterification and the subsequent grafting of pnBA chains using ATRP. A final chain extension with St produced the block copolymers. The final structure consisted of a macromolecule with a soft pnBA core and a hard pSt shell (167). High resolution AFM micrographs of the block copolymer [pBPEM-*g*-(pnBA-*b*-pSt)] brushes show a necklace morphology. The synthesis of well-defined brush block copolymers demonstrates the synthetic power of ATRP.

Other Systems. CRP has been recently applied to grafting from many surfaces, including colloidal particles, flat wafer surfaces, and delaminated clay nanolayers, in addition to irregular surfaces such as cellulose (filter paper), silica (glass frits), and many other solid substrates (168). All of them can be considered as copolymers of biopolymers, inorganics, and well-defined organic polymers. Some of the advantages of using CRP for the synthesis include large range of polymerizable monomers, undemanding reaction conditions, and simple functionalization of surfaces. For example, hydroxy groups on the surface of cellulose, or

essentially any oxidized polymer surface, can be esterified with α-bromoesters to provide ATRP initiating sites. In the same way silanol groups on glass or oxidized silicon surface can be condensed with chloro- and alkoxysilanes containing similar bromoesters (169). Then any polymer can be grown with a high precision from these functionalized surfaces. In this approach to material synthesis not only density of grafting and chain length can be controlled but also composition, yielding responsive block, gradients, or statistical copolymers.

A special case of control over the structure of copolymers may include the first stereoblock copolymers made by CRP. By applying either RAFT or ATRP to polymerization of acrylamides in the presence of rare-earth triflates such as $Y(OTf)_3$ and $Yb(OTf)_3$, it was possible to enhance isotacticity of *N*,*N*-dmiethylacrylamide (DMA) from ∼50% meso to ∼90% meso dyads (170). At the same time control of molecular weights and polydispersity was preserved. Similar results were obtained for RAFT of *N*-ispropylacrylamide (171). The ATRP and RAFT of DMA was applied to the first one-pot stereoblock synthesis by radical mechanism. RAFT or ATRP of DMA were started without Lewis acid to produce the first atactic block. Subsequently, the complexing agent was added at the desired conversion to continue the chain growth with the preferential isotactic placement (170).

Ionic Copolymerization

The copolymerization proceeding via an ionic mechanism is markedly different from the free radical copolymerization (172). The reaction of ions with a vinylic monomer molecule is generally governed by the polarity of the double bond and is therefore much more selective than the radical addition reaction, in which radical stability is the controlling factor. The reactivity ratios are significantly different from that measured in free-radical copolymerization (see Table 1) and cover a much wider range. (Tabulated values of reactivity ratios in anionic and cationic copolymerization can for instance be found in References 173 and 174.) The number of monomer pairs that undergo ionic copolymerizations is hence limited. In most cases one of the reactivity ratios is larger than 1; the resulting copolymerization favors the incorporation of one monomer into the polymeric chain leading to extensive blocks. Because of the inverse polarity of anions and cations the reactivity ratios exhibit an inverse behavior, that is, if $r_1 > r_2$ in an anionic copolymerization, $r_1 < r_2$ will hold in a cationic copolymerization (see Table 1). There is a tendency that the product $r_1 \cdot r_2$ is close to one when two resonance

Table 1. Monomer Reactivity Ratios of Selected Comonomer Pairs for Different Polymerization Mechanisms

Monomer		Free radical		Cationic		Anionic	
1	2	r_1	r_2	r_1	r_2	r_1	r_2
Styrene	Vinyl acetate	55	0.01	8.3	0.015	0.01	0.1
Styrene	Chloropren	0.005	6.3	15.6	0.24	–	–
Styrene	Methyl methacrylate	0.52	0.46	10.5	0.1	0.12	6.4
Acrylonitrile	Methyl methacrylate	0.18	1.35	–	–	7.9	0.25

stabilized monomers are involved. In such an ideal copolymerization the relative reactivities of the two propagating ionic species toward the two different monomers are approximately the same. The product is, however, often found to be much larger with one comonomer not stabilized, leading to block-copolymer behavior. This characteristic is for instance observed in the copolymerization of dimethyltrimethylene carbonate and pivalolactone in toluene initiated with K-naphtalene, which proceeds via an anionic ring-opening polymerization (175). The ^{13}C NMR analysis of the generated block copolymer only reveals signals corresponding to homodiads (176), demonstrating a well-defined crossover reaction. Less pronounced block copolymerization behavior in living ionic polymerization, however, will lead to a gradient composition profile along the chain (177). In the organolithium-initiated anionic copolymerization of isoprene (or butadiene) and styrene in hydrocarbon solvents, for instance, isoprene is polymerized almost exclusively in the first phase of the process, followed by polymerization of styrene, producing a terminal polystyrene block. The products formed by such a process are so-called tapered block copolymers, which are characterized by a fuzzy border between the two blocks. If the fuzzy border region reaches the length of the whole macromolecule, the polymeric material is called a gradient copolymer (see above). To obtain block copolymers with a distinct border, one of the monomers is first polymerized in the presence of an initiator to give an active homopolymer, which is then put into the medium of another monomer, the polymerization of which results in the formation of the second block (178). This sequential block copolymerization has been utilized in living ionic polymerizations to synthesize a wide variety of linear, and star-branched block copolymers [eg, carbocationic copolymerization of isobutylene (yielding a rubbery block) with styrene (179), α-methylstyrene (180), or indene (181) (generating a plastic segment)]. Block copolymers containing crystallizable blocks have improved properties since the interplay of crystallization and microphase segregation of crystalline–amorphous block copolymers greatly influences the final equilibrium ordered states and results in a diverse morphological complexity. Because of the lack of suitable vinyl monomers that give rise to a crystallizable segment by cationic polymerization, living cationic sequential block copolymerization is unsuitable for the synthesis of these types of block copolymers. An active-site transformation technique can be used to synthesize block copolymers consisting of two monomers that are polymerizable only by two different mechanisms (182,183). In this method, the propagating active center is transformed into a different kind of active center, and a second monomer is subsequently polymerized by a mechanism different from the first one. The key process in this method is the diligent control of end functionality, capable of initiating the second monomer. Following this idea, poly(isobutylene-*block*-pivalolactone) diblock and poly(pivalolactone-*block*-isobutylene-*block*-pivalolactone) triblock copolymers were synthesized using first cationic polymerization followed by anionic ring-opening polymerization (182) and polyisobutylene-*block*-poly(*tert*-butyl methacrylate) block copolymers were produced employing cationic polymerization followed by anionic polymerization after quenching with thiophene and subsequent metallization, yielding an anionic macroinitiator (184).

The preparation of triblock copolymers can be conducted either via subsequent addition of two different monomers or synthesizing a bifunctional growing chain. The success of any block copolymerization is always dependent on the ability

Table 2. Reactivity Ratios in the Anionic Copolymerization of Styrene and Isoprene in Different Solvents at Room Temperature, Using C_2H_5Li as the Initiator (186,187)

Solvent	Styrene r_1	Isoprene r_2
Toluene	0.25	9.5
Triethylamine	0.8	1.0
Tetrahydrofuran	9.0	0.1

of the active center to attack the next monomer. This general problem can, however, be circumvented via end group alterations of the generated polymer blocks in order to generate block copolymers of monomers that usually do not homopolymerize [eg producing amphiphilic poly(*tert*-butyl acrylate)-*block*-polystyrene-*block*-poly(4-vinylpyridine) (185)]. Ionic copolymerizations were throughout a long period of time the major technique to generate block copolymers. However, they seem to be superceded nowadays by the new living free-radical polymerizations, because of their versatility and robustness (see above).

Another characteristic feature of ionic copolymerization is the sensitivity of the reactivity ratios toward changes in the initiator, solvent, and temperature. The reaction conditions have in general a dramatic effect on the r values, as illustrated in Table 2 for the anionic copolymerization of styrene and isoprene in different solvents (186,187).

The usage of different counterions also significantly changes the copolymerization behavior: employing an organosodium initiator in the copolymerization of styrene and butadiene in toluene instead of an organolithium initiator leads to a change of the reactivity ratios from $r_1 = 0.004$ and $r_2 = 12.925$ to $r_1 = 0.42$ and $r_2 = 0.30$ (188), whereas usage of an organopotassium initiator yields the values $r_1 = 3.3$ and $r_2 = 0.12$ (189). The reactivity ratios may also be influenced by the presence of polar substances like ethers or amines in the reaction system. An indisputable advantage of ionic copolymerization over free-radical copolymerization is hence the possibility to control efficiently the reactivity ratios by varying the polymerization conditions.

These findings imply that the reactivity ratios are in general not only governed by the relative reactivities of the free ionic species, but additionally by the equilibrium between free ions and ion pairs. The conventionally determined reactivity ratios will therefore describe average reactivities. Considering an equilibrium that precedes the actual propagation step (see eqs. 39 and 40)

(39)

(40)

the rate-determining steps are the propagation reactions of the intermediate products with the rate coefficient k_p. The conventionally determined monomer

reactivity ratios are hence not measures for the reactivities of the macro-ions but rather for the concentration of the intermediates and the related rate coefficients. The different reactivity ratios in different solvent systems cannot solely be explained by macroscopic polar or electrostatic effects (190). The concept of preferential solvation of the growing ion by either the solvent or the comonomer is helpful (191); however, the whole process is still far from being understood in depth and additional effects (eg, complexation) have to be taken into account (192). The effect of solvents on monomer reactivity ratios cannot be considered independent of the counterion used. Whereas some comonomer systems show altered reactivity ratios for different initiator systems, others exhibit no significant effect.

Temperature has a greater influence on the r_1 and r_2 values of ionic copolymerizations than in free-radical copolymerization because of the greater spread of activation energies for the propagation reactions involving ions. There is no general trend observable and the monomer reactivity ratios may increase or decrease with temperature: in the isobutylene–styrene copolymerization r_1 increases by a factor of 1.5 and r_2 increases by a factor of 3 when going from -94°C to -30°C (193), whereas in acenaphtylene-α-methyl styrene r_1 increases from 0.075 to 1.49 and r_2 decreases from 8.3 to 0.1 when going from -70°C to 20°C (194).

In contrast to the free-radical copolymerization, the lack of termination in living ionic copolymerization enables the direct determination of the rate coefficients of the cross-propagation step. The reaction rate of monomer B with the living chain end a^- is directly accessible via the concentration decrease of a^-, which may be traced via a suitable spectroscopic method. Alternatively, the concentration of B can be determined as a function of time with the concentration of a^- being held constant. The latter experimental technique requires extrapolation of time toward zero, because the cross-propagation step is immediately followed by homopropagation of B.

Alternatively, the propagation step in ionic polymerization can be described using model reactions, arriving at an estimate of reactivity ratios. Mayr and coworkers, for instance, have developed a reactivity scale for the electrophilic attack of carbocations on nucleophiles (195–197). Employing (i) photometric and/or conductometric measurements of the consumption of persistent carbocations, (ii) photometric detection of laser flash photolysis generated carbocations, and (iii) competitive experiments yielding relative reactivities of different electrophiles toward nucleophiles, they obtained consistent results and established a general scale which assigns to all electrophiles and nucleophiles an electrophilicity parameter E (describing the carbocation) and a nucleophilicity parameter N (describing the monomer), respectively. It could be shown via correlation analysis that the reaction rate coefficient k follows the linear free-energy relationship

$$\log k(20^\circ\text{C}) = s(N + E) \tag{41}$$

with s being a slope parameter (198). For most π-nucleophiles the s parameter ranges between 0.8 and 1.1 and can therefore be generally neglected. It has been shown that copolymerization in the cationic polymerization can only be expected between monomers for which $N \approx -E$ holds (196).

The copolymerization behavior of heterocyclic monomers following an ionic mechanism (ie, ring-opening polymerization) is even more complex than that of vinylic monomers (199). In cationic ring-opening polymerization, for instance, there are often effects present which complicate the kinetic investigations: exchange reactions, macrocyclization, reversibility of polymerization (eg the homopolymerization step of the monomer with the smaller strain is often reversible) and multiplicity of active species. The concept of describing the whole process via the simple four-parameter equation for the calculation of the reactivity ratios is hence not applicable. The reactivity of the monomer in cationic ring-opening polymerization is increasing with its basicity, but it is not influenced by the ring strain. On the other hand, the active species (eg the onium ions) decrease their reactivity with increasing basicity and an enhanced ring strain leads to an increased reactivity. Further details of the ionic ring-opening polymerization may be found in References 200–202.

The different homo- and cross-propagation steps within one ionic copolymerization system generally exhibit significantly different rate coefficients. The resulting polymers therefore consist mainly of one comonomer species, constituting almost homopolymers. The industrial applications of ionic copolymerization are therefore limited. One of the few examples is the anionic copolymerization of butadiene and styrene in solution for the production of the so-called SBR (styrene–butadiene rubber) (203).The copolymer consists approximately of equal amounts of styrene, *cis*-1,4-butadiene, *trans*-1,4-butadiene, and 1,2-butadiene units. Stereoregularity, polymer composition, molecular weight, and branching can be determined via the process control which governs the concentration and nature of the active ionic species. Another industrially significant process is the cationic copolymerization of isobutylene with ∼2% isoprene using $AlCl_3/CH_3Cl$ at $-90^\circ C$ in boiling ethene (203–206). The incorporated double bonds may subsequently be vulcanized to give an elastomer with good impermeability to water and gas, weather stability, ozone resistance, and heat stability (207).

Cross-Linking

Monomers exhibiting two vinylic double bonds are often used as comonomers in order to achieve a cross-linked structure of the final polymeric chains (208,209). The cross-linking reaction occurs during the reaction or subsequently, depending on the reactivity of the second double bond. The bifunctional comonomer is generally employed in low concentrations, because a high concentration of dienes leads to a significant amount of unreacted double bonds in the final polymeric product, which lower the resistance toward outside physical and chemical influences. However, the extent of cross-linking is dependent on the amount of bifunctional monomer BB (with B indicating the double bonds of the diene comonomer). The critical reaction extent at which cross-linking occurs during a copolymerization with dienes can easily be derived mathematically for the case of equally reactive double bonds both in A and BB. The copolymerization of styrene and divinylbenzene (210), vinyl acetate with divinyl adipate (211), and methyl methacrylate with ethylene glycol dimethacrylate (212) are examples of such a behavior. At the double bond conversion c there are c[A] reacted monomer units A, c[B] reacted double bonds of the

monomer B and c^2[BB] reacted monomer units BB (with [B]=2[BB]). The number of crosslinks is simply the number of BB monomer molecules in which both B double bonds are reacted, that is c^2[BB]. The number of polymer chains is the total number of A and B double bonds reacted divided by the average degree of polymerization *DP*. The critical double bond conversion c_{crit} at which cross-linking occurs is reached when the number of crosslinks per chain is 1/2 and is therefore described by

$$c_{crit} = \frac{[A] + [B]}{[B] \cdot DP} \tag{42}$$

for long chains. *DP* is the mass-average degree of polymerization (for details see Ref. 213) that would be observed in the absence of any bifunctional comonomer. Equation 42—denoted as Flory–Stockmayer equation (213)—has been found useful for the prediction of the onset of the cross-linking, also denoted as the gel-point, for equally reactive double bonds, especially when low concentrations of dienes are employed (mole fraction of BB below 0.05). With increasing diene concentration, equation 42 predicts smaller critical conversions than found experimentally (214). This effect is called "delayed gelation." The primary factor for this observation is the significance of the thermodynamic excluded volume effect on the intermolecular cross-linking reaction between the growing radical and the preformed polymer, especially at higher molecular weights. Beyond the theoretical critical conversion, a secondary factor is related to the intramolecular cyclization (215) which becomes progressively important with conversion. The latter leads to the restriction of segmental motion of the preformed polymer and causes steric hindrance.

The critical conversion in the copolymerization process in which the double bond in comonomer A and the first double bond in comonomer BC has the same reactivity, but the second double bond in BC is less reactive, can be described by equation 43:

$$c_{crit} = 1 - \exp\left(\frac{-1}{2 \cdot x_{BC} \cdot DP \cdot r_{BC}}\right) \tag{43}$$

with x_{BC} being the mole fraction of BC and r_{BC} being the reactivity ratio between the B and C double bond. The copolymerization of methyl methacrylate and allyl methacrylate would be an example for such a behavior (216). The resulting copolymer will consist of copolymerized A and B double bonds. The relatively unreactive C double bonds start to react, ie, crosslink, in the later stage of the copolymerization.

CRYSTALLINITY DETERMINATION

Introduction

A variety of natural and synthetic polymers are well known to crystallize on cooling from the melt or from solution. In fact, roughly 1/2 to 2/3 of useful polymers are crystalline or crystallizable. Unlike many low molecular weight organic compounds and inorganic crystals, polymeric materials are semicrystalline and the extent of crystallinity formation is critically important in determining ultimate physical properties, and hence suitability for particular applications (see SEMICRYSTALLINE POLYMERS). Degrees of crystallinity vary over a wide range between crystallizable polymers, as well as within a given polymer system. The crystallinity developed is dependent on average molecular weight and distribution (which influence crystallization kinetics), crystallization/processing conditions (and its relationship to the glass-transition temperature, T_g, of the polymer), and the chemical structure of the chains [flexible like polyethylene (PE) and poly(ethylene oxide) (PEO), or more rigid like poly(ethylene terephthalate) (PET) and poly(ether ether ketone)]. Structural regularity of the chain is also of paramount importance: ie, whether the chains contain comonomer units, stereoirregularity, etc.

This article provides an overview of common methods for determining degrees of crystallinity in polymer systems, focusing on isotropic materials.

X-ray Diffraction

Traditional Approaches. For many purposes, relative degrees of crystallinity (sometimes referred to as the *crystallinity index*) are sufficient and a number of approximate wide-angle X-ray diffraction (WAXD) methods have been reported and utilized. Before the advent of modern computational tools, WAXD patterns were simply resolved into contributions from crystalline and amorphous reflections, and a "polynomial" background (1). The degree of crystallinity was then calculated as $I_c/(I_c + I_a)$, where I_c is the diffracted intensity from all resolved crystalline reflections, I_a the diffraction intensity under the amorphous halo, and $(I_c + I_a)$ the total intensity. This was an improvement over older work where peak separation was carried out arbitrarily (eg, by simply constructing a line between intensity minima; this results in lower determined crystallinity).

Similar approaches are used today to obtain relative degrees of crystallinity from WAXD experiments, but modern curve resolving routines are frequently employed. Of course, the "raw" WAXD data must be of sufficiently high quality, having low signal-to-noise ratio (ie, the data must be obtained at sufficiently slow angular scan speeds or for sufficiently long count times), to permit reliable curve fitting. If one is interested in absolute values of the crystallinty, it is important to multiply (ie, correct) the observed diffraction peaks by Lorentz and polarization factors to obtain a more accurate estimate of the total intensity diffracted by the crystalline phase (2).

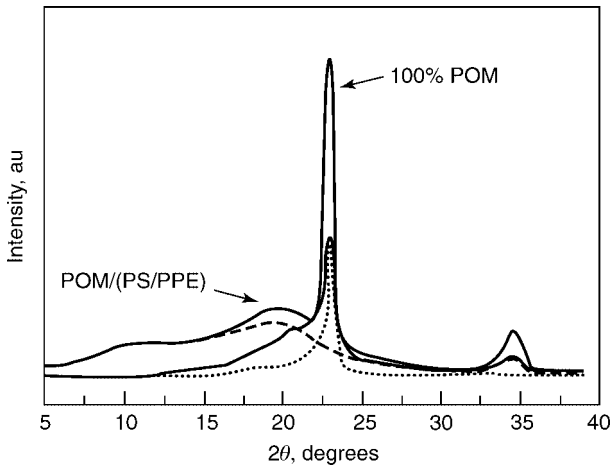

Fig. 1. Resolution of the WAXD pattern of a multiphase POM/PS/PPO blend. The experimental WAXD pattern of the ternary blend is represented by the full bold line and that of the amorphous component by the dashed line. The result after subtraction is given by the dotted line and this can be considered as the WAXD pattern of the POM phase alone. The full fine line represents normalization to 100% POM. From Ref. 3

As an example, determination of the crystallinity index of polyoxymethylene (POM) in a ternary blend with polystyrene (PS) and poly(phenylene oxide) (PPO) is presented (3). Although the latter polymer in this mixture is crystallizable, it does not do so under the processing conditions used in Reference 3. Degrees of crystallinity were estimated as the ratio of the integrated areas under the POM (100) and (105) diffraction peaks (A_{110} and A_{105}, respectively) to the total integrated diffracted intensity, ie, $X_{c,WAXD} = (A_{110} + A_{105})/(A_{110} + A_{105} + A_a)$, where A_a is the area under the amorphous halo (see Fig. 1). In this case, the amorphous halo was fit using a Lorentzian function and the crystalline reflections with a Pearson function, using commercial peak fitting software.

As another example, see the WAXD pattern for a monoclinic isotactic polypropylene (PP) in Figure 2. In this case, the amorphous halo of the semicrystalline material was obtained by scaling the diffraction pattern of noncrystalline atactic PP to obtain the best fit to the experimental spectrum. The authors of Reference 2 demonstrated that the WAXD pattern of isotactic PP at a temperature (T) greater than the melting point (T_m, 180°C in this case) was the same as that from atactic PP at the same temperature. The entire diffracted intensity from the crystalline reflections (I_c) was determined, and the crystallinity determined from $I_c/(I_c + I_a)$.

The use of traditional WAXD in the determination of degrees of crystallinity for some other semicrystalline polymers can be found in References 4–8.

As a result of the high X-ray flux available at synchrotron X-ray sources such as that at the National Synchrotron Light Source at Brookhaven National Labs, WAXD patterns (and hence degrees of crystallinity) can be determined during the course of crystallization at a specific temperature, or at programmed heating or cooling rates (see SYNCHROTRON RADIATION). Data is typically acquired over

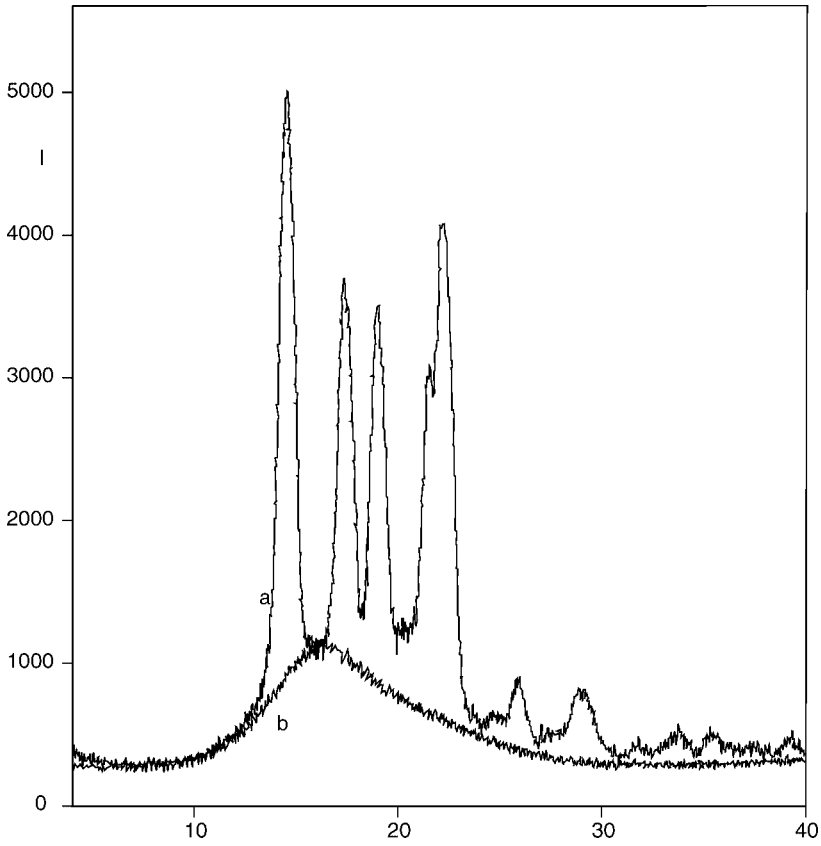

Fig. 2. X-ray diffraction patterns taken at room temperature: (**a**) isotactic polypropylene crystallized at 145°C and (**b**) a sample of atactic polypropylene. From Ref. 2.

a limited angular range in such experiments, and a crystallinity index or relatively crystallinity is generally the best one can do. In addition, such capabilities are often linked with small-angle X-ray scattering (SAXS) instrumentation allowing one to follow the development of the lamellar microstructure in real time, along with crystallinity development. References 9–13, and the references therein, provide details of such experiments on a variety of crystallizing polymer systems.

As an example, Figure 3 shows the sequence of WAXD patterns acquired (one every 30 s) during isothermal crystallization of high molecular weight PEO using a specially designed sample holder to allow for a rapid jump between the melt temperature and selected crystallization temperatures (T_c) (14). Degrees of crystallinity were determined using a curve-fitting program where the diffraction profile was separated into three crystalline PEO reflections and an amorphous halo (10). The apparent degree of crystallinity was defined as the ratio of the area under the resolved crystalline peaks to the total unresolved area. The first several patterns in Figure 3 originate from amorphous PEO. Crystallization begins subsequently and is largely complete at a time <900 s. No changes in the

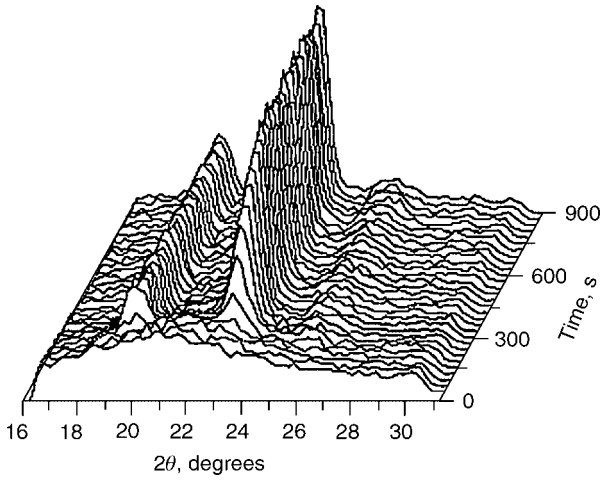

Fig. 3. Development of WAXD diffraction profiles as a function of crystallization time for PEO during crystallization at 45°C. 2θ is relative to $\lambda = 0.154$ nm. From Ref. 10.

positions of the WAXD crystalline reflections (indicative of changes in the crystalline unit cell or unit cell parameters) or the widths at half peak height (indicative of "crystallite size") were noted during the crystallization of PEO at this temperature.

Absolute Degrees of Crystallinity. Determination of the absolute degree of crystallinity from WAXD requires diffraction data over a wide angular range and correction for air scattering, incoherent scattering, and diffuse scattering arising from thermal fluctuations and paracrystalline disorder. Only a brief summary of this approach is presented here. The interested reader is directed to the original Ruland and Vonk References 15–17 as well as several more recent publications (18–20).

This approach (often referred to as the *Ruland method*) is based on the conservation of the total scattered intensity by a set of atoms, independent of their state of structural order. The experimental X-ray diffraction pattern is first acquired over a broad angular range [or equivantly, a broad s range: the reciprocal space parameter s is used here for consistency with References 16–21, where $s = (2\sin\theta)/\lambda$ and λ is the X-ray wavelength] and corrected for air and incoherent scattering. It was recognized that even completely crystalline solids exhibit diffuse scattering with corresponding loss of intensity in the crystalline reflections, as a result of thermal vibrations and imperfections in the crystalline lattice (ie, paracrystalline disorder). The absolute degree of crystallinity ($X_{\mathrm{abs,WAXD}}$) is then determined as

$$X_{\mathrm{abs,WAXD}} = \frac{\int_{s_1}^{s_2} s^2 I_c(s)\ ds}{\int_{s_1}^{s_2} s^2 I(s)\ ds} \cdot K \qquad (1)$$

where s_1 are s_2 are indicative of the angular limits of the experiment, and

$$K = \frac{\int_{s_1}^{s_2} s^2 \bar{f}^2 \; ds}{\int_{s_1}^{s_2} s^2 \bar{f}^2 D \; ds} \tag{2}$$

where $\bar{f}^2$ is the mean-square atomic scattering factor for the polymer. *D(s)* is the generalized Debye–Waller factor that takes into account thermal atomic vibrations as well as paracrystalline disorder, both of which result in crystalline peak intensities decreasing as θ (or s) increases. As for other methods discussed above, a critical feature of this procedure is the accurate separation of crystalline reflections from the overall background scattering.

Small-Angle X-ray Scattering. SAXS is an X-ray scattering method that is used frequently to investigate the lamellar microstructure of semicrystalline polymer systems; that is, to characterize structural periodicities on the order of 5–50 nm. For melt-crystallized systems, one typically observes a maximum in the scattered intensity at low angles associated with the so-called long period (L), which is associated with the mean center-to-center between lamellae. Figure 4 illustrates the room temperature SAXS profiles of a poly(L-lactide/D-lactide) random copolymer crystallized isothermally at selected temperatures. The parameter q in Figure 5 is the scattering vector [$q = \frac{4\pi}{\lambda}\sin(\theta/2)$ and θ is the scattering angle]. The

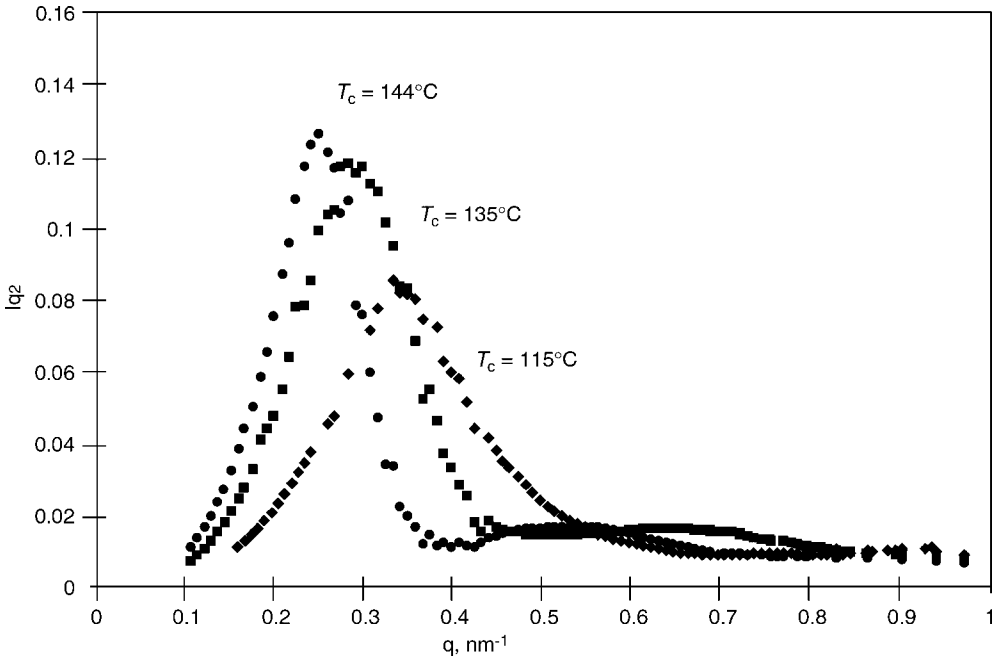

Fig. 4. Room temperature small-angle X-ray scattering patterns of a poly(L-lactide/D-lactide) random copolymer containing 1.5% D-lactide crystallized at the T_cs shown in the figure. The scattered intensities have been Lorentz-corrected (by q^2). From Ref. 22.

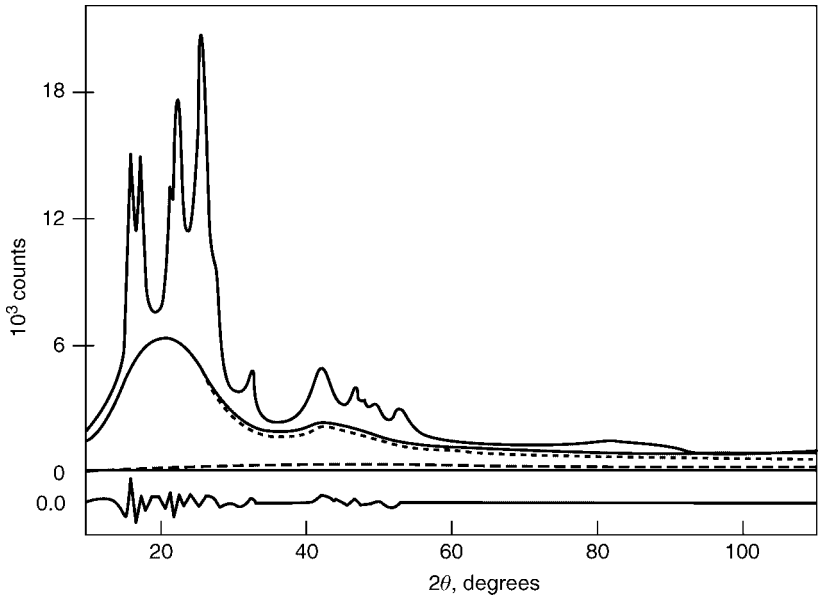

Fig. 5. Schematic of components in absolute crystallinity determination of an unoriented sample of PET. The dashed line represents the incoherent scattering and the dotted line represents the sum of the incoherent scattering and the scattering due to the amorphous component. The solid line (not bold) represents the global background scattering. The solid line at the bottom of the figure represents the residuals. The absolute crystallinity of this sample was determined to be 51%. From Ref. 18.

long periods ($L = 2\pi/q_{max}$) increase progressively with T_c, as is normally observed for crystalline polymers. Weak second-order reflections are also observed for several of these samples, particularly at higher T_c, indicating relatively well-ordered lamellar stacks.

It is sometimes assumed that the bulk degree of crystallinity is same as the SAXS "linear crystallinity." The linear crystallinity (w_c) is defined on the basis of a one-dimensional view of a lamellar stack morphology. For a stack of lamellae, the linear crystallinity is defined simply as l_c/L, where l_c is the crystalline thickness ($L = l_c + l_a$, where l_a is the amorphous layer thickness between lamellae). In the case of volume-filling lamellar stacks (the so-called "infinite stack" model), as might be anticipated for polymers exhibiting relatively high degrees of crystallinity like linear PE and PEO, the bulk crystallinity measured by another method such as WAXD or differential scanning calorimetry (DSC) would be expected to be near w_c. This has been shown to be the case in a number of instances (21). Therefore, to a first approximation, one can estimate the mean lamellar thickness for a given polymer that exhibits an infinite stack morphology from $l_c = L \cdot \phi_c$, where ϕ_c is the volume fraction crystallinity determined from DSC, WAXD, or another method.

However, this simple model is not generally valid, particularly for lower crystallinity materials. In the latter, the (linear) crystallinity of lamellar stacks can be relatively high, but the bulk crystallinity low. In this case $\phi_c = V_s \times w_c$ (where V_s is the volume fraction of lamellar stacks) and $V_s < 1$ and $w_c > \phi_c$.

Thermal Analysis

Probably the most widely used technique for determining degrees of crystallinity is differential scanning calorimetry (see THERMAL ANALYSIS). This is due to the ready availability of such instrumentation, rapid turn around time, and apparent simplicity. The heat of fusion is measured experimentally and the weight-fraction degree of crystallinity defined as:

$$X_{c,DSC} = \Delta H_f / \Delta H_f^0 \tag{3}$$

where ΔH_f is the measured heat of fusion (strictly, referred to temperature T) and $\Delta H_f{}^0$ is the heat of fusion of the 100% crystalline polymer (again, strictly, determined at T). Since ΔH_f is measure at the melting point and $\Delta H_f{}^0$ is estimated at comparable temperatures, it is important to recognize that $X_{c,DSC}$ is therefore defined near T_m, not at ambient temperature where values from other analytical methods are usually determined.

The main experimental problem encountered in measuring heats of fusion is the construction of an appropriate baseline delineating the melting endotherm from the underlying heat capacity contribution. The general equation relating measured heat capacity to thermal measurement is (23)

$$H = X_c \cdot H_c + (1 - X_c)H_a + (dX_c/dT)\Delta H_f \tag{4}$$

where H is the measured heat capacity and the subscripts c and a refer to the crystalline and amorphous states, respectively. In the melting region, the last term in equation 4 dominates and in the vast majority of the cases in the literature, a straight line is used to connect the onset to the last trace of melting. For relatively sharp-melting materials, the error involved in using a flat baseline is typically small. Some polymers, on the other hand, may melt over a wide temperature range, and it can be difficult to determine where melting actually begins. In addition, appreciable baseline curvature can arise from instrumental factors or changes in heat capacity with temperature. As a result, the simple linear baseline construction is not necessarily correct.

To avoid potential inconsistencies and uncertainties noted above, three similar methods have been proposed in literature. A brief summary of these approaches is provided below, and the interested reader is encouraged to consult the original publications. Although by all accounts these are preferred methods, they are not routinely applied in the literature.

The first of these is now often referred to as the *total enthalpy method* (24,25). In one version, the crystallinty is determined as follows (25). At a temperature T_1 below where melting begins, the total heat capacity can be written simply as

$$H_1 = X_{c,1} \cdot H_{c,1} + (1 - X_{c,1})H_{a,1} \tag{5}$$

where $X_{c,1}$ is the crystallinity at T_1 and $H_{c,1}$ and $H_{a,1}$ are the heat-capacity contributions from the crystalline and amorphous components, respectively, at T_1. At a temperature T_2 where the sample is completely molten: $C_{p,2} = C_{p,a,2}$. By

difference,

$$\Delta H_{2,1} = H_2 - H_1 = \Delta H_{a(2,1)} + \Delta H_{f,1}^0 \cdot X_{c,1} \quad (6)$$

where $H_{a(2,1)} = H_{a,2} - H_{a,1}$ and $\Delta H_{f,1}{}^0$ is the enthalpy required to convert 1 g of completely crystalline material into 1 g of completely amorphous material at T_1. Solving for $X_{c,1}$ leads to

$$X_{c,1} = m \cdot \Delta H_{2,1} - b \quad (7)$$

where $m = (\Delta H_{f,1}{}^0)^{-1}$ and $b = \Delta H_{a(2,1)}/\Delta H_{f,1}{}^0$. Equation 7 demonstrates that the degree of crystallinity at T_1 is related to the *total enthalpy* absorbed between T_1 and T_2 (measured from the DSC trace). The advantage of this method is that it provides the correct crystallinity at T_1 regardless of the path the polymer takes to T_2. However, the disadvantage is that $\Delta H_{a(2,1)}$ and $\Delta H_{f,1}{}^0$ must be known to calculate $X_{c,1}$.

A similar approach for determining $X_{c,1}$ has been proposed by Mathot and Pijpers (26,27). Finally, the so-called "First Law method" has been proposed by Hay and co-workers (28,29). This involves two measurements: (*1*) a DSC experiment that determines the enthalpy change on heating from T_1 to T_2 ($>T_m$) and (*2*) a virtual experiment determining the enthalpy change on cooling from T_2 to T_1 without crystallization taking place. The difference between steps 1 and 2 leads to a residual enthalpy; ie, the heat of fusion of the sample at $T_1 \cdot \Delta H_f{}^0$ reported in the literature is normally determined near the equilibrium melting point ($T_m{}^0$) but to determine $X_{c,1}$, $\Delta H_{f,1}{}^0$ is needed. It has been shown that the latter can be obtained from the experiments as

$$\Delta H_{f,1}^0 = \Delta H_f^0 - \int_{T_1}^{Tm^0} (H_a - H_c)\ dT \quad (8)$$

where H_a and H_c are the heat capacities of the completely amorphous and crystalline states, respectively. Once $\Delta H_{f,1}{}^0$ is determined from equation 8, $X_{c,1}$ can be calculated readily.

References 23 and 30 remain the best sources of a collection of $\Delta H_f{}^0$ values, but there has been considerable work on a variety of polymers since their publication and it is recommended to verify particular values by reference to more recent literature. Since perfectly crystalline materials are rarely available, $\Delta H_f{}^0$ values must be estimated, typically by an "extrapolation" method. For example, a series of samples of a particular polymer can be crystallized to varying degrees, and the experimental ΔH_f measured along with the sample densities. The measured ΔH_f values are then plotted vs density (or equivalently, specific volume) and the data linearly extrapolated to the density of the perfectly crystalline version of the polymer in question (19) [a value which is generally well established (see a following section)]. This extrapolation can be rather lengthy, especially for polymers of low crystallinity. In a similar fashion, measured ΔH_f values are plotted vs $l_c{}^{-1}$ and $\Delta H_f{}^0$ is obtained by extrapolating to $l_c{}^{-1} \rightarrow 0$ (31). Crystalline lamellar thicknesses are typically determined from SAXS experiments, although other

methods like the Raman longitudinal acoustic mode or microscopic techniques (ie, transmission electron or atomic force) are sometimes used. For polymers for which a series of analogs of various low molecular weights are available (eg *n*-alkane analogs for linear PE), measured heats of melting of the analogs can be plotted vs n^{-1} (where n = number of C atoms in an *n*-alkane) and ΔH_f^0 for the polymer obtained by extrapolation of the measured heats to $n^{-1} \rightarrow 0$ (32). Finally, ΔH_f^0 has been estimated from the melting point (dissolution temperature) depression observed in the presence of a miscible diluent (33). Particularly care must be exercised when using this latter approach to use equilibrium dissolution temperatures (ie, extrapolated values representing the dissolution of a perfect crystal of the polymer at a particular diluent concentration), not simply experimentally measured quantities.

Readers interested in additional background on Thermal Analysis (qv) techniques applied to polymeric materials, may see, for example, References 34–36.

Vibrational Spectroscopy

Infrared (IR) and Raman spectroscopies have been used for decades to routinely characterize polymeric and other materials. Vibrational Spectroscopy (qv), particularly Fourier transform IR (FTIR), has been used extensively to probe crystalline and amorphous conformations in a wide variety of polymers, as well as to determine a measure of the crystallinity of such materials. In the FTIR spectra of crystalline polymers, one or more absorption bands are often observed that disappear when crystallization is inhibited. Provided these bands can be genuinely assigned to 3-D crystalline order, and if the absorbance of this band in the specimen under examination is in the range for which the Beer–Lambert Law is applicable, then

$$A = \log(I_0/I) = a_c \cdot X_{c,ir} \cdot \rho \cdot t \tag{9}$$

where A is the absorbance or optical density, I_0 and I the incident and transmitted intensities, respectively, t the specimen thickness, ρ the overall density, and a_c the absorption coefficient of the 100% crystalline material. Since fully crystalline specimens are rarely available, a_c must be estimated, as will be discussed shortly. If the spectrum contains bands indicative of noncrystalline material, an expression similar to equation 9 can be written for the amorphous component.

Infrared bands should only be designated as crystalline bands if they disappear on melting, are predicted from group theory, and X-ray or other data proves the polymer to be crystalline. Only in a few rare cases have true crystalline bands been observed; for example, the 720–730 cm^{-1} CH_2 rocking doublet of crystalline PE is a reflection of a genuine crystallinity effect, as the splitting results from intermolecular interaction of segments in the orthorhombic unit cell (37). More frequently, reported "crystalline" bands are associated with a preferred crystalline conformation that may also be present (in lower concentration) in the noncrystalline phase.

As an example of crystallinity determination by FTIR, the procedure used in Reference 38 for polyethylene is summarized here. The infrared spectrum of a solution-crystallized sample of polyethylene in the region of its CH_2 rocking (and

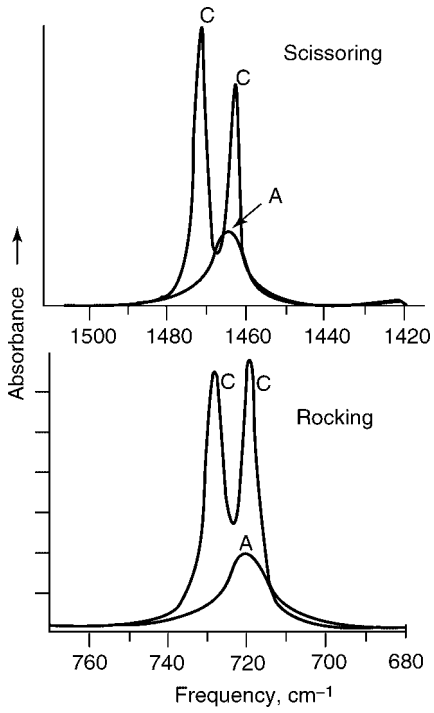

Fig. 6. FTIR spectrum of a solution-crystallized polyethylene (NIST standard SMR 1482, $M_w = 1.36 \times 10^4$) in the CH_2 rocking and bending (scissoring) regions. Pictured are the crystalline and amorphous components in each of these regions, as resolved using a band fitting procedure. From Ref. 38.

bending) modes is shown in Figure 6. The crystallinity was calculated from the ratio of the integrated intensities (absorbances) of the crystalline component in the CH_2 rocking region ($I_{722} + I_{730}$) to the total absorbance in this region. The latter is determined by $I_{722} + I_{730} + \gamma I_{723}$, where I_{723} is the contribution from the amorphous component, and γ is included to account for the fact that intrinsic intensities of the crystalline and amorphous bands are not equal ($\gamma = a_c/a_a$, where a_a is the absorption coefficient of the amorphous component). The value of γ was determined to be $\sim$1.2 in this case. Degrees of crystallinity were determined for a variety of polyethylene samples using this method and found to be the same within experimental uncertainty as those derived from DSC experiments on the same samples. This result led these authors to conclude that this FTIR method measures the "core crystallinity," as does DSC (38).

A similar approach has been used to determine the crystallinity of poly(ε-caprolactone) by FTIR, in which γ was measured by monitoring changes in the absorbances of the amorphous and crystalline components of the carbonyl band during isothermal crystallization (39). In many cases in the literature a "crystallinity index" is effectively determined, either because true crystalline or amorphous IR bands are rarely available and/or γ is assumed to be equal to 1. However, such an index may prove to be suitable for a variety of purposes.

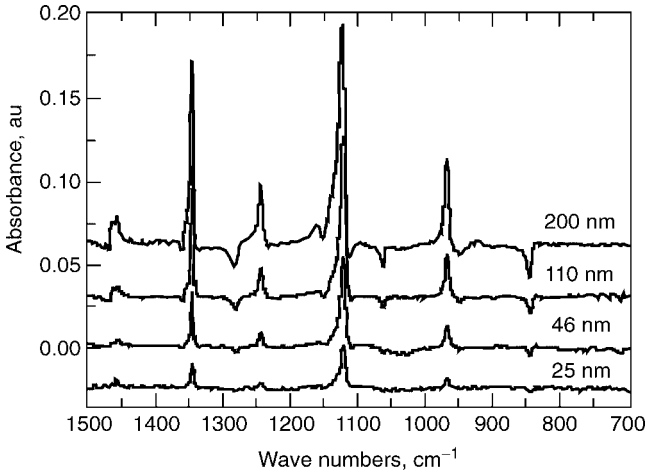

Fig. 7. Grazing incidence reflection FTIR spectra (p-polarized) of PEO (pyrene end-labeled) ultrathin films on oxidized silicon with different thicknesses (crystallized isothermally at 40°C). The negative bands are typical of grazing incidence reflection spectra on nonmetallic surfaces. From Ref. 42.

There is widespread interest in thin and ultrathin (thickness <100 nm) polymer films for use in packaging, electronics and other applications, and infrared spectroscopy is a particularly useful tool for characterizing the crystallinity in such systems. For example, attenuated total reflectance FTIR has been used to provide qualitative information on crystallinity and molecular orientation as a function of depth into drawn films of PET (40). Crystallinity measurements on ultrathin films are clearly difficult by conventional methods, but can be accomplished using FTIR spectroscopy in reflection mode (41,42). For example, grazing incidence reflection FTIR has been used to provide insight on molecular orientation as well as a qualitative measure of conformational order in ultrathin films of PEO on an oxidized silicon surface (42). Figure 7 shows grazing incidence reflection spectra of PEO films with different thicknesses. The absorbance near 1120 cm^{-1} is not sensitive to conformational order (ie, is an "internal thickness" band), and all spectra are therefore normalized to A_{1120} to permit evaluation of the relative crystallinity (conformational order) as a function of film thickness. The crystallinity was found to decrease significantly with decreasing film thickness, in keeping with the usual observation of slowing of crystallization for films with thicknesses below ca 100 nm (43,44). It has been postulated that a reduction in molecular mobility occurs in ultrathin films, resulting from the onset of diffusion control of crystallization (45,46).

Volumetric Methods

Measurement of sample densities also provides an effective way of determining degrees of crystallinity, (47–50), although this approach is not used as commonly as in the past because of the availability and ease of utilizing DSC, FTIR, and WAXD. The weight fraction degree of crystallinty can be determined from the

measured density by

$$X_{c,d} = \left(\rho_a^{-1} - \rho^{-1}\right) / \left(\rho_a^{-1} - \rho_c^{-1}\right) = (\bar{V}_a - \bar{V})/(\bar{V}_a - \bar{V}_c) \quad (10)$$

where ρ_a and ρ_c are the densities of completely amorphous and crystalline versions of the polymer in question, and $\overline{V}$ are the comparable specific volumes. The relationship between the weight fraction crystallinty and volume fraction crystallinty (ϕ_c), regardless of method used, is simply: $\phi_c = X_c\,(\rho/\rho_c)$. Values of ρ and ρ_c are generally such that ϕ_c and X_c are within several percent of each other.

Sample density can be measured using a variety of methods: density-gradient column, dilatometry, pycnometry, and flotation or buoyancy. The density-gradient column approach is probably used most frequently to determine sample densities for crystallinity measurements. When thermostated and appropriately calibrated with floats, this approach permits measurements to accuracies of 0.2 mg/cm^3 or better. Dilatometers are well suited for measuring specific volumes and following crystallization, as a function of temperature.

Although the above-mentioned techniques are routine, a number of problems can lead to errors in measured densities. For example, the solvent used must completely wet the specimen but not cause swelling, and the sample must be free of closed porosity. Solvents that induce further crystallization should be avoided.

Even in the absence of reliable ρ_a and ρ_c values, density measurements can be used for qualitative ranking of specimens of a given polymer on the basis of degree of crystallinity. Values for ρ_c are generally known reasonably well since they can be calculated from the dimensions of the appropriate unit cell for the polymer in question. The lattice parameters are determined from WAXD experiments, as discussed elsewhere in this edition. Estimation of ρ_a is generally more difficult. Some polymers can be prevented from crystallizing by quenching from above T_m to below T_g (eg isotactic polystyrene and PET) and their amorphous density can therefore be measured directly at ambient temperature. In other cases, ρ_a has been estimated by extrapolating specific volume data (from dilatometry) in the melt to ambient temperature. This extrapolation can be lengthy and introduces a degree of uncertainty in ρ_a.

It has been found in a number of cases that X_c from density and WAXD measurements is equivalent within experimental error, but is higher than that from DSC (19,47). These observations have led to the conclusion that DSC provides a measure of the core crystallinity only, while the crystallinity from density and WAXD is a measure of the core crystallinity along with the crystal–amorphous interphase.

Solid-State Nuclear Magnetic Resonance

This section provides a broad overview of the application of NMR spectroscopy to crystallinity determination in polymers. The approaches illustrated are certainly not exhaustive of those available for the powerful NMR technique and the interested reader is encouraged to consult one or more of the reference books on NMR spectroscopic investigations of polymeric materials (51–53) (see NUCLEAR MAGNETIC RESONANCE).

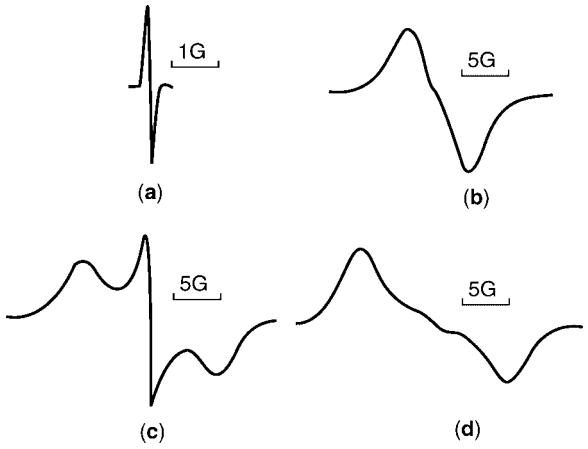

Fig. 8. Broadline ^{1}H NMR spectra: (**a**) polybutadiene at 20°C; (**b**) poly(ethylene terephthalate) at 20°C; (**c**) polyethylene at 20°C; and (**d**) polyethylene at −150°C. From Ref. 54.

Clasic Broadline ^{1}H NMR. This technique has been utilized for many decades. Broadline ^{1}H NMR spectra, the first derivatives of the NMR absorption spectra, of several polymers are shown in Figure 8.

At temperatures above their T_g, the resonance spectrum of noncrystalline polybutadiene (PB) (Fig. 8**a**) is clearly different from that of the semicrystalline polyethylene (Fig. 8**c**). Amorphous PB exhibits a narrow Lorentzian line shape with a width of ∼0.2 G. In contrast, the PE spectrum comprises two components, ie, narrow and broad line shapes. When the spectra of semicrystalline polymers are recorded in the glassy state (Figs. 8**b** and 8**d**), only a broad component is observed. This indicates that the line shape corresponds to molecular mobility and the line width reflects a correlation (or relaxation) time. Therefore, the broad and narrow components of semicrystalline PE (Fig. 8**c**) are related to protons of methylene groups in rigid and mobile (amorphous) environments, respectively. On the basis of this, it was proposed that the degree of crystallinity could be determined by resolving the area of the broad component (rigid phase) from the spectrum.

For many polymers, however, the degree of crystallinity estimated from the two-component analysis was found to be appreciably larger than that obtained from WAXD or density measurements on the same materials. In addition, although the crystallinity of PE determined by density methods remains constant below room temperature (∼60%), the broadline NMR "crystallinity" increases continuously to 100% at temperatures approaching T_g (55). Thus the area under the broad portion of the derivative curve is proportional to the number of immobile protons in both crystalline and rigid noncrystalline phases. As a result, methods to decompose such spectra into three components were developed (56,57).

Broadline NMR spectra can be expressed as

$$y(H) = w_b y_b(H, b_b) + w_m y_m(H, b_m) + w_n y_n(H, b_n) \tag{11}$$

where y_b, y_m, and y_n are the elementary spectra of the broad, medium, and narrow components, respectively, and w_b, w_m and w_n are the weight fractions of these

components ($w_b + w_m + w_n = 1$). The line widths of the broad, medium, and narrow components are b_b, b_m, and b_n, respectively. The calculated spectra of these components can be obtained as described in References 56 and 57. In the fitting process, the line widths and weight fractions of all elementary spectra are modified so as to minimize the difference between the calculated and experimental spectra. A detailed discussion and examples of the broadline H^1 NMR technique can be found in Reference 54.

Fourier Transform NMR. In Fourier transform NMR (FTNMR), a repetitive radio frequency (RF) pulse is applied in order to excite all of the nuclei of the particular nuclear species being studied. The sum of the free induction decay (FID) curves from each pulse is analyzed by a Fourier transform method in order to generate the familiar frequency domain spectra. Fundamentally, parameters such as the frequency, intensity, application time of the appropriate RF pulse, and time intervals between these pulses are important variables when using this technique. The principle of the pulsed Fourier transform technique can be found in books covering the fundamental concepts of NMR spectroscopy (58,59).

The application of a properly timed rf pulse disturbs the net equilibrium magnetization aligned parallel to the magnetic field H_0. The return of nuclear magnetization to equilibrium for solid polymers depends on the chain mobility and is monitored by the FID. The crystalline phase content can be extracted by deconvoluting the decay curve into portions corresponding to crystalline and noncrystalline components. Crystallinity determination of various polyethylene samples by FID ^{1}H NMR based on two- and three-component approaches, as well as

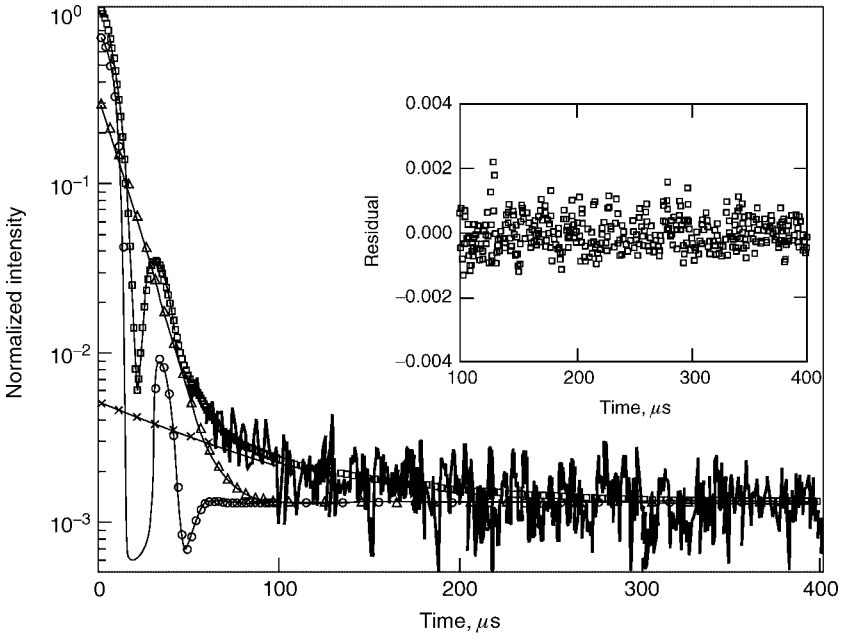

Fig. 9. FID resolution into three components for ultrahigh molecular weight PE reactor powder. The inset figure shows residuals between the observed and fitted data in the long decay region (100–400 μs). ——— Observed, □ fitted, ○ crystalline, △ intermediate, × mobile. From Ref. 62.

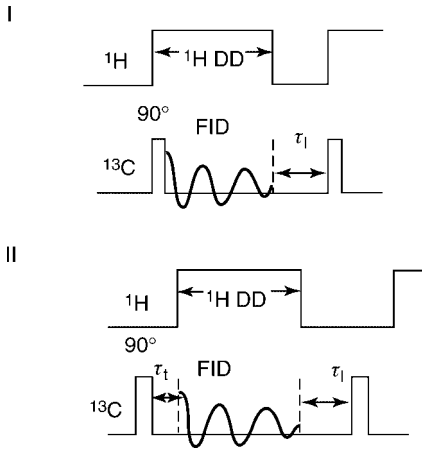

Fig. 10. Pulse sequences for DD/MAS ^{13}C NMR (without CP). From Ref. 65.

comparison of these crystallinities with those determined from other methods, is discussed in References 60–62. Figure 9 presents a summary of the FID ^{1}H NMR spectral analysis of PE, based on a three-component method (62). The crystallinity is determined by the initial normalized magnetization (zero time) of the calculated decay of the crystalline component.

The degree of crystallinity can be determined via FT ^{1}H NMR spectra as well (60,61) Similar to broadline ^{1}H NMR line shapes for the various components are fit to the experiment spectrum in order to extract that of the crystalline component, and the ratio of the area under the resolved crystalline spectrum divided by the total area represents the weight fraction of the crystalline phase. The use of this approach to determine the crystallinity of polyethylene, ethylene–vinyl alcohol copolymers and polypropylene can be found in References 60, 63 and 64, respectively.

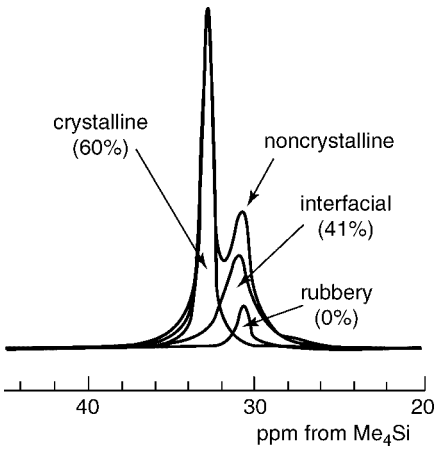

Fig. 11. Fully relaxed DD/MAS ^{13}C NMR spectrum of metallocene-catalyzed lineer low density polyethylene. From Ref. 67.

Solid-State High Resolution C^{13} NMR. C^{13} NMR with dipolar decoupling (DD), magic angle spinning (MAS), and cross-polarization (CP) can distinguish phases in semicrystalline polymers by differentiating their chemical shifts and relaxation times. Useful pulse sequences utilized to obtain NMR spectra are presented in Figure 10. Spectra with partial or total contribution from the respective components (phases) can be obtained by appropriate choice of the waiting times, τ_l and τ_t. The spectrum acquired from pulse sequences I and II depends on the material relaxation times, ie spin-lattice relaxation time (T_{1C}) and spin–spin lattice relaxation time (T_{2C}). With pulse sequence I (Fig. 10), if τ_l is longer than 5 times the longest spin-lattice relaxation time, the spectrum

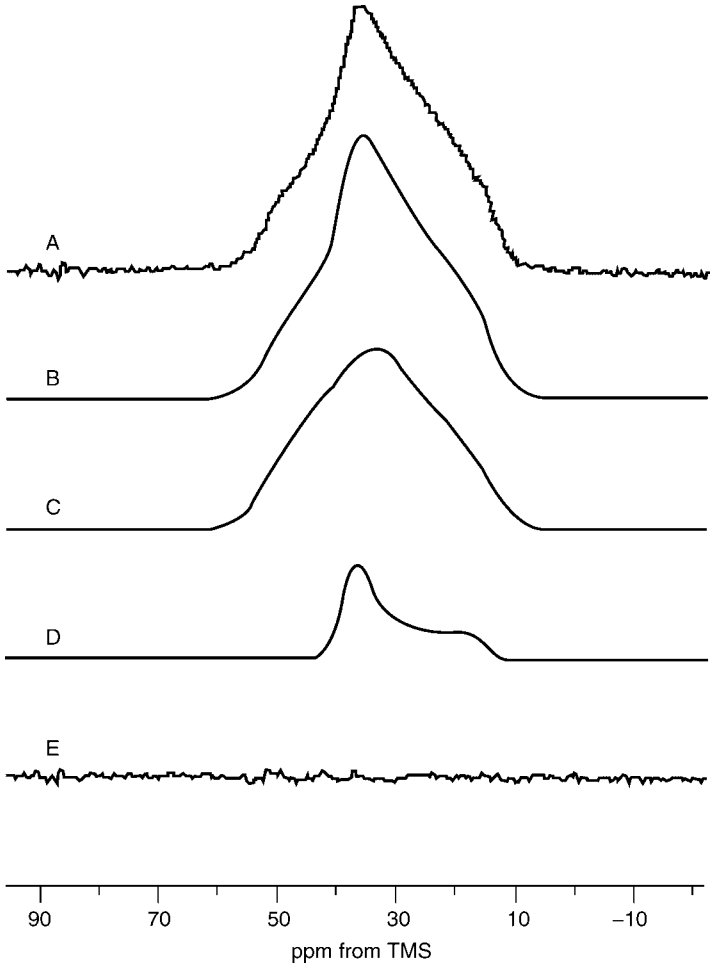

Fig. 12. A: Cross-polarized, ^1H-decoupled, static 25.152 MKz ^{13}C NMR spectrum of Phillips 6050 polyethylene. The spectral window was 5 KHz, no line broadening, 24150 transients. B: Calculated "best-fit" spectrum, the sum of the crystalline and the amorphous tensor components. C: The crystalline tensor. D: The amorphous tensor. E: Residual spectrum (A-B). The chemical shifts are relative to the methyl resonance of hexamethylbenzene (17.6 ppm from TMS). From Ref. 68.

(see Fig. 11) contains contributions from all structural phases. In order to extract the crystalline content, the location and shape of the resonance lines of each component and proper composition model are required.

For PE, it has been shown by many research groups (65–67) that the resonance line at 33, 31.3, and 31 ppm arise from the orthorhombic crystalline, the crystalline-amorphous interfacial, and the amorphous (rubbery) components, respectively. Detailed studies using different pulse sequences (varying τ_l and τ_t to extract the information of individual component from the partial relaxed NMR spectrum can be found in References 65–67. On the basis of chemical shifts of all components, the experimental spectrum is analyzed using three calculated Lorentzian curves centered at 33, 31.3, and 31 ppm, by least-squares fitting, as seen in Figure 11. In the NMR study of PE in Reference 66, the monoclinic crystal form (with the resonance line centered at 34.3 ppm) was observed in addition to the resonance of the usual orthorhombic form. Spectra were therefore analyzed using four components, using the same principles as described above.

In addition to DD/MAS ^{13}C NMR, the crystallnity of PE can be determined from the ^{1}H-decoupled/CP ^{13}C NMR. Spectra consist of contributions from the different phases, which are differentiated by their shielding tensors (anisotropic chemical shift), as seen in Figure 12 (68). The crystalline fraction is estimated from the ratio of the area under the crystalline tensor to the total area.

In summary, the key feature of these approaches is the deconvolution of the spectrum of interest, which is sensitive to the presence of the different phases, into spectra corresponding to each component. Although the above discussion focused on semicrystalline polyethylene, detailed discussion of crystallinity measurements by ^{13}C NMR for other selected polymers can be found in the following references: poly(vinyl chloride) (69), polypropylene (70), and polylactides (71).

Finally, in addition to ^{1}H and ^{13}C NMR, ^{19}F NMR has proven to be very useful for determining the degree of crystallinity of fluoropolymers such as polytetrafluoroethylene (72,73).

CRYSTALLIZATION KINETICS

Introduction

Crystallizable polymers form semicrystalline materials containing chains or fractions of chains that are trapped in nonequilibrium, amorphous states. Because of this semicrystalline nature, the crystal morphology, rather than the underlying crystal structure, often controls the final properties of a polymer article (see SEMICRYSTALLINE POLYMERS; MORPHOLOGY). Simply by changing the processing conditions, the mechanical properties, for example, Young's modulus, of a typical polymer such as polyethylene can be altered by several orders of magnitude.

Because polymers crystallize so far from equilibrium conditions, a simple examination of the phase diagram gives us little insight into the crystal morphology that is formed or the route that is taken to its formation. To understand, and ultimately control, such behavior, it is necessary to gain an understanding of the kinetics of crystallization, as it is the kinetics of the process that define the structure and properties of the material.

The above insight, gained soon after the discovery of polymer single crystals, and the subsequent discovery of chain folding (1–3), has mapped out the route taken by much of the research into polymer crystallization over the subsequent decades. It soon became clear that the thickness of polymer lamellae was controlled by the supercooling at which they were crystallized and defined by the kinetics of crystallization. The crystal thickness, or alternatively the thickness of each new crystalline layer in a growing crystal, is the one that grows the fastest (4,5) rather than the one that is at equilibrium (6). There is now a wealth of information available on the crystallization of many polymers, as well as several theories that aim to predict the crystallization rates, crystal shapes, and lamellar thickness.

Crystallization kinetics is the area of polymer science that deals with the rate at which randomly ordered chains transform into highly ordered crystals, and includes every aspect of the resultant structure that is dependent on the route that was taken between those different states. It is a broad and mature area of scientific research, given an uncommon diversity when compared to the crystallization of small molecules because of the wide range of different chemistries and chain topologies that are available to macromolecules. These add layers of complexity that can make it difficult to find generalizing principles. For the sake of brevity, this article, therefore, concentrates on areas that are of particular interest to the author, and to principles and observations that have, in the author's opinion, the widest applicability.

As in any transformation, it is possible to measure bulk rates of polymer crystallization and to characterize the process in terms of the shape of these transformation curves. Because of limitations on space the interested reader is pointed toward the relevant literature (7–12), as this approach, although useful for quantifying experimental observations, does not attempt to provide an insight into what is happening at the molecular scale. Polymer crystallization, like many phase transitions, occurs through a process of nucleation and growth, and it is often more revealing to look at the rates of these two processes independently, and to try to gain an understanding of the factors affecting each. Although of fundamental importance, the nucleation step is still poorly understood and only

occasionally studied. The next section outlines the key experimental data and the theories that have been developed to explain this data. A brief look at some more recent approaches is also given. The majority of this article considers the growth process itself, concentrating on linear, flexible polymers as this is where the most complete data set is available, but also touching on more complex materials. An outline of the theories that have been developed to explain and predict crystallization behavior is also given, concentrating on their fundamental assumptions and predictions rather than their mathematical intricacies.

Nucleation

Any supercooled or supersaturated system contains local fluctuations in order and density, which will, at times, correspond to crystallographic order. These crystalline regions are known as embryos and offer the chance, but not the certainty, of starting the process of phase transformation. Most of these embryos are short-lived, but there is a small probability (depending on the supercooling or supersaturation) of any particular fluctuation reaching a critical size. This critical size is the size at which it is in unstable equilibrium with the surrounding phase—it has formed a critical nucleus, and there is a high probability of it continuing to grow to macroscopic size.

Nucleation can be divided into homogeneous nucleation and heterogeneous nucleation, the former being the sporadic formation of critical nuclei from the pure phase, the latter occurring at the surface of impurities within the system. In high polymers heterogeneous nucleation dominates in most cases (13). Heterogeneous nucleation can be divided into different classes; epitaxy, in which there is a lattice match [usually within 10% (14,15)] between a crystal plane in the polymer and a free surface in the "impurity", and nonspecific surface nucleation, in which the presence of the impurity surface leads to a chain conformation closer to that in the crystal. A final class of nucleation is self-nucleation, in which during the melting of the polymer the temperature was too low, or the time at that temperature too short, to allow the whole sample to melt. This is particularly common in polymers and is caused by the broad range of melting temperatures typically present in any sample because of a combination of factors including the range of crystal sizes, molecular weight, chain perfection, and local environment. Small crystalline "seeds" are left in the sample, which then act as epitaxial sites for nucleation on cooling (16,17), leading to the name "self-seeding" being applied to this form of nucleation.

Experiments on Nucleation. The most commonly observed crystal morphology when polymers are crystallized from the quiescent melt is the spherulite (see SEMICRYSTALLINE POLYMERS) (18). Figure 1 shows a typical polarized light micrograph of the growth and intersection of a spherulitic sample, from which it can be seen that the individual spherulites intersect with each other to form polygons with straight sides. It is immediately apparent that, assuming the growth rate is constant across the sample, all of the nucleation sites must have become active at the same time, that is, the growth of all the spherulites started at the same time. If the same sample is melted and then recrystallized at the same temperature, the spherulites grow back in the same place. Nucleation is heterogeneous under these most common circumstances, occurring on impurities or added nucleating

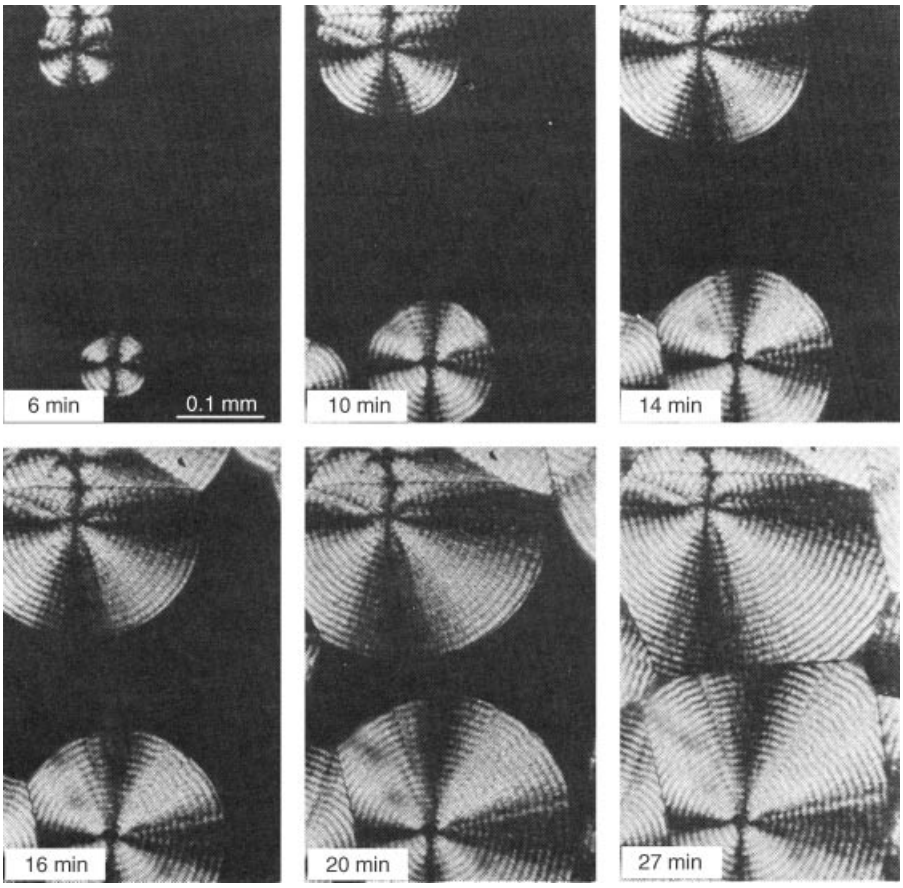

Fig. 1. A series of images showing the growth of spherulites of polyethylene. The uniformity of spherulite size, and the linear intersection of the spherulites once crystallization is complete, can be clearly seen. Exposures taken after the marked times. Optical micrographs with the sample between crossed polars. Reprinted from Ref. 19. Copyright (1982), with permission from John Wiley & Sons, Inc.

agents. Measurement of the size of the spherulites gives a measure of the number of nuclei per unit volume, and the variation of this with temperature can be simply obtained (20). Some polymers behave differently, nucleation occurring more sporadically, giving a measurable nucleation rate as a function of crystallizable volume at a particular temperature (21,22). An example of this behavior is shown in Figure 2 for polyethylene succinate, with the variation with molecular weight also included. Whether this nucleation is actually homogeneous, or if the number of heterogeneities and their relative activity is just low, is unclear.

Great lengths have been gone to in order to obtain truly homogeneous nucleation rates. Initially, one of the driving factors for this work was to obtain a figure for the side surface free energy for use in secondary nucleation crystal growth theory. In systems such as polyethylene, where nucleation rates are high and purity is low, it is necessary to divide the sample up into a large number of droplets

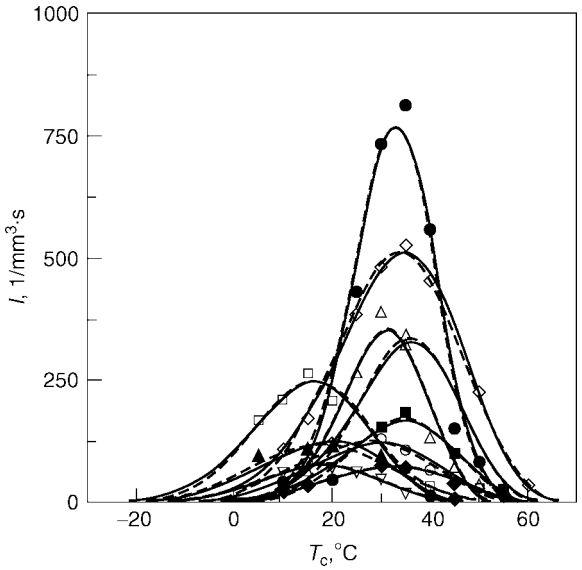

Fig. 2. A graph showing the temperature dependence of the nucleation rate for a series of different molecular weight fractions of polyethylene succinate. The molecular weight shown is the peak molecular weight as measured by GPC. mp: □ 1,160, ▲ 2,060, ▽ 3,380, ◆ 4,660, ○ 6,670, ■ 8,770, △ 10,980, ▼ 13,660, ◇ 18,340, ● 21,210. Reprinted from Ref. 23. (19,24–27). Many of the droplets will contain impurities and nucleate relatively early in the experiment; however, some will remain amorphous for long times, and, if the rate of nucleation in these droplets is measured, the variation of nucleation rate with temperature can be obtained. If the nucleation is truly homogeneous, and the droplet size is monodisperse, the nucleation rate should, at a particular temperature, depend only on the sample volume. Recently, similar experiments have been carried out on phase-separated block copolymers, in which the crystallizable domains are isolated spheres in the hard (or semihard) segregation limit (28,29). An example of data obtained by these two different methods is shown in Figures 3 and 4.

Nucleation Theory. Classical theories for nucleation in small molecules balance the reduction in free energy that occurs because the solid is more stable than the supercooled liquid against a surface term that accounts for the free-energy cost of creating a solid–liquid interface. For a spherical crystallite this is given by

$$\Delta G = \frac{4}{3}\pi r^3 \Delta G_v + 4\pi r^2 \sigma \tag{1}$$

Where ΔG is the Gibbs free energy, r is the radius of the sphere, ΔG_v is the difference in free energy between the bulk fluid and bulk crystalline phase, and σ is the surface free energy of the crystal fluid interface. The function ΔG goes through a maximum at the critical nucleus size, resulting in a nucleation barrier—the maximum in the increase in free energy necessary to form the critical

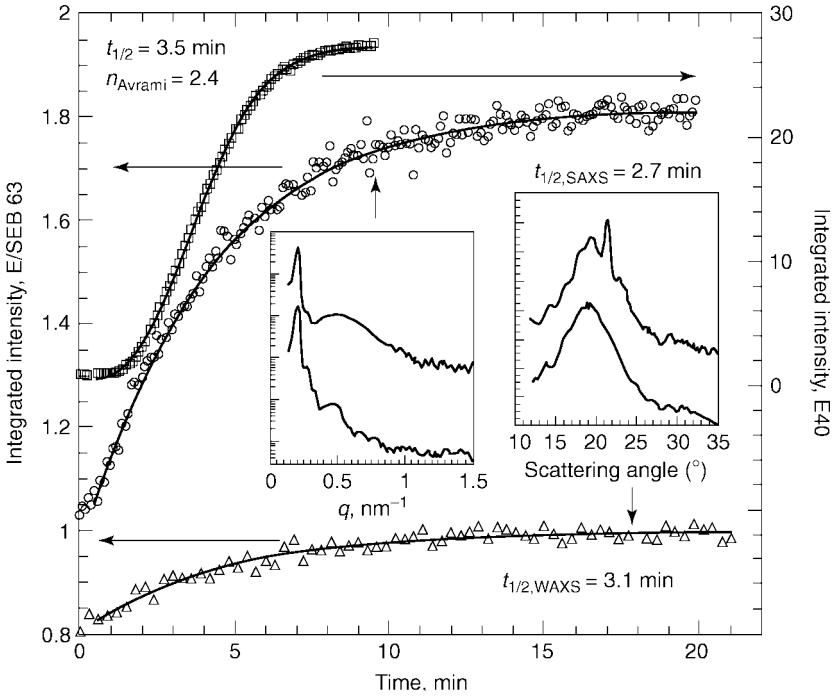

Fig. 3. A composite graph showing the crystallization of micro phase-separated spheres of E/SEB63 (polyethylene block styrene–ethylene–butene). The polyethylene block exists in spherical domains with a radius of 12.7 nm in a matrix of rubbery material. At sufficiently high supercoolings the polyethylene nucleates separately in each domain. The graph shows the time course of the integrated small-angle X-ray scattering (middle curve) and wide-angle X-ray scattering (bottom curve) intensities for E/SEB63 crystallized at 67°C (the insets show the regions of integration). The SAXS intensity for the polyethylene (E40) homopolymer, which shows a sigmoidal time evolution, is shown for comparison (top curve, 95°C, similar half-time). Reprinted from Ref. 28. Copyright (2000), with permission from the American Physical Society.

nucleus—given by

$$\Delta G^* = \frac{16\pi\sigma^3}{3(\Delta G_\upsilon)^2} \tag{2}$$

For polymers the situation is changed by two factors. Firstly, the connectivity along the chain of identical crystallizing units means that the nucleus is unlikely to be spherical, and a better first approximation is a cuboid. Secondly, the end surface (the surface perpendicular to the chains) has a very different energy from the side surface. These lead to a slightly different equation, allowing for the different geometry, given by

$$\Delta G = -\upsilon\mu l a_0 b_0 \Delta G_\upsilon + 2\mu\upsilon a_0 b_0 \sigma_e + 2\sigma l(\mu b_0 + \upsilon a_0) \tag{3}$$

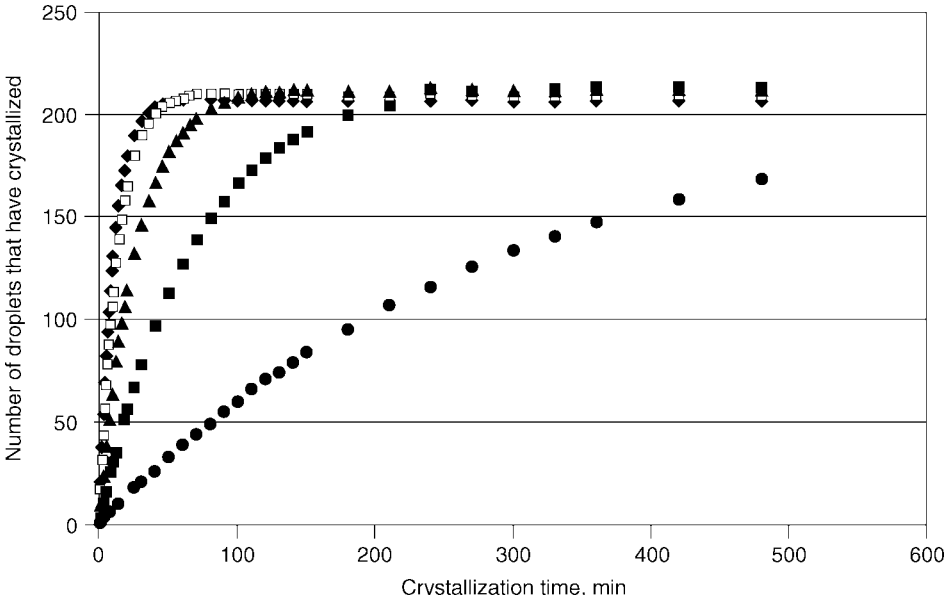

Fig. 4. A graph showing the rate of nucleation of droplets of polyethylene. Isolated droplets are produced by spraying from solution. As the droplets are only ~1 μm in size, most of them do not contain large heterogeneous nucleating agents so high supercoolings can be reached. The nucleation rate can be measured directly by counting the number of droplets that have crystallized as a function of time. The data were all collected from the same preparation of droplets, which could not be cooled below 87°C without all the droplets crystallizing. ◆ 87.5°C, □ 88.4°C, ▲ 89.6°C, ■ 90.1°, ● 90.8°C. Reprinted from Ref. 27. Copyright (2000), with permission from Kluwer Academic Publishers.

Where ν and μ are the number of stems in the length and breadth of the lamella, a_0 and b_0 are the cross-sectional dimensions of a stem, l is the thickness of the lamella, ΔG_v is the difference in bulk free energy between the crystalline and liquid phases, σ_e is the fold surface free energy, and σ is the side surface free energy. This then leads to the rate of formation I of folded chain nuclei given by

$$I = I_0 \exp\left[\frac{-\Delta F_D}{kT}\right] \exp\left[\frac{32\sigma^2\sigma_e(T_m^0)^2}{kT(\Delta T)^2(\Delta H_v)^2}\right] \tag{4}$$

which is equivalent to the well-known Turnbull–Fisher equation (30). The factor ΔF_D here corresponds to the energy barrier affecting transport of material across the crystal–liquid interface, and, under the assumption that this is an activated process, leads to the first exponential term. I_0 is essentially temperature-independent and depends on molecular parameters, ΔH_v is the enthalpy of fusion per unit volume, T_m^0 is the equilibrium melting temperature, and k is the Boltzmann constant. Heterogeneous nucleation is introduced simply by altering one of the side surface energies to allow for the relatively low energy penalty associated with the formation of a polymer-nucleating surface interface (13). Experimental studies (19,24–27) are broadly in agreement with the predicted behavior for the

supercooling dependence of nucleation rate under conditions of homogeneous nucleation.

Equations 3 and 4 apply to nucleation with chain folding, and so for a high molecular weight polymer only one or a few molecules might be involved in a single nucleus. This situation could occur in dilute solutions, but seems unlikely as the concentration is increased, or in the melt. An alternative is to assume that the nucleation is of a bundle of stems, each stem coming from a different polymer chain, forming a ciliated or "fringed-micelle" nucleus. Now, in addition to the unfavorable entropy contribution from demixing the polymer from solution, there is an unfavorable contribution from the restrictions on the conformations accessible to the noncrystalline portion of the polymer molecules imposed by their incorporation into the nucleus. Flory (31) [and later Mandelkern (32)] considered these contributions in his original work on polymer crystallization, and, although some of the initial assumptions have proven to be in disagreement with experiment, the resulting formalism is still relevant under certain situations such as the crystallization of parts of chains confined between lamellae. This approach leads to the following expression for the free energy of formation of a ciliated crystal, in the limit of high dilution (polymer volume fraction tends to zero):

$$\Delta G = -\upsilon\mu l a_0 b_0 \Delta G_\upsilon + 2\mu\upsilon a_0 b_0 \left(\sigma_e - \frac{kT \ln \nu_2}{2a_0 b_0}\right) + 2\sigma l(\mu b_0 + \upsilon a_0) \qquad (5)$$

where ν_2 is the volume fraction of polymer.

Testing the above theories, which are in essence just classical nucleation theory applied to polymers, has proved problematic because, as already mentioned, under most circumstances nucleation is heterogeneous and often virtually instantaneous. In the case of polyethylene, it is necessary to divide the polymer into such small volumes in order to observe something that might be homogeneous nucleation that the effect of the surfaces of the droplet might well start to play a significant role (33,34). Studies using block copolymers, although of great value, are studying nucleation in a different polymer, and the effect of connectivity to an uncrystallizable unit is complex (35).

Recently, several groups have reported data collected in the early stages of crystal growth that they have interpreted as being evidence of spinodal decomposition in the melt prior to nucleation and growth (36–38). These follow from similar suggestions made in the 1980s (39–41). The interpretations are based around the observation of small-angle X-ray scattering (SAXS), usually associated with the formation of lamellae, prior to the wide-angle signal that comes from crystallographic order. The evolution of the SAXS signal in this initial stage is characterized by first-order kinetics (Avrami exponent of one), and identified with a spinodal-like transformation. This is a difficult area, as identifying the point at which an increasing signal rises above the background noise is not clear-cut (38,42), and there are many problems associated with comparing wide- and small-angle data (38). It has been proposed that the components of the melt that are phase-separating are segments of the chain that are closer to, and further from, their crystalline conformation. This separation is driven by a coupling between density and order in the chain, in that by aligning, for instance, similarly helical chains they are able to pack more closely and increase the local density

(43). Thus the melt separates into regions of higher order/density and lower order/density, and nucleation is more likely to occur in the already more ordered regions. The "phase" separation drives a change in order into a state that is still far from crystalline, but has a higher probability of crystallizing than the initially supercooled melt. If the transformation occurs under conditions of constant pressure, as is usually the case, it will eventually result in an overall densification of the melt. The theory is internally consistent, but there is still an active debate as to whether or not it actually applies to the experimental situation. A priori, it seems more likely that it is of relevance to polymers with more rigid chains, and crystallization at high supercoolings.

Crystal Growth

In this section an overview of key experimental results on the growth of polymer crystals is given, concentrating on linear molecules with simple chemistry and moderate molecular weight. Although these molecules are the most commonly used in industrial applications, there are many other types of behavior that are markedly different, and some indication of these perturbing effects is given. This will provide the data against which any theory should be tested, and it is the basis of the different theories that are discussed in the next section. Finally, over the last 10 years, there has been a spate of new ideas, due both to the data provided by new experimental techniques such as synchrotron x rays and scanning probe microscopy and to the increasing power of computer simulation. These new approaches are covered in the last section.

Key Experimental Results. Polymer crystals grow in the form of lamellae in which the chain axis is oriented approximately perpendicular to the basal plane (1). As these lamellae are typically between 5 and 50 nm in thickness, the chains must fold back on themselves, reentering the same crystal many times. The extent to which chains reenter the crystal on average at the adjacent lattice site, or elsewhere, has been a subject of argument for 40 years (44). Although the exact nature of this "chain-folding" is still not agreed upon it is this morphological characteristic that signals most clearly the importance of kinetics in polymer crystallization. It has been widely accepted since the early 1960s that the equilibrium polymer crystal contains chains that are extended. The lamellae that are commonly observed are thinner than this, as the most rapid way that the available free energy can be consumed is by the formation of fast-growing thin crystals rather than slow-growing thick crystals.

Figure 5 shows a plot of crystal thickness vs supercooling, showing the increase in crystal thickness that occurs as the melting temperature is approached (45,46). The graph includes data for both solution and melt crystallization, showing that it is not the absolute temperature that is the controlling factor on crystal thickness, but rather the supercooling (or supersaturation) at which crystallization occurred. Supercooling is here defined as the equilibrium melting temperature (T_m^0) minus the crystallization temperature, where the equilibrium melting temperature is the temperature at which an equilibrium, infinite, extended chain crystal would melt. These data were collected for polyethylene, but similar data exist for a range of other polymers. The supercooling controls the crystal thickness,

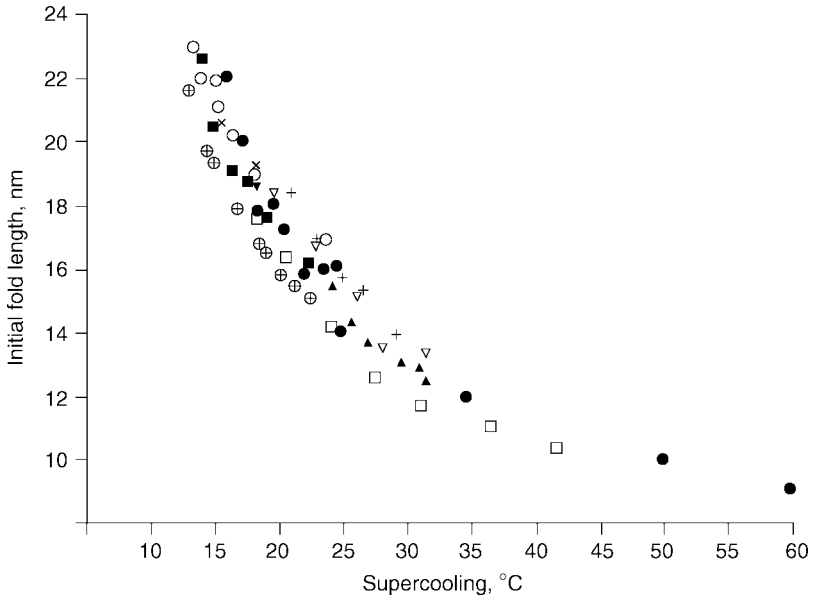

Fig. 5. A graph showing the variation of the fold length (l) with supercooling (ΔT) for polyethylene crystallized from a variety of solvents and from the melt. In the case of solvent crystallization, supercooling is taken with respect to the so-called equilibrium dissolution temperature. For the melt-crystallized data set the equilibrium melting temperature is used. The remarkable coincidence between the curves, despite the wide range of absolute temperatures to which each supercooling corresponds, is strong evidence in favor of the kinetic origin of crystal thickness selection. Solvents: □ xylene, ■ hexyl acetate, ⊕ ethyl esters, ○ dodecanol, ▽ dodecane, ▲ octane, × tetradecanol, + hexadecane, ● melt crystallized. Reprinted from Ref. 44. Copyright (1985), with permission from Kluwer Academic Publishers.

and the thickness that grows is just thicker than the minimum stable thickness at that temperature. This minimum stable thickness comes from the balancing of the increase in energy due to the presence of the crystal melt interface, with the reduction in free energy due to the bulk free energy of the crystal—that is, the Gibbs–Thomson equation. In the case of lamellae with large lateral dimensions this can be simplified to give

$$l_{\min} = \frac{2\sigma_e}{\Delta F} \tag{6}$$

where $l_{\min}$ is the minimum stable thickness, σ_e is the fold-surface free energy, and ΔF is the bulk free energy of crystallization per unit volume.

Interestingly, despite this clear evidence of the influence of kinetics on morphology, the crystal structure itself, and in many cases even the topology of the noncrystalline fold surface, seem to be controlled by equilibrium considerations (47). Recent computer simulations (48), in which a random polyethylene fold surface was allowed to relax, resulted in a 201 crystallographic fold plane, in agreement with experimental observations of crystallization (49).

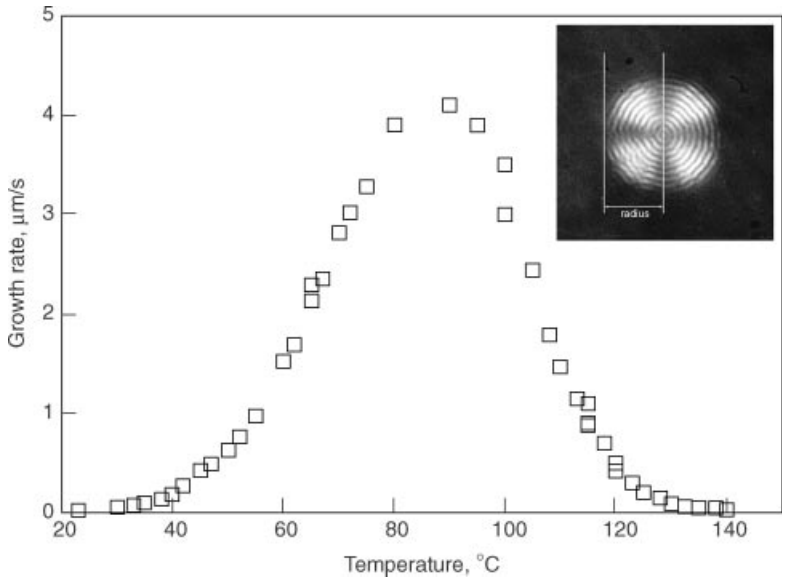

Fig. 6. A graph of the variation in growth rate with temperature for poly(hydroxybutyrate), showing the typically observed bell-shaped temperature dependence, with the crystallization rate reducing to zero well before the equilibrium melting temperature (∼198°C for this polymer) and, after passing through a maximum, again reducing to zero before the glass-transition temperature (∼0°C). (Unpublished data of the author.)

As detailed in the article on semicrystalline polymers, polymer lamellae, when crystallized from the melt, typically form aggregates. The most common of these aggregates, if the melt is unperturbed, is the spherulite. The growth rates of spherulites have been measured as a function of crystallization temperature for a wide range of different polymers. These rates are found to be approximately constant at a particular temperature for a particular polymer sample. An example of the variation in growth rate with temperature of polyhydroxybutyrate, a biodegradable thermoplastic, is shown in Figure 6. A bell-shaped relationship is apparent, typical of glass-forming liquids. Similar data have been obtained for many other polymers, the lower limit of the growth depending on the glass-transition temperature of the material, the upper limit depending on the melting temperature, and the peak rate varying from only a few nanometers per second to hundreds of micrometers per second, depending on the polymer. The inset shows an optical micrograph of a growing spherulite from which rate measurements can be made. The rate that is measured in a typical experiment is the average growth rate of many lamellae as they grow over a distance of several microns. It is not the growth rate of an individual lamella, and is certainly not measured over length scales comparable with either the size of the unit cell, or even the thickness of a lamella. This is simply a result of using diffraction-limited optics to measure rate.

It is common practice to replot ln(growth rate) against $1/T\Delta T$, so as to linearize the data and to allow its analysis in the context of secondary nucleation theory (see section under Secondary Nucleation Theory). A large body of data

exists in which these essentially linear plots contain one or two changes in slope, and the different linear portions are associated with different "regimes" of growth (50–58). This is a difficult area, and has been the subject of debate for many years (58,60). There certainly are instances when a true change in the temperature dependence of growth rate occurs, in many cases accompanied by a change in the crystal morphology. A systematic survey of the effect of varying the additional transport term that is often included in the y-axis of the plot, or of the often imprecisely defined value of $T_m{}^0$, is not available. However, growth rate is clearly exponentially dependent on $1/T\Delta T$ at small supercoolings.

The rate of growth is influenced not only by molecular architecture and temperature, but also by molecular weight (61). Figure 7 shows the effect of molecular weight on growth rate for a series of different molecular weight fractions of polyethylene succinate (62). The variation in growth rate with molecular weight leads to complex effects during polymer crystallization, as in all high polymer

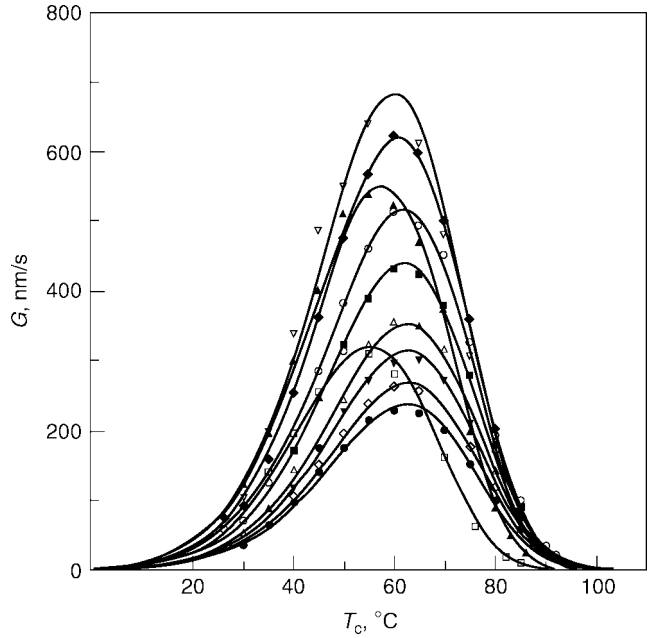

Fig. 7. A graph showing the variation in linear crystal growth rate with temperature for a series of different molecular weight fractions of polyethylene succinate, showing the typically observed behavior. Again, the molecular weight shown is the peak molecular weight as measured by GPC. In Ref. 61 the authors obtain a "master curve" for polymer growth rate by plotting the reduced growth rate G/G_{max} (where G is the growth rate and G_{max} is the fastest growth rate exhibited by the particular polymer sharp fraction) against the reduced temperature T/T_{cmax} (where T is the crystallization temperature and T_{cmax} is the temperature at which the maximum growth rate occurs). This leads to the intriguing possibility of a universal relationship between growth rate and molecular weight. In particular, it is found that the molecular weight dependence of G_{max} can be expressed as a power law, G_{max} proportional to MW^{α} where α depends on the adsorption mechanism for polymer molecules on the growth front and is equal to -0.5 for folded chain growth. MP: □ 1,130, ▲ 2,080, ▽ 3,220, ◆ 4,590, ○ 6,570, ■ 9,150, △ 10,900, ▼ 13,700, ◇ 17,900, ● 21,600. Reprinted from Ref. 62. Copyright (2002), with permission from Elsevier Science Ltd.

samples there is a distribution of chains with different molecular lengths. Careful studies of the molecular weight distribution within the crystallized and uncrystallized portions of a sample at different stages of growth have shown a remarkable degree of fractionation (63,64). At high temperatures the longest chains crystallize most readily and so fractionation occurs during growth, leaving the shorter molecules to either crystallize more slowly later, or on cooling if the distribution of lengths is very broad. At lower temperatures, the shorter chains are able to crystallize more rapidly, due to their shorter relaxation times, and thus they will have a stronger influence on the measured growth rate. The extent of fractionation, particularly apparent during solution crystallization, has lead to the suggestion that there must be a process of "molecular nucleation" (65), in which each molecule nucleates on the growth front as a separate object rather than the important step being the nucleation of parts of a chain or chains. This provides a mechanism by which the growth process can "feel" the molecular length of each chain that attaches to the growth front. A fuller discussion is given in Reference 65.

Crystallization studies carried out in dilute solution have frequently been used to gain additional insights into the process of growth, as the crystallizing lamellae can be more straight forwardly examined by electron microscopy after their growth (66,67). Figure 8 shows an atomic force microscope (AFM) topography image of a typical single crystal of polyethylene, from which the very regular crystal thickness can be seen. The well-defined crystallographic shape is typical of solution-grown crystals of many (but not all) polymers, their exact shape depending on the underlying crystallography and the interplay of growth rates of the different crystal faces, which also varies with crystallization temperature (see SEMICRYSTALLINE POLYMERS for more detail on crystal shape). Crystal thickness is typically plotted against the equilibrium dissolution temperature, a temperature that has an ill-defined meaning (68,69), but these plots give a remarkably similar temperature dependence of thickness to that seen for melt crystallization, in the case of polyethylene. Despite technical difficulties, growth rates as a function of temperature can be measured by careful experimentation (70–75), and can be plotted to give an approximately linear relationship with $1/T\Delta T$. An example is shown in Figure 9. The additional complexity that the effect of polymer concentration adds to the story has been studied in some detail (71–75), but is beyond the scope of this review.

There are many factors that can affect the way crystallization occurs, and lead to differences from the above outlined pattern of behavior. Linear homopolymers consist of repeating units, all of which can crystallize. Even in this simple case, the end groups are chemically different from the rest of the chain, and this can lead to some perturbations in behavior. End groups are usually excluded to the surface of crystals (76). For low molecular weight polymers ($M_w < 10{,}000$), the presence of end groups starts to play a role in the rate of crystallization (77–79). In polymers of very uniform molecular weight, such as the monodisperse alkanes (78), and sharp fractions of low molecular weight poly(ethylene oxide) (77,79), local minima in the variation in free energy with crystal thickness exist, such that the formation of crystals that are an integer fraction of the extended chain crystal thickness is strongly favored. In this case, steps and even minima in growth rate are observed in the region where the crystallization temperature allows thinner crystals to become stable (80). An example of these local minima in growth

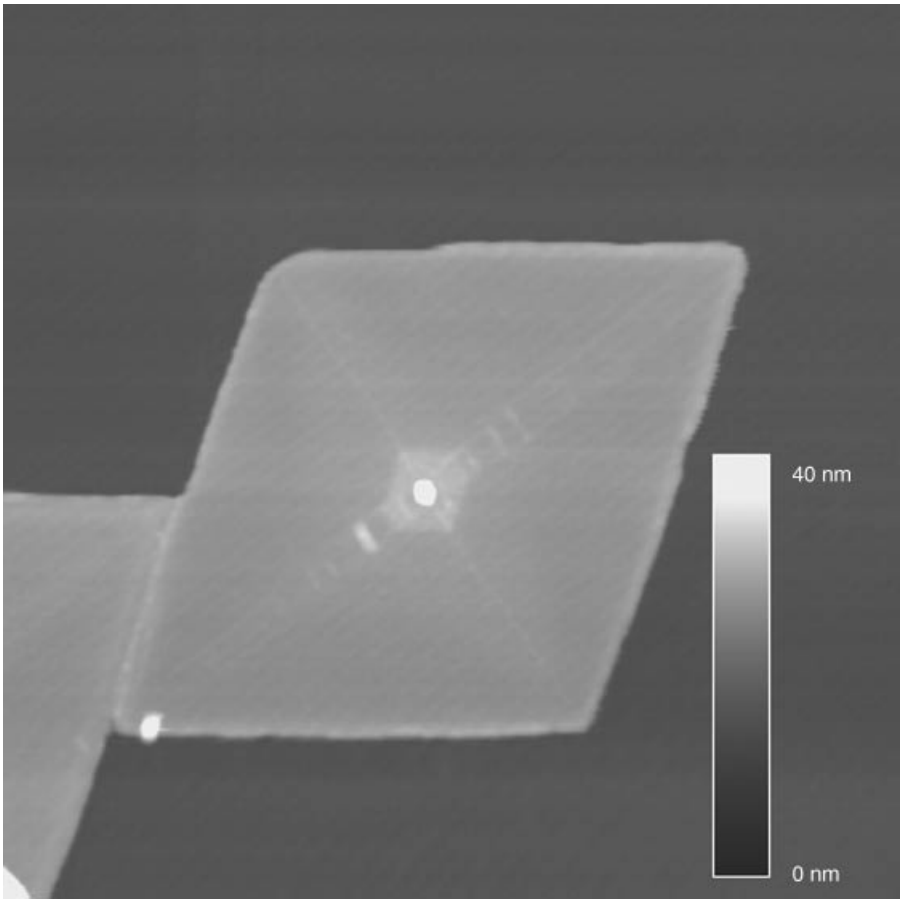

Fig. 8. An AFM topographic image showing a group of single crystals of polyethylene crystallized from xylene at 70°C. The grey scale shows the variation in height, from which the very uniform thickness of the crystal can be clearly seen. (Unpublished data; image courtesy of Dr. A. K. Winkel).

rate is shown in Figure 10 (81). These minima occur because of competition at the growth front between different metastable "phases"—for example once-folded and twice-folded crystals (82).

If copolymers are crystallized, it is necessary to consider the cocrystallizability of the different chemical species (31), the length and distribution of sequences, the miscibility of the melt (ie, do the comonomers mix) (83), and many other factors (84). These areas have all been extensively studied, and are still the subject of active debate. However, the recent advent of more controlled techniques for polymerization offers hope of reaching a greater understanding. In most cases, one of the copolymer species will crystallize, excluding the other from its lattice. Crystals can only form if sequence lengths are sufficiently long to span the thickness of the crystal, and so an additional control on crystal thickness, on top of kinetics, is added. It is now necessary to sort the molecules at the growth front so as to access the crystallizable sequences, and this additional step slows the growth

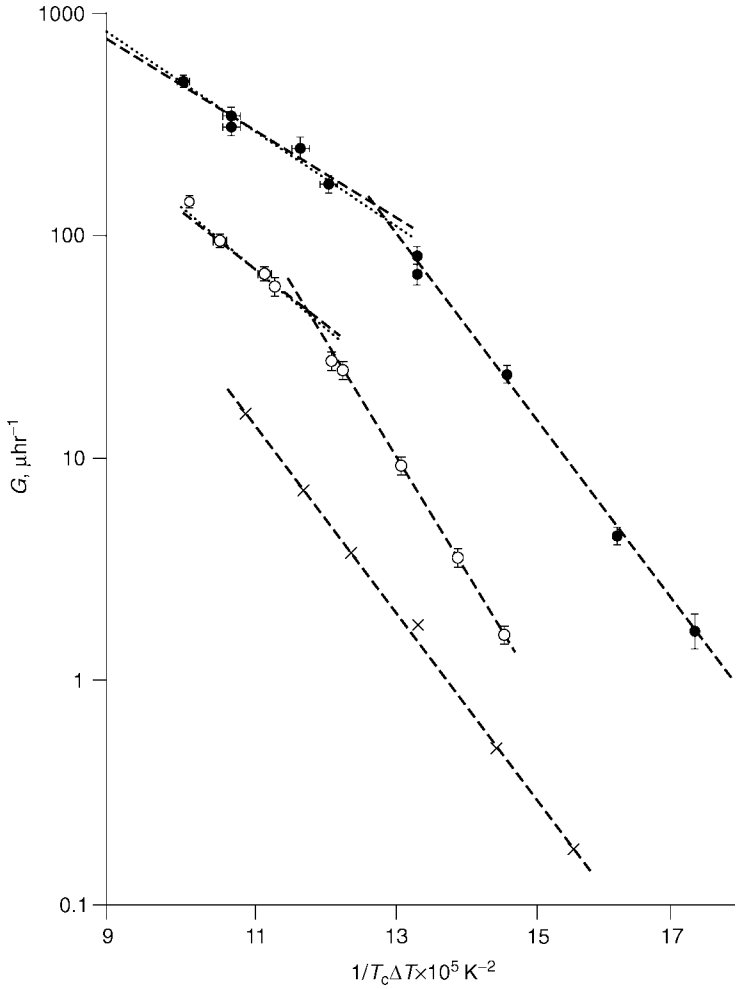

Fig. 9. A graph showing the variation in growth rate with $1/T\Delta T$ for single crystals of polyethylene grown from different solvents. The top data set is for 0.05% Rigidex 50 in tetradecanol, the middle one of 0.05% Rigidex 50 in hexadecane, and the bottom one for 0.l% Marlex 6009 in xylene. The best fit lines (dashed) show an approximate linear dependence, while the dotted lines in the top two data sets are lines in which the ratio of the slopes to the higher temperature lines is exactly 2, as predicted by theory (see section under Secondary Nucleation Theory). rate. Also, at a particular temperature, some sequences will be too short to crystallize (crystals of a thickness commensurate with the length of the sequence are not stable at that temperature), and so will be unable to crystallize until a lower temperature is reached. Lower total crystallinities are usually obtained, because it is not always possible for all of the sequences that are potentially crystallizable at a particular temperature to find a crystal into which to crystallize, considering the constraints due to the crystallization of other sequences in the same chain. A very similar behavior is observed with branched polymers, as longer branches

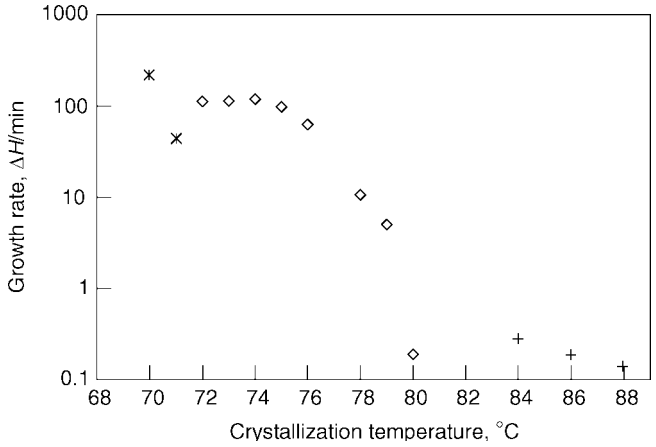

Fig. 10. A graph showing the variation in crystallization rate with temperature for the ultralong alkane $C_{246}H_{494}$. + extended chain growth, ◇ integer once-folded chain growth, ∗ twice-folded chain growth. A minimum in crystallization rate can be seen at the temperature where the transition from primary growth in different folded forms occurs. This is believed to be caused by competition at the growth front between the more stable thicker crystal and the now just stable, thinner form. Reprinted from ref. 81. Copyright (2000), with permission from Elsevier Science Ltd.

are excluded from the lattice (85). The distance between branch points defines the maximum crystal thickness into which a particular chain segment can crystallize. If this is thinner than the minimum stable thickness for a crystal, the chain segment cannot crystallize at that temperature. Again, this leads to a slowing of the overall growth rate, a reduction in the achieved crystallinity, and a widening of the temperature over which crystallization occurs. In the case of polyethylene, which has been extensively studied because of the commercial importance of low density polyethylene, some material is believed to not crystallize until temperatures below $-20^{\circ}C$ are reached. If high pressure is added, it has been shown (86) that it is even possible for the side branches to crystallize, albeit into a hexagonal phase.

As well as chain chemistry and chain length, different behaviors from the above outlined "typical behavior" can also be found because of differences in the crystallization conditions of an otherwise "typical" flexible linear polymer. Crystallization under flow leads to a change in morphology (87–89). Initially, oriented nuclei are formed with a largely extended chain character. These nuclei consist of the high molecular weight tail of the molecular weight distribution, both high molecular weight and polydispersity apparently being required (89–91). From these oriented backbones, plate-like lamellae then grow, largely perpendicular to the backbone, as shown in Figure 11 (92). These lamellae grow in a manner similar to that seen in the absence of flow, and have been used as model geometries for the study of lamellar growth (93). However, the growth of the backbone itself is very difficult to follow, due both to its size—although up to several microns in length, their width is typically less than 10 nm—and the very rapid rate of its formation.

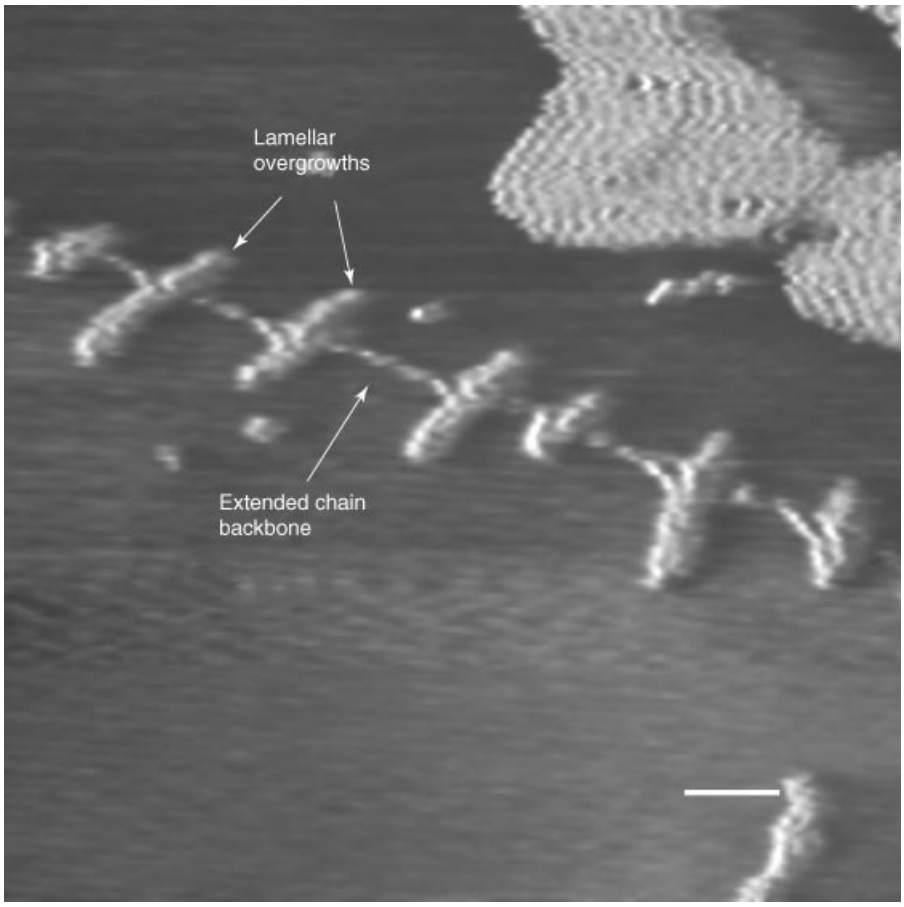

Fig. 11. An AFM micrograph (phase image) showing a shish-kebab crystal of polyethylene in a matrix of molten polymer. Image collected at 135°C. The bright area in the top right of the image is the glass substrate. The extended chain backbone and lamellar overgrowths can be clearly seen. The scale bar represents 100 nm. Reprinted from Ref. 92. Copyright (2001), with permission from the American Chemical Society.

In many commercial applications, polymers are now being used to add value through the use of very thin coatings whether protective, lubricating, or with some other purpose (94). This, combined with new techniques such as AFM, has led to an increased interest in crystallization in thin films (95–98). Once film thickness becomes comparable with the size (eg, radius of gyration) of the polymer molecule, both the morphology and kinetics of crystallization start to change. In very thin films, where the film thickness is thinner than the thinnest stable crystal thickness, it is clear that material transport dominates the morphology, leading to morphological instabilities [such as the Mullins–Sekerker instability (99)], and dendritic structures (100). An example of such a structure in poly(ethylene oxide), in which the morphology is dominated by material transport, is shown in Figure 12. Figure 13 shows the variation in growth rate, with film thickness at a constant temperature in isotactic polystyrene (98), in which a change in the

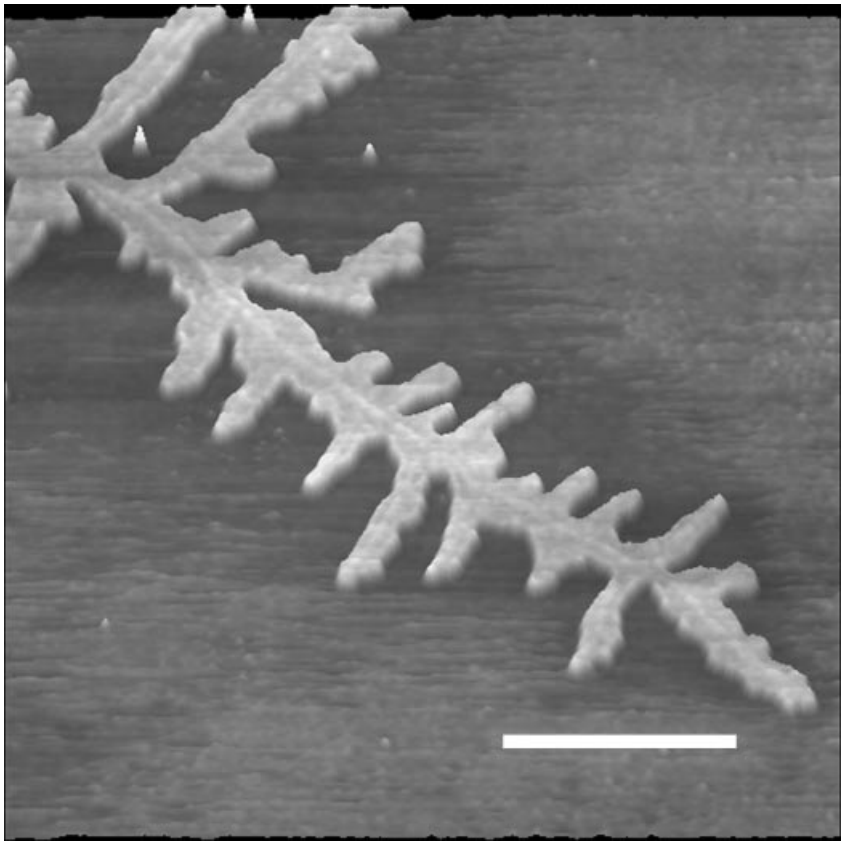

Fig. 12. An AFM image showing part of a growing poly(ethylene oxide) dendrite in an ultrathin film on a glass substrate. A topography image, black to white represents 20 nm, is presented in pseudo 3-D. The scale bar represents 1 μm. (Unpublished data of the author).

growth rate dependence once the film is thinner than the crystal thickness can be seen. Polymers can provide model systems for the study of diffusion-limited growth structures because of the tunability of the crystallization conditions, and the relatively slow rates of growth compared to small molecules (101,102).

It is worth noting that under industrial processing conditions, the behavior outlined above cannot be simply applied. Typical industrial grade polymers have wide molecular weight distributions, poorly characterized degrees of branching, and possibly copolymer content. Crystallization is often carried out during a rapid quench, and so the temperature varies during crystallization and across the sample. Also, crystallization often occurs at high supercoolings where, in polyethylene for instance, accurate growth rate data have not been obtained. The general assumption has been that the behavior during growth under these conditions is a simple superposition of the effects that have been studied under more controlled environments. However, this may not be the case, and predictive phenomenological models are only now starting to be produced for these complex but commercially important situations.

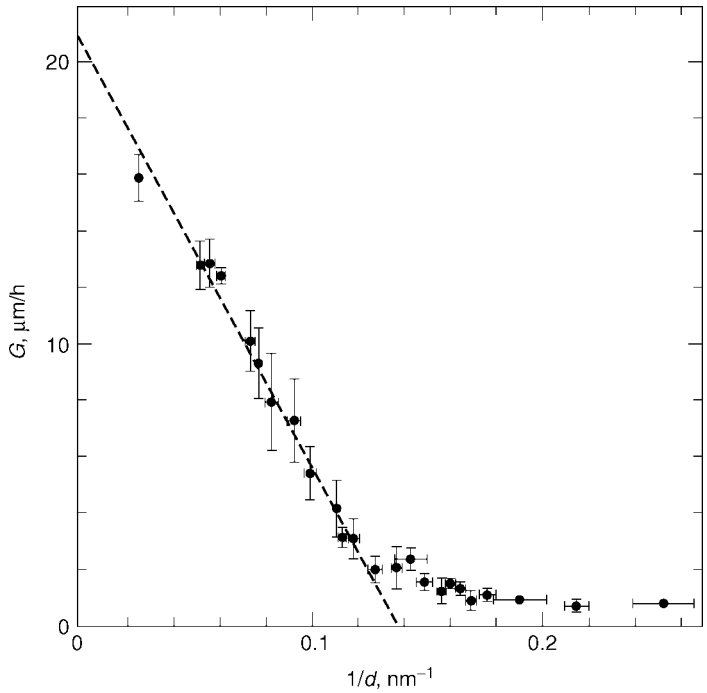

Fig. 13. A graph showing the variation of growth rate with the inverse of film thickness ($1/d$) for isotactic polystyrene crystals grown at 180°C in ultrathin films. A step in the behavior can be seen at a thickness of ~8 nm. At this temperature, this corresponds to the thickness of the single lamella, showing a change in thickness dependence once the film is thinner than the growing crystal. Reprinted from Ref. 98. Growth Theories

Polymer crystallization theory is a mature area, and there are several review articles available that present and discuss the different theories in great detail (eg, 103,104). Having said that, over the last 5 years or so there has been a flurry of new interest because of the increase in computational power, which has the potential to decisively enter the debate in some areas. In the following the underlying themes of the two principle theories of polymer crystallization, secondary nucleation theory and rough-surface or entropic barrier theory, are outlined. The results of more recent simulations are then briefly discussed, in which the constraints of the above theories, introduced to provide analytical solutions, have been relaxed. Finally, some of the more fundamentally different ideas that have recently appeared are discussed.

Out of the above overview of experimental data, crystallization theories have aimed primarily to explain three observations: the dependence of crystal thickness on supercooling, the dependence of crystal growth rate on supercooling, and the shape of single crystals grown from dilute solution.

In all systems, crystallization occurs because of the lower free energy, over a certain temperature range, of the crystalline phase compared to the disordered

melt, solution, or vapor phase. The processes that occur as the material transforms from one state to another are very complicated and diverse. However, they can be categorized into interface and diffusion-controlled growth. In diffusion-controlled growth it is the rate of transport of something—heat, mass, etc—either to or from the growth front that limits the rate of growth. In interface-controlled growth it is the actual process of attaching and detaching molecules at the surface that controls the growth rate. In some situations both processes can have a strong influence on the observed crystal morphology (100) and so it is not always simple to determine which is the rate-determining factor. In the case of polymer crystallization most activity has concentrated on the development of theories in which it is assumed that interface-controlled growth dominates. This is most likely a reasonable assumption in dilute solution and possibly also at small supercoolings during melt growth where faceted crystals are sometimes obtained. In both these situations it is intuitive that the physical process of attaching a long polymer molecule in register with a lattice is difficult when compared to small molecule growth. However, it is certainly not clear that it should always be the case as is often assumed. A more detailed discussion of this issue is contained in Reference 103, but suffice it to say that such theories can only be applied with confidence to solution crystallization.

Secondary Nucleation Theory. Polymer secondary nucleation theory is an extension of nucleation theory in small molecules, but allowing for the connectivity of the units that constitute the crystal (ie, the polymer chain). In all crystal growth theories there is a driving force for crystal growth that comes from the lower free energy of the crystalline phase when compared to the liquid phase (be that melt or solution). In nucleation theory the barrier to growth is provided by an increase in surface energy that is postulated to occur when a crystallizing unit attaches in crystallographic register onto the growth front. This energy increase is due to the formation of a new crystal–liquid interface. The attachment of a single unit does not release sufficient energy to make up for the increase in free energy associated with the formation of a new surface, and so several units must form together, through random fluctuations, to provide a "nucleus." This nucleus is a crystal patch of sufficient size that the addition of further units leads to a reduction in free energy rather than to an increase. The most probable process is then for the patch to continue to grow, rather than to dissolve. The process is termed *secondary nucleation* because it considers the nucleation of a new patch onto an existing crystal, in contrast to *primary nucleation* that deals with the formation of the first nucleation event.

The various nucleation theories differ in the exact way in which the attachment process is envisaged to occur, and in what nucleation process is presumed to be the most important (105–108). Figure 14 shows the situation that is usually considered and the definition of the different surfaces. In most nucleation theories, for instance Lauritzen–Hoffmann theory (105), the nucleation process is the attachment of the first stem. This occurs in a single step [more generalized cases where it occurs in multiple steps have been considered (109–111)], and the addition of further stems leads to a reduction in the total free energy of the crystal. Some justification and discussion of reducing the complex process of depositing an entire stem to a single step is given by Frank (4). Once the first stem has deposited, further increases in free energy only occur when a new fold is formed, and this has

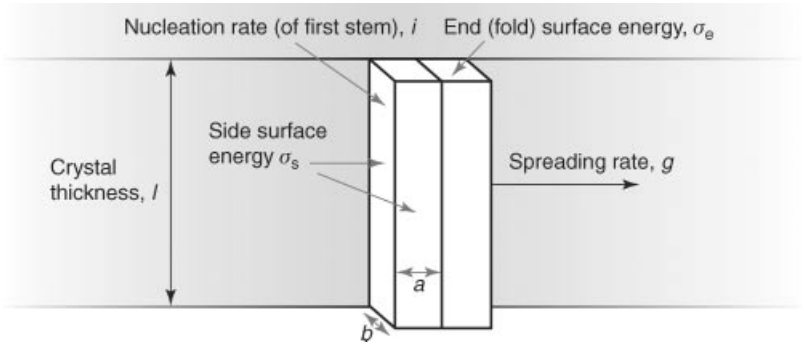

Fig. 14. A schematic diagram representing the growth front of a polymer lamella. The polymer chain is represented by a series of boxes (stems) with defined surface energies.

a high energy associated with it that can be approximated by the loss in energy that occurs from the exclusion of the fold monomers from the crystal lattice. Most forms of secondary nucleation theory assume that the chain folds back on itself into the adjacent lattice site, and so the deposition of each new stem leads to an additional fold surface energy.

The rate at which stable patches nucleate on an existing crystal substrate, i, and the rate at which stable patches grow, g, controls the overall rate of crystal growth. At a particular temperature, crystals with a thickness below a certain critical value (usually denoted $l_{\min}$) are unstable as, however many stems are added, the surface energy is always greater than the bulk free energy of the crystal (this is simply the Gibbs–Thomson melting point depression due to limited phase size). This minimum stable crystal thickness decreases with decreasing temperature, and gives a lower limit to the possible thickness that can grow at a particular temperature. Conversely, the rate of nucleation of stable patches, i, decreases as the thickness of the patch increases because of the increasing free-energy cost of creating the two new lateral surfaces on either side of the first stem. That is, the longer the stem the more side surface it will have and hence a higher barrier to growth. The competition between these two factors leads to a maximum in growth rate at a thickness that is slightly greater than $l_{\min}$.

From the above model of growth three different regimes can be defined, depending on the relative values of i and g.

(1) The rate of nucleation i is considerably smaller than the rate of spreading. Each new patch grows to fill the entire available substrate before a second patch is nucleated. In this case the overall growth rate will be proportional to i.

(2) The rate of nucleation i is sufficiently high that more than one growing patch exists on each substrate. Each patch is also able to support new nucleation events, and so the growth occurs in several layers. In this case the growth rate will be proportional to $\sqrt{(ig)}$

(3) A third situation can also be identified in which the rate of stem nucleation is greater than the rate of spreading, in which case the rate of growth is again proportional to i. Here the growth front has been kinetically roughened.

These three different situations have been termed regime I, II, and III respectively, and a large body of supporting experimental evidence on growth rates has been obtained, largely from melt crystallization, as detailed under Key Experimental Results.

To obtain actual values for the crystal thickness and growth rates, expressions for i and g need to be obtained. Here a brief outline is given, following the approach due to Lauritzen and Hoffmann (105).

The change in free energy ΔG for the formation of a patch with υ stems is given by

$$\Delta G = -abl\Delta F + 2bl\sigma_s + (\upsilon - 1)(-abl\Delta F + 2ab\sigma_e) \tag{7}$$

Where σ_s is the side surface free energy, σ_e is the end surface free energy, l is the thickness of the crystal, a and b are the width and thickness of the stem (as marked in Fig. 14), and ΔF is the bulk free energy of crystallization per unit volume. The term $2bl\sigma_s$ is due to the formation of the side surfaces, $(\upsilon - 1)(2ab\sigma_e)$ is due to the end surfaces, and the terms in ΔF are due to the reduction in free energy because of the lower energy of the bulk crystal compared to the bulk melt. In all cases it is assumed that the "known" macroscopic energies can be simply used. Four rate constants are defined:

(1) A_0: the rate constant for adding a new stem to the substrate
(2) B_0: the rate constant for removing an isolated stem from the substrate
(3) A_1: the rate constant for adding a stem next to an existing stem of the same length (ie, without the formation of any new side surface)
(4) B_1: the rate constant for removing a stem such as that added in A_1.

The excess energy that comes from adding the fold is not included in the initial stem deposition (ie, process A_0), but rather with the deposition of the adjacent stem. A choice is then made about how to apportion the different changes in free energy in view of the physical process of crystallization. This requires the introduction of an additional factor Ψ which defines the proportion of the bulk free energy that is released during the initial deposition of the stem and hence reduces the barrier to deposition that comes from the increase in surface free energies.

From here, the steady-state flux of stems over the barrier can be determined—that is, the net rate of transition of a patch with n stems to a patch with $n + 1$ stems assuming that the total number of patches with n stems in the ensemble remains constant. This flux will depend on the thickness of the crystal. At a particular temperature it is assumed that there is a range of different crystal thicknesses that will grow, and the probability of obtaining a particular thickness is proportional to the steady-state flux for that crystal thickness. This leads to the average thickness of an ensemble of crystals given by

$$\langle l \rangle_{av} = \frac{2\sigma_e}{\Delta F} + \delta l \tag{8}$$

where δl is a small additional thickness beyond the minimum stable thickness, an exact form for which can be straightforwardly obtained (105). Thus the observed crystal thickness is slightly greater than the minimum that would be stable at the crystallization temperature, and follows the experimentally observed dependence on $1/\Delta T$. Expressions for the growth rates in the different regimes of growth can be determined by finding the values of i and g (103,105). For example, in regime I, the growth rate is given by

$$G_{\mathrm{I}} = \frac{b}{a}\beta L_{\mathrm{p}} \exp\left(\frac{2ab\sigma_{\mathrm{e}}\Psi}{kT}\right) \exp\left(\frac{-4b\sigma_{\mathrm{s}}\sigma_{\mathrm{e}}}{\Delta FkT}\right) \tag{9}$$

where L_{p} is the persistence length of the crystal (the effective size of the crystal face onto which nucleation is occurring, usually equated with the distance between defects, rather than the total length of the crystal surface). These expressions exhibit the experimentally observed dependence of $\ln G$ on $1/T\Delta T$, although an additional front factor β, which governs the rate of transport of polymer to the crystal surface, is also included. When fitting experimental data to the theory, great care needs to be taken when deciding on the form to be used for β and on the range of other behaviors that could be obtained if a different form was used. In several cases it is possible to introduce or remove multiple kinks in the growth rate curve by the choice of β, and hence to introduce types of behavior, such as growth regime changes, when none may truly exist.

Secondary nucleation theory has had a great deal of success in fitting experimental data, and by so doing obtaining best values for the parameters of the model. It is a highly flexible model and has been adapted to agree with most of the new experimental observations as they have been made. It does, however, suffer from several internal flaws of varying importance (see, for example, References 102 and 111 for a discussion of these) as well as, arguably, an unacceptable level of disagreement with an increasing body of experimental evidence. Whether this can be rectified within the context of a model in which the barrier to growth is nucleation, is currently unclear.

Entropic Barrier Model. Although secondary nucleation theories have been very successful in fitting experimental data on growth rates and crystal thicknesses, there are several areas where, as initially formulated, they have failed. Solution-grown single crystals of polyethylene formed at low temperatures (crystallized from solvents in which there is a high entropy of mixing) have flat, crystallographic surfaces. However, if crystals are grown at higher temperatures, either from solution or in the melt, they have curved edges (113–115). If these surfaces are rough on a molecular scale, then there will be no obvious barrier to nucleation—there will always be a niche available into which a stem can deposit without having to create new side surfaces, so the initial stage of the nucleation of the first stem will never occur. It was also observed that when single crystals formed certain sorts of twins, a niche or reentrant corner exists at the twin boundary where a newly deposited stem would create no new side surfaces and the nucleation barrier would be removed (116). Thus, if the secondary nucleation model is correct, such twin crystals would be expected to grow very rapidly along the axis of the twin boundary. Such enhanced growth at twin boundaries is not generally observed in high polymers. These observations led Sadler and Gilmer

to reject the idea that polymer crystal growth was governed by a nucleation step, and instead to adopt a new approach, dependent on the assumption that polymer crystallization often occurred at sufficiently high temperatures to be above a roughening transition (117).

In simple terms, the roughening transition is the temperature above which the energy cost of forming a step on the surface is less than the entropy gained by its formation. The surface then becomes rough on a macroscopic and often molecular scale. The formation of curved crystal surfaces at high temperatures is immediately explained. However, above the roughening transition, the growth rate is expected to be proportional to ΔT, rather than the experimentally observed form $\ln G \propto 1/T\Delta T$. A new barrier to growth needed to be found, and the then recently developed tool of computer simulation was utilized to do this (118–121).

The thinking behind the computer simulations is as follows. Polymer units are continuously attaching and detaching from the crystal face. Growth occurs through the net accumulation of material onto the crystal face, but the possible positions in which a unit can attach are limited because of the connectivity of the polymer chain. If a stem has folded over, the stem cannot lengthen by the attachment of further units above the fold surface. If the stem is shorter than the minimum thickness it must first unfold (that is, undo the "incorrect" unit depositions) before it can lengthen so as to become stable. Similarly, if a chain forms stems at two sites that are well separated, it might not be possible for them to lengthen without the detachment of one of the stems, due to the length of the connection between the two stems. Through the process of random attachment and detachment a stable crystal will grow, but its growth will be hindered by the necessity to undo, or reject, unviable unit attachments. These fluctuations that occur in and out of unviable states therefore create a barrier to growth that is entropic in origin because it arises from the consideration of all of the pathways available to the system. As the thickness of the crystal increases, the number of possible unfavorable states will increase, giving a barrier to growth that increases with thickness. Models and approximate solutions to the problem show that the barrier increases exponentially with thickness, as required by experimental observation. Through Monte Carlo simulations growth rates and crystal profiles could be obtained, and these could, under certain conditions, agree with experimental observation. Analytical solutions of very simplified models could also be obtained.

The principle objection to the above theory lies in its assumption of a roughening transition, for which little evidence exists. However, as will be seen below, the insight that a nucleation barrier is not required to explain the experimental data is an important one.

New Approaches to Crystallization Kinetics

Over the past decade or so there have been several significant advances both in experimental techniques, and in the power of computer simulation, that have led to an ongoing reappraisal of our understanding of polymer crystallization. In the following, some attempt is made to outline the most significant features of these new ideas and to point the interested reader toward the literature.

Computer simulation has been used as a tool to study the predictions of existing theories, as well as to try to gain an insight into the controlling physics of crystal growth through direct or simplified simulation of the phase transition but with less constraint on how the process occurs (122–127). In a series of papers Doye and Frenkel (128–130) have simulated both secondary nucleation and Sadler's models but with the constraints removed that had previously been imposed either to give analytic tractability, or sufficiently short computation time. In the simulation of the secondary nucleation model the chain is allowed to deposit unit by unit, rather than in a single step, with both attachments and detachments being allowed. This work shows that the proposed nucleation step, that is the deposition of the first stem, does not exist if the first two stems are deposited together—as had been previously suggested by Point (131). The peak in free energy that has to be overcome for nucleation to occur is no longer seen. It is argued that this observation alone invalidates secondary nucleation theory.

In simulations that are not attached to any particular theory the same authors have suggested a new mechanism for the selection of crystal thickness. By carrying out simulations of the deposition of new crystal layers but without any constraint that the new layer must be the same thickness as the previous layer, or indeed that each stem must have the same length as its neighbors, it was found that the growing crystal quickly adopted an average stem length that was slightly thicker than the minimum stable thickness. The mechanism behind this was quite simple. As the chain deposits, there is always a finite probability of it turning back on itself and starting to form a new, adjacent stem. If it does this before the currently depositing stem has reached a stable length, it will most probably detach, and so stem lengths smaller than $l_{\min}$ are disallowed. However, once it is longer than $l_{\min}$, the probability of growing thicker becomes decreasingly small, as there is always the same fixed probability at each new segment attachment that it will fold back to make a new stem. Crucially, the probability of a new stem being longer than the stem in the previous layer is very small as it would no longer be part of a well-defined lattice. Thus there is a particular crystal thickness at every temperature where the most probable thickness of a new layer is the same as the thickness of the previous layer, and this is the crystal thickness that will grow. In other words, there is a fixed-point attractor at a crystal thickness that is slightly thicker than the minimum stable thickness at that temperature—that is, in agreement with the experimental data. Figure 15 shows an example of a growth front formed during a simulation, and a graph showing the most probable stem length of a new stem given the length of the neighboring stem. Perhaps most interestingly, however, is the conclusion that the thickness that grows is not in fact the fastest growing at that temperature but rather the most probable. The same group reanalyzed the Sadler–Gilmer model and concluded that it was predicting a similar type of behavior. The mechanism of thickness selection in that model was also the presence of a fixed-point attractor.

Simulations by Muthukumar and co-workers (133–135) have also thrown considerable doubt on some of the underlying premises of secondary nucleation theory, and also on some of the constraints that are in place in the Sadler–Gilmer model. Specifically, the assumption is generally made that each layer as formed has a particular thickness that is the final thickness of the crystal, the reorganization of the chain within the crystal is not allowed for. The simulations find that

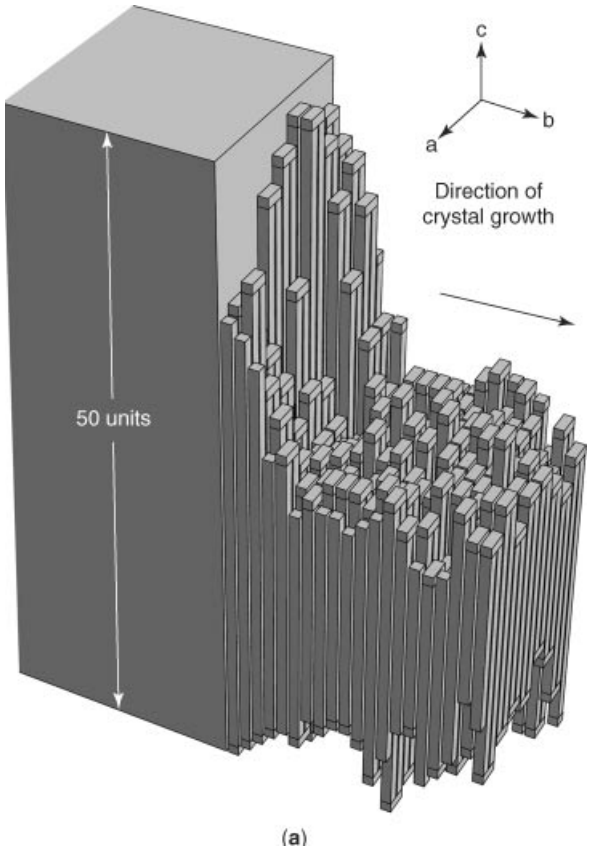

Fig. 15. (**a**) A cut through a polymer crystal grown in the simulation of Doye and coworkers. The crystal was produced by the growth of 20 successive layers on a surface with a uniform thickness of 50 units. The stems are represented by vertical cuboids. The cut is 16 stems wide. (**b**) A graph showing the dependence of the stem length on the length of the previous stem for growth of a single layer on a surface 50 units thick. There is a thickness, in this case 36 units, for which the average length of the next stem is the same as for the previous one, and this corresponds to the average thickness of the layer. This shows the way in which a new layer will converge to a particular thickness dependent on the thickness of the previous layer. Reprinted from Ref. 132. Copyright (1999), with permission from American Institute of Physics.

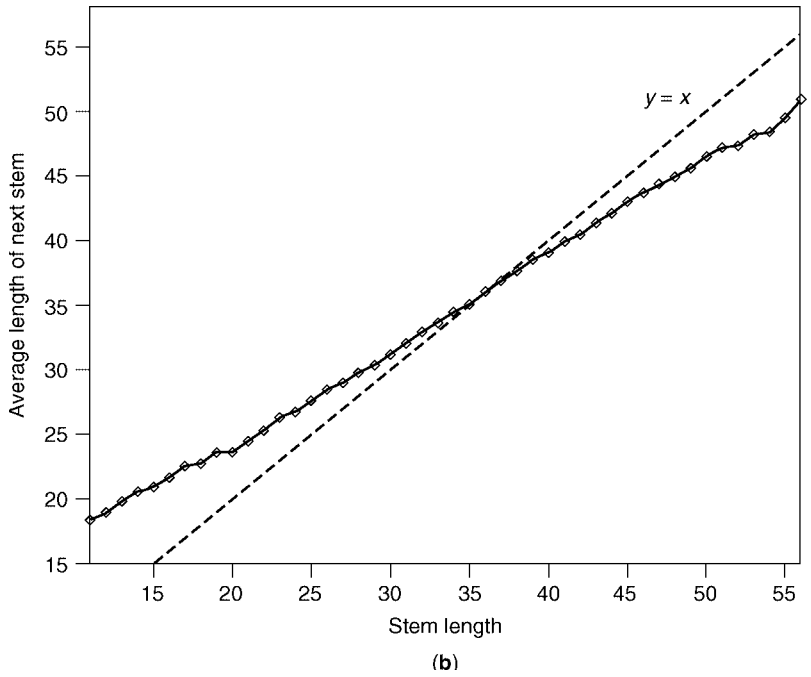
the process of reorganization is a key part of the crystallization process, and of the selection of the final crystal thickness. The barrier to crystal growth is again found to be entropic in origin.

All of these simulations apply to crystallization from solution but are still constrained by computing power to only a relatively limited extent of crystal growth. Some of the supporting evidence in favor of secondary nucleation theory, such as the crystallographic shape, has not been dealt with explicitly. However, there clearly is considerable conflict between the existing theories and these new data, and the acceptance of a model for polymer crystal growth from solution or under similar conditions (136), in which the barrier to growth is entropic in origin, is perhaps emerging.



(b)

Fig. 15. (continued)

In addition to new insights gained from computer simulation, new experimental techniques have led to some reassessments of previously accepted wisdom. The suggestion that spinodal decomposition of the melt could exist as a precursor to polymer nucleation has already been mentioned. Several groups have suggested that crystallization occurs through a series of intermediate stages and that the final crystal structure is not a reflection of the structure that initially formed from the supercooled melt (137–141).

The ideas of the Bristol group (137,138) were based on the observation that polyethylene has a stable hexagonal phase at high temperature and pressure, with a hexagonal–orthorhombic–liquid triple point at a temperature of $\sim$215°C and a pressure of $\sim$3.6 kbar. If the polymer was crystallized at slightly lower temperatures and pressures than the triple point, the initial crystal form was still clearly hexagonal, although at a later time a transformation into the more stable orthorhombic form sometimes occurred. This led to the suggestion that, even under ambient conditions, when polymer chains attach to the growth front they initially form a crystal with hexagonal symmetry, which rapidly thickens in the chain direction and transforms into the orthorhombic phase when a critical thickness is reached. It was suggested that the hexagonal phase is in fact more stable than the orthorhombic phase if the crystal thickness is sufficiently small, due to the difference in the ratio of surface energy to bulk free energy. This introduced the idea of a size-dependent phase transition. On a broader basis, Ostwald's Stage Rule (142) has been used to justify the suggestion that crystallization will occur through intermediate states if such states exist. As the material transforms from the high free-energy liquid state to the minimum free-energy

crystalline state (never reached in the case of polymers because of the kinetic trap of chain folding), it will pass through any intermediate states where local minima in free energy exist. In the case of polyethylene, the hexagonal phase in which the still mobile chains pack like parallel rods, is clearly a possible intermediate state. Direct experimental evidence of an intermediate hexagonal phase during the crystallization of polyethylene under ambient pressure has not been forthcoming. Some evidence from simulations of small molecule systems supporting the existence (and persistence) of a higher symmetry intermediate phase during nucleation has been published (143), but the complexity of polymeric systems puts similar studies beyond current computer power.

A very similar set of arguments to the above has been made by Strobl and co-workers (140,141) although coming from a somewhat different set of initial assumptions. In this case it is proposed that crystallization occurs through a partially ordered mesophase, which then transforms into crystalline blocks and these blocks in turn heal together to form the final lamellae. Experimentally this is justified by a series of observations both direct and indirect, although the primary data are a body of measurements on melting behavior and crystal thicknesses. In particular, the existence of a continuous distribution of melting temperatures for crystals of the same thickness is clear evidence of a variation in crystal perfection that is not accounted for in the traditional theories.

Although these new ideas are internally consistent and supported by some experimental evidence, it has been suggested that they are contradicted strongly by the behavior of several well-studied systems. In particular, the selection of chain chirality during crystallization has been used as an argument against the possibility of a loosely packed intermediate structure, both in achiral molecules where the chain can adopt helical conformations of either handedness, and in enantiomorphic mixtures of optically pure materials. For instance, in α-iPP, where left- and right-handed helices pack in a well-ordered antiparallel fashion dictated by the stable unit-cell structure, it is hard to envisage the existence of an essentially randomly packed intermediate state that could then sort itself out into the correct packing through a solid-state crystal–crystal transformation, considering the interconnectivity of the stems that make up the crystal. This argument is made very strongly in Reference 144 and is yet to be convincingly answered.

Clearly there still exists considerable controversy over the factors controlling polymer crystallization. New experimental techniques are, however, starting to become available that might lead to a resolution of some of these issues. Scanning probe microscopy offers the opportunity to follow crystal growth at a surface in real-time, with nanometer resolution, and hence to quantify the kinetics by direct observation at length scales that are close to those of the fundamental crystallizing unit, and to the size scale of the polymer chain (92,145–152). Several groups (145–147,149) have reported that lamella crystallization from the melt, at least where several lamellae are growing adjacently, does not occur at a constant temperature-controlled rate. Instead, growth rates are sporadic over length scales of several tens of nanometers, with lamellae or parts of lamellae spurting forwards briefly, then slowing down and being overtaken by their neighbors (146). Although this does not contradict the mean rates previously measured optically, because of the different length scale of the measurement, it does contradict the predictions of secondary nucleation theory, if it is applied to melt crystallization

(which is commonly the case; see above). Figure 16 shows a series of images of lamella crystallization, from which the growth rates can be measured. Currently it is only possible to use this technique to study crystallization at very slow rates, at the lower limits of those traditionally measured optically. However, with the advent of faster scanning techniques, it should be possible to obtain real-time growth rate measurements with nanometer resolution under more usual crystallization conditions, and provide a definitive test of theory.

A complimentary technique is the development of very fine beam micro-focus X-ray sources, in which submicron beams are starting to become available (153). This technique has not yet been applied to polymer crystallization, but is capable of providing spatially resolved scattering data from growth fronts that is of great

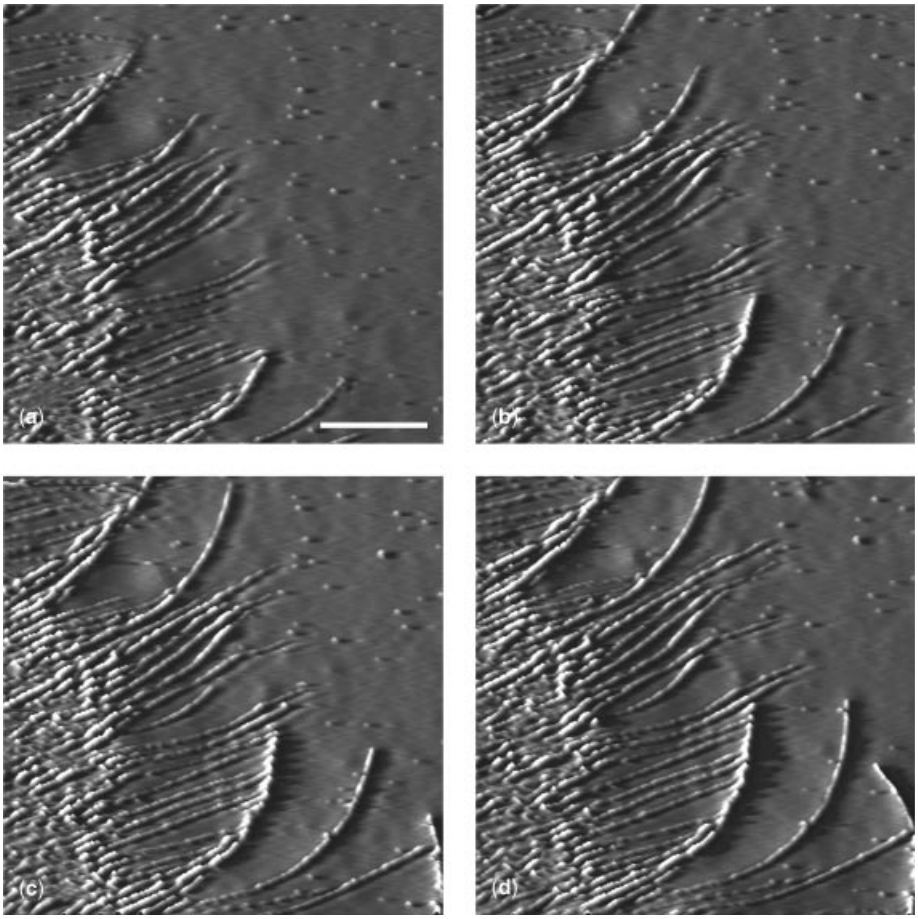


Fig. 16. A series of AFM amplitude images showing the growth of an oriented polyethylene structure. The individual lamellae can be resolved as they grow into the melt. The growth rates of lamellae can be measured and it is seen that they vary both from lamella to lamella, and with time for each lamella. The local environment of a growing lamella is also seen to have a profound effect on its growth. (**a**) taken at 0 s, (**b**) at 181 s, (**c**) at 344 s, (**d**) at 591 s. The scale bar represents 1 μm. Reprinted from Ref. 146. Copyright (2001), with permission from the American Chemical Society.

potential value. Similarly, advances in instrumentation in other techniques such as NMR, Raman microscopy, and electron microscopy toward higher spatial and temporal resolution, as well as new methods for materials synthesis that can produce cleaner, better-defined polymers, promise to have a significant impact on our understanding of polymer crystallization kinetics at the molecular level.

Conclusions

The complexity of polymeric systems has made the development of a full understanding of the crystallization process difficult. A wealth of experimental evidence has been gathered, but interpretation has often been problematic because of the ambiguities frequently found in such complex systems. The capabilities of new experimental techniques to obtain both time and spatially resolved information during the phase transformation is improving rapidly and may prove to be decisive.

Although secondary nucleation theory was, for a period, widely accepted, it is now coming under increasing pressure, from experimental data, from computer simulation, and from new approaches to the fundamental process of crystallization. It is not clear at this stage whether all that is required is a few adjustments to the theory, or whether the idea of a nucleation barrier is flawed, or even if the idea that the crystal thickness seen is the fastest growing is correct. With the development of new theoretical tools, and the increased integration of theory with computer simulation, it is hoped that a more complete model for polymer crystallization can be developed.

A full understanding of crystallization from the melt still seems elusive, with very little work being carried out to confront the issues of mass transport, of transient stresses caused by the volume reduction that accompanies crystallization [known to be sufficiently high to cause cavitation (154,155), or even to fracture the growing crystal (156)], or of the relationship between modes of growth and morphologies seen in polymers but also seen in other systems. The extent and importance of the role played by intermediate phases is also unclear, although this is an area that, with the development of new experimental techniques, and the pushing of the spatial resolution of existing techniques down toward the nanometer level, should be resolvable.

Despite these questions, the body of knowledge on crystallization kinetics is very extensive. As new theories are developed, it is clearly of paramount importance that they use as an input all of the available information. The wide variety of different chemistries and behaviors that are observed can lead to a temptation to discard generalizing principles, but it is the author's opinion that this temptation should be avoided. At a phenomenological level, polymer crystallization is well characterized, and the kinetics of growth can be controlled in a precise manner, at least on a macroscopic scale. It is hoped that, over the next few years, newly available experimental data can be married to the vast store of existing knowledge and assimilated, through the help of the growing power of computer simulation, to provide a new model for crystal growth that will provide the fundamental understanding necessary if crystallizable polymers are to meet the demands placed on them by the emerging fields of nanotechnology and nanoscience.

CYCLODEXTRINS

Introduction

A wide area of supramolecular chemistry focuses on host–guest interactions between two or more molecules that are not covalently bonded (1). A special part of this chemistry deals with cyclodextrins and their derivatives (2). It is well known that cyclodextrins tend to include several types of hydrophobic guest molecules into their cavity. Accordingly, a large number of applications have been found in many areas, eg, in food chemistry as well as in the pharmaceutical (3) and cosmetic industries. Furthermore, cyclodextrins may be used in organic chemistry and also in polymer chemistry.

Cyclodextrins (CDs) are produced in technical plants by enzymatically catalyzed degradation of starch. The naturally occurring products of cyclodextrin are cyclic oligosaccharides built up of 6 (α), 7 (β), or 8 (γ) glucopyranose units, which are connected with $\alpha(1\rightarrow4)$-glycosidic linkages, forming a torus-shaped ring structure with a hydrophobic cavity and a hydrophilic exterior. The primary hydroxy groups in the 6-position are located at the narrow side of the torus, whereas the secondary glucopyranose hydroxy groups are located at the wider side of the torus (Fig. 1). β-CD shows a water solubility about 1.85 g/L at 20°C. Intramolecular hydrogen bonding between the C2-OH group of one with the C3-OH of a neighboring glucose unit is probably responsible for the poor water solubility of β-cyclodextrin. Because of the high water solubility of randomly methylated β-cyclodextrin (RAMEB) with an average degree of methylation around 1.8 per glucose unit, it may be used in consumer products, and in industrially synthesized on a large scale.

Because of their polar hydrophilic outer shell and relatively hydrophobic cavity, cyclodextrins are able to form inclusion complexes with a wide variety of suitable hydrophobic molecules (4) eg, nonpolar hydrocarbons, polar carboxylic acid, and amine derivatives (Fig. 2, Table 2). This phenomenon leads to significant changes of the solubility and reactivity of the guest molecules without any chemical modification. Water-insoluble molecules become completely water-soluble by treatment with aqueous solution of native cyclodextrins or their derivatives, eg, methylated or hydroxypropylated cyclodextrins.

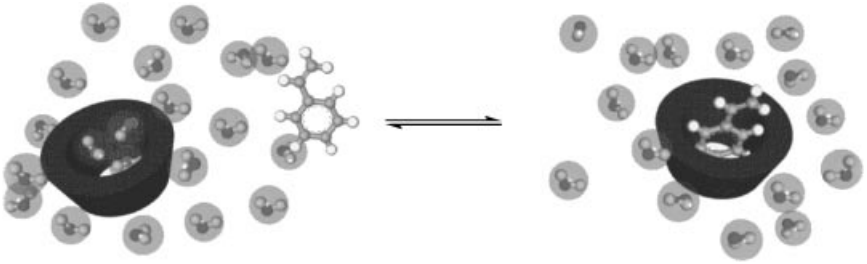

Fig. 2. Scheme of formation of styrene–cyclodextrin host–guest complex

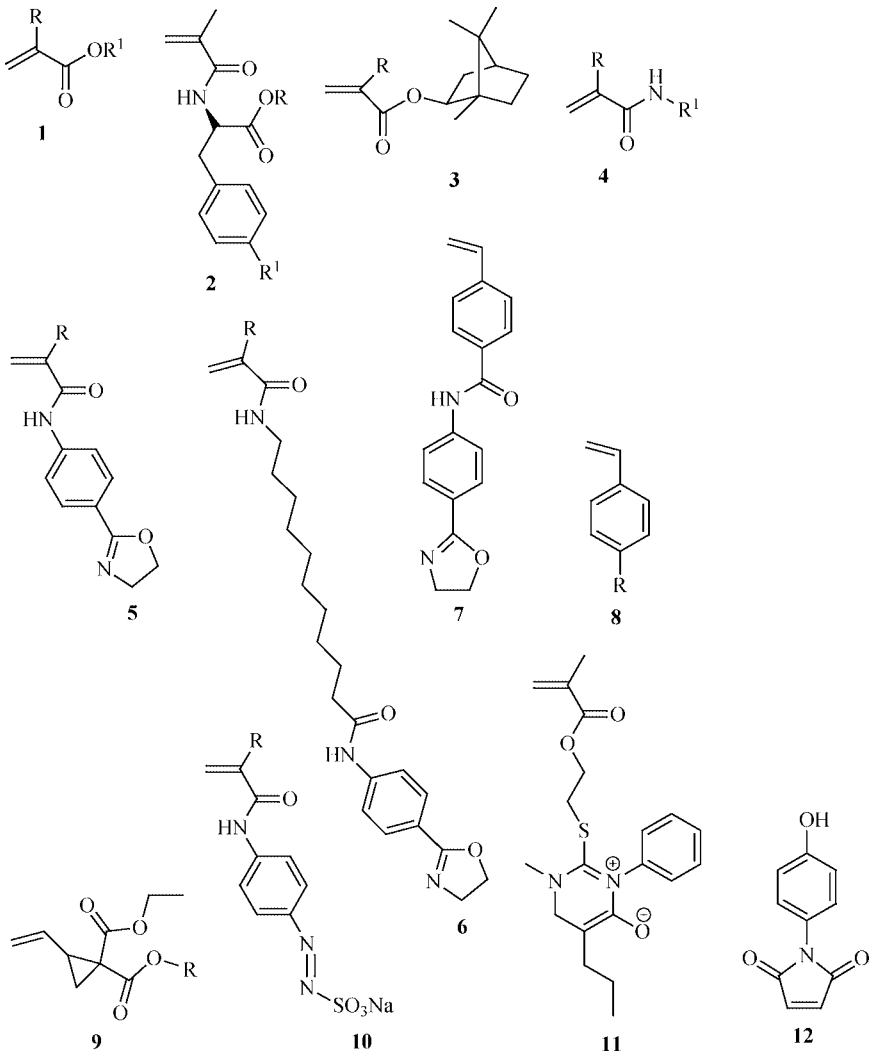
In this article, the synthesis of new monomers, their inclusion in cyclodextrin derivatives, and polymerization in aqueous medium are described.

Complexation with Cyclodextrins

Water-soluble cyclodextrin complexes of water-insoluble monomers were achieved by stirring a slight excess of cyclodextrin derivatives, in most cases RAMEB, and different monomers in water. Several methods were applied to the characterizations of the host–guest complexes. The most important behavior of the complexes is that the hydrophobic guest monomers become water-soluble by being included into cyclodextrin. Reaction control by thin-layer chromatography (TLC) with methanol as mobile phase, followed by UV detection and iodine development, shows complete conversion to the corresponding cyclodextrin complexes. The R_f values of the complexes are significantly different from the value of uncomplexed monomers and cyclodextrin (Table 1).

Table 1. R_f Values of Uncomplexed Monomers and Their RAMEB Complexes in Comparison to 2,6-Dimethylated Cyclodextrin

Monomer	$R_{f(monomer)}$	$R_{f(monomer/RAMEB)}$
Styrene	0.85	0.57
Methyl methacrylate (**1a**)	0.89	0.57
n-Butyl methacrylate (**1b**)	0.94	0.50
tert-Butyl methacrylate (**1c**)	0.92	0.54
Cyclohexyl methacrylate (**1d**)	0.80	0.54
Phenyl methacrylate (**1e**)	0.92	0.54
n-Propyl acrylate (**1f**)	0.78	0.54
n-Butyl acrylate (**1g**)	0.90	0.45
n-Pentyl acrylate (**1h**)	0.88	0.55
n-Hexylacrylate (**1i**)	0.85	0.77
Cyclohexyl acrylate (**1j**)	0.87	053
N-Methacroyl-L-tyrosin methylester (**2a**)	0.85	0.50
N-Methacroyl-L-tyrosin ethylester (**2b**)	0.78	0.42
Isobornyl acrylate (**3a**)	0.86	0.51
Isobornyl methacrylate (**3b**)	0.82	0.53
2,3-Ethylenedioxythiophen (**EDT**)	088	0.38
(2,6-Dimethyl)-β-cyclofextrin	0.66	



The formation of the complexes can also be verified by ^{1}H NMR spectroscopy and 2D-ROESY NMR analyses. For example, the ^{1}H NMR spectrum of *N*-methacroyl-L-tyrosin methylester (**2a**) in comparison to its complex with heptakis(2,6-di-*O*-methyl)-β-cyclodextrin (DIMEB) shows that in complex the signals of the aromatic protons in ortho position to OH group as well as the signals of the methacryl group are shifted to the lower magnetic field, whereas no changes occurred for the aliphatic protons and the ester groups (Fig. 3). The 2D-ROESY NMR spectrum of the RAMEB-complexed *N*-metacroyl-L-tyrosin ethylester (**2b**) shows strong interactions between the aromatic protons of the monomer with the H(3), H(5), and the methoxy groups of cyclodextrin (Fig. 4.)

The structure analysis of the RAMEB-complexed monomers by X-ray diffraction confirmed the results of the above-mentioned methods. As an example, the X-ray structure of DIMEB complexed isobornyl acrylate (**3a**) and *n*-butyl acrylate

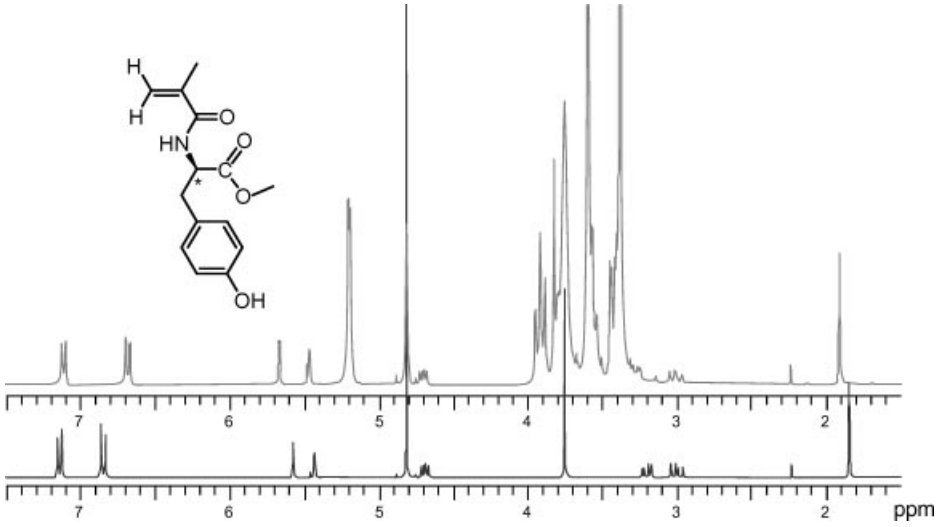


Fig. 3. 300 MHz ^{1}H NMR spectra of *N*-methacryoyl-L-tyrosine methylester (**2a**) and their DIMEB complex in D_2O[5].

(**1g**) show that the monomeric guest molecules are completely included within the cavity of β-cyclodextrin and the double bonds of acrylic groups are located at the narrow side of the host molecule bearing the primary methoxy groups (Figs. 5**a** and 5**b**). Surprisingly, the X-ray analysis of 3,4-diethylendioxythiophene (EDT)/α-cyclodextrin shows that the monomer does not fit into the cavity of α-cyclodextrin, but a 1:1 noninclusion channel-type packed supramolecular complex based on multiple hydrogen bonds (Fig. 5**c**). When DIMEB was used as a host molecule for EDT, it was observed that the complex crystallized out of the aqueous solution at higher temperatures, whereas upon cooling it was dissolved again. Additionally, the photophysical properties of inclusion complexes γ-cyclodextrin as host and 2,2′:5,2″-terthiophen (αT) as guest have been investigated. α-T is believed to form 1:2 or 2:2 complexes with γ-cyclodextrin.[6]

Polymerization of the Cyclodextrin Complexed Monomers

In recent years, much attention has been directed toward the use of cyclodextrin derivatives in polymer chemistry. The emulsion polymerization of vinyl monomers, eg, methacrylates in the presence of β-cyclodextrin using anionic surfactant, has been described (9,10). However, this type of polymerization leads often to polymer particles having a heterogeneous particle-size distribution (PSD).

In our group, different types of vinyl monomers showing low solubility towards water (Table 2) were complexed with cyclodextrin and the obtained water-soluble complexes were subjected to free-radical polymerizations and copolymerizations in aqueous phase. The optically clear solution of the complex becomes turbid because of the precipitating polymeric powder. It was shown in nearly all cases that higher monomer conversions were obtained as compared with polymerization

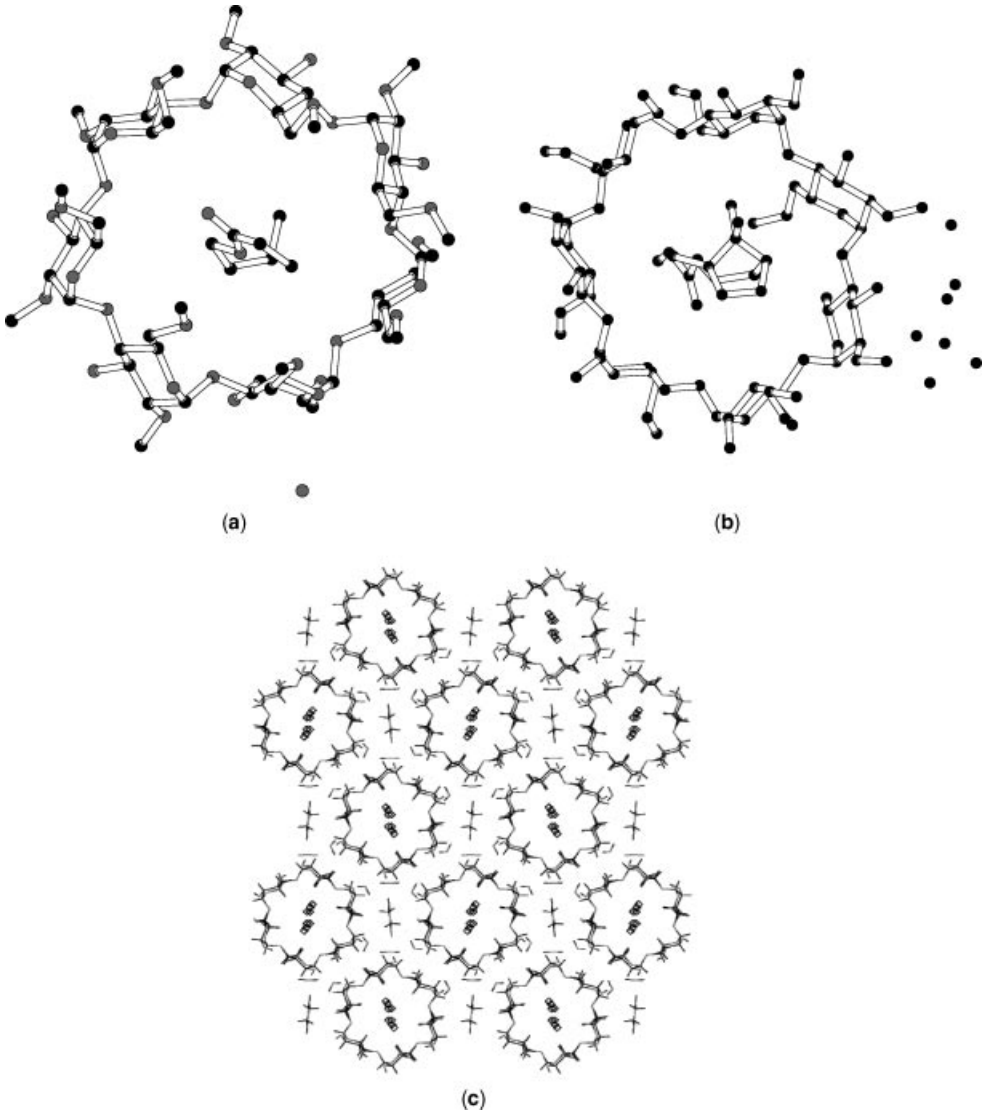

Fig. 4. 600 MHz ^{1}H, ^{1}H ROESY NMR spectrum of *N*-methacryoyl-L-tyrosine ethylester (**2b**) in D_2O[5].

of uncomplexed monomers. During polymerization, the cyclodextrin generally slips off from the guest monomer and remains nearly quantitatively in the aqueous phase owing to its high water solubility (Fig. 6). The received polymers contain only a trace of cyclodextrin (about <5 mol%). Furthermore, cyclodextrin solution can be reused to enclose new monomers. The surfactant free polymerization technique is a new alternative method to emulsion polymerization, which has been established as industrial processes since decades.

At the beginning of our research the interest was focused on commercial standard vinyl monomers, eg, styrene (**8a**) and methyl methacrylate (**1a**). An

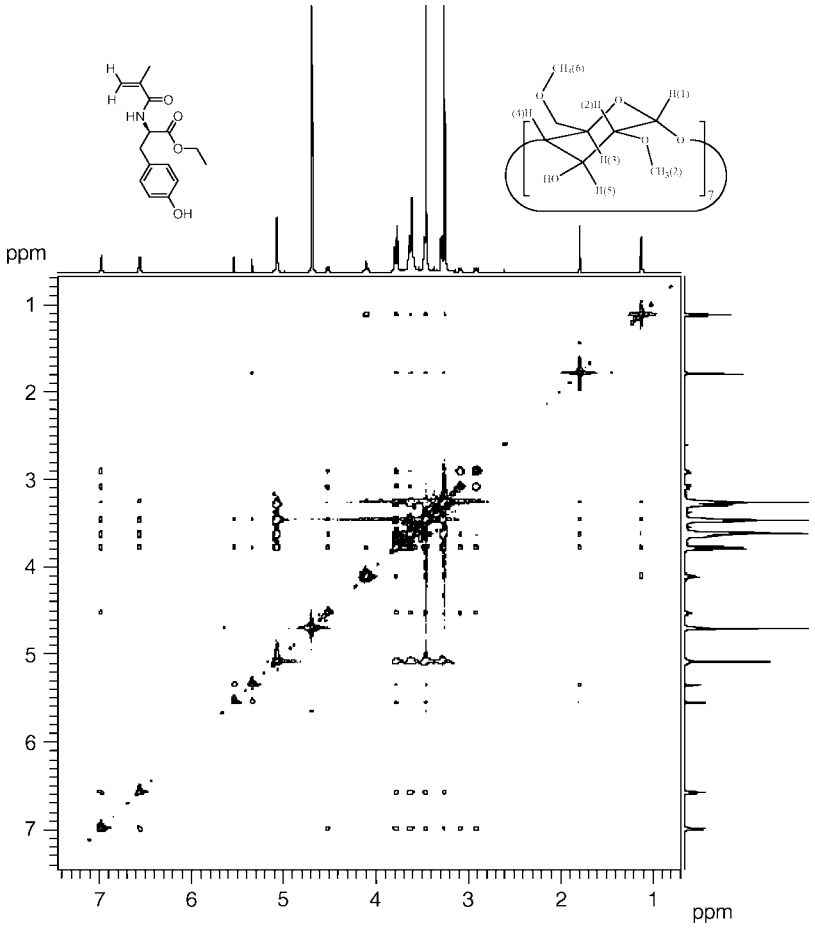

Fig. 5. X-ray structure of (**a**) *n*-butyl acrylate (**1g**)/DIMEB, (**b**) isobornyl acrylate (**3a**)/DIMEB (7), and (**c**) EDT/α-cyclodextrin (8).

equimolar of styrene or **1a** was dispersed in an aqueous solution of RAMEB and stirred at room temperature to give a clear homogenous solution of the complexed monomers. The complex stability of styrene with RAMEB in water is much higher (500 M^{-1}) than the complex stability of **1a** (25 M^{-1}) at room temperature. The aqueous solution of water-soluble complex was homopolymerized radically in water using a free-radical redox initiator $K_2S_2O_8/NaHSO_3$ at 60°C. In both cases, it was shown that polymerization in the presence of cyclodextrin is faster and ends up with higher yields, higher molecular weights, and higher polydispersity (PD) of polymers than polymerization in homogeneous organic solution (11). This observation was also in good agreement with the previous results obtained with RAMEB-complexed and uncomplexed cyclohexyl methacrylate (**1d**) and phenyl methacrylate (**1e**) (12).

Stereoregular polystyrene was prepared using various molar equivalents of β-cyclodextrin (13). A mixture of styrene and β-cyclodextrin was stirred for 30 min,

and polymerized with potassium peroxodisulfate as initiator, sodium lauryl sulfate as an emulsifying agent, and sodium hydrogen phosphate as buffer in water at 60–80°C. It was observed that the molecular weights of the polymers obtained in the presence of β-cyclodextrin were lower than that of the control experiments. Thus, an increase in the styrene/β-cyclodextrin ratios 20:1 caused an increase in the percentage of syndiotacticity. Also, the glass-transition temperature (T_g) of the polymers increased analogous to higher melting temperature at higher styrene/β-cyclodextrin ratios.

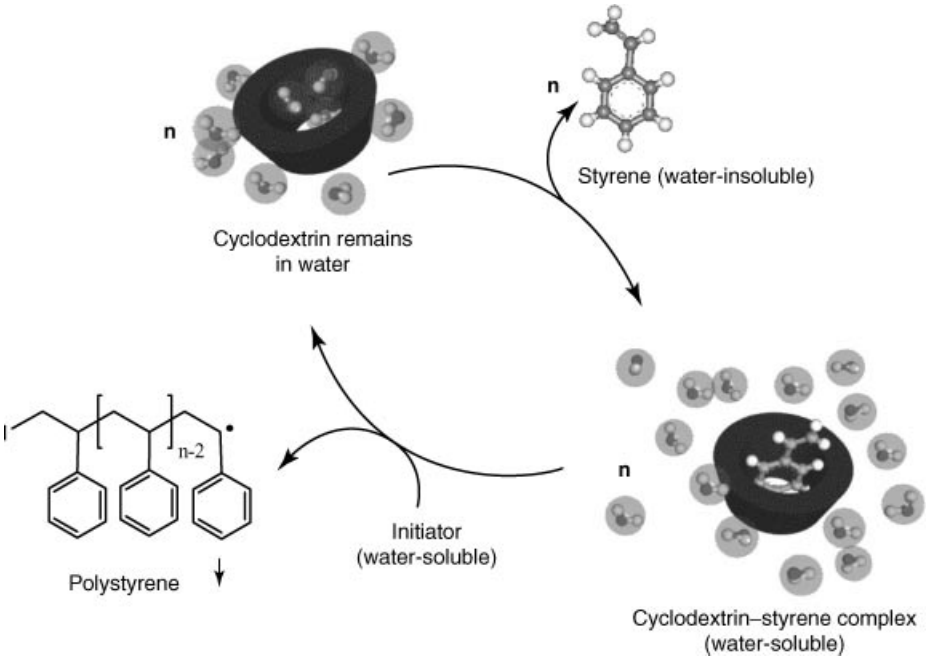

Fig. 6. Schematic presentation of complexation and polymerization of cyclodextrin complexed styrene.

Polystyrene (PS) and polymethyl methacrylate (PMMA) with a narrow particle-size distribution were synthesized under semicontinuous conditions in the presence of different amounts of RAMEB in water using potassium peroxodisulfate (14). The monomers were constantly added to a mixture of RAMEB/initiator solution at 80°C over a period of 2 h. Using these conditions, very stable latices of PS was obtained. It was observed that the polydispersities of PS latex particles prepared in the presence of cyclodextrin were much smaller than in the latices prepared without cyclodextrin. The average particle size decreased with increase in RAMEB concentration from 403 nm (0 wt% of RAMEB) to 267 nm (11 wt% of RAMEB) and increased again to 318 nm (22 wt% of RAMEB) (Fig. 7). The polydispersities of a PMMA latex, prepared in the presence of cyclodextrin, were in the same order as the polymer synthesized without RAMEB. The average particle size increased with increasing amount of RAMEB in the reaction mixture and the particle-size distributions were narrow. However, SEM images of PMMA particles (Fig. 8) showed that the use of cyclodextrin has no influence on the particle-size distribution. It turned out that all the latices contained no aggregates.

Butyl Methacrylate. The role of β-cyclodextrin in the emulsion polymerization of vinyl monomers has been investigated (9). Surfactant free polymerization of *n*-butyl methacrylate in the presence of β-cyclodextrin yielded stable lattices in a formulation which give a grossly coagulated product without cyclodextrin (15). The free-radical polymerization of cyclodextrin complexed *tert*-butyl methacrylate (**1c**) in aqueous phase has been described (10) The influence

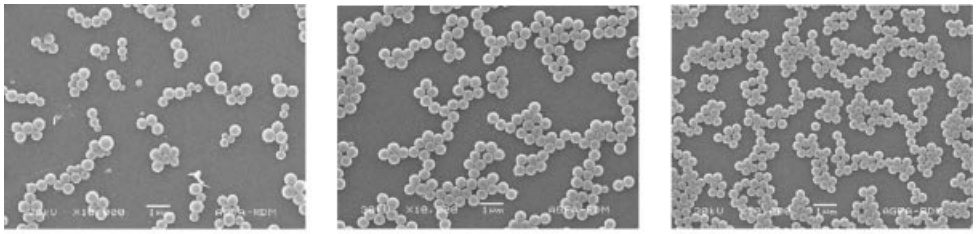

Fig. 7. SEM image of PS particles. (**a**) Polymer was obtained without cyclodextrin. Polymer synthesis in the presence of (**b**) 5.6 wt%, cyclodextrin (**c**) 11.1 wt% cyclodextrin (14).

of sodium nitrite and ascorbic acid on the free-radical polymerization of **1c** has been reported (16) in water at 80°C.

More recent, the free-radical polymerization of water-soluble *tert*-butyl methacrylate (**1c**) (water solubility $\sim 1.69 \times 10^{-3}$ mol/L) and its RAMEB complex at different temperatures has been studied (17). RAMEB and the hydrophobic **1c** were mixed in water in a molar ratio of 1.5:1 yielding the water-soluble complex with the binding constant $K = 65\ M^{-1}$. The homopolymerization reactions were carried out in the presence of water-soluble initiator 2,2′-azobis(amidinopropane)-dihydrochloride (VA044) or $K_2S_2O_8/Na_2S_2O_5$. The polymerization of the complexed monomer or free monomer at 80°C leads to poly(*tert*-butyl methacrylate) with molecular weights in the range of 16,000–41,000 g/mol. In contrast to these results the polymerization without cyclodextrin showed significantly lower yields. It was observed that no polymerization of free monomer occurred at 20°C, whereas, under the same condition, the homopolymerization of the RAMEB-complexed monomer leads to polymer in a high yield (∼75%) with high molecular weight (38,600–64,000 g/mol).

Fluorinated Methacrylates. Fluorinated polymers are very important materials because of their water- and oil-repellent properties. The synthesis of fluoropolymers is one case in which special polymerization techniques are required; eg, emulsion polymerization with added fluorinated surfactant, and

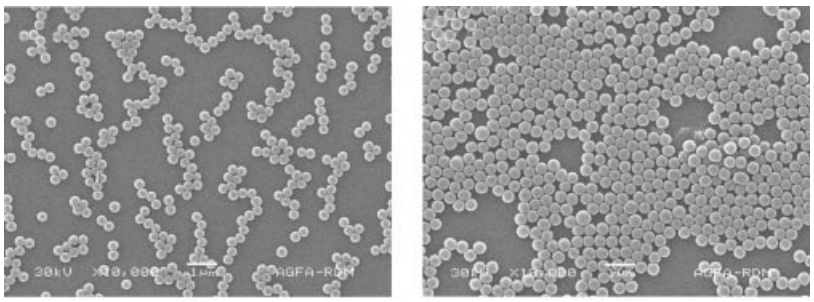

Fig. 8. SEM image of PMMA. Polymer was obtained (**a**) without RAMEB, (**b**) with 5.3 wt% RAMEB (14).

polymerization in organic solvents or solvent mixtures containing CFCs. On the other hand, because of hydrophobic and lipophobic nature of fluorinated monomers, the copolymerization with lipophilic or hydrophilic monomers has been carried out in organic solvents, in mixtures of different solvents, or in emulsion. The low solubility of the fluorinated monomers prohibits the copolymerization in water without addition of fluorinated surfactants or cosolvents. But the cyclodextrin-mediated polymerization in aqueous solution opens up new possibilities to the synthesis of fluorinated polymers without using surfactants or cosolvents. Therefore, fluorinated methacrylates (1*H*,1*H*-pentafluoropropyl) methacrylate (**1k**), (1*H*,1*H*,2*H*,2*H*-tridecafluorooctyl) methacrylate (**1l**) and (1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl) methacrylate (**1m**) were homopolymerized in the presence of 1 mol equivalent of RAMEB in water at 50°C using water-soluble azo initiator or the redox initiator. This concept was also applied to free-radical copolymerization of the monomers **1k, 1l**, and **1m** with styrene (**8a**) in complexed form. The copolymers were isolated via filtration, whereby in all cases almost quantitative yields of the "statistical copolymers" were achieved. The homopolymers poly(**1k**), poly(**1l**), and poly(**1m**) show glass-transition temperatures (T_g's) of 69.5°C, 39°C, and 71°C, respectively. Whereas the copolymers poly(**1k**-*co*-**8a**), poly(**1l**-*co*-**8a**), and poly(**1m**-*co*-**8a**) show higher T_g's at 79.9°C, 60°C, and 85°C.

An additional poly[(1*H*,1*H*,2*H*,2*H*-heptadecafluorodecyl acrylate (**1n**))-*co*-(stearyl methacrylate (**1o**))] was successfully obtained in water in the presence of RAMEB. The copolymer shows two broad endothermic transitions at 32°C and 50°C, which indicates a liquid-crystalline behavior. The results of X-ray diffraction of the copolymer poly(**1n**-*co*-**1o**) at 20°C indicate highly ordered lamella structure (18).

Polymerization of Methyl Methacrylate (1a) Using Atom-Transfer Radical Polymerization. Living Radical Polymerization (qv) (19) is the most significant and useful procedure to synthesize polymers with well-defined structure, controlled molecular weight, and narrow molecular weight distribution. Metal-catalyzed atom-transfer radical polymerization (ATRP) (20), nitroxide-mediated polymerization (21), and reversible addition–fragmentation chain transfer (RAFT) polymerization (22) have been widely used for this purpose. We have investigated for the first time the polymerization of host-guest complexe of methyl methacrylate (**1a**) and RAMEB in aqueous medium using atom-transfer radical polymerization ATRP (23). 4,4′-Di-(5-nonyl)-2,2′-bipyridyl (dNbpy) was used as a very effective ligand in the ATRP of **1a**, which was complexed with large (approximately 4-fold molar) excess of RAMEB in water. The polymerization of **1a**/RAMEB complex was initiated by ethyl 2-bromoisobutyrate (EBIB) in the presence of copper(I)bromide as catalyst. It was found that the polymerization of **1a** under this condition has a "living character." The obtained polymer shows much lower polydispersity (PD = 1.3–1.8) than those obtained from conventional free-radical polymerizations. Additionally, it was observed that a higher conversion of **1a** could be achieved using dNbpy/RAMEB as ligand compared to bipyridine (bipy). Furthermore, the block copolymerization of poly(methyl methacrylate) bearing a bromoester end-group with RAMEB-complexed styrene was also carried out under ATRP conditions in aqueous medium.

Synthesis and Polymerization of New (Meth)acrylic Derivatives

***N*-Methacryloyl Amino Derivatives.** *N*-methacryloyl-11-aminoundecanoic acid (**4a**) and *N*-methacryloyl-1-aminononane (**4b**) were easily prepared by the reaction of methacrylic anhydride with 11-aminoundecanoic acid and aminononane in dichlormethane. The relatively hydrophobic monomers were incorporated into the cavity of RAMEB. The homopolymerization of the complexed monomers was investigated in water or in mixture water:dimethyl sulfoxide (1:4 vol%) initiated by the redox initiator system potassium peroxodisulfate and potassium hydrogensulfite. The kinetics of the polymerization reactions in water/dimethyl sulfoxide measured by the use of ^{1}H NMR spectroscopy showed relatively high polymerization rates for the RAMEB-complexed monomers compared to the polymerization rates of the water-insoluble guest (Fig. 9) (24).

Furthermore, the water-soluble complex consisting of *N*-methacryloyl-11-aminoundecanoic acid (**4a**) and unmodified β-cyclodextrin was obtained at 65°C in water and polymerized in an aqueous medium using the water-soluble azoinitiator 2,2′-azobis(*N*,*N*′-dimethyleneisobutyramidine). The polymer with relatively high molecular weights was isolated in 93% yield after 24 h at 70°C (25).

Oxazoline Derivatives. Oxazolines are of great interest because of their ability to undergo cationic ring-opening polymerization. In this connection, the functionalized monomers *N*-[4-(4′,5′-dihydrooxazol-2-yl)phenyl]acryl amide (**5a**), *N*-[4-(4′,5′-dihydrooxazol-2-yl)phenyl]-2-methacryl amide (**5b**), *N*-{10-[4-(4′,5′-dihydrooxazol-2-yl)phenylcarbamoyl]decyl}-2-acryl amide (**6a**),

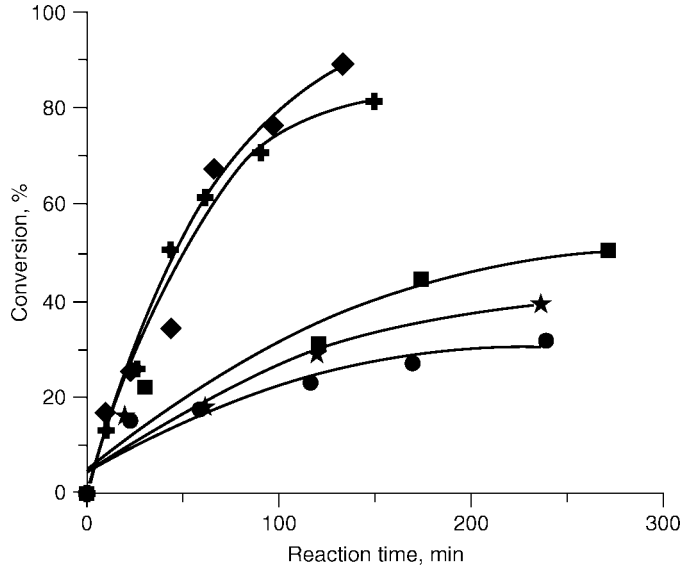

Fig. 9. The influence of methylated β-cyclodextrin on the polymerization rates: + *N*-methacryloyl-11-aminoundecanoic acid (**4a**)/CD complex in water; ◆ *N*-methacryloyl-11-aminononane (**4b**)/CD complex in water; ■ *N*-methacryloyl-11-aminoundecanoic acid (**4a**)/CD complex in water/DMSO; ★ *N*-methacryloyl-11-aminoundecanoic acid (**4a**) in water/DMSO; ● *N*-methacryloyl-11-aminononane (**4b**) in water/DMSO.

N-{10-[4-(4′,5′-dihydrooxazol-2-yl)phenylcarbamoyl]decyl}-2-methacryl amide (**6b**) and *N*-[4-(4′,5′-dihydrooxazol-2-yl)phenyl]-4-vinylbenz amide (**7**) were prepared by condensation of *p*-aminophenyl-2-oxazoline with corresponding acrylic monomers in the presence of 1-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinolin (EEDQ) in dioxane. Oxazoline derivatives were completely incorporated into the RAMEB at room temperature using methanol. As expected, after evaporating the organic solvent, the complexes were completely water-soluble. Their polymerization was carried out in water at 60°C in the presence of 2,2′-azobis(2-amidinopropane) dihydrochloride (AAP) as initiator. ^{1}H NMR and IR spectra of the polymers clearly showed the presence of oxazoline ring as a functional group, which offers possibilities of further modification of the polymers, eg, ionic grafting of alkyloxazoline (26).

Vinylcyclopropane Derivatives. Vinylcyclopropyl acrylates have a potential in the preparation of materials with low shrinkage. 1,1-disubstituted 2-vinylcyclopropane (**9**) containing electron-withdrawing and radical-stabilizing groups are known to undergo radical ring-opening polymerization leading to polymers that consist predominantly of 1,5-linear olefin structure (27, 28) and also isomer cyclobutane-ring structures probably formed by recyclization of the propagating ring-opened radical (29). According to these results, 1-ethoxycarbonyl-1-hexyloxycarbonyl-2-vinylcyclopropane (**9a**) and 1-ethoxycarbonyl-1-cyclohexyloxycarbonyl-2-vinylcyclopropane (**9b**) were synthesized by condensation of 1-ethoxycarbonyl-2-vinylcyclopropane-1-carboxylic acid in the presence of dicyclohexylcarbodiimide (DCC) and 4-dimethylaminopyridine (DMAP) or pyrrolidinylpyridine (PPy). It was found that the radical polymerization of the RAMEB-complexed monomers leads to polymers with higher yields and molecular weights compared to the corresponding values obtained from uncomplexed monomers (30,31).

1-Ethoxycarbonyl-1-[(1*H*,1*H*,2*H*,2*H*)perfluorodecyl]oxycarbonyl-2-vinylcyclopropane (**9c**) was prepared and complexed with RAMEB according to the above-mentioned procedure. Its copolymerization with different ratio of hexyl-substituted vinylcyclopropane **9a** was performed via their respective RAMEB complexes in aqueous solution. In all cases, upon polymerization the water insoluble polymers were isolated by filtration. The prepared polymers exhibited liquid crystalline behavior. The SEC analysis of soluble copolymer (eg, 29 mol% of fluorinated monomer) shows, in fact, monomodal curves with a molar mass of M_n = 68,000 g/mol and polydispersity of PD = 1.62. ^{1}H NMR spectrum of corresponding copolymers shows that the amount of olefin repeating units increased with decreasing content of fluorinated monomer (31).

Mesoionic 6-Oxo-1,6-dihydropyrimidin-3-ium-4-olates. Mesoionic 6-oxo-1,6-dihydropyrimidin-3-ium-4-olates are six-membered heterocycles. Their pharmacological activities are of certain interest, and it was found that irradiation of the mesoionic monomers leads irreversibly to the bis(β-lactame) (32). Up to now, different approaches toward preparing polymers containing mesoionic groups in the main chain in organic solution were attempted (33). Referring to the above results, we have synthesized high melting crystalline methacrylic esters containing mesoionic 6-oxo-1,6-dihydropyrimidin-3-ium-4-olates and then prepared their RAMEB complexes in aqueous medium.

For example, mesoionic 2-[2-(isopropenylcarbonyloxy)ethylthio]-1-methyl-6-oxo-3-phenyl-5-propyl-1,6-dihydro-pyrimidin-3-ium-4-olate (**11**) (34) was stirred in equimolar amount with a solution of RAMEB for 5 days at ambient temperature. The 2:1 host–guest complex **11**/RAMEB was isolated in 71% yield relative to the guest monomer. The water solubility of complex was about 800 mg in 1-ml water at ambient temperature. The radical polymerization of RAMEB-complexed monomer was carried out with 3.3 mol% of redox initiator potassium peroxodisulfate and sodium hydrogensulfite. According to the results of the gel-permeation chromatography (GPC) obtained for the polymer prepared from the uncomplexed monomer, 85% of **11** was unreacted after 1 h. Additionally, the molecular weight distribution of the polymer synthesized without RAMEB is bimodal with M_w = 11,000 g/mol and polydispersity of 4.5 (35).

***N*-Isopropyl Acrylamide.** Homopolymers from *N*-isopropyl acrylamide (NIPAAm) are well known and have been of great interest because of their low critical solution temperature (LCST) behavior in water-solution. The polymer is soluble at low temperatures in water and precipitates above the LCST upon heating. Those kinds of polymers are potentially useful in the pharmaceutical or medical area. The homo- and copolymerization with water-soluble comonomers such as 2-hydroxyethyl methacrylate and characterization of the corresponding polymers of NIPAAm are described in some papers. In the case of copolymerization with hydrophobic comonomers, the use of an organic solvent is necessary, otherwise the polymerization has to be carried out in emulsion. But the different solubilities of the monomers in water often make the copolymerization of water-soluble and water-insoluble monomers by classical emulsion polymerization difficult. Because of the above discussed property of cyclodextrin derivatives, these problems can be avoided if the copolymerization reactions are performed in the presence of cyclodextrin derivatives.

Regarding our current work on the polymerization using cyclodextrins, the copolymerization of RAMEB-complexed *n*-butyl methacrylate (**1b**), cyclohexyl methacrylate (**1d**), isobornyl acrylate (**3a**), isobornyl methacrylate (**3b**), and styrene (**8a**) with the water-soluble *N*-isopropyl acrylamide (NIPAAm) was examined. The RAMEB complexes of **1b, 1d, 3a, 3b**, and **8a** were copolymerized with NIPAAm in water in molar ratios of 1:9 (90 mol% NIPAAm) and 1:4 (80 mol% NIPAAm), respectively for 12 h at 80°C using 5.5 mol% of AAP. For comparison, the copolymerization of styrene (**8a**) with NIPAAm at the same initial concentrations at molar ratios of 1:2 (67 mol% of NIPAAm) and 1:1 (50 mol% of NIPAAm), respectively, were also carried out under similar reaction conditions, in a mixture of *N*,*N*′-dimethylformamide (DMF) and water (9:1, vol%), without RAMEB. Surprisingly, it was found by means of SEC data that for all molar ratios of the incorporated monomer units, the average weight M_w of the copolymers obtained from complexed styrene (**8a**) and NIPAAm is about 3 to 7 times higher than that corresponding to the copolymers obtained from uncomplexed styrene and NIPAAm in DMF/water solution. In all cases, UV signal and RI signal of SEC elution of the monomodalic SEC curves deviated only slightly by about 10% of the maximum (36).

The concept has been applied to the free-radical copolymerization of a water-soluble azo monomer with a water-insoluble monomer, eg, styrene. The RAMEB-complexed styrene was copolymerized in various molar ratios with sodium-4-(acrylamido)-phenyldiazosulfonate (**10**) at 40°C using 1.5 mol% of water-soluble

free-radical initiator 2,2′-azobis-(*N*,*N*′-dimethyleneisobutyramidine) dihydrochloride (VA 044) (37). Depending on the amount of styrene in the copolymer, water- or DMF-soluble copolymers with high molecular weights were obtained. In all cases, the azo content of the polymer was below that of the monomer feed, as was determined by elemental analysis and UV spectroscopy. These results indicate that the diazosulfonate monomer is less reactive than the complexed styrene (**4a**). The molecular weight of the polymers were in the range of M_n = 14,000-24,000 g/mol, with an unexpected low polydispersity (PD = 2.4–2.5). Because of the high absorption coefficient [above 15 000 $(mol \cdot cm)^{-1}$] of the diazosulfonates, rapid photochemical decomposition was observed upon irradiation with suitable wavelength of the UV light. The rapid degradation of the azochromophores during irradiation of the polymers in DMSO solution was observed by UV–visible analysis.

Finally, it was thus interesting to investigate the possibility to use a suitable cyclodextrin complexed photoinitiator for initiation of polymerization in aqueous medium. In comparison to the thermal polymerization, the main advantage of the photoinitiated radical polymerization is the high efficiency and the reduced energy consumption.

Thus, a mixture of photoinitiator 2-hydroxy-2-methyl-1-phenylpropan-1-one (Ciba) and RAMEB in water was sonificated for 5 min yielding a clear solution of the complexed initiator. To evaluate the influence of cyclodextrin, the polymerization of NIPAAm in aqueous solution initiated with complexed and uncomplexed photoinitiator Ciba was performed. After the addition of 2 mol% of RAMEB-complexed Ciba, the mixture was irradiated with a high pressure mercury lamp at 20°C. UV spectroscopic measurements (Fig. 10) revealed that the polymerization reaction initiated with the RAMEB-complexed initiator is faster and ends up with higher yield than the polymerization in the absence of cyclodextrin (38).

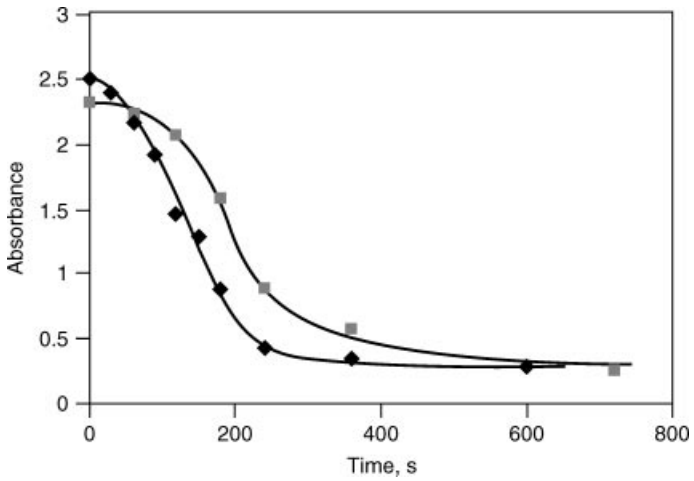

Fig. 10. UV absorbance of nonreacted NIPAAm during polymerization reactions initiated with 2-hydroxy-2-methyl-1-phenylpropan-1-one (Ciba) in the presence of cyclodextrin (■) without cyclodextrin (◆).

Unsaturated Polyester. Commercially available unsaturated polyester (39) has found a large number of applications in many areas, eg, auto industries and coating materials. A water-soluble unsaturated polymer with the molecular weights of 11,000–13,000 g/mol was cross-linked with the RAMEB-complexed styrene at 25°C using 4 mol% of the water-soluble redox initiator. A comparative experiment with uncomplexed comonomer styrene showed that higher yield and a higher content of polystyrene in the copolymer was achieved in the presence of RAMEB (40).

***N*-Methacryloyl-D,L-phenylalanine Methyl Ester.** The enantiodiscriminating influence of cyclodextrin in the free-radical polymerization of the racemic monomer *N*-methacryloyl-D,L-phenylalanine methyl ester (**2e**) (41) was investigated for the first time. **2e** was synthesized in 99% yield by the reaction of phenylalanine methyl ester hydrochlorides with methacryloyl chloride in the presence of triethylamine. The racemic monomer was subsequently added to an aqueous solution of RAMEB yielding a clear colorless solution of complexed monomer. Homopolymerizations were carried out in the presence of redox initiator at various temperatures. It was showed that the L-enantiomer is enriched in the residual monomer mixture. This observation confirms that complexed D-enantiomer polymerizes faster than the complexed L-enantiomer. No polymerization of **2e** was observed without cyclodextrin under the same conditions.

Cyclodextrin as Thermosensitive Stabilizer and Retardant

Cyclodextrin is not only used for improving the solubility of several water-insoluble hydrophobic monomers in aqueous medium, but also to stabilize some special monomers and to reduce the reactivity in the radical polymerization at room temperature. Because of the position of the vinyl group in the cyclodextrin cavity or strong interactions with the complexed monomer, cyclodextrin may act as thermosensitive stabilizer and also retard the free-radical polymerization process. For example, in the case of *N*-methacryloyl-L-tyrosine derivatives, no polymerization reactions were observed at room temperature in the presence of cyclodextrin (8).

4-Vinylbenzaldehyde. 4-Vinylbenzaldehyde (**8b**) was synthesized by Heck reaction of 4-bromobenzaldehyde with ethylene in the presence of palladium(II)acetate, tri(*o*-toluoyl)phosphine and triethylamine in dimethyl formamide (42), and then complexed with RAMEB to obtain a clear homogenous solution of the host–guest complex. The complex of **8b** was polymerized in water, and for comparison the uncomplexed monomer was polymerized in water and also in organic solution (43). The polymers obtained in the presence of cyclodextrin precipitated in lower yields and the molecular weights were higher than those of the polymers obtained in benzene. The lower yield of the polymer indicates that the spatial structure of the complex reduces the probability of chain radicals to react with the vinyl groups located in the center of the cyclodextrin cavity. However, at higher temperature (70°C), the mobility of 4-vinylbenzaldehyde in complexed form is strongly increased, which leads to a higher yield of polymer. The higher yields and slightly higher molecular weights of the polymers obtained from the uncomplexed **8b** under identical reaction conditions demonstrates the

ability of the cyclodextrin to act as spatial protection group for the vinyl double bond.

***N*-Methacryloyl-L-tyrosine Derivatives.** *N*-Methacryloyl-L-tyrosine methyl ester (**2a**) and *N*-methacryloyl-L-tyrosine ethyl ester (**2b**) were prepared by the reaction of trimethysilyl-protected L-tyrosine esters with methacryloyl chloride. The synthesis of acetyl derivatives **2c** and **2d** was carried out by reaction of *N*-methacryloyl-L-tyrosine esters **2a** and **2b** with acetyl chloride in the presence of triethylamine. The cyclodextrin complexes of the monomers were prepared by stirring an equimolar amount of RAMEB and the corresponding monomers **2a–2d** in water. The clear aqueous solution of the host–guest complexes was initiated with free-radical redox initiator $K_2S_2O_8/NaHSO_3$ at room temperature. The reaction mixture remained clear for up to five days, which suggests the existence of stable host–guest complexes at ambient temperature. At higher temperature ($>40^\circ$C) the mobility of the guest monomer increases, which leads to rapid polymerization of the RAMEB-complexed monomers **2a–2d** in aqueous medium. However, the polymerization of the monomers **2a–2d** in the presence of RAMEB at 60°C ends up with higher molecular weights and higher polydispersities (PD) than in the case of polymerization of uncomplexed monomers in water and also in organic solvents (8).

Oxidative Polymerization in the Presence of Cyclodextrin Derivatives

Enzyme-Catalyzed Polymerization. Horseradish peroxidase (HRP) has been used for the oxidation of a wide variety of compounds, eg, phenol derivatives in the presence of hydroperoxide (44). HRP is a kind of heme glycoprotein that catalyzes the oxidation of phenol to phenoxy radicals. Subsequently, the resulting phenoxy radicals couple each other to oligo or polyphenol derivatives step by step (see OXIDATIVE POLYMERIZATION).

The enzyme-catalyzed polymerization of phenol is an alternative to the production of conventional Phenolic Resins (qv), without use of toxic formaldehyde and under milder conditions. Because of the poor solubility of phenol derivatives and detrimental effect of excess of organic solvent on enzyme activity, the reactions catalyzed by HRP are often carried out in a mixture of water-miscible organic solvents, eg, dioxane and an aqueous buffer. To overcome the above limitations, the oligomerization process in the presence of cyclodextrin derivatives has been combined with the HRP-catalyzed oxidative coupling. Water-soluble complexes of para-substituted phenol derivatives *N*-(4-hydroxyphenyl)-maleimide (**12**), 4′-hydroxymethylacrylanilide (**4c**), *N*-methacryloyl-11-aminoundecanoyl-4-hydroxyanilide (**4d**), 1-[(4-hydroxyphenyl)aminocarbonyl)]-2-vinylcyclopropane carboxylate (**9d**), and RAMEB were formed in water and polymerized oxidative using HRP/H_2O_2 (45,46). The HRP-catalyzed oligomerization chemoselectively produced a polymer containing a reactive unsaturated group in the side chain.

The oligormer obtained from complexed *N*-(4-hydroxyphenyl)-maleimide had a high molecular weight fraction up to 3000 Da and was soluble in tetrahydrofuran. FT–IR spectrum of the oligomer showed no phenoxy ether linkages. It was found that the oligomerization rate of complexed monomer was about 10%

faster than that of the uncomplexed monomer. This indicates that the cyclodextrin molecules did not block the reactive sites of the phenoxy radical. Free-radical copolymerization of the corresponding oligomer obtained from monomer **12** with styrene and AIBN as initiator in tetrahydrofuran leaded to three-dimensional network. The powdery material was insoluble in common organic solvents, eg, methanol, dimethylformamide, or dimethylsulfoxide, and showed no glass transition or melting point below 300°C.

Also, free-radical ring-opening polymerization of oligomer obtained from complexed **9d** with AIBN in tetrahydrofuran at 65°C formed a network.

Oxidative Polymerizable Monomers. A further successful example of a cyclodextrin-mediated polymerization reaction is the oxidative oligomerization of heterocyclic aromatic compounds such as pyrrole or 3,4-substituted dioxythiophene EDT. Electrochemical and chemical polymerization [Fe(III)chloride or potassium peroxodisulfate] of homogenous aqueous solution of cyclodextrin-complexed monomers resulted in precipitation of the corresponding polypyrrole and PEDT. Conductivity measurements of the polymers showed identical electrical properties (10–100 S/cm) as a conventionally prepared polymer (7). Because of the substantial π-electron delocalization along their backbones, these polymers show interesting (nonlinear) optical properties and become good electric conductors when being oxidized or reduced (see ELECTRICALLY ACTIVE POLYMERS). Conducting polymers open up a variety of potential practical applications in industrial terms, eg, information storge, optical signal processing, recharged batteries, light-emitting diodes, field effect transistors, printed circuit boards, sensors, antistatic materials, electromagnetic interference (EMI) shielding, and solar energy conversion (47,48). Electropolymerization (qv) of aromatic and heteroaromatic compounds is one of the most valuable techniques for the synthesis of electrically conducting organic polymers (49). Because of the low water solubility of the monomers and the high reactivity of the initially formed radical cations towards water molecules, most conducting polymers are synthesized in organic solution. However, water is the ideal solvent for practical use and industrial applications. The high water solubility of the host–guest complex has led to considerable interest in usage of the cyclodextrin derivatives in the synthesis of conducting polymers.

Electrochemical properties of polypyrrole films grown in $LiClO_4$ acetonitrile solution (2% water) at gold electrodes modified with thiolated β-cyclodextrin self-assembled monolayers have been investigated. Scanning electron microscopic results show that thiolated β-cyclodextrin acts as a molecular template to restrict the growth sites within the β-cyclodextrin cavities (50).

Inclusion compounds using hydroxypropyl-β-cyclodextrin as host molecules have been used to electropolymerize bithiophene for the first time in aqueous medium (51). Thin films of polybiothiophene were produced by electrooxidation of an aqueous solution of bithiophene, cyclodextrin, and $LiClO_4$ at platinum electrodes, using cyclic voltametry and galvanostatic method.

The chemical synthesis and electrosynthesis of polypyrrole in the presence of sulfonated cyclodextrin as a dopant has been reported (52). In this case, cyclodextrin seems to play an important role in forming polymer with ordered structure.

Influence of Methylated β-Cyclodextrin as Host Molecule on the Kinetics of the Free-Radical Copolymerization

Reactivity Ratios. The new cyclodextrin-mediated polymerization method of hydrophilic monomers differs strongly from classical methods such as emulsion polymerization. For example, because of the inclusion of the monomers into the cyclodextrin cavities, the copolymerization parameters may be influenced significantly (see COPOLYMERIZATION). As an interesting observation, it was found that the reactivity ratios of the RAMEB-complexed monomers isobornyl acrylate (**3a**) and *n*-butyl acrylate (**1g**) ($r_{\mathbf{3a}/\mathrm{RAMEB}} = 0.3 \pm 0.1$), ($r_{\mathbf{1g}/\mathrm{RAMEB}} = 1.7 \pm 0.1$) differ significantly from the *r* values of the corresponding uncomplexed monomers in dimethyl formamide ($r_{\mathbf{3a}} = 1.3 \pm 0.1$) and ($r_{\mathbf{1g}} = 1{,}0 \pm 0.1$). Analogous to the above-described homopolymerization reactions, the molecular weights (M_n) of the copolymers obtained from the complexed monomer were about five times higher than those corresponding to the copolymers obtained from organic solution (53).

Additionally, copolymerization of RAMEB-complexed monomers *n*-butyl acrylate (**1g**), *n*-hexyl acrylate (**1i**) and cyclohexyl acrylate (**1j**) led to the following arithmeric averages of the reactivity ratios: copolymerization of **1g**/RAMEB and **1i**/RAMEB: ($r_{\mathbf{1g}/\mathrm{RAMEB}} = 1.01 \pm 0.01$, $r_{\mathbf{1i}/\mathrm{RAMEB}} = 1.04 \pm 0.01$); copolymerization of **1j**/RAMEB and **1i**/RAMEB: ($r_{\mathbf{1j}/\mathrm{RAMEB}} = 0.74 \pm 0.01$, $r_{\mathbf{1i}/\mathrm{RAMEB}} = 1.28 \pm 0.01$); copolymerization of **1j**/RAMEB and **1g**/RAMEB: ($r_{\mathbf{1j}/\mathrm{RAMEB}} = 0.75 \pm 0.04$, $r_{\mathbf{1g}/\mathrm{RAMEB}} = 1.13 \pm 0.01$). Only the copolymerization of water-soluble cyclodextrin-complexed **1g** with cyclodextrin-complexed **1i** leads to a nearly ideal statistical copolymer. The copolymerization in the absence of cyclodextrin in DMF/H_2O solution resulted to nearly ideal statistical copolymers in all cases: **1g** and **1i**: ($r_{\mathbf{1g}} = 1.01 \pm 0.01$, $r_{\mathbf{1i}} = 0.91 \pm 0.03$); **1j** and **1i**: ($r_{\mathbf{1j}} = 1.04 \pm 0.04$, $r_{\mathbf{1i}} = 1.04 \pm 0.08$); **1j** and **1g**: ($r_{\mathbf{1j}} = 0.95 \pm 0.02$, $r_{\mathbf{1g}} = 1.24 \pm 0.04$) (54). It can be concluded that the interactions between monomer and cyclodextrin are liable substantially for the control of copolymerization reactivity ratio. According to these experiments, it can be postulated that the stronger the interaction between host and guest, the lower the *r* value.

Initial Rate v_0. The influence of the hydrophilic character of acrylate side groups on the initial polymerization rate v_0 in the presence of cyclodextrin has also been investigated. For kinetic studies, the RAMEB-complexed monomers *n*-propyl, butyl, pentyl, hexyl, and cyclohexy acrylate **1f–1j** were polymerized in water by free-radical mechanism, using the water-soluble initiator 2,2′-azobis(2-amidinopropane) dihydrochloride (AAP). The concentration of nonreacted monomer in the reaction mixture was deteminated using UV spectroscopy or high performance liquid chromatography (HPLC). The initial reaction rate v_0 increases from RAMEB-complexed monomer **1f** (12.5 ± 1.18) via **1g** (27.5 ± 0.83) to **1h** (44.2 ± 3.54) to **1j** (49.4 ± 1.18) up to **1i** (75.8 ± 2.55) $\times 10^{-6}$ mol/L·s. However, the water solubility of uncomplexed monomer increases in the following order: *n*-hexyl acrylate > *n*-pentyl acrylate > cyclohexyl acrylate > *n*-butyl acrylate > *n*-propyl acrylate. The increasing hydrophobic character of the side group causes the reduced water solubility of the monomers **1f–1i**. Moreover, the stability of the host–guest complex generally increases with geometrical fit of the guest in the cyclodextrin cavity. Also, the complex and dynamic stabilities, which

are influenced by the sterical demands of the guest monomers, have an influence on the overall rate of polymerization. But the increase of the initial rate v_0 with the increasing hydrophobic character of the complexed monomers seems to be the most important factor for the involved monomers **1f–1i**. It was postulated that the more hydrophobic the monomer, the higher the local concentration of complexes close to the active radical chain end of the phase-separated polymer. This leads to higher values of the initial rate v_0 (55).

Chain-Transfer Agents. Radical chain-transfer agents, eg, various thiols, have been applied over several decades to control the molecular weight of the polymerization or to terminate the growing polymer chain, eg, in the case of telomerization (38). Recently, we have observed that the chain-transfer constants of the water-soluble *N*-acetyl-L-cystein to RAMEB-complexed monomers, eg, methyl methacrylate and styrene, are three times higher in water than in the case of a mixture of *N*,*N*′-dimethylformamide and water.

Also, for the determination of the chain-transfer constants the RAMEB-complexed monomers methyl methacrylate **1a** and styrene **8a** were polymerized for 4 h at 80°C using 0.3% (wt/wt) of the water-soluble free-radical initiator AAP in the presence of different amounts of the water-soluble chain-transfer agent *N*-acetyl-L-cystein from 0 to 3.0 mol%. Relatively high chain-transfer constants of *N*-acetyl-L-cysteine were found in the case of the complexed monomers **1a** and **8a** in water ($Cs_{\mathbf{1a}/\mathrm{RAMEB}} = 1.7 \pm 0.3$ and $Cs_{\mathbf{8a}/\mathrm{RAMEB}} = 2.6 \pm 0.3$). In contrast, the chain-transfer constants in DMF/water mixture are significantly lower for uncomplexed monomers **1a** and **8a** ($Cs_{\mathbf{1a}} = 0.7 \pm 0.1$ and $Cs_{\mathbf{8a}} = 0.7 \pm 0.1$). From these results, it can be concluded that the molecular weight of the polymer obtained from complexed monomers can be controlled more effectively using hydrophilic thiol-containing chain-transfer agents than in the case of a polymerization of the respective uncomplexed monomers in an organic medium (56). Furthermore, the chain-transfer constants of RAMEB-complexed dodecanethiol for **1a**/RAMEB ($Cs_{\mathbf{1a}/\mathrm{RAMEB}} = 0.5 \pm 0.2$) and for **4a**/RAMEB ($Cs_{\mathbf{8a}/\mathrm{RAMEB}} = 2.2 \pm 0.3$) were observed in water. They also differ significantly from the corresponding values obtained from the polymerization experiments with uncomplexed monomers in the presence of uncomplexed dodecanethiol in an organic solution ($Cs_{\mathbf{1a}} = 3.1 \pm 0.3$ and $Cs_{\mathbf{8a}} = 3.4 \pm 0.3$). In this case, the molecular weight of the polymers obtained from organic solution can be controlled more effectively by the uncomplexed hydrophobic thiol as the chain-transfer agent (57).

BIODEGRADABLE POLYMERS AND PLASTICS IN LANDFILL SITES

Introduction

Today, landfill may be regarded as a last resort for the waste management of plastics. Recycle through the reuse of plastic waste in fabrication, incineration for energy generation, and recycle through the natural cycle of biodegradation in compost or soil are much preferred disposal methods. However, considerable quantities of plastics (millions of tons annually), particularly packaging plastics, are still being dumped into landfills, where they occupy large volumes and contribute to capacity shortages.

Modern landfills are generally classified in several ways. One classification is by the types of waste that they receive, such as hazardous waste or municipal waste. In practice, these are not exclusive classifications since inevitably there is always some crossover because of source separation problems. An alternative classification is based on the functional mode of the landfill. Total containment landfills are designed to prevent any exchange with the surrounding environment and are particularly desirable for hazardous waste disposal. Leachate recycle landfills are designed to capture and recycle aqueous leachate to prevent or reduce environmental leakage of potentially harmful waste or degradation residues. Controlled contaminant release landfills allow for gradual migration of leachate into the environment under closely monitored conditions to ensure that no harmful events happen. Unrestricted contaminant release landfills, which are older waste dumps, are particularly prevalent in poorer nations, and have no controls of leachate or environmental contamination.

Plastics entering any of these landfill types may or may not degrade and/or biodegrade depending on their composition and the particular landfill environmental conditions to which they are exposed. By their nature, landfill

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

environments are initially aerobic and undergo transition into anaerobic environments at a rate dependent on the utilization of oxygen by the microorganisms present to degrade waste and on the depth of the landfill. This article reviews what is known regarding the fate of common plastics placed into landfill sites for disposal or for a specific application such as a landfill daily cover. Degradations in both aerobic and anaerobic environments are discussed for a variety of packaging plastics and other polymers commonly found in landfill sites.

Polyolefins, particularly polyethylene, have been studied extensively in the real-world environment of landfills, where evidence of degradation and some potential for biodegradation is becoming apparent, though not yet conclusive. For most other plastics, anaerobic testing in laboratory simulation of landfills has been the focus with mixed results. Some polymers, such as the naturally produced polyhydroxyalkanoates, are biodegradable in aerobic and anaerobic environments, whereas most others are not at all biodegradable in anaerobic environments. Clearly, much work remains to be done to understand degradation and biodegradation in landfills, both in the laboratory and in the real world. The results will be important and will have great impact on the future directions for polymer and plastics waste management.

Composition of Trash in Landfill Sites

William L. Rathje, Professor of Archeology at the University of Arizona, is one of the most experienced and articulate "garbage pickers" in the world today. As the founder of the Garbage Project, he, his colleagues, and his students have been investigating the contents of landfills for about 30 years. His published analyses include landfills in and around Chicago, the San Francisco Bay area, Tuscon, Phoenix, Toronto, and New York City (1). As well as providing an historical context [garbage through the ages, as it were (2)], Prof. Rathje relates differences in social patterns and life styles to what he finds in landfills, sanitary, or otherwise. He has also noted that there are common misperceptions about what materials are actually discarded, collected, and deposited in landfills.

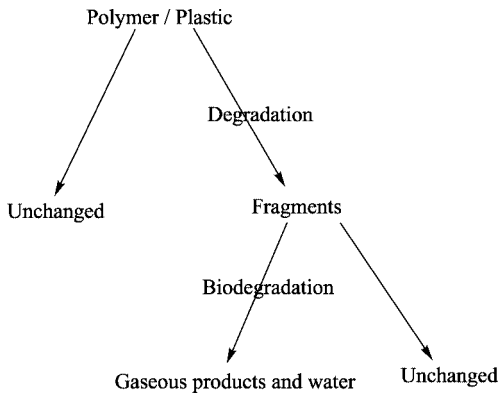
In 1991, Rathje estimated that every person in the continental United States generated an average of 1.8 kg (4 lb) of trash per day. The Fresh Kills Landfill (on Staten Island, now closed) received 15,500 t of garbage daily from New York City, 6 days a week. Prof. Rathje's assessment of the content by wt% is as follows: paper 50%, plastic 10%, metal 6%, glass 1%, and organic 13% (including yard waste, food waste, wood). The remaining 20% is a mixture that includes construction debris, disposable diapers, rubber, textiles, and tires. Rather more detail is available (3) about the composition of refuse from the Mallard North Landfill site (Chicago). Mean weight percent values are as follows: paper 32.7%, ash 22.2%, wood 12.3%, fines 8.6%, ferrous metal 7.4%, plastic 5.6%, glass 4.5%, textiles 3.8%, garden waste 1.9%, and rubber 1.0%; food, nonferrous metals, foamed polystyrene and cigarettes were each less than 1%. The waste, dated by means of discarded newspapers, was excavated in 1988, when it was about 20 years old.

The data derived from Prof. Rathje's excavations during October 1991 in the metropolitan Toronto area (4) are consistent with those obtained by his team of "garbologists" from analogous investigations throughout the United States.

Omitting the construction and demolition debris from the calculations, the composition (by volume this time) is as follows: paper and paperboard 50%, plastics 14%, metals 12%, glass 4%, organics 6%, and miscellaneous 14%. All plastic packaging (post-consumer, industrial, commercial, and institutional) represented about 8% of the overall refuse. It is a reasonable assumption that the composition of plastics discarded in landfills is a reflection of the quantities produced for packaging applications; the commodity plastics polyethylene, polypropylene, polystyrene, and poly(vinyl chloride) should be well represented (see ETHYLENE POLYMERS; PROPYLENE POLYMERS (PP); STYRENE POLYMERS; VINYL CHLORIDE POLYMERS).

Degradation Processes in Landfills

The fate of polymers and plastics in landfill can be represented schematically as shown below:



They may remain unchanged, or they may degrade by some biotic or abiotic process to fragments that either remain or biodegrade to gaseous products and water. The gaseous products are carbon dioxide in an aerobic environment and a mixture of carbon dioxide and methane in an anaerobic environment. The pathways obviously play a strong role in the subsequent stability and volume usage of the landfill, and there needs to be a thorough understanding of the chemistries involved with the particular polymer or plastic.

Biodegradation of organic materials is the result of activities of microorganisms, such microflora as fungi, yeasts, actinomycetes, and bacteria. Focusing on the first and last of these, the two main groups represent an enormous array of possibilities. Fungi operate primarily under aerobic, moist conditions, and proliferate by sporulation. Their spores and hyphal fragments are found universally and will generate new colonies whenever and wherever favorable conditions exist or arise. The environment "selects" which of the 80,000 or so species will germinate and grow. Bacteria, like fungi, are distributed universally throughout the surface of the earth and in the atmosphere. Around 2000 species of bacteria are known, but there are almost certainly many more species that are not known. Bacteria proliferate by cell division and require the presence of liquid water.

Biodegradation is nature's way of returning nonliving organic material to the carbon cycle. Commonly, microorganisms generate and secrete aqueous solutions of enzymes that chemically degrade and dissolve

supporting material (the substrate), which is then absorbed back into the organism through the cell walls, as food for growth and energy generation. Moisture is essential and the organic substrates should be hydrophilic and easily "wettable" to provide sites for enzyme activity. Under the right conditions, the proliferation of microorganisms can occur to a phenomenal extent. It has been calculated, for example, that the weight of microorganisms in arable land is 3 to 5 ton in an area of 4.05×10^3 m^2 (1 acre) to a depth of 30 cm (1 foot), and that 1 g of microorganisms may contain 10^{10} individuals. In soil, bacteria are found at greater depths than are fungi since many of them, the anaerobes, are able to survive without free oxygen in the reducing conditions that kill all other forms of life. This fact is relevant to microbial activity at the lower levels in landfills.

There is much evidence of extensive microbial activity in landfills, which is not surprising in view of the large organic content of waste, and the ubiquitous occurrence of fungi and bacteria, The heat generated by the microbes as they convert carbon into usable intermediates is significant, even at only moderate depths below the active face of the landfill. For some time (months, a year, or even longer) following the dumping of waste at the active face of a landfill, there will be enough oxygen present to allow for vigorous aerobic biodegradation of the susceptible refuse by fungi, bacteria, and the like. At some later stage, after a time period that will vary with conditions and operating procedures, a shortage of oxygen is likely to develop, and at the deeper levels of the landfill, anaerobic biodegradation largely by bacteria will begin and eventually dominate. It may be argued that it is entirely preferable to encourage as much biodegradation as possible during the aerobic period, for these reasons:

(1) The ultimate conversion product of the organic carbon in the waste from aerobic biodegradation is carbon dioxide, CO_2, whereas the major product from anaerobic biodegradation is methane, CH_4. The latter gas is 24.5 times more potent than carbon dioxide (5) as a greenhouse gas.
(2) The commodity of value in the operation of a landfill is space, and the more rapidly abiotic degradation and biodegradation occur, the longer the space will last before a new site is required.
(3) The more rapidly the biodegradation occurs, the shorter and less expensive will be the after-care period, and the sooner the site can be used safely for another purpose.

The Resource Conservation and Recovery Act, the US Federal Government, defines the criteria for the operation of Municipal Solid Waste Landfills (MSWLF), effective October 1993. Daily and alternative daily cover (ADC) requirements are described under Subtitle D, as follows:

(1) the owner or operator of all MSWLF must cover disposed solid waste with 150 mm (6 in.) of earthen material at the end of each operating day, or at more frequent intervals if necessary, in order to control disease vectors, fires, odor, blowing litter, and scavenging;
(2) alternative materials of a thickness other than 150 mm earthen material may be approved...if the owner or operator demonstrates that the alternative material performs the same functions as the 150 mm of soil.

In addition this ADC must not present a threat to human health and the environment.

A comprehensive investigation carried out (6) at the District of Chilliwack's Bailey Sanitary Landfill (approximately 60 km east of Vancouver, B.C.) based on the merits of ADC material evaluated technology developed by EPI Environmental Products Inc. as a landfill cover. This 76-μm (3 mil) polyethylene film contained an additive formulation (totally degradable plastic additives or TDPA) that results in a much higher than normal rate of oxidation. The heat generated by the activity of microorganisms in the landfill initiated the thermal oxidation of the polyethylene film, and the prodegradant in the additive dramatically increased the rate of oxidative degradation of the plastic. After burial for 98 days (December 18, 1995 to March 21, 1996) at a mean monthly air temperature between 1 and 5°C and a cumulative rainfall of about 700 mm, the film no longer existed as an intact layer but was punctured by numerous holes, and mixed up with the waste. The melt index of the plastic had increased, and the tensile breaking strength and elongation to break had decreased significantly. Fourier transform infrared (FTIR) spectroscopy of the recovered material indicated extensive film oxidation and degradation, as a result of thermal initiation. Similar observations were made (6) on the oxidation of a polyethylene ADC film used at the Shenzehu Xiapin landfill in China during the period October to December 1998. In this case, analysis of a sample exposed on the surface indicated that the EPI film, prepared using a TDPA formulation, is also susceptible to photochemically induced oxidation. Analogous results were obtained (7) in a study conducted by M. J. Carter Associates at the Edwin Richards Quarry landfill site located near Birmingham, England. A controlled trial showed that polyethylene containing a TDPA formulation undergoes significant chemical and mechanical degradation over a period of several months (2001–2002) in a landfill environment. Heavy rainfall and low ambient temperatures kept the average temperature in the waste below 30°C for the first seven months after the film samples were placed. After a further seven months, however, molar mass reduction of the polyethylene film that incorporated EPI's TDPA prodegradant formulation was from M_w 115,000 to 4250, well below the threshold for significant biodegradability. In contrast, the control film (containing no TDPA) had a final M_w of 107,000. The report by M. J. Carter Associates reached the conclusion that the results of this trial "confirm the benefits of using degradable plastic materials in a landfill environment." Simply stated these are as follows.

(1) "Refuse sacks that degrade will expose the enclosed refuse to water and micro-organisms and accelerate biodegradation of the waste."
(2) "Using degradable plastic sheets as cover for landfills will reduce the need for conventional imported cover materials and maximize void in the site for waste."

Degradation of Plastics

Standard laboratory testing methods have been developed by ASTM and others to measure degradation and biodegradation in landfill sites in both the initial

aerobic or oxygen-containing phase and in the later anaerobic or oxygen-deficient phase of this environment.

These laboratory simulation tests generally are used for estimating the degradation of condensation polymers, which hydrolytically degrade and then biodegrade in aerobic environments. In anaerobic environments, degradation and biodegradation are generally very slow. Poly(3-hydroxyalkanoates) (qv) produced naturally by bacteria, are an exception to this anaerobic rule as they are readily biodegradable in such environments.

Addition polymers, such as polyolefins, on the other hand, have had limited testing in the laboratory and extensive testing in the real world in working landfill sites. They degrade initially by oxidation and subsequently by biodegradation.

Degradation of Addition Polymers.

Conventional Polyolefins. Among the most versatile of all plastics, the polyolefins (all varieties of polyethylene, and polypropylene) are widely used in a very large number of applications. A partial list of their properties provides the explanation: inexpensive, light, strong, tough, stretchy, low glass-transition temperatures, easy to fabricate, excellent barrier properties and wet strength, and biologically inert. The last three items in particular contribute to the usefulness in food packaging applications, which are characterized by a relatively short use life followed by disposal in a landfill.

It has been recognized for many years that polyolefins are susceptible to oxidative degradation, and a great deal of research has been done to determine why and how, and what to do about it. The reader is encouraged to consult monographs and review articles (8–13) in order to acquire some of the details and complexities of polyolefin oxidation (see also DEGRADATION; STABILIZATION). In essence, oxidative degradation can be summarized as follows.

Even in the presence of a processing antioxidant, the heat and mechanical shear stress of extrusion will give rise to low levels of hydroperoxide group formation, by reactions 1, 2, and 3 where RH is a polyolefin. There is always a trace of oxygen present in extrusion equipment. It is the inevitable presence of hydroperoxide groups that renders polyolefins susceptible to oxidative degradation (frequently called peroxidation). Indeed polyolefins, if pure, would not absorb any radiation from terrestrial sunlight and would be inherently photostable. Such is not the case, however. The major difference between the oxidative degradation of polyolefins initiated by heat (thermal oxidation) and by near-UV light (photooxidation) is that ketone groups are stable to heat but are unstable to UV light, and this adds to the rate of photodegradation.

Oxidative Degradation

$$\mathrm{RH} \xrightarrow[\text{conditions}]{\text{Processing}} \mathrm{R}\cdot + \cdot\mathrm{H} \qquad (1)$$

$$\mathrm{R}^{\bullet} + \mathrm{O}_2 \Rightarrow \mathrm{ROO}^{\bullet} \qquad (2)$$

$$\mathrm{ROO}^{\bullet} + \mathrm{RH} \Rightarrow \mathrm{ROOH} + {}^{\bullet}\mathrm{R} \qquad (3)$$

$$\mathrm{ROOH} \xrightarrow[\text{UV light}]{\text{Heat or}} \mathrm{RO}\cdot + \cdot\mathrm{OH} \tag{4}$$

$$\mathrm{RO}\cdot \xrightarrow[\text{rapidly}]{\text{Very}} \text{Ketones (by } \beta\text{-scission)} \Downarrow \text{Acids, esters, etc} \tag{5}$$

or

$$\mathrm{RO}^{\bullet} \Rightarrow \text{Alcohols (by hydrogen abstraction)} \tag{6}$$

It should be noted that reaction 6 does not lead to polymer chain scission; ie, there is no molar mass reduction here, in contrast to reaction 5 where there is a molar mass reduction. It should also be noted that the formation and reaction of hydroperoxide groups attached to polymer molecules (reactions 3 and 4) are much slower, ie, rate determining, than the other processes shown. It will be apparent from the free-radical products formed in reactions 1 through 4 that this whole peroxidation procedure is a branching chain reaction. Additive chemistry is required to provide polyolefins with any sort of prolonged service life, and such chemistry is well known and entirely effective.

Polyolefins are semicrystalline materials in which oxidation is initially focused in the less-ordered (amorphous) zones. These zones are where impurities, oxygen, stabilizers, and virtually all other additives (if present) are located. In the absence of stabilizing additives, or after the depletion of them, chain scission will occur, tensile elongation values will decrease markedly, and the polyolefin will become brittle. It is generally accepted that at values of elongation at break below 10%, the material breaks into fragments very readily.

Differences in the rates at which various polyolefins undergo oxidative degradation are related primarily (but not entirely) to their molecular structures. There is a significant correlation, for example, between relatively high levels of susceptibility to oxidation and number of tertiary C—H bonds since these bonds have lower bond-dissociation energies than secondary C—H bonds. If this were the only relevant criterion, then the order of increasing susceptibility to oxidation would be HDPE < LDPE < LLDPE < PP. The actual situation is not that simple, but the important point is that there are differences.

As noted above, the primary products of the oxidative degradation (the peroxidation chain reaction) of polyolefins are hydroperoxides, which are unstable and undergo thermolysis or photolysis with chain scission. The products are lower molar mass materials including carboxylic acids, alcohols, aldehydes, and ketones (14,15). Depending on the amounts of antioxidant and other stabilizers that are present, and on the nature of the environment in which they are discarded, it may take a few years or even decades before conventional polyolefins undergo sufficient oxidative degradation to become brittle and disintegrate.

Activated Polyolefins. There are a number of ways of rendering polyolefins unusually photosensitive, the more effective of which involve copolymerizing

ethylene, for example, with other monomers such that ketone groups are introduced into the polymer chains. Such plastics photodegrade readily, but this is not a particularly useful characteristic for materials that will be disposed of in landfill sites. In this context, an activated polyolefin is one which incorporates an additive that will significantly increase the rate of oxidative degradation of the plastic that occurs in warm environments. The mechanism and products of the oxidation that is initiated thermally will normally be the same as for conventional polyolefins not containing the additive. In other words, this is the same situation that was described in the previous section for conventional polyolefins. The same chemistry occurs for activated polyolefins (only it all happens very much faster) at a rate controlled by the level of prodegradant additive. As was indicated above, the slowest part of the oxidation chain reaction is the decomposition of the hydroperoxide groups attached to the polyolefin molecules, and it is the thermolysis of these groups that will lead (much of the time, as shown) to molar mass reduction of polyolefins that are buried in landfills. It has been known for many years that traces of transition metals accelerate the thermal oxidation of polyethylene (and other hydrocarbons) by inducing hydroperoxide decomposition. The relevant mechanism is usually a redox reaction that is genuinely catalytic.

$$M^n + ROOH \Rightarrow M^{n+1} + RO^{\bullet} + OH^- \quad (7)$$

$$M^{n+1} + ROOH \Rightarrow M^n + ROO^{\bullet} + H^+ \quad (8)$$

Hydroperoxide decomposition by this pair of processes is essentially equivalent to the lowering of the activation energy of the bimolecular peroxide decomposition reaction. It is a major factor in both heat- and light-induced oxidation of activated polyolefins. In view of the mandatory requirement for a shelf life and a use life, even when these total only months rather than years, it is important to note that prodegradant additives for polyolefins that are based on transition metals are not oxidizing agents. In other words, the presence of these prodegradants does not render the plastic instantly unstable. They simply increase, typically by two or three orders of magnitude, the rate of polyolefin oxidation after it has been initiated by heat, UV light, mechanical stress, or some combination of these.

An early manifestation of the use of metal-containing prodegradants to convert polyolefin film products to oxo-biodegradable materials was the Scott/Gilead system (16,17, and references therein). In its simplest form, the additive here contains a metal ion complexed to sulfur (for example, a ferric dithiocarbamate) such that the metal complex is an antioxidant until exposed outdoors where it undergoes photolysis. The metal ion then acts as a prodegradant, as indicated in reactions 7 and 8. Products based on this and related clever chemistries have been used for many years with great success as agricultural mulch films, and the like. The relevance of that technology here is that Scott/Gilead systems can act as thermal pro-oxidants as well.

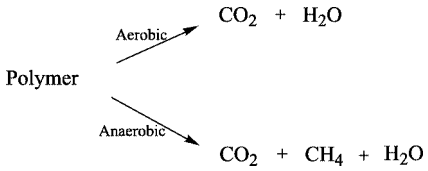
The prodegradant systems for polyolefins and polystyrene developed by EPI Environmental Products Inc. involve additives that also impart sensitivity to heat and/or UV light. The composition and quantity of their TDPA formulations added to conventional polyolefin resins provide performance that features a controlled

lifetime (storage, use) followed by rates of oxidation/biodegradation commensurate with the disposal environment. This combination of controlled but adjustable service life and a variety of degradation rates has been demonstrated (18–22) for a number of applications, such as agricultural mulch films, litter control, and compost bags. It should be noted, however, that the emphasis in the landfill disposal environment for the polyolefin products incorporating TDPA is for packaging plastics, shopping bags, ADC materials, and numerous other plastics that are disposed of in landfill. In this case, the activated materials become brittle and disintegrate in a matter of 6 to 18 months, much more rapidly than the corresponding products made from ordinary polyolefins.

Other Addition Polymers. There are few studies on other reported polymer and plastic components of landfills. Poly(vinyl chloride) seems to be inert in landfill showing no degradation in real-world tests (23,24) and laboratory simulations (25). In the latter study, plasticizer migration occurred with its subsequent biodegradation.

In an evaluation of cross-linked poly(acrylate) superabsorbents (26), little or no changes were seen and migration was not observed.

Condensation Polymers. The degradation pathways for condensation polymers are shown schematically below for both aerobic and anaerobic environments.



Testing for degradation in aerobic landfill environments is typified by an ASTM standard method for soil burial (27), by changing the environment, where measurements of carbon dioxide are related to rate and degree of biodegradation.

Notwithstanding the difficulties of testing in anaerobic environments, several laboratory methods, as indicated earlier, have been developed. These measure carbon dioxide and methane evolution. The ASTM standard was developed on the basis of work from Europe (28) and is widely used for these polymers (29). Several variants on this method reported for example by Barlaz and co-workers (30) for a variety of polymers including polyesters, acrylates, cellulosics, and others are used. Similarly, the earlier pioneering work of McCarthy and co-workers is also useful (31).

Polyhydroxyalkanoates, which are produced by bacterial synthesis, are well known to biodegrade (32) under anaerobic conditions, and several studies have been reported and compared with synthetic polyesters such as polycaprolactone (33). Radiolabeled C_{14} polyesters give credence to biodegradation by allowing methane and carbon dioxide to be readily quantified. R.-J. Mueller and co-workers (34) reported similar results in a comparative laboratory test with synthetic and natural polyesters. Work in Asia is also consistent with the anaerobic biodegradation of polyhydroxyalkanoates (35) in contrast with other condensation polymers including poly(lactic acid), and aromatic and aliphatic polyesters, which, apparently, do not biodegrade in the absence of oxygen.

Summary

Discarded plastics, especially packaging plastics, represent a significant part of the solid waste that is disposed of in landfills. They can persist for many years in this environment and thereby contribute to the premature filling of the sites. Activated polyolefins, such as those containing EPI's TDPA prodegradants, degrade and disintegrate as a result of the heat generated by microorganisms in landfills, and this permits much more rapid aerobic biodegradation of the other organic waste, thus prolonging the useful life of landfills. Little evidence has been acquired to date about the biodegradation of addition polymers in landfills. A number of hydrolyzable condensation polymers will biodegrade aerobically, but only the polyhydroxyalkanoates have been shown to biodegrade under anaerobic conditions.

DRAG REDUCTION

Introduction

The main objective of drag reduction is to reduce the fluid mechanical force known as "drag," which is exerted on an engineering system improving its efficiency. There are passive and active techniques to reduce the drag (1). The passive techniques do not require any energy input to flow; only installation and maintenance costs are involved. The riblets and large eddy breakup devices fall into this category. However, the maximum drag reduction is limited up to 10%. The active techniques require certain energy input. However, level of drag reduction achieved is up to 80%. Among all the techniques, additions of minute amount of high molecular weight polymers and surfactants have been very active area of research ever since Toms reported it in 1949 (2).

The discovery of turbulent drag reduction due to particle suspensions goes back to the 1930s. Forest and Grierson (3) reported the turbulent drag reduction in pipe flow of wood-pulp fiber suspensions of water. Vanoni (4) observed that water with suspended sand flowed more rapidly in an open channel. Toms (5) and Mysels (6) independently observed the striking reduction in turbulent drag in pipe flows

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

of solutions of high molecular weight poly(methyl methacrylate) (5–10 ppm by weight) in monochlorobenzene and of aluminum disoaps in hydrocarbon liquids, respectively. Since Toms (2,5) was the first to publish his results, the phenomenon of turbulent drag reduction is also known as Toms effect. Ever since the reporting of these results, there has been extensive research activity in this fascinating field of fluid mechanics and polymer science. Nadolink and Haigh (7) compiled an exhaustive bibliography on the subject containing over 4900 references dating from 1931 to 1994.

The soluble polymers are the most potential drag-reducing agents of all the additives mainly because drag reduction of up to 80% can be obtained with the addition of a few tens of ppm by weight in a particular solvent. The polymer solution drag reduction has been investigated in aqueous and hydrocarbon liquids, and a number of excellent reviews have been written by a number of experts (8–25). Many state-of-the-art papers have also appeared in number of conference proceedings (26–31).

Drag-reducing polymers have been successfully applied for potential benefits in various industrial processes and operations, such as long-distance transportation of liquids, oil-well operations, sewage and flood water disposal, fire fighting, transport of suspensions and slurries, irrigation, water-heating and [cooling circuits, jet cutting, and marine and biomedical operations. The developments in the above] cited fields are reviewed in the 1990s by Singh (20), Morgan and McCormick (21), Den Toonder (22), Gyr and Bewersdorff (23), Moussa (24), and Gad-El-Hak (25).

The most successful application of drag-reduction phenomenon has been in reducing the drag in crude oil transport through Trans Alaskan Pipelines (TAPS) and other pipelines in several countries. The first large-scale use of hydrocarbon-soluble drag reducer addition (DRA) in TAPS was accomplished in 1979. The technology made spectacular advancement since then. Within 10 years, the effectiveness of additives increased 12 times (32). Because of the effectiveness of the polymer injection technique, the need of building two delayed pumping stations disappeared. The 1 ppm of the drag reducer used in the pipeline increased the flow rate by 33%. Several important pipelines such as Tukey-Iraq, Bas Strait (Australia), Bombay Off Shore (India), etc, have used drag-reducing additive injection for saving considerable energy. Newer areas are being explored (23,25,33).

High molecular weight polymers ($>10^5$) are very effective drag reducers, but get degraded in turbulent flows and lose their effectiveness after a short interval of time or flow. Aluminum diasops and other surfactants form aggregates or micelles at a critical micellar concentration (CMC). These micelles are responsible for drag reduction. These micelles also degrade after critical shear stress though anionic soaps are found to be good and mechanically stable drag reducers (34). But when shear stress becomes lower than the critical shear stress, the micelles are reformed and restore the drag reduction effectiveness. Because of their repairability and the capability to withstand higher temperatures, the research activity in surfactant drag reduction has increased appreciably. The anionic, cationic, nonionic, and zwitterionic surfactants have been investigated for their drag-reduction effectiveness (DRE). Though anionic soaps are found to be good and mechanically stable drag reducers (34), their use is not favoured because of their vulnerability

to calcium and magnesium ions normally present in tap and sea water, and their foam-forming characteristics (35). Nonionic surfactants have narrow temperature window of applicability around their cloud points (36). Cationic surfactants show much broader effective temperature window of applicability, and thus have larger potential for practical applications (37). The drag-reducing characteristics of zwitterionic surfactants are being studied (38–40).

The potential application of surfactants exists in district heating and cooling systems. The characteristics of surfactant drag reducers differ from polymeric drag reducers in several aspects particularly having higher level of drag reduction crossing the Virk's maximum drag reduction asymptote (41,42).

Several attempts have been made to enhance the DRE and mechanical stability of polymer drag reducers. In general, homopolymers, alternate copolymers, graft polymers, and polyelectrolytes and polysaccharides from natural and microbial resources are efficient drag reducers in water, organic solvents, and crude oil (23,25,43). The extent of drag reduction increases with the molecular weight and length of the polymers, and so does their susceptibility to flow-induced degradation.

Recently, three approaches have been put forward to enhance the DRE and shear stability of polymers. The DRE of polysaccharides can be enhanced by grafting synthetic polyacrylamide branches onto their main chains; the resulting graft polymers combine efficiency of synthetic polymers and robustness of polysaccharide chains (44,45). The reversible intermolecular associations in solution increase the molecular weight of polymer associates and provide mechanical stability (46–49).

The third approach is by using cross-linking among the polymer molecules. The drag-reducing polymers such as guar gum can be cross-linked with concentration below those required for gel formation. The presence of intermolecular cross-links leads to increased dimensions of the macromolecules resulting in enhanced drag reduction though the induced degradation of the polymers is not appreciably affected by the addition of cross-linking agents (50). The first and third approaches have been pursued for water-soluble systems. It has been observed that in the first approach, the level of DRE is higher, that too at low concentrations ($<$100 ppm) of graft copolymers, and that cross-linking is not effective in shear degradation.

Rheology of polymers and surfactants solutions plays an important part in drag reduction. Though very dilute drag-reducing solutions have rheological behaviors similar to Newtonian solvents except for the anionic polyacrylamide solutions having shear-thinning behaviors at drag-reducing concentration of 50 ppm (51), their extensional effects may be important. Efforts are still in progress to measure and correlate the extensional effects to drag reduction (52–60). The degradation of polymers in turbulent flow needs to be investigated in order to enhance the effectiveness of polymers by modeling degradation mechanism (43,61–65).

There are three ways of introducing a polymer solution in the water flow. In the first case of homogeneous drag reduction, the polymer is allowed to mix homogeneously into the solvent. In the second case of heterogeneous drag reduction, a highly concentrated polymer solution is injected in the center or at the wall of the pipe, which disperses completely by turbulent diffusion to yield homogenous

solution some distance downstream the injector. In the third case, a concentrated polymer solution is injected into the center line of a turbulent flow at a high enough concentration that a single coherent unbroken polymer thread forms at the injector and continuous downstream for several hundred pipe diameters. The polymer threads have also been injected at the wall or buffer zone of the flow by Frings (66), who attained highly heterogeneous mixtures downstream. In some cases (67–69), high concentration strings of polymer develop rather than a single coherent thread.

All the above forms of drag reduction have been studied in the case of surfactant drag reduction as well. The origin of drag reduction in all cases has been indicated to be similar (70,71). The origin of drag reduction has been extensively investigated from the very beginning. With the advent of laser Doppler anemometry (LDA) (72), and later on with the phase laser anemometry (73), it was possible to measure and investigate velocity characteristics of flows with precision without interfering with them. LDA has been extensively used to study various aspects of drag reduction, particularly in channel flows (74).

Dodge and Metzner (75) developed a correlation between friction factor and Reynolds number for turbulent pipe flow of purely viscous shear-thinning liquids based upon a power-law model of shear viscosity. Metzner and Park (76) correlated the degree of drag reduction in turbulent flow of viscoelastic polymer solutions with the ratio of elastic to viscous stress, ie with N_i/τ_s, where N_i is the first normal stress difference for a given wall shear–strain rate γ, and τ_s the corresponding shear stress. Though the role of extensional viscosity in causing turbulent suppression or drag reduction is being debated till date, there is a persistent view that the elongational viscosity, possibly in combination with viscoelasticity, is responsible for drag reduction.

Gadd (77) was among the first to point out that the damping of the turbulence by polymer additives is due to their resistance to elongational strain, which suppresses shear formation and bursting in near-wall region. Lumley (78,79) suggested that the uncoiling of polymer molecules under fluctuating shear rate in the buffer region of turbulent flow causes drag reduction because of increase of extensional viscosity. Gyr (80), Durst and co-workers (81), and Bewersdorff and Berman (82) provided the extensional viscosity model of drag reduction. Vlassopoulos and Schowalter (51,52) suggested that the origin of DRE is due to the fluid elasticity inferred from oscillation-induced streaming. Matthys (83) pointed out the common origin of the extensional viscosity and viscoelasticity. de Gennes (84) hypothesized that the polymer drag reduction is due to the elastic, rather than the viscous, phenomenon. Several direct numerical simulations by Orlandi (85), Den Toonder and co-workers (64,86), and Massah and Hanratty (87) examined the role of viscoelasticity, extensional viscosity, and stress anisotropy in drag reduction. Direct numerical simulation (DNS) investigation of Den Toonder and co-workers (86) points out that drag increases rather than decreases when the elastic contributions are taken into account.

For the case of viscous anisotropic polymer model, almost all turbulence statistics and power spectra calculated agree in qualitative sense with experimental results. Dimitropolous and co-workers (88) did DNS for fully turbulent channel flow of a polymer solution using the finitely extensible nonlinear elastic head spring dumbbell model with Peterlin approximation (FENE-P) and the Giesekus

model. They demonstrated that the solution extensional viscosity plays the primary role in turbulent drag reduction. Comparing the mean velocity profiles and statistical features of the turbulent flow showed agreement with well-established experimental observations, such as enhanced buffer zone, increase in the spacing of the streamwise streaks, decrease in the streamwise vorticity fluctuations, and increase in the streamwise velocity fluctuations. This demonstrated the onset of drag reduction in a turbulent flow at a sufficiently high level of viscoelasticity in the flow and reinforced previously held hypothesis that one of the prerequisites for the phenomenon of drag reduction is sufficiently enhanced extensional viscosity.

However, Sreenivasan and White (89) point out that the connection between fluctuating strain rates and large extensional viscosity is circumstantial. Further polymer coils can only be partially stretched in a random field of strain rate. Sreenivasan and White (89) point out that the elastic theory proposed by de Gennes (84) is compatible with at least two experimental observations; ie, the dependence of drag reduction onset on polymer concentration and maximum drag reduction asymptote.

On the other hand, DNS of turbulence in channel flow based on FENE-P bead-spring chains in the presence of large-enough velocity gradients by Massah and Hanratty (87) indicates that polymers cause drag reduction by selectively changing the structures of eddies that produce Reynolds stresses. Their calculations (87) support the suggestions by Lumley (78) that the polymers can become unravelled by the turbulence in the buffer region. The calculated unravelling of a bead-spring chain in the viscous sublayer could explain the increased viscosity observed by Vismann and Bewersdorff (90) and by James and co-workers (91) in elongational flow when the solution is presheared in laminar Couette or channel flow. Thus these investigations point out the basis of further research on the origin of drag reduction and explanation of its various manifestations in both polymeric and surfactant drag reduction. A large number of reviews are available in literature till 1990. In this review, emphasis will be given on the researches reported since then, with comprehensive accounts of materials, mechanisms, and applications in the field of turbulent drag reduction in liquids.

Characteristics of Turbulent Drag Reduction

Mathematical Description. Lumley's (92) definition of drag reduction, "drag reduction is the reduction of skin friction in turbulent flow below that of the solvent," will be followed in this review. Most of the studies on drag reduction have been confined to hydraulically smooth pipe flows or channels; hence various physical parameters will be described in terms of smooth pipe flows.

Reynolds was the first to find out that transition from laminar to turbulent flow takes place in cylindrical-pipe flows of water at a particular value (=2300) of a dimensionless parameter known as the Reynolds number (R_e), where R_e is given by the following relation:

$$R_e = \frac{\bar{u}D}{\upsilon} \tag{1}$$

where $\bar{u}$ is the mean flow velocity, D is the pipe diameter, and $\upsilon(=\frac{\eta}{\rho})$ is the kinematic viscosity. υ is equal to the ratio of viscosity η and the density of the liquid, ρ.

The pressure loss in pipe is due to fluid friction resistance. The friction factor f may be derived as

$$f = \frac{\Delta p D}{2\rho \bar{u}^2 L} \tag{2}$$

where $\Delta\, p$ is the pressure drop and L is the pipe length. The wall shear stress, τ_{w}, in a fully developed pipe flow is related to the pressure drop by the following equation:

$$\tau_{\mathrm{w}} = \frac{\Delta p D}{4L} \tag{3}$$

Hence the Fanning friction factor:

$$f = \frac{\tau_w}{\frac{1}{2}\ \rho \bar{u}^2} \tag{4}$$

The friction velocity u_{T} can also be evaluated as

$$u_{\mathrm{T}} = \left(\frac{\tau_{\mathrm{w}}}{\rho}\right)^{1/2} \tag{5}$$

Prandtl–Karman coordinates ($f^{-1/2}$ vs $R_{\mathrm{e}}\ f^{1/2}$) are, in general, used to present the drag reduction data because in these coordinates Prandtl–van Karman law for Newtonian turbulent pipe flow appears as a straight line in a semilogarithmic diagram (see Fig. 1).

$$f^{-1/2} = \frac{u}{\sqrt{2}u_{\mathrm{T}}} \text{ as ordinate}$$

and

$$R_{\mathrm{e}} f^{1/2} = \sqrt{2}\frac{D u_{\mathrm{T}}}{\upsilon} \text{ as abscissa}$$

represent ratios of bulk to turbulent velocities and pipe to turbulent length scales respectively (10).

The drag-reducing polymers, such as poly(ethylene oxide) or polyacrylamide, exhibit drag reduction at such low concentrations that the solution viscosity is close to solvent viscosity. In laminar flows, the majority of drag-reducing polymer solutions obey Poisseulli's law, ie

$$f^{-1/2} = \frac{R_{\mathrm{e}} f^{1/2}}{16} \quad \text{or} \quad f = \frac{16}{R_{\mathrm{e}}} \tag{6}$$

In case there is no drag reduction, the friction factor is given by the Prandtl–van Karman law for Newtonian turbulent pipe flow, ie

$$\frac{1}{f^{1/2}} = 4.0\ \log_{10}\left(R_{\mathrm{e}} f^{1/2}\right) - 0.4 \tag{7}$$

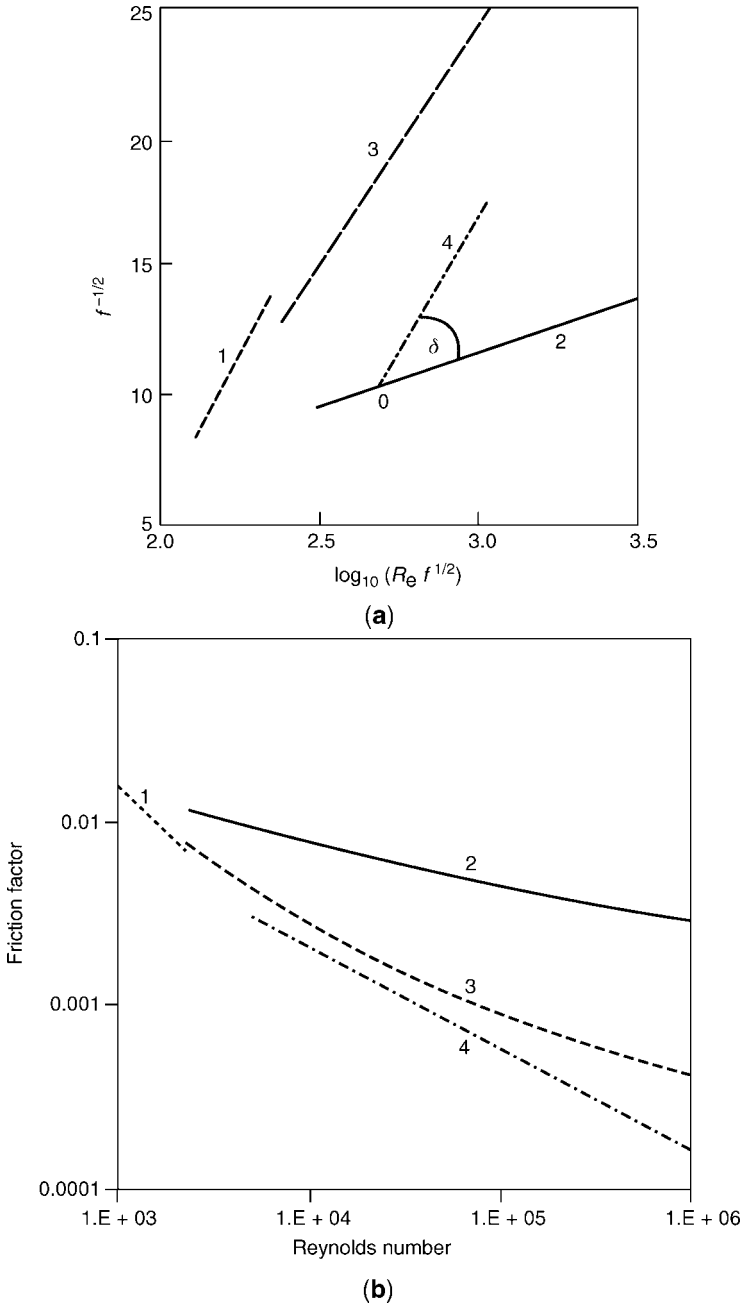

Fig. 1. (**a**) The variation of $f^{-1/2}$ with $\log_{10}(R_e f^{1/2})$ in case of dilute drag-reducing polymer solutions. The various regimes are depicted as follows: 1 by the Newtonian laminar region; 2 by the Prandtl–Karman curve for Newtonian fluids in a smooth pipe; 3 by Virk's maximum drag reduction asymptote; 4 by a typical curve for polymer solutions. δ is the slope increment. Adapted from Figure 1.3 of the Ref. 23. (**b**) The variation of friction factor with Reynolds number in case of drag-reducing surfactant solutions. 1, Laminar; 2, von Karman Linc; 3, Virk asymptote; 4, Zakin and co-workers asymptote. Adapted from Figure 2 of the Ref. 42.

Virk (10) observed that the maximum possible drag reduction asymptote (MDRA) is given by the following equation, where the drag reduction is insensitive to polymer properties:

$$\frac{1}{f^{1/2}} = 19 \log_{10}\left(R_e f^{1/2}\right) - 32.4 \tag{8}$$

In the regime below the maximum drag reduction asymptote, the friction factor varies with polymer properties and flow variables:

$$f^{1/2} = [4.0 + \delta] \log_{10}\left(R_e f^{1/2}\right) - 4.0 - \delta \log_{10}\left(\sqrt{2}D\right) w \tag{9}$$

where δ and w are polymer solution parameters.

In case of surfactant solutions, friction factors significantly lower than the predicted by MDRA for high polymer solutions are predicted. Zakin and coworkers (93) provided an equation given below for maximum drag reduction asymptote for surfactant solutions

$$f \approx 0.32\, R_e^{0.55} \tag{10}$$

The velocity profiles in terms of universal dimensionless coordinates [$u^+ = \frac{u}{u_T}$ and $y^+ = \frac{y\, u_T}{\upsilon}$] offer an alternative representation of drag reduction behavior. The local velocity u varies with y, the distance from the wall. There are three distinct regions that can be represented by the following equations:

Close to the wall, the flow in the viscous sublayer and in the buffer layer are represented by equations 11 and 12 respectively.

$$u^+ = y^+ \ (0 < y^+ < 5) \text{ (viscous sublayer)} \tag{11}$$

$$u^+ = y^+ \ (0 < y^+ \leq 30) \text{ (buffer layer)} \tag{12}$$

The logarithmic layer is given by

$$u^+ = 2.5 \ln y^+ + 5.5 \ (y^+ > 30) \tag{13}$$

The velocity profiles of drag-reducing flows in many cases show a peculiarity. A logarithmic profile starts at the intersection with a steeper slope and describes the velocity at maximum drag reduction. Virk's (10) maximum drag reduction profile is given by

$$u^+ = 11.7 \ln y^+ - 17 \tag{14}$$

For drag-reducing polymers, the velocity profile is parallel to the Newtonian profile and is separated by a factor ΔB depending on the polymer, and on pipe and flow characteristics (see Fig. 2).

$$u^+ = 2.5 \ln y^+ + 5.5 + \Delta B \tag{15}$$

The first region (viscous sublayer) extends to about $y^+ = 5$. The drag-reducing flows intersect the maximum drag reduction line instead of $u^+ = y^+$. The region between the viscous sublayer and Newtonian plug is known as the elastic sublayer

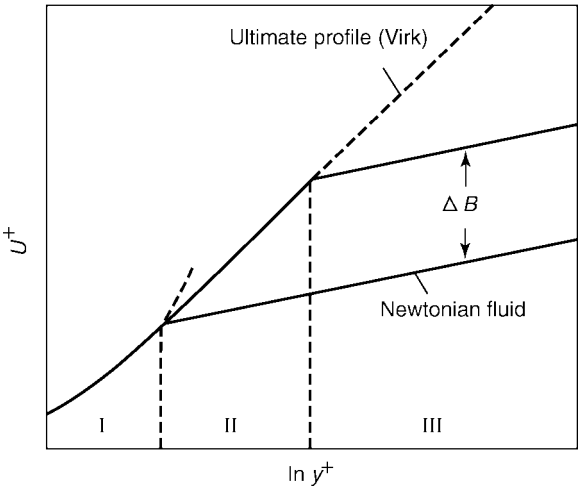

Fig. 2. Main stream velocity profile for drag-reducing fluids according to Virk's model: 1, viscous sublayer; 2, elastic buffer layer; 3, turbulent core.

since the solution in this zone exhibits an elastic flow behavior. In case of maximum drag reduction, the elastic region extends to the center of the pipe and the Newtonian region disappears. By integrating the equations, we obtain the total volumetric flow rate and friction factor:

$$\frac{1}{f^{1/2}} = 4\log_{10}(Rf^{1/2}) - 0.4 - \frac{\Delta B}{\sqrt{2}} \tag{16}$$

In the 19th century, Reynolds established the basic approach to analyze the turbulent flow. He introduced in the momentum equations the time fluctuating velocity whose average value over a period of time is zero but whose time-averaged squares and products are not zero. The relation for velocity components and pressure can be written as follows:

$$u = \bar{u} + u' \tag{17}$$

$$v = \bar{v} + v' \tag{18}$$

$$w = \bar{w} + w' \tag{19}$$

$$p = \bar{p} + p' \tag{20}$$

where u', v', and w' are fluctuating velocity components in turbulence in x, y, and z directions, respectively, and p' is the fluctuating pressure component in turbulence. The time average at a fixed point in space can be given as

$$\bar{u} = \frac{1}{t'}\int_{t_0}^{t_0+t'} u\, dt \tag{21}$$

u can be further split into time average mean and a phase-locked average (91), where $\tilde{u}$ is thought to be an oscillatory part of the velocity field and u' is the remaining turbulent fluctuation.

$$u = \bar{u} + \tilde{u} + u' \tag{22}$$

The components of stress tensor due to the turbulent velocity components of the flow are given by

$$\begin{vmatrix} \sigma'_{xx} & \sigma'_{xy} & \sigma'_{xz} \\ \sigma'_{xy} & \sigma'_{yy} & \sigma'_{yz} \\ \sigma'_{xz} & \sigma'_{yz} & \sigma'_{zz} \end{vmatrix} = -\rho \begin{vmatrix} \overline{u'^2} & \overline{u'v'} & \overline{u'w} \\ \overline{u'v'} & \overline{u'^2} & \overline{u'w'} \\ \overline{u'w'} & \overline{v'w'} & \overline{w'^2} \end{vmatrix} \tag{23}$$

The diagonal components $\overline{u'^2}$, $\overline{v'^2}$, and $\overline{w'^2}$ denote twice the average kinetic energy per unit mass of the respective velocity components. The nondiagonal terms $\overline{u'v'}$, $\overline{u'w'}$, and $\overline{v'w'}$ denote negative components of turbulent and Reynolds shear stress.

The correlation coefficient Ψ between the longitudinal and transverse fluctuations at the same point is defined as

$$\Psi = \frac{\overline{u'v'}}{\sqrt{\overline{v'^2}}\sqrt{\overline{u'^2}}} \tag{24}$$

Taylor (95) pointed out that in order to quantify special structure of turbulence, the velocity fluctuations at two neighbouring points, 1 and 2, in flow fields have to be observed. This will define correlation function $\bar{R}$ as

$$\bar{R} = \frac{\overline{u'_1}\,\overline{u'_2}}{\sqrt{\overline{u'^2_1}\,\overline{u'^2_2}}} \tag{25}$$

The integral of the correlation function $\bar{R}$ is known as scale of turbulence.

$$\bar{L} = \int_0^{1/2\,D} \bar{R}(r)\,dr \tag{26}$$

If the second quantity u_2' is measured at the same location but at a different instant of time (u_1' at instant t_1 and u_2' at instant $t_2 = t_1 + \tau$), we obtain the auto-correlation function κ. The x component of κ, ie κ_x, can be written as

$$\kappa_x = \overline{u'_1(x,t)u'_2(x,t+\tau)} \tag{27}$$

These functions are equivalent to a spectral decomposition of the kinetic energy of the fluctuations, K.

The alternate description of the structure of turbulence is obtained when a frequency analysis of the motion is provided instead of a correlation function.

These functions are equivalent to a spectral decomposition of the kinetic energy of the fluctuations in the respective directions, eg

$$\bar{u}_1^2 = \frac{1}{\pi} \int_0^\infty E_x(x,\omega)\, du \tag{28}$$

into components for each frequency ω, the so-called power spectrum. It follows from this definition that

$$K_x(\chi,\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} E_x(x,\omega)\, e^{-i\omega\tau}\, d\omega \tag{29}$$

and vice versa:

$$E_x(\chi,\omega) = \int_{-\infty}^{\infty} K_x(\chi,\tau) e^{-i\omega\tau}\, d\tau \tag{30}$$

A complete insight into the statistical turbulence and turbulence process not only requires the study of the axial and transverse fluctuations but also to measure space and time correlation functions.

Experimental Results: Investigations of Drag Reduction and Turbulence Parameters. In the last decade, a large number of experimental articles have appeared on polymer drag reduction in pipe and channel flows, where LDA and 2D LDA have been used to measure various velocity components and Reynolds stresses. Pinho and Whitelaw (96), Harder and Tiederman (97), Wei and Willmarth (98), Walker and Tiedermann (99), Tong and co-workers (100), Codot and co-workers (101), Den Toonder and co-workers (86), Dimitropoulos and co-workers (88), Hoyer and co-workers (102), Fortaine and co-workers (103), Nieder Schulte and co-workers (104), Bewersdorff and co-workers (105), and Massah and Hanratty (87) reported various measurements on velocity components and Reynolds stresses. The most important findings reported in these articles are that the polymers not only suppress the turbulent motion but also increase the streamwise turbulent intensity, while the normal turbulence intensity is decreased. Wei and Willmarth (98) reported that the energy in the normal turbulence intensity is drastically suppressed over all frequencies while there is redistribution of energy from high frequencies to low frequencies for the streamwise component.

The drag reduction (DR) for pipe flow of an incompressible fluid additive system (20,23) is defined as

$$\mathrm{DR} = (1 - \Delta P_\mathrm{f}/\Delta P_\mathrm{s}) \tag{31}$$

where ΔP_f is the pressure drop with a fluid additive system, and ΔP_s is the pressure drop with a pure fluid, measured at constant flow rate. It may be assumed

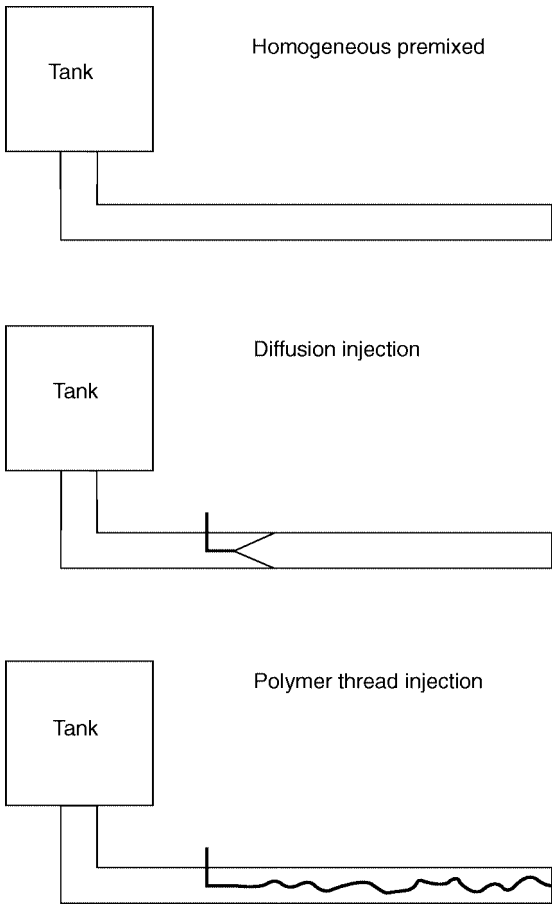

Fig. 3. Various methods of polymer addition for manifestation of the turbulent drag reduction phenomenon (63).

that small additions (at the ppm level) of the additives do not change the fluid density and shear viscosity. The fluid additive system is called drag-reducing if DR is positive.

Methods of Drag Reduction. There have been three basic methods for adding a polymer to the turbulent flow, and consequently three types of drag-reduction methods (70) (see Fig. 3). In homogeneous drag reduction, the polymer is mixed into the solvent and it disperses uniformly before it is allowed to flow in the pipe, and measurements are taken for various parameters of drag reduction. In another form of homogeneous drag reduction, the diffusive flow of the polymers takes place. Here the polymer is injected into the centre or at the wall of a pipe at a concentration which disperses completely by turbulent diffusion to yield a homogeneous solution some distance downstream the injector. In the second case, known as heterogeneous drag reduction, concentrated drag-reducing polymer solution is injected into the centerline of a turbulent flow so that a single coherent unbroken polymer thread forms at the injector and continues downstream for several hundred pipe diameters. The third type of drag reduction takes place (67)

when the injection is such that many high concentration strings of the polymer develop, rather than a single coherent thread from the centerline injector. Frings (66) used very high polymer concentrations in a wall injector and obtained highly heterogeneous mixtures downstream. Most of the wall injector studies yield flows similar to the second case, and the first case describes majority of the drag reduction studies.

Two other type of drag reduction (10,106) within the polymeric regime have been observed. In type A drag reduction, a family of additive solutions yield friction factor segments fanning outwards from a common "onset" point on the Pradtl–Karman line, their slopes increasing with increasing concentrations and drag reduction increasing with increasing $R_e f^{1/2}$. This is characteristic of random coiling macromolecules. In type B drag reduction, a family of additive solutions yield segments that are roughly parallel to that displaced upwards from the P-K line, with drag reduction essentially independent of $R_e f^{1/2}$ but increasing with increasing concentration. This behavior is exhibited by a variety of additives including extended polyelectrolytes, fibers, soaps, and clays. This drag reduction occurs without any discernible onset effect where the macromolecules causing the effect are already in the extended state and do not need to be stretched by a strong flow.

The various investigations on heterogeneous drag reduction carried out up to 1987 have been discussed by Singh (20) and Gyr and Bewersdorff (23). Hoyer and Gyr (71) have provided the critical analysis of heterogeneous drag reduction. Usui and co-workers (68,107,108) have investigated the velocity profile of the injected polymer phase and the surrounding water phase separately by seeding both liquids with tracer particles. They monitored the flow using a video camera, which was moved with flow velocity (see Fig. 4). On the basis of their results (68, 107,108), Usui and co-workers (108) suggested that the main interaction between polymer thread and the turbulence which results in drag reduction takes place in the central part of the flow and suppresses the large-scale motions of the flow in agreement with earlier results by Vleggar and Tells (109,110) and Bewersdorff (23,69,105). Gyr and Bewersdorff (23) showed that by varying the ratio of polymer injection velocity to the bulk velocity and by mounting contractions in pipe, the drag reduction increases with the elongation of the polymer thread as long as the thread stays intact and is not broken into pieces. Hoyt and Sellin (111) investigated the thread injection techniques using various viscoelastic solutions ranging from water-soluble polyacrylamide (PAM) and PEO and surfactant tetradecyltrimethyl ammonium bromide +2% sodium salycilate (C_{16}TASal) and hexadecyl trimethyl ammonium bromide +2% sodium salycilate (C_{16}TASal), as well as water-insoluble FLO (commercial pipeline drag reducer), polyisobutene, and PEO dissolved in dichloromethane. They attributed that the drag reduction effect is due to dissolved molecules removed from the thread at high Reynolds numbers, whereas at low Reynolds number an interaction of the thread with large-scale eddies should be responsible for the observed drag reduction.

A number of very precise measurements by Smith and Tiederman (70) and Hoyer and co-workers (71,102) reveal that the mechanism of polymer thread drag reduction is caused by a modification at or near wall, or by modification in the central portion of the flow. The drag reduction is ascribed to minute quantity of polymers removed from the thread and dispersed into the bulk of the fluid. Smith

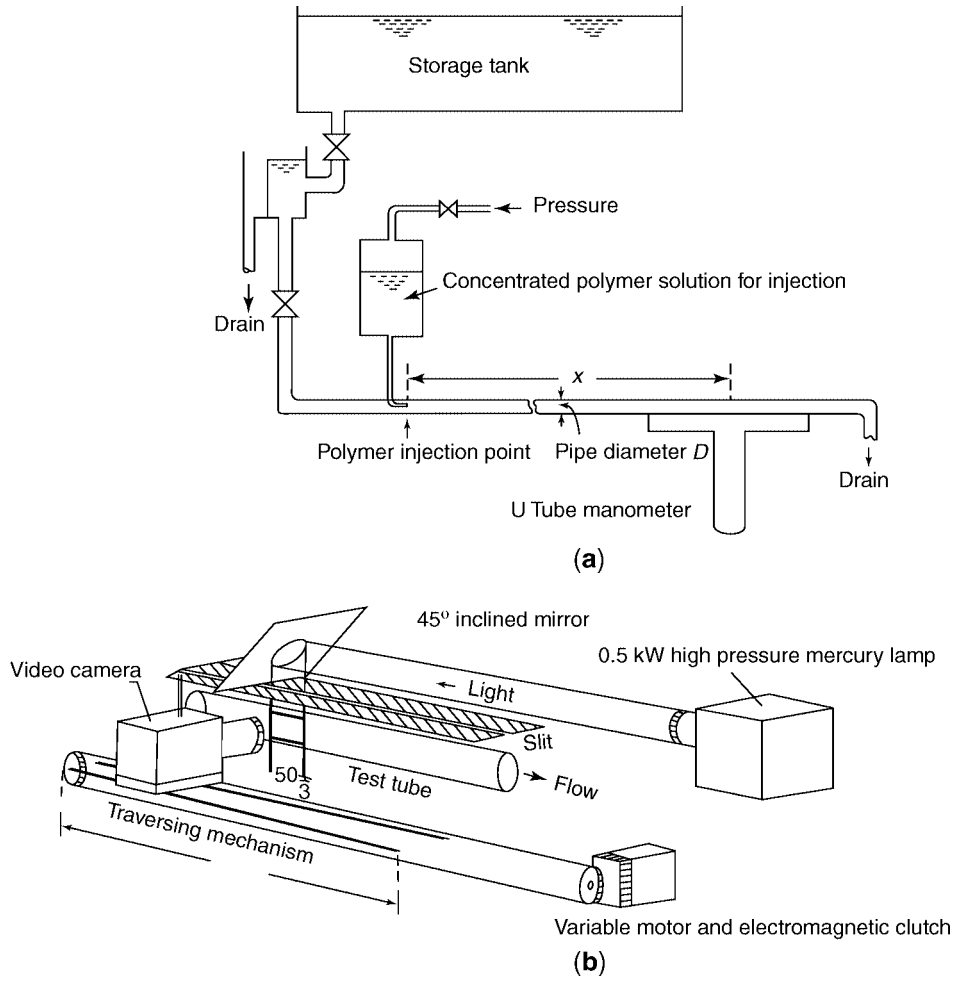

Fig. 4. Experimental setup for measurement of (**a**) drag reduction and (**b**) tracer particle trajectories; (**c**) profiles of turbulent intensity in the longitudinal direction: △, Water; ○, polymer injection (water phase); ●, polymer injection (polymer thread);□, premixed flow; ——— Pennel and co-workers (Newtonian fluid, $R_e = 11400$); —— —— McComb–Rabie (injection); – – – – Reishman–Tiederman (premix, 100-ppm Separan AP-273, $R_e = 44500$, DR = 39%).

and Tiderman (70) measured drag reduction, radial location of thread, and the polymer concentration in the near-wall region. The concentration was measured by laser-induced fluorescence utilizing fluorescin dye as tracer. In their experiment, the polymer injected was 500 ppm by weight of Separan AP273 dyed by 8.8 ppm by weight of fluorescin; the unbroken threads existed for more than 200 pipe diameters downstream the injector and produced drag reduction of the order of 40%. They found that the thread did not appear in the region $y^+ < 100$. When there was no polymer at $y^+ = 50$, there was no drag reduction. As soon as measurable amount of polymer was found at $y^+ = 50$, there was drag reduction. The major conclusion arrived at by Smith and Tiderman (70) was that low concentrations of

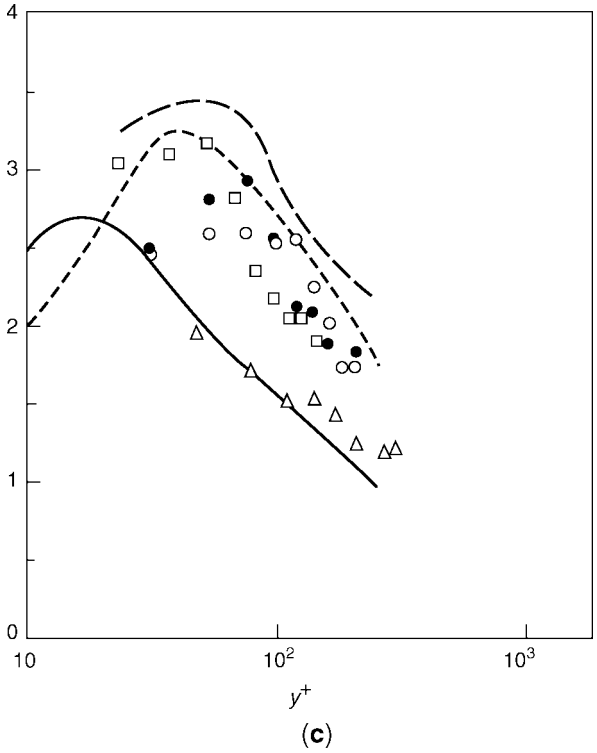

Fig. 4. (Continued).

polymer in the near-wall region are sufficient to cause drag reduction measured in the polymer thread experiments. The polymer that is diffused from the thread is the major cause of the drag reduction.

In the experiment of Hoyer and co-workers (102), the thread was sucked out and drag reduction downstream of the withdrawl point was measured, and in a second series of measurements near wall, the fluid was withdrawn and the drag reduction of that fluid in a bypass was measured (see Fig. 5). The thread trapping and bypass experiments indicate that the heterogeneous drag reduction is at least partly due to minute amounts of polymers removed from the thread and dispersed in the bulk of the fluid. It was found that the effect decreases if the thread ruptures into pieces instead of being enhanced as expected for a diffusion process. With decreasing u^*, the effect increases and the onset point is lowered. This suggests that diffusion is not the mechanism by which the polymer enters the bulk of the fluid. Further, it was observed that the drag reduction occurred whenever the thread started forming loops. In these loops, the thread unravelled locally into various strands which unified again when the thread was stretched. Hoyer in further experiments (71,102) collected near-wall fluid from 30-mm inner diameter circular pipe (D_1) using a slit suction device of height 0.25 mm and integrated in a 4-mm pipe for drag-reduction capability. The average thickness of collected wall layer never exceeded 22 viscous units and thus ensured that no part of the concentrated polymer thread was sampled. He observed the following:

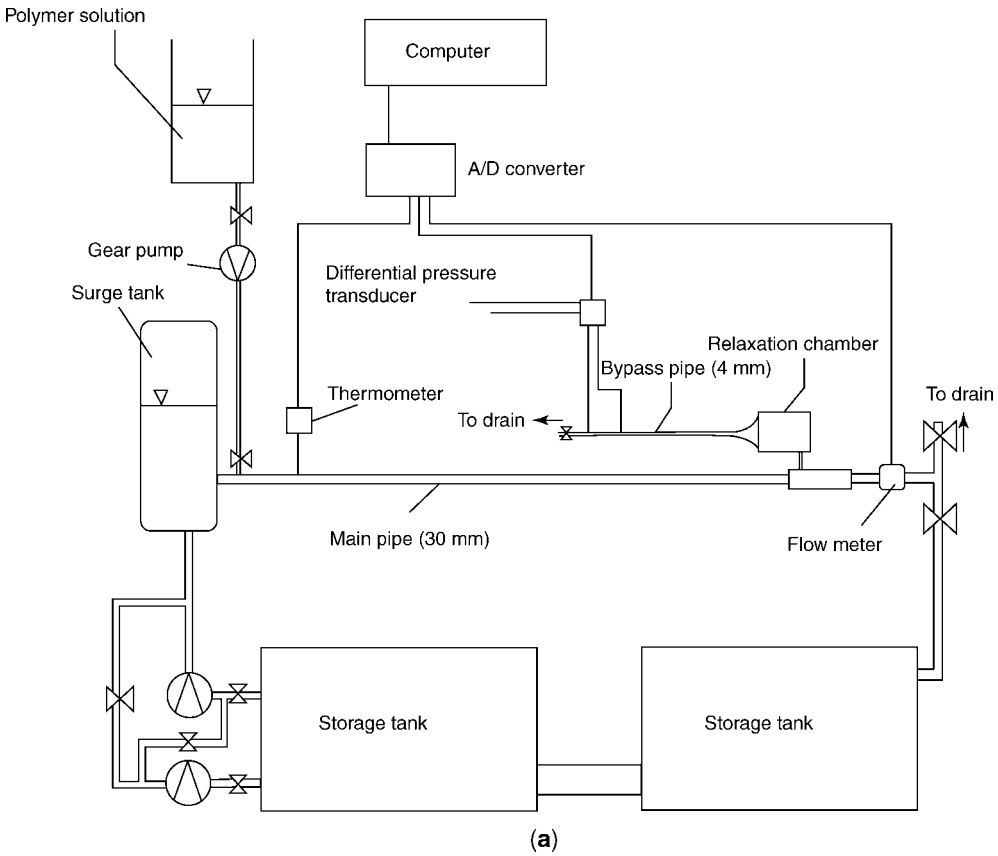

Fig. 5. (**a**) A typical experimental setup for measuring drag reduction using a bypass pipe; (**b**) influence of the injection ratio u^* on the friction behavior in round pipe with $c_P = 0.8\%$ and $c_R = 5$ ppm: ○, Commercial guar gum; ●, purified guar gum; △ GM_3. Adapted from Ref. 102.

(1) The near-wall fluid collected just before the onset in the main pipe showed no drag reduction.
(2) The fluid collected within increasing levels of drag reduction in the main pipe showed increasing drag reduction capabilities in the small pipe.

Polymeric Drag Reduction. The following macromolecular parameters seem to influence the drag-reduction characteristics, ie chemical and physical structure, molecular weight, length, extension, flexibility, and elasticity. Both synthetic and natural linear polymers having molecular weight of 5×10^5 or more have been found to be good drag reducers (19–24,112).

The lower molecular weight polymers capable of forming higher molecular weight aggregates have also been found to be effective drag reducers (46–48). Lodes and Macho (113) reported that the aqueous solutions of a 19000 kg/mol partially sponified poly(vinyl acetate) with various degrees of hydrolysis exhibited drag reductions close to the MDRA. In case of still lower molecular weight

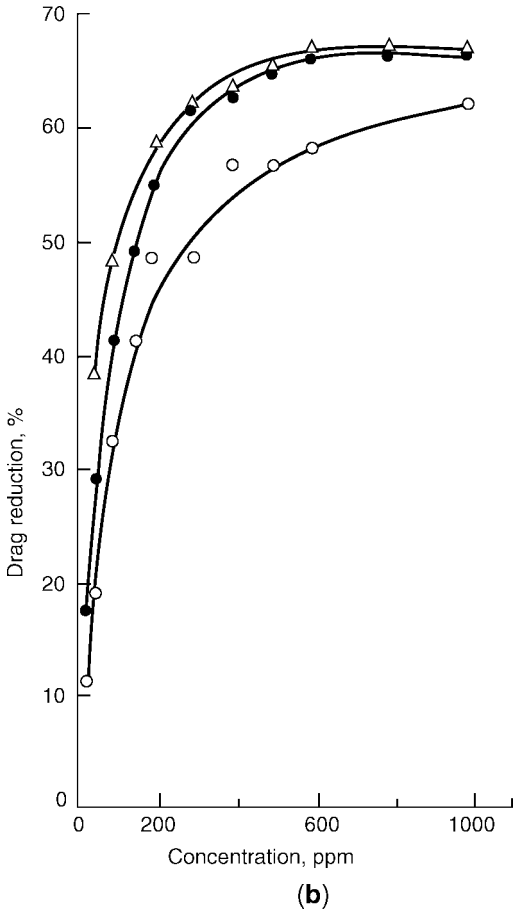

Fig. 5. (Continued).

(=6000), 0.4 and 0.6% by weight aqueous solutions of Tylose, a methylhydroxy cellulose from Hoechst, Pereira and Pinho (114) showed drag reductions (=25–35%) of the half that reported to occur with other low elasticity, shear-thinning, high molecular weight aqueous solution of CMC (molecular weight 300000 kg/mol) (96). The drag reduction caused by Tylose may be either due to the high molecular weight fractions present in its sample or associated complexes, which may be present at such high concentrations as tens of ppm (by weight) of polymers. On the other hand, rigid shear stable polymers such as polysaccharides (ie, guar gum, carboxymethylcellulose, and xanthan gum in the form of natural gum or formed by algae and bacteria) cause maximum drag reduction of up to 60% at the concentrations of a few hundred ppm by weight (20,23,115).

Among the synthetic polymers, poly(ethylene oxide) is the most efficient but relatively lesser shear stable than polyacrylamide. Molecular weight, length, and coil dimensions are the chief attributes of polymers to drag reduction (21). It has been shown by Olivier and Bakhtiyarov (116) that polyacrylamide of very high molecular weight, ie $M_w = 20–25 \times 10^6$, causes drag reduction in as low as

0.02-ppm solution. Gampert and Wagner (117) have prepared highly fractionated samples of polyacrylamide. They have shown that drag reduction increases with molecular weight. In mixtures of various fractions, it is the highest fraction that contributes the most in drag reduction.

Drag reduction is shown by polysaccharides, which are linear in nature. Highly branched materials such as gum arabic and dextran do not seem to reduce drag (17). Polyelectrolytes, such as partially hydrolyzed polyacrylamide (64,106), polyacrylic acid (118), acrylamide sodium acrylate copolymer (119), and sodium alginate (120), show higher drag reduction when the chain is extended or there is increment in coil dimensions. The coil expansion takes place because of coulombian repulsion and solvent steric hindrance of side group and main chain (119).

Virk and Wagger (106) reported that drag reduction results in case of partially hydrolyzed polyacrylamides (PAMH) of molecular weight $M_a = 15 \times 10^6$. When the charge neutralization was obtained by adding 0.1 M NaCl, the additive solutions yield friction factor segments fanning out from a common "onset" point on Prandtl–Karman line, their slopes increasing with increasing concentrations and drag reduction increasing with increasing $R_e f^{1/2}$. This is the characteristic of random coiling macromolecules. Virk designated it as type A drag reduction. In B type of drag reduction, obtained without adding any NaCl or adding up to 0.001 M NaCl to 0.0003 M NaCl (practically no or very little charge neutralizations took place), a family of additive solutions yield segments that are roughly parallel to, but displaced upwards from, the P-K line, with drag reduction essentially independent of $R_e f^{1/2}$ but increasing with increasing concentration. This type of behavior is exhibited by additives such as extended polyelectrolytes (PAMH), fibers, and soaps, and clays such as asbestos, xanthan, asbestos, paper-making fibers, and nylon fibers.

Among the polymers that show drag reduction in nonaqueous solvent and crude oil, polyisobutylenes, polyisoprene, polystyrene, homo and copolymers of alkylstyrene, acrylates, methacrylates, and FLO are the prominent ones. A detailed catalog of drag-reducing polymers has been given by Singh (20) and Gyr and Bewersdorff (23). The recently studied drag-reducing polymers are listed in Table 1.

In search for better drag-reduction efficiency and shear stability at low cost, a systematic investigation has been made in the author's laboratory by grafting efficient drag reducer such as polyacrylamide chains onto robust polysaccharide backbones to develop graft polymers having drag-reduction efficiency of synthetic polymers and shear stability of polysaccharides main chains (121–128). The maximum in drag reduction is also obtainable at the concentrations ranging from 50 to 100 ppm (see Fig. 6). As the grafting alters the regularity of the molecular structures, it inhibits the enzyme attack on main chain, thus enhancing the biodegradation resistance of graft copolymers and increasing the shelf life (44). Starch and low molecular weight (125000) poly(vinyl alcohol) are not drag-reducing. However, on grafting polyacrylamide branches, the graft copolymers show drag reduction efficiency and shear stability. A large number of graft polymers of amylose/amylopectin/CMC/guar gum/poly(vinyl alcohol)/starch/xanthan gum) have been synthesized. The graft polymers having longer and fewer polyacrylamide branches have been found to be more drag-reduction effective and shear stable. It has also been observed that purification of guar gum and xanthan

gum enhances their drag-reduction efficiency as removal of low molecular weight ingredients like fats and proteins increases the fraction of high molecular weight polymers, and hence improves their drag-reduction ability. The drag-reduction ability of grafted polymers is not affected by the salts present in seawater. These graft copolymers also have synergetic flocculation characteristics (44,45).

Bello and co-workers (50) have recently reported the effect of cross-linking agents on the drag-reduction efficiency of hydroxylpropyl guar and guar gum solutions in turbulent flow through a horizontal pipe. The results show that the addition of cross-linking agent (borax) to solution with concentrations below those required for gel formation enhances the drag reduction due to increased dimensions of the macromolecules in the presence of intermolecular cross-links. The

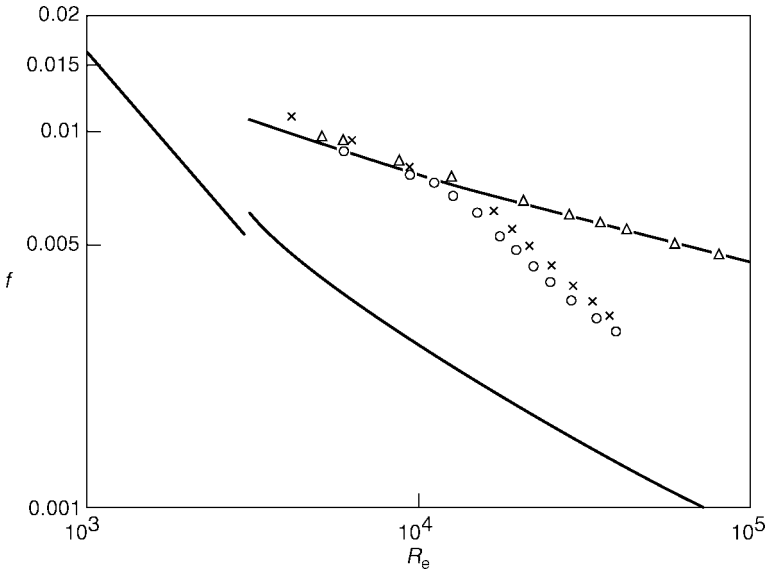

Fig. 6. The variation of drag reduction percentage with concentration in commercial, purified, and polyacrylamide grafted guar gum (GM_3) at R_e-14000: △ Water; × diameter = 1 mm, $u^* = 0.57$; ○ diameter = 3 mm, $u^* = 0.06$ (116,118).

flow-induced degradation of the polymers is not appreciably affected by the addition of cross-linking agent. The intermolecular bonds are stable to flow-induced degradation since their presence does not significantly alter the degradation rate. The enhancement of drag reduction also takes place at concentration of the macromolecules above 500 ppm. The enhanced drag reduction is up to 35%. On the other hand, grafting and purification enhance the drag reduction up to 68%, that too at concentrations below 100 ppm (121,123,128,129). Hence, it is worth investigating the effect of cross-linking of graft copolymers for further enhancement of drag-reduction efficiency.

McCormic and co-workers (130–136) have investigated the DRE of polyacrylamide copolymers. The various copolymers studied by this group include polyelectrolytes [(PAM-*co*-sodium-2-acrylamido-2-methylpropane sulphonate (NaAMPS); PAM-*co*-sodium-3-acrylomido-2-methylbutenoate (NaAMB)]; polyamphotytes [(poly-2-acrylimido-2-methyl propyl) dimethyl ammonium chloride-*co*-NaAMPS (ADAS); poly(acrylimide-*co*-2-acrylimido-methylpropenedimethyl ammonium chloride-*co*-sodium-2-acrylimido-methyl-propane sulfonate (ADASAM)]; and hydrophohically modified acrylamides [(PAM-*co*-diacetone acrylamide) (DAAM); PAM-*co*-*N*-*n*-decrylamide; PAMCO; (PAM-C_{10}), *N*-isopropylacrylamide-*co*-acrylamide (1PAM) copolymers]. Several of these copolymers showed better drag-reduction efficiency than PAM.

Kowalik and co-workers (46) and Malik and co-workers (47–49) presented a new approach in development of shear stable and efficient drag reducers based on intermolecular associations and intermolecular complexes based on secondary interactions. These systems displayed higher drag-reduction efficiency and shear stability. The associations may be caused by electrostatic, hydrogen-bonding, or

hydrophobic interactions. The increased shear stability was attributed to the reversible breakage of secondary bonds in preference to cleavage of polymer backbone. Malik and co-workers (47–49) introduced chemical moieties with interacting functionalities on the backbone of a polymer to cause association effects. These interpolymer complexes were based on a copolymer of 97 wt% dodecyl acrylate and 3 wt% methacrylic acid (proton-donating polymer), and a terpolymer is constituted by 50 wt% dodecylacrylate, 46 wt% styrene, and 4 wt% 4-vinyl pyridine (proton-accepting polymer). These hydrogen bonding mediated interpolymer complexes exhibited higher drag reduction and shear stability; though low molecular weight donor polymer is more shear stable than proton-accepting polymer, it is not an effective drag reducer. The shear stability has been discussed in terms of mechanistic considerations. It is apparent from the above discussion that though a lot of experimental results based on commercially available polymer drag reducers have been reported, the development of new drag-reducing agents with higher drag-reducing efficiency and shear stability is limited.

Mechanism of Drag Reduction

The effect of polymers on turbulence has been discussed by Singh (20), Gyr and Bewersdorff (23), and Gad-El-Hak (25), and several research articles have been published in 1990s. The gist of the past and present researches is being provided below and is the status of still eluding origin of drag reduction.

(1) The turbulent intensity of streamwise components has been reported for drag-reducing flows. All experiments indicated that the position of the maximum is further away from the wall than for Newtonian fluids and is generally found at $y^+ \cong 30$–60.

(2) For transverse intensity component in the presence of drag-reducing additives, the radial fluctuations are strongly damped in the buffer region and $(\overline{v}')^2$ maximum is shifted to $y^+ \cong 200$ or even to the centre of the pipe if large drag reduction is there. In the core region, the intensity is the same as for the solvent. The *xy* component of Reynolds shear stress is the measure of intensity of turbulence transport. In the pipe flow of Newtonian fluid, it starts growing from zero at the wall to a maximum at $y^+ \cong .05d^+$ and decreases nearly to zero at the pipe axis. In drag-reducing flow, the intensity is reduced and the maximum is shifted further from the wall.

(3) The frequency spectra of wall shear stress fluctuations for drag-reducing flows show the relative attenuation of high frequency components. The decrease in high frequency content and increase in low frequency are observed in the frequency spectra of axial as well as transverse fluctuations for drag-reducing flows.

(4) As streak spacing is a measure of the size of coherent eddies in viscous and buffer layers, the drag-reducing polymers change the structure of the flow. There is an increase in the nondimensional streak spacing as the drag reduction increases.

(5) The bursting period is an indication of time between occurrences of secondary instabilities. The burst produces extensive Reynolds stresses. The bursting is more energetic and its frequencies decrease as the drag reduction increases. In the maximum drag reduction region, the bursting period becomes two to three times as large as that of the Newtonian fluid at the same Reynolds number.

(6) In homogeneous drag reduction, only in the buffer region, the Reynolds stresses are produced in contrast to the case of heterogeneous drag reduction where there is a much larger region where the Reynolds and viscous shear stresses are of the same order of magnitude. The characteristic time of big eddies is of the same order as that of relaxation times of injected polymer solutions for shear rates of $10–10^3\ s^{-1}$, indicating an interaction between big eddies and polymer threads.

(7) The polymer threads influence the large-scale structures; it appears that highly elastic polymer threads restrict their motion leading to reduced transport of momentum from this region to the dissipating small eddies, and thus causing the observed drag reduction.

(8) According to the Lumley (78,79,92,137), the large eddies are formed in the viscous sublayer and are extended into the buffer layer. The polymer molecules are extended when subjected to fluctuating strain rate outside the viscous sublayer. This causes an increase in the extensional viscosity. This high extensional viscosity damps the small dissipating eddies. Because of the decreased intensity of small eddies, stress in the buffer layer delays the reduction in the mean profile slope, resulting in the thickening of the buffer layer. As the molecules are not extended in the viscous sublayer, it is not affected by polymer.

(9) The change in mean velocity profile causes the expansion of large eddies. The expanded large eddies produce an increased streamwise fluctuating velocity, primarily in the buffer layer. In the maximum drag reduction region, only large eddies are supposed to remain. According to the Lumley (78,79,92,137) hypothesis, the eddies in the buffer layer that are primarily responsible for Reynolds stress production are those associated with secondary instability on inflectional profile. These eddies are presumably damped.

(10) Luchik and Tiderman (138) postulated that turbulence and the polymer molecules in dilute polymer flows reach statistical equilibrium, where the remaining turbulent stretching keeps the molecule extended so that lower threshold motions can be damped by the viscoelastic properties of the dilute polymer solution. Gyr (80) was more specific and attributed the required molecular extension to a wall-layer structure of vortices.

(11) It seems that the high shear rates of a turbulent flow in the near-wall region are necessary to deform the spherical polymer molecule to an ellipsoid which becomes aligned with its long axis in flow direction. These deformed and aligned molecules are able to exhibit an increased resistance against vortex stretching and, therefore, can interact with turbulent structures.

(12) In the drag reduction by the surfactant solutions when a critical shear gradient is exceeded, the shear viscosity suddenly increases because of the formation of the so-called shear induced state (SIS). In SIS, the micelles become aligned in flow direction. Furthermore, in the SIS, the micelles have to build up larger, super-order structures. The critical shear rate for the occurrence of the SIS can be related with the onset of drag reduction (139), and it seems that drag-reducing surfactant solutions appear to exhibit an increased shear viscosity in the buffer zone of a turbulent velocity profile.

(13) The various theories explaining drag reduction may be divided into three categories: first, an explanation in which the increase in extensional viscosity for the polymer solution is the main ingredient; second, a theory that stresses the importance of anisotropic effects introduced by the extended polymer molecules; and third, a proposed explanation in which elastic effects are responsible for drag reduction.

(14) On the basis of DNS, a large number of investigations have been undertaken to explain the drag-reduction. Den Toonder (22,54,65,86) has proposed the following mechanism for the drag reduction by polymer additives. The polymers become extended by the flow at a certain Reynolds number, depending on the time scale of the polymer molecules in relation to the time scale of the turbulence. Hence, this "onset" phenomenon is determined by elastic properties of the fluid. When the polymers are extended, viscous anisotropic effects introduced by the extended polymers in the relation between the stress and the deformation cause a change in turbulent structure and the anisotropy production leading to a reduction in drag. At this stage, elasticity plays a counterproductive role in the drag-reduction process.

(15) Dimitropolous and co-workers (88) pointed out that previous work on numerical simulation on drag reduction has focused on the investigation of the role of elongational viscosity through the use of generalized Newtonian models. They used the nonlinear elastic model with the Peterlin approximation (FENE-P) and the Giesekus model (140) of viscoelasticity for the solution at high extensional rates. In both the cases, comparing the mean velocity profiles and the statistical features of the turbulent flow showed agreement with well-established experimental observations, such as the increase in the spacing of the streamwise streaks and the increase in the streamwise vorticity fluctuations. In addition, the hypothesis that drag reduction is primarily an effect of the extension of the polymer chains, where the increase in the extensional viscosity leads to the inhibition of turbulence-generating events, was once again reinforced.

(16) Sreenivasan and White (89) recently invoked the theory based on the elastic behavior of stretched polymers of de Gennes (84), who states that coil-stretch transition does not occur in turbulent flows in randomly fluctuating strain rates and that, if moderately stretched, the polymers produce no measurable change in viscosity. Sreenivasan and White (89) were able to explain the onset of drag reduction and maximum drag reduction asymptote on the basis of the elastic theory, and their results qualitatively explain the existing experiments.

Degradation and Shear Stability Mechanisms

Though the DRE of polymers is very high at extremely low dose, the practical problem in widespread applications of polymer additives is the degradation of polymers in turbulent flow. The degradation leads to a marked loss of the drag-reducing capability of the polymer.

There are two types of degradation, chemical degradation and mechanical degradation (65). Chemical degradation causes change in the structure of polymers by chemical reactions. It can occur, for example, by the presence of metal or any free-radical initiators when oxygen is present. The high salinity or calcium concentrations in solvent can also cause chemical degradation (141).

Mechanical degradation is caused by mechanical energy input to the polymers in solutions, which means passing the solution through pumps or pipes or both. Mechanical degradation has long been associated with shear flow. To some extent, the shear flow causes the degradation of dilute poly(enthylene oxide) solutions (14). Bueche (142) showed in his pioneering work that the elongational stresses which exist in some regions of turbulent pipe flow are more severe and cause scission of polymer molecules. A molecule in a shear flow is subjected to both rotation due to the presence of vorticity and to stretching and compressive stresses. Bueche (142) showed that in simple shear flows, the molecule is rotated past principle axes much too fast to allow the flow to stretch it to a large extent. On the other hand, in elongational type of flows, the vorticity is much less relative to the stretching and aligning action of the strain than in shear flows. A large number of investigations have been reported, which convincingly indicate that the molecules are fully extended followed by mid-chain scission under elongational flow field (143–147).

Mechanical degradation of polymers in turbulent flow has been extensively investigated and reviewed by Pollert and Sellin (148), Singh (20), Moussa and co-workers (149), Moussa and Tiu (43), Gyr and Bewersdorff (23), Den Toonder and co-workers (65), Nguyen and Kausch (146), Brostow and co-workers (62–64), Choi and co-workers (141), Rho and co-workers (150), Kim and co-workers (151–155), and Choi and co-workers (156–159).

It is well established that the extent of drag reduction increases with the molecular weight and length of polymers, and so does their susceptibility to flow-induced degradation (20). The rate of mechanical degradation increases with the increasing molecular weight. In most of the cases, it is possible to represent degradation by an exponential expression using flow time or number of passes as an independent variable. In turbulent flow, the degradation is more in poor solvent at low Reynolds number, whereas the opposite was observed at high Reynolds number. For constant wall shear stress and pipe diameter, the degradation rate was found to be directly proportional to the molecular weight of polymers. For constant wall shear stress and polymer concentration, the degradation rate was found to be inversely related to pipe diameter. For constant wall shear stress and pipe diameter, the degradation rate was found to be inversely propotional to polymer concentration. For constant polymer concentration and pipe diameter, the degradation rate was found to increase with wall shear stress. In general, the shear stability increased with solvation number. The higher the ratio of total length to the width of the polymer molecule, the faster will be the degradation. In

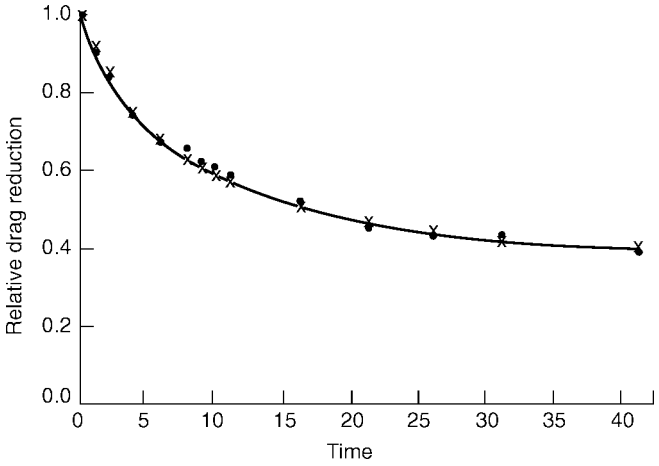

Fig. 7. The variation of relative drag reduction with time for mixtures of pure xanthan gum (10 ppm) and polyacrylamide (10 ppm): ×, Theoretical (Brostow Polymer Flow Model); ●, experimental (59).

high turbulent flow, the degradation is not caused not only by scission of polymer chains, but also by a radical propagation reaction initiated by scission of polymer chains.

The critical Reynolds number $R_e{}^*$ or apparent shear/extension rate $(v/d)^*$ was found to increase with polymer concentration and molecular weight as represented by the dimensionless concentration $c[\eta]$. Most of the degradation takes place at the entrance region because of high extensional straining of polymers.

The molecular degradation in turbulent flow is also explainable by the theoretical model of Brostow (62–64) (see Fig. 7). The mid chain scission in turbulent flow has been experimentally and theoretically explained (143–145,147). Recently, Kim and co-workers (153) studied the mechanical degradation of high molecular weight polystyrene under turbulent flow using a rotating disk apparatus for three various solvent systems. They found that the extent of the degradation depended on the solubility parameter of the solvents. Their experimental data for molecular degradation in turbulent flow gave an excellent fit with the Brostow model (62–64). Brostow (62) obtained the following relation:

$$\frac{\mathrm{DR}(t)}{\mathrm{DR}_0} = \frac{1}{1 + w\,(1 - \mathrm{e}^{ht})} \tag{32}$$

where $\mathrm{DR}(t)$ and DR_0 are the percentage drag reductions at times t and $t = 0$, respectively. A large value of h indicates fast degradation, and a large value of w implies a low shear stability. Their data give excellent fit to the equation.

Choi and co-workers (158) observed the following correlation between time-dependent drag reduction and mechanical degradation:

$$\frac{\mathrm{DR}(t)}{\mathrm{DR}_0} = \exp(-t/\lambda_0) \tag{33}$$

where DR(t) and DR_0 are the percentage drag reductions at times t and $t = 0$ respectively, and λ_0 is an adjustable parameter. $1/\lambda_0$ measures the rate of degradation. It describes the degradation mode very well for shear-resistant polymers such as various CMC and CMC-based graft copolymers (125) and xanthan gum (160).

However, the exponential equation deviates from the experimental data for drag reducers such as flexible PEO. Recently Sohn and co-workers (161) and Kim and co-workers (155) have studied the drag-reduction characteristics of polysaccharides such as xanthan gum and guar gum respectively. They are found to be reasonably shear-stable drag-reducing agents (123,162,163). They are highly susceptible to biodegradation. To overcome this disadvantage these polysaccharides have been grafted by flexible polyacrylamide branches (122,123). The solutions of both polymers conform to the empirical relationship between drag-reduction efficiency and polymer solution properties (156) at a fixed Reynolds number, ie

$$\frac{C}{\mathrm{DR}} = \frac{K[C]}{\mathrm{DR}_{\max}} + \frac{C}{\mathrm{DR}_{\max}} \tag{34}$$

where DR_{max} is the maximum drag reduction, K is the characteristic parameter which depends on the polymer solvent system, and C is the intrinsic concentration (W_{ppm}) defined by

$$[C] = \frac{\mathrm{DR}_{\max}}{\mathrm{Lim}_{C\to 0}\left(\frac{\mathrm{DR}}{C}\right)} \tag{35}$$

and the universal curve for drag reduction when normalized by the hydrodynamic volume fraction of the polymer solution (% DR/$[\eta]C$ vs $[\eta]C$) is due to McCormic and co-workers (130–137).

They reported that volume fraction normalization allows the comparison of drag-reduction efficiencies of polymers of widely differing structures. Xanthan gum molecules in deionized water exhibit higher drag reduction in the range of 50–60°C than at room temperature because of conversion to individual xanthan gum molecules from aggregated helics. In case of guar gum, it was confirmed that K is a characteristic constant of a particular polymer/solvent system and does not depend on molecular weight.

The turbulent drag reduction and drag reduction of DNA has been recently investigated by Choi and co-workers (164). Double-stranded DNA is found to be a good drag reducer when compared with the other normal linear polymers. However, the drag-reducing power of DNA disappears when DNA denatures into two single-stranded molecules. DNA is always cut in half by the turbulence. Its degradation is different from that of the normal flexible long-chain polymers.

In a number of graft copolymers (122,124,165,166), it has been found that the grafting increases the shear stability. However, in some cases, the grafting has been found to reduce the shear stability of graft copolymers (123,125,126), which supports the mechanistic analysis of Agrawal and Mashelkar (167).

A highly branched polymer of high molecular weight amylopectin and its graft copolymer with polyacrylamide have been investigated by subjecting the solutions by intensive turbulent flow in turbulent rheometer at Reynolds number

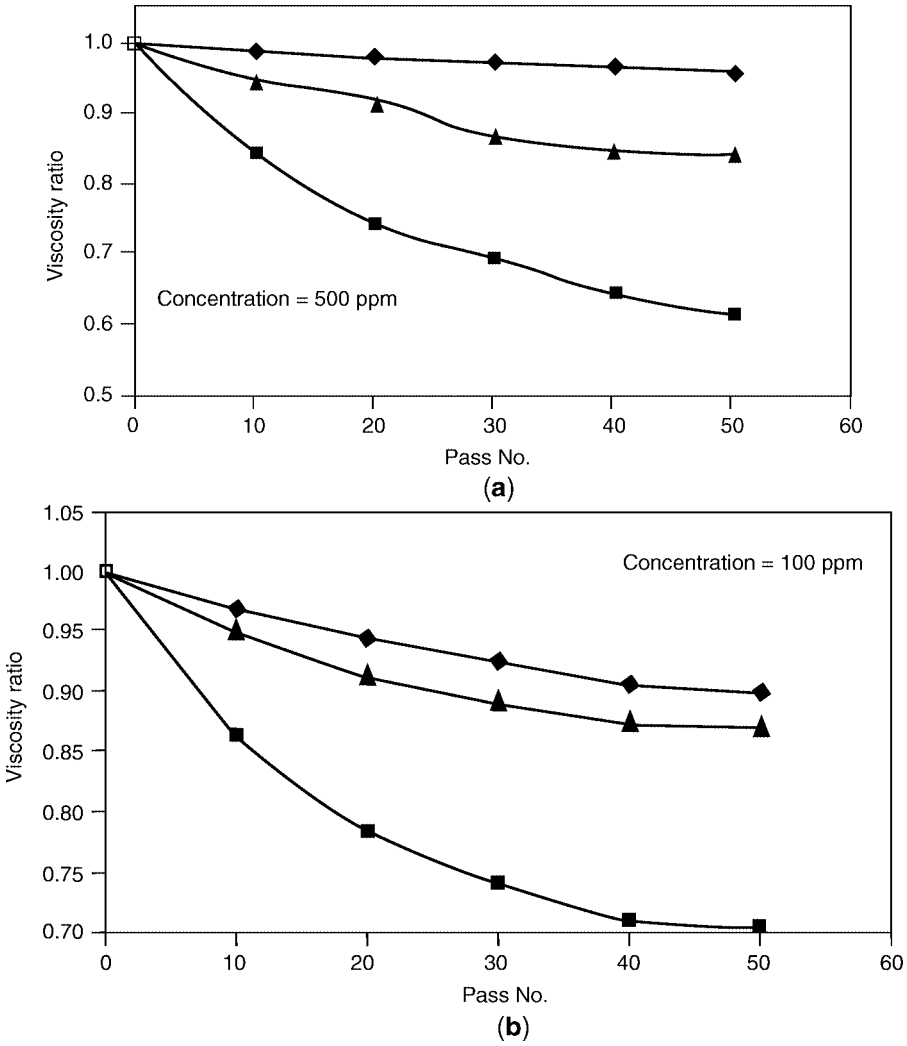

Fig. 8. The variation of viscosity ratio versus pass number at concentrations of 500 ppm (**a**) and 100 ppm (**b**) respectively in case of solutions of polyacrylamide grafted amylopectin (◆), amylopectin (▲) and polyacrylamide (■) ($R_e = 14000$), and at 50 ppm (**c**) for polyacrylamide (◇) experimental and (□) theoretical according to Brostow model ($R_e = 14000$). (161).

of 14,000 (168) (see Fig. 8). The solutions were investigated in the concentration range of 50–500 ppm, and mechanical degradation was monitored by measuring absolute viscosities of sheared solutions from 10 to 50 pass numbers in turbulent flow rheometer. As is evident from Figure 8, the results contradict the Agrawal and Mashelkar theory (167) and support the Brostow polymer model (62–64). Apart from grafting, two other approaches have been put forward to enhance the shear stability. The reversible intermolecular association in solution increases the molecular weight of polymer and provides enhanced shear stability (46–49). The drag-reducing polymers can be cross-linked to enhance drag reduction; the flow

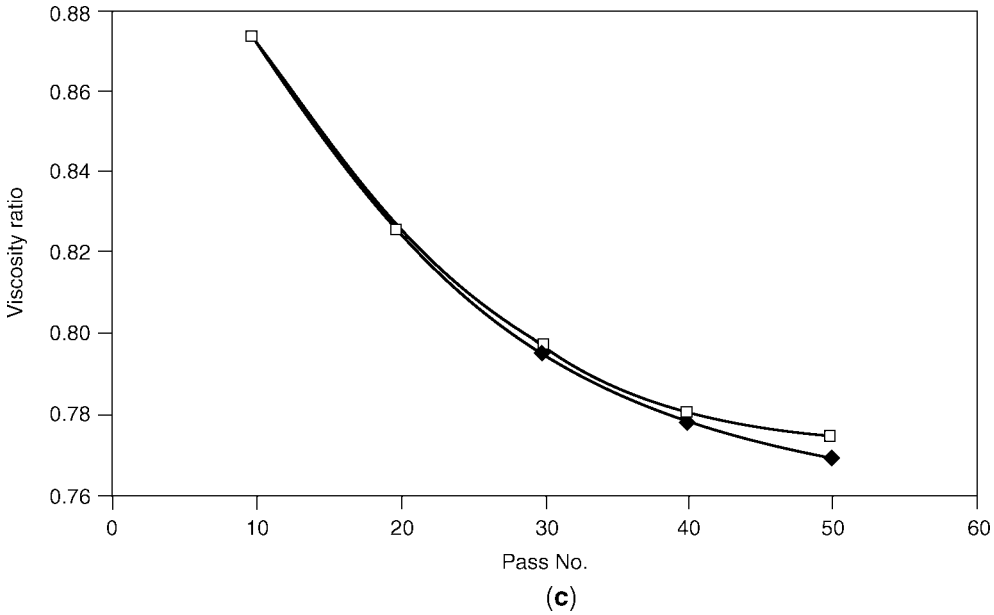

Fig. 8. (Continued).

induced degradation of the polymers is not appreciably affected by the addition of cross-linking agents (50).

Drag Reduction by Mixed Systems

The earlier work on drag reduction by fibers, polymer/polymer, polymer/fiber, and polymer/soap mixtures has been reviewed by Singh (20) and Gyr and Bewersdorff (23). It has been noticed that fibers with high aspect ratio (l/d), flexibility, and surface roughness show good drag-reduction effectiveness. At equal aspect ratio, fibers with smaller diameter cause more drag reduction. This can be attributed to the improved flexibility due to decrease in diameter of the fibers. The fibers of nylon, wood pulp, acrylic, glass, and asbestos have been reported to cause drag reduction in suspensions.

Both positive and negative deviations from the linear additive line have been observed in drag reduction caused by polymer/polymer mixtures depending upon their composition, flow rate, and polymer species. The maximum synergism is obtained at a specific composition. The random coil size, rigidity, and salvation of polymer molecules appear to be responsible for the synergism in drag reduction by polymer/polymer mixtures (169).

The maximum drag reduction caused by polymer/fiber mixtures is more than predicted by Virk's maximum drag reduction asymptote (170). Kale and Metzner (171,172) explained the reasons for synergism in drag reduction by high extensional effects on polymers along with fibers and consequent high extensional viscosities of polymer solutions. Reddy and Singh (169) found strong synergistic effect

with both guar gum and xanthan gums in combination with asbestos fibers. A 50:50 mixture by weight gave the maximum in both cases. As observed by Hoyt (17), both mass and length are responsible for suppression of turbulence by these systems.

Recently, Inaba and co-workers (173) pointed out that it is possible to reduce the pumping power, to downsize the transport system, and to decrease the heat loss to environment by using surfactant water solution as a thermal energy transport medium. The environmental pollution caused by discarding the used surfactant solution has become a serious problem. It is required that the new additive have the same flow drag reduction effect as surfactant solution, and also that little environment load be used. They used pulp fiber as the new type of flow drag reduction additive in a circular pipe. The pulp fiber consists of a vegetative fiber that forms paper. Therefore, pulp fiber does not have harmful effects on the environment. The fibers were of the diameter range 6.45–29 μm and had an aspect ratio of 50:1. The flow resistance and heat-transfer characteristics of water suspensions with pulp fibers were measured. The velocity distribution of the pulp fiber suspension was similar to the plug flow in the laminar flow. The flow drag reduction effect was observed. The enhancement effect of heat transfer in the laminar flow and the heat-transfer reduction effect in the turbulence were observed. The nondimensional correlation equations of pipe flow resistance and heat-transfer resistance were derived in terms of various nondimensional parameters in the above study (see Fig. 9).

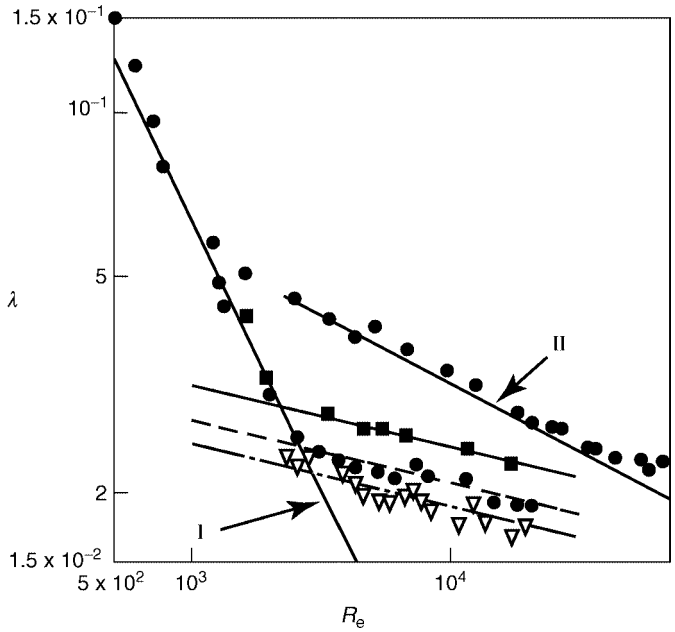

Fig. 9. Relationship between pipe friction coefficient λ and Reynolds number for various pulp water suspensions. I depicts the theoretical equation of the flow resistance in laminar flow in pipe and II depicts the Blasius resistance formula of turbulent flow. C_p, %: ●, 0 (Water); ■, 0.30 ———; ●, 0.55 —— ——; ▽, 0.72—-—. Adapted from Figure 9 of Ref. 166.

Drag reduction caused by passive devices such as riblets has been confirmed for various boundary layers and pipe flows (174–178). However, riblets have a narrow range of the effective flow rates, and if the flow rate is higher than this effective range, the riblets increase the friction drag just like normal rough wall (179). Walsh and co-workers (175–177) found that the triangular grooves of roughly equal height and azimuthal spacing, ie h/s ≈ 1, provided the optimal drag reduction performance. They further found that relative to a smooth wall, riblets with $h/s \approx 1$ exhibited two general flow regimes:

(1) For nondimensional riblet height $h^+ < 25$, the riblets reduced drag with the largest reduction of the order of 10% at $h^+ \approx 15$.
(2) For nondimensional riblet height $h^+ > 25$, the riblets enhanced the drag by as much as 30% at $h^+ \approx 50$.

It has been established that interflows of air and water in riblet-lined pipes (180–183) show the same behavior as the external flows over riblets. According to Walsh (175,176), riblets act as fences to isolate the low speed streaks that exist near the wall (184), and thus retard their bursting.

Bechert and co-workers (185) and Choi (186) have proposed that the riblets impede spanwise motions of streamwise vortex pairs associated with sublayer streaks, resulting in weakened bursts and lower shear stress. Choi and co-workers (187) and Pullese and co-workers (188) conducted measurements of three rms turbulence intensities and turbulence shear stress over riblet surfaces in their drag-reducing regimes. These physical entities were reduced relative to their respective magnitudes over smooth surfaces at the same force stream velocity. However, axial to transverse correlations near the riblets surface remain much the same as those near a smooth surface. This is in contrast to polymer drag reduction, where significant reductions in the axial to transverse velocity correlations relative to solvent are observed (10). The drag enhancement by riblets at high h^+ was attributed by Walsh (175,176) to adverse effects of the increased riblet wetted surface area overwhelming the riblet-induced drag reduction. However, Tani (189) observed the riblet drag enhancement as being akin to that by sand-roughened pipes and estimated the equivalent sand roughness of riblets to be about a quarter of their actual height.

Choi and co-workers (190) have carried out direct numerical simulation of turbulent flow over riblets at $h^+ \approx 20$ and 40, respectively, in drag-reducing and drag-enhancing regimes. Interpreting their calculations in terms of coherent structures, they pointed out that riblets reduce drag when the streamwise vortices above them are aligned such that only a small portion of a riblet, near the tip, is exposed to their downwash at higher h^+; the streamwise vortices become smaller relative to the riblets; and their downwash affects a greater fraction of the riblet surface, enhancing drag.

The combined polymer additives and riblets are expected to cancel out the drawbacks associated with applying each of these systems and to produce a positive synergistic effect. The effect of combined experiment would also elucidate the respective drag-reduction mechanism. Choi and co-workers (190) experimented on a ship model with riblets and then coated the model with polymer. The

measured drag of the model revealed that the combined system caused 2% higher drag reduction than the additives of each systems effect. Rohr and co-workers (191) measured the friction factor for dilute PEO in a pipe lined with 0.076-mm, V-groove riblets (3MCO). He found that the combined system produced the same drag reduction ratio as the polymer additive alone. Christodoulou and co-workers (192) and Anderson and co-workers (180) carried out similar experiments. In both experiments, results obtained for combined systems using PEO solutions showed that the drag-reduction rates were less than the sum of two systems. In contrast, Anderson and co-workers (180) observed for combined system using guar gum that the drag rate was greater than the sum of the drag-reduction rates of the individual systems and that the critical shear stress of the additive was lowered. Koury and co-workers (178) carried out a systematic experiment for a combined system of polyox and a riblet pipe. The positive synergistic effect was observed to occur.

Recently, Mijunuma and co-workers (179) investigated the drag reduction for combined system of polymer additives and riblet pipe. The riblet groups were V-shaped, the spacing of which was 1.3 mm and the height 1.01 mm. For higher h^+, a triangular riblet system including other geometries increases the drag to levels similar to those of normal transient roughness. The polymer additives were Aronfloc N-110 and separan AP-31. The critical shear stress, τ^*, at which N-110 started the drag reduction was approximately eight times higher than τ^* for AP-30. In the combined system, the synergistic drag reduction for higher h^* was discussed under the assumption that additives suppressed the drag increase resulting from riblets. Since additives thicken a wall layer covering the region from a viscous sublayer to a buffer layer, the relative height h to this wall layer thickness is lowered. Another cause of the synergistic effect is the flow enhancement due to additives, which suppresses the riblet-induced drag increase. Hence the combined effects almost cancel out the drag increase due to riblets. This synergistic effect exceeds 10%. The analysis based on velocity profiles indicated that these effects can produce synergistic drag reduction for higher h^*.

Drag reduction can be achieved by direct injection of microbubbles through slots or porous skin (193–196) or the generation of hydrogen by electrolysis at the wall (197). The primary parameters, independent of gas type and Reynolds number, appear to be the actual gas flow rate referenced to injector conditions of temperature and pressure (198–200) and the location of the bubbles in the turbulent boundary layer (198,199,201–203). Merkle and Deutsch (196) have provided a comprehensive review on skin friction reduction by microbubble injection. Mahadevan and co-workers (204) postulated that microbubbles like polymer solution destroy turbulence production by selectively increasing the viscosity near the buffer region. They increase the local dynamic viscosity. Pal and co-workers (205) demonstrated that microbubble and polymer solution shear stress statistics as measured by flush mounted hot film sensors are similar at equivalent value of drag reduction.

Fontaine and co-workers (206), on the basis of these similarities, envisaged that high levels of drag reduction can be achieved by combining low concentrations of polymer and surfactants with microbubble injection at low injection rates. The influence of homogeneous surfactant (Aerosol OT) and homogeneous polymer (PEO) solutions on the performance of microbubble skin friction reduction

was investigated on an axisymmetric body. Carbon dioxide was injected in water, homogeneous surfactant solution, and homogeneous polymer solutions. The integrated skin friction measurements were obtained at two free-stream velocities as a function of gas injection rate and PEO concentration. At similar gas injection rates, microbubble injection exhibited more drag reduction. At low gas injection rates, the results of this investigation indicate that the combination of microbubble injection with polymer additives can yield drag reduction levels exceeding those of the individual systems. Maximum drag reduction in the combined system was greater than 80% for 20-ppm polymer concentration and higher gas injection rates. This level of drag reduction is higher than the levels obtained with either polymer or microbubbles separately at these concentrations or injection rates. In this study, synergism between microbubble and polymers was not obtained. Reducing the bubble size through addition of surfactant did not affect the characteristics of microbubble drag reduction. The resulting size of microbubble is still large compared to turbulent scales and, thus, may explain the lack of effect on drag-reduction characteristics of microbubbles with and without surfactant.

Watanabe and co-workers (207–210) reported drag-reduction phenomena in different geometries having highly water-repellent walls in laminar region. The basic material of the highly repellent wall is fluorine alkane modified acrylic resin with added hydrophobic silica, and the contact angle of the wall is about 150°. Watanabe and co-workers (207) reported for the first time the laminar drag reduction of Newtonian fluids flowing in a channel with square and rectangular ducts with highly water-repellent walls. The maximum drag reduction ratio of water was 22% for the square duct. The drag-reduction phenomena were also observed for the frictional resistance of an enclosed rotating disk with highly water-repellent walls. The maximum drag reduction ratio for tap water was about 25% at the Reynolds number of 2×10^5. In their recent investigation (208–210), the drag-reduction phenomenon in which 14% drag reduction of tap water flowing in a 16-mm diameter pipe occurring in a laminar region has been explained. This phenomenon occurred because of the presence of fluid slip at the wall. The measured velocity profile gives the slip velocity at the pipe wall, and it was shown that the shear stress is directly proportional to the slip velocity. The friction factor formula for a pipe flow with fluid slip at the wall has been obtained analytically from the exact solution of the Navier Stokes equation, and it well agrees qualitatively with the experimental data. The main reasons for the fluid slip have been pointed out. In these cases, the molecular attraction between the liquid and the solid surface is reduced because the free energy of the solid is very low, and the contact area of the liquid is decreased compared with conventional smooth surface because the solid surface has many fine grooves. A liquid cannot flow into the fine grooves owing to surface tension. These concepts are supported by the experimental result that the drag reduction does not occur in the case of surfactant solutions.

Turbulent Drag Reduction by Surfactants

Recently, turbulent drag reduction by surfactants has been extensively reviewed by Gyr and Bewersdorff (23), Zakin and co-workers (42), and Myska and Zakin

(41). The main features of the surfactant drag reduction and their industrial applications are summarized here.

The polymer solutions are strongly affected by mechanical degradation during turbulent flow which limits the lifetime of their DRE. The surfactants have been found to reduce the frictional drag by 70–80%. At high stress, the surfactants also suffer temporary mechanical degradation of their microstructure, but they have the ability to repair themselves in the order of seconds (42).

The drag-reducing surfactant solutions are characterized by the presence of rod-like micelles which are formed by single surfactant molecules above a certain characteristic concentration (139). This critical concentration depends strongly on temperature and electrolyte concentration. As mentioned earlier, critical wall shear stress, a shear induced state (SIS), is achieved when the micelles are coalesced to form larger structure aligned in flow direction. This is also the onset stress of drag reduction by surfactant. The observed loss of drag reduction beyond this critical wall shear stress is reversible. The drag reduction is caused by anionic, cationic, nonionic, and zwitterionic surfactants. Nonionic surfactants are chemically stable, endowed with low toxicity, and biodegradable. However, their effective temperature range is limited. Zwitterionic surfactants are more useful as they have a larger effective temperature range. As they have both positive and negative charges in single surfactant molecule they may be sensitive to ions existing in water. The cationic surfactants with the organic counterions are excellent drag reducers in aqueous system. They have fairly wide temperature ranges and are not sensitive to calcium or magnesium ions present in water. Because of their potential for practical applications, they have been extensively investigated in the 1990s.

The DRE of cationic surfactant is greatly dependent on their chemical structures, surfactants, and counterion concentrations. Surfactants with short alkyl chains are effective at low temperatures, while those with long alkyl chains are effective at high temperatures. The dramatic effect of the counterion to surfactant concentration ratio on fluid characteristics of surfactant solutions has been found recently. The proper combination of both can extend the effective range widely.

The surfactant drag reducers may exhibit strong viscoelasticity and high extensional viscosity. Excess counterions in cationic surfactant may make the solution still nonviscoelastic with distinct extensional viscosity. This suggests the correlation between drag reduction and extensional viscosity.

The surfactant drag reduction may exceed Virk's drag reduction asymptote for high polymers, and velocity profiles may be steeper than his elastic sublayer. The turbulence in radial and tangential directions is suppressed by surfactants. The zero Reynolds stress profiles have been observed for surfactants. Though the drag reduction mechanism is not established for surfactant drag reduction like polymer drag reduction, its mechanism may be different.

Along with the reduction in momentum transport, drag-reducing fluids have also been found to reduce the heat-transfer coefficients particularly in tube-in-tube heat exchangers. The heat-transfer reduction accompanying drag reduction may be caused by the thickening of the viscous boundary near the wall, which increases the thermal resistance between wall and bulk fluid and reduces the radial turbulence intensity. Heat exchangers with flow channels which disturb the fluid more, such as plate exchangers, show less heat-transfer reduction. Despite

several successful fields tests in district heating and district cooling systems, no commercial scale applications of surfactant drag reduction have been undertaken so far (23,31,42).

Applications of Drag Reduction

Introduction. Ever since the discovery of the drag-reduction phenomenon, efforts have been made for its industrial applications. In the last five decades, the range of applications of drag reduction has increased tremendously. The possible areas include oil-well fracturing operations, crude oil and refined petroleum product transport through pipelines, fire fighting, sewerage and flood water disposal, irrigation, hydrotransport of solids, water-heating circuits, jet cutting, hydraulic machinery, and marine and biomedical applications. The detailed progress made in these areas has been reported in various reviews (14,15,17,20,23,42,44,112,211, 212).

In crude oil transport and storm sewers, because of the economic benefits, the drag-reducing polymers have been put into practice in Trans Alaska Pipeline and other 100 pipeline sites, as well as in other pipelines transporting refined petroleum products (213,214). Similarly, drag-reducing polymers in storm sewers for Knowle and Dallas sewers (15) have been put to practice. Exigency requirements are in favour of applications of the drag-reducing polymers in fire fighting. Hence the practice has been accepted by New York City Council and the City of Hamburg. Large-scale field experiments have shown the efficacy of using drag-reducing polymers in hydrotransport of fly ash and sludge, heating circuits, water power stations, and irrigation from Czechoslovakia (211). Use of drag-reducing polymers has been made in short diversion tunnels and culverts in Yugoslovakia (215). Drag-reducing polymers have been used in energy requirements of sprinkler irrigation, reduction of percolation losses, and development of slow-release urea in India (33,44).

The efficacy of drag-reducing polymers in reducing the drag, hull of a 42.7-m long HMS Highbortor has been reported from the United Kingdom (216). In other cases, laboratory scale experiments have been performed, indicating beneficial use of drag reduction. Large-scale applications are inhibited in many cases because of the high cost of polymers and their degradation. Large-scale laboratory experiments as well as field trials have been reported indicating efficacy of cationic surfactants in district heating circuits (42). Economically feasible applications are described in some important cases.

Crude Oil Transport and Refined Petroleum Products. The most spectacular success of the application of drag-reducing polymers has been in the Trans Alaskan Pipeline (TAPS) in 1979, where the throughput capacity has been above 2 million barrels of oil per day (BPD) from pipeline capacity of 1.5 million BPD without the use of polymeric drag reducers (DRA) at present. The pioneering use in TAPS was to increase throughput while pump stations were being constructed and commissioned. As the effectiveness of the DRAs improved in the period 1979–1984, the need to build pumping station nos. 5 and 11 of the 12 disappeared. Present day DRAs are 12 times as effective as the initial materials used in TAPS in 1979.

In the Iraq-Turkey pipeline, DRA is injected downstream from each of the 15 pump stations. The injections of 40–50 ppm of DRA at each pump station allowed for an increase in throughput to 1 million BPD from a base flow of 0.7 million BPD.

A similar application of DRA has been undertaken to oil being pumped from the offshore platforms to shore facilities (217). Since 1983, some pipelines have used DRA for pipeline transportation of refined petroleum products (213). Treated fluids include gasoline, diesel, heating oil, and C_4 carbon. Today, approximately 100 pipeline sites use DRA for increased throughput (213,214). Typical dose rates for 10–30% flow improvement in these pipelines are no more than 1–2 ppm polymer per injection. Tests indicate excellent drag reduction without adverse effect on engine (218). In 1994, DRAs were 14 times more effective than the initial material used in TAPS in 1980.

The rapid and completely dissolving formulation will increase DRA effectiveness and improve application predictability. In addition, the incorporation of DRA into the design status of new pipeline construction deserves consideration for either downsizing pipes or reducing the number of pumping facilities.

Applications of Drag-Reducing Agents in Agriculture. Drag-reducing polymers reduce the drag in a turbulent flow and increase the drag in laminar flow because of an increase in shear viscosity. This feature of drag-reducing polymers has been utilized in reducing the energy requirement of sprinkler irrigation system in which the flow is in turbulent region in laterals, risers, and jets. Their use also increases the throughput and the area of coverage of sprinkler irrigation system (33,44,219–226). Water containing the drag-reducing polymers percolates slowly in the soil. This is due to increased shear and elongation viscosities of aqueous polymer solutions. The increased elongational viscosity produces a higher resistance in the porous media flow in the soil. Utilizing this aspect, a slow-release urea has been developed by blending urea with guar gum (33,223), which has boosted yields of wheat and paddy by 20–25% in field trials at IIT Kharagpur. It also increased the yield of vegetables such as cauliflower and brinjal in another field trial done in IHRI, Ranchi, India (227).

As guar gum is biodegradable, it does not affect the soil adversely. As a matter of fact the residual positive effects in yield in subsequent crops have been observed by Kar and Sahoo (228). There have been considerable developments in materials and polymer solution injection systems in sprinkler irrigation system.

Singh and co-workers (229,230) have developed a series of polyacrylamide grafted polysaccharides as drag reducers which are biodegradable and shear stable. Of these, polyacrylamide grafted amylopectin has been found to be the most effective drag reducer, and it reduces percolation losses most effectively by 50% at a concentration of 100 ppm.

In most of the reported investigations on sprinkler irrigation system, homogeneous drag reduction has been used in which the drag-reducing polymers are dissolved in the inlet source itself. In field conditions, the main water source for sprinkler irrigation can be tubewell, open well, reservoir, or a running stream or canal. In case of such sources, the polymer solution is required to be injected either at the inlet or outlet of the main pump. As evident from Figure 10, outlet injection is most effective as the drag-reducing polymers are not

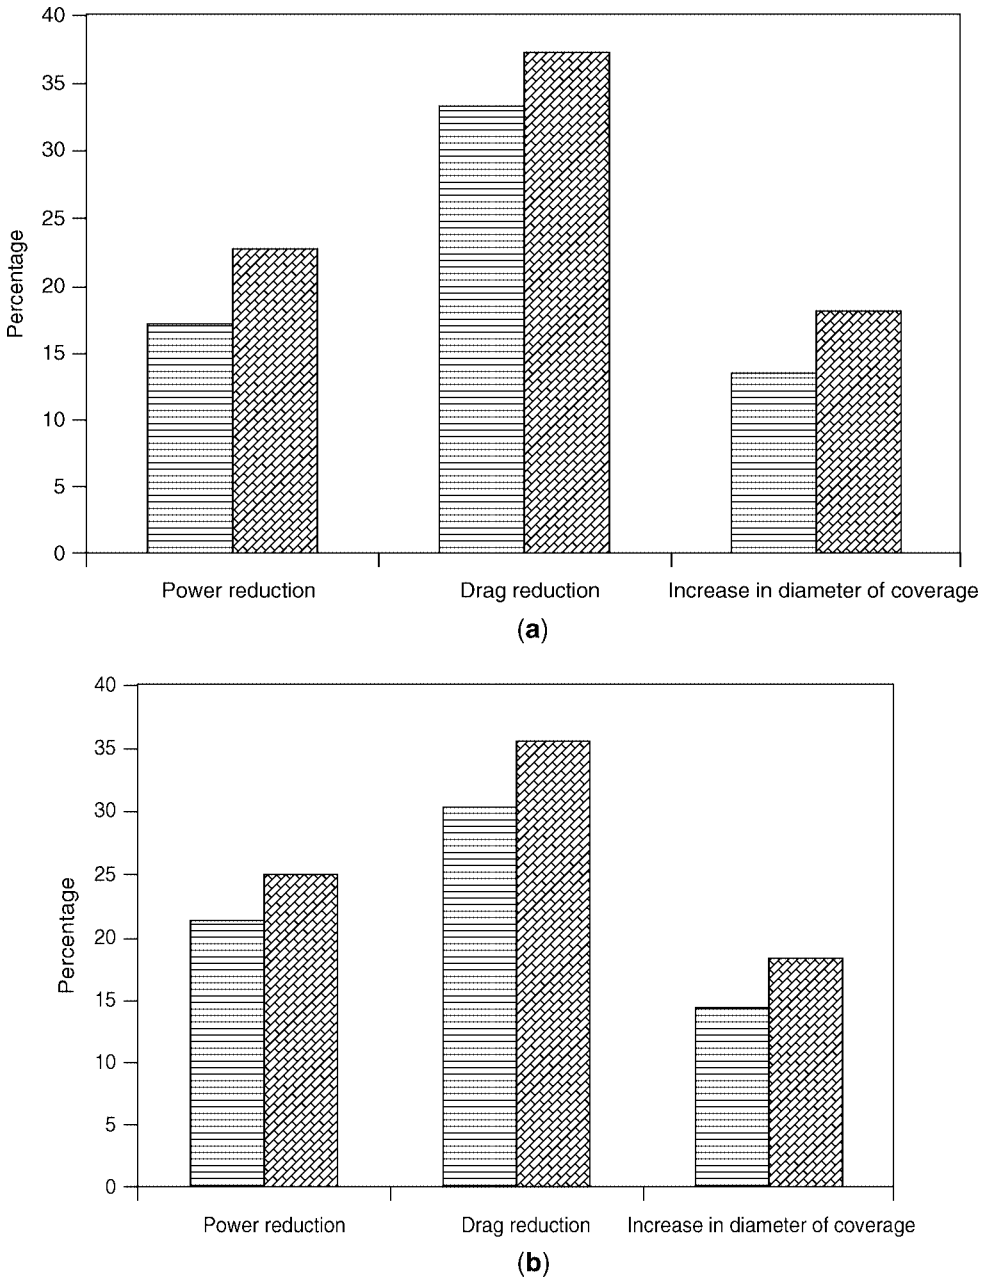

Fig. 10. Effect of injection method on drag-reduction characteristics of 50 ppm of polyacrylamide grafted amylopectin (AP-g-PAM) and 100 ppm of AP-g-PAM ▭ Inlet; ▨ Ventury (224).

degraded by the centrifugal pump (231). The cost benefit analysis shows that using drag-reducing polymers in sprinkler irrigation allows reduction in the pipe diameter and the power of centrifugal pump, which reduces the installation costs as well as the energy required. The reduction in the percolation losses

brings down the amount of water needed. This integrated technology is important for all those countries in the world which suffer from a shortage of water (23).

Storm Sewer Augmentation. Many sewers face overloading for a short duration during storms or heavy rains or because of increase in catchment area over the years owing to continued development. The capacity of sewers can be increased by drag-reducing polymer dosing. It has been shown by Sellin and coworkers (15) that the capital cost of dosing installations, recurring cost of polymers and maintenance, etc, are much lower than the capital cost involved in laying down a new sewer of 381-mm diameter in place of the existing 305-mm diameter sewer (in the rate of 1:15 according to prices in 1979). Fully automatic polymer dosing stations have already been installed in Buchman Creek (Dallas, Tex.) and Knowle (Bristol, U.K.). In these installations, drag-reducing polymer powder poly(ethylene oxide) water slurry is injected in the sewer. Bewersdorff and co-workers (232,233) showed that polyacrylamide suspensions (SEDIPUR AL436 containing 25% active material PAM by weight) can be injected economically to enhance the output of a sewer in Dortmund (Hohensyburg Sewer). During storms, 20–30 ppm of poly(ethylene oxide) or polyacrylamide can augment the flow capacity by 20–30%; economic feasibility studies together with 5-year data from an automatic dosing station (234) demonstrate that this is a viable and practical solution to many flooding situations.

Conclusions and Future Scope

The origin of drag-reducing polymers still remains enigmatic though considerable progress has been made in understanding it at the molecular level. Now it is possible to measure the extensional viscosity and other rheological properties of drag-reducing polymers at drag-reducing concentrations. The numerical simulations are also revealing other facets of the turbulent drag reduction phenomenon. Various molecular models such as FENE-P are being tested. As has been pointed out by Zhou and Akhavan (235), the most promising approach to accurate computation of polymer drag reduction at present is through stochastic simulations. However, on the application side, drag-reducing polymers are being used, as a routine practice, in crude oil and other petroleum product transport. The most prominent application seems to be yet realized in agriculture (236). On the materials side, the hydrolyzed and nonhydrolyzed grafted polysaccharides seem to have a bright future, because these materials have not only distinguished drag-reducing characteristics in turbulent flow of water but also distinguished flocculation and viscosifying attributes. Cationic surfactants seem to offer a shear- and heat-resistant material for district heating and cooling systems (31,34). Further research to identify a stable, low toxicity, and rapid biodegrading surfactant drag-reducing system is being focused for the coming decades (31,42,237–241). Biomedical applications of drag-reducing polymers also have a very bright future. In the years to come, turbulent drag reduction would remain an exotic field of research and applications.

DYNAMIC MECHANICAL ANALYSIS

Introduction

Dynamic mechanical analysis (DMA) is the technique of applying a stress or strain to a sample and analyzing the response to obtain phase angle and deformation data. The data collected allow the calculation of dynamic mechanical properties like the damping or tan delta (δ) as well as complex modulus and viscosity data. Modulus data in the form of the storage modulus is conceptually equivalent to that collected from traditional mechanical tests and gives a measurement of the strength and stiffness of the material. Viscosity information on how the material flows under stress can be obtained from the complex viscosity. The ratio of the storage to loss modulus is called damping or tan δ and is calculated directly from the phase angle δ. Damping is a measure of the internal friction of the material and indicates the amount of energy loss in the material as dissipated heat. This allows DMA to be used to predict how good a material is at acoustical or vibrational damping. Normally, DMA data for solids is displayed as storage modulus and damping versus temperature, with multicurve used to show frequency effects. Melt data is often shown against frequency like classical rheological data. Two approaches are used: (*1*) forced frequency, where the signal is applied at a set frequency and (*2*) free resonance, where the material is perturbed and allowed to exhibit free resonance decay. Most DMAs are of the former type while the torsional braid analyzer (TBA) is of the latter. In both approaches, the technique is very sensitive to the motions of the polymer chains and it is a powerful tool for measuring transitions in polymers. It is estimated to be 100 times more sensitive to the glass transition than differential scanning calorimetry (DSC) and it resolves other more localized transitions not detected in DSC. In addition, the technique

allows the rapid scanning of a material's modulus and viscosity as a function of temperature or frequency.

Theory and Operation of DMA

Forced Frequency Analyzers. If a constant load applied to a sample begins to oscillate sinusoidally (Fig. 1a), the sample will deform sinusoidally. This will be reproducible if the material is deformed within its linear viscoelastic region. For any one point on the curve, the stress applied is described in equation 1

$$\sigma = \sigma_0 \sin \omega t \tag{1}$$

where σ is the stress at time t, σ_0 is the maximum stress, ω is the frequency of oscillation, and t is the time. The resulting strain wave shape will depend on how much viscous as well as elastic behavior the sample has. In addition, the rate of stress can be determined by taking the derivative of the above equation in terms of time:

$$d\sigma/dt = \omega\sigma_0 \cos \omega t \tag{2}$$

The two extremes of the material's behavior, elastic and viscous, provide the limiting extremes that will sum to give the strain wave (see VISCOELASTICITY). The

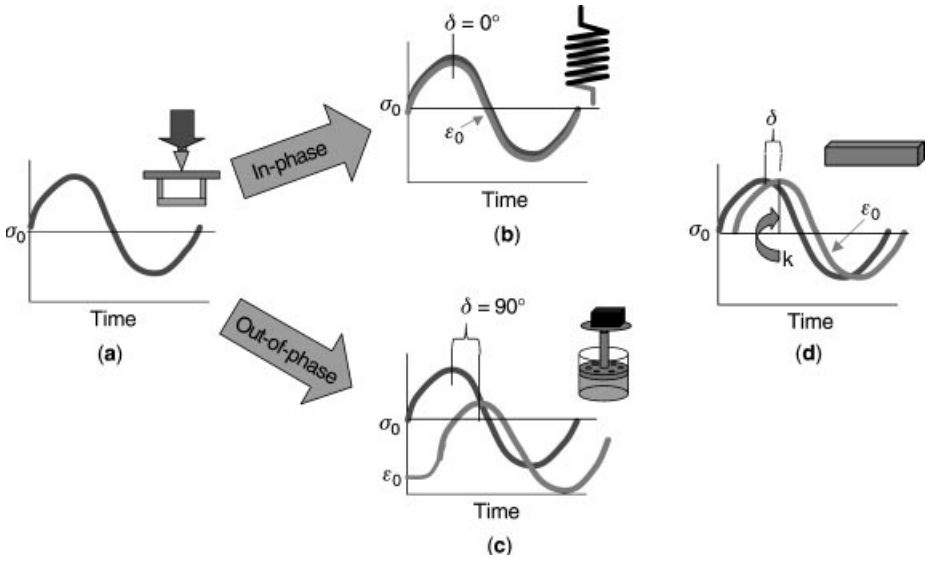

Fig. 1. (**a**) When a sample is subjected to a sinusoidal oscillating stress, it responds in a similar strain wave, provided the material stays within its elastic limits. When the material responds to the applied wave perfectly elastically, an in-phase, storage, or elastic response is seen (**b**), while a viscous response gives an out-of-phase, loss, or viscous response (**c**). Viscoelastic materials fall in between these two extremes as shown in (**d**). For the real sample in (**d**), the phase angle δ and the amplitude at peak k are the values used for the calculation of modulus, viscosity, damping, and other properties.

behavior can be understood by evaluating each of the two extremes. The material at the spring-like or Hookean limit will respond elastically with the oscillating stress. The strain at any time can be written as

$$\varepsilon(t) = E\sigma_0 \sin(\omega t) \tag{3}$$

where $\varepsilon(t)$ is the strain at any time t, E is the modulus, σ_0 is the maximum stress at the peak of the sine wave, and ω is the frequency. Since in the linear region σ and ε are linearly related by E, the relationship is

$$\varepsilon(t) = \varepsilon_0 \sin(\omega t) \tag{4}$$

where ε_0 is the strain at the maximum stress. This curve shown in Figure 1b has no phase lag (or no time difference from the stress curve) and is called the in-phase portion of the curve.

The viscous limit was expressed as the stress being proportional to the strain rate, which is the first derivative of the strain. This is best modeled by a dashpot, and for that element, the term for the viscous response in terms of strain rate is described as

$$\varepsilon(t) = \eta \, \mathrm{d}\sigma_0/\mathrm{d}t = \eta\omega\sigma_0 \cos(\omega t) \tag{5}$$

or

$$\varepsilon(t) = \eta\omega\sigma_0 \sin(\omega t + \pi/2) \tag{6}$$

where the terms are as above and η is the viscosity. Substituting terms as above makes the equation

$$\varepsilon(t) = \omega\sigma_0 \cos(\omega t) = \omega\sigma_0 \sin(\omega t + \pi/2) \tag{7}$$

This curve is shown in Figure 1c. Now, take the behavior of the material that lies between these two limits. The difference between the applied stress and the resultant strain is an angle δ, and this must be added to equations. So the elastic response at any time can now be written as

$$\varepsilon(t) = \varepsilon_0 \sin(\omega t + \delta) \tag{8}$$

Using trigonometry this can be rewritten as

$$\varepsilon(t) = \varepsilon_0[\sin(\omega t)\cos\,\delta + \cos(\omega t)\,\sin\,\delta] \tag{9}$$

This equation, corresponding to the curve in Figure 1d, can be separated into the in-phase and out-of-phase strains that correspond to curves like those in

Figure1b and 1c, respectively. These are the in-phase and out-phase moduli and are

$$\varepsilon' = \varepsilon_0 \sin(\delta) \tag{10}$$

$$\varepsilon'' = \varepsilon_0 \cos(\delta) \tag{11}$$

and the vector sum of these two components gives the overall or complex strain on the sample:

$$\varepsilon^* = \varepsilon'' + i\varepsilon'' \tag{12}$$

Free Resonance Analyzers. If a suspended sample is allowed to swing freely, it will oscillate like a harp string as the oscillations gradually come to a stop. The naturally occurring damping of the material controls the decay of the oscillations. This produces a wave, shown in Figure 2, which is a series of sine waves decreasing in amplitude and frequency. Several methods exist to analyze these waves and are covered in the review by Gillham (2,3). These methods have also been successfully applied to the recovery portion of a creep-recovery curve where the sample goes into free resonance on removal of the creep force (4). From the decay curve, the period T and the logarithmic decrement Λ can be calculated. Both manual and digital processing methods have been reported (2,3,5). Fuller details of the following may be found in References 2,3, and 5. The decay of the amplitude is evaluated over as many swings as possible to reduce error References:

$$\Lambda = 1/j \ln(A_n/A_{n+j}) \tag{13}$$

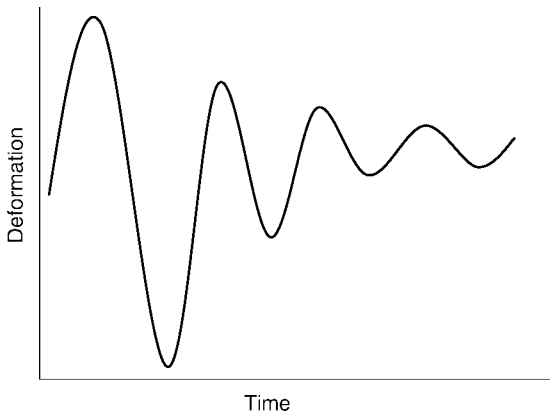

Fig. 2. The decay wave from a free resonance analyzer shows the decreasing amplitude of signal with time. Reprinted with permission from Ref. 1. Copyright (1999) CRC Press.

where j is the number of swings and A_n is the amplitude of the nth swing. For one swing, where $j = 1$, the equation becomes

$$\Lambda = \ln(A_n/A_{n+j}) \tag{14}$$

For a low value of Λ where A_n/A_{n+1} is approximately 1, the equation can be rewritten as

$$\Lambda \approx \tfrac{1}{2}\{(A_n^2 - A_{n+1}^2)/A_n^2\} \tag{15}$$

From this, since the square of the amplitude is proportional to the stored energy $\Delta W/W_{st}$ and the stored energy can be expressed as $2\pi \tan \delta$, the equation becomes

$$\Lambda \approx \tfrac{1}{2}(\Delta W/W_{st}) = \pi \tan \delta \tag{16}$$

which gives us the phase angle δ. The time of the oscillations, the period T, can be found using the following equation:

$$T = 2\pi\sqrt{\frac{M}{\Gamma_1}}\sqrt{\frac{1+\Lambda^2}{4\pi^2}} \tag{17}$$

where Γ_1 is the torque for one cycle and M is the moment of inertia around the central axis. Alternatively, T can be calculated directly from the plotted decay curve as

$$T = (2/n)(t_n - t_0) \tag{18}$$

where n is the number of cycles and t is time. From this, the shear modulus G can be calculated, which for a rod of length L and radius r is

$$G = \left(\frac{4\pi^2 ML}{NT^2}\right)\left(1 + \frac{\Lambda^2}{4\pi^2}\right) - \left(\frac{mgr}{12N}\right) \tag{19}$$

where m is the mass of the sample, g the gravitational constant, and N is a geometric factor. In the same system, the storage modulus G' can be calculated as

$$G' = (I/T^2)(8\pi ML/r^4) \tag{20}$$

where I is the moment of inertia for the system. Having the storage modulus and the tangent of the phase angle, the remaining dynamic properties can be calculated.

Free resonance analyzers normally are limited to rod or rectangular samples or materials that can be impregnated onto a braid. This last approach is how the curing studies on epoxy and other resin systems were done in torsion and gives these instruments the name of torsional braid analyzers (TBA).

Instrumentation. One of the biggest choices made in selecting a DMA is to decide whether to choose stress (force) or strain (displacement) control for applying the deforming load to the sample. Strain-controlled analyzers, whether for simple static testing or for DMA, move the probe a set distance and use a force balance transducer or load cell to measure the stress. These parts are typically located on different shafts. The simplest version of this is a screw-driven tester, where the sample is pulled one turn. This requires very large motors so that the available force always exceeds what is needed. They normally have better short-time response for low viscosity materials and can normally perform stress relaxation experiments easily. They also usually can measure normal forces if they are arranged in torsion. A major disadvantage is their transducers may drift at long times or with low signals.

Stress-controlled analyzers are cheaper to make because there is only one shaft, but somewhat trickier to use. Many of the difficulties have been alleviated by software and many strain-controlled analyzers on the market are really stress-controlled instruments with feedback loops making them act as if they were strain-controlled. In stress control, a set force is applied to the sample. As temperature, time, or frequency varies, the applied force remains the same. This may or may not be the same stress: in extension for example, the stretching and necking of a sample will change the applied stress seen during the run. However, this constant stress is a more natural situation in many cases and it may be more sensitive to material changes. Good low force control means they are less likely to destroy any structure in the sample. Long relaxation times or long creep studies are more easily performed on these instruments. Their biggest disadvantage is that their short-time responses are limited by inertia with low viscosity samples.

Since most DMA experiments are run at very low strains ($\sim$0.5% maximum) to stay well within a polymer's linear region, it has been reported that both the analyzers give the same results. However, when one gets to the nonlinear region, the difference becomes significant, as stress and strain are no longer linearly related. Stress control can be said to duplicate real-life conditions more accurately since most applications of polymers involve resisting a load.

DMA analyzers are normally built to apply the stress or strain in two ways (Fig. 3). One can apply force in a twisting motion so that one can test the sample in torsion. This type of instrument is the dynamic analog of the constant shear spinning disk rheometers. While mainly used for liquids and melts, solid samples may also be tested by twisting a bar of the material. Torsional analyzers normally also permit continuous shear and normal force measurements. Most of these analyzers can also do creep-recovery, stress-relaxation, and stress–strain experiments. Axial analyzers are normally designed for solid and semisolid materials and apply a linear force to the sample. These analyzers are usually associated with flexure, tensile, and compression testing, but they can be adapted to do shear and liquid specimens by proper choice of fixtures. Sometimes the instrument's design makes this inadvisable however. (For example, working with a very fluid material in a system where the motor is underneath the sample has the potential for damage to the instrument if the sample spills into the motor.) These analyzers can normally test higher modulus materials than torsional analyzers and can run TMA studies in addition to creep-recovery, stress-relaxation, and stress–strain experiments.

(d)

Fig. 3. (Continued)

There is considerable overlap between the type of samples run by axial and torsional instruments. With the proper choice of sample geometry and good fixtures, both types can handle similar samples, as shown by the extensive use of both types to study the curing of neat resins. Normally, axial analyzers cannot handle fluid samples below about 500 Pa · s.

Applications for Thermoplastic Solids and Cured Thermosets

As mentioned above, the thermal transitions in polymers can be described in terms of either free volume changes (6) or relaxation times. A simple approach to looking at free volume, which is popular in explaining DMA responses, is the crankshaft mechanism, where the molecule is imagined as a series of jointed segments. From this model, it is possible to simply describe the various transitions seen in a polymer. Other models exist that allow for more precision in describing behavior; the best seems to be the Doi–Edwards model (7). Aklonis and Knight (8) give a good summary of the available models, as does Rohn (9).

The crankshaft model treats the molecule as a collection of mobile segments that have some degree of free movement. This is a very simplistic approach, yet very useful for explaining behavior (Fig. 4). As the free volume of the chain segment increases, its ability to move in various directions also increases. This increased mobility in either side chains or small groups of adjacent backbone atoms results in a greater compliance (lower modulus) of the molecule. These movements have been studied and Heijboer (10) classified β- and γ-transitions by their type of motions. The specific temperature and frequency of this softening help drive the end use of the material.

Moving from very low temperature, where the molecule is tightly compressed, to higher temperatures, the first changes are the solid-state transitions. This process is shown in Figure 5. As the material warms and expands, the free volume increases so that localized bond movements (bending and stretching) and

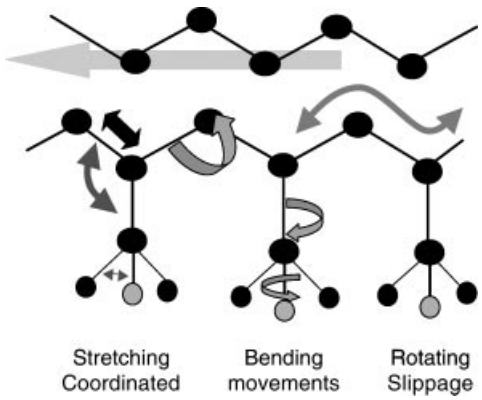

Fig. 4. The crankshaft mechanism is a simple way of considering the motions of a polymer chain permitted by increases in free volume. The molecule is visualized as a series of balls and rods and these move as the free volume increases.

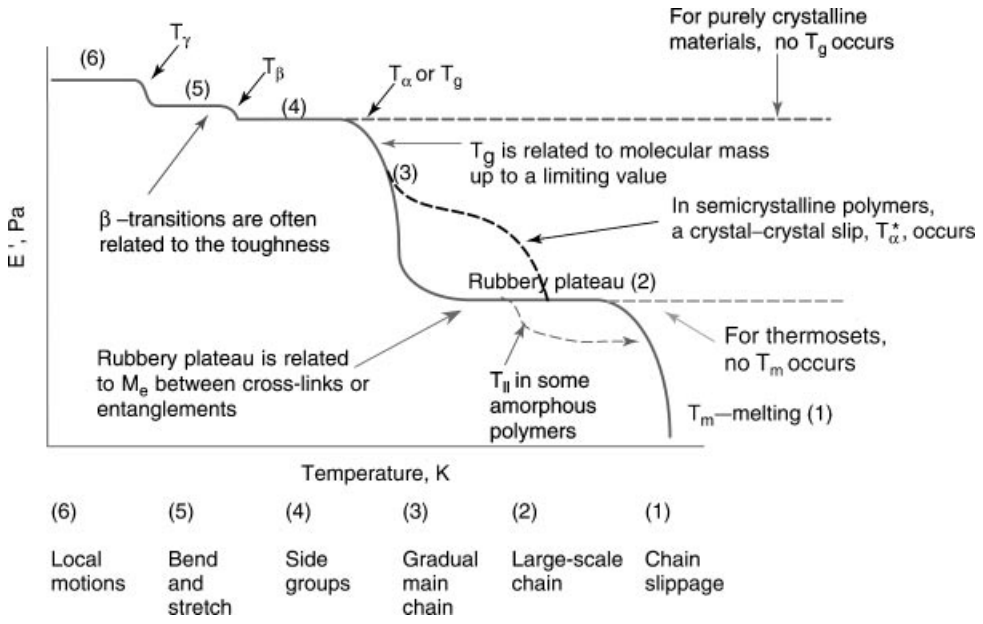

Fig. 5. Idealized temperature scan of a polymer: Starting at low temperature the modulus decreases as the molecules gain more free volume resulting in more molecular motion. This shows the main curve divided into six regions which correspond to local motions (6), bond bending and stretching (5), movements in the side chain or adjacent atoms in the main chain (4), the region of the T_g (3), coordinated movements in the amorphous portion of the chain (2), and the melting region (1). Transitions are marked as described in the text. Reprinted with permission from Ref. 1. Copyright (1999) CRC Press.

side-chain movements can occur. This is the gamma transition, T_γ, which may also involve associations with water. As the temperature and the free volume continue to increase, the whole side chains and localized groups of four to eight backbone atoms begin to have enough space to move and the material starts to develop some toughness (11). This transition, called the beta transition (T_β), is not as clearly defined as described here. Often it is the T_g of a secondary component in a blend or of a specific block in a block copolymer. However, a correlation with toughness is seen empirically (12).

As heating continues, the T_g or glass transition appears when the chains in the amorphous regions begin to coordinate large scale motions. One classical description of this region is that the amorphous regions have begun to melt. Since the T_g only occurs in amorphous material, in a 100% crystalline material there would not be a T_g. Continued heating drives the material through the $T_\alpha{}^*$ and T_{ll}. The former occurs in crystalline or semi-crystalline polymer and is a slippage of the crystallites past each other. The latter is a movement of coordinated segments in the amorphous phase that relates to reduced viscosity. These two transitions are not universally accepted. Finally the melt is reached where large-scale chain slippage occurs and the material flows. This is the melting temperature T_m. For a cured thermoset, nothing happens after the T_g until the sample begins to burn and degrade because the cross-links prevent the chains from slipping past each other.

This quick overview provides an idea of how an idealized polymer responds. Now a more detailed description of these transitions can be provided with some examples of their applications. The best general collection of this information is still McCrum's 1967 text.

Sub T_g Transitions. The area of sub-T_g or higher order transitions has been heavily studied (10,13–19) as these transitions have been associated with mechanical properties. These transitions can sometimes be seen by DSC and TMA, but they are normally too weak or too broad for determination by these methods. DMA, DEA (dielectric analysis), and similar techniques are usually required (20). Some authors have also called these types of transitions (9,10) second order transitions to differentiate them from the primary transitions of T_m and T_g, which involve large sections of the main chains. Boyer reviewed the T_β in 1968 (11) and pointed out that while a correlation often exists, the T_β is not always an indicator of toughness. Bershtein (21) has reported that this transition can be considered the "activation barrier" for solid-phase reactions, deformation, flow or creep, acoustic damping, physical aging changes, and gas diffusion into polymers as the activation energies for the transition and these processes are usually similar. The strength of these transitions is related to how strongly a polymer responses to those processes. These sub-T_g transitions are associated with the materials properties in the glassy state. In paints, for example, peel strength (adhesion) can be estimated from the strength and frequency dependence of the sub-ambient beta transition (22). For example, nylon-6,6 shows a decreasing toughness, measured as impact resistance, with declining area under the T_β peak in the tan δ curve. It has been shown, particularly in cured thermosets, that increased freedom of movement in side chains increases the strength of the transition. Cheng (15) reports in rigid rod polyimides that the beta transition is caused by the non-coordinated movement of the diamine groups although the link to physical properties was not investigated. Johari has reported in both mechanical (14) and dielectric studies (13) that both the β- and γ-transitions in bisphenol A based thermosets depend on the side chains and unreacted ends, and that both are affected by physical aging and postcure. Nelson (23) has reported that these transitions can be related to vibration damping. This is also true for acoustical damping (24). In both of this cases, the strength of the beta transition is taken as a measurement of how effectively a polymer will absorb vibrations. There is a frequency dependence in this transitions and this is discussed below.

Heijober (10) and Boyer (11) showed that this information needs to be considered with care as not all beta transitions correlate with toughness or other properties. This can be due to misidentification of the transition or that the transition does sufficiently disperse energy. A working rule of thumb (10,16,25,26) is that the beta transition must be related to either localized movement in the main chain or very large side chain movement to sufficiently absorb enough energy. The relationship of large side chain movement and toughness has been extensively studied in polycarbonate by Yee (27) as well as in many other tough glassy polymers (28).

Less use is made of the T_γ transitions and they are mainly studied to understand the movements occurring in polymers. Wendorff (29) reports that this transition in polyarylates is limited to inter- and intramolecular motions within the scale of a single repeat unit. Both McCrum (5) and Boyd (18) similarly limited

the T_γ and T_δ to very small motions either within the molecule or with bound water. The use of what is called two-dimensional IR, which couples at FTIR and a DMA to study these motions, is a topic of current interest (30,31).

The Glass Transition (T_g or T_α). As the free volume continues to increase with increasing temperature, the glass transition T_g occurs where large segments of the chain start moving. This transition is also called the α- transition, T_α. The T_g is very dependent on the degree of polymerization up to a value known as the critical T_g or the critical molecular weight. Above this value, the T_g typically becomes independent of molecular weight (32). The T_g represents a major transition for many polymers, as physical properties change drastically as the material goes from a hard glassy to a rubbery state. It defines one end of the temperature range over which the polymer can be used, often called the operating range of the polymer. For where strength and stiffness are needed, it is normally the upper limit for use. In rubbers and some semicrystalline materials like polyethylene and polypropylene, it is the lower operating temperature. Changes in the temperature of the T_g are commonly used to monitor changes in the polymer such as plasticizing by environmental solvents and increased crosslinking from thermal or UV aging (see GLASS TRANSITION).

The T_g of cured materials or thin coatings is often difficult to measure by other methods, and more often than not the initial cost justification for a DMA is measuring a hard-to-find T_g. While estimates of the relative sensitivity of DMA to DSC or DTA (differential thermal analysis) vary, it appears that DMA is 10–100 times more sensitive to the changes occurring at the T_g. The T_g in highly crosslinked materials can easily be seen long after the T_g has become too flat and broad to be seen in DSC. This is also a problem with certain materials like medical grade urethanes and very highly crystalline polyethylenes.

The method of determining the T_g in DMA can be a manner for disagreement as at least five ways are in current use (Fig. 6). Depending on the industry

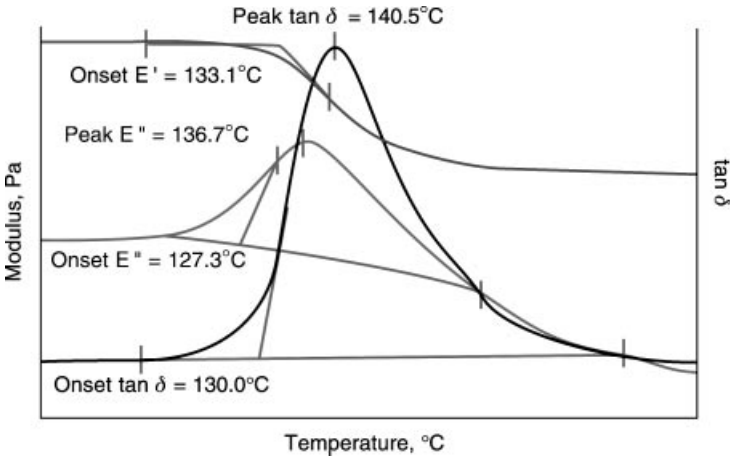

Fig. 6. Methods of determining the T_g are shown for DMA. The temperature of the T_g varies by as much as 10°C in this example depending on the value chosen. Differences as great as 25°C have been reported. Reprinted with permission from Ref. 1. Copyright (1999) CRC Press.

standards or background of the operator, the peak or onset of the tan δ curve, the onset of the E′ drop, or the onset or peak of the E″ curve may be used. The values obtained from these methods can differ up to 25°C from each other on the same run. In addition, a 10–20°C difference from the DSC is also seen in many materials. In practice, it is important to specify exactly how the T_g should be determined. For DMA, this means defining the heating rate, applied stresses (or strains), the frequency used, and the method of determining the T_g. For example, the sample will be run at 10°C° min^{-1} under 0.05% strain at 1 Hz in nitrogen purge (20 $\text{cc} \cdot \text{min}^{-1}$) and the T_g determined from the peak of the tan δ curve.

It is not unusual to see a peak or hump on the storage modulus directly preceding the drop that corresponds to the T_g. This is also seen in DSC and DTA and corresponds to a rearrangement in the material to relieve stresses frozen in below the T_g by the processing method. These stresses are trapped in the material until enough mobility is obtained at the T_g to allow the chains to move to a lower energy state. Often a material will be annealed by heating it above the T_g and then slowly cooling it to remove this effect. For similar reasons, some experimenters will run a material twice or use a heat–cool–heat cycle to eliminate processing effects.

The Rubbery Plateau, $T_\alpha{}^*$ and T_{ll}. The area above the T_g and below the melt is known as the rubbery plateau and its length as well as viscosity are dependent on the molecular weight between entanglements (M_e) (33) or cross-links. The molecular weight between entanglements is normally calculated during a stress-relaxation experiment but similar behavior is observed in DMA. The modulus in the plateau region is proportional to either the number of cross-links or the chain length between entanglements. This is often expressed in shear as

$$G' \cong (\rho RT)/\mathrm{M_e} \tag{21}$$

where G' is the shear storage modulus of the plateau region at a specific temperature, ρ is the polymer density, and M_e is the molecular weight between entanglements. In practice, the relative modulus of the plateau region shows the relative changes in M_e or the number of cross-links compared to a standard material.

The rubbery plateau is also related to the degree of crystallinity in a material, although DSC is a better method for characterizing crystallinity than DMA (34, 35). Also as in the DSC, there is evidence of cold crystallization in the temperature range above the T_g (Fig. 7). That is one of several transitions that can be seen in the rubbery plateau region. This crystallization occurs when the polymer chains have been quenched (quickly cooled) into a highly disordered state. On heating above the T_g, these chains gain enough mobility to rearrange into crystallites, which causes a sometimes-dramatic increase in modulus. DSC or its temperature-modulated variant, StepScan™ Differential Scanning Calorimetry, can be used to confirm this (36). The alpha star transition $T_\alpha{}^*$, the liquid–liquid transition T_{ll}, the heat-set temperature, and the cold crystallization peak are all transitions that can appear on the rubbery plateau. In some crystalline and semicrystalline polymer, a transition is seen here called the $T_\alpha{}^*$ (18,37). The alpha star transition is associated with the slippage between crystallites and helps extend the operating range of a material above the T_g. This transition is very susceptible to processing induced changes and can be enlarged or decreased by the applied heat history,

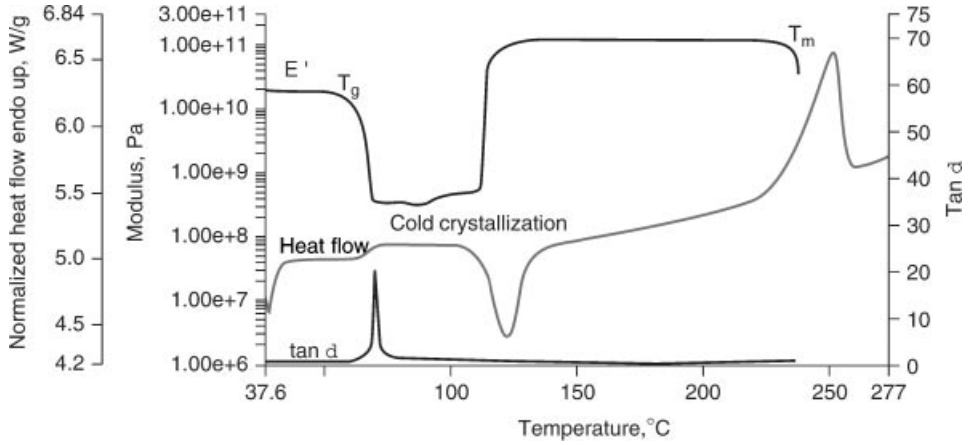

Fig. 7. Cold crystallization in PET caused a large increase in the storage modulus E' above the T_g. A DSC scan of the same material is included. Reprinted with permission from Ref. 1. Copyright (1999) CRC Press.

processing conditions, and physical aging (38,39). Hence, the $T_\alpha{}^*$ has been used by fiber manufacturers to optimize properties in their materials.

In amorphous polymers, the T_{ll} transition is seen instead, which is a liquid–liquid transition associated with increased chain mobility and segment–segment associations (40). This order is lost when the T_{ll} is exceeded and regained on cooling from the melt. Boyer (41,42) reports that, like the T_g, the appearance of the T_{ll} is affected by the heat history. The T_{ll} is also dependent on the number-average molecular weight M_n, but not on the weight-average molecular weight, M_w. Bershtein (19) suggests that this may be considered as quasi-melting on heating or the formation of stable associates of segments on cooling. While this transition is reversible, it is not always easy to see, and Boyer (43) spent many years trying to prove it was real. It is still not totally accepted. Following this transition, a material enters the terminal or melting region.

Depending on its strength, the heat-set temperature can also be seen in DMA. While it is normally seen in a TMA experiment, it will sometimes appear as either a sharp drop in storage modulus (E') or an abrupt change in probe position. Heat set is the temperature at which some strain or distortion is induced into polymeric fibers to change its properties, such as to prevent a nylon rug from feeling like fishing line. Since heating above this temperature will erase the texture, and polyesters must be heated above the T_g to dye them, it is of critical importance to the fabric industry. Many final properties of polymeric products depend on changes induced in processing (44,45).

The Terminal Region. On continued heating, the melting point T_m is reached. The melting point is where the free volume has increased so the chains can slide past each other and the material flows. This is also called the terminal region. In the molten state, this ability to flow is dependent on the molecular weight of the polymer (Fig. 5). The melt of a polymer material will often show changes in temperature of melting, width of the melting peak, and enthalpy as the material changes (46,47) resulting from changes in the polymer molecular weight and crystallinity.

Degradation, polymer structure, and environmental effects all influence what changes occur. Polymers that degrade by cross-linking will look very different from those that exhibit chain scission. Very highly cross-linked polymers will not melt as they are unable to flow.

The study of polymer melts and especially their elasticity was one of the areas that drove the development of commercial DMAs. Although a decrease in the melt viscosity is seen with temperature increases, the DMA is most commonly used to measure the frequency dependence of the molten polymer as well as its elasticity. The latter property, especially when expressed as the normal forces, is very important in polymer processing.

Frequency Dependencies in Transition Studies. The choice of a testing frequency or its effect on the resulting data must be addressed. A short discussion of how frequencies are chosen and how they affect the measurement of transitions is in order. Considering that higher frequencies induce more elastic-like behavior, there is some concern that a material will act stiffer than it really is if the test frequency is chosen to be too high. Frequencies for testing are normally chosen by one of three methods. The most scientific method would be to use the frequency of the stress or strain that the material is exposed to in the real world. However, this is often outside of the range of the available instrumentation. In some cases, the test method or the industry standard sets a certain frequency and this frequency is used. Ideally a standard method like this is chosen so that the data collected on various commercial instruments can be shown to be compatible. Some of the ASTM methods for TMA (thermomechanical analysis) and DMA are listed in Table 1. Many industries have their own standards so it is important to

[a]This standard qualifies a DMA as a acceptable for all ASTM DMA standards.

know whether the data is expected to match a Mil-spec, an ASTM standard, or a specific industrial test. Finally, one can arbitrarily pick a frequency. This is done more often than not, so that 1 Hz and 10 $rad \cdot s^{-1}$ are often used. As long as the data are run under the proper conditions, they can be compared to highlight material differences. This requires that frequency, stresses, and the thermal program be the same for all samples in the data set.

Lowering the frequency shifts the temperature of a transition to a lower temperature (Fig. 8). At one time, it was suggested that multiple frequencies could be used and the T_g should then be determined by extrapolation to 0 Hz. This was never really accepted as it represented a fairly large increase in testing time for a small improvement in accuracy. For most polymer systems, for very precise measurements, one uses a DSC. Different types of transitions also have different frequency dependencies and McCrum and co-workers listed many of these. If one looks at the slope of the temperature dependence of transitions against frequency, one sees that in many cases the primary transitions like T_m and T_g have a different dependence on frequency than the lower temperature transitions. In fact, the activation energies are different for α-, β-, and γ- transitions because of the different motions required, and the transitions can be sorted by this approach.

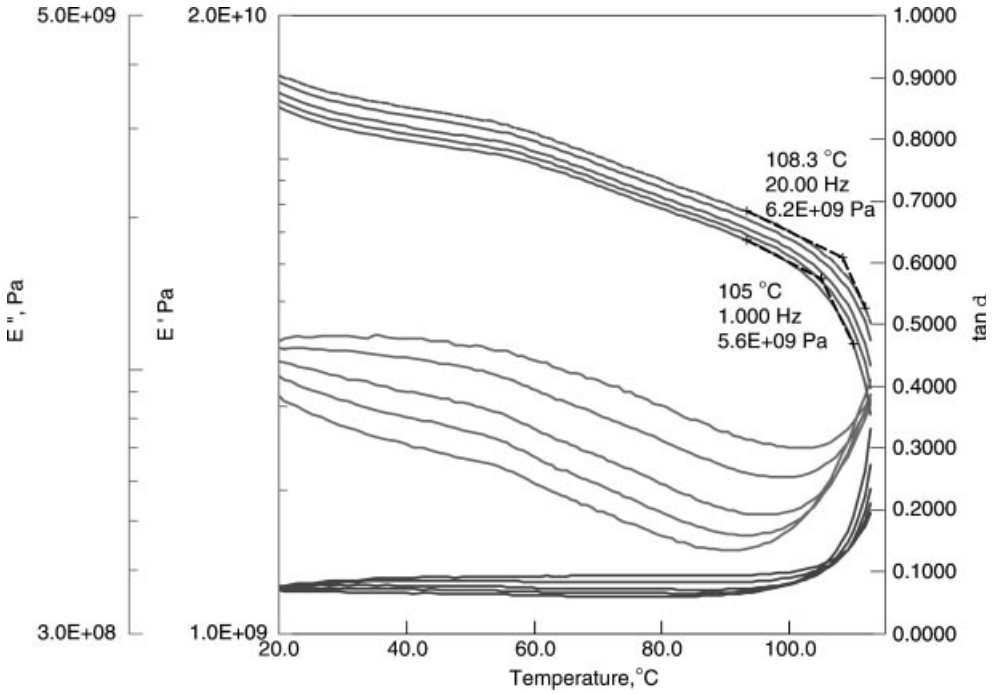

Fig. 8. Effect of frequency on transitions: the dependence of the T_g in polycarbonate on frequency. Data generated on a Perkin-Elmer Diamond DMA by the author.

Polymer Melts and Solutions, Applications

A fluid or polymer melt responds to strain rate rather than to the amount of stress applied. The viscosity is one of the main reasons why people run frequency scans. As the stress–strain curves and the creep recovery runs show, viscoelastic materials exhibit some degree of flow or unrecoverable deformation. The effect is the strongest in melts and liquids where frequency versus viscosity plots are the major application of DMA. Figure 9 shows a frequency scan on a viscoelastic material. In this example, the sample is a rubber above the T_g in three-point bending, but the trends and principles apply to both solids and melts. The storage modulus and complex viscosity are plotted on log scales against the log of frequency. In analyzing the frequency scans, trends in the data are more significant than specific peaks or transitions.

On the viscosity curve η^*, a fairly flat region appears at low frequency, called the zero shear plateau (9). This is where the polymer exhibits Newtonian behavior and its viscosity is dependent on molecular weight, not the strain rate. The viscosity of this plateau has been shown to experimentally relate to the molecular weight for Newtonian fluid

$$\eta \propto cM_v^1 \tag{22}$$

for cases where the molecular weight M_v is less than the entanglement molecular weight M_e, and for cases where M_v, is greater than M_e:

$$\eta_0 \propto cM_v^{3.4} \tag{23}$$

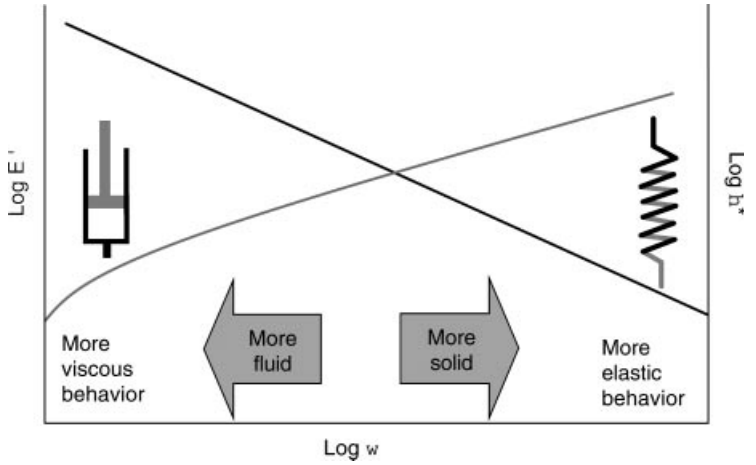

Fig. 9. An example of a frequency scan showing the change in a material's behavior as frequency varies. Low frequencies allow the material time to relax and respond, hence, flow dominates. High frequencies do not, and elastic behavior dominates. Reprinted with permission from Ref. 1. Copyright (1999) CRC Press.

where η_0 is the viscosity of the initial Newtonian plateau, c is a material constant, and M_v the viscosity average molecular weight. This relationship can be written in general terms, replacing the exponential term with the Mark-Houwink constant a. Equation 23 can be used as a method of approximating the molecular weight of a polymer. The value obtained is closest to the viscosity-average molecular weight obtained by osmometry (48). In comparison with the weight-average data obtained by gel permeation chromatography, the viscosity-average molecular weight would be between the number-average and weight-average molecular weights, but closer to the latter (49). This was originally developed for steady shear viscosity but applies to complex viscosity as well. The relationship between steady shear and complex viscosity is fairly well established. Cox and Merz (50) found that an empirical relationship exists between complex viscosity and steady shear viscosity when the shear rates are the same. The Cox–Merz rule is stated below:

$$|\eta(\omega)| = \eta(\dot{\gamma})|_{\dot{\gamma}=\omega} \tag{24}$$

where η is the constant shear viscosity, η^* is the complex viscosity, ω the frequency of the dynamic test, and $d\gamma/dt$ the shear rate of the constant shear test. This rule of thumb seems to hold for most materials to within about $\pm 10\%$. Another approach is the Gleissile (51) Mirror Relationship that states the following:

$$\eta\dot{\gamma} = \eta^+(t)|_{t=1/\dot{\gamma}} \tag{25}$$

when $\eta^+(t)$ is the limiting value of the viscosity as the shear rate $\dot{\gamma}$ approaches zero.

The low frequency range is where viscous or liquid-like behavior predominates. If a material is stressed over long enough times, some flow occurs. As time is the inverse of frequency, this means materials are expected to flow more at low frequency. As the frequency increases, the material will act in a more and more elastic fashion. Silly Putty (Billy and Smith, Inc.), the children's toy, shows this clearly. At low frequency, Silly Putty flows like a liquid, while at high frequency it bounces like a rubber ball. This behavior is also similar to what happens with temperature changes. A polymer becomes softer and more fluid as it is heated and it goes through transitions that increase the available space for molecular motions. Over long enough time periods, or small enough frequencies, similar changes occur. So one can move a polymer across a transition by changing the frequency. This relationship is also expressed as the idea of time–temperature equivalence (52). Often stated, as low temperature is equivalent to short times or high frequency, it is a fundamental rule of thumb in understanding polymer behavior.

As the frequency is increased in a frequency scan, the Newtonian region is exceeded and a new relationship develops between the rate of strain, or the frequency, and the viscosity of the material. This region is often called the power law zone and can be modeled by

$$\eta^* \cong \eta(\dot{\gamma}) = c\dot{\gamma}^{n-1} \tag{26}$$

where η^* is the complex viscosity, $\dot{\gamma}$ is the shear rate, and the exponent term n is determined by the fit of the data. This can also be written as

$$\sigma \cong \eta(\dot{\gamma}) = c\dot{\gamma}^n \tag{27}$$

where σ is the stress and η is the viscosity. The exponential relationship is why the viscosity versus frequency plot is traditionally plotted on a log scale. With modern curve fitting programs, the use of log–log plots has declined and is a bit anachronistic. The power law region of polymers shows shear thickening or thinning behavior. This is also the region in which the E'–η^* or the E'–E'' crossover point is found. As frequency increases and shear thinning occurs, the viscosity (η^*) decreases. At the same time, increasing the frequency increases the elasticity (E'). This is shown in Figure 9. The E'–η^* crossover point is used an indicator of the molecular weight and molecular weight distribution (53). Changes in its position are used as a quick method of detecting changes in the molecular weight and distribution of a material. After the power law region, another plateau is seen, the infinite shear plateau.

This second Newtonian region corresponds to where the shear rate is so high that the polymer no longer shows a response to increases in the shear rate. At the very high shear rates associated with this region, the polymer chains are no longer entangled. This region is seldom seen in DMA experiments and usually avoided in use because of the damage done to the chains. It can be reached in commercial extruders and can cause degradation of the polymer, which causes the poorer properties associated with regrind.

As the curve in Figure 9 shows, the modulus also varies as a function of the frequency. A material exhibits more elastic-like behavior as the testing frequency increases, and the storage modulus tends to slope upwards toward higher frequency. The storage modulus' change with frequency depends on the transitions involved. Above the T_g, the storage modulus tends to be fairly flat, with a slight increase with increasing frequency as it is on the rubbery plateau. The change in the region of a transition is greater. If one can generate a modulus scan over a wide enough frequency range, the plot of storage modulus versus frequency appears like the reverse of a temperature scan. The same time–temperature equivalence discussed above also applies to modulus, as well as compliance, tan δ, and other properties.

The frequency scan is used for several purposes that will be discussed in this section. One very important use, that is very straightforward, is to survey the material's response over various shear rates. This is important because many materials are used under different conditions. For example adhesives, whether tape, Band-Aids, or hot melts, are normally applied under conditions of low frequency and this property is referred to as tack. When they are removed, the removal often occurs under conditions of high frequency called peel. Different properties are required at these regimes and to optimize one property may require chemical changes that harm the other. Similarly, changes in polymer structure can show these kinds of differences in the frequency scan. For example, branching affects different frequencies (9).

In a tape adhesive, for example, sufficient flow under pressure at low frequency is desired to fill the pores of the material to obtain a good mechanical

bond. When the laminate is later subjected to peel, the material needs to be very elastic so that it will not pull out of the pores (54,55). The frequency scan allows measurement of these properties in one scan thus ensuring that tuning one property does not degrade another. This type of testing is not limited to adhesives as many materials see multiple frequencies in the actual use. Viscosity versus frequency plots are used extensively to study how changes in polymer structure or formulations affect the behavior of the melt. Often changes in materials, especially in uncured thermosetting resins and molten materials, effect a limited frequency range and testing at a specific frequency can miss the problem.

It should be noted that since the material is scanned across a frequency range, there are some conditions where the material–instrument system acts like a guitar string and begins to resonate when certain frequencies are reached. These frequencies are either the natural resonance frequency of the sample–instrument system or one of its harmonics. When the harmonics occur, the sample–instrument system oscillates like a guitar string and the desired information about the sample is obscured. Since there is no way to change this resonance behavior (and in a free resonance analyzer, this effect is necessary to obtain data), it is required to redesign the experiment by changing sample dimensions or geometry to escape the problem. Using a sample with much different dimensions, which change the mass, or changing from extension to three-point bending geometry changes the natural oscillation frequency of the sample and hopefully solves this problem.

Thermosets, Applications

The DMA's ability to give viscosity and modulus values for each point in a temperature scan allows the estimation of kinetic behavior as a function of viscosity. This has the advantage of describing how viscous the material is at any given time, so as to determine the best time to apply pressure, what design of tooling to use, and when the material can be removed from the mold. Recent reviews have summarized this approach for epoxy systems (56).

Curing. The simplest way to analyze a resin system is to run a plain temperature ramp from ambient to some elevated temperature (57,58). This "cure profile" allows collection of several vital pieces of information as shown in Figure 10. Samples may be run "neat" or impregnated into fabrics in techniques that are referred to as torsional braid. There are some problems with this technique, as temperature increases will cause an apparent curing of nondrying oils as thermal expansion increases friction. However, the "soaking of resin into a shoelace," as this technique has been called, allows one to handle difficult specimens under conditions where the pure resin is impossible to run in bulk (due to viscosity or evolved volatiles). Composite materials like graphite–epoxy composites are sometimes studied in industrial situations as the composite rather than the "neat" or pure resin because of the concern that the kinetics may be significantly different. In terms of ease of handling and sample, the composite is a better sample. Another area of concern is paints and coatings (59) where the material is used in a thin layer. This can be addressed experimentally by either a braid as above or coating the material on a thin sheet of metal. The metal is often run first and its scan

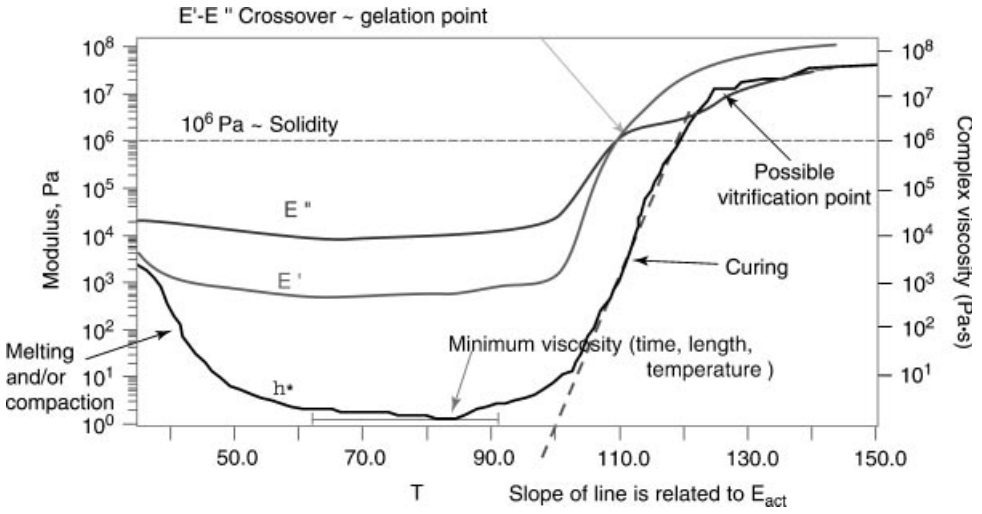

Fig. 10. The DMA cure profile of a two-part epoxy showing the typical analysis for minimum viscosity, gel time, vitrification time, and estimation of the action energy (see discussion in text). Reprinted with permission from Ref. 1. Copyright (1999) CRC Press.

subtracted from the coated sheet's scan to leave only the scan of the coating. This is also done with thin films and adhesive coatings.

From the cure profile seen in Figure 10, it is possible to determine the minimum viscosity ($\eta^*_{\min}$), the time to $\eta^*_{\min}$ and the length of time it stays there, the onset of cure, the point of gelation where the material changes from a viscous liquid to a viscoelastic solid, and the beginning of vitrification. The minimum viscosity is seen in the complex viscosity curve and is where the resin viscosity is the lowest. A given resin's minimum viscosity is determined by the resin's chemistry, the previous heat history of the resin, the rate at which the temperature is increased, and the amount for stress or strain applied. Increasing the rate of the temperature ramp is known to decrease the $\eta^*_{\min}$, the time to $\eta^*_{\min}$, and the gel time. The resin gets softer faster, but also cures faster. The degree of flow limits the type of mold design and when as well as how much pressure can be applied to the sample. The time spent at the minimum viscosity plateau is the result of a competitive relationship between the material's softening or melting as it heats and its rate of curing. At some point, the material begins curing faster than it softens, and that is where the viscosity starts to increase.

As the viscosity begins to climb, an inversion is seen of the E'' and E' values as the material becomes more solid-like. This crossover point also corresponds to where the tan δ equals 1 (since $E' = E''$ at the crossover). This is taken to be the gel point, (60) where the cross-links have progressed to forming an "infinitely" long network across the specimen. At this point, the sample will no longer dissolve in solvent. While the gel point correlates fairly often with this crossover, it doesn't always. For example, for low initiator levels in chain addition thermosets, the gel point precedes the modulus crossover (61). A temperature dependence for the presence of the crossover has also been reported (57,58). In some cases, where powder compacts and melts before curing, there may be several crossovers (62).

Then, the one following the $\eta^*_{\min}$ is usually the one of interest. Some researchers (63,64) believe that the true gel point is best detected by measuring the frequency dependence of the crossover point. This is done either by multiple runs at different frequencies or by multiplexing frequencies during the cure. At the gel point, the frequency dependence disappears (64). This value is usually only a few degrees different from the one obtained in a normal scan and in most cases not worth the additional time. During this rapid climb of viscosity in the cure, the slope for η^* increase can be used to calculate an estimated E_a (activation energy) (65). This will be discussed below, but the fact that the slope of the curve here is a function of E_a is important. Above the gel temperature, some workers estimate the molecular weight, M_c, between cross-links as

$$G' = RT\rho/\mathrm{M_c} \tag{28}$$

where R is the gas constant, T is the temperature in Kelvin, and ρ is the density. At some point the curve begins to level off and this is often taken as the vitrification point, T_{vf}.

The vitrification point is where the cure rate slows because the material has become so viscous that the bulk reaction has stopped. At this point, the rate of cure slows significantly. The apparent T_{vf} however is not always real: any analyzer in the world has an upper force limit. When that force limit is reached, the "topping out" of the analyzer can pass as the T_{vf}. Use of a combined technique like DMA–DEA DEA is dielectric analysis, where an oscillating electrical signal is applied to a sample. From this signal, the ion mobility can be calculated, which is then converted to a viscosity (see Ref. 5 for details). DEA will measure to significantly higher viscosities than DMA to see the higher viscosities or the removal of a sample from parallel plate and sectioning it into a flexure beam is often necessary to see the true vitrification point. Vitrification may also be seen in the DSC if a modulated temperature technique like StepScan is used (66). A reaction can also completely cure without vitrifying and will level off the same way. One should be aware that reaching vitrification or complete cure too quickly could be as bad as too slowly. Often an overly aggressive cure cycle will cause a weaker material as it does not allow for as much network development, but gives a series of hard (highly cross-linked) areas among softer (lightly cross-linked) areas. On the way to vitrification, an important value is 10^6 Pa · s. This is the viscosity of bitumen (67) and is often used as a rule of thumb for where a material is stiff enough to support its own weight. This is a rather arbitrary point, but is chosen to allow the removal of materials from a mold and the cure is then continued as a post-cure step. The cure profile is both a good predictor of performance as well as a sensitive probe of processing conditions. As discussed above under TMA applications, a volume change occurs during the cure (68). This shrinkage of the resin is important and can be studied by monitoring the probe position of some DMA's as well as by TMA and dilatometry.

The above is based on using a simple temperature ramp to see how a material responds to heating. In actual use, many thermosets are actually cured using more complex cure cycles to optimize the tradeoff between the processing

time and the final product's properties (69). The use of two-stage cure cycles is known to develop stronger laminates in the aerospace industry. Exceptionally thick laminates often also require multiple stage cycles in order to develop strength without porosity. As thermosets shrink on curing, careful development of a proper cure cycle to prevent or minimize internal voids is necessary. One reason for the use of multistage cures is to drive reactions to completion. Another is to extend the minimum viscosity range to allow greater control in forming or shaping of the material. The development of a cure cycle with multiple ramps and holds would be very expensive if done with full-sized parts in production facilities. The use of the DMA gives a faster and cheaper way of optimizing the cure cycle to generate the most efficient and tolerant processing conditions.

Because of the limits of industrial equipment and cost constraints, curing is done at a constant temperature for a period of time. This can be done both to initially cure the material or to "post-cure" it. (The kinetic models discussed in the next section also require data collected under isothermal conditions.) It is also how rubber samples are cross-linked, how initiated reactions are run, and how bulk polymerizations are performed. Industrially, continuous processes, as opposed to batch, often require an isothermal approach. UV light and other forms of nonthermal initiation also use isothermal studies for examining the cure at a constant temperature.

Photocuring. A photocure in the DMA is run by applying a UV light source to a sample (held a specific temperature or subjected to a specific thermal cycle) (70). Photocuring is done for dental resin, contact adhesives, and contact lenses. UV-exposure studies are also run on cured and thermoplastic samples by the same techniques as photocuring to study UV degradation. The cure profile of a photocure is very similar to that of a cake or epoxy cement. The same analysis is used and the same types of kinetics developed as is done for thermal curing studies.

The major practical difficulty in running photocures in the DMA is the current lack of a commercially available photocuring accessory, comparable to the photocalorimeters on the market. One normally has to adapt a commercial DMA to run these experiments. The Perkin-Elmer DMA-7e has been successfully adapted (71) to use quartz fixtures and commercial UV source from EFOS, triggered from the DMA's software. This is a fairly easy process and other instruments like the RheoSci^{TM} DMTA (dynamic mechanical thermal analyzer) Mark 5 have also been adapted.

Curing Kinetics by DMA. Several approaches have been developed to studying the chemorheology of thermosetting systems. MacKay and Halley (72) reviewed chemorheology and the more common kinetic models. A fundamental method is the Williams–Landel–Ferry (WLF) model, (73) which looks at the variation of T_g with degree of cure. This has been used and modified extensively (74). A common empirical model for curing has been proposed by Roller (75,76). In the latter approach, samples of the thermoset are run isothermally as described above and the viscosity versus time data collected. This is plotted as log (versus time in seconds, where a change in slope is apparent in the curve. This break in the data indicates the sample is approaching the gel time. From these curves, the initial viscosity, η_0 and the apparent kinetic factor k can be determined. By plotting the

log viscosity versus time for each isothermal run, the slope k, and the viscosity at $t = 0$ are apparent. The initial viscosity and k can be expressed ase

$$\eta_0 = \eta_\infty \, \mathrm{e}^{\Delta E_\eta / RT} \tag{29}$$

$$k = k_\infty \, \mathrm{e}^{\Delta E_k / RT} \tag{30}$$

Combining these allows setup of the equation for viscosity under isothermal conditions as

$$\ln \, \eta(\mathrm{t}) = \ln \, \eta_\infty + \Delta E_k / RT + t k_\infty \mathrm{e}^{\Delta E_k / RT} \tag{31}$$

By replacing the last term with an expression that treats temperature as a function of time, the equation becomes

$$\ln \, \eta(T, \, \mathrm{t}) = \ln \, \eta_\infty + \Delta E_\eta / RT + \int_0^t k_\infty \, \mathrm{e}^{\Delta E_k / RT} \, \mathrm{d}t \tag{32}$$

This equation can be used to describe viscosity–time profiles for any run where the temperature can be expressed as a function of time. The activation energies can now be calculated. The plots of the natural log of the initial viscosity (determined above) versus $1/T$ and the natural log of the apparent rate constant k versus $1/T$ are used to give us the activation energies ΔE_η and ΔE_k. Comparison of these values to the k and ΔE to those calculated by DSC shows that this model gives larger values (59). The DSC data is faster to obtain, but it does not include the needed viscosity information. Several corrections have been proposed, addressing different orders of reaction (77) (the above assumes first order) and modifications to the equations (78,79). Many of these adjustments are reported in Roller's 1986 review (76) of curing kinetics. It is noted that these equations do not work well above the gel temperature. This same equation has been used to predict the degradation of properties in thermoplastics successfully (80).

The Gillham–Enns Diagram. The most complete approach to studying the behavior of a thermoset was developed by Gillham (81,82) and is analogous to the phase diagrams used by metallurgists. The time–temperature–transformation diagram (TTT) or the Gillham–Enns diagram (after its creators) is used to track the effects of temperature and time on the physical state of a thermosetting material. Figure 11 shows an example. Running isothermal studies of a resin at various temperatures and recording the changes as a function of time can do this. One has to choose values for the various regions and Gillham has done an excellent job of detailing how one picks the T_g, the glass, the gel, the rubbery, and the charring regions (3,83). These diagrams are also generated from DSC data (84), and several variants, (85) like the continuous heating transformation and conversion–temperature–property diagrams, have been reported. While easy to develop and use, TTT diagrams have not yet been accepted in industry despite their obvious utility. This may be due to the fact that they take some time to generate. A recent review (3) will hopefully increase the use of this approach.

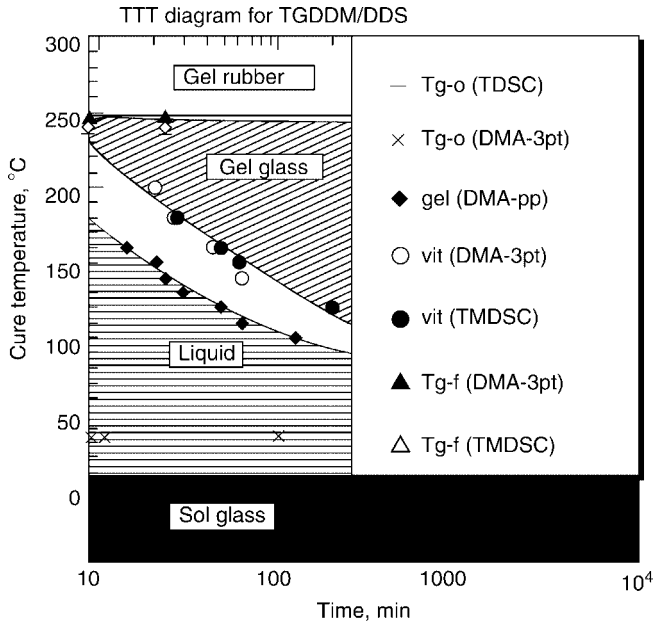

Fig. 11. An example of the Gillham–Enns diagram generated by the author on a commercial epoxy resin system. The lines of gelation and vitrification are marked.

Nomenclature

δ	phase angle
$\tan\delta$	tangent of the phase angle, also called the damping
σ	stress
γ	shear strain
ε	tensile strains
$\dot{\gamma}$	shear strain rate
$\dot{\varepsilon}$	strain rate
η	viscosity
η^*	complex viscosity
η'	storage viscosity
η''	loss viscosity
E^*	complex Modulus
E'	storage Modulus
E''	loss Modulus
J	compliance
k	deformation
T	period
ρ	density
G	shear modulus
M_e	entanglement molecular weight
M_c	molecular weight between cross-links
M_w	molecular weight
f	frequency
ω	frequency in Hertz
k	Rate constant
E_a	Activation Energy
v^f	free volume
$T_{\alpha\beta,\gamma}$	transition (subscript type)
Λ	logarithmic decrement
Γ	torque

ELECTROCHROMIC POLYMERS

Introduction to Electrochromism

Color changes in an object give visual signals that can be used to convey useful information to an observer (1). Furthermore, by selective absorption or transmission of light by a material, the light energy impinging upon an observer can be modulated (1). Where a chemical or physical external stimulus causes a reversible color change or variation in light transmission, the possible applications are considerable. For such systems, color change phenomena are classified after the stimulus that causes the change, such as electrochromism, photochromism, thermochromism and gasochromism (1). An *electrochromic material* is one where a reversible color change takes place upon reduction (gain of electrons) or oxidation (loss of electrons), on passage of electrical current after the application of an appropriate electrode potential (2–10).

Many chemical species can be switched between redox states that have distinct electronic absorption spectra. Such spectra arise from either a moderate-energy internal electronic excitation or an intervalence optical charge transfer where the chemical species has two centers of differing valence or oxidation state (2–10). While materials are considered to be electrochromic when marked visible color changes are shown under illumination, recent interest in electrochromic devices (ECDs) for multispectral energy modulation by reflectance and absorbance has extended the definition (11). Chemical species are now being studied for modulation of radiation in the near infrared (NIR) (10,12), thermal infrared and microwave regions, and "color" can mean response of detectors to these electromagnetic regions, not just the human eye (11).

Types of Electrochromic Materials. Electrochromic materials are of three basic types (2). In a given electrolyte solution, type I materials are soluble in both the reduced and oxidized (redox) states. Type II materials are soluble in one redox state, but form a solid film on the surface of an electrode following electron transfer. Electrochromic polymers are examples of type III materials, where both redox states are solids, generally studied as thin films on electrode surfaces. For types II and III, once the redox state has been switched, no further charge injection is needed to retain the new electrochromic state, and such systems are said to have "optical memory". In contrast, for type I electrochromic materials, diffusion of the soluble electrochemically-generated product material away from the electrode occurs and it is necessary to keep current flowing until the whole solution has been electrolyzed.

Where more than two redox states are electrochemically accessible in a given electrolyte solution, the electrochromic material may exhibit several colors and be termed polyelectrochromic, a frequent property of electrochromic polymers (2).

Applications of Electrochromic Materials. Commercial applications of electrochromic materials in devices include antiglare car rearview mirrors (4,8), electrochromic strips as battery state-of-charge indicators, and electrochromic sunglasses. Proposed applications include "smart windows" (based on modulation of either the transmitted or reflected solar radiation) for use in cars and in buildings (8), reusable price labels, protective eyewear, controllable aircraft canopies, glare-reduction systems for offices, devices for frozen-food monitoring (13), camouflage materials, spacecraft thermal control, and controllable light-reflective or light-transmissive devices for optical information and storage. In the case of long-term data displays, "paper-quality" railway termini information displays are now close to commercialization, using a new type of nanostructured electrochromic organic-inorganic hybrid system, where electrochromic groups such as phosphonated viologens and phenothiazine molecules are attached to the rough surface of a very high surface area porous oxide film (14,15). Typically, such films consist of networks of interconnected semiconducting or conducting metal oxide nanocrystals, deposited onto an optically transparent conducting glass electrode. On applying a negative potential, electrons are injected into the conduction band of the semiconductor and the absorbed molecule is reduced and changes color. Applying a positive potential reverses the process.

Chemical Classes of Electrochromic Material. There is a vast number of chemical species that show electrochromic properties (2), including both metal coordination complexes in solution and as polymer films (10), metal oxides (2,3) (especially tungsten oxide), viologens (4,4′-bipyridylium salts) (2,16), and conducting polymers (2,17–21) such as polypyrrole, polythiophene, and polyaniline. Other classes of electrochromic material include metal deposition/stripping systems (2) and Y, La, and Y/La alloys, which switch from a reflecting-mirror metallic state to a transparent semiconducting phase on hydride formation (8,22). It is important, however, to realize that whilst many types of chemical species exhibit electrochromism, only those with favorable electrochromic performance parameters (2) are potentially useful in commercial applications. Thus, most applications require electrochromic materials with a high contrast ratio, coloration efficiency, cycle life, and write-erase efficiency (2). Some performance parameters are application dependent; displays need low response times, whereas smart windows can tolerate response times of up to several minutes.

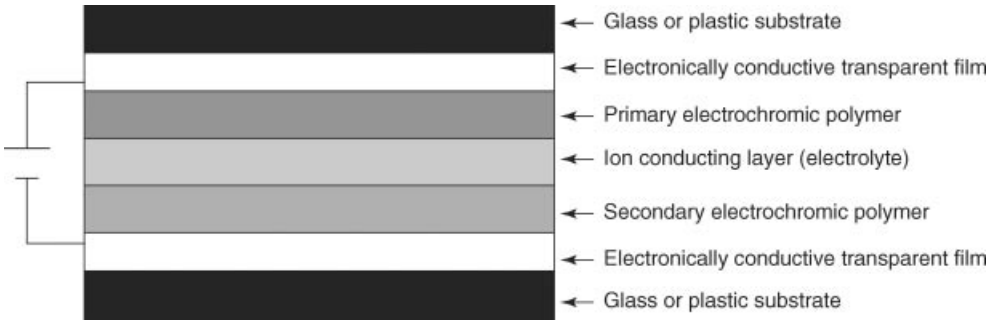

Fig. 1. Schematic design of an electrochromic device (ECD), suitable for a transmissive light-modulation application. In this case, a secondary electrochromic polymer is shown, the color change of which would need to be complementary to that of the primary electrochromic polymer.

Experimental Methods for Studying Electrochromic Materials. Redox systems which are likely to show promise as electrochromic materials are first studied, either as an electroactive surface film or an electroactive solute, at an electrochemically inert "working" electrode, under potentiostatic or galvanostatic control (2). Traditional electrochemical techniques (23), such as cyclic voltammetry (CV), coulometry, and chronoamperometry, all partnered by *in situ* spectroscopic measurements as appropriate (24,25), are employed for characterization. Three-electrode circuitry is generally employed, with "counter" and "reference" electrodes completing the electrical circuit (2).

For ECD investigations, a simple two-electrode circuit is used, with a solid (often polymeric), gel, or liquid electrolyte being sandwiched between the "primary" electrochromic electrode and a charge-balancing "secondary" electrode, in what is essentially a rechargeable electrochemical cell (Fig. 1). The electrode substrates are typically of glass or flexible plastic [generally of poly(ethylene terephthalate) (PET) such as Mylar] sheet, coated with an optically transparent electrically conducting film such as tin-doped indium oxide (ITO), antimony-doped tin oxide, or F-doped tin oxide. ECDs are designed to operate in either transmissive or, with one electrode substrate having a silvered backing, reflective modes. For type I and II systems, the electrochromic material is dissolved in the electrolyte solution. For type III systems, the electrochromic material is first deposited onto the electrode substrate (Fig. 1). Color switching of an ECD takes place on charge/discharge by application of an appropriate electrical potential.

The secondary electrode redox reaction is chosen to be a system where there is little perceptible visible color change or as an electrochromic system where the color change is complementary to that of the color change at the primary electrochromic electrode.

Electrochromic Polymers based on Transition Metal Coordination Complexes

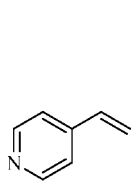
Transition metal coordination complexes are potentially useful as electrochromic materials because of their intense coloration and redox reactivity (10,26).

Chromophoric properties arise from low energy metal-to-ligand charge transfer (MLCT), intervalence CT, intraligand excitation, and related visible-region electronic transitions. Because these transitions involve valence electrons, chromophoric characteristics are altered or eliminated upon oxidation or reduction of the complex. Any colored transition metal coordination complex that is redox-switchable will undergo an accompanying color change, and will therefore be electrochromic at least to some extent. While these spectroscopic and redox properties alone would be sufficient for direct use of transition metal coordination complexes in solution-phase ECDs, polymeric systems based on coordination complex monomer units, which have potential use in all-solid-state systems, are frequently investigated.

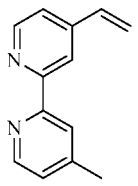
Electrochemical polymerization is often used to prepare redox active polymer films on electrode surfaces (27). This technique has the advantage that a wide variety of conducting substrates can be used, and that film thickness can be directly controlled by the electrochemical potential scan rate, the potential range, polymerization time, and the choice of monomer concentration and electrolyte solution.

Reductive Electropolymerization of Polypyridyl Complexes. Good examples of transition-metal coordination complexes that could have potential use in ECDs include the $[M^{II}(bipy)_3]^{2+}$ (M = iron, ruthenium, osmium; bipy = 2,2′-bipyridine) series which are respectively red, orange, and green in the M(II) redox state, due to the presence of an intense MLCT absorption band (26). Electrochromicity results from loss of the MLCT absorption band on switching to the M(III) redox state.

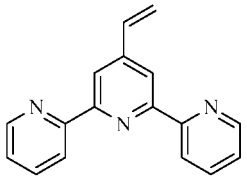
Reductive electropolymerization of suitably substituted $[M^{II}(bipy)_3]^{2+}$ complexes allows the preparation of electrochromic redox active polymer films (28). This technique relies on the ligand-centered nature of the three sequential reductions of complexes such as $[Ru(L^1)_3]^{2+}$ (L^1 = 4-vinyl-4′-methyl-2,2′-bipyridine **2**), combined with the anionic polymerizability of suitable ligands (28). Vinyl-substituted pyridyl ligands such as (**1-3**), are generally employed, although metallopolymers have also been formed from complexes of halo-substituted pyridyl ligands such as 4-(bromomethyl)-4′-methyl-2,2′-bipyridine, via electrochemically initiated carbon–halide bond cleavage (29).



1



2



3

In either case, electrochemical reduction generates radicals which lead to carbon-carbon bond formation and oligomerization. Oligomers above a critical size are insoluble and thus thin films of the electroactive metallopolymer are produced on the electrode surface. As noted above, the color of such metallopolymer films in the M(II) redox state may be selected by suitable choice of the metal.

In a novel approach, spatial electrochromism has been demonstrated in metallopolymeric films based on polymeric polypyridyl complexes (30). Photolysis of

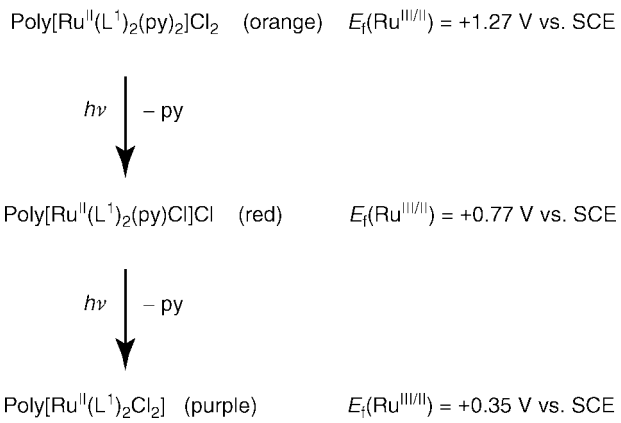


Fig. 2. Spatial electrochromism in metallopolymeric films using photolabile pyridine ligands.

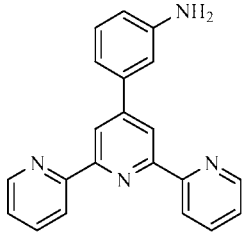
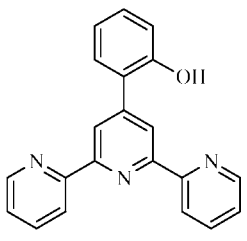
poly[$Ru^{II}(L^1)_2(py)_2$]Cl_2 thin films on ITO glass in the presence of chloride ions leads to photochemical loss of the photolabile pyridine (py) ligands, and sequential formation of poly-[$Ru^{II}(L^1)_2$(py)Cl]Cl and poly-[$Ru^{II}(L^1)_2Cl_2$]. Contact lithography can be used to spatially control the photosubstitution process to form laterally resolved bicomponent films with image resolution below 10 μm. Dramatic changes occur in the colors and redox potentials of such ruthenium(II) complexes upon substitution of chloride for the pyridine ligands (Fig. 2). Striped patterns of variable colors are observed on addressing such films with a sequence of potentials.

Oxidative Electropolymerization of Polypyridyl Complexes. Oxidative electropolymerization of suitably substituted $[M^{II}(bipy)_3]^{2+}$ complexes offers an alternative approach to the preparation of electrochromic redox active polymer films. Oxidative electropolymerization has been described for iron(II) and ruthenium(II) complexes containing amino-substituted (31) and pendant aniline-substituted (32) 2,2′-bipyridyl ligands, and amino- and hydroxy-substituted 2,2′:6′,2″-terpyridinyl ligands (33) [ligand structures (**4**) and (**5**)]. Analysis of IR spectra suggests that the electropolymerization of $[Ru(L^4)_2]^{2+}$ [L^4 = (**4**)], via the pendant aminophenyl substituent, proceeds by a reaction mechanism similar to that of aniline (33). The resulting metallopolymer film reversibly switches from purple to pale pink on oxidation of Fe(II) to Fe(III). For polymeric films formed from $[Ru(L^5)_2]^{2+}$ [L^5 = (**5**)], via polymerization of the pendant hydroxyphenyl group, the color switch is from brown to dark yellow (see ELECTROPOLYMERIZATION).



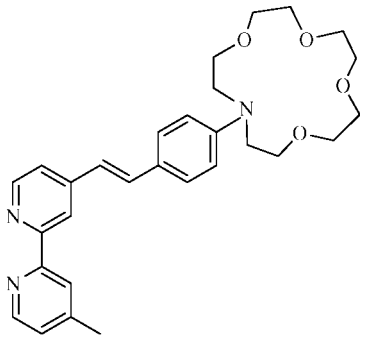
4



5

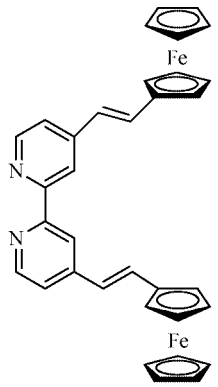
The dark yellow color is attributed to an absorption band at 455 nm, probably due to quinone moieties in the polymer formed during electropolymerization. IR spectra confirm the absence of hydroxyl groups in the initially deposited brown films.

Metallopolymer films have also been prepared by oxidative polymerization of complexes of the type $[M(phen)_2(4,4'\text{-bipy})_2]^{2+}$ (M = Fe, Ru, or Os; phen = 1,10-phenanthroline; 4,4′-bipy = 4,4′-bipyridine) (34). Such films are both oxidatively and reductively electrochromic; reversible film-based reduction at potentials below −1.00 V leads to dark purple films (34), the color and potential region being consistent with the viologen dication/radical cation electrochromic response. A purple state at high negative potentials has also been observed for polymeric films prepared from $[Ru(L^6)_3]^{2+}$ [L^6 = (**6**)] (35).

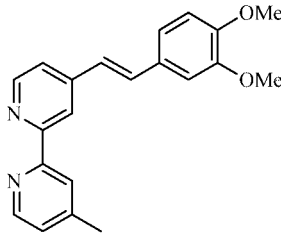


6

Electropolymerized films prepared from the complexes $[Ru(L^7)(bipy)_2][PF_6]_2$ (36) and $[Ru(L^8)_3][PF_6]_2$ (37,38) exhibit reversible orange/transparent electrochromic behaviour associated with the Ru(II)/Ru(III) interconversion [L^7 = (**7**); L^8 = (**8**)].



7



8

Electrochemical Routes to Polymeric Metallophthalocyanine Electrochromic Films. The porphyrins are a group of highly colored, naturally occurring pigments containing a tetrapyrrole porphine nucleus (Fig. 3) with substituents at the eight β-positions of the pyrroles, and/or the four

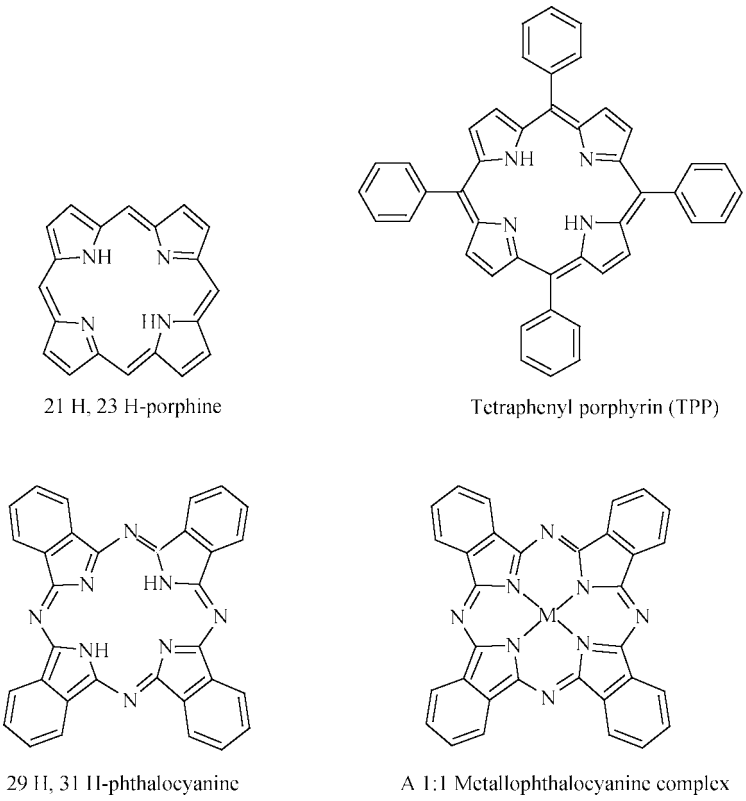


Fig. 3. Structures of a selection of porphyrins and phthalocyanines.

meso-positions between the pyrrole rings (39). The natural pigments are metal chelate complexes of the porphyrins. Phthalocyanines (Fig. 3) are tetraazatetrabenzo derivatives of porphyrins with highly delocalised π-electron systems.

The metal ion in metallophthalocyanines lies either at the center of a single phthalocyanine ligand (Pc = dianion of phthalocyanine) (Fig. 3), or between two rings in a sandwich-type complex (40). Phthalocyanine complexes of transition metals usually contain only a single Pc ring while lanthanide-containing species usually form bis(phthalocyanines), where the π-systems interact strongly with each other.

Since the discovery of the electrochromism of lutetium bis(phthalocyanine) [$Lu(Pc)_2$] thin films (2), the electrochromic properties of numerous (mainly rare-earth) metallophthalocyanines have been investigated. Lutetium bis(phthalocyanine) thin films are in fact polyelectrochromic, the initially deposited vivid green films being oxidized through a yellow-tan form, to a red form. Upon reduction, the green state can be switched first to a blue redox form, and then to a violet-blue form (2). Although, as described, [$Lu(Pc)_2$] films can exhibit five colors, only the blue-green transition is used in most prototype electrochromic devices. There are mechanical problems associated with the use of [$Lu(Pc)_2$]-based films, but in spite of such difficulties, electrochromic displays with good reversibility, fast response times, and little degradation over 5×10^6 cycles have been described.

The electrochromic properties of metallophthalocyanine films are generally investigated using low molecular weight sublimed (physical vapor deposition) films (40), although studies have also been carried out on films prepared using the Langmuir–Blodgett technique (40). More recently, methods for preparing thin films of polymeric phthalocyanines have been investigated. Such materials are attractive because of their rigidity, high stability, and strong, well-defined coupling of the electronic π-systems. Because polymeric phthalocyanines are not soluble and cannot be vaporized, new methods of thin-film formation have been developed.

For complexes with pendant aniline and hydroxy-substituted ligands, oxidative electropolymerization is a useful route to the preparation of metallophthalocyanine electrochromic films. Although polymer films prepared from $[Lu(L^9)_2]$ (L^9 = 4,4′,4″,4‴-tetraaminophthalocyanine) monomer show loss of electroactivity on cycling to positive potentials, in dimethyl sulfoxide (DMSO) the electrochemical response at negative potentials is stable, with the observation of two broad quasi-reversible one-electron redox couples (41). Spectroelectrochemical measurements reveal switching times of <2 s for the observed green-grey-blue color transitions in this region. The oxidative electropolymerization technique using pendant aniline substituents has also been applied to monophthalocyaninato transition-metal complexes (42); the redox reactions and color changes of two of the examples studied are given in equations (1–4).

$$\underset{\text{(blue-green)}}{\text{poly}-[Co^{II}(L^9)]} + ne^- \rightarrow \underset{\text{(yello-brown)}}{\text{poly}-[Co^{I}(L^9)]^-} \quad (1)$$

$$\underset{\text{(yellow-brown)}}{\text{poly}-[Co^{I}(L^9)]^-} + ne^- \rightarrow \underset{\text{[red-brown (thickfilms), deeppink (thinfilms)]}}{\text{poly}-[Co^{I}(L^9)]^{2-}} \quad (2)$$

$$\underset{\text{(green)}}{\text{poly}-[Ni^{II}(L^9)]} + ne^- \rightarrow \underset{\text{(blue)}}{\text{poly}-[Ni^{II}(L^9)]^-} \quad (3)$$

$$\underset{\text{(blue)}}{\text{poly}-[Ni^{II}(L^9)]^-} + ne^- \rightarrow \underset{\text{(purple)}}{\text{poly}-[Ni^{II}(L^9)]^{2-}} \quad (4)$$

The first reduction in the cobalt-based polymer is metal-centered, resulting in the appearance of a new MLCT transition, with the second reduction being ligand-centered. For the nickel-based polymer in contrast, both redox processes are ligand-based.

Electrochromic polymer films have been prepared by oxidative electropolymerization of the monomer tetrakis(2-hydroxyphenoxy)phthalocyaninato cobalt(II) (43). The technique involved voltammetric cycling at 100 $mV \cdot s^{-1}$ from -0.2 to $+1.2$ V vs SCE in dry acetonitrile, resulting in the formation of a fine green polymer. Cyclic voltammograms during polymer growth showed the irreversible

phenol oxidation peak at +0.58 V and a reversible phthalocyanine ring oxidation peak at +0.70 V. Polymer-modified electrodes gave two distinct redox processes with half-wave potentials at −0.35 [Co(II)/Co(I)] and −0.87 V (reduction of the ring). Color switching was from transparent light green [Co(II) state] to yellowish green [Co(I) state] to dark yellow (reduced ring).

The synthesis and electropolymerization of two tetrakis(2-pyrrol-1-ylalkoxy)phthalocyanines has been reported, and the electrical and optical properties discussed (44). This is the first example of the electropolymerization of a phthalocyanine where the electropolymerizable group (pyrrole) is electronically isolated from the phthalocyanine.

A complementary ECD using plasma-polymerized ytterbium bis(phthalocyanine) [PP-Yb($Pc)_2$] and thin films of the mixed-valence inorganic complex Prussian blue (PB) iron(III) hexacyanoferrate(II) films on ITO with an aqueous solution of 4 *M* KCl as electrolyte has been fabricated (45). Blue-to-green electrochromicity was achieved in a two-electrode cell by complementing the green-to-blue color transition (on reduction) of the PP-Yb($Pc)_2$ film with the blue (PB)-to-colorless (PW, Prussian white) transition (oxidation) of the PB. A three-color display (blue, green, and red) was fabricated in a three-electrode cell in which a third electrode (ITO) was electrically connected to the PB electrode. A reduction reaction at the third electrode, as an additional counter electrode, provided adequate oxidation of the PP-Yb($Pc)_2$ electrode, resulting in the red coloration of the PP-Yb($Pc)_2$ film.

Viologen Electrochromism and Polymeric Viologen Systems

Salts of quaternised 4,4′-bipyridine are herbicides and are manufactured on a large scale (16). The ready availability of 4,4′-bipyridine and the ease of varying the nature of the quaternizing agent have allowed intensive research into the electrochromic properties of such "viologens" (16). The prototype viologen, 1,1′-di-methyl-4,4′-bipyridilium, is known as methyl viologen (MV), with other simple symmetrical bipyridilium species being named "substituent" viologen. Of the three common viologen redox states (Fig. 4), the dication is the most stable and is colorless when pure unless optical charge transfer with the counter anion occurs. Reductive electron transfer to the viologen dication forms the radical cation, the stability of which is attributable to the delocalisation of the radical electron

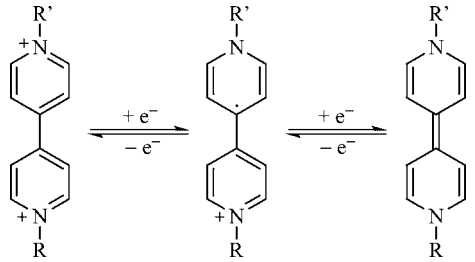

Fig. 4. The three common redox states of viologens, showing the two successive electron transfer reactions.

throughout the π-framework of the bipyridyl nucleus, the 1 and 1′ substituents commonly bearing some of the charge.

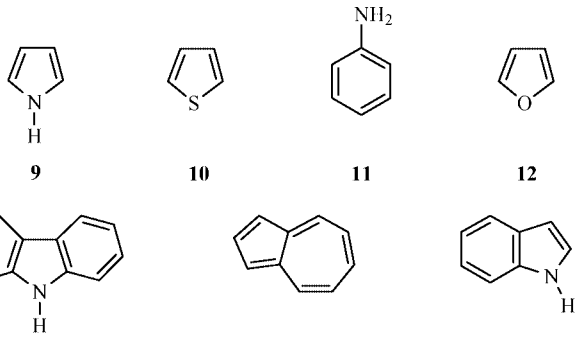
The viologen radical cations are intensely colored, with high molar absorption coefficients, owing to optical charge transfer between the (formally) +1 and zero valent nitrogens. Suitable choice of nitrogen substituents in viologens to attain the appropriate molecular orbital energy levels can, in principle, allow color choice of the radical cation. Simple alkyl groups, for example, promote a blue/violet color whereas aryl groups such as 4-cyanophenyl in 1,1′-bis(4-cyanophenyl)-4,4′-bipyridilium generally impart a green hue to the radical cation. The intensity of the color exhibited by di-reduced viologens (Fig. 4) is low since no optical charge transfer or internal transition corresponding to visible wavelengths is accessible.

Polymeric Viologen Systems. The write-erase efficiency of an ECD using for example aqueous MV would be low since both the dicationic and radical-cation states are very soluble. Improved MV-based systems may be made by retarding the rate at which the radical-cation product of electron transfer diffuses away from the electrode by use of an anionic polyelectrolyte such as poly(2-acrylamido-2-methylpropane-sulfonic acid) (polyAMPS) (46,47) or the sulfonated perfluorinated polyether, Nafion (48). An alternative approach is the surface modification of an electrode using silanization methodology (49), a preformed polymeric viologen salt (50) or oxidative electropolymerization of a pyrrole-substituted viologen (51) (Fig. 5).

In a more recent approach, polyelectrolyte multilayers of poly(butanyl viologen) dibromide (PBV) and poly(styrene sulfonate) sodium salt (PSS) have been prepared (52) using an alternating polyion solution deposition technique. In this technique, the ITO substrate is alternatively exposed to positive and negative polyelectrolytes, with spontaneous polymer deposition via coulombic interactions between surface and polyion of opposite charge. In this "layer-by-layer" deposition technique, all redox material is electrochemically addressable, with good electrochromic performance characteristics.

Conducting Electrochromic Polymers

Chemical or electrochemical oxidation of numerous resonance-stabilised aromatic molecules, such as pyrrole (**9**), thiophene (**10**), aniline (**11**), furan (**12**), carbazole (**13**), azulene (**14**) and indole (**15**), produces electronically conducting polymers (2,17–21,53–55) (see ELECTRICALLY ACTIVE POLYMERS).



9 **10** **11** **12**

13 **14** **15**

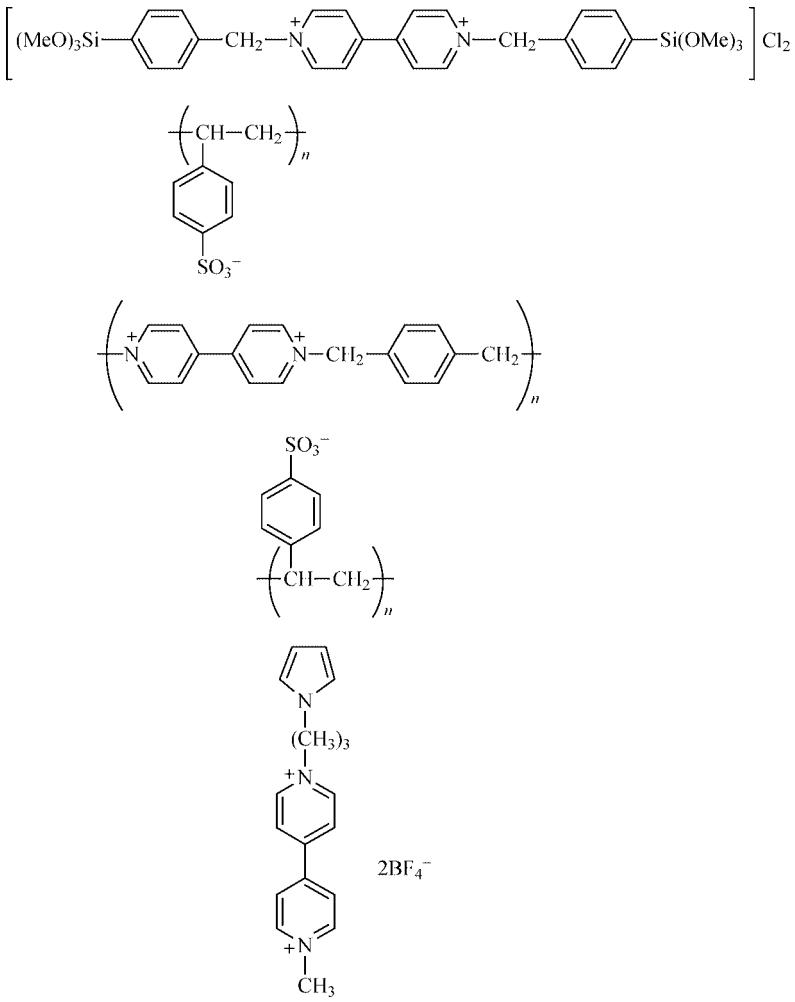


Fig. 5. Modified viologens used for surface modification.

Polymerization is initiated by monomer oxidation to yield the radical cation. The mechanism (55) is believed then to involve either radical-cation/radical-cation coupling or reaction of a radical-cation with a neutral monomer. The mechanism of electropolymerization of five-membered heterocycles with radical-cation/radical-cation coupling is shown in Fig. 6.

After loss of two protons and rearomatization, the dimer forms from the di-hydro dimer dication. The dimer (and succeeding oligomers) is more easily oxidized than the monomer and the resulting dimer radical cation undergoes further coupling reactions, proton loss, and rearomatization. Electropolymerization (qv) proceeds through successive electrochemical and chemical steps according to a general E(CE)n scheme, until the oligomer becomes insoluble in the electrolyte solution and precipitates onto the electrode surface (55).

In the oxidized state, conducting polymers are "doped" with counter anions ("p-doping") and have a delocalised π-electron band structure (55). The fairly large

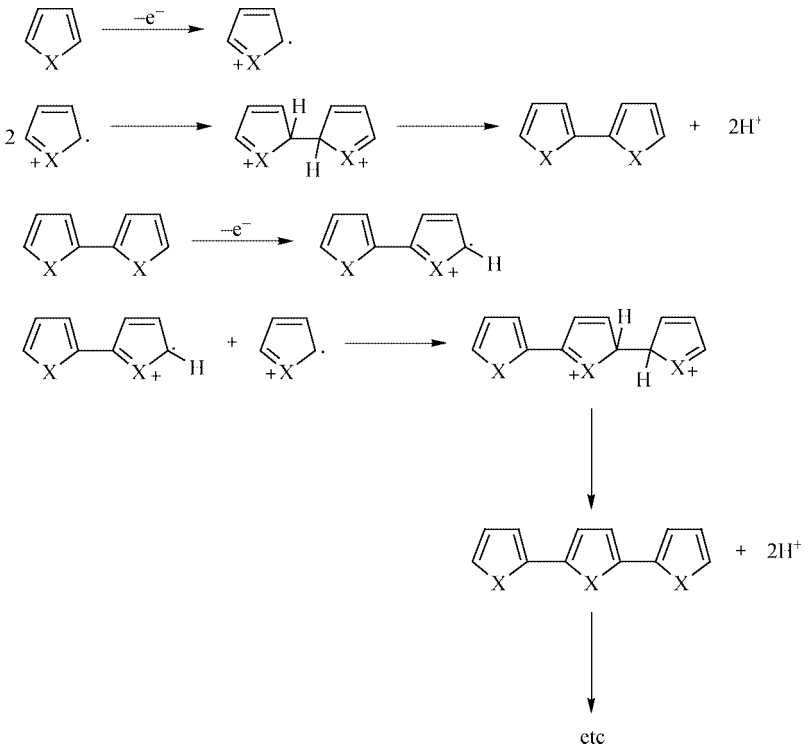

Fig. 6. Proposed mechanism of electropolymerization of five-membered heterocycles. The case of radical-cation/radical-cation coupling is shown.

energy bandgap (E_g) between the highest occupied π-electron band (valence band) and the lowest unoccupied band (the conduction band) determines the intrinsic optical properties of these materials. Reduction of p-doped conducting polymers, with concurrent counter anion exit, removes the electronic conjugation to give the "undoped" (neutral) electrically insulating form. On further reduction, the undoped neutral state can also undergo cathodic doping, with cation insertion ("n-doping") to balance the injected charge. However, the stability of the negatively charged polymer state is rather limited and n-doping is generally more difficult to achieve. It is to be noted that the p-doping and n-doping nomenclature comes from classical extrinsic semiconductor theory. The supposed similarity between conducting polymers and doped semiconductors arises from the way that redox changes in the polymer causes the incorporation (and hence doping) of counter ions into the polymer. In fact, the suitability of the terms *doping* and *dopant* has been criticised when referring to the movement of counter ions and electronic charge through these polymers because true doping involves such tiny (classically sub ppm) amounts of dopant. However, terms such as doping are now so widely used that additional, new terminology might confuse.

All conducting polymers are potentially electrochromic in thin-film form, redox switching giving rise to new optical absorption bands in accompaniment with simultaneous transport of electronic charge and counter ions in the polymer matrix. p-doping shifts the optical absorption band towards the lower energy

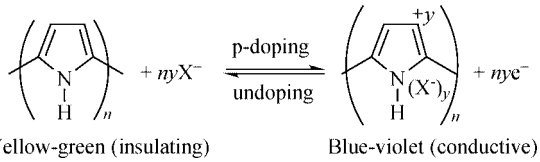

Fig. 7. Electrochromism in polypyrrole thin films. The yellow-green (undoped) form undergoes reversible oxidation to the blue-violet (conductive) form, with insertion of charge-compensating anions (X^-).

part of the spectrum. The color contrast between doped and undoped forms of the polymer depends on the magnitude of the bandgap of the undoped polymer. The final doped conducting state is characterized by the presence of positive charges along the polymer chains associated with charge-compensating anions. Thin films of conducting polymers with E_g greater than 3 eV (~400 nm) are transparent or slightly colored in the undoped form, and in the doped form are generally highly absorbant in the visible region. Those with small E_g [1.5 (~800 nm)–2 eV (~600 nm)] are highly absorbant in the undoped form but, after doping, the free carrier absorption is relatively weak in the visible region.

An early reported example of an electrochromic conducting polymer is polypyrrole (56), which in the undoped (reduced) insulating state is yellow/green, with a peak maximum characteristic of a π–π^* interband transition. The interband transition energy decreases upon doping to yield the blue/violet doped (oxidized) conductive state (Fig. 7).

The electrochromism of polypyrrole is unlikely to be exploited, because of the degradation of the film on repetitive color switching. Electrochromic conducting polymers based on thiophene and aniline have received greater attention.

Polythiophenes as Electrochromic Materials. Polythiophenes (55) are of interest as electrochromic materials due to their ease of chemical and electrochemical synthesis, environmental stability, and processability. A huge number of substituted thiophenes has been synthesized, and this has led to the study of numerous novel polythiophene(s), with particular emphasis on poly(3-substituted thiophenes) and poly(3,4-disubstituted thiophenes) (55).

Thin polymeric films of the parent thiophene are blue ($\lambda_{max} = 730$ nm) in the doped (oxidized) state and red ($\lambda_{max} = 470$ nm) in the undoped form. However, because of its lower oxidation potential, the electropolymerization of 3-methyl thiophene has been more intensively studied than the parent thiophene. Furthermore, the introduction of a methyl group at the β-position of the thiophene ring leads to a significant increase of the polymer conjugation length and hence electronic conductivity (55). This effect has been attributed to the statistical decrease in the number of α–β' couplings and to the decrease of the oxidation potential caused by the inductive effect of the methyl group (55). Poly(3-methylthiophene) is purple when neutral and turns pale blue on oxidation.

The evolution of the electronic band structure during electrochemical p-doping of poly(3-methylthiophene) has been followed by recording *in situ* visible and NIR spectra (55). The undoped polymer's strong absorption band, with a maximum at 530 nm (2.34 eV), is characteristic of a π–π^* interband transition. Upon doping, the interband transition decreases, and two new optical transitions (at

$\sim$1.5 and $\sim$0.5 eV) appear at lower energy, corresponding to the presence of two bipolaron (a double-charged spinless defect) bands. A pair of polarons (each single charged of spin $\frac{1}{2}$) is unstable with respect to the formation of a bipolaron, and in thiophene-based polymers the bipolaron states appear even at low doping levels. The characteristic absorption pattern of the free carrier of the metallic-like state then appears when the bipolaron bands finally merge with the valence and conduction bands.

Tuning of color states is possible by suitable choice of thiophene monomer, and this represents a major advantage of using conducting polymers for electrochromic applications. Subtle modifications to the monomer can significantly alter spectral properties. For example, the colors available with polymer films prepared from 3-methylthiophene–based oligomers are strongly dependent on the relative positions of methyl groups on the polymer backbone (57,58). Colors available include pale blue, blue, and violet in the oxidized form, and purple, yellow, red, and orange in the reduced form. The color variations have been ascribed to changes in the effective conjugation length of the polymer chain.

In research directed to using the same electrochromic material for both the primary and secondary electrodes, a series of conducting polymer films based on 3-(*p*-X-phenyl)thiophene monomers (X = —CMe_3, —Me, —OMe, —H, —F, —Cl, —Br, —CF_3, —SO_2Me) has been investigated (59). In this case the presence of electron-withdrawing groups on the phenyl ring serve to assist the stabilization of the n-doped state and these materials can be both reversibly reduced and oxidized (n- and p-doped). A model ECD using poly(cyclopenta[2,1-*b*; 4,3-*b*′]dithiophene-4-(cyano, nonafluorobutylsulfonyl)-methylidene), a low bandgap conducting polymer which is both p- and n-dopable, as both the anode and the cathode material has been reported (60).

Study of the effects of steric factors is provided by the electronic properties of polythiophenes with 3,4-dialkyl substituents. In principle, disubstitution at the β, β' positions should provide the synthetic basis to perfectly stereoregular polymers. However, this approach is severely limited by the steric interactions between substituents, which leads to a decrease in polymer conjugation length. In fact, poly(3,4-dialkylthiophenes) have higher oxidation potentials, higher optical bandgaps, and lower conductivities than poly(3-alkylthiophenes) (55). Cyclization between the 3 and 4 positions relieves steric hindrance in thiophenes, but many are harder to electropolymerize than, say, 3-methylthiophene. The electron-donating effect of alkoxy groups offers a solution here, and alkoxy-substituted polythiophenes are intensively investigated for their electrochromic properties (61,62). Materials based on poly(3,4-(ethylenedioxy)thiophene) (PEDOT) have a bandgap lower than polythiophene and alkyl-substituted polythiophenes, owing to the presence of the two electron-donating oxygen atoms adjacent to the thiophene unit.

The bandgap of PEDOT ($E_g = 1.6 - 1.7$ eV) itself is 0.5 eV lower than polythiophene, which results in an absorbance maximum in the NIR region. Compared to other substituted polythiophenes, these materials exhibit excellent stability in the doped state which is associated with high conductivity. Doped PEDOT is almost transparent in the visible region (with a sky-blue tint) and the neutral polymer is deep blue. Because PEDOT and its alkyl derivatives are cathodically-coloring electrochromic materials, they are suitable for use with "anodically-coloring" conducting polymers in the construction of dual polymer ECDs (63).

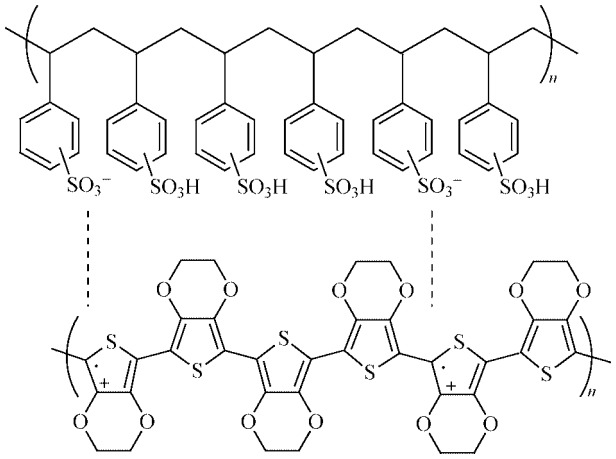

Fig. 8. Structure of the PEDOT:PSS blend (BAYTRON P).

PEDOT was first developed by Bayer AG research laboratories in Germany in an attempt to produce an easily oxidized and stable conducting polymer (64,65). By blocking the β-positions of the heterocyclic ring, the formation of α–β linkages during polymerization is prevented, resulting in a more regiochemically defined material. To aid processing, the insolubility of PEDOT can be overcome by the incorporation of a water-soluble polyelectrolyte [poly(styrene sulfonate), PSS] as the counter ion in the doped state, to yield the commercially available product PEDOT:PSS (BAYTRON P) (Fig. 8), which forms a dispersion in water. [Bayer AG now produce the EDOT monomer 3,4-(ethylenedioxy)thiophene, on a multiton scale and it is available commercially as BAYTRON M.]

As for thiophene, many substituted EDOT monomers have been synthesized, and this has led to the study of a range of variable-bandgap PEDOT-based materials (61,62). The bandgap of such conjugated polymers is controlled by varying the degree of π-overlap along the backbone via steric interactions, and by controlling the electronic character of the π-system with electron-donating or-accepting substituents. The latter is accomplished by using substituents and co-repeat units that adjust the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy levels of the α-system (61,62). An interesting set of materials is the family of EDOT-based polymers that has been prepared with higher energy gaps than the parent PEDOT. Using a series of oxidatively polymerizable bis-arylene EDOT monomers (Fig. 9), polymers with bandgaps ranging from 1.4 – 2.5 eV have been prepared (61,62). In the neutral polymers, a full "rainbow" of colors is available, from blue through purple, red, orange, green, and yellow. A few examples include bis-arylene EDOT-based polymers, with spacers of vinylene ($E_g = 1.4$ eV); 2,5-dialkoxyphenylene ($E_g = 1.75 - 2.0$ eV); biphenyl ($E_g = 2.3$ eV); dialkylfluorene ($E_g = 2.3$ eV); and carbazole ($E_g = 2.5$ eV).

Following earlier work (52) with polyviologen systems, the layer-by-layer deposition of PEDOT:PSS (as the polyanion) with linear poly(ethylene imine) (LPEI) (as the polycation) has recently been reported (66). The PEDOT:PSS/LPEI (cathodically coloring) electrode was then combined with a polyaniline/polyAMPS

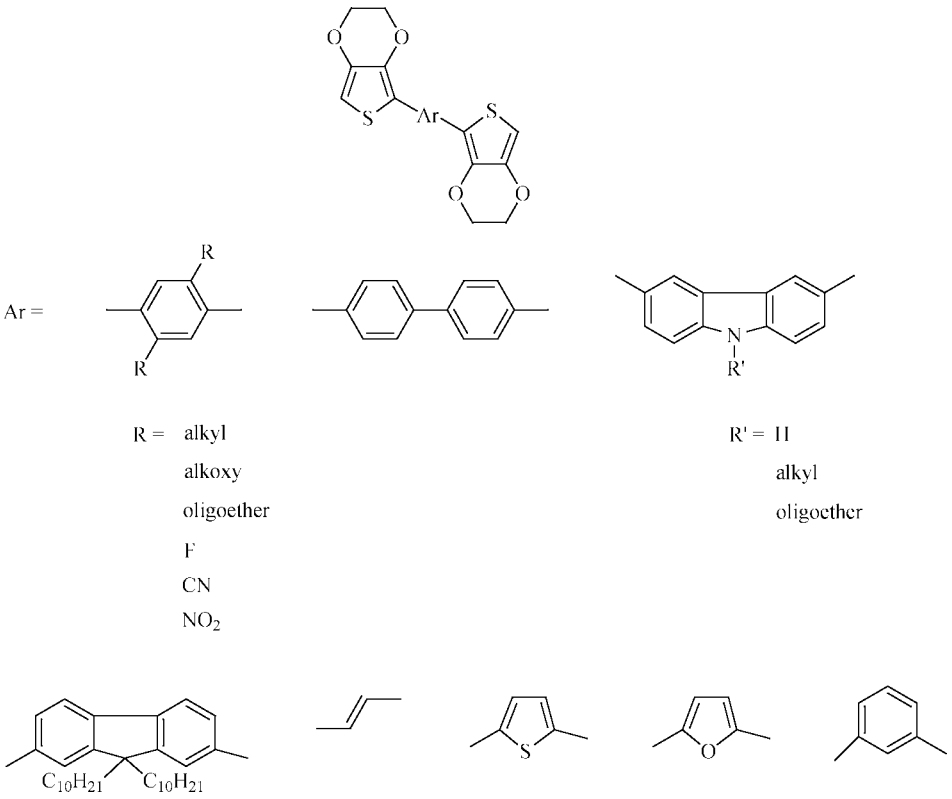

Fig. 9. Bis-EDOT-arylene co-oligomers.

(anodically coloring) layered system to give a blue-green to yellow electrochromic device. More recently, the redox and electrochromic properties of films prepared by the layer-by-layer deposition of fully water-soluble, self-doped poly(4-(2,3-dihydrothieno [3,4-*b*]-[1,4]dioxin-2-yl-methoxy))-1-butanesulfonic acid, sodium salt (PEDOT-S) and poly(allylamine hydrochloride) (PAH) onto unmodified ITO-coated glass have been studied (67). For this system, both the film preparation and redox switching is carried out in an aqueous medium. [PEDOT-S is a self-doping polymer where oxidation and reduction of the polymer backbone is coupled with cation movement out of (oxidized) and back into (reduced) the polymer film]. The PEDOT-S/PAH film was found to switch from light blue in the oxidized form to pink/purple in the reduced form.

A new organic/inorganic complementary ECD has recently been described (68) on the basis of the assembly of PEDOT/ITO glass and Prussian blue [PB, iron(III) hexacyanoferrate(II)]/ITO glass substrates with a poly(methyl methacrylate) (PMMA)-based gel polymer electrolyte (GPE: 1 *M* $LiClO_4$/propylene carbonate/10wt% PMMA). The color states of the PEDOT (blue/colorless) and PB (colorless/blue) films fulfill the complementary requirement.

"Star" conducting polymers, which have a central core with multiple branching points and linear conjugated polymeric arms radiating outward, are currently being investigated for electrochromic applications (69,70). Examples include star

conducting polymers in which the centrosymmetric cores include hyperbranched poly(1,3,5-phenylene) (PP) and poly(triphenylamine) (PTPA), and the radiating arms are regioregular poly(3-hexylthiophene), poly(3,4-ethylenedioxythiophene-didodecyloxybenzene) and poly(dibutyl-3,4-propylenedioxythiophene). These polymers have the advantage that they are all castable by spin coating from a carrier solvent such as tetrahydrofuran (THF), and several can be doped in solution, so that thin films of both doped and undoped forms can be prepared. Despite the branched structure, star polymers self-assemble into thin films with morphological, electrical, and optical properties that reveal a surprisingly high degree of structural order. The polymers, which are smooth and reflective, all have spectral features that produce a strong band in the visible region for the reduced state and a broad band extending into the NIR for the oxidized state. The color of the polymers ranges from red to violet to deep blue in the reduced state, and blue to very pale blue in the oxidized state.

Polyanilines as Electrochromic Materials. Polyaniline films are polyelectrochromic (transparent yellow-green-dark blue-black) (71), the yellow-green transition being durable to repetitive color switching (72). Several redox mechanisms involving protonation–deprotonation and/or anion ingress/egress have been proposed (73–75), with Figure 10 giving the composition of the various redox states.

The two low wavelength spectral bands observed in films of polyanilines are assigned to an aromatic π–π^* transition ($\leq$330 nm) related to the extent of conjugation between the adjacent rings in the polymer chain, and to radical cations formed in the polymer matrix ($\leq$440 nm) (76,77). With increase in applied potential, the $\leq$330 nm band absorbance decreases and the $\leq$440 nm increases. Beyond +0.30 V the conducting region is entered; the $\leq$440 nm band decreases as a broad free carrier electron band $\sim$800 nm is introduced.

Of the numerous conducting polymers based on substituted anilines that have been investigated, those with alkyl substituents have received much attention. Poly(*o*-toluidine) and poly(*m*-toluidine) films have been found to offer enhanced stability of polyelectrochromic response in comparison with polyaniline (78). Absorption maxima and redox potentials shift from values found for polyaniline because of the lower conjugation length in polytoluidines. Response times, τ, for the yellow-green electrochromic transition in the films correlate with the likely differences in the conjugation length implied from the spectroelectrochemical data. τ values for polyaniline are found to be lower than for poly(*o*-toluidine), which in turn has lower values than poly(*m*-toluidine). As for polyaniline, response times indicate that the reduction process is faster than the oxidation. Electrochemical quartz crystal microbalance (EQCM) studies have demonstrated the complexity of redox switching in poly(*o*-toluidine) films in aqueous perchloric acid solutions which occurs in two stages and is accompanied by nonmonotonic mass changes that are the result of perchlorate counterion, proton co-ion, and solvent transfers (79). The extent and rate of each of these transfers are dependent upon electrolyte concentration, experimental time scale, and the switching potential, so that observations in a single electrolyte on a fixed time scale cannot be unambiguously interpreted.

Although electropolymerization is a suitable method for the preparation of relatively low surface area electrochromic conducting polymer films, it may not

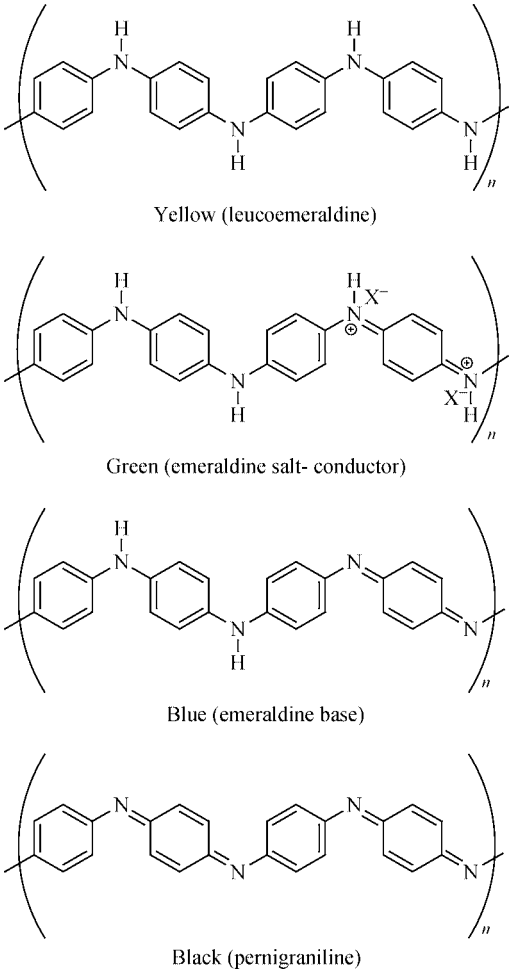

Fig. 10. Proposed composition of some of the redox states of polyaniline, from the fully reduced (leucoemeraldine) through to the fully oxidised (pernigraniline) forms. X^- is a charge-balancing anion.

be suitable for fabricating large-area coatings. Significant effort therefore goes into the synthesis of soluble conducting polymers such as poly(*o*-methoxyaniline) which can then be deposited as thin films by casting from solution. In a novel approach, large-area electrochromic coatings have been prepared by incorporating polyaniline into polyacrylate-silica hybrid sol–gel networks using suspended particles or solutions and then spray or brush-coating onto ITO surfaces (80). Silane functional groups on the polyacrylate chain act as coupling and cross-linking agents to improve surface adhesion and mechanical properties of the resulting composite coatings.

Similarly to the PEDOT/PB system noted above, numerous workers (81–88) have combined Prussian blue with polyaniline in complementary ECDs that exhibit deep-blue to light-green electrochromism. Electrochromic compatibility is

obtained by combining the colored oxidized state of the polymer with the blue PB, and the "bleached" reduced state of the polymer with Prussian green (PG) (eq. 5):

$$\underset{\text{(colored)}}{\text{Oxidizedpolyaniline}} + \text{PB} \rightarrow \underset{\text{(bleached)}}{\text{Emeraldinepolyaniline}} + \text{PG} \tag{5}$$

An electrochromic window for solar modulation using PB, polyaniline, and WO_3 has been developed (84,85,87,88), where the symbiotic relationship between polyaniline and PB, and incorporated PB together with polyaniline and WO_3, was exploited in a complete solid-state electrochromic window. The total device comprised

glass|ITO|polyaniline|PB|polyAMPS|WO_3|ITO|glass

Compared to earlier results with a polyaniline/WO_3 window, much more light was blocked off by inclusion of PB within the polyaniline matrix, while still regaining about the same transparency during the bleaching of the window. Other polyaniline-based ECDs include a device that exhibits yellow–transparent electrochromicity using electropolymerized 1,1′-bis[[p-phenylamino(phenyl)]amido-]ferrocene (89).

Composite Conducting Polymer Electrochromic Materials. The electropolymerization of monomers in the presence of other electrochromic additives which may have electrochromic or other properties has been a popular approach to the preparation of materials with tailored properties (2). A water-soluble poly(styrenesulfonic acid)-doped polyaniline has been prepared both by persulfate oxidative coupling and anodic oxidation of aniline in aqueous dialysed poly(styrenesulfonic acid) solution (90). Composites of polyaniline and cellulose acetate have been prepared both by casting of films from a suspension of polyaniline in a cellulose acetate solution and deposition of cellulose acetate films onto electrochemically prepared polyaniline films (91). The electrochromic properties of the latter films were studied by spectroelectrochemistry and the presence of the cellulose acetate was found not to impede the redox processes of the polyaniline. The electroactivity and electrochromism of the graft copolymer of polyaniline and nitrilic rubber have been studied using stress–strain measurements, cyclic voltammetry, frequency response analysis, and visible range spectroelectrochemistry (92). Results indicated that the graft copolymer exhibits mechanical properties similar to a cross-linked elastomer with the electrochromic and electrochemical properties typical of polyaniline.

An example of a case where the additive itself is electrochromic is the encapsulation of the redox indicator dye indigo carmine within a polypyrrole matrix (93,94). More recently, 3-D graphs have been constructed from absorbance data acquired during cyclic voltammetry. The enhancement and modulation of the color change on indigo carmine insertion into polypyrrole or polypyrrole/dodecylsulfonate films was shown (95). As expected, the use of indigo carmine as dopant improves the films' electrochromic contrast ratio.

Conclusions

The field of electrochromism is rapidly expanding both in terms of the range of electrochromic systems that has been reported and the novel commercial applications that are being proposed. In the case of electrochromic polymers, a number of representative examples of both redox and conductive polymers have been described in this article. Tailoring the color of electrochromic polymers remains an area of active research. Although not described here, in addition to the synthesis of novel functionalized monomers and use of composites, other chemical and physical methods are investigated for the control of the perceived color of electrochromic polymers. Methods include the use of copolymers, polymer blends, laminates and patterning using screen and ink-jet printing (96). Analysis of ECD color changes are now routinely measured by spectrocolorimetry using Commission Internationale de l'Eclairage (CIE) (x,y)-chromaticity coordinates. This method is useful for the comparison of the electrochemical and optical properties of conjugated polymers, and for gaining control of the color of dual polymer electrochromic devices (97). By controlling the electron density and steric interactions along conjugated polymer backbones, a set of electrochromic polymers that provide colors through the full range of color space have been developed through the study of twelve electrochromic polymers (97).

In addition to possible roles as the active electrochromic material, it should be recognized that polymers may also be used in electrochromic devices as electrolyte solution thickeners, as plasticizers, as the matrix or solid phase of gels, as solid polymer electrolytes, and even as sealants to insulate a glass unit configuration (98).

Further developments in the field of electrochromic polymers seem limited only by the skills, resources, and imagination of synthetic organic chemists, polymer chemists, and material scientists. However, the ultimate usefulness of such fascinating materials hinges on a detailed understanding of their fundamental redox operation and the accompanying physicochemical–structural changes, and therefore the field is truly interdisciplinary.

For comprehensive surveys of the field of electrochromism, readers should scan the now compendious review (2-10) and primary literature, proceedings of conferences (99–107), the extensive patent literature (quite neglected here), and the Internet. Electrochromism research conferences regularly take place under the auspices of the Electrochemical Society (ECS) (99–103). Other sponsors also participate, for example the American Institute of Chemical Engineers at the Annual Meeting held in Chicago, 11–16 November 1990 ("Fundamentals of Electrochromic Devices"), also published (104), and many, often under the "Displays" heading, in the United Kingdom and Europe. Since the first meeting in Venice in 1994, the International Meeting on Electrochromism (IME) series has established itself as a leading conference for the dissemination of scientific and technical information in the field of electrochromics. The Second International Meeting on Electrochromism (IME-2) in 1996 in San Diego, U.S., was reported in a special (and belated) issue of *Solar Energy Materials and Solar Cells* (105). IME-3 in 1998 in London, U.K., and IME-4 in 2000 in Uppsala, Sweden, appeared in special issues of *Electrochimica Acta* (106,107). The proceedings of IME-5 in 2002 in

Golden, Colorado, U.S., will be published in a special issue of *Solid State Ionics*. IME-6 (28 August – 2 September 2004) will take place in the Czech Republic.

ELECTRON SPIN RESONANCE

Introduction

Electron spin resonance (ESR) is a spectroscopic technique that detects the transitions induced by electromagnetic radiation between the energy levels of electron spins in the presence of a static magnetic field. The method can be applied to the study of species containing one or more unpaired electron spins; examples include organic and inorganic radicals, triplet states, and complexes of paramagnetic ions. Electron paramagnetic resonance (EPR) and EPR imaging (EPRI) are often used in the literature instead of ESR and ESRI. Spectral features such as resonance frequencies, splittings, line shapes, and line widths are sensitive to the electronic distribution, molecular orientations, nature of the environment, and molecular motions. Theoretical and experimental aspects of ESR have been covered in a number of books (1–8), and reviewed periodically (9–11).

The great sensitivity and specificity of ESR methods have been utilized to advantage in order to investigate and clarify important questions in polymeric systems (12). The most obvious candidates for initial studies were chain-growth and depolymerization reactions; in both cases radical intermediates are the driving force for reaction and can be detected by ESR (12–15). Analyses of radicals produced by high-energy irradiation (γ, electron beams) contributed to a better

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

understanding of the reaction mechanism, and to the determination of reaction rate constants; the most detailed studies were performed on polystyrene (PS) and poly(methyl methacrylate) (PMMA).

But even in systems that lack species with unpaired electrons, doping of the system with stable radicals as "spin probes," or attachment of radicals to polymeric chains as "spin labels," have extended the use of ESR methods to a large number of polymer types and self-assembled polymeric systems (9,16–21).

Since the last edition of *EPST*, ESR methods have undergone great advances in experimental techniques and in the simulation of ESR spectra. Examples include, but are not limited to, high-field ESR at frequencies up to 250 GHz, time domain (pulsed) ESR techniques, double resonance methods, and ESR imaging. Some of these important advances have extended the range and capabilities of ESR spectroscopy and have made possible the deduction of quantitative information on the structure, dynamics, transport, and distribution of paramagnetic species. The development of advanced methods for spectra simulations has made possible the deduction of detailed motional mechanisms. These novel ESR methods have been applied to polymeric systems: experimental results together with computer simulation of the line shapes have added important details concerning microphase separation and ion clustering in ionomers, chain aggregation in solutions of amphiphilic polymers, interaction of polyelectrolytes with their counterions, and structure of polyelectrolyte–surfactant complexes. In recent years ESR imaging (ESRI) methods have been developed and applied for measurements of diffusion coefficients, and for nondestructive spectral profiling of degradation processes in polymeric materials. For these reasons, this article will focus on the application and significance of recent advanced ESR methods to polymeric systems.

Fundamentals of Electron Spin Resonance (ESR) Spectroscopy

Basic Principles. The Hamiltonian energy operator $\mathcal{H}_{\text{spin}}$ for an electron spin is given by equation 1 (operators, vectors, and tensors are in bold),

$$\mathcal{H}_{\text{spin}} = g_{\text{e}}\beta_{\text{e}}\boldsymbol{S}\cdot\boldsymbol{H} \tag{1}$$

where $\boldsymbol{S}$ is the spin angular momentum, $\boldsymbol{H}$ is the magnetic field vector in gauss (G) or tesla (1 T $= 10^4$ G), β_{e} is the Bohr magneton equal to 9.274×10^{-21} erg/G (or 9.274×10^{-24} J/T), and g_{e} (equal to 2.0023 for a free electron) is the g factor or spectroscopic splitting factor (dimensionless). This spin Hamiltonian operates only on the spin wave functions α and β, whose spin angular momenta are $+1/2$ and $-1/2$ in units of $h/2\pi$; h is the Planck's constant. For a magnetic field oriented along the z direction equation 1 becomes

$$\mathcal{H}_{\text{spin}} = g_{\text{e}}\beta_{\text{e}}S_zH \tag{1a}$$

The energy difference between the two levels is $\Delta E = h\nu = g_{\text{e}}\beta_{\text{e}}H$. Typically ESR is carried out in a magnetic field of about 3500 G (or 0.35 T). The corresponding absorption frequency is ≈9.5 GHz, in the microwave frequency range known

as the X band. ESR measurements at other frequencies are also carried out, and will be described below.

The real power of electron spin resonance spectroscopy for structural studies is based on the interaction of the unpaired electron spin with nuclear spins. This interaction splits the energy levels and often allows determination of the atomic or molecular structure of species containing unpaired electrons, and of the ligation scheme around paramagnetic transition-metal ions. The more complete Hamiltonian is given in equation 2 for a species containing *one* unpaired electron, where the summations are over all the nuclei, n, interacting with the electron spin.

$$\mathcal{H}_{\text{spin}} = \beta_e \boldsymbol{H} \cdot g_e \cdot \boldsymbol{S} - \sum g_n \beta_n \boldsymbol{H} \cdot \boldsymbol{I}_n + h \sum \boldsymbol{S} \cdot \boldsymbol{A}_n \cdot \boldsymbol{I}_n + h \sum \boldsymbol{I}_n \cdot Q_n \cdot \boldsymbol{I}_n \tag{2}$$

In equation 2 $\boldsymbol{g}_e$ is the electronic g tensor, g_n is the nuclear g factor (dimensionless), β_n is the nuclear magneton in erg/G (or J/T), $\boldsymbol{I}_n$ is the nuclear spin angular momentum operator, $\boldsymbol{A}_n$ is the electron–nucleus hyperfine tensor in Hz, and $\boldsymbol{Q}_n$ (nonzero for $\boldsymbol{I}_n \geq 1$) is the quadrupole interaction tensor in Hz. The first two terms in the Hamiltonian are the electron and nuclear Zeeman interactions, respectively; the third term is the electron–nuclear hyperfine interaction; and the last term is the nuclear quadrupole interaction. For the usually investigated Kramers systems with an odd number of unpaired electrons, the transition moment is finite only for a magnetic dipole moment operator oriented perpendicular to the static magnetic field direction. In an ESR resonator in which the sample is placed, the microwave magnetic field must be therefore perpendicular to the external static magnetic field. The selection rules for the electron spin transitions are given in equation 3,

$$\Delta m_S = \pm 1 \text{ and } \Delta m_I = 0 \tag{3}$$

where m_S and m_I refer to the electron and nuclear spin quantum numbers, respectively. Transitions correspond therefore to a *change* in the electron spin orientation, and a *fixed* nuclear spin orientation. The energy difference between two adjacent transitions associated with the same type of nucleus is defined as the hyperfine constant, usually symbolized by A in frequency units (MHz). Since $\Delta m_I = 0$, the effect of the nuclear Zeeman term (second term on the right-hand side of eq. 2) and of the nuclear quadrupole term (last term on the right-hand side of eq. 2) in the spin Hamiltonian cancel out to first order. In the solid state the selection rules are not strictly obeyed when the hyperfine coupling and nuclear Zeeman interaction are of the same order of magnitude. Forbidden transitions with $\Delta m_S = \pm 1$ and $\Delta m_I = \pm 1$ then have a finite transition probability and can be used for measuring nuclear frequencies by time-domain techniques. In this situation ESR line shapes are slightly influenced by the nuclear Zeeman and nuclear quadrupole interactions.

Anisotropic g and Hyperfine Interaction. The hyperfine tensor $\boldsymbol{A}$ for each nucleus is a real 3×3 matrix that can always be diagonalized. The components of the diagonalized hyperfine tensor consist of an isotropic part, a_o, and a purely anisotropic part, $\boldsymbol{a}'$, whose orientational average is zero. Thus, the $\boldsymbol{a}'$ components are averaged out in fluid media and can only be determined in the solid state or in the case of highly restricted molecular motion. The diagonal elements

of a diagonalized hyperfine tensor are called the principal values. The *complete* hyperfine tensor (including anisotropic and isotropic contributions) is determined from single-crystal spectra, or by analysis of ESR spectra in disordered ("powder") samples, which consist of a superposition of all possible orientations.

The physical interpretation of the anisotropic principal values is based on the classical magnetic dipole interaction between the electron and nuclear spin angular momenta, and depends on the electron–nuclear distance, r_n. Assuming that both spins can be described as point dipoles, the interaction energy is given by equation 4, where θ is the angle between the external magnetic field and the direction of r_n.

$$\mathcal{H}_{spin}(\text{aniso}) = -g_e\beta_e g_n\beta_n\left[(1-3\cos^2\theta)/r_n^3\right]\boldsymbol{I}\cdot\boldsymbol{S} \tag{4}$$

Thus, for the general case of a delocalized electron spin, the anisotropic hyperfine components depend upon the orientation-weighted spatial average of ${r_n}^{-3}$ over the electronic orbital of the unpaired electron in a paramagnetic species. The number of spectral lines associated with a given interacting nucleus is $2\boldsymbol{I}_n + 1$ and the lines are of equal intensity. Often an anisotropic hyperfine interaction is accompanied by g anisotropy, and the components of the g tensor can be determined in a similar way, from ESR spectra measured in single crystals or disordered systems. Single crystal studies also allow the determination of the orientation between the principal directions of the g- and hyperfine tensors, and the crystal symmetry axes.

Analysis of the complete anisotropy (rhombic symmetry) allows the determination of the x, y, and z components of the $\boldsymbol{g}$ and $\boldsymbol{A}$ tensors. For point symmetries or pseudosymmetries that include a rotation axis C_n with $n \geq 3$, the tensors have axial symmetry; an example is seen in Figure 1**a**, for paramagnetic VO^{2+} in polyacrylamide gels swollen by water and measured at 253 K (23). The hyperfine interaction is between the electron spin and the ^{51}V nucleus ($I = 7/2$). In this case we measure the hyperfine interaction and the g value parallel to the symmetry axis of the $VO(H_2O)_5{}^{2+}$ complex ($A_\parallel$ and $g_\parallel$, respectively), and in the axial plane ($A_\perp$ and $g_\perp$), as indicated in the "stick" diagrams of Figure 1**a**.

Isotropic Hyperfine Analysis. The special case of isotropic g and hyperfine interaction will now be considered. This simplification is valid when the anisotropic interactions are averaged by rapid tumbling. The quadrupole interaction will be omitted because it is purely anisotropic. The resulting simplified spin Hamiltonian is given in equation 5.

$$\mathcal{H}_{spin}(\text{iso}) = g_e\beta_e\boldsymbol{H}\cdot S - \sum g_n\beta_n\boldsymbol{H}\cdot\boldsymbol{I}_n + h\sum A_n\boldsymbol{S}\cdot\boldsymbol{I}_n \tag{5}$$

In some systems, when an anisotropic spectrum is detected at low temperatures, increasing the temperature leads to averaging of the principal components of the hyperfine and g tensors, and therefore to isotropic spectra. As an example, we show in Figure 1**b** the ESR spectrum at 278 K of VO^{2+} in polyacrylamide networks swollen by a water/acetone mixture (80:20 v/v), which consists of eight equally spaced lines of equal intensity (22,23). The height of each line is different, because the dynamical process gives lines with different widths. The experimental spectrum is well reproduced (broken lines) using a theoretical expression for the

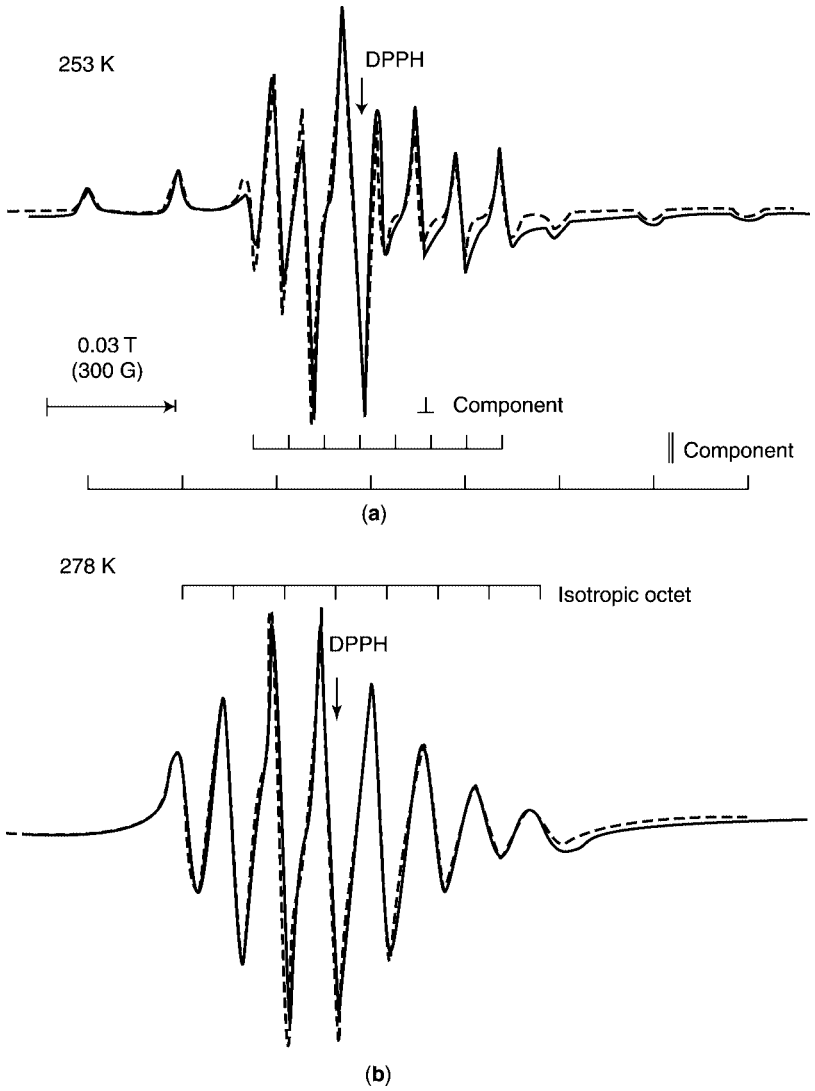

Fig. 1. X-band ESR spectra of VO^{2+} (—): (**a**) at 253 K, in chemically cross-linked polyacrylamide gels swollen by water; (**b**) at 278 K, in chemically cross-linked polyacrylamide gels swollen by water/acetone mixture (80:20 v/v). Simulated spectra (----) based on the rigid limit model in (**a**) and motionally narrowed model in (**b**). "Stick" diagrams show the positions of signals for the parallel and perpendicular components (**a**) and isotropic component (**b**). DPPH is used as a g-marker, $g = 2.0036$.

line width variation that is based on relaxation theory. The stick diagram above the spectrum shows the line positions.

Line Shape Analysis for Nitroxide Spin Probes. Nitroxide radicals as spin probes and labels are useful for the determination of the motional mechanism, rotational correlation time, τ_c, and local polarity. Figure 2**a** demonstrates that the relative line widths and line heights depend on the rotational correlation time τ_c, which is inversely proportional to the diffusion constant of rotational diffusion,

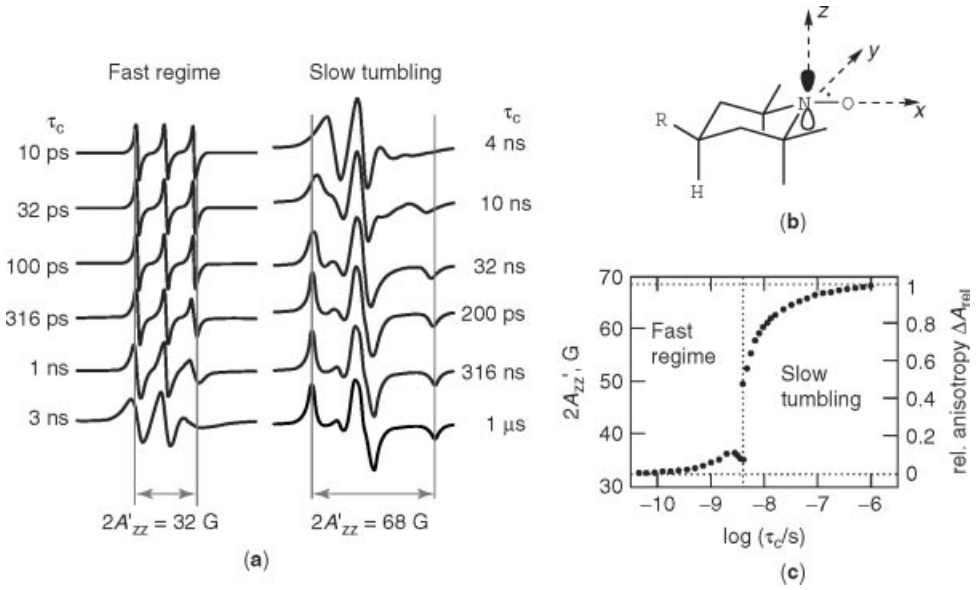

Fig. 2. (**a**) Dependence of nitroxide spectra on the rotational correlation time, τ_c, for isotropic rotational diffusion. (**b**) molecular axes system of a nitroxide radical. R is a hydrogen atom for TEMPO or a functional group in other nitroxides. (**c**) Dependence of the extreme separation, $2A'_{zz}$, and the relative anisotropy, ΔA_{rel}, on the rotational correlation time.

and can be deduced from simulating the ESR spectra. Qualitatively, τ_c can be interpreted as a typical time during which the paramagnetic species maintains its spatial orientation. The molecular axes system of a nitroxide radical is presented in Figure 2**b** (24). The motionally narrowed ESR spectrum of a nitroxide radical, corresponding to $\tau_c < 10$ ps, consists of three equally spaced signals separated by $\approx$16 G due to hyperfine splitting of ^{14}N nuclei ($a_N = 16$ G), top trace in the left panel of Figure 2**a**. The separation between the outer extrema of the spectrum in this limit is $2A_{zz,fast} \approx 32$ G. A dramatically different spectrum is observed in the rigid limit corresponding to $\tau_c > 1$ μs, where the extreme separation measured in the powder spectrum becomes $2A_{zz,slow} \approx 68$–70 G, depending on the local polarity.

In polymeric materials the rigid limit can be obtained at ambient temperatures if the polymer is below the glass-transition temperature, T_g; otherwise the sample must be cooled. For rotational correlation times between the two limits, the line shape depends strongly on τ_c. For unrestricted, isotropic tumbling, rotational correlation times can be determined from the extreme separation $2A'_{zz}$ (Fig. 2**c**). On the basis of the relative anisotropy defined in equation 6,

$$\Delta A_{rel} = (2A'_{zz} - 2A_{zz,fast})/(2A_{zz,slow} - 2A_{zz,fast}) \quad (6)$$

the line shape analysis becomes independent of the isotropic and anisotropic hyperfine coupling of the particular nitroxide.

The dynamics of spin probes in polymers is often characterized by T_{50G}, the temperature for which the extreme separation is 50 G, corresponding to $\Delta A_{rel} = 0.5$ and $\tau_c \approx 3.5$ ns. Below T_{50G} the nitroxide is in the slow tumbling regime and

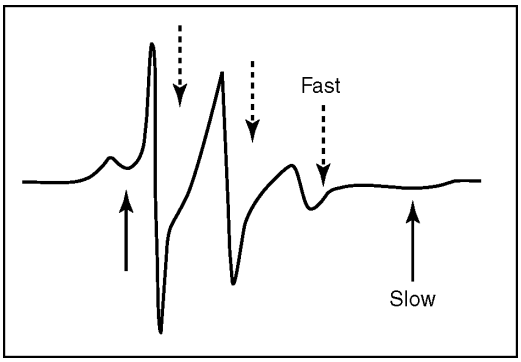

Fig. 3. X-band ESR spectrum at 300 K of a nitroxide radical derived from Tinuvin 770, a hindered amine stabilizer, in heterophasic poly(acrylonitrile–butadiene–styrene) (ABS). Fast and slow components are indicated (see text).

the spectra are anisotropic; above T_{50G} the fast regime is reached. The relation between T_{50G} (measured by ESR) and T_g (measured by DSC, for instance) depends, however, on the type of spin probe or label and its interaction with the polymer matrix.

In microphase-separated systems, ESR spectra may consist of two contributions, from nitroxides in both fast and slow tumbling regimes, thus providing evidence for the presence of two types of domains with different dynamics and transition temperatures. This case is illustrated in Figure 3 for a nitroxide radical in heterophasic poly(acrylonitrile–butadiene–styrene) (ABS); the fast and slow components in the ESR spectrum measured at 300 K are indicated, and represent radicals in butadiene-rich and acrylonitrile/styrene-rich domains, respectively (25).

Advanced ESR Methods

Multifrequency (MF) and High Field (HF) ESR. ESR spectra are often measured at a frequency of ≈9.4 GHz (X band), because of convenient sample size and availability of commercial spectrometers. Multifrequency ESR has been proven beneficial for both the quality and quantity of information that can be obtained. The optimal frequencies are system dependent: spectra at 35 GHz (Q band) are used to increase the separation (in G) when species differing in g values are present. The corresponding magnetic field at Q band is ≈12,000 G. Because large g anisotropies are detected for transition-metal ions, ESR spectra at Q band are useful for discriminating between ions in different environments. In recent years, however, it has become evident that microwave frequencies *lower* than 9 GHz are sometimes the best choice, especially in disordered systems, where local heterogeneities ("strain") lead to a distribution of ESR parameters and to considerable line broadening. This conclusion emerged from a study of $^{63}Cu^{2+}$ in Nafion perfluorinated ionomers swollen by acetonitrile: the line width of the parallel component, $\Delta H_{\parallel}$, in the ESR spectrum was studied at four microwave frequencies, in the range 1.2–9.4 GHz (26). The narrowest line widths for the $m_I = -3/2$ and $-1/2$ signals (the two low-field lines of the parallel quartet) were

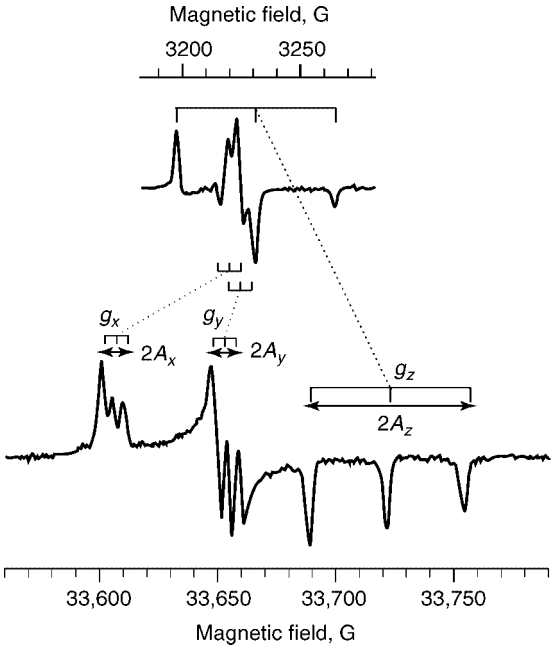

Fig. 4. ESR spectra of aqueous solution of a perdeuterated nitroxide PDTEMPONE in toluene-d_8 at 130 K (at or close to the rigid limit). Top: at 9 GHz. Bottom: at 94.4 GHz. Principal values of the g and A tensors are shown respectively by vertical bars and horizontal arrows. To convert G to T, multiply by 1×10^{-4}. Redrawn from Ref. 11, with permission.

detected at C band (4.7 GHz) and L band (1.2 GHz), respectively. Signals at Q band and higher frequencies are excessively broadened by strain.

HF ESR has been utilized to advantage for increasing the resolution in terms of the g tensor components; Figure 4 presents a comparison of ESR spectra of a nitroxide radical at 9 GHz (top) and at 94.4 GHz (bottom) (11). Major advantages of HF ESR are: improved accuracy in the determination of the principal values of the g tensor, the ability to measure splittings in the x and y directions that are not resolved at X band, and increased ability to resolve species with different magnetic parameters.

Time-Domain ESR Methods. Performing ESR experiments with pulsed instead of continuous irradiation provides great flexibility for designing experiments that can be adapted to specific problems. In general, such time-domain experiments can be used to distinguish between different types of spin relaxation and to separate the various interactions in the spin Hamiltonian (8). Separation of interactions corresponds to an increase in resolution and allows precise measurement of small contributions to the spin Hamiltonian in the presence of line broadening due to larger contributions. Such techniques are therefore most useful for solid materials or soft matter, where ESR spectra are usually poorly resolved.

Solid-state time-domain ESR is usually based on echo experiments. The transverse magnetization is excited by a pulse with a flip angle of $\pi/2$ and decays within the deadtime t_d of the spectrometer following the high-power pulse. In the two-pulse echo experiment this transverse magnetization is refocused by a second pulse with a flip angle of π, which is applied after a delay $\tau > t_d$ with respect

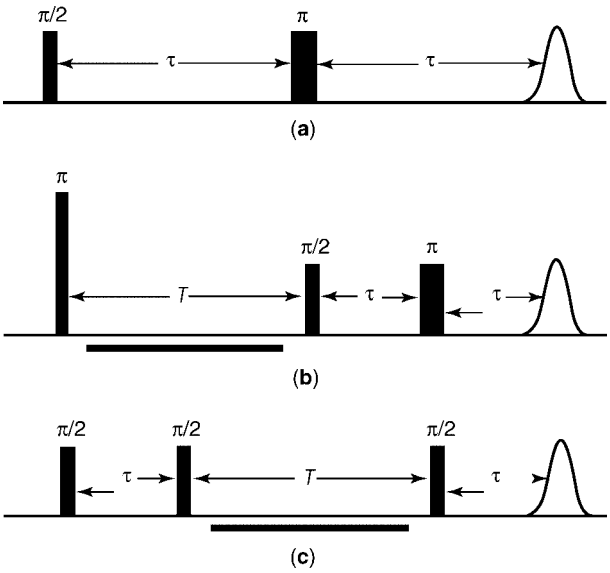

Fig. 5. Pulse sequences for basic time-domain ESR and pulsed ENDOR experiments. (**a**) Primary echo experiment. (**b**) Inversion recovery experiment (variation of T) or Davies ENDOR. (**c**) Stimulated echo experiment or Mims ENDOR. For ENDOR experiments, the horizontal bar in (**b**) and (**c**) indicates a radiofrequency pulse, whose frequency is varied while all interpulse delays are fixed.

to the first pulse (Fig. 5**a**). The integral of the echo signal centered at time 2τ is measured either as a function of the static field H at constant τ (echo-detected ESR spectroscopy), or as a function of τ at constant H. In the latter experiment we observe the echo decay due to transverse relaxation with time constant T_2. Combining the variations of the two parameters in a two-dimensional experiment allows the characterization of the anisotropy of T_2, which is in turn related to the specific motion of the paramagnetic center in the material.

To measure the longitudinal relaxation time T_1, an inversion or saturation pulse is applied, followed, after a variable time T, by a two-pulse echo experiment for detection (Fig. 5**b**). The inversion or saturation pulse induces a large change of the echo amplitude for $T \ll T_1$. With increasing T, the echo amplitude recovers to its equilibrium value with time constant T_1. The echo amplitude of the stimulated echo (Fig. 5**c**) decays with time constant T_2 when the interpulse delay τ is incremented, and with the stimulated-echo decay time constant $T_{SE} \leq T_1$ when the interpulse delay T is incremented. A faster decay, compared to inversion or saturation recovery experiments, can arise from spectral diffusion, because of a change of the resonance frequency for the observed spins, of the order of $\Delta\nu = 1/\tau$ on the time scale of T. Quantitative analysis of spectral diffusion can provide information on the reorientation dynamics of the paramagnetic centers.

Double Resonance Methods. Electron nuclear double resonance (ENDOR) is the effect of applying a radiofrequency that induces nuclear spin flips, in addition to the microwave frequency that induces electron spin flips. In the CW version of the experiment, the ENDOR effect is an *increase* in the intensity of

a partially saturated ESR signal when the applied radiofrequency field partially desaturates the transition (27,28).

Experimentally, ENDOR is carried out by fixing the external magnetic field on a hyperfine line, and sweeping the radiofrequency from 1 to ≈100 MHz. ENDOR lines are observed, corresponding to the different nuclei coupled with the electron spin in the paramagnetic system. ENDOR lines are centered on *either* the free nuclear frequency ν_n, *or* half the hyperfine constant $A/2$, depending on the relative magnitudes of these two frequencies. If $\nu_n > A/2$, as is common for small *proton* hyperfine couplings, the ENDOR lines are centered around ν_n; for spin 1/2 nuclei two ENDOR transitions, at $\nu_n \pm A/2$ for each chemically distinct nucleus, are observed. If $A/2 > \nu_n$, the ENDOR lines appear at $A/2 \pm \nu_n$ for each ESR line observed. In both cases the coupled nucleus can be identified from the value of ν_n.

Matrix ENDOR. Structural information can be obtained from an analysis of *matrix* ENDOR signals, from nuclei situated at large distances from the paramagnetic centers (usually >5Å); these nuclei interact with the electron only through dipolar interaction. By interpreting the matrix ENDOR signal, it is possible to measure distances between the paramagnetic center and the nuclei (for instance ^{19}F), even if the electron–nuclear interaction is too small to be measured directly by ESR. In liquids the matrix ENDOR line is averaged to zero by rapid tumbling of the radical. In disordered systems such as powders and glasses, the matrix ENDOR line dominates the spectrum and masks small splittings. In order to extract these small interactions, the matrix line must be simulated using a suitable theoretical model (29). The line width of the matrix ENDOR signal has been used to estimate the distance between the interacting nuclei and the electron spins in Nafion ionomers (30,31).

Pulsed ENDOR. In both the inversion recovery (Fig. 5**b**) and stimulated echo experiment (Fig. 5**c**), the echo amplitude is influenced by a radiofrequency pulse applied during the interpulse delay of length T, if this pulse is on-resonance with a nuclear transition. In the former experiment, such a pulse exchanges magnetization between inverted and noninverted transitions, so that echo recovery is enhanced (Davies ENDOR) (32). In the latter experiment the on-resonance radiofrequency pulse induces artificial spectral diffusion, so that the echo amplitude decreases (Mims ENDOR) (33). These pulsed ENDOR experiments exhibit less baseline artifacts and are easier to set up compared with CW ENDOR experiments, as the required mean radiofrequency power is smaller and the ENDOR effect does not depend on a certain balance of relaxation times. Davies ENDOR is better suited for couplings exceeding 1–2 MHz, while Mims ENDOR is better suited for small couplings, for instance matrix ENDOR measurements.

Pulsed ELDOR. Distances between electron spins can be measured by double electron–electron resonance (DEER) experiments such as the four-pulse experiment illustrated in Figure 6 (34). Similar to measurements of electron-nucleus distances, this technique is based on the r^{-3} dependence of the magnetic dipole interaction between electron spins and can determine larger distances, in the range 1.5–5 nm. One of two spins (color-coded green, observer) is observed by a refocused primary echo with fixed interpulse delays τ_1 and τ_2, so that relaxation does not induce variations in the echo amplitude during the experiment. The second spin (color-coded red, pumped) imposes a local dipole field at the site of the first spin, with a magnitude that depends on the distance. At a variable delay t with respect

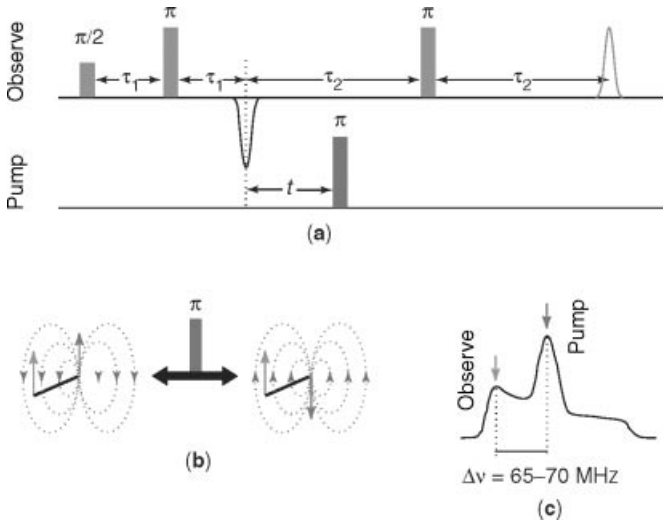

Fig. 6. The four-pulse DEER experiment. (**a**) Pulse sequence consisting of a refocused primary echo subsequence with fixed interpulse delays for the observer spins (top) and a pump pulse at variable delay t with respect to the first primary echo (bottom). (**b**) The pump pulse inverts the local field at the site of the observer spin (left arrow in each panel) imposed by a pumped electron spin (right arrow in each panel). (**c**) Observer and pump positions in an echo-detected EPR spectrum of a nitroxide.

to the first primary echo, a pump pulse inverts this local field (Fig. 6**b**). In this way the resonance frequency of the first spin is changed and the second echo refocusing is perturbed. As a result, the echo amplitude is modulated by the dipolar frequency

$$\nu_{\mathrm{dip}} = (g\beta_{\mathrm{e}})^2/h[(1-3\cos^2\theta)/r^3] \tag{7}$$

By analyzing the dependence of the echo amplitude on the delay t, it is possible to determine the spin–spin pair correlation function, which corresponds to the distribution of electron spins in the vicinity of the observed spin (35,36). Such spatial distributions of spin probes or spin labels can be interpreted by a model-free approach if they are reasonably narrow, or by simple models for the geometry of the system under investigation, if they are broad (37–39). The experiment requires that observer and pumped spins be excited separately, a condition that is easily achieved for nitroxide spin probes and labels by setting the difference of the two excitation frequencies to 65–70 MHz (Fig. 6**c**).

ESR Imaging

Paul Lauterbur was the first to propose, in his notebook entry of 2 September 1971, the use of magnetic field gradients in order to "tell exactly where a nuclear magnetic resonance (NMR) signal came from"; his first proton density map appeared soon afterwards (40). The name he coined for the technique, *zeugmatography*, comes from the Greek word for "joining together," meaning to join the magnetic field gradient and the corresponding radiofrequency in an NMR experiment. This connection allowed to encode spatial information in the NMR spectra. The use

of magnetic field gradients to separate the resonant frequencies corresponding to different spatial elements led to the development of NMR imaging (NMRI) or, in current language, magnetic resonance imaging (MRI). In the last 20 years, NMRI has blossomed into an essential diagnostic procedure in medicine that provides an image of previously hidden anatomic parts. Applications of NMRI to materials science and other important disciplines, although not as dramatic as the medical applications, are steadily developing (41). The wonderful story on the discovery of NMR imaging has been told recently (42).

Imaging based on magnetic field gradients can also be applied to imaging of unpaired electron spins via electron spin resonance (ESR) spectroscopy. The advantages of ESR imaging (ESRI) are the specificity for the detection of paramagnetic species, and the high sensitivity. Papers describing the feasibility of ESRI started to appear in the late 1970s and continue to this day. The early instrumentation, software, and applications of ESRI have been described in a 1991 monograph (43). The challenges in the application of the Lauterbur method to ESRI are numerous: First, higher gradients are needed compared to NMRI, usually 100–1000 times larger. Second, the ESR spectra are often complex and contain hyperfine splittings that complicate the ESRI experiments. Third, most systems do not contain stable paramagnetic species on which imaging is based; ESR imaging is usually performed on radicals produced by irradiation, paramagnetic transition-metal ions, or stable nitroxide radicals as dopants.

As seen in the 1991 monograph, the early efforts laid the foundation for the hardware necessary for ESRI and developed the software necessary for image reconstruction in 1-D (spatial) and 2-D (spectral–spatial and spatial–spatial). These studies also investigated the feasibility of ESRI experiments in a variety of "phantom" samples, and discussed and estimated the spatial resolution. The resolution in most ESRI experiments is of the order of 50–100 μm, but can vary widely, depending on the ESR line shapes and line widths.

Information on the spatial distribution of paramagnetic molecules deduced from ESRI experiments has been used successfully for measurement of the translational diffusion. Diffusion coefficients of paramagnetic diffusants can be deduced from an analysis of the time dependence of the concentration profiles along a selected axis of the sample. The determination of diffusion coefficients for spin probes in liquid crystals and model membranes, and the effect of polymer and probe polydispersity, have been described in a series of papers by Freed and co-workers (44). These papers represent an effort to move beyond phantoms, and to extract quantitative information from ESRI experiments.

The ability to perform ESRI is restricted to a small number of groups worldwide. While most groups study biological applications of ESRI (45–48), a small number of studies on polymeric materials have appeared: Diffusion coefficients of guests in ion-containing polymers, polymer solutions, cross-linked polymers swollen by solvents, and in self-assembled polymeric surfactants have been determined by 1-D ESRI (49–52). Lucarini and co-workers have determined by 1-D ESRI the distribution of the nitroxide radicals in UV-irradiated polypropylene (PP) containing a hindered amine stabilizer (HAS) (53–55). Ahn and co-workers have deduced the concentration profile of heat-induced radicals in a polyimide resin (56). *In vitro* degradation of poly(ortho esters) containing 30 mol% lactic acid has been studied by 1-D and 2-D spectral–spatial ESRI, based on pH-sensitive nitroxide spin probes (57). Spatially resolved degradation in heterophasic

polymer systems, such as poly(acrylonitrile-butadiene-styrene) (ABS) and ethylene–propylene copolymers (HPEC), has been described in a series of recent papers (19,25,55,58–64).

ESR Spectra in the Presence of Field Gradients. ESR spectroscopy can be transformed into an imaging method for samples containing unpaired electron spins, if the spectra are measured in the presence of magnetic field gradients. In an ESR imaging experiment the microwave power is absorbed by the unpaired electrons located at point x when the resonance condition, equation 8, is fulfilled.

$$\nu = (g\beta_e/h)(H_{\text{res}} + xG_x) \tag{8}$$

In equation 8 G_x is the linear magnetic field gradient (in G/cm) at x. As in NMR imaging, the field gradients produce a correspondence between the location x and the resonant magnetic field H_{res}. If the sample consists of two point samples, for example, the distance between the samples along the gradient direction can be deduced if the field gradient is known (65). An example is shown in Figure 7, for a "phantom" consisting of two parallel capillary tubes (55).

The spatial resolution, Δx, is an important parameter in imaging, and can de defined in various ways, as discussed recently (66); the resolution depends on the line width and line shape. Most commonly Δx is expressed as the ratio of the line width to the field gradient, $\Delta H/G_x$; this definition implies that two signals separated by one line width due to the field gradient can be resolved.

An ESR imaging system can be built with small modifications of commercial spectrometers: gradient coils fixed on the poles of the spectrometer magnet, regulated DC power supplies, and required computer connections. In most systems

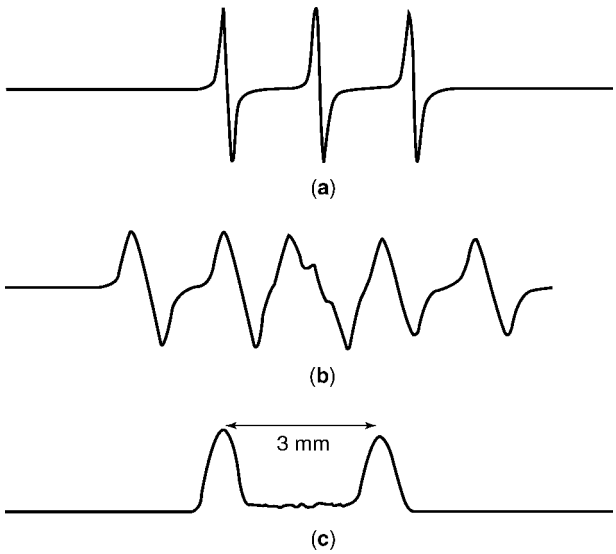

Fig. 7. 1-D ESRI at 298 K of a phantom consisting of two parallel capillary tubes separated by 3 mm and filled with a solution of TEMPO in benzene. (**a**) X-band ESR spectrum recorded in the absence, and (**b**) in the presence of the magnetic field gradient (100 G/cm). The radical distribution is shown in (**c**). Redrawn from Ref. 55, with permission.

the software for image reconstruction in 1D and 2D ESRI experiments must be developed on site.

Intensity Profiling from 1-D ESRI. In the general case, the sample contains a distribution of paramagnetic centers along a given direction, for example x. The ESR spectrum in the presence of the magnetic field gradient is a superposition of signals from paramagnetic centers located at different positions. In 1-D ESRI experiments, the intensity profile is obtained from two ESR spectra: $F_0(H)$ measured in the absence of magnetic field gradient, and $F(H)$ measured in the presence of the gradient.

Mathematically, $F(H)$ is a convolution of $F_0(H)$ with the distribution function of the paramagnetic centers (43,67), equation 9,

$$F(H) = \int_{-\infty}^{\infty} F_0(H - H^*)C(H^*)\mathrm{d}H^* \tag{9}$$

where $H^* = H_0 - xG, H_0 = h\nu/g\beta_e$, and $C(H^*)$ is the intensity distribution (profile) of the paramagnetic centers along the gradient direction. It is essential to note that the convolution expressed in equation 9 is correct only if the ESR line shape *has no spatial dependence.* As will be seen below, this requirement has dictated the conditions for data acquisition in the 1-D ESRI study of degradation processes.

Various optimization methods are viable alternatives to the deconvolution method. The process starts by assuming an initial distribution, which can be described by some parameters. In diffusion studies, for example, the initial distribution is calculated as a function of the diffusion coefficient, diffusion time, and other parameters that define the sample configuration (49,50). Optimization methods use the convolution of this initial distribution function with the experimental spectrum in the absence of magnetic field gradient in order to calculate the spectrum in the presence of the gradient. The deviation between the calculated and the experimental spectra is then minimized by an optimization procedure. In our initial ESRI studies, the concentration profiles of the radicals were deduced by Fourier transform followed by optimization with the Monte Carlo (MC) procedure (53–55). The disadvantage of this method is the high frequency noise present in the optimized profiles. In more recent publications, the intensity profile was fitted by analytical functions and convoluted with the ESR spectrum measured in the absence of the field gradient in order to simulate the 1-D image. The best fit was obtained by variation of the type and parameters of the analytical functions chosen (Gauss or Boltzmann, for example) in order to obtain good agreement with the 1-D image, and selected by visual inspection (62,63).

Lately the genetic algorithm for minimization of the difference between simulated and experimental 1-D images was implemented; this procedure allowed the best fit to be chosen automatically (64). A typical genetic algorithm (GA) consists of creation of the initial population, calculation of the fit to experimental data, selection of the couples, crossover (reproduction), and mutation. The approach and terminology are adopted from biology and resemble fundamental steps in evolution.

Line Shape Profiling from 2-D Spectral–Spatial ESRI. Each 2-D image is reconstructed from a complete set of projections, collected as a function of the magnetic field gradient, using a convoluted back-projection algorithm (58).

The number of points for each projection (1024) is kept constant. The maximum experimentally accessible projection angle, α_{max}, depends on the maximum gradient G_{max} according to $\tan \alpha_{max} = (L/\Delta H)G_{max}$, where L is the sample length, and ΔH is the spectral width. The maximum sweep width is $SW_{max} = \sqrt{2}\Delta H/\cos\alpha_{max}$. For a width $\Delta H \approx 65$ G (which is typical for the slow-motional spectral component of a nitroxide radical present in irradiated polymers), a sample length of 4 mm, and a maximum field gradient of 250 G/cm along the vertical axis, we obtain $\alpha_{max} = 57^\circ$ and $SW_{max} = 169$ G. A complete set of data for one image consists of 64–128 projections, taken for gradients corresponding to equally spaced increments of α in the range -90° to $+90^\circ$; for a total of 64 projections, typically 41 or 43 are experimentally accessible projections and the rest are projections at missing angles (for α in the intervals 60° to 90°, and -60° to -90°). The projections at the missing angles can be assumed to be the same as those at the maximum experimentally accessible angle α_{max}, or determined by the projection slice algorithm (PSA) with several iterations (43,63,64).

Spin Probes in Ion-Containing Polymers

Ionomers (qv) are polymers that contain a small fraction of ionic groups, typically less than 15 mol%. The percentage is calculated from the number of backbone atoms or repeat units to which the ionic groups are attached. This definition is not completely specific, because the ionic groups are often at the end of pendant chains of varying lengths or part of different structures. For this reason, the equivalent weight (EW), which is the amount of ionomer (in g) containing one mole of ionic groups, is also an indication of the ionic content. The definition in terms of ion content or EW is of course useful for comparison of ionomers with the same, or very similar, backbone and pendant groups (68–70).

The ionic groups, although present in small amounts, dominate the viscoelastic behavior of ionomers, their transport properties and their ability to sorb a variety of solvents; moreover, the ion effect is specific. In terms of morphology, the presence of ions leads to microphase separation into ionic and nonpolar domains. Increasing interest in structural aspects of ionomers is closely related to their numerous applications as bulk materials, in various devices, as catalysts, in controlled release systems, and as proton exchange membranes (PEM) in fuel cells (71).

Small-angle X-ray and neutron scattering, SAXS and SANS, respectively are important methods for the study of ionomer morphology, because an extra peak (the "ionic peak") is detected in ionomers and is absent in the polymers that consist of the organic backbone alone. The value of the scattering vector corresponding to maximum scattering intensity has been used to deduce a characteristic size of the ionic domains. The appearance of the ionic peak is a function of temperature, solvent structure and content, and degree of neutralization. The absence of the ionic peak is sometimes explained by a fortuitous cancellation of electron densities (72–75).

Spectroscopic data offer a more local view of the ionomer structure, and can be considered complementary to the small-angle scattering methods. Binding of paramagnetic cations in Nafion ionomers has been studied by multifrequency ESR and simulations (76). Self-assembling of ion-containing polymers, as swollen

membranes and in solutions, was extensively studied in recent years by ESR spectroscopy of nitroxide radicals as spin probes (76–83). The most important nitroxide spin probes used were the amphiphilic *n*-doxylstearic acids [*n*DSA (**1**, X = H, Na; $n = 5, 7, 10, 16$] and their corresponding methyl esters [*n*DSE (**1**), X = CH_3; $n = 5, 7$]; hydrophobic doxyl-substituted hydrocarbons such as 5-doxyldecane (5DD)(**2**) and 10-doxylnonadecane (10DND) (**3**); and cationic probes with different lengths of the alkyl substituents CAT1 (**4**) and CAT16 (**5**). The spin probe method is based on the exceptional sensitivity of the nitroxide ESR line shapes to the local environment, and of the ^{14}N hyperfine splittings to the polarity of the medium. Depending on probe hydrophobicity, charge, length of the alkyl chain, and, in the case of amphiphilic probes, position of the nitroxide group with respect to the polar head group, different regions of self-assembled systems can be identified and studied. The ESR spectra of the probes are a rich source of information on local properties such as viscosity, molecular packing and ordering, polarity, and the presence of ions in the probe vicinity, on a nanoscale range, typically 0.5–5 nm.

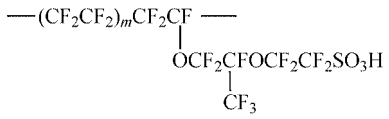
5

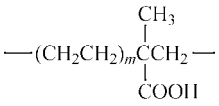
Some of the probes mentioned above have been used for a comparative study of Nafion perfluorinated ionomer (**6**) neutralized by Li^+, and the protiated ionomer

poly(ethylene-*co*-methacrylic acid) (EMAA) (**7**) neutralized by Na^+ and K^+, as dry or water-swollen membranes and in aqueous solutions.

Both materials at ambient conditions are insoluble in water. They can be dissolved, however, at high temperatures in an autoclave, using ethanol/water mixture as a solvent for Nafion, and alkaline water for EMAA. Aqueous solutions of Nafion can be obtained by dialysis of alcoholic solutions against water. Recent SAXS and SANS experiments on a range of Nafion concentrations, for volume fractions in the range 0.16–0.95 measured in a wide range of scattering vectors introduced the novel idea of Nafion organization, based on aggregation of ionomer chains into elongated polymer bundles surrounded by the electrolyte solution (74,75). Aggregation into spherical or elipsoidal micelles in EMAA has been demonstrated by SAXS experiments (72,73).



6



7

The ESR spectra of the nitroxide probes in Nafion and EMAA have been in agreement with the scattering results, and have provided additional local details on the aggregates. In addition, the spectra have revealed important differences between EMAA and Nafion systems. In the case of EMAA micelles, probes based on doxylstearic acid have exhibited the "dipstick effect": their dynamics became slower as the probe penetrated deeper inside the aggregate, from the hydrophilic *n*DSA to the hydrophobic *n*DSE, and from 5DSA or 5DSE to 10DSA or 10DSE, respectively. The ^{14}N hyperfine splitting, a_N, decreased in the same order, indicating a polarity gradient from the polar interface to the nonpolar aggregate interior (79,80,82).

In the case of Nafion micelles, the mobility also decreased in the order 5DSA > 10DSA > 10DSE, but all three probes reported a polar environment. The decreased mobility was explained by assuming that the probes intercalate between perfluorinated polymer chains; the high polarity at the probe site was thought to be a result of the water present inside the micelles. This explanation was supported by the results of a fluorescence study using pyrene (P) as a polarity probe (84). Results obtained for the cationic probes CAT*n* have also indicated the penetration of the protiated segments of the probe inside the perfluorinated host aggregates, and have suggested that the amount of water in Nafion micelles increases in more dilute ionomer solutions (81).

On the basis of the ESR study a structural model of internal structure of EMAA aggregates was proposed, as seen in Figure 8 (right panel). According to the model, the EMAA micelle consists of three regions: the hydrophobic core of polyethylene chains, an intermediate layer which contains both ionomer chains

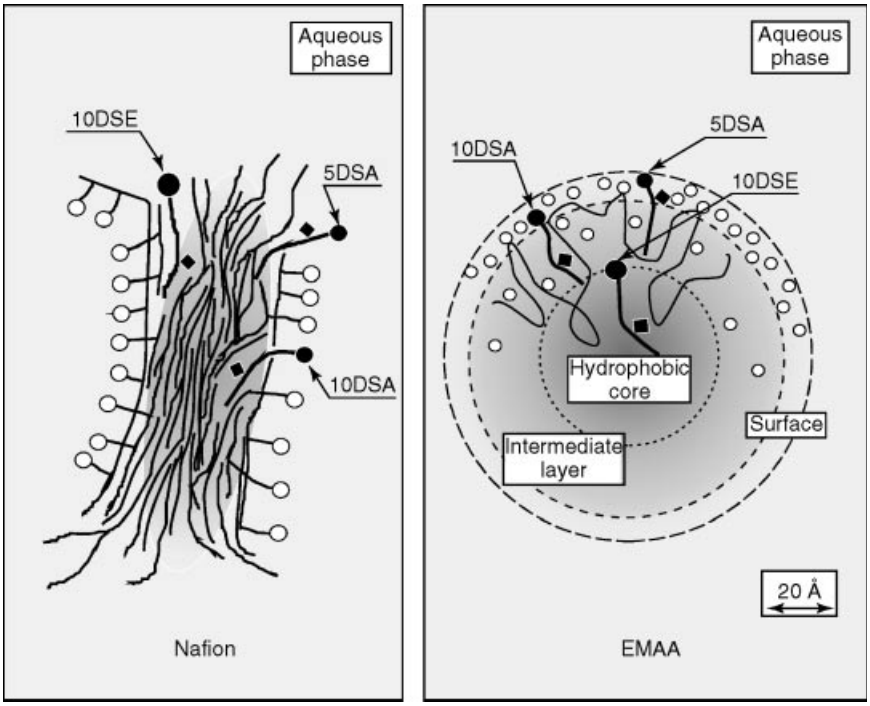


Fig. 8. Structural models of large aggregates in ionomer solutions, and suggested locations for doxyl spin probes based on ESR results: ●, probe head groups; ◆, nitroxide groups; ○, ionomer head groups.

and some ions, and a hydrophilic surface layer where most of the ions are located. The carboxylic groups of *n*DSA probes are anchored in this layer, while the heads of esters are located at the interphase between the core and intermediate layer (79,80). In Nafion micelles, as in EMAA micelles, the nitroxide group of 5DSA is located closer to the surface than that of 10DSA, and 10DSE radical is most deeply buried in the aggregate (Fig. 8, left panel). In the case of 10DSE the preferred chain orientation is parallel to the long axis of the rod, as suggested by the value of the parallel component of the rotational diffusion tensor, which was deduced from simulations (78).

The local structure in and near the ionic aggregates in EMAA ionomer membranes neutralized by Na^+ was investigated as a function of the degree of membrane neutralization, x, by spin probe ESR using 5DSA, 7DSA, 10DSA, 7DSE, and 10DND as spin probes (82). The ESR studies revealed that the five spin probes used are position-selective, and provide local information on different regions in the self-assembled ionomers. Three hydrophilic doxylstearic acid probes (*n*DSA) are anchored to the ionic aggregates, two (5DSA and 7DSA) are located in the ionic core and one (10DSA) is in the hydrocarbon shell; the two hydrophobic probes (7DSE and 10DND) report on the amorphous region. The extreme separation (ES) of the probes is sensitive to the local environment, as seen in Figure 9; ES is also sensitive to the degree of neutralization (82).

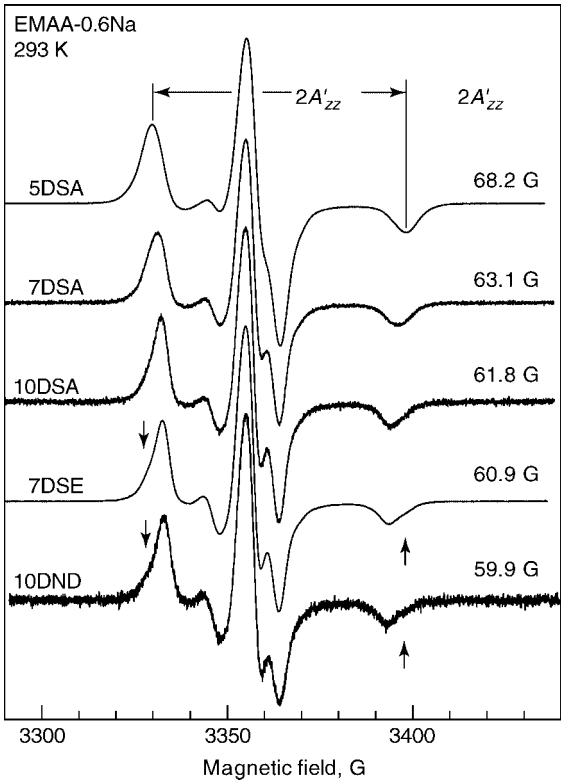

Fig. 9. X-band ESR spectra at 293 K for the indicated spin probes in EMAA-0.6Na. Spectra are normalized to a common microwave frequency (9.43 GHz). Microwave power, 1 mW; modulation amplitude, 1 G. (To convert G to T, multiply by 1×10^{-4}.) The corresponding extreme separation, $2A'_{zz}$, is shown on the right. Downward and upward arrows point to the incipient shoulders in the low field and high field signals for 7DSE and 10DND, respectively; these shoulders are more pronounced for higher degrees of neutralization. From Ref. 82, with permission.

The local polarity was expressed in terms of the polarity index $\Delta A_o = a_N$ (ionomer) $-a_N$ (np), where a_N (ionomer) is the isotropic ^{14}N hyperfine splitting in the ionomer, and a_N (np) is the corresponding value in a nonpolar medium; this definition implies a higher polarity index, ΔA_o, in a more polar environment, as seen in Figure 10**a**. The variation of the polarity indices of these position-selective probes as a function of the degree of neutralization indicated the presence of an ion-depleted zone (hydrocarbon shell) surrounding the ionic core, and also the presence of a small amount of isolated ionic groups in the amorphous regions. Suggested locations of the different probes in the membranes are shown in Figure 10**b**. The structural features deduced by spin probe ESR were in support of the SAXS profile analysis based on a depleted-zone core–shell structure of the aggregate. The SAXS studies provided additional information on the geometrical shape and size of the aggregate, and the number of ionic groups in each aggregate. Thus, microstructural insights into the ionic aggregate from both approaches, polarity from ESR and electron density from SAXS, are consistent and complementary.

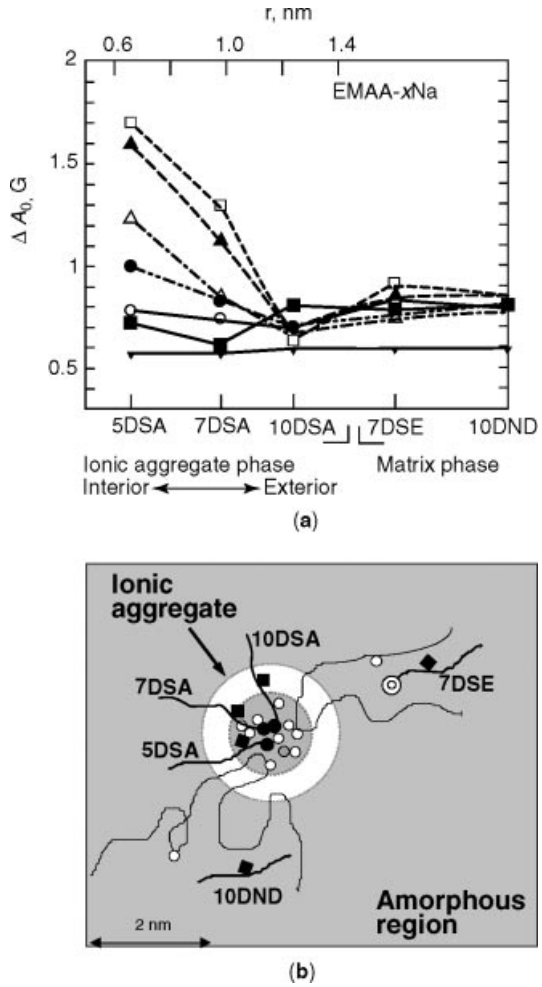

Fig. 10. (**a**) Variation of the polarity index, ΔA_0 in G, for the five spin probes in EMAA-xNa (x in the range 0–0.9) with the distance from the center of the ionic aggregate, r, together with the data for low density polyethylene (LDPE). The r values were assumed identical to the distance of the nitroxide group from the carboxylic group in the nDSA probes. —□— $x = 0.9$, —▲— $x = 0.8$,—△—$x = 0.6$, —●— $x = 0.4$, —○— $x = 0.2$, —■— $x = 0$ —▼— LDPE. (**b**) Suggested locations of 5DSA, 7DSA, 10DSA, 7DSE, and 10DND probes in dry EMAA ionomers, based on the analysis of the ESR results: ○ the carboxylate and carboxylic acid groups of the ionomer; ●, and the acid groups; ◎, the methyl ester group; and ■, the nitroxide groups of the probes are indicated. Dark shaded, white, and grey-shaded regions represent, respectively, the ionic core and hydrocarbon shell (ion-depleted zone) of the aggregate, and the amorphous region. From Ref. 82, with permission.

Pulsed ESR Studies in Ionically End-Functionalized Block Copolymers

Telechelic ionomers are a special class of ionic polymers in which the charged groups are situated exclusively at the chain ends (see TELECHELIC POLYMERS (85,86)) Accordingly, their solid-state structure is characterized by self-assembly of the chain ends into ion multiplets or ionic clusters. Because of this defined

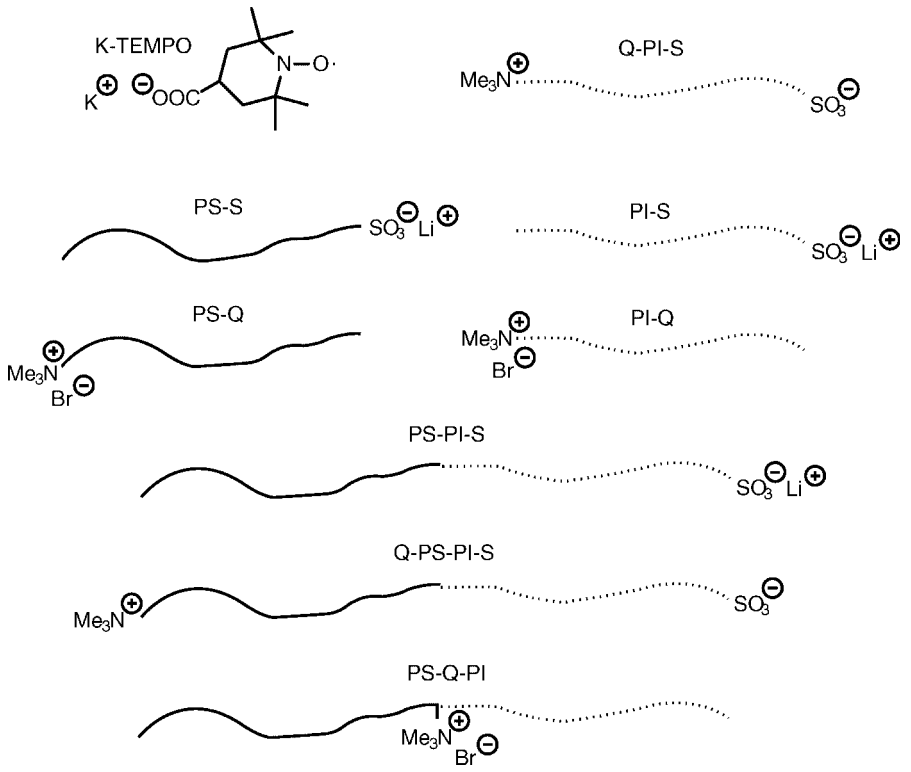

Fig. 11. Structure of the anionic spin probe K-TEMPO and schematic structures of telechelic ionomers. Solid lines denote polystyrene blocks, while dotted lines denote polyisoprene blocks.

topology, telechelic ionomers form less complex structures compared with random ionomers, and can be used as a point of departure for studying the balance between electrostatic self-assembly and self-assembly induced by microphase separation of diblock copolymers (87). For such a study it is advantageous to include reference samples that carry one ionic group at the chain junction (Fig. 11) in which ionic clusters are situated in the interface between the microphases. As in the case of random ionomers, the properties of the ionic clusters in such systems were interrogated by ionic spin probes (86,87), as initially established by the CW ESR techniques discussed in the previous section. With respect to its size and ion site, the anionic nitroxide probe K-TEMPO (Fig. 11) used with the telechelic ionomers resembles the cationic CAT1 probe and is thus expected to be located at the cluster surface or even inside the cluster.

Interestingly, K-TEMPO probes in monoionic block copolymers of type polystyrene–polyisoprene (notation PS-PI-S, where S stands for the spin probe) exhibited homogeneous dynamics, ie, a relatively narrow, monomodal distribution of rotational correlation times; by contrast, the same probes in zwitterionic block copolymers of type Q-PS-PI-S (where Q stands for a quaternary ammonium group) exhibited heterogeneous dynamics, ie, a bimodal distribution of rotational correlation times (87). By comparison of results for telechelic homopolymeric

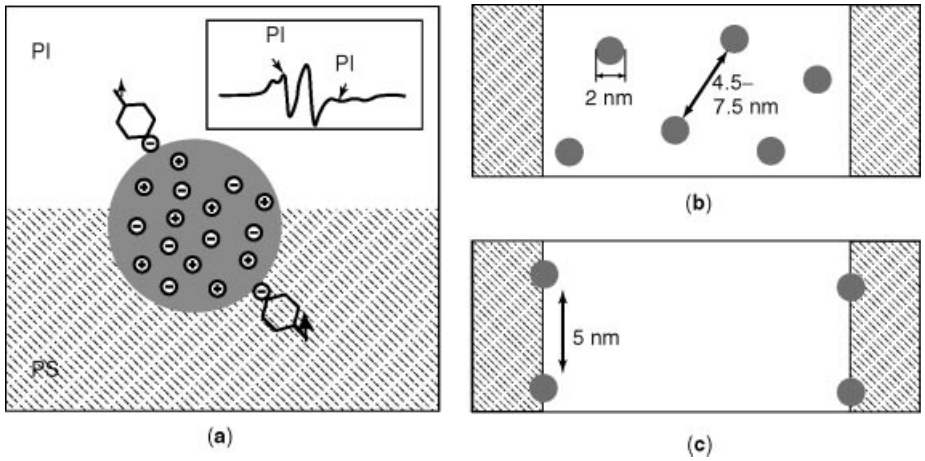

Fig. 12. Ionic clusters in telechelic ionomers based on diblock copolymers (see also Fig. 11). (**a**) Spin probes attached to ionic clusters located at the interface between the polystyrene (PS) and polyisoprene (PI) microphases. The inset shows the CW ESR spectrum for PS-Q-PI, where Q is a quaternary ammonium group. The fast component (arrows) was assigned to probes in the PI microphase. (**b**) The distribution of ionic clusters in monoionic diblock copolymers suggested by DEER experiments. (**c**) The distribution of ionic clusters in zwitterionic diblock copolymers suggested by DEER experiments.

ionomers PS-S, PS-Q, PI-S, and PI-Q, the fast component could be assigned to probes in a PI matrix, and the slow component to probes in a PS matrix. For both components, T_{50G} was significantly higher than for similarly sized spin probes in unfunctionalized PI and PS, respectively. Taken together, these results suggested that the probes are located at the surface of the ionic cluster, which in the zwitterionic case is situated at the interface between the PS and PI microphases (Fig. 12**a**). If the probes were located mainly inside the clusters or if the clusters would have a preference for one of the microphases, a monomodal distribution of rotational correlation times would be expected. The interpretation of clusters at the interface was supported by three additional results: the fractions of the two components are rather similar for the zwitterionic case, the same type of behavior is observed for the monoionic diblock copolymer with an ionic group at the chain junction (PS-Q-PI), and the fractions depend on the morphology of the diblock copolymer and thus on the curvature of the interface (87,88).

Characterization of cluster sizes and cluster distribution by SAXS was not successful, as the electron density contrast between PS and PI leads to SAXS curves that are strongly dominated by features due to block copolymer morphology. Therefore, the ionic peaks could not be detected. As the K-TEMPO spin probes are attached to the clusters and both cluster sizes and intercluster distances are expected to fall in the sensitive range of DEER experiments (1.5–8 nm), this problem was addressed by pulsed ELDOR distance measurements (37,88). For such studies, a ratio of 2:15 between the spin probe and chain end concentrations was chosen. Assuming that on the average 12–20 chain ends assemble into a cluster (89), the spin pairs have similar probabilities of being located on the same cluster and on directly neighboring clusters. Accordingly, the DEER signal is the product

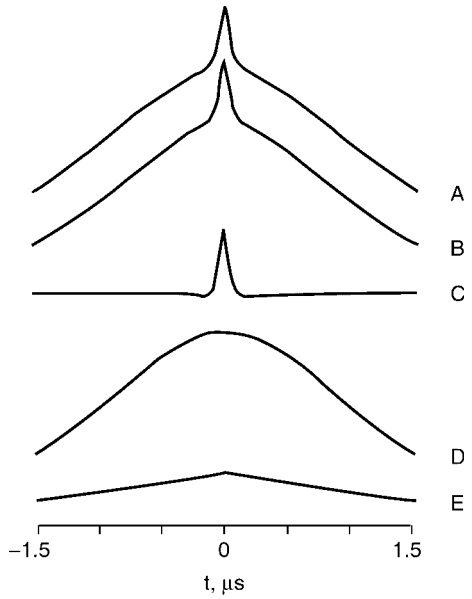

Fig. 13. Experimental four-pulse DEER signal for ionomer PI-Q and deconvolution into its components. (A) Experimental data. (B) Best fit. (C) Fast decaying component due to spin probes located in the same cluster, with a characteristic distance of 2.2 nm. (D) Slow modulation due to spin probes in vicinal clusters, with a characteristic distance of 6.6 nm. (E) Exponential background due to spin probes in remote clusters.

of three contributions: a fast decaying oscillatory part corresponding to spin probes located on the same cluster, a slowly decaying modulation corresponding to spin probes located on directly neighboring clusters, and a very slow exponential background decay due to spin probes located on remote clusters (Fig. 13). Mean distances and distance variations for the first two components were determined by fitting a distance distribution consisting of two Gaussian peaks and a constant background contribution to the data. The mean distance of the first peak (spin probes on the same cluster) roughly corresponds to the radius of the cluster, while the mean distance of the second peak corresponds to the intercluster distance for direct neighbors (37).

In general, we find that cluster radii vary only slightly (r_{cluster} = 1.8–2.2 nm); the only exception was a PS-S sample with a low molecular weight, M_{n} = 4.8 kg/mol, for which the radius was 1.4 nm. No significant correlation between cluster size and polymer chain length was found when varying the molecular weight of diblock copolymer samples between 10 and 50 kg/mol (see solid circles in Fig. 14**a**). This result agrees with earlier work on α, ω-dicarboxylatopoly(butadienes) and α,ω-dicarboxylatopolyisoprenes, in which the size of the clusters (or multiplets) also appeared to be independent of chain length (90). Analysis of SAXS data for ion domain radii was not attempted for the homopolymers or the diblock copolymers, but had been performed for the α, ω-dicarboxylatopoly(butadienes) and α, ω-dicarboxylatopolyisoprenes (90). In these cases r_{cluster} ranged from 0.6 to 1.1 nm, which is somewhat surprising given the fact that clusters of both quaternary ammonium end groups and sulfonate

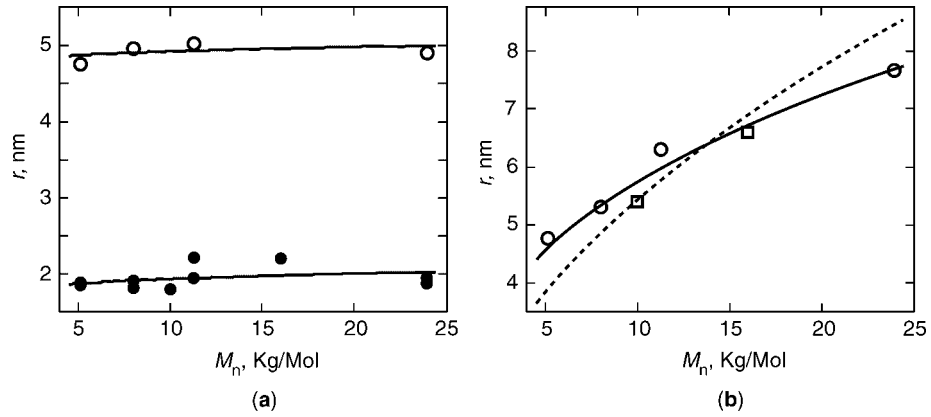

Fig. 14. Scaling of characteristic distances between anionic K-TEMPO spin probes in ionomers based on diblock copolymers. (**a**) Direct neighbor distance between clusters in zwitterionic diblock copolymers Q-PS-PI-S (○), cluster radii of all samples (●). Solid lines are best-fit scaling laws (see text). (**b**) Direct neighbor distance in monoionic diblock copolymers PS-PI-S (○) and in monoionic homopolymers PI-S (□). The solid line is the best fit for a scaling law with exponent 1/3, and the dashed line is the best fit for a scaling law with exponent 1/2.

end groups are apparently twice as large. Molecular modeling suggests that the cluster size for aggregates of 10–12 chain ends should be closer to the DEER values than to the SAXS values. In the latter case, radii were calculated from the surface-to-volume ratio S/V, which is measured, by assuming spherical objects. While for such spherical objects S/V scales with r^{-1}, slight deviations from a spherical shape lead to a large increase in S/V, which in turn corresponds to an underestimate of the mean radius (37).

Direct-neighbor distances between clusters obtained by SAXS and DEER could be compared to each other for the three homopolymeric ionomers PI-Q, PI-S, and Q-PI-S with molecular weights of the polymer chain of 10 kg/mol (37). Distances determined by DEER were found to be 1–1.5 nm shorter than distances obtained by SAXS, but showed the same trend, a decrease in the sequence PI-Q, PI-S, Q-PI-S. The difference may be due to the fact that the spin probes are attached to the cluster surface and the r^{-3} averaging inherent in DEER data overemphasizes shorter distances, so that DEER actually measures the surface-to-surface distance of the clusters while SAXS measures the distance between the centers of clusters. We note however that the Bragg equation underlying the analysis of SAXS data is not expected to be strictly valid for systems lacking long-range order, so that part of the deviation might also be attributed to a systematic error in the SAXS measurements.

Significantly, DEER measurements also provided intercluster distances for the homopolymers, for which the ionic peak cannot be detected reliably in SAXS curves, and for the diblock copolymers, where it cannot be detected at all. The scaling coefficient x in $r = AM_n^x$ for the intercluster distances r with molecular weight M_n provides information on the spatial distribution of the clusters. In earlier work on α, ω-dicarboxylatopolybutadienes and α, ω-dicarboxylatopolyisoprenes, the range of molecular weights was too narrow for a definite conclusion about

this scaling, but extrapolation of the SAXS data to $M_n = 0$ suggested a scaling coefficient of $x \approx 1/2$ (90). This result is somewhat surprising, as any deviation from $x = 1/3$ implies a nonuniform distribution of clusters in the matrix. A nonuniform distribution can be expected for the diblock copolymers if the clusters were either attracted or repelled by the interface between the two blocks, but cannot be easily understood for the homopolymers. Indeed, DEER data provided $x = 0.311$, ie, a scaling exponent very close to 1/3 even for monoionic diblock copolymers PS-PI-S with lamellar morphology (Fig. 14**b**). The M_n range of the PI block, 5.1–24 kg/mol, is broad enough to exclude a scaling coefficient of 1/2, which corresponds to a fit with a root-mean-square error that is 3 times larger than for the fit with scaling coefficient 1/3. This result indicates that the ionic clusters are distributed throughout the PI microphase, ie, they are neither repelled nor attracted by the interface region. Hence, electrostatic self-assembly and block copolymer morphology are apparently independent of each other for the *monoionic* telechelic ionomers.

A different cluster distribution was detected for the zwitterionic case, as seen by comparing the open circles in Figure 14**a** and 14**b**. For the zwitterionic samples Q-PS-PI-S the best fit $r = AM_n^x$ provided a scaling coefficient of 0.016, which does not significantly differ from zero. Indeed a scaling coefficient $x = 0$ is expected for a two-dimensional distribution of clusters that are strictly confined to the interface between the PS and PI microphases, as the number of clusters per unit interface area does not depend on M_n, as long as the number of chain ends per cluster does not depend on M_n. The latter assumption is strongly suggested by the constant size of the clusters. Nevertheless, the absence of any significant changes is somewhat suprising, given the fact that a solid-state NMR study of related nonionic diblock copolymers indicated a thickness of the interfacial region of several nanometers as far as chain ordering is concerned (91). Taken together the data may then suggest that the interactions that govern ion cluster distribution dominate over the interactions that govern this chain ordering close to the interface. This poses the question whether in monoionic diblock copolymers changes in chain dynamics imposed by the interface are still detectable close to the ion clusters, which reside exclusively in one of the microphases.

Comparison of T_{50G} values from CW ESR experiments on monoionic homopolymers (86) and diblock copolymers (87) does not indicate significant differences in the dynamics of the ionic spin probes. However, the CW ESR experiments may not be very suitable for answering this question, as they are most sensitive to differences in dynamics at 330 K, which is significantly higher than the T_g of the PI microphase (270–280 K). Dynamics at temperatures below T_g can be characterized by relaxation measurements in high field ESR echo experiments (92). Comparison of echo decay time constants for PI-S and PS-PI-S at 260 K revealed that only the longitudinal relaxation times T_1 obtained by saturation recovery are the same for both cases, while both T_2 and the decay time constant of the stimulated echo T_{SE} differ between the homopolymer and diblock copolymer. For an M_n of PI of approximately 10 kg/mol, T_2 values are up to 20% and T_{SE} values up to 50% longer than for the diblock copolymer. Hence, anchoring of PI chains to the more rigid PS blocks leads to a change of chain dynamics that is sufficient to influence small-angle reorientation of the ionic spin probe K-TEMPO. This probe is attached to the ionic clusters, ie, it resides in the vicinity of the other end of the PI chain. We note however that this result does not necessarily imply that

the changes in dynamics are transmitted by a single PI chain over its full length; the slight immobilization may be caused by the collective behavior of the PI microphase in the vicinity of the block copolymer interface.

A more detailed analysis of dynamics of the ionic spin probe for the monoionic homopolymer PI-S revealed hierarchical processes on different time scales (93). Fast *intramolecular* libration on a time scale of a few picoseconds is the dominating contribution to longitudinal relaxation (T_1), which explains why T_1 is rather insensitive to changes in the environment of the spin probe. This environment can be considered as a cage of the spin probe that consists of the polymer chains and, on one side, of the surface of the ionic cluster. Reorientation of this cage on a time scale of a few hundred nanoseconds is the main contribution to transverse relaxation, so that T_2 is sensitive to polymer chain dynamics. The anisotropy of this reorientation motion can be characterized in detail by performing the experiments at W-band frequencies of ~94 GHz, where the x, y, and z directions of the molecular frame of the nitroxide molecule (Fig. 2**b**) are resolved (Fig. 4). Using this information on anisotropy and the constraints on dynamics derived from the CW ESR line shape and stimulated echo decay, it can be shown that the local rearrangement has to be described as anisotropic free rotational diffusion that covers an angular range of only 3–4°. This process does not couple strongly to the glass transition.

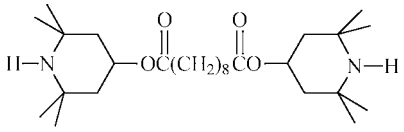
Finally, stimulated echo decay is sensitive to spin probe reorientation on a time scale of several microseconds. It can be demonstrated that the process governing T_2 is not sufficient to explain this decay, as is also suggested by the qualitatively different temperature dependence of T_2 and T_{SE} in the range $0.64 < T/T_g < 1.05$. Stimulated echo decay is almost independent of temperature below T_g but becomes much faster as the glass-transition temperature is approached, because stimulated echo decay requires jump reorientation, which becomes much more likely when cooperative dynamics sets in at T_g. Although DSC does not detect a significant change in T_g between PI matrices in homopolymeric and copolymeric ionomers, such changes are highly significant in the stimulated echo decay. Again this appears to be a matter of different time scales, on the time scale of DSC of a few seconds the subtle differences between the two polymers are lost.

Spatially Resolved Degradation from 1-D and 2-D Spectral–Spatial ESRI Experiments

During degradation (qv) processes polymers lose some of their most important properties: strength, flexibility, and the ability to withstand extreme temperatures and chemicals. Oxygen, sunlight, and heat are the major factors in the degradation process. The oxidative degradation of polymeric materials can be viewed on the molecular level as a cascade of events triggered by chemically reactive molecules such as free radicals ($R^\bullet$, $RO^\bullet$ and $ROO^\bullet$), and hydroperoxides (ROOH). The modification of the polymer properties due to exposure to environmental factors is both on the molecular and macroscopic levels: change of the chemical structure (double bond formation, chain scission, and cross-linking), and of the elastic moduli. Accelerated degradation is often performed in the laboratory, and the results are interpreted in terms of polymer lifetimes in actual applications (94–97).

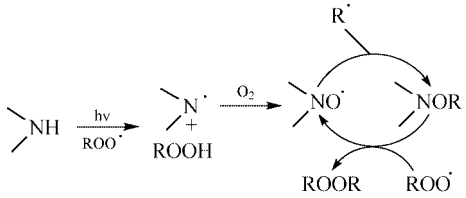
Recent advances in the understanding of degradation processes are anchored on the finding that polymer degradation is often spatially heterogeneous. When the rate of oxygen diffusion is not sufficient to supply all the oxygen that can be consumed, only outside layers in contact with oxygen are degraded, whereas the sample interior is protected: this is the diffusion-limited oxidation (DLO) regime (98–100). The DLO concept implies that in order to understand degradation and predict lifetimes of polymeric materials in different environments, it is necessary to develop profiling methods that determine the variation of the extent of degradation within the sample depth.

In this article the focus will be on the application of one-dimensional (1-D) and two-dimensional (2-D) spectral–spatial ESRI to the photo- and thermal degradation of poly(acrylonitrile-butadiene-styrene) (ABS) (19–55,58–63). The ESRI approach was applied to ABS because it represents a polymer that is exceptionally important in technological applications, yet is also vulnerable to photo- and thermal degradation, and can be used only in the presence of protective additives. Hindered amine stabilizers (HAS), for instance bis(2,2,6,6-tetramethyl-4-piperidinyl) sebacate (Tinuvin 770, (**8**)), are added for stabilization of polymeric materials (101,102).



8

The HAS-derived nitroxides are thermally stable, but can react with free radicals (as scavengers) to yield diamagnetic species; the hydroxylamines can regenerate the original amine, thus resulting in an efficient protective effect. Equation 10 presents some of the chemical processes involving HAS during exposure to radiation and oxygen. The presence of nitroxide radicals in HAS-stabilized polymers makes possible the ESRI experiments, with the radicals providing the imaging contrast.



10 (10)

The HAS-derived nitroxides in the ABS and in the heterophasic ethylene–propylene copolymers (HPEC) also studied (64) by ESRI perform a triple role. First, they provide the contrast necessary in imaging experiments; second, they probe the morphology of the system, in terms of glass-transition characteristics and dynamics; and third, they reflect the degradation process. Once ESRI data were collected, and transformed into intensity profile (from 1-D ESRI) and spectra

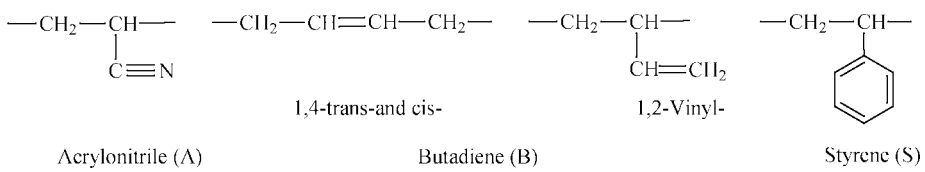


Fig. 15. Repeat units in ABS polymer.

as a function of sample depth (from 2-D ESRI), the remaining challenge is to translate information extracted from ESRI experiments into details on degradation kinetics and mechanism.

As will become clear from the results presented below, the spatial heterogeneity in the distribution of nitroxide radicals deduced by 1-D ESRI as a result of photo- and thermal degradation has been taken as an indicator of heterogeneous degradation Moreover, nitroxide radicals reflect not only the spatial extent of degradation, but also events that occur in different morphological domains: In recent studies of ABS polymers, 1-D and 2-D spectral–spatial ESRI images have enabled the visualization of the selective damage, along the sample depth, in butadiene (B)-rich domains, compared to styrene/acrylonitrile (SAN)-rich domains.

ABS polymers are complex, multiphase materials consisting of a butadiene (B) core to which a copolymer of styrene (S) and acrylonitrile (AN) has been grafted (Figure 15) (103). The SAN-rich phase is normally continuous, and the size of the B-rich ("rubber") domains is ≤ 1 μm in emulsion polymerization, and 0.5–5 μm in mass polymerization. The properties of ABS polymers can be modified by variation of the grafting conditions and monomer ratio, to produce a polymer suitable for specific applications (104). Most ESRI experiments were performed on ABS containing $\approx$10% B (Magnum 342 EZ, from Dow Chemical Co.), doped with 2 wt% Tinuvin 770 (**8**). The notation is ABS2H. For the ESRI experiments, cylindrical samples 4 mm in diameter were cut from the plaques; the samples were placed vertically in the ESR resonator, with the symmetry axis along the field gradient.

X-band ESR spectra at 300 K of the HAS-NO in UV-irradiated ABS for the indicated irradiation time in the weathering chamber are presented in Figure 16**a**. All spectra, except that corresponding to the longest irradiation time ($t = 2425$ h), consist of a superposition of two components, from nitroxide radicals differing in their mobility: a "fast" component (F, width $\approx$32 G), and a "slow" component (S, width $\approx$64 G). These spectra indicated the presence of HAS-NO radicals in two different environments, and were assigned to nitroxides located respectively in low T_g domains dominated by B sequences ($T_g \approx 200$ K), and in high T_g domains dominated by S ($T_g \approx 370$ K) or AN sequences ($T_g \approx 360$ K), as also seen in Figure 3. The relative intensity of the F component decreased with increasing irradiation time, and was negligible for $t = 2425$ h. Subtraction of the spectrum of the slow component (upper spectrum in Fig. 14**a**) from composite spectra gave the fast component; by superimposing the two components, it was possible to reproduce all composite spectra and to determine the relative concentration of each component. The decrease of the relative intensity of F with irradiation time was explained by the consumption of the HAS-derived nitroxide radicals located in B-rich domains of the polymer, as the B component is expected to be more vulnerable to degradation compared with the other repeat units in ABS (33).

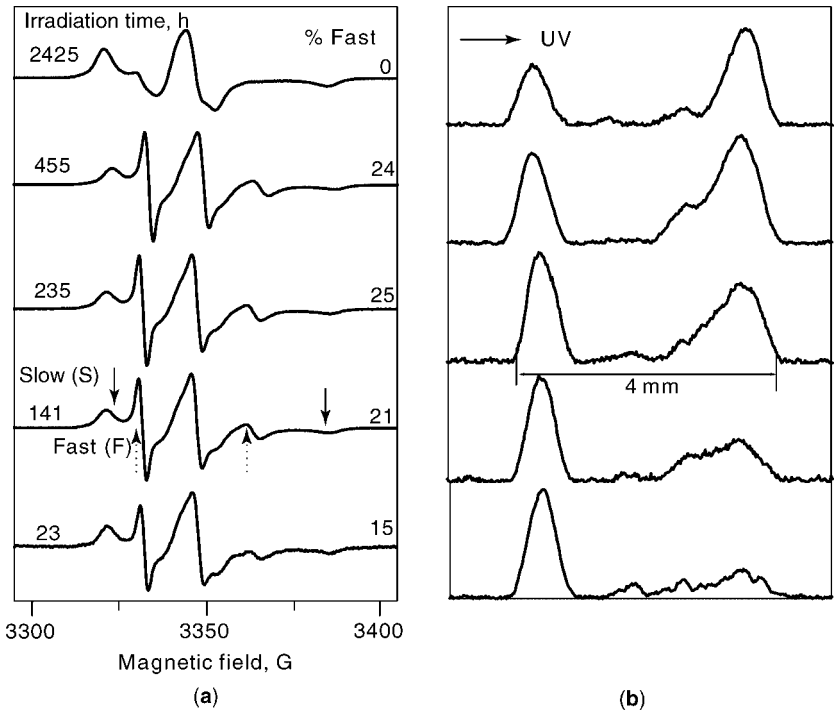

Fig. 16. (**a**) X-band ESR spectra at 300 K of ABS containing Tinuvin 770 for the indicated irradiation times. Vertical arrows point to the extreme low and high field features of the "slow" (S) and "fast" (F) spectral components, respectively. The percentage of the fast component, %F, in each spectrum is indicated. (**b**) Concentration profiles for the indicated irradiation times in the weathering chamber. The horizontal arrow indicates the irradiated side of the sample. From Ref. 55, with permission.

The presence of the two spectral components, F and S, is due to the heterophasic nature of ABS. The variation of the F/S ratio with irradiation time is, however, due to chemical reactions; in this way a connection was established between the concentration and ESR line shapes of the nitroxides, and the degradation process.

Figure 16**b** shows nitroxide profiles along the irradiation depth, deduced by deconvolution of 1D ESR images measured at 240 K; this temperature was chosen in order to avoid spatial variation of the line shapes. The larger nitroxide concentration near the outer planes of the sample and the gradual increase of the nitroxide concentration at the nonirradiated side clearly indicated the combined effects of oxygen and UV radiation, and the onset of DLO conditions. We note that the signal on the nonirradiated side appeared also in samples whose back was covered with aluminum foil, indicating that the radicals present on this side are not formed by direct irradiation, for instance, by scattered light. The mechanism responsible for the appearance of radicals on the nonirradiated side is currently under investigation in our laboratory.

Figure 17 presents 2-D spectral–spatial perspective and contour images of nitroxide radicals in ABS UV-irradiated for 70 h (in A) and for 643 h (in B) in the weathering chamber. The ESR intensity is presented in absorption mode.

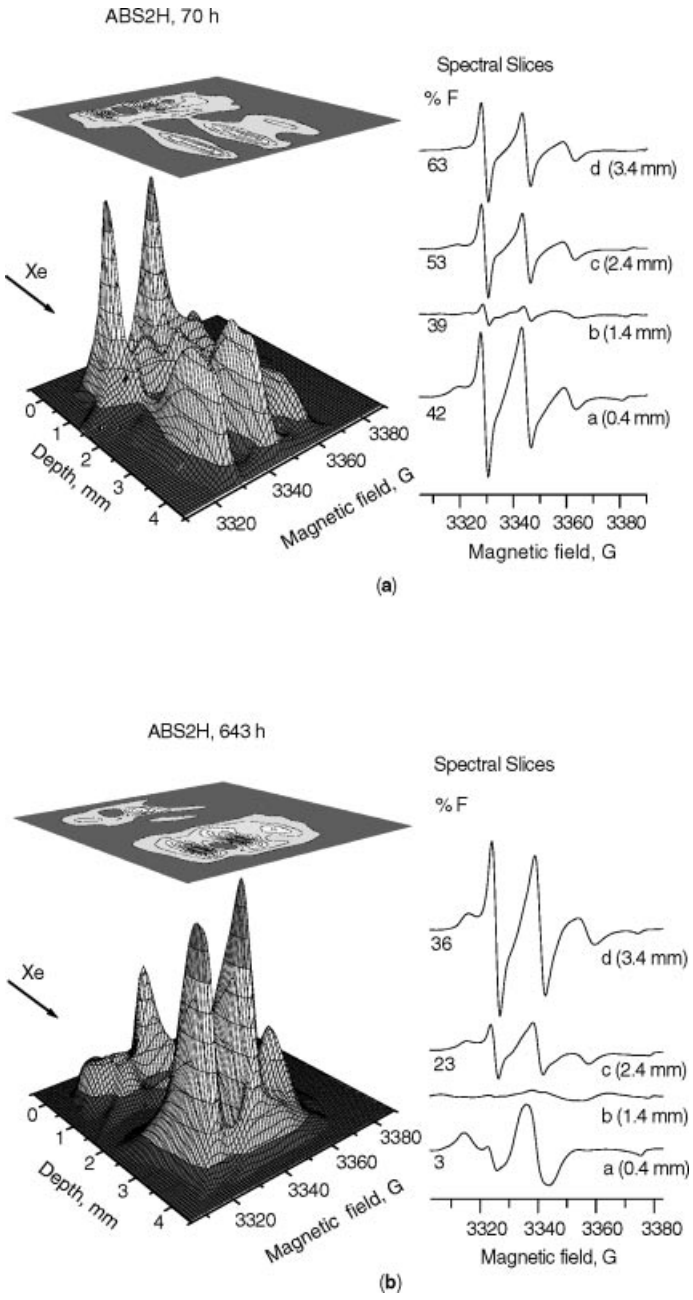

Fig. 17. 2-D spectral-spatial ESRI contour (top) and perspective (bottom) plots of HAS-derived nitroxides in ABS2H after 70 h (**a**) and 643 h (**b**) of irradiation by the Xe arc in the weathering chamber, presented in absorption. The spectral slices a, b, c, and d for the indicated depths are presented in the derivative mode; these slices were obtained from digital (nondestructive) sections of the 2-D image. %F is shown for a, b, c, and d slices in (**a**) and for a, c, and d slices in (**b**). Both 2-D images were reconstructed from 83 real projections, Hamming filter, 2 PSA iterations, $L = 4.5$ mm, $\Delta H = 70$ G, and were plotted on a 256×256 grid.

To the right we also present the corresponding "virtual" spectral slices (in the derivative mode) obtained nondestructively at the indicated depths of the sample (slices a–d). The perspective plot and the spectral slices indicate the line shape variation and the relative intensity of each spectral component as a function of depth. For the short irradiation time ($t = 70$ h) the ESR spectrum of the directly irradiated part of the sample exhibits two spectral components with $\%F \approx 42$; near the nonirradiated side $\%F = 63$. After 643 h of irradiation, the irradiated side contains no fast component, and %F is significantly lower at and near the nonirradiated side. Section b in Figure 17**b** represents a very weak signal and %F was not calculated for this section. The major conclusion from the 2-D images presented in Figure 17 is that the nitroxides in the B-rich domains are consumed rapidly on the irradiated side, and their concentration decreased to zero after 643 h of irradiation. On the nonirradiated side the degradation is less pronounced, but even on this side a decrease of %F is detected when the irradiation time increases from 70 to 643 h.

Spectral profiles can be deduced from 2-D spectral–spatial ESRI, as shown in Figure 18: the evolution of %F along the sample depth as a function of irradiation time ($t = 70$ and 643 h). The plots do not include data at depth range 0.5–1.7 mm because the intensity of the signal is too low and the margin for error in %F is too large. As the %F reflects the nitroxide radicals located in the B-rich domains, the profiles presented in Figure 18 can also be considered as *elastomer profiles*: a look into spatial changes in the elastomeric properties of ABS as degradation progresses.

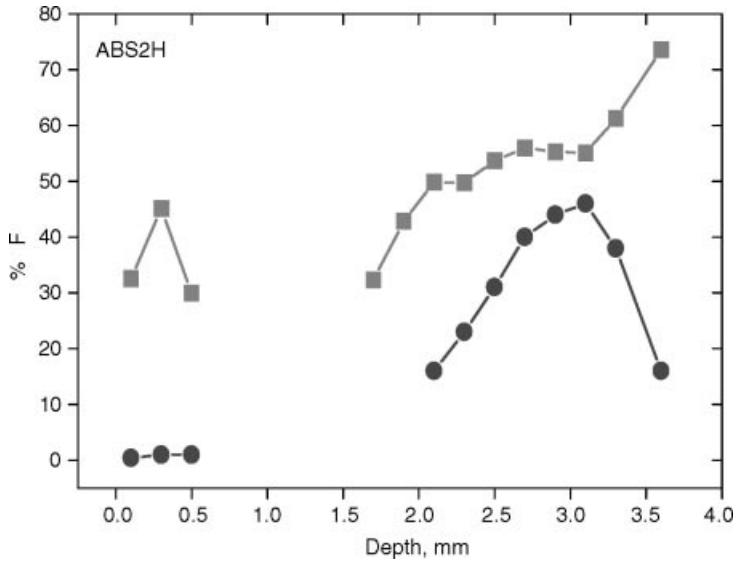

Fig. 18. Percentage of the fast component of HAS-derived nitroxides (%F) as a function of depth in ABS2H for the indicated irradiation times by the Xe arc in the weathering chamber: ■, 70 h Xe; ●, 643 h Xe. 834 h. Data were deduced from digital (nondestructive) sectioning of the 2-D spectral-spatial ESR images, such as those presented in Figure 17; see text. From Ref. 60, with permission.

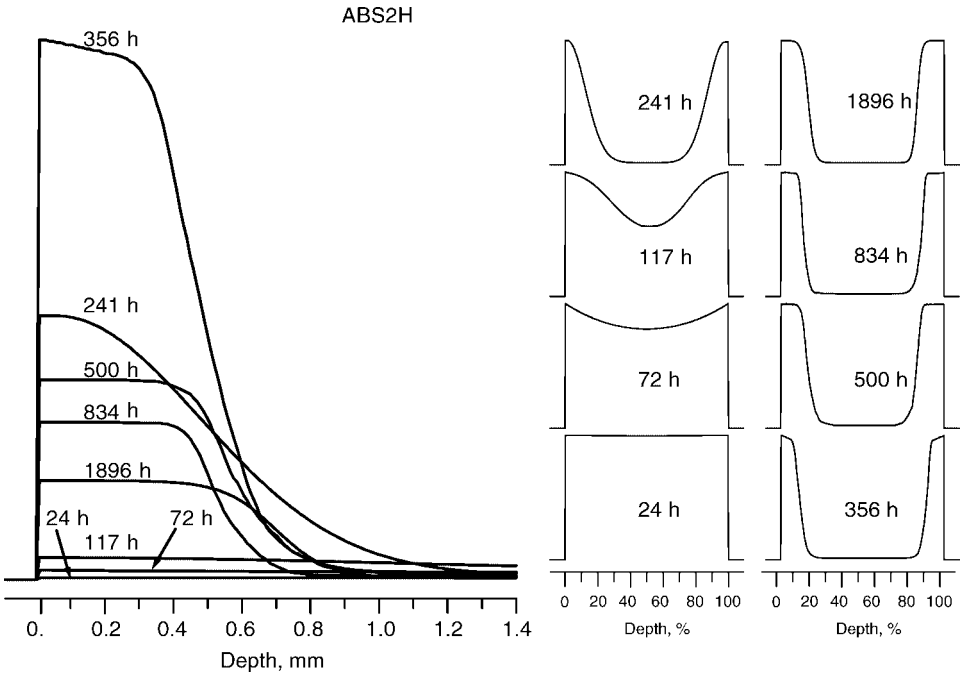

Fig. 19. Right: 1-D concentration profiles for ABS2H for the indicated time of thermal treatment at 393 K, Left: 1-D concentration profiles normalized to the corresponding nitroxide concentration. Only one side of each (symmetrical) profile is shown. From Ref. 62, with permission.

The concentration profiles for the indicated thermal treatment at 393 K are shown in Fig 19; the profiles were deduced by simulation of 1-D ESR images measured at 240 K. All profiles on the right side are presented with the same maximum height; the profiles on the left are given for one side of the samples (because of symmetry), and normalized by the nitroxide concentration measured in whole samples. The evolution from flat profiles in the initial stages of thermal ageing to spatially heterogeneous profiles due to DLO is clearly seen in Figure 19. The 1-D profiles indicate that the HAS-derived nitroxides are located at the two sample extremities, in regions of widths it is 500–600 μm in ABS2H. Figure 20 presents *spectral profiles* as a result of thermal treatment of ABS2H at 393 K for $t = 72$, 241, and 834 h. As in the data shown in Figure 18, the F component was assigned to nitroxides located in PB (elastomeric) domains. Conclusions from the ESRI experiments were substantiated by attenuated total reflectance (ATR) FTIR spectroscopy of microtomed samples of the polymer (60–63,105).

In conclusion, results from ESR imaging, together with the determination of the nitroxide concentration, allowed the mapping of the temporal and spatial variation of the nitroxides, depending on the irradiation source, and the time and temperature of treatment. Moreover, the nondestructive ESRI method is sensitive to early stages in the degradation process, and is expected to be complementary to existing profiling methods, for instance FTIR, which are normally applied to more advanced stages of degradation. Finally, the ESRI is of special interest for

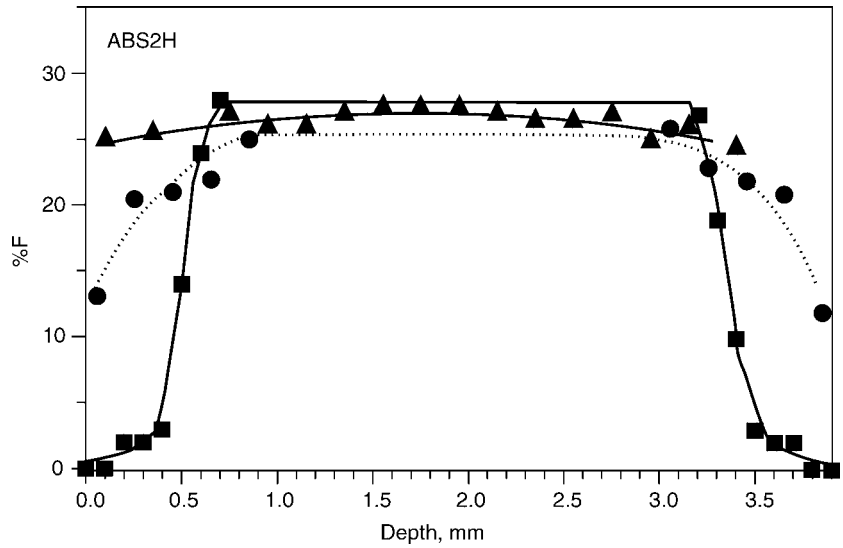

Fig. 20. Spectral profiling as a function of sample depth for ABS2H for the indicated time of thermal treatment at 393 K: ▲, 72 h; ●, 241 h; ■, 834 h. Data points were deduced from 200-μm-thick virtual slices in the corresponding 2-D spectral-spatial ESR images.

the study of polymers with phase-separated morphologies. In ABS and HPEC systems, ESRI studies have demonstrated a hierarchical variation of the HAS-derived nitroxide concentration: within the sample depth on the scale of millimeters, and within morphological domains on the scale of a few micrometers. As a result, it has become possible to establish an elastomer profile, which tracks the evolution of the elastomer properties as a function of sample depth, type and length of treatment, and temperature.

Conclusions and Prospects

The CW and pulsed ESR methods described above are exceptionally sensitive and specific to the presence of species with unpaired electron spins, such as organic and inorganic radicals, paramagnetic ions, and triplet states. Organic radicals are present in important polymerization processes, or are introduced deliberately as dopants, and report on the properties of the system in terms of dynamics, degree of order, and local polarity. In most cases the reporters are nitroxide radicals, which are available in a large range of structures, and can be selected for the specific system that is investigated and research goals.

Recent work has demonstrated that spin probes can be incorporated into complex materials and used as local reporters of the polymer host. By a judicious choice of the polarity, size, and chemical structure of the probe, it is possible to explore specific regions of microphase-separated or self-assembled system, thus by-passing the often difficult synthetic procedures of preparing covalently bound spin labels. The site selected by the probes is based on the very same weak intermolecular interactions (electrostatic, hydrogen bonding, metal coordination) that

govern supramolecular self-assembly. Basic CW ESR experiments can provide a wealth of information on spin probe dynamics and polarity of the local environment. Quantitative results can be deduced, based on line shape simulations. This is meaningful in particular if the spin probe can be regarded as a tracer for a specific component of a complex material, or if a set of probes with systematically varied structure is used, for example a series of *n*DSA or CAT*n* probes.

Once the attachment site of a spin probe is established by CW ESR, advanced ESR experiments can be used to characterize the spatial distribution of probes and the structure of the material in the vicinity of the probe. Such approaches are just emerging and have not yet reached their full potential. The spatial distribution of probes can be determined on macroscopic-length scales by ESR imaging (ESRI) and on microscopic-length scales in the nanometer range by DEER measurements. These two techniques complement each other but have not yet been applied simultaneously to the same system.

Polarity indices are a helpful tool for characterizing heterogeneous materials in general, including polymers. Separating the effects of matrix polarity and hydrogen bonding on the magnetic parameters of a spin probe is possible with high field ESR (106), but has not yet been utilized in materials science applications.

Matrix ENDOR of spin probes that reside in an internal interface has the potential to provide detailed information on the microscopic structure of this interface, but measurement techniques and data analysis are still in their infancy, so that only semiquantitative information can be obtained to date. Development of more precise and sensitivity-optimized measurement techniques and better quantification of the spectra are now in progress.

In recent years, advanced methods of polymerization such as living radical polymerization have been developed; the major advantages are the ability to synthesize polymers with narrow distributions of molecular weights, and tailor-made block copolymers of high purity (107,108). Some of these methods depend on the presence of nitroxide radicals in order to control the reactivity of growing chains via the equilibrium between alkoxy amine chain ends and active free-radical chain ends. ESR methods can be used to provide mechanistic details that are hard to obtain by other methods, for instance the electronic and steric effects of the penultimate unit in the propagating radical (109). It is expected that ESR methods will figure prominently in the field of living radical polymerization, for the detection and analysis of signals from free radicals (polymer-derived or nitroxides), and from transition-metal cations.

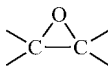
EPOXY RESINS

Introduction

Epoxy resins are an important class of polymeric materials, characterized by the presence of more than one three-membered ring known as the epoxy, epoxide, oxirane, or ethoxyline group.



The word "epoxy" is derived from the Greek prefix "ep," which means over and between, and "oxy," the combining form of oxygen (1). By strict definition, epoxy resins refer only to uncross-linked monomers or oligomers containing epoxy groups. However, in practice, the term *epoxy resins* is loosely used to include cured epoxy systems. It should be noted that very high molecular weight epoxy resins and cured epoxy resins contain very little or no epoxide groups. The vast majority of industrially important epoxy resins are bi- or multifunctional epoxides. The monofunctional epoxides are primarily used as reactive diluents, viscosity modifiers, or adhesion promoters, but they are included here because of their relevance in the field of epoxy polymers.

Epoxies are one of the most versatile classes of polymers with diverse applications such as metal can coatings, automotive primer, printed circuit boards, semiconductor encapsulants, adhesives, and aerospace composites. Most cured epoxy resins provide amorphous thermosets with excellent mechanical strength and toughness; outstanding chemical, moisture, and corrosion resistance; good thermal, adhesive, and electrical properties; no volatiles emission and low shrinkage upon cure; and dimensional stability—a unique combination of properties generally not found in any other plastic material. These superior performance characteristics, coupled with outstanding formulating versatility and reasonable costs, have gained epoxy resins wide acceptance as materials of choice for a multitude of bonding, structural, and protective coatings applications.

Commercial epoxy resins contain aliphatic, cycloaliphatic, or aromatic backbones and are available in a wide range of molecular weights from several hundreds to tens of thousands. The most widely used epoxies are the glycidyl ether derivatives of bisphenol A (>75% of resin sales volume). The capability of the highly strained epoxy ring to react with a wide variety of curing agents under diverse conditions and temperatures imparts additional versatility to the epoxies. The major industrial utility of epoxy resins is in thermosetting applications. Treatment with curing agents gives insoluble and intractable thermoset polymers. In order to facilitate processing and to modify cured resin properties, other constituents may be included in the compositions: fillers, solvents, diluents, plasticizers, catalysts, accelerators, and tougheners.

Epoxy resins were first offered commercially in the late 1940s and are now used in a number of industries, often in demanding applications where their performance attributes are needed and their modestly high prices are justified. However, aromatic epoxies find limited uses in exterior applications because of their

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

poor ultraviolet (UV) light resistance. Highly cross-linked epoxy thermosets sometimes suffer from brittleness and are often modified with tougheners for improved impact resistance.

The largest use of epoxy resins is in protective coatings (>50%), with the remainder being in structural applications such as printed circuit board (PCB) laminates, semiconductor encapsulants, and structural composites; tooling, molding, and casting; flooring; and adhesives. New, growing applications include lithographic inks and photoresists for the electronics industry.

History

The patent literature indicates that the synthesis of epoxy compounds was discovered as early as the late 1890s (2). In 1934, Schlack of I.G. Farbenindustrie AG in Germany filed a patent application for the preparation of reaction products of amines with epoxies, including one epoxy based on bisphenol A and epichlorohydrin (3). However, the commercial possibilities for epoxy resins were only recognized a few years later, simultaneously and independently, by the DeTrey Fréres Co. in Switzerland (4) and by the DeVoe and Raynolds Co. (5) in the United States.

In 1936, Pierre Castan of DeTrey Fréres Co. produced a low melting epoxy resin from bisphenol A and epichlorohydrin that gave a thermoset composition with phthalic anhydride. Application of the hardened composition was foreseen in dental products, but initial attempts to market the resin were unsuccessful. The patents were licensed to Ciba AG of Basel, Switzerland, and in 1946 the first epoxy adhesive was shown at the Swiss Industries Fair, and samples of casting resin were offered to the electrical industry.

Immediately after World War II, Sylvan Greenlee of DeVoe and Raynolds Co. patented a series of high molecular weight (MW) epoxy resin compositions for coating applications. These resins were based on the reaction of bisphenol A and epichlorohydrin, and were marketed through the subsidiary Jones-Dabney Co. as polyhydroxy ethers used for esterification with drying oil fatty acids to produce alkyd-type epoxy ester coatings. Protective surface coatings were the first major commercial application of epoxy resins, and they remain a major outlet for epoxy resin consumption today. Concurrently, epoxidation of polyolefins with peroxy acids was studied by Daniel Swern as an alternative route to epoxy resins (6). Meanwhile, Ciba AG, under license from DeTrey Frères, further developed epoxy resins for casting, laminating, and adhesive applications, and the Ciba Products Co. was established in the United States.

In the late 1940s, two U.S. companies, Shell Chemical Co. and Union Carbide Corp. (then Bakelite Co.), began research on bisphenol A based epoxy resins. At that time, Shell was the only supplier of epichlorohydrin, and Bakelite was a leading supplier of phenolic resins and bisphenol A. In 1955, the four U.S. epoxy resin manufacturers entered into a cross-licensing agreement. Subsequently, The Dow Chemical Co. and Reichhold Chemicals, Inc. joined the patent pool and began manufacturing epoxy resins.

In the 1960s, a number of multifunctional epoxy resins were developed for higher temperature applications. Ciba Products Co. manufactured and marketed *o*-cresol epoxy novolac resins, which had been developed by Koppers Co.

Dow developed the phenol novolac epoxy resins, Shell introduced polyglycidyl ethers of tetrafunctional phenols, and Union Carbide developed a triglycidyl *p*-aminophenol resin. These products continue to find uses today in highly demanding applications such as semiconductor encapsulants and aerospace composites where their performance justifies their higher costs relative to bisphenol A based epoxies.

The peracetic acid epoxidation of olefins was developed in the 1950s by Union Carbide in the United States and by Ciba AG in Europe for cycloaliphatic structures. Ciba Products marketed cycloaliphatic epoxy resins in 1963 and licensed several multifunctional resins from Union Carbide in 1965. The ensuing years witnessed the development of general-purpose epoxy resins with improved weathering characteristics based on the five-membered hydantoin ring and also on hydrogenated bisphenol A, but their commercial success has been limited because of their higher costs. Flame-retardant epoxy resins based on tetrabromobisphenol A were developed and commercialized by Dow Chemical for electrical laminate and composite applications in the late 1960s.

In the 1970s, the development of two breakthrough waterborne coating technologies based on epoxy resins helped establish the dominant position of epoxies in these markets: PPG's cathodic electrodeposition automotive primer and ICI-Glidden's epoxy acrylic interior can coatings.

While epoxy resins are known for excellent chemical resistance properties, the development and commercialization of epoxy vinyl ester resins in the 1970s by Shell and Dow offered enhanced resistance properties for hard-to-hold, corrosive chemicals such as acids, bases, and organic solvents. In conjunction with the development of the structural composites industry, epoxy vinyl ester resin composites found applications in demanding environments such as tanks, pipes and ancillary equipment for petrochemical plants and oil refineries, automotive valve covers, and oil pans. More recently, epoxy and vinyl esters are used in the construction of windmill blades for wind energy farms. Increasing requirements in the composite industries for aerospace and defense applications in the 1980s led to the development of new, high performance multifunctional epoxy resins based on complex amine and phenolic structures. Examples of those products are the trisphenol epoxy novolacs developed by Dow Chemical and now marketed by Huntsman (formerly Ciba).

The development of the electronics and computer industries in the 1980s demanded higher performance epoxy resins. Faster speeds and more densely packed semiconductors required epoxy encapsulants with higher thermal stability, better moisture resistance, and higher device reliability. Significant advancees in the manufacturing processes of epoxy resins led to the development of electronic-grade materials with lower ionic and chloride impurities and improved electrical properties. Dow Chemical introduced a number of new, high performance products such as hydrocarbon epoxy novolacs based on dicyclopentadiene. The 1980s also witnessed the development of the Japanese epoxy resin industry with focus on specialty, high performing and high purity resins for the electronics industry. These include the commercialization of crystalline resins such as biphenol diglycidyl ether.

More recently, in order to comply with more stringent environmental regulations, there has been increased attention to the development of epoxy resins

for high solids, powder, and waterborne and radiation-curable coatings. Powder coatings based on epoxy–polyester and epoxy–acrylate hybrids have continued to grow in the global markets, including new applications such as primer-surfacer and topcoats for automotive coatings. Radiation-curable epoxy–acrylates and cycloaliphatic epoxies showed tremendous growth in the 1990s in radiation-curable applications. These include important and new uses of epoxy resins such as the photoresists and lithographic inks for the electronics industry. Waterborne epoxy coatings are projected to grow substantially.

The continuing trend of device miniaturization in the computer industry, and the explosive growth of portable electronics and communications devices such as wireless cellular telephones in the 1990s demanded new, high performance resins for the PCB market. This has led to the development of new epoxies and epoxy hybrid systems having lower dielectric constants (D_k), higher glass-transition temperatures (T_g), and higher thermal decomposition temperatures (T_d) for electrical laminates. Environmental pressures in the PCB industry have fueled the development of a number of new bromine-free resin systems, but their commercialization is limited because of higher costs.

Significant efforts have been directed toward performance enhancements of epoxy structural composites. Advances have been made in the epoxy-toughening area. Epoxy nanocomposites and nanotube systems have been studied and are claimed to bring exceptional thermal, chemical, and mechanical property improvements. However, commercialization has not yet materialized.

In 1999, Dow Chemical introduced a new epoxy-based thermoplastic resin, BLOX*, for gas barrier, adhesives, and coatings applications.

Industry Overview

From the first commercial introduction of diglycidyl ether of bisphenol A (DGEBA) resins in the 1940s, epoxy resins have gradually established their position as an important class of industrial polymers. Epoxy resin sales increased rapidly in the 1970s and continued to rise into the 1980s as new applications were developed (annual growth rate >10% in the U.S. market, Table 1). More recently, the slower growth rates (3–4%) of the U.S., Japanese, and European markets in the 1990s were made up for by the higher growth rate (5–10%) in the Asia-Pacific markets outside of Japan, particularly in Taiwan and China. Epoxy resin growth has historically tracked well with economic developments and demands for durable goods, and so the growth of the epoxy markets in Asia-Pacific is expected to continue into the next decade.

The global market for epoxy resins is estimated at approximately 1.15 million metric tons (MT) for the year 2000 (8). This is an increase of 5% over 1999 demands. The North American market consumed over 330,000 MT of epoxy resins, the European market is estimated at more than 370,000 MT, and the Asian market has surpassed both the North American and European markets by consuming 400,000 MT of epoxy resins. About 50,000 MT of epoxies were consumed in the South American markets. Imports of epoxy resins from Asia into North America has steadily grown to about 120,000 MT in 2000. Epoxy resins were used with over

Table 1. History of U.S. Epoxy Resin Annual Production[a]

1955	10
1960	30
1965	55
1970	79
1975	100
1980	201
1985	347
1990	475
1994	433

[a] Data from U.S. International Trade Commission, *Synthetic Organic Chemicals*. Data include modified and unmodified epoxy resins. Modified epoxy resins include solid epoxy resin (SER), vinyl ester resins, epoxy acrylates, etc. There appear to be some discrepancies in epoxy resin production and market data as reported by different publications and organizations (7). This is primarily due to the fact that some epoxy resins such as liquid DGEBA resins and epoxy novolacs are used as raw materials to produce modified or advanced epoxy resins, which may be further converted to end-use products. Some publications report only unmodified epoxies.

400,000 MT of curing agents to produce an estimated 3 million MT of formulated compounds, worth over $20 billion.

Up until the mid-1990s, the major worldwide producers of epoxy resins were Dow Chemical, Shell, and Ciba-Geigy. However, both Shell and Ciba-Geigy have recently divested their epoxy resins businesses. Shell sold their epoxy business to Apollo Management LP (based in New York City) in the year 2000 and the company was renamed Resolution Performance Products. Similarly, Ciba's epoxy business was sold in 2000 to Morgan Grenfell, a London (U.K.)-based private equity firm, and the new company name was Vantico. More recently, in June 2003, the Vantico group of companies joined Huntsman. The Vantico business units are now named Huntsman Advanced Materials. The cycloaliphatic epoxy business of Union Carbide became part of The Dow Chemical Company after their merger in the year 2001. Together, these three producers continue to dominate the world market for epoxy resins, accounting for almost 65% of the global market. However, this is a reduction from over 70% of market shares owned by the three largest producers in the 1980s. Smaller producers of epoxy resins for the North American markets are Reichhold (owned by Dainippon Ink and Chemicals), CVC Specialty Chemicals, Pacific Epoxy Polymers, and InChem (phenoxy thermoplastic resins). Suppliers of epoxy derivatives include Ashland Specialty Chemical, UCB Chemicals (Radcure), AOC LLC, Eastman Chemical, and Interplastic Corp.

The market in Europe is similarly dominated by the three big producers: Dow, Resolution, and Huntsman and their affiliated joint ventures. Other smaller epoxy producers include Bakelite AG, LEUNA-Harze, Solutia, SIR Industriale, and EMS-CHEMIE. Imports from Asia have become significant in recent years.

The last two decades marked the emergence of the Asian epoxy industry. In the 1980s, the Japanese epoxy industry was transformed from a number of joint venture companies with Dow, Shell, and Ciba into independent producers and the emergence of a high number of new producers. This coincides with the development of Japan as a world-class manufacturing base. The Japanese epoxy industry is known for their special focus on high performance, high purity resins for the electronics industry. According to data from the Japan Epoxy Resin Manufacturers Association, the total Japanese market demand is estimated at approximately 200,000 MT for the year 2000. The production capacity is estimated at 240,000 MT annually. Exports accounted for an estimated 40,000 MT in 2000. Major Japanese epoxy resin producers are Tohto Kasei, Japan Epoxy Resins Corp. (formerly Yuka-Shell), Asahi Kasei, Dai Nippon Ink and Chemicals, Dow Chemical Japan, Mitsui Chemicals, Nihon Kayaku, Sumitomo Chemical, and Asahi Denka Kogyo. In Japan, Tohto Kasei is a leading resin producer, with epoxy technology licensing arrangements with numerous resin producers in Asia.

Outside of Japan, there have been significant increases in epoxy market demands and capacity in the 1990s. This is due to the migration of many PCB, electronic, computer, and durable goods manufacturing plants into the region, which has considerably lower manufacturing costs. Nan Ya, a subsidiary of the Formosa Plastics Group based in Taiwan, is emerging as a major epoxy resin producer with some import presence in North America and Europe. Similarly, Kukdo of Korea also exports to the North American and European markets. The output of these two companies now account for an estimated 15% of the world market. In China, there are numerous (more than 200) small domestic producers of epoxy resins. Recently, a number of major epoxy producers have announced joint ventures or plans to build manufacturing plants in China. These include a number of companies with integrated capacity into electrical laminates and PCB manufacturing, following the business model pioneered by the Formosa Plastics Group. Other notable Asian producers include Asia Pacific Resins, Chang Chun, and Eternal Chemical of Taiwan; Thai Epoxy of Thailand; Kumho, LG Chemical, and Pacific Epoxy Resins of Korea; and Guangdong Ciba Polymers, Sinopec Baling Petrochemical, Jiangsu Sanmu, and Wuxi DIC Epoxy Resin of China. The LG Chemical epoxy business was purchased by Bakelite in late 2002. A significant amount of resin produced in Taiwan and China is directed toward electrical laminates applications. The aggressive buildup of epoxy capacity in Asia has put significant pressures on resin prices, particularly the high volume products such as liquid epoxy resins based on bisphenol A (Table 2). But as of January 2004, the epoxy market demand in China alone has increased to more than 500,000 MT (Chinese Epoxy Industry Web site).

Estimated average prices for epoxy resin products in North America are given in Table 3. As with other petrochemical-based products, they depend on crude-oil prices. Prices of multifunctional resins are typically higher. They are based on more expensive raw materials than DGEBA resins and involve more complex manufacturing procedures. A listing of some major epoxy resin producers and the trade names of their products is shown in Table 4.

There are numerous suppliers of epoxy curing agents. Some of the major producers are Air Products and Chemicals, Cognis, Degussa, DSM, Huntsman, and Resolution.

Table 2. Epoxy Production Capacity in Asia-Pacific[a] (2001)

Country	Existing capacity, 1000 MT/year	Announced capacity, 1000 MT/year
Japan	240	
Taiwan	239	70
China	100	255
Korea	180	
Thailand	30	
Malaysia	10	
Philippines	10	
Total	*809*	*325*

[a] Compilation of published data by Dow Chemical.

Classes of Epoxy Resins and Manufacturing Processes

Most commercially important epoxy resins are prepared by the coupling reaction of compounds containing at least two active hydrogen atoms with epichlorohydrin followed by dehydrohalogenation:

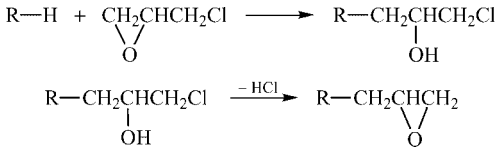

Table 3. U.S. Average Epoxy Resin Prices and Applications (2000)

Resin	$/kg	Applications
Liquid epoxy resins (Diglycidyl ether of bisphenol A, DGEBA)	2.2	Coatings, castings, tooling, flooring, adhesives, composites
Solid epoxy resins (SER)	2.4	Powder coating; epoxy esters for coatings; can, drum, and maintenance coatings
Bisphenol F epoxy	4.4	Coatings
Multifunctional		
Phenol epoxy novolac	4.8	Castings, coatings, laminates
Cresol epoxy novolac	8.8	Electronics encapsulants, powder coatings, laminates
Other multifunctional epoxies	11–44	Composites, adhesives, laminates, electronics
Cycloaliphatic epoxies	6.6	Electrical castings, coatings, electronics
Brominated epoxies	3.3–5.5	Printed wiring boards, composites
Epoxy vinyl esters	3.3	Composites
Phenoxy resins	11–17	Coatings, laminates, glass sizing
Epoxy diluents	4–11	

Table 4. List of Some Epoxy Resin Producers and Their Product Trade Names

Company	Trade name
Resolution Performance Products	Epon, Eponol, Eponex, Epi-Cure, Epikote
Dow Chemical	D.E.R., D.E.N., D.E.H., Derakane, E.R.L
Hunstman Advanced Materials (formerly Ciba, Vantico)	Araldite, Aralcast
Reichhold Chemical	Epotuf
Nan Ya	NPEL, NPES
Kukdo Chemical	YD
Dainippon Ink & Chemical (DIC)	Epiclon
Tohto Kasei	Epotohto
Japan Epoxy Resin (JER)	Epikote
Asahi Kasei	A.E.R.
Mitsui Chemical	Eponik
Sumitomo Chemical	Sumiepoxy
Thai Epoxy	Epotec
Chang Chun	
InChem	Paphen
Pacific Epoxy Polymers	PEP
CVC Specialty Chemicals	Erysis, Epalloy

These included polyphenolic compounds, mono and diamines, amino phenols, heterocyclic imides and amides, aliphatic diols and polyols, and dimeric fatty acids. Epoxy resins derived from epichlorohydrin are termed *glycidyl-based resins*.

Alternatively, epoxy resins based on epoxidized aliphatic or cycloaliphatic dienes are produced by direct epoxidation of olefins by peracids:

Approximately 75% of the epoxy resins currently used worldwide are derived from DGEBA. This market dominance of bisphenol A based epoxy resins is a result of a combination of their relatively low cost and adequate-to-superior performance in many applications. Figure 1 shows U.S. consumption of major epoxy resin types for the year 2000.

Liquid Epoxy Resins (DGEBA)

The most important intermediate in epoxy resin technology is the reaction product of epichlorohydrin and bisphenol A. It is often referred to in the industry as *liquid epoxy resin* (LER), which can be described as the crude DGEBA where the degree

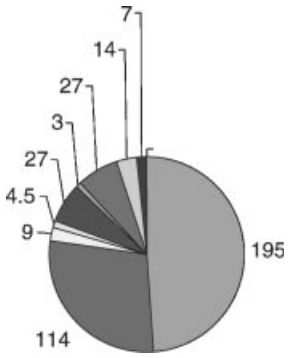

Fig. 1. Major epoxy resin and derivatives markets (10^3 MT). LER; SER; epoxy novolacs; other multifunctional epoxies; brominated epoxies; cycloaliphatic; vinyl esters; and epoxy acrylates.

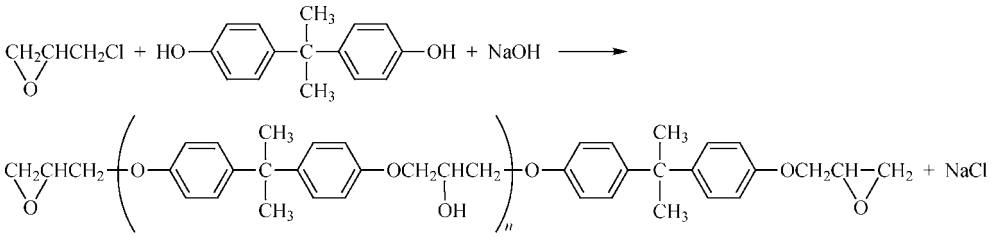
of polymerization, n, is very low ($n \cong 0.2$):



DGEBA

Pure DGEBA is a crystalline solid (mp 43°C) with an epoxide equivalent weight (EEW) of 170. The typical commercial unmodified liquid resins are viscous liquids with viscosities of 11,000–16,000 MPa·s (= cP) at 25°C, and an *epoxide equivalent weight* of ca 188.

EEW is the weight of resin required to obtain one equivalent of epoxy functional group. It is widely used to calculate reactant stoichiometric ratios for reacting or curing epoxy resins. It is related to the epoxide content (%) of the epoxy resin through the following relationship:

$$\mathrm{EEW} = \frac{43.05}{\%\mathrm{Epoxide}} \times 100$$

where 43.05 is the molecular mass of the epoxide group, $-C_2H_3O$. Other equivalent terminologies common in the industry include *weight per epoxide* (Wpe) or *epoxide equivalent mass* (EEM).

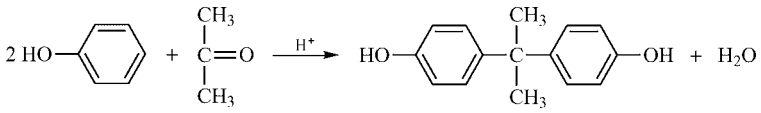
The outstanding performance characteristics of the resins are conveyed by the bisphenol A moiety (toughness, rigidity, and elevated temperature performance), the ether linkages (chemical resistance), and the hydroxyl and epoxy groups (adhesive properties and formulation latitude; reactivity with a wide variety of chemical curing agents).

LERs are used in coatings, flooring and composites formulations where their low viscosity facilitates processing. A large majority of LERs are used as starting materials to produce higher molecular weight (MW) solid epoxy resins (SER) and brominated epoxy resins, and to convert to epoxy derivatives such as epoxy vinyl esters, epoxy acrylates, etc. The bisphenol A derived epoxy resins are most frequently cured with anhydrides, aliphatic amines, phenolics, or polyamides, depending on desired end properties. Some of the outstanding properties are superior electrical properties, chemical resistance, heat resistance, and adhesion. Cured LERs give tight cross-linked networks having good strength and hardness but have limited flexibility and toughness.

Epichlorohydrin, or 3-chloro-1,2-epoxy propane (bp 115°C), is more commonly prepared from propylene by chlorination to allyl chloride, followed by treatment with hypochlorous acid. This yields glycerol dichlorohydrin, which is dehydrochlorinated by sodium hydroxide or calcium hydroxide (9).

In industrial practices, epichlorohydrin is produced by direct chlorohydroxylation of allyl chloride in chlorine and water (10–13). Alternatively, a new epichlorohydrin process has been developed and commercialized by Showa Denko (14) in Japan in 1985. It involves the chlorination of allyl alcohol as the precursor and is claimed to be more efficient in chlorine usage.

Bisphenol A (mp 153°C), or 2,2-bis(*p*-hydroxyphenyl)propane, is prepared from 2 *M* of phenol and 1 *M* of acetone (15,16)

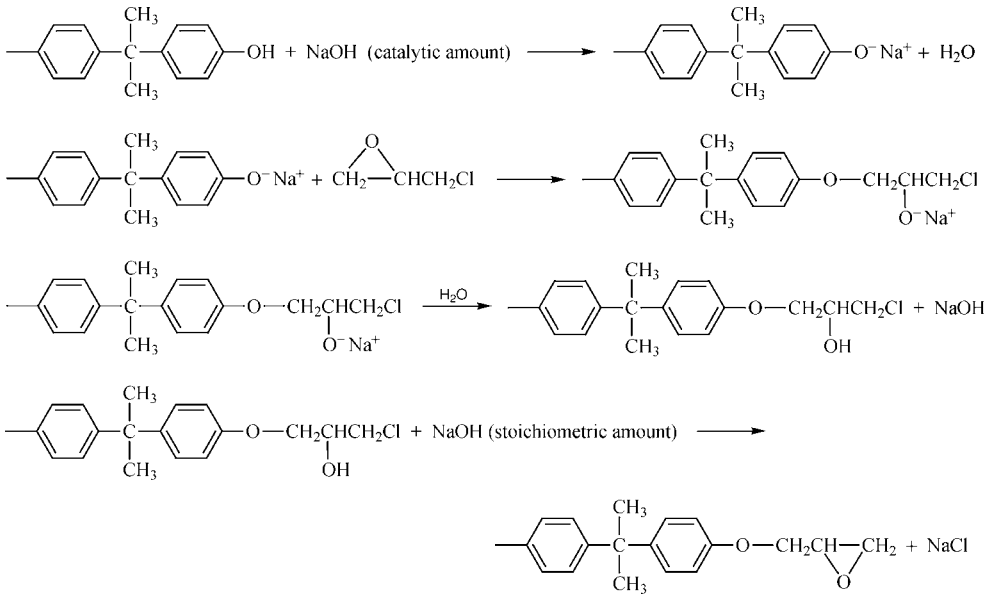


Bisphenol A based liquid epoxy resins are prepared in a two-step reaction sequence from epichlorohydrin and bisphenol A. The first step is the base-catalyzed *coupling* of bisphenol A and epichlorohydrin to yield a chlorohydrin.

Bases that may be used to catalyze this step include sodium hydroxide, lithium salts, and quaternary ammonium salts. Dehydrohalogenation of the chlorohydrin intermediate with a stoichiometric amount of base affords the glycidyl ether. Manufacturing processes can be divided into two broad categories according to the type of catalyst used to couple epichlorohydrin and bisphenol A (17,18).

Caustic Coupling Process. In this process, caustic is used as a catalyst for the nucleophilic ring-opening (coupling reaction) of the epoxide group on the primary carbon atom of epichlorohydrin by the phenolic hydroxyl group and as a

dehydrochlorinating agent for conversion of the chlorohydrin to the epoxide group:



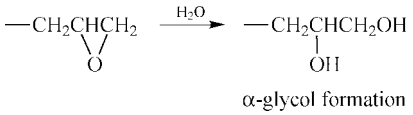
In caustic coupling processes, caustic (20–50% sodium hydroxide in water) is slowly added to an agitated mixture of epichlorohydrin and bisphenol A. The highly exothermic coupling reaction proceeds during the initial stages. As the coupling reaction nears completion, dehydrochlorination becomes the predominant reaction. A high ratio (usually 10:1) of epichlorohydrin/bisphenol A is charged to the reactor to maximize the yield of monomeric ($n = 0$) DGEBA. At a 10:1 level of epichlorohydrin/bisphenol A, the $n = 0$ monomer comprises >85% of the reaction product mixture.

Phase-Transfer Catalyst Process. Alternatively, the coupling reaction and dehydrochlorination can be performed separately by using phase-transfer coupling catalysts, such as quaternary ammonium salts (19), which are not strong enough bases to promote dehydrochlorination. Once the coupling reaction is completed, caustic is added to carry out the dehydrochlorination step. Higher yields of the $n = 0$ monomer (>90%) are readily available via this method.

Many variations of these two basic processes are described in process patents (20,21), including the use of co-solvents and azeotropic removal of water to facilitate the reactions and to minimize undesirable by-products such as insoluble polymers. The original batch methods have been modified to allow for continuous or semicontinuous production. New developments have been focused on improving manufacturing yield and resin purity.

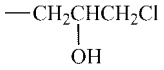
The description of liquid DGEBA resins presented so far is oversimplified. In reality, *side reactions* result in the formation of low levels of impurities that both decrease the epoxide content from the theoretical amount of 2 per molecule and affect the resins properties, both before and after curing (22). The five common side reactions are as follows:

(1) *Hydrolysis of epoxy groups.* Unavoidable hydrolysis of the epoxide ring gives a small amount (0.1–5%) of monohydrolyzed resin (MHR) or α-glycol. It has been reported that dispersability of pigments are enhanced and rates of epoxy resin curing with diamines can be dramatically increased by higher levels of MHR (23).



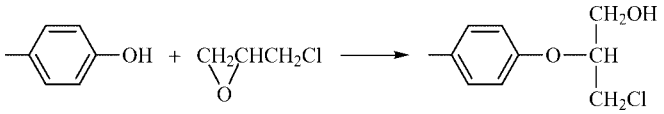
α-glycol formation

(2) *Incomplete dehydrochlorination* results in residual saponifiable or hydrolyzable chloride:

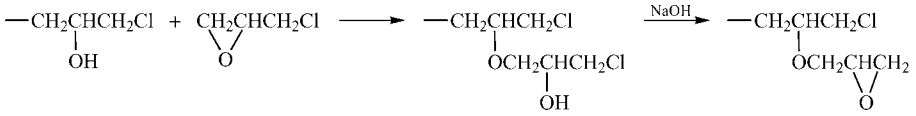


Incomplete dehydrochlorination increases the level of hydrolyzable chloride in the resin, which affects its suitablity for applications requiring superior electrical properties. In addition, hydrolyzable chlorides can affect reactivity by neutralizing basic catalysts such as tertiary amines. Many formulators adjust their formulations according to resin hydrolyzable chloride content. Typical hydrolyzable chloride contents of LERs range from <100 ppm for electronic grade resin to 200–1000 ppm for standard grade resins.

(3) *Abnormal addition of epichlorohydrin,* ie, abnormal phenoxide attack at the central carbon of epichlorohydrin results in an end group that is more difficult to dehydrochlorinate:



(4) *Formation of bound chlorides* by reaction of epichlorohydrin with hydroxy groups in the polymer backbones:



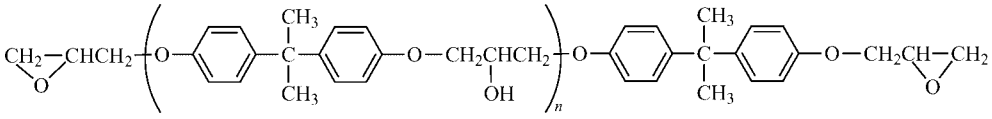
The bound chloride is not readily saponified with metal hydroxide solutions and is analyzed as part of the total chloride of the resin. Typical total chlorides values are 1000–2000 ppm.

(5) *Higher oligomer formation.* Reaction of a phenolic terminal group with another epoxy resin molecule instead of an epichlorohydrin molecule gives epoxy resins with broader oligomer distribution and increased viscosity ($n = 1$ and higher oligomers). Typical LERs contain 5–15% of the higher oligomers, mostly $n = 1$ and $n = 2$ compounds.

Pure DGEBA is a solid melting at 43°C. The unmodified commercial liquid resins are supercooled liquids with the potential for crystallization, depending on purity and storage conditions. This causes handling problems, particularly for ambient cure applications. Addition of certain reactive diluents and fillers can either accelerate or retard crystallization. Crystallization-resistant, modified resins are available. A crystallized resin can be restored to its liquid form by warming.

Solid Epoxy Resins Based on DGEBA

High molecular weight (MW) SERs based on DGEBA are characterized by a repeat unit containing a secondary hydroxyl group with degrees of polymerization, ie, n values ranging from 2 to about 35 in commercial resins; two terminal epoxy groups are theoretically present.



The epoxy industry has adopted a common nomenclature to describe the SERs. They are called type "1," "2" up to type "10" resins, which correspond to the increased values of n, the degree of polymerization, EEW, MW, and viscosity. Examples of SERs are D.E.R. 661, 662, 664, 667, 669 resins from Dow Chemical, and Epon 1001 to 1009 series from Resolution. A comparison of some key properties of LERs and SERs is shown in Table 5.

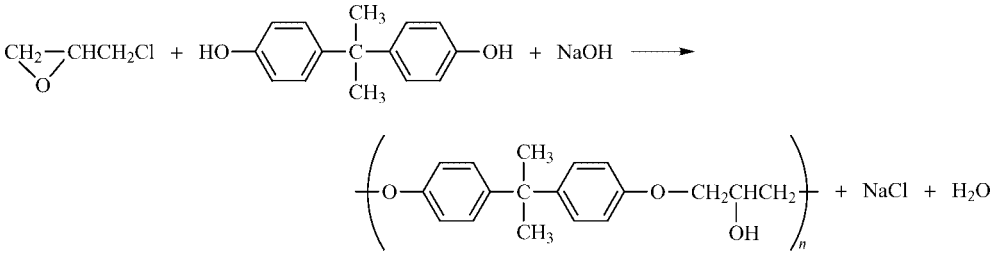
SERs based on DGEBA are widely used in the coatings industry. The longer backbones give more distance between cross-links when cross-linked through the terminal epoxy groups, resulting in improved flexibility and toughness. Furthermore, the resins can also be cured through the multiple hydroxyl groups along the backbones using cross-linkers such as phenol–formaldehyde resoles or isocyanates to create different network structures and performance.

SERs are prepared by two processes: the *taffy* process and the *advancement* or *fusion* process. The first is directly from epichlorohydrin, bisphenol A, and a stoichiometric amount of NaOH. This process is very similar to the *caustic coupling* process used to prepare liquid epoxy resins. Lower epichlorohydrin to bisphenol A ratios are used to promote formation of high MW resins. The term *taffy* is derived from the appearance of the advanced epoxy resin prior to its separation from water and precipitated salts.

Table 5. DGEBA-Based Epoxy Resins

Resin type	n value[a]	EEW	Mettler softening point, °C	Molecular weight (M_w)[b]	Viscosity at 25°C, MPa·s (= cP)
Low viscosity LER	<0.1	172–176		~350	4,000–6,000
Medium viscosity LER	~0.1	176–185		~370	7,000–10,000
Standard grade LER	~0.2	185–195		~380	11,000–16,000
Type 1 SER	~2	450–560	70–85	~1,500	160 – 250[c]
Type 4 SER	~5	800–950	95–110	~3,000	450 – 600[c]
Type 7 SER	~15	1,600–2,500	120–140	~10,000	1,500–3,000[c]
Type 9 SER	~25	2,500–4,000	145–160	~15,000	3,500–10,000[c]
Type 10 SER	~35	4,000–6,000	150–180	~20,000	10,000–40,000[c]
Phenoxy resin	~100	>20,000	>200	>40,000	

[a] n value is the number-average degree of polymerization which approximates the repeating units and the hydroxyl functionality of the resin.
[b] Molecular weight is weight average (M_w) measured by gel-permeation chromatography (GPC) using polystyrene standard.
[c] Viscosity of SERs is determined by kinematic method using 40% solids in diethylene glycol monobutyl ether solution.



In the taffy process, a calculated excess of epichlorohydrin governs the degree of polymerization. However, preparation of the higher molecular weight species is subject to practical limitations of handling and agitation of highly viscous materials. The effect of epichlorohydrin–bisphenol A (ECH–BPA) ratio for a series of solid resins is shown in Table 6.

In commercial practice, the *taffy* method is used to prepare lower MW solid resins, ie, those with maximum EEW values of about 1000 (type "4"). Upon completion of the polymerization, the mixture consists of an alkaline brine solution and a water–resin emulsion. The product is recovered by separating the phases, washing the taffy resin with water, and removing the water under vacuum. One disadvantage of the taffy process is the formation of insoluble polymers, which create handling and disposal problems. Only a few epoxy producers currently manufacture SERs using the taffy process. A detailed description of a taffy procedure follows (24).

Table 6. Effect of Epichlorohydrin–Bisphenol A Ratio on Resin Properties of Taffy SERs

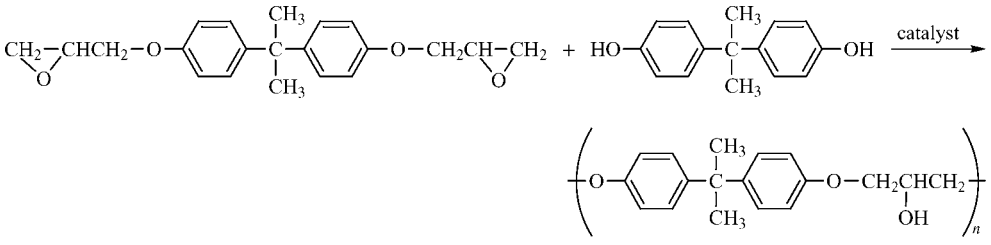
Mole ratio ECH/BPA	EEW	Softening point, °C
1.57:1.0	450–525	65–75
1.22:1.0	870–1025	95–105
1.15:1.0	1650–2050	125–135
1.11:1.0	2400–4000	145–155

A mixture of bisphenol A (228 parts by weight) and 10% aqueous sodium hydroxide solution (75 parts by weight) is introduced into a reactor equipped with a powerful agitator. The mixture is heated to ca 45°C and epichlorohydrin (145 parts by weight) is added rapidly with agitation, giving off heat. The temperature is allowed to rise to 95°C, where it is maintained about 80 min for completion of the reaction. Agitation is stopped, and the mixture separates into two layers. The heavier aqueous layer is drawn off and the molten, taffy-like product is washed with hot water until the wash water is neutral. The taffy-like product is dried at 130°C, giving a solid resin with a softening point of 70°C and an EEW of ca 500.

Alternatively, epichlorohydrin and water are removed by distillation at temperatures up to 180°C under vacuum. The crude resin/salt mixture is then dissolved in a secondary solvent to facilitate water washing and salt removal. The secondary solvent is then removed via vacuum distillation to obtain the taffy–resin product.

Resins produced by this process exhibit relatively high α-glycol values, ie, ca 0.5 eq/kg, attributable to hydrolysis of epoxy groups in the aqueous phase. Although detracting from epoxide functionality, such groups act as accelerators for amine curing. Resins produced by the taffy process exhibit n values of 0, 1, 2, 3, etc, whereas resins produced by the *advancement* process (described below) exhibit mostly even-numbered n values because a difunctional phenol is added to a diglycidyl ether of a difunctional phenol.

An alternative method is the chain-extension reaction of liquid epoxy resin (crude DGEBA) with bisphenol A, often referred to as the *advancement* or *fusion process* (25) which requires an advancement catalyst:



The advancement process is more widely used in commercial practice. Isolation of the polymerized product is simpler, since removal of copious amounts of NaCl is unnecessary. The reaction can be carried out with or without solvents.

Solution advancement is widely practiced by coatings producers to facilitate handling of the high MW, high viscosity epoxy resins used in many coating formulations. The degree of polymerization is dictated by the ratio of LER to bisphenol A; an excess of the former provides epoxy terminal groups. The actual MW attained depends on the purity of the starting materials, the type of solvents used, and the catalyst. Reactive monofunctional groups can be used as chain terminators to control MW and viscosity build.

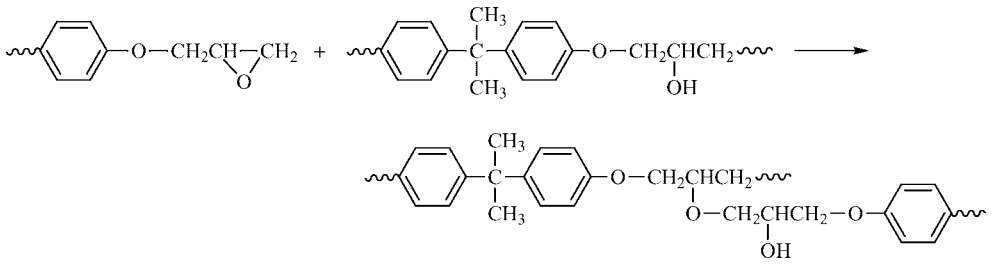
The following formula can be used to calculate the relative amount of bisphenol A that must be reacted with epoxy resin to give an advanced epoxy resin of predetermined EEW:

$$\text{Bis A} = \frac{\text{EEW}_i^{-1} - \text{EEW}_f^{-1}}{\text{EEW}_i^{-1} + \text{PEW}^{-1}}$$

where Bis A is the mass fraction of bisphenol A in the mixture prior to advancement, EEW_i is the EEW of the epoxy resin that is to be advanced, EEW_f is the EEW of the advanced epoxy resin, and PEW is the phenol equivalent mass of the bisphenol, which is 115.1 g per equivalent for bisphenol A.

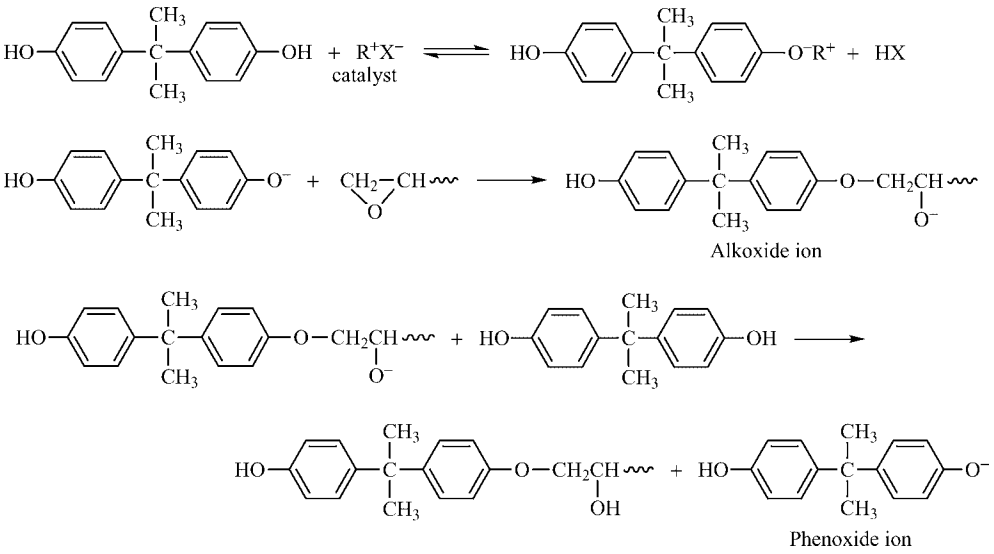
In a typical advancement process, bisphenol A and a liquid DGEBA resin (175–185 EEW) are heated to ca 150–190°C in the presence of a catalyst and reacted (ie, advanced) to form a high MW resin. The oligomerization is exothermic and proceeds rapidly to near completion. The exotherm temperatures are dependent upon the targeted EEW and the reaction mass. In the cases of higher MW resins such as type "7" and higher, exotherm temperatures of >200°C are routinely encountered.

Advancement reaction catalysts facilitate the rapid preparation of medium and high MW linear resins and control prominent side reactions inherent in epoxy resin preparations, eg, chain branching due to addition of the secondary alcohol group generated in the chain-lengthening process to the epoxy group (26,27). Nuclear Magnetic Resonance (NMR) spectroscopy can be used to determine the extent of branching (28).



Conventional advancement catalysts include basic inorganic reagents, eg, NaOH, KOH, Na_2CO_3, or LiOH, and amines and quaternary ammonium salts. One mechanism proposed for the basic catalysts involves proton abstraction of

the phenolic compound as the initiation step:



The phenoxide ion then attacks the epoxy ring, generating an alkoxide, which immediately abstracts a proton from another phenolic OH group. This is called the propagation step. Regeneration of the phenoxide ion repeats the cycle. The potential for side reactions increases after the phenolic OH groups have been consumed, particularly in melt (ie, fusion) polymerization reactions.

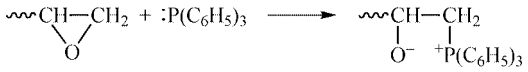
One key disadvantage of catalysts based on inorganic bases and salts is the increased ionic impurities added to the resin, which is not desirable in certain applications.

Imidazoles, substituted imidazoles, and triethanolamine have been patented as advancement catalysts (29). However, most of the inorganic bases, salts, and amines produce resins with broad MW distribution and viscosity instability. This is due to poor catalyst selectivity and the continuing activity of the catalyst after completion of the advancement reaction.

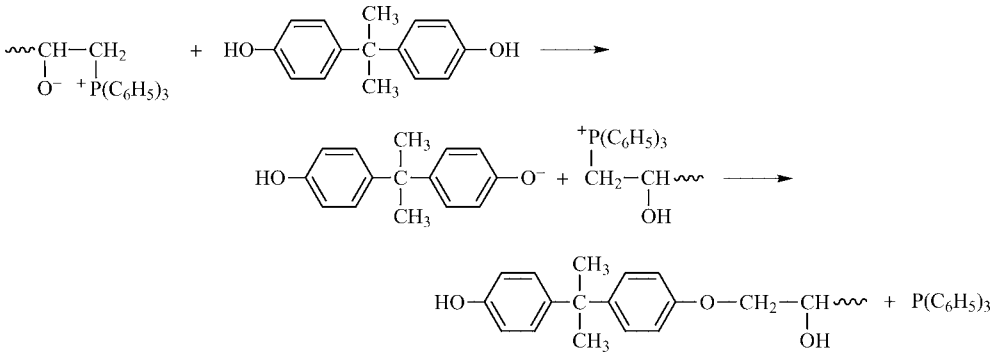
Alternatively, a broad class of catalysts derived from aryl or alkyl phosphonium compounds were developed. Extensive patent literature claims a high order of selectivity (30,31). Selections of the phosphonium cation and counter ion have been shown to affect initiation rate, catalyst selectivity, catalyst lifetime, and, consequently, product quality and consistency. Some of the phosphonium salts are deactivated at high temperatures by the reaction exotherm, and are claimed to give better resin stability in terms of viscosity, EEW, and MW during the subsequent finishing steps (32–35).

Few mechanistic studies have been published on the selectivity of phosphonium compounds, but one publication describes the role of triphenylphosphine in advancement catalysis (36). Nucleophilic attack by triphenylphosphine opens the

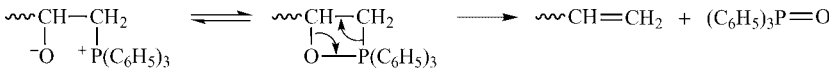
epoxy ring, producing a betaine:



Proton abstraction from bisphenol A yields the phenoxide anion, forming a phosphonium salt. The phenoxide reacts with the electrophilic carbon attached to the positive phosphorus regenerating the catalyst:



When the bisphenol A is consumed, the betaine decomposes into a terminal olefin and triphenylphosphine oxide:



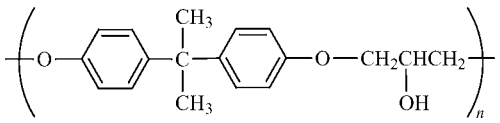
Branched epoxies (37) are prepared by advancing LER with bisphenol A in the presence of epoxy novolac resins. Such compositions exhibit enhanced thermal and solvent resistance.

SERs are available commercially in solid form or in solution. MW distributions of SERs have been examined by means of theoretical models and compared with experimental results (38). Taffy-processed resins were compared with advancement-processed resins by gel-permeation chromatography (GPC) and high performance liquid chromatography (HPLC) (39) in conjunction with statistical calculations. The major differences are in the higher α-glycol content and the repeating units of oligomers. Resin viscosity and softening points are also lower with taffy resins. In addition, certain formulations based on taffy resins exhibit different behavior in pigment loading, formulation rheology, reactivity, and mechanical properties compared to those based on advancement resins.

SER Continuous Advancement Process. The recent literature review indicates efforts to develop continuous advancement processes to produce SERs. Companies seek to improve process efficiencies and product quality. One of the major deficiencies of the traditional batch advancement process is the long reaction time, resulting in EEW and viscosity drift, variable product quality, and gel formation. In addition, it is difficult to batch process higher MW, higher viscosity SERs such as types "9" and "10" resins. Shell patented several versions of the

continuous resin advancement processes using modified reactor designs (40). Dow Chemical received patents covering the uses of reactive extrusion (41) (REX) to produce SERs and other epoxy thermoplastic resins (42). The latter process makes use of a self-wiping twin-screw extruder. LER, bisphenol A, and catalyst are fed directly to the extruder to complete the resin advancement reaction in several minutes compared to the traditional several hours in a batch process. The process is claimed to be very efficient and is particularly suitable for the production of high molecular weight SERs, phenoxy resins, and epoxy thermoplastic resins. Compared to the traditional taffy processes used to produce phenoxy resins, the chemistry is salt-free, and the resins made via the REX process are fully converted in a matter of minutes, significantly reducing manufacturing costs. Additional benefits include reduced lot-to-lot variations in MW distribution, the flexibility to make small lots of varying molecular weights with minimal waste, and the ability to make custom resins with a variety of additives such as pigments and flow modifiers.

Phenoxy Resins. *Phenoxy resins* are thermoplastic polymers derived from bisphenol A and epichlorohydrin. Their weight-average molecular weights (M_w) are higher (ie, >30,000) than those of conventional SERs (ie, 25,000 maximum). They lack terminal epoxides but have the same repeat unit as SERs and are classified as polyols or polyhydroxy ethers:



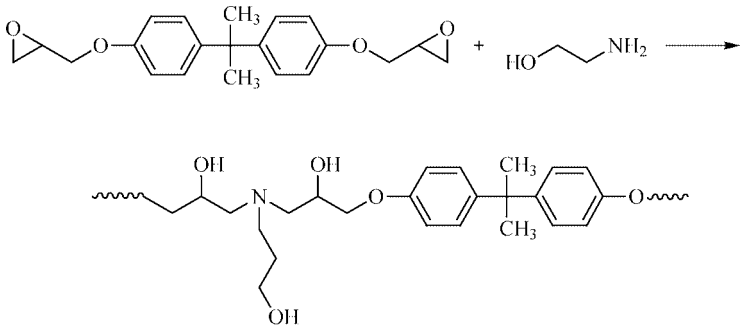
Phenoxy resins were originally developed and produced by Union Carbide (trade names PKHH, PKHC, PKHJ) using the taffy process. The process involves reaction of high purity bisphenol A with epichlorohydrin in a 1:1 mole ratio. Alternatively, phenoxy resins can be produced by the fusion process which uses high purity LER and bisphenol A in a 1:1 mole ratio. High purity monomers and high conversions are both needed to produce high MW phenoxy resins. The effects of monomer purity on phenoxy resin production are significant: monofunctional components limit MW, and functionality >2 causes excess branching and increased polydispersity. Solution polymerization may be employed to achieve the MW and processability needed (43). This, however, adds to the high costs of manufacturing of phenoxy resins, limiting their commercial applications.

The phenoxies are offered as solids, solutions, and waterborne dispersions. The majority of phenoxy resins are used as thermoplastics, but some are used as additives in thermoset formulations. Their high MW provide improved flexibility and abrasion resistance. Their primary uses are in automotive zinc-rich primers, metal can/drum coatings, magnet wire enamels, and magnetic tape coatings. However, the zinc-rich primers are being phased out in favor of galvanized steel by the automotive industry. Smaller volumes of phenoxy resins are used as flexibility or rheology modifiers in composites and electrical laminate applications, and as composite honeycomb impregnating resins. A new, emerging application is fiber sizing, which utilizes waterborne phenoxies. Literature references indicate

their potential uses as compatiblizers for thermoplastic resins such as polyesters, nylons, and polycarbonates because of their high hydroxyl contents.

Current producers of phenoxy resins include the Phenoxy Specialties division of InChem Corp., Resolution, Huntsman, Tohto Kasei, and DIC.

Epoxy-Based Thermoplastics. Some of the new epoxy products developed in the past few years are the thermoplastic resins based on epoxy monomers. Polyhydroxy amino ether (44,45) (PHAE) was commercialized by Dow Chemical in 1999 and trade named BLOX*. It is produced by the reaction of DGEBA with monoethanol amine using the reactive extrusion process. The high cohesive energy density of the resin gives it excellent gas-barrier properties against oxygen and carbon dioxide. It also possesses excellent adhesion to many substrates, optical clarity, excellent melt strength, and good mechanical properties. The product has been evaluated as a barrier resin for beer and beverage plastic bottles, as thermoplastic powder coatings, and as a toughener for starch-based foam (46). Another epoxy thermoplastic resin under development by Dow is the polyhydroxy ester ether (PHEE). It is a reaction product of DGEBA with difunctional acids. The ester linkage makes it suitable for biodegradable applications (47).



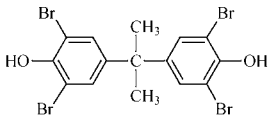
Polyhydroxy amino ether (PHAE) resin

Halogenated Epoxy Resins

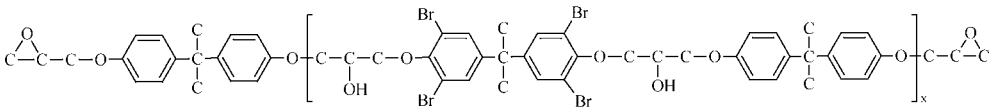
A number of halogenated epoxy resins have been developed and commercialized to meet specific application requirements. Chlorinated and brominated epoxies were evaluated for flame retardancy properties. The brominated epoxy resins were found to have the best combination of cost/performance and were commercialized by Dow Chemical in the late 1960s.

Brominated Bisphenol A Based Epoxy Resins. Many applications of epoxy resins require the system to be ignition-resistant, eg, electrical laminates for PCBs and certain structural composites. A common method of imparting this ignition resistance is the incorporation of tetrabromobisphenol A (TBBA), 2,2-bis(3,5-dibromophenyl)propane, or the diglycidyl ether of TBBA, 2,2-bis[3,5-dibromo-4-(2,3-epoxypropoxy)phenyl]propane, into the resin formulation. The diglycidyl ether of TBBA is produced via conventional liquid epoxy resin processes. Higher MW resins can be produced by advancing LERs or diglycidyl ether of TBBA with TBBA. The lower cost, advanced brominated epoxies based on LERs

and TBBA containing ca 20 wt% Br are extensively employed in the PCB industry. The diglycidyl ether of TBBA (ca 50 wt% Br) is used for critical electrical/electronic encapsulation where high flame retardancy is required. Brominated epoxies are also used to produce epoxy vinyl esters for structural applications. Very high MW versions of brominated epoxies are used as flame-retardant additives to engineering thermoplastics used in computer housings.



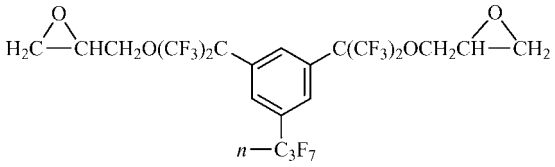
Tetrabromo bisphenol A



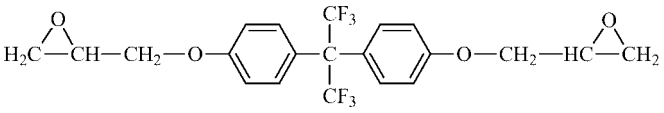
Advanced brominated epoxy resin

In order to meet increased requirements of the PCB industry for higher glass-transition temperature (T_g), higher thermal decomposition temperature (T_d), and lower dielectric constant (D_k) products, a number of new epoxy resins have been developed (48,49).

Fluorinated Epoxy Resins. Fluorinated epoxy resins have been researched for a number of years for high performance end-use applications (50). Fluorinated epoxies are highly resistant to chemical and physical abuse and should prove useful in high performance applications, including specialty coatings and composites, where their high cost may be offset by their special properties and long service life. The following fluorinated diglycidyl ether, 5-heptafluoropropyl-1,3-bis[2-(2,3-epoxypropoxy) hexafluoro-2-propyl] benzene, illustrates an example of fluoroepoxy resins (51) under development.



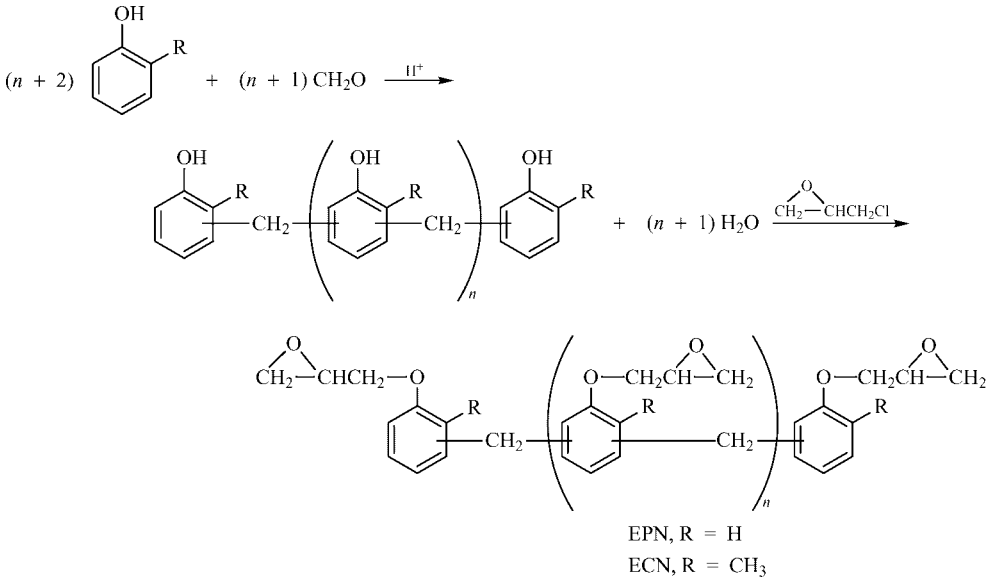
This resin is a viscous, colorless liquid (bp 118°C at 20 Pa · s) that contains 52 wt% fluorine. It has a low surface tension, which makes it a superior wetting agent for glass fibers. The reactivity of this resin with amine or anhydride curing agents is comparable to epoxy resins based on bisphenol A and results in a thermoset that has a low affinity for water and excellent chemical resistance. Another fluorinated epoxy resin derived from hexafluorobisphenol A was introduced to the marketplace aiming at the anticorrosion coatings market for industrial vessels and pipes. The key disadvantages of fluorinated epoxies are their relatively high costs and low T_g, which limit their commercialization (52).



Multifunctional Epoxy Resins

The multifunctionality of these resins provides higher cross-linking density, leading to improved thermal and chemical resistance properties over bisphenol A epoxies.

Epoxy Novolac Resins. Epoxy novolacs are multifunctional epoxies based on phenolic formaldehyde novolacs. Both epoxy phenol novolac resins (EPN) and epoxy cresol novolac resins (ECN) have attained commercial importance (53). The former is made by epoxidation of the phenol–formaldehyde condensates (novolacs) obtained from acid-catalyzed condensation of phenol and formaldehyde (see PHENOLIC RESINS). This produces random *ortho*- and *para*-methylene bridges.



An increase in the molecular weight of the novolac increases the functionality of the resin. This is accomplished by changing the phenol or cresol to formaldehyde ratio. Epoxidation with an excess of epichlorohydrin minimizes the reaction of the phenolic OH groups with epoxidized phenolic groups and prevents branching. The epoxidation is similar to the procedure described for bisphenol A. EPN resins range from a high viscosity liquid of $n = 0.2$ to a solid of $n > 3$. The epoxy functionality is between 2.2 and 3.8. Properties of epoxy phenol novolacs are given in Table 7. When cured with aromatic amines such as methylenedianiline, the heat distortion temperatures (HDT) of EPN-based thermosets range from 150°C to 200°C, depending on cure and post-cure schedules.

Table 7. Typical Properties of Epoxy Phenol Novolacs

Property	D.E.N. 431,[a] EPN 1139[b]	D.E.N. 438,[a] EPN 1138[b]	D.E.N. 439[a]

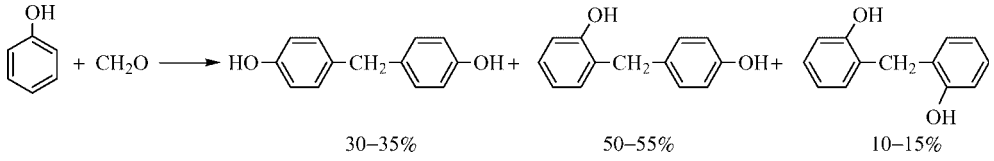
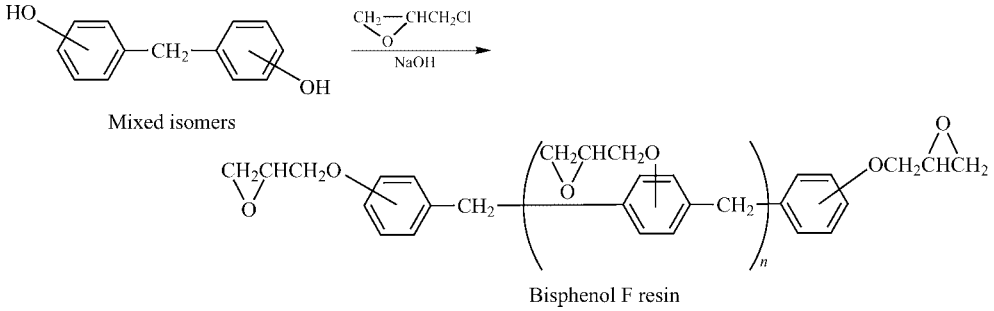
Curing agents that give the optimum in elevated temperature properties for epoxy novolacs are those with good high temperature performance, such as aromatic amines, catalytic curing agents, phenolics, and some anhydrides. When cured with polyamide or aliphatic polyamines and their adducts, epoxy novolacs show improvement over bisphenol A epoxies, but the critical performance of each cure is limited by the performance of the curing agent.

The improved thermal stability of EPN-based thermosets is useful in elevated temperature services, such as aerospace composites. Filament-wound pipe and storage tanks, liners for pumps and other chemical process equipment, and corrosion-resistant coatings are typical applications which take advantage of the chemical resistant properties of EPN resins. However, the high cross-link density of EPN-based thermosets can result in increased brittleness and reduced toughness.

Bisphenol F Epoxy Resin. The lowest MW member of the phenol novolacs is bisphenol F, which is prepared with a large excess of phenol to formaldehyde; a mixture of *o*,*o*′, *o*,*p*′, and *p*,*p*′ isomers is obtained:



Epoxidation yields a liquid bisphenol F epoxy resin with a viscosity of 4000–6000 MPa·s (= cP), an EEW of 165, and $n \cong 0.15$.



Bisphenol F resin

This unmodified, low viscosity liquid resin exhibits slightly higher functionality than unmodified bisphenol A liquid resins. Crystallization, often a problem with liquid bisphenol A resins, is reduced with bisphenol F resin. Consequently, noncrystallizing LERs which are blends of DGEBA and bisphenol F epoxy are available. Epoxy resins based on bisphenol F are used primarily as functional diluents in applications requiring a low viscosity, high performance resin system (eg, solvent-free coatings). Higher filler levels and faster bubble release are possible because of the low viscosity. The higher epoxy content and functionality of bisphenol F epoxy resins provide improved chemical resistance compared to conventional bisphenol A epoxies. Bisphenol F epoxy resins are used in high solids, high build systems such as tank and pipe linings, industrial floors, road and bridge deck toppings, structural adhesives, grouts, coatings, and electrical varnishes.

Cresol Epoxy Novolacs. The *o*-cresol novolac epoxy resins (ECN) are analogous to phenol novolac resins. ECNs exhibit better formulated stability and lower moisture adsorption than EPNs, but have higher costs. ECN resins are widely used as base components in high performance electronic (semiconductors) and structural molding compounds, high temperature adhesives, castings and laminating systems, tooling, and powder coatings. Increasing demands by the semiconductor industry has led to significant advances in ECN resin manufacturing technologies to reduce impurities, mainly the ionic content, hydrolyzable chlorides, and total chlorides. The use of polar, aprotic solvents, such as dimethyl sulfoxide (DMSO), as a co-solvent to facilitate chloride reduction has been patented (54). Typical high purity ECN resins contain $<$1000 ppm total chlorides and $<$50 ppm hydrolyzable chlorides.

The melt viscosity of these resins, which are solids at room temperature, decreases sharply with increasing temperature (Table 8). This affords the formulator an excellent tool for controlling the flow of molding compounds and facilitating the incorporation of ECN resins into other epoxies, eg, for powder coatings. While Ciba-Geigy was the first producer of ECN resins, many Japanese companies (Nippon Kayaku, Sumitomo Chemical, DIC, and Tohto Kasei) supply the majority of high purity ECN resins for the semiconductor industry today. Other suppliers are based in Korea and Taiwan.

Glycidyl Ethers of Hydrocarbon Epoxy Novolacs. In response to the increased performance demands of the semiconductor industry, hydrocarbon epoxy novolacs (HENs) were developed by Dow Chemical in the 1980s. HENs exhibit a much lower affinity for water compared to cresol or phenol epoxy novolacs. This translates directly into increased electrical property retention, which is important

Table 8. Typical Properties of Epoxy Cresol Novolac Resins[a]

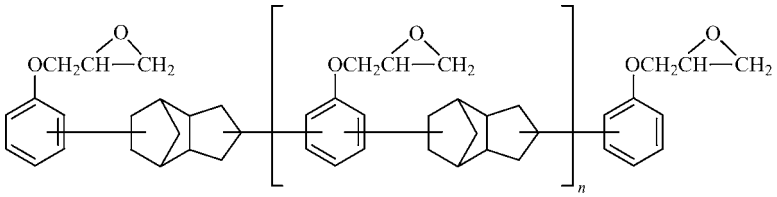
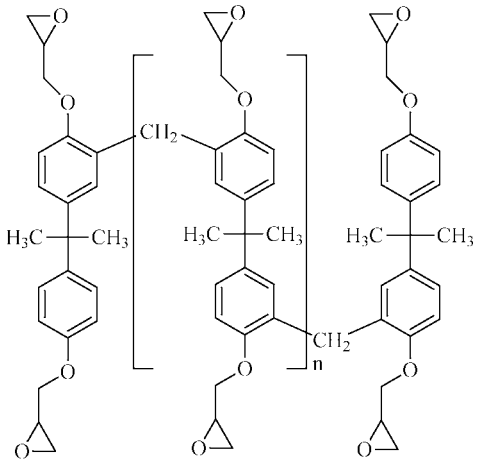
[a] Huntsman.
[b] Epoxide equivalent weight.

in the reliability of an electronic device encapsulated in the resin. An epoxy resin that is typical of this class is based on the alkylation product of phenol and dicyclopentadiene (55) ($n = 0.1$), 2,5-bis[(2,3-epoxypropoxy) phenyl]octahydro-4,7-methano-5*H*-indene (272 EEW; softening point 85°C; η at 150°C 0.4 Pa · s). The product is available from Huntsman as TACTIX∗ 556. Similar products based on *o*-cresol are commercialized in Japan by DIC (EPICLON HP-7200L).



Bisphenol A Epoxy Novolacs. Bisphenol A novolacs are produced by reacting bisphenol A and formaldehyde with acid catalysts. Epoxidation of the bisphenol A novolacs gives bisphenol A epoxy novolac (BPAN) with improved thermal properties such as T_g, T_d of the epoxy-based electrical laminates.

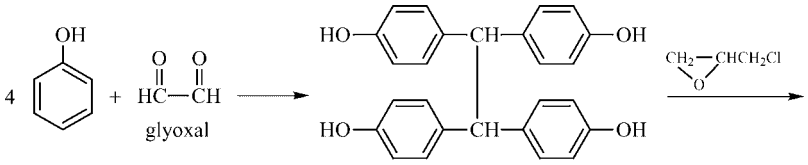


Bisphenol A epoxy novolac

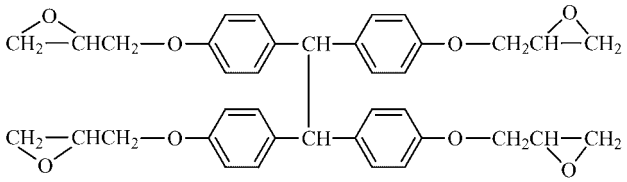
Other Polynuclear Phenol Glycidyl Ether Derived Resins. In addition to the epoxy novolacs, there are other epoxy resins derived from

phenol–aldehyde condensation products. New applications that require increased performance from the epoxy resin, particularly in the electronics, aerospace, and military industries, have made these types of resins more attractive despite their relatively high cost.

Glycidyl Ether of Tetrakis(4-hydroxyphenyl)ethane. One of the first polyfunctional resins to be marketed (by Shell) is based on 1,1,2,2-tetrakis[4-(2,3-epoxypropoxy)phenyl]ethane (56). It is used primarily as additives in standard epoxy resin formulations for electrical laminates, molding compounds, and adhesives in which increased heat distortion temperature and improved chemical resistance are desired. Tetrakis(4-hydroxyphenyl)ethane is prepared by reaction of glyoxal with phenol in the presence of HCl. The tetraglycidyl ether (mp ca 80°C, and an EEW of 185–208) possesses a theoretical epoxide functionality of 4.



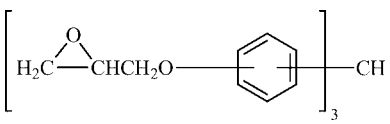
Tetrakis(4-hydroxyphenyl)ethane



Tetraglycidyl ether of tetrakis(4-hydroxyphenyl)ethane

The commercial products Araldite 0163 (Huntsman) and Epon 1031 (Resolution) are tan-colored solids. They are widely used in high temperature resistance electrical laminates for high density PCBs and military applications. Their costs are typically higher than those of phenol and cresol epoxy novolacs.

Trisphenol Epoxy Novolacs. In the 1980s, new trifunctional epoxy resins based on tris[4-(2,3-epoxypropoxy)phenyl]methane isomers were introduced by Dow Chemical to help close the performance gap between phenol and cresol epoxy novolacs and high performance engineering thermoplastics (57). These products were later sold to Ciba-Geigy and continued to be marketed under the TACTIX* 740 and XD 9053 trade names by Huntsman.



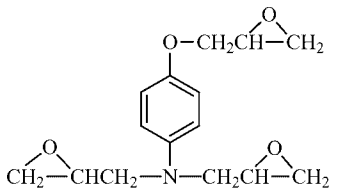
The resins are prepared via acid-catalyzed condensation of phenol and a hydroxybenzaldehyde, eg, salicylaldehyde, to afford the trifunctional phenol, which is epoxidized with epichlorohydrin. These resins range from semisolids (162 EEW;

Durran softening point 55°C; η at 60°C 11.5 Pa · s, at 150°C 0.055 Pa · s) to nonsintering solids (220 EEW; Durran softening point 85°C; η at 150°C 0.45 Pa · s).

The semisolid resins are used in advanced composites and adhesives where toughness, hot-wet strength, and resistance to high temperature oxidation are required. Their purity, formulated stability, fast reactivity, and retention of electrical properties over a broad temperature range make the solid resins suitable for use in the semiconductor molding powders industry. The trisphenol-based epoxies command significant high prices ($28–48/kg), limiting their uses.

Aromatic Glycidyl Amine Resins. Among the multifunctional epoxy resins containing an aromatic amine backbone, only a few have attained commercial significance. Their higher costs limit their uses to critical applications where their costs are justified. Glycidyl amines contain internal tertiary amines in the resin backbone, hence their high reactivity. Epoxy resins with such built-in curing catalysts are less thermally stable than nitrogen-free multifunctional epoxy resins.

Triglycidyl Ether of p-Aminophenol. The triglycidyl derivative of *p*-aminophenol was originally developed by Union Carbide (58) and is currently marketed by Huntsman under the designation MY 0500 and 0510. Epoxidation of *p*-aminophenol is carried out with a large excess of epichlorohydrin under carefully controlled conditions, since the triglycidylated resin exhibits limited thermal stability and polymerizes vigorously under the influence of its tertiary amine moiety.



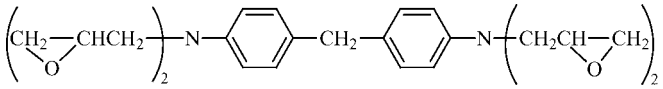
Triglycidyl-*p*-aminophenol

The resin exhibits a low viscosity, 2500–5000 MPa·s (= cP) at 25°C, and an EEW of 105–114; a molecularly distilled version (0510) has a viscosity of 550–850 MPa·s (= cP) at 25°C and an EEW of 95–107. It is considerably more reactive toward amines than standard bisphenol A resins. The trifunctional resin permits curing at low temperatures, ie, 70°C, and rapidly develops excellent elevated-temperature properties. Used as additives to increase cure speed, heat resistance, and T_g of bisphenol A epoxy resins, it has utility in such diverse applications as high temperatures adhesives, tooling compounds, and laminating systems.

Tetraglycidyl Methylenedianiline (MDA). These resins are used as binders in graphite-reinforced composites and are the binders of choice for many military applications. Epoxidation of MDA is carried out with stoichiometric excess of epichlorohydrin and under carefully controlled conditions to avoid rapid polymerization side reactions.

The tetrafunctional glycidylated MDA resins range in viscosity from 5000 to 25,000 MPa·s (= cP) at 50°C and have an EEW of 117–133; they are commercially available as Araldite MY 720 (Huntsman) and Epiclon 430 (DIC). When used in combination with the curing agent 4,4′-diaminodiphenylsulfone (DADS), it is the

first system to meet the performance requirements set by the aerospace industry and is the standard against which other resin systems are judged (59). Because of its outstanding properties, this resin is often used as the primary resin in high heat resistance formulations for military applications, despite its high costs (~$22/kg). Among its attributes are excellent mechanical strength, high T_g, good chemical resistance, and radiation stability.

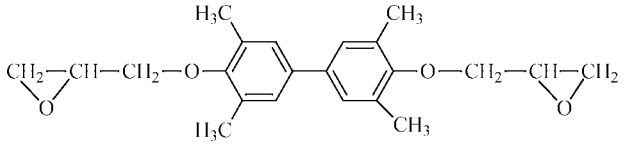


N,N,N′,N′-Tetraglycidyl-4,4′-diaminodiphenylmethane

Another commercially important aromatic glycidyl amine resin is triglycidyl isocyanurate (TGIC), which is discussed in the "Weatherable Epoxy Resins" section.

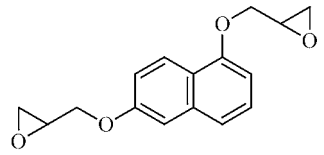
Specialty Epoxy Resins

Crystalline Epoxy Resins Development. A number of new epoxy resins used in epoxy molding compounds (EMC) have been developed by Japanese resin producers in response to the increased performance requirements of the semiconductor industry. Most notable are the commercialization of crystalline epoxies based on biphenol by Yuka-Shell (60):

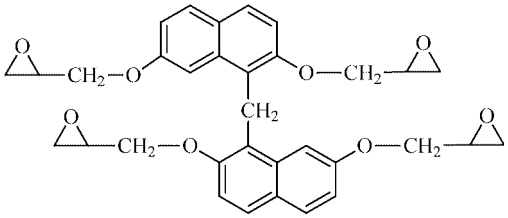


Diglycidyl ether of tetramethyl biphenol

The very low viscosity of these crystalline, solid epoxies when molten allows very high filler loading (up to 90 wt%) for molding compounds. The high filler loading reduces the coefficient of thermal expansion (CET) and helps manage thermal shock and moisture and crack resistance of molding compounds used in new, demanding semiconductor manufacturing processes such as Surface Mount Technology (SMT). It should be noted that cured thermosets derived from these crystalline resins do not retain crystallinity. Recently, a number of capacity expansions were announced for biphenol epoxies (sold as YX-4000 resin by Japan Epoxy Resins Corporation, formerly Yuka-Shell). DIC has developed dihydroxy naphthalene based epoxies (61) as the next generation product for this high performance market. Prices for crystalline epoxies are generally high ($22–26/kg), limiting their uses to high end applications.

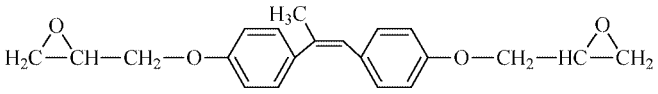


Diglycidyl ether of 1,5-dihydroxy naphthalene



Tetraglycidyl ether based on dihydroxy napthalene

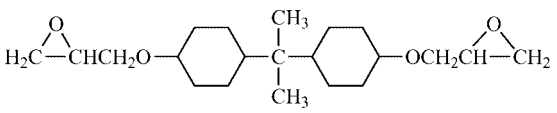
Dow Chemical developed liquid crystalline polymers (LCP) based on diglycidyl ether of 4-4′-dihydroxy-α-methylstilbene in the 1980s (62,63). Liquid crystal thermoplastics and thermosets based on this novel chemistry showed excellent combinations of thermal, mechanical, and chemical properties, unachievable with traditional epoxies. However, commercialization of these products has not materialized.



Diglycidyl ether of 4-4' -dihydroxy-α-methylstilbene

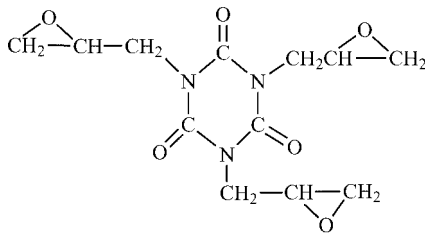
Weatherable Epoxy Resins. One of the major deficiencies of the aromatic epoxies is their poor weatherability, attributable to the aromatic ether segment of the backbone, which is highly susceptible to photoinitiated free-radical degradation. The aromatic ether of bisphenol A absorbs UV lights up to about 310 nm and undergoes photocleavage directly. This in turn produces free radicals that lead to oxidative degradation of bisphenol A epoxies, resulting in chalking. Numerous efforts have been devoted to remedy this issue, resulting in a number of new weatherable epoxy products. However, their commercial success has been limited, primarily because of higher resin costs and the fact that end users can topcoat epoxy primers with weatherable coatings based on other chemistries such as polyesters, polyurethanes, or acrylics. The following epoxy products when formulated with appropriate reactants can provide certain outdoor weatherability.

Hydrogenated DGEBA. In 1976, Shell Chemical Co. introduced epoxy resins based on the diglycidyl ether of hydrogenated bisphenol A, 2,2-bis[4-(2,3-epoxypropoxy)cyclohexyl]propane (232–238 EEW; η at 25°C 2–2.5 Pa · s).



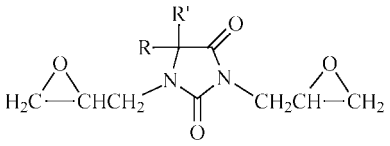
These resins resist yellowing and chalking because of their aliphatic structure. Epoxy resins based on hydrogenated bisphenol A are made by the epoxidation of the saturated diol, 2,2-bis(4-hydroxycyclohexyl)propane or 2,2-bis(4-hydroxycyclohexyl)propane with epichlorohydrin, or by the hydrogenation of a low molecular weight DGEBA resin (64). Commercially available products include an Epalloy 5000 resin from CVC. One disadvantage is their much higher costs, and consequently, the products have not found broad acceptance in the industry. Furthermore, cross-linked networks based on hydrogenated bisphenol A epoxies lose some of the characteristic temperature and chemical resistances inherent with the bisphenol A backbone.

Heterocyclic Glycidyl Imides and Amides. In the 1960s, considerable work was devoted to preparing triglycidyl isocyanurate, 1,3,5-tris(2,3-epoxypropyl)-1,3,5-perhydrotriazine-2,4,6-trione (65). The epoxidation of cyanuric acid with epichlorohydrin gives triglycidyl isocyanurate (TGIC), marketed as PT 810 by Huntsman. It is a crystalline compound (mp 85–110°C) with an EEW of ca 108. Miscibility with organic compounds is limited. Because of its excellent weatherability, TGIC is widely used in outdoor powder coatings with polyesters (66), despite its higher cost (~$12/kg).



Triglycidyl isocyanurate

Hydantoin-Based Epoxy Resins. These resins were commercialized by Ciba-Geigy. Hydantoins are prepared from carbon dioxide, ammonia, hydrogen cyanide, and ketones via the Bucherer reaction and can be epoxidized with epichlorohydrin (67). Cured and uncured resin properties depend greatly on the nature of the substituents R and R′. The hydantoin derived from acetone furnishes a low viscosity, water-dispersable epoxy resin, 5,5-dimethyl-1,3-bis(2,3-epoxypropyl)-2,4-imidazolidinedione ($R = R' = CH_3$; 145 EEM; η at 25°C 2.5 Pa · s). A nonsintering solid epoxy resin is obtained if $R = R' = -(CH_2)_5-$.



When cured with aromatic amines or anhydrides, these resins show high heat distortion temperatures and excellent adhesion and weatherability. A variety of applications are suggested for these new resins, particularly in applications in which a non-yellowing epoxy resin is desirable.

Elastomer-Modified Epoxies. Epoxy thermosets derive their thermal, chemical, and mechanical properties from the highly cross-linked networks. Consequently, toughness deficiency is an issue in certain applications. To improve the impact resistance and toughness of epoxy systems, elastomers such as BF Goodrich's CTBN rubbers (carboxyl-terminated butadiene nitrile) are often used as additives or pre-reacted with epoxy resins (68). Most commonly used products are reaction adducts of liquid epoxy resins (DGEBA) with CTBN in concentrations ranging from 5 wt% to 50 wt%. They have been shown to give improved toughness, peel adhesion, and low temperature flexibility over unmodified epoxies. Primary applications are adhesives for aerospace and automotive and as additives to epoxy vinyl esters for structural composites. Formation of adducts of epoxy resins and carboxylated butadiene–acrylonitrile copolymers (CTBN) is promoted by triphenylphosphine or alkyl phosphonium salts. Other elastomers used to modify epoxies include amine-terminated butadiene nitrile (ATBN), maleated polybutadiene and butadiene–styrene, epoxy-terminated urethane prepolymers, epoxy-terminated polysulfide, epoxy–acrylated urethane, and epoxidized polybutadiene.

Monofunctional Glycidyl Ethers and Aliphatic Glycidyl Ethers

A number of low MW monofunctional, difunctional, and mutifunctional epoxies are used as reactive diluents, viscosity reducers, flexiblizers, and adhesion promoters. Recent trends toward lower VOC, higher solids and 100% solids epoxy formulations have resulted in increased utilization of these products. Most of these epoxies are derived from relatively compact hydroxyl-containing compounds, such as alcohols, glycols, phenols, and epichlorohydrin. Epoxidized vegetable oils, such as epoxidized linseed oils, are also used as reactive diluents. They are produced using a peroxidation process and are discussed in more detail in the cycloaliphatic epoxies and epoxidized vegetable oils section. Typically, these products have very low viscosity (1–70 cP at 20°C) relative to LERs (11,000–16,000 cP). They are often used in the range of 7–20 wt% to reduce viscosity of the diluted system to 1000 cP. However, the uses of reactive diluents, especially at high levels, often result in decreased chemical resistance and thermal and mechanical properties of the cured epoxies.

Important products include butyl glycidyl ether (BGE), alkyl glycidyl ethers of C8–C10 (Epoxide 7) and C12–C14 (Epoxide 8), *o*-cresol glycidyl ether (CGE), *p-tert*-butyl glycidyl ether, resorcinol diglycidyl ether (RDGE), and neopentyl glycol diglycidyl ether (Table 9). While BGE is the most efficient viscosity reducer and has been widely used in the industry for many years, it has been losing market share because of its volatility and obnoxiousness. Phenyl glicidyl ether (PGE) is no longer used by many formulators because of its toxicity. The industry trend is moving toward longer chain epoxies such as Epoxide 8 or neopentyl glycol diglycidyl ether.

Major suppliers of these products are Resolution, Air Products, Ciba Specialty Chemicals, Huntsman, CVC Specialty Chemicals, Pacific Epoxy Polymers, and Exxon.

An example of multifunctional aliphatic epoxies is the triglycidyl ether of propoxylated glycerine (Heloxy 84) from Resolution. A similar product is based on

Table 9. Some Common Commercial Glycidyl Ether Reactive Diluents

Name	Structure
n-Butyl glycidyl ether	C12–C14 Aliphatic glycidyl ether	
o-Cresol glycidyl ether	Neopentylglycol diglycidyl ether	Butanediol diglycidyl ether	
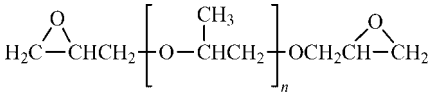
epoxidized castor oil (Heloxy 505). These products are used primarily as viscosity reducers while increasing functionality and cross-linking density of the cured systems.

Epoxy resins based on long-chain diols, such as the diglycidyl ether of polypropylene glycol [α,ω-bis(2,3-epoxypropoxy)poly(oxypropylene)] (305–335 EEW; η at 25°C 0.055–0.10 Pa · s), are used as flexibilizing agents to increase a thermoset's elongation and impact resistance. Because of the low reactivity of the aliphatic diols toward epichlorohydrin, these epoxies are produced by first coupling the diols with epichlorohydrin using phase-transfer catalysts such as ammonium salts or Lewis acid catalysts (boron trifluoride, stannic chloride), followed by epoxidation with caustic (69,70). A prominent side-reaction is the conversion of aliphatic hydroxyl groups formed by the initial reaction into chloromethyl groups by epichlorohydrin. The resultant epoxy resins are known to have lower reactivity toward conventional amine curing agents relative to bisphenol A epoxies. Dow Chemical manufactures D.E.R. 732 and D.E.R. 736 aliphatic epoxy resins. They are derived from polyglycols with different chain lengths.

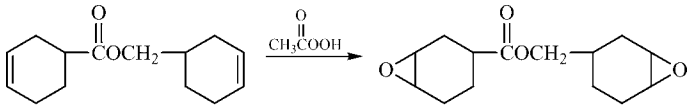


Polyglycidyl ethers of sorbitol, glycerol, and pentaerythritol are used as adhesion promoters for polyester tire cords. Their high chloride content improves adhesion to rubber.

Cycloaliphatic Epoxy Resins and Epoxidized Vegetable Oils

Resins based on the diepoxides of cycloaliphatic dienes were first commercialized in the 1950s by Union Carbide Corp. The combination of aliphatic backbone, high oxirane content, and no halogens gives resins with low viscosity, weatherability, low dielectric constant, and high cured T_g. This class of epoxy is popular for diverse end uses including auto topcoats, weatherable high voltage insulators, UV coatings, acid scavengers, and encapsulants for both electronics and optoelectronics. A comparison of some properties of two common aliphatic epoxies with those of LER (DGEBA) is shown in Table 10.

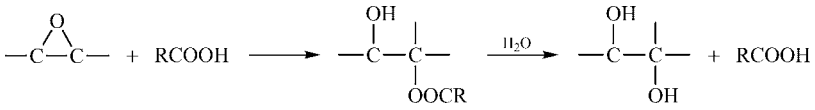
The preferred industrial route to cycloaliphatic epoxy resins is based on the epoxidation of cycloolefins with peracids, particularly peracetic acid (71). Few side reactions are encountered. Some properties of various commercial products are given in Table 11. The peracid cannot be made *in situ* because the cyclic olefins are sensitive to impurities generated in this process.



3′-Cyclohexenylmethyl 3-Cyclohexenecarboxylate

3′,4′-Epoxycyclohexylmethyl 3,4-Epoxycyclohexanecarboxylate

An important secondary reaction is the acid-catalyzed hydrolysis of the epoxide groups. The reaction is minimized at low temperatures and strongly depends on the constituents and the reaction medium.



The cycloaliphatic epoxides are more susceptible to electrophilic attack because of the lower electronegativity of the cycloaliphatic ring relative to the bisphenol A aromatic ether group in DGEBA resins. Consequently, cycloaliphatic epoxies do not react well with conventional anionic epoxy curing agents such as amines. They are commonly cured via thermal or UV-initiated cationic cures. In addition,

Table 10. Comparative Viscosities of Cycloaliphatic Epoxies, Epoxidized Oils, and DGEBA

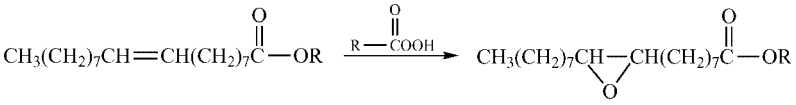
cycloaliphatic epoxy resins are low viscosity liquids that can be thermally cured with anhydrides to yield thermosets having a high heat distortion temperature. They are often used as additives to improve performance of bisphenol A epoxies. Their higher prices ($6.60–8.80/kg) have limited their commercial applications to high end products.

The largest end uses of cycloaliphatic epoxies in order of volume are electrical, electronic components encapsulation, and radiation-curable inks and coatings. A potentially large volume application is UV-curable metal can coatings for beer can exterior and ends, but the market has not been growing significantly in recent years. Other uses include acid scavengers for vinyl-based transformer fluids and lubricating oils; filament winding for aerial booms and antennas; and as viscosity modifier for bisphenol A LERs in tooling compounds. An epoxy silicone containing cycloaliphatic epoxy end groups and a silicone backbone is used as radiation-curable release coatings for pressure-sensitive products. Dow Chemical is the largest producer of cycloaliphatic epoxies. Daicel of Japan has entered the cycloaliphatic epoxy resin market.

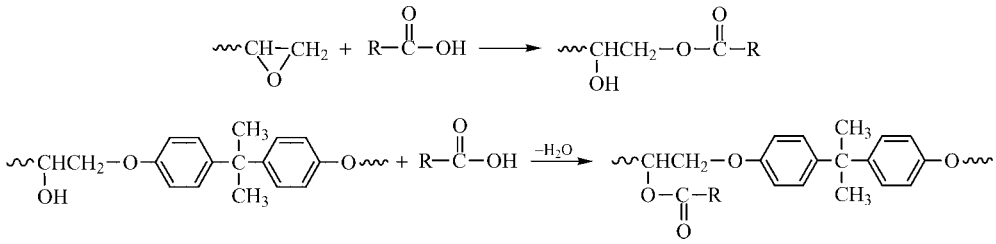
Epoxidation of α-olefins, unsaturated fatty acid esters, and glycerol esters is affected readily by peracids including *in situ* peracids generated from hydrogen peroxide and carboxylic acids.



α-Olefin epoxies find utility as reactive diluents for coatings and as chemical intermediates for lubrication fluids. Larger volume epoxidized soybean and linseed oils are most frequently used as *secondary* plasticizers and co-stabilizers for PVC.

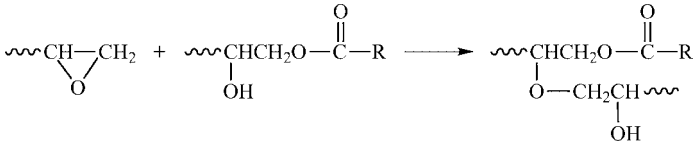
Epoxy Esters and Derivatives

Epoxy Esters. The esterification of epoxy resins with commercial fatty acids is a well-known process that has been employed for industrial coatings for many years. The carboxylic acids are esterified with the terminal epoxy groups or the pendant hydroxyls on the polymer chain.



A wide variety of saturated and unsaturated fatty acids are utilized to confer properties useful in air-dried, protective, and decorative coatings. Typical fatty

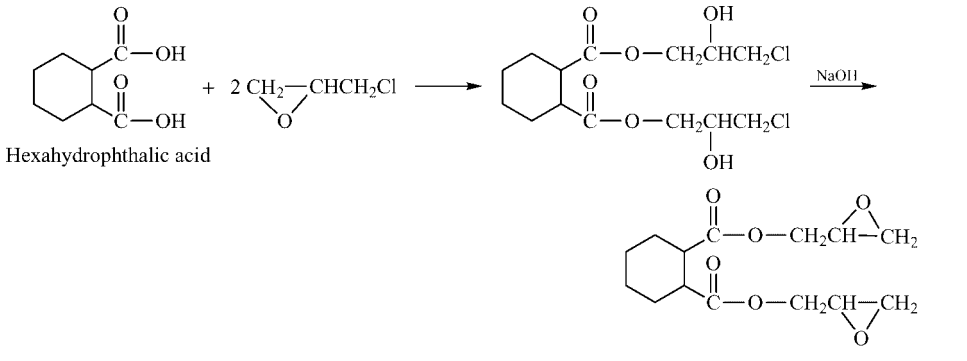
acids include tall oil fatty acids, linseed oil fatty acid, soya oil fatty acid and castor oil fatty acid. A medium molecular weight SER, a so-called 4-type, is commonly used. Catalysts such as alkaline metal salts (Na_2CO_3) or ammonium salts are essential to prevent chain branching and gelation caused by etherification of the epoxy groups.



Esterification is generally conducted in an inert atmosphere at 225–260°C, with sparging to remove by-product water. The course of the reaction is monitored by acid number to a specified end point and by viscosity. The product is then dissolved in a solvent (72).

Metallic driers are incorporated in unsaturated ester solutions to promote cure via air-drying, ie, oxidative polymerization of the double bonds of the fatty acids. Chemical resistance is generally lower than that of unmodified epoxy resins cured at ambient temperatures with amine hardeners. Epoxy esters are also used to produce anodic electrodeposition (AED) coatings by further reaction with maleic anhydride followed by neutralization with amines to produce water-dispersable coatings. Epoxy esters were widely used as automotive primer-surfacer and metal can ends coatings for many years, but are being replaced by other technologies. Their high viscosity limited their uses in low solids, solvent-borne coatings. Waterborne epoxy esters are now available and are used in flexographic inks for milk cartons.

Glycidyl Esters. Glycidyl esters are prepared by the reaction of carboxylic acids with epichlorohydrin followed by dehydrochlorination with caustic:

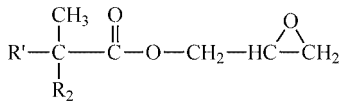


Hexahydrophthalic acid

Diglycidyl ester of hexahydrophthalic acid

The viscosity of these esters is low, ie, ca 500 MPa·s (= cP), and their reactivity resembles that of bisphenol A resins. Similar epoxy resin derived from dimerized linoleic acid is also commercially available. They are often used as flexiblizing agents instead of epoxidized long-chain diols.

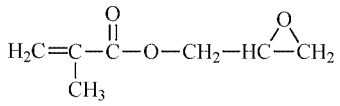
The *glycidyl ester of versatic acid* or neodecanoic acid is an example of high MW monoglycidyl aliphatic epoxy. The molecule is highly branched, thus providing steric effects to protect it from hydrolysis, resulting in good weatherability and water resistance. On the other hand, it suffers from high viscosity, and therefore it is not an effective diluent. It is often used to improve scrubability, chemical resistance, and weatherability of coatings. The product is commercially available from Resolution (Cardura E-10) and Exxon (Glydexx N-10).



Where R's = alkyl or substituted alkyls

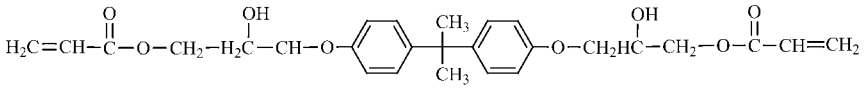
Glycidyl ester of versatic acid

A commercially important glycidyl ester is *glycidyl methacrylate (GMA)*, a dual functionality monomer, containing both a terminal epoxy and an acrylic C=C bond. It is produced by the reaction of methacrylic acid with epichlorohydrin. The dual functionality of GMA brings together desirable properties of both epoxies and acrylics, eg, the weatherability of acrylics and chemical resistance of epoxies, in one product. GMA is useful as a comonomer in the synthesis of epoxy-containing polymers via free-radical polymerization. The resultant epoxy-containing polymers can be further cross-linked. An example of such polymers is GMA acrylic, which is an acrylic copolymer, containing about 10–35% by weight of GMA. Cure is by reaction with dodecanedioic acid. Its primary uses are in automotive powder coatings. GMA-containing polymers are also used as compatiblizers for engineering thermoplastics, in adhesives and latexes, and as rubber and asphalt modifiers (73). Dow Chemical and Nippon Oils & Fats are two major producers of GMA.



Glycidyl methacrylate (GMA)

Epoxy Acrylates. Epoxy resins are reacted with acrylic acid to form epoxy acrylate oligomers, curable via free-radical polymerization of the acrylate C=C bonds initiated by light (74). UV lights are most commonly used, but electron beam (EB) curing is becoming more common because of its decreasing equipment costs. This is a fast-growing market segment for epoxy resins because of the environmental benefits of the UV cure technology: low to zero VOC, low energy requirements. Major applications include coatings for overprint varnishes, wood substrates, and plastics. Radiation-cured epoxy acrylates are also growing in importance in inks, adhesives, and photoresists applications. The 2001 global market for epoxy acrylates was estimated at 40,000 MT with an annual growth rate projected to be 8–10%.

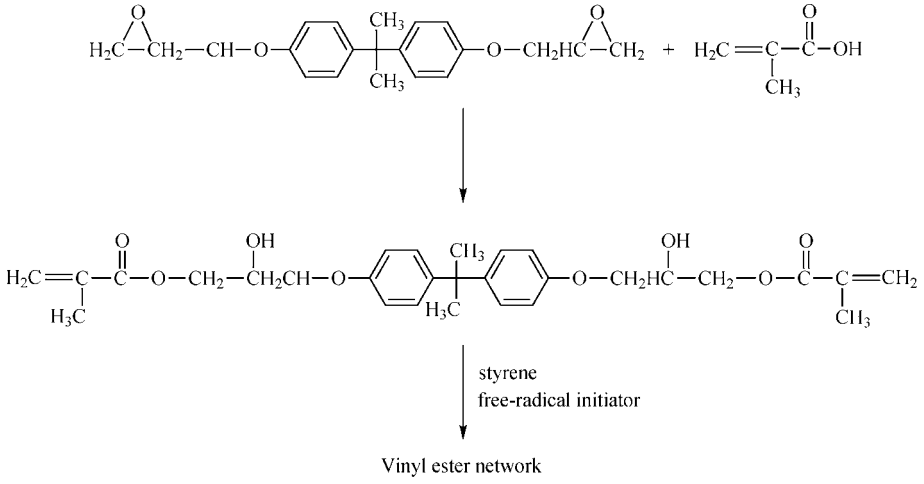


Epoxy acrylate based on DGEBA

Liquid epoxy resins such as DGEBA are most commonly used to produce epoxy acrylates. When higher thermal performance is required, multifunctional epoxies such as epoxy novolacs are used. Epoxy acrylates from epoxidized soybean oil and linseed oil are often used as blends with aromatic epoxy acrylates to reduce viscosity of the formulations. Major producers of UV-curable epoxy acrylates are UCB, Radcure, Dow Chemical, Sartomer, and Henkel.

Epoxy Vinyl Esters. A major derivative of epoxy resins is the epoxy vinyl ester resin. Originally developed by Dow Chemical (75,76) and Shell Chemical in the 1970s, it is considered a high performance resin used in glass-reinforced structural composites, particularly for its outstanding chemical resistance and mechanical properties. The resins are made by reacting epoxy resins with methacrylic acid and diluted with styrene to 35–40% solvent by weight. Liquid epoxy resins (DGEBA) are commonly used. Epoxy novolacs are used where higher thermal or solvent resistance is needed. Brominated epoxies are also used to impart flame retardancy for certain applications. In the final formulation, peroxide initiators are added to initiate the free-radical cure reactions of the methacrylic C=C bonds and styrene to form a random copolymer thermoset network.

The vinyl ester functionality of the epoxy vinyl esters provides outstanding hydrolysis and chemical resistance properties, in addition to the inherent thermal resistance and toughness properties of the epoxy backbone. These attributes have made epoxy vinyl esters a material of choice in demanding structural composite applications such as corrosive chemicals storage tanks, pipes, and ancillary equipment for chemical processing. Other applications include automotive valve covers and oil pans, boats, and pultruded construction parts. Significant efforts have been devoted to improve toughness and to reduce levels of styrene in epoxy vinyl ester formulations because of environmental concerns. In addition to Dow Chemical, other major suppliers of epoxy vinyl esters include Ashland, AOC, DSM, Interplastic, and Reichhold (DIC).



Epoxy Phosphate Esters. Dow Chemical developed the epoxy phosphate ester technology in the 1980s (77). Epoxy phosphate esters are reaction products of epoxy resins with phosphoric acid. Depending on the stoichiometric ratio and

reaction conditions, a mixture of mono-, di- and triesters of phosphoric acid are obtained. Subsequent hydrolysis of the esters is used as a way to control the esters distribution and product viscosity. Epoxy phosphate esters can be made to disperse in water to produce waterborne coatings. They are used primarily as modifiers to improve the adhesion property of nonepoxy binders in both solvent-borne and waterborne systems for container and coil coatings.

Characterization of Uncured Epoxies

Most industrial chemicals and polymers are not the 100% pure, single chemicals as described in their general chemical structures. In the case of epoxy resins, they often contain isomers, oligomers, and other minor constituents. As a first requirement, one would need to know the epoxy content or EEW of the epoxy resin so the proper stoichiometric amount of cross-linker(s) can be calculated. However, a successful thermoset formulation must also have the proper reactivity, flow, and performance. Consequently, other epoxy resin properties are required by the formulators and supplied by the resin producers.

Liquid epoxy resins are mainly characterized by epoxy content, viscosity, color, density, hydrolyzable chloride, and volatile content (78). Less often analyzed are α-glycol content, total chloride content, ionic chloride, and sodium. Solid epoxy resins are characterized by epoxy content, solution viscosity, melting point, color, and volatile content. Less often quoted are phenolic hydroxyl content, hydrolyzable chloride, ionic chloride, sodium, and esterification equivalent. Table 12 lists analytical methods adopted by ASTM (79) as standard testing methods for epoxy resins.

In addition, gel-permeation chromatography (GPC), high performance liquid chromatography (HPLC) (39,80), and other analytical procedures such as nuclear magnetic resonance (NMR) (28) and infrared spectroscopy (IR) (81) are performed to determine MW, MW distribution, oligomer composition, functional groups, and impurities.

Table 12. Uncured Epoxy Resin Test Methods

Test Item	Unit	Condition	ASTM method
EEW			D1652-97
Viscosity, neat	cP[a]	25°C	D445-01
Viscosity, solution	cSt[b]	25°C	D445-01
Viscosity, melt	cSt[b]	150°C	D445-01
Viscosity, ICI Cone and Plate	Pa · s		D4287-00
Viscosity, Gardner–Holdt			D1545-98
Color, Co-Pt			D1209-00
Color, Gardner			D1544-98
Color, Gardner in solution			D1544-98
Moisture	ppm		E203-01
Softening point	°C		D3104-99

[a] cP = MPa·s.
[b] cSt = mm^2/s.

Resin components such as α-glycol content and chloride types and levels are known to influence certain formulation reactivity and rheology, depending on their interactions with the system composition such as basic catalysts (tertiary amines) and/or amine curing agents. Knowing the types and levels of chlorides guides formulators in the adjustment of their formulations for proper reactivity and flow.

Epoxide Equivalent Weight. The epoxy content of liquid resins is frequently expressed as *epoxide equivalent weight (EEW)* or *weight per epoxide (WPE)*, which is defined as the weight in grams that contains 1 g equivalent of epoxide. A common chemical method of analysis for epoxy content of liquid resins and solid resins is titration of the epoxide ring by hydrogen bromide in acetic acid (82). Direct titration to a crystal violet indicator end point gives excellent results with glycidyl ethers and cycloaliphatic epoxy resins. The epoxy content of glycidyl amines is determined by differential titration with perchloric acid. The amine content is first determined with perchloric acid. Addition of tetrabutylammonium iodide and additional perchloric acid generates hydrogen iodide, which reacts with the epoxy ring. The epoxy content is obtained by the second perchloric acid titration to a crystal violet end point.

In another procedure, a halogen acid is generated by the reaction of an ionic halide salt, eg, tetraethylammonium bromide in acetic acid with perchloric acid with subsequent formation of a halohydrin; the epoxy group is determined by back-titration with perchloric acid using crystal violet indicator (83). The end point can be determined visually or potentiometrically. A monograph on epoxide determinations was published in 1969 (84). This is the method adopted by ASTM and is currently used by most resin producers.

Viscosity of epoxy resins is an important characteristic affecting handling, processing, and application of the formulations. For example, high viscosity LERs impede good mixing with curing agents, resulting in inhomogeneous mixtures, incomplete network formation, and poor performance. On the other hand, too low viscosity would affect application characteristics such as coverage and appearance.

Viscosities of liquid resins are typically determined with a Cannon–Fenske capillary viscometer at 25°C, or a Brookfield viscometer. The viscosity depends on the temperature, as illustrated in Figure 2. Viscosities of solid epoxy resins are determined in butyl carbitol (diethylene glycol monobutyl ether) solutions (40% solids content) and by comparison with standard bubble tubes (Gardner–Holdt bubble viscosity). The Gardner color of the same resin solution is determined by comparison with a standard color disk. Recently, data have been reported for solid epoxy resins using the ICI Cone and Plate viscometers, which are much more time-efficient because they do not require sample dissolution.

Hydrolyzable chloride (HyCl) content of liquid and solid epoxy resins is determined by dehydrochlorination with potassium hydroxide solution under reflux conditions and potentiometric titration of the chloride liberated by silver nitrate. The solvent(s) employed and reflux conditions can influence the extent of dehydrochlorination and give different results. The "easily hydrolyzable" HyCl content, which reflects the degree of completion of the dehydrochlorination step in the epoxy resin manufacturing process, is routinely determined by a method using methanol and toluene as solvents. This is the method most commonly used to characterize LER and SER.

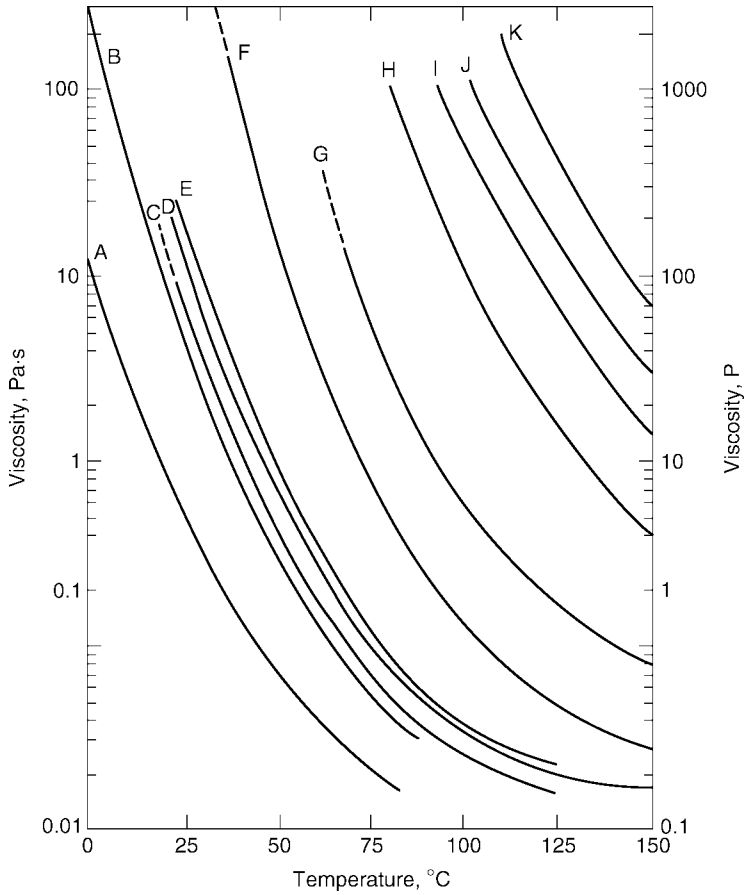


Fig. 2. Viscosity–temperature profiles for bisphenol A epoxy resins with the following EEW (epoxide equivalent weight): A, 175–195 and 195–215 diluted resins; B, 172–178; C, 178–186; D, 185–192; E, 190–198; F, 230–280; G, 290–335; H, 450–550; I, 600–700; J, 675–760; K, 800–975.

For epoxy resins used in electronic applications, such as cresol epoxy novolacs, more powerful polar aprotic solvents such as dioxane or dimethyl formamide (DMF) have been used to hydrolyze the difficult-to-hydrolyze HyCls, such as the abnormal chlorohydrins and the organically "bound" chlorides. The issue here is the inconsistency in results obtained by different methods (78). The presence of ionic hydrolyzable chlorides and total chlorides has been shown to affect electrical properties of epoxy molding compounds used in semiconductor encapsulation (85). For these applications, producers offer high purity grade epoxy resins with low ionic, hydrolyzable and total chloride contents.

Total chloride content of epoxy resins can be determined by the classical Parr bomb method in which the sample is oxidized in a Parr bomb, followed by titration with silver nitrate (78). The major disadvantage of this method is that it is time-consuming. Alternatively, X-ray fluorescence has been used successfully as a simple, nondestructive method to determine total chloride of epoxy resins.

The method, originally developed by Dow Chemical, has been under consideration for adoption by ASTM.

The "ball and ring" and Durran's methods traditionally measure the softening point of SERs, which is important in applications such as powder coatings. The Durran's method involves heating a resin sample topped with a certain weight of mercury in a test tube until the resin reaches its softening point and flows, allowing the mercury to drop to the bottom of the test tube. The method is accurate but involves handling of highly hazardous mercury at elevated temperatures. The Mettlers' softening point method is more widely used recently because of its simplicity.

The esterification equivalent of solid resins is defined as the weight in grams esterified by one mole of monobasic acid. This value includes both the epoxy and hydroxyl groups of the solid resin. It is determined by esterification of the sample with acetic anhydride in the presence of pyridinium chloride, followed by titration with sodium methoxide to a thymol blue–phenolphthalein end point.

Molecular structure of epoxy resins. Infrared spectroscopy (IR) is used to determine the epoxide content of resins as well as their structure. A compilation of IR spectra of uncured resins has been published (86) and their use in quality control and identification of components of resin blends has been described. Recently, near IR (NIR) has emerged as a useful tool to characterize epoxy resins (87).

NMR has been utilized to characterize epoxy resins, formulations and cured networks. It has been shown to be useful in determining the level of branching in epoxy resins and isomers distribution in epoxy novolacs (88,89).

GPC and HPLC are utilized to characterize both liquid and solid epoxy resins (90). MW and MW distributions are obtained from GPC measurements, but differences in chemical composition of resin samples are more apparent from HPLC chromatograms because of better resolution (91).

HPLC has proven to be a good fingerprinting tool to characterize LERs and SERs. Chromatograms of liquid epoxy resins (crude DGEBA) indicate a homologue distribution of $n = 0$, 85%, and, in a specific case, $n = 1$, 11.5%, although the values obtained depend on the source of the liquid resin. HPLC analysis of both liquid and solid epoxy resins has been studied in some detail using normal-phase and reversed-phase columns, respectively (39).

The difference between taffy-processed and fusion advancement solid resin can be noted in HPLC chromatograms. In the advancement process, the even-membered oligomers predominate, whereas taffy-produced resins exhibit both even- and odd-numbered oligomers. Compounds that contribute to hydrolyzable chloride and α-glycol content can be quantified by HPLC. The presence of branched chain components is detectable in studies using an improved reversed-phase gradient HPLC method (92,93). Excellent reviews of applications of chromatographic techniques to the analysis of epoxy resins are available (94).

Curing of Epoxy Resins

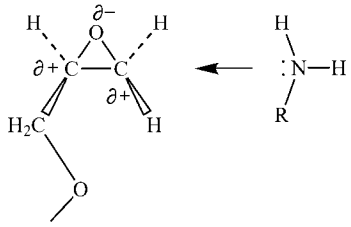
With the exception of the very high MW phenoxy resins and epoxy-based thermoplastic resins, almost all epoxy resins are converted into solid, infusible, and insoluble three-dimensional thermoset networks for their uses by curing with

cross-linkers. Optimum performance properties are obtained by cross-linking (qv) the right epoxy resins with the proper cross-linkers, often called hardeners or curing agents. Selecting the proper curing agent is dependent on the requirements of the application process techniques, pot life, cure conditions, and ultimate physical properties. Besides affecting viscosity and reactivity of the formulation, curing agents determine both the types of chemical bonds formed and the degree of cross-linking that will occur. These, in turn, affect the chemical resistance, electrical properties, mechanical properties, and heat resistance of the cured thermosets.

Epoxy resins contain two chemically reactive functional groups: epoxy and hydroxy. Low MW epoxy resins such as LERs are considered difunctional epoxy monomers or prepolymers and are mostly cured via the epoxy group. However, as the MW of SERs increases, the epoxy content decreases, whereas the hydroxyl content increases. High molecular weight SERs can cross-link via reactions with both the epoxy and hydroxyl functionalities, depending on the choice of curing agents and curing conditions. Reaction of the epoxy groups involves opening of the oxirane ring and formation of longer, linear C—O bonds. This feature accounts for the low shrinkage and good dimensional stability of cured epoxies. The polycondensation curing is accompanied by generation of volatile by-products, such as water or alcohol, requiring heat for proper cure and volatiles removal.

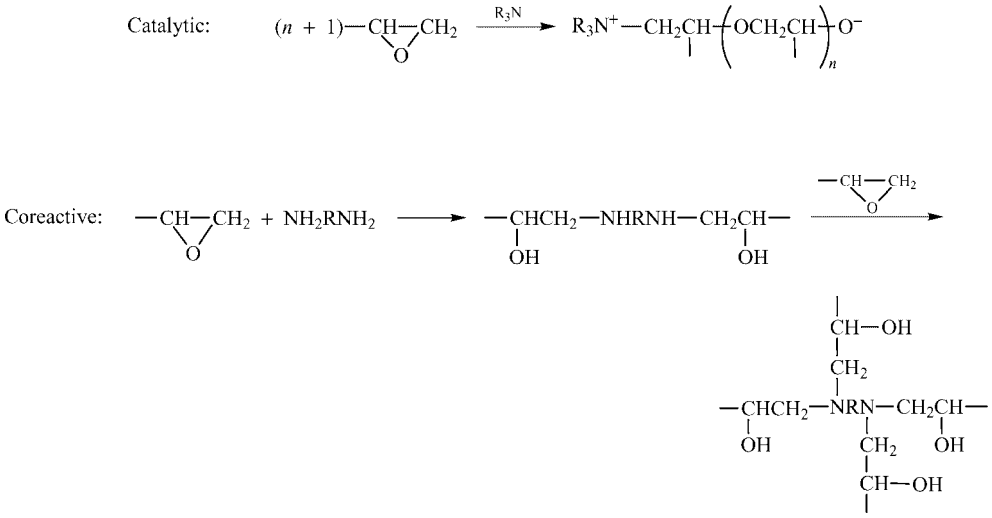
It is the unique ability of the strained epoxy ring to react with a wide variety of reactants under many diverse conditions that gives epoxies their versatility (95). Detailed discussions on the probable electronic configurations, molecular orbitals, bond angles, and reactivity of the epoxy ring are available in the literature (96).

Compared to noncyclic and other cyclic ethers, the epoxy ring is abnormally reactive. It has been postulated that the highly strained bond angles, along with the polarization of the C—C and C—O bonds account for the high reactivity of the epoxide. The electron-deficient carbon can undergo nucleophilic reactions, whereas the electron-rich oxygen can react with electrophiles. It is customary in the epoxy industry to refer to these reactions in terms of anionic and cationic mechanisms. The terminology was attributed to the fact that an anionic intermediate or transition state is involved in a nucleophilic attack of the epoxy while a cationic intermediate or transition state is formed by an electrophilic curing agent (97). For the sake of clarity, the nucleophilic and electrophilic mechanism terminology is used in this article.



Curing agents are either catalytic or coreactive. A catalytic curing agent functions as an initiator for epoxy resin homopolymerization or as an accelerator for other curing agents, whereas the coreactive curing agent acts as a comonomer in the polymerization process. The majority of epoxy curing occurs by nucleophilic

mechanisms. The most important groups of coreactive curing agents are those with active hydrogen atoms, eg, primary and secondary amines, phenols, thiols, and carboxylic acids (and their anhydride derivatives). Lewis acids, eg, boron trihalides, and Lewis bases, eg, tertiary amines, initiate catalytic cures.



The functional groups surrounding the epoxide resin also affect the curing process. Steric factors (98,99) can influence ease of cure. Electron-withdrawing groups adjacent to the epoxide ring often enhance the reactivity of the epoxy resin to nucleophilic reagents, while retarding its reactivity toward electrophilic reagents (98,100,101). In general, aromatic and brominated aromatic epoxy resins react quite readily with nucleophilic reagents, whereas aliphatic and cycloaliphatic epoxies react sluggishly toward nucleophiles (102).

Figure 3 shows the pseudo first-order kinetic response for the disappearance of the epoxy in buffered methanol solutions (lines are for clarity only).

Table 13. U.S. Consumption of Curing Agents for Epoxy Resins (2001)

Curing agents	Consumption, 10^3 MT	Market percentage
Amine functional compounds	50	48
Aliphatic amines and adducts	16	
Polyamides	14	
Amidoamines	9	
Cycloaliphatic amines	6.8	
Phenalkamines	1.8	
Dicyandiamide (DICY)	1.8	
Aromatic polyamines	0.9	
Carboxylics	37	36
Polycarboxylic polyesters	22	
Anhydrides	15	
Resole resins	9	9
Amino formaldehydes	4.5	
Phenol formaldehyde	4.5	
Novolacs and other phenolics	2.7	2.6
Polysulfides and polymercaptans	14	1.3
Catalysts	3.2	3
Anionic	3.1	
Cationic	0.1	
Others	0.9	<1

Clearly the epoxy structure dramatically influences the cure response of the epoxy as a function of pH. Cycloaliphatic epoxies are fast-reacting under low pH conditions. Aromatic glycidyl ethers are faster under high pH conditions. These results generally agree with "practical" cures: aromatic epoxies are easily cured with amines and amidoamines. Cycloaliphatics (102) are cured with acids and superacids. The behavior of the aliphatic epoxies is more complex but on balance is similar to that of cycloaliphatics.

In 2001, the U.S. market for epoxy curing agents was estimated at 165×10^3 MT (see Table 13), while approximately 318×10^3 MT of epoxy resins was consumed. The most commonly used curing agents are amines, followed by carboxylic-functional polyesters and anhydrides.

A description of advantages, disadvantages and major applications of typical curing agents is given in Table 14.

Coreactive Curing Agents

Commercially, epoxy resins are predominantly cured with coreactive curing agents. Following are important classes of epoxy coreactive curing agents.

Amine Functional Curing Agents. This section describes one of the most important classes of epoxy coreactive curing agents.

Primary and Secondary Amines. Primary and secondary amines and their adducts are the most widely used curing agents for epoxy resins, accounting for close to 50% of all the epoxy curing agents used in the United States in 2001.

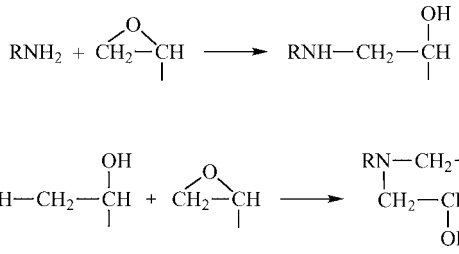
Table 14. Curing Agents for Epoxy Resins

Type	Advantages	Disadvantages	Major applications
Aliphatic amines and adducts	Low viscosity; ambient cure temperature; little color; low cost	Short pot life; rapid heat evolution; critical mix ratio; some are moderately toxic; high moisture absorption; blush; carbonation; limited high temperature performance (<100°C)	Flooring; civil engineering; marine and industrial coatings; adhesives; small castings
Cycloaliphatic amines	Low viscosity; long pot-life; room temperature (RT) cure and heat-curable; adhesion to wet cement; good color; low toxicity; good electrical, mechanical, thermal properties (high T_g)	Slower reactivity; high costs	Flooring; paving; aggregate; industrial coatings; adhesives; tooling; composites; castings
Aromatic amines	Excellent elevated temperature performance (150°C); good chemical resistance; long pot life; low moisture absorption	Solids; incompatibility with resins; long cure cycles at high temperature (150°C); toxicity	High performance composites and coatings; adhesives; electrical encapsulation
Amidoamines	Low viscosity; reduced volatility; good pot life; ambient cure temperature; convenient mix ratios; good toughness	Poor performance at high temperature (<65°C); some incompatibility with epoxies	High solids, solvent-free coatings; floorings; concrete bonding; troweling compounds
Polyamides	Good mix ratios; pot life; RT cure; good concrete wetting; flexibility; low volatility and toxicity	High viscosity; low temperature performance; poor color; higher cost	Marine and maintenance coatings; civil engineering; castings; adhesives
Anhydrides	Low exotherm; good thermal (high T_g), mechanical,	Long cure cycles at high temperature (200°C)	Composites; castings; potting; encapsulation

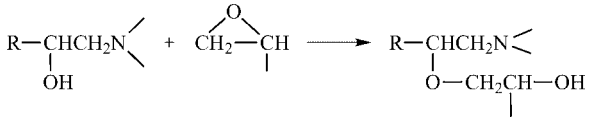
Table 14. (Continued)

Type	Advantages	Disadvantages	Major applications
	electrical properties; low shrinkage and viscosity; long pot life; little color		
Catalytic	Long pot life; high temperature resistance	Brittle; moisture-sensitive	Adhesives; prepregs; electrical encapsulation; powder coatings
Dicyandiamide	Good electrical properties; high temperature resistance; latent systems	Incompatibility with epoxy resins	Electrical laminates; powder coatings; single-package adhesives
Carboxylic-terminated polyesters	Good weatherability, corrosion resistance, and mechanical properties; low cost	Poor chemical resistance	Powder coatings
Isocyanates	Fast cure at low temperature; good flexibility and solvent resistance	Moisture-sensitive; toxic	Powder coatings; maintenance coatings
Phenol–formaldehyde, novolacs	Good chemical resistance, electrical properties, shelf stability, and compatibility with epoxies; high temperature resistance	High melting solids; high temperature cure; poor UV stability	Molding compounds; powder coatings; electrical laminates
Polysulfides and polymercaptans	RT rapid cure times; flexible systems; moisture insensitive	Poor performance at high temperature; odorous	Consumer adhesives; sealants; traffic paints
Melamine–formaldehyde	Good color and hardness; stable one-component systems	High temperature cure	Stove paints; can coatings
Urea–formaldehyde	Stable one-component systems; little color; low cost	High temperature cure; formaldehyde emission	Fast-bake enamels; stove primers; can and drum coatings
Phenol–formaldehyde resoles	Stable one-component systems; excellent chemical resistance	High temperature cure; brittle; gold color	Baked enamels; can, drum and pail coatings; high temperature service coatings

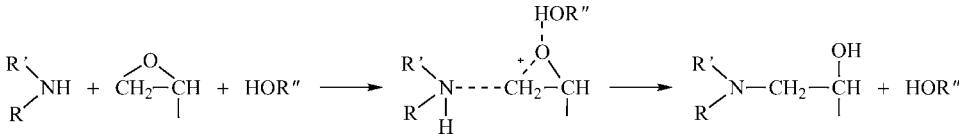
The number of amine hydrogen atoms present on the molecule determines the functionality of an amine. A primary amine group, one which has two hydrogens bound to it, will react with two epoxy groups while a secondary amine will react with only one epoxy group. A tertiary amine group, which has no active hydrogen, will not react readily with the epoxy group, but will act as a catalyst to accelerate epoxy reactions. Reactions of a primary amine with an oxirane group or an epoxy resin are shown in the following (103).



It has been reported that primary amines react much faster than secondary amines (101,104). Reaction of an epoxy group with a primary amine initially produces a secondary alcohol and a secondary amine. The secondary amine, in turn, reacts with an epoxy group to give a tertiary amine and two secondary hydroxyl groups. Little competitive reaction is detectable between a secondary hydroxyl group in the backbone and an epoxy group to afford an ether (100), provided a stoichiometric equivalent or excess amine is maintained. However, with excess epoxy, the secondary hydroxyl groups formed gradually add to the epoxide groups (105). This reaction can be catalyzed by tertiary amines.



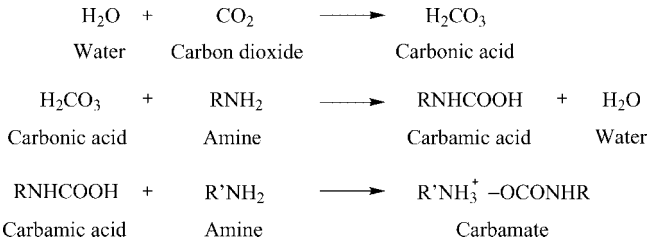
Hydroxyl compounds accelerate the rate of amine curing. A mechanism has been proposed (100) in which the hydrogen atom of the hydroxyl group partially protonates the oxygen atom on the epoxy group, rendering the methylene group more susceptible to attack by the nucleophilic amine. Reactivity is proportional to the hydroxyl acidity and functionality; phenolics, aryl alcohols, and polyfunctional alcohols afford the best results.



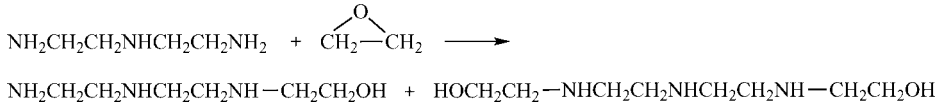
In general, reactivity of amines toward aromatic glycidyl ethers follows their nucleophilicity: aliphatic amines > cycloaliphatic amines > aromatic amines. Aliphatic amines cure aromatic glycidyl ether resins at room temperature (RT) without accelerators, whereas aromatic amines require elevated temperatures.

However, with the help of accelerators, the cure rates of aromatic amines can approach those of some aliphatic amines. In general, the steric and electronic effects of substituents of the epoxy and the amine influence the reaction rate of an amine with an epoxy resin.

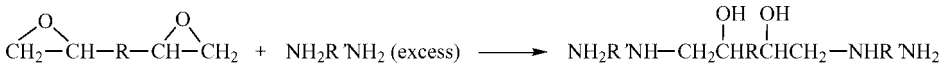
Aliphatic Amines. The liquid aliphatic polyamines such as polyethylene polyamines (PEPAs) were some of the first curing agents used with epoxies. They give good RT cures with DGEBA-type resins. The low equivalent weights of the ethylene amines give tightly cross-linked networks with good physical properties, including excellent chemical and solvent resistance but limited flexibility and toughness. Good long-term retention of properties is possible at temperatures up to 100°C. Short-term exposure to higher temperatures can be tolerated. Certain aliphatic amines cured epoxies will blush (or bloom) under humid conditions. This undesirable property has been attributed to the incompatibility of some amine curing agents with epoxy resins. Incompatible amines can exude to the surface during cure and react with atmospheric carbon dioxide and moisture to form undesirable carbamates (carbonation). This, in turn, leads to gloss reduction and intercoat adhesion and recoatability problems in coating applications (106).



Mixing ratios with epoxy resin are very critical, and working pot lives are too short for some applications. Aliphatic polyamines are hygroscopic and volatile, have bad odor, and cause dermatitis if improperly handled. Another disadvantage is high exotherm in thick sections or large mass parts that can lead to thermal decomposition. Consequently, significant efforts have been devoted toward remedying these shortcomings by modifications of the polyethylene polyamines. Adducts with epoxy resins (resin adducts), carboxylic acids (polyamides, amidoamines), ketones (ketimines), and phenols/formaldehyde (Mannich bases) (107) are widely used commercially. Longer chain alkylenediamines such as hexamethylenediamine (HMD) and polyetheramines (polyglycol-based polyamines) have also been developed. Currently, very small amounts of unmodified polyamines are used as curing agents for epoxies. They are primarily used to produce epoxy adducts (up to 90%). Chemical modification by reaction with epoxy groups to yield epoxy adducts affords products with better handling properties, lower vapor pressure, reduced tendency to blush, and less critical mix ratio. For example, diethylenetriamine (DETA) readily reacts with ethylene oxide in the presence of water to give a mixture of mono- and dihydroxyethyl diethylenetriamine with a longer pot life and fewer dermatitic effects than free DETA.

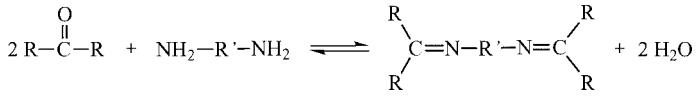


Resinous adducts are produced by reaction of excess diamine with epoxy resins.

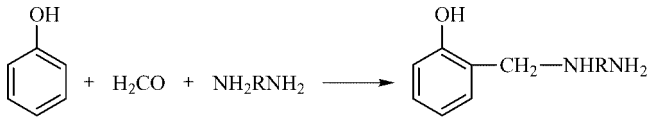


The higher molecular weight of the adduct affords a more desirable, forgiving ratio of resin to curing agent, lower water absorption, and better resin compatibility.

Ketimines. Ketimines are the reaction products of ketones and primary aliphatic amines. In the absence of reactive hydrogens, they do not react with epoxy resins. They can be considered blocked amines or latent hardeners, since they are readily hydrolyzed to regenerate the amines. They have low viscosity, cure rapidly when exposed to atmospheric humidity, and are useful in high solids coatings. Similar products have been obtained with acrylonitrile.



Mannich Base Adducts. Mannich base adduct is the reaction product of an amine with phenol and formaldehyde.



Mannich base

The resultant product has an internal phenolic accelerator. Compared to unmodified amines Mannich base adducts have lower volatility, less blushing and carbonation, and, despite their higher MW, faster reactivity.

Polyetheramines. Polyetheramines are produced by reacting polyols derived from ethylene oxide or propylene oxide with amines. The more commercially successful adducts are based on propylene oxide and are available in different MWs (JEFFAMINE* from Huntsman). The longer chain backbone provides improved flexibility but slower cure rate. Chemical and thermal resistance properties are also reduced. Polyetheramines are often used in combination with other amines in flooring, and adhesive and electrical potting applications.

Cycloaliphatic Amines. Cycloaliphatic amines were originally developed in Europe, where their use as epoxy curing agents is well established. Compared to aliphatic amines, cycloaliphatic amines produce cured resins having improved thermal resistance and toughness. Glass-transition temperatures (T_g) approach those of aromatic amines (>150°C), while percent elongation can be doubled.

However, chemical resistance is inferior to that of aromatic amines. Because cycloaliphatic amines are less reactive than acyclic aliphatic amines, their use results in a longer pot life and in the ability to cast larger masses. Unmodified cycloaliphatic amines require elevated temperature cure, but modified systems are RT-curable. Properly formulated, they can give an excellent balance of properties: fast cure, low viscosity, low toxicity, good adhesion to damp concrete, and excellent color stability. They are, however, more expensive than other types of curing agents.

Isophorone diamine (IPDA), bis(4-aminocyclohexyl)methane (PACM), and 1,2-diaminocyclohexane (1,2-DACH) are the principal commercial cycloaliphatic polyamine curing agents. IPDA is the largest volume cycloaliphatic amine. Commercial cycloaliphatic amines are formulated products. In addition to the cycloaliphatic amines, other components such as aliphatic amines and plasticizers are also included to improve RT cure speed and end-use properties. One popular formulation consists of IPDA used in combination with trimethylhexamethylenediamines (TMDA) or *meta*-xylenediamine (MXDA), and plasticizers/accelerators such as nonyl phenol or benzyl alcohol. In some ambient cure coating applications, cycloaliphatic amines can be reacted with phenol and formaldehyde to form the Mannich base products, which have an internal phenol accelerator and cure readily at ambient temperatures.

The largest market for cycloaliphatic amines is in flooring, followed by high solids coatings, composites, adhesives, castings, and tooling. Cycloaliphatic amines experienced significant growth in the early 1990s as replacements for more toxic aromatic amines such as MDA. However, anhydrides have been more successful at replacing aromatic amines in composite applications.

Aromatic Amines. Because of conjugation, aromatic amines have lower electron density on nitrogen than do the aliphatic and cycloaliphatic amines. Consequently, they are much less reactive toward aromatic epoxies. They have longer pot-lives and usually require elevated temperature cures. Aromatic amines are usually solid at room temperature. These hardeners are routinely melted at elevated temperatures and blended with warmed resins to improve solubility. Eutectic mixtures of *meta*-phenylenediamine (MPD) and methylenedianiline (MDA or DDM) exhibit a depressed melting point resulting in an aromatic hardener that remains a liquid over a short period of time. MDA or 4,4′-diaminodiphenylmethane (DDM), 4,4′-diaminodiphenyl sulfone (DDS or DADPS), and MPD are the principal commercial aromatic amines. A new aromatic amine, diethyltoluenediamine (DETDA) has gained more significant uses in recent years.

Epoxies cured with aromatic amines typically have better chemical resistance and higher thermal resistance properties than products cured with aliphatic and cycloaliphatic amines. Their best attribute is their retention of mechanical properties at long exposures to elevated temperatures (up to 150°C). Consequently, they are widely used in demanding structural composite applications such as aerospace, PCB laminates, and electronic encapsulation. 4,4′-DDS is the standard curing agent used with a multifunctional amine epoxy (MY 720) for high performance aerospace and military composite application. 3,3′-DDS is used in aerospace honeycomb for its excellent peel strength. MDA, which has excellent mechanical and electrical properties, is the most widely used aromatic curing agent, but recently has been classified as a potential human carcinogen and its

volume has been declining. Alkyl-substituted MDAs such as tetraethyl-MDA have been developed with lower toxicity and improved performance (108,109). However, none of the replacement products has the performance/cost combination of MDA. Anhydrides and cycloaliphatic amines have been used to replace aromatic amines in a number of composite applications. Efforts have been made to develop ambient-curable aromatic amines by adding accelerators such as phenols to MDA.

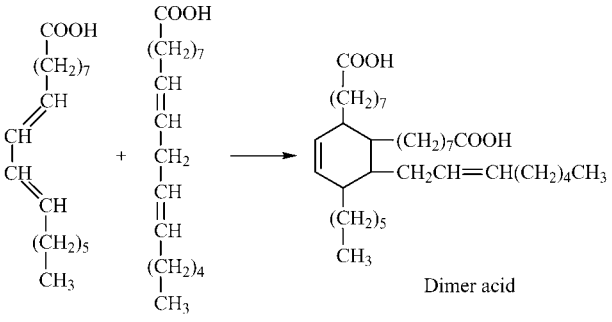
Arylyl Amines. These amines have cycloaliphatic or aromatic backbones, but the amine functional groups are separated from the backbone by methylene groups (benzylic amines). Consequently, arylyl amines are much more reactive toward epoxies than aromatic amines while having improved thermal and chemical resistance over aliphatic amines. Fast cures at ambient and sub-ambient are possible with arylyl amines. These amines are more widely used in Japan and Europe than in North America. Meta-Xylylene diamine (MXDA) and its hydrogenated product, 1,3-bis(aminomethyl cyclohexane) (1,3-BAC) are popular arylyl amines.

The commercial polyamine curing agents are given in Table 15.

The stoichiometric quantity of polyamine used to cure an epoxy resin is a function of the molecular weight and the number of active hydrogens of the polyamine (amine equivalent weight, AEW) and the EEW or equivalent weight of epoxy resin; it is expressed as follows:

$$\left(\frac{\text{AEW}}{\text{EEW}}\right) \times 100 = \text{parts by weight polyamine per 100 parts by weight epoxy resin}$$

Polyamides. Polyamides are one of the largest volume epoxy curing agents used. They are prepared by the reaction of dimerized and trimerized vegetable-oil fatty acids with polyamines. Dimer acid is made by a Diels–Alder reaction between 9,12- and 9,11-linoleic acids. Subsequent reaction with diethylenetriamine or other suitable multifunctional amines yields the amine-terminated polyamides. They are available in a range of molecular weights and compositions.



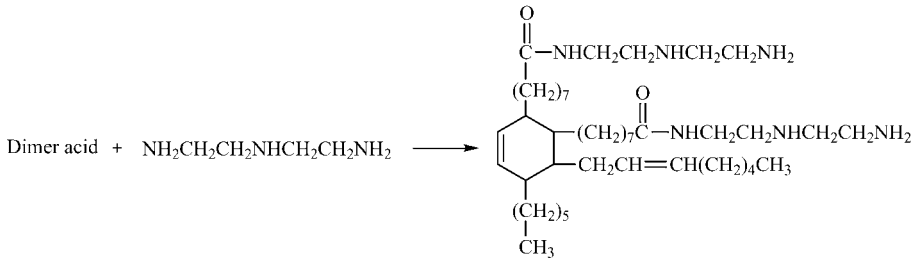


Table 15. Commercial Amine Curing Agents

Formula	Name	Abbreviation
Aliphatic		
$NH_2CH_2CH_2NHCH_2CH_2NH_2$	Diethylenetriamine	DETA

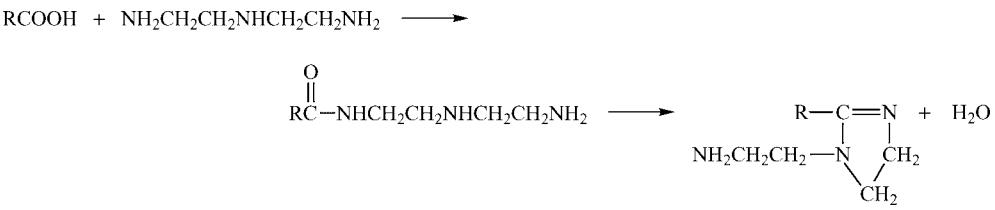
Polyamides are extremely versatile curing agents. The polyamides react with the epoxide group through the amine functionality in the polyamide backbone. The unreacted amide NH groups in the backbone provide good intercoat adhesion and the fatty acid structures provide good moisture resistance and mechanical properties. Wetting of cement surfaces is excellent. As a result of their relatively higher molecular weight, the ratio of polyamide to epoxy is more forgiving than with low MW polyamines. They are inexpensive, less toxic to handle; give no blushing; exhibit readily workable pot lives; and cure under mild conditions. Polyamides are mainly used in coating and adhesive formulations, mostly in industrial maintenance and civil engineering applications. The various MW polyamides exhibit different degrees of compatibility with epoxy resins. To ensure optimum properties, the polyamide/epoxy mixture must be allowed to react partly before being cured. This partial reaction assures compatibility and is known as the *induction period*.

Disadvantages of polyamides include slower cure speeds and darker color than polyamine-cured epoxies. Polyamide-cured epoxies lose structural strength rapidly with increasing temperature. This limits their use to applications not subjected to temperatures above 65°C. Formulations with tertiary amines, phenolic amines, or co-curing agents help to speed up cures at low temperatures. Alternatively, polyamides derived from polyamines with phenolic-containing carboxylic acids are called *phenalkamines* (110). These curing agents have low viscosity and fast ambient cure speed and are widely used in on-site marine coatings and concrete deck applications.

The high viscosity of polyamides limits their uses primarily to low solids coatings, which have been losing ground to higher solids coatings. Waterborne polyamides have been developed for use with waterborne epoxies, but their growth has been modest over the past decade because the conversion to waterborne epoxy coatings has been slower than expected. Commercial polyamides include

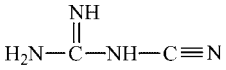
the Versamid resins from Cognis, Ancamide resins from Air Products, and Epicure resins from Resolution.

Amidoamines. Amidoamines have all the properties of polyamides, except for a significantly lower viscosity, which make them useful in high solids and solvent-free coating formulations. They are prepared by the reaction of a monofunctional acid like tall-oil fatty acid with a multifunctional amine such as DETA, resulting in a mixture of amidoamines and imidazolines.



Imidazoline is formed by intramolecular condensation at high reaction temperatures. Commercial amidoamines are produced with different imidazoline contents to regulate reactivity and cured product performance. The pot life/reactivity of amidoamines varies with imidazoline content. High imidazoline contents offer longer pot life and semi-latent curing system activated by moisture. They are useful in wet concrete applications. Like the polyamides, amidoamines can be used over a range of additive levels to enhance a specific property. However, amidoamines offer several advantages over aliphatic amines and polyamides. They offer more convenient mix ratios, increased flexibility, and better moisture resistance than aliphatic polyamines, and they offer lower color and viscosity than polyamides. Consequently, the volume of amidoamines has grown significantly in the past decade.

Dicyandiamide. Dicyandiamide (DICY) is a solid latent hardener (mp 208°C). Its latent nature is due to its insolubility in epoxy resins at RT. DICY can be mixed in with epoxy resins to provide a one-package formulation with good stability up to 6 months at ambient temperatures. Cure of epoxies with DICY occurs with heating to 150°C. It is often used with imidazoles as catalysts. DICY offers the advantage of being latent (reacts with epoxy resin upon heating and stops reacting temporarily when the heat is removed). This partially cured or "B-staged" state is ideal for prepreg applications. Typically, DICY is used at levels of 5–7 parts per 100 parts of liquid epoxy resins and 3–4 parts per 100 parts of solid epoxy resins.



DICY

DICY is one of the first curing agents to be used with epoxy resins. It cures with epoxies to give a highly cross-linked thermoset with good mechanical strength, thermal properties, and chemical resistance, and excellent electrical properties. Because of its latency, low quantity requirements and excellent balance of properties, DICY is a widely used curing agent in powder coating and

electrical laminate applications. These two applications account for 85% of DICY consumption as epoxy curing agent.

The curing mechanism is rather complex, involving several simultaneous reactions. There are a number of conflicting proposed mechanisms in the literature. One study proposed the initial reaction of all four active hydrogens with epoxy resin catalyzed by tertiary amine catalysts followed by epoxy homopolymerization. The last step involves reactions between the hydroxyl groups of the epoxy resin with the cyano group (108,109). One of the more recent and plausible mechanism of DICY cure with epoxies is that of Gilbert and co-workers (111). The Gilbert mechanism is summarized in Figure 4. Gilbert and co-workers investigated the reaction of DICY with methyl glycidyl ether of bisphenol A (MGEBA). Products were analyzed using HPLC, NMR, and FTIR. On the basis of products that were isolated and characterized, Gilbert and co-workers proposed the mechanism shown in Figure 4.

The first step in the mechanism is the reaction of DICY with epoxy to form the alkylated DICY. This was confirmed by the imide IR peak at 1570 cm^{-1}. The second step involves further alkylation of the nitrogen that reacted in step 1, to form the *N*,*N*-dialkyldicyandiamide. No alkylation of the other amino group was suggested. The third step is the intramolecular cyclization step to form a zwitterionic five-membered intermediate. This involves the intramolecular reaction of the secondary alcohol formed in step 2 with the imide functionality (—C=N—). This is in contrast with the Zahir mechanism (112) where the intramolecular cyclization involves the hydroxy and the nitrile groups. The fourth step involves the elimination of ammonia and the formation of 2-cyanimidooxazolidine. The formation of this heterocycle is consistent with the observed bathocromic IR shift from 1570 cm^{-1} to 1650 cm^{-1}. The ammonia that is eliminated can then react with epoxy to form a trifunctional cross-link. The last step involves the hydrolysis of the oxazolidine to form the oxazolidone and cyanamide. The hydrolysis step accounts for the formation of the carbonyl group.

Carboxylic Functional Polyester and Anhydride Curing Agents. Carboxylic polyesters and anhydrides are the second most important class of epoxy curing agent. Together, they constitute 36% of the total curing agent volume used in the U.S. market (2001 data). Polyesters have been growing rapidly in powder coatings formulations with epoxy resins, consuming the highest tonnage of epoxy curing agents. This is driven in part by the conversion to the more environmentally friendly powder coating technologies, and in part by the versatility and cost efficiency of polyester–epoxy hybrid powder coatings. Anhydrides have been successfully replacing more toxic aromatic amines in composites. They account for 70% of the volume of curing agents used in structural composite applications. Both polyesters and anhydrides are used in heat-cured applications only.

Carboxylic Functional Polyesters. The reaction of polyacids with polyalcohols produces polyesters. The terminal functionality is dictated by the ratio of the reactants. By virtue of their relatively cheap, widely available raw materials and good flexibility and weatherability, acid functional polyesters are used in hybrid epoxy powder coatings for a wide range of applications. For applications requiring good weatherability, triglycidyl isocyanurate (TGIC) is often used as curing agent for acid functional polyesters.

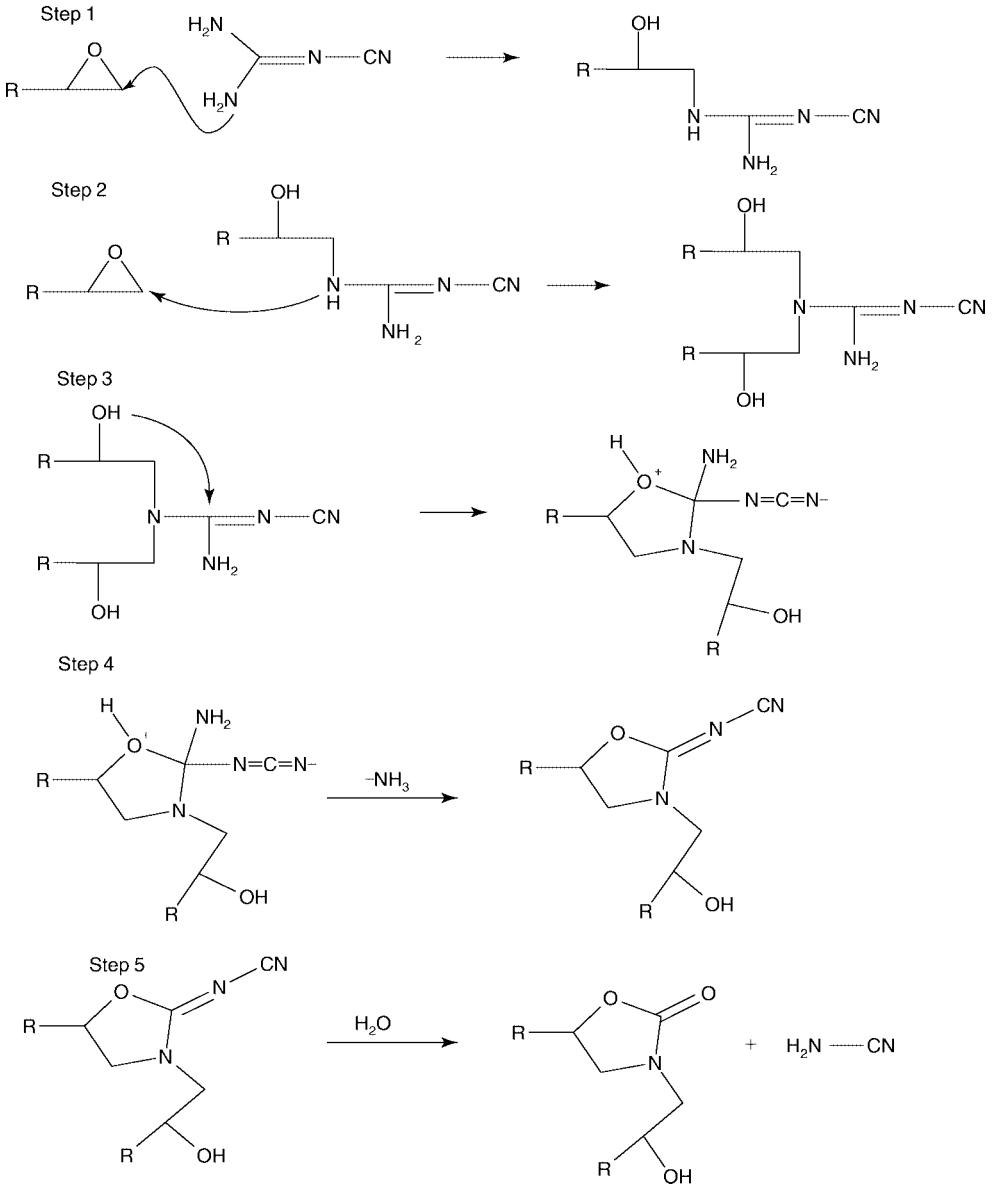


Fig. 4. The Gilbert mechanism for the DICY curing of epoxy. From Ref. 111.

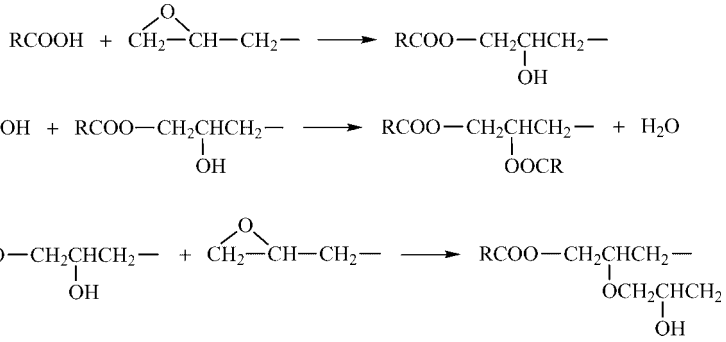
Terephthalic acid, trimellitic anhydride, and neopentyl glycol are commonly used raw materials to produce polyesters. Other acids, anhydrides, and glycols can also be used to modify functionality, MW, viscosity, and mechanical properties (after curing) of the polyesters. This versatility of the polyester building blocks allows many useful combinations of epoxy–polyester hybrid systems to be developed for a wide range of applications (113). Major applications include coatings for metal furniture, general metal finishing, appliances, machinery and equipment,

automotive, and wood. Automotive is a new, large, and fast growing market with many car makers converting to primer-surfacer based on epoxy–polyester powder coatings. Wood coatings are a new, emerging market.

The curing mechanism of epoxy–polyester thermosets involves reaction of the acid functionality with epoxy followed by esterification of the epoxy hydroxyl groups with the acids (114). Compounds such as amines and phosphonium salts catalyze these reactions. Water is a condensation reaction by-product that must be allowed to escape during the curing process to avoid coating defects.



The first product is a β-hydroxypropyl ester, which reacts with a second mole of carboxylic acid to yield a diester. The hydroxyl ester can also undergo polymerization by reaction of its secondary hydroxyl group with an epoxy group.

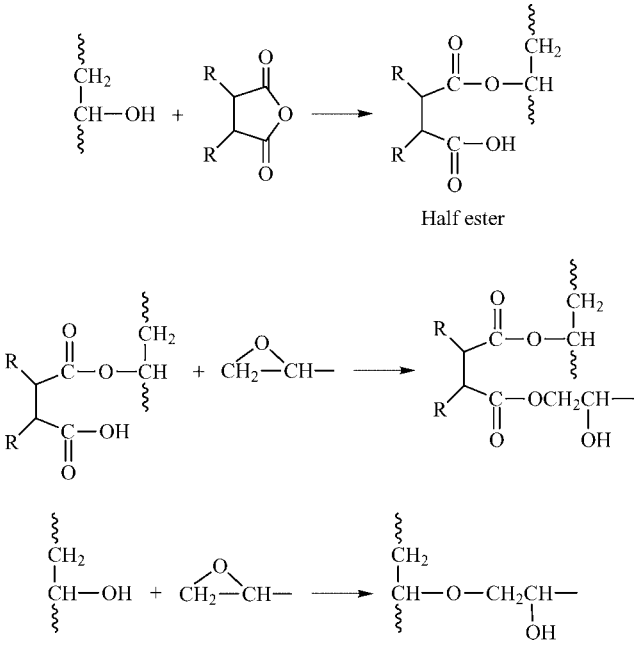
Acid Anhydrides. Anhydrides are some of the very first epoxy curing agents used, and they remain a major class of curing agents used in heat-cured structural composites and electrical encapsulation. Their consumption volume equals that of all aliphatic amines and adducts in 2001 in the United States. While the carboxylic-terminated polyesters find widespread uses in coatings, anhydride use in coatings is minimal.

Epoxy–anhydride systems exhibit low viscosity and long pot life, low exothermic heats of reaction, and little shrinkage when cured at elevated temperatures. The low exotherm heat generation is a unique attribute of anhydrides, making them suitable for uses in large mass epoxy cures. Curing is slow at temperatures below 200°C and is often catalyzed by Lewis bases or acids. Post-cure is often needed to develop optimum properties. Tertiary amines such as benzyldimethylamine, dimethylaminomethylphenol, tris(dimethylaminomethyl)phenol, boron trihalide amine complexes, stannic chloride, ammonium salts, phosphonium salts, and substituted imidazoles are effective catalysts. Proper catalyst concentration (0.5–2.5% of resin weight) is critical, depending on the types of anhydrides and resins used and the cure schedules, and is known to affect high temperature performance.

Cured epoxy–anhydride systems exhibit excellent thermal, mechanical, and electrical properties, and are used in filament-wound epoxy pipe, PCB laminates, mineral-filled composites, and electrical casting and encapsulation applications. Anhydride-cured epoxies also have better aqueous acid resistance than similar amine-cured systems. Anhydrides are the principal curing agents for cycloaliphatic and epoxidized olefin resins in electrical casting and potting. Some

key physical properties of exemplary epoxy resins cured with hexahydrophthalic anhydride are shown in Table 16.

The mechanism of anhydride cure is complex and controversial because of the possibility of several competing reactions. The uncatalyzed reaction of epoxy resins with acid anhydrides proceeds slowly even at 200°C; both esterification and etherification occur. Secondary alcohols from the epoxy backbone react with the anhydride to give a half ester, which in turn reacts with an epoxy group to give the diester. A competing reaction is etherification of an epoxy with a secondary alcohol, either on the resin backbone or that formed during the esterification, resulting in a β-hydroxy ether. It has been reported that etherification is a probable reaction since only 0.85 equivalents of anhydrides are required to obtain optimum cross-linked density and cured properties (103).



Lewis bases such as tertiary amines and imidazoles are widely used as epoxy–anhydride catalysts. Conflicting mechanisms have been reported for these catalyzed reactions (115). The more widely accepted mechanism (103) involves the reaction of the basic catalyst with the anhydride in the initiation step to form a betain (internal salt). The propagation step involves the reaction of the carboxylate anion with the epoxy group, generating an alkoxide. The alkoxide then further reacts with another anhydride, propagating the cycle by generating another carboxylate which reacts with another epoxy group. The end result is the formation of polyester-type linkages. In practice, it has been observed that optimum properties are obtained when stoichiometric equivalents of epoxy and anhydride are used with high temperature cures, which is consistent with this mechanism and does not involve etherification reactions. At lower anhydride/epoxy ratios (0.5:1)

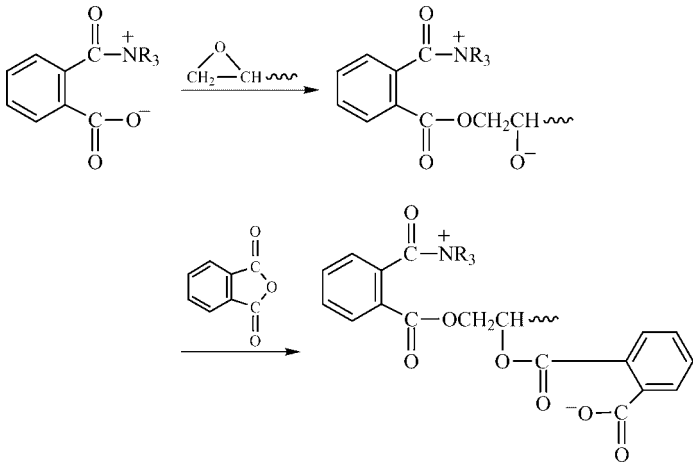
and lower cure temperatures, some etherifications can take place by reaction of the alkoxide with an epoxy group.



Numerous structurally different anhydrides can be used as epoxy curing agents, but the most widely used are liquids for ease of handling. The most important commercial anhydrides are listed in Table 17. Methyltetrahydrophathalic anhydride (MTHPA) is the largest volume anhydride, used in filament-winding composites. Phthalic anhydride (PA) is the next largest volume and is inexpensive; so it is used widely in mineral-filled laboratory bench top manufacturing, which requires low exotherm heat generation to avoid cracking. Dodecylsuccinic anhydride (DDSA) has a long aliphatic chain in the backbone and is used as blends to improve flexibility. Benzophenonetetracarboxylic dianhydride (BTDA) is a relatively new, multifunctional anhydride developed for high temperature applications, capable of achieving a high cross-linking density with a heat distortion temperature (HDT) of 280°C. It has been used as a replacement for more toxic aromatic amines. Tetrachlorophthalic anhydride (TCPA) is used in epoxy powder coatings for small electronic components with flame-retardancy requirements.

Phenolic-Terminated Curing Agents. Phenolics form a general class of epoxy curing agents containing phenolic hydroxyls capable of reacting with the epoxy groups. They include phenol-, cresol-, and bisphenol A terminated epoxy resin hardener. More recent additions include bisphenol A based novolacs. Cure takes place at elevated temperatures (150–200°C) and amine catalysts are often used.

The bisphenol A terminated hardeners are produced using liquid epoxy resins and excess bisphenol A in the resin advancement process. They are essentially epoxy resins terminated with bisphenol A. They are popular in epoxy powder coating applications for rebar and pipe, providing more flexible epoxy coatings than the novolacs.

The novolacs are produced via the condensation reaction of phenolic compounds with formaldehyde using acid catalysts. They are essentially precursors to epoxy novolacs. Novolacs are multifunctional curing agents and can impart higher cross-link density, higher T_g, and better thermal and chemical resistance

Table 17. Commercially Important Anhydride Curing Agents

Name	Structure
Phthalic anhydride (PA)	Tetrahydrophthalic anhydride (THPA)	Methyltetrahydrophthalic anhydride (MTHPA)	Methyl hexahydrophthalic anhydride (MHHPA)	Hexahydrophthalic anhydride (HHPA)	Nadic methyl anhydride or methyl himic anhydride (MHA)	Benzophenonetetracarboxylic dianhydride (BTDA)	Tetrachlorophthalic anhydride (TCPA)	
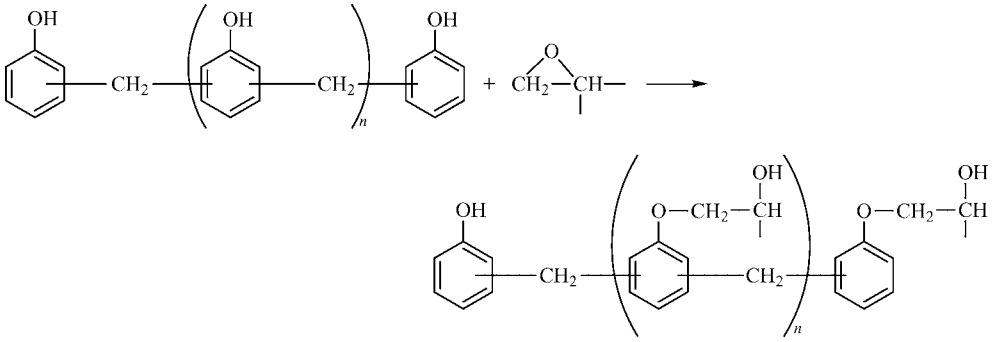
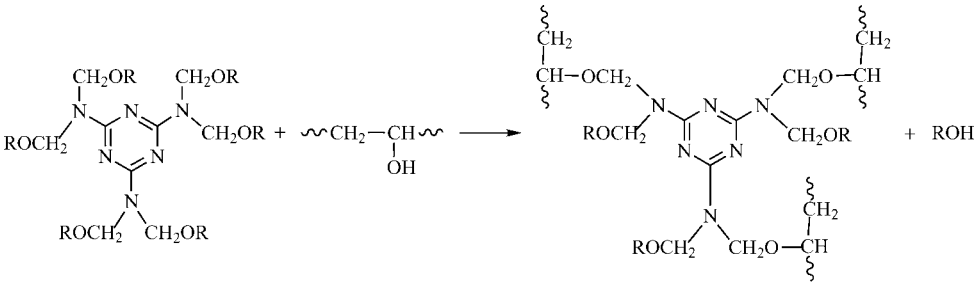
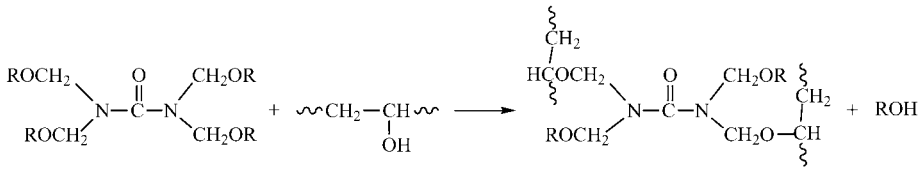
than other phenolics. Cresol novolacs provide higher solvent and moisture resistance, but are more brittle than their phenol novolac counterparts. Recently, bisphenol A based novolacs have been used in electrical laminate formulations to improve thermal performance (T_g and T_d) (116). Novolacs are widely used in composites, PCB laminates, and electronic encapsulation applications. Their uses in coatings are limited to high temperature applications such as powder coatings for down-hole oil-field pipe coatings.



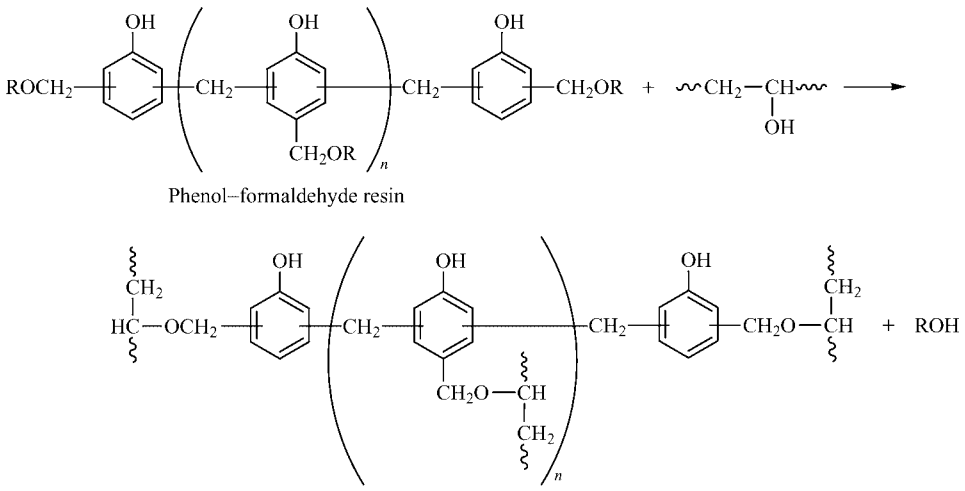
Melamine–, Urea–, and Phenol–Formaldehyde Resins. Melamine–formaldehyde, urea–formaldehyde, and phenol–formaldehyde resins react with hydroxyl groups of high MW epoxy resins to afford cross-linked networks (72).



Melamine–formaldehyde resin



Urea–formaldehyde resin



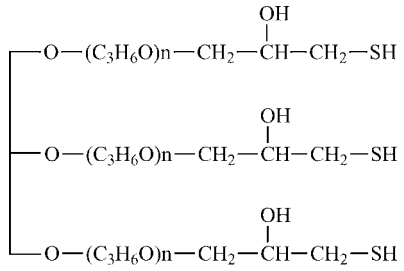
The condensation reaction occurs primarily between the methylol or alkylated methylol group of the formaldehyde resin and the secondary hydroxyl group on the epoxy resin backbone. The high bake temperatures used in these applications drive off the condensation by-products (alcohol or water). Acids such as phosphoric acid and sulfonic acids are often used as catalysts.

There are two types of phenol–formaldehyde condensation polymers: resoles and novolacs (117). Phenol–formaldehyde polymers prepared from the base-catalyzed condensation of phenol and excess formaldehyde are called resoles. In most phenolic resins commonly used with epoxies, the phenolic group is converted into an ether to give improved alkali resistance. At elevated temperatures (>150°C), resole resins react with the hydroxyl groups of the epoxy resins to provide highly cross-linked polymers.

The melamine- and urea–formaldehyde resins are also called amino resins (118). The phenol–formaldehyde resoles are often called phenolic resins, which is rather easily confused with phenolic-terminated cross-linkers such as novolacs and bisphenol A terminated resins.

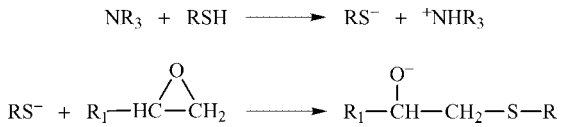
These formaldehyde-based resins are widely used to cure high MW solid epoxy resins at elevated temperatures (up to 200°C) for metal can, drum, and coil coatings applications. The resultant coatings have excellent chemical resistance, good mechanical properties, and no effects on taste (adding or taking away taste from packaged foods or drinks). The vast majority of the food and beverage cans produced in the world today are coated internally with epoxy–formaldehyde resin coatings. The phenol–formaldehyde resoles are also used with epoxies in coatings for high temperature service pipes and to protect against hot, corrosive liquids.

Mercaptans (Polysulfides and Polymercaptans) Curing Agents. The mercaptan group of curing agents includes polysulfide and polymercaptan compounds which contain terminal thiols.



Polymercaptans

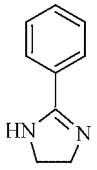
In the language commonly used in this industry, "polysulfides" typically have a functionality of 2, while "polymercaptans" have an average functionality of 3. By itself, the thiol or mercaptan group (SH) reacts very slowly with epoxy resins at ambient temperature. However, when converted by a tertiary amine to a mercaptide ion, they are extremely reactive (119).



Increasing the basic strength of the amine increases the reaction rate. Polar solvents are also known to speed up these reactions. Fast curing at ambient conditions is the primary attribute of this class of curing agent, lending themselves to applications such as the "5-minutes" consumer adhesives, concrete road repairs, and traffic marker adhesives. In practice, they are often formulated with co-curing agents such as amines or polyamides to achieve a balance of fast cure with improved mechanical properties. The tertiary amine accelerated polymercaptan/epoxy systems exhibit good flexibility and tensile strength at ambient temperature. They are used in high lap-shear adhesion applications such as concrete patch repair adhesives. One disadvantage of polymercatans is their strong odor. Aliphatic amine/polysulfide co-curing agent systems yield improved initial elevated temperature performance and are widely used as building adhesives for their excellent adhesion to both glass and concrete. However, both systems lose some flexibility on aging.

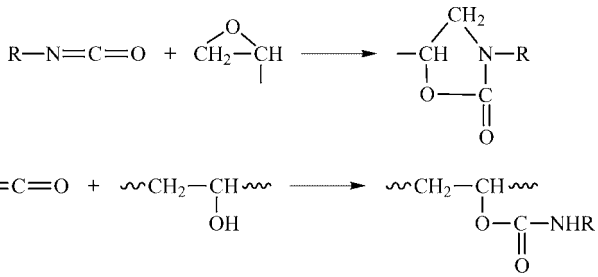
Cyclic Amidines Curing Agents. Cyclic amidine curing agents are typically used in epoxy powder coating formulations and in decorative epoxy–polyester hybrid powder coatings to produce matte surface for furniture and appliance finishes. 2-Phenyl imidazoline has been used successfully to produce low gloss epoxy powder coatings. It is highly reactive, capable of curing at relatively low temperatures (140°C) and is suitable for curing of coatings on temperature-sensitive substrates such as wood and plastics. Other curing agents in this group include salts of polycarboxylic acids and cyclic amidines. Their volume is currently small but is expected to grow as the markets for low gloss and low temperature cure

powder coatings develop. They can also be used as tertiary amine catalysts similar to imidazoles.

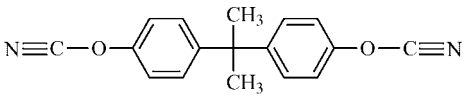


2-Phenyl imidazoline

Isocyanate Curing Agents. Isocyanates react with epoxy resins via the epoxy group to produce an oxazolidone structure (120,121) or with a hydroxyl group to yield a urethane linkage. The urethane linkage provides improved flexibility, impact, and abrasion resistance. The oxazolidone products have been successfully commercialized in high temperature resistance coating and composite applications. Blocked isocyanates are used as cross-linkers for epoxy in PPG's cathodic electrodeposition (CED) coatings. Isocyanates are also used to cure epoxies in some powder coatings, but their toxicity has limited their use.



Cyanate Ester Curing Agents. Cyanate esters can be used to cure epoxy resins to produce highly cross-linked thermosets with high modulus and excellent thermal, electrical, and chemical resistance properties. They are used in high performance electrical laminate and composite applications. Cure involves oxazoline formation catalyzed by metal carboxylates in addition to homopolymerization of both cyanate ester and epoxy (122). The high costs of cyanate esters however limit their uses.



Bisphenol A based dicyanate ester

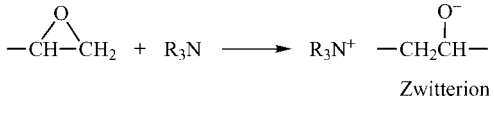
Catalytic Cure

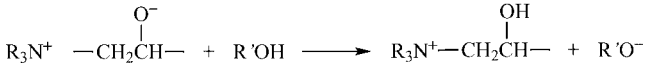
The catalytic curing agents are a group of compounds that promote epoxy reactions without being consumed in the process. In some of the epoxy literature, catalysts

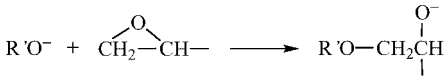
are referred to as "accelerators"; the distinction of these two types of additives is discussed in later sections.

Lewis Bases. Lewis bases contain an unshared pair of electrons in an outer orbital and seek reaction with areas of low electron density. They can function as nucleophilic catalytic curing agents for epoxy homopolymerization; as co-curing agents for primary amines, polyamides, and amidoamines; and as catalysts for anhydrides. Tertiary amines and imidazoles are the most commonly used nucleophilic catalysts. Several different mechanisms are possible:

(1) The catalytic curing reactions of tertiary amines with epoxy resins follow two different pathways, depending on the presence or absence of hydrogen donors, such as hydroxyl groups. In the absence of hydrogen donors (123), tertiary amines react with the electron-poor methylene carbon of the epoxy group to form an intermediate zwitterion. The zwitterion then attacks another epoxy group to continue homopolymerization via an anionic mechanism. In the presence of hydrogen donors such as alcohols, the zwitterion abstracts the proton from the alcohol to generate an alkoxide,

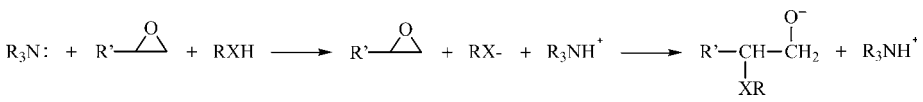




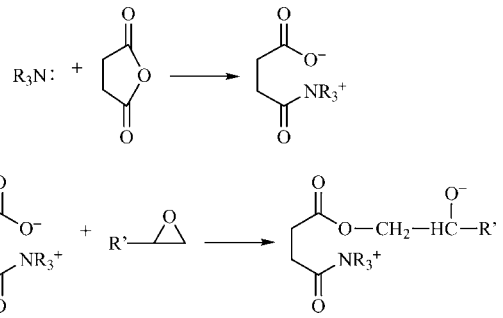


which further reacts with an epoxide group. Chain propagation continues by way of a polymeric anion mechanism.

(2) With more acidic hydrogen donors such as benzyl alcohol, phenols, or mercaptans, the tertiary amine acts as a co-curing agent by first abstracting the proton from the hydrogen donor:



(3) With anhydrides, the catalyst facilitates the anhydride ring opening:



Commonly used tertiary amines include 2-dimethylaminomethylphenol (DMAMP) and 2,4,6-tris(dimethylaminomethyl)phenol (TDMAMP, trade name DMP-30 of Rohm and Haas), which contain built-in phenolic hydroxyl groups and can be used as a good catalysts and co-curing agents for room temperature cure of epoxies.

The rate of cure of epoxy resins with tertiary amines depends primarily upon the extent to which the nitrogen is sterically blocked. The homopolymerization reaction depends on the temperature as well as the concentration and type of tertiary amine. Benzyldimethylamine (BDMA) and TDMAMP are mainly used as accelerators for other curing agents, in the curing of anhydride- and dicyandiamide-based systems. Other tertiary amine catalysts include 1,4-diazabicyclo(2,2,2)octane (DABCO) and diazabicycloundecene (DBU).

Imidazoles such as 2-methylimidazole (2-MI) and 2-phenylimidazole (2-PI) contain both a cyclic secondary and a tertiary amine functional groups and are used as catalysts, catalytic curing agents, and accelerators (124,125). They are widely used as catalysts for DICY-cured epoxies in electrical laminates. For powder coatings, 2-MI adducts of LER are often used to facilitate dispersion of the components in powder coating formulations and to enhance shelf-life. Other modified imidazoles are also commercially available. The main advantage of imidazoles is the excellent balance of pot life and fast cure. 2-PI is used to increase T_g and thermal resistance.

Cyclic amidines such as 2-phenylimidazoline have also been used as a catalyst and co-curing agent in epoxy–polyester and epoxy powder coatings.

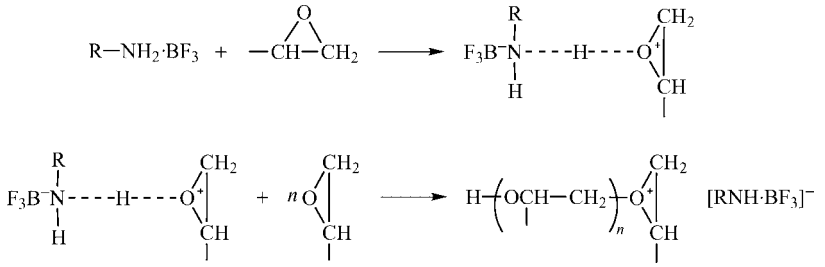
Substituted ureas are another group of epoxy nucleophilic catalytic curing agent, derived by blocking of isocyanates with dimethylamine. They are commonly used as catalysts for DICY cure of epoxies in adhesives, prepregs, and structural laminates. The ureas exhibit outstanding latency at room temperature and are widely used in one-pack adhesives. The catalytic mechanism of ureas is not well understood, but it has been postulated that DICY assists in deblocking of the urea to generate a tertiary amine, which in turns acts as epoxy curing catalyst. Commercially important substituted ureas are 3-phenyl-1,1-dimethyl urea (Amicure UR by Air Products), a reaction product of phenyl isocyanate with dimethylamine; and Amicure UR 2T, a reaction product of toluene diisocyanate (TDI) with dimethylamine.

Quaternary phosphonium salts such as the tetraalkyl and alkyltriphenylphosphonium halides have been used as fast catalysts for curing of phenolics, carboxylic acid-terminated polyesters, or anhydrides with epoxies (126). Used in powder coatings, they showed good latency and fast cure rates at moderate temperatures.

Air Products is a major epoxy catalyst supplier. Others include Huntsman, Cognis, and SKW Chemicals.

Lewis Acids. Lewis acids, eg, boron trihalides, contain an empty outer orbital and therefore seek reaction with areas of high electron density. Boron trifluoride, BF_3, a corrosive gas, reacts easily with epoxy resins, causing gelation within a few minutes. Complexation of boron trihalides with amines enhances the curing action. Reasonable pot lives using these complexes can be achieved because elevated temperatures are required for cure. Reactivity is controlled by the choices of the halide and the amine. The amine choice also affects other properties such as solubility in resin and moisture-sensitivity. Boron trifluoride monoethylamine ($BF_3 \cdot NH_2C_2H_5$), a crystalline material which is a commonly used catalyst, cures epoxy resins at 80–100°C. A chloride version is also commercially available. Other Lewis acids used in epoxy curing include stannic chloride and tin octanate.

Different mechanisms have been proposed for curing epoxy resins with BF_3 complexes or salts. In general, it is assumed that complexation with the oxirane oxygen is involved, facilitating proton transfer and ether formation. Thermal dissociation of the BF_3–amine complex may form a proton that further reacts with the epoxy group to initiate the curing process (127). Another mechanism assumes an amine adduct or salt is solvated by the epoxy groups, resulting in an oxonium ion (128). The curing reaction is initiated and propagated by attack of other epoxy groups on the oxonium ion.



Photoinitiated Cationic Cure. Photoinitiated cationic curing of epoxy resins is a rapidly growing method for the application of coatings from solvent-free or high solids systems. This technology allows the formulation of epoxy coatings and adhesives with essentially "infinite" shelf life, but almost "instantaneous" cure rates. Cycloaliphatic epoxies are widely cured using photoinitiated cationic initiators.

Photoinitiators used for epoxy curing include aryldiazonium salts ($ArN_2^+X^-$), diaryliodonium salts ($Ar_2I^+X^-$), and onium salts of Group VIa elements, especially salts of positively charged sulfur ($Ar_3S^+X^-$). The anions must be of low nucleophilicity, such as tetrafluoroborates or hexafluorophosphates, to promote polymer chain growth rather than chain termination. Upon UV irradiation,

photoinitiators yield a "super" acid, which polymerizes the epoxy resins by a conventional electrophilic mechanism.

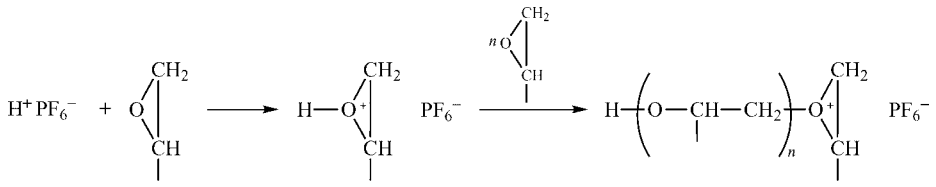
The photolysis of diaryliodonium and triarylsulfonium salts may proceed via formation of a radical cation, which abstracts a hydrogen atom from a suitable donor.

$$Ar_3S^+\ PF_6^- \xrightarrow{UV} Ar_2S^{+\cdot} + Ar\cdot + PF_6^-$$

$$Ar_2S^{+\cdot} + R{-}H \longrightarrow Ar_2SH^+ + R\cdot$$

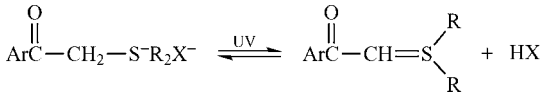
$$Ar_2SH^+ + PF_6^- \rightleftharpoons Ar_2S + HPF_6$$

Subsequent loss of a proton yields the Brønsted acid HPF_6. Catalytic curing of the epoxy resin proceeds through an onium intermediate:



In the presence of triarylsulfonium and diaryliodonium salts, polymerization continues even if UV irradiation is terminated. This phenomenon is called "dark cure" and is due to the "living" nature of the "superacid" generated cation. The cure regime can be thought of as UV-initiated but "thermally cured." Thermally initiated cationic catalysts are also available (129).

In contrast, dialkylphenacyl sulfonium salts undergo reversible dissociation upon photolysis with formation of an ylid and a Brønsted acid. Cessation of UV activation results in termination of epoxy homopolymerization, since the acid is consumed in a reverse reaction with the ylid.



This type of behavior provides a means of controlling the degree of cure. Dialkylphenacyl sulfonium salts are thermally stable in epoxy resins at room temperature and up to 150°C for 1–2 h. Significant interest in thermal cationic cure of epoxies, especially cycloaliphatic epoxies, has developed (130).

Formulation Development With Epoxy Resins

The most important step in using epoxy resins is to develop the appropriate epoxy formulation since most are used as precursors to a three-dimensional cross-linked network. With the exception of the very high MW phenoxy resins and the epoxy-based thermoplastics, epoxy resin is rarely used by itself. It is usually formulated with modifiers such as fillers and used in composite structures with glass fiber or

metal substrates (coatings). To design a successful epoxy formulation that will give optimum *processability* and *performance*, the following factors must be carefully considered:

(1) Selection of the proper combination of epoxy resin(s) and curing agent(s) structures
(2) Epoxy/Curing agent stoichiometric ratio
(3) Selection of catalyst/accelerator
(4) Curing/post-curing processes and conditions
(5) Formulation modifiers such as fillers, diluents, toughening agents, etc
(6) Interactions among the formulation ingredients and with the composite materials (fibers, metals, etc) on the system chemistry, adhesion, rheology, morphology, and performance

The development of an epoxy formulation containing a high number of components can be very resource and time-consuming. Techniques such as design of experiments (DOE) are useful tools to facilitate the formulation development process and to obtain optimum performance (131,132). Future developments should include application of high throughput techniques to epoxy formulation development and optimization.

Relationship Between Cured Epoxy Resin Structure and Properties. The following diagram illustrates the formation of cured epoxy networks using different ratios of a difunctional epoxy and a tetrafunctional hardener. The structures formed are significantly different, depending on the ratio used. Consequently, it is expected that performance of these networks will be quite different despite the fact that they are derived from identical building blocks (Fig. 5).

The structure between the cross-linking position and the distance between any two of these points are important characteristics. *Molecular weight between cross-links* (M_c) and *cross-link* density are terms developed to describe "distance" between cross-link points. The concept originated with the rubber elasticity theory developed for the lightly cross-linked elastomers and has been adopted for use with epoxy thermosets with mixed success (133,134). The cured epoxy system derives its properties mostly from a combination of cross-link density, monomer structure and the curing process. The two-dimensional schematic network structures do not represent spatial reality but have been devised to help understand the nature of the various structures (135). A good understanding of the structure/property relationship is critical in designing the appropriate epoxy/curing agent combination. For example, cross-linking with dicarboxylic anhydrides yields polyesters that are resistant to oxidation, but less so to moisture, especially in the presence of basic components. Amine cross-linked systems are resistant to saponification but not to oxidation. There is a large body of specific structure/property relationship knowledge in the epoxy industry and literature, but only a few systematic treatments are available (136–138).

Cross-link density increases with degree of cure up to its limit at full conversion of the (limiting) functional groups. The curing temperature and process strongly influence cross-link density, molecular architecture, network morphology, residual stress, and the ultimate performance. The effects of degree of cure

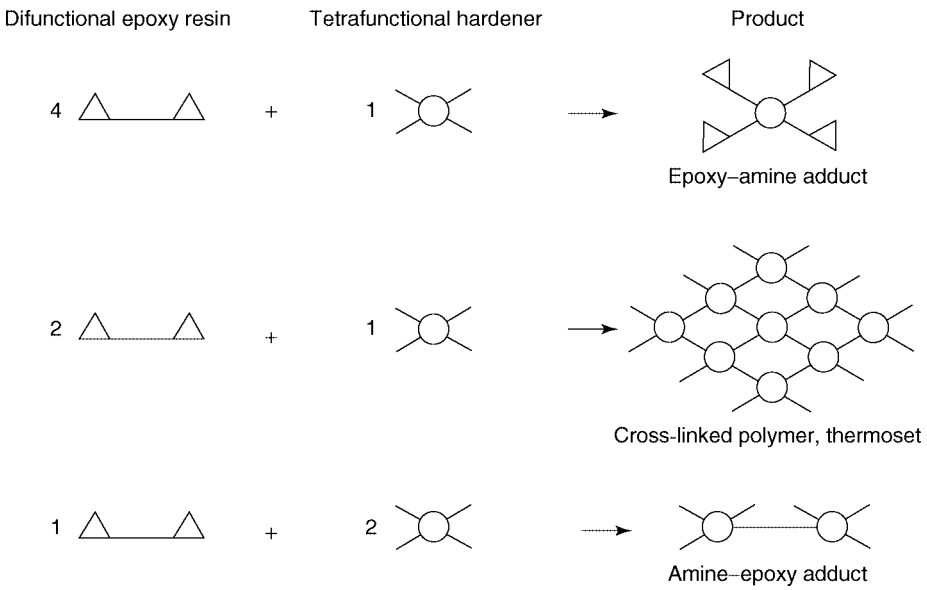


Fig. 5. Formation of resin–hardener networks.

and subsequent cross-link density on the chemical resistance of a cured DGEBA–aromatic polyamine adduct system are depicted in Figure 6. The increase in chemical resistance properties after post-cure also demonstrates the effects of increased cross-link density. The cross-link density of a cured epoxy system can be estimated by a number of different techniques as described in the characterization of cured epoxy section.

Selection of Epoxy Resins. Successful performance of epoxy-based systems depends on proper selection and formulation of components. The components that have the most significant influences are the epoxy resins and the curing agents. As discussed in earlier sections, there are numerous choices of epoxy resins and curing agents presenting a wide variety of structure and functionality. Figure 7 shows the general attributes of common types of epoxy resins.

Epoxy resins can be used separately or in combination, such that formulations can be designed to take advantage of the desirable characteristics of several components. Because combining resins from different families can result in certain trade-offs, a careful balance of components should be investigated to produce optimal performance for specific applications. Table 18 shows effects of different resin backbones on cured properties with formulations based on hexahydrophthalic anhydride as curing agent.

The difunctional DGEBA resins are offered commercially in a wide range of molecular weights. As the molecular weight increases, so does the chain length between the epoxy end groups. Table 5 shows the effects of increasing EEW and MW of bisphenol A based epoxy resins on resin properties. The cross-link density of a difunctional resin cured by way of the epoxy group decreases as the resin molecular weight increases. High molecular weight resins are frequently cured via the secondary hydroxyl group, chemistry that results in a different set of structure–property relationships.

Multifunctional epoxy resins are available with functionalities ranging from above 2 to about 5. When cured to the same degree using a given curing agent at stoichiometric ratios, they produce a higher cross-link density, higher glass-transition temperature, better thermal and chemical resistances compared with difunctional epoxy resins.

Selection of Curing Agents. The selection of curing agents is just as critical as the selection of resins. As discussed in the Curing Agents section, there are numerous types of chemical reagents that can react with epoxy resins. Since coreactive curing agents become part of the network structure, careful consideration must be paid to their contributions. Besides affecting viscosity and reactivity of

the formulation, curing agents determine both the types of chemical bonds formed and the functionality of the cross-link junctions that are formed. Table 18 show performance examples of a liquid epoxy resin cured with different curing agents. Several authors have attempted to rationalize the curing agent selection process for different applications (106,139).

The effect of hardener structure on heat resistance of a cross-linked DGEBA resin is shown in Table 19 (140). Thermal stability is affected by the structure of the hardener. The heat resistance of aliphatic amine cured epoxy is low as measured by TGA. The nitrogen atoms are oxidized by atmospheric oxygen to amine oxides, which attack the polymer backbone. Anhydride systems tend to split off the anhydride at temperatures well below their decomposition point at about 390°C. The ether segments formed by 2-MI and phenolic cured epoxies have the highest thermal stability.

Epoxy/Curing Agent Stoichiometric Ratios. In addition to the choices of epoxy resins and curing agents, the stoichiometric ratio of epoxy/curing agent is another factor that has significant effects on the network structure and performance. A variety of products are obtained from different ratios. Network formations for a difunctional epoxy resin and a tetrafunctional amine are illustrated in Figure 5. The products range from an epoxy–amine adduct with excess epoxy to an amine–epoxy adduct with excess amine.

Theoretically, a cross-linked thermoset polymer structure is obtained when equimolar quantities of resin and hardener are combined. However, in practical applications, epoxy formulations are optimized for *performance* rather than to complete stoichiometric cures. This is especially true when curing of high MW epoxy resins through the hydroxyl groups.

In primary and secondary amines cured systems, normally the hardener is used in near stoichiometric ratio. Because the tertiary amine formed in the reaction has a catalytic effect on reactions of epoxy with co-produced secondary alcohols, slightly less than the theoretical amounts should be used. However, if substantially less than the theoretical amount of amine is used, the epoxy resin will not cure completely unless heat is applied (post-cure). The use of excess amine will result in unreacted amine terminated dangling chain ends and reduced cross-linking, yielding a polymer that can be somewhat tougher but which is considerably more susceptible to attack by moisture and chemicals. In formulations containing anhydrides, less than stoichiometric ratios of curing agents normally are used (0.50 to 0.85 of anhydride to 1 epoxy stoichiometric ratio) because of significant epoxy homopolymerization.

Ladder studies are often conducted varying the stoichiometric ratios and other factors to determine the optimum formulations. Statistical design of experiment (DOE) methodology has been used to efficiently carry out ladder studies (141). Information concerning network structures can be obtained using dynamic mechanical analysis (DMA) (142,143) and chemorheology to guide formulation development (144,145).

Catalysts. The choice of a catalyst and of its amount is important. As discussed in previous sections, some tertiary amine catalysts can play multiple roles in the curing reaction. Anhydride cure in particular is highly sensitive to catalyst amount. Nucleophilic catalysts, used with acidic curing agents such as

anhydrides and novolacs, can greatly reduce the gel time. In the case of anhydrides, a nucleophilic catalyst attacks the anhydride ring, causing the ring to open and promote bonding to the epoxy ring. Figure 8 shows the effect of BDMA and 1-propylimidazole levels on the pot life of a system combining D.E.R. 331 resin and nadic methyl anhydride at 90°C (194°F) (146). Imidazoles are more efficient accelerators than tertiary amines; only half the concentration is required to produce the same catalytic effect.

Accelerators. Accelerators are commonly added to epoxy systems to speed up curing. This term should be used to describe compounds which increase the rate of catalyzed reactions but which by themselves are not catalysts. However, the term *accelerator* is often used synonymously with *catalyst* in some of the literature. Hydrogen donors such as hydroxyl groups facilitate epoxy reactions via hydrogen bonding or reaction with the oxygen on the epoxide ring. More acidic donors such as phenols and benzyl alcohols increase the rate of acceleration. However, very strong acids can interfere with amine curing agents by protonation of the amine to form an amine salt, resulting in increased pot life. Figure 9 shows the effects of different accelerators on the rate of a DGEBA/triethylenetriamine formulation.

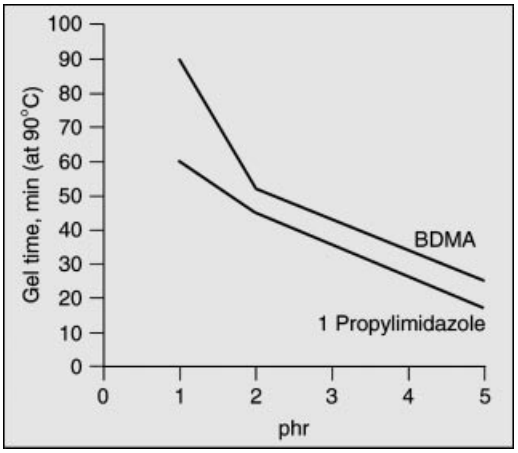

Fig. 8. Effects of accelerator on epoxy/nadic methyl anhydride cure.

Epoxy Curing Process

The epoxy curing process is an important factor affecting the cured epoxy performance. Consequently, it is imperative to understand the curing process and its kinetics to design the proper cure schedule to obtain optimum network structure and performance. Excellent reviews on this topic are available in the literature (147,148).

The curing of a thermoset epoxy resin can be expressed in terms of a time–temperature-transformation (TTT) diagram (Fig. 10) (149,150). Later, a CTP (cure-temperature–property) diagram was proposed as a modification of the TTT diagram (151). For nonisothermal cure, the conversion-temperature-transformation (CTT) diagram has been shown to be quite useful (152). In the TTT diagram, the time to gellation and vitrification is plotted as a function of

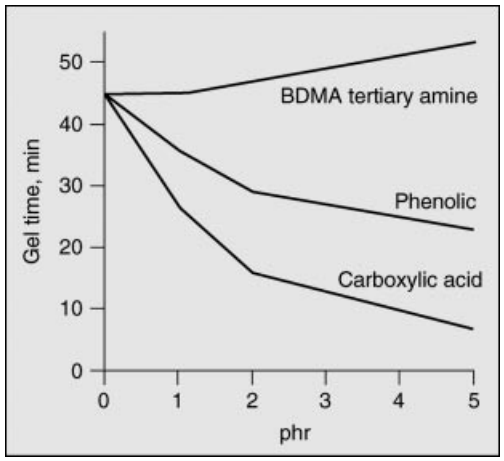

Fig. 9. Effects of accelerator on epoxy/triethylene triamine cure.

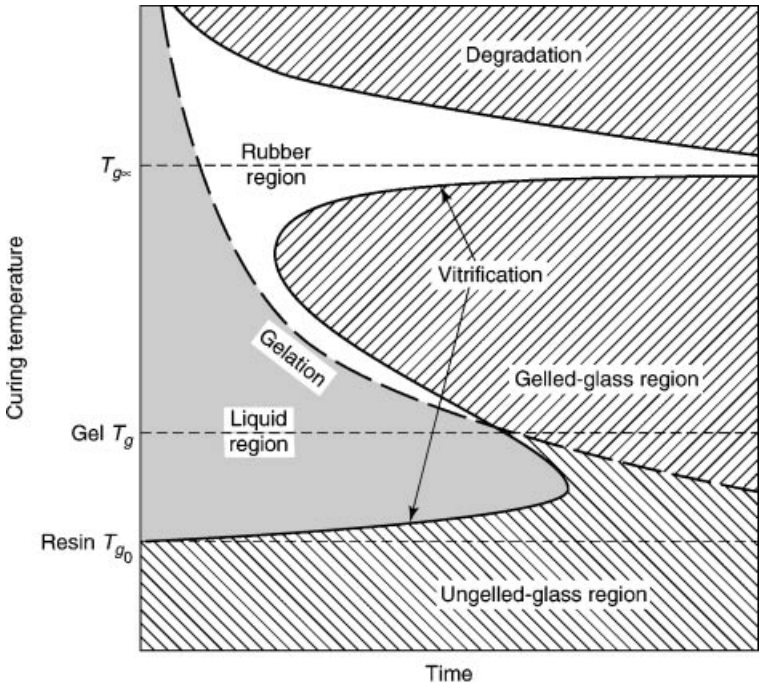

Fig. 10. Time–temperature-transformation diagram.

isothermal cure temperature. Important features are the gel point and the onset of vitrification. The gel point (qv) is defined as the onset of the formation of insoluble, cross-linked polymer (gel fraction) in the reaction mixture. However, a portion of the sample may still be soluble (sol fraction). The onset of vitrification is when the glass-transition temperature (T_g) of the curing sample approaches the curing temperature T_c. Ideally, a useful structural thermoset would cure until all monomers are built into the network, resulting in no soluble fraction.

The S-shaped vitrification curve and the gelation curve divide the time–temperature plot into four distinct states of the thermosetting-cure process: liquid, gelled rubber, ungelled glass, and gelled glass. T_{g0} is the glass-transition temperature of the unreacted resin mixture; $T_{g\infty}$ the glass-transition temperature of the fully cured resin; and gel T_g the point where the vitrification and gellation curves intersect.

In the early stages of cure prior to gelation or vitrification, the epoxy curing reactions are kinetically controlled. When vitrification occurs the reaction is diffusion controlled, and the reaction rate is orders of magnitude below that in the liquid region. With further cross-linking of the glass, the reaction rate continues to decrease and is eventually quenched. In the region between gelation and vitrification (rubber region) the reaction can range from kinetic to diffusion control. This competition causes the minimum in vitrification temperature seen in the TTT diagram between gel T_g and $T_{g\infty}$. As the cure temperature is raised the reaction rate increases and the time to vitrification decreases until the decrease in diffusion begins to overcome the increased kinetic reaction rate. Eventually,

slower diffusion in the rubbery region decreases the overall reaction rate and thus the increase in time to vitrify is seen. Below $T_{g\infty}$, the reaction does not go to completion. As curing proceeds, the viscosity of the system increases as a result of increasing molecular weight, and the reaction becomes diffusion-controlled and eventually is quenched as the material vitrifies (153). After quenching, the cure conversion can be increased by raising the temperature. This is often practiced as post-cure for certain epoxy systems to achieve maximum cure and performance. Post-cure is only effective at temperatures higher than $T_{g\infty}$. However, it must be noted that at temperatures sufficiently above $T_{g\infty}$, onset of network degradation can also be seen if sufficient time is involved. Thus one must be careful about potential "over-curing."

The TTT diagram is useful in understanding the cure kinetics, conversion, gelation, and vitrification of the curing thermoset. Gelation and vitrification times can be determined from the intersections of the storage and loss moduli and the maxima in the loss modulus of an isothermal dynamic mechanical spectrum, respectively. Recently, techniques have been developed using rheological and dynamic mechanical analysis instruments to determine the gel point and vitrification (154). Understanding the gelation and vitrification characteristics of an epoxy/curing agent system is critical in developing the proper cure schedule/process to achieve optimum performance.

One important application is the management of cure temperatures (T_c) and heating rate: if T is too low, vitrification may occur before gelation and further reactions may not be completed, resulting in an incomplete network structure and poor performance. This is of particular relevance in ambient cures and radiation cures (155). Furthermore, attention must be paid to the relationship between mixing of reactants and gel point. Epoxy resins and curing agents must be thoroughly mixed prior to the gel point since the rapid viscosity buildup at gel point inhibits homogeneous mixing of reactants, resulting in potential network and morphological inhomogeneities and defects (156).

Curing and quenching processes of epoxies have been reported to affect performance of certain epoxy coatings and composites. These effects have been attributed to phenomena known as internal or residual stress and physical aging of cured epoxies (147).

Internal stresses arise mainly because of the diminishing capacity of the cross-linked polymer to expand or contract to the same extent (volume) with the solid substrate to which it is adhered. This phenomenon is caused by mismatches of coefficients of thermal expansion (CTE) of the substrates (metal, glass, etc) and the cross-linked epoxies during nonisothermal cures; and cure shrinkage (solvent loss, cross-linking). The effect often contributes to adhesion failures and is more prominent in metal coatings and large composite parts manufacturing, especially when the T_g of the cross-linking polymer approaches T_c. As discussed previously, while curing of epoxy functional groups via polycondensation reaction results in relatively low shrinkage, failures attributable to internal stresses such as delamination have been observed in certain epoxy coatings of metal substrates, epoxy encapsulants for electronic devices and glass-fiber-reinforced composites (157). The effect can be very severe in the case of photoinitiated curing of epoxy acrylates as well as free-radical curing of epoxy vinyl esters. Shorter bonds are formed during these free-radical curing processes, which result in significant shrinkage.

Post-cure with heat is often required to release some of the internal stresses and to improve adhesion. Efforts have been focused on understanding the mechanism of stress development, and stress minimization by modifications of the cure and post-cure cycles (158).

Physical aging is a well-known phenomenon in glassy polymers and has been studied quite extensively in amorphous thermoplastics (see AGING, PHYSICAL; AMORPHOUS POLYMERS) (159). The term *physical aging* refers to the gradual changes in polymer physical properties with time after a glassy polymer is heated above its T_g and rapidly cooled (quenching) to temperatures below T_g. The physical aging process differs from chemical aging processes, in which breakage or formation of chemical bonds are involved such as continuing cure, hydrolytic aging, and photochemical and thermal degradation. The phenomenon has been attributed to the nonequlibrium state of the glassy polymer at temperatures below its T_g, in which the polymer contains excessive free volume as it is quenched. As the polymer recovers gradually over time to approach equilibrium, a reduction in free volume and an increase in density results. Consequently, the term *densification* is sometimes used to describe physical aging. For certain epoxy systems, physical aging has been reported to cause increases in stiffness and decreases of toughness (160,161). Hardening of certain baked epoxy coatings with time and failures of the coatings due to loss of ductility have been observed. However, physical aging has been reported to be reversible (erasable) by post-heating above polymer T_g. Proper selection of the cure and post-cure schedules including quenching cycle is important to minimize the potential detrimental effects of physical aging (162). In some epoxy systems, it is difficult to distinguish physical aging from the effects of residual solvent loss and/or continuing cross-linking. They all can contribute to increases in stiffness of the system.

To develop a proper curing process, it is important to understand the reactivity of different curing agents toward the epoxy structure of interest. The effect of hardener structure on reactivity of a cross-linked DGEBA resin (determined by DSC) is shown in Table 19. Aliphatic amines show a maximum reaction rate, called T, at 90°C (heating rate 10°C/min). The same epoxy resin is somewhat less reactive ($T_{rmax} = 126$°C) when homopolymerized via initiators. Aromatic amines and phenols cure considerably more slowly, requiring higher curing temperatures. The highest temperatures are required for dicyandiamide curing, which can, however, be accelerated by basic components.

Relative reaction rates are often expressed in terms of the activation energy E_a (Arrhenius type relationship). E_a allows comparisons of reaction rates at different temperatures and is influenced by the type of chemical reactions involved in the cure. Curing of epoxy resins with phenols or aromatic and aliphatic amines proceeds with a fairly low activation energy of 50–58.5 kJ/mol (12–14 kcal/mol). Activation energies are higher when epoxy compounds having low hydroxyl content are cured alone in the presence of catalysts (92 kJ/mol = 22 kcal/mol) or with dicyandiamide (125.5 kJ/mol = 30 kcal/mol).

Characterization of Epoxy Curing and Cured Networks. Cured thermoset polymers are more difficult to analyze than thermoplastics since they are insoluble and generally intractable. Their properties are influenced by factors at the molecular level, such as backbone structures of epoxy resin and curing agent; nature of the covalent bond developed between the epoxy resin and the curing

agent during cross-linking; and density and extent of cross-linking, ie, degree of cure.

Epoxy resin formulators are concerned with formulation reactivity and flow during application. Reactivity tests or gel time tests are used to determine the proper reactivity of the formulations. Formulators also developed flow tests to check for the formulation rheology profile. The coatings industry widely uses MEK (methyl ethyl ketone) double rubs as an indication of cure. While the test does give a relative indication of cure for a certain system, caution must be exercised when comparing different systems, which may have very different inherent resistance against MEK. In general, these end-use tests do not provide insights on the structure–property relationship of the system.

Epoxy curing process can be monitored by a number of different techniques:

(1) Analysis of the disappearance and/or formation of functional groups
(2) Indirect estimation of cure conversion
(3) Measurements of changes in thermal, physical, and mechanical properties of the system

Comprehensive reviews of different techniques for epoxy cure monitoring are available (86,94). Wet chemical or physical analysis methods, such as solvent swell (163), titration of functional groups, IR, near IR (164), or NMR spectroscopy, are commonly used to monitor epoxy cure.

The thermal properties of the system reflect the degree of cure, and Thermal Analysis (qv) (DSC, DMA, TGA) has been used extensively in studies of epoxy resins (156). Correlation between T_g and degree of cure has been well established for many systems.

Viscosity build is observed with increased reaction conversion in epoxy curing. More recently, chemorheology, which utilizes rheological measurement (qv) and thermal analysis such as DSC, has been applied to study epoxy cure (166,167).

Since epoxy curing involves epoxy ring opening and the generation of polar groups, which have a high dipole moment, dielectric measurements have been applied to monitor cures. Dielectric methods (168,169) encompass both macroscopic and microscopic features: the dipoles being oriented during dielectric measurements are on a microscopic scale, whereas the degree and rate of orientation may depend on macroscopic properties such as viscosity and density.

The mechanical properties of a resin system can also be used to estimate the degree of cure (170). The methods range from hardness (qv) evaluation to complex static measurements or sensitive dynamic mechanical analysis (qv) (DMA). Table 20 gives ASTM standard procedures for measuring the properties of cured or partially cured epoxy resin systems.

Direct measurement of the cross-link density of thermoset polymers including those from epoxy resins remains one of the most difficult analytical challenges in the field. A far too common approach simply relates the rubbery modulus (G_r), the thermoset modulus above T_g, to the molecular weight between cross-links (M_c) using the theory of rubbery elasticity (133,134). Unfortunately thermoset networks have much more complex features than do true elastomers, including non-Gaussian chain behavior, interchain interactions, and entanglements (172).

Hardness, Rockwell M	D785

[a]From Ref. 171.

These factors render rubbery elasticity theory inadequate as an absolute measure of M_c from G_r, and doing so can lead to totally erroneous conclusions on the network structure (173). In a given family of thermosets, changes in G_r can be considered to reflect *relative* changes in M_c. Estimates of the expected M_c can be calculated from monomer MW and functionality for stochiometric systems (174). More extensive network structure calculations including M_c are done using statistical relations developed by Miller and Makosco (175).

In many applications, epoxy systems derive their high thermal and mechanical performance (qv) of plastics characteristics from highly cross-linked network structures. However, this often results in brittleness of the epoxy thermosets and loss of end-use properties such as impact resistance. Elongation at break (% elongation) has been a popular test used in the industry for many years to measure *toughness*, ability to resist failure under tensile stress. While useful in certain applications, good correlations between elongation at break and end-use properties of cured epoxies are not always possible. The failure envelope concept has been useful in looking at the entire time–temperature failure spectrum of epoxies (176). More recently, progress in the field of fracture mechanics (177,178) has led to advanced fracture toughness tests that are more useful in characterizing cured epoxy performance. Examples of such tests are critical elastic strain release rate (G_{IC}) and critical stress intensity factor (K_{IC}) (179).

Dynamic mechanical analysis (DMA) of cross-linked epoxy resins typically shows, in order of decreasing temperature, an α transition corresponding to T_g, a β transition associated with relaxation of the glyceryl groups, and a γ transition due to methylene group motions (180). Both the β and the γ transitions, which are typically observed at -30 to $-70^{\circ}C$ and at about $-140^{\circ}C$, respectively, are attributed to crankshaft motions of the polymer chain segments. The appearance of transitions between the α and β transitions is highly variable and has been attributed to segmental motions due to particular curing agents (181). No definitive correlations between the appearance of sub-T_g relaxations and mechanical properties have been observed (182). Like many other plastics, cross-linked epoxy resins undergo a change in fracture mechanism from brittle to ductile (T_b) with increasing temperature. The window between T_g and T_b has been shown to correlate well with the formability of epoxy can coatings in the draw-redraw (DRD) process (183,184).

Adhesion (qv) is an important issue in epoxy applications since epoxy is almost always used as part of a composite system. Examples are epoxy coatings on metal substrates, epoxy adhesives for metal surfaces, and matrix resin in fiber-reinforced composites such as PCB laminates and aerospace composites. Consequently, optimum epoxy adhesion to the substrate is a prerequisite for good system performance in terms of static and dynamic mechanical properties and environmental durability. In rubber-toughened composite systems, it has been reported that a threshold of interfacial adhesion between both phases (rubber and resin matrix) is needed for maximum toughening by promoting the cavitation mechanism and by activating the crack-bridging mechanism (185). Excellent review papers are available on the issue of adhesion of epoxy in composites (186), coatings, and adhesives (187). Effects of internal stresses on coating adhesion failures including the role of coating defects and pigments as potential stress concentrators have been reported (188).

Surface analysis such as dynamic contact angle and surface tension are used to ensure proper wetting of epoxy and the substrate. Microscopic techniques, such as scanning electron microscopy (SEM), transmission electron microscopy (TEM), and atomic force microscopy (AFM), are widely used to study morphology, fracture, and adhesion issues of cured epoxy systems. Chemical analysis techniques, such as micro-IR, X-ray photoelectron spectrometry (XPS), and secondary ion mass

spectrometry (SIMS), are useful in providing functional group analysis at the interfaces.

Consumers of products which use epoxy resins have developed increasing expectations for longer and more reliable performance. In automobiles, for example, the coating is expected to maintain its initial "Class A" finish for 10 years and the composite leaf spring is designed to last for the life of the vehicle. To meet these expectations, the long-term durability of epoxy thermosets is a key material-specific and application-specific consideration. The durability of polymeric materials in general depends on phenomena such as physical aging, environmental exposure (such as weathering), and mechanical experience (such as impact and load). A detailed discussion of this topic is beyond the scope of this review; interested readers are referred to a leading reference (189).

In addition, the processing of epoxy formulations into their final thermoset structure and form has a major effect on ultimate performance. Material properties such as rheology and reaction kinetics interplay with processing variables such as temperature and shear rate to affect key properties of extent of cure, orientation, and residual stress. Design of the final form of the material also should incorporate fundamental thermoset properties using finite element analysis methods. Optimization of any given epoxy thermoset application is therefore very specific to formulation, processing conditions, and final form and use of the material, and involves the contributions from chemistry, engineering, and material science disciplines to be fully successful.

Formulation Modifiers

The processing behavior (mainly viscosity and substrate wetting) and other properties of an epoxy system can be modified by diluents, fillers, toughening agents, thixotropic agents, etc. Most commercial epoxy resin systems contain modifying agents.

Diluents. Diluents affect the properties of the cured resin system and, in particular, lower the viscosity in order to improve handling and wetting characteristics. They are often used in the range of 2–20 wt% based on the epoxy resin. Diluents can be classified into *reactive* and *nonreactive* types.

The *reactive* diluents are products with low viscosity (1–500 cP at 25°C) used to lower the viscosity of standard epoxy formulations. The effect of reactive diluents on DGEBA viscosity is illustrated in Figure 10. Lower viscosity allows higher filler loading, lower costs, and/or improved processability. Because of the epoxy functionality, the diluents become part of the cured networks. However, the reactive diluents can negatively impact properties, and so balancing of viscosity reduction and property loss is an important consideration. Decreases in tensile strength, glass-transition temperature, chemical resistance, and electrical properties are usually observed. Toxicity is another concern, particularly the aromatic mono glycidyl ethers such as phenyl glycidyl ether (PGE) and *o*-cresol glycidyl ether (CGE). *n*-Butyl glycidyl ether (BGE) is one of the most efficient viscosity reducers, but it has been losing favor because of its volatility and noxiousness. Longer chain alkyls, polyfunctional or aromatic glycidyl ethers such as bisphenol F epoxy, neopentylglycol diglycidyl ether, and triglycidyl ether of propoxylated

glycerine are gaining popularity as epoxy reactive diluents. Cycloaliphatic epoxies and glycidyl esters of acids such as neodecanoic acid are also used as reactive diluents.

Acrylics such as 1,6-hexanediol diacrylate and trimethylolpropane triacrylate are nonepoxy multifunctional diluents, which react readily with primary and secondary amines by means of Michael addition of the the amine to the acrylic double bond (190). They have been used to increase cure speed or to lower cure temperature of epoxy–amine systems. Caprolactone acrylates have also been used for this application (191).

Solvents and plasticizers are *nonreactive* diluents. The most common nonreactive diluents are nonyl phenol, furfuryl alcohol, benzyl alcohol, and dibutyl phthalate. These materials have the advantage of being able to add to the amine side of the system to better balance mix ratios. Nonyl phenol and furfuryl alcohol also improve wet-out and accelerate cure slightly. They are also capable of reacting with the epoxy group under high temperature cure conditions. Benzyl alcohol is a popular diluent used with amine-cured systems. In addition to viscosity reduction, it is also known to increase cure speed. Benzyl alcohol can be used up to 10 wt% level without significant effects on cured properties. Dibutyl phthalate is widely used as a nonreactive diluent for liquid resins. However, performance properties will drop off more quickly with increasing levels of nonreactive diluents than with increasing levels of reactive diluents.

Aromatic hydrocarbons, such as toluene or xylene, significantly reduce the viscosity of liquid DGEBA resins, but their use can be accompanied by a 15–25% decrease in compressive yield strength and a 10–20% reduction in compressive modulus (Fig. 11). If the solvent is trapped in the cured system, solvent resistance is reduced and cracks develop if the resin is used in heat-cured castings. The use of solvents and reactive diluents in epoxy systems is reviewed in References 192 and 193.

Thixotropic Agents. *Thixotropy* is the tendency of certain colloidal gels to flow when subjected to shear, and then to return to a gel when at rest. A thixotropic gel can be produced through the addition of either high surface area fillers such as colloidal silicas and bentonite clays or of chemical additives. Thixotropy is desirable in applications such as encapsulation where the coating is applied by dipping. The resin will wet out and coat the object being dipped, but will not run off when the object is removed from the dipping bath.

Fillers. Fillers (qv) are incorporated in epoxy formulations to enhance or obtain specific desired properties in a system. The type and amount of filler used are determined by the specific properties desired. Fillers can also reduce the cost of epoxy formulations. Inert commercial fillers (qv) can be organic or inorganic, and spheroidal, granular, fibrous, or lamellar in shape. The properties of commercial fillers are given in Table 21, and some effects on epoxy resins are shown in Tables 22 and 23. Some formulations contain up to 90 wt% fillers. For certain applications, fillers can have significant effects on thermoset morphology, adhesion, and the resulting performance.

Filler loading is often limited for a given application by the maximum viscosity allowable and/or the reduction in some mechanical properties such as tensile and flexural strength in the cured material. Viscosity can be modified by heat or by addition of a reactive diluent; heating is preferred since diluents affect overall

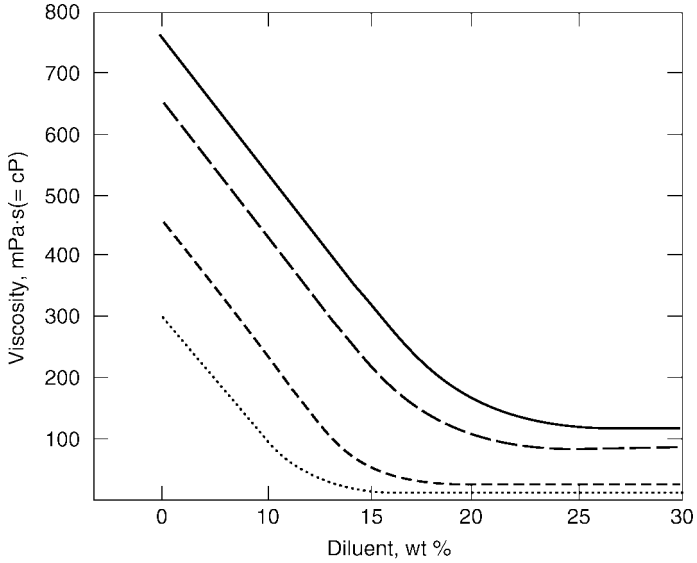

Fig. 11. Reduction of DGEBA viscosity by reactive diluents:——, *o*-cresol glycidyl ether; – – –, butanediol diglycidyl ether; ----------, C_{12}–C_{14} aliphatic glycidyl ether (Epoxide 8); ·····, *n*-butyl glycidyl ether.

system properties. Some of the major property enhancements affected by fillers are described below.

Pot life and exotherm. Fillers can increase pot life and lower exotherm of epoxy systems. Fillers reduce the reactant concentration in the formulation and act as a heat sink. Generally, they have higher heat capacities than the epoxy resins. They are also better heat conductors than the resins, and thus help to dissipate exotherm heat more readily. Commonly used fillers are silica, calcium carbonate, alumina, lithium aluminum silicate, and powdered metals.

Thermal shock resistance. Fillers help to increase thermal shock resistance and to decrease the thermal expansion coefficient of an epoxy system by replacing part of the resin with a material that does not change its volume as significantly with temperature variations. Such fillers are clay, alumina, wood flour, sawdust, silica, and mica. Epoxy molding compounds (EMC) can contain up to 90% of fused silica to manage the thermal stress experienced by the encapsulated semiconductors. Powdered metals are used when bonding metals together to better match the coefficient of thermal expansion of the bond with that of the metal, thus minimizing thermal stress.

Shrinkage. Using fillers as a partial replacement for a reactive resin that shrinks on curing can reduce shrinkage of the system. Any inert filler will decrease shrinkage, but the most commonly used are silica, calcium carbonate, alumina talc, powdered metals, and lithium aluminum silicate.

Machinability and abrasion resistance. The addition of fillers can increase the machinability and abrasion resistance of an epoxy resin system by

Table 21. Typical Properties of Fillers

Name	Composition	Particle shape	Surface area volume	Bulk density, kg/m^3	Characteristics and main use
Marble flour, dolomitic	Magnesium–calcium carbonate	Granular	Medium	1120–1300	General-purpose fillers, particularly recommended for castings requiring machining
Chalk powder	Precipitated calcium carbonate	Crystalline	High	800–880	
Sand	Quartz, feldspar, and subsidiary minerals	Spheroidal	Low	1500–1700	Bulk filler giving high compressive strength and abrasion resistance; difficult to machine
Silica flour	Ground quartz	Granular	Medium	1100–1150	Standard filler for large electrical castings; high abrasion resistance; difficult to machine
Mica flour	Muscovite[a]	Lamellar	High	300–400	Filler giving high crack resistance to castings exposed to mechanical and thermal shock
Slate powder	Slatea	Mainly lamellar	Medium	700–900	General-purpose filler giving high abrasion resistance; difficult to machine
Vermiculite[b]	Vermiculite[a]	Exfolidated laminae	High	100–150	Fillers giving lightweight bulk in cores or thick backing to increase the rigidity of thin sections
Phenolic microballoons	Phenolic resins	Hollow spheres	Medium	100–150	
Zircon flour	Zircon[a]	Granular	Medium	1700–1900	Filler giving high abrasion resistance; difficult to machine

Aluminum powder	Metallic aluminum	Granular	Medium	1000–1100	Filler imparting thermal conductivity, eg, to prevent excessive temperature buildup in electrical components or in tools for hot-forming plastics
Chopped glass strand[c]	Low alkali glass	Fibrous	Medium	100–250	Fillers improving the mechanical strength of prominent edges and thin sections
Hydrated aluminum oxide	Alumina trihydrate	Granular	Medium	700–1300	Filler improving wet and dry arc-track resistance and flame retardance

[c] Length = 0.60 cm.

Table 22. Effect of Fillers

Advantages	Disadvantages
Lower cost of product	Increased weight[a]
Reduced shrinkage upon curing	Loss of transparency
Decreased exothermic temperature rise on curing[a]	Tendency to entrap air
Increased thermal conductivity[a]	Difficulty of machining hard fillers
Reduced expansion and contraction with temperature change	Decreased impact and tensile strengths
Higher deflection temperature	Increased dielectric constanta and power factor[a]
Improved heat-aging properties[a]	
Reduced water absorption[a]	
Improved abrasion resistance[a]	
Increased surface hardness[a]	
Increased compressive strength[a] and Young's modulus[a]	
Increased electric strength[a]	

[a] Certain fillers, such as vermiculite and phenolic microballoons, have the reverse effect.

increasing the hardness of the thermoset. Greater hardness leads to a higher energy required to scratch but cleaner cuts upon machining. Fillers used for this purpose are powdered metals, wood flour, calcium carbonate, sawdust, clay, and talc.

Electrical conductivity. In certain applications, conducting fillers are added to epoxy formulations to reduce the good insulating properties of the epoxy systems. The most commonly used fillers are graphite and powdered metals.

Other properties that can be affected with the proper choice of fillers for a specific application include compressive strength, adhesion, arc and tracking resistance, density, and self-lubricating properties.

Epoxy Nanocomposites. Significant recent developments in polymer property enhancement involve polymer nanocomposites. This is a special class of fillers (mostly clay derivatives) in which the nanoscale, highly oriented particles are formed in the polymer matrix through monomer intercalation and particle aggregate exfoliation (see NANOCOMPOSITES, POLYMER-CLAY) (194,195). The objective is to combine the performance attributes of both hard inorganic and plastic materials. Significant efforts have been dedicated to develop epoxy nanocomposites in the past decade. Improvements in electrical and mechanical properties, chemical resistance, high temperature performance, and flame retardancy have been reported. Other silica-based organic hybrids have been developed (196) for military and aerospace applications.

The emerging field of nanotechnology has produced new materials such as the carbon nanotubes, which are filaments of carbon with atomic dimensions. Recent publications claimed exceptional property enhancement from nanotube-laced

[b] Porosity of filler reduces protection provided by resin.

epoxy (hardness, electrical and heat-conducting properties) (197). However, cost remains a barrier for commercialization.

Toughening Agents and Flexiblizers. Some cross-linked, unmodified epoxy systems exhibit brittleness, poor flexibility, and low impact strength and fracture resistance. Modifiers can be used to remedy these shortcomings. However, there usually will be some sacrifices of properties. In general, there are two approaches used to modify epoxies to improve these features.

(1) *Flexiblization.* Aliphatic diepoxide reactive diluents enhance the flexibility or elongation by providing chain segments with greater free rotation between cross-links. Polyaminoamide hardeners, based on aliphatic polyamines and dimerized fatty acids, perform similarly. Liquid polysulfide polymers possessing terminal mercaptan functionality improve impact properties in conjunction with polyamine hardeners.
Flexible chain segments are incorporated in an epoxy resin by many means (189). One approach is the incorporation of oligomeric aliphatic polyesters containing carboxylic acid end groups, forming an epoxy resin adduct. This is one of the reasons that epoxy–polyester hybrid powder coatings have become very popular. The effects of flexiblizers are shown in Table 24. Flexiblization can enhance elongation of the system but is often accompanied by a reduction of glass-transition temperature, yield stress, and elastic modulus. Other properties (eg, water absorption and thermal and chemical resistance) may also be affected.

(2) *Toughening* refers to the ability to increase resistance to failure under mechanical stress. Epoxies derive their modulus, chemical, and thermal resistance properties from cross-link density and chain rigidity. Increasing cross-link density to meet higher thermal requirements (T_g) often comes

Table 24. Effect of Flexiblizers

Flexiblizers	Concentration, %	Advantages	Disadvantages
Poly(propylene glycol) diglycidyl ether	10–60	Low viscosity, good flexibility	Poor water resistance fair impact resistance
Polyaminoamides	30–70	Good abrasion resistance, good flexibility	Fair chemical resistance
Liquid polysulfides	10–50	Good corrosion resistance, excellent flexibility	Odor Poor heat resistance tendency to cold flow
Aliphatic polyester adducts	10–30	Good water resistance Fair flexibility over a range of temperatures	High viscosity

at the expense of toughness. Toughening approaches for epoxies (199–202) include the dispersion of preformed elastomer particles into the epoxy matrix and reaction-induced phase separation of elastomers or thermoplastic particles during cure.

Elastomers such as carboxyl-terminated poly(butadiene-*co*-acrylonitrile)s (CTBN) have been popular tougheners for epoxies. Toughening by elastomers can be attributed to the incorporation of a small amount of elastic material as a discrete phase of microscopic particles embedded in the continuous rigid resin matrix. The rubbery particles promote absorption of strain energy by interactions involving craze formation and shear deformation. Craze formation is promoted by particles of 1–5-μm size, and shear deformation by particles >0.5 μm. Systems possessing both small and large particles, ie, bimodal distribution, provide maximum toughness (203). The rubber is incorporated in the epoxy resin in a ratio of 1:8 in the presence of an esterification catalyst. The product is an epoxy ester capped with epoxy groups. The adduct is then formulated with unmodified resin and cured with standard hardeners and accelerators. Phase separation, of the adduct occurs during the curing process, resulting in the formation of segregated domains of elastomer-like particles covalently bound to the epoxy resin matrix. Optimum particle size and particle-size distribution, phase separation, and phase morphology are crucial for the development of desirable properties of the system. If the elastomer remains soluble in the epoxy matrix, it serves as a flexiblizer and reduces the glass-transition temperature significantly. Some reductions in T_g and modulus are typical of CTBN-modified epoxies. Amine-terminated poly(butadiene-*co*-acrylonitrile)s (ATBN) are also available (68).

Elastomer-modified epoxy resins are used in composites and structural adhesives, coatings, and electronic applications. Similar approach to toughen epoxy vinyl esters using other elastomeric materials has been reported (204). Other elastomer-modified epoxies include epoxy-terminated urethane prepolymers, epoxy-terminated polysulfide, epoxy–acrylated urethane, and epoxidized polybutadiene. Preformed dispersions of epoxy-insoluble elastomers have been developed and reported to achieve toughening without T_g reduction (205,206).

Other epoxy toughening approaches include chemical modifications of the system either through the epoxy backbone and/or crosss-linker. Dow Chemical developed a cross-linkable epoxy thermoplastic system (CET) (207). The concept involves introducing stiffer polymer segments into the network structure to maintain the glass-transition temperature while allowing cross-link density reduction to improve toughness. Thermoplastics, core-shell rubbers (CSR), and liquid crystal polymers (LCP) have also been used. Semi-interpenetrating network (IPN) approaches involve formation of a dispersed, cross-linked epoxy second phase in a thermoplastic matrix. The systems were reported to have good combinations of toughness, high T_g, high modulus, and processability.

Incorporation of block copolymers (qv) has been shown to improve toughness of certain epoxy systems (208). More recently, nanocomposites and self-healing epoxy systems (209) represent new approaches to develop more damage-tolerant epoxies.

Through the proper selection of resin, curing agent, and modifiers, the cured epoxy resin system can be tailored to specific performance characteristics. The choice depends on cost, processing and performance requirements. Cure is possible at ambient and elevated temperatures. Cured epoxies exhibit good combinations of outstanding properties and versatility at moderate cost: excellent adhesion to a variety of substrates; outstanding chemical and corrosion resistance; excellent electrical insulation; high tensile, flexural, and compressive strengths; good thermal stability; relatively low moisture absorption; and low shrinkage upon cure. Consequently, epoxies are used in diverse applications.

Coatings Applications

Commercial uses of epoxy resins can be generally divided into two major categories: protective coatings and structural applications. U.S. consumption of epoxy resins is given in Figure 12. The largest single use is in coatings (>50%), followed by structural composites. Among the structural composite applications, electrical laminates contribute the largest epoxy consumption. A similar trend is observed for the European market, but the Asian consumption is heavily tilted toward electrical laminate and electronic encapsulant applications (210). Electrical and electronic applications account for the largest consumption of epoxy resins in Japan (>40%). In 2000, it is estimated that the Asia-Pacific region consumed up to 70% of all epoxies used in electrical laminate production worldwide. While the overall epoxy markets continue to grow at a steady pace over the past two decades, more rapid growth has occurred in powder coatings, electrical laminates, electronic encapsulants, adhesives, and radiation-curable epoxies.

The majority of epoxy coatings are based on DGEBA or modifications of DGEBA. Chemical and corrosion-resistant films are obtained by curing at ambient

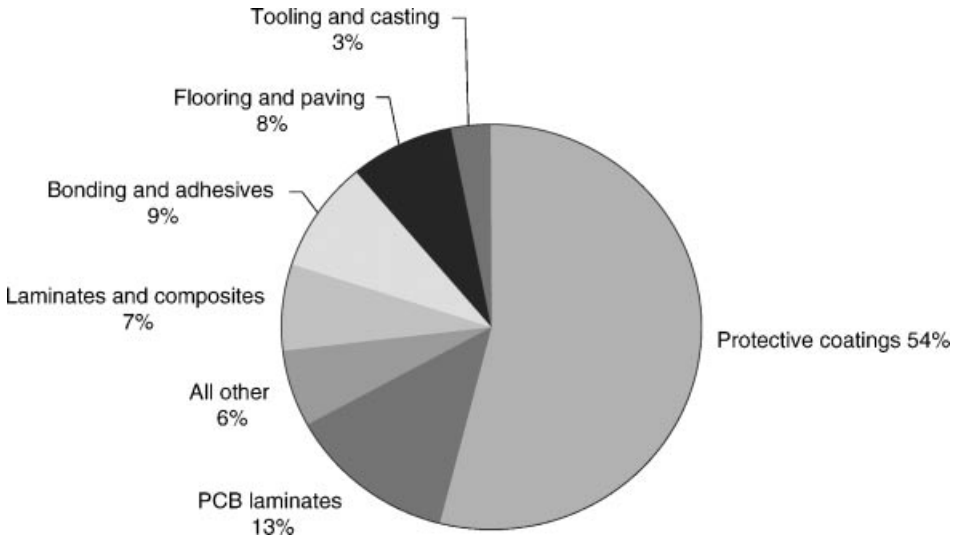

Fig. 12. End-use markets of epoxy resins (U.S. data, 2000).

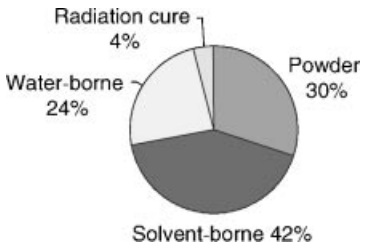

Fig. 13. Global epoxy coating application technologies (211).

and/or elevated temperatures. Ambient temperature cured coatings primarily involve cross-linking of the epoxy groups in mostly two-package systems, while elevated temperature cured coatings in one-package systems take advantage of the reactivity of both the epoxy and the secondary hydroxyl groups. As a class, epoxy coatings exhibit superior adhesion (both to substrates and to other coatings), chemical and corrosion resistance, and toughness. However, epoxy coatings have been employed mainly as primers or undercoats because of their tendency to yellow and chalk on exposure to sunlight.

Epoxy-based coatings are the preferred and dominant choices for cathodic electrodeposition of automotive primers, marine and industrial maintenance coatings, and metal container interior coatings. Use of epoxy flooring for institutions and industrial buildings has been growing at a steady rate as the industry becomes more aware of its benefits.

Solvents are commonly used to facilitate dissolution of resins, cross-linkers, and other components, and for ease of handling and application. Although most of the epoxy coatings sold in the 1970s were solvent-borne types, they made up only 40% of epoxy coating consumption in 2001 (211). Economic and ecological pressures to lower the volatile organic content (VOC) of solvent-borne coatings have stimulated the development of high solids, solvent-free systems (powder and liquid), and waterborne and radiation-curable epoxy coatings technologies (212). These environmentally friendly coating technologies have experienced rapid growth in the past decade. For example, epoxy powder coatings have been growing at rates exceeding those of other coating technologies as new applications such as automotive primer-surfacer and low temperature cure coatings for heat-sensitive substrates are developed. Radiation-curable liquid coatings based on epoxy acrylates and cycloaliphatic epoxies have also been growing significantly over the last decade. The current distribution of coating technologies is summarized in Figure 13.

Coatings Application Technologies.

Low Solids Solvent-Borne Coatings. These traditional low solids coatings contain less than 60% solids by volume (typically 40%). Their advantages include established application equipment and experience, fast drying and cure at ambient temperatures and excellent film formation at extremely fast cure conditions like those used in coil coatings (<30 s, $>200^{\circ}$C). However, because of stricter VOC regulations, solvent-based coatings have been losing market share steadily to more environmentally friendly technologies.

High Solids Solvent-Borne Coatings. High solids coatings contain 60–85% by volume of solids. They are mostly based on standard LERs or low molecular weight SERs modified by reactive diluents, low viscosity multifunctional aliphatic epoxies, or bisphenol F epoxy resins. High film build is one key advantage of high solids coatings. Examples include the coal-tar epoxy coatings that contain up to 85% solids used in industrial protective coatings.

Solvent-Free Coatings (100% Solids). Ecological concerns have led to increasing uses of these materials. Low viscosity LERs based on bisphenol A and bisphenol F epoxies are often used in combination with reactive diluents. The advantages include high buildup in a single application, minimization of surface defects owing to the absence of solvents, excellent heat and chemical resistance, and lower overall application costs. Disadvantages include high viscosity, difficulties to apply and produce thin films, poor impact resistance and flexiblity, short pot life, and increased sensitivity to humidity. Weatherable cycloaliphatic epoxies can be used to formulate solvent-free thermally curable coatings because of their low viscosities (213).

Waterborne Coatings. In the switch from solvent-borne to waterborne systems, epoxies are successfully bridging the gap largely by adaptation of conventional resins. Waterborne coatings accounted for almost 25% of epoxy coating consumption in 2001.

In addition to the waterborne epoxy dispersions which are typically supplied by epoxy resin producers, significant advances in waterborne coatings have been made by coatings producers such as PPG Industries, ICI Paint, and others utilizing modified epoxies. PPG coatings are used in cathodic electrodeposition systems that are widely accepted for automobile primers. Many patents have been issued for this important technology (214). The Glidden Co. (now ICI Paint) developed a waterborne system for container coatings based on a graft copolymerization of an advanced epoxy resin and acrylic monomers (215). These two waterborne epoxy coatings were significant breakthroughs in the coatings industry in the 1970s and are still widely used today.

For ambient temperature cure applications such as industrial maintenance and marine coatings, LERs or low molecular weight SERs (type 1 resin) are dispersed in water with a surfactant package and small amounts of co-solvents (216). Some producers offer waterborne curing agents that, typically, are salts of polyamines or polyamides. Key disadvantages include higher costs, slow cure at ambient and humid conditions, and tendency to cause flash rush. In addition, expensive stainless steel equipment are required for application. Recent developments include the elimination of co-solvents in some epoxy dispersions (217). Custom synthesized acrylic latexes have shown promise when thermally cured with cycloaliphatic epoxies (218). While the overall volume is still relatively modest (estimated at <20,000 MT in 2000 for the global market), it is expected that future growth rate for this segment will be much higher than standard epoxy resins, particularly in Europe where environmental pressures are stronger.

Powder Coatings. Epoxy-based powder coatings exhibit useful properties such as excellent adhesion, abrasion resistance, hardness, and corrosion and chemical resistance. The application possibilities are diverse, including metal finishing, appliances, structural rebars, pipes, machinery and equipment, furnitures,

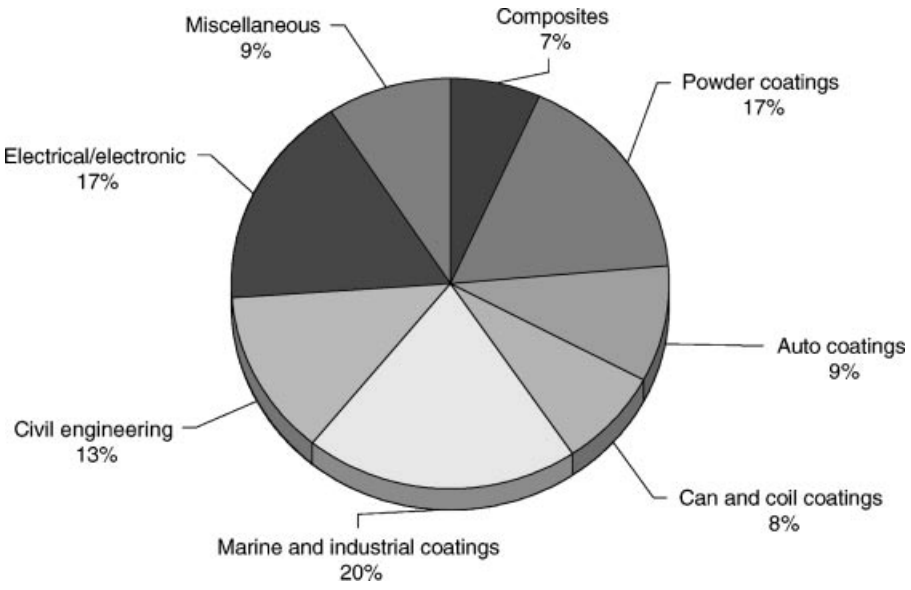

Fig. 14. Major global epoxy resin markets (Dow Chemical data, 2001).

and automotive coatings. Together, these applications accounted for 30% of epoxy coatings (Fig. 13) and 17% of epoxy resin consumption globally in 2001 (Fig. 14). This is a high growth segment of epoxy coatings (see COATING METHODS, POWDER TECHNOLOGY).

The development of highly reactive powder systems which cure using low energy (150°C) and the possibility of economical thin films (30–40 μm) have made powder coatings competitive with waterborne and high solids systems. Powder coatings can be applied by fluidized-bed (thick films, 50–150 μm) or electrostatic spray (thin films, 30–40 μm).

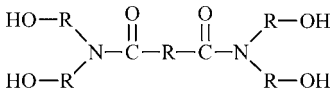
In powder coatings, epoxies are continuing to grow at rates exceeding other technology segments mainly because of the 100% solids feature, improved coverage, and recyclability of overspray materials. Pipeline projects, important because of worldwide energy problems, are significant consumers of epoxy powder coatings. The value of improved service life is being increasingly accepted even at the somewhat higher material cost of epoxy systems. Four types of epoxy resin systems are commonly used as powder coatings.

(1) *Epoxy powder coatings* are based on SERs of intermediate molecular weight (800–2000 EEW). They provide good flow and reactive terminal epoxy functionality. The properties of these thermoset coatings depend on the curing agents, which are friable solids such as dicyandiamide (DICY), phenol-terminated epoxy hardener, and anhydrides. Epoxy powder coatings are generally employed for interior or undercoat uses. Functional epoxy powder coatings are thick films (0.1–0.5 mm, 5–20 mil) used to protect automotive and truck parts, pipe, and concrete reinforcing bars. Fusion-bonded-epoxies (FBE), first developed by 3M Co., are epoxy powder coatings used

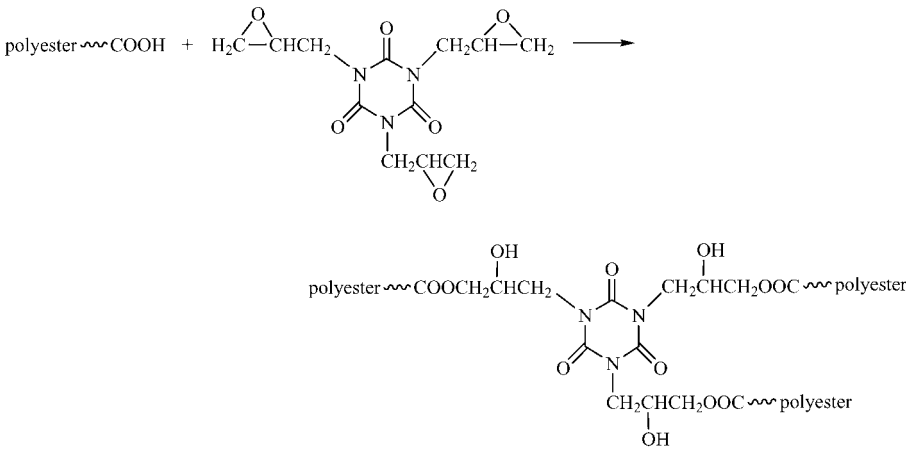
to protect oil and gas pipelines where long-term corrosion protection under adverse conditions (for example, the Alaska oil and North Sea underwater pipelines) is critical. The performance requirements for FBEs are challenging as the hard, cross-linked coatings are expected to survive the pipe bending/unwinding processes and handling abuses in the field. FBEs are also used to protect rebars embedded in critical concrete structures such as bridges, tunnels, and highways. Their primary function is to extend the lifetime of the concrete structures (5–10 years when built with uncoated rebars) to 20–30 years, reducing maintenance and repair costs. Epoxy powder coatings also serve as electrical insulation for bus bars, motor armatures, and similar articles. Decorative epoxy coatings are applied as a thin film (0.02–0.1 mm, 1–5 mil) and used mainly in appliance and general metal product applications. Coating for heat-sensitive substrates is an emerging market for epoxy powders.

(2) *Epoxy–polyester hybrids* are mixtures of solid epoxy resins based on bisphenol A and acid-terminated polyester solid resin (25–85 acid equivalent weight). These hybrids are typically less expensive than the epoxy-based powder coatings and offer improved weatherability, and better resistance to overbake yellowing while retaining many of the properties of the standard epoxies. Corrosion resistance is equivalent to epoxy powders in most cases, although solvent and alkali resistance is inferior. One significant new application of the epoxy–polyester hybrids is the primer-surfacer coating for automobiles. Primer-surfacer coatings based on epoxy–polyester hybrid is applied in between the epoxy primer and the topcoats. Its functions are to provide intercoat adhesion and to improve the chip resistance properties of the coatings. Automakers have also found that the epoxy–polyester hybrid primer-surfacer give a smoother surface under the top coats, resulting in a better quality appearance (219). Epoxy–polyester hybrids have experienced exceptional growth in the global market in the past decade.

(3) *Polyester–TGIC*, a third type of epoxy powder coating, is based on a mixture of polyester polycarboxylic acids (18–37 acid equivalent mass) and triglycidyl isocyanurate (TGIC). The TGIC-cured powder coatings have excellent UV resistance, good gloss and color retention, as well as good adhesion and mechanical properties. They were originally developed in Europe for coating metal window frames and buildings, exterior siding, outdoor hardware, high quality outdoor furniture, and other articles requiring superior outdoor durability. These polyester–TGIC powder coatings have gained popularity worldwide. In recent years, there have been concerns over toxicity of TGIC, and a number of potential replacement compounds have been developed. Among these, β- hydroxyalkylamide (HAA), trade named Primid by EMS-Chemie is gaining in popularity, particularly in Northern Europe.



Hydroxy alkylamide (HAA)



Reaction scheme of TGIC with carboxylic-terminated polyesters

(4) *Glycidyl methacrylate–acrylic.* These powder coatings are based on copolymers of glycidyl methacrylate (GMA) and acrylic monomers. They are often thermally cured with dodecanedioic acid (DDDA) and are used in automotive primer-surfacer and clear coats of luxury automobiles such as BMW (220,221).

Recent developments in powder coatings based on epoxy include UV-curable GMA–acrylic coating for automotive parts; lower temperature cure coatings for heat-sensitive substrates such as wood (222,223) and plastics; and dual cure (thermal/UV) systems.

Radiation-Curable Coatings. UV and electron beam (EB) radiation curable coatings (74) is a fast-growing segment of epoxy coatings, increasing at 8–10% annual growth rate. The technology is environmental-friendly. No solvent is used, and volatile emission is essentially eliminated. Cure is highly effective and energy-efficient at ambient temperatures, lending the technology highly applicable to heat-sensitive substrates such as wood, plastics, and paper. Capital cost requirements are low especially when compared to new thermal ovens for solvent-borne and waterborne coatings. EB cure is a relatively new technology which initiates cure via highly energetic electron beams, and unlike UV cure no photoinitiator is needed. However, EB capital cost is higher.

Epoxy acrylates are widely used as the base resin in many UV-initiated free-radical cure varnish formulations. Epoxy acrylates provide varnishes with excellent scuff resistance, high gloss, and good adhesion. Major markets are overprint varnishes for papers (books, magazines, cards, labels, etc) and exterior can coatings. Wood furniture and particle board are new but growing markets for this technology. Alternatively, cycloaliphatic epoxies can be UV-cured via a photo-initiated cationic mechanism. They are used in metal container exterior overprint varnish and inks, and high performance electronic applications. While cycloaliphatic epoxies are more expensive than epoxy acrylates, they offer several advantages: better adhesion to metals, fewer hazards in handling, and continued curing in the dark (which is important in certain applications). A related and high value market is

inks and resists, where radiation and heat-curable epoxies and epoxy acrylates are used. As discussed in the powder coatings section, radiation-curable epoxy powder coatings are being developed for a number of applications.

Epoxy Coatings Markets. The major global market segments of epoxies are represented in Figure 14. The marine and industrial protective coating is the largest market for epoxy coatings, followed by powder coatings, automotive, and container coatings.

Marine and Industrial Maintenance Coatings. The combined marine and industrial maintenance coatings application constitutes the largest epoxy coating market segment globally. While the end-use markets and application requirements are different, the basic epoxy systems utilized in these two markets are quite similar. The basic function of these coatings is to protect metal and concrete structures from degradation in aggressive environments for extended periods of time. The long service life of the coating and/or extended intervals between repairs are critical requirements, especially for marine applications, because of the high costs of dry-docking of ships for re-painting. The excellent corrosion, abrasion, and chemical resistance properties of epoxy coatings allow their dominant position in these markets. They are used in new construction as well as in maintenance and repair works. Examples are corrosion-resistant coatings for ships, shipping containers, offshore oil rigs and platforms, transportation infrastructures such as bridges, rail car coatings, coatings for industrial storage tanks, and primers for light industrial and agricultural equipment.

Most coatings used in these markets are two-component systems applied and cured at ambient conditions. LERs and low molecular weight SERs based on bisphenol A and bisphenol F epoxies are commonly used (224). Aliphatic polyamines, adducts of epoxy resins with aliphatic and aromatic amines, ketimines, phenalkamines, amidoamide, and polyamide resins are employed as curing agents. The working pot life of the amine–epoxy resin systems depends on the curing agent, solvents, catalysts, and temperature. High solids solvent-borne coatings are most popular. Tighter VOC regulations have facilitated the development of lower VOC, 100% solids, and waterborne epoxy coating systems. Important types of epoxy coatings in this segment include the following.

(1) *Two-component epoxy–amine coatings* are used primarily as a primer or mid-coat over the inorganic zinc-rich primer coating. High solids epoxy mastics can be applied over contaminated substrates and form thick, good barrier coatings. These coatings account for the majority of epoxies used in marine and industrial protective coatings markets.

(2) *Organic (epoxy) zinc-rich primers* are used in place or to repair imperfections of the inorganic zinc-rich primer. Their advantages over inorganic zincs include improved adhesion to the epoxy primer coating and better tolerance to poor surface cleaning.

(3) *Coal-tar epoxies* are historically some of the most popular high solids epoxy coatings, having excellent water barrier, chemical resistance properties, and low costs. They are typically cured with polyamides and are used as ship bottom or primer coatings for tanks, pipes, and steel pilings. However, their use has been declining or banned in certain countries because of concerns and regulations over the toxicity of coal-tar as a suspected carcinogen.

(4) *Epoxy esters* are used as primers in less demanding applications. Their performance is inferior to epoxy–amine systems but their costs are lower.

(5) *Waterborne coatings.* These are based on two-component epoxy–polyamine/polyamidoamine or epoxy–acrylic latex hybrids. One limitation of the water-borne systems is their poor cure in high humidity conditions. They have made some penetration in industrial maintenance coatings and are expected to grow more significantly in the future.

Epoxy coatings are known to have poor weatherability and often chalk when exposed to sunlight for long periods of time. Over the years, significant efforts have been dedicated to develop weatherable epoxy resin systems such as hydrogenated bisphenol A epoxy cured with siloxane-modified epoxy curing agent (225), but higher costs and compromises in curing characteristics and performance limited their commercialization. Today, most industrial structures are only coated with epoxy coatings which can last up to 10–15 years. When appearance is critical, epoxy primers are often top-coated with aliphatic isocyanate based polyurethane coatings. Marine coatings have very diverse requirements depending on the specific functions of the parts of the ship being coated. For example, ship decks are coated with antislip, abrasion- and corrosion-resistant epoxy coatings; the cargo tanks require highly chemical-resistant coatings; ship exteriors above the water line are coated with epoxy primers followed by urethane top coats for appearance; underwater ship bottoms are coated with multilayer coatings including a zinc-rich or epoxy primer, epoxy intermediate coats and antifouling top coats based on vinyls or acrylates.

Concerns over the safety of large tankers have led to regulations and construction of double-hull ships, increasing epoxy coatings consumption. While Japan was the center of the ship-building industry since the 1980s, Korea and China have emerged as major players in this market because of their low cost advantages. According to data from the Japanese Ship Building Industry Association, Korea has overtaken Japan as the global leader in ship building in the year 2000. The combined market shares of these three Asian countries now account for more than 80% of the global ship-building business. In addition, China already owns 80% of the world shipping container construction business.

The migration of ship building yards to Korea and China has led to significant increases in marine epoxy coatings consumption in that region, and has resulted in increased demands for lower temperature cure (LTC) epoxy systems. Traditional ambient-cure epoxy coatings do not cure well at temperatures below 10°C (50° F). They often require excessive cure time, affecting productivity and performance, and shorten the painting season in colder climates such as in Korea. A number of LTC epoxy coating technologies have been developed. Uses of accelerators such as tertiary amines, organic acids or alkyl-substituted phenols have allowed cures at 4.45°C (40° F) temperature range. However, shorter pot-life is a limitation of these systems. Newer epoxy coatings utilizing cycloaliphatic amines, phenalkamines as curing agents can cure at temperatures of about 30°F (0°C). For industrial protective coatings, systems developed by Ameron International (Amerlock 400) and ICI-Devoe (Bar-Rust 235) are claimed to achieve LTC down to 0°F (−18°C).

Other new technology developments in this market segment include surface-tolerant epoxy coatings for aged or marginally-prepared surfaces, interval-free

epoxy coatings to extend coating service life, mineral spirit-soluble epoxy coatings for shipping containers repairs, and styrene-free coatings to replace foul-smelling and regulated organic solvents such as toluene and xylene in coatings for new shipping containers.

Metal Container and Coil Coatings. Metal container and coil coatings represent a major outlet for epoxy resins considering there are more than 100 billion beverage cans and 30 billion food cans produced annually in the United States. Globally, the metal can market is estimated at over 300 billion cans. While the majority of metal containers coated with epoxy coatings are aluminum and steel food and beverage cans, coatings for drums, pails, and aerosol spray cans are included in this market segment. Coil coating is a highly efficient, automated coating process used to produce precoated metal coils, which are subsequently stamped and fabricated to parts. The majority of epoxy coil coatings are used to produce metal can ends and can bodies with smaller amounts going to building products, appliance panels, transportation, and metal furniture applications.

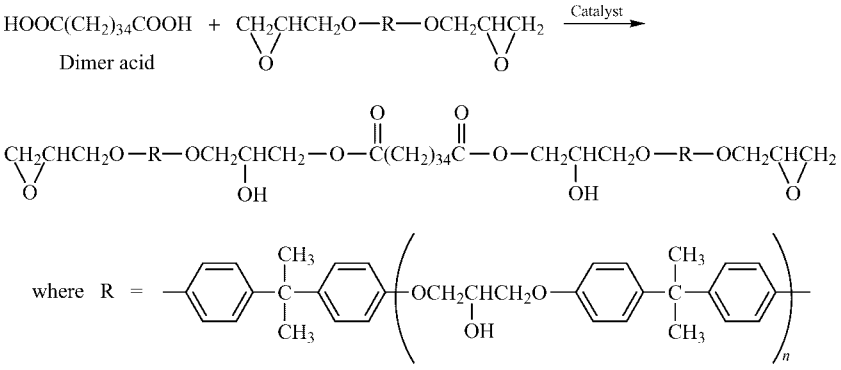
Higher molecular weight SERs (EEW = 2000–4000), which contain predominantly secondary hydroxyl groups, are used in these coatings where maximum resistance, to chemicals, good flexibility, freedom from taste, good thermal stability, blush (hydrolysis) resistance, and the ability to hold corrosive foods and beverages are needed. In addition, compliance with food regulations such as the Food and Drugs Administration (FDA) rules is required for food and beverage interior can coatings. This application is where the unique combination of properties of epoxy resins stand out.

The can and coil coatings, generally, are cross-linked with phenol, melamine, or urea–formaldehyde condensation products at elevated temperatures (150–200°C) with acid catalysts. Normal epoxy–amino resin weight ratios are epoxy–urea, 70:30; epoxy–benzoguanamine, 70:30; epoxy–melamine, 80:20, and 90:10. Increasing cross-linker levels give improved thermal and chemical resistance at the sacrifice of coating flexibility and adhesion.

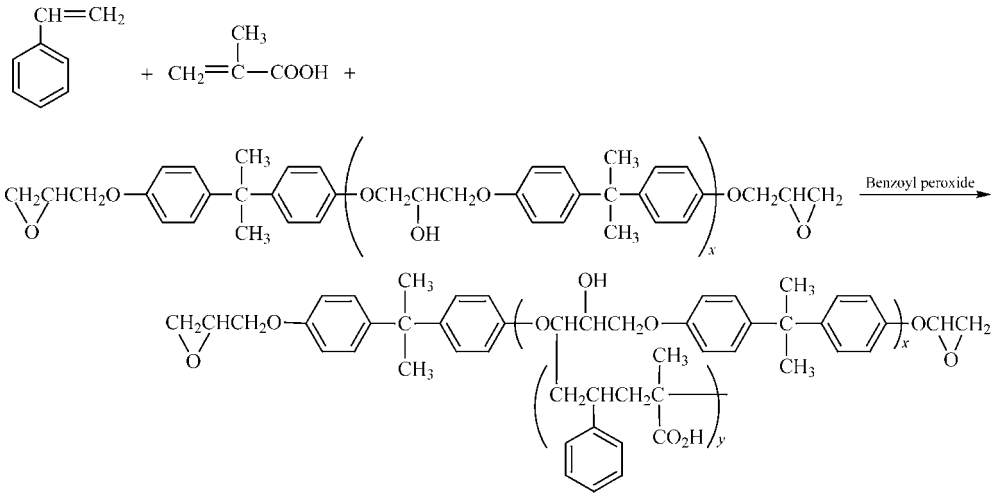
Phenol–formaldehyde resole cured epoxies have excellent chemical resistance and hardness and are the popular choices for drum coatings. Their golden color is affecting their uses in food can coatings because of the increasing popularity of the water-white coatings based on melamine–formaldehyde resins, which are perceived to be "cleaner" by the consumers and the food industry. Melamine–formaldehyde resins are the primary cross-linker for beer and beverage interior can coatings. Urea–formaldehyde resins can be cured at lower temperatures and faster speed than phenol and melamine–formaldehyde resins and are widely used in the coil coatings industry where cure schedules are extremely short. However, their use has been declining because of concerns over the release of formaldehyde fumes. Recently, there have been regulatory issues in the can industry concerning worker exposure to volatile formaldehyde emission from the formaldehyde resins. A number of new, formaldehyde-free coating formulations have been introduced by coating suppliers (226).

High solids binders for metal can coatings have been developed on the basis of dimer acid modification of epoxy resins, whereby a flexible C_{34} difunctional acid is used to esterify a conventional diepoxide resin (227). The resultant epoxy ester possesses a sufficiently lower viscosity to provide binders with solids contents >70

vol%. Curing is accomplished by a melamine–formaldehyde resin (Cymel 303, from Cytec) in conjunction with phosphoric acid catalyst.



In the 1970s, a waterborne coating system for aluminum beverage can coatings was developed by the Glidden Company (ICI Packaging Coatings) on the basis of a graft copolymerization of an advanced epoxy resin and acrylic monomers (228,229). The acrylic–vinyl monomers are grafted onto preformed epoxy resins in the presence of a free-radical initiator; grafting occurs mainly at the methylene group of the aliphatic backbone on the epoxy resin:



The polymeric product is a mixture of methacrylic acid–styrene copolymer, SER, and graft copolymer of the unsaturated monomers onto the epoxy resin backbone. It is dispersible in water upon neutralization with an amine, and cured with an amino–formaldehyde resin. The technology revolutionized the can coatings industry in the 1970s which was primarily based on low solids, solvent-borne coatings. This waterborne epoxy coating system and its variations continue to be the dominant choices for interior beer and beverage can coatings globally today.

They are also formulated with phenol–formaldehyde resole and used as interior coatings in the new two-piece food can plants in the United States.

UV-curable coatings based on cycloaliphatic epoxies are used on the exterior of some beer, beverage, and food cans, as well as food and composite can ends. The technology is environmentally friendly and energy-efficient.

Coil coatings have been gaining in the appliance market. More OEMs have turned to precoated metal coils as an efficient manufacturing alternative to produce appliance panels, eliminating the needs for post-formed coating processes. PVC organosol (copolymers of vinyl chloride and vinyl acetate) coatings for coil-coated can ends and bodies have been under environmental pressures and epoxy has been gaining as PVC coatings are replaced (230).

The growth of can coatings has been steady globally because of the expansion of new can plants in Asia-Pacific and South America in the 1980s and early 1990s, which made up for the stagnant growth of the U.S. market. However, growth of plastic bottles based on PET [poly(ethylene terphthalate)] has recently eroded the metal can position in beverage packaging, affecting epoxy can coatings growth. In addition, new can fabrication technologies utilizing other polymers are being developed which may challenge the dominant position of epoxy coatings in metal cans.

In the 1980s, Toyo Seikan Co. of Japan successfully developed and commercialized TULC (Toyo Ultimate Laminate Cans), a revolutionary technology in which cans are fabricated using a deep draw process from metal coils laminated with thermoplastic polyester films (231,232). No epoxy coating is used in this technology. Special polyester film combinations were used (in a much higher thickness than typical epoxy coatings) to facilitate the demanding deep draw process while maintaining all of the other requirements of can coatings. This technology is a significant breakthrough with claimed benefits such as no solvent emission, lower energy and water usage, and excellent quality cans. The costs however are significantly higher than those of conventional cans, and the technology has found widespread application only in Japan where higher packaging costs are acceptable. Other companies such as British Steel have been actively promoting laminated cans as a way to produce differentiable packaging like shaped cans with very limited success. Higher cost is the biggest barrier to their broad commercialization. Recent developments include attempts to fabricate can ends and bodies from extrusion-coated metals by companies such as Alcoa. Thermoplastics like modified polyesters are providing challenges to epoxies in these new technologies due to their excellent formability. However, their resistance against aggressive drinks, foods, and retort are inferior to those of epoxies.

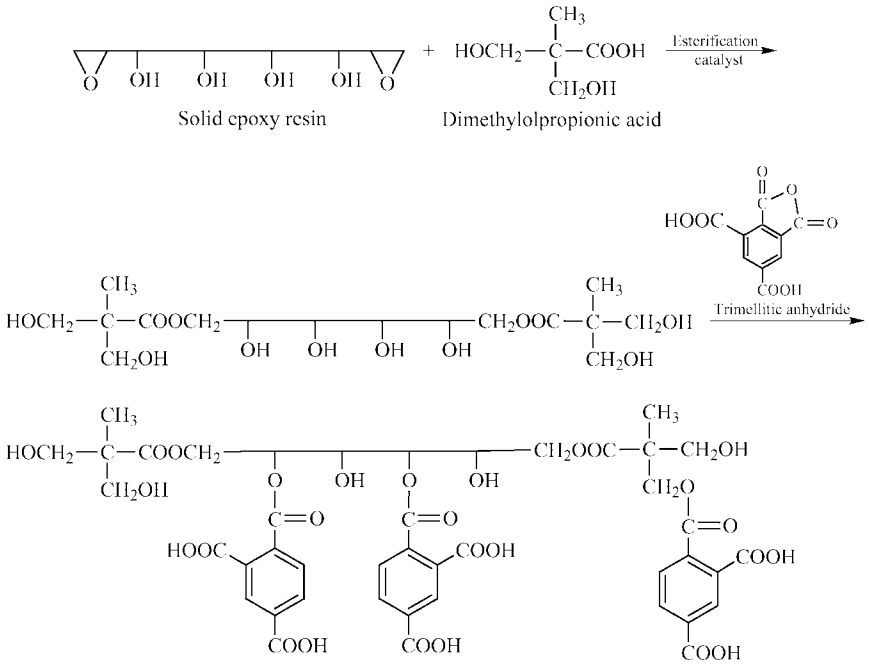
More recently in the United States, Campbell Soup Co. has successfully launched a new line of microwaveable, ready-to-eat plastic cans. These cans are constructed from a molded thermoplastic can body (polypropylene, high density polyethylene) and an easy-open-end (EOE) of coated metal. In addition, flexible pouches have made inroad as an alternative for metal cans in certain markets such as packaged tuna fish.

Recently, there have been debates in the can coatings industry concerning the potential health effects of residual bisphenol A and DGEBA in epoxy can coatings. The resin suppliers, can coatings producers, and can makers have jointly formed an industry group to coordinate a number of studies on this issue. Results

indicated that epoxy can coatings, when properly formulated and cured, are safe and in compliance with global food contact regulations. Current regulatory guidelines such as the Specific Migration Levels for Europe set extractable limits of 1 mg/kg for DGEBA and 3 mg/kg for bisphenol A. Additional information is available in the references (233,234). Some polyester coatings have been developed as epoxy coating alternatives, but high costs and inferior pasteurization-resistance limit their uses (235).

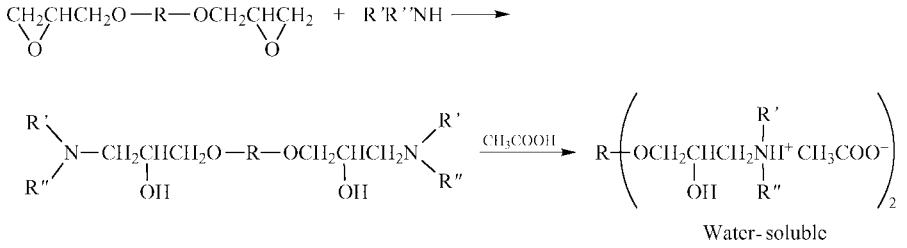
Automotive Coatings. Automotive coatings are another major application for epoxy resins. The excellent adhesion and corrosion resistance properties of epoxies make them the overwhelming choice for automotive primers. One new, growing application is the use of epoxy–polyester or acrylic–GMA powders in primer-surfacer coatings. In addition, glycidyl methacrylate (GMA) is used as a comonomer in etch-resistant liquid top coats containing acrylic acid/anhydride (236) and in GMA-acrylic powder coatings for clear coats and automotive parts (220). Epoxy powder coatings for automobiles are expected to grow significantly in the near future.

Electrodeposition processes using epoxy-based automotive primers were developed for anodic and cathodic systems. Anodic systems (AED) employ carboxylated epoxy resins neutralized with an amine. A typical binder is prepared by the esterification of the terminal epoxy groups of a solid resin (EEW = 500) with stoichiometric quantities of dimethylolpropionic acid to form a hydroxyl-rich resin. This intermediate is subsequently treated with a cyclic anhydride to form an acid functionalised polymer, which is then neutralized with the amine.

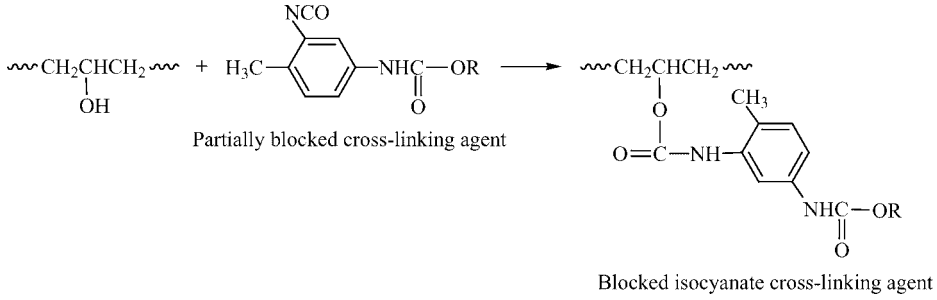


Significant advances in waterborne automotive coatings have been made by PPG Industries and others utilizing epoxies as co-resins in the 1970s. These

coatings are used in cathodic electrodeposited (CED) systems, which are widely accepted for automobile primers. Many patents have been issued for this important technology (214). Cathodic systems, which have superior corrosion resistance, have replaced anodic systems. A typical epoxy binder for cathodic electrodeposition is prepared by first forming a tertiary amine adduct from an epoxy resin and a secondary amine, followed by neutralization with an acid to form a water-soluble salt:



Cross-linking is achieved by reaction of the hydroxyl groups with a blocked isocyanate, which is stable at ambient temperature.



where R = 2-ethylhexanol

The ability of the CED coating system to thoroughly coat all metal surfaces of the car and the resultant superior corrosion resistance was a significant breakthrough, enabling its dominant position in the global automotive industry.

PPG has continued to develop new generations of improved CED epoxy coatings (237). Dupont, BASF, and a number of Japanese coating companies such as Nippon Paint and Kansai Paint have contributed to the epoxy primer coating technology by developing advanced coating systems to meet higher performance and regulatory requirements of the automotive industry (238–240). The popular pigment systems based on heavy metals such as lead and chromium in primer coatings have been recently banned in certain countries, leading to efforts to develop new formulations with improved corrosion resistance. Nippon Paint has proposed pigment-free CED systems (241).

Epoxy–polyester and acrylic–GMA powder coatings have made significant advances recently in the area of primer-surfacer coatings. They offer better adhesion to topcoats and significantly improve chip resistance compared to the traditional liquid polyester and epoxy ester coatings. This translates to warranty cost reductions, leading many car manufacturers to convert to the powder coating technologies.

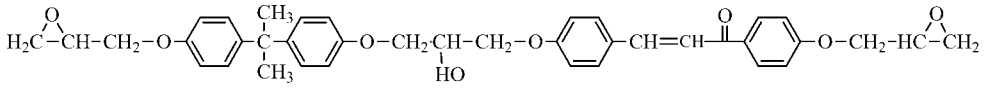
While epoxy coatings based on DGEBA and other aromatic epoxies are limited to undercoats and under-the-hood applications because of their poor UV resistance, GMA-based coatings have been developed for improved acid-etch performance automotive top coats. They compete with traditional acrylic polyol–melamine topcoats that are highly susceptible to acid rain-induced hydrolysis, and offer better mar resistance and less worker exposures than isocyanate-based topcoats (242,243). BMW has coverted to a GMA–acrylic powder clear coat developed by PPG.

Inks and Resists. Inks and resists comprise a relatively small but high value and growing market for epoxies and epoxy derivatives. In 2001, there were an estimated of 6800 MT of epoxies and epoxy derivatives used in this market to produce ink and resist formulations worth almost $400 million in the U.S. market. Epoxies are often used with other resins such as polyester acrylates and urethane acrylates in these formulations. The largest applications are lithographic and flexographic inks followed by electronic inks and resists.

Resist technology is widely used in the electronics industry to manufacture printed circuits (see Lithographic Resists). The resist (a coating or ink) is applied over a conducting substrate such as copper in a pattern to protect its surface during etching, plating, or soldering. Cure is either by radiation or heat. The uncured coating (or ink) is removed later by solvents. Solder masks perform similar functions in the manufacturing of printed circuit boards. The growth of the computer and electronics industries has fueled growth of epoxy-based inks and resists. The market is projected to grow at 10% annually.

The primary resins used in this market are the radiation-curable epoxy acrylates, accounting for 60% of the resins used. A small amount of cycloaliphatic epoxies are also used in UV-curable inks and resists. Phenol and cresol epoxy novolacs, and bisphenol A based epoxies are used in thermally cured formulations. The epoxy novolacs are used where higher heat resistance is needed such as in solder masks. Both free-radical and cationic-curable UV inks and colored base coats have grown rapidly because of the needs for higher line speeds, faster cleanup or line turnaround, less energy consumption, less capital for a new line, and fewer emissions.

A unique epoxy (epoxy chalcone) produced by Huntsman can be used for dual cure (244):



Radiation-initiated free-radical cure is possible via the double bonds, while the epoxy groups are available for thermal cure. Epoxy chalcone is used as a photopolymerizable solder mask and in photoresists.

Structural Applications

Next to coatings, structural applications account for the second largest share of epoxy resin consumption (~40%). Epoxy resins in structural applications can be

divided into three major areas: fiber-reinforced composites and electrical laminates; casting, encapsulation, and tooling; and adhesives. Within this segment, the largest applications are electrical laminates for PCB and composites made of epoxy and epoxy vinyl ester for structural applications.

Structural Composites. Epoxy resins and epoxy vinyl ester resins are well suited as fiber-reinforcing materials because they exhibit excellent adhesion to reinforcement (qv), cure with low shrinkage, provide good dimensional stability, and possess good mechanical, electrical, thermal, chemical, fatigue, and moisture-resistance properties. Epoxy composites are formed by aligning strong, continuous fibers in an epoxy resin-curing agent matrix. Processes currently used to fabricate epoxy composites include hand lay-up, spray-up, compression molding, vacuum bag compression molding, filament winding, resin transfer molding reaction, injection molding, and pultrusion (see COMPOSITES, FABRICATION).

Important fiber materials are surface-treated glass, boron, graphite (carbon), and aromatic polyaramides (eg, DuPont's Kevlar). In most composites the reinforcement constitutes ca 65% of the final mass. Orientation of the fibers is important in establishing the properties of the laminate. Unidirectional, bidirectional, and random orientations are possible. The characteristics of the cured resin system are extremely important since it must transmit the applied stresses to each fiber. A critical region in a composite is the resin–fiber interface. The adhesive properties of epoxy resins make them especially suited for composite applications.

The most important market for epoxy composites is for corrosion-resistant equipment where epoxy vinyl esters is the dominant material of choice. Other smaller markets are automotive, aerospace, sports/recreation, construction, and marine. Because of their higher costs, epoxy and epoxy vinyl esters composites found applications where their higher mechanical strength and chemical and corrosion resistance properties are advantageous.

Epoxy Composites. Composites made with glass fibers usually have a bisphenol A based epoxy resin–diamine matrix and are used in a variety of applications including automotive leaf springs and drive shafts, where mechanical strength is a key requirement. A large and important application is for filament-wound glass-reinforced pipes used in oil fields, chemical plants, water distribution, and as electrical conduits. Low viscosity liquid systems having good mechanical properties when cured are preferred. These are usually cured with liquid anhydride or aromatic–amine hardeners. Similar systems are used for filament-winding pressure bottles and rocket motor casings. Other applications that use fiber-reinforced epoxy composites include sporting equipment, such as tennis racquet frames, fishing rods, and golf clubs, as well as industrial equipment. The wind energy field is emerging as a potential high growth area for epoxy composites, particularly in Europe where a number of new wind energy farms are planned. With windmill blades increasing in lengths (up to 50 m), the strength and fatigue properties of epoxy composites provide benefits over competitive chemistries.

In the aerospace industry, particularly in military aircraft construction, the use of graphite fiber-reinforced composites has been growing because of high strength-to-weight ratios. Some newer commercial airliners now contain up to 10% by weight of composite materials. High performance polyfunctional resins, such as the tetraglycidyl derivative of methylenedianiline in combination with

diaminodiphenylsulfone or nadic methyl anhydride, are used to provide good elevated temperature properties and humidity resistance. Handling characteristics are well suited to the autoclave molding technique primarily used in the manufacture of such components. The low viscosity and high T_g of cycloaliphatic epoxies has led to their use in certain aerospace applications. Newer resins such as diglycidyl ether of 9,9′-bis(4-hydroxyphenylfluorene) have been developed.

While the overall growth of composites in the aerospace industry is continuing, epoxy has been facing stiff competition from other materials and the growth rate has been relatively small (2% annually). While epoxies are still used in many exterior aircraft parts, carbon fiber composites based on bismaleimide and cyanate esters have shown better temperature and moisture resistance than epoxies in military aircaft applications. In the commercial aircraft arena, phenolic composites are now preferred for interior applications because of their lower heat release and smoke generation properties during fires. High performance thermoplastics, such as polysulfone, polyimides, and polyetherether ketone (PEEK), have also found some uses in aerospace composites.

Epoxy Vinyl Ester Composites. Epoxy vinyl ester composites are widely used to produce chemically resistant glass-reinforced pipes, stacks, and tanks by contact molding and filament-winding processes. Epoxy vinyl ester resins provide outstanding chemical resistance against aggressive chemicals such as aqueous acids and bases and are materials of choice for demanding applications in petrochemical plants, oil refineries, and paper mills. Epoxy vinyl ester composites are also used in demanding automotive applications such as engine and oil pan covers where high temperature performance is required. Exterior panels and truck boxes are also growth automotive applications for vinyl esters. However, in less demanding automotive applications, cheaper thermoplastics and thermosets such as unsaturated polyesters or furan resins are often used. In general, epoxy vinyl ester is considered to be a premium polyester resin with higher temperature and corrosion resistance properties at higher costs. It is used where the cheaper unsaturated polyesters cannot meet performance requirements. For the same reason, epoxy vinyl ester has not grown significantly in less demanding civil engineering applications. Other uses of epoxy vinyl ester composites include boat hulls, swimming pools, saunas, and hot tubs.

Improved versions of the high performance resin systems continue to be developed (245,246). Toughening of epoxies and epoxy vinyl esters has emerged as an area for investigation (247). Lower styrene content vinyl esters have been developed to reduce worker exposure. Performance enhancements with epoxy and vinyl ester nanocomposites have been reported in the literature, but commercialization has not been yet realized.

Mineral-Filled Composites. Epoxy mineral-filled composites are widely used to manufacture laboratory equipment such as lab bench tops, sinks, hoods, and other laboratory accessories. The excellent chemical and thermal resistance properties of epoxy thermosets make them ideal choices for this application. Typically, liquid epoxy resins of bisphenol A are cured with anhydrides such as phthalic anhydride, which provide good exotherm management and excellent thermal performance. The systems are highly filled with fillers such as silica or sand (up to 70 wt%). Multifunctional epoxy novolacs can be added when higher chemical and thermal performance is needed.

Civil Engineering, Flooring, and Construction. Civil engineering is another large application for epoxies, accounting for up to 13% of total global epoxy consumption. This application includes flooring, decorative aggregate, paving, and construction (248). Key attributes of epoxies such as ease of installation, fast ambient cure, good adhesion to many substrates, excellent chemical resistance, low shrinkage, good mechanical strength, and durability make them suitable for this market. In the United States an estimated 20,000 MT of resins were used for flooring applications in 2000. The building boom in China has provided significant growth for this market during the past decade. Epoxy flooring compounds are expected to grow well as the construction industry becomes more aware of their benefits.

Epoxy resins are used for both functional and decorative purposes in monolithic flooring and in factory-produced building panel applications. Products include floor paints, self-leveling floors, trowelable floors, and pebble-finished floors. Epoxy floorings provide wear-resistant and chemical-resistant surfaces for dairies and food processing and chemical plants where acids normally attack concrete. Epoxies are also used in flooring for walk-in freezers, coolers, kitchens, and restaurants because of good thermal properties, slip resistance, and ease of cleanup. In commercial building applications, such as offices and lobbies, terrazzo-like surfaces can be applied in thin layers. Continuous seamless epoxy floors are competitive with ceramic tiles. They are usually applied by trowel over a prepared subfloor. Semiconductive epoxy/carbon black floorings are used in electronics manufacturing plants because of their ability to dissipate electrical charges. Decorative slip-resistant coatings are available for outdoor stair treads, balconies, patios, walkways, and swimming-pool decks. Epoxy aggregates are highly filled systems, containing up to 90% of stones or minerals. They are used for decorative walls, floors, and decks.

Usually, two-component systems consisting of liquid epoxy resin, diluents, fillers (eg, sands, stones, aggregates), pigments, thickening agents, and polyamine or polyamide curing agents are employed. Cycloaliphatic amines and their adducts are used when either better low temperature cure or adhesion to wet concrete is desired. The other components of the flooring formulation are as critical as the resin and hardener. Typical filler and pigment levels are 10% for paving, 30% for flooring, and 40% or higher for decorative aggregates. Self-leveling floors consist of resin-hardener mixtures with low filler content or unfilled compositions with high gloss. In epoxy terrazzo floors, an epoxy binder replaces the cement matrix in a marble aggregate flooring, providing impact resistance, mechanical strength, and adhesion.

Epoxy systems for roads, tunnels and bridges are effective barriers to moisture, chemicals, oils, and grease. They are used in new construction as well as in repair and maintenance applications. Typical formulations consist of liquid epoxy resins extended with coal tar and diethylenetriamine curing agent. Epoxy resins are widely used in bridge expansion joints and to repair concrete cracks in adhesive and grouting (injectable mortar) systems. Epoxy pavings are used to cover concrete bridge decks and parking structures. Formulations of epoxy resins and polysulfide polymers in conjunction with polyamine curing agents are used for bonding concrete to concrete. After cleaning the old surface, the epoxy

adhesive is applied and good adhesion between the old and the new concrete is obtained.

Recent developments in the construction and civil engineering industry include the development of "intelligent concrete" with self-healing capability in Japan (249). Some of the systems are based on epoxy resins encapsulated in concrete which when triggered by cracks open and cure to repair the concrete.

Electrical Laminates. Printed wiring boards (PWB) or printed circuit boards (PCB) are used in all types of electronic equipment. In noncritical applications such as inexpensive consumer electronics, these components are made from paper-reinforced phenolic, melamine, or polyester resins. For more critical applications such as high end consumer electronics, computers, complex telecommunication equipment, etc, higher performance materials are required and epoxy resin based glass fiber laminates fulfill the requirements at reasonable costs. This application constitutes the single largest volume of epoxies used in structural composites. In 2000, an estimated 200,000 MT of epoxy resins were used globally to manufacture PCB laminates.

Systems are available that meet the National Electrical Manufacturers Association (NEMA) G10, G11, FR3, FR4, FR5, CEM-1, and CEM-3 specifications. Both low viscosity liquid (EEW = 180–200) and high melting solid (EEW = 450–500) epoxy resins are used in printed circuit prepreg manufacture. Currently, the most widely used boards (>85%) are manufactured to the flame-retardant FR4 specification using epoxy thermosets. Flame retardance is achieved by advancing the liquid DGEBA epoxy resin with tetrabromobisphenol A (TBBA). This relatively low cost resin which contains about 20 wt% bromine is the workhorse of the PCB industry. Epoxy resins based on diglycidyl ether of TBBA are also available, which allow the preparation of resins with even higher bromine content, up to 50 wt%. Multifunctional epoxy resins such as epoxy novolacs based on phenol, bisphenol A, and cresol novolacs or the tetraglycidyl ether of tetrakis(4-hydroxyphenyl)ethane are used as modifiers to increase the glass-transition temperature ($T_g > 150^\circ C$), thermal decomposition temperature (T_d), and chemical resistance.

The most commonly used curing agent for PWBs is dicyandiamide (DICY) catalyzed with imidazoles such as 2-methylimidazole (2-MI), followed by phenolic novolacs and anhydrides.

The epoxy–DICY systems offer the following advantages:

(1) Cost effectiveness (DICY is a low equivalent weight, multifunctional curing agent)
(2) Stable formulations
(3) Excellent adhesion to copper and glass
(4) Good moisture and solder resistance
(5) Good processability

The primary disadvantage of the standard epoxy–DICY systems is their relatively low thermal performance ($T_g < 140^\circ C$, $T_d = 300^\circ C$), which limits their uses in more demanding applications such as the FR-5 boards and other high density circuit boards. Specialty epoxy–DICY systems are available with T_g approaching

190°C but at higher costs. Alternatively, high temperature epoxy systems are obtained using diaminodiphenyl sulfone (DDS) as curing agent and boron trifluoride monoethylamine (BF_3/MEA) complex, benzyldimethylamine (BDMA), or various imidazoles as catalysts. However, concerns over the toxicity of DDS have led to significant decrease of its use. More recently, higher thermally resistant laminates using novolac curing agents, including bisphenol A based novolacs, have become popular in the industry. However, brittleness is a significant disadvantage of these systems.

Prepreg is commonly prepared by passing the glass cloth through a formulated resin bath followed by heat treatment in a tower to evaporate the solvent and partially cure the resin to an intermediate or B stage. Prepreg sheets are stacked with outer layers of copper foil followed by exposure to heat and high pressure in a laminating press. This structure is cured (C-staged) at high temperature (150–180°C) and pressure for 30–90 min. Attempts to develop continuous prepreg and laminating processes have only achieved limited commercialization. Laminate boards may be single-sided (circuitry printed on only one side), double-sided, or multilayered (3 to 50 layers) for high density circuitry boards. Electrical connections for mounted components are obtained via drilled holes which are plated with copper.

The 1990s witnessed the explosive growth of the personal computer, consumer electronics, and wireless telecommunication industries, resulting in significant demands for PWB based on epoxy resins. The PWB industry trends toward device miniaturization, multilayer laminates, high density circuitries, lead-free solder, and faster signal transmission speeds have resulted in increased performance requirements. For example, lead-free legislation which bans electronics containing lead in the European Union became law in 2003 with an implementation date of 2006. This legislation is expected to speed up the phase-out of lead-based solders globally, forcing the industry to use alternatives such as tin alloys which have much higher soldering temperatures, and thereby drives the need for epoxy systems with higher thermal performance.

The end-use industries' demands for PCB boards with better heat resistance (250,251), higher glass-transition temperature (T_g), higher thermal decomposition temperatures (T_d), lower water absorption, lower coefficient of thermal expansion (CTE), and better electrical properties (dielectric constant D_k and dissipation factor D_f) have led to the development of new, high performance epoxies and cross-linker systems (252). Toughness is also becoming an issue as electrical connection holes are drilled in the highly cross-linked, high T_g laminates.

Since reinforcing materials make up from 40 to 60 wt% of the PCB laminates, their contributions to the laminate dielectric properties are significant. The standard reinforcing glass–cloth compositions in electrical laminates are designated E (electrical) glass. Woven E glass is most commonly used, but other reinforcing materials such as nonwoven glass mat, aramid fiber, S-2 glass, and quartz are available. In recent years, the PCB industry has been evaluating materials with better dielectric properties, but they are much more expensive than standard E glass (Table 25).

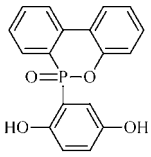
In recent years, environmental concerns over toxic smoke generation during fire and end-of-life incineration of electronic equipment containing brominated

Table 25. Reinforcing Material Comparison[a]

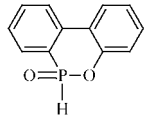
Reinforcing material	D_k (at 1MHz)	D_f (at 1MHz)	Relative cost
E glass	6.5	0.003	1
S-2 glass	5.3	0.002	4
D glass	3.8	0.0005	10
Quartz	3.8	0.0002	30
Aramid	3.8	0.012	10

[a]From Ref. 253.

products, particularly in Europe and Japan, have driven development efforts on halogen-free resins. This has resulted in a number of alternative products such as phosphorous additives and phosphor-containing epoxies (254–256). Some examples of these phosphorous compounds are as follows:



9,10-Dihydro-9-oxa-10-phosphathenanthrene-10-oxide



6*H*-dibenz(*C*,*H*)(1,2)oxaphosphorin,6-oxide

However, commercialization of phosphor-containing epoxies has been limited because of higher costs and other disadvantages such as poorer moisture resistance and lower thermal performance. In addition, concerns over phosphine gas emission during fires and potential leakage of phosphorous compounds in landfills have raised questions about their long-term viability. Alternatively, the industry has been researching new epoxy resins based on nitrogen, silicon, sulfur-containing compounds, and new phenolic resins as potential halogen-free, phosphor-free replacements. Inorganic fillers such as alumina trihydrate, magnesium hydroxide, and zinc borate have also been evaluated as flame-retardant alternatives in epoxy systems.

While brominated epoxy resin remains the workhorse of the PCB industry (FR-4 boards) because of its good combination of properties and cost, it is facing competition from other thermoset and thermoplastic materials as industry performance requirements increase. Thermosets with higher temperature performance ($>180^\circ$C T_g) and lower dielectric properties include polyimides, cyanate esters, and bismaleimide–triazine (BT) resins. They are used alone or as blends with epoxies in high performance chip-packaging boards and military applications. GE's GETEK system is an interpenetrating network of polyphenylene oxide (PPO) in epoxy and has lower dielectric constant than standard epoxies. Polytetrafluoroethylene (PTFE) has a very low dielectric constant (Table 26) and is

Table 26. Base Resin Systems Used in PCB Laminates

Resin system	T_g, °C	D_k (at 1MHz)	D_f (at 1MHz)	Estimated relative resin cost	Laminate cost
Standard Epoxies	135–140	4.6–4.8	0.015–0.020	1	1
High performance Epoxy	170–180	4.6–4.8	0.015–0.020	1.5–2	1.5
PPO/Epoxy	175–185	3.6–4.2	0.009–0.015	4–6	2–3
BT/Epoxy	170–220	3.9–4.2	0.008–0.013	8–15	2–5
Polyimide	260	3.9–4.4	0.012–0.014	5–16	3–6

used primarily in high performance PCBs for military and high frequency (eg, radars) applications. While these alternative materials offer certain performance advantages over standard epoxies, they are generally more expensive and more difficult to process. Thermosets such as polyimides, cyanate ester, and BT resins are very brittle and have higher water absorption than epoxies. PTFE has very poor adhesion to substrates, requiring special treatments. Consequently, they are limited to niche, high performance applications (250).

In flexible printed circuits, polyimide and polyester films are the preferred choices over epoxies. Molded interconnects based on heat-resistant thermoplastics such as polyether sulfone, polyether imide, and polyarylate have been developed to replace epoxy-based PCBs in certain applications. However, their uses are limited to special applications.

There has been a significant migration of the PCB laminate manufacturing capacity to Asia (mainly Taiwan and China) in the late 1990s. In 2001, 70% of epoxy resins used in PCB laminates was consumed in the region and the trend is expected to continue in the near future.

Other Electrical and Electronic Applications.

Casting, Potting, and Encapsulation. Since the mid-1950s, electrical-equipment manufacturers have taken advantage of the good electrical properties of epoxy and the design freedom afforded by casting techniques to produce switchgear components, transformers, insulators, high voltage cable accessories, and similar devices.

In casting, a resin-curing agent system is charged into a specially designed mold containing the electrical component to be insulated. After cure, the insulated part retains the shape of the mold. In encapsulation, a mounted electronic component such as a transistor or semiconductor in a mold is encased in an epoxy resin based system. Coil windings, laminates, lead wires, etc, are impregnated with the epoxy system. Potting is the same procedure as encapsulation except that the mold is a part of the finished unit. When a component is simply dropped into a

resin-curing agent system and cured without a mold, the process is referred to as *dipping*. It provides little or no impregnation and is used mainly for protective coatings.

The choice of epoxy resin, curing agent, fillers, and other ancillary materials depends on factors such as cost, processing conditions, and the environment to which the insulated electrical or electronic component will be exposed.

The type and amount of filler that can be incorporated into the system are very important and depend on the viscosity of the resin at the processing temperature. Filler loading reduces costs, increases pot life, improves heat dissipation, lowers exotherms, increases thermal shock resistance, reduces shrinkage, and improves dimensional stability.

The exotherm generated during the resin cure must be controlled to prevent damage to the electrical or electronic component. The exotherm is easily controlled during the production of small castings, pottings, and encapsulations. In the production of large castings, the excess heat of reaction must be dissipated in order to prevent locked-in thermal stresses. During the 1970s, the pressure gelation casting process was developed (257); this method provides better temperature control and reduces cycle times. The heat generated by polymerization is used to heat the resin mass and is not dissipated in the mold.

Both DGEBA and cycloaliphatic epoxy resins are used in casting systems. Most systems are based on DGEBA resins cured with anhydride hardeners and contain 60–65 wt% inert fillers. The cycloaliphatic resin systems exhibit good tracking properties and better UV resistance than DGEBA resins, the latter of which causes crazing (qv) and surface breakdown. An electrical current is more likely to form a carbonized track in aromatic-based resins than in nonaromatic ones. Their lower viscosity also facilitates device impregnation. The cycloaliphatic epoxies are often used as modifiers for DGEBA resin systems. This application represents a significant outlet for cycloaliphatic epoxies.

Amine curing agents are used in small castings, and anhydrides are used in large castings. Anhydrides are less reactive and have lower exotherms than amines. In addition, their viscosity and shrinkage are low and pot lives are longer.

Transfer Molding. Epoxy molding compounds (EMC) are solid mixtures of epoxy resin, curing agent(s) and catalyst, mold-release compounds, fillers, and other additives. These systems can be formulated by dry mixing or by melt mixing and are relatively stable when stored below room temperature. Molding compounds become fluid at relatively low temperatures (150–200°C) and can be molded at relatively low pressures (3.5–7.0 MPa) by compression, transfer, or injection molding. Advantages of molding over casting are elimination of the mixing step immediately before use, improved handling and measuring procedures, and suitability for high production quantities. A typical standard EMC formulatio gn contains approximately 30% epoxies, 60% filler, and 10% of curing agents and other additives such as release agent.

An important application of epoxy molding compounds is the encapsulation of electronic components such as semiconductor chips, passive devices, and integrated circuits by transfer molding. Transfer molding is a highly automated, efficient method of encapsulation. High purity phenol and cresol epoxy novolacs and phenol and cresol novolacs and/or anhydride curing agents are used most often in semiconductor applications. For passive device encapsulation, standard

epoxy novolacs can be used as blends with bisphenol A based solid resins. The ECN or EPN molding powders can be processed at relatively low pressures and provide insulation for the electronic components. Ionic impurities, ie, NaCl or KCl, must be kept to a minimum, since trace quantities can cause corrosion and device failure. In addition, residual stress and thermal and mechanical shock resistances are issues that must be managed properly (258).

Efforts have been made to improve the high temperature performance of these systems by replacing the epoxy novolacs with other multifunctional epoxy resins. Hydrocarbon based epoxy novolacs (HEN) were developed to improve the moisture resistance of molding compounds. Crystalline epoxy resins derived from biphenol and dihydroxy naphthalenes were developed for high end semiconductor encapsulants using Surface Mount Technology (SMT). The emergence of SMT as a key semiconductor manufacturing technology requires epoxy molding compounds with a high filler loading capacity (up to 90 wt%) to enhance solder crack resistance. SMT uses new solder alloys to attach components to the PCB board at high temperatures (215–260°C). Solder reflow, delamination, and package cracks are problems often encountered with conventional molding compounds based on cresol epoxy novolacs. The high filler content helps lower costs, reduces moisture absorption, and decreases the thermal expansion coefficient of the system. Crystalline products with very low melt viscosity such as biphenyl epoxies facilitate the processing of the high silica filler formulations while maintaining other critical requirements: moisture resistance and electrical, thermal, and mechanical properties (61). The majority of high purity epoxies used in epoxy molding compounds (EMC) for semiconductor encapsulations are supplied by Japanese producers and a few Asian companies.

Adhesives. Epoxy-based adhesives provide powerful bonds between similar and dissimilar materials such as metals, glass, ceramics, wood, cloth, and many types of plastics. In addition, epoxies offer low shrinkage, low creep, high performance over a wide range of usage temperatures and no by-products (such as water) release during cure. The epoxy adhesives were originally developed for use in metal bonding in the aircraft industry (259,260). In aircraft wing assemblies, high strength epoxy adhesives are used in place of metal fasteners to avoid corrosion problems inherent with metal fasteners, to reduce weight, and to eliminate "point" distribution by spreading the load over a large area. Today, epoxy is the most versatile engineering/structural adhesive, widely used in many industries including aerospace, electrical/electronic, automotive, construction, transportation, dental, and consumer. The market is of high value, consuming 25,000 MT of epoxies in North America in 2001 worth almost $500 million.

The broad range of epoxy resins and curing agents on the market allows a wide selection of system components to satisfy a particular application. Although the majority of epoxy adhesives are two-pack systems, heat activated one-pack adhesives are also available. Low molecular weight DGEBA liquid resins are the most commonly used. Higher molecular weight (EEW = 250–500) DGEBA epoxy resins improve adhesive strength because of the increased number of hydroxyl groups in the resin backbone. For applications requiring high temperature or improved chemical performance, the multifunctional epoxy phenol novolac and triglycidyl-*p*-aminophenol resins are employed. More recent products include vinyl epoxies. Adhesive systems modified with reactive diluents facilitate wetting of the

Table 27. Epoxy Adhesive Lap-Shear Strengths

Hardener	Lap-shear strength,[a] MPa[b]

substrate, allowing more filler to be added and modifying handling characteristics; however, adhesive strength is reduced. Toughened epoxy adhesives are available.

Polyamines or polyamides are the curing agents for ambient, or slightly elevated, temperature cures, and aromatic polyamines or anhydride hardeners are used for hot cures. These systems provide exceptional bonding strength but slower cure time. Boron trifluoride amine complexes and dicyandiamide are used in one-component adhesives. Polythiols (polysulfides, polymercaptans) are the fast-curing hardeners in "5-min" consumer epoxy formulations. The lap-shear strengths of a DGEBA epoxy cured with different hardeners are given in Table 27.

Cationically cured UV laminating adhesives based on cycloaliphatic epoxies are emerging as an alternative to solvent-based adhesives. The "dark cure" of cationics allows UV exposure and post lamination in line. This process does not require UV exposure "through" the plastic barrier material.

Epoxy adhesives are expected to grow at GDP (3–4%) over the next decade. Increased usage in the automotive and recreational markets, and replacement of mechanical fasteners help offset the slowdown in the aerospace industry (see also Adhesive Compositions).

Tooling. Tools made with epoxy are used for producing prototypes, master models, molds and other parts for aerospace, automotive, foundry, boat building, and various industrial molded items (261). Epoxy tools are less expensive than metal ones and can be modified quickly and cheaply. Epoxy resins are preferred over unsaturated polyesters and other free-radical cured resins because of lower shrinkage, greater interlaminar bond strength and superior dimensional stability.

Most epoxy-based tooling formulations are based on liquid DGEBA resins. Aliphatic polyamines, amidoamines, or modified cycloaliphatic amines are used for ambient temperature cure, and modified aromatic diamines and anhydrides are used for high temperature cure. When high heat resistance is required ($>350^{\circ}$F), epoxy novolac resins can be employed. Reactive diluents such as aliphatic glycidyl ethers are often employed to permit higher filler load or to reduce the system viscosity for proper application. Fillers, reinforcing fibers, toughening agents, thixotropic agents, and other additives are often used depending on the desired application and final properties.

Tooling production uses four major processing methods: lamination, surface cast, splining, and casting. Lamination is made by alternating layers of glass cloth or fabric and formulated resin, usually on a framework of metal or plastic. Surface cast utilizes a filled resin compound that is applied onto the surface of a mold,

which is later filled with a core material that adheres to the casting compound. Splining employs heavily filled formulations that are directly applied to a surface and manually molded or leveled to the desired shape, before or after curing, with the help of proper tools. Lastly, casting compounds are filled formulations that are directly poured or compressed into a mold coated with a release agent.

Health and Safety Factors

There have been many investigations of the toxicity of various classes of epoxy-containing materials (glycidyloxy compounds). The use and interpretation of the vast amount of data available has been obscured by two factors: (*1*) proper identification of the epoxy systems in question and (*2*) lack of meaningful classification of the epoxy materials. In general, the toxicity of many of the glycidyloxy derivatives is low, but the diversity of compounds found within this group does not permit broad generalizations for the class. Information on toxicity and safe handling of epoxy compounds are summarized in References 262,263, and 264.

Diglycidyl ether of bisphenol A. Bisphenol A based epoxies are the most commonly used resins. Although unmodified bisphenol A epoxy resins have a very low order of acute toxicity, they should be handled carefully and personal contact should be avoided. Prolonged or repeated skin contact with liquid epoxy resins may lead to skin irritation or sensitization. Susceptibility to skin irritation and sensitization varies from person to person. Skin sensitization decreases with an increase in MW, but the presence of low MW fractions in the advanced resins may present a hazard to skin sensitization. Inhalation toxicity does not present a hazard because of low vapor pressure. DGEBA-based resins have been reported to cause minimal eye irritation. Toxicological studies support the conclusion that bisphenol A based epoxy resins do not present a carcinogenic or mutagenic hazard. Because of the solvents used, solution of epoxy resins are more hazardous to handle than solid resins alone. Depending on the solvents used, such solutions may cause irritation to the skin and eyes, are more likely to cause sensitization responses, and are hazardous if inhaled.

Epoxy phenol novolac resins. Acute oral studies indicate low toxicity for these resins. Eye studies indicate only minor irritation in animals. The EPN resins have shown weak skin sensitizing potential in humans.

Low MW epoxy diluents, particularly the aromatic monoepoxides such as phenyl glycidyl ether (PGE) are known to have high toxicity and should be handled with care. They are capable of causing skin and eye irritation and sensitization responses in people. They may also present a significant hazard from inhalation.

Curing agents. In general, amine curing agents are much more hazardous to handle than the epoxy resins, particularly at elevated temperatures. Aliphatic amines and anhydrides are capable of serious skin or eye irritation, sensitization, and even burns. Other curing agents possess consideration

variation in the degree of health hazards because of the variety of their chemical structures and it is impossible to generalize.

All suppliers provide material safety data sheets (MSDS), which contain the most recent toxicity data. These are the best sources of information and should be consulted before handling the materials.

Acknowledgments

The authors would like to acknowledge the contributions of Robert F. Eaton of the Dow Chemical Co. in Bound Brook, N.J., who contributed to the sections on cycloaliphatic epoxies and epoxidized vegetable oils and the cationic curing mechanism. We also would like to thank Timothy Takas of Reichhold who kindly reviewed the article. We are indebted to many colleagues in the Epoxy Products and Intermediates business at Dow Chemical for their assistance in many ways to make this article possible.

ETHYLENE COPOLYMERS. See Volume 6.

ETHYLENE OXIDE POLYMERS

Introduction

Poly(ethylene oxide) [25322-68-3] (PEO) is a water-soluble, thermoplastic polymer produced by the heterogeneous polymerization of ethylene oxide. The white, free-flowing resins are characterized by the following structural formula:

$$-(CH_2CH_2O)_n-$$

The resins are available in a broad range of molecular weight grades, from as low as 100,000 to over 7×10^6. Although most commonly known as poly(ethylene oxide) resins, they are occasionally referred to as poly(ethylene glycol) or poly-oxyethylene resins. The CAS Registry Number of these resins is also used for low molecular weight oligomers of ethylene oxide, eg, tetraethylene glycol.

Physical Properties

Crystallinity. At molecular weights of 105–107, poly(ethylene oxide) forms a highly ordered structure. This has been confirmed by NMR and X-ray diffraction patterns and by the sharpness of the crystalline melting point (62–67°C). However, the highest degree of crystallinity (ca 95%) is obtained at a molecular weight of 6000. The polymer chain contains seven structural units per fiber identity period (1.93 nm) (1). The diffraction pattern of the monoclinic unit cell of poly(ethylene oxide) contains four molecular chains, in which $a = 0.796$ nm, $b = 1.311$ nm, $c = 1.939$ nm, and $\beta = 124°48'$. Infrared studies show that the oxygen atoms of the crystalline polymer are in the gauche configuration. Because of this arrangement, the intermolecular dipole forces are oriented along the axis of the helix and ca 15 monomer units are involved within a single repeat unit. The heat of fusion of the polymer is 8.3 kJ (1980 cal) per structural unit (2). The high molecular weight poly(ethylene oxide) resins are of the spherulitic structure (3). Proper annealing of a melt-cast film produces a distinct lamellar structure. The molecular conformation of poly(ethylene oxide), as determined by the use of X-ray diffraction, IR, and Raman spectroscopic methods, is shown in Figure 1.

Density. Although the polymer unit cell dimensions imply a calculated density of 1.33 g/cm^3 at 20°C, and extrapolation of melt density data indicates a density of 1.13 g/cm^3 at 20°C for the amorphous phase, the density actually measured is 1.15–1.26 g/cm^3, which indicates the presence of numerous voids in the structure.

Glass-Transition Temperature. The glass transition (qv) temperature, T_g, of poly(ethylene oxide) has been measured over the molecular weight range of 10^2–10^7 (4,5). The T_g–molecular weight relationship is shown in Figure 2. These data indicate a rapid rise in the transition temperature to a maximum of −17°C for a molecular weight of 6000. The highest percentage of crystalline character

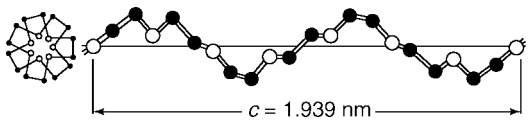

Fig. 1. Molecular conformation of poly(ethylene oxide).

develops at that molecular weight, and it is at that point that T_g is the highest. Beyond this point, chain entanglement reduces crystallinity.

Solubility. Poly(ethylene oxide) is completely soluble in water at room temperature. However, at elevated temperatures (>98°C) the solubility decreases. It is also soluble in several organic solvents, particularly chlorinated hydrocarbons. Aromatic hydrocarbons are better solvents for poly(ethylene oxide) at elevated temperatures. Solubility characteristics are listed in Table 1.

Aqueous poly(ethylene oxide) solutions of higher molecular weight (ca 10^6) become stringy at polymer concentrations less than 1 wt%. At concentrations of 20 wt%, solutions become nontacky elastic gels; above this concentration, the solutions appear to be hard, tough, water-plasticized polymers.

Concentration and Molecular Weight Effects. The viscosity of aqueous solutions of poly(ethylene oxide) depends on the concentration of the polymer solute, the molecular weight, the solution temperature, the concentration of dissolved inorganic salts, and the shear rate. Viscosity increases with concentration and this dependence becomes more pronounced with increasing molecular weight. This

combined effect is shown in Figure 3, in which solution viscosity is presented as a function of concentration for various molecular weight polymers.

The dependence of the intrinsic viscosity $[\eta]$ on molecular weight M for these polymers can be expressed by the Mark-Houwink relationship:

$$[\eta] = KM^a$$

The constants K and a for high molecular weight poly(ethylene oxide) in several solvents at various temperatures are summarized in Table 2.

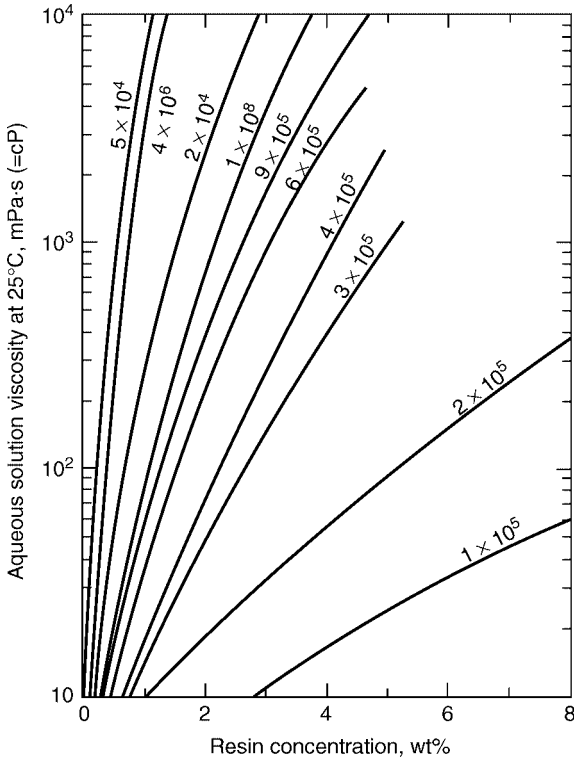

Fig. 3. Solution viscosity vs concentration for ethylene oxide polymers (7). The molecular weight of the polymer is indicated on each curve.

Temperature Effect. Near the boiling point of water, the solubility–temperature relationship undergoes an abrupt inversion. Over a narrow temperature range, solutions become cloudy and the polymer precipitates; the polymer cannot dissolve in water above this precipitation temperature. In Figure 4, this limit or cloud point is shown as a function of polymer concentration for poly(ethylene oxide) of 2×10^6 molecular weight.

The viscosity of the aqueous solution is also significantly affected by temperature. In polymers of molecular weights $(1–50) \times 10^5$ the solution viscosity

Table 2. Mark–Houwink Constants for Poly(ethylene oxide)

Solvent	Temperature, °C	$K \times 10^5$	a	Approx. M	Ref.
Water	25	11.92	0.76	$(5–40) \times 10^5$	8
	35	6.4	0.82	10^4–10^7	9
	45	6.9	0.91	10^4–10^7	9
0.45 M $K2SO_4$ (aq)	35	130	0.5	10^4–10^7	9
0.39 M $MgSO_4$ (aq)	45	100	0.5	10^4–10^7	9
Benzene	25	39.7	0.686	$(8–500) \times 10^4$	10
	30	61.4	0.64	$(3–20) \times 10^5$	7

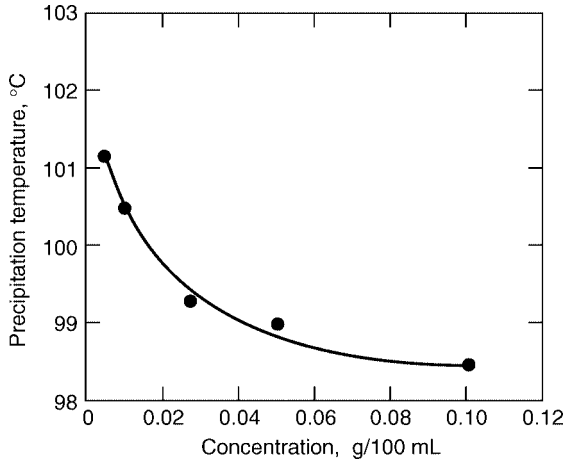

Fig. 4. Upper temperature limit for solubility of poly(ethylene oxide) in water. Molecular weight is 2×10^6 (3).

may decrease by one order of magnitude as the temperature of measurement is increased from 10 to 90°C. Figure 5 shows this effect.

Effects of Salts. The presence of inorganic salts in aqueous solutions of poly(ethylene oxide) reduces the upper temperature limit of solubility and viscosity. The upper temperature limit of solubility decreases in proportion to the concentration and valence of the ionic species present. The size of the ions is also important; eg, smaller hydrated ions have the greatest effect. The effect of a number of inorganic salts on the upper temperature limit of solubility of poly(ethylene oxide) in water is illustrated in Figure 6. The decrease in temperature is nearly

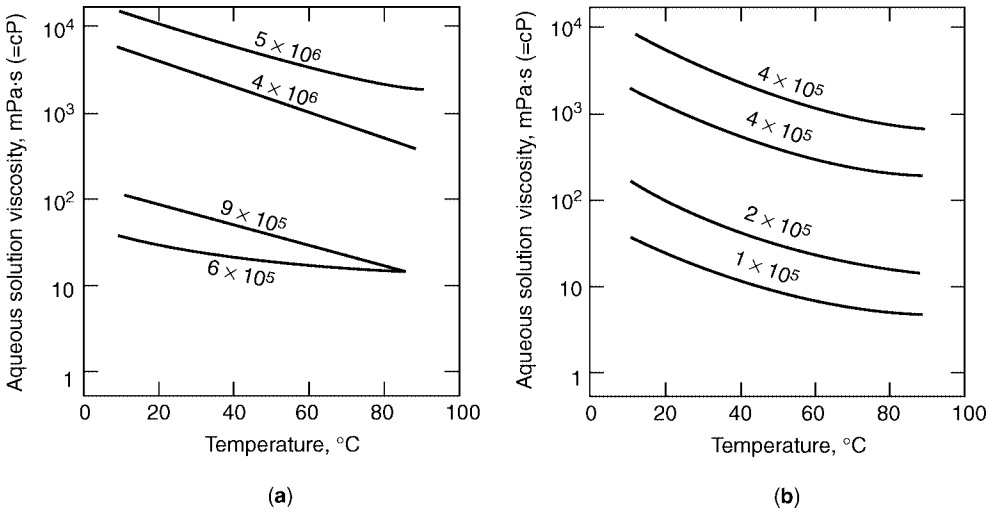

Fig. 5. Solution viscosity vs temperature: (**a**) 1.0 wt% solution and (**b**) 5.0 wt% solution (11) for polymers of various molecular weights, indicated on the curves.

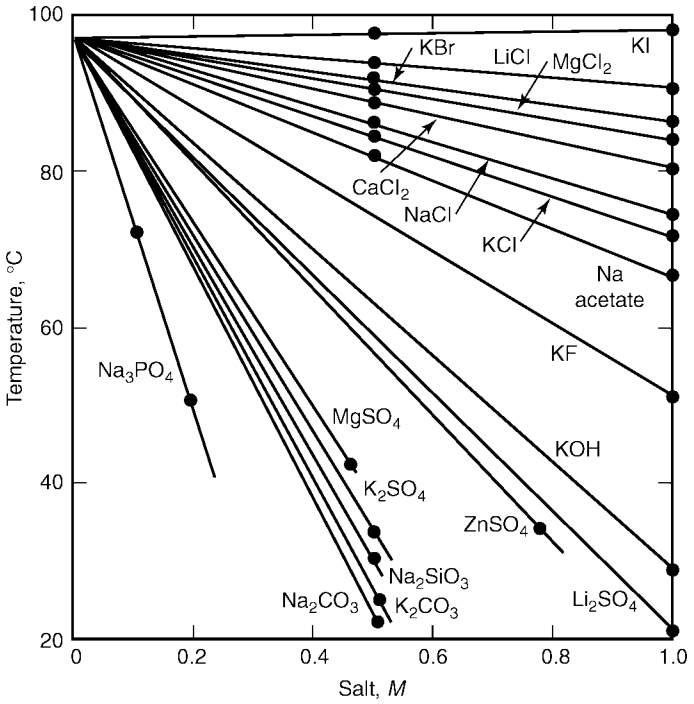

Fig. 6. Upper temperature limit of solubility in salt solution. Resin concentration is 5.0 wt% (7).

a linear function of salt concentration. However, this salting-out effect cannot always be correlated with the ionic strength principle. For example, potassium and magnesium sulfate have approximately the same effect, but potassium halides are widely different. Thus, it appears that the anion has the greater effect on the upper temperature limit of solubility. The effectiveness of anions to reduce the Θ temperature of aqueous poly(ethylene oxide) solution decreases in the following order: $PO_4^{3-} > HPO_4^{2-} > S_2O_3^{2-} > H_2PO_4^{-} > F^{-} > HCO_2^{-} > CH_3CO_2^{-} > Br^{-} > I^{-}$. The order for cations was found to be $K^{+} \approx$; $Rb^{+} \approx$; $Na^{+} \approx$; $Cs^{+} > Sr^{2+} > Ba^{2+} \approx$; $Ca^{2+} > NH^{+}_4 > Li^{+}$ (12). The presence of inorganic salts in solutions of poly(ethylene oxide) also can reduce the hydrodynamic volume of the polymer, with attendant reduction in intrinsic viscosity; this effect is shown in Figure 7.

Effect of Shear. Concentrated aqueous solutions of poly(ethylene oxide) are pseudoplastic. The degree of pseudoplasticity increases as the molecular weight increases. Therefore, the viscosity of a given aqueous solution is a function of the shear rate used for the measurement. This relationship between viscosity and shear rate for solutions of various molecular weight poly(ethylene oxide) resins is presented in Figure 8.

Thermoplasticity. High molecular weight poly(ethylene oxide) can be molded, extruded, or calendered by means of conventional thermoplastic processing equipment (13). Films of poly(ethylene oxide) can be produced by the blown-film extrusion process and, in addition to complete water solubility, have

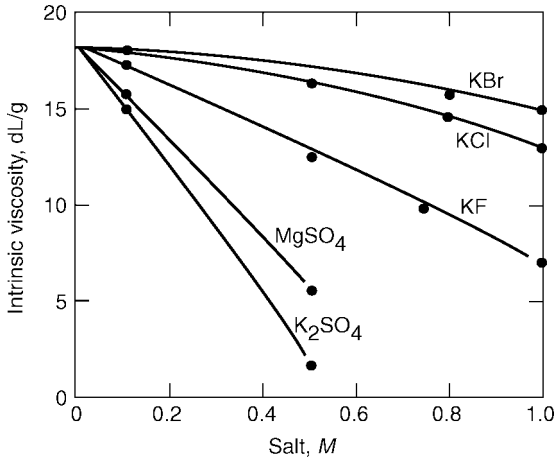

Fig. 7. Effects of salts on the intrinsic viscosity of poly(ethylene oxide) at 30°C. Molecular weight is 5.5×10^6 (3).

the typical physical properties shown in Table 3. Films of poly(ethylene oxide) tend to orient under stress, resulting in high strength in the draw direction. The physical properties, melting behavior, and crystallinity of drawn films have been studied by several researchers (14–17).

At 100–150°C above the melting point, the melt viscosities of these polymers may exceed 10 kPa·s (10^5 P) (Fig. 9). These high melt viscosities indicate extremely high molecular weight. Melt viscosities are relatively unaffected by temperature changes but are directly proportional to the molecular weight of the polymer. Thus, polymers with molecular weights of $(1–3) \times 10^5$ are usually used for applications involving thermoplastic forming processes.

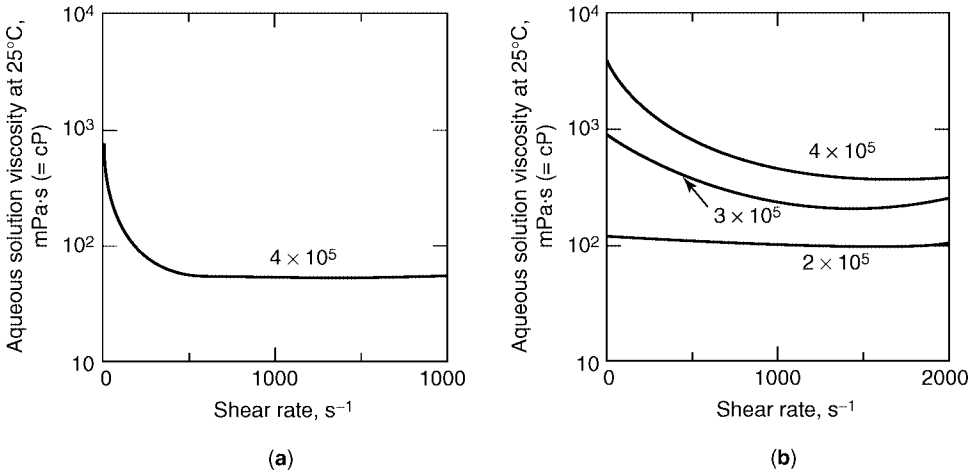

Fig. 8. Effect of shear on aqueous solution viscosities of poly(ethylene oxide) resins: (**a**) 1.0 wt% solution; (b) 5.0 wt% solution (7). Each curve represents a different molecular weight.

Table 3. Typical Physical Properties of Poly(ethylene oxide) Film

Polymer Blends. The miscibility (qv) of poly(ethylene oxide) with a number of other polymers has been studied, eg, with poly(methyl methacrylate) (18–23), poly(vinyl acetate) (24–27), polyvinylpyrrolidinone (28), nylon (29), poly(vinyl alcohol) (30), phenoxy resins (31), cellulose (32), cellulose ethers

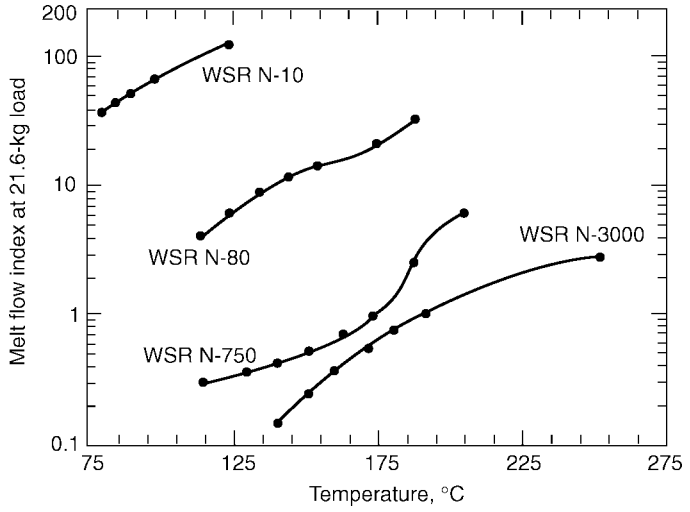

Fig. 9. Melt flow index as a function of temperature for varying molecular weights of poly(ethylene oxide). WSR = Polyox water-soluble resins.

(33), poly(vinyl chloride) (34), poly(lactic acid) (35), polyhydroxybutyrate (36), poly(acrylic acid) (37), polypropylene (38), polyethylene (39) , and poly(styrene-*co*-maleic anhydride) (40). The crystallization behavior of representive PEO blends have been studied using time-resolved wide- and small-angle X-ray scattering (41).

Chemical Properties

Association Complexes. The unshared electron pairs of the ether oxygens, which give the polymer strong hydrogen bonding affinity, can also take part in association reactions with a variety of monomeric and polymeric electron acceptors (42,43). These include poly(acrylic acid), poly(methacrylic acid), copolymers of maleic and acrylic acids, tannic acid, naphtholic and phenolic compounds, as well as urea and thiourea (44–49).

When equal amounts of solutions of poly(ethylene oxide) and poly(acrylic acid) are mixed, a precipitate, which appears to be an association product of the two polymers, forms immediately. This association reaction is influenced by hydrogen-ion concentration. Below ca pH 4, the complex precipitates from solution. Above ca pH 12, precipitation also occurs, but probably only poly(ethylene oxide) precipitates. If solution viscosity is used as an indication of the degree of association, it appears that association becomes more pronounced as the pH is reduced toward a lower limit of about 4. The highest yield of insoluble complex usually occurs at an equimolar ratio of ether and carboxyl groups. Studies of the poly(ethylene oxide)–poly(methacrylic acid) complexes indicate a stoichiometric ratio of three monomeric units of ethylene oxide for each methacrylic acid unit.

These association reactions can be controlled. Acetone or acetonylacetone added to the solution of the polymeric electron acceptor prevents insolubilization, which takes place immediately upon the removal of the ketone. A second method of insolubilization control consists of blocking the carboxyl groups with inorganic cations, ie, the formation of the sodium or ammonium salt of poly(acrylic acid). Mixtures of poly(ethylene oxide) solutions with solutions of such salts can be precipitated by acidification.

Poly(ethylene oxide) associates in solution with certain electrolytes (50–54). For example, high molecular weight species of poly(ethylene oxide) readily dissolve in methanol that contains 0.5 wt% KI, although the resin does not remain in methanol solution at room temperature. This salting-in effect has been attributed to ion binding, which prevents coagulation in the nonsolvent. Complexes with electrolytes, in particular lithium salts, have received widespread attention on account of the potential for using these materials in a polymeric battery. Variable temperature IR studies have been used to explain the structural changes in these systems (55). The use of complexes of poly(ethylene oxide) in analytical chemistry has also been reviewed (56).

Oxidation. Because of the presence of weak C—O bonds in the backbone, high molecular weight polymers of ethylene oxide are susceptible to oxidative degradation in bulk, during thermoplastic processing, or in solution. The mechanistic aspects of poly(ethylene oxide) oxidation have been reviewed (57). During thermoplastic processing at elevated temperature, oxidative degradation

is manifested by a rapid decrease in melt viscosity with time. In aqueous solution at ambient temperatures, the decay of solution viscosity also is an indication of oxidative degradation, and the rate of decay is increased by the presence of traces of chlorine, peroxides, permanganate, or persulfate and certain transition-metal ions such as Cu^{+}, Cu^{2+}, Cu^{3+}, Fe^{3+}, and Ni^{2+}. A combination of these agents can lead to severe viscosity losses.

Several stabilizers are useful in minimizing oxidative degradation during thermoplastic processing or in the bulk solid. Phenothiazine, hindered phenolic antioxidants such as butylated hydroxytoluene , butylated hydroxyanisole, and secondary aromatic amines in concentrations of 0.01–0.5% based on the weight of polymer, are effective.

Aqueous solutions can be stabilized against viscosity loss by addition of 5–10 wt% anhydrous isopropyl alcohol, ethanol, ethylene glycol, or propylene glycol. The manganous ion (Mn^{2+}) also is an effective stabilizer at concentrations of 10^{-5}–10^{-2} wt% of the solution.

Manufacture and Processing

Heterogeneous Catalytic Polymerization. The preparation of polymers of ethylene oxide with molecular weights greater than 100,000 was first reported in 1933. The polymer was produced by placing ethylene oxide in contact with an alkaline-earth oxide for extended periods (58). In the 1950s, the low yield and low polymerization rates of the early work were improved upon by the use of alkaline-earth carbonates as the catalysts (59). Further improvements in reaction rates and polymerization control have led to the commercial availability of poly(ethylene oxide) of varying molecular weights.

The polymerization of ethylene oxide to produce high molecular weight polymer involves heterogeneous reaction with propagation at the catalyst surface. The polymerization can involve anionic or cationic reactions of ethylene oxide that generally produce lower molecular weight products. The mechanism for production of extremely high molecular weight polymers is thought to involve a coordinate anionic reaction where ethylene oxide is coordinated with a metal atom of the catalyst and is then attacked by an anion. The various polymerization mechanisms have been described (60).

Catalysts capable of polymerizing ethylene oxide to high molecular weight polymers include many metal compounds. Among those reported are alkaline-earth carbonates and oxides (61), alkyl zinc compounds (62–64), alkyl aluminum compounds and alkoxides (65–67), and hydrates of ferric chloride, bromide, and acetate (68,69). Other catalysts include various alkyls and alkoxides of aluminum, zinc, magnesium, and calcium, and mixtures of these materials with various other inorganic salts. The preparation and utilization of the various catalysts have also been described (70,71). The molecular weight of the polymer appears to be controlled by the catalyst systems as well as by polymerization conditions. Rigid control of catalyst preparation and raw material quality appear to be mandatory for successful laboratory preparation of high molecular weight poly(ethylene oxide).

Polymer Suspensions. Poly(ethylene oxide) resins are commercially available as fine granular solids. However, the polymer can be dispersed in a nonsolvent to provide better metering into various systems. Production processes involve the use of high shear mixers to disperse the solids in a nonsolvent vehicle (72–74).

Thermoplastic Processing. Poly(ethylene oxide) resins can be thermoplastically formed into solid products, eg, films, tapes, plugs, retainers, and fillers (qv). Through the use of plasticizers (qv), poly(ethylene oxide) can be extruded, molded, and calendered on conventional thermoplastic processing equipment. Sheets and films of this resin are heat sealable (75,76).

Irradiation and Cross-Linking. Exposure of poly(ethylene oxide) to ionizable radiation (gamma irradiation, electron beam, or ultraviolet light) can result in molecular weight breakdown or cross-linking, depending on the environmental conditions. If oxygen is present, hydroperoxides are formed and chain scission leads to an overall decrease in molecular weight (77). However, in the absence of oxygen, cross-linking becomes the preferred reaction (78,79,90). The resulting polymer network exhibits hydrogel properties of high water capacity (81,82).

Studies of the cross-linking mechanism and structure of the cross-linked polymer indicate that a complex network of cross-linked chains of varying lengths is present (83–86). When the cross-linking is performed in solution, the cross-links can be both intermolecular and intramolecular; the overall structure of the cross-linked polymer is the combined result of chain scission, intramolecular bonding, and intermolecular bonding. Under conditions of high aggregation in solution, for example, high concentration, intermolecular cross-linking is preferred and a continuous gel is formed. When the polymer is not aggregated in solution, intramolecular cross-linking predominates, and microgels, rather than a cohesive gel network, are formed. Detailed positron annihilation studies have been used to reveal the evolution of small pore structure for semicrystalline PEO under gamma irradiation (87).

Economic Aspects

Only Japan and the United States have significant commercial facilities for the production of poly(ethylene oxide) resins. In Japan, Meisei Chemical Works Ltd. produces Alkox and Sumitomo Seika Kagaky Co., Ltd. produces PEO. In the United States, The Dow Chemical Corp. produces Polyox. Precise figures have not been released on capacities or annual production.

Specifications, Standards, and Quality Control

The primary quality control measure for these resins is the concentrated aqueous solution viscosity, which is related to molecular weight. Specifications for Polyox are summarized in Table 4. Additional product specifications frequently include moisture content, particle-size distribution, and residual catalyst by-product level.

Table 4. Aqueous Solution Viscosity Specifications for Polyox Resins[a]

Grade	Approximate M_w	Concentration wt%	Brookfield Viscometer Spindle Number	Speed, rmp	Viscosity at 25°C, Pa · s[b]
WSR-308	8×10^6	1.0	2	2	10,000–15,000
WSR-303	7×10^6	1.0	2	2	7,500–10,000
COAG	5×10^6	1.0	2	2	5,500–7,500
WSR-301	4×10^6	1.0	1	2	1,650–5,500
WSRN-60K	2×10^6	2.0	3	10	2,000–4,000
WSRN-12K	1×10^6	2.0	1	10	400–800
WSR-1105	9×10^5	5.0	2	2	8,800–17,600
WSR-205	6×10^5	5.0	2	2	4,500–8,800
WSRN-3000	4×10^5	5.0	1	2	2,250–4,500
WSRN-750	3×10^5	5.0	1	10	600–1000
WSRN-80	2×10^5	5.0	1	50	65–115
WSRN-10	1×10^5	5.0	1	50	12–50

Analytical and Test Methods

Molecular Weight. Measurement of intrinsic viscosity in water is the most commonly used method to determine the molecular weight of poly(ethylene oxide) resins. However, there are several problems associated with these measurements (89,90). The dissolved polymer is susceptible to oxidative and shear degradation, which is accelerated by filtration or dialysis. If the solution is purified by centrifugation, precipitation of the highest molecular weight polymers can occur and the presence of residual catalyst by-products, which remain as dispersed, insoluble solids, further complicates purification.

A number of techniques, including static and dynamic light scattering (91), viscometry (92), and gel-permeation chromatography (GPC) with low angle laser light-scattering detection (93), have been used to study the behavior of poly(ethylene oxide) in solution. Dynamic light scattering (94,95) has also been used to determine the molecular weight distribution of poly(ethylene oxide) and to study crystallization from dilute solutions (96,97).

Attempts to measure average molecular weight and molecular weight distribution of poly(ethylene oxide) for molecular weights above 1 million, using GPC, are extremely difficult because of the effect of shear on the high molecular weight polymer molecules in the GPC column and the lack of adequate standards for calibration of the columns. However, one group has been successful in using high speed gel filtration to fractionate high molecular weight poly(ethylene oxide) and provide materials with narrow molecular weight distributions suitable for use as standards for GPC (98). An alternative method for average molecular weight determination is cloud point titration (99) (see MOLECULAR WEIGHT DETERMINATION).

Aqueous Solution Viscosity. A special solution preparation method is used for one type of measurement of aqueous solution viscosity (100). The appropriate amount of poly(ethylene oxide) resin is dispersed in 125 mL of anhydrous isopropyl alcohol by vigorous stirring. Because the resin is insoluble in anhydrous

isopropyl alcohol, a slurry forms and the alcohol wets the resin particles. An appropriate amount of water is added and stirring is slowed to about 100 rpm to avoid shear degradation of the polymer. In Table 4, the nominal resin concentration reported is based on the amount of water present and ignores the isopropyl alcohol.

Analysis for Poly(ethylene oxide). Another special analytical method takes advantage of the fact that poly(ethylene oxide) forms a water-insoluble association compound with poly(acrylic acid). This reaction can be used in the analysis of the concentration of poly(ethylene oxide) in a dilute aqueous solution. Freshly prepared poly(acrylic acid) is added to a solution of unknown poly(ethylene oxide) concentration. A precipitate forms, and its concentration can be measured turbidimetrically. Using appropriate calibration standards, the precipitate concentration can then be converted to concentration of poly(ethylene oxide). The optimum resin concentration in the unknown sample is 0.2–0.4 ppm. Therefore, it is necessary to dilute more concentrated solutions to this range before analysis (101). Low concentrations of poly(ethylene oxide) in water may also be determined by viscometry (102) or by complexation with KI_3 and then titration with $Na_2S_2O_3$ (103).

Health and Safety Factors: Toxicology

Poly(ethylene oxide) resins are safely used in numerous pharmaceutical and personal care applications. Poly(ethylene oxide) resins show a low order toxicity in animal studies by all routes of exposure. Because of their high molecular weight, they are poorly adsorbed from the gastrointestinal tract and are completely and rapidly eliminated (104). The resins are not skin irritants or sensitizers, nor do they cause eye irritation.

Considerable interest has been shown in poly(ethylene oxide) for diverse applications in food, drug, and cosmetic products. Such uses fall within the scope of the Federal Food, Drug, and Cosmetic Act. The U.S. Food and Drug Administration (FDA) has recognized and approved the use of poly(ethylene oxide) for specific food and food packaging uses. USP/NF grades of Polyox water-soluble resins (The Dow Chemical Co.) that meet all requirments of the United States Pharmacopeia/National Formulary (USP/NF) are available for pharmaceutical applications (105).

Uses

Significant use properties of poly(ethylene oxide) are complete water solubility, low toxicity, unique solution rheology, complexation with organic acids, low ash content, and thermoplasticity.

Pharmaceutical and Biomedical Applications. On account of its low toxicity and unique properties, poly(ethylene oxide) is utilized in a variety of pharmaceutical and biomedical applications.

Denture Adhesives. Fast hydration and gel-forming properties are ideally mated to produce a thick, cushioning fluid between the dentures and gums (106).

The biologically inert nature of poly(ethylene oxide) helps reduce unpleasant odors and taste in this type of personal care product. The use of PEO blends has also been shown as a means to optimize denture adhesive properties (107).

Mucoadhesives. Poly(ethylene oxide) has good adhesive properties to mucosal surfaces because of its high molecular weight, linear molecules, and fast hydration properties. *In vivo* results have shown that the duration of adhesion increases with molecular weight up to 400,000. Further increase in molecular weight results in a concomitant decrease in adhesive properties, most likely because of the swelling of the resulting hydrogel (108). The mucoadhesive properties have been utilized in the design of buccal-sustained drug delivery systems (109,110) and occular delivery systems (111).

Ophthalmic Solutions. The viscoelastic properties of poly(ethylene oxide) produce unique benefits for vitreous fluid substitution for ophthalmic surgery. Solutions of high molecular weight poly(ethylene oxide) have been used as vehicles for therapeutics for the eye (112) and as a contact lens fluid for hard or gel-type lenses (113). A treated lens appears to have a high viscosity layer at the low shear rates that occur on the inside surface. This provides a thick, comfortable cushioning layer. At high shear rates caused by the blinking eyelid, the apparent viscosity is much lower. This allows the lid to move smoothly and effortlessly over the outside surface of the lens. Unlike the cellulosics, poly(ethylene oxide) does not support bacterial growth. Lens solutions are easier to keep sterile.

Wound Dressings. Cross-linked poly(ethylene oxide) solutions form hydrogels which contain about 90–97% of water. These hydrogels (qv) are clear, transparent, permeable to gases, and absorb 5–100 times their weight in water. Such characteristics make these hydrogels interesting materials for wound dressings. Compared to other occlusive dressings, these hydrogels have shown the promotion of rapid healing (114) . Release of therapeutic substances from these dressings has been demonstrated (115,116).

Oral Drug Release. The dissolution rate of tableted poly(ethylene oxide) depends on the molecular weight and particle-size distribution. High molecular weight resin provides an excellent tablet binder for sustained drug release from matrix tablets (117–119) (see CONTROLLED RELEASE TECHNOLOGY). The good flow properties and compressibility of poly(ethylene oxide) powder can be advantageously exploited in preparing tablets by direct compression. The high swelling capacity of high molecular weight poly(ethylene oxide) tablets when exposed to intestinal fluids has been successfully used in osmotic delivery systems for water-insoluble drugs (120–123). A detailed review of these osmotic systems is available (124). A zero-order drug release has been reported from films produced from poly(ethylene oxide) and polycaprolactone. The change in drug release profile with respect to film composition, thickness, and morphology has been described (125). Novel PEO matrix systems aimed at gastric delivery and chewable forms have been described (126,127). The thermoplastic properties of PEO lend themselves to the use of extrusion methods in the preparation of oral delivery systems (128,129).

Biomaterials with Low Thrombogenicity. Poly(ethylene oxide) exhibits extraordinary inertness toward most proteins and biological macromolecules. The polymer is therefore used in bulk and surface modification of biomaterials to develop antithrombogenic surfaces for blood contacting materials. Such modified

surfaces result in reduced concentrations of cell adhesion and protein adsorption when compared to the nonmodified surfaces (130,131).

Lubricious Coatings for Biomaterials. Coatings of poly(ethylene oxide) when dry are tactile. If brought into contact with water, the poly(ethylene oxide) hydates rapidly and forms a lubricious coating. This type of technology is of great interest for biomedical devices introduced into the human body, such as catheters and endotracheal tubes, and for sutures (132–135).

Industrial Applications. Poly(ethylene oxide)s also have numerous industrial uses.

Flocculation. Poly(ethylene oxide)s of molecular weights greater than 4 million have been used as specialty flocculants. The ability of the PEO molecule to hydrogen-bond with the surface hydroxyl layers of silica, kaolinites, and other mineral oxides leads to adsorption of the polymer on the substrate. The balance between the hydrophilicity of the ether oxygen moiety and the hydrogen-bonding forces on the solid substrate results in a loop-tail conformation essential to flocculation. Some of the end uses for PEO as a flocculant are as a fines retention aid in the paper industry, a low pH flocculant of silica in beryllium, uranium, and copper mines that use acid leaching, and as a dewatering aid in industrial waste treatment. In the paper industry, PEO is widely used as a retention aid and pitch control agent in the newsprint industry (136–157). Typically, a phenol formaldehyde-type resin is added to the substrate before the addition of PEO. The chemical that is added before PEO has been referred to as an *enhancer*. Recent publications on designing enhancers that work with PEO have resulted in expanding the use of PEO in flocculation of several substrates (146,147,158,159).

Several technical articles suggest that the use of PEO increases the dewatering efficiency of mineral sludges significantly (160–176). In the mining industry, PEO is used to flocculate siliceous substrates at pH <2 during the acid leaching operations. The low pH stability provides PEO polymers with unique advantages in this application.

Drag Reduction. The addition of 0.03% of high molecular weight PEO (greater than 4 million) to aqueous solutions has resulted in a 100% increase in the flow rate at fixed pump pressures (177). The significant reduction in friction as a result of the addition of PEO has been attributed to supermolecular structure formation of PEO (178) and to expansion and orientation of the polymer in rotation-free draining flow (179,180). Drag reduction (qv) properties have been demonstrated by trials using fire hoses, which show that water travels 50% further because of the addition of small quantities of PEO. Investigations on the effect of Reynold's number, orifice size of the pumping device, and polymer blends have led to a better understanding for suitable drag-reducing systems that may use PEO (177–191). Degradation of PEO and point of addition of the polymer appear to play a significant role in successful manipulation of this property in end uses (192,193). Some references also suggest the use of this property in reducing arterial pressure in medical applications (190) and in ocean transport (194–197).

Binders in Ceramics, Powder Metallurgy, and Water-Based Coatings for Fluorescent Lamps. In coatings and ceramics applications, the suspension rheology needs to be modified to obtain a uniform dispersion of fine particles in the

finished product. When PEO is used as a binder in aqueous suspensions, it is possible to remove PEO completely in less than 5 min by baking at temperatures of 400°C. This property has been successfully commercialized in several ceramic applications, in powder metallurgy, and in water-based coatings of fluorescent lamps (198–201).

Personal Care. The addition of PEO provides a silky feel to solid and liquid products. This unique lubricious property has been successfully exploited in formulation of razor strips (202,203) and in shampoos, detergents, and other personal care applications. The combination of water solubility and the ability to produce films and other devices by thermoplastic processing enables the use of the PEO in flushable articles (204–207). PEO has also been used as an antimisting agent in personal care and cleaning formulations (208) and has been shown to enhance the deposition of active ingredients to the hair and skin, as well as to act as a foam enhancer (209). Fundamental investigations have examined the interaction of PEO and surfactants in aqueous solutions (210–213).

Adhesives. High concentration (>10%) solutions of poly(ethylene oxide) exhibit wet tack properties that are used in several adhesive applications (214). The tackiness disappears when the polymer dries, and this property can be successfully utilized in applications that require adhesion only in moist conditions. PEO is also known to form solution complexes with several phenolic and phenoxy resins. Solution blends of PEO and phenoxy resins are known to exhibit synergistic effects, leading to high adhesion strength on aluminum surfaces.

Acid Cleaners. The addition of PEO can significantly increase the viscosity of acid solutions. Highly viscous acid solutions are used in cleaning formulations for glass, ceramic, and metal surfaces. The increase in viscosity increases the contact time of the cleaning solution when it is sprayed on vertical surfaces. Some acids that can be thickened by using PEO are hydrochloric, sulfuric, phosphoric, and oxalic . The order of addition of the polymer and oxidative stabilizers appears to play an important role in formulating highly viscous acid solutions. The manufacturers provide several formulations to thicken different acids.

Drift and Mist Control. The pseudoplastic properties of PEO solutions reduce mist formation during spraying of aqueous solutions that contain PEO. This property is used in metal-working fluids to lower worker exposure to mists from the cutting and grinding aids. PEO may also be used to focus the spraying area of herbicides and water-based coatings.

Construction. The addition of PEO to concrete has been a subject of several investigations (215). Research studies and patent literature suggests that PEO can be used as a pumping aid to concrete, where the lubricity of PEO allows concrete to be pumped to longer distances (216–219). In addition, PEO is also used to disperse the water more uniformly in the concrete mixture, which promotes better uniformity of the concrete mixture. Formulations in the construction industry are proprietary and not easily available.

Batteries. Polymer electrolytes based on PEO have been widely reviewed (220,221). The prospect of using a thin-layer, flexible battery for applications ranging from cellular phones to electric vehicles has led to several patents (222,223) and research papers in this field. Typically, a salt such as potassium iodide, lithium triflate, or lithium perchlorate is complexed with PEO in a methylene chloride solvent. The solution complex is cast into thin films and the solvent

is evaporated. The complex has been characterized; it is believed that the 7C2 helical structure of PEO allows an ideal structure for ion transport and leads to effective use as a battery. The dissociation of the anion–cation pair in the PEO salt complex has been attributed to the oxygen atoms, which form a cage around the cation and lead to ionic conductivity. The crystallinity of PEO at room temperature has limited the use of this technology to batteries that are used at temperatures higher than 65°C, the melting point of PEO. Research in the 1990s focuses on modifying the complex or the PEO molecule to overcome the crystallinity problem and in understanding the interaction of PEO with lithium salts (224–235).

Other Applications. PEO has also been used as an antistat additive (236,237), a water-soluble packaging material of seeds and fertilizers (238), and a rheology modifier in aqueous flexographic printing inks (239), and for the production of nanofibers containing multiwalled carbon nanotubes (240).

FILLERS

Introduction

By definition, fillers are used to extend a material and to reduce its cost. However, few inexpensive fillers, such as walnut shells, fly ash, wood flour, and wood cellulose, are still being used purely for filling purposes; nearly all fillers employed provide more than space filling. Considering their relative higher stiffness compared to the material matrix, they will always modify the mechanical properties of the final filled products, or composites. Fillers can constitute either a major or a minor part of a composite. The structure of filler particles ranges from precise geometrical forms, such as spheres, hexagonal plates, or short fibers, to irregular masses. Fillers are generally used for nondecorative purposes in contrast to pigments, although they may incidentally impart color or opacity to a material. Additives that supply bulk to drugs, cosmetics, and detergents, often referred to as fillers, are actually applied as diluents because their primary purpose is to adjust the dose or concentration of a product, rather than modify its properties or reduce cost. Fibers and whiskers are not discussed here because they are generally regarded as reinforcements, not fillers, although a majority of the fillers discussed here have reinforcing effects (see REINFORCEMENT). Also, fillers and additives that primarily modify or impart electromagnetic properties, such as electrical conductivity, are not discussed (see CONDUCTIVE POLYMER COMPOSITES).

The first manmade composites appeared in ∼5000 BC in the Middle East region, where pitch was used as a binder for reeds in building boats. Although

glass fiber was known to be used by Phoenicians for bottle making, the use of fillers to modify the properties of a material started in early Roman times, when artisans used ground marble in lime plaster, frescoes, and pozzolanic mortar. It was not until the establishment of the modern polymer industry in the mid-nineteenth century that the rapid development of commercial fillers occurred. The first polyester resin was prepared by the Swedish chemist Berzelius in 1847, although the first commercial plastic was not forthcoming until 1862 when Parkes introduced a cellulose nitrate plastic. With the marketing of Bakelite resin in 1909, a phenol–formaldehyde plastic filled with paper or cloth, along with the usage of Carbon Black (qv) fillers by B. F. Goodrich in natural rubbers, the modern age of filled polymers was ushered in.

Fillers can be classified according to their source, function, composition, and/or morphology. No single classification scheme is entirely adequate due to the overlap and ambiguity of these categories. Considering some examples of fillers used in modern polymers listed in Table 1 (1), the emphasis of this article is on particulate fillers. Extensive usage of particulate fillers in many commerical polymers is for the enhancement in stiffness, strength, dimensional stability, toughness, heat distortion temperature, damping, impermeability, and cost reduction, although not all of these desirable features are found in any single filled polymer. The properties of particulate-filled polymers are determined by the properties of the components, by the shape of the filler phase, by the morphology of the system, and by the polymer-filler interfacial interactions.

Table 1. Fillers Used in Commercial Polymers

Particulate		Fibrous	
Organic	Inorganic	Organic	Inorganic
Wood flour	Glass	Cellulose	Whiskers
Cork	Calcium carbonate	Wool	Asbestos
Nutshell	Beryllium oxide	Carbon/graphite	Glass
Starch	Iron oxide	Aramid fiber	Mineral wool
Polymers	Magnesia	Nylons	Calcium sulphate
Carbon	Magnesium carbonate	Polyesters	Potassium titanate
Proteins	Titanium dioxide		Boron
Carbon nanotube	Zinc oxide		Alumina
	Zirconia		Metals
	Hydrated alumina		
	Antimony oxide		
	Metal powder		
	Silica		
	Silicates		
	Organo-nanoclays		
	Clays		
	Barium ferrite		
	Silicon carbide

Physical Properties of Fillers

The overall value of a filler is a complex function of intrinsic material characteristics, such as average particle size, particle shape, intrinsic strength, and chemical composition; of process-dependent factors, such as particle-size distribution, surface chemistry, particle agglomeration, and bulk density; and of cost. Abrasion and hardness properties are also important for their impact on the wear and maintenance of processing and molding equipment.

Particle Morphology, Shape, Size, and Distribution. Filler particles come in a variety of shapes and sizes. In general, for most polymer applications, the filler size required is <40 μm. Finer particles, <3 μm, provide stronger enhancements in properties. Nanoparticles, with dimensions ranging up to 100 nm, deliver the strongest enhancements when they all are properly dispersed. Due to increases in both the surface area and the corresponding surface area to volume ratio with a reduction in filler particle size, finer particles are prone to agglomerate for the conservation of internal energy (2) and are more difficult to be dispersed.

The shape of an individual particle has great impact on the flexural modulus (3), permeability (4), and flow behavior (5) of a filled polymer. Although there are many ways to measure the shape (6) of a filler particle, the aspect ratio, or the ratio of the longest length of particle to its thickness, is most commonly used. A sphere, regardless of its size, has the lowest aspect ratio equal to 1.0. As a filler's shape progresses from a sphere to a block, to a plate, or to a flake, the aspect ratio increases. The aspect ratio of a filler affects its packing and, hence, its loading level in a polymer. Theoretically, percolation, or filler networking, occurs when the volume fraction of monodispersed spherical particles reaches 0.156 (7). The increase in the filler's aspect ratio lowers the percolation threshold and this reduction, in turn, is of critical importance in loading electrical conductive fillers in a material to achieve electrical conductivity (8).

Almost all fillers do not exist as the discrete individual particles of their primary structure. They form aggregates, ie, secondary structure, which can agglomerate into tertiary structures in the material to be filled. An aggregate is a collection of primary particles that are chemically bonded together. The surface area of an aggregate is less than the sum of surface areas of all primary particles in that aggregate. In general, aggregates are extremely difficult to be broken down into individual primary particles by physical methods such as mechanical mixing. The union of aggregates, although weakly associated through nonbonded physical interactions, leads to an agglomerate. Filler materials often exist as agglomerates in their natural state. The total surface area of an agglomerate is similar to the sum of individual surface areas of aggregates in that agglomerate. The mixing and dispersion of fillers in a material involves primarily the incorporation and distribution of filler pellets or powders, and breakdown into agglomerates, and then into aggregate structures.

In any commercial filler grade, there exists a collection of multiple shapes and sizes. The particle size and shape distributions of fillers can be best measured by direct microscopic inspection together with image processing although there are other methods to determine particle sizes and shapes. The size distribution of fillers that are >40 μm and are also moderately spherical in shape could

be determined conveniently by sieving in accordance to the ASTM E-11-70 sieve designation. The Coulter technique could be used to measure fillers in sizes ranging form 4–40 μm. Filler particle-size distributions <4 μm could be obtained by sedimentation, permeametry, or light-scattering methods (9,10). Laser light-scattering method can now analyze particles ranging from 0.05 to 2000 μm. Most descriptions of particulate fillers are given in terms of equivalent spherical diameter, ie, the diameter of a sphere having the same volume as the particle. Although microscopy can provide direct observation of filler particles, two-dimensional (2D), instead of the true three-dimensional (3D), size and shape distributions are acquired in most cases. Statistical transformation of a 2D size distribution into a 3D size distribution for near-spherical, randomly distributed, particles can be performed (11).

Intrinsic Strength, Hardness, and Abrasivity. The intrinsic strengths and moduli of some crystalline fillers can be calculated along the crystallographic axes using molecular simulation (12,13). For these crystalline fillers, such as talc and mica, the common fracture results from the delamination between the crystalline planes. As for the hardness, the primary measure is based on the Mohs hardness scale, which is an empirical hardness measure according to the ability of one material to scratch another (14) (see HARDNESS). The Mohs hardness goes from 1, such as for talc, to 3, such as for calcite, to 7, such as for quartz, to 10, such as for diamond, on a nonlinear scale. Abrasivity of a filler particle depends on its hardness, but also on its size and shape. Particles with sharp edges or rod shapes are more abrasive than those of smooth and round particles, and large particles are more abrasive than smaller particles of the same shape. Additionally, the coefficient of friction, surface treatment, surface energy, and purity of a filler all affect its abrasivity. Purity is important since one of the most common contaminants in natural fillers is the highly abrasive sand.

Surface Area, Chemistry, Wetting, and Coupling. Available surface areas of fillers include surfaces of filler aggregates and agglomerates and surfaces in their pores, crevices, and cracks. Measured values of surface area of fillers vary depending on the measurement methods. The direct method of surface area summation from microscopic imaging of filler particle size distribution typically yields a lower surface area value because of the inability to measure surfaces in pores and crevices by microscopy. In practice, surface area is determined from the measured nitrogen adsorption assuming monolayer coverage on the filler particle surface (15) according to the BET theory (16) and is expressed in square meters per gram (m^2/g).

The chemical compatibility between the filler surface and a polymer to be filled is critically important in both the wetting and dispersion of this filler by the polymer and the final physical performance of the resulting filled polymer. Filler surfaces are commonly defined, according to water affinity, as hydrophilic, which has a high affinity for water, to hydrophobic. Many commercial fillers, especially mineral types, are surface coated or chemically treated with hydrophobic wetting agents to modify their surface chemistry, to alter wetting characteristics, and to aid their dispersion in organic polymers, particularly in nonpolar polymers. These wetting agents also assist in deagglomerating filler particles which, in turn, allow for higher filler loadings with lower viscosities during filler incorporation. A filler particle's oil or water absorption value provides an indirect measurement of filler

relative wetting properties. The wettability can also be estimated by the contact angle (17) measured between a drop of water or oil and the filler surface. Commercial wetting agents typically include polymeric esters, stearates, fatty-acid esters, and organosilanes, among which the organosilanes, are the most widely used.

Organosilane wetting agents are also called silane coupling agents (qv) and, in general, consist of a trialkoxy group and a functional group having a $(RO)_3$—Si—R^* structure. The trialkoxy [$(RO)_3$ group provides chemical interactions or reactions with functional groups on the filler surface, and the R^* functional group delivers compatibility with the polymer matrix across the silane coupling bridge. This functional group can be selected from various chemical groups, such as isobutyl, mercapto, aminopropyl, methacryl, vinyl, epoxy, or haloalkyl, in accordance to the desirable interactions required with the polymer matrix (3). However, the extent and uniformity of the alkoxide reaction with a filler particle's surfaces vary depending on the treatment method. The pretreatment of fillers generally results in a more uniform reaction with a coupling agent than that obtained by mixing all ingredients in an internal mixer, particularly under low shear conditions.

Loading and Density. The amount of filler in a filled polymer is termed the *loading* and is always expressed quantitatively although the quantitative measures vary from industry to industry. In plastics and rubber industries, filler loading is formulated according to parts of filler used per 100 parts of polymer (phr), weight percent (wt%), or volume percent (vol%). In the paint industry, volume percent pigment (filler) in the dry paint film or the volume ratio of filler to binder is commonly used. In the paper industry, filler weight percent of sheet weight or percent ash based on a loss-on-ignition method is applied.

The optimal loading of fillers in a polymer is a balance between physical property enhancement and trade-off, and processing and material cost over the filler loading range. A theoretical maximum filler loading based on packing efficiency of monodispersed particles sets the upper limit of filler loading. The maximum volume fraction of spherical fillers in a hexagonal close packing is 0.74, whereas the maximum volume fractions achievable in a random close packing and in a cubic packing are 0.64 and 0.52, respectively (18). In practice, the maximum packing varies with particle shape, particle size distribution, and state of particle agglomeration. Agglomerates and nonspherical particles generally have smaller maximum packing than that of spheres (19). It is possible to achieve maximum packing with minimum void volumes by having very wide particle-size distribution (20). Except in a few cases, it is difficult to predict the maximum volume fraction from theory.

The average mass per unit volume of the individual particle is the true density or specific gravity of the filler. It is used to calculate the volume fraction of fillers and is determined by a simple liquid displacement method for large, nonporous, and spherical particles. Densities of finely divided, porous, and irregular fillers are typically measured by a gas pycnometer that ensures all pores and crevices of filler agglomerates are penetrated. Apparent, or bulk, filler density refers to the total amount of volume occupied by a given mass of dry fillers and it includes the void volumes in the filler aggregates and agglomerates. Bulk density is used in weighting fillers during filler purchasing, shipping, and storage.

Filled Polymers

It is probably true that all polymers contain some form of additive, ranging from small fractions of catalyst residue to large-scale incorporation of fillers. Fillers commonly used in plastics and rubbers and their primary functions have been extensively discussed (21,22). Fillers such as clay, kaolin, talc, calcium carbonate, or silica, and pigments such as titanium dioxide, are typically added in paper in a pulp slurry prior to its deposition onto the wire for paper making. Similarly, these types of fillers along with pigments are incorporated into paint formulations prior to paint application. All fillers are employed for such reasons as processing improvements, mechanical reinforcements, thermal stability, optical properties, permeability reduction, or cost saving.

Rheology and Processability. The presence of fillers affects the flow characteristics of the filled polymers. The immediate effect of a filler is to increase viscosity, interfere with the polymer flow pattern in a given process, produce thixotropy, and give rise to machine wear. The relevant properties of the filler are concentration, size, aspect ratio, stiffness, strength, and specific interaction between filler and the polymer matrix. Within these are the special cases of easily deformable fillers that could easily be broken down or shaped during flow.

In a simplest case with nondeformable, or rigid, spherical fillers in a very diluted concentration, the viscosity of the filled Newtonian polymer melt can be predicted by a simple Einstein equation (23).

$$\eta = \eta_s(1 + 2.5\ \varphi) \tag{1}$$

Here, the viscosity of the filled polymer, η, is related to the viscosity of the polymer, η_s, and the filler volume fraction, φ. At higher filler concentrations where the particles start to physically interact with one another, the Einstein equation is no longer applicable.

When filler spheres are close enough, hydrodynamic interactions between particles need to be considered. By factoring in the effects of two-body interactions, a modified equation was derived that is applicable up to $\varphi = 0.1$ (24).

$$\eta/\eta_s = 1 + 2.5\varphi + 6.2\varphi^2 \tag{2}$$

For filled Newtonian polymer melts of even higher filler volume fractions, a general empirical expression can be used to calculate shear viscosity of the composite (25).

$$\eta/\eta_s = (1 - \varphi/\varphi_m)^{-[\eta]\varphi_m} \tag{3}$$

Here, φ_m is the maximum packing volume fraction and its value and $[\eta]$ have been tabulated (26) for a variety of particles from spheres to glass fibers. It needs to be emphasized that at high filler loading the particle size distribution has a strong effect on viscosity.

With an increase in filler concentration that exceeds the filler percolation threshold, a loose filler network is formed that would show elastic behavior and,

in particular, a yield stress or thixotropy (5,27,28). This non-Newtonian behavior is not limited to filled polymers with high filler concentrations. Many polymer melts are viscoelastic and non-Newtonian. In these filled polymer melts, flow behavior is governed by viscoelastic properties of polymer compounded by the diverse properties of densely packed fillers and cannot be modeled and predicted theoretically. However, fine and particulate fillers are known to suppress elasticity of viscoleastic gum rubbers and render them better processability, such as less die swell, less shrinkage, and less melt fracture.

Mixing and Dispersion. In preparation of filled polymers, the process of uniformly distributing fillers without forming any filler composition gradients is most important. The process of mixing consists of three basic elements: incorporation, distribution, and dispersion. These elements occur simultaneously throughout the mixing cycle. Incorporation, which predominates the early stage of mixing, involves blending of separate ingredients into a coherent, although still inhomogenous, mass. In the distribution step, homogenizing occurs in which the ingredient becomes randomly distributed throughout the polymer matrix.

Dispersion is specifically concerned with the breakdown of filler agglomeration or physical association. It consists of three stages: initial wetting, breakdown of agglomerates, and intimate wetting of particles to displace air pockets. Dispersion becomes increasingly more difficult as particle size decreases and as processing continues. The actual choice of mixing and dispersion process and equipment depends on cost and polymer-filler system. Typically, it involves the high viscosity shear mixing, such as internal mixing, blade mixing, and single-or twin-screw extrusion.

The lower the filler loading, the more physical mixing is required to attain a suitable distribution. It is for this reason that the technique of masterbatching a concentrated mix of polymer and filler is commonly used in polymer compounding for adding smaller amounts of filler in a polymer by diluting the masterbatch with the polymer. The acceptable level of mixing depends on the particular filled polymer system and its property requirements. Not all filled polymers require fillers to be completely randomized.

Mechanical Properties. In addition to the hydrodynamic effects of particulate fillers on polymer flow behavior, an enhanced stiffening effect is observed in filled polymers. For soft polymers, such as elastomers, with diluted filler loading, effects of filler on modulus are proportional to that on viscosity and can be represented by the Einstein equation, equation 1, with viscosity terms replaced by modulus terms. However, this viscosity to modulus relationship only holds when the polymer is incompressible, such as elastomers with Poisson's ratio of 0.5, and when the rigidity of the filler is very much greater than that of the polymer.

The Guth–Gold model (29) is an extension of the Einstein model, whereby interactions of neighboring particles are incorporated. Normalized initial moduli, normalized against the polymer modulus, of filled polymers are related to the filler volume fraction by a polynomial series as follows:

$$E/E_s = (1 + 2.5\ \varphi + 14.1\varphi^2) \tag{4}$$

Here, E_s is the modulus of the polymer and φ is the filler volume fraction. Further modification of the Guth-Gold model leads to the Guth model (30) in which a geometric factor, g, was introduced. The Guth model is shown below.

$$E/E_s = [1 + 0.67\, g\varphi + 1.62(g\varphi)^2] \tag{5}$$

This geometric factor is applied to account for the fact that the filler aggregate structure could affect the stiffness strongly at high filler loading and represent initially the ratio of the length to the width of the filler aggregate. Typically, g is used as a fitting parameter and has a value between 4 and 10. According to 3D finite element simulations with randomly placed filler particles in polymers, the modulus enhancement of filled polymers can be well modeled by amplification of the first stretch invariant (31,32). The polynomial amplification factor employed for the stretch invariant is similar to the Guth-Gold model but with different prefactor for φ^2 term.

Although the modulus increases for polymers upon filler addition, the tensile strength and elongation to break values do not follow the same relationship. Tensile strengths of rigid polymers filled with rigid fillers, in general, decrease with increasing filler loading due to stress concentration effects. However, for some filled soft elastomers, tensile strength increases with an increase in filler concentration, up to an optimal concentration (33). Other factors that could affect the ultimate tensile properties are interfacial adhesion, particle size, and geometric shape. Large particles give rise to higher stress concentration, and thus lower tensile strength, than do smaller particles. It is for this reason that fillers used especially in elastomers are preferred to be smaller than micron size.

Rigid fillers, in general, cause a decrease in elongation to break since, proportionally, more of the experimental strain is being sustained by intrinsically less polymer. Additionally, the actual strain experienced by the polymer matrix is much higher than the applied strain around rigid fillers (34). For filler particles that have good adhesion with the polymer matrix, it was found that the elongation to break of the filled polymers, ε, follows (34,35)

$$\varepsilon = \varepsilon_s(1 - \varphi^{1/3}) \tag{6}$$

where ε_S is the elongation to break of the unfilled polymer. If there is poor adhesion between fillers and the polymer matrix, the decrease in elongation to break with increasing filler loading is more gradual than that calculated from equation 6. However, there are cases where fillers promote craze formation that give rise to an increase in elongation to break with filler addition (36).

Rigid fillers in a rigid polymer generally decrease the impact strength of a polymer (37). Impact strength in a filled polymer is largely determined by the dewetting and crazing phenomena. Typically, dewetting and cavitation at the poles of spherical particles during tensile loading of polymers occur first, followed by crack–craze formation at the equators of filler particles (38). Although debonding and crack formation lower the strengths in filled polymers, there are cases in which the actual fracture energy of brittle plastics, such as polyesters and epoxies, increase in the presence of fillers. It is believed that, in these cases, fillers can

impede crack growth (1). Additionally, rigid polymers filled with elastomeric particles could have high impact strengths if good interfacial adhesion exists between fillers and polymers (39).

Thermal Properties. Since polymers generally have a much larger thermal expansion coefficient than most rigid fillers, there is a significant mismatch in thermal expansion in a filled polymer. This mismatch could lead to generation of thermal stresses around filler particles during fabrication and, most severely, induce microcracks at the filler interface that could lead to premature failure of the filled polymer. As for the thermal expansion coefficient of a filled polymer, it generally falls below the value calculated from the simple rule of mixtures but follows the Kerner equation (40) for nearly spherical particles.

$$\alpha = \alpha_1\varphi_1 + \alpha_2\alpha_2 - (\alpha_1 - \alpha_2)\varphi_1\varphi_2(1/B_1 - 1/B_2)/(\varphi_1/B_2 + \varphi_2/B_1 + 3/4G) \tag{7}$$

The volume coefficients of thermal expansion of the composite, polymer, and filler are α, α_1, and α_2 respectively. The bulk moduli of the components are B_1 and B_2, respectively. The parameter G is the shear modulus of the polymer. The more the filler particles deviate from spherical, the greater the divergence of the thermal expansion coefficient from this equation. In such cases, the Thomas equation (41), or the logarithmic rule of mixtures, provides a better estimate.

$$\log \alpha = \varphi_1 \log \alpha_1 + \varphi_2 \log \alpha_2 \tag{8}$$

Polymers have lower thermal conductivity compared to metals and many inorganic materials (1). By the incorporation of metal or carbon fillers, a substantial increase in thermal conductivity can be obtained. Considering that thermal conductivities of filled polymers typically lie in between the limits set by rule of mixtures, Ziebland (42) proposed the use of the arbitrary relationship:

$$\log k = \varphi_1 \log k_1 + \varphi_2 \log k_2 \tag{9}$$

where k and k_1 are the thermal conductivities of the composite and polymer, respectively. The parameter k_2 is the hypothetical thermal conductivity of the particulate filler and it is determined from a one-point solution based on a single reading on the filled polymer of known composition. It is noted that this equation is similar to that of the Thomas equation for thermal expansion coefficient.

The melting temperature of a crystalline polymer is largely unaffected by the presence of fillers, whereas the glass transition temperature of a polymer is slightly raised by fillers. But the increase in heat distortion temperature in the presence of fillers could be quite substantial, often by as much as 10–20°C or more. In general, fillers raise the heat distortion temperature of a material by the increase in modulus and the reduction in high temperature creep of a material in the presence of fillers (43–45).

Optical Properties. The use of fillers has indirect effect, or direct in the case of pigments, on the optical properties of polymers. The light transmissivity in a filled polymer is controlled primarily by light scattering, which in turn depends on the differences in refractive indexes between the polymer and filler. A filler with a refractive index near to that of the polymer, such as silica in polyester, can

provide a translucent filled polymer. If the filler is optically anisotropic, such as calcite and talc, the corresponding filled polymers may appear in color under the polarized light or by optical interference. When the filler particle size is smaller than the wavelength of the light, $<0.4\ \mu$m, the filled polymer becomes transparent, which is one reason for the interest in using nanofillers.

Permeability. High aspect-ratio plate-like fillers can drastically lower the diffusivity or permeability of gases in solid polymers. Experimentally, it has been demonstrated that the barrier properties of a polymer could be significantly improved with just a few percent of exfoliated high aspect-ratio silicate fillers (46–49). Without considering the possible changes in the local permeability values due to molecular-level transformation by the presence of silicates, this permeability reduction simply arises from the increase in diffusion path lengths. Since molecules are now required to make long detours around the platelets, Nielsen (4) developed a simple model to determine the reduction in permeability in a polymer by accounting for the increase in torturosity with impermeable and planarly oriented platy fillers.

$$P/P_s = (1-\varphi)/(1+a\varphi/2) \tag{10}$$

Here, P is the permeability, P_s is the permeability of the polymer without fillers, φ is the filler volume fraction, and a is the aspect ratio. Cussler and coworkers (50) and Fredrickson and Bicerano (51) provided further refinements of the model by removing the position order but with perfect orientation. Recently, Gusev and Lusti (52) conducted direct 3D finite-element permeability calculations with a multiinclusion computer model comprising of randomly dispersed, perfectly oriented, and nonoverlapping platelets. They found all their numerical simulated permeability values could be well represented with a stretched exponential function as

$$P/P_s = \exp[-(a\varphi/3.47)^{0.71}] \tag{11}$$

This Gusev and Lusti equation, despite its empirical nature, has been demonstrated to model excellently the literature data for nylon-layered silicate nanocomposites.

Filler Types

Mineral Fillers. Mineral fillers (21,53) are naturally occurring materials that are mined and are ground to a specified particle size. Grinding may be done dry using mechanical mills. For a finer product the ore is ground wet. Wet grinding may be autogenous where the ore grinds by attrition with itself or a grinding media may be employed. Additional processing may include a combination of steps. They include (*1*) separation of fine and coarse particles by use of screens, by air- or water flotation, or by centrifugal filtration; (*2*) removal of impurities by washing, heat treatment, magnetic separation, or chemical treatment; and/or (*3*) surface treatment with a variety of chemicals to improve the compatibility with the polymer matrix.

Calcium carbonate ($CaCO_3$), also known as whiting, limestone, marble, chalk, or calcite, that has been ground is added to polymer compounds to reduce cost and to impart hardness and opacity to polymer articles. Particle sizes range from 2 to 80 μm for dry-ground product and from 0.5 to 11 μm for wet-ground product. The chemical composition and crystalline nature depend on the limestone deposit that is mined, eg, chalk or marble, and the color of the deposit. The most important applications of calcium carbonate by the polymer industry are uses in electrical wire and cable insulation, where the low moisture content and natural insulating properties make it a preferred filler in the production of articles, where low cost and smooth surface appearance are desired, such as footwear; and in extruded hoses and automotive sealing parts. Typical calcium carbonate levels used in polymer compounds range from 20 to 300 phr.

Baryte is predominately barium sulfate ($BaSO_4$) that is available in particle sizes from 1 to 20 μm. It is used as a filler when a high specific gravity is required of the polymer article. Typical polymer loading levels are 25–100 phr for articles such as stoppers and seals.

Crystalline silica (SiO_2) from sand or quartz can be ground and used as a degrading or extending filler for low cost polymer articles. To minimize the health hazards of exposure to airborne crystalline silica, particle sizes are large, normally ranging from 2 to 20 μm. Naturally occurring silica (SiO_2) or dolomite is often referred to as diatomaceous earth since the primary deposits are the exoskeletons formed by diatoms that have extracted silicic acid from sea water and formed amorphous silica shells. Diatomaceous earth is usually very high in surface area because the shells retain the radial and/or rod-like structures of the living creature. The largest deposits are several million years old and have been partially converted to crystalline silica over time. Diatomaceous earth obtained from sedimentary rocks often contains up to 30% organic matter and inorganic impurities such as sand, clay, and soluble salts (54) requiring separation or treatment to remove crystalline content, which could represent a health hazard. Biogenic silica is used as a semireinforcing filler or as a solid carrier for liquid compounding ingredients.

Kaolin clay (55,56), also called kaolinite or China clay, is hydrous aluminum silicate [$Al_2Si_2O_5(OH)_4$] consisting of platelets with alternating layers of silica and alumina in the structure. The fine particles of clay are formed by the weathering of granite. Clay deposits are classified as primary, secondary, and tertiary. Primary deposits are mixtures of clay and granite that are found where the clay was originally weathered. They contain only 40–50% particles <2 μm in diameter. Secondary deposits are formed when fine particles from primary deposits are carried by water flow and are deposited in a new location. Tertiary deposits are the most important commercial deposits because of their fine particle size with $>80\%$ of the particles being <2 μm in diameter. Their high purity results when water carries the fine particles of a secondary deposit to a new location. The most significant deposits of tertiary clay in the world are found in the southeastern United States, Cornwall, United Kingdom, the Amazon region of Brazil, and Australia. Clay is broadly divided into soft and hard clay in that they produce softer and harder polymer compounds, respectively, at a given loading level. Because clay is mined as a fine particle-size material, it does not require significant grinding for use in polymers. There are five basic processes for producing clay for polymer

reinforcement from the mined form. (*1*) Air-floated clay, in which the ore is milled to break up lumps and air classified, is the least expensive form of clay and imparts moderate reinforcement. (*2*) Water-washed clay involves gravity separation of impurities, bleaching, magnetic separation to improve color properties, and centrifuging to produce the desired particle-size range to impart higher reinforcement by the control of pH, color, and particle size. (*3*) Delaminated kaolin uses chemical and/or mechanical means to break apart the platelet structure of the clay, which further increases the available surface area and reinforcement properties. (*4*) Metakaolin is partially calcined by heat treating to 600°C. (*5*) Calcined clay is formed by heating to 1000°C, which produces a very white, high surface area mineral with an inert surface.

Clay is a widely used filler for polymer compounds of all types including components of tires such as fiber adhesive compounds, and the entire range of nontire polymer applications where good reinforcement, moderate cost, and good processability is desired. Clays are usually added to polymer compounds at levels of 20–150 phr. The aspect ratio of clay is between 4 and 12, with average particle size ranging from 0.5 to 2.3 μm.

Talc [$Mg_3Si_4O_{10}(OH)_2$] is a platelet form of magnesium silicate with a high aspect ratio, 5–20. Because the platelets can orient in the extrusion process, it provides polymer extrudates with smooth surfaces that can be extruded at high rates. It is commonly used in compounds, which have critical surface appearance such as exterior automotive components or consumer goods. Talc is used in tires in white sidewall compounds to provide a smooth appearance to the buffed sidewall. The large platelets of talc provide a barrier to gas and moisture permeability in compounds which allows talc to be used in applications such as hydraulic and automotive hoses, barrier films, and tire innerliners. Talc is usually used in addition to other fillers with total filler content of 30–150 phr. The average particle size of talc ranges from 5 to 8 μm.

Mica is a generic name given to a family of hydrous potassium aluminum silicates having similar physical properties. Mica is a common rock-forming mineral and is found around the world. Muscovite and phlogopite micas are most commonly used. Muscovite mica, $K_2Al_4(Al_2Si_6O_{20})(OH)_4$, has a layer structure composing of three planes and has an average particle size of 5 μm. The center is a pseudo-octahedral gibbsite plane that is chemically bonded to two tetrahedra silica planes. Phlogopite mica, $K_2(Mg, Fe)_6(Al_2Si_6O_{20})(OH,F)_4$, with the same structure as that for Muscovite mica, is opaque to ultraviolet (UV) radiation. Phlogopite mica has a particle size of 20 μm and has an aspect ratio from 30 to 100 similar to that of muscovite mica. The largest usage of mica is in polyolefins. The high aspect ratio of mica could provide enhancements in properties as stiffness, tensile strength, dimensional stability, and heat deflection temperature.

Nanoclays. Nanocomposites are materials that contain nanofillers, or fillers of nanometer dimensions. The successful synthesis of nylon–clay nanocomposites (57–59) ushered in nylon nanocomposites that could attain high modulus, heat distortion temperature, dimensional stability, impermeability, and strength with only a few percent modified clay nanofillers. Although it has been long known that polymers could be mixed with appropriately modified clay minerals and synthetic clays, the field of polymer-layered silicate nanocomposites has gained

tremendous momentum since the initial publications. The nylon–clay nanocomposites have since been commercialized and were utilized for automotive timing-belt covers and packaging barrier films (see NANOCOMPOSITES, POLYMER CLAY).

The layered silicates used in nylon–clay nanocomposites are 2:1 phyllosilicates with layers made up by fusing two silica tetrahedra to an edge-shared octahedral sheet of aluminum hydroxide. Isomorphic substitution within the layers, such as Al^{3+} replaced by Mg^{2+}, generates negative charges defined by the charge exchange capacity (CEC). Stacking of the layers leads to a gap between layers called the interlayer or gallery that is pristinely filled with exchangeable hydrated alkali metal cations to counterbalance these negative charges. Ion exchange of these alkali metal cations with various organic cations, such as alkyl ammonium cationic surfactants, could render the normally hydrophilic silicate surface hydrophobic. These layered silicates, or phyllosilicates, intercalated by organic cations are called organosilicates.

Commonly used 2:1 phyllosilicates include hectrite, saponite, montmorillonite, and synthetic mica. These silicates are stacks of layers of 1 nm in thickness and about 50 nm (hectrite), 170 nm (saponite), 200 nm (montmorillonite), and 1230 nm (synthetic mica) in length (60). In particular, naturally occurring montmorillonite with CEC ranging from 0.9 to 1.2 mequiv/g, depending on the mineral origin, is most frequently used and was the type employed in the initial nylon–clay nanocomposites. Organosilicates consisting of alkyl ammonium-exchanged montmorillonites are also commercial.

The nylon–clay nanocomposites were prepared by *in situ* polymerization in the presence of organically modified, with aminolauric acid, montmorillonite. The reaction between nylon monomer and modified montmorillonite rendered nylon chains end-tethered though aminolauric acid to the silicate surface leading to exfoliated silicates (61). However, not all polymer nanocomposite systems could be produced via *in situ* polymerization processes because of the chemical sensitivity of polymerization catalysts. Direct melt blending of hydrophilic polymers with montmorillonite in its pristine state or polymers with surfactant-intercalated montmorillonite was found to be possible to deliver polymer intercalated or exfoliated nanocomposites (62,63).

Commercial organosilicates based on montmorillonites are effective agglomerates of smaller, primary particles consisting of 10–20 layers in a coplanar orientation. Those primary particles are usually referred to as the tactoids. The first step of melt mixing is to break up the agglomerates of organosilicates to their primary particles through diffusion of polymer chains into the agglomerates. This, in turn, will provide fillers from micron in size with aspect ratios of about 1 to fillers of submicron, 0.1–0.2 μm, with aspect ratios of $\sim$20. The ultimate goal in melt mixing is to diffuse polymers into the silicate galleries to completely exfoliate organosilicates leading to fillers 1 nm thick with aspect ratios of $\sim$200.

Synthetic Fillers. Synthetic fillers are generally manufactured by precipitation of soluble materials under carefully controlled conditions to provide tailored properties. They may be found as colloidal particles that may be spherical, ellipsoid, rod, or tube-shaped; as aggregates which are covalently bonded groupings of individual particles; or as agglomerates that are loosely held associations of aggregates physically interacting. Reinforcement properties are a function of the colloidal particle size and shape, the aggregate dimensions and morphology,

and the ability of agglomerates to break down during mixing. Additionally, the composition and surface chemistry of the filler plays a significant role.

Precipitated calcium carbonate is formed by dissolving limestone and precipitating $CaCO_3$ as very fine particles using carbon dioxide (Aroganite Process) or sodium carbonate (Solvay Process). Typical particle sizes range from 0.02 to 2 μm. Most commercially available precipitated calcium carbonate is spherical colloidal particles or aggregates consisting of a few spherical particles. Additional shapes and aggregates of varying morphology are possible and provide increased reinforcement. Precipitated calcium carbonate is used as a semireinforcing filler in shoe products and industrial polymer goods, particularly when resistance to alkali solutions is needed. The low moisture content and good reinforcement allow precipitated calcium carbonate to be used in wire and cable insulation applications.

Zinc oxide, which is formed from the burning of zinc metal, was the first nonblack filler used for reinforcement of rubber compounds. Although zinc oxide and magnesium oxide are still used as reinforcing fillers in some specialty compounds, particularly those that require heat resistance, their role in rubber compounding in the last several decades is that of an activator for the sulfur cure system or as curatives for chloroprene rubber compounds.

The rutile form of titanium dioxide (TiO_2) is an important filler for white and colored polymer articles. The ability of the titanium dioxide particle to scatter light provides high whiteness and opacity to polymer, which gives the filler particle the ability to cover background colors. The anatase crystalline form of titanium dioxide is also used.

Alumina trihydrate ($Al_2O_3{\cdot}3H_2O$), ATH, is an intermediate mineral that is formed in the conversion of bauxite to aluminum. The major types of ATH are ground and precipitated. Alumina trihydrate is ground and classified using the same procedures as other minerals, and is available in particle sizes from <1 μm to several micrometers in diameter. Alumina trihydrate is used to provide flame-retardant properties to polymer articles and to suppress smoke formation. The water of hydration of the ATH crystal is released beginning at 230°C, which absorbs heat and provides water vapor to cool the polymer article and disperse smoke.

Amorphous silica (64) consists of ultimate particles of the inorganic polymer $(SiO_2)_n$ where a silicon atom is covalently bonded in a tetrahedral arrangement to four oxygen atoms. Each of the four oxygen atoms is covalently bonded to at least one silicon atom to form either a siloxane (—Si—O—Si—) or a silanol (—Si—O—H) functionality. Surface silanol groups can be isolated from one another such that hydrogen bonding between the silanols cannot occur, vicinal to one another promoting the formation of intramolecular hydrogen bonding, or geminal to one another where two silanol groups are bonded to the same silicon atom. Particulate silicas are made by precipitation from aqueous solution. The physical and chemical properties of precipitated silicas can vary according to the manufacturing process. Reinforcement and control of suspension pH, temperature, and salt content can vary the ultimate particle and aggregate sizes of silicas precipitated from solution. The surface area, as determined by nitrogen (16) or cetyltrimethylammonium bromide (CTAB) adsorption (65) is a function of the ultimate particle size. Ultimate particles can range from 5 to 50 nm in diameter. Aggregates are 3D clusters of ultimate particles covalently bonded to one another via siloxane bonds, and range in size up to 500 nm in diameter. Aggregates can physically

agglomerate through intermolecular hydrogen bonding of surface silanol groups of one aggregate to a silanol group of another aggregate affording structures up to ~100 μm in diameter. The median agglomerate particle size is generally 20–50 μm in diameter, but can be reduced in size by milling to ~1 μm. Precipitated silica is prepared from an alkaline metal silicate solution, such as sodium silicate in a ratio of ~2.5–3.3 SiO_2:Na, but using lower concentrations of silicate than is used in silica gel preparation (66). In the absence of a coagulant, silica is not precipitated from solution at any pH value (66). Silica is precipitated by adding acid to sodium silicate to reduce the pH value of the hot suspension to a pH value of 9 to 10, where the concentration of sodium ion exceeds approximately 0.3 *N*. Sulfuric acid is normally used to neutralize sodium silicate and precipitate silica.

Because of its small particle size and complex aggregate structure, precipitated silica imparts the highest degree of reinforcement to elastomer compounds among all of the nonblack particulate fillers. This superior reinforcement is employed in a variety of polymer compounds for shoe soles, industrial polymer goods, and tires (67–69). Precipitated silica is used in shoe soles for its resistance to wear and to tearing, its nonscuffing characteristics, and in order to obtain compounds with light color, or even a transparent material. Precipitated silica is used to improve the tear strength and resistance to flex fatigue (cracking, cut-growth) and heat aging in a wide variety of manufactured rubber goods including conveyor and power transmission belts, hoses, motor and dock mounts, and bumper pads. Rubber rolls that utilize the abrasion resistance, stiffness, and nonmarking characteristics of precipitated silica are important for use in paper processing and the dehulling of grains, particularly rice (70).

Amorphous pyrogenic or fumed silicas are generally less dense and of higher purity than silicas precipitated from solution. They are much less hydrated and are sometimes completely anhydrous, with the surface silanol group density ranging from 2 to 4/nm^2 of surface area. The $SiCl_4$ can be burned with methane (CH_4) or hydrogen (H_2) gases to produce SiO_2, H_2O, and HCl, an important commercial method (71). Particle size is controlled by combustion conditions during the flame hydrolysis. Pyrogenic silicas with surface areas <300 m^2/g are essentially nonporous, while those with higher surface areas can have some porosity. They generally contain a few hundred ultimate particles fused into branched-chain, 3D aggregates (71). Pyrogenic silicas in the 100–2000-nm particle size range are common (72). Pyrogenic silica is used in applications which require a low level of surface water per unit surface area of the silica, primarily as a reinforcement in adhesives, sealants (73), and elastomer compounds based on silicone polymers (74,75). They are used as a thixotropic agent, free flow, antistatic agent, carrier, coating additive, and antifoaming agent (76).

Amorphous silicates (77) are precipitated from aqueous blends of soluble silicate, typically sodium silicate, and soluble salts of other metals. The most important types for reinforcement of elastomers are aluminosilicates with mixed Al_2O_2 and SiO_2 structures, magnesium aluminosilicates, and calcium silicates. The silicates have surface areas and resultant reinforcement that span the range from the highest surface area clays (~30 m^2/g) to the lower end of the precipitated silicas (~100 m^2/g).

Nanoscale Oxides and Metals. Using vapor-phase plasma-based techniques, precipitation sol–gel reaction, or simple grinding, nanoscale metal oxides

are being produced in competition with existing fumed oxide products (78). On the basis of physical vapor synthesis methods developed in the 1980s, zinc oxide nanoparticles are produced for use as a sunscreen and fungicide in personal care and cosmetics products. Using a pulsed plasma process, nanometals, such as aluminum and silver nanoparticles, and nanoscale oxides, are being produced. Potential commerical markets for nanometals include aluminum nanoparticles in explosives and pyrotechnics and sliver nanoparticles in electronics and medicines.

Carbon Fillers. The application of carbon black (qv) in rubber compounds is over a hundred years old. Unlike the well-known crystalline forms of carbon, such as diamond and graphite, carbon black is amorphous and is a manufactured product (79,80). Carbon blacks are prepared by incomplete combustion of hydrocarbons or by thermal cracking. Presently, almost all rubber-reinforcing blacks are manufactured by the oil furnace process. A fuel is burned in an excess of air to produce finely divided carbon. Furnace blacks have low oxygen contents with neutral or alkaline surfaces. In the thermal process, oil or natural gas is cracked in an absence of oxygen to produce unoxidized blacks of small surface areas, or thermal blacks.

Many grades of carbon blacks are manufactured for various applications. These include blacks of higher surface area, different internal porosity, and higher surface oxidation. There are also electrical conductive blacks, such as acetylene black. The American Society of Testing Materials (ASTM) has established a carbon black classification system based on particle size and surface oxidation, ASTM D1765. The degree of surface oxidation affects the cure time of carbon-black–filled rubber compounds. The "N" denotes normal curing blacks and the "S" refers to slow curing blacks. After N or S, the first number of the three-digit suffix identifies the particle size and the remaining two digits are assigned arbitrarily. Specifications are given both in terms of analytical processes of characterizing the black and of resulting physical properties of carbon-black–filled rubbers prepared in standard recipes. In accordance to the designation, N550 black, for example, denotes a normal-curing carbon black with particle size in the range of 40–48 nm.

Carbon black owes its reinforcing character to the size, shape, and surface chemistry of the aggregate structures that consists of primary particles essentially spherical in shape that are chemically bonded to one another (80). The two most important properties of carbon black are surface area and structure. Surface area depends inversely upon the size of the primary particles and is one measure of the area available for physical interaction with the polymer. Surface area ranges from 10–140 m^2/g with thermal blacks having the lowest values based on nitrogen adsorption via ASTM D4820. The structure of carbon black depends on the size and grouping of these primary particles in the aggregate. The more primary particles in the aggregate, the higher structure of the carbon black due to the more complex shape and void volume (porosity). Structure varies from 35 to 130 $cm^{-3}/100$ g as measured by dibutylphthalate oil absorption via ASTM D2414. Surface activity refers to the strength of the carbon black/polymer interaction either from physical adsorption or chemisorption. The small (2–3%) but significant amount of noncarbon heteroatoms, such as hydrogen, oxygen, and sulfur, that are present on the carbon black surface results in surface activity differences. During mechanical mixing with polymers, it is desirable to minimize the presence of agglomerates.

Aggregate structures are not thought to be broken down into primary particles by simple mechanical processes.

Carbon blacks are extensively used in rubbers and elastomers, in loading from 10 to 150 phr, and for improvements in stiffness, strength, processability, and abrasion resistance (79). Particle size and concentration are optimized on the basis of balances in mixing–compounding, heat buildup, property improvement, and cost. Carbon black fillers, without considering the electrical conductive blacks, are used in plastics, predominantly as pigment or colorant.

Carbon Nanotubes. Carbon nanotubes are graphene cylinders end-capped with pentagonal rings. They were discovered in 1991 (81) during the arc-evaporation synthesis of fullerenes. The arc-evaporation method produces only multilayered tubes. Multiwalled nanotubes were first produced in 1983 before their structure was fully understood. These multiwalled nanotubes are sold in commercial quantities for electrostatic discharge control in polymers for electronic and automobile applications. Addition of metals to the graphite electrodes was found in 1993 (82) to synthesize single-layer–wall carbon nanotubes. An alternative method of preparing single-walled nanotubes was developed in 1996 (83) leading to the commercialization of single-walled carbon nanotubes, or buckytubes. Single-walled nanotubes have fewer defects and much improved performance compared to multiwalled tubes. The use of single-walled tubes in flat panel displays, conductive plastics, and high performance fibers are recent application developments.

Economic Aspects

Sales of fillers worldwide were estimated to be on the order of 10^6 t and $9 billion for 1990, with paint (42%), paper (21%), and plastics (16%) as the principal consumers on a dollar basis. When viewed on a volume basis, paint and paper are even at 37% each, plastics use 21%, and rubber 6%. Titanium dioxide represented 67% of the dollar volume, with 60% of its use in paint. The filler industry appeared to approach market saturation in 1998 (84) before the introduction of nanofillers. The nanomaterials business, at the present time, consists of three lines: nanoclays, nanoscale oxides and metals, and carbon nanotubes. The most established market now is nanoclays. The nanomaterials market is expected to increase by 12.8%/year, to $900 million by 2005 (85). The global market for coupling agents used in plastics grew at about 7% in 2001 and was expected to reach $300 million (86). The coupling agent market has three major categories: silanes, which make up ~85% of demand; organometallics acount for 10%; and maleated polyolefins have 5%.

Health and Safety

The principal hazard involved in the handling and use of many fillers is inhalation of airborne particles (dusts) in the respirable size range, ie, 10 μm and below. Filler dusts may be classified as nuisance particulates, fibrogens, and carcinogens. Nuisance particulates are dusts that have a long history of little adverse effect

on the lungs and do not produce significant organic disease or toxic effect when exposures are kept under reasonable control. The American Conference of Governmental and Industrial Hygienists (AC-GIH) establishes threshold limit values for the airborne concentration of many fillers in workroom air (87). A new manner of occupational and environmental legislation is aimed at the hazards of ultrafine particles, and OSHA regulations effective in 1992 regulate the total workplace, including nonproduction areas (88). In addition, concern for the toxicity of many metals and their compounds is limiting the use of many fillers, eg, Pb, Co, Cr, and Ba compounds, and possibly the use of certain organometallic surface coatings. Suppliers have information on proper usage and handling of their products. The use of National Institute for Occupational Safety and Health – Occupational Safety and Health Administration (NIOSH–OSHA)-approved dust masks or respirators is required when dust concentrations exceed permissable exposure limits. It has been reported that because of concerns by some international agencies over the possibility that crystalline silica might be a carcinogen, a 0.1% max silica (crystalline) specification has been mandated in mineral fillers (89).

FLAME RETARDANCY

Introduction

The retardants discussed herein are those believed to be in actual use or in advanced stage of development. Where no reference is cited, the information is principally from the manufacturers' literature.

The global usage of flame retardants was estimated in 2003 to be almost 1 million metric tons/year valued at $2.2 billion. On the basis of value, brominated materials comprise about 35–37%, chlorine (and chlorine–phosphorus) about 5%, nonhalogenated phosphorus about 25%, antimony oxide about 16%, alumina trihydrate about 11%, and others (melamines, magnesium hydroxide, borates, etc) about 6%. Both the entire industry and the brominated segment are growing at about 4% annually (1,2).

In terms of usage, the main applications are construction, electrical equipment, and motor vehicles. Other important areas are textiles, paper, and wood products.

Inorganic Flame Retardants

Inorganic phosphorus compounds are described in the section, commercial Phosphorus-Based Flame Retardants.

Oxides.

Alumina Trihydrate (Aluminum Hydroxide, Aluminum Trihydroxide, ATH)[21645-51-2]. On a weight basis, ATH is the largest flame retardant in current use http://www.manufacturing.net/pur/article/CA147910 (Nov. 1999). A review of ATH and other metal hydroxides and hydroxycarbonates is available (3). Much proprietary technology, involving either grinding (generally less costly) or precipitation achieves the desired particle size distribution, morphology, surface properties, and consistency (4–6). There are various surface-treated versions where the treatment (such as silanation) improves the miscibility or the mechanical properties of the final composition.

Major applications are vinyl and polyolefin cable jacket, unsaturated polyester resin (sanitary ware, counter tops), cast artificial stone, elastomers such as conveyer belts, and carpet backing. ATH tends to suppress smoke as well as flame. The mode of action is believed to be attributable mainly to endothermic dehydration at about 230°C with 34.5% weight loss of water by 350°C, consuming

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

1190 J/g of heat. This water loss acts to withdraw heat, which would otherwise serve to pyrolyze the polymer, and the resultant emission of water vapor also dilutes and cools combustible volatile fragments emitted from breakdown of the polymer. The residual anhydrous alumina also serves as a thermal barrier. Typical levels of addition are at least 50 parts by weight per 100 parts of polymer.

Magnesium Hydroxide[1309-42-8]. An estimated 8000 ton (value about $15 million) was used as flame and smoke suppressant in 2003. Its use appears to be growing more rapidly than ATH despite higher cost per pound (3,7,8). In contrast to ATH, magnesium hydroxide can be used in polymers with processing temperatures up to about 340°C, for example, in polypropylene or polyamides. It is also less abrasive than ATH.

The largest-volume uses are wire and cable, and increasingly in thermoplastic polyolefin roofing membranes (9). Grades in use range from the natural mineral brucite to tailored particle morphologies such as Kyowa's KISUMA. A typical less-specialized and inexpensive grade is Martin Marietta's MAGSHIELD, which can be used at up to about 330–340°C (8).

The mode of action is endothermic water release as in the case of ATH, but not starting until about 340°C completing itself with 30.9% weight loss and consuming 1300 J/g of heat by about 450°C. The residual MgO serves as a highly reflective thermal barrier. In some polymers, magnesium hydroxide favors charring to a greater degree than ATH (8).

The main disadvantage is the high loading required; for example about 60% $Mg(OH)_2$ is needed to reach V-0 in polypropylene. Some synergists have been found to lower this level somewhat (10). The stiffening effect is less detrimental in softer polymers such as polyolefin or ethylene vinyl acetate cable jacket or TPO roofing membranes.

Antimony Oxides. Antimony oxide is available both as the commodity antimony trioxide (Sb_2O_3) [1309-64-4], and various specialty products such as colloidal antimony pentoxide (Sb_2O_5) [1314-60-9] or sodium antimonate [15432-85-6]. There are also various proprietary combinations such as zinc/antimony oxide. Antimony oxides are not primary flame retardants but are important synergists for the halogen flame-retardant additives and halogen-containing plastics. Antimony trioxide is sold by Albemarle, Great Lakes Chemical, Anzon, Atofina, Campine, Harcros, Laurel, PQ, and others, and is largely supplied from China.

Antimony trioxide is a white powder, dusty unless oil-treated or pelletized. It remains solid at all polymer-processing temperatures. The synergism with halogen results from thermal formation of $SbCl_3$ or $SbBr_3$, which inhibit flame by scavenging hydrogen atoms and other radicals.

In contrast to antimony trioxide, which acts as a white pigment, the particle size of antimony pentoxide (colloidal), available as powders, dispersions, or polymer concentrates from Nyacol Nano Technologies, is small enough to cause minimal light scattering and thus able to produce translucent or transparent polymer formulations. It is more costly than antimony trioxide but this may be partially offset by lower loadings.

In acid-sensitive thermoplastic polyesters such as PET, PBT, or PC, sodium antimonate is advantageous since it avoids some undesired catalytic action of the oxide itself.

Borates.

Boric Acid [10043-35-3]. This powdered solid, sold by U.S. Borax and others, serves to prevent smoldering combustion of cotton batting (11), and is used in mattresses and furniture, where it is mixed in mechanically, its binding to the fibers aided by oil. Boric acid probably works by melting and coating the cellulose, although some vapor action is also likely.

Sodium Borates (11). These water-soluble salts, made by U.S. Borax and others, have been known since the eighteenth century as nondurable flame retardants for cotton, rope, canvas, and paper. The hydrated salts can act as endothermic heat sinks and moreover the salt fuses to a nonflammable glassy barrier layer. Sodium borates, in particular borax (sodium tetraborate decahydrate [1303-96-4]), are used in disposable paper and nonwoven cellulosic products, and as wood flame retardants where their water solubility can be tolerated. The borate salts are effective on flaming combustion but allow severe afterglow; they are best used in formulations with afterglow preventatives, and often used with boric acid.

Zinc Borates. These are usually used as hydrates, one of the most common being U.S. Borax's FIREBRAKE ZB, which is $2ZnO \cdot 3B_2O_3 \cdot 3.5H_2O$ [138265-88-0]. These hydrated salts have an endothermic action and also, at the elevated temperature of burning, they can flux with or sinter with other minerals such as alumina to form nonflammable barriers. For plastics processed at higher temperature, a lower hydrate FIREBRAKE 415, $4ZnO \cdot B_2O_3 \cdot H_2O$ [149749-62-2 or 1332-07-6] is used. A main use of zinc borates is as smoke suppressants and flame-retardant synergists in PVC or in other polymers with halogen additives. They can replace all or part of the usual antimony oxide synergist, often with the result that the smoke evolution during burning is lowered (12). The endothermic loss of water from these hydrates is a substantial part of their mode of action; in the case of PVC, they also induce dehydrochlorination at fire exposure temperatures.

Zinc borates, including the very thermally stable anhydrous $2ZnO \cdot 3B_2O_3$ [12767-90-7 or 1332-07-6], FIREBRAKE 500, have been found to act as synergists with magnesium hydroxide or aluminum trihydroxide in polyolefin and other thermoplastic formulations, by promoting char/ceramic barrier formation (13–15). Several other zinc borates are available from R. J. Marshall Co., Barium metaborate (Chapman Chemical's FLAMEBLOC 550), calcium borates, and magnesium borates are also used as flame retardants and smoke suppressants. These borates can serve also as anticorrosives and preservatives, especially in coatings.

Other Inorganics.

Molybdates. Calcium molybdates and zinc molybdates and various modifications thereof (15) are commercially available from Sherwin Williams as KEMGARDS, and are principally used in PVC as smoke suppressants (15).

Ammonium octamolybdate (AOM), $(NH_4)_4Mo_8O_{26}$ [12411-64-2], a slightly water-soluble crystalline salt, is a smoke suppressant for PVC (15). It is used in wire and cable, mass transit vehicle interiors, and carpet backing. It is believed to work by forming a barrier and by modifying the decomposition of the PVC.

Stannates. Zinc stannate [12036-37-2], Alcan's FLAMTARD S, and zinc hydroxystannate [12027-96-2], FLAMTARD HS, are both white water-insoluble powders useful as smoke suppressants in PVC. They can partly replace antimony oxide as flame-retardant synergists in halogen-containing flame-retardant formulations, with reduced smoke (16,17).

Zinc Sulfide [1314-98-3]. This stable white pigment shows synergistic flame-retardant action in PVC and can be partially substituted for antimony oxide. It can enhance other flame retardants in nylons and nylon blends (18).

Potassium Hexafluorozirconate [16923-95-8]. This water-soluble compound is a flame retardant for wool by the "Zirpro" process. Applied in combination with formic acid and citric acid, the fluorozirconate exhausts onto wool and after mild heating, provides a fairly wash-durable flame-retardant finish. Wool upholstery for aircraft makes use of this treatment (19).

Layered Clays ("Nanoclays") and Other Finely Divided Inorganic Additives. Layered clays such as montmorillonite or hectorite, when treated with substances which can penetrate between the layers, such as quaternary ammonium compounds, can be made to separate (exfoliate) into individual layers with nanometer thicknesses. At loadings of only a few percent in many polymers, physical properties such as modulus and heat deflection temperature may be improved. Moreover, the rate of heat release during burning as measured by cone calorimetry can be greatly reduced (20,21). Generally, this effect is not enough to pass typical flame retardancy requirements except in combination with some other flame retardant, and frequently faster ignition is an undesirable side-effect. However, commercially useful flame retardancy improvements with nanoclays in combination with, for example, alumina trihydrate, can be achieved in polyolefin cable (22). Synthetic platy silicates can be used in place of the montmorillonite (23). Besides the layered clays, some other finely divided minerals such as attapulgite, kaolinite, talc, or silica can have this beneficial effect, which may be related to heat-transfer- or mass-transfer-barrier formation or barrier strengthening in cooperation with char formation. In polycarbonates or polycarbonate blends, nanodimensioned titania or boehmite can be used in conjunction with other flame retardants (24).

At higher loadings, as are often used in elastomer formulations, nonlayered clays such as kaolin clays and attapulgite serve to impart flame retardance by dilution of the combustible material, and heat sink action enhanced by water loss if the clays are not calcined.

Expandable Graphite Flake. This product, which has long been known, is made by treating graphite flake with nitric and sulfuric acid, which intercalate between the graphite layers. It is available commercially from Graftech and Nyacol in the United States and from Asian manufacturers. When heated by fire exposure to above about 160°C, gases generated by the action of the oxidizing acids on the graphite cause the flakes to swell up greatly to form elongated twisted "wormlike" fibrils. This expanded material is an excellent heat insulator. Elastomeric polymers, such as flexible foams and coatings, putties, and firestop products can be flame retarded with expandable graphite, used by itself or compounded with other flame retardants.

Halogenated Flame Retardants

The products containing both halogen and phosphorus are discussed under Phosphorus. Brominated products have their own section because they are the largest category of flame retardants.

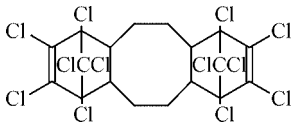
The mode of action of halogenated flame retardants is often described as proceeding with the production of hydrogen halide (or, in the presence of antimony oxide, antimony trihalide), which enters the flame zone and serves as a flame inhibitor. Part of this flame inhibition is generally believed to result from the scavenging of free hydrogen atoms, which are responsible for the rate-controlling chain branching steps in flame chemistry; however another part of the mode of action appears to be physical dilution, heat capacity, and endothermicity (25,26).

Chlorine-Containing Flame Retardants.

Chloroparaffins. These range from pourable liquids to waxes to rather high melting solids, depending on the chain length of the paraffin and the level of chlorination. The liquid lower chlorinated ones are mainly of interest in metal cutting formulations. Some highly chlorinated liquid chloroparaffins are used in PVC and elastomers to function as secondary plasticizers and as flame retardants. A wide range of chloroparaffins is available from Dover Chemical Co.

At or above 70% chlorine content, the materials are solids with softening temperatures from 103 to 160°C. These are useful as flame-retardant additives particularly for polyolefins, rubber, paints and adhesives. A typical formula for meeting UL 94 V-0 with polyethylene uses 20–24% chloroparaffin and 8–10% antimony oxide (27). Above the 13-carbon chain length, the toxicological characteristics of the long-chain chloroparaffins [63449-39-8] is very favorable.

Polycyclic Chlorohydrocarbon (DECHLORANE PLUS) [13560-89-9]. There is only one commercial additive flame retardant in this group, Oxychem's DECHLORANE PLUS, which is a polycyclic chlorohydrocarbon of the structure

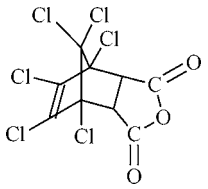


in which all of the chlorine atoms are so positioned that dehydrochlorination cannot readily occur. Thus, the molecule is thermally very stable.

It was originally developed for polyethylene and other polyolefins, and is still used to some extent in those applications, but its use in polyamide 6,6 has become more important.

DECHLORANE PLUS can be synergized by antimony oxide, but better results including lower smoke levels are achieved by use of some iron oxide as synergist or as cosynergist with antimony oxide (28).

Chlorendic Anhydride (HET Anhydride) [115-27-5]. This compound is the Diels–Alder adduct of hexachlorocyclopentadiene and maleic anhydride, having the following structure:



It has been used since the 1960s as a component of unsaturated polyester resins, where it imparts, besides flame retardancy, an enhanced degree of corrosion resistance (solvent resistance) and thus resins made from it are useful for industrial vessels and ducts.

Brominated Flame Retardants

This is the largest flame retardant category, in terms of economic value. At present, the leading US sources are Great Lakes Chemical Co. and Albemarle, both of whom have access to the warm bromine-rich brine found in Arkansas, and an Israeli producer, Dead Sea Bromine Group (DSBG), using the bromine-rich Dead Sea brine. Recently, these American producers have also begun to use bromine from the Dead Sea. Overviews of the usage of brominated flame retardants and the environmental aspects are available (29,30).

Additive Brominated Flame Retardants.

Hexabromocyclododecane [25637-99-4]. This product is a solid mixture (31,32) of stereoisomers, mp about 175–195°C. It is available from Great Lakes, Albemarle, and DSBG. The main application is in expanded polystyrene foam. It is generally used without antimony oxide, and allows for the melt-flow mode of extinguishment in addition to quenching the flame by evolved hydrogen bromide. It may be synergized with a small amount of a peroxide or other free-radical generator which probably work by degrading the polymer under fire-exposure conditions, thus aiding extinguishment by dripping. A heat-stabilized grade (32) can also be used in polypropylene to reach UL 94 V-2 ratings such as for building/construction applications in pipe, lamp sockets, and stadium seats. Hexabromocyclododecane is also useful in textile flame-retardant backcoating, in combination with antimony oxide and a binder. A recent review for the CPSC by a toxicology panel gave a favorable report to this use (33).

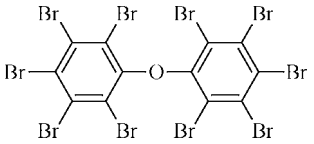
Pentabromodiphenyl Ether [32534-81-9]. This is a very viscous liquid or low melting solid, mp <30°C. It is made as Great Lakes Chemical's DE-71 by direct catalyzed bromination of diphenyl ether. It has been used in admixture with a triaryl phosphate as a flame retardant for flexible polyurethane slab-stock foam, the major advantage in that application being its stability and freedom from causing "scorch" (discoloration and deterioration of the foam at the peak temperature of water-initiated blowing). In this kind of mixture, it has been marketed as Akzo Nobel's FYROL PBR and Great Lakes Chemicals's DE-60(F) or DE-61.

In recent years, pentabromodiphenyl ether has been detected widely in the environment such as in marine animals and the milk of nursing mothers. In view of concern regarding possible chronic toxicity (34), it has been largely discontinued and the only US producer is halting production in 2004.

Octabromodiphenyl Ether[32536-52-0]. This is a solid melting in the range 70–150°C, comprising a mixture of several isomers of octa- with lower and higher brominated diphenyl ethers. It has been a preferred flame-retardant additive for ABS, polyamides, or PBT because it does not reduce the impact strength as badly as less soluble additives.

Recently (in 2003), the EU required that the use of this product be discontinued because of toxicological concerns. In 2003, it was banned in California (effective as of 2007) but its use has already declined.

Decabromodiphenyl Ether[1163-19-5]. This is the second largest brominated flame retardant, and is used in HIPS, textile backcoating, and in polyolefins, generally together with antimony oxide. It is made, as are the other members of this series, by bromination of diphenyl ether and is commercially available by Albemarle as SAYTEX 102, Great Lakes Chemical as DE-83, and Dead Sea Bromine (DSBG) as FR-1210. In view of the large volume and multiple producers, it is priced favorably. The structure is as follows:



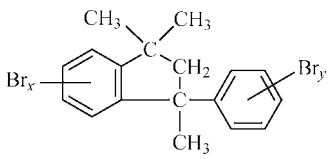
Decabromodiphenyl ether is a solid, melting at about 304–309°C, substantially insoluble in water, and with negligible vapor pressure. In contrast to the lower brominated diphenyl ethers, it has only rarely been found as an environmental pollutant and is low in toxicity. Risk studies conducted in the United States and the European Union (33,35) indicate a low degree of risk in the use of this flame retardant. It is the major flame retardant used in high impact polystyrene (HIPS) with antimony oxide, and has substantial use in polyolefin wire and cable as well as electrical parts made of other plastics such as polyamides and thermoplastic polyesters.

Tetradecabromodiphenoxybenzene [58965-66-5]. This product has an advantage for use in polyamide 6,6 because it has less tendency to "bloom" (to come to the surface) than decabromodiphenyl ether. It is available from Albemarle as SAYTEX 120.

1,2-Bis(2,4,6-tribromophenoxy)ethane [37853-59-1]. This product, mp 223–225°C, containing 70% Br, sold by Great Lakes as FIREMASTER 680, is used mainly in ABS where it appears compatible and has only a moderate tendency to bloom.

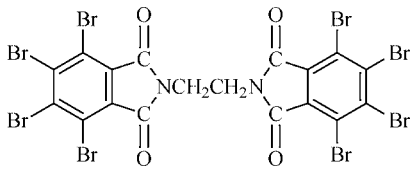
Decabromodiphenylethane (1,2-Bis[pentabromophenyl]ethane) [84852-53-9]. This solid additive, Albemarle SAYTEX 8010, is an alternative to the polybromodiphenyl ethers. It has 80% Br, a very high melting point (above 350°C), excellent thermal stability (good recyclability), fair UV stability, and gives performance similar to decabromodiphenyl ether in polyolefins and styrenics. An important use is in HIPS for TV and other electrical or electronic enclosures.

Octabromo-1-phenyl-1,3,3-trimethylindane [155613-93-7]. This is a solid 73% bromine additive, mp 240–255°C, produced by DSBG as FR-1808, which can also be substituted for decabromodiphenyl ether. The structure is as follows:



In styrenics, polyamide 6,6, and engineering thermoplastics, it is effective with antimony oxide and has good flow and impact properties even in filled formulations (36).

Ethylenebis(tetrabromophthalimide) [32588-76-4]. This is a high melting crystalline compound, mp 450–455°C, made from tetrabromophthalic anhydride and ethylenediamine. It is available from Albemarle as SAYTEX BT-93.



It has better sunlight stability than the polybrominated diphenyl ethers and thus can be used in nonyellowing polyolefins and styrenics. By removal of a small impurity, Albemarle has made available a grade SAYTEX BT-93W with even better color photostability.

Tris(2,4,6-tribromophenoxy)-1,3,5-triazine [25713-60-4]. This is a newer member of the bromine additive family made by DSBG as FR-245 from 2,4,6-tribromophenol and cyanuric chloride. It is a white solid, mp 230°C, containing 67% Br. It can be substituted for decabromodiphenyl ether in styrenics and their alloys, and has melt flow advantages (permitting shorter cycle times and thinner walls) as well as good impact and UV stability (36).

Tetrabromobisphenol A Bis(2,3-dibromopropyl) Ether [21850-44-2]. This is a rather low melting (∼95–111°C) colorless solid containing 68% bromine which is effective as an economical flame retardant in polypropylene, olefin copolymers, and HIPS. It is available from Albemarle as SAYTEX HP-800A, from DSBG as FR-720, and from Tosoh as FLAMECUT 121K. Principal uses are in wire and cable, and in electrical sockets to achieve a UL 94 V-2 rating.

Poly(2,6-dibromophenylene Oxide) [69882-11-7]. This is a light tan melt-processable solid, softening range 210–240°C, containing about 64% Br. It is used in unfilled and reinforced PBT and PET, and polyamides 6 and 66. It allows good chemical resistance and light stability. It is available from Great Lakes Chemical as PO-64P and from Unitex as UNIPLEX FRP-64.

Tetrabromobisphenol A Polycarbonate Oligomer (Tribromophenyl End Capped) [71342-77-3]. This is a thermally stable resinous solid made from tetrabromobisphenol A and phosgene. It is principally used as a flame-retardant additive for PBT, ABS, and polycarbonate for electrical and electronic apparatus housing. It is available from Great Lakes Chemical as BC-58.

Brominated Epoxy Oligomers (BEO) [68928-70-1] as Additives. The reaction of tetrabromobisphenol A with epichlorohydrin can be conducted in a ratio to make either diglycidyl ether or to make oligomers of reduced epoxy functionality, or end capped with tribromophenol to avoid functionality. These oligomers are mainly used as melt-blendable additives useful in many thermoplastics, notably in ABS, HIPS, and polyamides. Processing and UV stability advantages are often superior to those of decabromodiphenyl ether, and a good balance of properties is obtained for use in ABS in business machine applications (37). These

additives are available from DSBG and a similar series from Resolution Performance Products. The lower molecular weight members have enough epoxy functionality for use as reactives in epoxy, phenolic, and unsaturated polyester resins.

Brominated Polystyrenes. There are two main classes of brominated polystyrenes. The older class, suitable for the principal polyamides, is made by brominating a low molecular weight polystyrene, probably with bromine chloride or a mixture of bromine and chlorine. A version with 68% Br and improved thermal stability has been developed by Albemarle as SAYTEX HP-7010, particularly for glass-filled engineering resins (38). The other class of brominated polystyrenes, more thermally stable and preferred for use in higher temperature polyamides, is made from brominated styrene monomers. A further variant is a copolymer of dibromo- and tribromostyrene with some glycidyl methacrylate (Great Lakes FIREMASTER CP-44HF which improves melt flow, compatibility, and mechanical properties in engineering thermoplastics.

Bis(2-ethylhexyl) Tetrabromophthalate [20566-35-2][26040-51-7]. This liquid ester with plasticizing character and containing 45% Br is available from Great Lakes Chemical as DP-45, by Oxychem as PYRONYL 45, and by Unitex as UNIPLEX FRP-45. It is mainly used in PVC wire and cable insulation, coatings, and elastomers.

2-Ethylhexyl Tetrabromobenzoate [183658-27-7]. This liquid ester was recently introduced by Great Lakes Chemical as FIREMASTER BZ-54 mainly for use in combination with a triaryl phosphate as a nonscorching flame retardant for water-blown flexible polyurethane foam slab stock.

Poly(pentabromobenzyl acrylate) [59447-57-3]. This polymeric additive, DSBG's FR-1025, is melt-blendable with polyolefins, and at 8.5% in polypropylene produces a V-2-rated formulation. It is also useful in engineering thermoplastics such as PBT and polyamides.

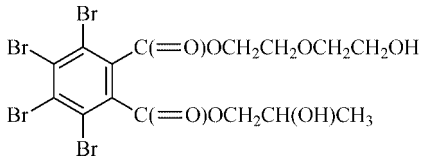
Disodium Tetrabromophthalate [25357-79-3]. This is a water-soluble salt, available as Great Lakes FR-756, used in nondurable textile flame-retardant finishing.

Reactive Bromine Compounds.

Tetrabromophthalic Anhydride [632-79-1]. This is a reactive aromatic bromine compound, available from Albemarle as SAYTEX RB-49 and from Great Lakes as PHT-4, with several diverse uses in flame retardancy. It can be reacted with diols and, generally, maleic anhydride to make polyesters, which are then diluted with styrene to produce flame-retardant unsaturated polyester resins suitable for panels and bulkheads in buildings and public transport.

Tetrabromophthalic anhydride can be reacted with ethylenediamine to make the bisphthalimide additive discussed above, and also converted to a diol, discussed below.

Hydroxethoxyethyl Hydroxypropyl Tetrabromophthalate [20566-35-2]. This diol, a viscous liquid, is available from Albemarle as SAYTEX RB-79 and from Great Lakes Chemical as PHT4-DIOL. It has the following main component:

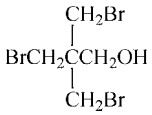


It is useful for the preparation of flame-retardant flexible or rigid polyurethane foams. In the foam applications, where it is often used as a blend with a triaryl phosphate such as in SAYTEX RB 7980 (higher hydroxyl number) or RX 8500 (lower hydroxyl number). Its advantage is that it allows flexible polyurethane foam to reach high temperatures in the water-blown foaming step without "scorch" (thermal damage).

More recently, a more reactive analog was introduced by Great Lakes Chemical as FIREMASTER 520. This probably has a hydroxyethyl group instead of hydroxypropyl.

Dibromoneopentyl Glycol [3296-90-0]. This diol, available from DSBG as FR-522, is made by reaction of pentaerythritol with hydrogen bromide. It is a crystalline compound, mp 109–110°C, and has been used in flame-retardant unsaturated polyester resins and polyurethane foams.

Tribromoneopentyl Alcohol [1522-92-5]. This is also made by DSBG as FR-513 by reaction of pentaerythritol with hydrogen bromide. It is a crystalline compound, mp 62-67°C, with the following structure:



It can be used by itself or more conveniently in a liquid mixture with a triaryl phosphate as a reactive for the preparation of nonscorching flexible polyurethane foams.

Another use for this alcohol is as a precursor of tris(tribromoneopentyl) phosphate, discussed below in the Phosphorus Flame Retardants section.

Tetrabromobisphenol A [79-94-7]. This compound, a solid, mp 179-181°C is the largest of the bromine-containing flame retardants. Tetrabromobisphenol A is available from Albemarle as SAYTEX CP-2000, Dead Sea Bromine as FR-1524, and Great Lakes Chemical as BA-59P.

The largest volume use is in epoxy circuit boards (printed wiring boards) to meet the FR-4 standard in electronic equipment (computers, printers, communication equipment). The usual mode of usage is as a "chain extender," wherein it is reacted with a nonhalogenated epoxy resin.

A related use is to produce the diglycidyl ether of tetrabromobisphenol A, which can be used as such in epoxy thermoset fabrication but is mainly reacted with methacrylic acid to make flame-retardant vinyl ester resins. These are useful for making fiber-reinforced corrosion resistant containers and ducts. The diglycidyl ether can also be chain extended with more tetrabromobisphenol A to make a family of, mainly, additives for thermoplastics.

Another important mode of usage of tetrabromobisphenol A is as an additive in styrenics, particularly in dark-pigmented ABS. It is typically used at 18–22% plus 4–8% antimony oxide. This application is favored by the low cost of tetrabromobisphenol A.

Pentabromobenzyl Acrylate[59447-55-1]. This monomer, available from DSBG as FR-1025M, can be used in reactive extrusion to graft onto polypropylene

and various other thermoplastics. Dyeable flame-retardant polypropylene fibers can be produced. The homopolymer is discussed under Additives.

Vinyl Bromide[593-60-2]. This low boiling monomer (bp 15.8°C) is mainly used for copolymerization with other vinyl monomers to make modacrylic fibers, for inherently flame-retardant textiles. Copolymers with vinyl chloride are also useful in flame-retardant coatings.

Commercial Phosphorus-Based Flame Retardants

Phosphorus compounds comprise, value-wise, the second largest group of flame retardants, and are probably the fastest growing segment as a result of environmental concerns with various bromine–antimony retardants. An earlier review is available (39).

Inorganic Phosphorus Compounds.

Red Phosphorus [7723-14-0]. This polymeric form of phosphorus is relatively nontoxic, not spontaneously flammable, and stable up to ~450°C. In finely divided, coated, and stabilized form it is available from Clariant, Rhodia, Italmatch, and Tosoh. It has been found to be a powerful flame-retardant additive (40) effective at relatively low loadings. In Europe, it is used in molded nylon electrical parts in a coated and stabilized form. Handling hazards and color have deterred usage in the United States. The development of masterbatches by Italmatch overcomes the flammable dust problem, but evolution of trace phosphine from reaction with water is still a concern (41).

Ammonium Phosphates. Monoammonium Phosphate [7722-76-1], $NH_4H_2PO_4$, and diammonium phosphate [7783-28-0], $(NH_4)_2HPO_4$ (or mixtures of the two), have long been used for low cost flame retarding and afterglow prevention of paper, textiles, disposable nonwoven cellulosic fabrics, and wood products (42–44). Ammonium phosphate finishes are resistant to dry-cleaning solvents but not to water.

Formulations of ammonium phosphates and ammonium bromide, sometimes with wetting and softening agents, are sold for use on cellulosic–synthetic fiber blends. A large-volume use in the United States for ammonium phosphate is in forest fire control, usually by aerial application and often combined with ammonium sulfate.

Water-soluble ammonium pyrophosphates and lower molecular weight (water-soluble) ammonium polyphosphates have uses on textile and paper similarly to ammonium phosphates but have less tendency to crystallize and to impair the texture.

Insoluble Ammonium Polyphosphate. When ammonium phosphates are heated in the presence of urea, relatively water-insoluble ammonium polyphosphate [68333-79-9] is produced (45) consisting of long chains of repeating —$OP(O)(ONH_4)$— units.There are several crystal forms (type II is the least-soluble), and the commercial products, available from a number of manufacturers, differ in molecular weight, particle size, solubility, and surface coating (46). These finely divided solids are principal ingredients of intumescent paint and mastics (47). In such formulations, ammonium polyphosphate is considered to function as a catalyst for charring an organic component such as pentaerythritol or an

aminoplast resin (48,49). A blowing agent such as melamine or chlorowax is also present to impart a foamed character to the char, thus forming a fire-resistant insulating barrier. In addition, the intumescent formulations typically contain resinous binders, pigments, ceramic components, and other fillers.

A series of compounded flame retardants, based on finely divided insoluble ammonium polyphosphate together with char-forming nitrogenous resins, has been developed for polyolefins, ethylene–vinyl acetate, and urethane elastomers (50–56). Ammonium polyphosphate is also an efficient flame retardant in rigid polyurethane foam, with minimal adverse effects on other foam properties (57).

Additive Organic Phosphorus Flame Retardants.

Melamine Phosphates and Other Amine Phosphates. Commercial products in this group include melamine orthophosphate [20208-95-1], $C_3H_6N_6 \cdot H_3O_4P$, and melamine pyrophosphate [15541-60-3], $2C_3H_6N_6 \cdot H_4O_7P_2$. The pyrophosphate, available from Cytec, Chemische Fabrik Budenheim, and Broadview Technology, is less water-soluble (0.09 g/100 mL water) and also more thermally stable. These are available as finely divided solids and used principally in flame-retardant coatings (58), although plastic and elastomer applications also show promise (59). A detailed study of the thermal decomposition of the these compounds has been published (60).

A more recent member of this family is melamine polyphosphate (MELAPUR 200, originally from DSM, now from Ciba), which has a thermal stability advantage for use in polyamide 6 and 66 (61) and in combination with char-assisting additives, in polyolefins such as those used for stadium seating.

Ethylenediamine Salt of Phosphoric Acid. This is a finely divided solid, mp 250°C, slightly soluble in water. It was introduced by Albright & Wilson as Amgard EDAP and is now available as Broadview Technology's INTUMAX AC-3, mainly as an additive for polyolefins, EVA, and PVC. Unlike ammonium polyphosphate, it is self-intumescent and does not require a char-forming synergist (62). It is synergized by melamine or melamine pyrophosphate, and is available as a blend with these, respectively from Unitex Corp. and Broadview Corp.

Triethyl Phosphate. Triethyl phosphate [78-40-0], $C_6H_{15}O_4P$, is a colorless liquid boiling at 209–218°C containing 17 wt% phosphorus, made by Eastman from diethyl ether and phosphorus pentoxide (63,64). Triethyl phosphate has been used commercially as an additive for polyester laminates and in cellulosics. In polyester resins, it functions as a viscosity depressant as well as a flame retardant, and permits high loadings of alumina trihydrate (65).

Dimethyl Methylphosphonate (DMMP) [756-79-6]. This is a water-soluble liquid, bp 185°C, with the formula $CH_3P(=O)(OCH_3)_2$, contains 25% phosphorus, which is near the maximum possible for a phosphorus ester, and therefore highly efficient as a flame retardant. It is sold by Akzo Nobel as FYROL DMMP. Applications include use as a viscosity depressant and flame retardant in alumina trihydrate (ATH)-filled polyester resins (66) such as used for bathtubs and shower stalls. Some applications have been found in rigid polyurethane foams and as an intermediate for making other flame retardants. In Europe, DMMP has an "R46" (mutagen) classification, which deters its use.

Diethyl Ethylphosphonate (DEEP) [78-38-6]. This is a liquid compound introduced by Bayer as LEVAGARD VP AC 4048 for applications similar to those

of DMMP. It is less susceptible to undesirable interactions with blowing agents or amine catalysts. It has a less toxic European rating than DMMP.

Dimethyl Propylphosphonate (DMPP) [18755-43-6]. This liquid additive was recently introduced by Bayer as LEVAGARD DMPP, an alternative to the chloroalkyl phosphates for flame-retarding rigid polyurethane foams.

Aluminum Diethylphosphinate. This solid additive, available in combination with a melamine or inorganic synergist as Clariant's EXOLIT OP 1311 and 1312, is a highly effective additive in polyamides, PBT, and epoxy (67–69).

Oligomeric Ethyl Phosphates. An oligomeric ethyl phosphate additive containing 19% phosphorus has been introduced for use in flexible polyurethane foams by Akzo Nobel as FYROL PNX. Because of the high percentage of phosphorus, it is quite efficient and as little as 5 php is effective in passing the California 117 test and MVSS 302 in a 1.5–1.8 lb/cu.ft. foam. For automotive applications, this low-volatility additive has the advantage of not causing windshield fogging. A lower viscosity version is available as FYROL PNX-S.

Halogenated Aliphatic Phosphates and Phosphonates. The principal use of these additives is in polyurethane foams; broader reviews of this important flame retardant application area have been published (70,71).

2-Chloroethanol Phosphate (3:1). Tris(2-chloroethyl) phosphate [115-96-8], $C_6H_{12}Cl_3O_4P$ [2-chloroethanol phosphate (3:1)], is a low viscosity liquid product that has found widespread usage because of low cost, low odor, high percentage of phosphorus, and compatibility with essentially all polymers containing polar groups. Akzo Nobel's FYROL CEF contains 10.8% phosphorus and 36.7% chlorine, and is made from ethylene oxide and phosphorus oxychloride (72). This phosphate is used in rigid polyurethane and polyisocyanurate foams, carpet backing, flame-laminated and rebonded flexible foam, flame-retardant coatings, most classes of thermosets, adhesives, cast acrylic sheet, and wood–resin composites such as particle board. It is used with melamine in flexible urethane foam cushions and institutional mattresses.

1-Chloro-2-Propanol Phosphate (3:1). Tris(1-chloro-2-propyl) phosphate [13674-84-5], $C_9H_{18}Cl_3O_4P$, is a liquid containing 33% chlorine and 9.5% phosphorus. It is produced by reaction of propylene oxide and phosphorus oxychloride. Because of the branchy structure, this phosphate is much lower in reactivity to water and bases than the 2-chloroethyl homologue (73). It is sold as Akzo Nobel's FYROL PCF, Bayer's LEVAGARD PP, or Albright & Wilson's (now Albemarle's) ANTIBLAZE 80 or TMCP and is a preferred additive for rigid urethane foams where good storage stability in the isocyanate or the polyol–catalyst mixture is required. It is used in isocyanurate foam to reduce friability and brittleness, and is also used on a large scale in flexible urethane foams, often with melamine.

1,3-Dichloro-2-Propanol Phosphate (3:1). Tris(1,3-dichloro-2-propyl) phosphate [13674-87-8], $C_9H_{15}Cl_6O_4P$, sold by Akzo Nobel as FYROL FR-2 and by Albright & Wilson (now Albemarle) as ANTIBLAZE 180 or 195, contains 49% chlorine and 7.2% phosphorus. It is made from epichlorohydrin and phosphorus oxychloride . The principal structure has 1,3-dichloro-2-propyl groups with a minor percentage of 2,3-dichloro-1-propyl groups.

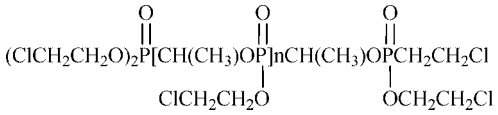
Compared to the foregoing chloroalkyl phosphates, this product has a greatly reduced volatility, much lower water solubility, and high stability toward the

amine catalysts used in foam manufacture. It is a long-established and a leading additive for flexible urethane foams (74) and can be added to the isocyanate or the polyol-catalyst mixture. This phosphate shows little tendency to scorch, ie to cause discoloration and degradation, except in some low density water-blown foams. Flexible foam formulations containing this and other haloalkyl phosphates can be further stabilized against scorch by appropriate antioxidants and acid acceptors (75–78). Scorch is believed to be aggravated if the flame retardant can alkylate an aminoaryl group resulting from hydrolysis of isocyanate (79).

Combinations of tris(dichloroisopropyl) phosphate or tris(1-chloro-2-propyl) phosphate with melamine are used in cushioning formulations and are effective for passing antismoldering requirements (80) as well as stringent British furniture standards. Tris(dichloroisopropyl) phosphate is also useful as a flame retardant in styrene–butadiene and acrylic lattices for textile backcoating and binding of nonwovens.

The mode of action of tris(dichloroisopropyl) phosphate in flexible polyurethane foams appears to be both physical and chemical (81).

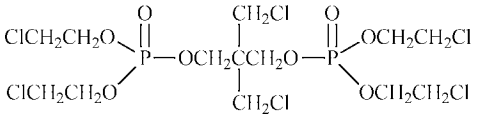
Oligomeric 2-Chloroethyl 1-Ethylidine Phosphonate. This is made from the reaction of tris(2- chloroethyl) phosphite with acetaldehyde, and has the following structure:



This liquid oligomer, Clariant's EXOLIT 5087, contains 27–28% Cl and 15% P, and is useful as an additive flame retardant for transparent cast polymethyl methacrylate, unsaturated polyester resins, or rigid polyurethane foams. It has good light stability, but is not stable to heat above about 180°C.

Aliphatic Diphosphates. These have low volatility and good to fair thermal stability, and are thus useful in those open-cell (flexible) foams which have requirements for improved resistance to dry and humid aging.

A diphosphate introduced originally as Monsanto's Phosgard 2XC20 [38051-10-4], $C_{13}H_{24}Cl_6O_8P_2$, is now available as Albemarle's) ANTIBLAZE 100 or V6. The compound has the following structure:



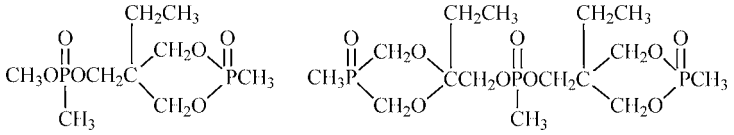
This compound has enhanced hydrolytic stability in addition to low volatility. It is useful in many types of flexible foam, as well as in adhesives and epoxy- or phenolic-based laminates.

Oligomeric 2-Chloroethyl Phosphate. Akzo Nobel's FYROL 99 [109640-81-5] (82,83) is low in volatility and useful in resin-impregnated air filters, in flexible urethane foam, rebonded foam, structural foam and flame-retardant coatings.

Tris(tribromoneopentyl) Phosphate [19186-97-1]. This solid, mp 181°C, compound has stable but highly efficient bromine. It can be used as an additive, with or without an antimony oxide synergist, in a wide range of thermoplastics including polypropylene and HIPS (84). It is particularly advantageous in polypropylene fiber, since it melts at the spinning temperature, does not require high loadings, and can be used without antimony oxide. It has good light stability and favorable toxicology. It is available from DSBG at FR-370 (special carpet fiber grade as FR-372) and from Unitex as BAP-370. It can be synergized to favor the melt-flow mode of extinguishment by small amounts of a hydrocarbon radical generator (Akzo Nobel's PERKADOX 30) (85).

Cycloaliphatic Phosphates and Phosphonates.

Oligomeric Cyclic Phosphonates. AMGARD CU or CT, also Clariant's EXOLIT OP 910, and AMGARD 1045 are mixtures of the diphosphonate and triphosphonate with the following structures ($C_9H_{20}O_6P_2$ [41203-81-0], and $C_{15}H_{31}O_9P_3$ [42595-49-9]).

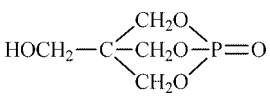


These are made via the bicyclic phosphite from trimethylolpropane subjected to the Arbuzov reaction with dimethyl methylphosphonate (86,87). The bicyclic phosphite intermediate is highly neurotoxic, but, after the ring-opening step, the product is low in toxicity. AMGARD CU (higher viscosity) or CT (lower viscosity) is largely the diphosphonate. AMGARD 1045 (high viscosity) contains a larger amount of the triphosphonate. Both materials are water-soluble, thermally stable low volatility liquids having about 20–21 % phosphorus content and no halogen. AMGARD CU or CT is used as a flame-retardant finish for polyester fabric by the "thermosol" process. After the phosphonate is applied from an aqueous solution, the fabric is heated to swell and soften the fibers, allowing the phosphonate to be absorbed and strongly held after the fabric cools. Many formulated polyester textile finishes are on the market based on this active ingredient.

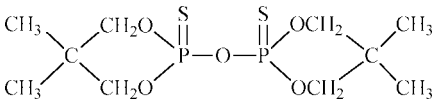
AMGARD 1045 can advantageously be added to polyethylene terephthalate melt before spinning. These products are also useful flame retardants for other thermoplastics, thermoset polyester resins, polyurethanes, polycarbonates, nylon 6, and textile backcoating.

Pentaerythritol Phosphates. These products take advantage of the excellent char-forming ability of the pentaerythritol structure (88).

A bicyclic pentaerythritol phosphate, Great Lakes CN-1197 or Unitex UNIPLEX FRX 44-33, [5301-78-0], was introduced for use in thermosets, preferably in combination with melamine or ammonium polyphosphate (89). It is a high melting solid with the following structure:

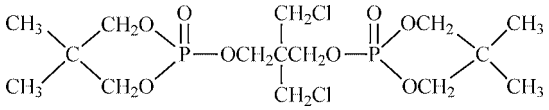


Cyclic Neopentyl Thiophosphoric Anhydride. This solid additive, SANDOFLAM 5060, was commercialized in Europe by Sandoz (sold now by Clariant as EXOLIT 5060) for use in viscose rayon (regenerated cellulose) (90,91). It is sold as an aqueous dispersion or wet filter cake, and has the following structure [4090-50-1]:



Despite the anhydride structure, it is remarkably stable, surviving addition to the highly alkaline viscose, the acidic coagulating bath, and also resisting multiple laundering of the rayon fabric. Typical levels of addition are 12–22%.

2,2-Bis(chloromethyl)propanediol Bis(cyclic neopentyl phosphate). This solid additive, originally commercialized by Sandoz (90,91), has been sold by Clariant as EXOLIT 5085 (VP). It has the following structure:



The neopentyl structure increases thermal stability, so that this compound is useful as a flame-retardant additive in extruded polymethyl methacrylate sheet.

Aryl Phosphates. Aryl phosphates were introduced into commercial use early in the twentieth century as plasticizers (qv) for flammable plastics such as cellulose nitrate and later for cellulose acetate and PVC (92). Principal applications are in wire and cable insulation, connectors, automotive interiors, vinyl moisture barriers, plastic greenhouses (Japan), furniture upholstery, conveyer belts (especially in mining), and vinyl foams (93).

In vinyls, the aryl phosphates are frequently used in combinations with phthalate plasticizers. The proportion of the more expensive phosphate is usually chosen so as to permit the product to reliably pass the flammability specifications. In plasticized vinyls used in automotive interiors, these phosphates are used to pass the Federal Motor Vehicle Safety Standard 302.

Triaryl phosphates are also used on a large scale as flame-retardant hydraulic fluids, lubricants, and lubricant additives. Smaller amounts are used as nonflammable dispersing media for peroxide catalysts.

Triaryl phosphates are produced from the corresponding phenols (usually mixtures) by reaction with phosphorus oxychloride, usually in the presence of a catalyst (94,95). Tricresyl phosphate was originally made from petroleum-derived or coal-tar-derived cresylic acids (cresols). Discovery of the neurotoxicity of the ortho-cresyl isomers led manufacturers to select cresols having very little ortho-isomer.

In the 1960–1980 period, the use of more economical synthetic isopropyl- and *t*-butylphenols as alternatives to cresols was developed (96,97). Commercial triaryl phosphates such as FMC's (now Great Lakes') KRONITEX 100 and Akzo Nobel's PHOSFLEX 31P and 41B are based on partially isopropylated or *t*-butylated

phenol. The relative volatilities and oxidative stabilities of these phosphates have been compared; the *t*-butylphenyl phosphates are the most oxidatively stable of the alkylphenyl phosphates (98).

Triphenyl Phosphate [115-86-6]. This is a colorless solid, mp 48–49°C, usually produced in the form of flakes or shipped in heated vessels as a liquid. It is available from Akzo Nobel as PHOSFLEX TPP. An early application was as a flame retardant for cellulose acetate safety film. It is also used in cellulose nitrate, various coatings, triacetate film and sheet, and rigid urethane foam. It has been used as a flame-retardant additive for engineering thermoplastics such as polyphenylene oxide–high impact polystyrene and ABS–polycarbonate blends.

Cresyl Diphenyl Phosphate [26444-49-5]. This is the most efficient plasticizer of the liquid phosphates, but it is relatively volatile. It is used, especially in Europe, in vinyls and in ABS–polycarbonate blends.

Tricresyl Phosphate [1330-78-5] and Trixylyl Phosphate [25155-23-1]. The commercial tricresyl phosphate has been for many years a mainly *m*,*p*-isomer mixture to avoid the neurotoxicity caused by the *o*-cresyl isomer. Typical products of this class are Akzo Nobel's LINDOL [1330-78-5], $C_{21}H_{21}O_4P$, or FMC's (now Great Lakes') KRONITEX TCP [68952-35-2]. These are nearly colorless liquids, bp about 260–275°C at 1.3 kPa (10 mm Hg). Tricresyl phosphate is used as a relatively flame-retardant plasticizer in flexible and semi-rigid PVC, cellulose nitrate, ethylcellulose coatings, and various rubbers. Typical applications are vinyl tarpaulins, mine conveyer belts, air ducts, wire and cable insulation, and vinyl films. Trixylenyl phosphate is a related product of lower volatility and less extractability, having advantages for wire and cable insulation.

Isopropylphenyl Diphenyl Phosphate [28108-99-8], [68937-41-7], [68782-95-6]. The plasticizer efficiency is close to that of tricresyl phosphate. It is made from the product of isopropylation of phenol by propylene. The phosphate is a mixture of mainly *o*- and *p*-isomers and contains a distribution of different levels of alkylation (99–101). It is sold by Akzo Nobel in the PHOSFLEX series and by Great Lakes in the REOFOS series. Main uses are in PVC and as a component of nonscorching or non-windshield-fogging formulations for flexible polyurethane foams (97a). There are also functional fluid applications outside the scope of this article.

tert-Butylphenyl Diphenyl Phosphate [56803-37-3], [68937-40-6]. This is a slightly less efficient plasticizer than the isopropyl homolog although in admixture with dialkyl phthalates the difference can be minimal and it can be used in such formulations as a PVC plasticizer with reduced flammability. It has been used as a flame retardant in engineering thermoplastics (102) and as a fire-retardant hydraulic fluid. The products from different manufacturers (Akzo, Great Lakes) are somewhat different in isomer distribution and alkylation levels.

Alkyl Diphenyl Phosphates. These are products originally developed to provide improved low temperature flexibility, a fault of triaryl phosphate plasticizers in PVC (103). These phosphates generally provide slightly less flame-retardant efficacy but are generally superior to the triaryl phosphates in regard to smoke when the vinyl formulation is burned. Two commercial products of this family are 2-ethylhexyl diphenyl phosphate [1241-94-7], $C_{20}H_{27}O_4P$, Ferro's SANTICIZER 141 or Akzo Nobel's PHOSFLEX 362, and isodecyl diphenyl phosphate [29761-21-5], $C_{22}H_{31}O_4P$, Ferro's SANTICIZER 148 or Akzo Nobel's PHOSFLEX 390. A

newer member of this group was introduced by Monsanto; it is believed to be a slightly higher alkyl chain length and has improved low temperature properties with reduced volatility (104).

Aromatic Diphosphates and Oligomeric Phosphates.

Tetraphenyl Resorcinol Diphosphate [57583-54-7]. This is the main component of an oligomeric phosphate flame retardant, Akzo Nobel's FYROLFLEX RDP or Great Lakes Chemical's REOFOS RDP, designed for use in engineering thermoplastics such as polyphenylene oxide blends (105,106), thermoplastic polyesters, polyamides, polycarbonates, and ABS–polycarbonate blends. A major use was in PPO–HIPS blends and later in ABS–polycarbonate blends (107). It is a colorless to light-yellow liquid, viscosity 400–800 mPa · s at 25°C, and a pour point of −12°C. It is less volatile than the triaryl phosphates and has a higher percentage of phosphorus (11% P) than triphenyl phosphate.

A closely related diphosphate with 2,6-dimethylphenyl groups is available from Daihachi (Japan), and has improved hydrolytic resistance but is higher in price.

Tetraphenyl Bisphenol-A Diphosphate [5945-33-5]. This is the main component of an oligomer, Akzo Nobel's FYROLFLEX BDP, Great Lakes' REOFOS BAPP, or Albemarle's NCendX P30, and is used for the same applications as the RDP discussed above. RDP and BDP are mainly the diphosphates with small amounts of the higher oligomers. Although BDP has a lower percentage of phosphorus (9%) than RDP (11%), it is lower in cost, and has a substantial hydrolytic stability advantage (108), a factor of particular importance for the application in polycarbonate–ABS blends.

Substantial development work has been done on other tetraaryl diphosphates and higher oligomers thereof, such as with aliphatic linking groups (109).

Reactive Organic Phosphorus Compounds.

Organophosphorus Monomers. Many vinyl monomers containing phosphorus have been described in the literature (110,111), but few have gone beyond the laboratory. Methacryloxyethyl acid phosphates are commercially available but appear to be used in coatings as adhesion improvers, not as flame retardants. Bis(2-chloroethyl) vinylphosphonate [115-98-0] and the corresponding acid are available from Rhodia but do not seem to have commercial use as flame retardants probably due to cost. These and related monomers have been reviewed and their copolymerization behavior has been studied (110,111).

Phosphorus-Containing Diols and Polyols. The commercial development of several phosphorus-containing diols occurred in response to the need to flame retard rigid urethane foam insulation used in transportation and construction. There are a large number of references to phosphorus polyols (112) but only a few of these have been used commercially.

Albright & Wilson's (now Albemarle's) VIRCOL 82 is a mixed diol mixture containing bis(hydroxypropyl) dibutyl propanediol diphosphates (113). The neutral liquid has an OH number of 205 mg KOH/g and contains 11.3% phosphorus. It is used in rigid foam.

Diethyl N,N-bis(2-hydroxyethyl)aminomethylphosphonate [2781-11-5]. Over several decades, commercial usage (limited by cost) has been made of this phosphonate diol (Akzo Nobel's FYROL 6, Bayer's LEVAGARD 4090N) (114), $(HOCH_2CH_2)_2NCH_2P(O)(OC_2H_5)_2$.

The product contains 12.6% phosphorus and has an OH number in the 450 mg KOH/g range. FYROL 6 is used to impart a permanent Class II E-84 flame-spread rating to rigid foam for insulating walls and roofs. Particular advantages are low viscosity, stability in polyol-catalyst mixtures, and outstanding humid aging resistance. FYROL 6 is used in spray foam, froth, pour-in-place, and slab stock. Its mode of action is believed to be increased char formation (115).

Oligomeric Ethyl Ethylene Phosphate Diol. This halogen-free phosphorus-containing diol was developed by Hoechst for rigid or flexible foams and is now marketed as EXOLIT 550 by Clariant (116). The product is a hydroxyethyl-terminated ethyl ethyleneglycol phosphate oligomer with about 17% phosphorus content and is said to be useful for rigid and flexible foams, especially molded or high density slabstock.

Oligomeric Phosphate—Phosphonate. A commercially used reactive oligomeric alcohol, Akzo Nobel's FYROL 51 [70715-06-9], is a mixture of methylphosphonate units and methyl phosphate units with mainly hydroxy end groups. A typical component has the structure as follows (110):

$$HOCH_2CH_2O[P(O)(CH_3)OCH_2CH_2O]_x[P(O)(OCH_3)OCH_2CH_2O]_yH$$

FYROL 51 is a water-soluble liquid containing about 21% phosphorus. The end groups are principally primary hydroxyl and the compound can thus be incorporated chemically into aminoplasts, phenolic resins, and polyurethanes. FYROL 51, or 58 (diluted) is used with amino resins to produce a flame-retardant resin finish on paper used for automotive air filters, or for backcoating of upholstery fabric to pass the British or California flammability standards. Under the trade name FYROLTEX HP (Akzo Nobel), it has been in development for cotton textile finishing, in combination with an amino resin (117).

Combinations with FYROL 6 permit the OH number to be adjusted to typical values used in flexible foam, urethane coating, or reaction injection molding (RIM) applications (118,119).

Reactive Organophosphorus Compounds in Textile Finishing. The flame retarding of cotton requires the application of a textile finish. Markets for finishes have been in military goods, industrial protective clothing, curtains, hospital goods, and children's sleepwear. An extensive review is available (120).

Tetrakis(hydroxymethyl)phosphonium Salts. The reaction of formaldehyde and phosphine in aqueous hydrochloric or sulfuric acid yields tetrakis-(hydroxymethyl)phosphonium chloride [124-62-1 or the sulfate [55566-30-8]. These are made by Rhodia, Cytex, and Chinese producers. The salts have the general structure $(HOCH_2)_4P^+X^-$. They are water-soluble crystalline compounds sold as concentrated aqueous solutions. The methylol groups are highly reactive (121–125) and capable of being cured on the fabric by reaction with ammonia or amino compounds and post-oxidized to form durable cross-linked phosphine oxide structures.

Finishes based on these reagents are durable to numerous launderings. This finish is primarily used on work clothing. This finishing process, developed by Albright & Wilson (now marketed by Rhodia), is known as the PROBAN process, which employs a precondensate of the phosphonium compound with urea (125, 126).

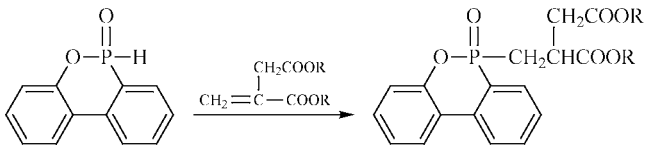
Dimethyl N-Methylolphosphonopropionamide or 3-([Hydroxymethyl]-Amino)-3-oxopropyl)Phosphonic Acid, Dimethyl Ester. This cotton finish, Ciba's PYROVATEX CP, was introduced by Geigy (later Ciba) in the 1970s especially for children's sleepwear and upholstery. It has the structure $(CH_3O)_2P(O)CH_2CH_2C(O)NHCH_2OH$ with some related compounds (127). The methylol group is the reactive part of the molecule. PYROVATEX CP coreacts on cellulose with an amino resin such as a methylolmelamine in the presence of a phosphoric acid catalyst or latent acid catalyst, to produce finishes durable to as many as 50 washes (128,129). A higher assay version, PYROVATEX CP New, has been introduced. An apparently similar product, PEKOFLAM DPN, is available from Clariant. This finish is practiced in Europe and the Far East but very little in North America. Recent efforts have been made to lower the formaldehyde emissions from this system (130).

Phosphorus-Containing Polymers as Textile Fibers. A large number of addition and condensation polymers having phosphorus built in have been described, but few have been commercialized (131). No general statement seems warranted regarding the efficacy of built-in vs additive phosphorus (132). However, in textile fibers, there is greater assurance of permanency.

Polyester Fibers Containing Phosphorus. Numerous patents describe poly(ethylene terephthalate) (PET) flame retarded with phosphorus-containing difunctional reactants. At least two of these appear to be commercial (see POLYESTERS, FIBERS).

Hoechst-Celanese's TREVIRA 271 (now practiced by KoSa) appears to be based on a cyclic phosphinic carboxylic anhydride [15171-48-9] which is reacted with glycol and then introduced into the PET backbone to produce a flame-retardant polyester [82690-14-0], having phosphinate units of the structure $-OP(O)(CH_3)CH_2CH_2COO-$ (133,134). FR TREVIRA 271 is used for children's sleepwear, work clothing, and home furnishings. A phosphorus content as low as 0.6% is reported to be sufficient to pass drapery and upholstery tests.

Toyobo's HEIM II (former GH) is apparently based on the following chemistry via a phosphinate intermediate dihydrooxaphosphaphenanthrene oxide (DOPO) [63562-31-2] produced from *o*-phenylphenol and phosphorus trichloride (135):



This dicarboxylic ester is then copolycondensed with the other reactants in PET manufacture to produce a flame-retardant polyester [63745-01-7]. The advantage of this rather unusual phosphinate structure is its high thermal and hydrolytic stability. The fabric is probably used mainly for furnishings in public buildings in Japan.

Phosphorus-Containing Printed Wiring Boards. This same phosphinate intermediate, dihydrooxaphosphaphenanthrene oxide (DOPO), is also the subject of substantial efforts in the Far East and Europe to react it into epoxy printed wiring boards and encapsulated electronic circuit elements as a

hypothetically "green" alternative to the established use of tetrabromobisphenol A (136). A number of other approaches to use of reacted-in phosphorus structures have been proposed and are in field trials at present (136).

Sulfur-Containing Flame Retardants

Ammonium Sulfate [7723-20-2]. This is a very inexpensive water-soluble salt used as a paper or wood flame retardant. In combination with ammonium phosphates, it is used in fighting forest fires from the air. In cellulosics, its acidity can cause discoloration and strength loss, so it is usually used in disposable items such as temporary decorations.

Ammonium Sulfamate [7773-06-0]. This salt is similar to ammonium sulfate but somewhat less acidic and corrosive. It is applied as an aqueous solution to paper or cellulosic fabric to obtain a flame retardant finish nondurable to washing. It has fairly good afterglow retardation.

Potassium Perfluorobutylsulfonate [29420-49-3] (3M's FR-2025), Potassium Diphenylsulfonesulfonate [63336-43-8] (Sloss Industries and Seal Sands, Ltd.), and Sodium Trichlorophenylsulfonate [53423-65-7] (Sloss Industries). These substantially neutral salts are used at levels below 1% as flame retardants in polycarbonate, often in combination with other retardants. These sulfonates permit clear formulations. At levels as low as 0.2%, the sulfonates accelerate carbon dioxide evolution and the breakdown of the polymer to phenolic fragments, thence to char (137).

Nitrogen-Based Flame Retardants

Melamine [108-78-1]. This inexpensive solid melts with vaporization at about 350°C and, if evaporation is constrained, decomposition also occurs to ammonia and nonvolatile condensation products—melam, melem, and eventually melone. It is occasionally used by itself as a flame retardant but more often used as a blowing agent and flame-retardant adjuvant in intumescent coatings, elastomers, and plastic formulations (138) as well as in flexible polyurethane foams (139,140).

Melamine Cyanurate [37640-57-6]. This 1:1 adduct (salt) of melamine and cyanuric acid, decomposition temperature ~413°C, is a leading flame retardant for unfilled polyamide 6, where it is typically used at 5–10% by weight, but it does not work very well in most glass-filled polyamide 6. It is also less efficient in polyamide 6,6. It is available from Ciba and several other producers. The mode of action has been studied (141–143).

Hindered Amine Ethers. This unusual new family of flame retardants (or synergists) was discovered by Ciba, which had been exploring the light stabilizer family of 2,2,6,6-tetramethylpiperidine derivatives (see UV STABILIZERS). The *N*-alkoxy or cycloalkoxy derivatives appear to have flame-retardant action particularly in polyolefins. One member of this group, where the *N*-cyclohexyloxy-2,2,6,6-tetramethylpiperidinyl group is attached to an oligomeric polymer chain, has been in market development as Ciba's NOR 116 (144).

Health, Safety and Environmental Aspects

Several factors should be considered: the toxicity of the compounds themselves, the effect of the flame retardants on combustion product toxicity and visible smoke, and environmental effects.

Broad Studies of Flame Retardants. Several broad studies of health, safety, and environmental factors of flame retardants have been published by public agencies. A critical review by a US government–appointed toxicology panel was conducted to facilitate CPSC regulations on flammability of furniture upholstery (145). The panel found ammonium polyphosphate, alumina trihydrate, zinc borate, hexabromocyclododecane, decabromodiphenyl ether (oxide), PYROVATEX CP, and THPC to be usable with minimum risk on residential furniture even with worst-case assumptions. Antimony trioxide, several organophosphates, chlorinated paraffins, and molybdate salts were said to need more exposure studies.

A study at the University of Surrey sponsored by the UK Department of Trade and Industry weighed health risks (toxicity and exposure) of a wide range of flame retardants *vs* their benefits (146). This study encompassed alumina trihydrate, antimony trioxide, decabromodiphenyl ether, tetrabromobisphenol A, and tris(chloroisopropyl) phosphate, and in general found that the benefits outweighed the risks.

An overview of the health, exposure, and environmental aspects of flame retardants was issued in 1997 by the International Programme on Chemical Safety of the World Health Organization, International Labor Organization, and UN Environment Programme (147).

Toxicity, exposure, and environmental data on many of the commercial flame retardants can be found conveniently in an Australian database (148), which is supplemented as new products are imported. Ongoing assessments of flame retardants in use, particularly the brominated ones, and possible alternatives are published by the Danish Environmental Department (149).

Comparative fire tests with a variety of flame-retarded items such as might be found in a typical room *vs* the same set of items without flame retardants have been run under the auspices of the National Institute of Standards and Technology. These tests showed that the room with the flame-retardant objects afforded 15-fold better escape time, lower material consumption, less heat, and less carbon monoxide (150).

A number of risk assessments are being done on flame retardants under EU auspices, and reasonably current status reports are available (151,152). Prioritization factors for the assessments, including tonnage, recognized aquatic hazards, bioamplification and persistence have been summarized as of 2004 (153).

Broad studies of the emissions of brominated and phosphorus flame retardants from consumer products and building materials show, as expected, that the more volatile ones such as tris(1-chloro-2-propyl) phosphate, triphenyl phosphate, and the brominated additives up to 6 bromine atoms are detectible in indoor air (154,155).

Organohalogens. Much attention has been directed to organohalogen products, in view of the legacy of environmental concern over such materials as DDT insecticide, PCB transformer fluid, and PBB (a flame retardant which in one incident contaminated cattle feed).

Some halogenated flame retardants, such as the polychlorinated polycyclic hydrocarbon DECHLORANE PLUS, have escaped adverse reports. Chloroparaffins have been found to be of toxicological concern at the low molecular weight end of the series (IARC 2B rating: possible carcinogen) but above C13, the chloroparaffins are rated as noncarcinogenic (156,157). Likewise, the aquatic toxicity favors the long-chain chloroparaffins.

Many workshops and conferences on the bromine compounds have been held under auspices of government/nongovernmental organizations and industry (examples: References 158–160). Concern has lately focused on the lower brominated diphenyl ethers (such as penta-) which are detected widely in the environment. In a review, Dutch researchers conclude that the toxicity mechanism of polybrominated diphenyl ethers is the same as that of the dioxins, and, although the present concentrations are not a large risk, these ethers are accumulative. Decabromodiphenyl oxide is less toxic than the less-brominated congeners, and its absorption from the gastrointestinal tract is low.

At the present time, pentabromodiphenyl ether and octabromodiphenyl ether have been judged by authorities in California and the European Union to have enough environmental presence and health risk to require a ban (161). Decabromodiphenyl ether, which is of large commercial importance as a flame retardant, seems much less of an environmental contamination problem, and its toxicology per se elicits less concern. However, its photolytic and biological debromination to lower brominated diphenyl ethers (162,163) is a factor which is being weighed by the EU and California authorities. A final decision as to its regulatory status is not available at the time of writing.

Risk analyses are underway (2004) in the European Union on hexabromocyclododecane.

Militating against a ban to include all of the polybrominated additives is the evidence that the high thermal and hydrolytic stability of decabromodiphenyl ether and related polyhalogenated flame retardants makes it feasible to recycle the flame-retarded plastics, which is more difficult with the halogen-free flame retardants (164). An overview, from an industry standpoint, of the effects of regulations on the bromine-containing flame retardants is available as of early 2004 (165). Recyclability of these plastics appears to provide an advantage.

Antimony Oxide. Antimony oxide is used very often as a synergist with halogenated flame retardants. There are some toxicological concerns about antimony oxide because of some equivocal carcinogenicity data, but, on balance, the risk is deemed acceptable (particularly since it is extremely water-insoluble and poorly bioavailable). It is still used in large amounts (166,167). A World Health Organization toxicology critique and drinking water guideline is available (2003) as a draft (168).

Phosphorus Flame Retardants. The original version of tricresyl phosphate was found in the 1930–1940 period to cause paralysis on ingestion as a food or liquor adulterant. However, as a result of basic studies, it was shown that the neurotoxicity characteristic was related to the *o*-cresyl isomer and the manufacturers thereafter have avoided using *o*-cresol to make triaryl phosphates (169). The newer isopropylphenyl and *t*-butylphenyl phosphates have little or no neurotoxicity (170).

The structure–toxicity relationships of organophosphorus compounds have been extensively researched and are relatively well understood (169–174).

A critical review of the toxicity of the haloalkyl phosphates and the potential metabolic products is available (175). The flame retardant "tris" (tris-2,3-dibromopropyl) phosphate was found to be mutagenic in laboratory tests; its production and use were discontinued in the 1970s. Tris(2-chloroethyl) phosphate and tris(dichloroisopropyl) phosphate have voluntary "R40" labels (limited evidence of carcinogenicity in animal tests). Tris(chloroisopropyl) phosphate does not require special classification. The chloroalkyl phosphates are undergoing (as of 2004) an EU risk assessment. They have been detected at various locales in municipal waste water (176), indoor dust, or indoor air (177,178).

Analytical data indicates the emission of trace vapors of triphenyl phosphate, which is controversially claimed to have some allergenic properties, from warm HIPS TV cabinetry (179). However, this emission results in air concentrations far below those which might be considered hazardous (180). The higher molecular weight diphosphates and oligomers appear to avoid toxicological problems (181).

Effect of Flame Retardants on Combustion Products. There appears to be no documented case of any type of fire retardant contributing to human fire casualties. There is ample evidence that carbon monoxide is the main acute toxicant in flames, although oxygen depletion and other toxic gases may contribute. This topic has been studied intensively (182–185).

It appears that in a large fire (which cause most of the casualties), the carbon monoxide yield and the overall smoke toxicity are almost independent of the material burning; this belief has had a dampening effect on combustion toxicology studies (186–188).

Although hydrogen halides (from halogen-containing plastics) are toxic, it is difficult to find cases of fire deaths attributable to them. Using quantitative assessment methods for the fire gases, the Federal Aviation Authority (189,190) model does not ascribe a heavy contribution by HCl and HBr compared to CO and HCN.

The concern about halogens in combustion often focuses on the formation, environmental contamination, and chronic (not acute) toxicity of halogenated dibenzodioxin ("dioxin") or halogenated dibenzofurans, particularly during disposal of halogen-containing plastics by incineration. Much study has been done on the dioxins by analytical chemists, toxicologists, and epidemiologists, a copious literature including books has been produced (191,192), and major international conferences are held annually (159) (A thorough overview of the chemistry, biochemistry, toxicology, environmental occurrence, and risk aspects can be found in Reference 193.). Some but not all authorities consider the dioxins to be carcinogenic; they may be cocarcinogens. The linkage of human health problems to incineration products is tenuous and the link to dioxins even more so. It has been shown that dioxins are produced by all chlorine- or bromine-containing fuels, and predate the era of plastics. EPA data shows that present-day government-approved incinerator–scrubber installations (waste-to-energy facilities) have reduced dioxin emissions to very low levels (194,195). Certain metal smelters such as Boliden in Sweden have also been found to handle halogen-containing waste with acceptably minimal dioxin emissions (165).

A survey of data from small-scale combustion or pyrolysis experiments revealed no consistent pattern of decrease or increase in the yields of toxic gases (CO, HCN) when phosphorus flame retardants were present (196). Experimental conditions (such as burning temperature) seem to dominate over the composition of the material being burned (197).

Effects on Visible Smoke. Smoke is a main impediment to egress from a burning building. In general, the halogen–antimony systems tend to increase the smoke yield relative to the mass burned, but when successful as retardants, they may reduce the total smoke by lessening the mass burned (198,199).

A comparative study of fire performance of halogenated and nonhalogenated cables discusses the smoke performance (200).

Chlorine–antimony systems or chlorine–bromine–antimony systems usually tend to be less smoky than bromine–antimony (201), and it is also possible to lower smoke in some plastics by use of further additives such as zinc borate, molybdates, or iron oxides. In general, the use of ATH or $Mg(OH)_2$ as part of the flame-retardant system results in lower smoke with most polymers (202,203).

Although some examples are known where specific phosphorus flame retardants increased visible smoke in small-scale tests, other instances are reported where the presence of the retardant reduced smoke. The effect appears to be a complex function of burning conditions and of other ingredients in the formulation (204,205). In one careful study, ammonium phosphate was found to raise or lower visible smoke from wood depending on the pyrolysis temperature (206). Where the phosphorus flame retardant functions by char enhancement, lower smoke levels are likely to be observed.

Environmental Considerations. The halogenated flame retardants differ greatly in environmental contamination. As mentioned already, pentabromodiphenyl ether has become widely dispersed, but decabromodiphenyl ether much less so due to its negligible solubility and vapor pressure. Antimony trioxide also is nonmigratory because of its very low solubility and negligible vapor pressure but nonetheless is under close scrutiny from the regulatory authorities (166,207).

The newer families of polymeric or oligomeric or reacted-in bromine, as well as very high molecular weight chlorine- or bromine-containing flame retardants are well designed to avoid migration and to be innocuous environmentally, since they have essentially no water solubility or vapor pressure.

The phosphate flame retardants have come under close environmental scrutiny. Results published to date on acute toxicity to aquatic algae, invertebrates, and fish indicate substantial differences between the various aryl phosphates (208–212). It has been found that the higher molecular weight phosphorus compounds are much better in terms of toxicity to aquatic organisms (213,214).

Tests in pure water, river water, and activated sludge showed that commercial triaryl phosphates and alkyl diphenyl phosphates undergo reasonably facile degradation by hydrolysis and biodegradation (215,216), the chloroalkyl phosphates less so.

Several risk–benefit analyses have favored the use of the flame retardants, since fire and smoke cause severe environmental injury besides the direct losses of life and property. For example, the polycyclic aromatic hydrocarbons which occur in copious amounts in soot have been indicated to be orders of magnitude more

serious than the dioxins, as was revealed in life-cycle assessments of TV sets (217) and furniture (218) with and without flame retardants. The fact that fire is, itself, a severe environmental pollutant, in the absence of a flame retardant, is reemphasized (219).

Nevertheless, environmental pressures continue to impact the flame retardant field, in some cases reinforced by "green" marketing strategies, "eco labels" and misleading generalizations about entire families of chemicals. These pressures have stimulated serious effort, some already successful, to find flame retardants less subject to criticism. Current research and development efforts are in the direction of halogen-free phosphorus compounds, inorganics, high molecular weight halogen compounds, polymeric additives, reactives, flame-retardant polymer modifications and blends.

FORENSIC ANALYSIS

Introduction

Sir Arthur Conan Doyle is believed by many to have first popularized the application of forensic analysis through his newspaper serials originally published in 1887 featuring the fictional character Sherlock Holmes. This work is thought to have inspired many of the early forensic scientists. One of these was Frenchman Edmond Locard, who proposed that when two objects come into contact with one another, a cross-transfer of evidence occurs (1,2). This is the basis of Locard's Exchange Principle and is the foundation of how we can often use physical evidence to link or at least associate a suspect to a crime scene or a victim. Depending on the nature of the evidence, a wide range of analytical methods are used in forensic casework.

A broad definition of the term *forensic*, according to *Webster's New World Dictionary*, is "suitable for a law court or public debate." With the application of forensic science, one must demonstrate in court that the evidence analyzed has relevance to the case in question. The significance of evidence related to a case is often determined by whether the physical evidence has individual or class characteristic properties. Individual characteristics are properties of evidence that can be attributed to a common source with an extremely high degree of certainty. Class characteristics are properties of evidence that can only be associated with a group and never with a single source. (3)

Fingerprint and DNA evidence are accepted as having individual characteristics. Fibers or copy toners, however, are identified by their class characteristics, and because of the large production of these materials, they cannot be

Encyclopedia of Polymer Science and Technology. Copyright John Wiley & Sons, Inc. All rights reserved.

individualized. The strength of fiber evidence depends on the likelihood of those type fibers being randomly found on the suspect. Common fibers such as blue or white cotton from jeans or shirts, respectively, have little evidential value. But, blue Nylon 6,6 fibers with an unusual cross section would have more significant value because there are fewer in existence. Forensic scientists have thoroughly developed statistical values for DNA and fingerprint data to demonstrate individual characteristics. Statistics are more difficult to apply to class evidence, but approaches to apply them are being investigated. The information obtained during polymer analysis is usually characteristic of classes of materials, but in some instances the identification of specific components and physical properties demonstrates an uncommon characteristic. If a contaminant found on an evidential material is identified as a rare substance specific to the crime scene, the evidence would demonstrate a high likelihood of originating from the crime scene. Therefore, forensic polymer analysis is used to identify chemical and physical properties that contribute in varying degrees to the evidential value in criminal forensic analysis.

Forensic science is a hybrid, applied science encompassing any of the natural, engineering, or medical sciences that may be used in analysis for the administration of criminal or civil justice. Criminalistics is a branch of forensic science. Although variously defined, it is generally thought of as utilizing the physical sciences, especially chemistry, physics, and biology to characterize, identify, compare, and individualize items of physical evidence. The forensic scientist may be a full-time employee of a municipal, state, federal, or private laboratory, or a specialist from an academic or industrial laboratory, who is called upon to conduct forensic examinations and provide expert testimony in courts of law.

A forensic scientist must not only possess expertise in an area of specialization, but must also be able to communicate with clarity, because of the importance of conveying accurate scientific results and their interpretation to the court. The forensic scientist, whose qualifications have been accepted by the court, is given the status of expert. This status allows the scientist/witness to offer opinions on the basis of reasonable scientific certainty—an option not allowed by lay witnesses. Because a person's property, reputation, and, very often, life may be at stake in a trial, a special burden of responsibility is placed on the scientist who testifies as an expert.

Polymers as Evidence

This article is concerned principally with the utilization of polymers as items of trace evidence. The small size of samples usually available makes their examination nonroutine. Methods such as tensile testing, fractography, and burning are rarely conducted on a microscale in forensic investigations. A significant part of the forensic examination of polymeric substances is concerned with factors other than those derived from the polymer itself. Criminalistics is distinguished from the other sciences by its unique attempt to individualize as opposed to most natural sciences, where the emphasis is on generalization and the establishment of laws that can be universally applied.

It has only recently become possible to identify microscopic polymer samples by spectroscopic and other instrumental methods. Even with this advantage, and

in spite of the many possible modifications in polymer composition, it is the trace components that serve to individualize these substances and distinguish them from their close relatives. The identification of low concentration additives makes polymer materials more specific, and therefore more evidentially important. However, when trace elements, resulting as random constituents of polymer starting materials and fillers, are identified and quantified, they can render the sample as unique. When crime scene material in question and a known material in the possession of a suspect are analytically identical to these random trace elements, a strong link is realized. This is an area that has not been significantly explored and is open to extensive research.

It is not only important to analyze the composition of a polymer, but to look for and identify subtle post-manufacturing changes that may have occurred. Changes resulting from mechanical or environmental effects can make a sample uniquely identifiable to its source.

Polymers are of interest to the forensic scientist for one or the following reasons:

Trace Evidence. Polymers may be crushed to powder, melted, left behind or carried away, burned, or broken. Particles—usually microscopic—of fibers, paint chips or smears, and rubber or plastic particles may be transferred to the clothing or environment of a suspect or victim. Evidence may also be in the form of soluble or dispersable polymers, such as gums, resins, adhesives, asphalts, etc.

Failures. Polymeric materials, like others, fail. Such failures are often studied as a result of civil liability litigation; however, they occasionally bear importance in criminal cases. Examples include the failure of a suture in an operation, peeling paint from a bridge or building, or failure of plastic parts in a prosthetic implant.

Burned Polymers. Most cases of this type are civil, but on occasion may arise in a criminal investigation. Examples include the flammability of various fabrics or plastics and their suitability for a particular use, determination of the quantity and identity of toxic gases that may have been given off by polymer products in a fire, and the determination of the fiber composition of a fabric after a fire.

Evidence Collection

Successful forensic trace evidence analysis is characterized by the ability to locate, collect, manipulate, identify, and compare microscopic particles. However, sample poverty is common in legal investigations. The sample size is frequently limited, and oftentimes only a portion of the sample can be used, pending the need for additional analysis. This places a further burden on the analyst, techniques, or instruments used. Accordingly, microscopy is the first choice for most forensic examinations.

Once particles of interest are located, they must be isolated for further study and analysis. This may be accomplished by handpicking with fine, pointed forceps

or sharpened tungsten needles while observing through a stereomicroscope. In some cases, the evidence may be collected with sticky, transparent tape. This collection method is not recommended for paint or lacquer particles because of the inevitable mixing of the polymeric evidence and adhesive. In other cases, vacuuming, washing, or scraping with a spatula are useful techniques. Criteria for choosing the proper collection method are given in the literature (4–6).

It is rare that an item of trace evidence can be completely examined *in situ*. Since the original location of the specimen is changed and at least a portion of the specimen is frequently altered in testing, photography at each step of the examination is recommended, and often required, particularly in civil cases. Equipment should be available for ordinary studio photography, macrophotography, and photomicrography. The recent widespread use of digital cameras has made recording images almost routine. These permanent records not only serve to document the course of the investigation, but also help to explain the examination to a jury in the courtroom or to enhance written reports. The value of such exhibits to help the court understand the process cannot be overemphasized. For example, a comparison color photomicrograph of polished cross sections of known and questioned multiple layered paint flakes from a hit-and-run accident offers the jury a visual presentation that is easier to understand than a statement that the paint chips have the same layer structure. Photographs showing the colors of the coat layers, especially a repainted vehicle, can show a vivid match of two compared paints.

Alphabetical/numerical designations are used to label evidence exhibits of known and suspect samples for comparison. In the example cited above, the questioned paint chips recovered from the victims clothing could be labeled "Q-1," and the street where the accident took place labeled "Q-2." Paint samples from the suspect vehicle would have a known origin and be designated with K-numbers, eg, K-1 "Paint from damage to the driver's side fender." This provided systematic references that are easily understood.

Analysis

In most cases, the analytical methods of the forensic chemist are different from those of the usual analytical, quality control, or materials chemists. The most important tests are usually those that lead to identification of the substances under examination. Tests, such as those found in compilations of standard methods of analysis, are rarely of use in the criminalistics laboratory, because they generally require more sample than is available and are usually intended to measure some quantitative aspect of a material. For forensic purposes, initially, a qualitative identification is more important than a quantitative determination. Before the analyst can compare or attempt to individualize a trace sample, it is essential that it be identified. Comparisons performed on traces that have not been accurately identified represent a *fault in principle* and may come back to haunt the scientist during cross-examination.

Microscopical methods are most commonly employed, because they allow the examination of minute specimens and are usually nondestructive. Table 1 describes many of the microscopes and instruments useful for the examination of polymer microtraces. Other equipment less frequently used, because larger

Table 1. Methods for Examining Minute Specimens

Methods	Uses	Refs.
Microscopical		
Stereo binocular		
May be equipped for reflected and transmitted light; a boom stand is a useful accessory for studying bulk objects, clothing, etc	Upright image and long-working distance are excellent for particle manipulation and preliminary examination	7
Comparison		
Two microscopes joined by an optical bridge so that images from both microscopes can be seen on either side of a fine dividing line in the same field of view	Comparison of hairs and fibers, paint chips, layer structure; physical matches	8,9
Polarizing (PLM)		
Standard petrographic microscope; the addition of tilting compensators and a hot stage are useful for the study of synthetic fibers	Essential for the identification of vegetable and synthetic fibers	10–12
Phase contrast and interference contrast	Qualitative systems allow image enhancement; qualitative interference systems permit the most accurate measurement of refractive indexes of synthetic fibers for patent work	12,13
Fluorescence	Autofluorescence can distinguish certain plastics and various layers of white house paints; optical brighteners can be detected on single fibers; fluorochromes can be used to detect substance such as polymer coatings on fibers	14
Scanning electron microscope (SEM)		
Useful alone but enhanced by energy dispersive X-ray analyzer (EDS) system	Of exceptional use in the study of fractures and failure of fibers; the elemental-analysis capability assists in identifying polymers containing characteristic elements, egg, silicone (Si), and neoprene (Cl)	15
Analytical electron microscopy (AEM)		
Transmission (TEM) and scanning transmission electron microscopy (STEM) coupled with elemental analysis and electron diffraction	Identification of phases in polymers, location of copolymers in blends, and identification of inorganic pigments and fillers	16

Table 1. (Continued)

Methods	Uses	Refs.
Micro-Fourier transform infrared spectroscopy (FT-IR)		
The addition of a microscope to an FT-IR, especially when coupled to a mecury cadmium telluried (MCT) detector, allows the collection of ir spectra on particles down to ~10 μm in size	The single most useful instrument for identifying microtraces of polymers of all types	17–20
Micro-Raman spectroscopy	Identification of polymers and pigments	21–23
Ultraviolet, visible, and fluorescence microspectrophotometry (MSP)	Comparison of questioned and known materials, especially fibers and paints, by their spectral characteristics	24
Electron microprobe analyzer		
A more dedicated elemental analyzer than the SEM, although the distinction between electron microprobes and SEM has lessened with time	Quantitative analysis of element in small particles; detects elements of low atomic number	25
Surface analytical		
Secondary ion mass spectrometry (SIMS)	Provides elemental and chemical analysis of surfaces; can reveal thin layers of corrosion of deposition	26
Auger spectroscopy		
Electron spectroscopy for chemical analysis (ESCA)		
Separation		
Pyrolysis gas chromatography (Py-GC)	Sensitive separation of components of polymer mixtures and blends; identification by mass spectra	27–29
Pyrolysis gas chromatography/mass spectrometry (Py-GC/MS)		
Thin-layer chromatography		
High performance liquid chromatography (HPLC)		

samples are required, include those used to perform other tests such as Instron testers, thermal analysis instruments (differential thermal analysis, differential scanning calorimetry, thermogravimetric analysis) and apparatiuses for determining molecular weights, such as size exclusion chromatography. Micromodifications of some of these instruments and techniques have been described and may have occasional significance in forensic investigations (30,31).

Separation methods such as thin layer chromatography (TLC) and pyrolysis-gas chromatography (Py-GC) are useful for comparison of questioned and known specimens when there is sufficient material and the destruction of the specimens is not an issue. In order to identify polymers and certain additives, numerous trace evidence examiners have established libraries of known Py-GC. Commercial

libraries of Py-GC chromatograms have not successfully been established, because analysts have difficulty on agreeing to standard GC conditions. Pyrolysis-gas chromatography/mass spectrometry (Py-GC/MS) can be used successfully to identify materials with commercial mass spectrometry libraries.

The nature of the specimen and the question that has been raised about it determine the course of action and the avenue of the analysis. After consideration of all known facts, and after nondestructive observations are completed, a particular test is selected in an attempt to answer a specific question. The results of this test determine the next step chosen. Some of the methods that may be employed for specific groups of polymers are discussed in the following sections. Microscopic and spectroscopic methods yield a great amount of information in the least amount of time, and, subsequently, are most frequently used by forensic trace examiners. Therefore, microscopy and spectroscopy are discussed in the greatest depth.

Microscopy. Visual light microscopes come in several optical configurations that are used for specific purposes. Low magnification *stereomicroscopes* (SMs) are of particular value in searching large areas for items of question and then separating them as potential evidence. The areas could include portions of garments to scan for foreign debris. Pill boxes of garment scrapings are scanned with SMs to seek potential fibers for comparisons. In addition, they are used for manipulation of the items that have been isolated to preparae toward more detailed microscopical or instrumental analysis. SMs are required in virtually any laboratory that examines micro-traces regardless of what other microscopes or instruments are employed.

The most useful microscope in the hands of a trained microscopist is the *polarizing light microscope* (PLM). Although considerable training and experience are necessary to fully utilize the capabilities of this microscope, a relatively short period of training can give a chemist the necessary skills to use the microscope to identify both natural and synthetic fibers. With minimal training, one can utilize morphological and optical properties to compare polymers regardless of their form or composition when received as items of trace evidence.

Additional microscopes include the *comparison microscope* that permits the microscopist to look at two specimens side by side. This is a useful early step in the comparison of two fibers or paint chips believed to have originated from the same source. The items can be observed and photographed side by side, permitting detailed scrutiny by both the forensic scientist and the court. Other light microscopes such as *fluorescence*, *hot stage*, *phase contrast*, and *interference* instruments may be of value in certain investigations, as shown in Table 1.

The scanning electron microscope (SEM) has some value to the forensic study of polymers, but it is principally the elemental information provided by an energy dispersive X-ray spectrometer (EDS) attached to most SEMs that usually gives the most information in forensic analyses. Using an EDS, the elemental composition of an isolated paint smear or fiber dye may be determined on even the smallest samples. The SEM provides high magnification images of the surfaces of materials. It is less useful for the examination of the interior of a particle of evidence. In this case, microtomed cross sections and freeze fractures can be used to look at interiors. A fairly recent and valuable application of the imaging capability of the SEM in the study of polymers is the examination of the ends of fibers to determine the cause of failure. Cutting with various instruments, crushing, breaking, etc, can

all be studied with the SEM and conclusions can be drawn by careful analysis of the images. Care must be taken, however, since all of the fibers in a multistrand cord or rope may not show the same characteristics as the fibers that initially failed. For example, some of the strands may have been cut with a knife under tension and the rest of the fibers (once there were too few to support the load) may have failed under tension. Other scanning microscopes, such as atomic force microscope (AFM), and instruments have yet to find significant forensic applications (see ATOMIC FORCE MICROSCOPY).

Spectroscopy. The ability to obtain spectroscopic information from microscopic samples has considerably increased the value of spectroscopy in the forensic study of microtraces. Vibrational Spectroscopy (qv) is applicable to a wide range of physical evidence. Polymeric materials, such as fibers, paints, and adhesive tapes, are frequently analyzed to identify characteristic information regarding the composition. Modern infrared and Raman spectrometers with microscopes attached are capable of obtaining chemical information from even the smallest samples. With the development of Fourier transform infrared (FT-IR) spectroscopy, the application of infrared to forensic analysis became more prevalent because of the increased speed and sensitivity of FT-IR. The development of diffuse reflection (DR) accessories provides ease of sample introduction for several forensic applications. Samples with matte-finished surfaces can be directly analyzed with no sample preparation, thus avoiding difficult pellet preparation by grinding the sample and subsequent mixing in potassium bromide. Internal reflectance spectroscopy (IRS), commonly referred to as attenuated total reflectance (ATR), has become widely used with a variety of recently developed accessories. Sample areas of less than one millimeter in diameter can be analyzed using single-reflection bench compartment accessories and diameters on the order of 10 μm can be analyzed with microscope attachments. Raman spectroscopy requires even less sample preparation than FT-IR, and artist's pigments are being identified today by their Raman spectra obtained directly from a painting without removal of sample material (32).

Applications, General Polymers

Because polymers are so common and vary so widely in composition, they are frequently found at crime scenes and subsequently play an evidentiary role in criminal cases. Polymeric materials, such as fibers, paints, and adhesive tapes, are frequently analyzed to identify characteristic information regarding their composition. Physical and chemical information on these materials is increasingly being stored in computer databases to help determine the manufacturer or supplier, or simply to discriminate between many similar samples of material. Some of the available databases will be described as a part of the analyses mentioned in the following pages. Other general polymeric materials found as evidence do not fall into a particular category and must be studied on a case-by-case basis without the aid of comparison to similar material in a database.

The following is a case example where a polymeric material became important evidence. Early one morning on a luxury cruise ship off the coast of California, a man reported to the captain that his wife had been blown overboard. Considering

the minimal wind conditions, the captain became suspicious and alerted the law enforcement authorities. Several hours after the overboard report, the woman's body was recovered by the U.S. Coast Guard. The clothing that both the man and woman were wearing at the time of the incident was forwarded to the FBI Laboratory. The woman's running pants appeared soiled with an orange substance on both legs. Careful examination of her pants with a stereomicroscope revealed orange colored, rubbery particles. Examination of the man's running pants also revealed rubbery particles that appeared identical. On the ship's deck, at the location of the overboard incident, there was an orange colored, rubberized running track. A portion of the track material was removed from the ship and forwarded to the laboratory for analysis. The particles were removed from both pairs of running pants and flattened in a compression cell to make them sufficiently thin to perform transmission analysis using an FT-IR microscope system. Particles from the track material were prepared in the same way and the spectra of all three samples were compared as shown in Figure 1.

The three spectra of the rubberized material compared closely. The material was heavily filled with calcite (hexagonal $CaCO_3$), identified by the intense, broad C—O asymmetric stretch near 1450 cm^{-1}, and narrow out-of-plane and in-plane bends near 880 and 710 cm^{-1}, respectively. To determine the force required to embed the particles in the pants, a fabric similar to that of the pants was rubbed across the removed track piece at different degrees of pressure. The investigators found that it was necessary to rub the fabric with significant pressure, such as in the case of dragging a person, to cause the transfer and embed the material in the fabric. They determined that the transfer of particles suggested an altercation

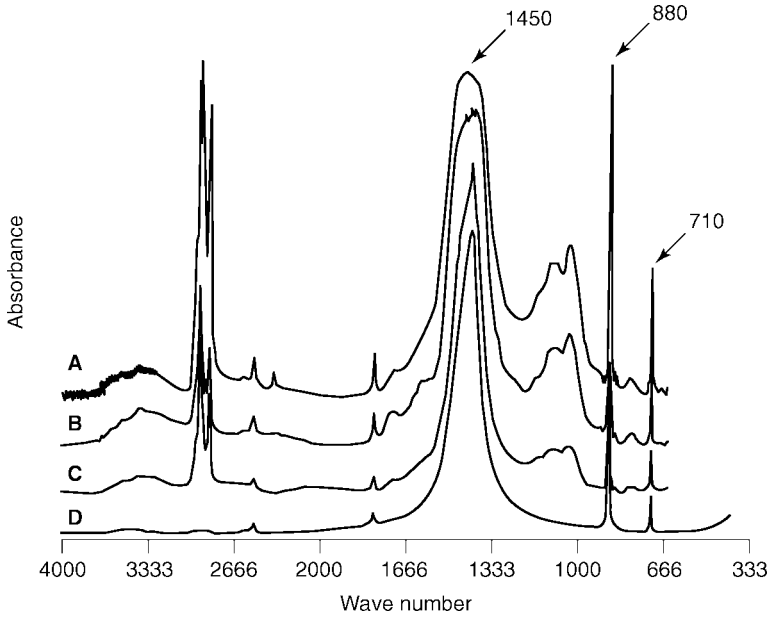

Fig. 1. Cruise ship homicide case. Spectra of rubber particle evidence from, sweat pants from both (**A**) victim and (**B**) the suspect, (**C**) running track and (**D**) calcite reference.

between the individuals, and, therefore, this evidence was heavily weighed and resulted in a homicide conviction. The combined comparison of evidential materials by microscopical examination, infrared analysis, and physical testing played a significant role in this case without witnesses.

Particles of plastic or rubber are often recovered from crime scenes or from victim's and suspect's clothing. Occasionally, these have forensic significance and must be identified and compared as described above. Rubber particles mounted on a microscope slide are recognizable because they can be compressed when pressure is applied to the coverslip with a needle, and recover fully when the pressure is released. Plastics are more easily recognized by an experienced eye by ruling out other types of particles. Particles of plastic are readily identified today by FT-IR analysis.

Plastics may provide evidence in determining passenger location with vehicles in serious accidents when questions arise as to who was driving when the accident occurred. This question is often answered by examination of hairs embedded in the dashboard, sun visor, etc. It has been shown that many thermoplastics can melt and transfer to clothing in the high energy environment that momentarily exists during a high impact collision. Molten plastic from clothing (eg, nylon jackets, cotton polyester shirts) can be collected from dashboards, airbags, and window pillars and identified. Colored polymers may sometimes be compared by light microscopy alone, but any comparison of unknown polymers should always be confirmed by FT-IR spectroscopy.

Fiber Applications

In cases of sexual assault and homicide, the transfer of single fibers often have important forensic significance. The case that most significantly impacted the realization of the importance of fiber evidence was the Atlanta murders that occurred between 1979 and 1981 (33,34). The bodies of 28 boys and young men were found under similar conditions. Although many of the bodies contained fiber and hair evidence that compared closely, Wayne Williams was prosecuted and convicted for only two of the homicides. The conviction was based solely on multiple transferred hairs and fibers with an emphasis on uncommon carpet fiber found in the bedroom of Williams's home.

In the forensic study of fibers, five questions are commonly asked:

(1) What is the polymeric composition of the fiber?
(2) Could the questioned fiber have the same source as the known?
(3) How was the fiber broken?
(4) Who manufactured the fiber or fabric?
(5) What is the commonality of the fiber?

The first question can almost always be answered by PLM, and often more specifically by FT-IR microspectroscopy, regardless of how little fiber is available. The other four may often be more difficult.

In fiber examinations, the analyst receives evidence fibers from a known source and fibers from a suspect source that must be compared to decide whether or not the questioned and known fibers could have a common origin. As part of this comparison, the fibers must be classified according to their generic type. The foremost method of analysis for this type of evidence is light microscopy; however, IR is often valuable to further specify fiber type. Fibers from the clothing of the victim and suspect are screened microscopically for similarity by closely comparing physical and optical properties of the fibers. Laboratories that collect fibrous evidence on clear tape now have the option of using fiber finders that automatically search for target fibers, which saves considerable time in complex cases involving many exhibits. The useful properties may vary significantly because of the color, shape, texture, and chemistry of the fibers. Polarized light microscopy is used to determine the generic classification (eg, nylon, polyester, acrylic) and FT-IR microspectroscopy plays an important role in identifying subclasses of synthetic and regenerated fibers. A spectral library of 83 polymeric fiber types, obtained by transmission spectroscopy on flattened single fibers, was developed to aid forensic examiners in the identification of fiber composition (35–37). IR spectroscopy is particularly useful for subclassifying acrylic fibers that are seen frequently as a wool alternative in sweaters. These fibers are readily transferred between individuals during contact. According to U.S. Federal Trade Commission rules, acrylic fibers must contain at least 85% polyacrylonitrile (38). The other 15% may be copolymers and ionic end groups that enhance the dying properties of the otherwise undyeable fibers. Figure 2 shows spectra of the three most common acrylic

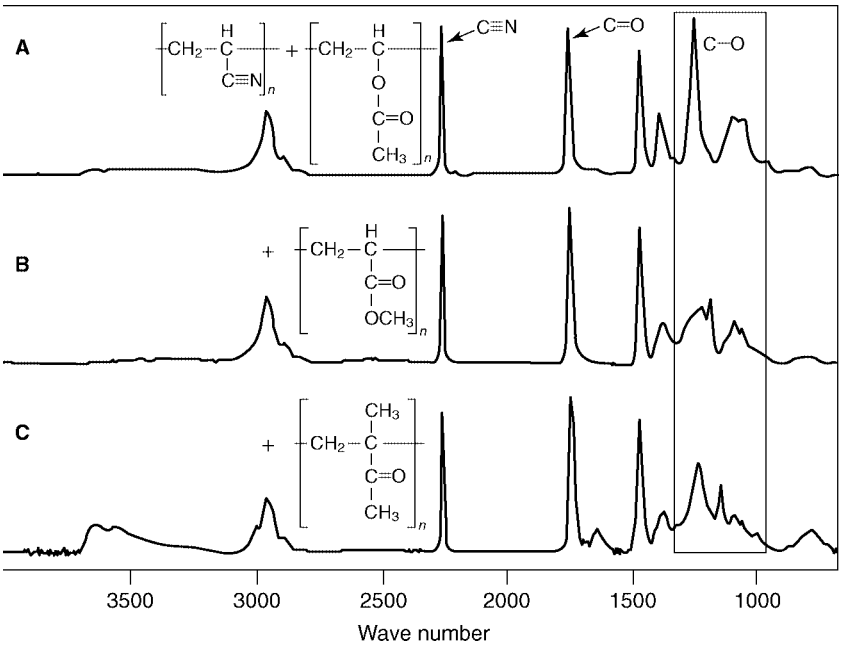

Fig. 2. IR spectra of acrylic copolymer fibers: (**A**) poly(acrylonitrile:vinyl acetate); (**B**) poly(acrylonitrile:methyl acrylate); and (**C**) poly(acrylonitrile:methyl methacrylate).

copolymers. The band shape of the C—O stretch, as shown in the region between 1300 and 1000 cm^{-1}, varies as a result of its position or environment within the different comonomer structures. Over 20 variations of acrylics can be identified by IR (39). Thus, IR is a very useful tool in providing information that further discriminates fiber types in order to enhance the evidential value of a sample.

Tests designed to distinguish the fibers from each other are used to complete a comparison. If the fibers cannot be distinguished at the conclusion of the tests, they are reported as nondistinguishable and it can be said that they may have a common origin. However, at best, fibers provide class-type evidence; they are not as individual as fingerprints or body fluids. It is not the number of tests that are performed, but the discriminating power of each test selected, as well as the independence of each test performed from the others, that determines the completeness of the examination and thus the strength of the conclusions that can be drawn. Table 2 lists various measurements and tests that can be performed on synthetic fibers. Most of the methods shown in Table 2 are applicable to regenerated fibers as well as synthetics. For identification of vegetable fibers (natural cellulose polymer), one must rely almost entirely on a detailed study of morphology for identification. Identification to the genus level of the plant from which the fibers originate is usually as far as a comparison can be taken. For example, having identified both known and questioned fibers as ramie (*Boehmeria nivea*), other tests of comparison are not possible (other than dyed or oiled cordage or rope), since the fibers consist of almost pure cellulose.

The optical and morphological properties of fibers are useful in comparisons when trying to determine possible end use and in manufacturer of the fiber. The optical properties of fibers include color (as well as pleochroism and fluorescence), refractive indices (parallel and perpendicular to the length of the fiber), birefringence (the numerical difference between the two refractive indices), and sign of elongation. The latter is determined by convention. A fiber is said to have a positive sign of elongation if the higher refractive index is parallel to the length of the fiber. The possibility of determining the manufacturer of a single fiber is nearly impossible in most cases. However, in some cases, where the fiber possessed a very characteristic property and manufacturers have given assistance, it has been done. In the Atlanta murder case the manufacturer of the carpet fibers from Williams's home was determined from the unique cross-sectional shape.

The solution of a child murder in Alaska was brought to a successful conclusion by a forensic examination of particles of polymeric trace evidence recovered from her body, which was found lying in a secluded area, not far from her home. These included short ($\sim$1 mm long), brittle red and blue polypropylene fibers and single layered particles of paint in a wide variety of colors. Iron spheres and fragments were also found on the victim's clothing. The girl was freshly dressed when she went off to meet her friend after school. There was no source of particles such as these in her normal environment. A suspect developed in the case had a workshop surrounded by nonfunctioning automobiles and trucks, and he often did repairs on children's bicycles.

It was possible to trace the manufacturer of the fibers by an examination of their cross sections, which were made with difficulty, because of their brittle nature. Infrared microspectroscopy revealed that the fibers were photo-oxidized on the basis of a significant carbonyl absorption band of $\sim$1730 cm^{-1}. The fibers were

Table 2. Fiber Comparison Techniques for Single Fibers and Fiber Fragments

Method	Measurement	Information
Comparison microscope	Side-by side viewing	Diameter, color, pigment, and/or delustrant density and distribution
Polarized light microscopy	Crystallographic properties: refractive indexes[a]	Fiber-identity differences in draw ratio, heat setting
	Sign of elongation	Distinguishes fibers with high bond polarization perpendicular to fiber axis, eg, acrylics
	Birefringence	Fiber identity (qualitative), draw ratio, and end use (quantitative)
Cross section	May be deduced to some extent by logitudinal view; most information is obtained from cut sections	Determination of fineness (tex or denier), modification ratio: can aid in manufacturer identification
Fluorescence microscopy	Autofluorescence	Blues and blue-whites indicate optical brighteners: other colors due to dyes
Microspectrophotometry	Visible spectrophotometry on a microscale	Dye comparison of dye components from known and questioned fibers
Thin-layer chromatography	Separation of dyes	Comparison of dye components from known and questioned fibers
Electron microprobe	Elemental composition	Identity of catalyst residue and elemental tags for comparison and manufacturing origin
Micro FT-IR and Raman	Polymer comparison	Recognition of coploymers in acrylics and modification to polyesters, etc
Thermal microscopy	Melting range	Distinguishes nylon; crystallinity differences

[a]The refractive indexes measured perpendicular ($\eta_{\text{perpendicular}}$) and parallel ($\eta_{\text{parallel}}$) to the length of the fiber. The isotropic refractive index (η_{iso}) is the refractive index the fiber would exhibit in the absence of orientation.

made by Phillip's Fibers and consultation with experts at the company suggested that, most likely, they originated from a "fake" oriental rug that had been left out-of-doors. This carpet, if it ever existed, was never found, but the fibers from the suspect's environment made their way onto the body of the victim.

Fibers identical in all respects to those found on the victim's body were discovered in the truck and workshop of the suspect. Single-layered paint chips in a wide variety of colors and metal particles and spheres were also found in the suspect's workshop. The finding of particles identical to those from the suspect's environment on the victim was a practical example of Locard's Exchange Principle. Since the girl did not have these particles on her clothing when she left the

house with fresh clothing and she did not move after she was murdered, the particles must have been associated with the environment of the murderer. The jury convicted the suspect of the child's murder.

Raman spectrometry promises to complement IR analysis of textile fibers because of the ease of sampling and the additional information it can provide. Light microscopy analysis requires fiber samples to be mounted in a liquid medium, under coverslips, on a glass slide. Because glass absorbs strongly in the IR, the fibers must be removed and cleaned prior to IR analysis. Raman analysis, on the other hand, has been successfully performed on single fibers while mounted on glass microscope slides (21), thus omitting the need to remove the fibers from the slide mount. The additional sample preparation time is not required and, once mounted, the chance of fiber loss is minimal. Figure 3 illustrates the process of obtaining a Nylon 6 fiber spectrum using microscopical Raman analysis. Figure 3**A** includes spectral contributions from the fiber, Permount mounting medium, and glass from the coverslip. Figure 3**B** shows the result of Permount subtracted from the original spectrum. The Nylon 6 spectrum that remains after the glass contributions are subtracted is shown in Figure 3**C**. The baseline is flattened for the final spectrum in Figure 3**D**. The signal-to-noise ratio is less than obtaining a spectrum without being mounted under a coverslip, but it is sufficient to identify the fiber by the prominent characteristic bands as labeled. The band assignments of the major peaks are labeled in accordance with Hendra and coworkers (40). Raman spectra differ from IR spectra, because the selection rules

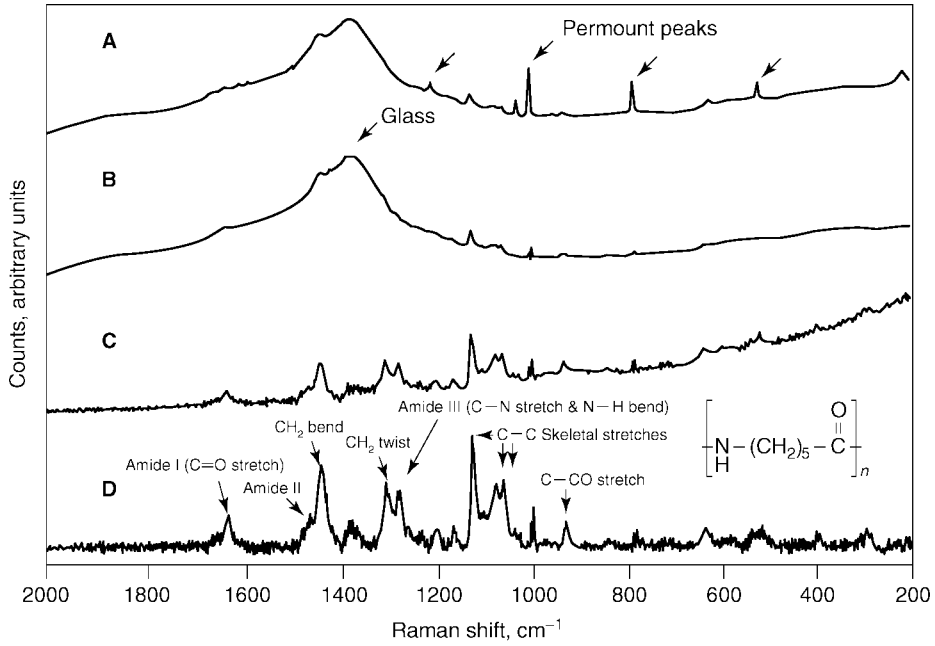

Fig. 3. Raman spectra of a nylon-6 fiber mounted under a coverslip on a glass microscope slide: (**A**) original spectrum; (**B**) Permount mounting medium subtracted; and (**C**) baseline flattened with the major characteristic bands labeled.

for Raman vary from that of IR, thereby producing complementary information. The information obtained by Raman is at times more definitive in determining the polymeric structure. Since Raman spectroscopy demonstrates spectral response from dyes, the dye information can be useful. However, the dye spectral features can interfere with identification of the polymeric composition of fibers. To further characterize the fibers, dye spectral features could provide information regarding the dye type. Studies have been conducted using surface enhanced Raman spectroscopy (SERS) to study dye composition using silver colloid substrates (41,42). While the spectral features are significantly enhanced by SERS, this method requires that the fibers are removed from the glass slides, resulting in an additional step and chance of fiber loss. Raman analysis has demonstrated certain advantages over IR, but the strengths and limitations of both are still under study to determine where each of the methods can be used to obtain the greatest information with the most convenient analysis procedure.

Paint

Paint evidence is usually submitted to the forensic scientist for comparison with paint from a known source. Automotive, architectural, art, marine, aircraft, tool, and other types of paints may become evidence in a variety of crime scenarios (43). Within the United States, most of these examinations involve automotive finishes as related to automotive accidents and hit-and-run cases. The question frequently posed is, what kind of vehicle could have contributed the paint flakes recovered from the scene of a hit-and-run homicide case? Additionally, house paints may be examined in connection with burglaries, and paint from tools in cases involving industrial sabotage. Rarely is it necessary to determine the manufacturer of a particular paint.

The examination proceeds differently, depending on whether the questioned evidence is in the form of flakes or a smear. Individual spray-paint spheres are occasionally encountered and treated in the same manner as individual particles from a smear. Table 3 summarizes the comparison methods employed.

After light microscopy, IR analysis offers the most information in forensic paint examinations. The organic binders are frequently identified by IR, and both organic and inorganic pigments can often be identified. Since the 1970s, scientists from the Royal Canadian Mounted Police (RCMP) have been classifying automotive paints on the basis of chemical composition (50–52). The original analysis was performed with the use of high pressure diamond anvil cells in beam condensers on dispersive IR spectrometers. Since then, the RCMP and other analysts have changed to using the less cumbersome, low pressure, compression diamond cells with beam condensers in FT-IR systems. Inorganic pigment components in paints have revealing spectral features at the lower wave numbers. Beam condensers are used rather than FT-IR microscopes to overcome the limited frequency range of liquid nitrogen cooled mercury cadmium telluride (MCT) detectors used in IR microscopes. For paint analysis, the extended range to near 200 cm^{-1} is obtained with CsI optics and a standard deuterated triglycine sulfate (DTGS) detector in the spectrometer bench.

Table 3. Comparative Methods for Paint Traces

Methods	Measurement	Information	Refs.
Color comparison	Chips laid side by side under a stereo microscope	Visual matching, adhering debris, possible to automotive-paint reference collection	
Spectrophotometry	Visible spectrum	Nonsubjective comparison of color and aid in identifying some pigments	24,44
Cross section	Layer structure	Proof of similarity or dissimilarity for multilayered flakes; even white house paints can be studied by staining with rhodamine and observing with a fluorescence microscope	45
Physical match	Observation of fit between two chips of paint	Only positive form of paint identification; a physical match is regarded as the equivalent of a fingerprint	
Polarized light microscopy	Magnification, optical properties	Observation of properties; identification of a filler	
Microchemical tests	Identification of chemical and physical properties		
	Solvent tests (emperical or select)	Behavior to selected solvents	
	Microchemical reaction	Identification of inorganic fillers and crystalline organic pigments	43,46,47
X-ray diffraction	Identifies crystalline phases	Identification of inorganic fillers and crystalline organic pigments	48
Electron microprobe	Elemental analysis	Identification of inorganic pigments and fillers	
Micro FT-IR	IR spectrum	Identification of polymers and copolymer comprising vehicle; limited identification of pigment	19,43,49
Pyrolysis gas chromatography	Separation of pyrolysis product	"Fingerprint" for comparison; some limited chemical information on chemical type	28

Databases are maintained to search for unknown automotive paints from hit-and-run cases. The FBI Laboratory in Quantico, Va, maintains the National Automotive Paint File, which is the largest automotive paint collection in the United States. The largest forensic collection in the world, with over 50,000 samples, is maintained at the Bundeskriminalamt Research Laboratory in Wiesbaden,

Germany. Scientists at the RCMP have developed a software package called PDQ, ie, Paint Data Query (53). This database uses microscopic and IR spectroscopic analysis results to search for automotive information leading to the identity of make, model, and year of vehicles in question, typically from hit-and-run cases. Through the FBI-sponsored Scientific Working Group for Materials Examination (SWGMAT), this database has expanded to include entries from North American, European, Japanese, and Australian Collections. The international cooperation of forensic scientists has served to assist in casework involving paint evidence from international automobiles that have a global market. This worldwide effort helps everyone that applies the PDQ database for searching an unknown automobile paint found on a hit-and-run victim.

When two paint samples are compared, and comparison results are analytically the same, the analyst may report that the two are similar in all respects and that they may, therefore, have originated from the same source. Comparisons of two paint specimens are made on the layer structure, elemental composition, polymer identity, fillers, and pigments. The analyst must take great care to point out that in the case of an automotive finish, this does not mean that the paint necessarily came from a particular car. From the scientifically determined facts, it could have originated from any of hundreds, or perhaps thousands, of vehicles painted with the same topcoat. However, significance would be attached to the fact that the suspect car was registered and driven in the state where the accident occurred; that this particular car sustained damage to the front end, for example, and that evidence stuck to the bumper was in the form of fiber fragments identical to the fibers from the victim's trousers. If a fragment of paint from the victim's clothing or the accident scene can be found and fits like a jigsaw puzzle in the damaged areas of the suspect car, the association is unequivocal.

Most paints do not usually display as much diversity in chemistry, color, and layer structure as do automotive ones. Therefore, a wider variety of analytical instruments are often used to characterize them. Along with microscopy and IR spectroscopy, other methods frequently used are pyrolysis GC/MS and inorganic elemental analysis by X-ray spectroscopy in the SEM. X-ray diffraction is also of use in the identification of crystalline pigments and fillers.

The study of coatings is also important in litigation concerning peeling paint. The examination in these cases focuses on the two surfaces that were once in contact with each other. Light and scanning electron microscopy of the surfaces are often able to pinpoint the cause, usually improper or inadequate surface preparation. In a very few cases, the surfaces appear to be perfectly clean and yet will still not adhere to each other. Surface analysis techniques such as electron spectroscopy for chemical analysis and Auger spectroscopy can reveal thin layers of otherwise invisible coatings on the surface of the substrate. The chemical composition of these thin coatings can be determined with these techniques, which in turn can help assess the cause of nonadhesion. FT-IR microspectroscopy was used to identify crystals that were implicated in a peeling paint problem. The IR spectra identified the crystals as a fungicide which had exsolved from the paint and recrystallized on the undersurface, pushing the film away from the wood substrate.

Paint comparisons are most often conducted in conjunction with criminal proceedings, but civil cases often arise. In one civil case, the owners of a high rise

office building suspected that their building, especially the windows, was being coated by paint from a bridge a half-mile away that was being spray-painted. Microscopical examination of the glass windows revealed the presence of tiny green spherical particles that were compared visually and by visible microspectrophotometry. The elemental composition was determined using energy-dispersive X-ray spectroscopy and the polymer was identified by FT-IR. These tests could all be conducted on a single sphere and compared with spheres that had formed and fallen around the bridge. The paints from both sources were identical in all respects and the painting contractors were held liable for the damage to the high rise.

A criminalist in California was assigned to rework a murder investigation originally tried in the early 1960s in 1987 after the U.S. Supreme Court overturned

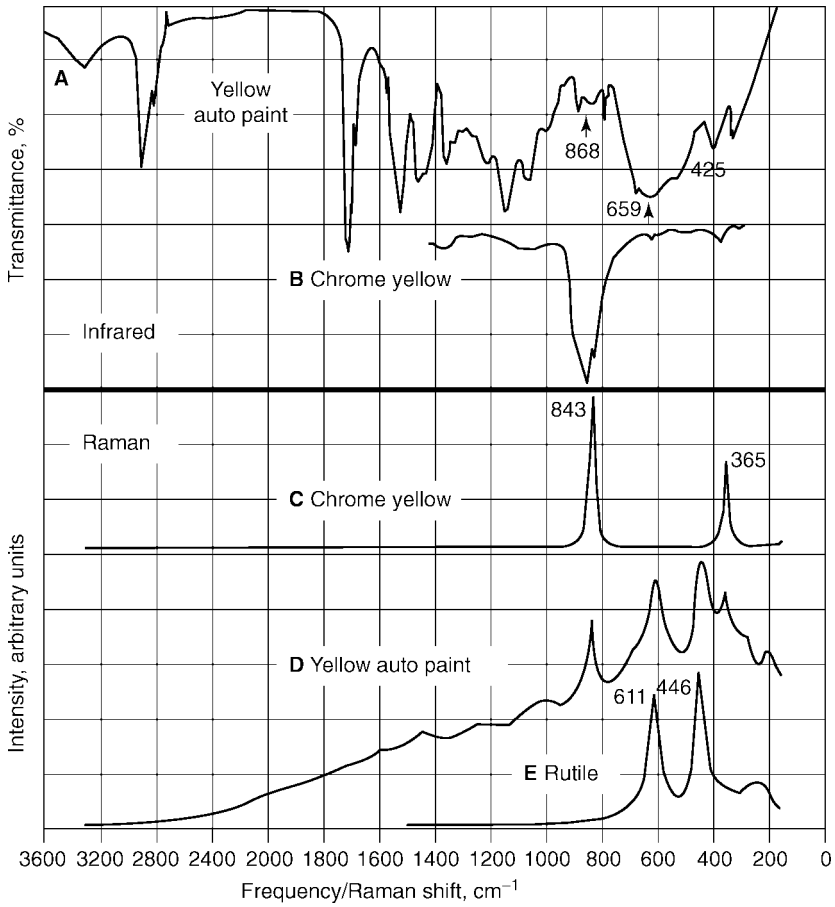

Fig. 4. IR and Raman spectra of yellow acrylic melamine enamel auto paint with pigments: (**A**) IR spectrum of the auto paint; (**B**) IR spectrum of chrome yellow pigment; (**C**) Raman spectrum of chrome yellow pigment; (**D**) Raman spectrum of the yellow auto paint; (**E**) Raman spectrum of rutile. Spectra provided by E. Suzuki, Washington State Patrol, Forensic Laboratory, Seattle, Wash.

the conviction of the defendant on a technical issue. The murdered 16-year-old girl was found in a dry drainage canal near the California desert, some distance from her home. The original suspect in the case was placed at the crime scene on the basis of a partial footprint and tire track in the soil outside the victim's home. During the reinvestigation, the criminalist was surprised to find small, pale green football-shaped particles among the items of evidence associated with the victim and the suspect. Consulting a forensic microscopist, he was informed that they were originally wet spheres of spray paint that had deformed by capillary action because they had a fiber running through them. These particles, whatever their origin, were significant because they were associated with both the suspect and the victim. They had been observed during the original investigation 25 years earlier, but the analysts involved did not feel that they could be analyzed by the techniques available at the time. The forensic microscopist took over the investigation of the particles when the criminalist discovered their source. The headliner of the suspect's vehicle, which was still in custody, had been spray-painted green. The headliner was cotton at that time and many of the droplets dried around the fibers. When the cotton became brittle, the particles broke away and dusted the car with these green football shaped particles. Microanalysis of the particles was conducted for the purpose of comparing the particles from the victim (shoelace, dust from her house, etc) and the suspect (his clothing, dust from his hotel room, etc) to the paint particles from the vehicle headliner. The analysis was exhaustive and it was possible to say that the paint from all three sources was identical in elemental composition, polymer composition, color, fluorescence, and microscopical examination of the fillers and pigments in terms of size and quantity. In addition, the particles were all spray paint, and all of the particles had been sprayed over cotton fibers. These fibers also had the same properties among the three sources. The jury convicted the defendant for the murder a second time.

Researchers are beginning to demonstrate the usefulness of Raman analysis for organic and inorganic pigment identification in paint (22,23). Figure 4 compares IR and Raman paint spectra of a yellow acrylic melamine enamel automotive paint. The IR spectrum in Figure 4**A** clearly shows the resin binder features. The N—H stretch near 3350 cm^{-1}, the C—H stretching near 3000 cm^{-1}, the C═O stretch near 1730 cm^{-1}, the C—N stretch near 1540 cm^{-1}, and the typical C—O envelope from 1300 to 1000 cm^{-1} are observed in the IR. Of particular interest in paint analysis are any contributions by pigments. The weak, broad band at 868 cm^{-1} appears to be contributed by chrome yellow, as shown in the Figure 4**B** reference spectrum. However, because of the band's comparatively low intensity and lack of detail in the paint spectrum, it would be difficult to positively identify chrome yellow by this method alone. The peaks labeled at 659, 425, and 357 cm^{-1} are rutile, a polymorph of titanium dioxide. Figure 4**D** is the Raman spectrum of the yellow auto paint. The major peaks at 843 and 365 cm^{-1} match up with the Raman spectrum of chrome yellow shown in Figure 4**C**. Peaks at 611 and 446 cm^{-1} are contributed by rutile, as shown in Figure 4**E**. With Raman spectroscopy, the high scattering efficiency of some of the pigments, relative to those of the binders, helps to easily determine the pigment components, as interfering binder peaks are not a problem.

FRACTIONATION

Introduction

Synthetic polymers are heterogeneous materials. Measuring this heterogeneity is the key to understand structure-property relationships, polymerization mechanisms and kinetics, and polymer reaction engineering. Polymer fractionation techniques attempt to fractionate polymers according to specific characteristics of their microstructures as defined by their distributions of molecular weight, chemical composition, comonomer sequence length, tacticity, and long-chain branching.

All synthetic and some natural polymers have a distribution of molecular weights caused by the statistical nature of the polymerization mechanism. Polymers produced via living polymerization have the narrowest molecular weight distributions, while long-chain branched polymers or polymers made with multiple-site catalysts such as heterogeneous Ziegler–Natta catalysts have the broadest molecular weight distributions. Nonetheless, regardless of the polymerization mechanism involved in their production, all polymers have a molecular weight distribution that must be quantified to unequivocally define their microstructures and their physical properties. This explains why the vast majority of polymer fractionation techniques were developed to fractionate polymers according to molecular weight.

For instance, the instantaneous chain-length distribution of many polymers is given by Flory–Schultz's most probable distribution (1),

$$f_n = \frac{1}{N_\mathrm{n}} \exp\left(-\frac{n}{N_\mathrm{n}}\right) \tag{1}$$

where f_n is the number distribution of chains of length n, and N_n is the number-average chain-length. The molecular weight distribution can be obtained from the chain-length distribution by multiplying the latter by the molecular weight of the repeating unit.

The equivalent weight chain-length distribution, w_n, is given by

$$w_n = \frac{n}{N_\mathrm{n}^2} \exp\left(-\frac{n}{N_\mathrm{n}}\right) \tag{2}$$

Polymers whose chain-length distributions follow equation 1 have a polydispersity index $N_\mathrm{w}/N_\mathrm{n}$ of 2, where N_w is the weight-average chain length of the polymer. Figure 1 shows the number and weight chain-length distributions of a polymer with $N_\mathrm{n} = 1000$. Notice that, even for the relatively narrow polydispersity of 2, a significant range of chain lengths is encompassed by the distribution.

Nowadays the most common technique for determining the molecular weight distribution of polymers is size-exclusion chromatography (SEC), also known as gel-permeation chromatography (GPC). Other methods for measuring molecular weight distributions exist, but the ease of use and universality of SEC makes it the technique of choice for this type of fractionation.

Copolymerization adds another level of complexity to polymer microstructure. Superimposed on the molecular weight distribution, we now have to

account for the distributions of chemical composition and comonomer sequence length. The instantaneous bivariate weight distribution of chain length and chemical composition, $w_{n,y}$, of many linear binary copolymers was derived by Stockmayer (2):

$$w_{n,y} = \frac{n}{N_n^2} \exp\left(-\frac{n}{N_n}\right)\sqrt{\frac{n}{2\pi F_1(1-F_1)\kappa}} \exp\left(-\frac{ny^2}{2F_1(1-F_1)\kappa}\right) \tag{3}$$

where y is the deviation from the average fraction of monomer 1 in the copolymer F_1. The parameter κ is defined as a function of F_1 and the reactivity ratios r_1 and r_2:

$$\kappa = \sqrt{1 - 4F_1(1-F_1)(1-r_1r_2)} \tag{4}$$

The average fraction of comonomer in the copolymer can be estimated as usual using the Mayo–Lewis equation:

$$F_1 = \frac{(r_1-1)f_1^{\,2} + f_1}{(r_1+r_2-2)f_1^{\,2} + 2(1-r_2)f_1 + r_2} \tag{5}$$

where f_1 is the molar fraction of monomer 1 in the reactor.

Notice that equation 3 reduces to Flory–Schultz's most probable distribution upon integration over all copolymer compositions, ie integrating y from $-\infty$ to

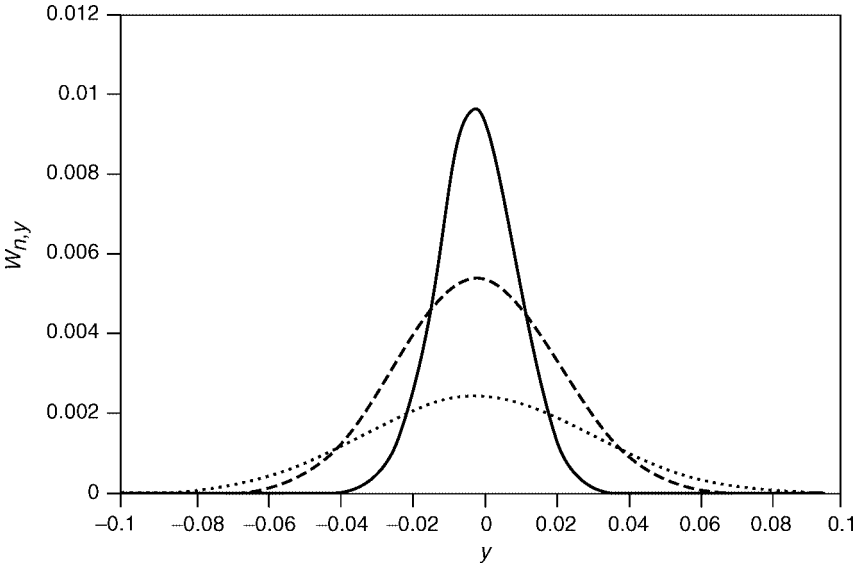

Fig. 2. Stockmayer's distribution for chains of different length of a model random copolymer ($r_1r_2 = 1.0$) with $F_1 = 0.5$ and $N_n = 1000$. - - - $n = 250$; ▬ ▬ $n = 500$; ——— $n = 2000$.

$+\infty$. Consequently, linear binary copolymers described by Stockmayer's bivariate distribution also obey Flory–Schultz's distribution for chain length.

Figure 2 compares the chemical composition distribution of polymers of different chain lengths for a random binary copolymer ($r_1r_2 = 1.0$). Notice how the distribution gets broader with decreasing chain-lengths. It is easy to understand this behaviour considering that, as chain length tends to infinity, the composition of all copolymer chains should be the same for a given probability of polymerization of monomer 1 and monomer 2. On the other hand, chains with short lengths are more likely to deviate from the average copolymer composition on purely statistical grounds, in the same way as it is more likely to get three consecutive heads by tossing a coin three times than it is to get one hundred consecutive heads by tossing a coin one hundred times.

Figure 3 shows how the chemical composition distribution of copolymer chains of the same length varies when the comonomer incorporation varies from alternating ($r_1r_2 \to 0$) to random ($r_1r_2 = 1$) to block ($r_1r_2 \to \infty$). As expected, the distribution gets broader with increasing tendency to form comonomer blocks: all chains of a perfectly alternating binary copolymer have the same composition (ie $F_1 = F_2 = 0.5$) but the tendency to form long comonomer sequences or blocks ($r_1r_2 \to \infty$) may broaden the distribution considerably.

There are no general analytical solutions to describe the chemical composition distribution of ternary or higher copolymers, although an analytical solution for the particular case of random multicomponent copolymers has been derived (3). For nonrandom polymerizations, the chemical composition distribution of multicomponent copolymers can be calculated using techniques such as Monte Carlo simulation or population balances (4).

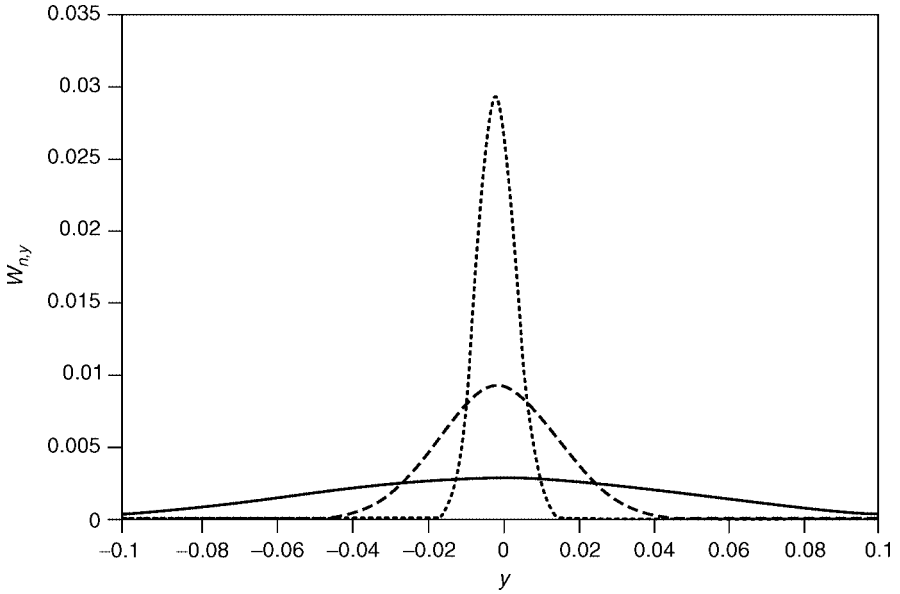

Fig. 3. Stockmayer's distribution for chains with $F_1 = 0.5$ and $N_n = 1000$ as a function of reactivity ratio product. Alternating: $r_1r_2 = 0.01$; random: $r_1r_2 = 1$; and block: $r_1r_2 = 10$. - - - $r_1r_2 = 0.01$; —— —— $r_1r_2 = 1.0$; ———— $r_1r_2 = 10$.

Asymmetrical monomers such as propylene and styrene form polymers with different tacticity. Isotactic and syndiotactic chains have regular molecular structures and are generally semicrystalline, while atactic polymers are amorphous because of the random placement of the monomer units in the chain. The tacticity distribution may be modeled as a comonomer distribution, where the different monomer orientations during chain insertion (meso or racemic) are treated as pseudo-comonomer types. Therefore, at least in principle, Stockmayer's distribution can be used to approximate the tacticity distribution of homopolymers.

The most common techniques to measure the chemical composition distribution of semicrystalline copolymers are temperature rising elution fractionation (TREF) and crystallization analysis fractionation (Crystaf). These two techniques are based on the differences among the crystallizabilities of copolymer chains with distinct comonomer contents. Because variations in tacticity affects polymer crystallinity, Crystaf and TREF have also been used to measure the tacticity distribution of polymers. No direct methods are available for measuring the complete chemical composition distribution of amorphous copolymers, although some field flow fractionation, ultracentrifugation, and chromatography methods are sensitive to differences in comonomer content. The use of matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry as a detector for SEC has also been proposed to determine the bivariate distribution of molecular weight and chemical composition of some copolymers, either semicrystalline or amorphous.

The last and most complex polymer microstructural distribution is the one for long-chain branching. Long-chain branches can be formed according to very

different mechanisms, and analytical solutions for long-chain branch distributions are only known for a few particular cases. For the case of terminal branching with coordination catalysts, the instantaneous joint distribution of chain-length, chemical composition, and long-chain branching, $w_{i,n,y}$, is given by the equation (5,6)

$$w_{i,n,y} = \frac{1}{(2i+1)!}\frac{n^{2i+1}}{N_n^{2i+2}}\exp\left(-\frac{n}{N_n}\right)\sqrt{\frac{n}{2\pi F_1(1-F_1)\kappa}}\exp\left(-\frac{ny^2}{2F_1(1-F_1)\kappa}\right) \quad (6)$$

where i is the number of long-chain branches per chain. Notice that Stockmayer's distribution, equation 3, is a particular solution of equation 6 for linear chains, ie for $i = 0$.

Figure 4 and Figure 5 illustrate how the distributions of chain length and chemical composition vary as a function of the number of long-chain branches per chain for a model copolymer. Notice how chains with more long-chain branches are longer and have narrower distributions of chain length and chemical composition. The increase in average chain length with increasing branching is self-explanatory; the narrowing of the distributions is caused by the averaging effect of randomly combining chains of different lengths and compositions via long-chain branch-formation reactions.

Unfortunately, there are no techniques that can be used to fractionate polymers exclusively according to long-chain branching. A measure of average long-chain branching as a function of molecular weight can be obtained when SEC is combined with a viscometer or a light-scattering detector, but the results are

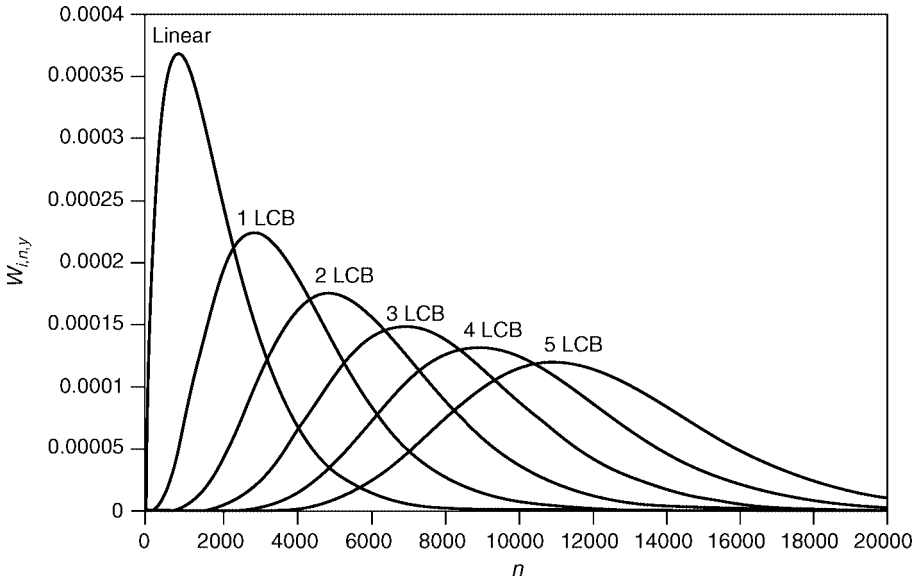

Fig. 4. Chain-length distribution as a function of long-chain branching frequency for a model polymer with $N_n = 1000$, $F_1 = 0.5$, and $r_1 r_2 = 1.0$. The curves are obtained by integrating equation 6 over the entire composition range, $-\infty < y < +\infty$. For details see Ref. 6.

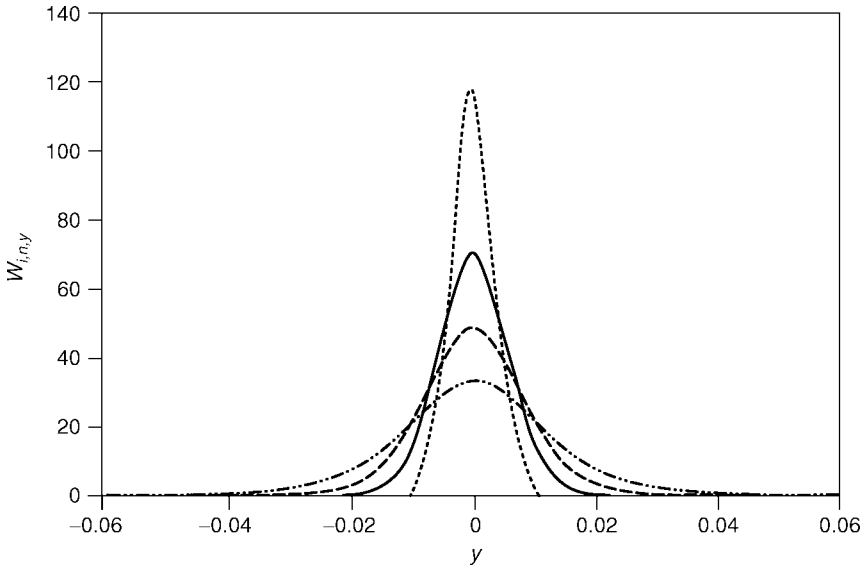

Fig. 5. Chemical composition distribution as a function of long-chain branching frequency for a model polymer with $N_n = 1000$, $F_1 = 0.5$, and $r_1 r_2 = 1.0$.— - -—Linear;▬ ▬ 1 LCB;▬▬ 3 LCB;_ _ _ 10 LCB. The curves are obtained by integrating equation 6 over the entire chain-length range, $0 < n < \infty$. For details see Ref. 6.

semiquantitative at the best for most polymers because of the complex fractionation process that takes place in nonuniformly branched polymers. Considering the importance that long-chain branching has on altering rheological and mechanical properties of polymers, this poses a significant limitation on the understanding of a very important class of polymers.

These three theoretical distributions describe only a very small portion of the diversity of polymer microstructures that are produced every day in academia and industry. Even for the polymerization systems they describe, they are only strictly valid as instantaneous distributions. If conditions in the polymerization reactor fluctuate as a function of time or spatial location, the distributions for the polymer product may be considerably more complex. In this case, it is very difficult to find a mathematical model precise enough to describe the complete polymer microstructure, and we must rely solely on experimental fractionation for its determination. In fact, the comparison of experimentally-measured microstructural distributions with the ones predicted by theory is a powerful tool to investigate polymerization mechanisms and understand polymer reactor nonidealities. Nonetheless, these distributions are essential to realize the complexity of polymer microstructure and the interdependency of the distributions of molecular weight, chemical composition (or tacticity), and long-chain branching. This interdependency should always be kept in mind when interpreting the fractionation data from any experimental technique.

In this article we will review some relevant fractionation techniques that can be used to elucidate the main aspects of the polymer microstructures delineated above.

Batch Fractionation

It has been claimed that polymer batch fractionation is almost as old as polymer science itself (7). Batch fractionation relies on the separation of polymer chains, initially present in a dilute solution, in two phases (liquid–liquid or liquid–solid). Fractionation occurs by altering the goodness of the solvent, either by changing the ratio of solvent to nonsolvent or by varying the temperature of the polymer solution. The nonsolvent, most often, must be miscible with the solvent, but should not be able to dissolve the polymer.

Batch fractionation was developed to determine the molecular weight distribution of polymers. Even though molecular weight fractionations nowadays are more efficiently achieved with chromatographic techniques such as size-exclusion fractionation, batch fractionation is still important when the objective is to obtain large fractions of polymers with narrow molecular weight distributions that may be required, for instance, to establish structure-property relationships or to elucidate polymerization mechanisms. In this way, batch fractionation is still relevant today, albeit to serve a different purpose from which it was originally developed.

Semicrystalline polymers can be fractionated according to their molecular weights by the solvent/nonsolvent approach at temperatures above their melting point, or by crystallizability by the temperature variation approach. Amorphous polymers are fractionated only according to their molecular weights. We will describe the fractionation of amorphous polymers first, followed by a discussion on the fractionation of semicrystalline polymers later.

A comprehensive compendium of laboratory procedures for batch fractionation of polymers was written by Francuskiewicz (8). The readers are directed to this reference for more specific details on the several experimental techniques described below.

Fractionation of Amorphous and Semicrystalline Polymers by Molecular Weight. Flory–Huggin's theory for dilute polymer solutions is still convenient to describe the liquid–liquid batch fractionation of amorphous polymers between a polymer-rich phase and a polymer-lean phase. Even though Flory–Huggin's theory for dilute solution is based on several simplifying assumptions, it correctly describes the trends during the batch fractionation of polymers and provides a useful theoretical framework to rationalize its qualitative features. The discussion in this section will follow closely the elegant development adopted by Flory in his remarkable book on polymer chemistry (9).

Semicrystalline polymers can be fractionated by either molecular weight or crystallizability. All the considerations that will be made in this section for the fractionation of amorphous polymers by chain length are equally valid for semicrystalline polymers, provided that the polymer is kept above its melting point throughout the fractionation to eliminate chain crystallization effects.

For a liquid–liquid system, the volume fractions of polymer of chain length n in the polymer-rich phase, $\upsilon_n{}^*$, and in the polymer-lean phase, υ_n, are conveniently described by the simple exponential equation:

$$\frac{\upsilon_n^*}{\upsilon_n} = e^{\sigma n} \tag{7}$$

The parameter σ can be estimated with the expression

$$\sigma = \upsilon_S\left(1-\frac{1}{N_n}\right) - \upsilon_S^*\left(1-\frac{1}{N_n^*}\right) + \chi\left[(1-\upsilon_S)^2 - \left(1-\upsilon_S^*\right)^2\right] \tag{8}$$

where N_n is the number average chain length, χ is the Flory–Huggin's interaction parameter between polymer and solvent, and $\upsilon_S{}^*$ and υ_S are the volume fractions of solvent in the polymer-rich and polymer-lean phases, respectively. In the following discussion, the exact value of the parameter σ is immaterial; it suffices to know that σ depends on the properties of the polymer and solvent(s) used in the fractionation.

Calling V and V^* the volume fractions of the polymer-lean and polymer-rich phases, respectively, and defining $R = \frac{V^*}{V}$, the fraction of polymer chains with chain length n in the polymer-lean phase, f_n, is given by

$$f_n = \frac{V\upsilon_n}{V\upsilon_n + V^*\upsilon_n^*} = \frac{1}{1+R\frac{\upsilon_n^*}{\upsilon_n}} = \frac{1}{1+Re^{\sigma n}} \tag{9}$$

Similarly, the fraction of polymer with chain length n in the polymer-rich phase, $f_n{}^*$, is given by the expression

$$f_n^* = 1 - f_n = \frac{Re^{\sigma n}}{1+Re^{\sigma n}} \tag{10}$$

Equation 7 shows that, for positive values of σ, the *partition ratio* $\frac{\upsilon_n^*}{\upsilon_n}$ is always greater than 1. Therefore, the polymer chains, independently of their chain lengths, will always have a higher volume fraction in the polymer-rich phase. Since the partition ratio increases exponentially with chain length, longer chains will be more selective towards the polymer-rich phase than shorter chains. This simply reflects the fact that shorter chains have fewer units to interact with the poor solvent in the polymer-lean phase, and therefore are less discriminating than the longer chains. Batch fractionation of amorphous polymers relies solely on this small selectivity difference among chains of different lengths.

Precipitation Fractionation. In this method, fractions of decreasing molecular weights are obtained in each successive fractionation step. Because of the decreasing molecular weight of the fractions, this technique is also called *downward* precipitation fractionation, to distinguish it from another variant named *upward* precipitation fractionation that will be described later in this section. In either case, it is instructive to notice that precipitation fractionation is a misnomer, since the polymer does not in fact precipitate, but rather forms a separate polymer-rich liquid phase.

The precipitation fractionation method starts with a dilute polymer solution. Liquid–liquid separation, with the formation of a polymer-rich and a polymer-lean phase, is induced by either decreasing the temperature or by adding a specified amount of a nonsolvent. A third, less common technique, involves the evaporation of solvent from a solvent/nonsolvent mixture. All these procedures increase the value of χ, until it eventually exceeds its critical value, thus leading to phase separation.

The Flory–Huggin's interaction parameter, χ, is defined by the equation

$$\chi = \frac{V_S}{RT}(\delta_S - \delta_P)^2 \tag{11}$$

where V_S is the molar volume of the solvent, T is the temperature, R is the gas constant, and δ_S and δ_P are the solubility parameters for the solvent and polymer, respectively. Therefore, a decrease in temperature will increase the value of χ, and consequently the value of σ as well (cf eq. 8). An exception to this rule may happen for systems that have a lower critical solution temperature (LCST). In the latter case, an increase in temperature will instead increase the value of χ.

Similarly, if the solubility parameter for the solvent/nonsolvent mixture is calculated by the simple additive rule

$$\delta_S = \upsilon_{\text{solvent}}\delta_{\text{solvent}} + \upsilon_{\text{nonsolvent}}\delta_{\text{nonsolvent}} \tag{12}$$

then adding a nonsolvent to the solution will increase the term $(\delta_S - \delta_P)^2$ in equation 11 and accordingly increase the value of χ, leading to the formation of the polymer-rich phase.

If the initial polymer solution is very dilute, the volume of the polymer-rich phase, V^*, will be much smaller than the volume of the polymer-lean phase, V; ie $R \ll 1$. Since the partition ratio for longer chains is higher than for shorter chains, the concentration of longer chains will be higher than the concentration of the shorter chains in the polymer-rich phase. Because of this selective partition, it is advantageous to assure that the volume of the polymer-lean phase is much larger than the volume of the polymer-rich phase. In this case, the majority of the less selective shorter chains will stay in the polymer-lean phase, simply because its volume is much larger than the volume of the polymer-rich phase. This effect is illustrated, in a rather exaggerated manner, in Figure 6, where a plot of f_n versus n for several R values is shown when the value of the parameter σ was selected (arbitrarily) so that $f_{2000} = \frac{1}{2}$. Notice how the separation efficiency gets increasingly better as R tends to zero. In this theoretical limit, an almost perfect partition between the phases would be possible, but evidently this operation condition cannot be reached experimentally.

The polymer-rich phase is then separated from the polymer-lean phase, and a new fraction of lower molecular weight can be collected by either further lowering the temperature or by adding more nonsolvent. The polymer-rich phase is once more separated from the polymer-lean phase, and the process is repeated as many times as required.

Since chains of all molecular weights will be partitioned between the two phases, precipitation fractionation is not capable, even at very high dilutions, to obtain polymer fractions of very sharp chain-length distributions. This effect is illustrated in Figure 7 for a model polymer that follows the most probable chain-length distribution given by equation 2. Notice that even at high dilutions (small R), there is significant overlapping of the distributions of each of the fractions.

This interesting phenomenon is further illustrated in Figure 8 for the simulated fractionation of a model polymer into five fractions. The dotted lines indicate the chain-length distributions of the polymer in the polymer-lean phase,

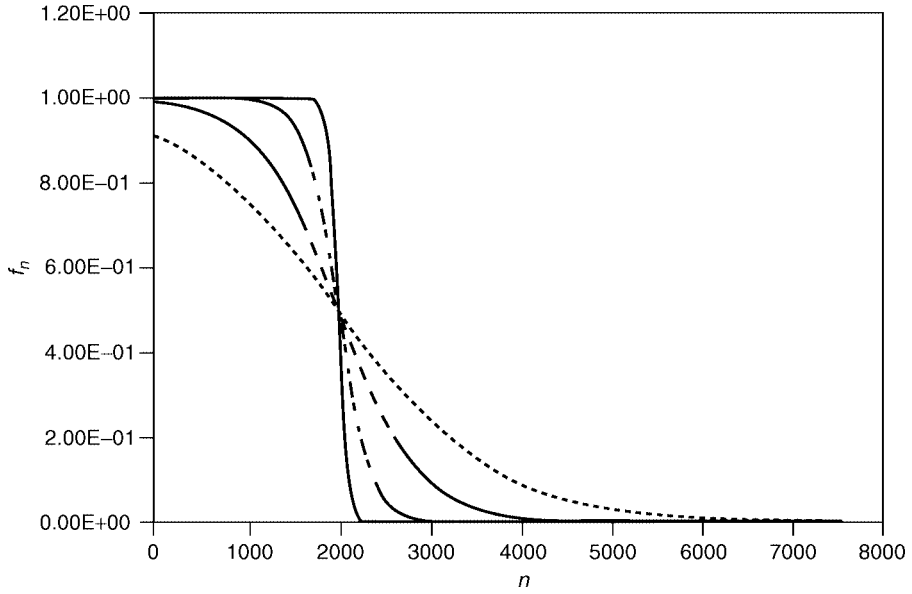

Fig. 6. Molar fraction of polymer in the polymer-lean phase (f_n) as a function of chain length (n) and the ratio of the volume of polymer-rich to polymer-lean phases (R). R = 1.0 E-1; R = 1.0 E-2; R = 1.0 E-5; R = 1.0 E-20. The value of the parameter σ was selected so that $f_{2000} = \frac{1}{2}$.

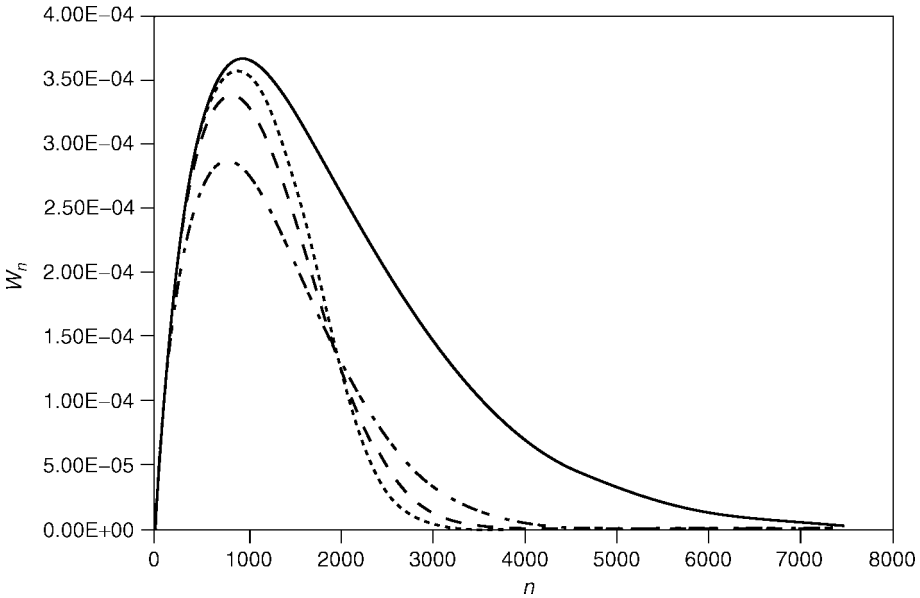

Fig. 7. Chain-length distributions in the polymer-lean fraction as a function of the ratio of volumes of polymer-rich to polymer-lean phases (R). Parent distribution; R = 1.0 E-1; R = 1.0 E-2; R = 1.0 E-3.

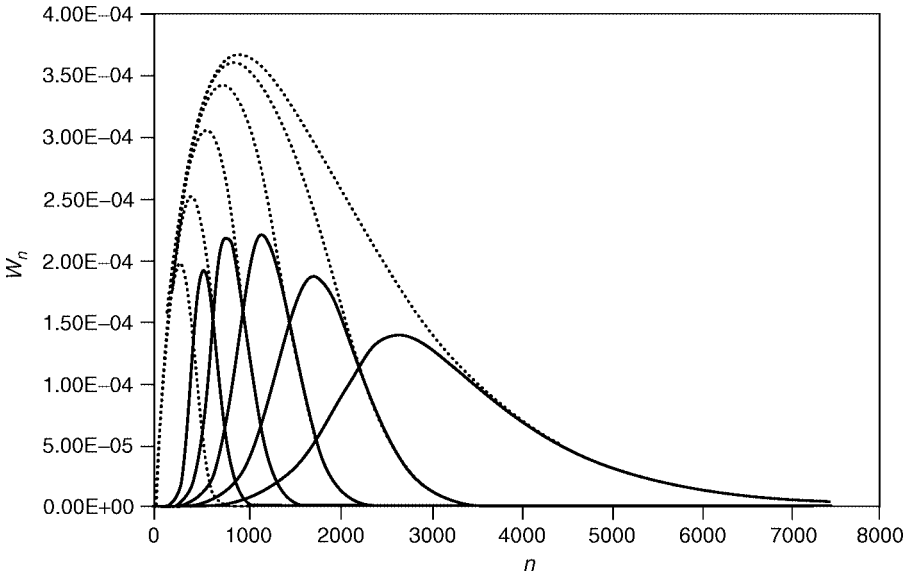

Fig. 8. Simulated chain-length distributions for precipitation fractionation of a model polymer sample that follows Flory–Schultz's distribution with $N_n = 1000$. The following parameters were used to simulate the fractionation: $R = 1 \times 10^{-3}$ and $\sigma = 3 \times 10^{-3}$, 4.5×10^{-3}, 6.75×10^{-3}, 1.01×10^{-2}, and 1.52×10^{-2}.

and the solid lines the chain-length distributions in the polymer-rich phase. The chain-length distribution of the original model polymer follows the most probable distribution with $N_n = 1000$. The parameter σ is arbitrarily increased from fractions 1 to 5 to simulate either a decrease in temperature or the addition of a nonsolvent. The distribution of the first polymer-rich solution is given by $w_n[1 - f_n^{(1)}]$, where w_n is the most probable chain-length distribution of the parent resin. Similarly, the distribution of the first polymer-lean phase is simply $w_n f_n^{(1)}$. After separation of the polymer-rich phase, the second fraction is obtained by decreasing the temperature of (or adding nonsolvent to) the polymer-lean phase. The distribution of the second polymer-rich phase is $w_n f_n^{(1)}[1 - f_n^{(2)}]$, and that of the polymer-lean phase is $w_n f_n^{(1)} f_n^{(2)}$. It is easy to see that this process can be repeated for k fractions, leading to the following equations for the chain-length distributions of polymer in the two phases:

$$w_n^{(k)} = w_n \prod_{i=1}^{k} f_n^{(i)}, \text{ polymer-lean phase} \tag{13}$$

$$w_n^{*(k)} = w_n \left[\prod_{i=1}^{k-1} f_n^{(i)} \right] \left(1 - f_n^{(k)}\right) = w_n^{(k-1)} \left(1 - f_n^{(k)}\right), \text{ polymer-rich phase} \tag{14}$$

where $w_n^{(k)}$ is the chain-length distribution of the kth fraction and the asterisk superscript indicates the polymer-rich phase. Notice that even though the chain-length distributions of the fractions is narrower than that of the parent sample,

significant overlapping takes place in all fractions because of the lower values of the partition ratios for the shorter chains. The reader is directed to the review by Kamide (7) for extensive and more rigorous simulations of batch fractionations of polymer solutions.

Rigorously speaking, for the case of solvent/nonsolvent precipitation fractionation the general mathematical treatment described above must be modified to treat the ternary solvent/nonsolvent/polymer system, but the trends are the same. It has been proposed that solvent/nonsolvent fractionation can be more effective for chain-length fractionation than temperature reduction, and in fact solvent/nonsolvent fractionation is generally a more commonly used technique to fractionate polymer chains according to molecular weight.

Upward Precipitation Fractionation. In this method, fractions of increasing molecular weights are obtained in each successive fractionation step. A large amount of nonsolvent is added to the original polymer solution, driving most of the polymer to the polymer-rich phase. Contrarily to the downward precipitation fractionation discussed above, in this method most of the polymer will be concentrated in the polymer-rich phase. The polymer-lean phase is recovered as the first fraction with the lowest average molecular weight. The remaining polymer-rich phase is completely redissolved and more nonsolvent is added, preferentially driving the high molecular weight chains into the polymer-rich phase. The polymer-lean phase is recovered as the second fraction with higher molecular weight and the cycle of redissolutions and solvent/nonsolvent additions is repeated. A similar result can be obtained by altering the temperature of the solution. The mathematical description adopted above for the downward precipitation fractionation method is also adequate for the upward precipitation fractionation method.

Notice that the high molecular weight fractions are only obtained after several fractions of lower molecular weights have been recovered. Considering the lower phase selectivity of the low molecular weight chains, the upward precipitation fractionation method can remove most of the shorter chains before isolating the high molecular weight fractions. As a consequence, the high molecular weight fractions isolated with the upward precipitation fractionation method will have narrower molecular weight distributions than the ones obtained with the downward precipitation fractionation technique.

It should be clear that both upward and downward precipitation fractionations require the use of very large amounts of solvent to ensure the low polymer concentration necessary for efficient fractionation. To minimize this inconvenience, several refractionation mechanisms have been suggested. The refractionation schemes involve the fractionation of polymer-rich solutions into two fractions that must subsequently be refractionated several times until the required degree of separation is achieved (10).

An informative summary of the several steps required to fractionate polymers by precipitation fractionation is given in Figure 9.

Extraction or Solution Fractionation. In extraction fractionation, polymer chains of increasing molecular weights are extracted from the polymer-rich phase by gradually increasing the goodness of the solvent, either by increasing the temperature or the ratio of solvent to nonsolvent. Many of the considerations made above for the precipitation fractionation methods are also valid for the extraction fractionation techniques.

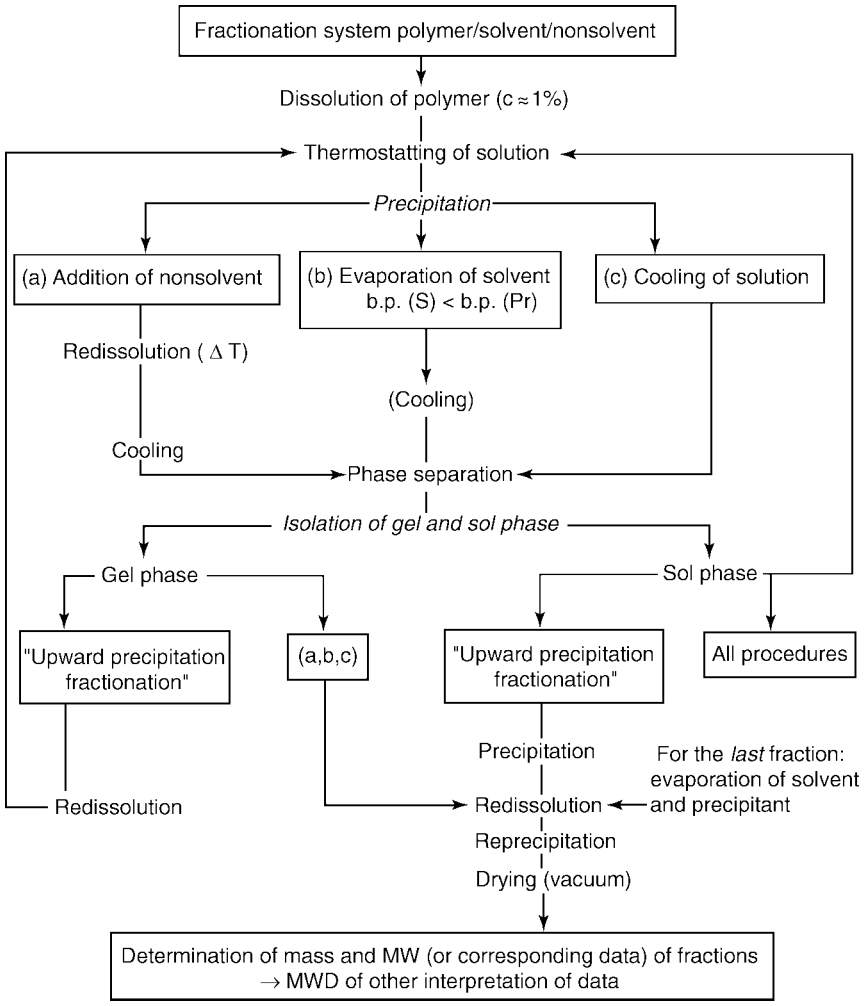

Fig. 9. Steps required for precipitation fractionation. From Table 5.2 in Ref. 8. Copyright (1994) Springer-Verlag.

A large contact area between the polymer-rich and polymer-lean phases is a very important requirement in extraction fractionation to reduce mass-transfer limitations between the phases during extraction. In the simplest extraction technique, *direct extraction*, this is achieved by using finely divided polymer particles or powder. Direct extraction is commonly performed in Sohxlet extractors. Diffusion limitations, polymer swelling, and equipment plugging make direct extraction a technique of limited use.

The contact area between the phases can be enlarged in *film extraction* and *column extraction*. The discussion of column extraction techniques will be postponed to the section on TREF. In film extraction, a thin polymer film is deposited onto a support material with a large surface area. This technique can also be performed inside Sohxlet extractors, but it is also prone to several experimental difficulties (11).

In *coacervate extraction* the polymer is initially present as a dilute solution. A large amount of nonsolvent is added, causing most of the polymer to separate into the polymer-rich phase. The polymer-lean phase, containing the low molecular weight chains, is recovered as the first fraction. Then more solvent is added to the polymer-rich phase. The liquid–liquid mixture is vigorously stirred to ensure good contact between the phases. Upon equilibration, the newly formed lean phase is recovered as the second fraction and the process is repeated as many times as required. A similar fractionation can be obtained by increasing the temperature of the solution.

As apparent from the last paragraph, coacervate extraction is similar to upward precipitation fractionation. However, differently from the last technique, the polymer-rich phase is not redissolved during coacervate extraction. As a consequence, smaller volumes of solvent and nonsolvent are required, but care must be taken to avoid occlusion of chains in the polymer-rich phase and mass-transfer limitations during fractionation. Similarly to upward precipitation fractionation, coacervate extraction is more adequate to isolate high molecular weight fractions with narrower molecular weight distributions.

Fractionation Equipment. Until recently, no fully automated instrument existed to perform batch fractionation of polymers. Most of the older experimental apparatuses consisted of simple glassware equipment that required considerable operator time and the manipulation of sizeable amounts of solvent. Some of these experimental fractionation systems have been thoroughly described by Francuskiewicz (8).

A fully automated batch fractionation instrument called mc2-PREP is now available. Figure 10 shows a schematic of mc2-PREP. The two stirred fractionation vessels placed inside a temperature-programmable oven can fractionate polymers into eight fractions by either solvent/nonsolvent or temperature variation techniques. Operator intervention is only required to precipitate and filter the polymer fractions after they are isolated from the parent polymer solution.

The coacervate extraction method is recommended in the molecular weight fractionation mode of mc2-PREP (the "m" in mc2-PREP), although the precipitation method (both upward and downward) is also possible in principle. As usual, the initial polymer solution is precipitated by the addition of a large amount of nonsolvent or reducing the temperature. The polymer-lean phase is transferred from the fractionation vessel to a fraction collection vial between each solvent/nonsolvent injection or temperature-increase steps through the transfer line located inside the fractionation vessel. The two fractionation vessels can be operated in parallel, with either the same or different samples. At the end of the fractionation, the fractions collected in the fraction collection vials are precipitated and filtered. mc2-PREP can also be used to fractionate polymers according to crystallizability, as described in the next section.

Fractionation of Semicrystalline Polymers by Crystallizability. The temperature variation method is the most common approach to fractionate semicrystalline polymer chains according to crystallizability. In this case, since chain crystallization is the main fractionation mechanism, the temperature should be lowered below the melting point of the polymer in solution during the fractionation.

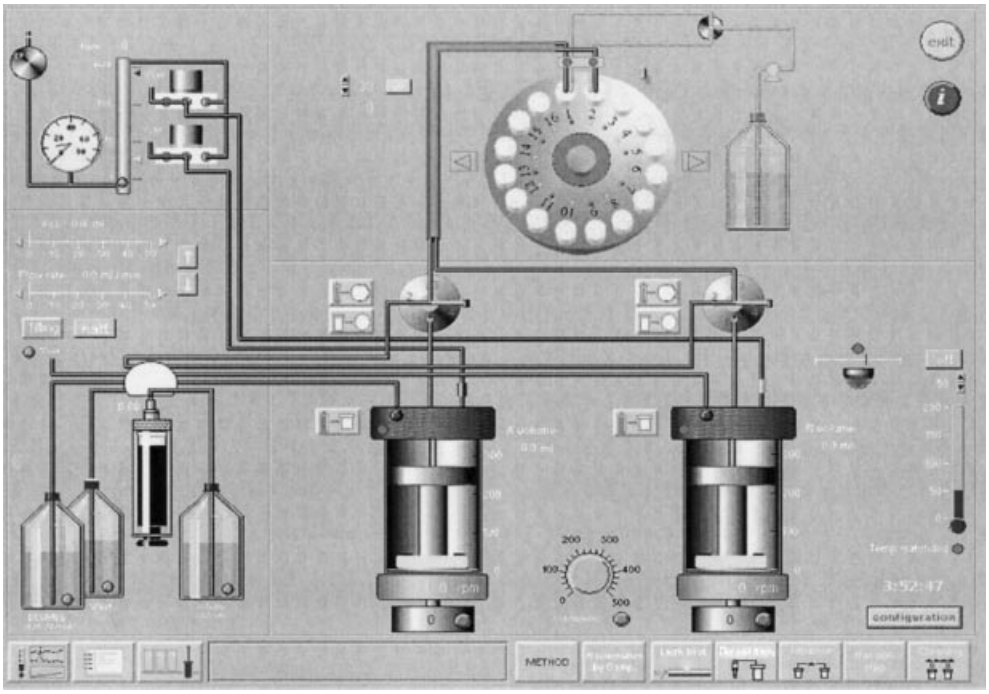

Fig. 10. Diagram of mc2-PREP. Courtesy of Polymer C*h*ar.

Chain crystallizability is strongly influenced by the degree of regularity of the chains. In the case of binary copolymers, generally the comonomer present in the smallest fraction does not crystallize and acts as a chain defect. The melting temperature, therefore, decreases with increasing amounts of this comonomer. Typical examples are copolymers of ethylene and α-olefins, where the α-olefin molecules are generally too large to be included in the crystalline lattice and lead to the formation of smaller polymer crystallites with lower melting temperatures. For the case when the two comonomers crystallize, such as for ethylene/propylene copolymers, the comonomer present in less amount acts as a defect and the melting temperature passes through a minimum located between the melting points of the two semicrystalline homopolymers. A similar phenomenon takes place with stereoregular homopolymers such as isotactic polypropylene. In this case, propylene molecules inserted in a racemic configuration will decrease the melting temperature of the isotactic polymer. Similarly, regioirregular insertions will also decrease the melting point of the polymer (12).

The melting point depression of a random binary AB copolymer, where the comonomer B does not crystallize, is described by the equation 15

$$\frac{1}{T_m} - \frac{1}{T_m^0} = -\frac{R}{\Delta H_u} \ln x_A \tag{15}$$

where $T_m{}^0$ is the melting point of an infinitely long-chain of homopolymer A, T_m is the melting temperature of the random copolymer AB, ΔH_u is enthalpy of melting

of the repeating unit A, and x_A is the molar fraction of the crystallizable unit A. In principle, this equation can also be used to describe the melting point depression of stereoregular homopolymers due to stereoirregular insertions. For instance, in the case of isotactic polypropylene, x_A could represent the molar fraction of meso insertions and $(1 - x_A)$ would then represent the molar fraction of racemic insertions.

Fractionation by crystallizability takes place by either decreasing or increasing the temperature, similarly to what is done in the methods of fractional precipitation or coacervate extraction for molecular weight fractionation. However, differently from those, solid–liquid phase separation occurs during fractionation by crystallizability. We will call *Crystaf-mode* the fractionation that takes place upon cooling the polymer solution, and *TREF-mode* the fractionation that takes place by dissolving previously precipitated polymer crystallites. This nomenclature is consistent with the continuous analysis techniques of Crystaf and TREF, which will be described later in this article, and is more adequate for fractionation by crystallizability.

Irrespective of the fractionation mode, one starts with a dilute polymer solution at high temperature. In Crystaf-mode, fractions of decreasing crystallinity (increasing noncrystallizable comonomer content) are obtained as the temperature is reduced. The more crystalline chains are precipitated at higher temperatures and separated from the remaining solution before the temperature is lowered to obtain the next polymer fraction. In TREF-mode, all or most of the polymer is precipitated by reducing the temperature to its lowest value at the beginning of the fractionation. The first fraction is collected at the lowest fractionation temperature and it is, therefore, the one that has the highest fraction of the non-crystallizable comonomer. Fractions with increasing crystallizabilities and lower comonomer contents are collected by increasing the temperature at predetermined intervals. A slow cooling rate is a requirement for good fractionation even in the TREF-mode, since it permits the growth of well-formed crystals and enhances the resolution of the fractionation.

Fractionation Equipment. Similar to molecular weight fractionation, most of the conventional equipment for crystallization fraction is rather simple and requires significant operator time. Fully automated crystallization fractionations are possible using mc2-PREP, in both Crystaf-mode and TREF-mode (the "c2" in mc2-PREP stands for these two fractionation modes).

In TREF-mode the polymer solution is initially placed inside a crystallization vessel at high temperature. The temperature is then slowly reduced, precipitating most of the polymer. The polymer that remains in solution is transferred via the in-line filter to a fraction collection vial as the first, least crystalline fraction. More solvent is transferred to the fractionation vessel and the temperature is increased by a predetermined amount, dissolving the next, more crystalline fraction. The process is then repeated with the recovery of polymer solutions at increasing dissolution temperatures. Two polymer samples can be fractionated simultaneously in the TREF-mode, one in each fractionation vessel.

The two fractionation vessels are required to fractionate one sample in Crystaf-mode. The polymer solution is initially placed in one of the fractionation vessels at high temperature (vessel 1). The temperature is then decreased, causing part of the polymer to crystallize out of solution. The polymer solution

is transferred from vessel 1 to vessel 2 via an in-line filter to avoid sampling the polymer crystallites that constitute the first, high crystallinity fraction. The crystallized polymer remaining in vessel 1 is then redissolved and the resulting solution is transferred to a fraction collection vial. The fractionation process is then repeated by decreasing the temperature in vessel 2, transferring the remaining solution to vessel 1, and recovering the polymer precipitated in vessel 2 as the second fraction. These steps can be repeated several times to obtain the number of polymer fractions of decreasing crystallinity required by the fractionation.

Several of the issues related to the fractionation efficiency of these two techniques have been investigated with their continuous counterparts, Crystaf and TREF, and will be discussed in the next section.

Crystallization Analysis Fractionation

Crystallization analysis fractionation (Crystaf) fractionates polymer chains according to differences in crystallizability. Crystaf can be used to fractionate polymers due to differences in chemical composition, comonomer sequence length, and tacticity. It may also respond to long-chain branching, provided that the polymer is branched enough to affect its crystallinity. The fractionation principle operative in Crystaf was discussed in the section on batch fractionation for the case of slowly cooling (or warming) solutions of semicrystalline polymers.

In Crystaf, a dilute solution of a semicrystalline polymer is slowly cooled from a high temperature to room or subambient temperatures, while the polymer concentration is monitored as a function of crystallization temperature by an on-line mass detector to obtain its *cumulative distribution*. The *differential distribution* is calculated by taking the first derivative of the cumulative distribution with respect to the crystallization temperature. Both cumulative and differential Crystaf curves for a bimodal blend of two ethylene/α-olefin copolymers are shown in Figure 11. A calibration curve must be used to translate the crystallization temperature distribution into a polymer microstructural distribution, as will be explained later in this section.

The Crystaf apparatus shown in Figure 12 has five crystallization vessels that can be operated in parallel. Sample injection, dissolution, analysis, and disposal are completely automated. Small aliquots of the solution are taken through an in-line filter to avoid sampling polymer crystals with the polymer solution and sent to the on-line mass detector. The mass detector is commonly an infrared cell that is less sensitive to temperature fluctuations of the polymer solution. Additional detectors can also be installed on the sampling line to measure complementary properties, such as viscosity and copolymer composition.

Usually, Crystaf is operated at a cooling rate of 0.1°C/min. It will be shown later that cooling rates can significantly influence the results of Crystaf analysis. The concentration of the polymer solution is not considered to affect the fractionation results, provided it is kept in the range of 0.2–1.0 mg/mL (14). The type of solvent only affects the crystallization temperature: polymers crystallize at lower temperatures in the presence of better solvents, but the effect on fractionation efficiency is negligible (15).

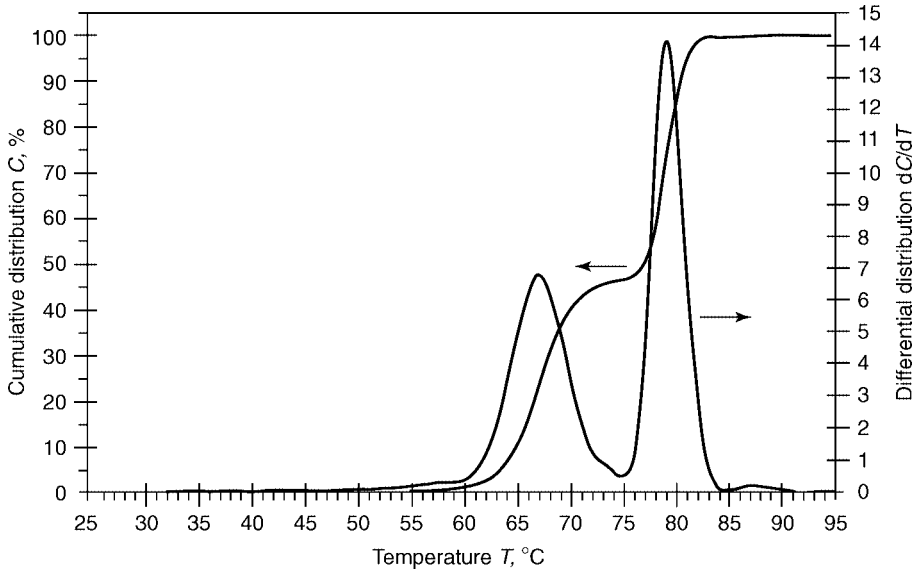

Fig. 11. Cumulative and differential Crystaf curves of a blend of polyolefins.

The raw Crystaf profile provides information about the distribution of crystallizabilities of the polymer sample that can be correlated to molecular structure with the use of a proper calibration curve. Contrary to SEC, there is no universal calibration curve for Crystaf: for quantitative analysis, calibration curves should be prepared with narrow standards that have microstructures as similar as possible to the sample being analyzed.

Calibration standards for Crystaf are not commercially available and have to be prepared by either preparative fractionation of a broad sample with similar characteristics (generally obtained by using the batch fractionation techniques described previously) or by synthesis of samples with narrow distributions. Figure 13 shows the Crystaf profiles of a set of calibration standards for ethylene/1-hexene random copolymers, and Figure 14 is the resulting calibration curve (16). The calibration curves for Crystaf for random (or near random) copolymers are generally linear, in good agreement with the prediction of equation 15 for copolymers with small amounts of comonomer. In this case, the following approximations apply:

$$\frac{1}{T_{\mathrm{m}}} - \frac{1}{T_{\mathrm{m}}^0} = \frac{T_{\mathrm{m}}^0 - T_{\mathrm{m}}}{T_{\mathrm{m}} T_{\mathrm{m}}^0} \cong \frac{T_{\mathrm{m}}^0 - T_{\mathrm{m}}}{\left(T_{\mathrm{m}}^0\right)^2} \tag{16}$$

$$\ln x_A = -(1 - x_A) = -x_B \tag{17}$$

Substituting these expressions in equation 15,

$$T_{\mathrm{m}} \cong T_{\mathrm{m}}^0 - \frac{R\left(T_{\mathrm{m}}^0\right)^2}{\Delta H_{\mathrm{u}}} x_B \tag{18}$$

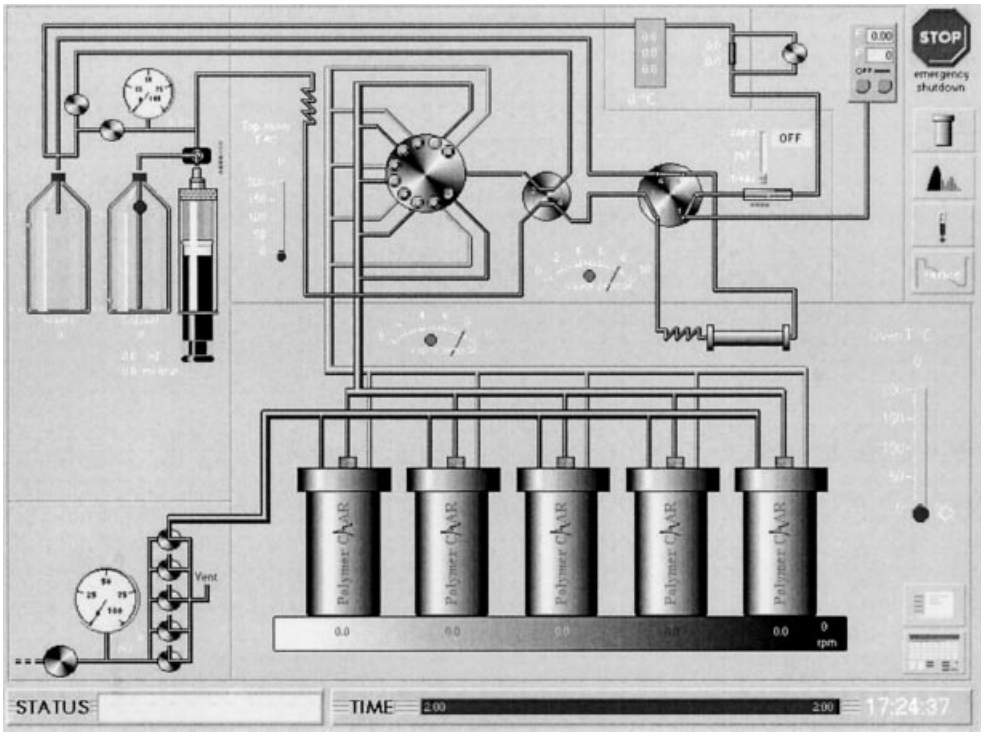

Fig. 12. Schematic of Crystaf. Courtesy of Polymer C*h*ar.

which shows that the melting temperature depression is a linear function of the fraction of non-crystallizable comonomer in the copolymer.

One of the main difficulties for the quantification of Crystaf is the nonuniversality of its calibration curves. Even for a series of ethylene/α-olefin copolymers, the calibration curves will vary as a function of comonomer type, as illustrated in Figure 15. The general rule of thumb for these copolymers (from propene to 1-octene) is, the longer the α-olefin, the lower the crystallization temperature for a given α-olefin molar fraction. This has been explained by several authors on the basis of the difference in the degree of inclusion of the α-olefin in the crystalline lattice: shorter α-olefins are more likely to cocrystallize with ethylene and therefore depress the crystallization temperature to a lesser extent.

Sequence length distribution is another factor that may affect calibration curves in Crystaf. This is easy to visualize if we compare the extreme cases of block and random ethylene/α-olefin copolymers with the same α-olefin content. We start by assuming that the α-olefin units cannot crystallize and the crystallization temperature is a function only of the average length of the ethylene sequences in the chain. Since the average sequence of crystallizable ethylene units is much longer in block copolymers than in random copolymers with the same comonomer content, block copolymers will have much higher crystallization temperatures than random copolymers. This limitation is easily overcome by using calibration standards with microstructure similar to the polymers being analyzed.

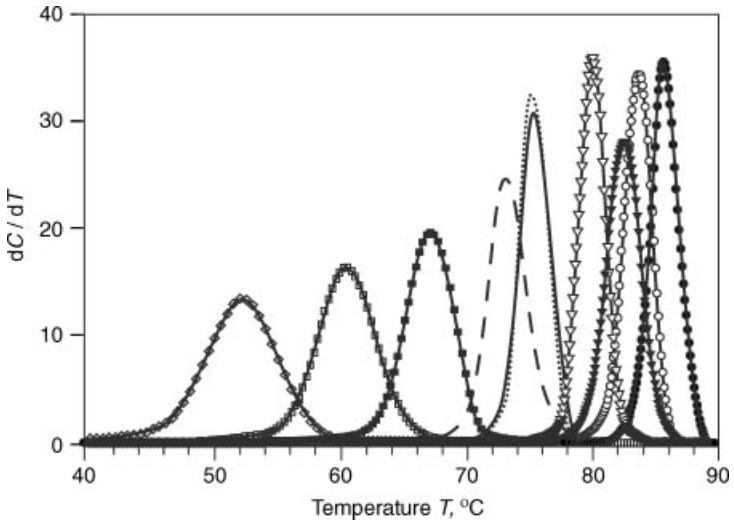

Fig. 13. Crystaf profiles for a set of random ethylene/1-hexene copolymer calibration standards. —●— 0r (0 mL); —○— 5d (0.5 mL); —▼— 10e (1.0 mL); —▽— 23b (2.3 mL); _____ 41a (4.1 mL); . . . 41e (4.1 mL); — —65b (6.5 mL); —■— 100f (10.0 mL); —□— 150a (15.0 mL); —◇— 200a (20.0 mL). From Ref. 16.

Molecular weight effects are practically negligible in determining the Crystaf peak temperatures for polyethylene chains with molecular weights higher than 5000, and even these effects can be corrected by taking into account the terminal methyl groups of the chains. Likewise, small amounts of long-chain branching (in the range of 1 to 4 LCB per 1000 C atoms) do not influence Crystaf profiles appreciably. On the other hand, the shape of Crystaf profiles is affected by molecular

weight: distributions with a low molecular weight tail are characterized by a low crystallinity tail in Crystaf, perhaps because the low molecular weight chains crystallize at lower temperatures (18,19).

Cooling rate is the most important operating variable in Crystaf. It significantly affects Crystaf peak temperatures (Fig. 16) and the cocrystallization of

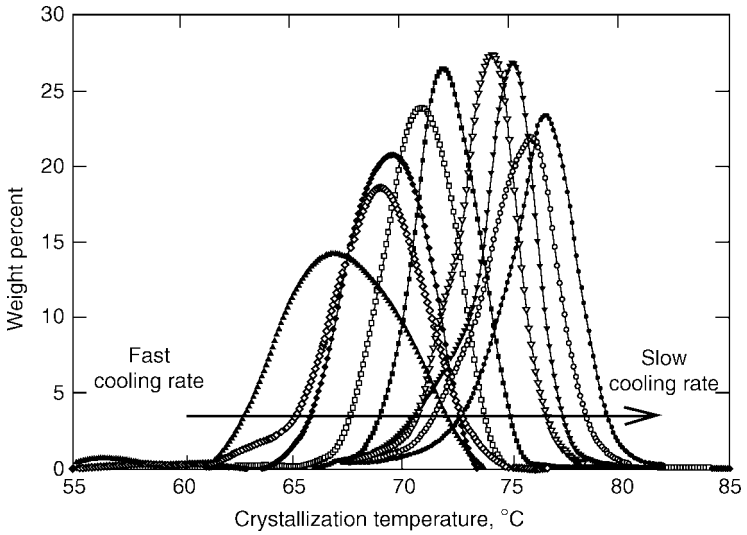

Fig. 16. Crystaf peak temperatures as a function of cooling rate for an ethylene/1-hexene copolymer sample. —●— 0.0033 CPM; —○— 0.01 CPM; —▼— 0.02 CPM; —▽— 0.05 CPM; —■— 0.1 CPM; —□— 0.2 CPM; —◆— 0.5 CPM; —◇— 1 CPM; —▲— 2 CPM. CPM = °C per minute. From Ref. 14.

chains with different average comonomer contents. This is particularly important to keep in mind when analyzing polymers made with multiple-site catalysts, such as heterogeneous Ziegler–Natta systems, where chain populations with different comonomer contents are present (17). Good resolution among these populations can only be achieved under very slow cooling rates, often slower than the standard Crystaf rates of 0.1°C/min. Figure 17 illustrates this situation for ternary blends of ethylene/1-hexene copolymers made with a metallocene catalyst. The dotted lines represent the Crystaf profile estimated for the blend if no cocrystallization takes place. Cocrystallization becomes more significant with increasing cooling rate and proximity of the crystallization peaks of the different polymer populations. Interestingly, the type of α-olefin does not seem to play a role in the cocrystallization phenomena (20).

Temperature Rising Elution Fractionation

Temperature rising elution fractionation (TREF) is based on the same principles of Crystaf, but involves two consecutive steps: precipitation (or crystallization) and elution. In the precipitation step, polymer is crystallized from a dilute solution by slowly decreasing the temperature inside a column packed with an inert support. Alternatively, the precipitation step can be done in a stirred vessel in the presence of the support and the polymer-coated support is subsequently transferred to the TREF column for the elution step. In the elution step, the polymer deposited onto the support is eluted from the column with a continuous flow of solvent at increasing temperatures. An on-line detector measures the concentration of the polymer solution exiting the column as a function of elution temperature. Figure 18 shows a schematic of a TREF apparatus and a typical TREF curve for linear low density polyethylene.

Polymer fractionation takes place during the precipitation step according to crystallizability. The precipitation step in TREF is essentially analogous to the crystallization that takes place in Crystaf. As for Crystaf, a slow cooling rate is the most important requirement to minimize cocrystallization of polymer populations with different crystallizabilities and enhance peak resolution. Since there is no monitoring of the polymer solution concentration during the precipitation step, the elution step is required to measure the concentration of polymer recovered as a function of elution temperature.

Given that the fractionation mechanism in Crystaf and TREF are very similar, they both provide analogous information about polymer microstructure, with the TREF profiles shifted to higher temperatures due to the supercooling effect in Crystaf, as exemplified in Figure 19. Crystaf analysis times tend to be shorter because of the extra time required by the additional elution step in TREF.

Table 1 compares the analysis times for Crystaf and TREF at different cooling and heating rates (14). Similar to Crystaf, TREF calibration curves are not universal and depend on the microstructure of the polymer being analyzed (21).

It has long been considered that the elution step in TREF was mainly required to recover and monitor the concentration of the polymer already fractionated during the precipitation step. However, recent studies with ethylene/α-olefin copolymer blends indicate that for the same cooling rate, TREF can better resolve

the peaks of the individual populations, as indicated in Figure 20. The slow heating during the elution step may lead to recrystallization of the crystals formed during the precipitation step, enhancing the peak resolution of TREF as compared to Crystaf. This is an attractive TREF feature when analyzing complex blends or polymers made with multiple-site catalysts (14).

The performance of TREF is relatively insensitive to polymer concentration in the range of 1–4 mg/mL. When compared to Crystaf, TREF peak positions are less dependent on the cooling rate, maybe because of recrystallization during the elution step. Solvent flow rate and heating rate can also affect peak position and breadth, but it has been demonstrated that these variations can be eliminated by operating TREF at constant ratio of heating rate to solvent flow rate, as illustrated in Figure 21. These conditions ensure that each volume element exiting the column contains polymer chains that were eluted during the same time/temperature interval (14).

Solvent and support type have only a minor effect on TREF fractionation. Better solvents lead to lower elution temperatures. The effect of different support types has not been systematically investigated, although some authors claim that it may lead to peak broadening in TREF (15,21).

TREF can also be operated in preparative mode. In this case, a larger column is used and samples are collected at predetermined time intervals for posterior analysis by other techniques. The efficiency of TREF preparative fractionation is essentially the same as for batch fractionation by temperature.

An interesting variation of TREF uses supercritical fluids as solvents and columns containing a high surface stainless steel mesh packing. The main advantage of supercritical TREF (CITREF: critical, isobaric TREF) over conventional TREF is that supercritical solvents such as propane can be easily separated from the polymer by pressure reduction after the column, recompressed, and recycled back to the column in a closed loop. Because of this, CITREF can be used as a

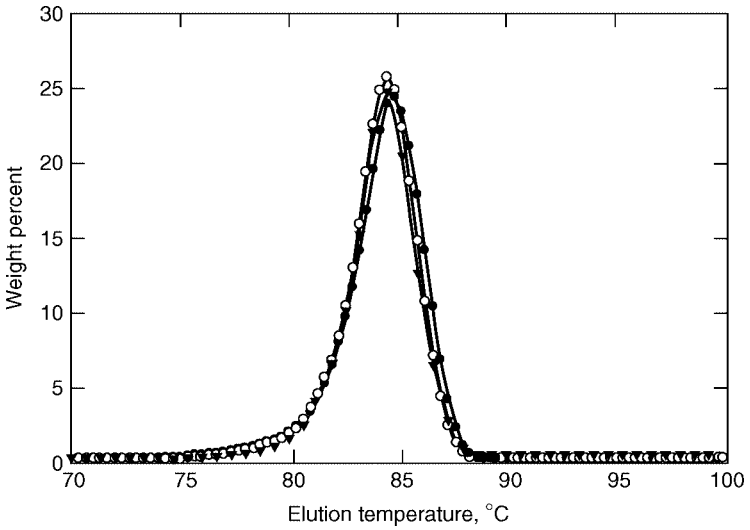

Fig. 21. Comparison of the TREF profiles for an ethylene/1-hexene sample measured at a ratio of 1:1:1 for cooling rate: heating rate: solvent flow rate. —●— Rate = 0.1°C/min; —○— rate = 0.2°C/min; —▼— rate = 0.5°C/min. From Ref. 14.

preparative method to fractionate much larger polymer samples than can be practically accomplished with conventional TREF using organic chlorinated solvents (22–24). Interestingly, because the density of supercritical fluids can be changed over a wide range of values by varying the pressure, CITREF can also be operated at constant temperature and varying pressure to fractionate polymers according to their molecular weights (25), provided they are kept above their melting points for the case of semicrystalline polymers. In this way, the term $(\delta_S - \delta_P)^2$ in equation 11 can be regulated by varying the pressure of the supercritical fluid without the addition of a nonsolvent.

Mathematical Models for Crystaf and TREF. Existing mathematical models for Crystaf and TREF suffer from several limitations because of the complex nature of the fractionation process that takes place in these techniques. For binary linear copolymers made with single site catalysts, Stockmayer's distribution (eq. 3) can be used to model the chemical composition distribution, but its translation into actual Crystaf and TREF curves is a much harder task.

A very simple model relating Crystaf or TREF curves to Stockmayer's distribution has been proposed (26), but this approach was later found to be unsatisfactory to describe quantitatively the chemical composition distribution of polyolefins made with single site catalysts, as illustrated in Figure 22 (27). Notice, however, that even though the Crystaf profiles and Stockmayer's distribution do not agree quantitatively, Stockmayer's distribution predicts the correct trends, particularly the broadening of the chemical composition distribution with decreasing molecular weight of the samples. A new model was proposed on the basis of the crystallization of the longest crystallizable monomer sequence per chain (28). In this approach, the longest ethylene sequence per chain, and not the overall comonomer distribution, determines the temperature at which the chain crystallizes in Crystaf or
